WileyPLUS Learning Space

Includes **ORION** Adaptive Practice

An easy way to help students learn, collaborate, and grow.

Designed to engage today's student, WileyPLUS Learning Space will transform any course into a vibrant, collaborative, learning community.

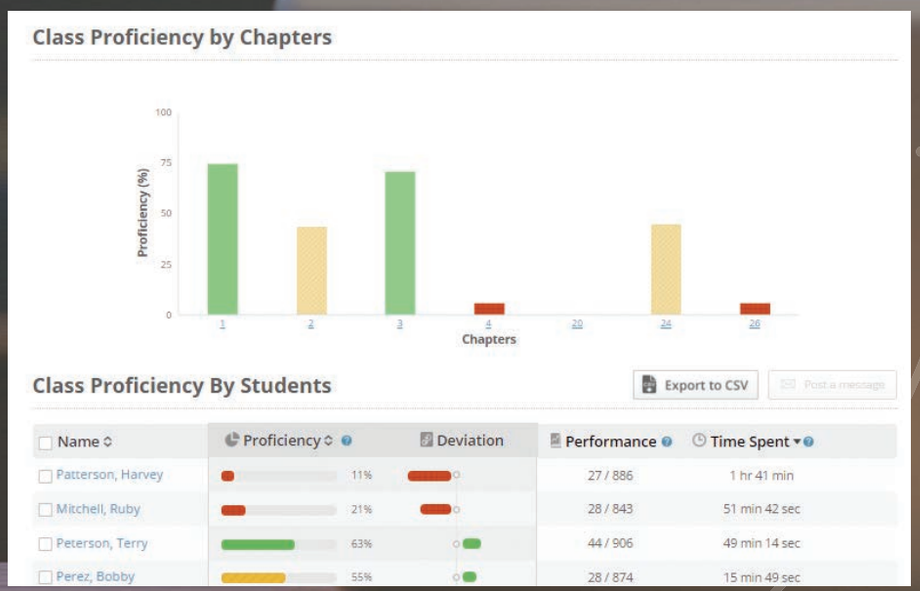

Photo credit: Sam Edwards/Getty Images

Identify which students are struggling early in the semester.

Educators assess the real-time engagement and performance of each student to inform teaching decisions. Students always know what they need to work on.

Facilitate student engagement both in and outside of class.

Educators can quickly organize learning activities, manage student collaboration, and customize their course.

Measure outcomes to promote continuous improvement.

With visual reports, it's easy for both students and educators to gauge problem areas and act on what's most important.

This book was set in 10/12 BT Baskerville by Cenveo Publisher Services. Book and cover are printed and bound by Quad Graphics/Versailles. This book is printed on acid-free paper. ∞

Founded in 1807, John Wiley & Sons, Inc. has been a valued source of knowledge and understanding for more than 200 years, helping people around the world meet their needs and fulfill their aspirations. Our company is built on a foundation of principles that include responsibility to the communities we serve and where we live and work. In 2008, we launched a Corporate Citizenship Initiative, a global effort to address the environmental, social, economic, and ethical challenges we face in our business. Among the issues we are addressing are carbon impact, paper specifications and procurement, ethical conduct within our business and among our vendors, and community and charitable support. For more information, please visit our website: www.wiley.com/go/citizenship.

DEDICATIONS

DAVID R. WESSNER

To the wonderful students at Davidson College for making it so much fun to do what I do. Most importantly, thanks to Connie and Ian.

CHRISTINE DUPONT

To microbiologists and students everywhere, even if they never get a chance to read this textbook.

TREVOR C. CHARLES

To the students who have been an inspiration, as I have had the privilege of watching them discover and be captivated by the world of microbes.

JOSH D. NEUFELD

For my students and the love of microbiology.

About the Authors

Courtesy Bill Giduz

DAVID R. WESSNER

Professor of Biology at Davidson College, **David R. Wessner** teaches introductory biology and courses on microbiology, genetics, and HIV/AIDS. His research focuses on viral pathogenesis. He is a member of the American Society for Microbiology Committee for K–12 Education. He also is a coauthor of Vision and Change in Undergraduate Education: A Call to Action. Prior to joining the faculty at Davidson, David conducted research at the Navy Medical Center. He earned his Ph.D. in Microbiology and Molecular Genetics from Harvard University and his B.A. in Biology from Franklin and Marshall College.

Courtesy of John Lumsden

CHRISTINE DUPONT

Lecturer in the Department of Biology at the University of Waterloo in southern Ontario, Canada, **Christine Dupont** teaches undergraduate courses in genetics, biotechnology, virology, and bacterial pathogenesis. She earned her Ph.D. from Massey University, Faculty of Veterinary Science, New Zealand; B.Ed. from the University of Windsor, Ontario; and M.Sc. and B.Sc. in Microbiology from the University of Guelph, Ontario. Prior to her Ph.D. studies, Christine taught high school science for several years, developing a passion for teaching and working with students.

Courtesy Trevor C. Charles

TREVOR C. CHARLES

A Professor in the Department of Biology, University of Waterloo, Trevor Charles teaches undergraduate courses in microbiology and synthetic biology, and runs a research program that focuses on plant-microbe interactions and functional metagenomics. Prior to joining the faculty at Waterloo, he held a faculty position at McGill University and did postdoctoral research at the University of Washington. He earned his Ph.D. from McMaster University, and his B.Sc. in Microbiology from the University of British Columbia.

Courtesy of Jon Schroeder

JOSH D. NEUFELD

As a Professor in the Department of Biology at the University of Waterloo, Josh Neufeld explores microbiology with undergraduate students in the classroom and both undergraduate and graduate students in his microbial ecology research program. Josh earned his B.Sc. and M.Sc. in Microbiology from McGill University's Macdonald Campus prior to completing a Ph.D. at the University of British Columbia and postdoctoral research at the University of Warwick.

Why We Wrote This Book

We wrote this book for one simple reason—we have a passion for microbiology. Moreover, we want to share this passion with as many students as possible. First, we want to show students that microbiology is a dynamic discipline. The field has changed dramatically over the past 25 years, and we can only guess what remarkable changes the future will bring. Second, we want to show students that experimentation is at the very heart of microbiology. Since the development of the microscope over 300 years ago, microbiologists have asked probing questions, developed elegant experiments, and formulated testable hypotheses. This scientific exploration continues today. To achieve these two major goals, we have written this textbook as an engaging narrative that brings the story of microbiology to life. Our textbook not only provides students with a historical understanding of the field but also gives them an appreciation for the dynamic, exciting nature of today's microbiology. Indeed, we hope that our textbook will make students as passionate as we are about the science of microbiology.

Exploration and Experimentation

To achieve our goals, we present material within the context of exploration and experimentation. Knowing myriad facts about microbiology is not sufficient. To have a true understanding of this subject, students need to understand experimentation and be able to critically analyze information. Several features within the book will help our students understand and appreciate the science behind our knowledge.

First, each chapter begins with an opening vignette—a short story that frames a basic question within the context of both contemporary and historical issues—visually supported by a dynamic illustration. As the chapter unfolds, references back to the opening vignette are made repeatedly. At the conclusion of each chapter, an additional feature, The Rest of the Story, again refers back to this opening vignette and art. This also ties into an active learning feature, Image in Action, that includes several critical-thinking questions.

Second, each chapter contains a Mini-Paper, a synopsis of a scientific journal article that includes original data and Questions for Discussion. Through the use of this feature, students will see how microbiologists ask intelligent questions, rationally design experiments, and evaluate data. Again, this feature will improve students' critical-thinking skills and show them that our knowledge is evidence-based.

Third, several chapters contain scientific methodology figures, diagrams that provide a brief overview of a specific experiment, including the original observation, hypothesis, experiment, results, and conclusions. Again, this feature will emphasize to our students the science behind our knowledge.

Three Pillars: Genetics, Physiology, and Ecology

Throughout the textbook, we frame information around the three pillars of genetics, physiology, and ecology. The pillars help weave concepts in evolution, structure and function, and the interactions between individual microbes, between different types of microbes, between microbes and other organisms, and between microbes and the environment. Often, the importance of these key interactions are presented from different perspectives at different places within the textbook: from that of the molecular biologist, of the ecologist, of the physician, of the engineer, or even of the microbe itself.

An Emphasis on Connections

Finally, we make explicit the interconnectedness of topics, both within a chapter and between chapters. This goal is achieved in several ways. Important concepts are reintroduced throughout appropriate chapters with Connection notes. Through such layering, students gradually deepen their understanding of complex topics as the semester progresses. Thus, students gain an appreciation of gene regulation by seeing how it affects different processes.

Ultimately, of course, we want our students to gain a more complete understanding of and appreciation for microbiology. By presenting information within the dual contexts of experimentation and the interconnectedness of topics, we encourage students to learn important material not as discrete bits of information, but as pieces of a much larger body of knowledge. Through this approach, students will better understand and connect the basic concepts of this exciting, dynamic field.

Thank you for taking the time to read these opening remarks and learn more about our book. Hopefully, our book will help you share your fascination with microbiology with your students. Who knows? Maybe an undergraduate student in today's microbiology class will make tomorrow's big discovery!

Best,
Dave Wessner
Christine Dupont
Trevor Charles
Josh Neufeld

Special Features

Mini-Papers: In every chapter, primary research articles are summarized and interpreted, helping students sharpen critical thinking skills and deepen their understanding of what microbiologists do.

Mini-Paper: A Focus on the Research
THE THREE DOMAINS OF LIFE

C. R. Woese, O. Kandler, and M. L. Wheelis. 1990. Towards a natural system of organisms: Proposal for the domains Archaea, Bacteria, and Eucarya. Proc Natl Acad Sci USA 87: 4576–4579.

Context

Aristotle categorized life into just two fundamental groups, animals and plants, and this categorization persisted until the dawn of microbiology as a science. In 1868, two centuries after van Leeuwenhoek's discovery of microbial life, German biologist Ernst Haeckel proposed a third fundamental group, or kingdom, *Protista*, for microscopic lifeforms. In 1938, Herbert Copeland suggested that microorganisms should actually be divided into two kingdoms, *Protista* and *Bacteria*, thereby recognizing the difference between eukaryotic and prokaryotic cells. Twenty years later, Robert Whittaker advocated further separation of eukaryotic microorganisms into kingdoms of *Fungi* and *Protista*, but kept prokaryotic cells in a single kingdom called *Monera*. This five-kingdom taxonomic system—*Animalia*, *Plantae*, *Fungi*, *Protista*, and *Monera*—became the accepted standard for the next few decades until DNA and protein sequences became widely accessible.

Carl Woese, a microbiologist at the University of Illinois, was fascinated by a group of prokaryotes known at the time as "archaebacteria." Initially, these strange microorganisms were found primarily in marginal environments such as anoxic sediments, hypersaline ponds, and hot springs. The sequence of this molecule changes very slowly because of the functional constraints on the molecule. Random mutations that occur within the gene encoding the small subunit rRNA often have serious negative consequences, so relatively few changes are passed on to subsequent generations. Nevertheless, there are enough differences in the roughly 1,600 nucleotide sequence to differentiate between species to map patterns of similarity. If one assumes that overall mutation rates are similar between species (which seems to be true with respect to rRNA genes), then one can quantify sequence differences between SSU rRNA genes in multiple species to infer relationships. Ultimately, Woese discovered that the methane-producing microorganisms were no more closely related to other bacteria than they were to the eukaryotes. They were not bacteria at all! Let's examine the scientific work that led to this conclusion.

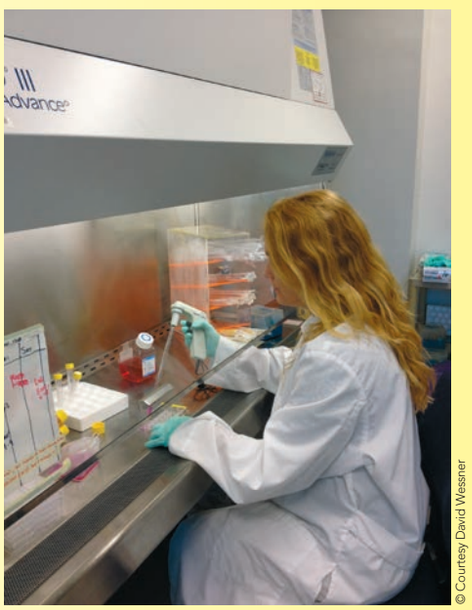
Experiments

The 1990 Woese *et al.* paper actually presented no new experimental data. Its importance was in articulating a new view of the phylogeny of life. To understand the genesis of this idea, we should step back and examine the data. The biggest challenge Woese faced in the 1970s in developing ribosomal RNA sequences as a tool for phylogenetic analysis was the difficulty in determining such sequences. Woese and colleagues developed a laborious method to infer the sequence of 16S ...cules, which they described in a 1977 article, "Comparative

Toolbox 5.1
CELL CULTURE TECHNIQUES

Because viruses only can replicate within living host cells, virologists are presented with an interesting problem; before researchers can effectively study viruses in the laboratory, they must be able to grow appropriate host cells. Prior to the development of mammalian cell culture methodologies, the propagation of animal viruses occurred via serial passage of the virus in animals. A susceptible animal would be inoculated with a small sample of the virus of interest. At a later time, perhaps when the infected animal became sick, virus would be isolated from this animal and a second susceptible animal would be inoculated, thereby allowing the virus to continue replicating. Clearly, this method of viral propagation was not terribly practical; it required the researcher to maintain appropriate animal hosts. As you can imagine, this requirement greatly reduced the study of viruses that infect humans!

During the 1940s and 1950s, this difficulty was overcome with the development of cell culture techniques. In 1949, John Enders, Thomas Weller, and Frederick Robbins demonstrated that poliovirus could replicate in various embryonic tissues. This discovery directly led to the development of the poliovirus vaccine a few years later and earned the three researchers the Nobel Prize in Physiology or Medicine in 1954. George Gey and colleagues cultured the first human cell line in 1952. This cell line, derived from a human cervical carcinoma, was named HeLa, in recognition of Henrietta Lacks, the young woman from whom the cells were isolated. She died of cervical carcinoma in 1951. The HeLa cell line still is widely used by researchers throughout the world, and this contribution of Henrietta Lacks to modern biomedical research is immeasurable. A final important contribution to the budding field of virology came in 1955 when Harry Eagle and colleagues developed a well-characterized nutrient medium that could be used for the maintenance of cells in the laboratory. With the availability of defined growth media and several different cell lines, researchers could propagate animal viruses easily and conduct controlled experiments. Thus, the history of animal virology is inextricably linked to the



© Courtesy David Wessner

Figure B5.2. Propagation of mammalian cells In the laboratory, mammalian cells typically are grown at 37°C in an atmosphere containing 5 percent CO_2. Here, a researcher is dislodging cells from a flask and transferring them to another flask. She is working in a laminar flow hood to prevent contamination of the cells.

Toolboxes: Every chapter contains Toolboxes—in-depth descriptions of experimental techniques relevant to the chapter.

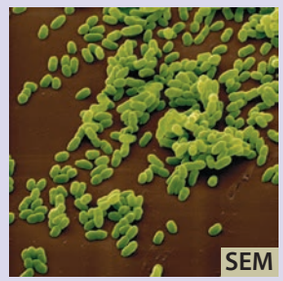
Microbes in Focus Examples: These examples provide students with more detailed information about the habitats and key features of microbes mentioned in the chapter.

Microbes in Focus 20.1
SLIPPERY *HAEMOPHILUS INFLUENZAE*

Habitat: Strictly human inhabitant carried asymptomatically in the nasopharynx by approximately 40 percent of adults

Description: Gram-negative coccobacillus, 0.3–0.8 μm in length

Key Features: Pathogenic strains all possess one of six different types of capsule carbohydrate. Strains carrying type b capsule cause 95 percent of *H. influenzae* disease in children, predominantly meningitis and pneumonia. The capsule interferes with phagocytosis by preventing C3b opsonization of the bacterial cells (see Sections 19.4, 19.5, and 21.1). Antibody produced against the polysaccharide capsule successfully opsonizes the bacteria and provides protection.



Eye of Science/Science Source

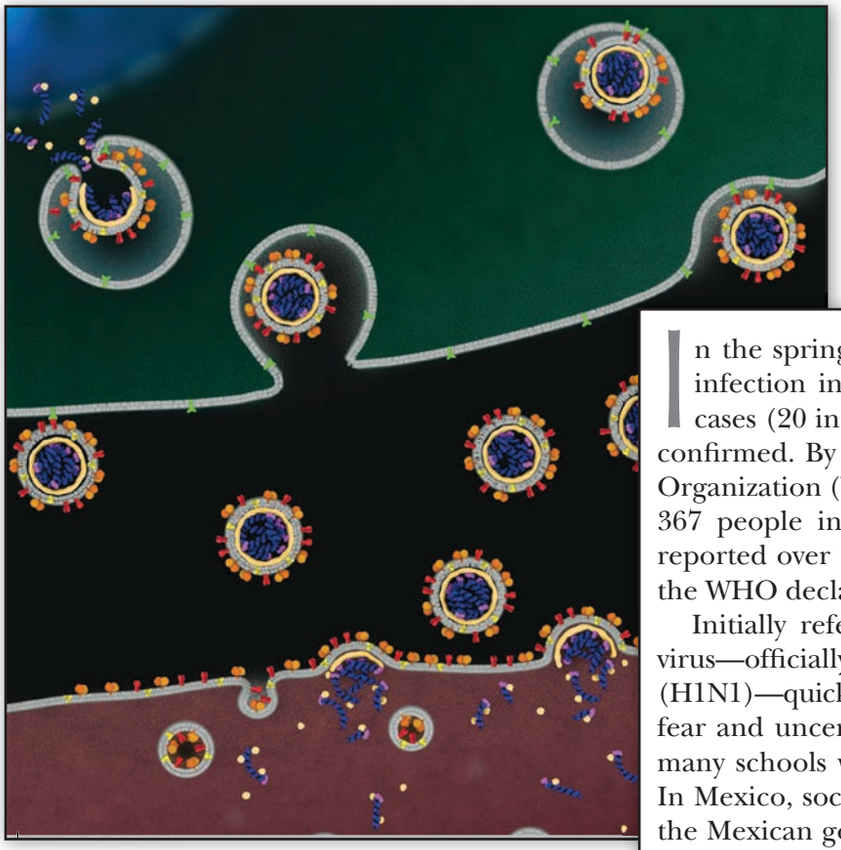
Perspective Examples: In these examples, students see how topics may be viewed or used by different groups.

Perspective 17.2
COWS CONTRIBUTE TO CLIMATE CHANGE

In reading the previous section, you may have recognized that the major gases produced by cows—carbon dioxide and methane—are greenhouse gases. When present in the atmosphere, these gases trap radiant energy, preventing its dissipation to space. Thus, cows pose a concern for climate change because methane is a potent greenhouse gas. Cow populations have increased greatly over the past century as a result of human demand for meat and dairy products. Currently, there are an estimated 1.4 billion cattle on the planet—a source of approximately 15 percent of the total methane released into the atmosphere. When you consider the biochemistry involved in methane production in cows, it is their microbes that present the problem, although the two can hardly be separated. Researchers have been trying to find ways to reduce methane production in cows. They have found that high-quality feeds, like alfalfa pasture, results in significantly less methane than cattle kept on grass pasture **(Figure B17.3)**. However, high-protein diets are more costly to supply and increase the danger of bloat.

Courtesy Christine Dupont

Figure B17.3 Cows grazing on grass Cattle fed grass produce more methane than those fed high-protein fodder, such as alfalfa.



Chapter vignette with original art: Every chapter begins with an opening vignette that frames a basic question. These vignettes are visually supported by original art.

In the spring of 2009, outbreaks of a novel influenza virus infection in Mexico were reported. By April 26, 2009, 38 cases (20 in the United States and 18 in Mexico) had been confirmed. By the beginning of May 2009, the World Health Organization (WHO) reported that this new virus had infected 367 people in 13 countries. On June 11, 2009, the WHO reported over 28,000 cases in 74 countries. Also on this date, the WHO declared an influenza virus pandemic.

Initially referred to as swine flu, this strain of influenza virus—officially known as influenza A/California/07/2009 (H1N1)—quickly spread throughout the world. With its spread, fear and uncertainty also spread. During the spring of 2009, many schools were closed to avoid transmission of the virus. In Mexico, soccer matches occurred in empty stadiums when the Mexican government prevented fans from attending. Several countries urged caution to citizens traveling to the United States and Mexico. Common questions were hotly debated:

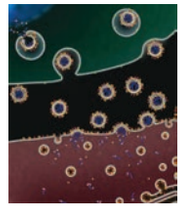
The Rest of the Story

As we noted in the opening story, Tamiflu reduces the severity and length of the influenza disease. But how does it work? Tamiflu (oseltamivir) is a neuraminidase inhibitor (NAI). The neuraminidase protein (NA) is located in the influenza virus envelope, along with the hemagglutinin protein (HA). V virion first encounters a host cell, HA binds to sialic acid, a the virus to enter the cell. During budding of newly replicat particles, NA cleaves sialic acid residues present on the i cell's plasma membrane. So? The cleavage of sialic acid r by NA prevents the newly formed viruses from getting stuc infected cell. In other words, NA increases the likelihood t virus particles will move to other cells **(Figure 8.24)**.

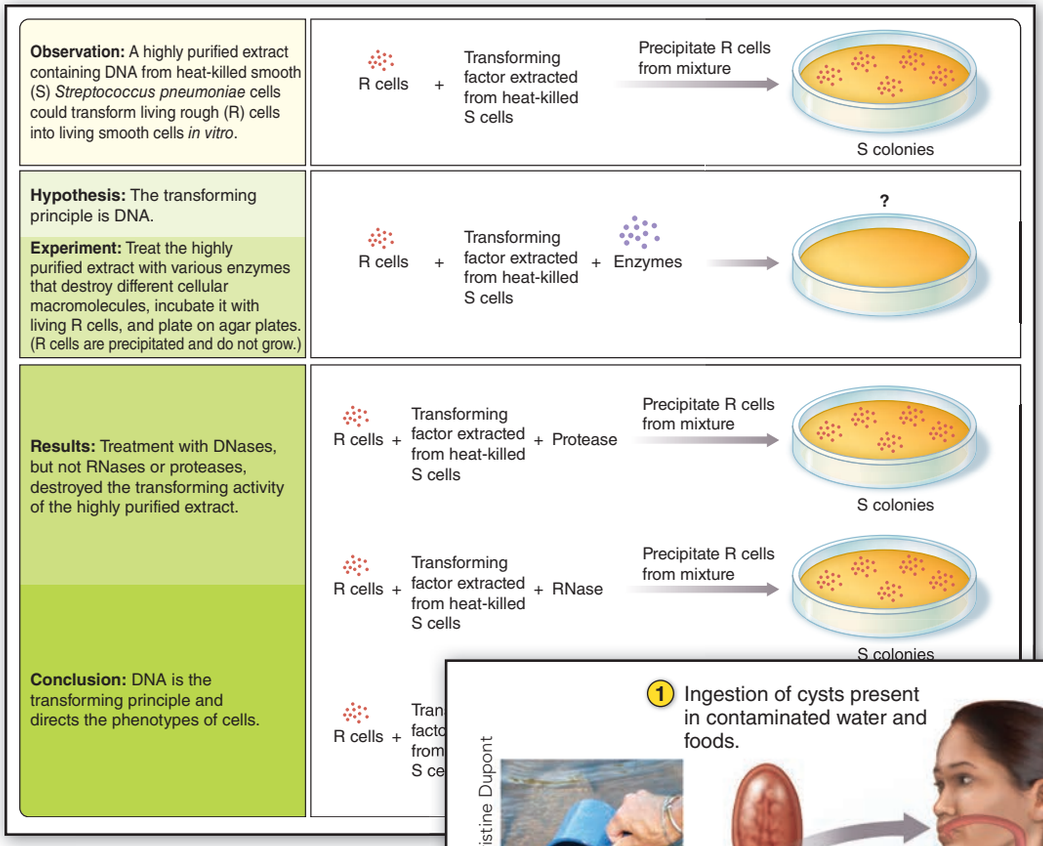
The Rest of the Story and Image in Action: At the end of each chapter, these features revisit the opening vignette and art, linking them explicitly to the chapter content.

Image in Action

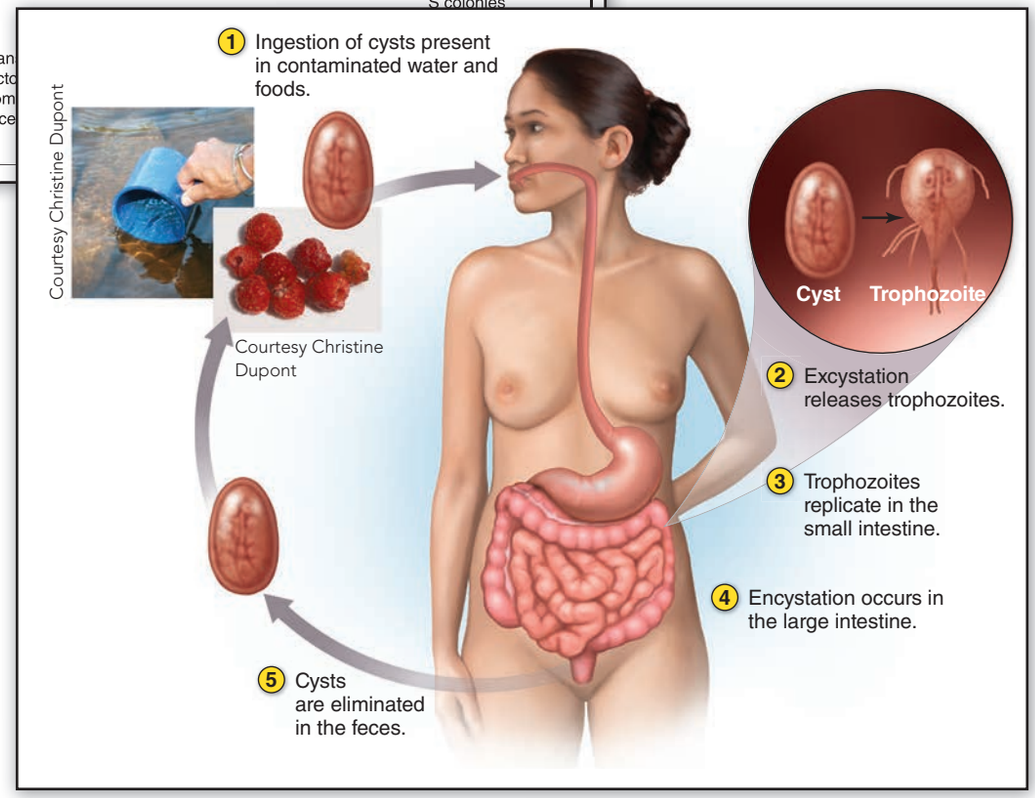
WileyPLUS Learning Space This image depicts the replication cycle of influenza viruses leaving one host cell (*bottom*) and infecting another (*top*).



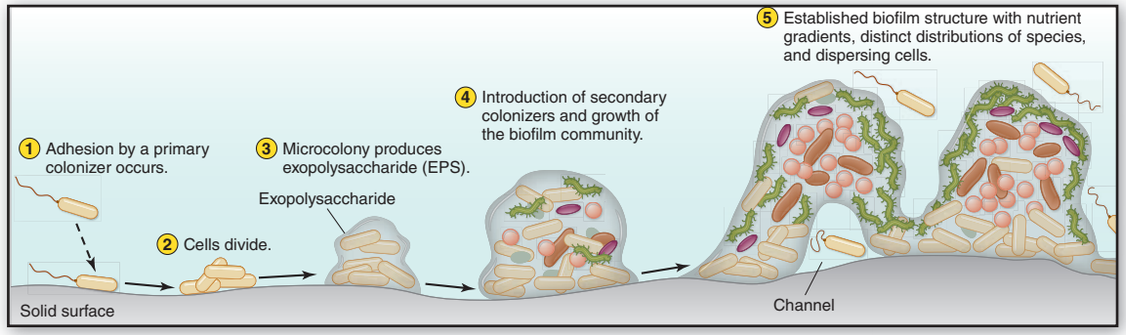
1. Describe the molecular steps that occur when a virus initially interacts with a host cell. Identify and include a description of the specific roles of the green- and red-colored components.
2. Imagine that Tamiflu was administered and is present now in this situation. Describe the antiviral effects of Tamiflu and outline how this image would look different if this drug were present.



Experimental Figures: These figures allow students to better understand how an experiment proceeds, from Observation to Hypothesis to Results to Conclusions.



Life-cycle Figures: Often combining art and photographs, these figures provide a clear overview of how microbes replicate.



Process Diagrams: These figures lend clarity to the flow of complex processes.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Microbes used for biotechnology may be obtained from existing collections or isolated from nature.

- Figure 12.2: Microbial culture collections
- Perspective 12.1: Bioprospecting: Who owns the microbes?
- Figure 12.4: Types of bioreactors

To improve their usefulness, microbes can be genetically modified in numerous ways.

- 3D Animation: Using molecular biology tools to improve microbial strains
- Microbes in Focus 12.2: *Penicillium chrysogenum*: The mold that started the antibiotic revolution
- Toolbox 12.1: Site-directed mutagenesis
- Figure 12.8: Process Diagram: Directed enzyme evolution
- Figure 12.13: Process Diagram: Design and construction of a synthetic organism
- Mini-Paper: Making a synthetic genome

Red biotech involves the use of biotechnology in the pharmaceutical sector.

- Figure 12.15: Production of recombinant insulin

White biotech involves the use of biotechnology in the industrial sector.

- Figure 12.18: Commercial ethanol production using different feedstocks
- Perspective 12.3: Biofuels: Biodiesel and algae
- Figure 12.22: Structures of bacterial polyhydroxyalkanoates (PHAs)

Green biotech involves the use of biotechnology in the agricultural sector.

- 3D Animation: *Agrobacterium* in agricultural biotechnology
- Toolbox 12.3: Plant transformation using bacteria
- Figure 12.33: Process Diagram: *Bacillus thuringiensis* crystals and mode of action

CONNECTIONS for this chapter:

Using metagenomics to find potential genes for biotechnology applications in uncultured microbes **(Section 10.4)**

Use of GFP fusion proteins **(Section 3.1)**

Effects of endotoxin on humans **(Section 19.3)**

Interactions between plants and soil microbes **(Section 17.2)**

Chapter Navigator: This feature organizes the chapter by key concepts and directs students to the most important elements.

CONNECTIONS In **Section 17.2**, we will investigate the intimate associations that many plants have formed with soil microorganisms that live as endosymbionts inside the plant. Some of these bacteria can fix nitrogen, and the cultivation of several important crops takes advantage of this bacterial capability. Because of these bacteria, the application of nitrogen fertilizer is not required for optimal crop yield. The agricultural inoculant industry provides cultures of endosymbiotic nitrogen-fixing root nodule bacteria, as well as free-living bacteria and fungi with plant growth-promoting properties such as phosphate solubilization.

Connections: Throughout each chapter, we highlight the interconnectedness of topics, both within and between chapters.

Fact Check: Each section ends with a few questions to test students' understanding of the content.

12.1 Fact Check

1. Describe what is meant by red, white, and green biotechnology.
2. How are culture collections used in biotechnology?
3. What is bioprospecting?
4. Explain how bioreactors are used for biotechnology fermentation processes.
5. Distinguish between fed-batch bioreactors and chemostats.
6. Distinguish between a primary and a secondary metabolite.

Summary

Section 23.1: How do pathogenic eukarya cause disease?

Eukaryal pathogens can be transmitted between hosts in various ways.

- Insect vectors passively transport spores between hosts for eukaryal pathogens like *Ophiostoma novo-ulmi*.
- Some eukaryal pathogens have a complex life cycle in which they undergo sexual reproduction in the **definitive host** and asexual reproduction and differentiation in the **intermediate host**.
- The eukaryal pathogen *Plasmodium falciparum* must replicate and develop within the mosquito to be transmitted.
- The eukaryal pathogen *Giardia lamblia* undergoes a simple life cycle. It is transmitted via the ingestion of cysts, which then give rise to **trophozoites**.
- Upon entering an appropriate host, eukaryal pathogens must evade the host defenses.
- Some opportunistic pathogens, like *Pneumocystis jirovecii*, only cause disease in immunocompromised individuals, such as people with HIV disease or people on immunosuppressive drugs.
- Other opportunistic pathogens, like *Candida albicans*, cause disease when the normal microbial inhabitants of the host change.
- Some pathogens, like *Trypanosoma brucei* subspecies, actively subvert the host defenses through antigenic variation. These
- Sporozoites can be transmitted to a human when an infected mosquito bites.
- In the human, these sporozoites initially infect liver cells, where they replicate, releasing diploid **merozoites**, which then infect erythrocytes.
- In an infected human, *P. falciparum* replication leads to malaria.
- To facilitate attachment to red blood cells, the merozoites express a series of merozoite surface proteins (MSPs).
- Once inside an erythrocyte, the merozoites obtain hemoglobin from the host cell through **cytostomes**. Digestion of hemoglobin by the pathogen releases **heme**, which *P. falciparum* then converts to **hemozoin**.
- Replication of merozoites within erythrocytes leads to the destruction of these cells, resulting in **anemia**.
- Although malaria remains a huge global problem, methods of preventing malaria and treating it do exist.
- Insecticide-treated mosquito sleeping nets can prevent the transmission of *P. falciparum*.
- The antimalarial drug chloroquine blocks the formation of hemozoin.

Summary: Organized by section, the Summary lists the introductory questions, along with short descriptions of the key points. Key terms also are incorporated and highlighted.

Application Questions: Each chapter ends with a series of thought-provoking questions that test the students' factual understanding of the chapter and their ability to apply their knowledge.

Application Questions

1. From a virus's perspective, explain the potential advantages of acute and persistent infections.
2. Why might stress cause the reactivation of a latent human virus?
3. Explain why apoptosis of infected cells may be beneficial to an organism.
4. We mentioned that cancer may be an unintended outcome of certain virus replication strategies. Explain.
5. Define antigenic drift and antigenic shift. How are these two events similar? How are they different?
6. Explain how bacteriophage lysogeny occurs.
7. What is an endogenous retrovirus?
8. An HIV-infected cell can fuse with adjoining, non-infected cells, forming a syncytium. Explain how this process might occur.
9. Some researchers are concerned that the current H1N1 human influenza virus and the H5N1 avian influenza virus may give rise to a more deadly human virus. How could this occur?
10. For a virus, which is more advantageous: evolving to become highly virulent or evolving to become less virulent? Explain your answer and provide examples.
11. For a respiratory virus like rhinovirus, transmission often occurs through the air. Viral particles exit an infected individual when the host coughs or sneezes and then are inhaled by another susceptible host. The viral particles must remain infectious during this exposure to the outside environment. Devise an experiment that would allow you to measure infectivity of a virus after exposure to various environmental conditions.

Key Features

- CHAPTER VIGNETTE WITH ORIGINAL ART Every chapter begins with an opening vignette that frames a basic question within the context of both contemporary and historical issues. Each vignette is visually supported by original art created by Janet Iwasa, University of Utah.
- CHAPTER NAVIGATOR Organizes the chapter by key concepts and directs students to the most important elements (such as examples, animations, tables) within the chapter to support each concept.
- MINI-PAPERS: A FOCUS ON THE RESEARCH & MINI-PAPER PROJECT ACTIVITIES In every chapter, primary research articles are summarized and the original data is presented and interpreted, helping students sharpen critical thinking skills and deepen their understanding of microbiological research. The Mini-Paper examples are brief, edited versions of actual scientific papers designed to expose students to highly relevant and current research. Each Mini-paper article is accompanied by critical-thinking questions, and questions for discussion to help students learn to ask intelligent questions and design and evaluate experiments rationally.
- TOOLBOXES IN MICROBIOLOGY Every chapter contains Toolboxes, which are in-depth descriptions of experimental techniques relevant to the chapter. These examples present and explain important techniques and/or experiments and are accompanied by Test Your Understanding questions.
- PERSPECTIVES IN MICROBIOLOGY EXAMPLES Perspectives In Microbiology Examples show students how topics may be viewed or used by different groups. They examine how someone, such as an ecologist or geneticist, would study or use the information presented in the chapter.
- MICROBES IN FOCUS EXAMPLES Microbes in Focus Examples provide students with more detailed information about the habitats and key features of the microbes that are mentioned in each chapter. Detailed photomicrographs throughout this textbook magnify the microbial world for your eyes. Look to the bottom corner for information about how each image was obtained. Notice the many differences in magnification and information provided by light microscopy (LM), fluorescence microscopy (FM), scanning electron microscopy (SEM), and transmission electron microscopy (TEM). Appendix B explores these different forms of microscopy in more detail.
- FACT CHECKS Each section of the chapter ends with 3 to 5 questions to test students' understanding of the content covered in that section.
- CONNECTIONS Emphasize the interconnectedness of topics, both within a chapter and between chapters. These notes serve as reminders to the students that related material was covered previously or that related material will be introduced again in a subsequent chapter.
- PROCESS DIAGRAMS Each chapter includes selected, numbered Process Diagrams to lend clarity to the flow of complex processes.
- EXPERIMENTAL FIGURES These figures allow students to better understand how an experiment proceeds, from Observation to Hypothesis to Results to Conclusions.
- LIFE-CYCLE FIGURES Often combining art and photographs, these figures provide a clear overview of how microbes replicate.
- THE REST OF THE STORY At the end of each chapter, this feature revisits the opening vignette, linking them explicitly to the chapter content.
- IMAGE IN ACTION Here we revisit the chapter opener art and ask students questions about how the art and the chapter content are connected.
- SUMMARY Organized by section, introductory questions are included along with short narrative descriptions of the key points, allowing students to gauge their understanding of the topics. Key terms are also incorporated as appropriate throughout the Summary.
- APPLICATION QUESTIONS Each chapter ends with 10 to 15 thought-provoking questions that not only test students' factual understanding of the chapter but also test their ability to apply their knowledge.

Additional Resources for Instructors and Students

Student Resources Available in WileyPLUS Learning Space:

ANIMATIONS 55 animations, many of which have been developed using 3D animation techniques by Janet Iwasa, University of Utah. Following the unique style of the chapter opener illustrations and developed to support learning objectives in the text, these animations help students visualize and master the most challenging topics in microbiology. A series of system-gradable assessments specific to the animations can be assigned by the instructor in WileyPLUS Learning Space.

VIDEOS Each chapter contains a chapter opening and closing video featuring the authors of this text. The authors first present a remarkable example of microbiology in action or provide historical perspective pertaining to the upcoming chapter content. In the chapter summary section, the author videos revisit the opening vignette, explicitly linking them to the material they have read, helping students make important connections.

READING AND UNDERSTANDING THE PRIMARY LITERATURE As students prepare lab reports or science research papers, it is important to know what types of information are relevant, appropriate, and available to assist in developing a meaningful connection with the material through the incorporation of primary literature. The goal of this resource is to assist students in navigating this wealth of information.

ILLUSTRATION AUDIO TUTORIALS A set of downloadable audio tutorials walk students through the detail in many of the chapter opener illustrations throughout the text.

ORION ADAPTIVE PRACTICE ORION assesses student understanding at the learning objective level and identifies areas where further studying is needed. Personalized practice meets students at just above their level in order to keep them challenged, but not frustrated. Adaptive practice includes extensive actionable reports that focus student study in key areas individual to each learner.

INTERACTIVE GRAPHICS 120 static text illustrations have been visualized as interactive figures allowing students to engage with the art in dynamic ways enhancing their connection to the content.

CONCEPT CHECK QUESTIONS Each reading section is followed by a series of questions for low-stakes student practice to measure their understanding of the reading content. Students are allowed multiple attempts and receive instant feedback on their performance.

Instructor Resources Available in WileyPLUS Learning Space:

ASSESSMENT: An expansive selection of system-gradable Assessment content with prebuilt Assignments are available to instructors using WileyPLUS Learning Space, including the following banks of questions for each chapter:

- **Image in Action Questions** based on the chapter opener art for every chapter
- **Animation Questions** based on many of the animations available
- **Pre Lecture Quiz and Post Lecture Quiz** 70 questions per chapter provide opportunities for students to prepare prior to class and to assess post lecture understanding.
- **Application Questions** Each chapter ends with a series of thought-provoking questions that test the students' factual understanding of the chapter and their ability to apply their knowledge.
- **Test Bank** (also available in Respondus and RTF formats)
- **INSTRUCTOR'S MANUAL**
- **LECTURE POWERPOINT**
- **IMAGES AND TABLES IN POWERPOINT**
- **CLICKER QUESTIONS**

STUDENT AND INSTRUCTOR RESOURCES AVAILABLE IN THE TEXT:

Mini-Papers: A Focus On The Research & Mini-Paper Project Activities

The following is a list of each Mini-Paper per chapter. Links to additional topics can be found throughout WileyPLUS Learning Space.

Chapter 1 The Three Domains of Life

Chapter 2 New Microscopy Methods Reveal a Periplasm in Gram-Positive Bacterial Cells

Chapter 3 Lipid Rafts: Organized Clustering of Lipids Within a Membrane

Chapter 4 The Role of Archaea in Our Digestive System

Chapter 5 New Findings in the Packaging of DNA by the Model Bacteriophage T4

Chapter 6 Bringing to Life the Previously Unculturable Using the Soil Substrate Membrane System (SSMS)

Chapter 7 Telomeres with Promoter Activity

Chapter 8 The Discovery of Reverse Transcriptase

Chapter 9 The Discovery of Transduction

Chapter 10 Genome Sequence of a Killer Bug

Chapter 11 Tuning Promoters for Use in Synthetic Biology

Chapter 12 Making a Synthetic Genome

Chapter 13 Genome Sequence of a Deep Sea Symbiont

Chapter 14 The First Isolation and Cultivation of a Marine Archaeon

Chapter 15 Insights into the Phylogeny and Coding Potential of Microbial Dark Matter

Chapter 16 Enhanced Biological Removal of Phosphorus

Chapter 17 Fecal Bacteriotherapy: "RePOOPulation" of the Gut

Chapter 18 Epidemiology of an Infectious Disease

Chapter 19 Mammalian Cells Can Recognize Bacterial DNA

Chapter 20 Attempting to Engineer a Virus to Improve Immuno-contraception

Chapter 21 *Escherichia coli* Injects its Own Receptor

Chapter 22 Viruses That Cause Cancer by Affecting Cellular Proliferation

Chapter 23 An Experimental System for the Genomic Study of Dutch Elm Disease

Chapter 24 Soil Microbes Possess Extensive Resistance to Antibiotics

Toolboxes in Microbiology

The following is a list of each Toolbox in Microbiology per chapter.

Toolbox 1.1 Polymerase Chain Reaction Amplification of rRNA Genes

Toolbox 2.1 The Gram Stain

Toolbox 3.1 Using Microscopy to Examine Cell Structure

Toolbox 4.1 Vaccine Delivery Strategies

Toolbox 5.1 Cell Culture Techniques

Toolbox 5.2 Reverse Transcriptase Polymerase Chain Reaction (RT-PCR)

Toolbox 6.1 Phenotype Microarrays for Examining Microbial Growth

Toolbox 6.2 FISHing for Uncultivated Microorganisms

Toolbox 7.1 Using a Gel Shift Assay to Identify DNA-binding Proteins

Toolbox 8.1 The Western Blot

Toolbox 9.1 Isolating Nutritional Mutants

Toolbox 10.1 Genome Databases

Toolbox 11.1 Using RNA Molecules to Decrease Gene Expression

Toolbox 12.1 Site-directed Mutagenesis

Toolbox 12.2 Fusion Protein Purification

Toolbox 12.3 Plant Transformation Using Bacteria

Toolbox 13.1 Metabolism and Rapid Bacterial Identification Systems

Toolbox 14.1 Using Microarrays to Examine Microbial Communities: The GeoChip

Toolbox 14.2 Biogeochemistry in a Bottle: The Winogradsky Column

Toolbox 15.1 Flow Cytometry

Toolbox 16.1 Measuring Biochemical Oxygen Demand (BOD)

Toolbox 16.2 Most Probable Number (MPN) Method

Toolbox 17.1 Germfree and Gnotobiotic Animals

Toolbox 18.1 Measuring the Virulence of Pathogens

Toolbox 19.1 The Complement Fixation Test

Toolbox 19.2 The Limulus Amoebocyte Assay for LPS

Toolbox 20.1 Monoclonal Antibody (mAb) Production

Toolbox 20.2 Enzyme-linked Immunosorbent Assay (ELISA)

Toolbox 21.1 Serotyping

Toolbox 21.2 The Tuberculin Test for Tuberculosis

Toolbox 22.1 Immunoprecipitation

Toolbox 23.1 Testing for Malaria

Toolbox 24.1 Drug Susceptibility Testing and MIC

Perspectives in Microbiology Examples

The following is a list of each Perspective Example per chapter.

Perspective 1.1 Creating Life in the Laboratory: The Miller–Urey Experiment

Perspective 2.1 Marvelous Magnetosomes!

Perspective 2.2 The Protective Shells of Endospores

Perspective 3.1 Hijacking the Cytoskeleton

Perspective 3.2 Secondary Endosymbiosis: The Origins of an Organelle with Four Membranes

Perspective 4.1 Extremophiles and Biotechnology

Perspective 5.1 Ribozymes: Evidence for an RNA-based world

Perspective 5.2 Measurement of HIV Viral Load

Perspective 6.1 The Discovery of *Heliobacter pylori*

Perspective 6.2 *Mycobacterium leprae*, An Extraordinarily Slow-growing Pathogen

Perspective 6.3 The Human Intestine—A Continuous Culture

Perspective 7.1 Using Mutations to Control Viral Infections

Perspective 8.1 DNA Microarrays and the SARS Virus

Perspective 8.2 Phage Therapy: Biocontrol for Infections

Perspective 9.1 Plasmids That Produce Pathogens

Perspective 10.1 Rate of DNA Sequencing

Perspective 10.2 The Minimal Genome

Perspective 11.1 The Use of Lactose Analogs in Gene Expression Studies

Perspective 12.1 Bioprospecting: Who Owns the Microbes?

Perspective 12.2 The International Genetically Engineered Machine (IGEM) Competition, Standard Biological Parts, and Synthetic Biology

Perspective 12.3 Biofuels: Biodiesel and Algae

Perspective 13.1 Who Needs Vitamins?

Perspective 13.2 Electricigenic Bacteria and Microbial Fuel Cells

Perspective 14.1 CO_2 as a Greenhouse Gas and Its Influence on Climate Change

Perspective 14.2 Life in a World without Microbes

Perspective 14.3 The Microbiology of Environmentally Toxic Acid Mine Drainage

Perspective 15.1 Naming the Uncultured and Uncharacterized

Perspective 15.2 Dead Zones

Perspective 16.1 Implication of Sludge Bulking

Perspective 17.1 Food Probiotics—Do They Work?

Perspective 17.2 Cows Contribute to Climate Change

Perspective 17.3 Midichlorians—Not Just for Jedi

Perspective 17.4 Death of Coral Reefs

Perspective 18.1 Genome Editing: A Powerful and Controversial New Technique
Perspective 18.2 The Armadillo—An Ideal Animal Model?
Perspective 19.1 Messy Mucus
Perspective 20.1 Too Much of a Good Thing?
Perspective 20.2 Vaccines Against T-independent Antigens
Perspective 20.3 Turning Antibody Upside Down
Perspective 21.1 Iron, Vampires, Fashion, and the White Plague
Perspective 21.2 The Good, the Bad, and the Ugly Side of Botulinum Toxin
Perspective 21.3 Superabsorbent Tampons and Superantigens
Perspective 21.4 Antibiotics Trigger Toxins?
Perspective 22.1 Vertical Transmission of HIV
Perspective 22.2 Viral Induction of Apoptosis
Perspective 22.3 SV40 and Human Cancers
Perspective 22.4 Ethical Concerns about Avian Flu Research
Perspective 23.1 *Pneumocystis jirovecii* or *carinii*: The Evolving Field of Taxonomy
Perspective 23.2 Magic Mushrooms
Perspective 23.3 Chytrid Fungus: An Emerging Fungal Pathogen
Perspective 24.1 The Pursuit of New Antibiotics: Why Bother?
Perspective 24.2 Health Care-Associated Infections: A Recipe for Resistance
Perspective 24.3 Variolation: Deliberate Infection with Smallpox Virus
Perspective 24.4 The War Against Vaccines

Microbes in Focus Examples

The following is a list of each Microbes in Focus per chapter.

Microbes in Focus 1.1 *Bacillus anthracis*
Microbes in Focus 2.1 *Epulopiscium fishelsoni*: Remarkable for More Than Its Size
Microbes in Focus 2.2 *Proteus mirabilis*: A Swarming Bacterium
Microbes in Focus 3.1 *Chlamydomonas reinhardtii* and the Study of Cell Motility
Microbes in Focus 3.2 *Entamoeba histolytica*: The Cause of Amoebic Dysentery
Microbes in Focus 3.3 *Phytophthora infestans* and the Irish Potato Famine
Microbes in Focus 4.1 *Haloquadratum walsbyi*: The Square Microbe
Microbes in Focus 4.2 Living in "Hot Vinegar": *Thermoplasma acidophilum*
Microbes in Focus 4.3 The Salty Life of *Halobacterium salinarum*
Microbes in Focus 4.4 *Methanobrevibacter smithii*
Microbes in Focus 5.1 The Many Contributions of Bacteriophage T2
Microbes in Focus 5.2 Poliovirus and the Race for a Vaccine
Microbes in Focus 6.1 The Metabolic Diversity of *Pseudomonas aeruginosa*
Microbes in Focus 6.2 A Picky Eater—*Bordetella pertussis*
Microbes in Focus 7.1 *Streptococcus pneumoniae* in the Laboratory and the Hospital
Microbes in Focus 7.2 The Extreme Life of *Sulfolobus solfataricus*
Microbes in Focus 8.1 Mouse Hepatitis Virus (MHV)
Microbes in Focus 8.2 Human Papillomaviruses (HPVs) and Cervical Cancer
Microbes in Focus 9.1 *Escherichia coli*
Microbes in Focus 9.2 *Bacillus subtilis*
Microbes in Focus 10.1 *Mycoplasma genitalium*
Microbes in Focus 10.2 *Yersinia pestis*
Microbes in Focus 11.1 *Aliivibrio fischeri*
Microbes in Focus 12.1 *Streptomyces*: A Gold Mine of Natural Products
Microbes in Focus 12.2 *Penicillium chrysogenum*: The Mold That Started the Antibiotic Revolution
Microbes in Focus 12.3 *Bacillus thuringiensis*: The Natural, Safe Insecticide
Microbes in Focus 13.1 *Chlorobium tepidum*: The Bacterium That Does It All
Microbes in Focus 13.2 *Sinorhizobium meliloti*
Microbes in Focus 14.1 *Methanococcus maripaludis*: A Methane Producer
Microbes in Focus 14.2 *Methylosinus trichosporium*: A Methane Eater
Microbes in Focus 14.3 *Nitrobacter winogradskyi*
Microbes in Focus 15.1 *Synechocystis* sp. PCC6803—From Unpleasant Cyanobacterial Blooms to Science and Biotechnology Workhorse
Microbes in Focus 16.1 *Lactococcus lactis*
Microbes in Focus 16.2 *Cryptosporidium parvum*
Microbes in Focus 17.1 *Malassezia*
Microbes in Focus 17.2 *Streptococcus mutans*, A Sweet Tooth and Cavities
Microbes in Focus 17.3 *Candidatus* Carsonella ruddii: Is It a Cell or an Organelle?

Microbes in Focus 18.1 Measles: A Highly Contagious Disease

Microbes in Focus 18.2 *Salmonella* Typhi: The Cause of Typhoid Fever

Microbes in Focus 18.3 Chikungunya virus: An Emerging Pathogen

Microbes in Focus 18.4 Life in the Stomach: *Helicobacter pylori*

Microbes in Focus 18.5 *Borrelia burgdorferi* and Lyme Disease

Microbes in Focus 19.1 Covert Operations of Human Cytomegalovirus

Microbes in Focus 20.1 Slippery *Haemophilus influenzae*

Microbes in Focus 21.1 *Neisseria gonorrhoeae*

Microbes in Focus 21.2 *Clostridium botulinum*

Microbes in Focus 21.3 *Corynebacterium diphtheriae*

Microbes in Focus 21.4 *Clostridium perfringens* and Gas Gangrene

Microbes in Focus 21.5 *Streptococcus pyogenes*

Microbes in Focus 21.6 *Mycobacterium tuberculosis*

Microbes in Focus 21.7 *Vibrio cholerae*

Microbes in Focus 21.8 *Legionella pneumophila*: The Accidental Pathogen

Microbes in Focus 22.1 Human Rhinoviruses and the Common Cold

Microbes in Focus 22.2 Lifelong Infections: Herpes Simplex Viruses 1 and 2

Microbes in Focus 22.3 Ebola Virus: The Cause of a Zoonotic Disease

Microbes in Focus 22.4 Tomato Spotted Wilt Virus: A Major Agricultural Pest

Microbes in Focus 23.1 An AIDS-defining Opportunistic Infection: *Toxoplasma gondii*

Microbes in Focus 23.2 *Trypanosoma brucei*: The Cause of African Sleeping Sickness

Microbes in Focus 23.3 The Rice Blast Pathogen: *Magnaporthe grisea*

Microbes in Focus 23.4 Getting Through the Cell Wall: Lessons from *Cochliobolus carbonum*

Microbes in Focus 23.5 *Ascaris lumbricoides*: A Roundworm Parasite of Humans

Microbes in Focus 23.6 *Pyrenophora tritici-repentis*: The Cause of Tan Spot in Wheat

Microbes in Focus 24.1 Foot-and-Mouth Disease Virus

Acknowledgments

We acknowledge the invaluable contributions of our colleagues: Barbara Butler, Brian Driscoll, Heidi Elmendorf, Craig Stephens, and Dave Westenberg. We also thank the editorial and production team at Wiley: Executive Editor Ryan Flahive, Freelance Developmental Editors Kathy Naylor and Deborah Allen, Production Editor Trish McFadden, Executive Marketing Manager Clay Stone, Associate Product Designer Lauren Elfers, Development Editor Melissa Whelan, and Senior Photo Editor Mary Ann Price for their guidance and support. We would like to thank Sarah J. VanVickle-Chavez, Ph.D., of Washington University in St. Louis who wrote Appendix A, Reading and Understanding the Primary Literature. We also would like to extend a very warm thanks to Kelly Prior for her efforts in writing the in-text questions and to Janet Iwasa for her amazing cover and chapter opener illustrations. Her art has helped us bring microbiology to life.

A very special thank you to the members of our advisory board and to all the instructors who helped along the way as we wrote our book.

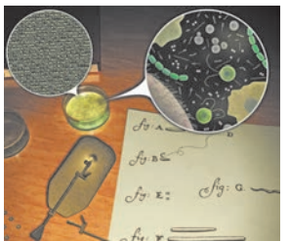
Contents

PART I THE MICROBES



1 The Microbial World 2

1.1 The Microbes 4

Mini-Paper: A Focus on the Research THE THREE DOMAINS OF LIFE 10

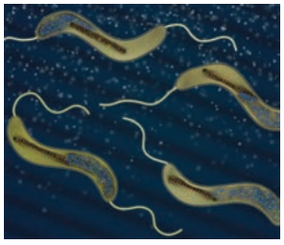
Toolbox 1.1 POLYMERASE CHAIN REACTION AMPLIFICATION OF rRNA GENES 12

1.2 Microbial Genetics 15

Perspective 1.1 CREATING LIFE IN THE LABORATORY: THE MILLER–UREY EXPERIMENT 18

1.3 Microbial Physiology and Ecology 23

1.4 Microbes and Disease 26



2 Bacteria 34

2.1 Morphology of Bacterial Cells 36

2.2 The Cytoplasm 38

2.3 The Bacterial Cytoskeleton 41

2.4 The Cell Envelope 43

Perspective 2.1 MARVELOUS MAGNETOSOMES! 44

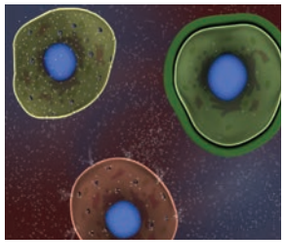
Toolbox 2.1 THE GRAM STAIN 53

Perspective 2.2 THE PROTECTIVE SHELLS OF ENDOSPORES 54

Mini-Paper: A Focus on the Research NEW MICROSCOPY METHODS REVEAL A PERIPLASM IN GRAM-POSITIVE BACTERIAL CELLS 58

2.5 The Bacterial Cell Surface 59

2.6 Diversity of Bacteria 66



3 Eukaryal Microorganisms 72

3.1 The Morphology of Typical Eukaryal Cells 74

Mini-Paper: A Focus on the Research LIPID RAFTS: ORGANIZED CLUSTERING OF LIPIDS WITHIN A MEMBRANE 80

Toolbox 3.1 USING MICROSCOPY TO EXAMINE CELL STRUCTURE 82

Perspective 3.1 HIJACKING THE CYTOSKELETON 86

3.2 Diversity of Eukaryal Microorganisms 86

3.3 Replication of Eukaryal Microorganisms 91

3.4 The Origin of Eukaryal Cells 94

Perspective 3.2 SECONDARY ENDOSYMBIOSIS: THE ORIGINS OF AN ORGANELLE WITH FOUR MEMBRANES 97

3.5 Interactions Between Eukaryal Microorganisms and Animals, Plants, and the Environment 98

4 Archaea 106

4.1 Evolution of Archaea 108

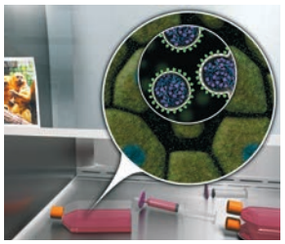
4.2 Archaeal Cell Structure 110

Toolbox 4.1 VACCINE DELIVERY STRATEGIES 115

4.3 Diversity of Archaea 118

Perspective 4.1 EXTREMOPHILES AND BIOTECHNOLOGY 120

Mini-Paper: A Focus on the Research THE ROLE OF ARCHAEA IN OUR DIGESTIVE SYSTEM 124



5 Viruses 130

5.1 A Basic Overview of Viruses 132

5.2 Origins of Viruses 140

Perspective 5.1 RIBOZYMES: EVIDENCE FOR AN RNA-BASED WORLD 141

5.3 Cultivation, Purification, and Quantification of Viruses 143

Toolbox 5.1 CELL CULTURE TECHNIQUES 144

Perspective 5.2 MEASUREMENT OF HIV VIRAL LOAD 147

5.4 Diversity of Viruses 150

Toolbox 5.2 REVERSE TRANSCRIPTASE POLYMERASE CHAIN REACTION (RT-PCR) 154

5.5 Virus-Like Particles 155

5.6 Virology Today 158

Mini-Paper: A Focus on the Research NEW FINDINGS IN THE PACKAGING OF DNA BY THE MODEL BACTERIOPHAGE T4 160

6 Cultivating Microorganisms 164

6.1 Nutritional Requirements of Microorganisms 166

6.2 Factors Affecting Microbial Growth 168

Toolbox 6.1 PHENOTYPE MICROARRAYS FOR EXAMINING MICROBIAL GROWTH 169

6.3 Growing Microorganisms in the Laboratory 173

Perspective 6.1 THE DISCOVERY OF *HELICOBACTER PYLORI* 178

Toolbox 6.2 FISHING FOR UNCULTIVATED MICROORGANISMS 180

6.4 Measuring Microbial Population Growth 181

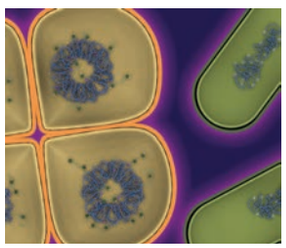
Mini-Paper: A Focus on the Research BRINGING TO LIFE THE PREVIOUSLY UNCULTURABLE USING THE SOIL SUBSTRATE MEMBRANE SYSTEM (SSMS) 182

Perspective 6.2 *MYCOBACTERIUM LEPRAE*, AN EXTRAORDINARILY SLOW-GROWING PATHOGEN 189

Perspective 6.3 THE HUMAN INTESTINE—A CONTINUOUS CULTURE 191

6.5 Eliminating Microbes and Preventing Their Growth 192

PART II MICROBIAL GENETICS



7 DNA Replication and Gene Expression 202

7.1 The Role of DNA 204

7.2 DNA Replication 210

7.3 Transcription 217

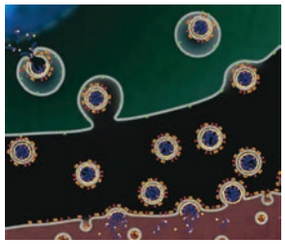
Toolbox 7.1 USING A GEL SHIFT ASSAY TO IDENTIFY DNA-BINDING PROTEINS 219

7.4 Translation 222

7.5 The Effects of Mutations 229

Mini-Paper: A Focus on the Research TELOMERES WITH PROMOTER ACTIVITY 232

Perspective 7.1 USING MUTATIONS TO CONTROL VIRAL INFECTIONS 234



8 Viral Replication Strategies 238

8.1 Recognition of Host Cells 240

Perspective 8.1 DNA MICROARRAYS AND THE SARS VIRUS 242

Toolbox 8.1 THE WESTERN BLOT 244

8.2 Viral Entry and Uncoating 246

8.3 Viral Replication 249

Perspective 8.2 PHAGE THERAPY: BIOCONTROL FOR INFECTIONS 256

8.4 Viral Assembly and Egress 258

Mini-Paper: A Focus on the Research THE DISCOVERY OF REVERSE TRANSCRIPTASE 260

9 Bacterial Genetic Analysis and Manipulation 264

9.1 Bacteria as Subjects of Genetic Research 266

9.2 Mutations, Mutants, and Strains 269

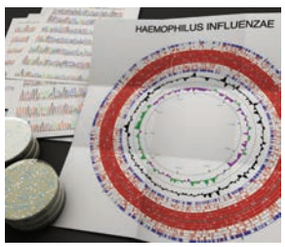
Toolbox 9.1 ISOLATING NUTRITIONAL MUTANTS 271

9.3 Restriction Enzymes, Vectors, and Cloning 276

9.4 Recombination and DNA Transfer 283

Perspective 9.1 PLASMIDS THAT PRODUCE PATHOGENS 287

Mini-Paper: A Focus on the Research THE DISCOVERY OF TRANSDUCTION 294



10 Microbial Genomics 300

10.1 Genome Sequencing 302

Perspective 10.1 RATE OF DNA SEQUENCING 306

Toolbox 10.1 GENOME DATABASES 310

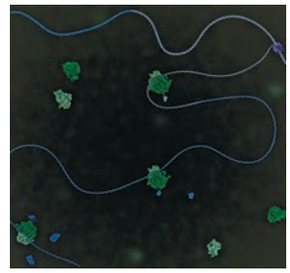
10.2 Genomic Analysis of Gene Expression 312

10.3 Comparative Genomics 318

Perspective 10.2 THE MINIMAL GENOME 318

Mini-Paper: A Focus on the Research GENOME SEQUENCE OF A KILLER BUG 320

10.4 Metagenomics and Related Analyses 323



11 Regulation of Gene Expression 328

11.1 Differential Gene Expression 330

11.2 The Operon 332

11.3 Global Gene Regulation 337

Mini-Paper: A Focus on the Research TUNING PROMOTERS FOR USE IN SYNTHETIC BIOLOGY 338

Perspective 11.1 THE USE OF LACTOSE ANALOGS IN GENE EXPRESSION STUDIES 342

11.4 Post-initiation Control of Gene Expression 345

Toolbox 11.1 USING RNA MOLECULES TO DECREASE GENE EXPRESSION 347

11.5 Quorum Sensing 348

11.6 Two-Component Regulatory Systems 351

11.7 Chemotaxis 354

12 Microbial Biotechnology 360

12.1 Microbes for Biotechnology 362

Perspective 12.1 BIOPROSPECTING: WHO OWNS THE MICROBES? 364

12.2 Molecular Genetic Modification 366

Toolbox 12.1 SITE-DIRECTED MUTAGENESIS 368

Toolbox 12.2 FUSION PROTEIN PURIFICATION 374

Mini-Paper: A Focus on the Research MAKING A SYNTHETIC GENOME 376

Perspective 12.2 THE INTERNATIONAL GENETICALLY ENGINEERED MACHINE (IGEM) COMPETITION, STANDARD BIOLOGICAL PARTS, AND SYNTHETIC BIOLOGY 378

12.3 Red Biotechnology 379

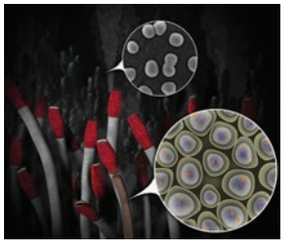
12.4 White Biotechnology 381

Perspective 12.3 BIOFUELS: BIODIESEL AND ALGAE 384

12.5 Green Biotechnology 390

Toolbox 12.3 PLANT TRANSFORMATION USING BACTERIA 392

PART III MICROBIAL PHYSIOLOGY AND ECOLOGY



13 Metabolism 400

13.1 Energy, Enzymes, and ATP 402

Perspective 13.1 WHO NEEDS VITAMINS? 405

13.2 Central Processes in ATP Synthesis 406

13.3 Carbon Utilization in Microorganisms 412

13.4 Respiration and the Electron Transport System 421

Perspective 13.2 ELECTRICIGENIC BACTERIA AND MICROBIAL FUEL CELLS 425

13.5 Metabolism of Non-glucose Carbon Sources 429

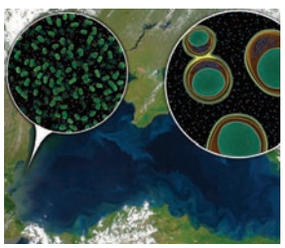
Toolbox 13.1 METABOLISM AND RAPID BACTERIAL IDENTIFICATION SYSTEMS 431

13.6 Phototrophy and Photosynthesis 433

13.7 Nitrogen and Sulfur Metabolism 442

Mini-Paper: A Focus on the Research GENOME SEQUENCE OF A DEEP SEA SYMBIONT 443

13.8 Biosynthesis of Cellular Components 448



14 Biogeochemical Cycles 456

14.1 Nutrient Cycling 459

Toolbox 14.1 USING MICROARRAYS TO EXAMINE MICROBIAL COMMUNITIES: The GeoChip 461

14.2 Cycling Driven by Carbon Metabolism 462

Perspective 14.1 CO_2 AS A GREENHOUSE GAS AND ITS INFLUENCE ON CLIMATE CHANGE 464

14.3 Cycling Driven by Nitrogen Metabolism 471

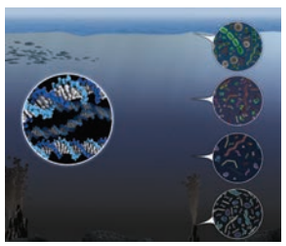
Mini-Paper: A Focus on the Research THE FIRST ISOLATION AND CULTIVATION OF A MARINE ARCHAEON 476

14.4 Other Cycles and their Connections 476

Perspective 14.2 LIFE IN A WORLD WITHOUT MICROBES 478

Perspective 14.3 THE MICROBIOLOGY OF ENVIRONMENTALLY TOXIC ACID MINE DRAINAGE 479

Toolbox 14.2 BIOGEOCHEMISTRY IN A BOTTLE: THE WINOGRADSKY COLUMN 481



15 Microbial Ecosystems 486

15.1 Microbes in the Environment 488

15.2 Microbial Community Analysis 493

Toolbox 15.1 FLOW CYTOMETRY 498

Mini-Paper: A Focus on the Research INSIGHTS INTO THE PHYLOGENY AND CODING POTENTIAL OF MICROBIAL DARK MATTER 500

Perspective 15.1 NAMING THE UNCULTURED AND UNCHARACTERIZED 502

15.3 Aquatic Ecosystems 502

Perspective 15.2 DEAD ZONES 503

15.4 Terrestrial Ecosystems 509

15.5 Deep Subsurface and Geothermal Ecosystems 515

16 The Microbiology of Food and Water 524

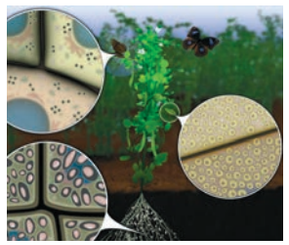
16.1 Food Spoilage 526
16.2 Food Preservation 530
16.3 Food Fermentation 535
16.4 Foodborne and Waterborne Illness 542
16.5 Microbiological Aspects of Water Quality 545

Perspective 16.1 IMPLICATIONS OF SLUDGE BULKING 550

Toolbox 16.1 MEASURING BIOCHEMICAL OXYGEN DEMAND (BOD) 551

Mini-Paper: A Focus on the Research ENHANCED BIOLOGICAL REMOVAL OF PHOSPHORUS 553

Toolbox 16.2 MOST PROBABLE NUMBER (MPN) METHOD 556



17 Microbial Symbionts 562

17.1 Types of Microbe-Host Interactions 564
17.2 Symbionts of Plants 566
17.3 Symbionts of Humans 571

Toolbox 17.1 GERM-FREE AND GNOTOBIOTIC ANIMALS 575

Perspective 17.1 FOOD PROBIOTICS—DO THEY WORK? 577

Mini-Paper: A Focus on the Research FECAL BACTERIOTHERAPY: "REPOOPULATION" OF THE GUT 580

17.4 Symbionts of Herbivores 582

Perspective 17.2 COWS CONTRIBUTE TO CLIMATE CHANGE 588

17.5 Symbionts of Invertebrates 588

Perspective 17.3 MIDICHLORIANS—NOT JUST FOR JEDI 592

Perspective 17.4 DEATH OF CORAL REEFS 595

PART IV MICROBES AND DISEASE

18 Introduction to Infectious Diseases 600

18.1 Pathogenic Microbes 603

Toolbox 18.1 MEASURING THE VIRULENCE OF PATHOGENS 605

18.2 Microbial Virulence Strategies 607

Perspective 18.1 GENOME EDITING: A POWERFUL AND CONTROVERSIAL NEW TECHNIQUE 613

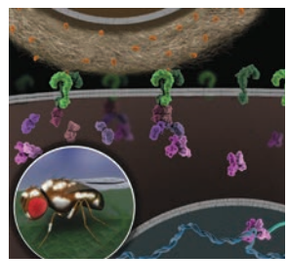
18.3 The Transmission of Infectious Diseases 614

Mini-Paper: A Focus on the Research EPIDEMIOLOGY OF AN INFECTIOUS DISEASE 622

18.4 Proving Cause and Effect in Microbial Infections 624

Perspective 18.2 THE ARMADILLO—AN IDEAL ANIMAL MODEL? 628

18.5 The Evolution of Pathogens 629



19 Innate Host Defenses Against Microbial Invasion 638

19.1 Immunity 640
19.2 Barriers to Infection 641

Perspective 19.1 MESSY MUCUS 644

19.3 The Inflammatory Response 645
19.4 The Molecules of the Innate System 646

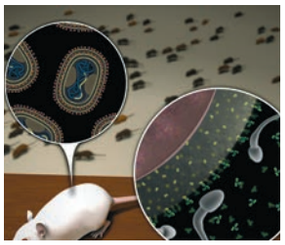
Mini-Paper: A Focus on the Research MAMMALIAN CELLS CAN RECOGNIZE BACTERIAL DNA 650

Toolbox 19.1 THE COMPLEMENT FIXATION TEST 654

19.5 The Cells of Innate Immunity 657

19.6 Invertebrate Defenses 665

Toolbox 19.2 THE LIMULUS AMOEBOCYTE ASSAY FOR LPS 667



20 Adaptive Immunity 672

20.1 Features of Adaptive Immunity 674

20.2 T Cells 677

20.3 Antigen Processing 682

20.4 Antigen-Presenting Cells 684

20.5 Humoral and Cell-Mediated Immune Responses 688

Mini-Paper: A Focus on the Research ATTEMPTING TO ENGINEER A VIRUS TO IMPROVE IMMUNOCONTRACEPTION 690

Perspective 20.1 TOO MUCH OF A GOOD THING? 691

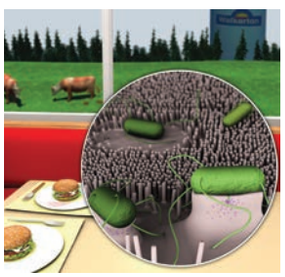
20.6 B Cells and the Production of Antibody 692

Perspective 20.2 VACCINES AGAINST T-INDEPENDENT ANTIGENS 696

Toolbox 20.1 MONOCLONAL ANTIBODY (mAb) PRODUCTION 698

Perspective 20.3 TURNING ANTIBODY UPSIDE DOWN 703

Toolbox 20.2 ENZYME-LINKED IMMUNOSORBENT ASSAY (ELISA) 704



21 Bacterial Pathogenesis 710

21.1 Bacterial Virulence Factors 712

Mini-Paper: A Focus on the Research *ESCHERICHIA COLI* INJECTS ITS OWN RECEPTOR 718

Perspective 21.1 IRON, VAMPIRES, FASHION, AND THE WHITE PLAGUE 722

21.2 Bacterial Virulence Factors—Toxins 723

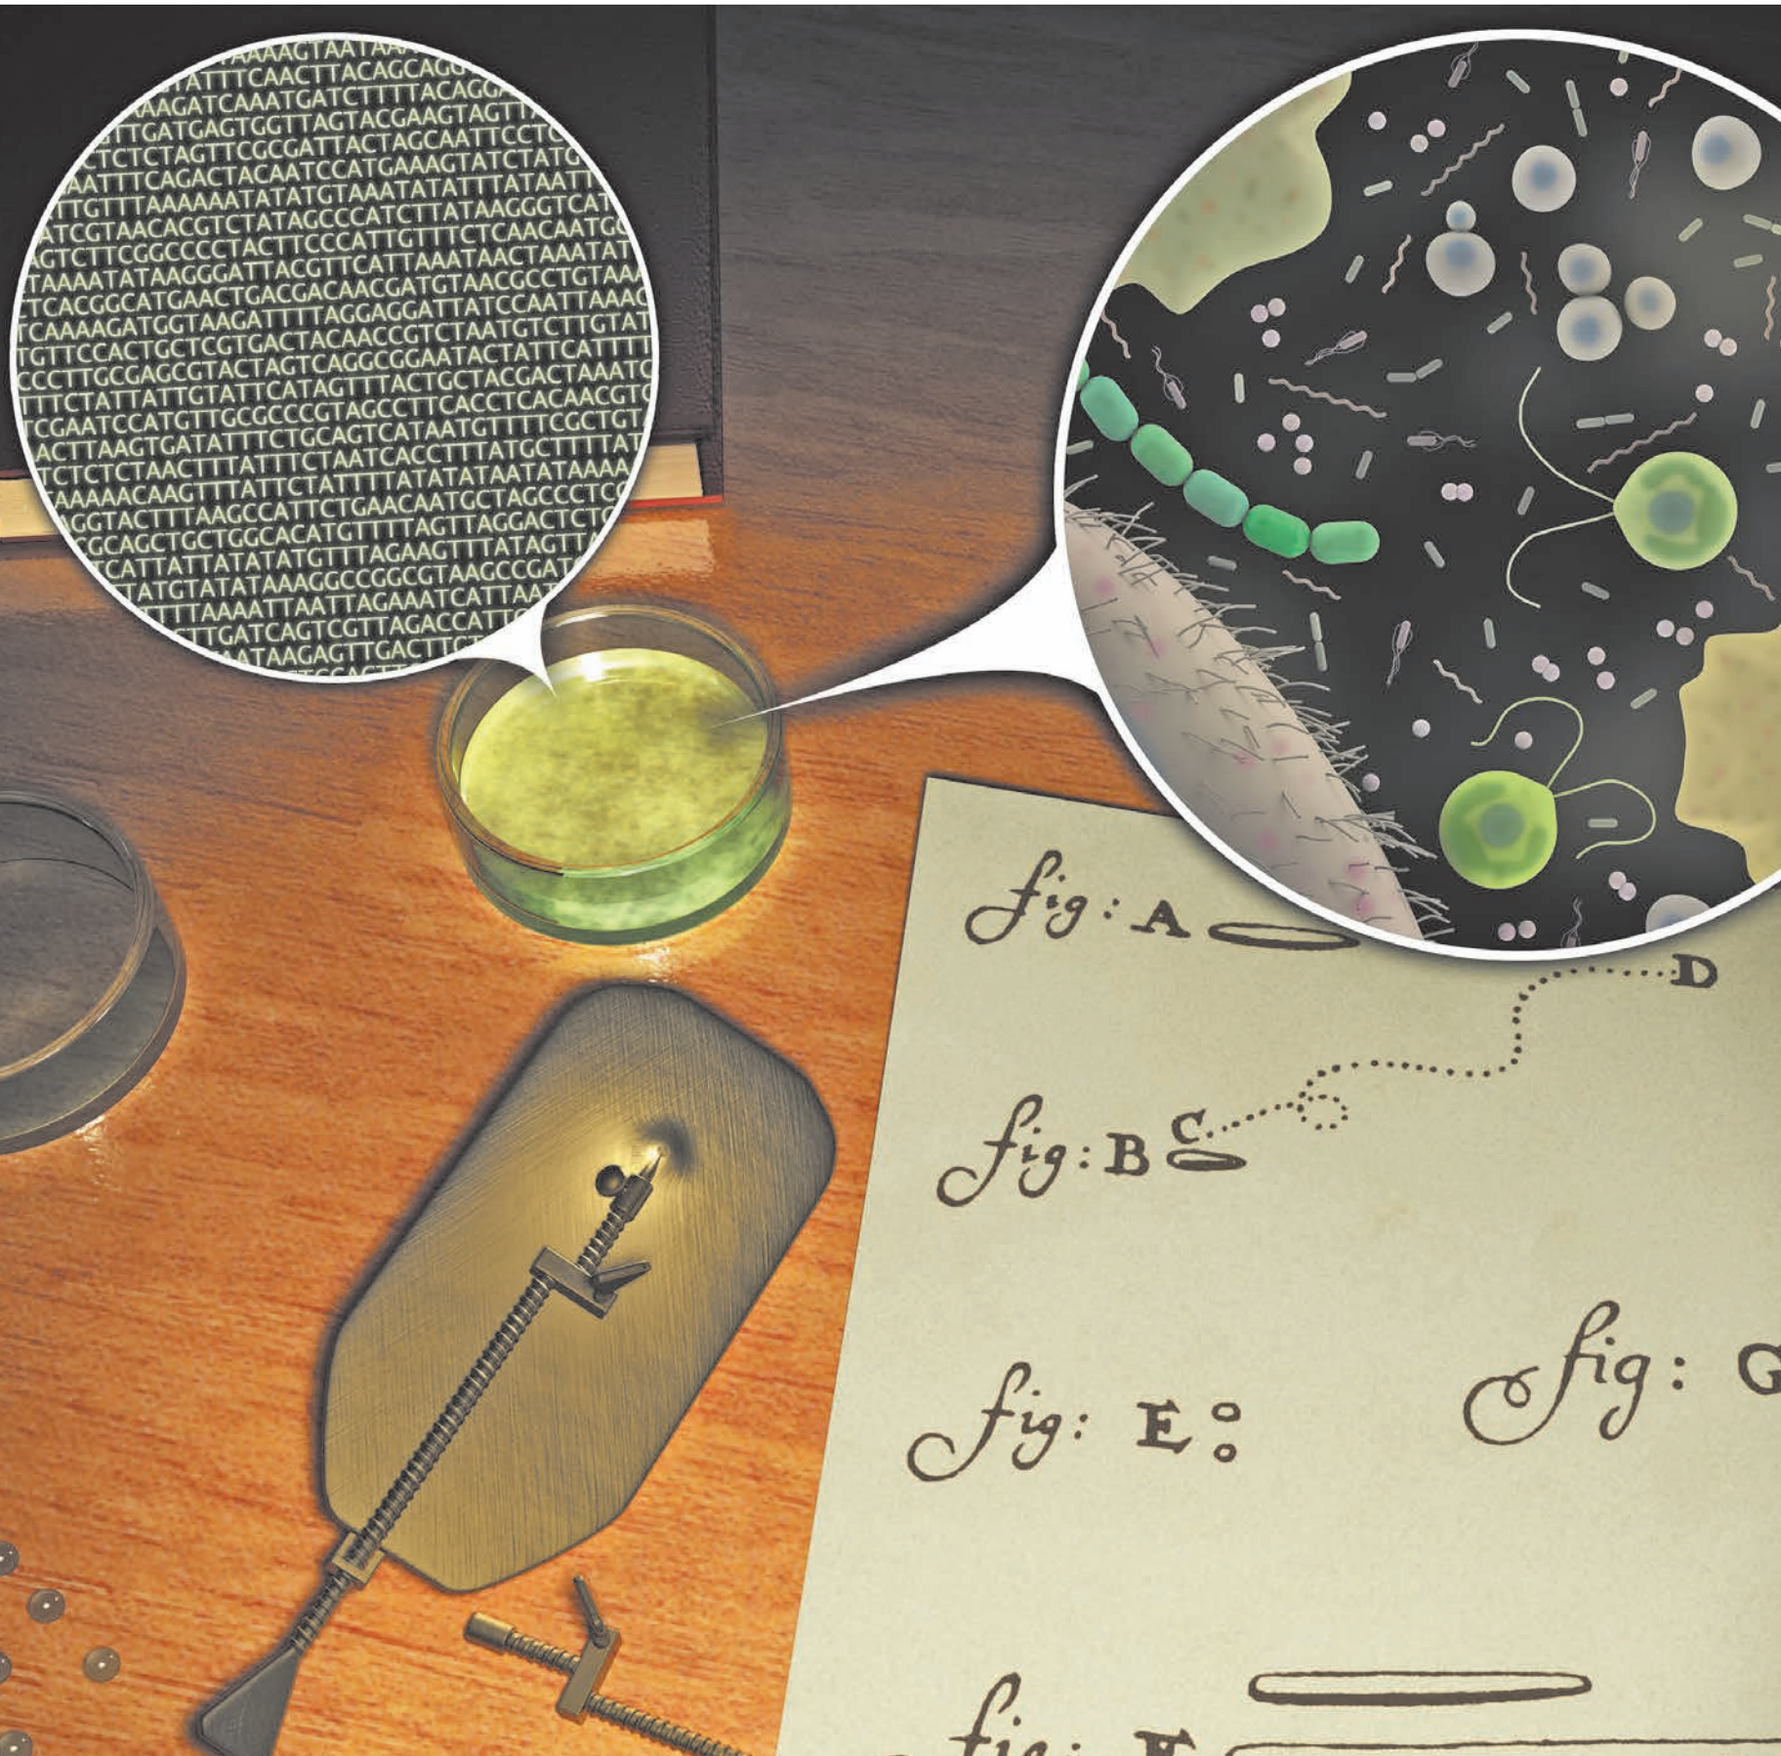
MICROBIOLOGY

CHAPTER 1

The Microbial World



Anton van Leeuwenhoek was a successful textile merchant in the city of Delft, in the Netherlands, in the late seventeenth century. He used magnifying lenses in his trade to examine cloth, but in 1665, after reading Robert Hooke's book *Micrographia*, van Leeuwenhoek became fascinated with using microscopes to explore the natural world. Hooke, an Englishman of about the same age as van Leeuwenhoek, had laboriously constructed microscopes that magnified objects roughly 30 times and used them to examine the fine structure of materials both living and dead. His greatest contribution to biology was the discovery of cells, which he first observed in cork slices, as the units from which living organisms are assembled. Hooke's writings inspired van Leeuwenhoek, who enjoyed blowing glass and grinding tiny lenses, to fabricate simple but remarkably powerful microscopes. Some of the 400 or so microscopes that van Leeuwenhoek built magnified images almost 300-fold, and could be used to observe objects one-tenth the size that Hooke had seen. If we consider that the best modern light microscopes of today are limited to around 1000-fold magnification, van Leeuwenhoek's accomplishments are even more astounding!

With his extraordinary lenses, van Leeuwenhoek pushed the frontiers of human knowledge to ever-smaller dimensions. No one had imagined living creatures so small they could not be seen by the human eye, yet van Leeuwenhoek saw them all around us, on us, even inside us. In a letter to the Royal Society of London in 1684, he related that:

> The number of these Animals in the scurf of a man's Teeth, are so many, that I believe they exceed the number of Men in a kingdom. For upon the examination of a small parcel of it, no thicker than a Horse-hair, I found too many living Anima's therein, that I guess there might have been 1000 in a quantity of matter no bigger then the 1/100 part of a sand.

In another letter, he confided with amazement that:

> I then most always saw, with great wonder, that in the said matter there were many very little living animalcules, very prettily a-moving.

Thus, this modest Dutch merchant revealed a whole new "microscopic" world to humanity. Van Leeuwenhoek discovered microorganisms.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Microbiology involves the study of bacteria, archaea, eukaryal microorganisms, and viruses.

- Table 1.1: Macromolecules in microbial cells
- Animation: Classification systems
- Toolbox 1.1: Polymerase chain reaction amplification of rRNA genes
- Mini-Paper: The three domains of life

Studies of microbes have provided insight into the evolution of life and genetics.

- Perspective 1.1: Creating life in the laboratory: The Miller–Urey experiment
- Animation: Endosymbiosis
- Figure 1.20: Effects of mutations
- Figure 1.22: Recombinant DNA techniques

The metabolic properties of microorganisms are related to their habitats.

- Figure 1.24: Glycolysis, fermentation, and aerobic respiration
- Figure 1.25: Role of microbes in the global nitrogen cycle

Microbes remain important causes of disease throughout the world.

- Microbes in Focus 1.1: *Bacillus anthracis*
- Figure 1.30: Infectious disease deaths in the United States during the twentieth century
- Figure 1.32: Impact of malaria in sub-Saharan Africa

CONNECTIONS for this chapter:

Development of antimicrobial and antiviral drugs **(Section 24.2)**

Evolution of eukaryal cells through an endosymbiotic process **(Section 3.4)**

Oxygenic and anoxygenic photosynthesis **(Section 13.6)**

Epidemiology: The study of how infectious diseases spread within populations **(Section 18.3)**

Introduction

With wonder in his voice, Anton van Leeuwenhoek shared his observations of microbial life with a skeptical public. In the three centuries since van Leeuwenhoek first viewed these "animalcules," the scientific community and the general public have become much more appreciative of the importance of microbes. We now know that microscopic life on Earth is enormously abundant and diverse, that microbes appeared billions of years before humans, and that the health of the entire biosphere depends on its tiniest microbial inhabitants. We also know that microbes interact with each other and with multicellular organisms, including humans, in many ways. Because of our increased understanding of microbes, we now can use them to help us in many agricultural and industrial settings. Additionally, we now better understand how our own bodies work. We also have learned to fear microbes; some of them cause diseases that have resulted in the suffering and death of untold millions of people through the ages.

Throughout this book, we will explore all of these aspects of microbiology. While we will use specific examples to illustrate our points, we will focus on the general principles. We will emphasize the relationships between microbes and the evolutionary history of biological processes. We also will learn how the study of microbes relates to various other disciplines, like genetics, chemistry, and environmental science. Finally, we will see that microbiology itself is a dynamic, evolving science. Our knowledge of microbiology is predicated on thoughtful, interesting, and exciting experiments. Much more still awaits our discovery. As we will note throughout this book, we do not know all the answers. We probably do not even know all the questions! The field of microbiology is ever changing. Today's basic research will lead to tomorrow's revelations.

So, let's start our exploration of this dynamic field. In this chapter and in the book as a whole, we first will learn about the microbes. Then, we will examine the genetics of microbes. Next, we will look at the metabolism of microorganisms and how microbes interact with their environment. Finally, we will explore the role of microbes in disease. We will frame our initial discussion around these questions:

What is microbiology? (1.1)
What do we know about the evolution of life and the genetics of microbes? (1.2)
How do microbes get energy and interact with the world around them? (1.3)
How are microbes associated with disease? (1.4)

1.1 The microbes

What is microbiology?

Microorganisms are microscopic forms of life—organisms that are too small to see with the unaided eye. They usually consist of a single cell and include bacteria, archaea, fungi, protozoa, and algae. We will include viruses in many of our discussions as well. Viruses are not living, but they are microscopic; they use biological molecules and cellular machinery (borrowed from their host) to replicate, and they can cause infectious diseases like some microorganisms. Although viruses are not microorganisms, we can refer to them as **microbes**, a more general term that includes microorganisms and viruses. **Microbiology**, then, is the study of microbes.

Our relationship with the microbial world is complex and dynamic. On one hand, harmful bacteria, viruses, fungi, and protozoa kill millions of people each year and sicken billions. On the other hand, beneficial microbes associated with our bodies help us digest food and protect us from potentially harmful microbial invaders (Figure 1.1). Some microbes cause crops to fail, while others provide essential nitrogen to plant roots through symbiotic relationships. Some microbes cause food to rot, but others carry out fermentations that produce yogurt, wine, beer, and other foods and beverages (Figure 1.2).

In the past few decades, we have learned so much about the molecular machinery of life through the study of microbes, like the bacterium *Escherichia coli*. Indeed, scientists now routinely alter microbial cells to produce high-value, lifesaving medical products (Figure 1.3). Whether helpful or harmful, the microbial world is deeply intertwined with our lives, and with the very fabric of life on Earth. Let's begin our exploration of microbiology, then, by asking a very fundamental question. What is life?

CONNECTIONS Throughout this book, we will show you many micrographs, photographs or digital images obtained through a microscope. For each one, an icon will tell you what type of microscopy was used. Specifically, LM indicates light microscopy, SEM refers to scanning electron microscopy, TEM signifies transmission electron microscopy, and FM represents fluorescence microscopy. A detailed examination of microscopy is provided in **Appendix B**.

The basis of life

So, what is life? This question has fascinated humans for millennia—perhaps since our ancestors first developed conscious, introspective thought. As biologists, we will focus on a practical definition of "life" that distinguishes living organisms from non-living objects.

Figure 1.3. Microbes and medicine Using recombinant DNA techniques, researchers can alter genes of microbes such that the microbes produce large quantities of medically important compounds. As we will see later in this chapter, human insulin today is produced by the bacterium *Escherichia coli*. Here, researchers monitor conditions in a large-scale bioreactor used to grow recombinant bacteria.

First, living organisms are composed of **cells**, the smallest units of life as we know it. Second, living organisms are capable of:

- **Metabolism**: A controlled set of chemical reactions that extract energy and nutrients from the environment, and transform them into new biological materials.
- **Growth**: An increase in the mass of biological material.
- **Reproduction**: The production of new copies of the organism.

To accomplish these tasks, organisms contain a biological instruction set to guide their actions. These instructions need to be reproduced as the organism itself reproduces. Other features that living organisms share include:

- Genetic variation, allowing the possibility of **evolution**, or inherited change within a population, through natural selection over the course of multiple generations.
- Response to external stimuli and adaptation to the local environment (within genetic and physiological constraints).
- **Homeostasis**: Active regulation of their internal environment to maintain relative constancy.

Does this list represent a complete description of what it means to be alive? Probably not. It's easy to come up with situations that challenge these criteria. Consider the curious case of bacterial endospores, specialized, metabolically inert cells produced by some bacterial species under highly stressful conditions. After shutting down metabolism, growth, and reproduction, endospores can remain dormant for long periods of time, even thousands of years, awaiting a favorable environment to germinate. Is an endospore alive during this state of suspended animation? These spores have all the components of living cells and, when conditions are appropriate, they will again develop into cells that meet the criteria listed above. As we will see later in this section, viruses—subcellular microbes—represent an even more interesting anomaly to the standard definition of life. As a result, our definition of life should be applied holistically; an organism may not exhibit all of these traits at all times.

Most microorganisms live and function as single, autonomous cells. A free-living unicellular, or single-celled, organism can carry out all the necessary functions of metabolism, growth, and reproduction without physical connection to any other cells. In contrast, multicellular organisms are composed of many physically connected and genetically identical cells. The constituent cells that contribute to a multicellular organism can have distinct, specialized functions. A complex organism like a human can have hundreds of cell types organized into tissues and organs. Although the distinction between unicellular and multicellular organisms seems obvious, you might rethink this issue later as we learn more about the microbial world. Some unicellular organisms, for instance, only can survive in close association with cells of another species. Other unicellular microorganisms can communicate, behave socially, form three-dimensional structures containing millions of cells with different functions, and enter into dependent relationships with other cells. These behaviors blur the boundaries between unicellular and multicellular lifestyles. The slime mold *Dictyostelium discoideum*, for instance, exists as a rather typical unicellular organism when food is readily available. However, individual cells aggregate and form a complex structure during periods of nutrient depletion, with cells differentiating to assume specialized tasks **(Figure 1.4)**. Before we investigate these more unusual arrangements, though, let's learn more about the chemical makeup of cells.

Chemical makeup of cells

As we shall see in this section, all cells share some basic features. Notably, all cells are built from **macromolecules**, large, complex molecules composed of simpler subunits **(Table 1.1)**. Typically, macromolecules make up over 90 percent of a cell's dry weight, or the weight obtained after the removal of all water. In this section, we will explore the four major types of macromolecules found in cells: polypeptides, nucleic acids, lipids, and polysaccharides. For each, we will look briefly at their structure and functions.

Polypeptides, polymers of amino acids, constitute the most abundant class of macromolecules. Polypeptides, also often referred to as proteins, fold into elaborate structures and can execute a vast array of important jobs. Some proteins function as **enzymes**, macromolecules that catalyze chemical reactions within the cell **(Figure 1.5)**. Other proteins may facilitate the movement of material into or out of the cell. Still other proteins comprise critical structures such as microfilaments that facilitate cell movement **(Table 1.2)**.

Nucleic acids, polymers of nucleotides, make up most of the remainder of the macromolecules within a cell. This category includes deoxyribonucleic acid (DNA), a polymer of deoxyribonucleotides, and ribonucleic acid (RNA), a polymer of ribonucleotides. Individual nucleotides are composed

Figure 1.5. Structure and function of enzymes In cells, many polypeptides function as enzymes, macromolecules that can catalyze chemical reactions. The function of the enzyme depends on its structure. The three-dimensional shape creates an active site with which the substrate interacts.

of a sugar molecule (deoxyribose in DNA, ribose in RNA), a phosphate moiety, and one of four nitrogen-containing bases (abbreviated A, T, C, and G in DNA; A, U, C, and G in RNA). In all cells, DNA constitutes the main informational molecule, containing instructions for the production of RNA molecules. These RNA molecules fulfill numerous functions within the cell, most of which are associated with protein production.

Lipids, hydrophobic hydrocarbon molecules, represent another important class of macromolecules. The primary role of lipids in most cells is to form the foundation of the plasma membrane, a barrier surrounding the cell that, quite simply, separates inside from outside. This membrane restricts the movement of materials into and out of the cell, thereby

TABLE 1.1 Macromolecules in microbial cells

Macromolecule	Subunits	Functions	Dry weight of cell (%)
Polypeptides	Amino acids	Enzymes catalyze the vast majority of biochemical reactions in the cell. Other proteins are structural components of cells.	50–55
Nucleic acids	Deoxyribonucleotides	Informational: DNA provides the instructions for assembly and reproduction of the cell.	2–5
	Ribonucleotides	Many functions, most of which are involved in the production of polypeptides. Some serve structural or catalytic functions.	15–20
Lipids	Diverse structures	Structural: Make up cellular membranes that form physical boundaries between the inside of a cell and its surroundings and membranes of internal organelles.	10
Polysaccharides	Sugars	Structural (such as cellulose and chitin) and energy storage (such as glycogen and starch).	6–7

TABLE 1.2 Functions of selected polypeptides

Polypeptide	Location	Function
RNA polymerase	Cytoplasm of bacteria and archaea, nucleus of eukarya	Produces RNA molecules from DNA template
Glycogen phosphorylase	Cytoplasm	Conversion of glycogen into glucose monomers
K^+ channel	Plasma membrane	Passive transport of K^+ across the membrane, from an area of high concentration to an area of low concentration
Na^+/K^+ ATPase	Plasma membrane	Active transport of Na^+ and K^+ across the membrane, from areas of low concentration to areas of high concentration
Flagellin	Bacterial flagellum	Monomers polymerize to form flagellum, which aids in bacterial motility
FtsZ	Associated with plasma membrane of bacteria	Key component of cell division machinery

allowing the cell to capture and concentrate nutrients for metabolism and growth and prevent the products of metabolism from escaping (Figure 1.6).

Polysaccharides are polymers of monosaccharides, or sugars. These molecules are composed entirely of carbon, hydrogen, and oxygen, with the general formula of $C_m(H_2O)_n$. Some polysaccharides serve as energy storage molecules. Starch and glycogen, for instance, are both polymers of the monosaccharide glucose ($C_6H_{12}O_6$). Other polysaccharides serve as structural molecules. Cellulose, the primary structural component of plant cell walls, also is a polymer of glucose monomers. Chitin, the primary structural component of fungal cell walls, consists of a derivative of glucose: *N*-acetylglucosamine. Many bacterial and archaeal cells use other polysaccharides for their cell walls.

The domains of life

Although polypeptides, nucleic acids, lipids, and polysaccharides exist in all living organisms, major groups of organisms also differ in substantial ways. Today, we categorize all living organisms and, by extension, their cells, into three domains: *Bacteria*, *Archaea*, and *Eukarya*. Until the late 1900s, however, biologists divided cells into only two types: **prokaryotes** and **eukaryotes** (Figure 1.7). The term "eukaryote" is derived from Greek roots meaning "true kernel," in contrast to the term "prokaryote," which translates as "before kernel." The "kernel" refers to the membrane-enclosed nucleus of eukaryal cells. The nucleus contains the genetic material of the eukaryal cell during most of the cell cycle and was clearly visible to microscopists in the 1800s. Its function as the organizer of the hereditary material was not understood until well into the 1900s.

Biologists noted other differences between these cell types. Additional membrane-enclosed organelles exist within eukaryal cells, with each organelle serving a unique and important function. Prokaryotes and eukaryotes also differ strikingly in the organization of their genetic material. Prokaryotes usually contain a single circular chromosomal DNA molecule. In contrast, eukaryotes usually contain multiple linear DNA molecules. At some point in their life cycle, most eukaryal organisms have two copies, or a $2n$ complement, of their genetic material. Most prokaryotes, in contrast, possess a single copy of their genetic material.

Conventional wisdom through the better part of the twentieth century stated that prokaryotes represented a fairly uniform group, until scientists started looking in more detail at the molecular machinery for the most ancient, important, and conserved processes in cells—the synthesis of DNA, RNA,

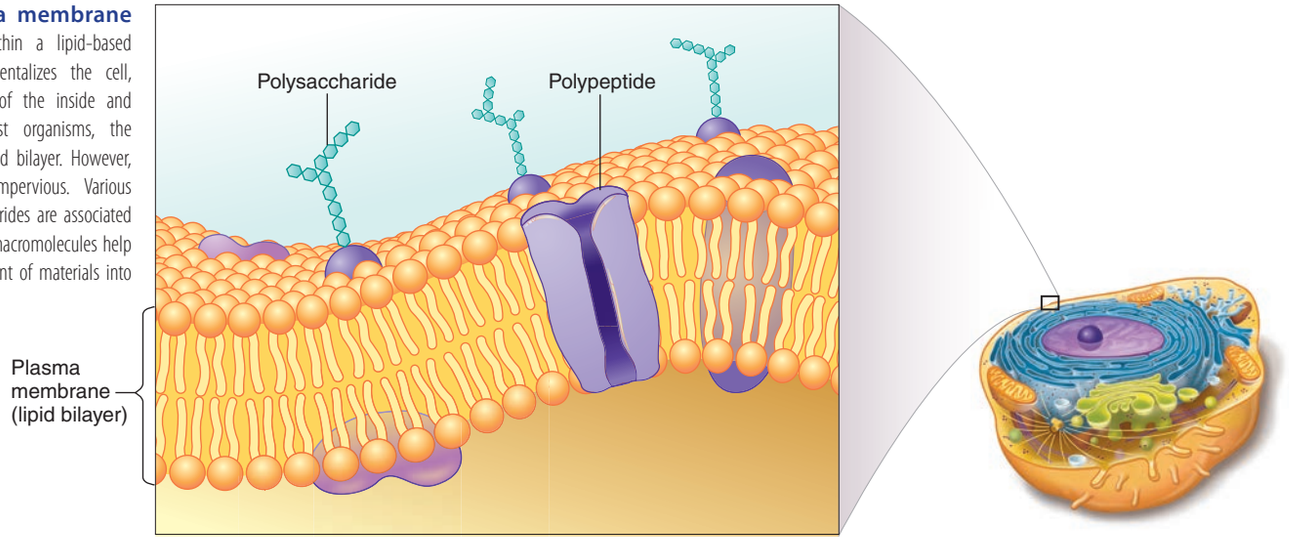

Figure 1.6. Plasma membrane All cells are enclosed within a lipid-based membrane that compartmentalizes the cell, allowing the composition of the inside and outside to differ. In most organisms, the membrane consists of a lipid bilayer. However, this membrane is not impervious. Various polypeptides and polysaccharides are associated with the membrane. These macromolecules help the cell control the movement of materials into and out of the cell.

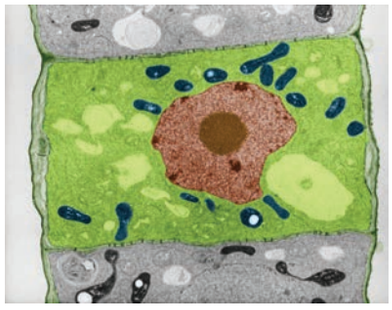
A. Prokaryotic cell



© David M. Phillips / Science Source Images

B. Eukaryotic cell

Figure 1.7. Prokaryotic and eukaryotic cells A. Prokaryotic cells, as seen in this colorized micrograph of *Escherichia coli*, lack a membrane-bound nucleus. They include organisms in the domains *Bacteria* and *Archaea*. **B.** Eukaryotic cells contain a membrane-bound nucleus, as seen in purple in this artist's rendition of a plant cell. Until the latter decades of the twentieth century, biologists divided all cells into these two main types: prokaryotes and eukaryotes. Today, we recognize that all living organisms really should be divided into three categories, or domains: *Bacteria*, *Archaea*, and *Eukarya*. Eukarya contain nuclei. Bacteria and archaea do not.

and polypeptides. In the 1970s, microbiologists studying some prokaryotes noted that their molecular machinery resembled that of eukaryotes more than it did other prokaryotes. Leading the way in these studies was Dr. Carl Woese of the University of Illinois. Woese focused his attention on the structure and sequence of one of the RNA molecules that serves as a scaffold for assembly of the ribosome—the small subunit (SSU) ribosomal RNA. This molecule is a critical component of the ribosome in all living organisms and interacts with the messenger RNA during translation (see Section 7.4). His work paved the way for a revolution in thinking about the **phylogeny**, or evolutionary history, of organisms (Figure 1.8). His studies also led to a major revision in the taxonomy, or the classification, of living organisms. Because of Woese's work, we now categorize all living organisms into one of three domains: Bacteria, *Archaea*, or *Eukarya* (Mini-Paper).

Thanks largely to the development of the **polymerase chain reaction (PCR)**, a technique that allows researchers to quickly amplify specific pieces of DNA (Toolbox 1.1), we now have a richer and more accurate phylogenetic tree. This tree is consistent with the idea that the archaeal and eukaryal domains shared a common ancestor after they split from the bacterial domain. It probably is impossible, though, to determine when the divergence of these lineages actually occurred; microorganisms do not fossilize well. That said, fossilized stromatolites, mineralized mats built up by layer upon layer of photosynthetic bacteria and other microbes in shallow marine habitats, have been observed in rock formations nearly 3.5 billion years old (see Figure 1.13). If such elaborate microbial communities, including bacteria capable of photosynthesis (see Section 2.4), existed 3.5 billion years ago, then the split between *Bacteria* and the *Archaea/Eukarya* domains probably occurred much earlier.

Although all cells share many features, studies have demonstrated clearly that bacteria, archaea, and eukarya are evolutionarily distinct. Some of their differences are listed in Table 1.3. We will discuss each of these types of cells in much more detail in Chapters 2–4.

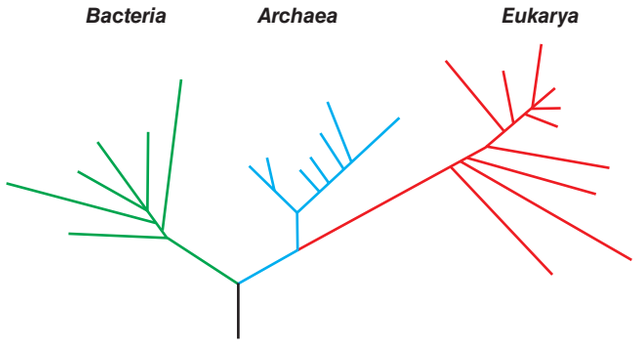


Figure 1.8 Phylogenetic tree of life By comparing the sequences of small subunit (SSU) ribosomal RNA gene sequences, researchers now classify all living organisms into one of three domains: *Bacteria*, *Archaea*, or *Eukarya*. In this phylogenetic tree, bacteria are shown in green, archaea are shown in blue, and eukarya are shown in red. The linear distance between the endpoints of any two lines is proportional to the sequence similarity of the SSU rRNA gene sequences from the organisms corresponding to the endpoints. Sequence similarity reflects evolutionary distance.

Viruses

Are viruses alive? They are not cellular, but they certainly replicate and evolve. Viruses, however, require host cells for replication. Outside of a host cell, virus particles are essentially inert. An isolated virus has no metabolism—it takes up no nutrients and extracts no energy from its environment. Viruses also lack most of the basic machinery needed for the synthesis of macromolecules. Viruses do not respond to stimuli, except perhaps when they bind to receptors on a new host cell, and they do not maintain internal homeostasis. When a virus enters a host cell, it does not grow and reproduce in the same sense that cellular organisms do. Virus particles are more or less completely disassembled in the host cell, and new virus particles are only assembled after the genetic material has been replicated and the host cell has synthesized new viral proteins. Cellular organisms have no comparable state of disassembly during their growth and reproduction.

C. R. Woese, O. Kandler, and M. L. Wheelis. 1990. Towards a natural system of organisms: Proposal for the domains Archaea, Bacteria, and Eucarya. Proc Natl Acad Sci USA 87: 4576–4579.

Context

Aristotle categorized life into just two fundamental groups, animals and plants, and this categorization persisted until the dawn of microbiology as a science. In 1868, two centuries after van Leeuwenhoek's discovery of microbial life, German biologist Ernst Haeckel proposed a third fundamental group, or kingdom, *Protista*, for microscopic lifeforms. In 1938, Herbert Copeland suggested that microorganisms should actually be divided into two kingdoms, *Protista* and *Bacteria*, thereby recognizing the difference between eukaryotic and prokaryotic cells. Twenty years later, Robert Whittaker advocated further separation of eukaryotic microorganisms into kingdoms of *Fungi* and *Protista*, but kept prokaryotic cells in a single kingdom called *Monera*. This five-kingdom taxonomic system—*Animalia*, *Plantae*, *Fungi*, *Protista*, and *Monera*—became the accepted standard for the next few decades until DNA and protein sequences became widely accessible.

Carl Woese, a microbiologist at the University of Illinois, was fascinated by a group of prokaryotes known at the time as "archaebacteria." Initially, these strange microorganisms were found primarily in marginal environments such as anoxic sediments, hypersaline ponds, and hot springs. Other than their curious ability to colonize extreme habitats, the feature of archaebacteria that generated the most interest among the wider biological community was the ability of some of these organisms to produce methane. These microorganisms remain the only organisms known to produce this gas.

To understand the phylogeny, or evolutionary history, of these methane-producing microorganisms, Woese followed the lead of Zuckerkandl and Pauling, who had first demonstrated in the 1960s that comparisons of protein sequences could reveal evolutionary relationships. If two organisms were closely related, these researchers reasoned, then the amino acid sequence of a common protein in the organisms should be very similar. Conversely, if two organisms were distantly related, then the amino acid sequence of a common protein should be more divergent. Woese and colleagues began to focus not on protein sequences, but on RNA sequences. Woese reasoned that the ribosomal RNAs (rRNAs), because of their universal presence in all cells, could be excellent molecules to compare. In bacteria, the 16S rRNA molecule is part of the small subunit of the ribosome. In eukaryotes, the equivalent ribosomal RNA is the 18S rRNA. These molecules, collectively referred to as "small subunit (SSU) rRNA" molecules, are critical in the ribosome, helping to bring together the ribosomal structure, and interacting with messenger RNA. Not only are ribosomal RNAs universally distributed, but they also have the same function in all cells.

The SSU rRNA gene sequence has been referred to as a "molecular chronometer," a slowly ticking clock that measures evolutionary time. The sequence of this molecule changes very slowly because of the functional constraints on the molecule. Random mutations that occur within the gene encoding the small subunit rRNA often have serious negative consequences, so relatively few changes are passed on to subsequent generations. Nevertheless, there are enough differences in the roughly 1,600 nucleotide sequence to differentiate between species to map patterns of similarity. If one assumes that overall mutation rates are similar between species (which seems to be true with respect to rRNA genes), then one can quantify sequence differences between SSU rRNA genes in multiple species to infer relationships. Ultimately, Woese discovered that the methane-producing microorganisms were no more closely related to other bacteria than they were to the eukaryotes. They were not bacteria at all! Let's examine the scientific work that led to this conclusion.

Experiments

The 1990 Woese *et al.* paper actually presented no new experimental data. Its importance was in articulating a new view of the phylogeny of life. To understand the genesis of this idea, we should step back and examine the data. The biggest challenge Woese faced in the 1970s in developing ribosomal RNA sequences as a tool for phylogenetic analysis was the difficulty in determining such sequences. Woese and colleagues developed a laborious method to infer the sequence of 16S rRNA molecules, which they described in a 1977 article, "Comparative cataloging of 16S ribosomal ribonucleic acid: A molecular approach to procaryotic systematics," *Journal of Bacteriology*, vol. 27, pp. 44–57. First, RNA was extracted from cells. The isolated rRNA then was cut into small chunks using a ribonuclease enzyme that yields short fragments of nucleic acid usually 5–20 bases long. The sequence of each oligonucleotide was determined by further chemical and enzymatic analysis. In its original incarnation, this method did not actually yield a complete rRNA sequence, but rather a catalog of short oligonucleotide sequences present in the rRNA. Catalogs from different species then were compared.

The underlying assumption of molecular sequence comparisons is that the number of nucleotide differences between two sequences is proportional to the time since the two species diverged from a common ancestor. Species that share a more recent common ancestor will have fewer differences than species that have been separated for longer periods of time. Exactly how long ago two species separated depends on the rate at which mutations accumulate, which can be very difficult, if not impossible, to know. Fortunately, to determine phylogenetic relationships, we do not need to know *exact* times of divergence. We are just interested in *relative* times: if organisms A and B shared a common ancestor *after* they shared an ancestor with organism C, then A and B would have fewer sequence differences with each other than either would have with C. The Woese method essentially took each 16S rRNA sequence and compared it against all of the other species. A method for quantifying the similarity between sequences

was developed to yield an association coefficient between 0 and 1. A perfect match between sequences would result in an association coefficient of 1, whereas no matches would give a score of 0. From these scores, a computer algorithm was used to plot the most likely phylogenetic tree.

Starting with papers in 1977 and continuing through the 1980s, Woese and colleagues built a "universal phylogenetic tree" through comparison of SSU rRNA sequences from diverse organisms, including members of each of the five kingdoms of life, as defined at that time. The great strength of this universal tree is that it compares all organisms using a common standard, a molecule they all possess. Woese noted that this universal tree supports *three* primary branches of life, not the five kingdoms previously accepted. In the 1990 paper, Woese and his coauthors propose that these very ancient branches—*Bacteria*, *Eukarya* (or *Eucarya*, as it is spelled in the 1990 paper), and *Archaea*—be referred to as domains (see Figure 1.8).

The domain *Archaea* is composed of species previously known as archaebacteria. Though archaea lack a nucleus, they turned out to be no more similar to bacteria than they are to eukaryotic organisms, or eukarya. In fact, Woese's tree suggests that the domains *Archaea* and *Eukarya* share a more recent common ancestor than either does with the domain *Bacteria*. As we will see in Chapter 4, archaea are similar in size and shape to bacteria. Many of the enzymes used by archaea for DNA replication, transcription, and translation, however, more closely resemble the corresponding enzymes found in eukarya. Perhaps most interestingly, the plasma membrane of archaea differs chemically from the plasma membranes of bacteria or eukarya. The exact evolutionary history of these organisms is yet to be determined.

In this three-domain phylogenetic tree, *Monera* and *Protista* disappear as kingdoms. In fact, if kingdoms are to be defined by equivalent depth of branching—which implies roughly equivalent evolutionary times since divergence—rRNA gene sequence comparisons support many more kingdoms than were previously known, most of which are populated by microorganisms. As we will see in Chapter 4, Woese and coauthors proposed two kingdoms within the domain *Archaea*: *Crenarchaeota* and *Euryarchaeota*. The authors also noted the presence of heat-loving microorganisms in several other branches of life. It is quite possible, then, that the organism at the root of the tree (the last common ancestor of all life on Earth) was thermophilic, or heat-loving. We will return to this point in Section 1.2.

Impact

For the first time, biologists could create a natural taxonomic system in which all organisms are compared by the same criteria. The realization that the prokaryotes could not be united as a phylogenetic group raised many questions regarding the validity of the five-kingdom system. Not surprisingly, there was initial resistance. Many scientists challenged the validity of this approach and the computational methods on which it was based. Since Woese first conducted his experiments, there have been methodological improvements, specifically in the ability to amplify entire rRNA genes using the polymerase chain reaction (PCR; see Toolbox 1.1), followed by rapid and straightforward DNA sequencing. The basic concept of using rRNA gene sequence comparisons to derive phylogenetic relationships is now accepted as an essential method of phylogenetic analysis.

Sequence-based phylogenies have had more impact on microbiology than any other branch of science. Since this paper was published in 1990, databases containing ribosomal RNA gene sequences have grown explosively. The universal phylogenetic tree is now much richer and more complex, but the three-domain organization remains unchallenged. Using PCR, microbiologists can characterize organisms using rRNA gene sequences even if the microorganisms cannot be grown in culture. Because the majority of microbes apparently will not grow in laboratory culture (see Section 6.3), this approach is enormously important for understanding the true diversity of life on Earth and its evolutionary history. Proposals for new bacterial and archaeal kingdoms, based on rRNA gene analysis of uncultured organisms, have appeared regularly since 1990. Classification of eukaryal microorganisms also is affected by rRNA-based phylogenetics.

Ribosomal RNA sequences do not tell the entire evolutionary story of an organism. In the last decade, the DNA sequences of hundreds of entire genomes have been determined, most of them from microorganisms. It is clear that microbes are rampant sharers of genes, which we will discuss more in Chapters 9, 10, and 21. Although it is likely that rRNA genes are rarely shared and do accurately reflect the evolutionary history of the "core" genome, large fractions of genetic material in many organisms may have distinct histories, a finding that Carl Woese could scarcely have imagined when he began his revolutionary efforts to clarify microbial taxonomy.

Questions for Discussion

1. What features make SSU rRNA gene sequences ideal for phylogenetic studies?
2. What drawbacks do you see with the use of rRNA for these studies?
3. If we discover forms of life on another planet, would studies of rRNA gene sequences be useful for categorizing these life-forms?

Toolbox 1.1

POLYMERASE CHAIN REACTION AMPLIFICATION OF rRNA GENES

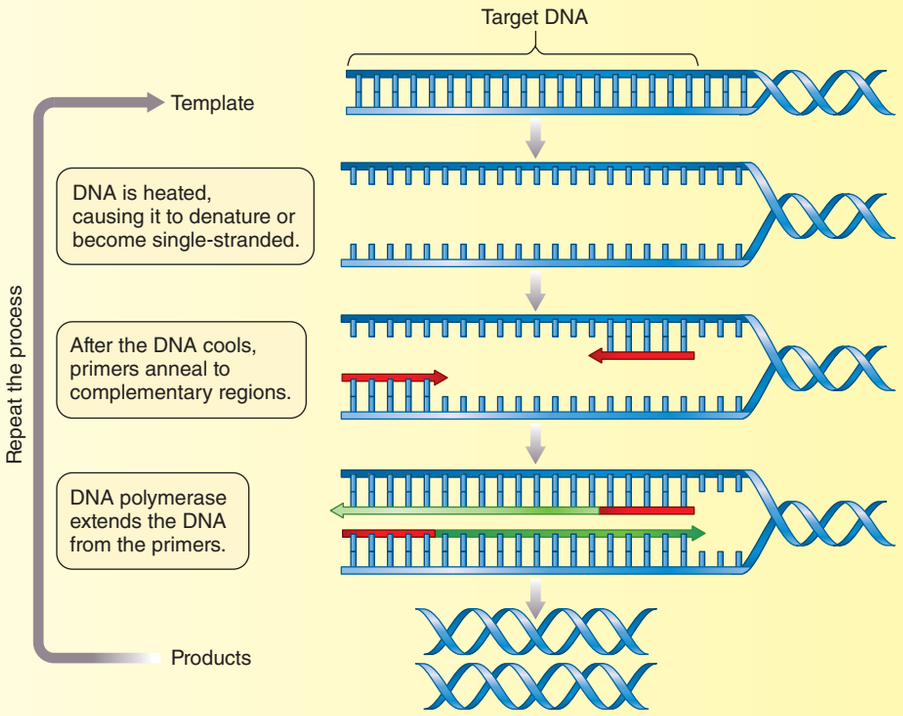

Figure B1.1. The polymerase chain reaction (PCR) After heating the DNA to denature, or separate, the two strands, the mixture is cooled, allowing the short, single-stranded DNA primers to anneal to their complementary regions. The DNA polymerase then extends these primers, using the opposite strand as a template. This process is repeated multiple times, resulting in the generation of many copies of the segment of DNA bounded by the primers. In this fashion, a small amount of input DNA can be amplified sufficiently to perform routine chemical analyses.

The method of ribosomal RNA sequencing developed by Carl Woese was extremely laborious. Fortunately, techniques just being developed in the 1970s and 1980s, as Woese and colleagues were initially developing the universal phylogenetic tree, made nucleic acid sequencing much simpler. The most important of these techniques was the polymerase chain reaction (PCR). With this technique, researchers can create millions of copies of a specific piece of DNA.

Polymerase chain reaction
ANIMATION

Kary Mullis, then a scientist at Cetus Corporation, a biotechnology company in Emeryville, California, invented PCR in 1983 and was awarded the Nobel Prize in Chemistry in 1993 for this discovery. The technique basically mirrors the process of DNA replication utilized by all cells. However, rather than replicating an entire DNA molecule, PCR results in the repeated replication, or amplification, of a small, defined segment of a larger DNA molecule. The reaction requires only a few basic reagents:

- DNA containing the sequence to be amplified
- Deoxyribonucleotides (dATP, dCTP, dTTP, and dGTP)
- DNA polymerase
- Oligonucleotide primers

The process begins with the denaturation of double-stranded DNA, making it single-stranded. This step is achieved by heating the DNA to around 95°C for a short period of time. The primers, 15–30 nucleotide-long pieces of single-stranded DNA synthesized in the laboratory, then bind to complementary regions on this newly denatured DNA. The primers are designed such that one primer binds to one strand of the denatured DNA, while the other primer binds to the other strand of the DNA. Additionally, the two primers bind to regions of the DNA flanking the sequence to be amplified **(Figure B1.1)**.

After the primers bind, the DNA polymerase begins generating new DNA, using the denatured DNA as a template. We will see in Section 7.2 that DNA polymerases generate new DNA by

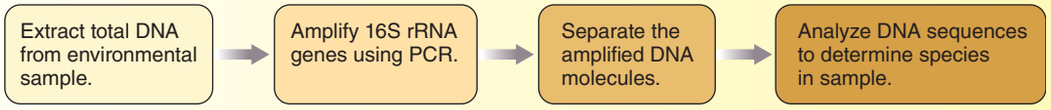

Figure B1.2. Use of PCR to identify microorganisms With PCR, microbial species can be identified simply by isolating a little of their DNA. As shown in this schematic, DNA can be isolated from an environmental source without isolating and growing pure cultures of specific bacterial species. By doing PCR with primers specific for the 16S rRNA gene, this region of the genome can be amplified and subsequently sequenced, thereby providing the investigator with enough information to determine which species are present.

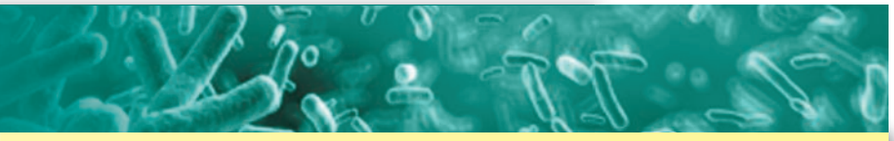

attaching deoxyribonucleotides to primers bound to a template strand. Because PCR usually employs only two primers that bind on either side of a specific region of DNA, these primers delineate which segment of the original DNA molecule will be replicated. The whole process, then, involves three steps:

- Denaturation, or melting, of the DNA
- Attachment, or annealing, of the primers
- Generation of new DNA by DNA polymerase

These steps are repeated multiple times, resulting in the exponential amplification of the region bounded by the two primers. After 10 cycles, the number of these amplified DNA molecules increases over 1000-fold. After 20 cycles, the increase is over one million-fold, and 30 cycles will generate over one billion new copies!

The crucial development that made PCR widely usable was the discovery of thermostable DNA polymerases that could withstand the high temperature (> 90°C) used to separate DNA strands. The first thermostable polymerase used for PCR was Taq DNA polymerase, which came originally from the bacterium *Thermus aquaticus*, isolated from hot springs in Yellowstone National Park in the United States. Today, a variety of thermostable DNA polymerases are commercially available, several of which have been isolated from heat-loving archaea. We will discuss these fascinating microorganisms more throughout Chapter 4.

PCR has revolutionized SSU rRNA gene sequence analysis and species identification. Today, just a bit of chromosomal DNA, extracted from an environmental sample, can be used as a template for PCR **(Figure B1.2)**. The PCR-amplified DNA products then can be separated and sequenced. By analyzing the sequences, researchers can accurately identify the species present in the original sample without isolating and growing pure cultures. The techniques available today certainly represent big improvements over Woese's method of sequencing fragments of rRNA molecules.

The uses of PCR in microbiology extend much further. PCR-based tests have been developed to detect the human pathogen ***Chlamydophila pneumoniae***, a bacterium that typically is difficult to identify. As we will see in Perspective 5.1, a form of PCR routinely is used to monitor the viral load, or amount of virus present, in people with HIV disease. PCR also allows us to learn more about microbes that currently cannot be grown in the laboratory, a topic we will explore in Section 6.3. Virtually all areas of microbiology have been affected by the conceptually simple polymerase chain reaction.

Test Your Understanding

Explain how PCR amplification would differ if a standard DNA polymerase, instead of a thermostable DNA polymerase such as Taq, were used. What would be the result and why?

CONNECTIONS Viruses infect all cellular forms of life. They replicate in various ways, but all depend on using host cell machinery for their replication. This makes them obligate intracellular parasites. We will examine viral replication in **Section 8.3**.

Although viruses are not cellular, they are still very important biological entities to study **(Figure 1.9)**. Viruses are molecular parasites that probably have been around since shortly after the first cells evolved. Microbiologists are interested in viruses not only because they cause many important infectious diseases in humans, crop plants, and livestock, but also because they are fascinating biological systems in their own right. Viruses have taught us a great deal about how cellular organisms function. As parasites, viruses must adapt to their host organism. To be taken up by host cells, most viruses have evolved to bind to host cell surface molecules and often enter cells by hijacking host systems ordinarily used for taking up non-viral molecules. Many viruses rely on host enzymes for the production of mRNA, and all viruses use host cell ribosomes for the production of proteins. By studying how viruses use the machinery of their host cells, scientists have gained insight into many critical processes in eukaryal, bacterial, and archaeal cells.

Microbes as research models

Basic research on the structure and function of microbes has laid a solid foundation for understanding the biology of all cells, including our own. Unicellular microorganisms generally possess the same genetic code and many of the same biochemical pathways as multicellular organisms. Additionally, microbes have many advantages for use in research:

- Many are easily cultivated in the lab using inexpensive equipment; they grow rapidly to high cell density on cheap nutrient sources.
- They facilitate the production of enzymes, other proteins, and various biomolecules for industrial and medical uses.
- Most have relatively small numbers of genes to analyze. Even the largest bacterial and archaeal genomes are smaller than the smallest eukaryal genomes, and eukaryal microorganisms have substantially fewer genes than complex multicellular eukarya.
- Many can be genetically manipulated much more easily than complex eukarya.

Popular microbial model systems for research include the intestinal bacterium *Escherichia coli* and the eukaryal yeast *Saccharomyces cerevisiae*, which is also known as baker's yeast or brewer's yeast, because of its long historical use in food and beverage production **(Figure 1.10)**. These model microorganisms have been subjected to the vast experimental armaments of the fields of biochemistry, genetics, molecular biology, and cell biology. Our current understanding of the complexities of biochemical pathways, DNA replication and cell division, the nature of genes, control of gene expression, and protein synthesis, folding, and function has arisen largely from studies of model microbes.

TABLE 1.3 Selected characteristics of the three domains

	Bacteria	*Archaea*	*Eukarya*
Nuclear membrane	No	No	Yes
Membrane-bound organelles	Rare, a few types found in a few species	Rare, a few types found in a few species	Multiple distinct types, found in all species
Plasma membrane	Similar to *Eukarya*	Different from *Bacteria* and *Eukarya*	Similar to *Bacteria*
Cell wall	Found in nearly all species, constructed of peptidoglycan	Found in nearly all species, constructed of various materials	Found in some species, constructed of various materials
RNA polymerases	Single polymerase	Single polymerase, eukaryal-like RNA pol II	Three main polymerases (RNA pol I, II, and III)
Histones	Histone-like proteins	Yes	Yes

Research on the biology of microbial cells has virtually unlimited practical applications. For example, to understand how some antimicrobial drugs work against their microbial targets while sparing host cells, we need to understand differences in structure between bacterial and eukaryal cells, or perhaps between fungal and human cells. Paul Ehrlich, a towering figure in the history of medicine and immunology, was among the first to recognize that such differences had medical implications. From his experience in the field of histology, Ehrlich was familiar with dyes that differentially stained bacterial and human cells. Based on this observation, he speculated that molecular "magic bullets" that specifically target microbial invaders were feasible. He had little knowledge of the actual structures present on or in cells of any kind, but this concept that certain drugs may adversely affect specific types of cells, while sparing other types of cells, remains at the heart of our drug development initiatives today.

Members of Ehrlich's research group discovered an organic arsenic-containing compound, arsphenamine, which in 1910 became the first effective commercial drug for the treatment of *Treponema pallidum*, the bacterium that causes the sexually transmitted disease syphilis (Figure 1.11). Because it also exhibited toxicity to host cells, arsphenamine, known by its trade name Salvarsan, was abandoned in the 1940s in favor of penicillin, the first widely used antibiotic capable of killing many different kinds of bacteria.

Salvarsan's historical importance was in establishing that lethal agents specifically targeted at microbial cells are indeed possible. In the century since Salvarsan came on the market, an enormous amount has been learned about the molecular differences between bacterial and eukaryal cells. Hundreds of new antimicrobial and antiviral drugs have been discovered, and hopefully there will be many more to come.

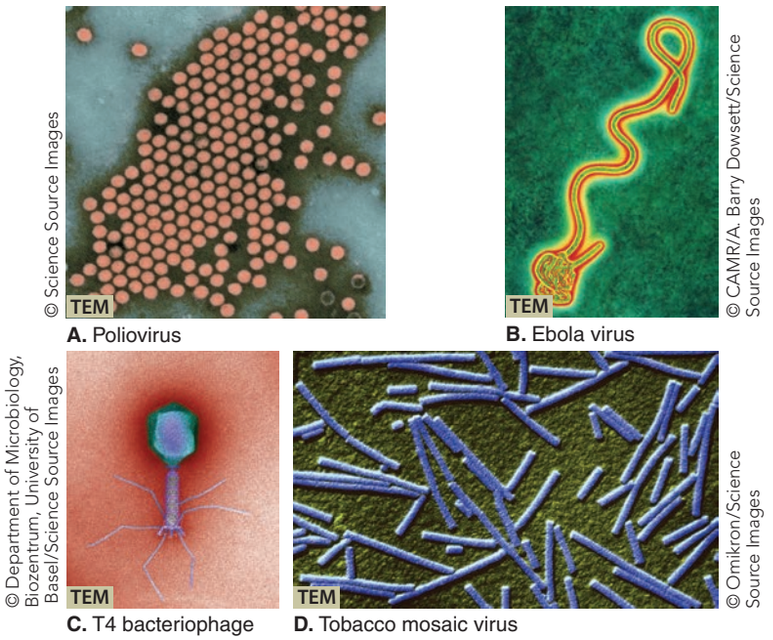

Figure 1.9. Viruses Different viruses have different shapes, and some can cause horrific infectious diseases. All images are artificially colored to enhance their appearance. **A.** Poliovirus, the cause of paralytic polio. **B.** Ebola virus, the cause of hemorrhagic fever, a rapidly progressing, highly fatal disease. **C.** T4 bacteriophage, a virus that infects bacteria and has been extensively used in research. **D.** Tobacco mosaic virus, a virus that infects plants, was the first virus to be discovered.

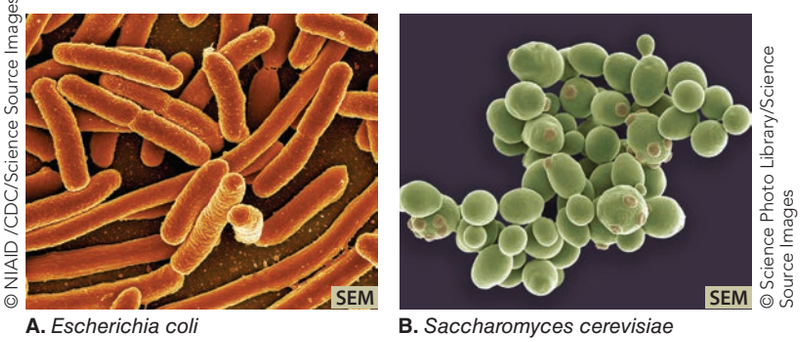

Figure 1.10. Microbes as model organisms Microbes have been used extensively in research. Because they replicate quickly, are cheap to grow, and have relatively simple structures, they have been used extensively to study basic cellular processes like DNA replication, transcription, and translation. Two of the most-studied microbial model organisms are **A.** the bacterium *Escherichia coli* and **B.** the eukarya *Saccharomyces cerevisiae*, a yeast.

Figure 1.11. The development of antimicrobial drugs The bacterium *Treponema pallidum* causes syphilis, a sexually transmitted disease. Salvarsan, the first commercially available drug to combat syphilis, was developed in 1910. Although Salvarsan prevented the replication of this bacterium, it also was toxic to human cells, and its use was curtailed after the development of penicillin.

CONNECTIONS Basic research into the structure and replication of microbes has led to the development of numerous antimicrobial and antiviral drugs. Many of the currently approved drugs for the treatment of HIV, for instance, interfere with specific viral enzymes needed for the production of new virus particles. We will discuss how a particular class of these drugs—nucleoside analogs—works in **Section 24.2**.

1.1 Fact Check

1. What are the key features of living organisms?
2. Describe the macromolecules found in cells.
3. What are the three domains of living organisms?
4. Explain why microbes are useful model systems in research and provide examples of microbial model systems.

1.2 Microbial genetics

What do we know about the evolution of life and the genetics of microbes?

Although groups of microbes may be different from each other, they all share common information processes. Indeed, one of the most remarkable aspects of life as we know it is the constancy of these information processes. In all cells, the main informational molecule is double-stranded DNA. In all cells, a specific type of RNA, messenger RNA, or mRNA, serves as the conduit between the information in DNA and the actual production of proteins. In all cells, the code used to convert the information present in DNA to RNA to protein is the same. This conserved genetic code probably represents the most compelling evidence for evolution. All living organisms share a common informational pathway, suggesting that all living organisms share a common ancestor.

Because all living organisms, and the genetic processes of these organisms, are evolutionarily related, we will begin our exploration of microbial genetics by examining the origins of life. We then will look at how genetic processes occur in microbes and how microbiologists study these processes. We will end this section with a brief overview of how researchers today use these processes to learn more about living organisms.

The evolution of life on Earth

Earth is home to a huge variety of microbes. To understand how this incredible diversity evolved, we need to consider the history of Earth and the origins of life itself. The geochemical changes that have occurred on Earth in the past four billion years—in the oceans, on land, and in the atmosphere—have been dramatic. These changes have profoundly affected, and were profoundly affected by, microorganisms. The vast majority of the living organisms we see today, at least without microscopes, are large multicellular eukarya that arose within the last few hundred million years, the last 10 percent of Earth's history. But most of the major evolutionary events that moved life toward today's world occurred in the distant past, when microbes alone ruled the planet. To get some perspective on this point, let's take a brief walk through the history of life.

Prebiotic Evolution

When Earth formed approximately 4.5 billion years ago (abbreviated ybp, for years before present), it was a hot and sterile place. Oceans of liquid water formed around 4 billion ybp, once the crust and atmosphere had cooled sufficiently for liquid water to condense **(Figure 1.12)**. These oceans may have been partially or completely converted to steam on multiple occasions by the energy of asteroid impacts, which were far more common in the early solar system. Depending on when the first life-forms evolved, such impacts could have resulted in mass extinctions, coupled with selection for life-forms that could live in this extreme environment. By 3.8 billion ybp, life clearly had gained a permanent foothold. The first microorganisms appeared as life transformed from a semiorganized set of chemicals and reactions to a true cellular form. By 3.5 billion ybp, microbial cells were abundant on Earth, as is

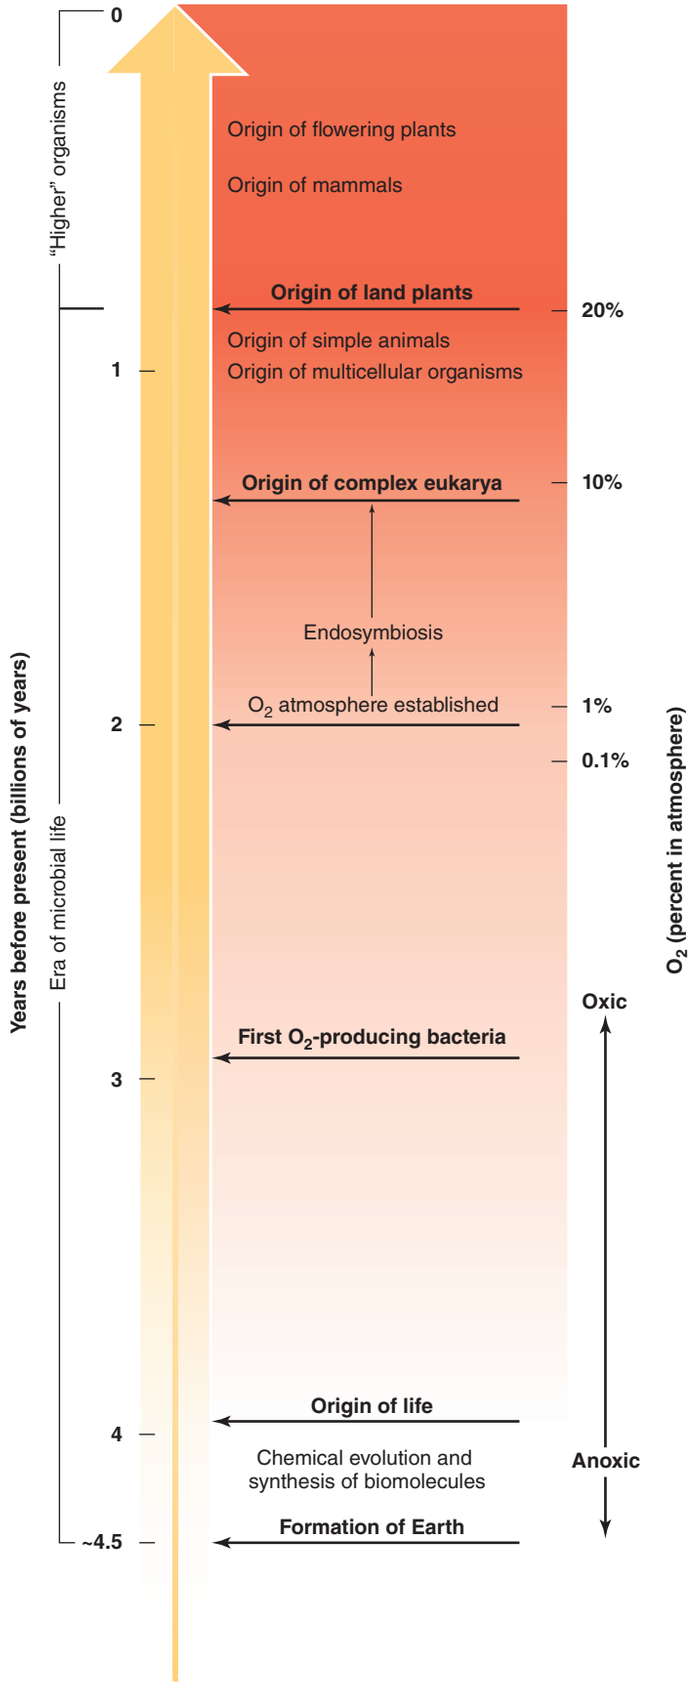

Figure 1.12. Evolutionary time line of life on Earth Current evidence suggests that Earth formed roughly 4.5 billion years ago. Life appeared around 3.8 billion ybp. Some early eukarya first appeared around 1.5 billion ybp. Mammals first appeared about 200 million ybp. Oxygen did not become a major constituent of the atmosphere until the advent of oxygen-producing photosynthesis.

evident from fossilized stromatolites containing cyanobacteria-like structures **(Figure 1.13)**.

Cyanobacteria, we should note, are photosynthetic bacteria. The evolution of these organisms, and their oxygen-releasing photosynthetic capabilities, led to the eventual oxygenating of Earth's atmosphere. Given that multicellular algae and marine invertebrates are not evident in the fossil record until 0.5 billion ybp, it appears that microbial life ruled Earth for over 3 billion years. Only during the last 500 million years has Earth seen the rise of plants and animals! Our planet has changed drastically since its violent birth, but, with the exception of dramatic events like asteroid impacts and volcanic eruptions, changes have occurred gradually. Microbes had plenty of time to evolve an incredible array of talents, allowing them to exploit every possible habitat. Given the eons that have gone by, we can only imagine the diversity of microbial life that has existed since Earth's origins; we still do not fully comprehend the richness of microbial life on present-day Earth.

When life first appeared, Earth was a harsh place. The average temperature was quite hot, probably over 50°C. The composition of the atmosphere is not known for sure, but researchers hypothesize that it had a high concentration of CO_2, perhaps up to 30 percent. Other atmospheric gases may have included nitrogen (N_2) and hydrogen (H_2). Whether gases such as ammonia (NH_3), methane (CH_4), cyanide (HCN), and hydrogen sulfide (H_2S) were present in substantial concentrations is not known with certainty. It is clear, though, that there was little or no molecular oxygen (O_2). The oceans probably were fairly acidic due to the high concentration of dissolved CO_2. By comparison, today's atmosphere consists of about 0.03 percent CO_2 and 21 percent O_2, with a moderate average temperature of 13°C. What changed the O_2 and CO_2 concentrations so dramatically since life began? Microbial activities over the past four billion years are part of the answer.

The First Microbial Life

It is generally assumed that life-forms present on early Earth have not survived unaltered to modern times. Conditions on our planet have changed radically over the past four billion years, and it is reasonable to assume that evolutionary innovations incorporated into living systems during that time outcompeted and displaced primitive cells long ago. Nevertheless, the biochemical origins of life are of great interest. As we look outward for life elsewhere in our solar system and beyond, simple living systems—microorganisms—are far more likely to be discovered than are advanced civilizations in flying saucers. The better we understand the evolution of life on Earth, the better idea we have of what to look for elsewhere.

Many hypotheses have addressed the origin of life. The Miller–Urey experiment envisioned an early Earth where organic molecules accumulated in the oceans, creating a rich "prebiotic soup" from which organized cellular life eventually emerged **(Perspective 1.1)**. Perhaps the organic molecules would have required a surface on which to accumulate, rather than simply floating in the open ocean. Günter Wächtershäuser has theorized that life evolved on iron-containing surfaces, such as iron pyrite (FeS_2), an insoluble, positively charged surface

B. Stromatolites

Figure 1.13. Ancient fossils **A.** Fossilized cyanobacteria. These fossils of cyanobacteria were found in Wyoming and date back about 50 million years. **B.** Stromatolites. Modern stromatolites, like these from Western Australia, can be observed in several locations. Fossilized stromatolites that are 3.5 billion years old have been identified, indicating that photosynthetic bacteria existed on Earth at least this long ago.

with affinity for organic compounds. Metabolic processes that occur in modern cells could have evolved from reactions among surface-bound organic compounds. Many modern proteins, such as cytochromes and hemes, bind iron and other metallic atoms; many enzymes, including DNA polymerases, require bound metals for activity. These interactions with metals may reflect a very ancient relationship.

As we try to envision the origins of life, the formation of chains of ribonucleotides (RNA) and amino acids (polypeptides) clearly represents a necessary event. These polymers, as we noted, contain information and carry out cellular functions. Some researchers, including Carl Woese, have suggested that information was initially stored in RNA molecules, rather than DNA. We now know that certain RNA molecules, **ribozymes**, can catalyze chemical reactions, much like the protein-based enzymes with which we are more familiar. Early in the history of life, then, RNA may have had dual functions, serving as the primary informational molecule and catalyzing important reactions.

We noted earlier that all cells contain a plasma membrane. As we think about the origins of life, let's ask another question. How did the first membranes form? We know that hydrocarbons coupled to charged groups, such as phosphates, form polar lipids, which can spontaneously organize into micelles and even bilayer membranes that close back upon themselves to form a sealed compartment **(Figure 1.14)**. Perhaps such primitive membranes initially formed around fragments of minerals, such as FeS_2, that also happened to serve as surfaces for the aggregation of organic molecules, as just discussed. If a membrane encapsulated an informational molecule and a catalytic molecule, like a ribozyme, then something like a cell would have been formed.

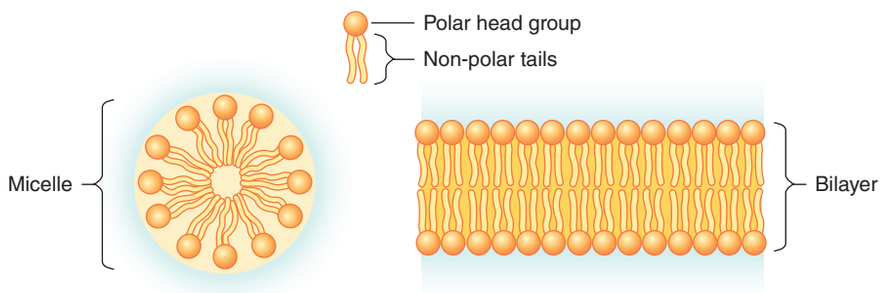

Figure 1.14. Micelles and bilayer membranes Phospholipids, consisting of non-polar fatty acid tails and polar phosphate heads, can spontaneously form micelles, spherical units with polar surfaces and non-polar cores. These molecules also can form bilayers, in which the non-polar regions exist between two polar surfaces.

Perspective 1.1

CREATING LIFE IN THE LABORATORY: THE MILLER–UREY EXPERIMENT

We cannot go back in time to the prebiotic world to watch how life actually evolved. We can imagine scenarios, formulate hypotheses, and test them in the laboratory to gain insight into potential pathways to life. In 1953, Stanley Miller described the first laboratory investigation intended to simulate prebiotic Earth. Miller, then a graduate student at the University of Chicago, designed a reactor with his mentor, Harold Urey, to test for abiotic production of biologically relevant molecules. The Miller–Urey experiment revolutionized the thinking of many scientists, and a fair number of non-scientists as well, about the origin of life on Earth.

The Miller–Urey experiment started with a water-filled flask, heated by a burner. The atmosphere in the apparatus was intended to simulate that of primitive Earth and consisted of a mixture of ammonia (NH_3), methane (CH_4), and hydrogen (H_2). The water was heated to boiling, at which time water vapor mixed with the various gases in the atmosphere and circulated through the apparatus. A separate chamber discharged electrical sparks through the atmosphere, after which the tubing was cooled so that water vapor would condense and drip back into the original flask **(Figure B1.3)**.

After a few days of continuous operation, Miller observed that the water in the flask was changing color. Within a week, the solution in the flask had turned a deep red, and had become turbid. Miller examined the solution after a week and found that the solution contained organic molecules, or molecules containing carbon-hydrogen bonds. Most notably, the simple amino acids glycine and alanine were readily detectable, along with aspartic acid. These amino acids are among the 20 primary amino acids used by life on Earth for protein synthesis, and presumably were abundant as life evolved. Miller's flask provided the first evidence that such molecules could be synthesized from inorganic precursors under conditions believed to mimic primordial Earth, where energy inputs could have included electrical discharge from lightning strikes as well as heat from both the sun and Earth's crust.

The Miller–Urey experiment stimulated other scientists to design experiments to simulate hypothetical atmospheric, oceanic, and geological conditions on prebiotic Earth. Experiments done in hydrogen-rich reducing atmospheres similar to Miller's showed that many amino acids, nitrogenous bases, and other organic compounds could be produced abiotically. Questions about these experiments arose, however, as the consensus of scientists shifted in the 1970s to favor an atmosphere on early Earth that was much richer in CO_2 and N_2. In a Miller-type apparatus, these atmospheric conditions yield few or no organic molecules such as amino acids. Models of early Earth conditions continued to evolve. By 2005, scenarios with much higher levels of H_2 in early atmospheres, co-existing with CO_2, were tested. Jeffrey Bada, a professor at Scripps Institution of Oceanography and a former graduate student of Miller's, further altered the composition and atmosphere in a Miller-type reactor and was able to reproduce Miller's yield of organic material.

Because we do not know the exact chemical and physical conditions on early Earth, controversies continue. Predicting the pathway by which life arose depends greatly on what conditions are assumed to have existed. To further complicate the situation, some evidence suggests that substantial amounts of organic molecules could have been delivered to Earth by comets and asteroids crashing into the planet during the tumultuous early days of the solar system. Hydrocarbons and complex nitrogen-containing organic molecules, including amino acids, have been detected on comets in space and in meteorites on Earth. The magnitude of the contribution of these impacts remains unclear.

Bettmann/©Corbis

Stanley Miller in laboratory in 1952

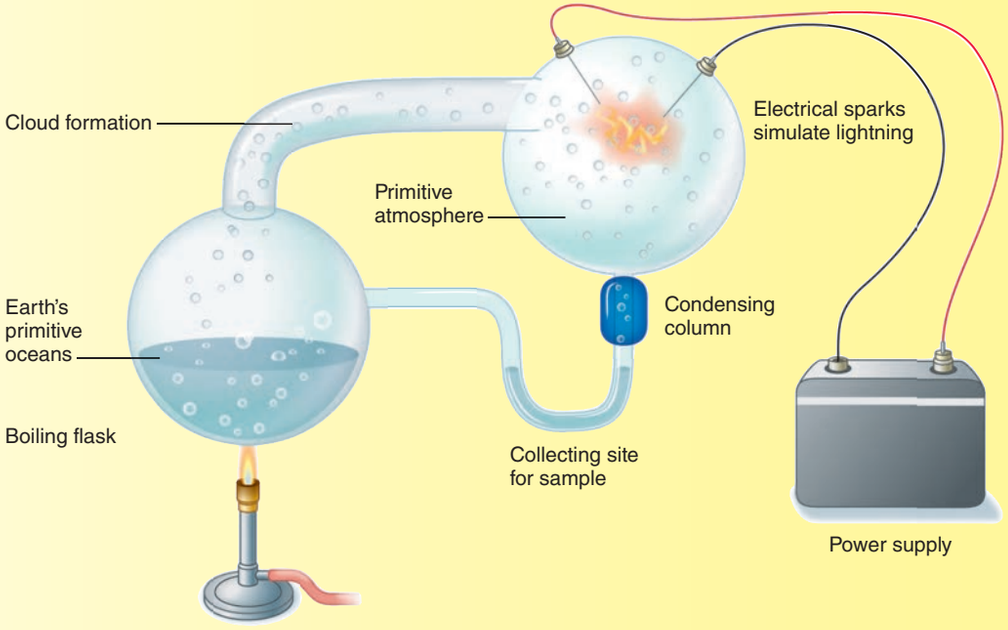

Figure B1.3. The Miller–Urey experiment To explore the origins of life, Miller (pictured here) and Urey created an early Earth atmosphere within a closed apparatus. After supplying heat and electricity to the apparatus (simulating energy sources on ancient Earth), they extracted samples for analysis. Their chemical analysis showed that organic molecules had been formed, including amino acids. This experiment suggested that the building blocks for living systems could have formed on Earth from small inorganic precursors.

The Appearance of Eukarya

How did complex cells arise? Most biologists now agree that mitochondria and chloroplasts, two of the most distinctive organelles in eukaryal cells (Figure 1.15), are derived from bacterial cells through a process known as "endosymbiosis." These organelles have their own circular genomes, though these genomes are far smaller than the genomes of contemporary bacteria. The genes present in the chloroplast and mitochondrial genomes include a gene encoding 16S rRNA, the SSU rRNA molecule present in bacterial ribosomes. Sequence analysis of the mitochondrial and chloroplast 16S rRNA gene indicates that mitochondria and chloroplasts are related to specific groups of bacteria.

Endosymbiosis ANIMATION

Lynn Margulis, a biologist who worked at the University of Massachusetts–Amherst, long championed endosymbiosis as a mechanism for the origins of mitochondria and chloroplasts. Indeed, substantial molecular evidence indicates that these organelles became part of eukaryal cells through endosymbiotic relationships that became permanent. Mitochondria probably were added first to a developing eukaryal cell; they are present in most, but not all, modern eukarya. We can imagine that the endosymbiont provided the host with extra ATP. In return, the host provided the endosymbiont with nutrients and a safe place to live. The extra ATP ultimately allowed for an increase in cell size, and for multicellular arrangements.

Chloroplasts probably were added later, leading to the evolution of algae and plants. A bacterium capable of photosynthesis, the ability to harvest the energy present in sunlight to produce organic molecules, would provide a host with a new energy source and allow the host to expand into new habitats. During the evolution of eukarya, multiple endosymbiotic events leading to chloroplasts may have occurred. We now know that some differences exist between the chloroplasts present in different algal and plant groups. Regardless, photosynthesis brought solar power to eukaryal cells. Algae and plants, as a result, have been phenomenally successful, and now account for a major fraction of the biomass on land (plants) and sea (algae). Once these mitochondria and chloroplasts became permanently established in eukaryal hosts, their own genomes degenerated until only a few essential genes were left.

CONNECTIONS We will look more closely at the origins of eukaryal cells in **Section 3.4** and explore the evidence supporting the endosymbiotic theory. In **Chapter 17**, we'll see that endosymbiotic relationships between microbes and host cells are actually very common in nature. In most cases, the host cannot survive without the essential functions supplied by the endosymbiont.

In the earliest cells, RNA may have been the major informational and catalytic molecule. Eventually, double-stranded DNA supplanted RNA as the major informational molecule and proteins arose as the major catalytic molecules, giving rise to the first living organism. Carl Woese refers to this first living organism as a **progenote**, a cell hypothesized to store information in genes not yet linked together on chromosomes (Figure 1.16).

When a progenote replicated itself, each of the progeny may have had a different subset of the parental genes, and thus a number of variations could have arisen in one generation. Genetic variation and mutation were probably frequent, given that these primitive cells would have lacked the sophisticated genetic repair mechanisms seen in modern cells. Though they might not have looked much like modern life, progenotes would have been just as subject to Darwinian evolution. Darwinian evolution, we should note, depends on (1) genetic variation in a population, (2) the environment exerting selective pressure(s), and (3) differential reproductive success among genetic variants as a result of that selective pressure. Primitive cells that not only survived, but reproduced more efficiently and passed gene sets to their progeny, would have spread most rapidly. Assuming that genetic variation was common in progenotes, the rate of evolutionary change could have been quite high.

By 500 million years ago, multicellular eukarya had begun to dominate the macroscopic landscape of life on Earth. Microbes had set the stage for them. As we will see in the next section, the evolution of oxygenic photosynthesis in cyanobacteria led to the abundance of molecular oxygen we see in the

B. Chloroplast

Figure 1.15. Mitochondria and chloroplasts These two distinctive eukaryal organelles probably originated via endosymbiosis. **A.** Mitochondrion, which may have originated when a developing eukaryal cell engulfed another bacterial cell capable of undergoing efficient aerobic respiration. **B.** Chloroplast, which may have originated in a similar fashion when an early eukaryal cell engulfed a cyanobacterial-like bacterium capable of photosynthesis.

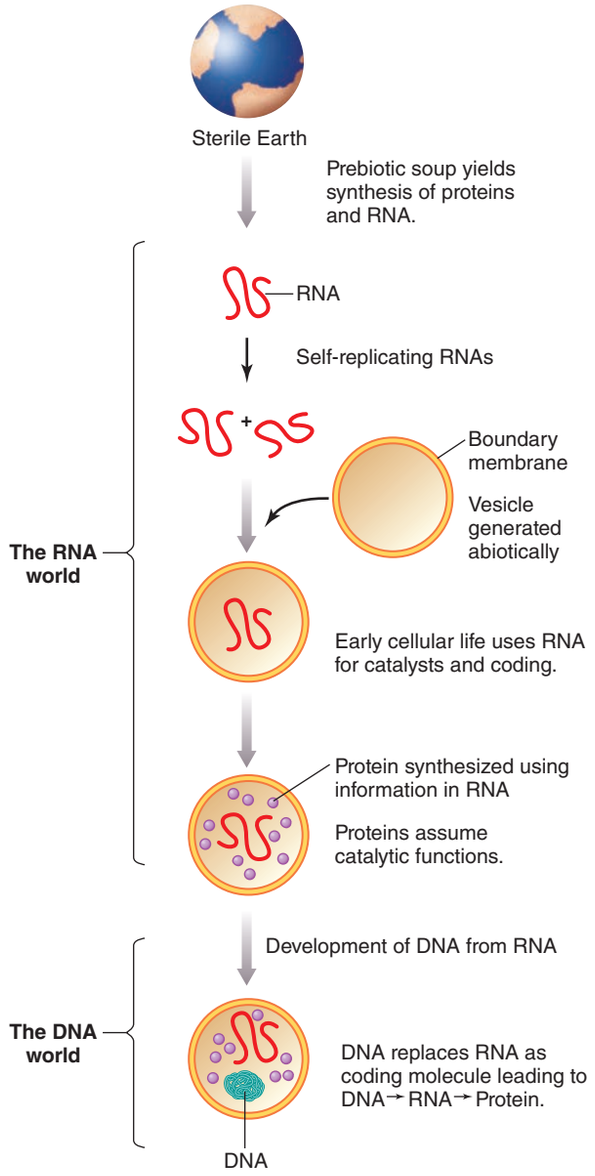

Figure 1.16. The origins of life We probably will never know for sure how life began, but we can make a reasonable hypothesis. Shortly after Earth was formed, natural processes yielded a variety of substances, including RNA. Self-replicating and catalytic RNA molecules became enclosed within a boundary membrane, leading to an early version of cellular life. Eventually, proteins became the major catalytic molecules and DNA supplanted RNA as the dominant informational molecule.

atmosphere today. Highly efficient aerobic respiration became possible. Aerobically respiring bacteria then entered into the symbioses that led to mitochondria in eukaryal cells. Without mitochondria to efficiently power cellular metabolism, large multicellular eukaryal organisms would never have appeared.

DNA and RNA: The genetic molecules

In all organisms today, genes are linked together in long molecules of double-stranded DNA. DNA is an elegant, albeit enormously long, molecule whose structure is beautifully suited for information storage and replication. Because each strand of a double-stranded DNA molecule is complementary to the other strand, one can easily imagine a mechanism of faithfully

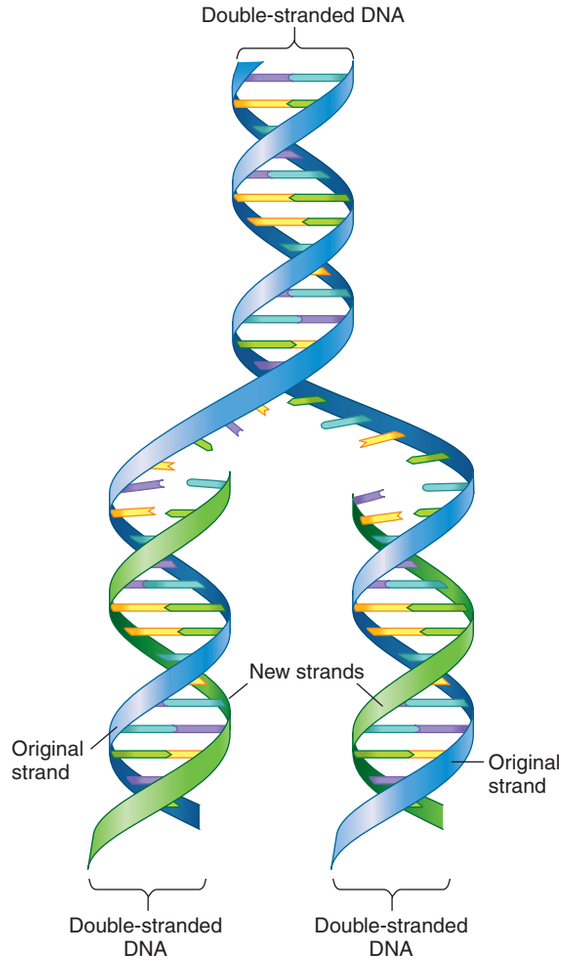

Figure 1.17. Replication of DNA Because of the double-stranded nature of DNA, and the fact that each strand within the double-stranded molecule is complementary to the other strand, a method of replication seems quite obvious. If the two strands are separated, then each strand can serve as a template for the formation of another new strand, resulting in the production of two identical double-stranded molecules.

replicating the molecule. If the two strands denature, or come apart, then each strand contains the information necessary to re-form the other strand (Figure 1.17). When a cell divides, identical copies of DNA can be produced so that each progeny cell will contain the exact same informational molecule.

The companion nucleic acid, RNA, also plays a critical role in the information flow in cells (Figure 1.18). Messenger RNA

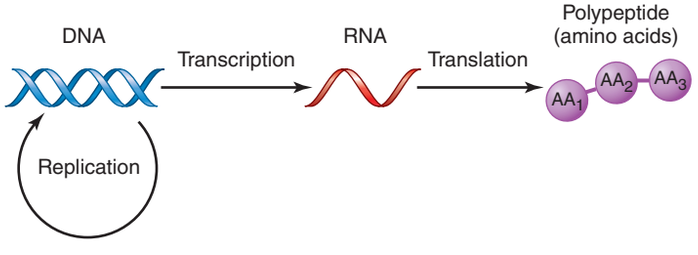

Figure 1.18. The flow of information in cells The main informational molecule, DNA, generally is replicated prior to cell division, ensuring that each daughter cell possesses the same genetic material. Information within DNA is copied into RNA during transcription. The information in RNA specifies a corresponding sequence of amino acids during translation of the RNA into a polypeptide.

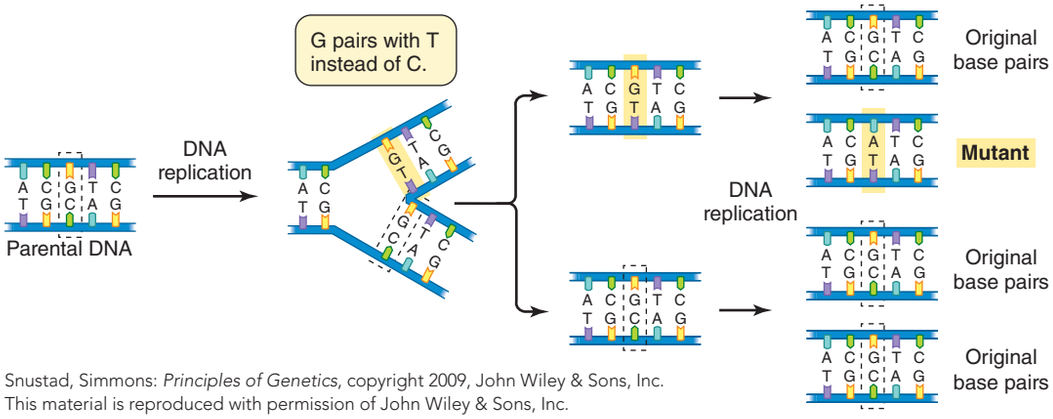

Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 1.19. Heritable changes in the DNA During DNA replication, errors may occur, such as in this example where G pairs with T, instead of with C. When this molecule of DNA undergoes a second round of replication, then one of the new molecules will contain the original CG base pair, while the other newly formed molecule will contain a mutant TA base pair at this location. The mutation, at this point, has become incorporated into this molecule of DNA and will appear in all progeny DNA.

(mRNA) is synthesized from a DNA template during the process of transcription and delivers instructions to the ribosome for the production of a specific chain of amino acids. Ribosomes are the protein synthesis factories of the cell. During translation (polypeptide synthesis), transfer RNAs (tRNAs) deliver amino acids to the ribosome. The ribosome itself is composed of proteins and ribosomal RNA (rRNA) molecules, which provide a structural framework. One of the rRNAs contributes catalytically to peptide bond formation. As we noted earlier, the functional versatility of RNA has suggested to scientists that it could have played a central role in the origin of living systems.

CONNECTIONS While most living organisms share a common genetic code, significant differences in some of the details of the code and various genetic processes exist between members of the domains *Eukarya*, *Archaea*, and *Bacteria*. We will examine translation more in **Section 7.4** and explore some of these domain- and organism-specific differences.

Genetic analysis

The ability to faithfully replicate the genome and convert the information contained within the genome into functional proteins represents only part of the story. As we noted earlier, living organisms must contain some genetic variation in order for evolution to occur. The ultimate source of this variation is **mutation**, a heritable change in the genome. As we will first see in Section 7.5, mutations can result from errors made during replication or from various physical or chemical insults to the DNA. Regardless of their source, these changes in the genotype, or genetic composition of an organism, can be passed on when the genome replicates and the cell divides (Figure 1.19). More importantly, these mutations may alter the genetic information in such a way that the proteins produced by the cell differ (Figure 1.20). These changes in the proteins, in turn, can alter the phenotype, or observable characteristics of the cell.

Although bacteria do not undergo sexual reproduction by the formation and uniting of gametes, they do exchange genes between cells, a process referred to as horizontal gene transfer. As we will see in Section 9.4, genetic material can be transferred between bacteria in several ways. Moreover, more and more evidence suggests that genetic material can be transferred not only between different bacterial types, but also between organisms in different domains. This exchange of genetic material muddies somewhat our ability to construct a perfect phylogenetic tree of all living organisms (Figure 1.21).

In recent years, improved DNA-sequencing techniques have allowed researchers to determine the exact DNA sequences of entire genomes of organisms. Rather than just studying specific genes, we now can study entire genomes, a field of inquiry known as genomics. Along with these improved sequencing techniques, we also now have improved

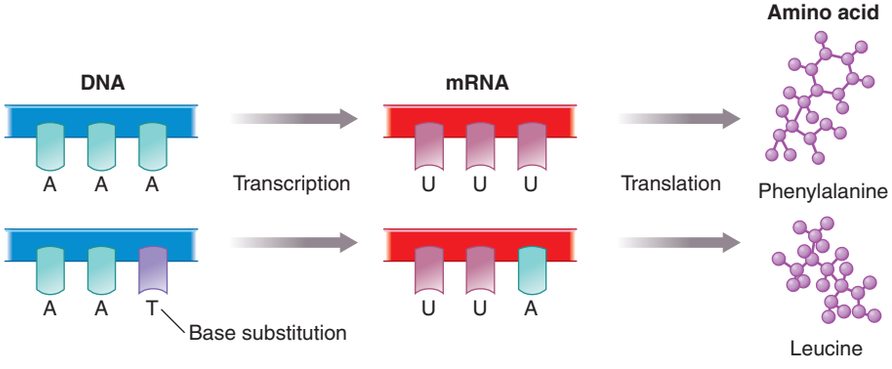

Figure 1.20. Effects of mutations Alterations in the DNA sequence can lead to changes in the mRNA and amino acids that constitute the resulting polypeptides. Here, a change in the DNA sequence results in a change in the amino acid present in the resulting polypeptide. Amino acid changes could alter the shape of the polypeptide, which, in turn, may affect the phenotype of the organism.

computing power. The computer tools available today allow us to analyze and compare genomes, which is the basis of the burgeoning field of bioinformatics. With these new tools at our disposal, we are learning more about the evolutionary history of life, the diversity of organisms, and the functioning of our cells. The flood of microbial genome sequences in recent years has clearly shown that horizontal gene transfer is ubiquitous in microorganisms. In reality, most microbial genomes are composites of DNA fragments with distinct evolutionary histories.

CONNECTIONS Genomics has revealed the profound impacts of gene transfer in regard to pathogen evolution. In Section 21.4, we'll explore several examples of how transfer events have led to the development of a pathogen.

Biotechnology and industrial microbiology

Scientists studying genetics and molecular biology revolutionized all of biology in the late 1970s with the development of methods for producing **recombinant DNA** molecules—DNA sequences linked together to form a single molecule that never existed previously in the natural world. This revolutionary technology has allowed genes from humans and many other organisms to be inserted into bacteria and other microbes. This technique has allowed microbes to be used as low-cost manufacturing plants for the production of valuable proteins such as human insulin and human growth hormone. The incredible range of applications for recombinant DNA methods could not have been realized without the availability of well-studied microorganisms such as *Escherichia coli*.

The process of creating recombinant DNA is surprisingly simple. From bacteria, researchers first can isolate plasmids, small circular DNA molecules that replicate independently of the chromosome. Using restriction endonucleases, bacterial enzymes that cleave DNA at specific locations, researchers can insert foreign DNA into a plasmid, thereby creating a new molecule. Finally, this recombinant DNA molecule can be added back to bacteria. As the bacteria replicate, the recombinant plasmid also replicates. More importantly, foreign genes inserted into the plasmid will be expressed **(Figure 1.22)**.

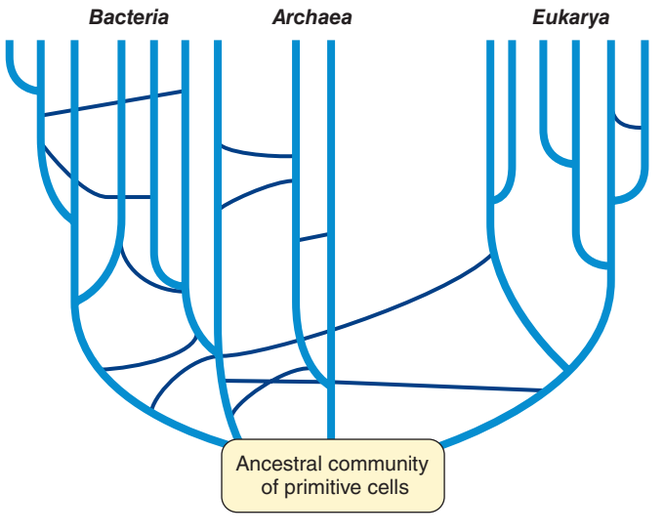

Figure 1.21. Genetic exchange occurs between species and between domains Gene transfer usually takes place between members of the same species by sexual reproduction or other transfer of DNA. However, there now is evidence that gene transfer also can occur between bacteria, archaea, and eukarya (indicated by thin lines). Although this genetic exchange does not disrupt the phylogenetic tree, it does mean that individual genomes may contain segments of DNA obtained recently from distantly related organisms.

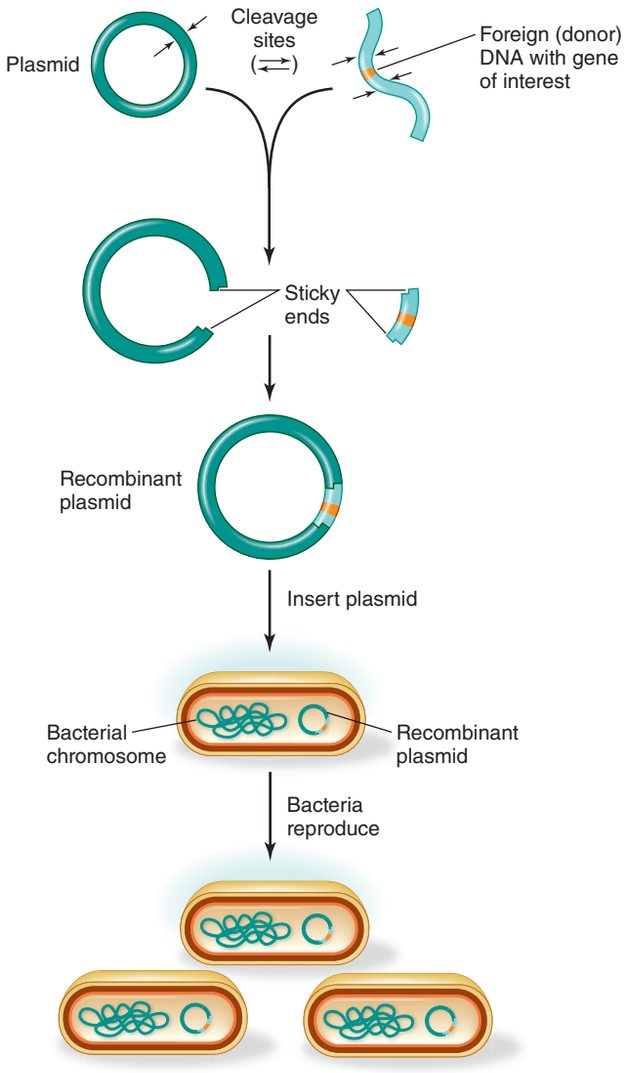

Figure 1.22. Recombinant DNA techniques Plasmid DNA and donor DNA can be cleaved with a restriction endonuclease, or restriction enzyme. When mixed together, the foreign DNA can become incorporated into the linearized plasmid, resulting in the formation of a recombinant plasmid. This plasmid can be introduced into bacteria. As the bacteria reproduce, the plasmid will be replicated, resulting in the replication of the foreign DNA. If the donor DNA contains a gene, then the bacteria can express that gene, resulting in the production of a foreign protein, coded by the donor (foreign) DNA.

Following a related process, researchers at Genentech, a biotechnology company based in San Francisco, announced in 1978 that they had engineered *E. coli* to produce human insulin. This achievement marked the first time that a medical product was produced via recombinant DNA technology. Today, a vast majority of insulin used by people with diabetes is produced in an analogous fashion.

CONNECTIONS As we will see in **Section 12.2,** researchers now can use techniques like site-directed mutagenesis to intentionally modify natural gene products. In **Section 12.4,** we will investigate how biotechnology may help to alleviate our dependence on fossil fuels.

1.2 Fact Check

1. Describe how double-stranded DNA, mRNA, tRNA, and rRNA are involved in the information flow in cells.
2. How might the first membranes have formed and how could this event have resulted in something resembling a cell?
3. Describe how mitochondria may have arisen in eukaryal cells.
4. How has DNA sequencing affected our understanding of microbes?

1.3 Microbial physiology and ecology

How do microbes get energy and interact with the world around them?

So far we have seen that microbes not only share many structural and functional features, but also exhibit a great deal of diversity. We also have seen, at least briefly, how life may have evolved and how genetic information is transmitted and interpreted within microbes. As we continue our introduction to microbiology, let's ask two more important questions. First, how do microorganisms get the energy needed to support biosynthesis and growth? Second, how do microorganisms interact with their environment? As we will see, these two questions are intricately linked.

Bacteria and archaea have greater metabolic diversity and inhabit more diverse environments than eukarya, particularly multicellular eukarya. Environments inhabited by bacteria and archaea range from deep sea thermal vents with temperatures of greater than 110°C, to Antarctic ice sheets, to deserts that rarely if ever see a drop of rain, to porous rocks a kilometer or more beneath Earth's surface. Microorganisms thrive in acidic hot springs with a pH of 1 and alkaline lakes with a pH of greater than 11. They live in distilled water taps and saturated brine solutions in salt-evaporating ponds. Their ability to live in these varied habitats reflects their ability to acquire energy from these environments. Their metabolic capabilities, in other words, dictate the habitats in which they can live.

Photosynthesis, respiration, and the appearance of atmospheric oxygen

All microorganisms, indeed, all living organisms, must acquire energy and produce macromolecules. Most macroscopic eukarya exhibit relatively limited types of metabolism. Microorganisms, as we will see briefly in this section and more fully in Chapter 13, exhibit more diverse types of metabolism. This metabolic diversity allows microorganisms to inhabit a wide range of habitats. Because different microorganisms can utilize various nutrients, they can exist in environments that may be uninhabitable by other organisms.

In a very basic sense, all living organisms need organic molecules. **Heterotrophs**, or "other feeders," ingest organic molecules. These preformed molecules can be used for the biosynthesis of other macromolecules or as an energy source. **Autotrophs**, or "self feeders," can produce their own organic molecules from an inorganic carbon source. We typically think of plants when we think of autotrophs. These photosynthetic organisms harvest the energy present in sunlight to convert the carbon in CO_2 into organic molecules.

In cyanobacteria, the presumed descendants of the organisms that gave rise to chloroplasts, membrane-bound pigment molecules absorb the energy present in sunlight. This absorbed energy results in the transfer of an electron from the pigment molecule to a series of membrane-bound proteins. Ultimately, the movement of this electron powers the formation of ATP, the energy currency of the cell **(Figure 1.23)**. The cells can use this ATP to incorporate inorganic carbon from CO_2 into an organic molecule. To complete the process, the pigment molecule must regain an electron to replace the one that was lost. In cyanobacteria and plants, the pigment molecule regains this electron by removing electrons from water, resulting in the liberation of O_2:

$$2\ H_2O \rightarrow 4\ H^+ + 4\ e^- + O_2$$

This liberation of oxygen via photosynthesis ultimately led to the increased atmospheric O_2 concentration that we discussed previously.

CONNECTIONS Not all photosynthetic organisms produce O_2 as a by-product. Some photosynthetic organisms gain electrons from hydrogen sulfide (H_2S), instead of water. For these organisms, elemental sulfur (S^0), not O_2, is liberated. This anoxygenic photosynthesis will be discussed in more detail in **Section 13.6**.

Regardless of how organisms acquire organic molecules, all living organisms also need a mechanism of oxidizing those molecules to generate ATP. One of the simplest means of

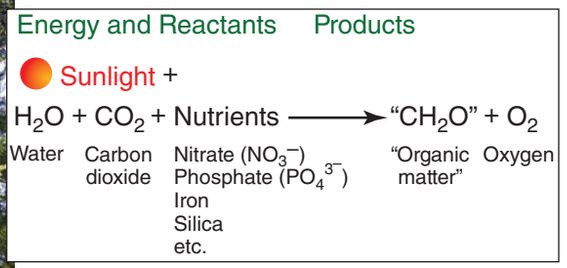

Figure 1.23. Overview of oxygenic photosynthesis Energy from sunlight is harvested by a membrane-bound pigment molecule, resulting in the loss of an electron. The harvested energy is used to form organic molecules from CO_2. The electron lost by the pigment molecule is replaced by the breakdown of water, resulting in the generation of O_2.

acquiring energy from organic molecules is glycolysis, the reaction in which glucose is converted to pyruvate, with the subsequent generation of two ATP molecules:

$$\text{Glucose} + 2\ \text{ADP} + 2\ \text{Pi} + 2\ \text{NAD}^+ \rightarrow 2\ \text{Pyruvate} + 2\ \text{ATP} + 2\ \text{NADH} + 2\ \text{H}^+$$

In some cases, glycolysis is coupled with fermentation, a process in which the NADH produced by glycolysis is converted back to NAD^+ and the pyruvate molecules are converted to a waste product, such as ethanol or lactate. While this system of obtaining energy from glucose is fairly simple, it is not particularly efficient; much of the potential energy present in the original glucose molecule is not converted to ATP **(Figure 1.24)**.

A more effective means of obtaining ATP from glucose involves respiration, a set of metabolic processes whereby the glucose is more completely utilized, resulting in the production of larger quantities of ATP. Plants, animals, and many undergo aerobic respiration, a form of respiration that involves the addition of electrons to O_2, resulting in the formation of H_2O. Some bacteria perform respiration in which a terminal electron acceptor other than oxygen is used. This type of respiration generally results in the formation of less ATP than respiration involving oxygen.

The presence of O_2 in the atmosphere had profound consequences for life on Earth. Respiration utilizing oxygen allows organisms to harvest a significant amount of energy from organic molecules. During this process, though, oxygen is converted to a series of highly reactive molecules. These by-products can damage cells through their ability to oxidize other molecules and their ability to generate even more potent compounds through interactions with light. Until oxygenic photosynthesis evolved, *all* life, by necessity, was anaerobic. When O_2 began accumulating in the atmosphere, organisms either had to develop strategies for defending themselves against these dangerous by-products or retreat to habitats where O_2 remained less abundant or absent. This remains true today. Anaerobic microorganisms are still with us, living in specialized habitats free from molecular oxygen.

CONNECTIONS During aerobic respiration, O_2 can be converted to hydrogen peroxide (H_2O_2). This reactive molecule can damage cells. As a result, most organisms that can survive in the presence of O_2 produce catalase, an enzyme that converts H_2O_2 to H_2O and O_2. We will learn more about toxic oxygen species in **Section 6.3**.

The increase of O_2 in the atmosphere also created an ozone layer in the stratosphere, approximately 10–25 miles above Earth's surface. Ozone (O_3) is generated naturally from O_2 and strongly

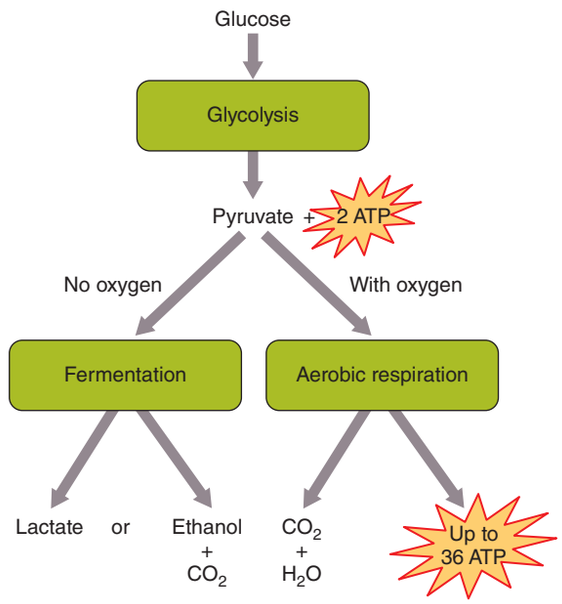

Figure 1.24. Glycolysis, fermentation, and aerobic respiration In almost all organisms, glucose can be converted to pyruvate, resulting in the production of some ATP. The process of aerobic respiration allows cells to generate much more ATP from pyruvate. In plants, animals, and many bacteria, respiration occurs in the presence of oxygen (aerobic respiration) and results in the generation of CO_2 and H_2O. Some bacteria undergo anaerobic respiration, utilizing a terminal electron acceptor other than oxygen. If respiration cannot occur, some organisms undergo fermentation reactions. Two well-studied types of fermentation result in the production of lactate or ethanol. These products of fermentation generally are toxic to the microorganism, but may be helpful to humans.

absorbs short wavelength ultraviolet (UV) light. UV light is dangerous to cells because it causes damaging chemical reactions in DNA. Because UV light does not penetrate water very well, aquatic life is fairly well protected from its harmful effects. Terrestrial organisms, however, are not so lucky. The accumulation of ozone in the atmosphere reduced the amount of UV radiation reaching Earth's surface. The rise of O_2 in the atmosphere, therefore, indirectly facilitated the colonization of land by microorganisms.

Microorganisms and biogeochemical cycling

Microbes have been intimately involved in modulating conditions within the **biosphere**, those regions of Earth that can support life. Not only did microorganisms, through photosynthesis, create the oxygen-rich atmosphere on which most life on Earth relies, but they are also involved in **biogeochemical cycling**, the transitioning of various chemicals between organic and inorganic forms. The amount of carbon contained within living bacteria on Earth, for instance, is estimated to be nearly as great as the amount of carbon in all the multicellular organisms combined. Photosynthetic cyanobacteria convert CO_2 from the atmosphere into organic molecules. Microbial metabolism ultimately converts much of this organic carbon back into CO_2.

As we saw in Section 1.1, nucleic acids and polypeptides, two important categories of cellular macromolecules, contain nitrogen. Only certain types of bacteria and archaea can convert nitrogen gas (N_2) from the atmosphere into forms that can be readily used by other organisms to form these molecules. This **nitrogen fixation** is accomplished both by free-living bacteria and by bacteria living in symbiotic associations with plants (Figure 1.25). Bacteria also convert nitrogen present in organic material back to N_2 gas, through both denitrification and ammonia oxidation. In terrestrial habitats, denitrification and ammonia oxidation are of special concern to farmers, as they can decrease the fertility of agricultural soils. In the marine environment, these processes can limit ocean productivity.

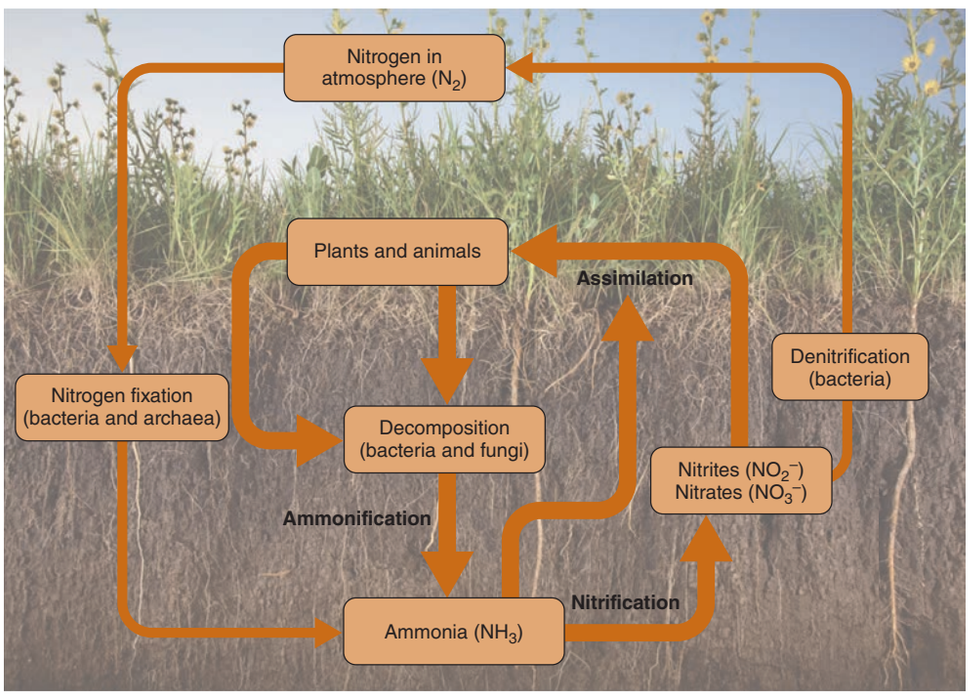
Microbial interactions

Before we leave this section, we should note that microbes do not exist in isolation. As we will investigate more thoroughly in Chapter 15, microbes exist in diverse communities of organisms that interact with each other and the environment. As we will see in Chapter 3, vast numbers of eukaryal microorganisms exist within the Rio Tinto, a river in Spain with a pH of approximately 2. As we will see in Chapter 4, communities of organisms live in the waters surrounding deep sea thermal vents, in a large part dependent on archaea that thrive in the superheated water near these thermal vents. As we will see in Chapter 17, many microbes live with, in, or on various plants, invertebrates, and vertebrates.

Microbes, of course, also live in and on humans. Van Leeuwenhoek, remember, described microorganisms living on a person's teeth over 300 years ago. In fact, we can view the human body as a complex ecosystem. Microbes exist throughout our bodies, often in a symbiotic relationship with us. Microorganisms within our body produce vitamins for us and help us digest our food. Some microbes, as we will discuss in Chapter 23, even help us control the replication of other, unwanted microbes, thereby aiding in the prevention of disease.

1.3 Fact Check

1. Differentiate between the terms "heterotroph" and "autotroph."
2. Describe the roles of glycolysis, fermentation, and respiration in energy production in different environments.
3. Explain how bacteria are involved in nitrogen cycling.



© Jim Richardson/National Geographic/Getty Images, Inc.

Figure 1.25. Role of microbes in the global nitrogen cycle Only certain bacteria and archaea can convert gaseous nitrogen (N_2) into forms that can be used by other living organisms. Nitrogen incorporated into ammonia (NH_3), nitrites (NO_2^-), and nitrates (NO_3^-) can be used to synthesize amino acids. These molecules also can be used in the synthesis of nucleic acids. Other microorganisms decompose nitrogen-containing molecules, and act on the resulting products, converting various forms of nitrogen back into N_2 and thereby completing the nitrogen cycle.

1.4 Microbes and disease

How are microbes associated with disease?

Although we now know that some microbes can cause diseases, this concept was not common knowledge for most of human history. People thought that diseases had various causes from angry gods to bad air. These views prevailed mostly because people could not see the bacteria associated with bacterial infections. Even after the development of the microscope, people still did not understand that microbes could be transmitted from person to person. Rather, many assumed that microbes arose from inanimate materials, a process known as spontaneous generation. This belief negated a need to even consider the transmission or prevention of microbial diseases. If microbes arose spontaneously, then there was no reason to investigate how a person became infected.

While many scientists worked to disprove the widely held belief in spontaneous generation, Louis Pasteur's experiments in the mid-1800s provided the most compelling evidence refuting this idea. As with so many classic experiments, his experiment was both simple and elegant. Pasteur added nutrient broths to swan-necked flasks and then boiled the broths to kill any contaminating microorganisms. He then observed the broths for signs of microbial growth **(Figure 1.26)**.

With this approach, Pasteur reasoned, outside air could enter the flask. Bacteria present in the outside air, though, would become trapped in the neck of the flask, never coming in contact with the sterile broth. No bacteria, he hypothesized, would grow. If the flask were tilted such that the broth traveled to the neck of the flask and then returned to the upright position, however, bacteria trapped in the neck would flow back into the nutrient broth and growth would occur. In other words, microbial life in the broth could result only from microbial life present in the neck of the flask; it did not arise spontaneously.

CONNECTIONS What signs of microbial growth did Pasteur observe? In **Section 6.2**, we will examine how bacteria grow under standard laboratory conditions. In **Section 6.5**, we will explore how we can block this growth.

Microbes in Focus 1.1
BACILLUS ANTHRACIS

Habitat: Infects various mammals, including cattle, sheep, and horses. Also can infect humans. Spores can be found in soil.

Description: Gram-positive rod-shaped bacterium, measuring approximately 1 μm in width and 3 μm in length

Key Features: When nutrients are lacking, *B. anthracis* can form endospores, metabolically inert structures that are largely resistant to harsh environmental conditions. The endospores can begin replicating again when conditions improve, even after years in the endospore state. Although naturally occurring human infections with *B. anthracis* are rare, this bacterium still remains actively studied by researchers, mainly because of its potential use as a bioweapon. We will explore this topic more in Chapter 6.

© Dr. James Feeley / CDC

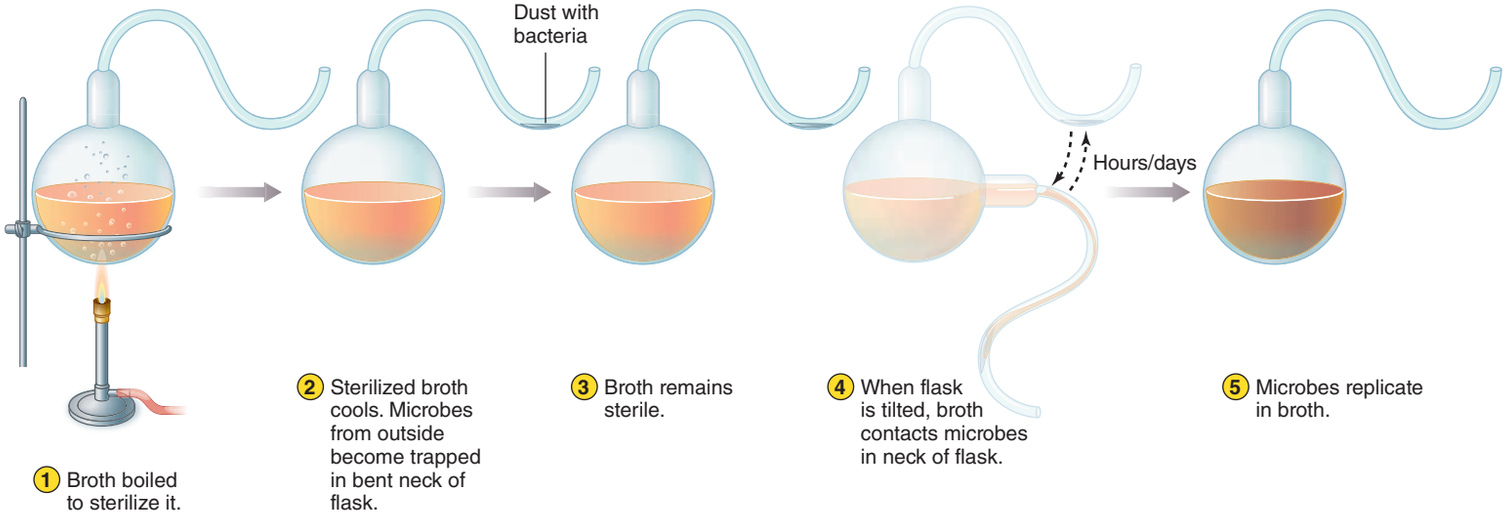


Figure 1.26. Process Diagram: Pasteur refutes spontaneous generation By showing that bacterial growth did not occur in sterile broth within swan-necked flasks, but did occur when the sterile broth contacted outside contaminants, Pasteur demonstrated that microorganisms did not arise spontaneously.

The identification of infectious agents

About 200 years after van Leeuwenhoek's first observations of microbes, and just 15 years after Pasteur showed that microorganisms do not arise by spontaneous generation, Robert Koch provided the first clear demonstration that a bacterium, *Bacillus anthracis* **(Microbes in Focus 1.1)**, was the cause of a specific disease, anthrax, in livestock.

Robert Koch was a German physician and scientist, and a true pioneer in the field of microbiology. Aside from his anthrax work **(Figure 1.27)**, he was responsible not only for developing important laboratory techniques—for example, the use of media solidified with agar for the isolation of bacteria in the laboratory—but also for developing clear criteria linking particular microorganisms to specific diseases. We will explore the details of these criteria, referred to as Koch's postulates, in Section 18.4.

Koch used these criteria to establish the cause of other important diseases, including tuberculosis, which is caused by the bacterium *Mycobacterium tuberculosis*. The identification of other infectious microbes quickly followed. The late 1800s, in fact, were a golden age of sorts, in which medical science finally began to achieve real insight into many infectious diseases.

CONNECTIONS As our understanding of infectious diseases, and our experimental techniques, have changed, so too have our interpretations of Koch's postulates. Molecular correlates of his basic postulates are explored in **Section 18.4**.

The effects of infectious diseases

As van Leeuwenhoek observed, many microbes exist in and on our bodies. Most of the time, these microbial partners are just that—partners. When the relationship between microbes and host becomes unbalanced, then disease can arise. Microbial diseases, as we all know, have profoundly affected human life. As we will see in the final section of this book, our understanding of how microbes cause disease—and how we can prevent these diseases or alleviate their effects—is constantly changing.

We all feel the effects of microbial infections through the course of our lives. A runny nose and a cough often are signs of a cold, which may be due to a rhinovirus infection of the upper respiratory tract. The onset of winter portends the flu season, when hundreds of millions of people each year suffer from fevers, headaches, coughs, and muscle aches caused by the influenza virus. The average person in the United States experiences several bouts of diarrhea per year, which could have any number of different causes, including viruses, bacteria, or protozoa, all of which can be acquired through food or drink. If you are studying this book in the United States, Canada, or Europe, it's unlikely (but not unheard of) that you will have to deal with the constant threat of infections with serious, or even life-threatening consequences. If you live in one of the many regions of the world where affordable effective public health measures are lacking, infectious diseases may have a more prominent role in your life. AIDS, malaria, tuberculosis, and other diseases of microbial origin take millions of lives per year in these regions; we are far from a solution to this enormous problem.

History is full of examples of the powerful impact of infectious diseases. Modern medicine has greatly improved our ability to deal with these diseases. We now understand how infectious diseases spread, and the widespread availability of vaccines and antimicrobial drugs facilitates prevention and treatment. But we have not eliminated the threat of new infectious diseases. The human immunodeficiency virus (HIV), which was only discovered in the 1980s, has caused over 40 million deaths since then, and there is still no vaccine to prevent HIV infection. The influenza virus has caused devastating pandemics, or worldwide outbreaks, in centuries past, and now there is great concern that a new serotype could enter the human population, with potentially catastrophic consequences. Finally, an outbreak of Ebola that began in December of 2013 has devastated parts of western Africa.

CONNECTIONS As we saw during the summer and fall of 2009, the H1N1 strain of influenza virus quickly spread throughout the world. What factors led to the rapid dissemination of this microbe? We will discuss epidemiology, or the study of how diseases spread in populations, in **Section 18.3**.

An exceptionally devastating pandemic occurred when plague, popularly referred to as "The Black Death," killed a third or more of the population of Europe, Asia, and North Africa in a 60-year span from 1340 to 1400 **(Figure 1.28)**. Plague is caused by the bacterium *Yersinia pestis*, which infects rodents and humans, and is transmitted between them by fleas **(Figure 1.29)**. This bacterium is commonly present in rodents such as mice, rats, and squirrels in many parts of the world. The plague pandemic of the 1300s is thought to have originated in central Asia or China and probably moved westward with trading caravans and/or Mongol armies. Historical records indicate that plague was absolutely devastating. Up to 60 million people,

C. Vaccination

Figure 1.27. Robert Koch proved that anthrax was caused by a microorganism Koch showed that a specific microbe, the bacterium *Bacillus anthracis*, caused anthrax in livestock. Koch also developed Koch's postulates, a series of criteria that needed to be met to prove that a specific microorganism caused a specific disease. **A.** Robert Koch. **B.** *B. anthracis* (color enhanced). **C.** Cow about to receive anthrax vaccination.

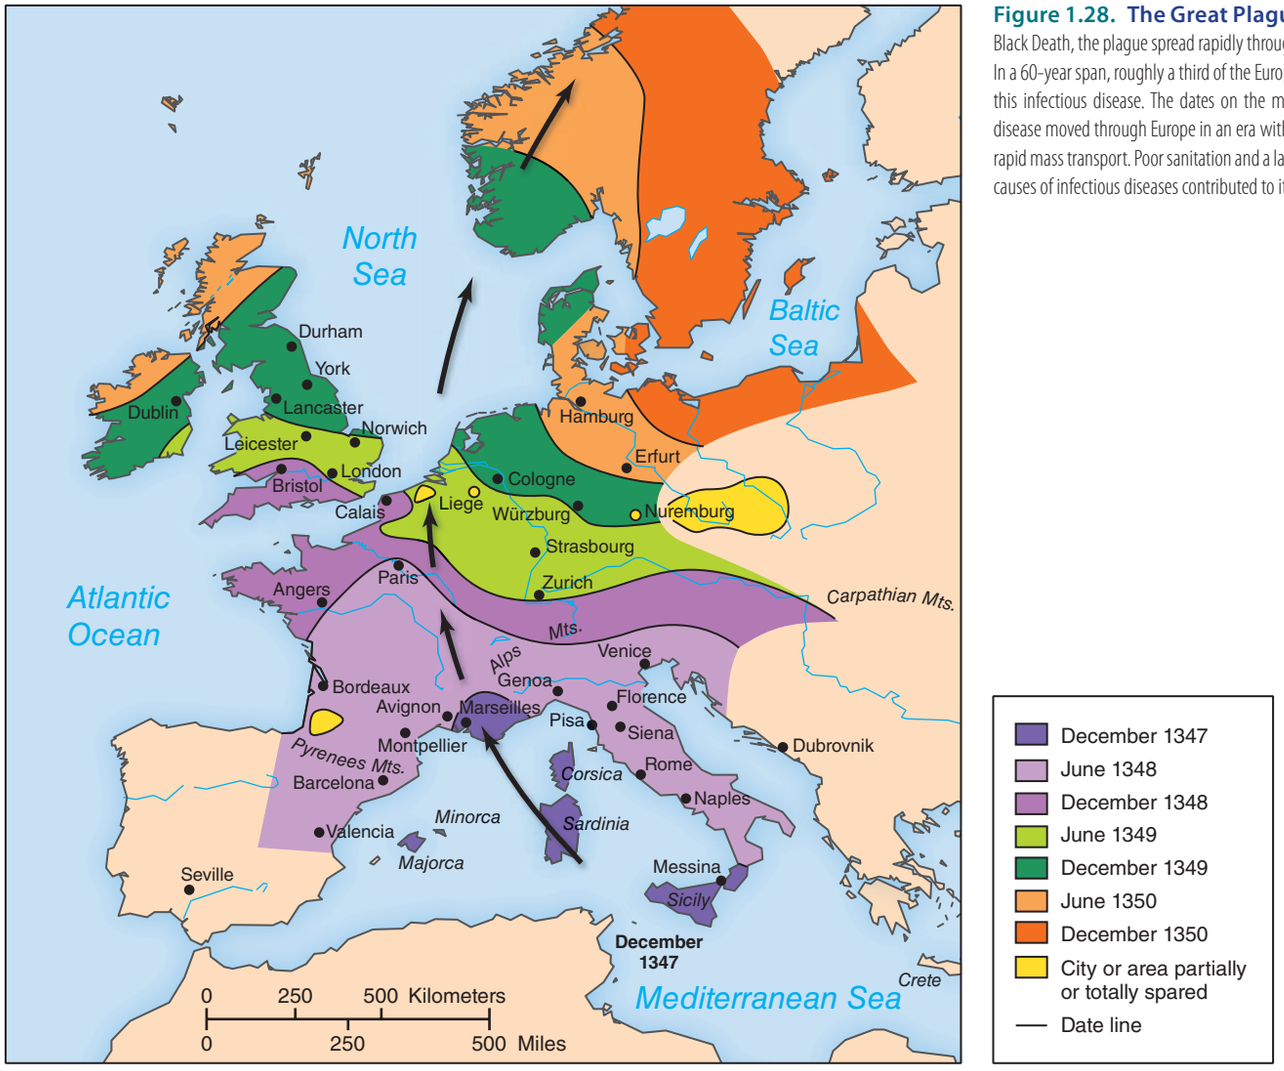

Figure 1.28. The Great Plague Also referred to as The Black Death, the plague spread rapidly throughout Europe in the 1300s. In a 60-year span, roughly a third of the European population died from this infectious disease. The dates on the map show how rapidly the disease moved through Europe in an era without the modern means of rapid mass transport. Poor sanitation and a lack of knowledge about the causes of infectious diseases contributed to its spread.

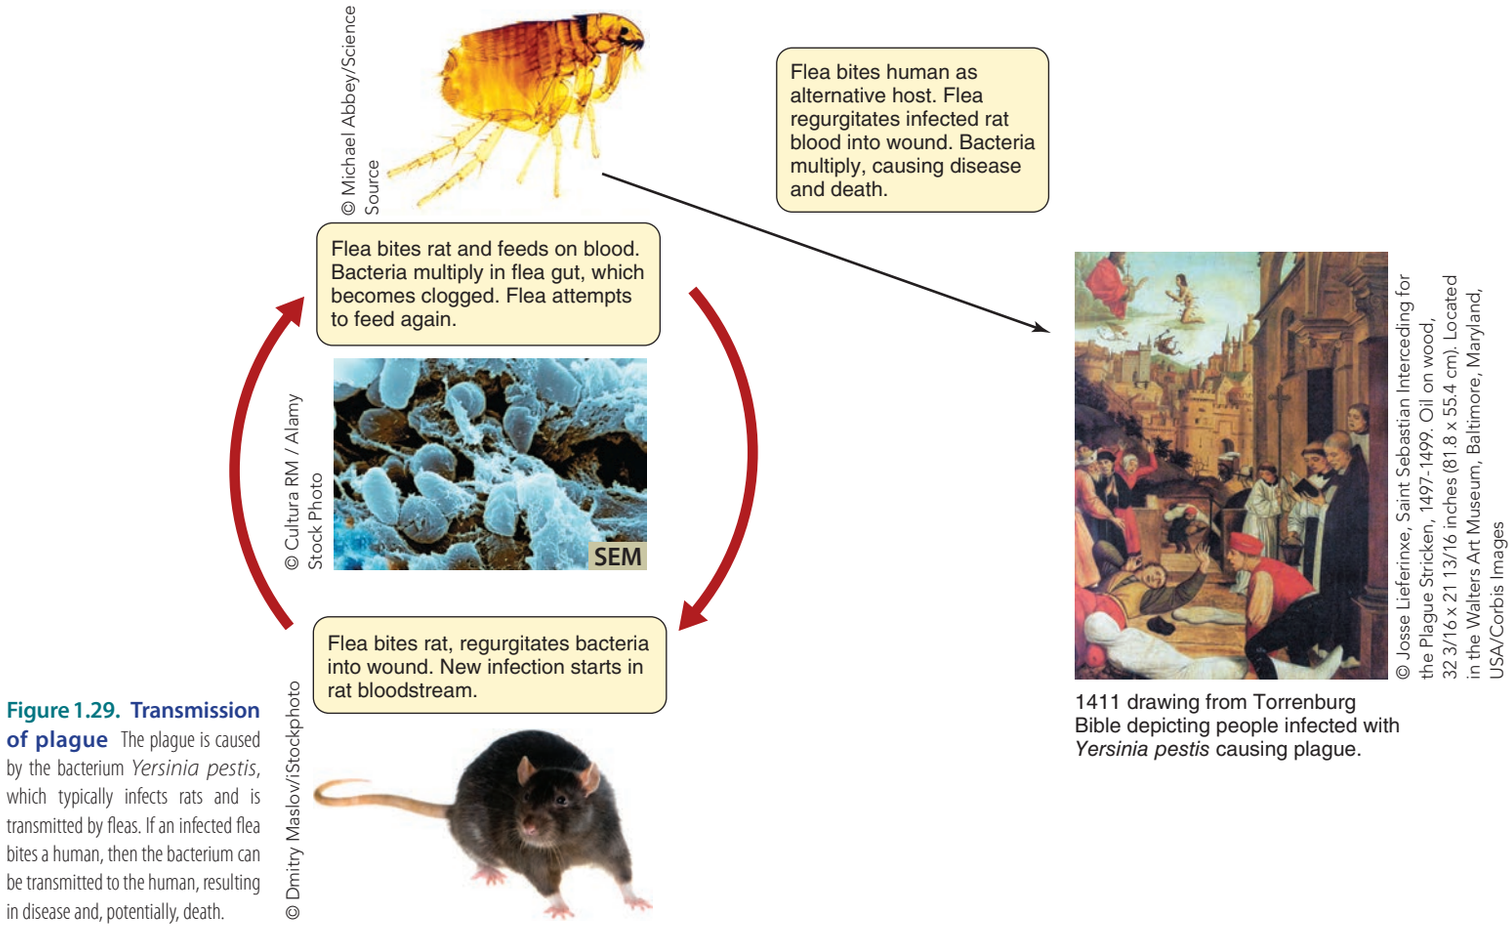
perhaps half of its population, may have died from plague in China in the 1300s. In Europe, 25–50 million people perished, largely between 1347 and 1351. Several million more people were killed by plague in the Middle East and northern Africa.

To put the global death toll due to the plague pandemic of the 1300s into perspective, imagine a modern pandemic that resulted in the death of *over one billion people* within a few years! Even the modern AIDS and influenza pandemics pale by comparison. In the Middle Ages, people did not understand the underlying cause of this horrifying disease. Supernatural explanations of disease were universally accepted; diseases were punishments from God or the results of curses, witchcraft, or "bad air." The true cause of plague, in fact, was not discovered until 1893, when Alexandre Yersin isolated the bacterium *Y. pestis* during a plague outbreak in Hong Kong. Today, plague is rare and treatable with antibiotics.

The massive social disruptions caused by epidemics such as plague in the Middle Ages are rivaled only by the effects of war, famine, and natural disasters. From the perspective of public health, these events are not unrelated. Until very recently, most people who died during wartime, both military and civilian, were victims of microbes. Before the advent of antibiotics during World War II, battlefield wounds were highly likely to become infected, the end result of which was often death. Troops in the field for prolonged periods often were affected by disease. Cholera, typhus, and dysentery were common due to the poor sanitation conditions. Diseases spread by carriers such as lice and fleas, which thrive in crowded conditions, also are a great risk to soldiers and displaced civilians (refugees) during wartime. Malnutrition resulting from war or famine (or both) blunts the effectiveness of the immune system, leaving soldiers and civilians more susceptible to disease.

Control of infectious diseases

As researchers learned more about the causes of infectious diseases in the late 1800s and early 1900s, the medical treatment of these diseases gained a scientific basis. Even before Koch linked specific microbes to specific diseases, the British physician Joseph Lister had discovered the value of cleanliness and disinfection measures in reducing mortality from post-surgical and post-childbirth infections. Doctors' offices and hospitals strove for the universal application of such disinfection measures to decrease the incidence of disease. Although these methods of preventing infections were effective, methods for treating infectious diseases remained inadequate.



1411 drawing from Torrenburg Bible depicting people infected with *Yersinia pestis* causing plague.

Figure 1.29. Transmission of plague The plague is caused by the bacterium *Yersinia pestis*, which typically infects rats and is transmitted by fleas. If an infected flea bites a human, then the bacterium can be transmitted to the human, resulting in disease and, potentially, death.

Even though Salvarsan was the first scientifically developed antimicrobial to be commercially marketed, it was not until penicillin and sulfa drugs came into use in the 1940s that antimicrobial drugs had a major impact on the treatment of infectious diseases. Indeed, people in developed countries saw a dramatic decrease in deaths due to infectious disease during the twentieth century because of improved sanitation and the development of antimicrobial drugs and vaccines **(Figure 1.30)**. A new problem, however, now faces us. Increasingly, infections result from antibiotic-resistant bacteria. Our existing antibiotics are not effective against these microorganisms, and our ability to treat some infectious diseases is declining.

CONNECTIONS Recall that bacteria are masters at sharing genes through horizontal gene transfer. This facilitates the passing of genes for antimicrobial resistance. History has shown that the more effective an antimicrobial drug is, the more it is prescribed, and the faster resistance spreads, rendering the drug ineffective. See **Section 24.3** for more on the acquisition of drug resistance.

Vaccines also have had an enormous impact in reducing the sickness and death associated with infectious diseases. Vaccination involves exposing a person to an inactivated or weakened version of a microbe, or even just a part of the microbe, to create immunity to a disease. The past century has seen vaccines developed for many deadly diseases, including polio, diphtheria, rabies, and many others. Historically, vaccination began roughly 2,000 years ago in China and India as a defense against smallpox. Smallpox, a viral disease, was common in Europe and Asia, in some areas being responsible for 20 percent of all deaths. It was fatal to one of every four people infected. Those who survived carried characteristic smallpox scars for the rest of their lives, but they also carried a lifelong protection from the disease.

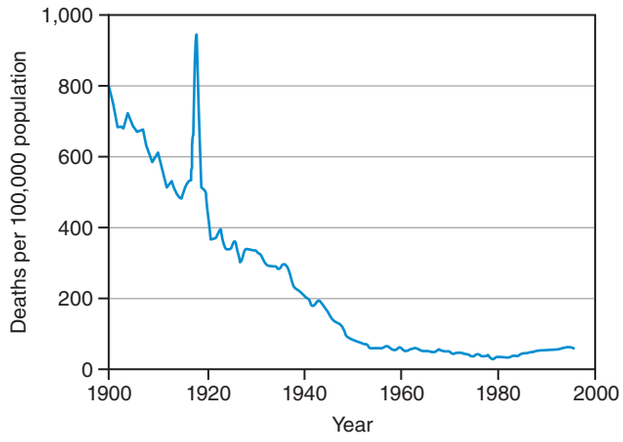


Figure 1.30. Infectious disease deaths in the United States during the twentieth century Deaths associated with infectious diseases decreased dramatically in the United States during the twentieth century. The spike in deaths due to infectious diseases around 1920 represents the increased deaths caused by the 1918 influenza pandemic. While the overall infectious disease burden in the United States has remained low, new infectious agents, like HIV, have emerged and existing infectious diseases, like measles, have shown an increased prevalence.

Vaccination against smallpox was occasionally practiced in eighteenth century Europe, but it was the famous experiment of English physician Edward Jenner in 1796 that popularized the procedure. Jenner used material from a cowpox infection of a milkmaid to inoculate a boy, who was later shown to be immune to smallpox (Figure 1.31). We now know that cowpox virus is closely related to the smallpox virus, explaining why exposure to it generated immunity to smallpox. Thanks to the smallpox vaccine, in fact, no naturally occurring cases of smallpox have occurred since 1977. In one of the greatest achievements in medical history, we have eliminated this scourge from the face of Earth.

People in developing regions of the world, particularly in sub-Saharan Africa, continue to suffer from infectious diseases. These diseases include AIDS, tuberculosis, and malaria, which combined take nearly five million lives per year (Figure 1.32). Vaccines are not yet available that can prevent HIV or malaria infection, and the current tuberculosis vaccine is far from ideal. Drugs to treat these three diseases are available, but they are expensive, which means that many people do not have adequate access to these therapies. Additionally, it is not uncommon to find people in developing countries simultaneously affected by at least two of these diseases, lowering their life expectancy even further.

Other major historical factors that have reduced death from infectious diseases include improvements in personal hygiene, public sanitation, and food and water safety. Indoor plumbing, water treatment measures, and large-scale sewage disposal systems have led to a decrease in waterborne infectious diseases. **Pasteurization**, the process in which milk is heated briefly to kill most microorganisms, freezers, and refrigerators all have contributed to the increased safety of food. Many of us take these advances for granted. Unfortunately, these simple measures are not universally available. As a result, we now are faced with what Dr. Paul Farmer refers to as the "great epi (epidemiology) divide." People in developing countries and people in developed countries without access to adequate health care suffer a disproportionate infectious disease burden.

In this chapter, we have barely scratched the surface of microbiology. We have been introduced to the microbes. We have learned about the evolution of life and the genetics of microbes. We have begun to explore how microorganisms acquire energy. Finally, we have seen how microbes can cause diseases. In later chapters, we will further explore these topics. We will see how important microbes are in our world. As we investigate these topics, we will see that extensive experimental evidence supports our current understanding of the microbial world. We also will see that many questions and ambiguities still remain.

1.4 Fact Check

1. Why was the role of microbes in causing disease not accepted for so many years?
2. What is spontaneous generation and how was it disproved?
3. Describe measures that have been effective in controlling and reducing deaths from infectious diseases.

C. Vaccinia virus

Figure 1.31. Edward Jenner and the development of vaccination
Although the Chinese practiced forms of vaccination against smallpox for hundreds of years, vaccination was not practiced in Europe until the end of the eighteenth century. In 1796, Edward Jenner showed that he could inoculate a boy with material obtained from the pox marks on a woman infected with cowpox and provide the boy with immunity to smallpox. Global vaccinations have eliminated smallpox. **A.** 1798 illustration from Jenner of cowpox lesions on a milkmaid's hand. **B.** Painting of Jenner vaccinating a person against smallpox. **C.** Vaccinia virus, the virus used as the smallpox vaccine.

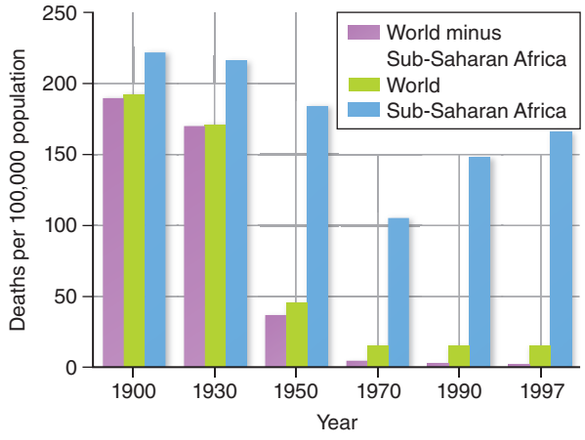

Figure 1.32. Impact of malaria in sub-Saharan Africa During the twentieth century, global deaths associated with malaria, an infectious disease caused by the protozoan *Plasmodium falciparum*, decreased dramatically. However, malaria remains a major problem in sub-Saharan Africa. According to the World Health Organization, about 9 in 10 deaths due to malaria in 2012 occurred in this region. Many other infectious diseases also disproportionately affect people in developing countries and people without clean water or access to adequate health care.

Throughout this book, we will see that microbiology is a dynamic science. Microbiologists continue to make new discoveries using an expanding selection of laboratory tools. They also continue to refine, modify, and, occasionally, reject existing hypotheses. As we saw in the Mini-Paper, inquisitive minds, continuous experimentation, and the development of new tools can combine to result in completely new ways of seeing the world around us. Such dramatic advances have occurred throughout the history of microbiology and certainly will continue to occur (Table 1.4).

During our exploration, we will make connections between topics. We will see how intimately related microbes are to each other, to their environment, and to us. We will see how the genetics, physiology, and habitat of microbes are intertwined. We also will see how, as the evolutionary biologist Theodosius Dobzhansky wrote in 1973, "Nothing in biology makes sense except in the light of evolution." Most importantly, we will see that the microbial world presents as many surprises to us today as it did to van Leeuwenhoek over 300 years ago.

The Rest of the Story

Van Leeuwenhoek noted that the number of microbes on a person's teeth may "exceed the number of Men in a kingdom." It most certainly does. Today, many researchers estimate that the human body consists of 10^{13} human cells. On us and in us, though, there may be an additional 10^{13} microbial cells. In other words, one could argue that we are equal parts microbe and human! The study of these microbes has moved well beyond the use of the microscope. In this chapter, we reviewed how the microbes present today have evolved to occupy a plethora of habitats using a vast array of metabolic processes, even within the human body. Growth conditions for many of these microbes are well understood, and they have been isolated and grown in the laboratory. However, a large subset still remains a mystery because their specific growth microenvironments have not been determined, or cannot be reproduced experimentally.

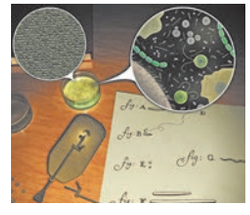
TABLE 1.4 Selected advances in microbiology

Year	Scientist	Advance
Late 1600s	Anton van Leeuwenhoek	Uses microscope to see microorganisms
1860s	Louis Pasteur	Disproves idea of spontaneous generation
1860s	Joseph Lister	Practices infection control
1876	Robert Koch	Identifies *Bacillus anthracis* as cause of anthrax
1928	Alexander Fleming	Discovers penicillin
1950s	Jonas Salk and Albert Sabin	Develop poliovirus vaccines
1966	Lynn Margulis	Proposes endosymbiotic theory
1983	Kary Mullis	Invents PCR
1990	Carl Woese	Proposes three-domain classification of living organisms
1995	Craig Venter	Publishes first complete bacterial genome sequence
2006	Harald zur Hausen	Discovers that human papillomaviruses cause cervical cancer, leading to development of the HPV vaccine

In 2007, the Human Microbiome Project was launched with an aim to identify, analyze, and catalog the hundreds of microbial species residing in or on the human body (the human microbiota). As part of this project, researchers amplified and sequenced bacterial small subunit ribosomal RNA (SSU rRNA) genes, as described in Section 1.1, from various body sites on nearly 250 people. The initial results, published in June of 2012, were astounding. Every one of us is home to hundreds of different bacterial species, and the inhabitants of one person often differ from the inhabitants of another person. This "non-cultivation-based" approach ultimately will facilitate the genetic sequencing and more complete understanding of the microbes that have a major influence on human health and disease.

Image in Action

WileyPLUS Learning Space Anton van Leeuwenhoek is examining a sample of pond water using the microscope he built by hand. Today, microbiologists also can analyze DNA sequences (represented in the upper left) to study environmental samples.



1. What types of microorganisms (and from what domains of life) did Anton van Leeuwenhoek most likely observe? What microbes was van Leeuwenhoek unable to observe with his simple microscope? Explain.
2. Imagine that you were given access to the same drop of pond water observed by van Leeuwenhoek. How could you use PCR to identify or characterize some of the microbes he observed or even those he didn't observe?

Summary

Section 1.1: What is microbiology?

Microbiology is the study of **microorganisms**, including bacteria, archaea, and eukaryal microorganisms, and viruses. Collectively, we can refer to all of them as **microbes**.

- All living organisms share certain features, including **metabolism**, **growth**, **reproduction**, genetic variation resulting in **evolution**, response to outside stimuli, and internal **homeostasis**.
- A **cell** is the simplest structure capable of carrying out all the processes of life.
- All cells contain various **macromolecules**, including **polypeptides**, **nucleic acids**, **lipids**, and **polysaccharides**. Many polypeptides function as **enzymes**.
- Historically, all living organisms were classified as **eukaryotes** or **prokaryotes**, depending on whether they did, or did not, have a nucleus. Today, the taxonomy of living organisms consists of three domains, *Bacteria*, *Archaea*, and *Eukarya*.
- This classification scheme reflects the **phylogeny** of all living organisms.
- Our ability to classify microorganisms has been aided greatly by the **polymerase chain reaction (PCR)**.
- Viruses are subcellular and can be classified as microbes.
- Because of their relatively simple structures, microbes have been useful research models.

Section 1.2: What do we know about the evolution of life and the genetics of microbes?

All living organisms possess remarkably similar informational molecules and processes for converting this genetic information into functional molecules. This conservation of genetic processes provides compelling evidence that all living organisms are evolutionarily related.

- Life probably evolved on Earth around 3.8 billion years ago. Simple organic molecules, possibly associated with iron-containing surfaces, became enclosed within a lipid membrane.
- The identification of **ribozymes** lends support to the idea that the precursors of life, the so-called **progenote**, may have used RNA as the major informational molecule.
- Eukarya arose through endosymbiosis, in which free-living bacteria became engulfed within a developing eukaryal cell, providing the host with the ability to harvest sunlight or undergo aerobic respiration.
- In all cells, the main informational molecule is double-stranded DNA, a molecule ideally suited for containing information and for faithful replication. This DNA-based information is converted into functional molecules through the processes of transcription and translation.
- **Mutation** in the DNA allows for genetic variation, a prerequisite for evolution.
- Our understanding of the basic genetic processes has led to the development of **recombinant DNA** technologies. We now can alter DNA molecules and produce human proteins in microbial hosts.
- Recent advances in DNA-sequencing technologies and increased computing power have led to the emerging fields of genomics and bioinformatics.

Section 1.3: How do microbes get energy and interact with the world around them?

All living organisms must obtain organic molecules. **Heterotrophs** ingest them. **Autotrophs** produce their own organic molecules.

- Most autotrophs generate organic molecules through photosynthesis.
- Through the processes of glycolysis, fermentation, and respiration, organic molecules are utilized to produce ATP.
- Microbial metabolism has affected the **biosphere**, and microbes are intimately involved in the **biogeochemical cycling** of many chemicals, including nitrogen, phosphorus, and sulfur, in the biosphere.
- Microbes interact with each other and other organisms in many complex ways.

Section 1.4: How are microbes associated with disease?

The work of a number of microbiologists, including Louis Pasteur, led to the development and acceptance of the germ theory of disease.

- Koch's postulates, developed in the 1800s, provide a means of demonstrating that a particular microorganism causes a particular disease.
- Infectious diseases have had, and continue to have, a profound impact on humans.
- Today, we have an assortment of antibiotics, antivirals, and vaccines that treat or prevent many infectious diseases. The development of these therapies has depended, in large part, on our understanding of the structure of these microbes and their replication strategies. Other techniques, like **pasteurization**, also have led to a decrease in the incidence of certain infectious diseases.
- Unfortunately, infectious diseases remain horrific threats to people throughout the world.

Application Questions

1. A researcher is studying a newly discovered microbe and must first determine whether this microbe should be considered alive. What characteristics will she examine to make this determination?
2. Given what we learned about proteins in Section 1.1, what might be the effects of an antimicrobial drug that halts protein synthesis in cells?
3. Imagine a researcher is examining several cell samples in the laboratory and needs to categorize each sample as either bacterial or eukaryal. What features should the researcher examine and why?
4. Inspired by the Miller–Urey experiment described in Perspective 1.1, a researcher continues to explore the origins of life on Earth. The first task is to design a simulation of prebiotic Earth. What conditions should be considered when creating this simulation?
5. According to the endosymbiotic theory, mitochondria and chloroplasts are derived from bacterial cells. What evidence exists to support this theory?

6. If a species of microbe were discovered that did not appear to mutate, scientists probably would hypothesize that its lack of mutation would be detrimental to its evolution. Explain why the scientists would make this prediction.
7. In Section 1.3, oxygenic photosynthesis and aerobic respiration were described. Based on our discussion of these two processes, explain why oxygenic photosynthesis must have evolved on Earth before aerobic respiration.
8. Oxygen is not always a "good thing." In fact, O_2 can be considered dangerous. Explain why oxygen can be harmful and what microbes must do to deal with the dangers of an oxygenated world.
9. In Section 1.4, we discuss the great epi (epidemiology) divide between developing and developed countries. List several policy and funding changes that could be implemented in developing countries to decrease the number of infectious disease cases. Explain each of these recommendations.
10. A research group has received funding to study the diversity and evolutionary relatedness of microbes in a marine ecosystem. The head of the laboratory has decided to sequence and analyze the SSU rRNA genes of the microorganisms in this ecosystem.
    a. What are SSU rRNA genes?
    b. Why are these gene sequences ideal for studying the evolutionary relationships of the microorganisms found there?
    c. How is this process conducted?
    d. After sequencing and analyzing three gene samples, the researchers conclude that two of the samples are from closely related microorganisms, while the third sample is very distantly related. Describe the sequencing results that would lead to this conclusion.
11. In Section 1.1, we discussed Paul Ehrlich's foundational research in which he noted differences between bacterial and human cells. Those observed differences became the basis for the development of antimicrobial drugs that "spare" eukaryal human cells. Based on these observed differences between bacterial and eukaryal cells:
    a. Identify an aspect of bacteria that would NOT be a good target for a drug because it would not "spare" the host. Explain why this bacterial component is not a good choice for an antimicrobial drug.
    b. Identify an aspect of bacteria that might be worth further exploration as a potential target for an antimicrobial drug that would not harm human cells. Explain.

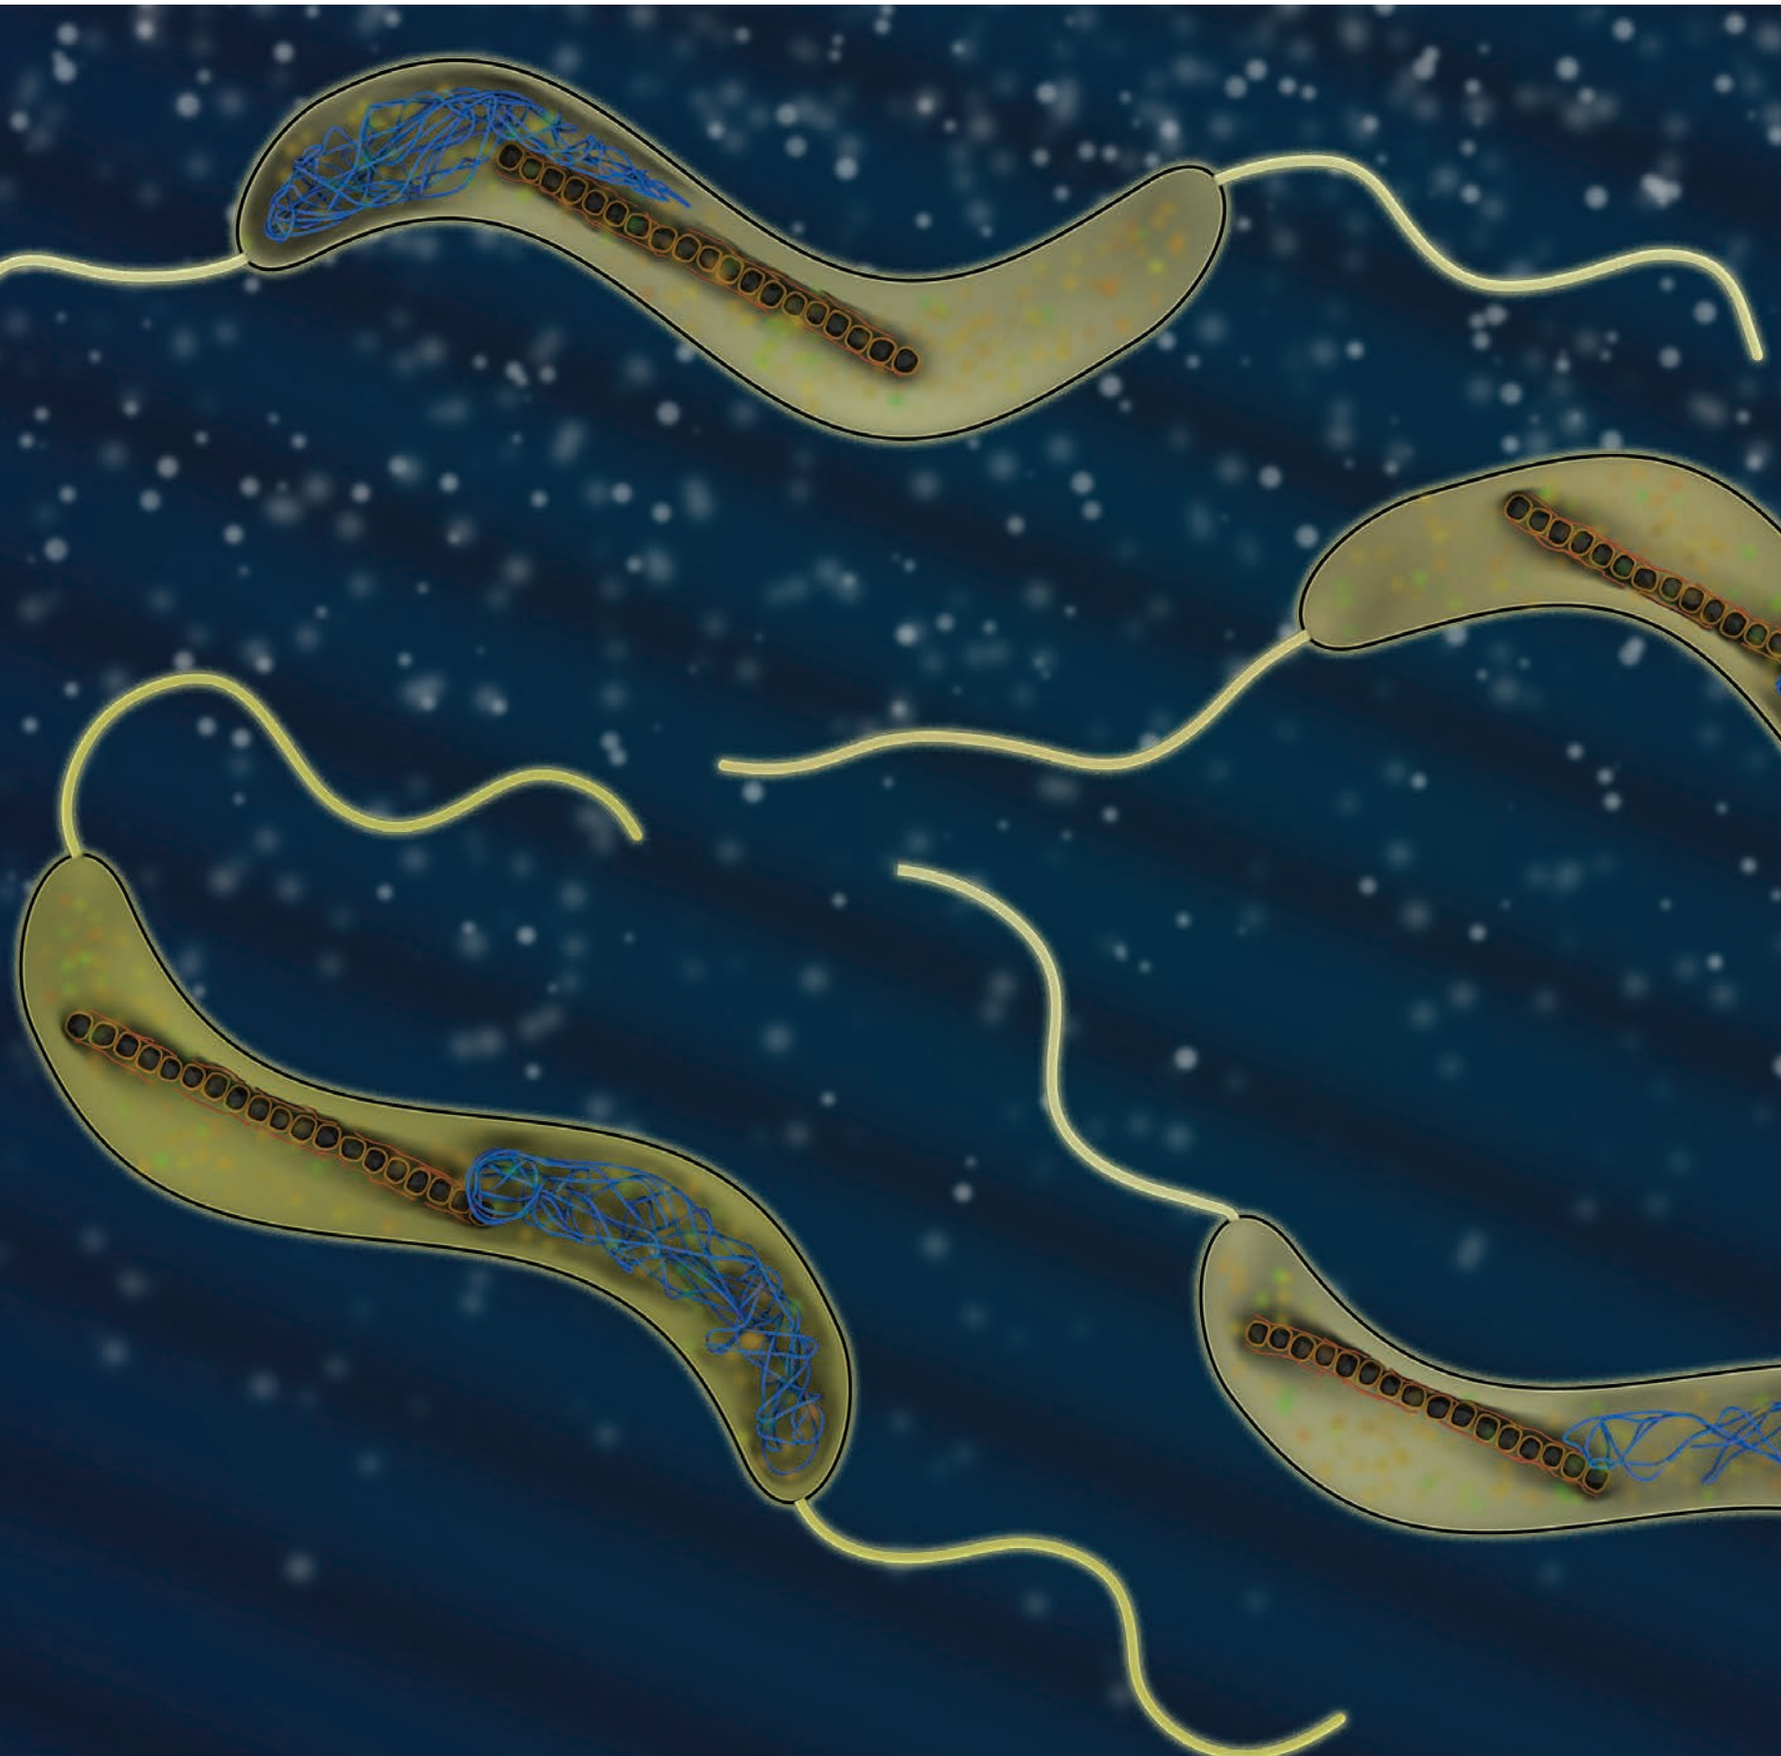
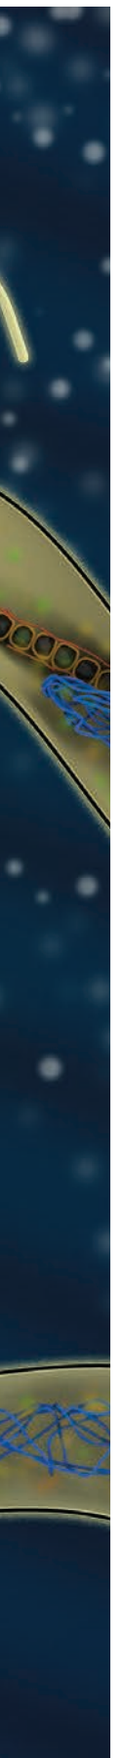
CHAPTER 2

Bacteria





In 1974, Richard Blakemore, a graduate student at the University of Massachusetts–Amherst, was examining sediment samples with his microscope. He noticed something curious. Within this muddy microbial menagerie, some bacteria consistently accumulated on one side of the slide. More interestingly, a magnet placed near the microscope stage altered the movement of these bacteria. Placing one pole of the magnet directly next to the stage would cause them to swim toward or away from it, depending on which pole of the magnet was closest to the stage (Blakemore's bacteria turned out to be north-seeking). It was not simply magnetic attraction pushing or pulling the bacteria (dead bacteria aligned along their long axis in a magnetic field, like tiny compass needles, but otherwise were not active). The live bacteria used flagella—tiny propeller structures common in bacteria—to power their movement and somehow used a magnetic field for steering. Blakemore called this phenomenon "magnetotaxis."

Magnetotaxis provided a simple way for Blakemore to capture these bacteria. He put mud in a container with a magnet next to one side, allowed the magnetotactic bacteria to accumulate, collected the cells, and then repeated this process until he had a nearly pure population of magnetic bacteria. With this basic strategy, plus some trial and error to figure out how to grow the bacteria, he eventually isolated pure cultures of these magnetotactic bacteria. Closer analysis of the cells found them to be rich in iron due to chains of membrane-enclosed magnetite particles (dubbed "magnetosomes") lined up parallel to the long axis of the cell. The force exerted by the magnetosome chain, as it aligns with Earth's magnetic field, orients the bacterium with respect to the magnetic field.

Thirty years after their discovery, magnetotactic bacteria still are being studied by microbiologists. We continue our attempt to understand how these small and supposedly "simple" cells build such a fascinating structure. We will learn more about the magnetosome in this chapter as we explore the structure and function of bacterial cells.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements in the text and online:

While most bacteria are small, they exhibit a wide range of shapes.

- 3D Animation: What do bacteria look like?
- Figure 2.1: Common shapes of bacteria
- Figure 2.3: Multicellular arrangements of bacteria
- Microbes in Focus 2.1: *Epulopiscium fishelsoni:* Remarkable for more than its size

Major structures in the cytoplasm

- 3D Animation: Structures found inside of bacteria
- Table 2.1: Features of the bacterial cytoplasm
- Figure 2.7: Specialized cytoplasmic organelles in bacteria

Cytoskeletal proteins help organize bacterial cells.

- Figure 2.8: Functions of cytoskeletal elements in bacteria
- Perspective 2.1: Marvelous magnetosomes!

The cell envelope serves many functions.

- 3D Animation: Types of cell envelopes found in bacteria
- Figure 2.14: The structure of the peptidoglycan cell wall
- Toolbox 2.1: The Gram stain
- Perspective 2.2: The protective shells of endospores
- Mini-Paper: New microscopy methods reveal a periplasm in Gram-positive bacterial cells

Additional structures exist on the cell surface.

- 3D Animation: Features found on the surface of bacteria
- Table 2.2: Molecules and structures on bacterial cell surfaces
- Figure 2.28: Directed motility lets bacteria respond to outside chemical signals
- Microbes in Focus 2.2: *Proteus mirabilis*: A swarming bacterium
- Figure 2.34: Biofilms

Classification of bacteria reflects their evolutionary relationships.

- Table 2.3: Classification hierarchy within the domain *Bacteria*, using *Brucella melitensis* as an example

CONNECTIONS for this chapter:

Methods of eliminating bacteria from solutions **(Section 6.5)**

Occurrence of histones **(Section 4.2)**

Control of DNA replication **(Section 7.2)**

Penicillin and drug design **(Section 24.2)**

Bacteria in complex communities, such as biofilms **(Section 15.1)**

Introduction

In Chapter 1, we briefly explored the incredible world of microbes. In this chapter, we will look specifically at bacteria, followed in Chapters 3, 4, and 5 by more thorough examinations of eukarya, archaea, and viruses. Although bacterial cells appear to be less complex than eukaryal cells, they certainly are not "simple." Our tour of the bacterial cell will start with the nucleoid and cytoplasm, then progress outward through the plasma membrane and cell wall, and ultimately reach the cell surface. Along the way we will address several key questions:

What do bacteria look like? (2.1)
What is in the cytoplasm of bacterial cells? (2.2)
What kinds of internal structures help to organize bacterial cells? (2.3)
What are the critical structural and functional properties of the bacterial cell envelope? (2.4)
How do structures on the surface of bacterial cells allow for complex interactions with the environment? (2.5)
What are the different types of bacteria? (2.6)

2.1 Morphology of bacterial cells

What do bacteria look like?

Bacteria exhibit several distinct shapes, or morphologies (Figure 2.1). The most common shapes, and the terms they are given by microbiologists, are:

- Spherical = **coccus** (plural: cocci, see Figure 2.1A)
- Rod = **bacillus** (plural: bacilli, see Figure 2.1B)
- Curved rod = **vibrio** (plural: vibrios, see Figure 2.1C)
- Spiral = **spirillum** (plural: spirilla, see Figure 2.1D)

The shape of bacterial cells is determined by the organization of the cell wall, the semi-rigid structure surrounding the cell. Morphology is a fairly reliable feature of most bacterial species.

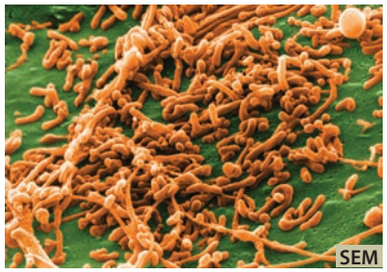
D. Spirilla are spiral-shaped.

Figure 2.1. Common shapes of bacteria **A.** Sometimes found on skin, *Staphylococcus aureus* cells are spherical, as are *Streptococcus pyogenes*, which may cause mild or serious infections, including scarlet fever. **B.** The rod-shaped bacterium *Bacillus anthracis* causes anthrax, whereas *Escherichia coli* typically is a non-disease-causing inhabitant of the intestines of many animal species. **C.** *Vibrio cholerae* are curved and cause cholera in humans. **D.** Spiral-shaped bacteria include spirochetes like *Treponema pallidum*, which causes syphilis in humans.



© David M. Phillips / Science Source Images

Figure 2.2. Pleiomorphic *Mycoplasma* These bacteria are very small (about one-tenth the size of *E. coli* cells). Lacking a cell wall, the cells may have an irregular shape—some may appear sphere-like, others more rod-shaped. Although cells may stick together, *Mycoplasma* are not multicellular.

For instance, *Escherichia coli* cells generally are straight rods, *Vibrio cholerae* cells are curved, *Staphylococcus aureus* cells are spherical, and *Treponema pallidum* cells are long, thin spirals. However, because many bacterial species have similar morphologies, and because environmental conditions and stresses can sometimes cause changes in bacterial morphology, physical appearance is seldom conclusive for identifying bacterial species.

For many bacterial species, like *E. coli*, individual cells typically remain separate from each other. The cells of other bacteria stay physically connected after they divide. For example, the rod-shaped cells of *Bacillus anthracis*, the cause of anthrax, and the spherical cells of *Streptococcus pyogenes*, the cause of strep throat, often are seen in long chains. In contrast, *Staphylococcus* cells tend to form clusters rather than chains (see Figure 2.1). Some bacteria do not exhibit regular shapes, but may exhibit highly variable cell morphologies. These bacteria are referred to as **pleiomorphic**. Examples of pleiomorphic bacteria include members of the genus *Mycoplasma*, which do not make a cell wall and, as a result, do not have a regular shape (Figure 2.2).

CONNECTIONS As we will discuss in **Section 6.5,** most bacteria can be removed from solutions by passing the solutions through fine filters. Because of their small size and lack of a cell wall, mycoplasma cells often are not retained by these fine filters.

Some bacteria grow in more complex multicellular arrangements (Figure 2.3). Soil bacteria of the Actinomycete group grow as irregularly branching filaments called **hyphae** that are composed of chains of cells. Hyphae can form three-dimensional networks called **mycelia** that can rise above the substrate, penetrate down into soil, or both. A distinctive multicellular arrangement found in cyanobacteria is the formation of smooth, unbranched chains of cells called **trichomes** that may have a polysaccharide sheath coating the entire filament. In both trichomes and hyphae, the partitions between cells contain channels for intercellular passage of materials such as nutrients and signaling molecules.

Just as they come in a range of shapes, bacteria also come in a range of sizes, with cells of most bacterial species being somewhere between 0.5 μm and 5 μm in length. Bacteria are usually smaller than eukaryal cells; even small eukaryal microorganisms such as yeast are typically at least 5 μm in diameter. Most bacteria cannot be seen by the unaided human eye. Therefore, microscopy is an integral tool for the microbiologist. Different types of microscopes, like electron microscopes and light microscopes, allow us to see objects of different sizes (Figure 2.4). In Appendix B: Microscopy, we will explore these various types of microscopes, how they work, and their specific applications. We already have seen images, or micrographs, taken with cameras linked to microscopes. Throughout this text, these micrographs will be marked with a microscopy icon that provides us with some information about the image. An "LM" label, for example, indicates that the image was generated with a light microscope. Thanks to continuing advances in microscopy and photography, we can see an increasingly detailed view of the microbial world.

Although most bacteria are less than 5 μm in diameter, some amazingly large bacteria have been discovered in recent years (Figure 2.5). The spherical bacterium *Thiomargarita namibiensis* can be up to 700 μm in diameter, and the cigar-shaped *Epulopiscium fishelsoni* (Microbes in Focus 2.1) can be over 600 μm long. At the other extreme, some atypically small bacteria exist, too. Mycoplasmas, as we noted previously, are only 0.2 μm in diameter. In early 2015, researchers reported the identification of even smaller bacteria. These ultra-small bacteria, which have not yet been cultivated, appear to have a volume of approximately 0.009 μm^3. These newly observed bacteria may be near the lower size limit for cellular life as we know it. After all, even a single ribosome, the machinery for protein synthesis, is roughly 50 nm (0.05 μm) in diameter, and even the smallest cell would have to contain multiple ribosomes, a genome, messenger RNA, and various key enzymes in the cytoplasm.

As we have seen in this section, bacterial cells exhibit great variation in their shapes and sizes. All bacterial cells, however, also share many common properties. In the next section, we will begin to explore the various structures found within a typical bacterial cell, focusing on the functions of these structures and, in some cases, their evolutionary history.

B. Trichomes

Figure 2.3. Multicellular arrangements of bacteria Some bacteria show more complex organization and specialization. **A.** *Streptomyces* species grow into irregularly branching hyphae that can form a three-dimensional network, or mycelium, in their soil habitat. **B.** Cells of the cyanobacterium *Spirulina* grow into a long, smooth, unbranched structure, or trichome, surrounded by a sheath.

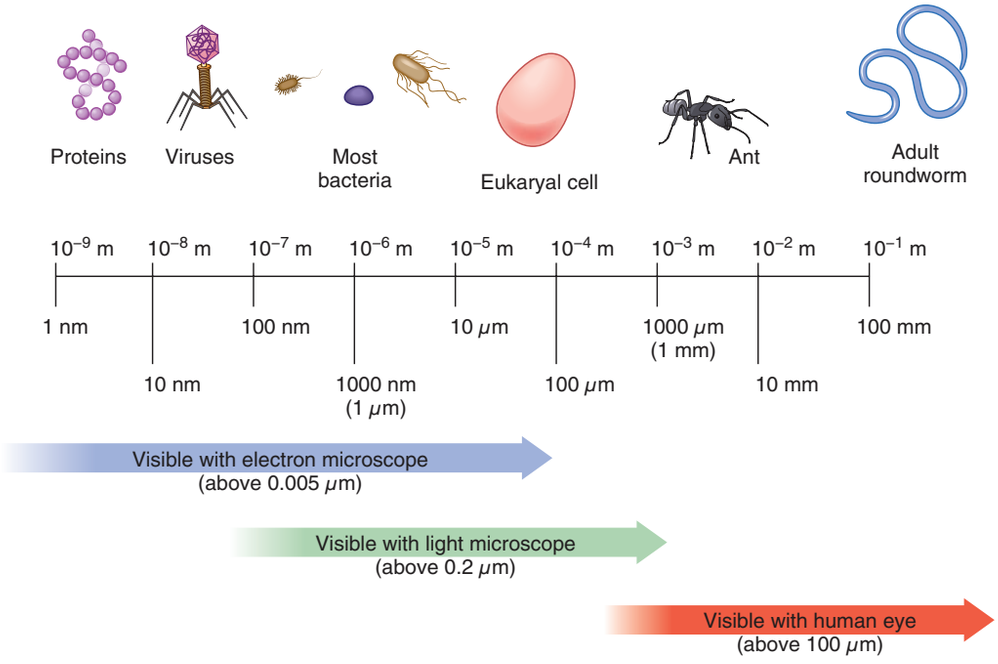

Figure 2.4. Relative sizes of microbes Bacteria range in size from as small as 200 nm (0.2 μm) to several hundred μm, but the vast majority of individual bacterial cells are between 0.5 and 5 μm. Because of this small size, most bacteria only can be seen with a microscope. Objects need to be about 100 μm in diameter or larger to be seen by the unaided human eye. *NOTE*: m = meter, mm = millimeter, μm = micrometer, nm = nanometer. More information about microscopy can be found in Appendix B.

2.2 The cytoplasm

3D ANIMATION

What is in the cytoplasm of bacterial cells?

The **cytoplasm** of a bacterial cell, the aqueous environment within the plasma membrane, contains a diverse array of components (Table 2.1). The largest single entity in the cytoplasm is the **nucleoid**, a convoluted mass of DNA (usually a single, circular chromosome) coated with proteins and RNA molecules still in the process of being synthesized. In contrast to the nucleus of eukaryal cells, a membrane does not surround the nucleoid of bacterial cells (Figure 2.6).

If an average-size bacterial chromosome were stretched out in linear form, it would be hundreds of times longer than the bacterial cell in which it resides. To pack the DNA into a manageable form, bacteria use several strategies. Cations, such as Mg^{2+}, K^+, or Na^+, shield negative charges on the sugar-phosphate backbone of each strand of the DNA helix, allowing the DNA molecule to pack more closely. Also, molecules of small, positively charged proteins bind to the chromosome to help maintain the condensed structure of the nucleoid. Finally, the topology of the DNA molecule is adjusted by **topoisomerases**, enzymes that encourage the chromosome to coil upon itself (**supercoiling**) in order to collapse it into a more compact mass.

B. *Epulopiscium fishelsoni*

Figure 2.5. Giants of the bacterial world **A.** *Thiomargarita namibiensis* cells can be up to 700 μm in diameter. The nearly spherical cells, often filled with sulfur granules, are almost visible to the unaided human eye. **B.** Cigar-shaped *Epulopiscium fishelsoni* is so large (200–700 μm × 80 μm) that when it was discovered by Avi Fishelsoni in 1985 it was believed to be a eukaryal organism. This giant bacterium lives symbiotically in the guts of surgeonfish. It produces offspring internally, a unique mechanism of reproduction for a bacterium.

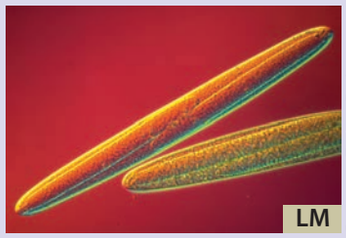
Microbes in Focus 2.1

EPULOPISCIUM FISHELSONI: REMARKABLE FOR MORE THAN ITS SIZE

Habitat: Only found within the gut of surgeonfish

Description: Gram-positive bacterium, 200–700 μm in length and up to 80 μm in diameter

Key Features: Aside from its enormous size, this bacterium also exhibits a remarkable genome and replication cycle. Each cell contains hundreds to thousands of copies of its genome, organized into many separate nucleoids located on the periphery of the cytoplasm. Stranger yet, unlike most bacteria, in which one cell divides into two progeny cells, *Epulopiscium* offspring arise within the parent cell, as seen in this image. Some types of *Epulopiscium* have as many as 12 smaller cells inside the parent! How genomes and nucleoids are distributed into the offspring is unknown. The new cells appear to break out all at once by perforating the membrane of the parental cell, destroying it in the process.



Courtesy Esther R. Angert, Cornell University

2.1 Fact Check

1. What are the most common bacterial shapes?
2. Describe the various multicellular arrangements formed by some bacteria as a result of their cellular division.
3. What are the general size ranges of bacteria?

CONNECTIONS In eukaryal cells, the DNA is compacted by histones **(Figure 7.5B)**. In **Section 4.2,** we will see that histones also exist in archaeal cells.

Many other proteins are located around the nucleoid, including enzymes involved in replicating and transcribing the DNA (DNA and RNA polymerases, respectively), and proteins that control gene expression. As RNA polymerases produce messenger RNA, ribosomes assemble on the mRNA and begin producing polypeptide chains. Ribosomes are thus indirectly associated with the nucleoid in living bacterial cells, although they fall off for the most part when the nucleoid is extracted from cells in the laboratory. The nucleoid isolated from *Escherichia coli* after gentle cell lysis is roughly 60 percent DNA, 30 percent RNA, and 10 percent protein by weight.

Aside from the nucleoid, the cytoplasm is a complex aqueous stew of macromolecules, with hundreds to thousands of proteins, transfer RNAs, messenger RNAs, and ribosomes. Most enzyme-catalyzed metabolic reactions occur in the cytoplasm. Some enzymes involved in the synthesis of membrane lipids and cell wall precursors are found in the cytoplasm, as are several proteins organized into filamentous structures that appear to have a guiding role in cell wall synthesis and cell division. We will talk more about these cytoskeletal proteins in the next section. In addition to macromolecules, a variety of smaller organic molecules (amino acids, nucleotides, and metabolic intermediates) and inorganic ions spice up the cytoplasmic soup.

Depending on the environment and growth conditions, bacterial cells sometimes store extra carbon, nitrogen, or phosphorus in **inclusion bodies** large enough to be seen by microscopy as granules within the cytoplasm. A separate membrane does not surround these inclusion bodies. As an example,

TABLE 2.1 Features of the bacterial cytoplasm*

Structure	Composition	Function
Nucleoid	DNA, RNA, protein	Genetic information storage and gene expression
Chromosome-packaging proteins	Protein	Protection and compaction of genomic DNA
Enzymes involved in synthesis of DNA, RNA	Protein	Replication of the genome, transcription
Regulatory factors	Protein, RNA	Control of replication, transcription, and translation
Ribosomes	RNA, protein	Translation (protein synthesis)
Plasmid(s)	DNA	Variable, encode non-chromosomal genes for a variety of functions
Enzymes involved in breaking down substrates	Protein	Energy production, providing anabolic precursors
Inclusion bodies	Various polymers	Storage of carbon, phosphate, nitrogen, sulfur
Gas vesicles	Protein	Buoyancy
Magnetosomes	Protein, lipid, iron	Orienting cell during movement
Cytoskeletal structures	Protein	Guiding cell wall synthesis, cell division, and possibly partitioning of chromosomes during replication

*Not all features are present in all species

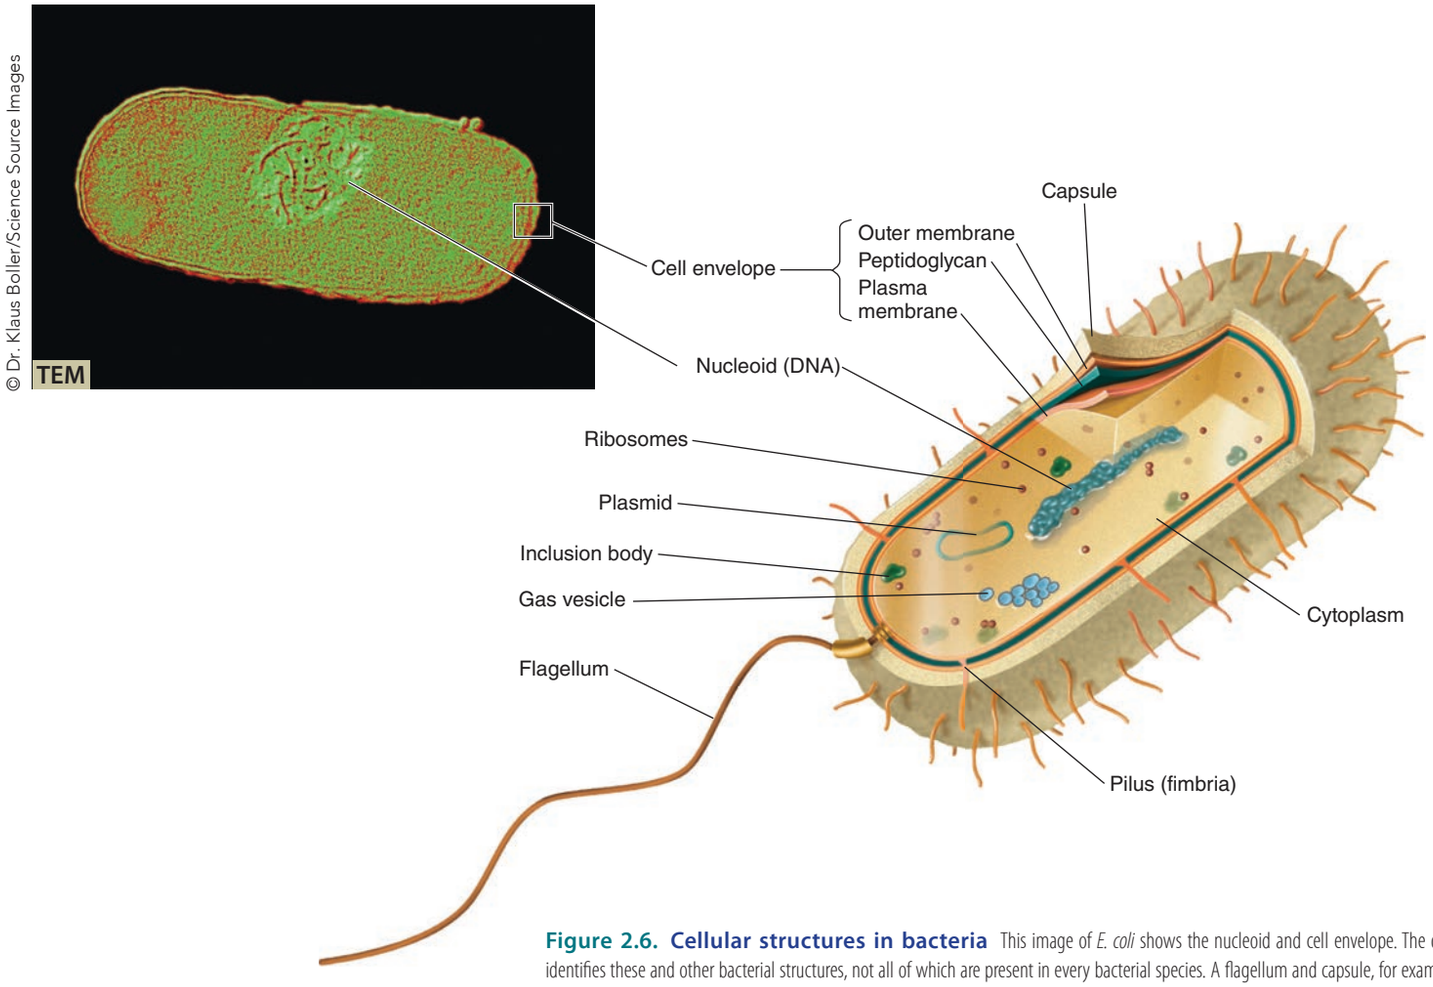


Figure 2.6. Cellular structures in bacteria This image of *E. coli* shows the nucleoid and cell envelope. The drawing identifies these and other bacterial structures, not all of which are present in every bacterial species. A flagellum and capsule, for example, are present in some species, but not others.

polyhydroxybutyrate, or PHB, is a lipid polymer used for carbon storage. PHB granules can compose over 50 percent of the cell's dry weight. PHB is an example of a broader group of polymers called polyhydroxyalkanoates that have been the subject of much industrial interest in recent years due to their ability to substitute for plastics that are derived from petrochemicals (see Section 12.4 for a discussion of these polyhydroxyalkanoate bioplastics). **Sulfur globules**, composed of elemental sulfur (S^0), represent another form of intracellular storage. Cells of the giant bacterium *Thiomargarita namibiensis* (see Figure 2.5A) often contain large numbers of sulfur globules as a by-product of massive oxidation of sulfide (S^{2-}); the sulfur in these globules can be further oxidized to sulfate (SO_4^{2-}) to yield energy when sulfide is limiting.

Some bacteria produce protein-encased compartments within the cytoplasm that carry out specialized functions (Figure 2.7). Some aquatic bacteria, for example, produce air-filled **gas vesicles** that provide buoyancy to the cells. These gas vesicles can regulate the cell's position in a water column in response to light or nutrient levels. Cyanobacteria also can produce **carboxysomes** that contain the key enzymes involved in the conversion of inorganic carbon into organic matter.

Several examples of membrane-bound organelles also exist within bacteria. **Magnetosomes**, the magnetite-containing particles we introduced in the beginning of this chapter, are a rare example of a membrane-enclosed cytoplasmic organelle in a bacterial cell. Some bacteria in the *Planctomycetes* phylum contain an intracellular membrane-bound compartment, the anammoxosome, where ammonium is oxidized for energy. Researchers studying these bacterial organelles believe they may provide clues to the early evolution of membrane-enclosed organelles in ancestral cellular life-forms.

2.2 Fact Check

1. What is the nucleoid and how is it different from the eukaryal nucleus?
2. Describe the strategies used by bacterial cells to package the large chromosome into a "manageable form."
3. What additional components are contained within the cytoplasm of bacterial cells?
4. What are inclusion bodies and what is their role in the bacterial cell?

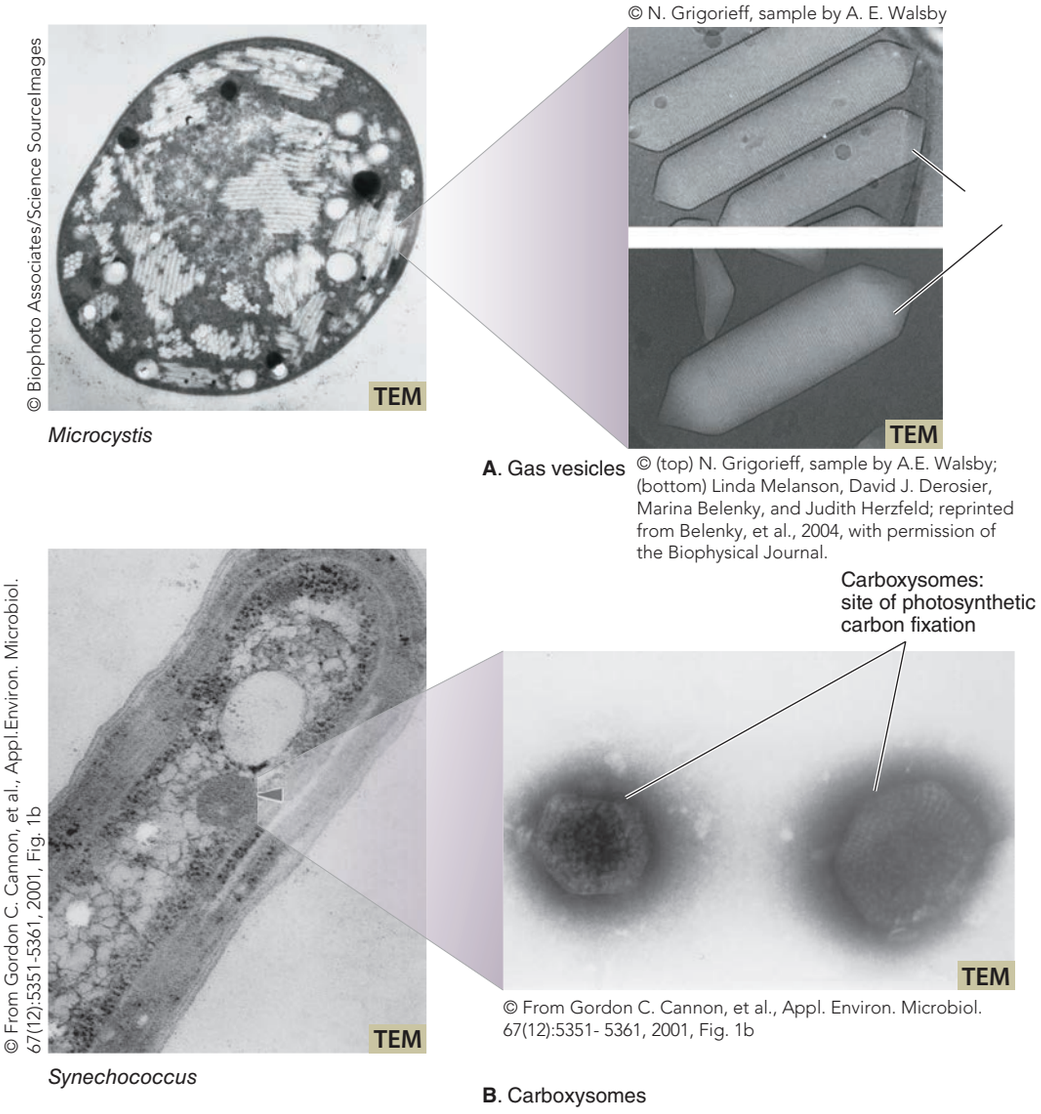

Figure 2.7. Specialized cytoplasmic organelles in bacteria **A.** In this cross section of a *Microcystis* cell, gas vesicles, hollow microcompartments that permit gas to move in and out but prevent the entry of water, are visible. By regulating gas content in these vesicles, this cyanobacterium can regulate its position in water for best access to light or nutrients. **B.** Some cyanobacteria, like *Synechococcus*, contain carboxysomes (indicated by the arrow), protein-encased structures containing enzymes involved in the photosynthetic transformation of CO_2 into organic material.

2.3 The bacterial cytoskeleton

What kinds of internal structures help to organize bacterial cells?

Just as our skeleton provides a structural framework for organizing our organs and tissues, the **cytoskeleton** is important for the internal organization of cells. In bacteria, a few key proteins have been discovered that form filamentous structures that organize cell growth and division **(Figure 2.8)**. The major cytoskeletal proteins discovered so far in bacteria are located in the cytoplasm, but the key role of these proteins involves interacting with the plasma membrane and the cell wall, structures that will be discussed in the next section.

The FtsZ protein forms a ring, the **Z-ring**, which is needed for bacterial cell division (see Figure 2.8A). FtsZ is evolutionarily related to tubulin, a protein that serves as the main building block of eukaryal microtubules, a major component of the cytoskeleton of eukaryal cells (see Section 3.1). FtsZ monomers polymerize into filaments that bundle together to form the Z-ring. The formation of the Z-ring on the inner face of the plasma membrane is a critical step in cell division, because this ring interacts with membrane proteins that ultimately direct synthesis of the bacterial cell wall. As the Z-ring contracts through controlled release of subunits from FtsZ polymers by GTP hydrolysis, the cell envelope is forced inward at the eventual division site by reoriented cell wall synthesis. By the time cell division is finished, the Z-ring has disappeared. It is then rebuilt from cytoplasmic FtsZ during the next cell cycle.

The MreB protein is another important cytoskeletal component in bacteria. MreB is evolutionarily related to actin, a eukaryal cytoskeletal protein. MreB polymerizes into filaments that look strikingly similar to actin filaments, the heart of cytoskeletal structures called microfilaments in eukaryal cells. In bacteria, MreB forms long helical bands underlying the plasma

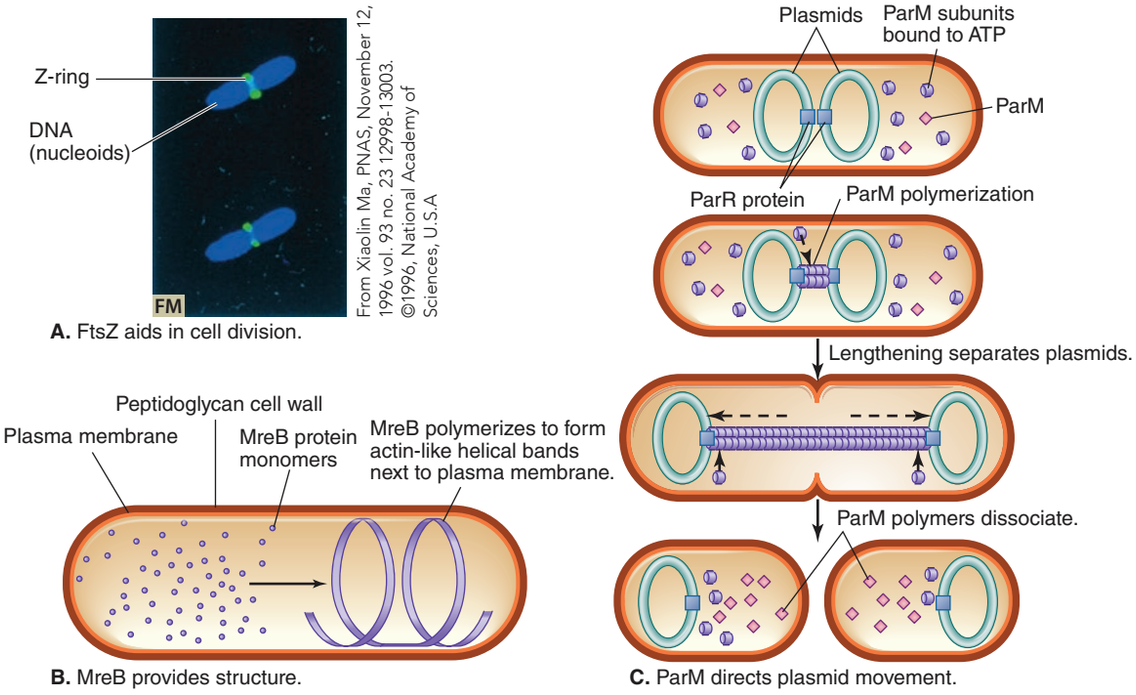

Figure 2.8. Functions of cytoskeletal elements in bacteria **A.** This fluorescence micrograph shows *E. coli* cells undergoing cell division. The FtsZ "Z-ring" (green) is seen at the middle of each cell. Nucleoids that have already divided can be seen in blue on either side. **B.** MreB forms filaments in helical patterns on the inner face of the plasma membrane, aiding in providing shape to the cell. **C.** ParM forms filaments that direct plasmid movement to either side of the cell, ensuring plasmid segregation. ParM subunits bound to ATP (blue cylinder) polymerize into a rod, propelling plasmid molecules toward the poles as the ParM grows outward. Blue squares are the ParR protein, which recognizes the plasmid DNA and connects with the ParM filament. After division, ParM dissociates from the filament (pink diamonds).

membrane (see Figure 2.8B). MreB is nearly universal in nonspherical bacteria, but is rarely if ever present in cocci. Experiments with *E. coli* and *Bacillus subtilis* suggest that MreB helps guide cell wall formation to produce an elongated cylinder, rather than a spherical shape. Scientists are still figuring out how bacterial cytoskeletal proteins help to guide the synthesis and organization of the cell wall, and there is considerable interest in how such processes might be modified in bacteria that form more elaborate shapes, such as vibrios, spirilla (e.g., *Magnetospirillum*), and hyphae.

CONNECTIONS Tubulin and actin represent two of the major cytoskeletal proteins in eukaryal cells. We will investigate their functions in **Section 3.1**. In **Toolbox 3.1**, we will see how immunofluorescence microscopy can be used to visualize cytoskeletal structures.

Cytoskeletal structures may aid in the distribution of cytoplasmic components during bacterial cell division. We will examine more closely the role of actin-like filaments in organizing magnetosomes **(Perspective 2.1)**, but the distribution of genetic information during cell division is a more critical function. Like MreB, the ParM protein forms actin-like filaments. Experiments have shown that ParM filaments aligned with the long axis of the *E. coli* cell are responsible for moving copies of **plasmids**, extrachromosomal molecules of DNA, to opposite sides of the cell. This separation ensures that copies of the plasmid will be found on either side of the division site, so they will be passed along to each of the new cells (see Figure 2.8C).

Of course, newly replicated chromosomes also must be separated before cytokinesis occurs. There is some evidence that, as with plasmids, bacterial chromosomes are carefully positioned in the cell prior to cell division, and newly replicated origins of replication, the site at which DNA synthesis starts, move rapidly and specifically to opposite sides of the cell. These observations suggest that cytoskeletal filaments could actively participate in the positioning and segregation of bacterial chromosomes during cell division. Currently, however, chromosomal segregation in bacteria remains enigmatic.

CONNECTIONS As we have seen briefly in this section, the distribution of genetic material within a dividing cell is well regulated. The initiation of DNA replication represents another well-regulated event. We will examine the factors controlling where bacterial DNA replication begins and how DNA replication is initiated in **Section 7.2**.

2.3 Fact Check

1. How are cytoskeletal-like proteins involved in magnetotaxis?
2. Describe the functions of the FtsZ protein and the Z-ring in bacterial cells.
3. What is the purpose of the MreB protein in bacteria?
4. What role do ParM proteins play in bacterial cell division?

2.4 The cell envelope

What are the critical structural and functional properties of the bacterial cell envelope?

All cells have at least one membrane, the plasma membrane (Figure 2.9). Most bacterial cells also contain a semi-rigid cell wall made of peptidoglycan and some bacteria contain a second membrane, the outer membrane. Collectively, these layers are referred to as the **cell envelope**. In this section, we will examine the structure and function of these layers. In Section 2.5, we will examine other structures that may surround bacterial cells.

The plasma membrane

The **plasma membrane**, also referred to as the cell membrane or the cytoplasmic membrane, is a bilayer composed primarily of phospholipids. The structure of these phospholipids is amphipathic, meaning that they have a polar portion and a non-polar portion. Most cellular membranes contain mixtures of phospholipids that can vary in the chemical structure of the polar head group, as well as in the length of the non-polar hydrocarbon tail and the frequency and position of double bonds within the hydrocarbon chain (see Figure 2.9). The polar head is hydrophilic and thus interacts with water inside and outside the cell, whereas the non-polar hydrocarbon chains associate to form the interior of the membrane. Bacterial membranes lack sterol lipids, such as cholesterol, which are major components of eukaryal membranes. Some bacteria produce sterol-like molecules called **hopanoids** (Figure 2.10). Like sterols, hopanoids are largely planar molecules that are thought to stabilize the plasma membrane. Although only about 10 percent of bacteria produce hopanoids, these molecules often are quite abundant in soils and sediments because they are very stable.

Biological membranes are not static structures. Lipids move relatively freely within the two layers of the membrane. The fluidity of the membrane depends on the types of lipids present, environmental factors such as temperature, and the presence of other molecules associated with the membrane. Biological membranes are far from pure lipid structures; roughly half of the mass of the bacterial plasma membrane is protein. Many proteins either cross or are integrated into the membrane bilayer (see Figure 2.9). These proteins have hydrophobic surfaces that interact with the interior of the membrane, and hydrophilic domains exposed to the cytoplasmic or outside environments. Key functions of the plasma membrane proteins include:

- The control of access of materials to the cytoplasm through differential permeability.
- The capture and/or storage of energy through photosystems, oxidative electron transport, and maintenance of chemical and electrical gradients.
- Environmental sensing and signal transduction.

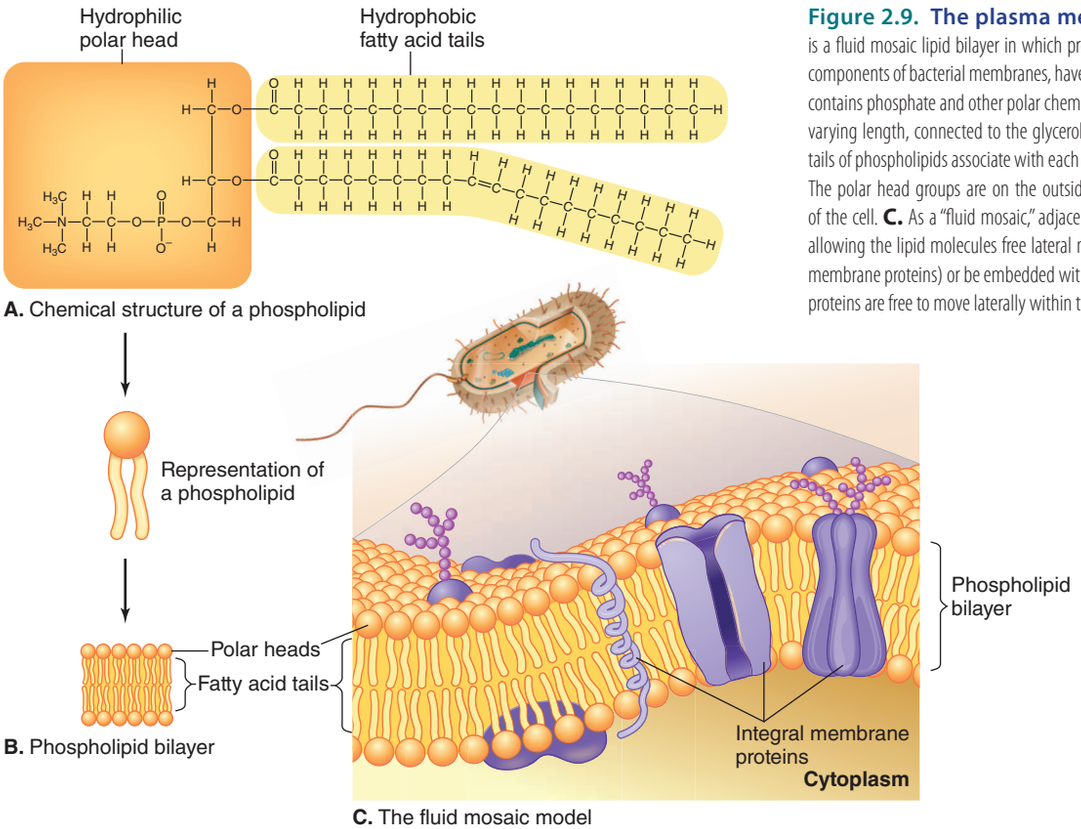

Figure 2.9. The plasma membrane of bacteria The plasma membrane is a fluid mosaic lipid bilayer in which proteins are embedded. **A.** Phospholipids, the major lipid components of bacterial membranes, have both polar and non-polar regions. The hydrophilic "head" contains phosphate and other polar chemical groups. The hydrophobic "tails" are fatty acid chains of varying length, connected to the glycerol backbone. **B.** In an aqueous solution, the hydrophobic tails of phospholipids associate with each other to exclude water, creating the interior of the bilayer. The polar head groups are on the outside, interacting with the aqueous cytoplasm and exterior of the cell. **C.** As a "fluid mosaic," adjacent phospholipids are not covalently linked to each other, allowing the lipid molecules free lateral movement. Proteins may span the entire bilayer (integral membrane proteins) or be embedded within just one leaf of the bilayer (peripheral proteins). These proteins are free to move laterally within the membrane.

Perspective 2.1
MARVELOUS MAGNETOSOMES!

Bacteria have various systems to direct their movement, but magnetotaxis is undoubtedly one of the most unusual. As we described in the opening story, magnetotaxis involves orienting movement in response to Earth's magnetic field. The bacteria achieve this orientation through the use of organelles called magnetosomes, tiny magnets made of magnetite (Fe_3O_4) crystals that align in chains in the cytoplasm of magnetotactic bacteria. Magnetosomes have a membrane around them **(Figure B2.1)**, which high-resolution imaging experiments have shown to be formed from the plasma membrane. The magnetosome chain acts like a compass needle powerful enough to physically align the long axis of the cell with Earth's geomagnetic field. To generate enough force to orient the cell body, magnetosomes must be organized into a linear chain, in which the total dipole moment is summed across the individual magnetosomes. In *Magnetospirillum*, typical cells have around 20 magnetosomes in a chain. These chains probably do not form spontaneously. Indeed, protein filaments can be found alongside the magnetosome chains and may play a role in organizing them.

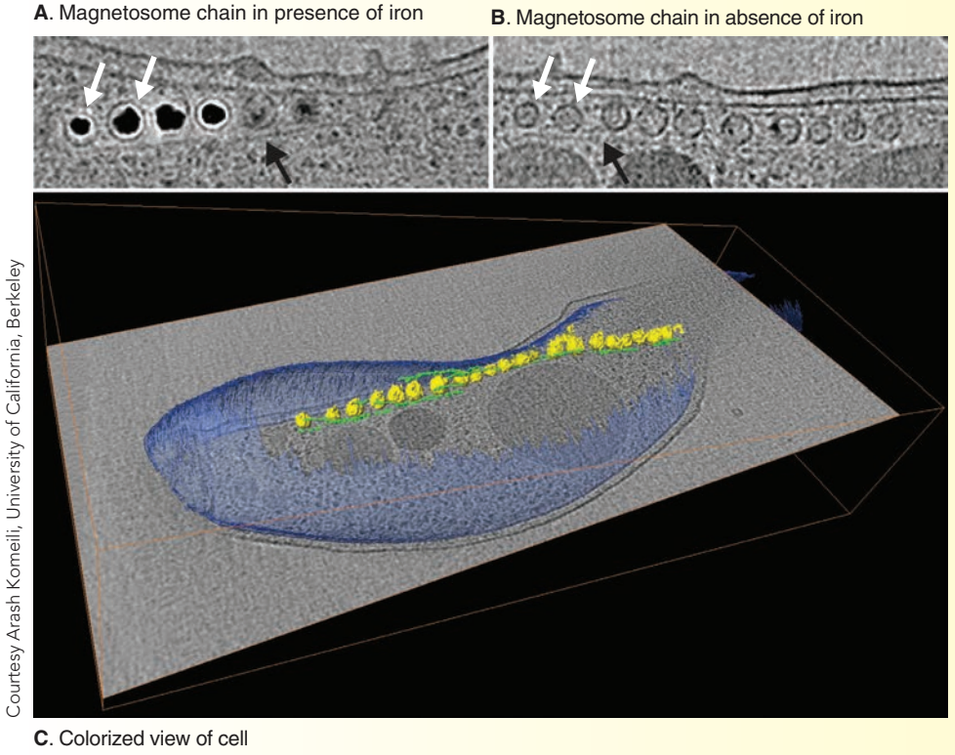

Figure B2.1. Magnetosome organization **A.** *Magnetospirillum magneticum* cell showing a chain of magnetosomes (white arrows). Each magnetosome is enclosed by a membrane vesicle. One or more cytoskeletal filaments (black arrow) flank the chain. **B.** Similar view of a magnetosome chain from a cell grown in the absence of iron, which prevents the formation of magnetite crystals. Empty vesicles and filaments are still present. **C.** Three-dimensional reconstruction of a *Magnetospirillum* cell (blue), showing magnetosomes (yellow) and their associated filaments (green). A form of electron microscopy, cryo-EM, was used to generate these images.

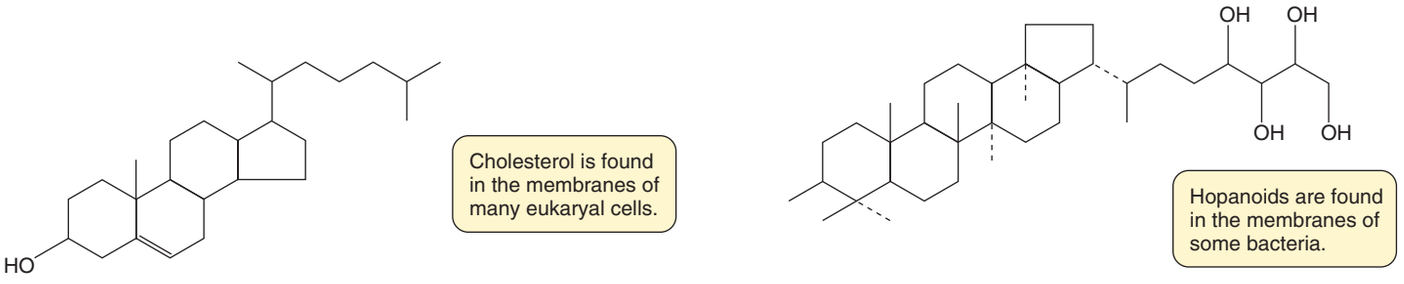

A. Cholesterol **B.** Bacteriohopanetetrol

Figure 2.10. Bacterial membranes lack cholesterol, but may contain hopanoids **A.** Cholesterol is a common example of sterol lipids found in many eukaryal membranes. **B.** Hopanoids, such as this bacteriohopanetetrol, are present in the membranes of some bacteria. These molecules are structurally similar to cholesterol and provide some of the same functions, strengthening the membrane.

The amino acid sequence of the *Magnetospirillum* MamK protein is similar to actin and the bacterial cytoskeletal protein MreB, and the filaments observed alongside the magnetosome chains are approximately the same dimension as actin filaments. Convincing evidence that MamK assembles into filaments comes from experiments using green fluorescent protein (GFP) fusion proteins. This method, which has been tremendously useful to cell biologists, involves first creating a gene fusion in which the coding sequence of a target protein is linked, or fused, to the coding sequence of green GFP, a jellyfish protein that fluoresces naturally when illuminated with certain wavelengths of light. When inserted into a cell, the fused gene creates a hybrid protein that fluoresces, thereby allowing researchers to determine the cellular location of the protein of interest by viewing the cells with high-resolution fluorescence microscopy (see Toolbox 3.1). When scientists examined *Magnetospirillum* cells containing MamK-GFP fusions **(Figure B2.2)**, they observed beautiful green filaments coinciding with magnetosome chains. Furthermore, when the *mamK* gene is removed from the *Magnetospirillum* genome, these magnetosome-associated filaments disappear and magnetosomes disperse throughout the cell.

The story does not end there. Another group of scientists studying MamJ, a highly acidic and repetitive protein thought to be involved in magnetite crystal formation, found that when the *mamJ* gene is removed, magnetosomes still form, but the magnetosomes do not arrange in a line. In contrast to the MamK observations, the organizing filament is still present in the *mamJ* deletion mutant. In fact, the MamJ-GFP fusion is localized to this filament in normal cells. It appears that MamJ may facilitate the interaction between the magnetosomes and the filament. How might MamJ carry out this function? How could you test your hypothesis?

Figure B2.2. Magnetosome organization is dependent on the actin-like protein MamK **A.** *Magnetospirillum* cells containing the MamK protein fused to GFP (green). MamK appears to form filaments that lie along the inner curvature of the cell. The cell membrane is stained with a red fluorescent dye. **B.** Three-dimensional reconstruction of a cell, showing the cell membrane (gray), magnetosomes (yellow), and magnetosome-associated filaments (green). **C.** Reconstruction of a mutated cell in which the *mamK* gene has been deleted. Magnetosomes appear disordered and no filaments are found in their vicinity.

Permeability of the Plasma Membrane to Water

A fundamental property of the plasma membrane is its differential or selective permeability. Small and uncharged molecules, such as O_2 and CO_2, can diffuse freely across a phospholipid bilayer. Larger compounds, or molecules that are more polar or charged, cross the membrane less readily. Although they are polar, water molecules are small enough to cross phospholipid bilayers. Their transit may be facilitated, and perhaps regulated, by protein channels called **aquaporins**. Water concentration differences between the interior and exterior of the cell create an osmotic gradient. The cell is in a hypotonic solution when the cytoplasm has a higher solute concentration than the external environment, causing water to move into the cell. Because phospholipid bilayers are quite flexible, the cell expands, like a balloon being inflated. Without a structure to provide stability, cells would risk explosive destruction. The cell wall prevents this outcome. Conversely, the cell is in a hypertonic solution when the cytoplasm has a lower solute concentration than the external environment, causing a net loss of water from the cell. Like a deflating balloon, cells risk structural collapse in a hypertonic solution. Once again, a protective cell wall helps to prevent this outcome.

Osmosis ANIMATION

CONNECTIONS Salt-loving archaea are found in hypertonic environments that would draw water from most cells. In **Section 4.3**, we will examine the effects of tonicity on living cells, and see how archaea deal with the osmotic challenge.

Nutrient Transport

Cellular metabolism depends on a cell's ability to obtain nutrients from the surrounding environment and, to a lesser extent, on its ability to export waste products. Because movement of charged or polar molecules, which include many potential nutrients, is restricted by limited permeability of the phospholipid bilayer, transport proteins embedded in the membrane are needed to provide routes of entry into the cell for such compounds. Transport systems are often very specific in the molecules they admit, such that the cell takes in useful compounds but ignores molecules that are not useful or are harmful. Because of this specificity, microbial cells use many different transporters to bring in the mix of nutrients they need (Figure 2.11).

Some transport proteins simply facilitate diffusion, allowing specific molecules to pass through the membrane from higher to lower concentration. These transport proteins require no investment of energy, but their role in nutrient uptake is limited to molecules that are abundant in the environment. If there is not a favorable concentration gradient to drive a particular nutrient into the cell at the rate an organism needs, another mechanism must be used. **Active transport systems** in the plasma membrane are driven by the expenditure of energy to drive the movement of solutes against a concentration gradient. One way this transport can be done is to bring the desired molecule into the cell along with another molecule that is traveling down a favorable concentration gradient. As the one molecule travels down its concentration gradient, energy is released that, in turn, can be used to move the primary molecule against its gradient. This hitchhiking strategy is called **symport**. The most common type of bacterial symport system couples the import of a substrate, such as a sugar, to the uptake of one or more protons. This strategy takes advantage of the favorable proton concentration gradient across the membrane generated by respiratory electron transport (see Chapter 13 for description of the electron transport system). With **antiporters**, the energy-requiring uptake of one molecule is driven by the energetically favorable ejection of another. Both symport and antiport mechanisms are examples of co-transport, in which two different molecules are being moved.

One of the most common types of active transport involves the **ABC transporters**. ABC stands for "ATP-binding cassette," reflecting the fact that these proteins include a nucleotide-binding domain by which ATP is hydrolyzed to provide the energy for transport. Each ABC transporter is specific for a given compound or a range of compounds, and consists of four subunits (Figure 2.12). The membrane channel is formed by two hydrophobic subunits. Two hydrophilic subunits are located on the cytoplasmic surface of the membrane and contain the ATP-binding domain. An associated subunit is a high-affinity solute-binding protein that binds to substrates outside the plasma membrane and delivers them to the membrane-bound components, effectively increasing the affinity of the transport system for substrates.

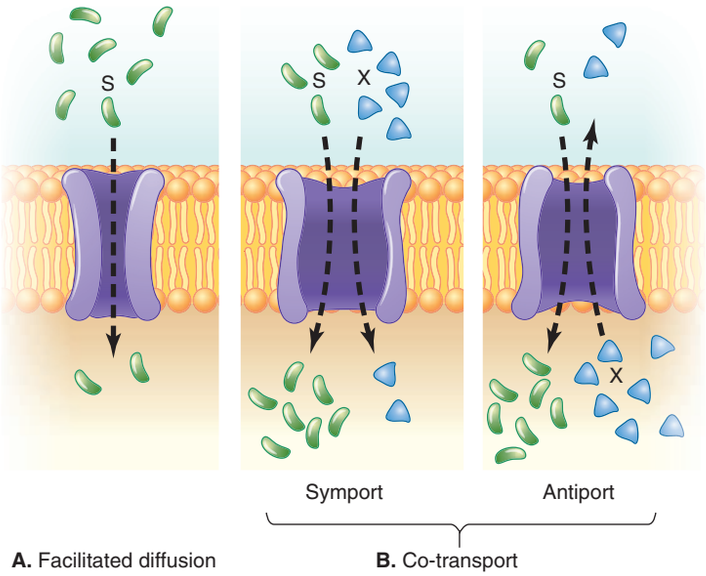

Figure 2.11. Movement across a membrane by facilitated diffusion and co-transport **A.** In facilitated diffusion, one kind of molecule (labeled S) moves across the membrane. Diffusion allows a molecule to move across the membrane from the side of higher concentration to the side of lower concentration. **B.** Co-transporters can move a substance (S) against its concentration gradient by coupling that movement to the diffusion of another substance (X) down its concentration gradient. Symport proteins facilitate the movement of both substances in the same direction. Antiport proteins facilitate the movement of both substances in opposite directions.

Energy Capture

The plasma membrane hosts critical parts of the energy-capturing machinery of many bacterial cells. These include cytochromes and other membrane-soluble electron carriers that form the electron transport system of microorganisms. These molecules are crucial components of two important processes: cellular respiration and photosynthesis. In **cellular respiration**, organic molecules are oxidized and the released energy is used to drive the synthesis of ATP. In **photosynthesis**, light energy is captured and used to reduce inorganic carbon, forming organic molecules. Both processes rely on the movement of protons from the cytoplasm, across the plasma membrane. As they accumulate outside the plasma membrane, these protons create concentration and charge gradients that combine to create a proton motive force. We will discuss the importance of this proton gradient more fully in Chapter 13. For now, let's note that the proton gradient is a very useful energy source. As we mentioned previously, it can be used to drive the active transport of nutrients across the membrane. The proton gradient also powers rotation of the flagellum in most bacteria. Perhaps most importantly, protons can re-enter the cell through a membrane protein complex called ATP synthase, which couples proton re-entry to the production of ATP, the main energy source for biochemical reactions inside the cell (see Figure 13.27).

Sensory Systems

The plasma membrane senses the environment around bacterial cells with sensor proteins that transduce signals to cytoplasmic response systems. These signals often result in changes

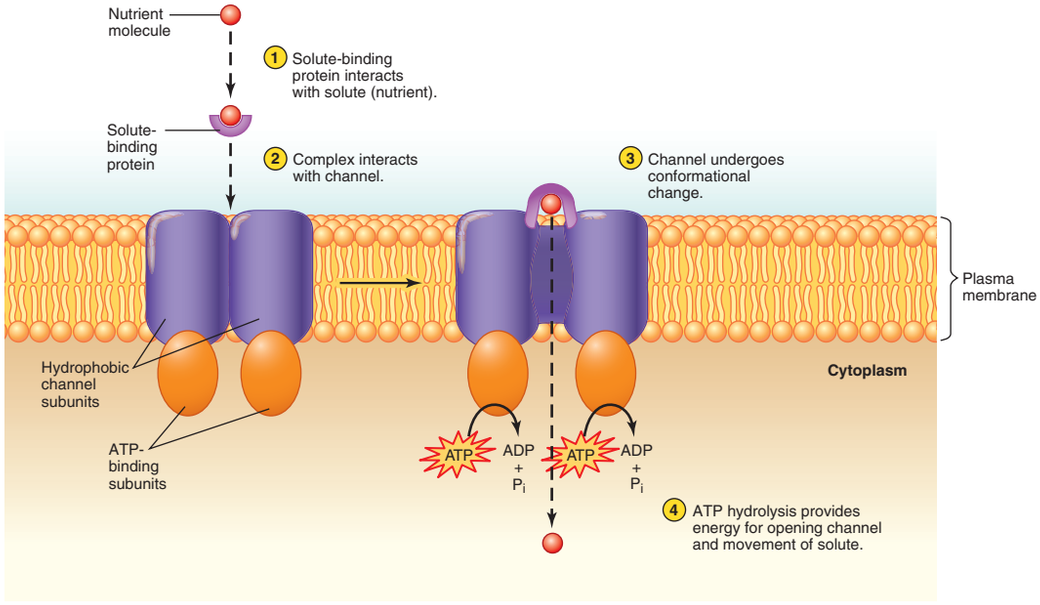

Figure 2.12. Process Diagram: Active transport systems require an input of cellular energy, often as ATP ABC (ATP-binding cassette) transport systems carry out active transport using ATP hydrolysis to open a specific transmembrane channel. The solute to be transported, perhaps a nutrient molecule, first is bound by a high-affinity solute-binding protein outside the membrane. The solute-binding protein delivers the molecule to an integral protein, which then changes conformation to open a channel allowing the molecule to enter the cell. ATP hydrolysis is necessary for the cycle of opening and closing.

in gene expression that ensure production of an appropriate set of proteins. A particular transporter, for instance, might be made only when its substrate is present. Not all of these signaling processes, we should note, necessarily happen at or in the membrane. Bacteria also utilize many cytoplasmic sensors.

Protein Secretion

The plasma membrane contains proteins for the **general secretory pathway**, allowing the transmembrane movement of proteins that are needed outside the cytoplasm **(Figure 2.13)**. To ensure that only the correct proteins exit the cytoplasm, proteins targeted to this secretory pathway are identified by a **signal peptide**, a short sequence of largely hydrophobic amino acids at the amino-terminal end of the protein. The SecB protein binds to the nascent polypeptide as it leaves the ribosome, preventing it from folding in the cytoplasm and delivering it to SecA. In turn, SecA associates with SecYEG, a membrane channel complex. Using energy derived from the hydrolysis of ATP, SecA facilitates movement of the polypeptide through the SecYEG channel. Once the polypeptide crosses the plasma membrane, a signal peptidase removes the signal peptide and the protein assumes its functional conformation.

The bacterial cell wall

The bacterial cell wall consists of a highly crosslinked polysaccharide-peptide matrix called **peptidoglycan (Figure 2.14)**. The cell wall is necessary for bacteria to resist damage from osmotic pressure, mechanical forces, and shearing. The organization of peptidoglycan also gives bacterial cells their characteristic shapes. In contrast to the plasma membrane, the cell wall is not a permeability barrier. A few bacteria, most notably the mycoplasmas (see Figure 2.2), survive without peptidoglycan, but these bacteria generally live inside eukaryal host cells where they are protected from osmotic stress.

Peptidoglycan forms a net-like structure composed of a glycan backbone made up of alternating molecules of *N*-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM), connected by β-1,4-glycosidic bonds. The *N*-acetylmuramic acid carries a short peptide chain that is used to crosslink peptidoglycan strands, creating the protective network surrounding the cell. The sequence of amino acids in the peptide chain can vary somewhat between species. *Escherichia coli*, for example, has a slightly different sequence than *Staphylococcus aureus* **(Figure 2.15)**.

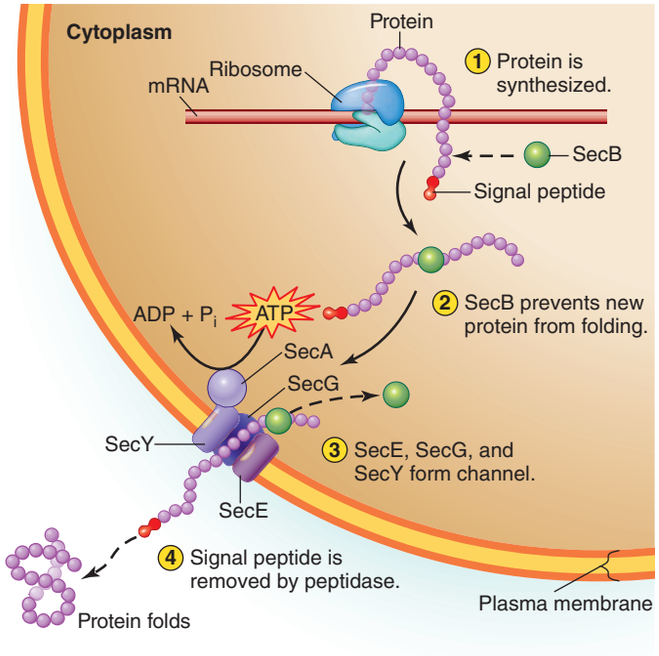

Figure 2.13. Process Diagram: Polypeptide secretion in bacteria SecB binds to polypeptides to be secreted as they leave the ribosome and delivers them to SecA, which associates with SecYEG. Using energy derived from the hydrolysis of ATP, SecA facilitates movement of the polypeptide through the SecYEG channel. After the polypeptide crosses the plasma membrane, a signal peptidase removes the signal peptide and the polypeptide assumes its functional conformation. The signal peptide, represented here by two red spheres, generally ranges from 5 to 30 amino acids in length.

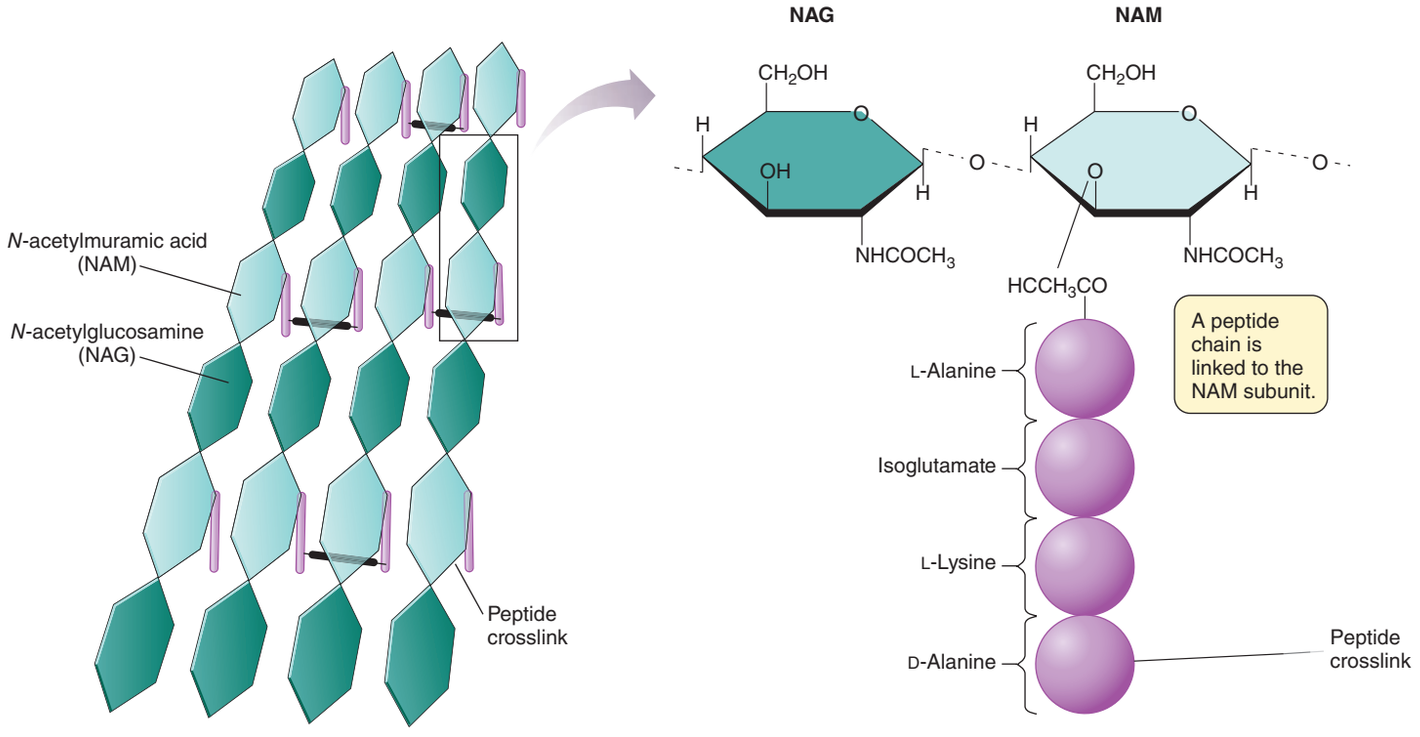
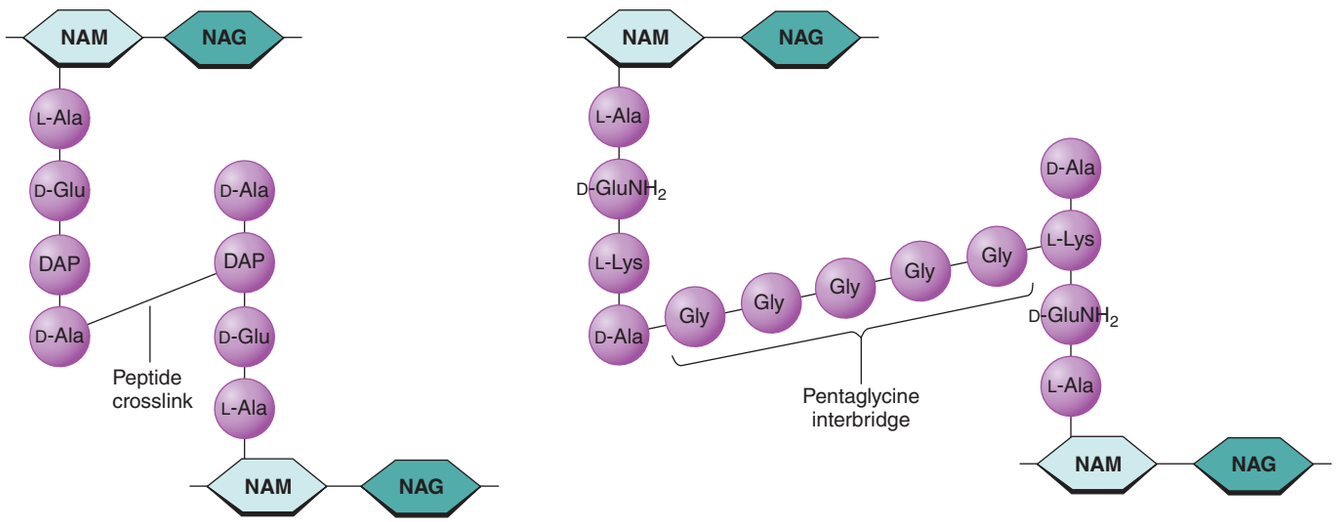


A. Crosslinked peptidoglycan

B. Disaccharide backbone with peptide chain

Figure 2.14. The structure of the peptidoglycan cell wall **A.** Layers of polysaccharide (*N*-acetylglucosamine and *N*-acetylmuramic acid) are linked together by short peptide chains (indicated by solid black lines). The chemical basis of this linkage differs between species. **B.** The basic peptidoglycan subunit consists of *N*-acetylmuramic acid (NAM) and *N*-acetylglucosamine (NAG) monomers connected by β-1,4-glycosidic bonds. The NAM group is linked to a short peptide chain (indicated by purple spheres), which crosslinks to another NAM molecule. This peptide chain consists of different amino acids in different species.



A. Peptidoglycan crosslinking in *E. coli*

B. Peptidoglycan crosslinking in *S. aureus*

Figure 2.15. Crosslinking of peptide chains provides strength to the peptidoglycan To increase the strength of the peptidoglycan, crosslinking between the peptide chains occurs. **A.** In *E. coli*, peptide chains are directly linked by a covalent bond between a D-alanine (D-Ala) amino acid and a *meso*-diaminopimelic (DAP) amino acid. **B.** In *Staphylococcus aureus*, a pentaglycine interbridge connects the D-Ala amino acid on one chain to the L-lysine (L-Lys) on another chain.

In most bacteria, the first amino acid of this peptide chain is L-alanine (L-Ala), whereas the fourth and fifth amino acids typically are D-alanine (D-Ala). As we will see later in this section, the fifth amino acid is removed when crosslinking occurs. Gram-negative bacteria generally contain D-isoglutamate (D-Glu) in the second position, whereas Gram-positive bacteria generally contain D-isoglutamine (D-GluNH_2) in this position. Amino acids at the third position vary more widely.

Crosslinking between the peptide chains is very important for the strength of the peptidoglycan network, and bacterial species can achieve this crosslinking through different mechanisms. For example, in *E. coli* and most other Gram-negative bacteria, the fourth amino acid attached to one NAM residue is directly linked to the third amino acid present on another NAM residue. In most Gram-positive species, the tetrapeptide chains are crosslinked via a short peptide interbridge. As shown in Figure 2.15, *S. aureus* uses a pentaglycine interbridge. The exact composition and length of the interbridge varies between species.

We should note that several amino acids found in peptidoglycan are rarely found in proteins, including *meso*-diaminopimelic acid, and the D-stereoisomer of several amino acids. Stereoisomers are molecules with the same chemical formula and bond structure, but different arrangements of atoms (Figure 2.16). The amino acids used by ribosomes for polypeptide synthesis are almost always the L-stereoisomer.

The production of peptidoglycan starts in the cytoplasm, where enzymes first link NAM and uridine diphosphate (UDP). This molecule then is linked to a pentapeptide (Figure 2.17). The UDP-NAM-peptide complex is coupled to a lipid carrier called bactoprenol, which holds it on the cytoplasmic face of the membrane. A second sugar, *N*-acetylglucosamine, then is added to form the basic disaccharide-peptide unit. This complex then pulls a remarkable trick, still not well understood, in which the bactoprenol carrier flips the disaccharide-peptide complex to the other side of the membrane. Only there can the new subunit be attached to the terminal sugar of a growing peptidoglycan chain. Other enzymes, most notably transpeptidase, then crosslink the pentapeptide precursor to another strand. This transpeptidation reaction results in the removal of the terminal D-alanine of the pentapeptide precursor leaving a tetrapeptide.

Many potential enemies of bacteria, including bacteriophages and animals, encode or produce the enzyme **lysozyme**, which degrades peptidoglycan. Lysozyme hydrolyzes the β-1,4-glycosidic bond between NAG and NAM, profoundly weakening the cell wall (Figure 2.18). If a bacterium encounters lysozyme under isotonic conditions (water leaves the cell at the same rate it enters), then it may survive as a protoplast, the term given to the generally fragile form of the cell with its protective cell wall removed. If a bacterium encounters lysozyme under hypotonic conditions, then water may enter the protoplast, swelling it until it bursts. Lysozyme in human tears and other secretions helps to control bacterial populations in and on our body. We will see later in this chapter that some bacteria (Gram-negative bacteria) cover their peptidoglycan with another membrane, effectively shielding the cell wall from lysozyme.

CONNECTIONS Archaea also possess a cell wall. The chemical structure of the archaeal cell wall differs significantly from the peptidoglycan present in bacteria. We will explore this structural difference in **Section 4.2**.

Lysostaphin, an enzyme discovered in *Staphylococcus simulans*, cuts the pentaglycine crossbridge of *S. aureus* and some related species (see Figure 2.18B). The cloned lysostaphin gene has been engineered experimentally into dairy cattle to generate cows that suffer much less frequently from mastitis, a painful udder infection usually caused by *S. aureus*. Such genetically engineered animals, resistant to various infectious organisms, may become common in our future.

Figure 2.16. Stereoisomers are mirror images of each other D-Alanine and L-alanine have the same chemical formula. The arrangement of the bonds on the central carbon, however, differs.

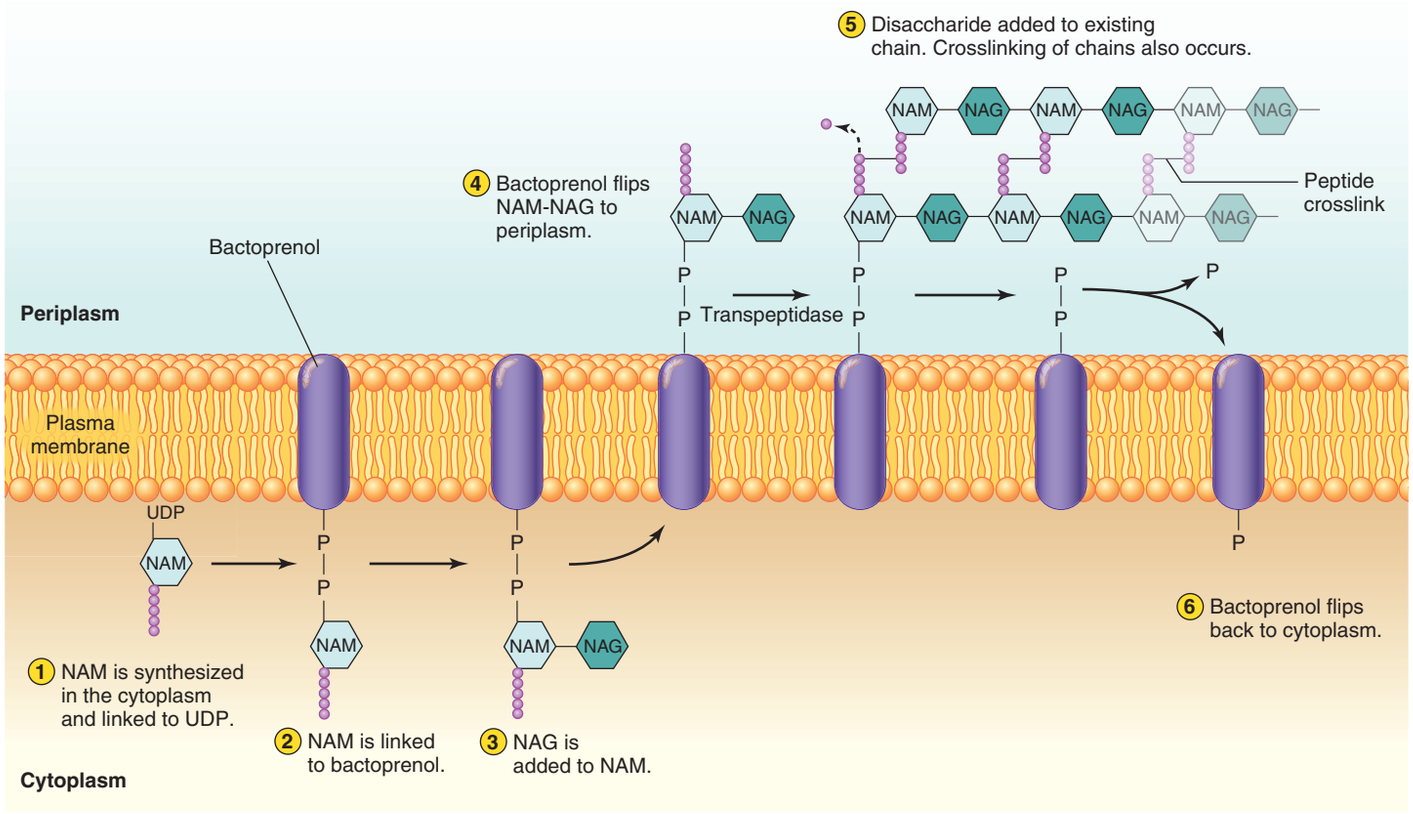

Figure 2.17. Process Diagram: Synthesis of peptidoglycan Synthesis begins in the cytoplasm, where NAM is linked to UDP, and then coupled to a short peptide chain. This complex associates with the integral membrane protein bactoprenol via two phosphates (P). NAG then is linked to the NAM, forming the NAM-NAG disaccharide. This disaccharide flips across the membrane, transporting the NAM-NAG complex across the plasma membrane. The NAM-NAG disaccharide is linked to the growing polysaccharide chain. The peptide chain of the newly added NAM-NAG subunit is crosslinked by a transpeptidase enzyme to another strand of peptidoglycan to form the final structure.

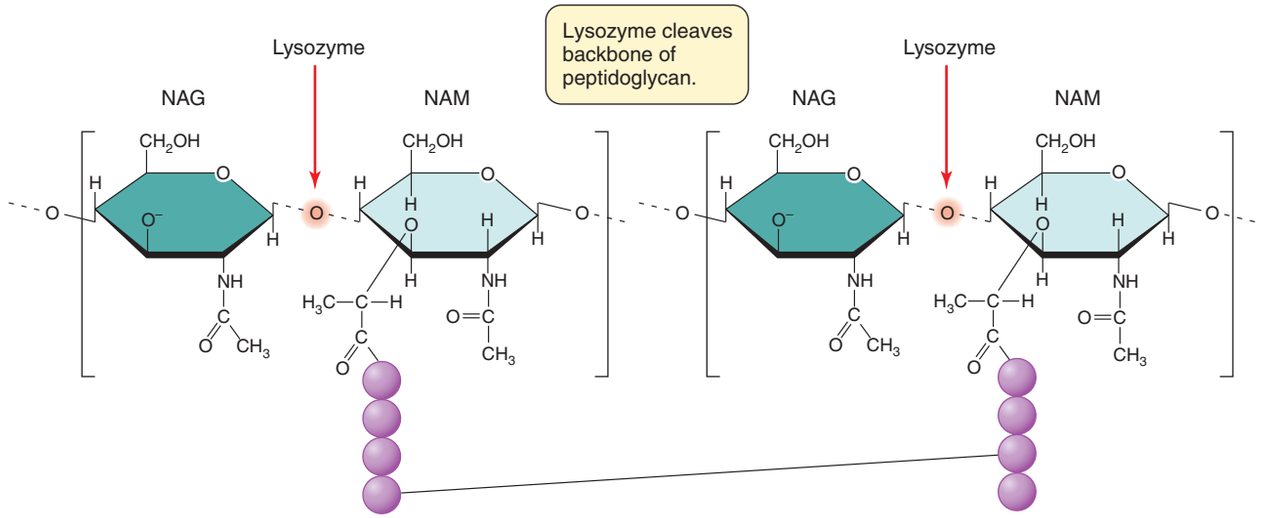
Several important families of antibiotics inactivate transpeptidase enzymes that crosslink peptidoglycan. The ***β*-lactam** family, for example, is represented in **Figure 2.19**. The three-dimensional structure of the *β*-lactam ring mimics the terminal D-alanine of peptidoglycan precursors well enough to fool peptidoglycan crosslinking enzymes. These enzymes bind to *β*-lactam antibiotics and attempt to catalyze the crosslinking reaction, but instead attach the antibiotic molecule covalently to their active site, permanently destroying the enzyme. This inhibition of the enzyme causes big problems for growing bacterial cells, as they try to integrate new strands of peptidoglycan into their cell wall. The cell wall becomes ever weaker, and osmotic pressure can eventually burst the cell, as it does when lysozyme attacks. A key difference is that only growing cells that must add new peptidoglycan are sensitive to *β*-lactam drugs, whereas lysozyme, which directly cleaves peptidoglycan chains, also attacks non-growing cells.

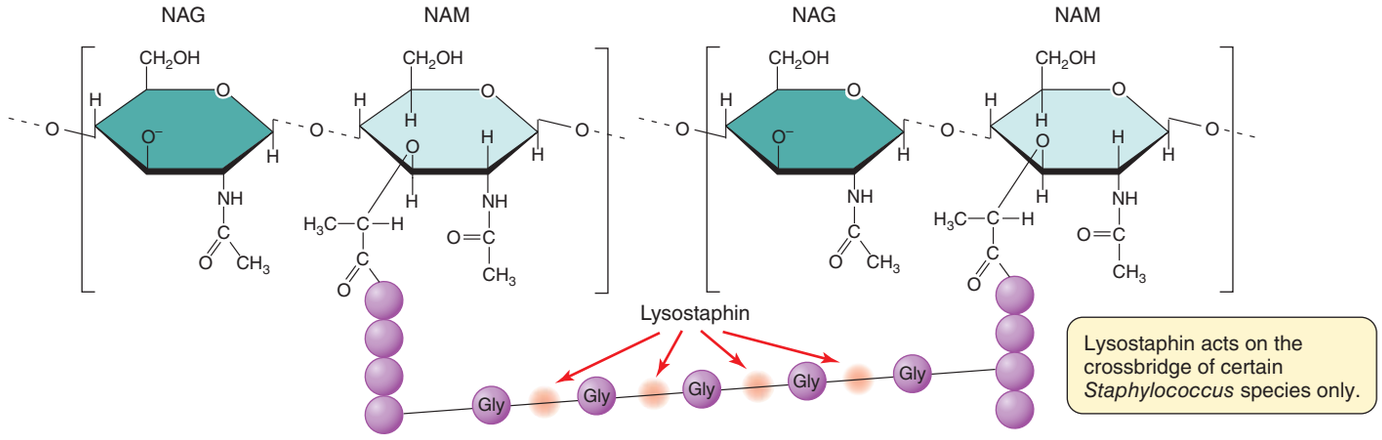
One way for bacteria to become resistant to an antibiotic is to produce enzymes that modify or destroy the antibiotic. ***β*-Lactamases** hydrolyze the C—N bond in the *β*-lactam ring of antibiotics, such as penicillin and cephalosporin (see Figure 2.19A). This ring structure is necessary for these antibiotics to bind to their target. Cleavage of the ring inactivates the antibiotics. Soil fungi have produced these antibiotics for millions of years. In response, some bacteria long ago evolved *β*-lactamases to combat these fungal weapons.

A few short years after the introduction of *β*-lactam antibiotics into medical practice, resistant bacteria that produce *β*-lactamases became fairly common. Modified *β*-lactam antibiotics that are more resistant to *β*-lactamase attack have been developed over the past few decades, but bacteria have responded with altered *β*-lactamases that also inactivate these newer drugs. An alternative strategy for subverting bacterial defenses was spurred by the discovery of *β*-lactam variants, such as clavulanic acid **(Figure 2.20)**, that bind to and strongly inhibit *β*-lactamases even though they do not function as antibiotics by themselves. Clavulanic acid is now combined with *β*-lactam antibiotics such as amoxicillin (in the popular combination marketed as Augmentin) or ticarcillin (in Timentin) to protect these drugs from inactivation.

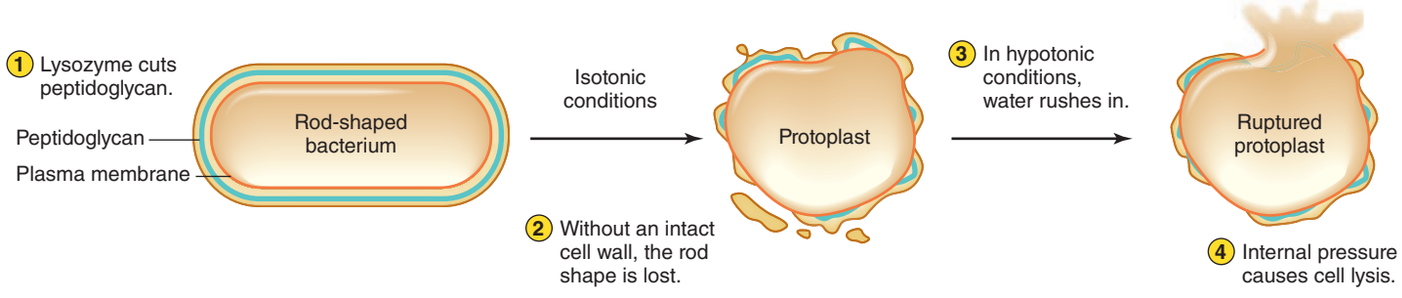
CONNECTIONS Chemists have designed semisynthetic versions of penicillin that can more readily pass through the outer membrane of Gram-negative organisms, thereby making these drugs more effective against a wider range of bacterial pathogens. These advances in drug design will be discussed more fully in **Section 24.2**.



A. Chemical action of lysozyme



B. Chemical action of lysostaphin



C. Effects of lysozyme on cell

Figure 2.18. Process Diagram: Bacterial wall disruption and its consequences **A.** Lysozyme enzymatically cleaves the β-1,4-glycosidic bonds linking NAG and NAM residues (highlighted), thereby disrupting the polysaccharide backbone of peptidoglycan. Brackets indicate the NAG:NAM disaccharide. **B.** Lysostaphin cleaves the glycine-glycine linkages (highlighted) of the pentaglycine interbridge specifically found in some *Staphylococcus* species. Brackets indicate the NAG:NAM disaccharide. **C.** As the peptidoglycan network surrounding the cell is degraded, the cell wall loses its mechanical strength. Non-spherical cells will become round protoplasts. If the external medium is hypotonic (lower solute concentration) relative to the cytoplasm of the protoplast, the pressure created by the osmotic influx of water will likely cause the cell to rupture.

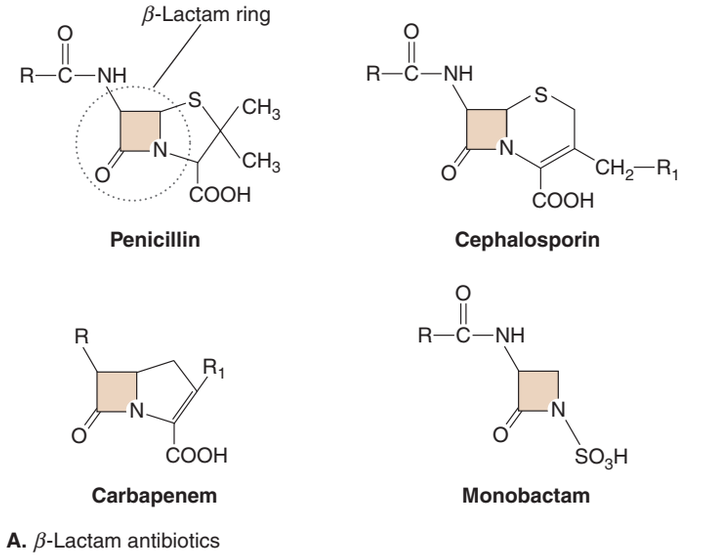


Figure 2.19. Beta-lactam antibiotics inhibit cell wall formation **A.** All antibiotics within the beta-lactam family contain a β-lactam ring, which is shaded in these drawings. **B.** In some bacteria, β-lactamases hydrolyze the C—N bond of the β-lactam ring and destroy the activity of these antibiotics. *NOTE*: R represents a variable chemical group.

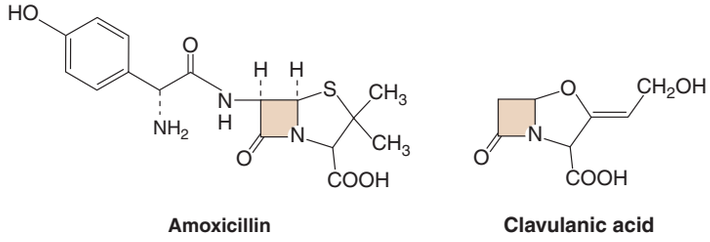

Figure 2.20. Combination antibiotics can be manufactured Augmentin, a combination antibiotic, is designed to overcome the resistance of bacteria that produce β-lactamases. This drug contains amoxicillin (*left*) and clavulanic acid (*right*). Both amoxicillin and clavulanic acid contain the β-lactam ring. Clavulanic acid has little or no antibiotic activity by itself but binds to and inhibits the activity of many β-lactamases, allowing the accompanying amoxicillin to attack peptidoglycan synthesis.

Variation in the bacterial cell envelope

The **Gram stain**, a technique for staining bacterial cells developed by Hans Christian Gram in 1884, allows us to differentiate two types of bacteria: **Gram-positive** and **Gram-negative** **(Toolbox 2.1)**. Electron microscopic examinations of bacteria have revealed that these two categories of bacteria differ in the organization of the cell wall, and the presence or absence of an additional outer membrane. In this section, we will explore these structural differences more fully.

Gram-Positive Cells

Gram-positive bacteria have a thick cell wall with many overlapping strands of peptidoglycan **(Figure 2.21)**. Beneath this structure is the **periplasm**, the space between the cell wall and the plasma membrane **(Mini-Paper)**. The Gram-positive cell wall is exposed to the environment, and provides an important protective function for the cell, but it is not impermeable. After all, nutrients must be able to get to the plasma membrane, where they can be taken into the cell. Peptidoglycan is the

Toolbox 2.1
THE GRAM STAIN

Hans Christian Gram developed the Gram-stain technique in 1884 for detecting bacteria in lung tissue samples of patients who had died of pneumonia. Over a century after it was first developed, the Gram stain remains a key step in bacterial identification strategies in clinical microbiology laboratories.

Staining bacteria ANIMATION

The Gram stain is an excellent example of a differential stain; bacterial species differ in their response to the staining procedure, depending on the structure of the cell envelope. This staining method classifies bacteria into two major groups: Gram-positive and Gram-negative. The structural basis for these staining patterns is described in the text. The Gram-stain procedure consists of just a few simple steps **(Figure B2.3)**.

First, the specimen is placed on a microscope slide. Then, the specimen is fixed, or attached, to the slide by heating the underside of the slide. The cells first are stained with crystal violet, the primary stain—virtually all bacteria are stained by crystal violet. The cells then are stained with iodine, which interacts with the crystal violet, forming a larger, more stable complex. The slide then is immersed in an alcohol, or an alcohol/acetone mixture, often referred to as a decolorizer. Exposure to this reagent results in the loss of the crystal violet-iodine complex from Gram-negative cells. Crystal violet-iodine complexes remain in Gram-positive cells because of their thick cell walls. The slide then is dipped into a counterstain, safranin. This final stain provides a light red or pink color to cells, thereby allowing the viewer to see cells from which the primary stain was removed. The stained cells can be viewed with a light microscope **(Figure B2.4)**.

Interpretation

Gram-positive = Purple (retains the crystal violet primary stain)

Gram-negative = Pink or light red (loses the crystal violet but is stained with safranin)

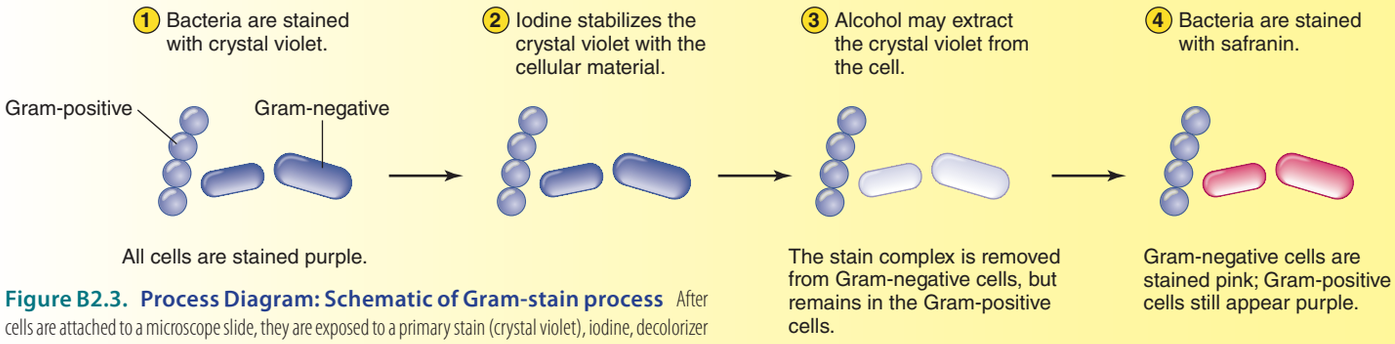

Figure B2.3. Process Diagram: Schematic of Gram-stain process After cells are attached to a microscope slide, they are exposed to a primary stain (crystal violet), iodine, decolorizer (alcohol), and a counterstain (safranin). Gram-positive and Gram-negative cells then can be distinguished by light microscopy.

Figure B2.4. Gram-stained mixture of bacterial cells In this image, a mixture of Gram-negative (pink) and Gram-positive (purple) bacteria can be seen. Developed over 125 years ago, the Gram-staining technique remains an easy and useful means of assisting with bacterial identification and classification.

Test Your Understanding

A student carried out the Gram stain on a culture of Gram-negative cells but forgot to add the safranin in the last step. What would the student see when she examines the stained cells under the microscope? Explain.

Perspective 2.2
THE PROTECTIVE SHELLS OF ENDOSPORES

Endospores have dramatically thickened cell envelopes **(Figure B2.5)**, with additional layers of protein outside of the peptidoglycan. This thick protective coat makes them resistant to desiccation and chemical attack. Endospores shut down their metabolism completely and compress chromosomal DNA tightly with protective proteins. As a consequence, they are incredibly durable and can remain viable for many years. Exactly how long endospores can survive is not known—thousands of years seems likely. Some research even suggests that endospores may be capable of survival for millions of years.

Regardless of the precise longevity of endospores, the formation of these specialized cells has fascinated many microbiologists as a model for cellular remodeling and development. The cellular remodeling involved in endospore formation requires major changes in gene expression. Studies of endospore formation, as a result, have provided important insight into basic properties of gene regulation. Endospores also have historic and practical relevance in the field of microbiology. Robert Koch, one of the founding fathers of microbiology, first observed endospore formation while studying *Bacillus anthracis*, the bacterium that causes anthrax.

The formation of endospores by *B. anthracis* has significant implications for the natural transmission of this pathogen. Usually, a person becomes infected by inhaling or ingesting endospores. These endospores can be present in the soil or associated with animal products, such as wool. Terrorists also have used endospores to spread disease. During the fall of 2001, letters containing *B. anthracis* endospores were mailed to several people in the United States by a terrorist or terrorist group. After handling or opening these letters, several people became infected, five of whom died.

B. Endospores in the mother cells

Figure B2.5. Endospores **A.** This colorized image of a *Bacillus subtilis* endospore shows the dramatically modified cell structure. The cytoplasm is shrunken and almost completely dehydrated, with densely packed chromosomal DNA and ribosomes. A thick protective coat surrounds this material. **B.** In this micrograph of *B. subtilis* cells undergoing sporulation, the endospores (which appear as light purple ovals within the darkly stained cells) are visible within the mother cell.

most abundant polymer in the Gram-positive cell wall, but a mixture of other polymers can constitute up to half of the dry weight of the cell wall, depending on the species. A charged polymer called **teichoic acid**, which is not found in Gram-negative bacteria is intermingled with the peptidoglycan. Teichoic acids are polymers of either ribitol phosphate or glycerol phosphate (see Figure 2.21). Many of the teichoic acid molecules are firmly anchored in the cell wall by covalent attachment to peptidoglycan chains. Alternatively, some teichoic acids are connected to the plasma membrane through the covalent addition of a lipid tail. This membrane-anchored subset of teichoic acid molecules is called **lipoteichoic acid (LTA)**.

CONNECTIONS During an infection, the lipoteichoic acid of Gram-positive bacteria can induce a strong inflammatory response in the host. The mechanism and potential dangers of this process are addressed in **Section 21.2**.

Some Gram-positive bacteria, such as *Bacillus* and *Clostridium* species, can undergo an amazing process of cellular remodeling called **endospore** formation, which is initiated as a survival mechanism under stressful conditions, such as imminent starvation **(Perspective 2.2)**. The endospores are largely metabolically inert structures that exhibit increased resistance to many harsh environmental conditions, such as desiccation, UV light exposure, and high temperatures.

Gram-Negative Cells

A relatively thin layer of peptidoglycan surrounds Gram-negative bacteria. This slim cell wall may seem like scant protection, but it is supplemented by another structure, the **outer membrane (Figure 2.22)**. For this reason, the plasma membrane of Gram-negative bacteria often is referred to as the inner membrane. The space between the inner and outer membranes is the periplasm. The width of the periplasm is not clear, and probably fluctuates; the *Escherichia coli* periplasm is

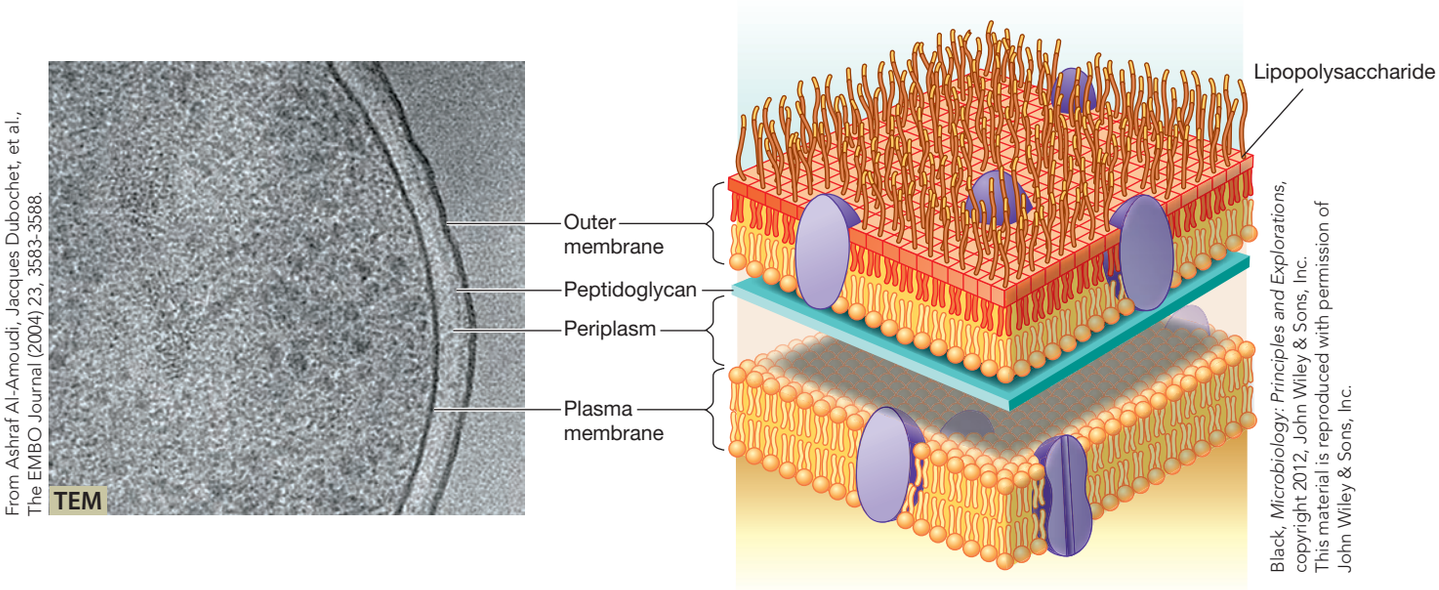

Figure 2.22. Gram-negative bacteria have an outer membrane In Gram-negative bacteria, an outer membrane surrounds a thin peptidoglycan layer. The presence of this second membrane creates the periplasm as a separate compartment. The outer membrane contains phospholipids on its inner surface and lipopolysaccharide (LPS) on its outer surface. Like the plasma membrane, it also contains proteins.

estimated to be 13–25 nm wide, with the peptidoglycan layer occupying roughly a third of that space. In addition to peptidoglycan assembly enzymes, the periplasm contains a roster of proteins that includes proteins to aid in nutrient uptake and components of protein export systems. The periplasm also can contain oligosaccharides that help the bacteria adjust to changes in the osmolarity of their environment.

The outer membrane of Gram-negative bacteria is a bilayer, but it only contains phospholipids in the inner leaf of the bilayer. The outer leaf is composed of a molecule called **lipopolysaccharide (LPS)** (Figure 2.23). LPS molecules have three distinct parts: lipid A, a core polysaccharide, and the O side chain. The hydrophobic portion of LPS constitutes the outer layer of the membrane bilayer, while the polysaccharide

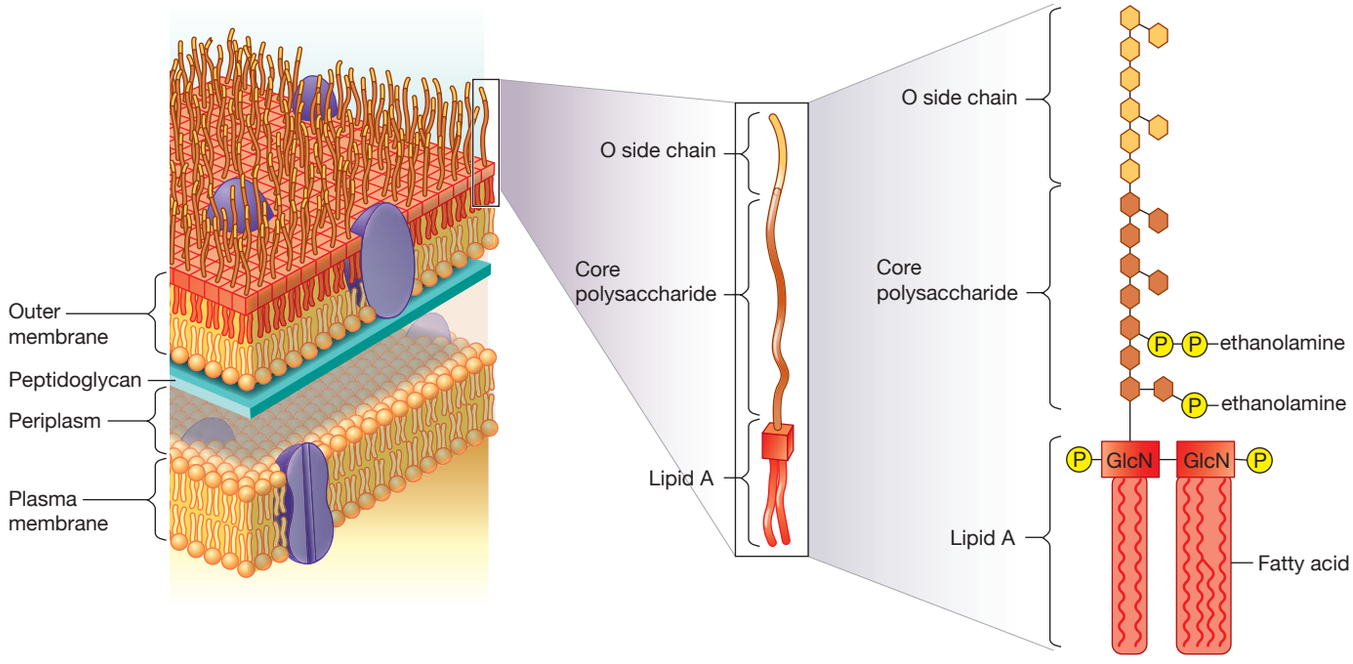

Figure 2.23. The structure of lipopolysaccharide The lipid A component, which is structurally conserved between Gram-negative species, contains the hydrocarbon chains composing the hydrophobic interior of the membrane. The sequence of the sugar building blocks in the core polysaccharide is less conserved between species, while the sugars in the outer O side chain can vary even more extensively in sequence, even between variants of a species. Representative sugars are shown here.

portion is exposed on the cell surface. The lipid A component, which is very similar in all Gram-negative bacteria, includes the hydrophobic hydrocarbon chains. The organization of the core polysaccharide also is conserved, although the identities and sequence of the sugar building blocks can vary somewhat between species. In contrast, the sugars in the O (outer) side chain can vary substantially, even between different variants of bacteria that clearly are members of the same species. Like the LTA of Gram-positive bacteria, LPS from invading Gram-negative bacteria, especially the lipid A component, triggers a powerful inflammatory response in the human body that is responsible for many of the symptoms of infections.

The outer membrane of Gram-negative bacteria provides protection from at least some environmental threats. Because large polar molecules generally cannot cross this membrane, it serves to retain periplasmic proteins and can keep proteins from the outside world out of the periplasm and away from the plasma membrane. We noted earlier that lysozyme is one of the human body's defenses against bacteria, but the outer membrane protects Gram-negative bacteria from its attack.

The outer membrane is attached to the cell wall by numerous proteins. The most abundant of these proteins is murein lipoprotein, which is covalently linked to the peptidoglycan through its carboxyl terminal amino acid (a lysine) and is covalently linked to lipid chains embedded in the outer membrane through its amino-terminal amino acid (a cysteine). Both murein lipoprotein and another attachment protein, peptidoglycan-associated lipoprotein, have been shown to be critically important for the stability of the outer membrane in Gram-negative bacteria.

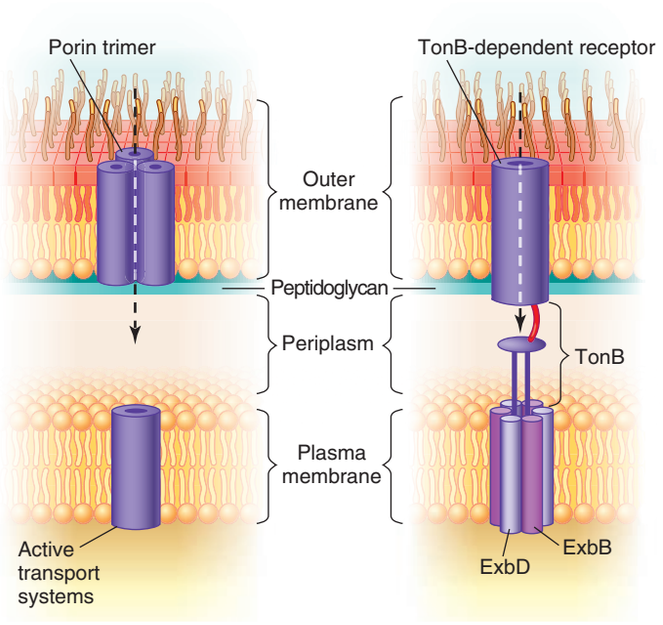

Figure 2.24. Porins and TonB-dependent receptors facilitate movement across the outer membrane **A.** Porins create trimeric (three-subunit) protein channels for the facilitated diffusion of hydrophilic molecules across the outer membrane. Once in the periplasm, these molecules then may cross the plasma membrane via an active transport system. **B.** The TonB-dependent transporter system allows high-affinity active transport of substrates through the outer membrane. The TonB receptor binds to its ligand. Energy from the proton motive force allows TonB, complexed with ExbB and ExbD, to interact with this receptor and triggers the movement of the substance across the outer membrane. Again, a plasma membrane active transport system then facilitates the movement of the substance into the cytoplasm.

Nutrient Transport Through the Outer Membrane The outer membrane of Gram-negative bacteria is not completely impervious. Various nutrients, for instance, must cross this barrier and then the plasma membrane to be used by the cell. To allow the entry of these essential molecules, the outer membrane of Gram-negative bacteria contains numerous channels. The most common of these channels are the **porins**. Porin proteins typically form trimeric, or three-subunit, pores through the outer membrane. These pores allow diffusion of small polar molecules, including some nutrients, across the outer membrane from the external environment into the periplasm, where they are available to plasma membrane transport systems (Figure 2.24). For example, glucose enters the periplasm by passing through a porin channel in the outer membrane of *E. coli*. Once inside the periplasm, glucose is transported into the cytoplasm via an active transport system.

The largest porin channel will allow entry of molecules up to a molecular weight of approximately 600 daltons. For reference, the disaccharide sucrose has a molecular weight of 342 Da. This molecular weight restriction helps to explain why Gram-negative bacteria are naturally resistant to large peptidoglycan-targeting antibiotics like vancomycin (MW ~1.5 kDa), as well as proteins such as lysozyme (MW ~14.3 kDa). Gram-positive bacteria, which have no protective outer membrane, are generally susceptible to vancomycin. Some antibiotics are small enough to pass through outer membrane pores, but under the selective pressure of antibiotic exposure, bacteria containing mutant porins have been isolated. In these cases, the altered porins are apparently even more exclusive, keeping the antibiotics out that normally would have entered the periplasm.

When nutrients are present in low concentrations in the environment, passive nutrient uptake systems that depend on favorable concentration gradients, such as porins, may be inadequate to supply the cell's needs. Bacteria then rely on high-affinity transporters. In addition to porins, the outer membrane contains proteins called TonB-dependent receptors that bind scarce nutrients (such as iron and vitamin B_{12}) with high affinity, and deliver them into the periplasm by active transport. In addition to the TonB-dependent receptor in the outer membrane, this active transport system consists of three other proteins. The ExbB and ExbD proteins are embedded in the plasma membrane and seem to form a complex with the TonB protein (see Figure 2.24B). Active transport across the outer membrane requires a source of energy, which the TonB system obtains from the proton motive force across the plasma membrane. The energy in this proton gradient allows the TonB protein to interact with the TonB-dependent receptor, triggering it to change its conformation and release its substrate into the periplasm. How energy is used in this process is not well understood. From the periplasm, the substrate can then be delivered into the cytoplasm by another plasma membrane transport system, such as the ABC transporter used for vitamin B_{12} in *E. coli*. Gram-negative bacteria that live in nutrient-rich mammalian guts have just a few kinds of TonB-dependent receptors, but

free-living bacteria from nutrient-poor habitats often have dozens of different TonB-dependent receptors, ensuring access to a wider range of available nutrients.

Protein Export and the Outer Membrane For Gram-negative bacteria, secreted proteins require special export systems to cross the outer membrane. Research has revealed that several distinct mechanisms seem to be involved in secretion. Often the general secretory pathway (see Figure 2.13) is first used to transport the protein into the periplasm. Some proteins, called "autotransporters," then catalyze their own transit across the outer membrane, but most proteins seem to need the assistance of export systems.

Some exported proteins avoid the general secretory pathway because they lack a hydrophobic signal peptide at the amino-terminus of the polypeptide chain. These proteins cross the plasma membrane and outer membrane in a single step, with no periplasmic intermediate. One of these single-step export systems, called the **type III secretion system**, has a particularly unusual evolutionary history. The secretory apparatus resembles a hypodermic syringe projecting from the surface of the bacterium **(Figure 2.25)**. This form is appropriate as it literally injects proteins, such as toxins, into host cells. Several of the components of the type III secretion system are evolutionarily related to proteins involved in making flagella. Flagellar proteins and proteins exported through the type III secretion system appear to be secreted by a similar mechanism, entering a pore at the base of the flagellum or type III needle, then moving through a channel in the core of the flagellar filament or secretory syringe to emerge at the other end. Flagellins assemble at the tip of the growing filament, whereas type III substrates are released outside the cell, or directly into a host cell penetrated by the secretory needle. Flagella are common in both Gram-positive and Gram-negative bacteria, so the flagellum is probably an ancient invention. Only Gram-negative bacteria, however, possess the type III secretion system, so it may have evolved by a duplication of genes encoding flagellar secretory components in a Gram-negative ancestor.

Many questions remain about protein export in Gram-negative bacteria. Why are there so many routes to get out of the cell? How are the substrates for these pathways identified? What energizes protein export across the outer membrane, given that there is no ATP in the periplasm, and no proton motive force across the outer membrane? How are export systems configured in the outer membrane? Finally, can we determine a way to block protein export and disarm pathogens that rely on it?

CONNECTIONS Many bacterial pathogens cause disease by secreting proteases, toxins, and other factors that damage host cells. As we will see in **Section 21.2,** some Gram-negative pathogens use the type III secretion system to deliver toxins directly into target cells.

Summary: Gram-Negative Versus Gram-Positive Cell Envelopes

The cell envelopes of Gram-negative and Gram-positive bacteria differ significantly. As we have seen, Gram-positive bacteria, with their multiple layers of peptidoglycan, have a much thicker cell wall than do Gram-negative bacteria. Gram-negative bacteria, on the other hand, have an additional outer membrane layer not found in Gram-positive species. Clearly the surfaces these cells expose to the outside world are distinctive—peptidoglycan, teichoic acids, and proteins in the case of Gram-positives, versus lipopolysaccharides and proteins for Gram-negative bacteria. Although these bacterial lineages diverged from each other billions of years ago, both types of cell envelope have been successful in evolutionary terms. Both Gram-negative and Gram-positive bacteria are abundant on Earth today, and most contemporary microbial communities include at least some species of both types of bacteria. Furthermore, our understanding of these basic structures continues to advance **(Mini-Paper)**.

Now that we have discussed the structural differences between these kinds of cells, you might ask why the Gram-positive cell envelope allows bacteria to retain the

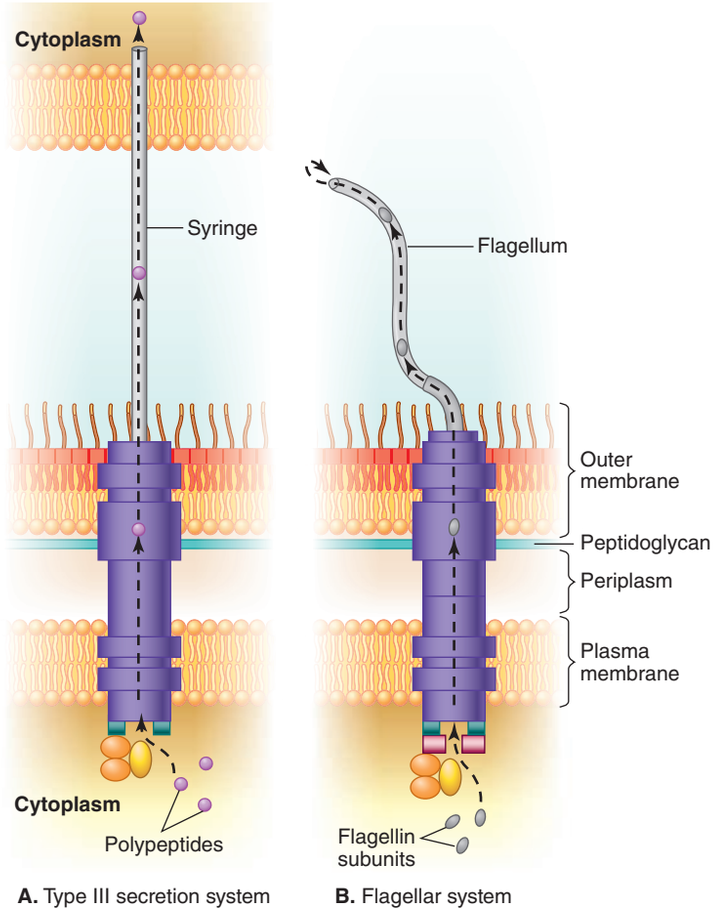

Figure 2.25. Type III secretion pathway and flagellar synthesis **A.** The type III secretion apparatus consists of several cytoplasmic and integral membrane proteins, as well as a hollow, syringe-like extension. Newly synthesized polypeptides in the cytoplasm are delivered to the secretory channel in the plasma membrane. They pass through a gated channel created by integral membrane proteins, then continue out through the hollow "syringe." The syringe is capable of penetrating the surface of host cells and injecting various cytotoxins. **B.** Several proteins involved in flagellar assembly are evolutionarily related to the type III secretion system, particularly the plasma membrane components that contribute to the secretory channel. Flagellin subunits, the primary substrates for this secretory system, move through the hollow filament and are added to the tip of a growing flagellum.

Mini-Paper: A Focus on the Research

NEW MICROSCOPY METHODS REVEAL A PERIPLASM IN GRAM-POSITIVE BACTERIAL CELLS

V. R. F. Matias and T. J. Beveridge. 2005. Cryo-electron microscopy reveals native polymeric cell wall structure in *Bacillus subtilis* 168 and the existence of a periplasmic space. Mol Microbiol 56:240–251.

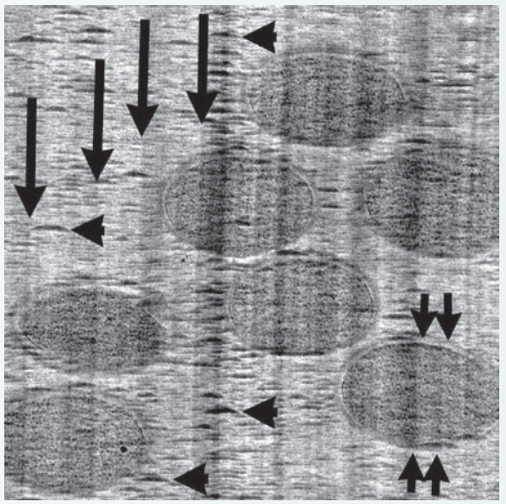
Context

One of the earliest recognized differential characteristics of bacteria was the structure of the cell envelope. As we saw earlier, the Gram stain allows us to differentiate Gram-positive and Gram-negative bacteria. The thick peptidoglycan cell wall of Gram-positive cells retains crystal violet stain following treatment with iodine and washing with ethanol, whereas the thinner cell wall and outer membrane of the Gram-negative cells does not retain this stain. Transmission electron microscopy (TEM) has been used to investigate the structure of Gram-negative and Gram-positive cell envelopes. From these studies, it is clear that Gram-negative cells have a space between the plasma membrane and the outer membrane, called the periplasm, which is partially filled by the thin peptidoglycan cell wall. In contrast, Gram-positive cells have no outer membrane and their cell wall consists of peptidoglycan, polymers such as teichoic acids, and proteins. There is no periplasm detectable in these cells by TEM. Recognizing that the preparation of cells for visualization by TEM is an exacting process involving harsh conditions, researchers worried that the preparation process might result in a flawed visualization of the structure of the Gram-positive cell envelope. To address this concern, Professor Terry Beveridge and graduate student Valério Matias at the University of Guelph in Canada used a powerful technique of sample preparation in which cells are frozen and then visualized in the TEM in this frozen state. The resulting images provide a clearer view of the structure of the Gram-positive cell envelope and reveal that these cells do indeed have a periplasm!

Experiment

The work presented in this paper consisted of the application of an ultralow temperature method of sample preparation and examination called cryo-electron microscopy (CEM). This method involves rapid freezing of the samples to temperatures of −140 to −180°C in the presence of glycerol to prevent ice crystal formation, and then cutting of thin sections immediately before viewing in the electron microscope. It is a challenging method because it is not possible to stain the sections before viewing, and the use of a dry knife at very low temperatures to prepare the thin sections tends to introduce knife marks and sample compressions, as apparent in **Figure B2.6**.

The sample preparation began with broth cultures of *Bacillus subtilis*, from which cell pellets were recovered by centrifugation. The pellets then were injected into a thin copper cooling tube and rapidly frozen under high pressure. Cross sections, approximately 50 nm thick, were produced by cutting with a diamond knife, and then viewed in the electron microscope at −170°C.



From V.R.F. Matias, et al., Mol. Microbiol. 56:240-251, 2005, John Wiley & Sons

Figure B2.6. Artifacts associated with cryo-electron microscopy The cryo-electron microscopy technique results in many artifacts, including knife marks, crevasses (short arrows), and compressions (double arrows). The pictures are not always pretty, but they can be very informative.

crystal violet, even after being washed with ethanol, but the Gram-negative cell envelope does not. The alcohol probably acts as a solvent to dissolve the outer membrane of Gram-negative bacteria, helping the crystal violet to leach out of the thin peptidoglycan layer. Although there is no outer membrane to protect the Gram-positive cell, the cell wall is much thicker, and the alcohol may toughen it further by dehydrating the structure, helping to trap enough crystal violet that the cells retain the intense purple color. Bacteria that lack a peptidoglycan layer, like the mycoplasmas that we discussed earlier, cannot be Gram-stained and are not classified as Gram-negative or Gram-positive.

2.4 Fact Check

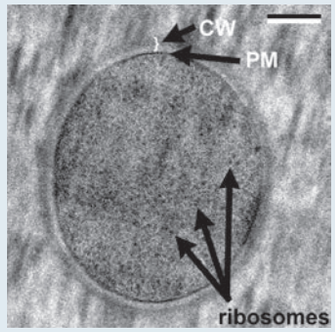
1. What are the key components of the bacterial plasma membrane and what are its functions?
2. Describe the structure and function of the bacterial cell wall.
3. Differentiate between Gram-positive and Gram-negative bacterial cell envelopes.
4. Describe the role of porins and TonB-dependent receptors in Gram-negative bacteria.
5. What is the type III secretion pathway?

The images showed something that had never been seen before. The cell walls, rather than being uniformly dense, had two well-defined layers. The less-dense inner layer, about 22 nm wide, was called the inner wall zone (IWZ). The denser outer zone, about 33 nm wide, was called the outer wall zone (OWZ) **(Figure B2.7)**. Based on these images, the researchers concluded that the OWZ is the true peptidoglycan cell wall, while the IWZ is a periplasm. Although the IWZ appears to be very low density, it is likely filled with important cellular components such as enzymes, secreted proteins, and proteins involved in building of the peptidoglycan cell wall.

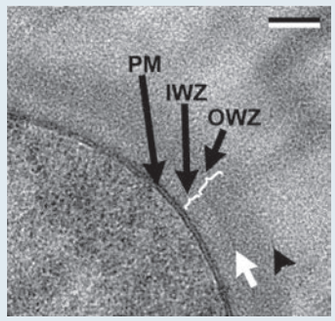
Impact

The real breakthrough of this study was using a method that allowed the direct comparison of material density within the cell envelope. Commonly used methods of sample preparation for TEM involve embedding samples into plastic followed by cutting of sections and the use of heavy metal stains to bind charged molecules to detect beyond the background of the plastic. The resulting images are therefore not representative of the actual differences in material density, but rather indicate where the staining occurred. In comparison, the direct visualization of frozen sections that had not been embedded in plastic allows a truer view of the actual density.

Since this study was published, similar studies have been done in other Gram-positive bacteria such as *Staphylococcus aureus*, and the results have been similar. Perhaps, a periplasm is a common feature of Gram-positive organisms. Given the diversity of microorganisms that are known, it will be interesting to use this type of microscopy to provide a more accurate view of the cell envelope ultrastructure. Interestingly, other work in which this technique has been applied to visualization of the Gram-negative cell envelope has suggested that the Gram-negative periplasm is very low density, rather than the higher density gel that was previously thought to be the case.



A. Ribosomes



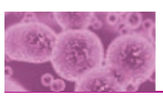
B. Plasma membrane

From V.R.F. Matias, et al., Mol. Microbiol. 56:240-251, 2005, John Wiley & Sons

Figure B2.7. Cryo-electron microscopy cross sections of *B. subtilis* cells **A.** Ribosomes are visible in the cytoplasm. **B.** Three distinct layers can be seen in the cell envelope: the plasma membrane (PM), the inner wall zone (IWZ), and the outer wall zone (OWZ).

Questions for Discussion

1. What molecular activities do you think are carried out in the Gram-positive periplasm?
2. Do you think that a periplasm might be a requirement for all cells that have a cell wall? Why or why not?



2.5 The bacterial cell surface

3D ANIMATION

How do structures on the surface of bacterial cells allow for complex interactions with the environment?

Cells directly interact with the outside world at the cell surface. Molecules present on the cell surface perform many jobs: allowing movement, sticking to surfaces, sensing the environment, and acquiring nutrients **(Table 2.2)**. In this section, we discuss the specialized surface structures and organelles of bacterial cells that mediate these activities.

Motility from flagella

For active movement, bacteria commonly use **flagella**, spiral filaments that extend from the surface of the cell and rotate in order to propel the cell **(Figure 2.26)**. Some bacteria have flagella only at the ends of the cell, in which case they are called

TABLE 2.2 Molecules and structures on bacterial cell surfaces*

Structure	Composition	Location	Function
Lipopolysaccharide (LPS)	Lipid, polysaccharide	Outer layer of Gram-negative outer membrane; lipid portion embedded in membrane; polysaccharide exposed on surface	Stabilizes membrane; elicits an inflammatory response in the human body
Lipoteichoic acid (LTA)	Lipid, polysaccharide	Found in peptidoglycan layer of Gram-positive bacteria	Unknown; elicits an inflammatory response in the human body
Peptidoglycan	Polysaccharide backbone crosslinked with peptides	In Gram-positive bacteria, usually exposed to environment	Maintains shape and provides structural integrity to cell
		In Gram-negative bacteria, covered by the outer membrane	
Porins	Proteins	Embedded in Gram-negative outer membrane	Form pores that allow diffusion of nutrients and water through outer membrane
TonB-dependent receptors	Proteins	Embedded in Gram-negative outer membrane	Catalyze high-affinity active transport of molecules across outer membrane
Flagella	Protein subunits	Extend outward from surface, except in spirochetes, where periplasmic flagella wrap around cell	Provide motility
Pili	Protein subunits	Extend outward from cell	Allow attachment; tip often binds to specific molecules. In some bacteria, pili are retractable and allow "twitching motility."
Capsule	Usually loose network of polysaccharides	Covers surface of cell	Protects from phagocytes; contributes to biofilm formation
Surface array (S-layer)	Protein	Covers surface of cell	May protect from bacteriophages

* Not all structures are present in all species.

polar flagella. **Monotrichous** bacteria have only a single polar flagellum (*trich* being Latin for "hair"). **Lophotrichous** (*lopho* being Greek for "tuft") bacteria have more than one flagellum at one or both ends of the cell, and **peritrichous** bacteria have multiple flagella spread all over the surface of the cell.

The flagellar filament is built from many copies of the flagellin protein. Often 5–10 μm in length, the flagellar filament is usually longer than the cell itself. The flagellum is anchored in the cell envelope by the basal body, a disc-like structure that serves as the structural foundation of the flagellum and interfaces with the motor that drives rotation of the flagellar filament. The central rod emerging from the basal body transitions to a curved hook, to which the filament is attached. The helical filament acts as a screw propeller, driving or pulling the bacterium through the surrounding fluid like a submarine. The flagellar motor is located in the plasma membrane, where it converts energy from the proton motive force to drive rotation of the filament. Bacterial flagella are complex structures that involve more than 40 distinct proteins, assembled in modular fashion from the plasma membrane outward. As we noted earlier in this chapter, most of the protein subunits that contribute to the flagellum structure exit the cytoplasm through a pore in the center of the basal body, before assembling at the tip. The expression, secretion, and assembly of flagellar subunits in bacteria compose a highly ordered process that has served as a model system for understanding developmental regulation in microorganisms.

Structures of bacterial, archaeal, and eukaryal flagella are distinct. Archaeal flagellar filaments look similar to bacterial flagella superficially and likewise function as rotating propellers. Archaeal flagella seem to be constructed differently, though, growing from the base rather than the tip, and lacking rings in the basal body. The known protein components of archaeal flagella are generally not related to bacterial flagellar subunits, so similarities in structure and function between bacterial and archaeal flagella probably resulted from convergent evolution. In other words, the structures arose independently in both groups of organisms to serve the same function. Eukaryal flagella are structurally and functionally distinct from both bacterial and archaeal structures; they are surrounded by the plasma membrane and do not actually rotate. Internally, eukaryal flagella are built from a bundle of microtubules. We will talk about eukaryal flagella in more detail in Section 3.1.

Bacteria with a single polar flagellum will be pushed or pulled by the flagellum, depending on which direction it rotates. It is a bit more complex for bacteria such as *E. coli* and *Salmonella enterica*, which have peritrichous flagella. In this case, rotation of the flagellar motor in one direction (counterclockwise for *E. coli* and related Gram-negative bacteria) causes the flagella to bundle together and push the cell forward. Rotation in the other direction causes the flagella to fly apart and point in different directions, which causes the cell to tumble in place (Figure 2.27). This tumbling randomly reorients the cell, so that

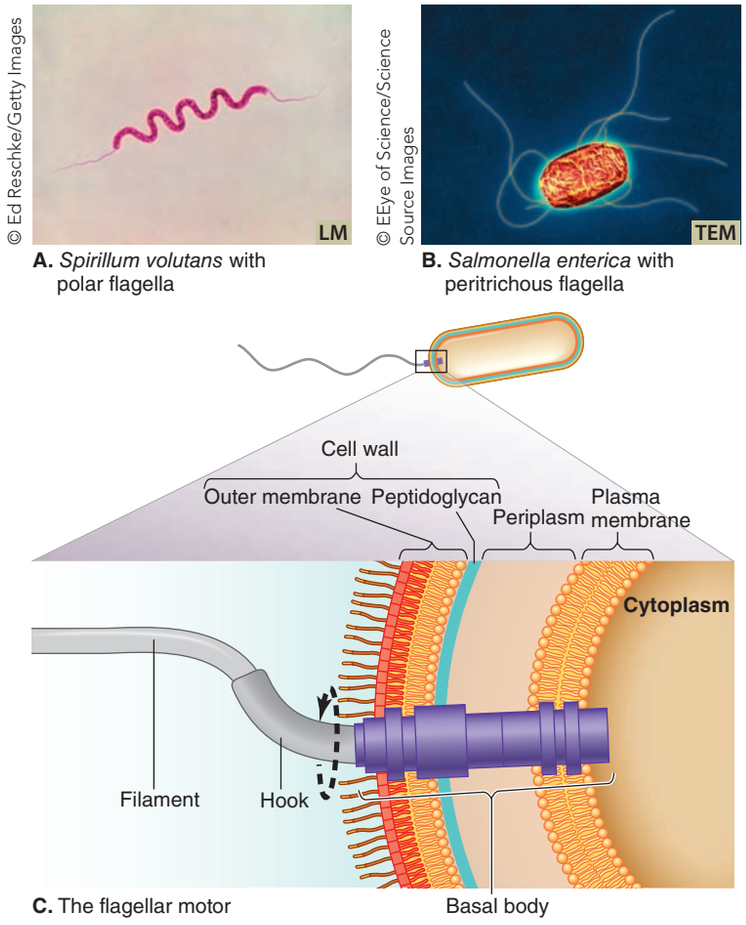


Figure 2.26. Bacterial flagella all have a common molecular structure **A.** Bacteria with polar flagella, such as *Spirillum volutans*, only have flagella emerging from the ends of the cell. **B.** Peritrichous flagella, as seen on this *Salmonella enterica* cell, are distributed across the cell surface. **C.** The flagellum is embedded in the cell wall and plasma membrane through the basal body. The flagellar motor, a protein complex embedded in the plasma membrane, rotates the flagellum.

Figure 2.27. Bacterial movement by straight line "runs" and random "tumbles" Peritrichous flagella rotating in one direction will bundle together and cause the bacterium to move in a straight direction. When the direction of rotation of the flagella is changed, the bacterium tumbles and randomly reorients. When flagellar rotation switches again, the cell takes off in a new direction. Bacterial cells with a single polar flagellum are pushed or pulled depending on the direction of flagellar rotation.

when flagellar rotation is reversed once again, the cell sets off in a new direction.

Bacterial cells sense many chemicals in their environment through receptors in the plasma membrane that communicate indirectly with the flagellar motor through intermediary proteins in the cytoplasm. This process of using chemical signals from the environment to direct motility is called **chemotaxis** (Figure 2.28). The cytoplasmic control system ensures that all of

Figure 2.28. Directed motility lets bacteria respond to outside chemical signals **A.** A peritrichously flagellated bacterium such as *E. coli*, detecting no chemical signals, will undergo alternating runs and tumbles, resulting in no directed movement. This type of non-directed movement often is referred to as a "random walk." **B.** Prolonging the swimming mode ("running") by delaying tumbles will move the bacterium toward higher concentrations of a desirable compound, resulting in positive chemotaxis. **C.** Similarly, bacteria can move away from undesirable compounds, resulting in negative chemotaxis.

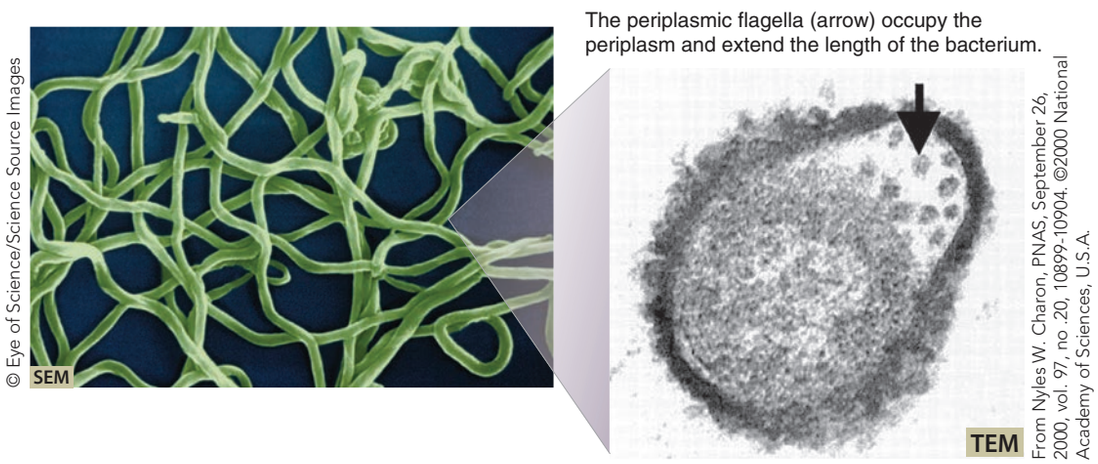

Figure 2.29. *Borrelia burgdorferi*, the spirochete that causes Lyme disease As seen in this colorized image, flagella are not visible on the surface of *B. burgdorferi* cells. However, a cross section of these cells (inset) shows a large number of periplasmic flagella.

the motors in cells with multiple flagella tend to rotate in the same direction. If the chemoreceptors detect a higher attractant concentration as a bacterial cell moves, then the flagellar motors tend to continue rotating in the direction causing forward motion. The bacterium, in other words, moves up the gradient of the desired nutrient. This type of movement is referred to as a run. If the concentration of an attractant is not increasing, or if the concentration of a repellent, a chemical the cell wants to avoid, is increasing, the flagellar motor switches more often to the direction that results in a tumble. The tumbling state is transient, and the cell sets off on a run in a new direction.

Chemotactic attractants are often molecules that can be productively metabolized (e.g., sugars and amino acids), whereas chemicals that could damage the cell (e.g., acids and alcohols) are more likely to be interpreted as repellents. Bacterial species often have many different **chemoreceptors**, receptors that detect these attractants and repellents. The different chemoreceptors, in turn, each have different specificities. They interact with, and thus signal a response to, different chemical signals. This degree of receptor specificity should not surprise us. Depending on where bacteria live, and what they can transport and productively metabolize, different microorganisms might reasonably find different chemicals attractive or repellent. Several bacterial pathogens rely on motility and chemotaxis to establish infections, including some variants of *E. coli* that cause diarrhea. These **strains**, or genetically and often phenotypically distinct subtypes, of *E. coli* attach to the lining of the intestine. Chemotaxis may help them reach this surface before they are flushed through the intestinal tract.

Spirochetes are long, thin, corkscrew-like cells **(Figure 2.29)**. These unusually shaped cells do not have surface flagella. Surprisingly, they do depend on flagella for motility, but they keep the flagellar filament shielded inside the periplasm. The filament is basically around the cell body. When the flagellum rotates, it causes the entire cell to spin like a tiny screw propeller through the medium. Spirochetes move best in viscous environments, such as in mucus that lines the intestinal tract. Some spirochetes, such as *Borrelia burgdorferi*, the cause of Lyme disease (see Section 18.5), and *Treponema pallidum*, which causes syphilis, are important pathogens of humans. This unique form of motility probably affects their ability to invade host tissues.

Flagellar motility works best in liquid environments. However, some bacteria, like the urinary tract pathogen *Proteus mirabilis*, adapt to contact with surfaces by becoming long, hyper-flagellated swarmer cells **(Microbes in Focus 2.2)**. In the laboratory, *P. mirabilis* swarming can be easily observed. Colonies growing on agar plates rapidly spread over the entire surface of the agar in the course of a few hours. The cells coordinate swarming with the expression of other genes needed for infection, suggesting that this mode of motility is useful during infection, perhaps because it facilitates movement in host tissues.

Microbes in Focus 2.2
PROTEUS MIRABILIS: A SWARMING BACTERIUM

Habitat: Exists in soil and water. Also commonly found in the intestinal tract of humans. Can cause urinary tract infections.
Description: Gram-negative, rod-shaped, motile bacterium, approximately 0.5 μm wide and 2.0 μm long.
Key Features: In the laboratory, *P. mirabilis* can be identified by its swarming abilities. In an aqueous environment, *P. mirabilis* cells typically exist as swimmers, relatively short cells with about ten flagella. Upon contact with a solid surface, some cells differentiate into swarmer cells that are much longer and may contain hundreds of flagella. These swarmers cause colonies of *P. mirabilis* on agar plates to spread out over the plate.

Figure 2.30. Process Diagram: *Shigella* move within and between infected cells *Shigella flexneri* cell (red) within a HeLa cell develops an actin tail (green) to propel the bacterium. Initially, *Shigella* cells are taken up in a vesicle by an epithelial cell. The *Shigella* are released from the vesicle and recruit actin from the cytoskeleton to build an actin "tail" on one end of the bacterial cell. The growing tail (driven by actin polymerization) pushes the bacterium through the cytoplasm of the human cell and can propel it into adjacent cells as well, where it continues to divide.

Non-flagellar motility

Some forms of bacterial motility do not depend on flagella. During **gliding motility**, some non-flagellated bacteria, such as myxobacteria and cyanobacteria, slide smoothly over surfaces. The mechanism of gliding motility is not well understood, and there may be more than one mechanism. Other bacteria that exhibit surface-dependent motility rely on fibers called pili that help the bacteria move along surfaces by a slow, jerky process called twitching motility. The pili bind to the surface and appear to be capable of rapid retraction to pull the cell body along. *Neisseria meningitidis* and *Pseudomonas aeruginosa* can use this type of motility, although *P. aeruginosa* usually relies on flagella for motility. Only some pili-forming bacteria are capable of twitching motility, suggesting that this action is not an intrinsic property of all pili.

Another fascinating mechanism of motility has been observed in some bacteria that invade eukaryal cells. *Shigella dysenteriae*, a Gram-negative, rod-shaped bacterium that causes bloody diarrhea (dysentery), and *Listeria monocytogenes*, a Gram-positive bacterium that can cause serious food poisoning, have evolved a strategy for hijacking the mammalian actin cytoskeleton. When these bacteria invade cells, they induce actin polymers to form at one end of the bacterium. Polymerization of actin propels the bacterium through the cytoplasm of the host cell **(Figure 2.30)**, and the force generated can actually shoot the bacterial cell through the host plasma membrane into an adjacent cell, which may be the real purpose of this actin-based motility. When they take up residence within intestinal cells, these bacteria are protected from antibodies produced by the immune system. By spreading directly from one cell to another, they effectively evade the host immune response, thereby taking full advantage of this sheltered habitat.

Adherence

Many bacteria have fibers called **pili** sticking out from the cell surface. These fibers are constructed from a single type of protein subunit, called pilin. As with flagella, some bacteria display pili only at the cell poles, while others have them spread across the entire cell surface. Although we mentioned pili in the context of motility above, the more common purpose of pili is to allow bacteria to attach to surfaces, including other cells. The tip of the pilus usually contains distinct proteins that serve as adhesins designed to bind specific molecules on target surfaces. Pili can be very important for pathogenic microorganisms because adherence to target cells in the host is often an early step in the infection process. Even in non-pathogens, pili that mediate surface attachment can be important for persistence in any environment where there is fluid flow.

A special type of pilus, the **sex pilus**, or conjugal pilus, is used to connect bacterial cells for the transfer of plasmid DNA. Genes for constructing sex pili are found on some large plasmids that have evolved to move between bacteria. Both adhesive and conjugal pili may be found on the same *E. coli* cell. Some microbiologists prefer to use the term "pilus" exclusively for the structures involved in conjugation, and they assign the alternative term **fimbria** (plural: fimbriae) to cell surface fibers used for adhesion and lacking the associated intracellular machinery for conjugal plasmid transfer **(Figure 2.31)**.

CONNECTIONS For many pathogenic bacteria, like *Bordetella pertussis* and *Neisseria gonorrhoeae*, fimbriae allow the bacteria to adhere to host tissues, thereby serving as virulence factors. We will examine the role of these structures more fully in **Section 21.1**.

Gram-negative bacteria such as *Caulobacter* and *Hyphomonas* attach to surfaces using a **stalk**. The stalk is not simply a protein assembly (like flagella and pili), but is a tubular extension of the entire cell envelope **(Figure 2.32)**. The stalk is often tipped by an adhesive structure, called a holdfast, made from secreted polysaccharides. Because the stalk extends the cell envelope and contains nutrient transport systems, it increases the surface-to-volume ratio of the cell and boosts nutrient uptake efficiency. Stalked bacteria are common in aquatic habitats, particularly where nutrient concentrations are very low. The

Figure 2.32. *Caulobacter crescentus* cells alternate between free-swimming and attached forms Stalks can be seen emerging from the lower poles of cells. *Caulobacter* has a unique life cycle in which a flagellated swarmer cell is produced each cell cycle from a non-motile stalked cell at division. The swarmer cells, with a single polar flagellum, can move in search of nutrients and then differentiate into stalked cells.

stalks, researchers hypothesize, serve as extensions of the cell surface that can aid in nutrient acquisition due to their relatively high surface-to-volume ratio.

Capsules

Colonies of some pathogenic bacteria, such as *Streptococcus pneumoniae*, a cause of bacterial pneumonia, and *Neisseria meningitidis*, a major cause of bacterial meningitis, have a smooth, glistening appearance. A thick layer of polysaccharides, called a **capsule**, surrounds these cells (Figure 2.33). Many pathogens use capsules to shield themselves from host defense systems, particularly phagocytic host cells that are capable of engulfing and destroying bacteria. Phagocytic cells often cannot recognize encapsulated microbes as foreign invaders worthy of destruction. Capsules also may serve other purposes. Because most capsules are made of hydrophilic material that retains water, capsules may be useful for surviving desiccation. Some species of bacteria have a less well-defined outer layer, known as the **slime layer**. Again, this structure typically consists of polysaccharides and can serve several purposes. The term **glycocalyx** can refer to both capsules and slime layers.

Bacterial cell structure
ANIMATION

CONNECTIONS In **Section 7.1,** we will explore one of the classic experiments of modern biology—Frederick Griffith's demonstration of natural transformation, or the transfer of genetic material from one cell to another. Although he did not know it at the time, Griffith observed the transfer of genetic material needed for the production of a capsule from one strain of *S. pneumoniae* to another.

Polysaccharide coatings on microorganisms can aid in adherence of the microbes to surfaces. In wet habitats, microorganisms can form attached communities called **biofilms** (Figure 2.34). Biofilms often contain more than one kind of microorganism. A biofilm may be initiated by a bacterium sticking to a surface using pili or some other attachment mechanism. The number of adherent cells grows as a result of

division or aggregation from the surrounding environment. As the cells pile up, extracellular polysaccharides form a matrix holding the biofilm together. Over time, the biofilm may get deeper and spread outward, developing into a complex structure with distinct microenvironments.

CONNECTIONS Biofilms represent complex communities in which various members of the community benefit from the presence of the other members. We will examine in **Section 15.1** how individual members of a biofilm community contribute to and benefit from the association with other members.

Surface arrays ("S-layers")

A regular, crystalline-like layer of protein referred to as a **surface array** or **S-layer** (Figure 2.35) has been observed in many bacterial cells, both Gram-positive and Gram-negative. As you might imagine, making this protein coat represents a tremendous investment of resources by the cell. Surface arrays are generally thought to act like a microbial suit of armor, providing protective functions such as:

- Prevention of infection by bacteriophages (viruses that attack bacteria).
- Prevention of penetration by predatory bacteria such as *Bdellovibrio*.
- Prevention of attack by a host's immune system.

As we can see from this brief list, the presence of an S-layer can be quite useful and worth the required expenditure of resources for its synthesis. When an S-layer is not needed, such as when bacteria are grown in pure culture, its synthesis often stops and it is lost.

2.5 Fact Check

1. What are the roles of bacterial flagella and how do bacterial flagella differ from archaeal and eukaryal flagella?
2. Describe how chemoreceptors and flagella are involved in the process of chemotaxis.
3. Explain the processes of gliding motility and actin-based motility. Provide examples.
4. Differentiate between the terms "pili" and "fimbriae."
5. Speculate on some potential benefits to bacteria of biofilm formation.

2.6 Diversity of bacteria

What are the different types of bacteria?

In Chapter 1, we briefly explored the three-domain classification of life on Earth. Bacteria make up the largest and most ubiquitous domain, living in virtually every habitat. Because these microorganisms have evolved for over four billion years on a planet that has undergone continual change, bacteria exhibit incredible diversity. All of this diversity must be taken into account when categorizing them. In this section, we will examine how bacteria are classified and named. In addition, we also will provide a brief introduction to bacterial taxonomy, profiling a few important phylogenetic groups. As we discuss these topics, we should note that the majority of bacteria have not yet been discovered or cultivated. As microbiologists succeed in cultivating more organisms and sequencing the genes of uncultivated bacteria, new organisms and taxonomic groups will continue to expand the known diversity of the *Bacteria*.

Classification and nomenclature

Biologists classify bacteria using a hierarchical taxonomic system following the same general outline used for plants and animals. Thus, bacteria conform to the binomial naming system of Linnaeus; each organism has a Latinized scientific name, which always is italicized. For bacteria, the basic taxonomic group of species can be regarded as a grouping of strains that share common features, while differing considerably from other strains. A genus consists of closely related species. Organizational categories above the genus level are family, order, class, phylum, and domain **(Table 2.3)**. Each named grouping is considered a **taxon** (plural: taxa). More detailed information about the classification of living organisms can be found in Appendix C.

For each new taxon that is named, a corresponding culture must be deposited in at least two different culture collections in two different countries. The *World Federation for Culture Collections* maintains a database of more than 500 collections from over 60 countries. These cultures represent specimens that are available so that other scientists can make direct comparisons, without relying solely on the published descriptions.

TABLE 2.3 **Classification hierarchy within the domain *Bacteria*, using *Brucella melitensis* as an example**

Taxonomic level	Example
Phylum	*Proteobacteria*
Class	*Alphaproteobacteria*
Order	*Rhizobiales*
Family	*Brucellaceae*
Genus	*Brucella*
Species	*melitensis*

The availability of culture collections ensures that as scientists develop new analysis techniques, these techniques can be applied to the type of strains that define the taxon. Note that each characterized bacterial species has a single type strain, which is the original isolate that defines the species.

CONNECTIONS Typically, a formal taxonomic name is only assigned to bacteria that have been isolated in pure culture. What about candidate species that have not yet been cultivated to purity? See **Perspective 15.1** and **Appendix C** to learn how scientists can communicate their findings about uncultivated bacteria using the designation *Candidatus*.

Historically, bacterial classification was determined by comparison of cell and colony morphology, growth characteristics, biochemistry, and physiology. Today, the classification of bacteria relies primarily on DNA sequence analysis. This shift follows from the initial breakthroughs in molecular phylogenetics made by Carl Woese that offered a more natural view of how microorganisms are related to each other. In addition to sequence information from cultured organisms, we also have an increasing amount of sequence data from organisms that have not yet been cultured. These data have affected classification tremendously, in many cases helping to resolve ambiguous relationships by comparing the sequences of shared genes, greatly improving the reliability of identification methods.

Phylogeny of Bacteria

As we noted in the previous section, bacteria can be organized into several major groups, called phyla (singular "phylum"). Shown in **Figure 2.36** are the major phyla of cultured bacteria, along with some examples of the better-known genera within each phylum. Note that the majority of bacteria are not shown in this illustration. Many bacteria are known only through the detection of their DNA sequences from the environment; we know very little about what they do and the extent of their diversity. Throughout this book, we will introduce you to specific bacteria, providing you with important details and discussing them within the context of specific topics. Here, we provide a snapshot of bacterial diversity by profiling a few selected phyla.

Proteobacteria

Probably best known for its most famous member, *Escherichia coli*, the phylum *Proteobacteria* includes a wide range of Gram-negative bacteria displaying an enormous diversity of metabolic and nutritional strategies. Members of this phylum include several human pathogens such as *Helicobacter pylori*, *Vibrio cholerae*, and *Neisseria gonorrhoeae*. Also within this phylum are nitrogen-fixing soil bacteria in the genus *Rhizobium* and the important plant pathogen *Agrobacterium tumefaciens*. This phylum also contains some of the best-known photosynthetic

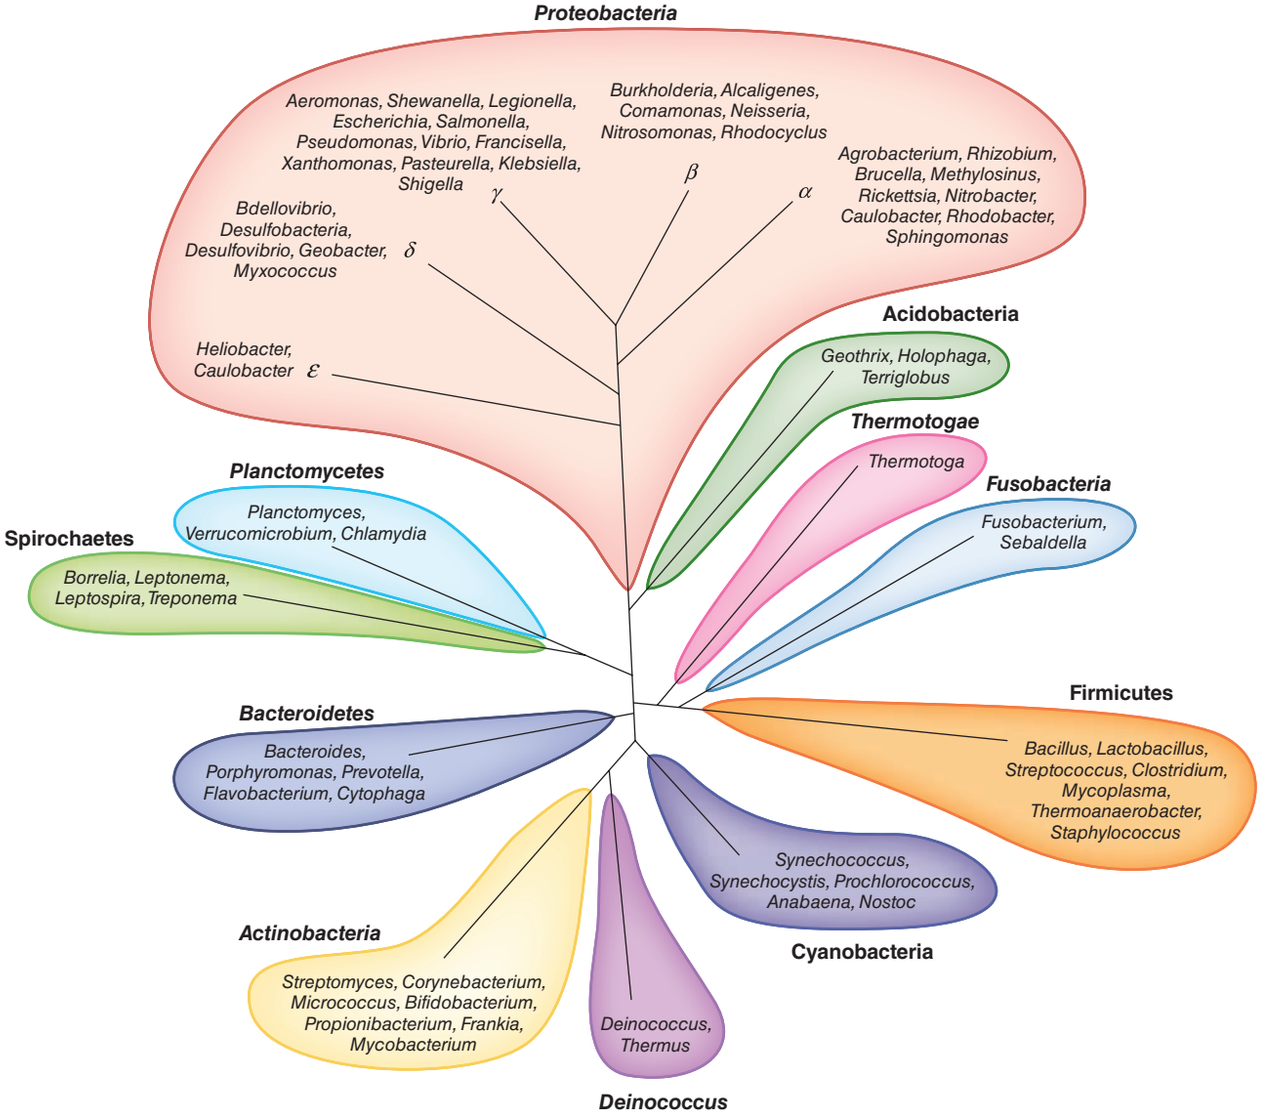

Figure 2.36. Illustrated selection of bacterial phyla Based on a combination of physical characteristics and DNA sequence data, bacterial species have been grouped into a series of related phyla. These phyla include *Proteobacteria, Firmicutes, Actinobacteria, Bacteroidetes*, and *Cyanobacteria*.

bacteria, such as the purple sulfur and purple non-sulfur bacteria. The mitochondria of most eukaryal cells are most closely related to modern day members of a class of the *Proteobacteria*, the *Alphaproteobacteria*, as judged by ribosomal RNA sequence similarity. See Section 3.4 for more information about the origin of mitochondria within eukaryal cells.

Firmicutes

The phylum *Firmicutes* contains a wide range of Gram-positive bacteria that have a low proportion of guanine and cytosine (G+C) in their DNA. Certain *Firmicutes*, like *Bacillus anthracis*, can undergo endospore formation, allowing them to remain largely dormant for extended periods of time. Some *Firmicutes*, like members of the genus *Mycoplasma*, lack a cell wall and thus technically cannot be classified as Gram-positive. Finally, members of the genus *Lactobacillus* are important for the production of various foods, like yogurt and cheese. We will examine this important use of bacteria in Section 16.3.

Actinobacteria

Members of the phylum Actinobacteria are Gram-positive. In contrast to the *Firmicutes*, their DNA has a high G+C content. As described in Chapter 24, many species in the genus *Streptomyces* produce antibiotics and have led to the discovery of many common antibiotics used in medicine today. Some *Actinobacteria* can produce geosmins, organic compounds possessing an aroma that humans and other animals can detect readily. You might recognize the scent of geosmins as the smell of soil or the scent in the air when it rains on a hot summer day.

Bacteroidetes

These Gram-negative microorganisms can be found in many different habitats, including the ocean, soil, and the gastrointestinal tract of many animals, including humans. Indeed, species in the genus *Bacteroides* are among the predominant inhabitants of the human gut. In this location, these bacteria

aid in the degradation of various organic polymers. In the Chapter 4 Mini-Paper, we will see how a specific member of this phylum, *Bacteroides thetaiotaomicron*, is involved in the digestion of food. The role of these and other bacteria in digestion will be examined more thoroughly in Section 17.4.

Cyanobacteria

Most members of the phylum *Cyanobacteria* share a very obvious characteristic; they are photosynthetic, producing oxygen due to their use of light energy to split water for use of its electrons. As we saw in Section 1.3, the evolution of oxygenic photosynthesis, which occurred in cyanobacteria, had an enormous impact on global biogeochemistry, leading to the build-up of oxygen in Earth's atmosphere. This development, in turn, led to the eventual evolution of aerobic respiration to take advantage of that oxygen. As we will see in Section 3.4, the ancestors of today's cyanobacteria gave rise to the chloroplasts we see in present-day algae and plants. Some cyanobacteria are unicellular and others are colonial, occurring as filaments of cells, and these colonial forms are commonly capable of gliding motility, as discussed earlier in this chapter.

2.6 Fact Check

1. Identify the taxonomic groups used to classify bacteria.
2. Each bacterium's scientific name is binomial and based on which taxonomic categories?
3. Members of the phylum *Proteobacteria* exhibit substantial diversity. What feature unites them in a single phylum?
4. What major feature unites members of the phylum *Cyanobacteria*?

The Rest of the Story

Since their discovery in 1974, magnetotactic bacteria have been found in freshwater and marine sediments worldwide. As we discussed in Perspective 2.1, scientists are beginning to understand how the magnetosomes that control this movement are formed. Another question still remains. How could this trait be useful, and thus evolutionarily advantageous, to a microorganism?

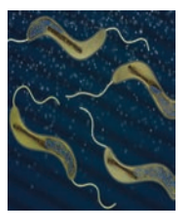
The magnetotactic bacteria isolated so far prefer habitats with no O_2 (anoxic) or very low O_2 concentrations. Most microbiologists now hypothesize that magnetotaxis tells the bacteria which direction is "down." In the Northern Hemisphere, following Earth's geomagnetic field toward the North Pole would result in a downward trajectory. In a water column, this downward trajectory should direct a bacterium toward the sediment and more anoxic conditions. The bacteria utilize a process of magneto-aerotaxis; they move along a magnetic field toward their preferred concentrations of oxygen.

Research now focuses on understanding magneto-aerotaxis and the role that magnetosomes play in this process. In the laboratory, researchers have compared naturally occurring magnetotactic bacteria with an engineered magnetosome-free strain. The magnetosome-free strain still responded to an oxygen gradient in the absence of a magnetic field. However, without the magnetic advantage, aerotaxis took twice as long in the experiments, compared to the aerotaxis of the bacteria containing magnetosomes. While research continues to unravel the details of this magneto-aerotaxis, these results indicate that magnetosomes provide bacteria with the selective advantage of reaching their ideal environment more quickly. A greater understanding of these fascinating microbial structures will not only provide insight into this process, but also set the stage for industrial and commercial applications in the future.

Image in Action

WileyPLUS Learning Space Within the Northern Hemisphere, Earth's geomagnetic field exerts a downward force, as indicated by the black lines in this illustration. Magnetotactic bacteria align themselves with this force. Within these bacteria, the magnetosome organelle, composed of MamK protein and vesicles containing magnetite (dark gray with orange), facilitates this behavior. As the bacteria move in this direction, they not only move lower in the water column, but also move toward areas of lower oxygen content (indicated by white circles).

1. The microorganisms in this diagram are classified as bacteria but contain a cytoplasmic organelle. Why might this observation be considered "confusing" to a student studying them?



2. Imagine you are studying the MamK protein shown in orange in this image. When using bioinformatics tools to compare it to other known proteins, what would you likely determine?
3. Imagine the cell at the top was missing the filamentous MamK protein. Describe how that cell would appear different in this diagram compared to the other cells.

Summary

Section 2.1: What do bacterial cells look like?

Although different bacterial species exhibit great diversity, the morphology of a given species is fairly consistent.

- Bacterial cells can have several distinct morphologies: spheres (**cocci**), rods (**bacilli**), curved rods (**vibrios**), and spirals (**spirilla**).

- Some bacterial species are **pleiomorphic**; they exhibit highly variable shapes.
- In many bacterial species, cells can stay attached after cell division. Within a given species, cells may form clusters, chains, and branching filaments. Some bacteria grow more complex multicellular arrangements, forming **hyphae**, **mycelia**, or **trichomes**.
- Bacterial cells range in size from 0.2 μm to 700 μm in diameter, but most are in the range of 0.5–5 μm.

Section 2.2: What is in the cytoplasm of bacterial cells?

The **nucleoid**, which is primarily composed of chromosomal DNA and associated proteins, is the most massive component of the **cytoplasm**.

- The nucleoid is not partitioned from the cytoplasm by a membrane.
- Chromosomal DNA is compacted significantly, through the action of **topoisomerases**, which cause **supercoiling** of the DNA, and interaction with packaging proteins.
- Ribosomes produce proteins within the cytoplasm.
- The cytoplasm contains many different soluble organic metabolites and inorganic ions and may contain large **inclusion bodies** storing various nutrients.
- Other structures, such as **sulfur globules**, **gas vesicles**, **carboxysomes**, and **magnetosomes**, exist in the cytoplasm of some bacteria.

Section 2.3: What kinds of internal structures help to organize bacterial cells?

Bacterial cells contain **cytoskeleton**-like structures that are important for cell shape and division.

- The dynamic **Z-ring**, formed from the tubulin-like FtsZ protein, guides cell division. It is associated with the inner face of the plasma membrane and, as it undergoes depolymerization, causes the membrane to constrict.
- Actin-like proteins, such as MreB, form filaments that control cell shape in many bacteria. A related protein, ParM, ensures that **plasmids** are evenly distributed during cell division.
- Other cytoskeletal proteins may have roles in distribution of chromosomal DNA in bacteria.

Section 2.4: What are the critical structural and functional properties of the bacterial cell envelope?

The **plasma membrane** is a phospholipid bilayer in which many proteins and, in some species, **hopanoids** are embedded. This membrane mediates many critical cellular processes, including nutrient transport, energy metabolism, environmental sensing, and protein secretion.

- Protein channels called **aquaporins** regulate the transit of water across the plasma membrane.
- **Active transport systems**, like the **ABC transporters**, aid in transporting nutrients across the membrane. These molecules may cross the membrane through **symport** or **antiport** mechanisms.
- The plasma membrane contains crucial components of two energy-capturing processes, **cellular respiration** and **photosynthesis**.
- Protein secretion involves a **general secretory pathway** and the presence of **signal peptides** on proteins targeted for secretion.
- The bacterial cell wall, which lies outside the plasma membrane, is composed of a crosslinked network of **peptidoglycan** that determines shape and provides mechanical strength and protection for bacterial cells.
- **Lysozyme**, an enzyme found in human tears and mucus, hydrolyzes specific bonds within the peptidoglycan.
- **Lysostaphin**, an enzyme produced by *Staphylococcus simulans*, affects the peptidoglycan of *Staphylococcus aureus*.
- Antibiotics in the **β-lactam** family also attack peptidoglycan. **β-Lactamases** destroy these antibiotics, providing bacteria with resistance to them.
- There are two major types of **cell envelopes** in bacteria, which can be distinguished by the **Gram stain**.
- **Gram-positive bacteria** have a thick cell wall composed of multiple layers of peptidoglycan, along with **teichoic** and **lipoteichoic acids**. Some Gram-positive bacteria form structurally modified, metabolically inactive cells called **endospores** under stressful conditions.
- **Gram-negative bacteria** have an additional **outer membrane** outside a relatively thin layer of peptidoglycan. The space between the plasma and outer membranes of Gram-negative cells is called the **periplasm**.
- The outer membrane of Gram-negative cells contains **lipopolysaccharide (LPS)** and transport systems such as **porins** and TonB-dependent transporters for nutrient passage. The **type III secretion system** is used to transport some materials across the outer membrane.

Section 2.5: How do structures on the surface of bacterial cells allow for complex interactions with the environment?

Cell surface structures allow bacteria to interact with the environment in many important ways. These structures allow them to move, stick to surfaces, sense the environment, and acquire nutrients.

- **Flagella** are cell surface structures that propel bacterial cells through liquid environments. Bacteria with flagella may be **monotrichous**, **lophotrichous**, or **peritrichous**.
- Bacterial, archaeal, and eukaryal flagella are structurally and evolutionarily distinct.
- **Chemotaxis** is used to direct bacterial motility in response to concentration gradients of attractants and/or repellents and involves **chemoreceptors**. Other forms of taxis also exist.
- Some bacteria utilize non-flagellar-based motility, including pilus-mediated twitching, **gliding motility** across solid surfaces, and actin-based motility inside mammalian host cells.
- Adherence can be mediated by cell surface proteins, **pili**, **stalks**, **fimbriae**, or **sex pili**.
- Some bacterial cells are surrounded by a polysaccharide **capsule**, whereas other cells are surrounded by a less well-defined **slime layer**. The term **glycocalyx** can refer to both capsules and slime layers.
- **Strains** may differ in their ability to adhere.
- Surface adhesion can be the first step in the creation of **biofilms**, or adherent communities of microorganisms.
- Crystalline-like **surface arrays**, or **S-layers**, surround some bacterial cells.

Section 2.6: How are bacteria categorized and named?

The evolution of bacteria over four billion years has resulted in extensive physical, biochemical, physiological, and genetic diversity.

- A regulated system of nomenclature ensures that bacteria are described and named effectively.
- The classification system for bacteria is a hierarchical taxonomic system, in which the basic taxonomic level of **species** refers to groups of strains that share common physical, metabolic, and genetic features. **Taxon** refers to a named grouping within the classification system.
- Phyla within the domain *Bacteria* contain many diverse species that have sequence similarities and may exhibit several common properties.
- Bacterial taxonomy is dynamic, accommodating newly identified taxa and phylogenetic relationships.

Application Questions

1. Under the microscope, a student observes a mixed culture consisting of *Escherichia coli* and *Bacillus anthracis*. Both are bacillus shaped, but one type has formed a long chain of cells while the other type of bacteria is scattered individually across the slide. Explain what might cause these different arrangements.
2. Mammalian cell cultures often are used for experimentation. The cell culture medium typically is supplemented with penicillin to prevent bacterial contamination of the cell line. However, researchers know that this antibiotic will not prevent *Mycoplasma* growth. Explain why penicillin does not protect the culture from *Mycoplasma* contamination.
3. The nucleoid of *E. coli* contains roughly 60 percent DNA, 30 percent RNA, and 10 percent proteins, by weight. Identify the proteins that would be nucleoid associated and explain their functions.
4. In the laboratory, a researcher identified mutant bacteria deficient in the FtsZ protein. Their growth appears filamentous, displaying an incomplete cell division. Explain the role of the FtsZ protein and how a deficiency would account for this altered growth.
5. Researchers analyze an engineered strain of *E. coli* with a non-functional *parM* gene and an *E. coli* strain containing a functional *parM* gene. How might the growth of these two strains differ? Why?
6. Lysozyme is added to certain cheeses as an antibacterial agent. Explain how this enzyme works to destroy certain bacterial contaminants in the cheese and why it does not harm humans.
7. When carrying out the Gram-stain procedure, adding too little or too much alcohol to the sample is a common mistake. Suppose a student added too little alcohol to a sample of Gram-negative bacteria. What would she observe? Why?
8. Some antibacterial drugs interrupt lipid A biosynthesis. What types of bacteria would these drugs affect? Why?
9. Some Gram-negative bacterial cells contain porins and TonB-dependent transporters in their outer membranes. Based on your understanding of each of these structures, explain how their mechanisms of transport differ and why both might be needed in the cell.
10. Imagine a company develops a chemical that inhibits bacterial capsule formation and is non-toxic in humans. Based on your understanding of capsules, explain some medical or commercial applications of this chemical.
11. Suppose researchers want to design an antibacterial compound that will target the bacterial cell surface.
    a. Select a structure on the bacterial cell surface and describe its normal function.
    b. Imagine a compound is engineered that interferes with this surface structure. Describe how the compound would alter the normal function of the structure.
    c. Describe how researchers could test the effectiveness of this compound in the laboratory.
12. *Borrelia burgdorferi* is a motile bacterium that causes Lyme disease. To study the chemotaxis of *B. burgdorferi*, researchers added an attractant to one end of a capillary tube and bacteria to the opposite end of the tube (capillary tube assay). The concentration of bacteria that entered the capillary tube toward the attractant was then measured.
    a. What is an attractant and what effect does it have on the flagella and movement of bacteria?
    b. Several mutant *B. burgdorferi* strains were generated that were deficient in different chemotaxis-regulating genes. How do you think the chemotaxis responses of these mutants compared to the chemotaxis response of the non-mutant strain?
    c. The LC-A2 strain is deficient in a certain chemotaxis protein known as CheA2. Based on these results, what conclusion can be drawn about this chemotaxis protein?

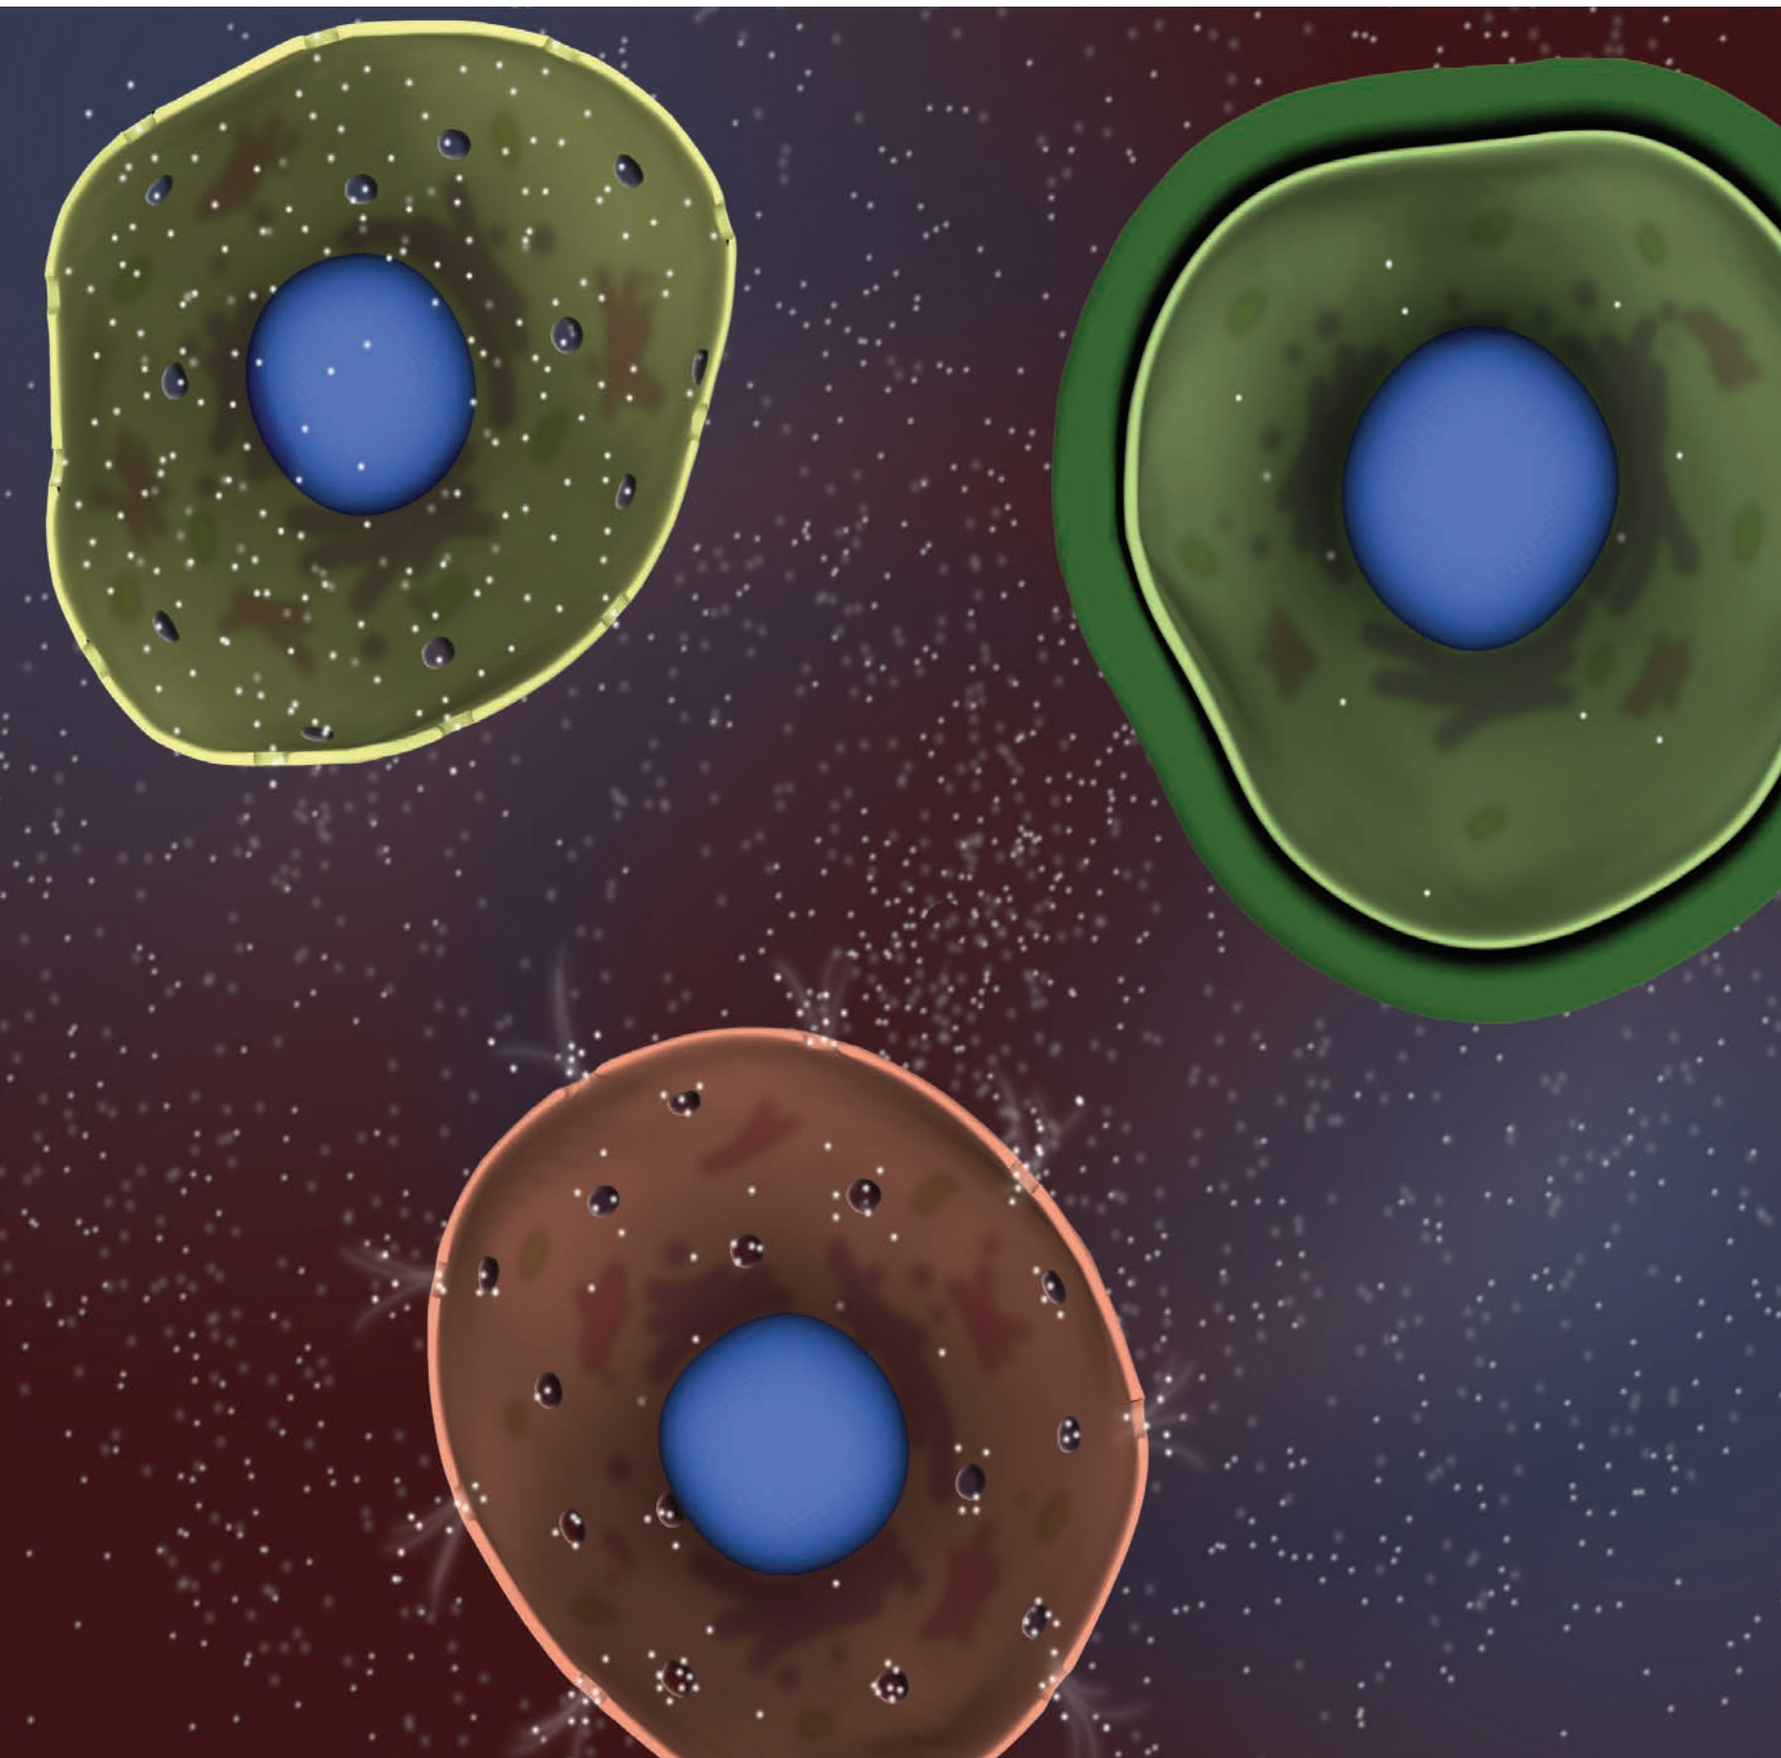
CHAPTER 3

Eukaryal Microorganisms



The Rio Tinto ("Red River") in Spain hovers at a pH of 1.7 to 2.5 because of an abundance of acidic iron compounds and other heavy metals that are typically toxic to cells. So, it might seem safe to conclude that this harsh environment would be virtually devoid of life. Or, if you remember the discussion in Chapter 2 about the relatively durable cell wall of bacteria, you might think that any life-forms found would be bacterial cells. What scientists discovered in the Rio Tinto, however, was a wide variety of eukaryal microorganisms, including protozoa, fungi, and algae. This diversity was observed using a combination of molecular, microscopic, and culture techniques. From water and biofilm samples, they isolated and sequenced DNA, observed the samples under the microscope, and cultured samples in the laboratory.

These findings raise many questions that we can start to address in this chapter. What kinds of eukaryal microorganisms exist in the world? How do they vary in cell structure and function? How are they related to each other? Considering the diversity observed in the Rio Tinto, can we make predictions about how that microbial ecosystem operates? Algae, such as the *Chlamydomonas* found in the Rio Tinto, typically are the primary producers of a community. They contain chloroplasts that allow them to bring energy into the system via photosynthesis and to bring organic carbon into the system via carbon fixation. Fungi and protozoa typically are heterotrophic. In other words, they act as consumers or decomposers. Fungi, for instance, often decompose organic matter and recycle it back into the community. In the case of the Rio Tinto, the fungi serve another notable role of sequestering the toxic heavy metals, thereby protecting more sensitive cell types.

How do the microbes of the Rio Tinto withstand acidic conditions? Three possibilities seem possible. First, the cells could let the hydrogen ions flow in and, as a result, have a reduced intracellular pH (most cells maintain a cytosolic, or intracellular, pH close to 7). Second, they could erect a barrier against hydrogen ions. Third, they could actively defend themselves against the influx of hydrogen ions. Resolution of this question would require further research.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements in the text and online:

Eukaryal cells share many characteristics but also exhibit great diversity.

Introduction

This chapter introduces another domain of life: *Eukarya*. Historically, eukaryal microorganisms have been underappreciated because of our limited understanding of their remarkable diversity and their evolutionary relationships. Today, however, scientists are particularly interested in defining the spectrum of their diversity. How many different types of eukaryal microorganisms are there? What unique structural and functional properties define them? How did such diversity evolve? Where are they found? What roles do they play in our world? The opening story about the discovery of eukaryal microorganisms in the Rio Tinto exemplifies this area of research by raising questions, not only about eukaryal microbial diversity, but also the relationship between cell structure and function. In this chapter, we will provide an overview of this exciting and important group of microorganisms by describing some of its members, their activities, and their relationships to each other. Along the way we will focus on several questions:

What do eukaryal cells look like? (3.1)
What are the different types of eukaryal microorganisms? (3.2)
How do eukaryal microorganisms replicate? (3.3)
How did eukaryal microorganisms originate? (3.4)
What harmful and beneficial roles do eukaryal microorganisms play? (3.5)

3.1 The morphology of typical eukaryal cells

What do eukaryal cells look like?

Before examining the morphology of eukaryal microorganisms, let's address a more fundamental question: What are eukaryal cells? Members of the domain ***Eukarya*** are defined by the presence of a membrane-bound nucleus. The term "eukaryote," in fact, means "true nucleus." Thus, while the chromosome of bacteria and archaea exists within a nucleoid region, only eukarya possess true nuclei in which chromosomes are packaged in a membrane-bound compartment that forces a spatial and temporal separation of transcription and translation. Eukaryal cells typically are larger than bacterial and archaeal cells and contain other intracellular compartments, or **organelles** (Figure 3.1).

Within these organelles, eukarya compartmentalize different biochemical activities that in turn have important implications for cellular processes (Table 3.1). The entire cell is surrounded by a plasma membrane and, in some cases, a cell wall. Finally, a complex cytoskeleton provides both structure and flexibility to eukaryal cells. In this section, we will examine these various structures. More importantly, we will investigate specific functions that eukaryal cells perform and examine which cell structures accomplish those functions and in what ways structure and function are linked.

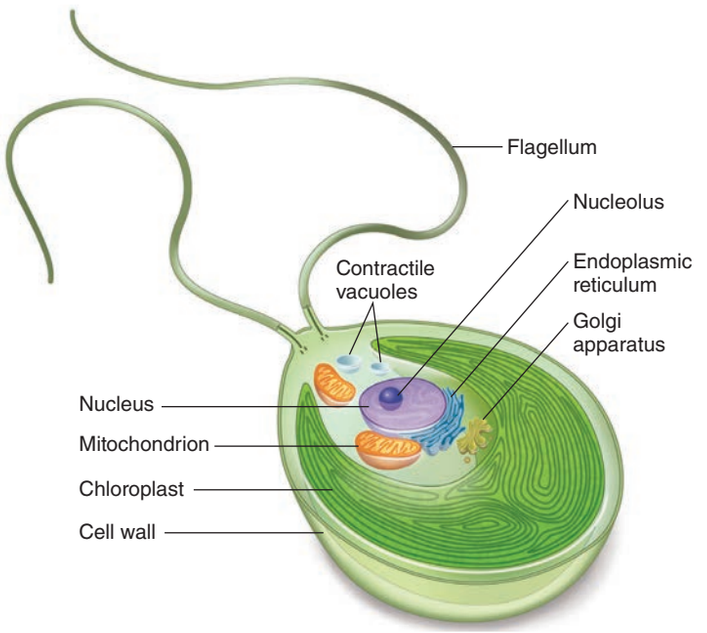

Figure 3.1. Organelles The algae *Chlamydomonas* displays general eukaryal cell structures, including a nucleus, Golgi apparatus, and mitochondria. You might conclude that *Chlamydomonas* is a photosynthetic cell because it has a chloroplast and that it is motile because it has two flagella.

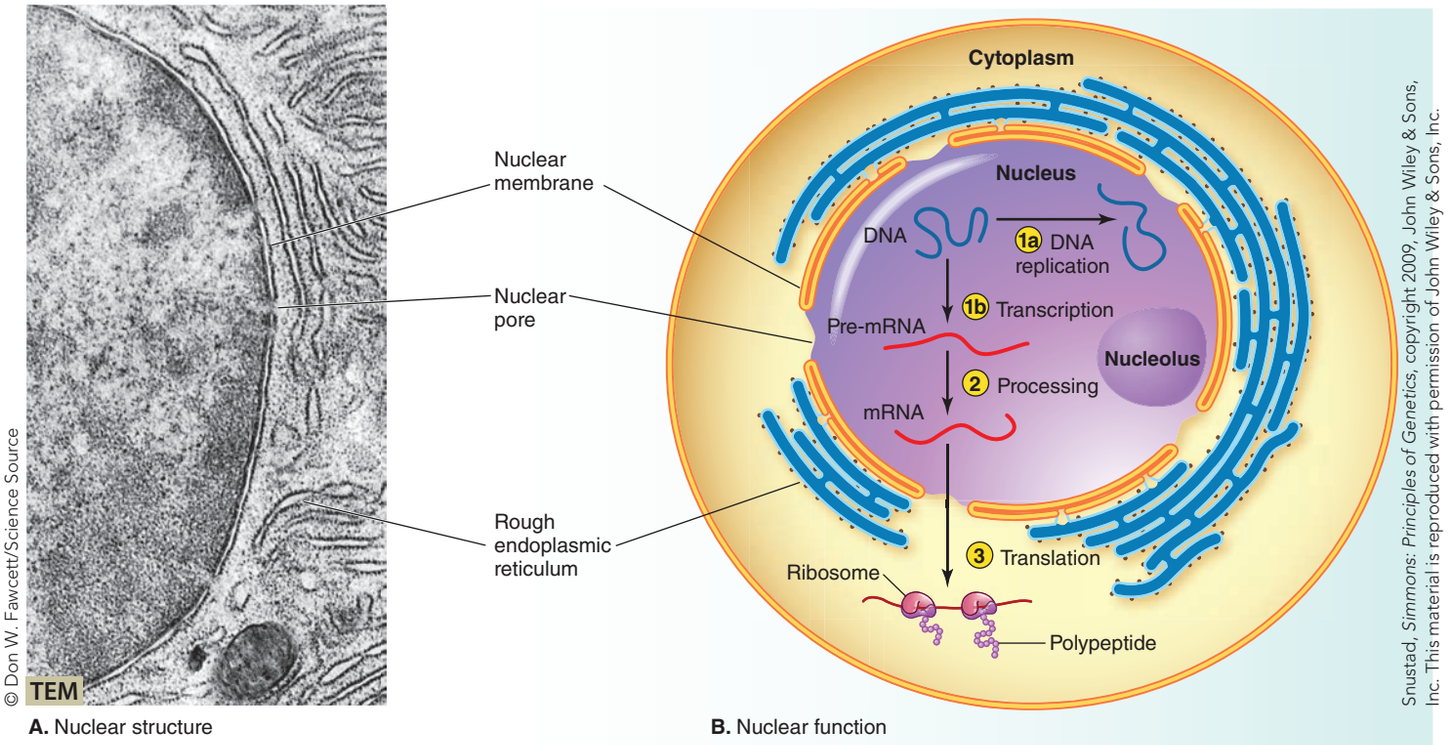
The nucleus: A role in the storage and expression of information

The **nucleus** is the defining organelle of eukaryal cells (Figure 3.2A). Surrounded by a double phospholipid bilayer (the nuclear membrane), it contains the genomic content of the cells with DNA packaged into linear chromosomes. Additionally, the nucleolus, a non-membrane-bound structure, exists within the nucleus. Ribosome synthesis begins here. In bacterial and archaeal cells, the genomic DNA sits within the cytoplasm. Thus, the processes of transcription and translation (the production of mRNA and proteins, respectively) can occur at the same time. In other words, as the information from a gene is being transcribed into mRNA, that same strand of mRNA can be translated into protein by ribosomes. In contrast, the genomic DNA of eukaryal cells is contained within the nucleus. Thus, the process of transcription occurs first within the nucleus, and the completed mRNA strand must be exported through nuclear pores into the cytoplasm before translation can occur (Figure 3.2B). Once mRNA molecules enter the cytoplasm, translation is initiated.

TABLE 3.1 Selected internal organelles of *Eukarya*

Organelle	Main function	Interesting features
Nucleus	Contains most of cell's DNA, site of transcription	Double membrane containing pores Outer membrane continuous with endoplasmic reticulum Contains DNA
Mitochondrion	Energy production	Double membrane Contains DNA Independent replication Not present in amitochondriates
Chloroplast	Photosynthesis	Double membrane Contains DNA Independent replication Unique to photosynthetic organisms
Rough endoplasmic reticulum (ER)	Site of translation and protein folding	Rough ER has protein-synthesizing ribosomes attached to it
Golgi apparatus	Modifies, sorts, and transports proteins	Connected to the ER through a series of vesicles
Vacuole	Storage and structure	Food vacuoles serve as sites of digestion Contractile vacuoles help maintain water balance
Lysosome	Digestion of macromolecules	Contains digestive enzymes
Peroxisome	Breakdown of fatty acids	Contains various oxidative enzymes, like catalase and oxidase
Hydrogenosome	Production of H_2 and ATP	Double membrane Found in some amitochondriates May be remnant of mitochondrion



A. Nuclear structure **B.** Nuclear function

Figure 3.2. Process Diagram: The nucleus **A.** Note the nuclear membrane, the nuclear pores, and the surrounding rough endoplasmic reticulum. **B.** DNA replication and transcription occur within the nucleus. Following transcription, mRNA leaves the nucleus through the nuclear pores. Translation occurs in the cytoplasm. Ribosome synthesis begins in the nucleolus.

CONNECTIONS In eukarya, each mRNA generally results in the production of one polypeptide. In bacteria, however, several different polypeptides can be translated from a single mRNA. We will explore this fundamental difference in **Section 7.4**.

The secretory pathway: A role in protein trafficking

Newly made proteins in eukarya have a wide array of possible destinations: the cytoplasm, various organelles, or destinations outside of the cell. As with bacterial proteins, destination is dictated by signal sequences contained in the amino acid code within individual proteins. One key difference between the trafficking of proteins in eukarya and bacteria is that with so many different destinations, a much larger set of signal sequences is needed (Table 3.2). Many times, multiple signals will distinguish a precise destination within an organelle. Some proteins, for instance, may be targeted to the lumen of the mitochondrion, while other proteins may be targeted specifically to the inner membrane, the intermembrane space, or the outer membrane of the mitochondrion. Typically, signal sequences are removed by specific cellular proteases once the protein has reached its destination. Removal of signal sequences can be detected in the laboratory by observing size differences between the larger pre-proteins and the smaller mature proteins.

To examine this trafficking process in more detail, let's follow one important subset of proteins: those proteins that will enter into the **secretory pathway**, a series of organelles consisting of the rough **endoplasmic reticulum (ER)** and the **Golgi apparatus** that are connected via vesicles and tubules (Figure 3.3). The "rough" appearance of the rough ER results from ribosomes that stud the surface of this structure. As translation occurs, proteins leave these ribosomes and enter the rough ER. These proteins eventually may be secreted from the cell at the plasma membrane (see Step 5, Figure 3.3B) or become embedded in the plasma membrane or membranes of organelles. A signal peptide, located at the N-terminus of the protein, directs it to the secretory pathway.

This N-terminal signal peptide directs the ribosomes translating these proteins to the surface of the rough ER and then further directs the protein to be transported into the lumen (inside) of the rough ER. At this stage, the signal peptide usually is removed from the protein. Additional signals then determine whether proteins should remain within one of the organelles of the secretory system. At this stage, proteins often proceed to the Golgi apparatus. Here, the proteins may be modified or packaged before being shipped to their final destination. Proteins transported to the plasma membrane may be secreted from the cell, a process known as exocytosis, or remain associated with the membrane. As shown in Figure 3.3B, eukaryal cells also contain another structure, the smooth endoplasmic reticulum. The function of the smooth ER differs in various cell types, but most typically is involved in lipid and carbohydrate synthesis. As we showed with the rough ER, vesicles can move between the smooth ER and the Golgi apparatus. Unlike the rough ER, however, the surface of the smooth ER is not studded with ribosomes.

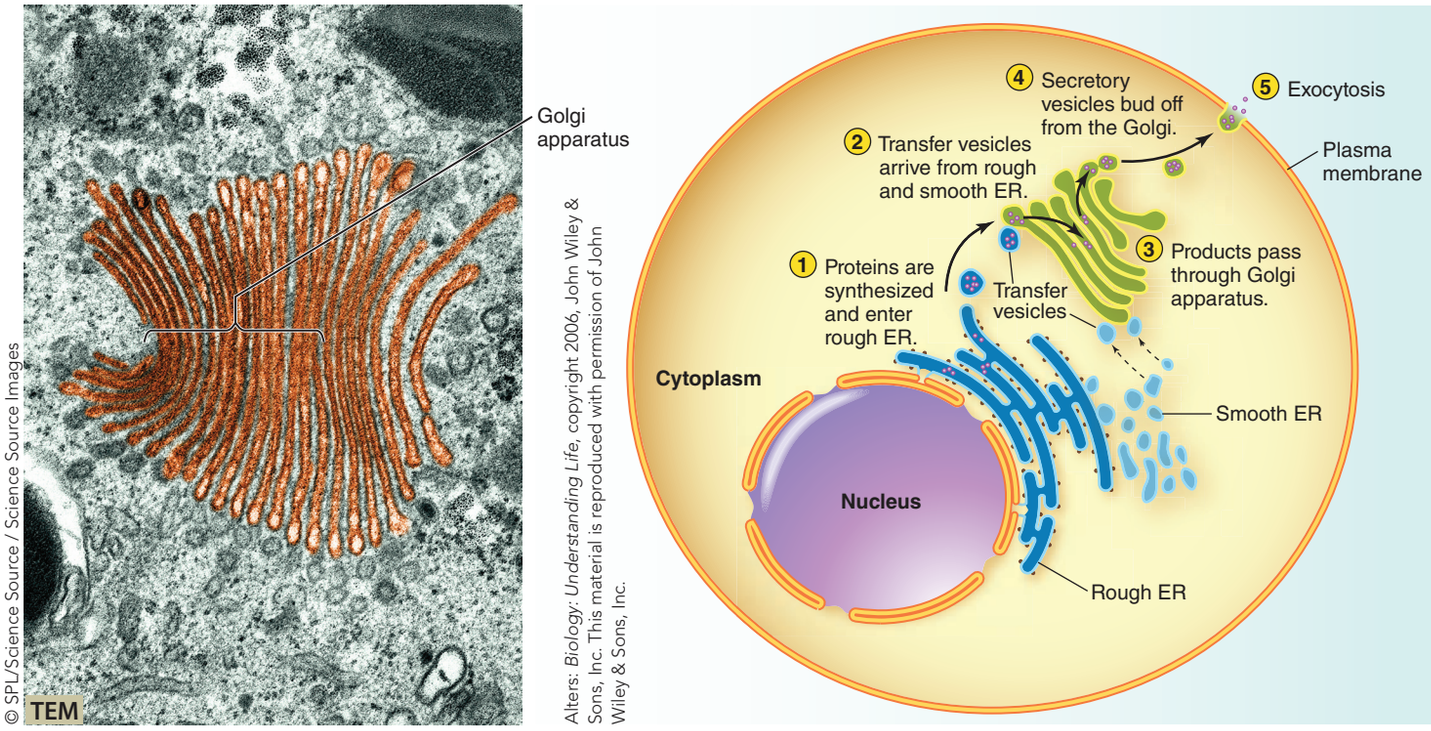
One characteristic of protein secretion within eukaryal cells is the extensive modification that proteins undergo post-translationally. Following translation, a protein folds into a complex structure. For secreted proteins, this folding takes place in the lumen of the endoplasmic reticulum and involves the assistance of chaperone proteins. These molecular chaperones transiently interact with growing proteins and assist in the folding process. The folding involves the formation of hydrogen bonds and, in some cases, disulfide bridges. The proteins also are modified by the addition of sugars, lipids, and/or other functional groups, such as acetyl or phosphate groups, as the proteins pass through the rough ER and Golgi apparatus. These functional groups affect the overall activity of the protein. Most fully mature proteins are abundantly decorated with a thick and diverse array of these chemical additions.

TABLE 3.2 Protein trafficking and signal sequences

Organelle	Purpose of signal	Signal properties	Sample signal sequence[a]
Nucleus	Import into nucleus (nuclear localization signal or NLS)	Internal sequence. One or two short series of lysine (K) and arginine (R)	KKKRK
	Export from nucleus (nuclear export signal or NES)	Internal sequence enriched in leucine (L)	$LX_{1\text{-}3}\ LX_{2\text{-}3}\ LXL$[b]
Rough endoplasmic reticulum	Import into rough ER binding by signal recognition particle or SRP	5–10 hydrophobic amino acids at N-terminus	H_2N-MSFVFLLLVGILFWAGA
	Retention in rough ER	4 amino acids at C-terminus	KDEL
Mitochondria	Import of nuclear-encoded proteins into the mitochondria	Enriched in lysine (K), arginine (R), histidine (H) Cleavage site for removal of signal sequence	RSIYHSHHPT RKLKFSPIKY RX(F/L/I)XX(G/S/T)XXXX

[a]Letters in the signal sequence refer to the single-letter amino acid codes. There are typically other variations not shown here. Sequences can vary both within a species and between species.

[b]The letter X in a sequence refers to any amino acid. H_2N: N-terminus of protein. COOH: C-terminus of protein.



A. Golgi apparatus structure

B. Endoplasmic reticulum and Golgi apparatus function

Figure 3.3. Process Diagram: The protein secretory pathway **A.** The endoplasmic reticulum and Golgi apparatus are a series of distinct membrane-bound compartments. Products can be shuttled between these compartments via vesicles and tubules. **B.** Proteins destined to be secreted from the cell pass through the rough ER and Golgi apparatus via transfer vesicles. Secretory vesicles filled with these proteins bud off of the Golgi apparatus and fuse with the plasma membrane, secreting their contents into the extracellular space, a process known as exocytosis. Products from the smooth ER also can be transferred to the Golgi apparatus via transfer vesicles.

CONNECTIONS Molecular chaperones are present in all domains of life. High temperatures typically cause proteins to unfold. In **Section 4.3**, we will explore how these molecular chaperones may be utilized by archaea that live at high temperatures to maintain the integrity of their proteins.

The mitochondria and chloroplasts: A role in cell metabolism

Eukarya compartmentalize energetic processes within the **mitochondrion** (*pl.* mitochondria) and **chloroplast** (Figure 3.4). The key to ATP synthesis in both cellular respiration and photosynthesis is the passage of electrons along an electron transport chain and the use of energy released during this passage to generate a proton gradient that, in turn, drives the synthesis of ATP. This process, known as **chemiosmosis**, requires a membrane barrier for the creation of the proton gradient. Thus, mitochondria and chloroplasts contain inner membranes that maximize surface area and facilitate energy production.

Mitochondria maximize the amount of energy that cells can derive from the breakdown of organic molecules. This process of cellular respiration is the means by which heterotrophs acquire both energy and building blocks for cellular activities (see Section 2.4). To generate a proton gradient, electrons move along a series of electron transport proteins that are embedded within the mitochondrial inner membrane. As the electrons move from protein to protein, protons (H^+) are moved across this membrane, into the intermembrane space. The proton gradient then forms in the space between the inner and outer membranes. As the protons flow down the resulting concentration gradient, through a protein known as ATP synthase, inorganic phosphate is added to ADP, forming ATP (see Figure 3.4B).

Chloroplasts convert solar energy into cellular energy and reducing power that can drive the fixation of carbon dioxide into organic molecules by the process known as photosynthesis. In chloroplasts, the proton gradient forms within the thylakoids, internal membrane-bound structures. Electron transport chain proteins are embedded within the thylakoid membrane, and protons are transported into the interior, or lumen, of the thylakoid. As protons flow down their concentration gradient, again through ATP synthase, ATP is generated (see Figure 3.4D). Please remember that although bacteria and archaea do not possess mitochondria or chloroplasts, they still perform almost identical metabolic processes by simply substituting the plasma membrane for the organelle membrane.

The early steps of cellular respiration occur in the cytoplasm of eukaryal cells. The later steps, which are more energetically favorable, occur in the mitochondria. The tricarboxylic acid (TCA) cycle takes place within the matrix (the innermost area) of the mitochondria, while the conversion of

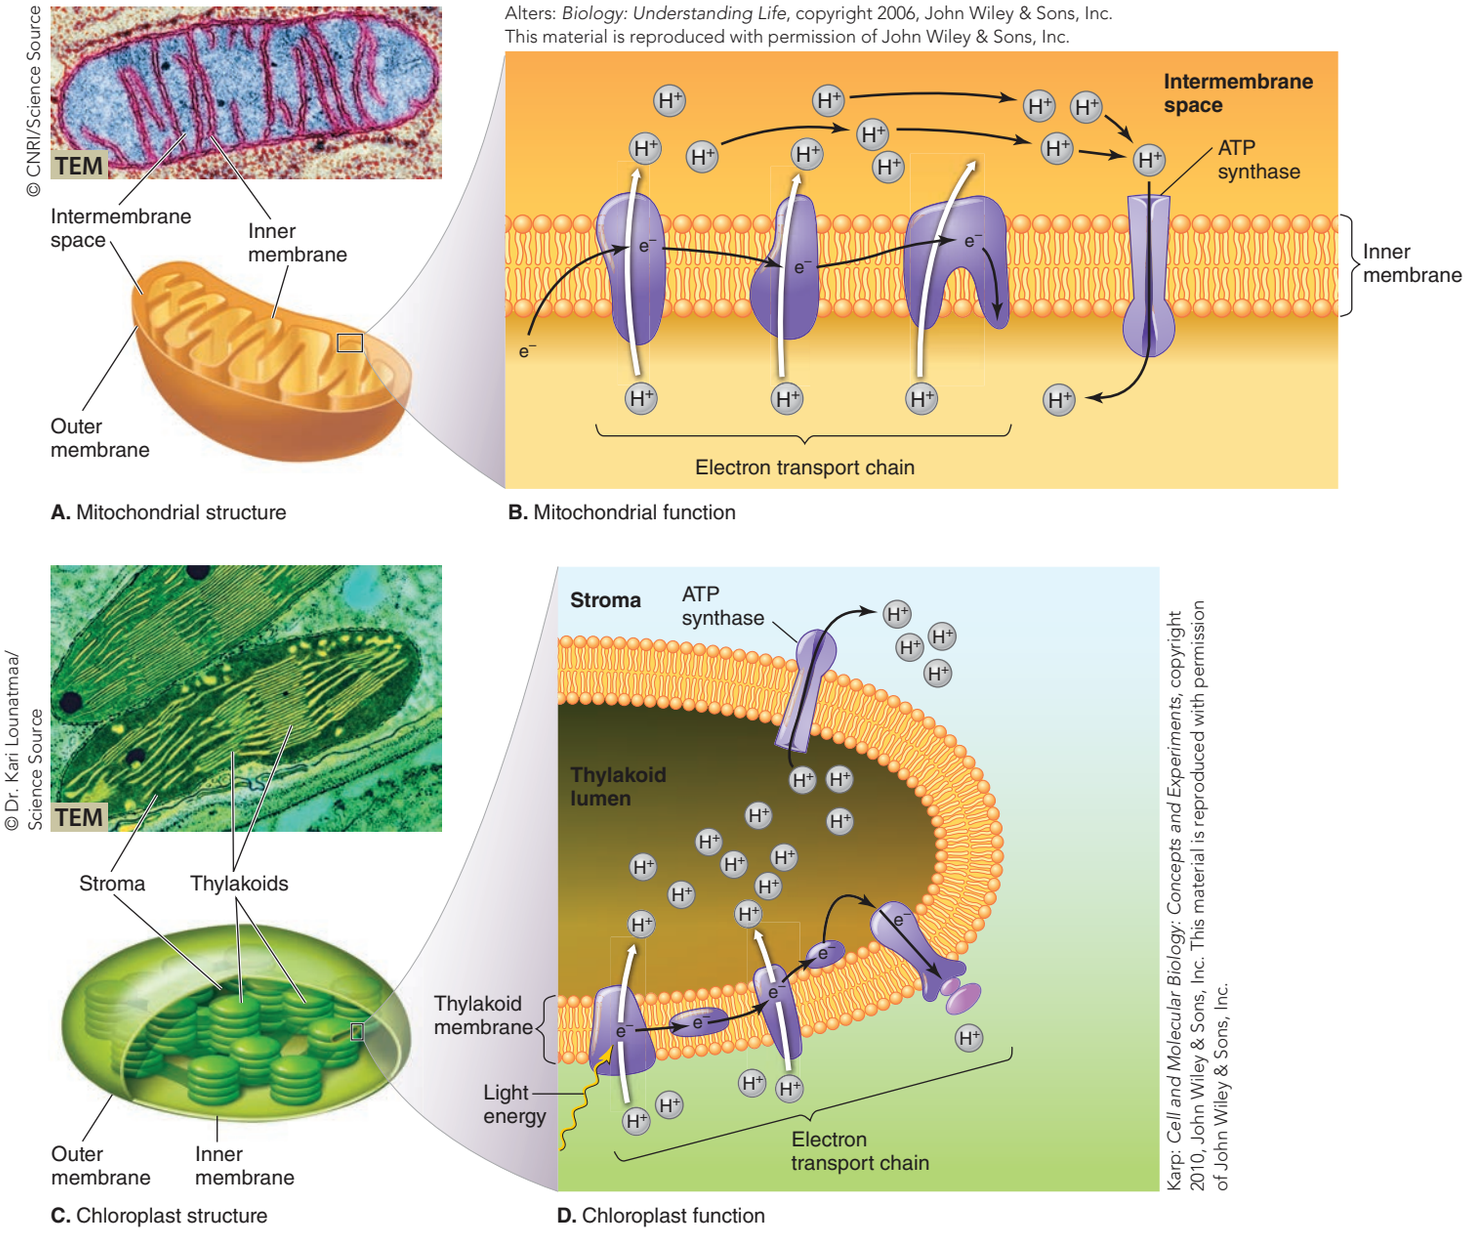


Figure 3.4. Mitochondria and chloroplasts **A.** The extensive, deeply involuted, inner membrane increases surface area. **B.** Electrons move along the electron transport chain proteins embedded in the inner membrane and help to transport protons into the intermembrane space. As these protons flow back across the inner membrane, through ATP synthase, ATP is generated. **C.** Chloroplasts contain outer and inner membranes and a series of internal membrane-bound structures known as thylakoids. **D.** Harnessing energy from sunlight, electrons move along electron transport chain proteins embedded in the thylakoid membranes and help to transport protons into the interior, or lumen, of the thylakoids. ATP is generated in the stroma, as protons flow out of the thylakoids, through ATP synthase.

the reducing power stored in the form of NADH and $FADH_2$ is converted to ATP through the process of chemiosmosis across the inner membrane. Cells have different numbers of mitochondria, and their abundance is typically linked to the energetic needs of the cell. Some intracellular pathogens will gather the mitochondria of the host cell around themselves to gain first access to the cell's ATP production.

Some eukaryal microorganisms do not possess mitochondria. The evolutionary history of these organisms, termed **amitochondriates**, is discussed in more detail in Section 3.4. Some of these cells appear to have simply lost mitochondria they once possessed (perhaps through adaptation to an anaerobic lifestyle) and survive on glycolysis, whereas others possess novel organelles such as the glycosome and hydrogenosome. These organelles share a common purpose in helping these anaerobic cells derive the most energy possible without chemiosmosis.

Mitochondria and chloroplasts are semi-autonomous organelles. They contain some DNA that codes for certain organelle proteins and have transcription and translation machinery for these genes. They also can replicate independently of the host cell. This feature enables the cell to rapidly regulate the number of mitochondria in a cell in response to

cell needs. However, most proteins required by mitochondria and chloroplasts are coded for in the nucleus, synthesized on ribosomes free in the cytoplasm, targeted to the organelles by specific signal sequences, and then imported after translation.

The plasma membrane: A role in homeostasis

A key premise of cell function is homeostasis—the ability of cells to maintain an internal equilibrium despite a changing external environment. The **plasma membrane** contributes to homeostasis by separating the environment within compartments from that on the outside and also regulating the passage of molecules. For the organisms living in the Rio Tinto, these basic functions must occur at a very low pH.

CONNECTIONS In **Section 2.4**, we examined the structure of the bacterial plasma membrane. As we noted in that section, bacteria possess several distinct mechanisms for transporting molecules across this membrane.

Proteins can be embedded in (integral membrane proteins) or affixed to (peripheral membrane proteins) the plasma membrane (see Figure 2.9). You can think of the proteins floating in a sea of phospholipids—an analogy that captures the essence of the official language used to refer to membranes as a **fluid mosaic model**. Because the hydrophobic core of the phospholipid bilayer does not allow large polar or charged molecules to cross it, transmembrane proteins are essential to the transport of these molecules into and out of cells. These transmembrane proteins typically function with great specificity, generally transporting only a single class of molecules. They can act as simple tunnels through which molecules move down a chemical gradient by a process known as facilitated diffusion. Alternatively, the proteins may expend energy to move molecules against a gradient through a process known as active transport.

Historically, cell biologists assumed that the distribution of various types of phospholipids within the cell membrane was relatively random. If these molecules could move freely within the membrane, then their distribution should not be organized. It now seems clear, however, that localized pockets of specific lipids, referred to as **lipid rafts**, exist within the membrane. Moreover, specific proteins appear to localize to these lipid rafts. Recent evidence suggests that these lipid microdomains play important roles in protein movement, cell signaling, and the entry and exit of some viruses from cells (Mini-Paper).

As we saw in Chapter 2, bacteria also contain membranes that separate inside from outside. Important differences in the structures of plasma membranes found in bacteria, archaea (as we will see in Chapter 4), and eukarya exist, however, and these structural differences affect the strength and flexibility of the membranes (Table 3.3). Comparisons of membrane characteristics in various organisms have led researchers to hypothesize that membranes may have a complicated evolutionary history. Eukarya and bacteria, for instance, both have phospholipids as the dominant membrane lipid with ester linkages between the glycerol molecule in the head group and straight-chain fatty acid tails. Archaea, in contrast, have a wide array of different membrane lipids. Additionally, eukaryal membranes contain sterols (e.g., cholesterol) and have a low protein content. The membranes of bacteria and archaea, on the other hand, lack sterols and have a high protein content. The geometry of the fatty acid chains and the abundance of sterols and proteins all help to dictate the fluidity of the membrane by affecting packing of molecules. Thus, branched and unsaturated fatty acid chains make membranes more fluid. Sterols and proteins, conversely, typically make membranes less fluid. The membrane composition often changes in response to changing environmental conditions. At low temperatures, some cells alter the fatty acid profile to increase unsaturated fatty acids and maintain fluidity. Other molecules, such as sterols, behave differently at different temperatures and can increase membrane fluidity as the temperature drops.

TABLE 3.3 Comparison of plasma membranes in *Bacteria*, *Archaea*, and *Eukarya*

Characteristic	Function	*Bacteria*	*Archaea*	*Eukarya*
Membrane structure	Membrane assembly Hydrophilic surface Hydrophobic core	Phospholipid bilayer	Bilayer or monolayer Diverse lipid composition (sulfo⁻, glyco⁻, isoprenoid)	Phospholipid bilayer
Lipid structure	Membrane fluidity	Ester linkage Straight fatty acid chains[a]	Ether linkage Branched isoprenoid chains[a]	Ester linkage Straight fatty acid chains[a]
Sterols	Membrane stability	No[b]	No	Yes
Proteins	Structural	High abundance	High abundance	Low abundance

[a]This designation refers to whether the main backbone of the fatty acid chain is straight or branched. It does not specify whether the fatty acids are saturated or unsaturated. Both branched and unbranched fatty acids can be saturated or unsaturated.

[b]A few bacteria have sterol-like compounds for membrane stability: cyanobacteria have hopanoids and mycobacteria (a group of wall-less bacteria) integrate sterols from host cell membranes.

Mini-Paper: A Focus on the Research

LIPID RAFTS: ORGANIZED CLUSTERING OF LIPIDS WITHIN A MEMBRANE

P. A. Scheiffele, A. Rietveld, T. Wilk, and K. Simons. 1999. Influenza viruses select ordered lipid domains during budding from the plasma membrane. J. Biol. Chem. 274:2038–2044.

Context

With the initial description of the fluid mosaic model of the cell membrane by Singer and Nicolson in 1972, it became easy to envision the lipid component of the cell membrane as a relatively uniform "sea" in which proteins were floating. The lipids, one could imagine, served only to house the proteins. However, experiments showed that certain regions of the membrane are resistant to detergent extraction; they are detergent insoluble. These regions are rich in cholesterols and sphingolipids, harboring high concentrations of membrane proteins. As we have seen, these regions were called "rafts" and appeared to be involved in specific functions associated with the membrane, such as the detection and transduction of signals. Other studies demonstrated that the lipid composition of some enveloped viruses (those surrounded by a membrane derived from the host cell; see Section 5.1) differs from the overall lipid composition of the host cell's plasma membrane. This finding suggests that the viral budding might occur preferentially at sites with different lipid composition, such as the lipid rafts. This paper presents a series of experiments in which three different kinds of viruses were compared to see whether they incorporated lipid rafts in their membranes.

Experiments

The three viruses used in this study were fowl plague virus (FPV), vesicular stomatitis virus (VSV), and Semliki Forest virus (SFV). All three viruses were propagated in baby hamster kidney (BHK) cells. The envelope of each of these viruses is derived from the host cell plasma membrane as the virus leaves the cell by budding, and also contains the virus glycoproteins. In the first set of experiments, researchers attempted to determine if lipid raft-derived material is found in the envelope of these viruses. Viruses produced after infection of the BHK cells were isolated, and proteins were extracted from the envelope using detergent. Although the VSV and SFV glycoproteins were solubilized easily by the detergent, the FPV glycoproteins were not soluble. The presence of the FPV glycoproteins in these detergent-insoluble complexes (called detergent-insoluble glycolipid-enriched complexes, or DIGs, in the paper) suggested that the FPV envelope was derived from detergent-insoluble lipid rafts, whereas the envelopes of the other two viruses were derived from non-lipid raft regions of the host cell plasma membrane.

Next, the solubility of cholesterol, which is known to be enriched in detergent-insoluble complexes of cellular membranes, was measured in the different viral envelopes. This experiment required that the BHK cells first were labeled with radioactive cholesterol, thereby making tracking easier. Viruses were produced using those labeled cells, and the solubility of the cholesterol in the resulting viruses was determined by tracking the radioactivity. The results **(Figure B3.1)** clearly show that the FPV cholesterol was much more insoluble in detergent than was the VSV and SFV cholesterol.

To examine the lipids present in the envelopes, the BHK host cells were incubated with radioactive phosphate before the virus was produced, resulting in labeling of the membrane lipids that could be separated by thin-layer chromatography. As shown in **Figure B3.2**, the sphingomyelin lipid (SM) that is known to be associated with lipid rafts was found to be mostly in the detergent-insoluble fraction of the FPV (in pellet, P), while mostly in the detergent-soluble fraction (in supernatant, S) of the VSV and SFV viral particles.

Other lipids that were measured, phosphatidylethanolamine (PE) and phosphatidylcholine (PC), were distributed between the soluble and insoluble fractions in a manner roughly similar to their distribution in the membranes of the BHK host cells. It was further shown that removal of cholesterol from the membranes using cyclodextrin resulted in improved solubility of the SM in the FPV envelope. The

One final point worth noting is that the swimming appendages of eukaryal cells, the **cilia** and flagella, are encased within the phospholipid bilayer of the plasma membrane. In bacteria and archaea, the flagella protrude through the plasma membrane. As we will see later in this chapter, the swimming appendages of eukaryal microorganisms differ in several ways from their archaeal and bacterial counterparts.

The cell wall: A role in cell support

Cellular support can be provided either by an external casing (cell wall) or by an internal scaffold (cytoskeleton), and the choice of which a cell uses has a large impact on the cell's life cycle. Thus, eukarya fall into two broad categories: those with cell walls and those without cell walls. As always, these simplified categories obscure important details. The term **cell wall** refers to a semi-rigid structure at the cell periphery that holds the cell in a certain shape, limits cellular access to chemical compounds, and protects it from environmental pressures (osmotic stress as well as physical stresses). A wide array of chemical structures can form a wall, and a fascinating diversity exists within eukarya **(Table 3.4)**. Microscopy and molecular biology techniques can be combined to give us a richer understanding of these structures and their roles in the dynamic life of a cell **(Toolbox 3.1)**.

All algae have cell walls, which are composed predominantly of **cellulose**, like the cell walls of their plant relatives. Cellulose is a linear carbohydrate polymer (polysaccharide) in which glucose molecules are linked via β-1,4-glycosidic bonds **(Figure 3.5)**. Individual cellulose chains are crosslinked by

Figure B3.2. Distribution of specific lipids in viral envelopes and host cell membrane Cells were incubated with radioactive phosphate, which would result in labeling of the membrane lipids. Viruses were produced in these labeled cells and isolated. Lipids from the viruses and host cells then were separated into detergent-insoluble (in pellet, P) and detergent-soluble (in supernatant, S) fractions and analyzed. The lipids phosphatidylethanolamine (PE) and phosphatidylcholine (PC) are found in the same fractions in BHK cell membranes and the viral envelopes. The lipid sphingomyelin (SM) is found primarily in the supernantant fraction of BHK cells, VSV, and SFV, but in the pellet fraction of FPV.

overall conclusion was that cholesterol is involved in the formation of the detergent-insoluble lipid rafts and the association of the proteins with them. Influenza viruses such as FPV select the lipid rafts during budding.

Impact

This study was a very good demonstration of the use of viruses to examine membrane structure. Clearly, viruses differ in the extent of their association with lipid rafts during budding. These differences were used to emphasize that such lipid rafts, as determined by detergent insolubility, are genuine features of cell membranes. The lipid rafts depend on cholesterol for their insolubility. It is now recognized that many intracellular bacterial and viral pathogens invade host cells via lipid rafts, making them potentially important host virulence factors.

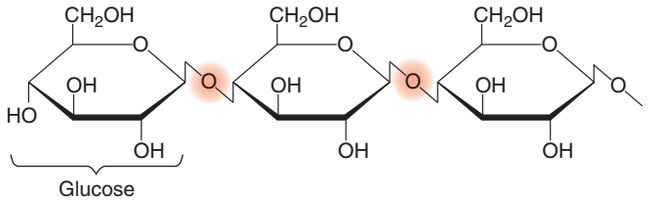
Questions for Discussion

1. If lipid rafts make host cells susceptible to infection by intracellular pathogens, why do you think they are present in these cells?
2. Different viruses appear to have different affinities for lipid rafts during budding. What might account for these differences?

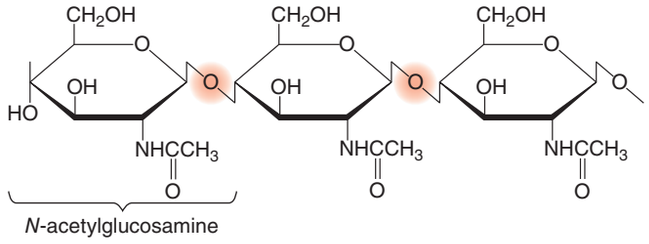
TABLE 3.4 Comparison of cell walls in *Bacteria*, *Archaea*, and *Eukarya*

	Bacteria		*Archaea*	*Eukarya*		
	Gram-positive	**Gram-negative**		**Fungi**	**Algae**	**Protozoa**
Basic structural components	Thick peptidoglycan[a] layer (~40 nm) comprises 40–80% of cell wall dry weight	Thin peptidoglycan[a] layer (~2 nm) comprises 5% of cell wall dry weight	Varied Methanogens: glycopeptides or pseudopeptidoglycan	Chitin	Cellulose[b]	None[c]
	Surface of peptidoglycan layer decorated by teichoic acid	Outer membrane has phospholipid inner leaflet and lipopolysaccharide outer leaflet	Halogens and Hyperthermophilic: glycopeptides			

[a]The precise chemical structure of peptidoglycan varies between species.
[b]Diatoms have cell walls, called "frustules," which are made of silicon dioxide, proteins, and polysaccharides.
[c]Glycoproteins may be assembled into a cell wall during particular developmental stages to produce cysts or spores.



A. Chemical structure of cellulose



B. Chemical structure of chitin

Figure 3.5. Eukaryal cell walls: Contrasting chemical compositions and structures **A.** In cellulose, glucose monomers are linked by β-1,4-glycosidic bonds. **B.** In chitin, *N*-acetylglucosamine monomers are linked by β-1,4-glycosidic bonds. In both molecules, the β-1,4-glycosidic bonds are highlighted.

hydrogen bonds to increase their tensile strength. One exception to this general rule are the diatoms, which have cell walls made of a silicon compound. Researchers hypothesize that this silicon compound may be an energy-efficient alternative to cellulose because silica bonds are weaker and require less energy to assemble into polymers.

Most fungi also have cell walls, but their cell walls are usually made of chitin, the same compound found in the exoskeleton of insects (see Figure 3.5). Like cellulose, chitin is a polysaccharide, with sugar monomers again linked via β-1, 4-glycosidic bonds. Unlike cellulose, the monomer building blocks of chitin are *N*-acetylglucosamine. This molecule contains a modified glucose molecule in which an acetylamino group (—NH—CO—CH_3) replaces a hydroxyl group (—OH). Again, linear chains of chitin are crosslinked to one another with hydrogen bonds, but the acetylamino groups permit more hydrogen bonds. Thus, chitin is a stronger polymer than cellulose. Glucosamine may be familiar to you in a different guise: it is a compound your body makes to stimulate the formation of cartilage and is commonly taken as a dietary supplement by people with arthritis.

Although protozoa generally lack cell walls (a feature commonly used to distinguish members of this group), some protozoa have cell walls at certain points in their cell cycle. *Giardia, Cryptosporidium*, and *Entamoeba* are three pathogenic protozoa that have two different life-cycle stages: the trophozoite (*Giardia* and *Cryptosporidium*) and amoeba (*Entamoeba*) stages in which the parasites cause disease within the intestinal tract of hosts, and the cyst stage required for transmission between hosts. During the trophozoite and amoeba stages, these organisms lack cell walls. During the cyst stages, however, these organisms possess cell walls made of carbohydrate-modified proteins. The absence of a cell wall in trophozoites and amoebas permits parasite motility and enhances the interaction with the host intestine. The cell walls in cysts are thought to be important

Toolbox 3.1
USING MICROSCOPY TO EXAMINE CELL STRUCTURE

What structures and processes might we want to visualize when studying cells? We may want to see how the cytoskeleton is configured within cells. We may want to study the fine structure of the components of the cytoskeleton. We may want to identify which proteins make up the cytoskeleton. We also may want to observe the dynamic and flexible properties of the cytoskeleton that give cells structure, shape, and movement. Microscopy can allow us to address all of these wants.

In Appendix B, we will examine various types of microscopy. Here, we will investigate one essential tool in cell biology—immunofluorescence microscopy. In this technique, cells are killed and their structures fixed in space and time using chemicals (usually formaldehyde or glutaraldehyde) to crosslink molecules with a network of molecular spot welds. The permeability of the cells then is increased (often by treatment with detergents), thereby allowing reagents to pass through the cell membrane and enter the interior of the cell. Now, specific proteins can be detected using antibodies. Antibodies are proteins made by the immune system designed to bind to a specific region of another molecule. The immune system then triggers the attack and destruction of the bound molecule. In this research technique, the antibodies bind to the protein the scientist is interested in locating. In direct immunofluorescence, the antibody that binds to the protein of interest can be tagged with a fluorescent molecule. In a related technique called "indirect immunofluorescence," the antibody that binds to the protein of interest may not be tagged but is the target of a secondary antibody that is tagged with a fluorescent molecule. In either case, when light of the proper wavelength is shone on the sample, the fluorescent molecule will glow and the location will literally light up like a beacon. With immunofluorescence microscopy, we can observe, for example, the arrangement of microtubules and microfilaments in a human cell **(Figure B3.3)**.

A newer approach allows scientists to study proteins in living cells. With this technique, researchers can learn not only about protein localization, but also protein dynamics. In this technique, scientists make use of a naturally fluorescent protein (green fluorescent protein, or GFP, and its many colorful relatives). Using various molecular biology techniques, scientists modify a cell so that a protein of interest is produced that is attached to GFP. When the cell is illuminated by light of the proper wavelength, the GFP-tagged protein will glow **(Figure B3.4)**. The dynamics of the fusion protein can now be watched over time.

Studies of various GFP fusion proteins have been instrumental in furthering our understanding of cellular processes. By inserting into cells recombinant genes that produce GFP-tubulin fusion proteins, researchers can see the assembly and disassembly, in real time, of the spindle fibers involved in chromosome separation during mitosis, a process shown in Figure 3.13. Using similar approaches, researchers have been able to better understand how viruses move within cells. After entering an appropriate host cell, some portion of the virion must travel within the cell to its site of replication. As we will see in Perspective 3.1, herpesviruses travel along host cell microtubules from the plasma membrane to the cell's nucleus. GFP-tagged proteins have more clearly revealed the dynamics of this remarkable process. We will explore additional type of fusion proteins, and their uses, in Section 12.2.

Figure B3.4. Generation and use of green fluorescent fusion proteins Fusion proteins can be created by adding the DNA coding sequence of the green fluorescent protein gene to the coding sequence of a gene of interest. When this recombinant gene is transcribed and translated, a fusion protein will be generated that has the green fluorescent protein attached to the protein of interest. The micrograph shows cells expressing the GFP-tubulin fusion protein.

Test Your Understanding

Imagine you are trying to detect the locations of tubulin protein in a cell, but no tagged antibody is commercially available that is specific for tubulin. You do have an untagged tubulin antibody, however. What would you have to do to detect the tubulin using this untagged antibody if you wanted to utilize immunofluorescence?

not only for survival in freshwater that would otherwise destroy the cells with osmotic pressure when the parasites are between hosts, but also for survival in the harsh conditions of the stomach after a new host ingests the parasites. Indeed, this trio of pathogenic protozoa appears to actually use the acids and enzymes of the stomach to start the process of excystation that destroys the cyst walls and allows the parasites to emerge in time to establish infections within the intestinal tract.

The cytoskeleton: A role in cell structure

Historically, a defining characteristic of eukaryal cells was the presence of a **cytoskeleton**, literally a cellular skeleton. However, as we saw in Chapter 2, evidence indicates that bacteria also may possess cytoskeleton-like elements. In this section, we will examine the eukaryal cytoskeleton structure and functions more fully. Before addressing these points, let's ask a more basic question: What is the cytoskeleton?

Three major types of structures comprise the cytoskeleton: **microtubules**, **microfilaments**, and **intermediate filaments**. These structures differ in composition and function (Table 3.5). Microtubules consist of polymers of α- and β-tubulin dimers that assemble into fibers about 24 nm in diameter. They typically act as an intracellular organization network onto which organelles and chromosomes are attached. Microfilaments are polymers of actin that assemble in fibers about 7 nm in diameter. They typically can be found at the periphery of cells providing cell shape. Finally, intermediate filaments are polymers of a diverse array of proteins rich in alpha-helices (regions that display a spiraled structure) that form fibers 9–11 nm in diameter. Intermediate filaments can exist in the nucleus to give it shape or at the cell periphery in some animals to coordinate cell-cell interactions.

All of these structures, to some extent, contribute to the shape of the cell. In cells without cell walls (i.e., most protozoa and animal cells), the cytoskeleton serves a vital role in providing structure and support. It is important to recognize that the cytoskeleton cannot protect cells to the same extent as cell walls. Without cell walls, cells are more vulnerable to environmental stresses. One dramatic consequence is manifested by cell behavior in water. When cells are placed in pure water, water enters the cell by osmosis because the cell has a higher solute concentration. If the cell is a wall-less eukaryal cell, the water entering the cell will cause the cell to burst; the water pressure entering the cell exceeds the strength of the membrane. In contrast, if cells with walls are placed in pure water, the entering water pressure is less than the strength of the cell wall; the cell will swell within the wall but then stop filling with water.

Components of the cytoskeleton participate in a variety of intracellular dynamics, such as the assortment of organelles and chromosomes during cell division and protein trafficking in eukaryal cells. Generally, this movement occurs through one of two mechanisms: cycles of polymerization and depolymerization (a process referred to as "turn-over") or the action of molecular motors. The classic example of movement achieved by turn-over is the action of spindle fibers (a type of microtubule) during mitosis. During metaphase, these fibers are attached at one end to specific chromosomal structures, the centromeres, and are associated at their other ends with

TABLE 3.5 Cytoskeleton structures and proteins in eukarya

Fiber	Functions	Structure	Building blocks	Motors
Microtubules 	Intracellular transport Separation of chromosomes in mitosis and meiosis Cell movement (e.g., cilia and flagella)	25 nm 13 protofilaments that form a hollow tube	α- and β-Tubulin	Dyneins, kinesins
Microfilaments 	Maintain cell shape Create division furrow in cytokinesis Cell movement (e.g., pseudopods)	7 nm in diameter, 2 protofilaments twisted around each other in a helix	Actin	Myosins
Intermediate filaments 	Nuclear structure Cell-cell interactions	8–11 nm in diameter	Varied: lamin, keratin, vimentin	None

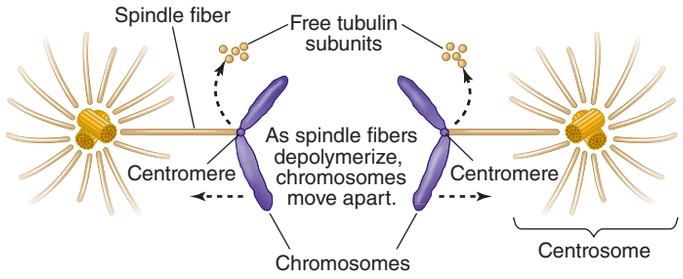

Figure 3.6. Disassembly of spindle fibers During anaphase, tubulin monomers are removed from the spindle fibers through a process of depolymerization. As the spindle fibers shorten, the chromosomes move toward the centrosomes.

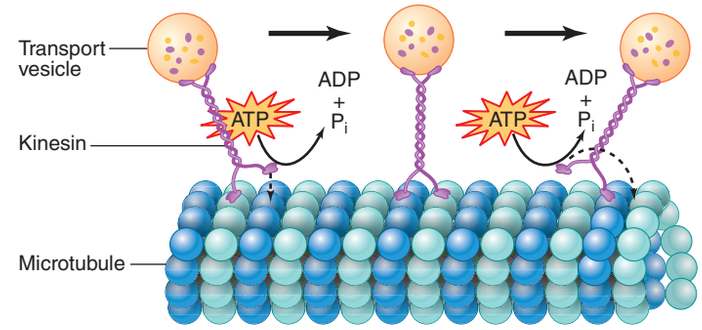

Figure 3.7. Molecular motors convert chemical energy into motion. Intracellularly, dynein and kinesin transport vesicles along microtubules, using energy derived from the conversion of ATP to ADP. As shown here for kinesin, a transport vesicle, or cargo, attaches to one end of the molecule while the other end of the molecule allows the complex to "walk" along the microtubule.

centrosomes. In animal cells, the centrosomes contain two centrioles, tube-like structures that serve as the organizing centers of microtubules. During anaphase, tubulin monomers are removed one by one from the chromosomal ends of the spindle fiber microtubules. This disassembly causes the spindle fibers to shorten, and the copies of each chromosome are pulled toward the centrosomes at opposite poles of the cell (Figure 3.6). This action results in the accurate assortment of chromosomes into daughter cells during cell division. Finally, we should note that bacterial and viral pathogens also make use of microtubules present in their host cells (Perspective 3.1).

Motors provide a diverse range of cell movements. Two different motors, dynein and kinesin, interact with and move along microtubules (Figure 3.7). These motors are responsible for moving vesicles along microtubules during intracellular protein trafficking. Generally, dyneins move along microtubules toward the center of the cell. Kinesins, conversely, tend to move from the center of the cell toward the periphery. Dyneins also are involved in the movement of cilia and flagella in a process quite different from the flagellar motion in bacteria that we explored in Chapter 2. Eukaryal cilia and flagella emerge from basal bodies (the flagella microtubule organizing centers) within the cell body and consist of an array of microtubules in which nine microtubule doublets form a tube around a core pair of microtubules. This array is referred to as the axoneme. The motion of axonemes resembles that of a cracked whip with undulating motion created by the sliding of microtubules past one another in the axoneme. Dynein and associated proteins perform this sliding action (Table 3.6).

3.1 Fact Check

1. What are the key features of members of the domain *Eukarya*?
2. What is the secretory pathway and what post-translational modifications are made to proteins being secreted via this pathway?
3. Describe the process of chemiosmosis.
4. Describe the components of a eukaryal plasma membrane and each of their roles in cell function.
5. Which eukarya have cell walls? How do their cell walls differ from those of bacteria?

TABLE 3.6 Comparison of flagella in *Bacteria* and *Eukarya*

Feature	*Bacteria*	*Eukarya*
Structure	Non-flexible hollow helical filament	Flexible
	Extends outside of cell membrane and cell wall	Covered by the cell membrane
	Composed of flagellin subunits	Composed of a 9 + 2 array of microtubules termed the axoneme
Assembly	At distal tip	At distal tip
	Flagellin monomers are transported out inside of hollow flagella	Microtubule segments are transported out along the outside of the axoneme via an intraflagellar transport system
Arrangement	Polar (one or multiple)	Varies by cell type
	Peritrichous (multiple)	
Motion	Motor in membrane turns flagella in a screw-like motion	Dynein spokes slide microtubules along each other within the axoneme. This bends the axoneme and gives a whip-like motion to the flagella
	Energy from a proton motive force	Energy from hydrolysis of ATP

Perspective 3.1
HIJACKING THE CYTOSKELETON

Humans are not the only ones who have noticed that the cytoskeleton guides dynamic processes in eukaryal cells. A number of bacterial and viral intracellular pathogens use the cytoskeleton to facilitate their movement during infections of eukaryal cells. Many viruses hitch rides on microtubules to speed and direct their intracellular movement. Herpes simplex viruses, for example, enter host cells at the plasma membrane and then travel along microtubules to the host cell nucleus, where the viral genome replicates

The intracellular bacterium *Listeria monocytogenes* employs another fascinating means of locomotion. *Listeria* causes a dangerous foodborne infection. Once inside a host cell, *Listeria* depletes cell resources as it multiplies, but then must spread its progeny to new host cells to expand the infection. To accomplish this movement, *Listeria* actually hijacks actin proteins from the host cell, assembling them rapidly into a "tail" at the base of the bacterium **(Figure B3.5)**. The growth of the tail pushes the bacterium, attaining such a force and velocity that it can actually inject the bacterium from one cell into a neighboring cell.

Some pathogenic *E. coli* strains, such as O157:H7 also use the host cell's actin and form a pedestal that sets the bacterium further into the intestinal lumen (see Figure 21.3), possibly to aid in nutrient acquisition. The bacterial proteins necessary for actin polymerization in these two species, however, share no sequence similarity. This finding has suggested to researchers that *Listeria* and these pathogenic *E. coli* strains evolved this mechanism of motility independently.

The actin in host cell microfilaments is also stained in red. **B.** Electron micrograph of the actin tail pushing a *Listeria* bacterium outward from the periphery of a cell. The action of the actin tail may be sufficient to propel the bacterium into a neighboring cell, spreading the infection.

3.2 Diversity of eukaryal microorganisms

What are the different types of eukaryal microorganisms?

The domain *Eukarya* encompasses a remarkable diversity of organisms, from unicellular microorganisms to multicellular animals, plants, and fungi that make up the visible biological world. Indeed, *Eukarya* is the only domain of life that includes multicellular organisms. In this section, we will examine the phylogeny of the eukaryal microorganisms and explore several model organisms within this group in depth. To start our examination of the diversity of eukaryal microorganisms, let's first look at the phylogeny of these organisms.

The phylogeny of eukaryal microorganisms

As we saw in Chapter 1, we currently classify all living organisms into three domains: *Bacteria, Archaea*, and *Eukarya* (see Figure 1.8). Classifications within the domain *Eukarya* traditionally have been based on overt similarities: animals are multicellular, heterotrophic, and capable of voluntary motion, whereas plants are multicellular, photosynthetic, and not capable of voluntary motion. What can SSU rRNA gene sequence

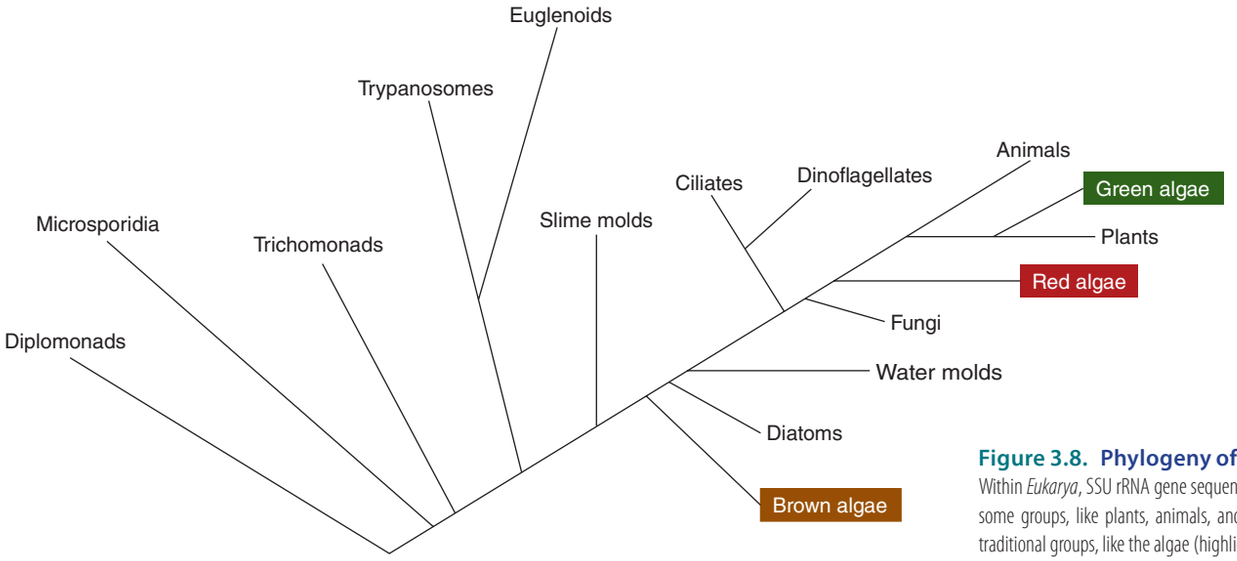

Figure 3.8. Phylogeny of the eukaryal domain
Within *Eukarya*, SSU rRNA gene sequence comparisons demonstrate that some groups, like plants, animals, and fungi, are monophyletic. Other traditional groups, like the algae (highlighted), are more diverse.

comparisons tell us about phylogeny within the domain *Eukarya*? When we examine the 18S rRNA gene sequences of various eukarya, we see that several traditional groups, most notably the plants, animals, and fungi, do indeed represent monophyletic groups; all species within these groups share a common ancestor. Other traditional groups, most notably the algae, seem to appear at various places within the phylogenetic tree **(Figure 3.8)**. Green algae are closely related to land plants. Red algae and brown algae, however, seem to be more distantly related. Thus, the algae, a traditional classification within the eukarya, do not represent a monophyletic group.

Another interesting group of organisms, the amitochondriates, seem to be very distantly related to the other eukarya. As we will see later in this chapter, the amitochondriates lack mitochondria. Compelling evidence indicates that these organisms may once have contained mitochondria. Does that make them the earliest eukarya? The answer to that question also remains to be determined.

CONNECTIONS Analysis of SSU rRNA gene sequences demonstrated that archaea are genetically distinct from bacteria. This realization led to the development of the three-domain classification scheme. Details about this major shift in the classification of organisms are described in **Section 1.1**.

Despite the important information about phylogeny that we can glean from SSU rRNA gene sequence comparisons, these studies may not provide us with the perfect answer. To determine more accurately the phylogeny of eukarya, researchers have compared the sequences of genes for several other common proteins. Most notably, researchers have constructed phylogenetic trees based on the sequences of several proteins, including tubulins, elongation factor 1-alpha, and most recently, heat shock proteins. While the major groupings remain in these alternative trees, these trees often differ from the SSU rRNA tree, and from each other. These alternative trees raise some interesting issues. Phylogenetic trees based on these alternative markers show all of the eukarya radiating from a single point. In other words, it does not appear that plants, animals, and fungi are advanced eukarya and amitochondriates are more primitive eukarya. Some researchers have used information like this to postulate that all major groups of eukarya arose relatively quickly after the appearance of the mitochondrion, an event referred to as an evolutionary Big Bang.

To construct a phylogenetic tree of eukaryal organisms, researchers have combined the information gleaned from several molecular marker studies and morphological and structural data **(Figure 3.9)**. The resulting tree divides *Eukarya* into five major groups, the *Plantae*, *Excavata*, *Rhizaria*, *Unikonta*, and *Chromalveolata*. Even though there is significant evidence supporting this classification scheme, uncertainty still exists. Our understanding of the phylogeny of *Eukarya* remains in flux.

Eukaryal microorganisms: Model organisms

In this section, we'll look at four different eukaryal microorganisms, representing four traditional groups. We will focus on a fungus (*Saccharomyces cerevisiae*), a protozoan (*Giardia lamblia*), a slime mold (*Dictyostelium discoideum*), and an alga (*Chlamydomonas*). These four organisms are chosen because together they represent traditional groups within the eukaryal microbial world while having unique features of interest **(Table 3.7)**. They are called **model organisms** because they have been so thoroughly studied that their traits define much of our scientific understanding about eukaryal cells.

Fungi: *Saccharomyces cerevisiae*

Fungi are a diverse group of eukarya, not all of which are single-celled microorganisms **(Figure 3.10)**. Like all other eukarya, fungi compartmentalize cell functions into membrane-bound compartments termed organelles, such as the nucleus, endoplasmic reticulum, mitochondria, and Golgi. Also, like all other eukarya, fungi control cell shape and dynamics via proteins of the cytoskeleton. Knowing that a cell is a fungus immediately

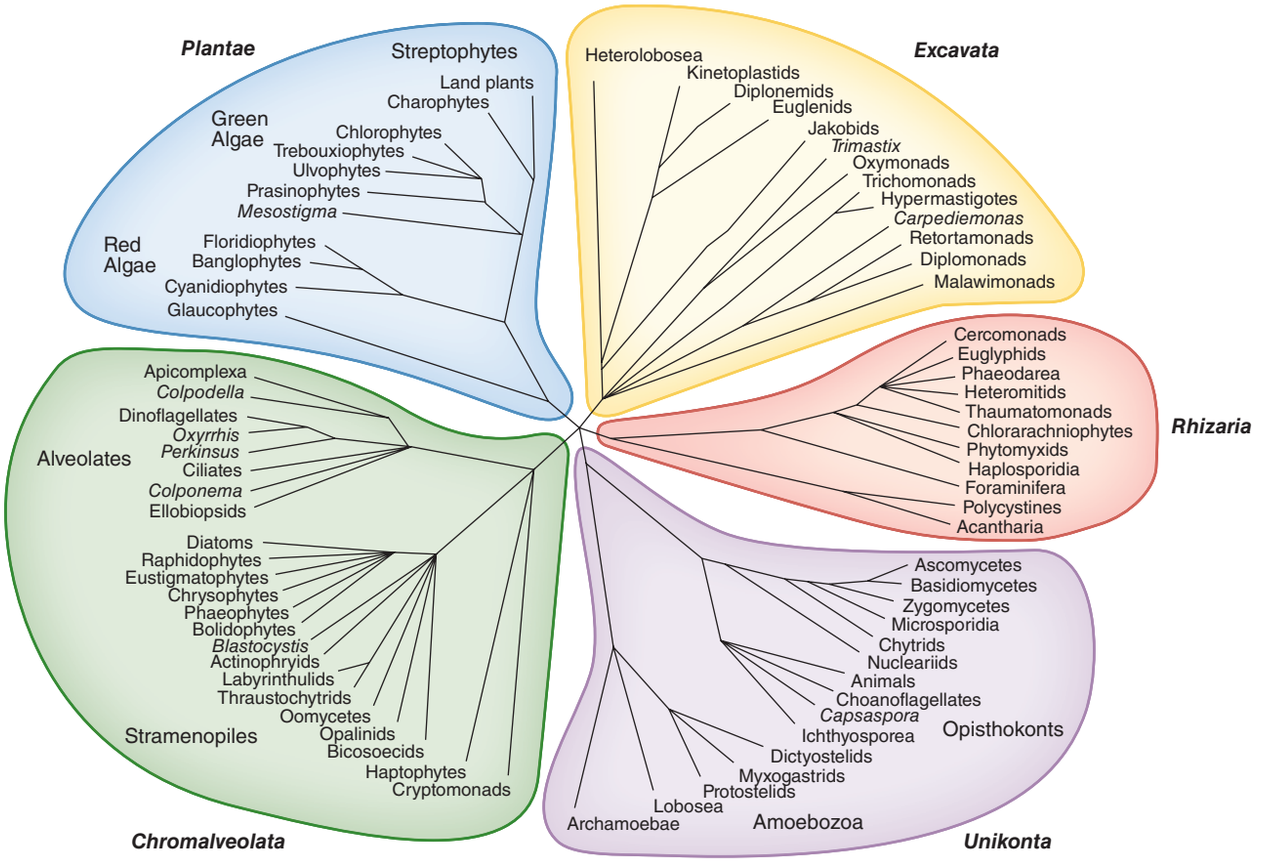

Figure 3.9. Classification of *Eukarya* By combining sequence data from several molecular markers with morphological data, researchers have developed a fairly detailed eukaryal tree. In this model, all eukarya are grouped into five major super-groups. Although strong data support this model, uncertainties still remain.

helps to further define both structural and functional features of the cell. A distinguishing feature of all fungi is their cell wall, which generally is a chitin-based structure quite distinct from either the peptidoglycan-based cell wall of bacteria or the cellulose-based structure of algae and plants. Also, all fungi are heterotrophic, meaning that they derive energy and gain building blocks by ingesting organic compounds.

S. cerevisiae is a natural choice as an exemplar eukaryal microorganism (see Figure 1.10B). This staple of applied microbiology is sometimes called brewer's yeast, because of its role in the

TABLE 3.7 Traditional categories of eukaryal microorganisms and their characteristics

	Fungi	Protozoa	Slime molds	Algae
Cell functions				
Metabolism	Heterotrophic	Heterotrophic	Heterotrophic	Phototrophic
Motility	Typically non-motile	Varied: Swimming: cilia/flagella Amoeboid: pseudopods	Amoeboid: pseudopods	Non-motile or Swimming: flagella

Figure 3.10. Diversity of fungi **A.** Members of the genus *Penicillium* produce the antibiotic penicillin. Other species are present in and contribute to the tastes of Camembert and Roquefort cheeses. **B.** Several species in the genus *Aspergillus* cause disease in humans. *Aspergillus flavus* produces aflatoxin, a toxin occasionally found in various agricultural products. **C.** Members of the genus *Rhizopus* can be found in many environments. Some species are associated with human diseases. Other species are used in the production of cheeses. **D.** *S. cerevisiae* is used in baking. Biologists also use it extensively as a model eukaryal organism.

fermentation of alcoholic beverages, or baker's yeast, because it makes bread rise. It is one of the best-studied model organisms. You name the biological problem, and some researcher somewhere probably uses *S. cerevisiae* to study it! Perhaps most notable is the work done with yeast to develop sophisticated molecular tools that can aid researchers studying various questions in different organisms. Because it is inexpensive to study and easy to manipulate, scientists use *Saccharomyces* to address fundamental questions about genes, gene expression, and protein interactions. Information from these studies has provided important insight into the molecular workings of other eukaryal cells, including human cells.

CONNECTIONS In **Section 23.1**, we will briefly examine mushrooms, fruiting bodies produced during the replication of some fungi. Some mushrooms are edible. Others produce powerful toxins, like the transcription-inhibitor α-amanitin.

Protozoa: *Giardia lamblia*

The protozoan group probably represents the broadest category of eukaryal microorganisms and one that is losing meaning as we come to better understand the evolutionary diversity of the group. As you may guess from examining the representative protozoa in **Figure 3.11**, there is little we can designate to define the group. Protozoa can be either heterotrophic or photosynthetic. Although most protozoa never have cell walls, some protozoa have cell walls throughout their life cycle, and others develop cell walls only at certain stages. Protozoa also have different strategies of motility. *Giardia lamblia*, a commonly studied model organism, is a flagellate, using its flagella for motility. Other protozoa are amoeboid and move through extension and contraction of pseudopods (literally "false feet"). Still other members of this group are not self-propelled but rely on external physical forces to move them. The means of reproduction within the protozoa are quite varied as well. In fact, some ciliated protozoa even have two nuclei, one that is primarily used for gene expression and one that serves as the basis for genetic inheritance between generations.

Giardia is fascinating because of its evolutionary position. Estimates from rRNA and protein phylogenies suggest that *Giardia* diverged from the main branch of the eukaryal domain over one billion years ago, making it one of the earliest-diverging eukarya that we can readily culture in the laboratory. Studies of its biology may illuminate many aspects of eukaryal evolution. As we will see later in this chapter, *Giardia* may provide clues to the origins of eukaryal cells; unlike most eukaryal organisms, *Giardia* does not possess mitochondria. Finally, *Giardia* causes significant health problems in humans worldwide. Indeed, the World Health Organization estimates that this microorganism causes intestinal problems in up to a billion individuals annually.

C. *Giardia lamblia*

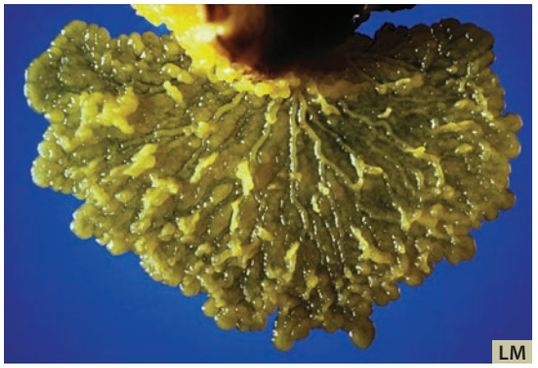
Figure 3.11. Diversity of protozoa Protozoa exhibit a wide range of morphologies. These groups also show distinct methods of motility. **A.** Amoeba exhibit an amorphous shape. Motility seems to rely on the extension and contraction of pseudopods and subsequent movement of cytoplasm. **B.** The ciliated *Tetrahymena* have a more defined, teardrop shape. Beating cilia provide motility. **C.** *Giardia* also has a more well-defined shape. Flagella power the movement of these organisms.

Slime Molds: *Dictyostelium discoideum*

Unlike other protozoa, slime molds come in two basic types: the cellular forms, represented by the model organism *Dictyostelium discoideum*, and the acellular forms, represented by species in the genus *Physarum*. Slime molds generally spend most of their lives as individual cells. At times, though, these cells form a larger structure that facilitates eating and reproduction. For the cellular slime molds, individual cells aggregate to form a multicellular mass. In the acellular slime molds, in contrast, the individual cells fuse, forming a large, multinucleated aggregate called a "plasmodium" **(Figure 3.12)**.

Dictyostelium has been a model organism for studying the basis of amoeboid cell motility. Additionally, its complex developmental cycle has provided key insights into intercellular communication. During a developmental cycle, individual cells aggregate, thus allowing the organism to hover on the brink between single-celled and multicellular status (see Figure 1.4). This aggregation of *Dictyostelium* occurs via a cyclic adenosine monophosphate (cAMP) signaling pathway, a pathway also common in humans. Therefore, the study of *Dictyostelium* organization may provide answers to questions about the evolution of multicellularity and cell signaling. Finally, the role that *Dictyostelium* plays in soil ecology is a key area of research. Because the slime molds feed primarily on other microorganisms present on decaying vegetation, they may be a key player in nutrient recycling. As we seek more natural solutions to maintaining soil health for crop growth, a better understanding of natural soil ecology is imperative.

A. *Dictyostelium discoideum*



B. *Physarum* sp.

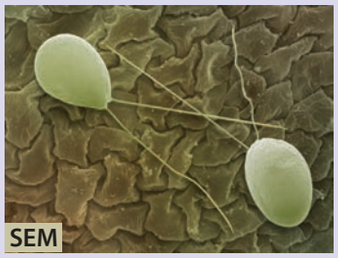
Figure 3.12. Diversity of slime molds **A.** In cellular slime molds, like *Dictyostelium discoideum*, individual cells come together, forming a multicellular aggregate. Shown here is a developing fruiting body. These fruiting bodies can be 1–2 mm tall. **B.** In acellular slime molds, like *Physarum polycephalum*, individual cells fuse, forming a multinucleated giant cell. In the structure shown here, the cytoplasm is continuous.

Microbes in Focus 3.1
CHLAMYDOMONAS REINHARDTII AND THE STUDY OF CELL MOTILITY

Habitat: Soil and freshwater throughout the world

Description: Single-celled alga, approximately 10 μm in diameter, with two flagella and an "eyespot" that allows it to move toward light sources

Key Features: *Chlamydomonas reinhardtii* can be induced to shed their flagella by exposing the cells to a low-pH medium. In a short time, the cells regrow their flagella. Studies of this flagellar regeneration have provided researchers with important insight into the assembly of microtubules in eukaryal organisms. Additionally, studies with laser-based "optical tweezers" have allowed researchers to measure the swimming force of these flagella, thereby providing insight into the mechanism of cellular motility.



© Andrew Syred/Science Source

Algae: *Chlamydomonas*

Algae represent a diverse category of photosynthetic eukarya. *Chlamydomonas*, for instance, is a single-celled alga **(Microbes in Focus 3.1)**. Other algae, in contrast, form multicellular colonies. Different algae also may vary greatly in size, shape, and motility. Like all algae, *Chlamydomonas* contains chloroplasts and converts solar energy to cellular energy via the light reaction of photosynthesis. During the corresponding dark reaction, it converts carbon dioxide into organic forms of carbon. Thus, algae are autotrophic and, unlike heterotrophic organisms, can survive in relatively nutrient-poor water. Of course, there are limits to their self-sufficiency. *Chlamydomonas* and other algae must scavenge from the environment nitrogen, sulfur, phosphorus, and other elements required to build organic molecules.

CONNECTIONS *Chlamydomonas*, like all algae and plants, undergoes oxygenic photosynthesis, which means that oxygen is generated as a by-product. As we will see in **Section 13.6**, some bacteria undergo anoxygenic photosynthesis. In these organisms, oxygen is not released.

Like all other algae, *Chlamydomonas* has a cell wall made of cellulose that protects the cell from toxic molecules, osmotic stresses, and physical damage. *Chlamydomonas* has two flagella and forms zoospores—motile, flagellated, reproductive structures that can withstand harsh environmental conditions and remain dormant until the conditions become more favorable.

Like *Saccharomyces*, *Chlamydomonas* has contributed to our understanding of the biology of eukaryal cells. We know a great deal about it and can ask very detailed questions about cellular function that can then be extrapolated to algae and other eukaryal cells. Researchers are investigating the genetic content of *Chlamydomonas*, the gene expression patterns of this organism, and the protein composition of its flagella and associated structures. *Chlamydomonas* is the definitive model organism for understanding the biogenesis and function of eukaryal flagella. *Chlamydomonas* also has some unique properties that earned it the name "cockroach of the algae world." This title easily could be interpreted as a stinging critique of the cell, but rather it is a tribute to the properties that make it an extraordinarily durable cell.

3.2 Fact Check

1. What eukaryal microorganisms are studied as model organisms?
2. Describe the benefits and drawbacks of studying model organisms.
3. Algae do not seem to form a monophyletic group. How could you explain this?
4. Why are slime molds logical organisms in which to study cell aggregation?

3.3 Replication of eukaryal microorganisms

How do eukaryal microorganisms replicate?

The genetic mechanisms of eukaryal cells differ significantly from those of their bacterial and archaeal counterparts. Unlike bacteria and archaea, eukaryal microorganisms may be **haploid** (have a single copy of their chromosomes) at some stages of their life cycle and **diploid** (have two copies of their chromosomes) at other stages. They can replicate asexually through the process of mitosis and also can reproduce sexually through the process of meiosis (true sexual recombination). This life cycle is in contrast to bacteria and archaea that replicate asexually by binary fission and for which meiosis is impossible. In this section, we will examine the processes of mitosis and meiosis. We also will examine the life cycles of several eurkaryal microorganisms, focusing on their transitions between haploid and diploid genomes.

Mitosis

Mitosis is a type of nuclear division that produces two nuclei with identical chromosomes, typically followed by division of the cytoplasm forming two genetically identical daughter cells, a process known as **cytokinesis**. In animals and plants, growth occurs by mitosis. In single-celled eukaryal microorganisms, mitosis results in asexual replication leading to population growth. In either case, the process begins with DNA replication, resulting in the production of two identical copies of the cell's genetic material **(Figure 3.13)**.

Mitosis ANIMATION

CONNECTIONS Cells possess several mechanisms to limit the number of mutations, or mistakes, that occur during DNA replication. In **Section 7.5**, we will explore some of these DNA repair pathways.

Although we often focus exclusively on the movement of chromosomes in mitosis, we should remember that eukaryal cells also must ensure that representatives of each type of organelle are distributed to the daughter cells. Typically, the organelles are not counted nearly as carefully as chromosomes.

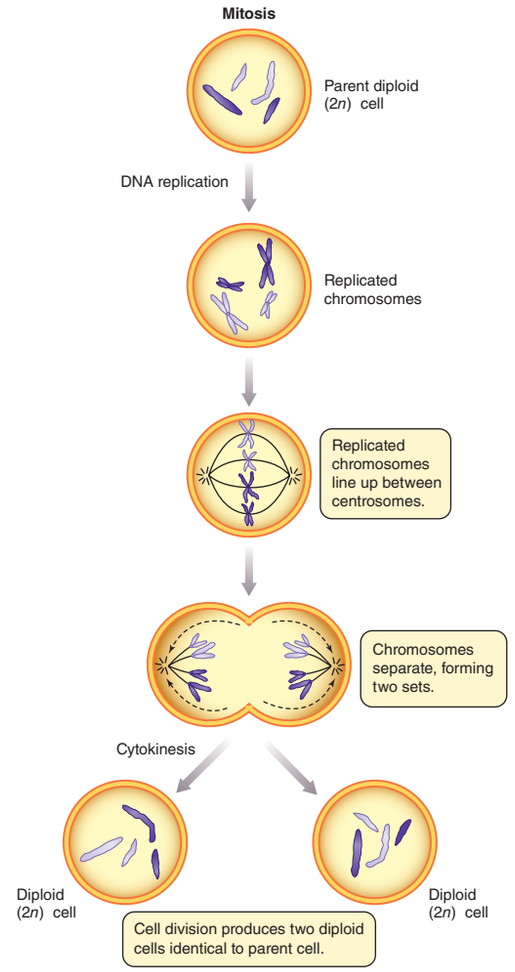


Figure 3.13. Mitosis yields genetically identical cells. Following replication of the DNA, replicated chromosomes align in the middle of the cell, between the centrosomes, and then are separated. Following cytokinesis, or cell division, two cells with genetic complements identical to the parent cell are created. The newly produced cells, in other words, have the same amount and kinds of chromosomes as the original cell. In this example, the initial cell is diploid, containing two copies (light purple and dark purple) of the large chromosome and two copies (light purple and dark purple) of the short chromosome.

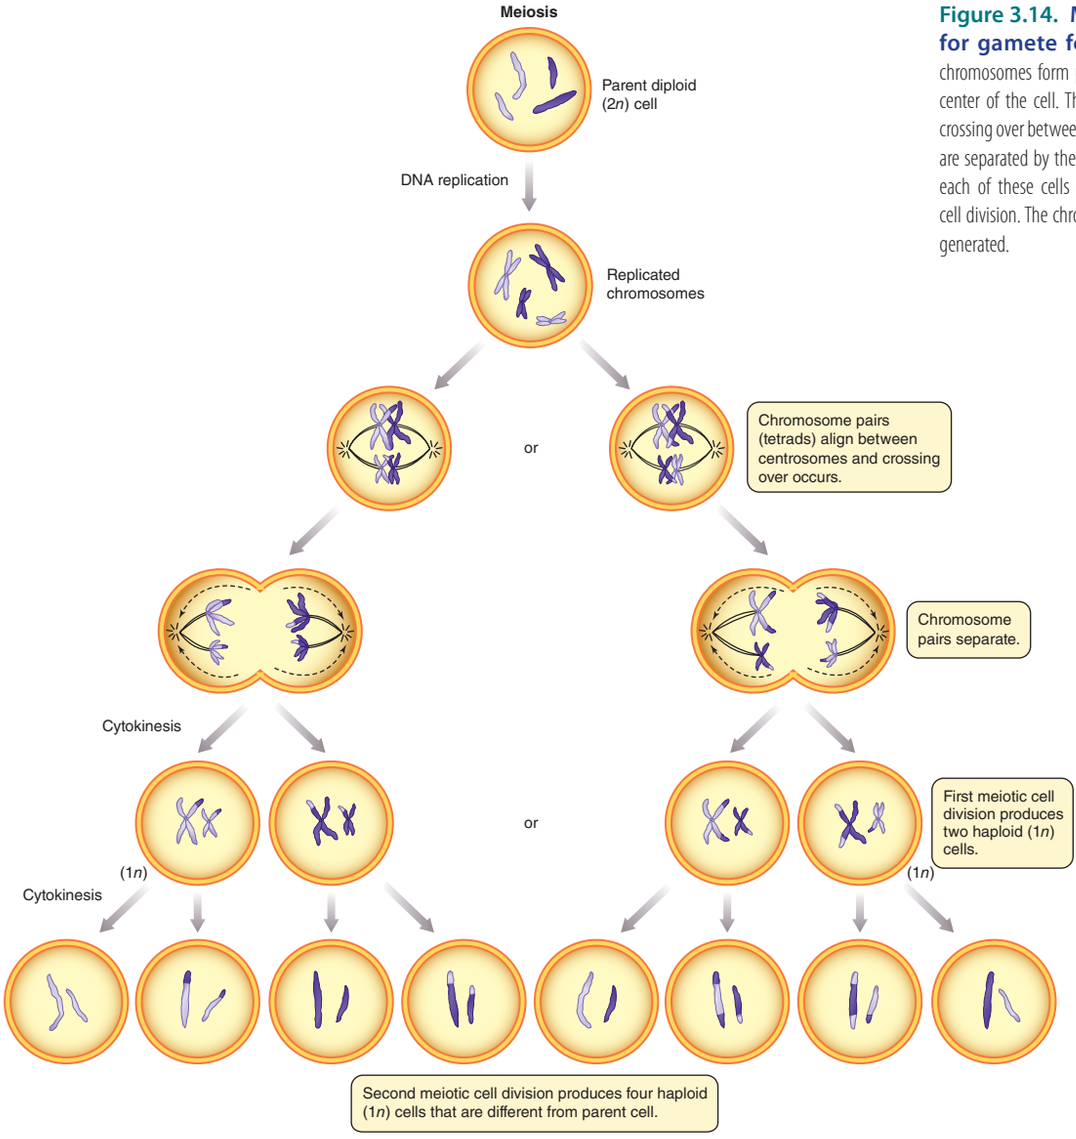

Figure 3.14. Meiosis reduces chromosome number for gamete formation. Following DNA replication, homologous chromosomes form pairs, or tetrads. These chromosome pairs align near the center of the cell. The chromosome pairs can line up in various orders, and crossing over between homologous pairs can occur. The chromosome pairs then are separated by the first meiotic cell division. Without more DNA replication, each of these cells undergoes a mitosis-like process—the second meiotic cell division. The chromatids separate and genetically distinct haploid cells are generated.

Because mitochondria and chloroplasts can replicate autonomously, as long as a single one makes it into a daughter cell, it can divide by fission as many times as needed to generate a sufficient number. Other membrane-bound organelles, like the endoplasmic reticulum and Golgi apparatus, break down into small vesicles prior to mitosis, and it is left to chance that this pool of vesicles will be adequately distributed. The organelles then reassemble in the daughter cells.

Meiosis

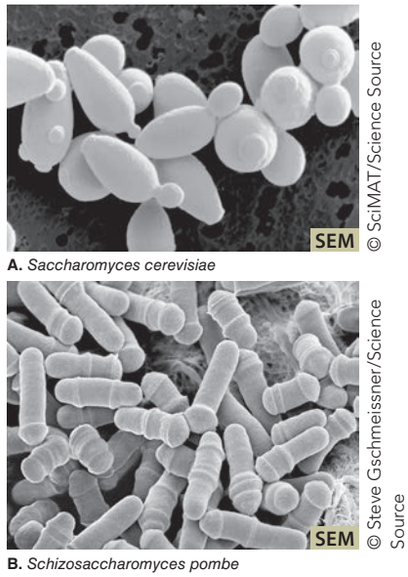
Meiosis is a process that results in a reduction of the genome from diploid to haploid. This process results in the rearrangement of the genetic material and the production of cells that may be involved in sexual reproduction. These two goals can be achieved in meiosis because two rounds of cell division follow a single round of DNA replication. Consequently, the resulting cells are haploid ($1n$); they contain only a single copy of each chromosome **(Figure 3.14)**. Moreover, the genetic material can be rearranged in meiosis, as shown in Figure 3.14. This rearrangement occurs in two ways. First the independent assortment of paternal and maternal chromosomes within a cell (indicated by the light purple and dark purple copies of each chromosome) allows for the production of haploid cells that contain various combinations of chromosomes. Furthermore, crossing over, a form of genetic recombination, also occurs in meiosis, as indicated by the exchange of light purple and dark purple material in Figure 3.14. The resulting haploid cells, then, differ in their genetic content.

In sexual reproduction, one haploid cell, or gamete, combines with another haploid cell to form a new diploid offspring. During this event, new pairings of gene variants result. Remember that the new combinations are not necessarily good; the results can be either advantageous or detrimental. The rearrangement of genetic material, however, is one of the key sources of genetic variation upon which natural selection acts in evolution.

Life cycles of model organisms

Alternating cycles of mitosis and meiosis are closely linked to developmental cycles in eukaryal microorganisms. These cycles serve two functions. First, they generate the haploid and diploid stages of the cells that are involved in asexual replication and sexual reproduction. Second, they permit the cells to enter a phase in which they are better able to withstand harsh environmental conditions. Some cells develop protective spore coats under harsh conditions and enter a quiescent metabolic phase. Others become motile to facilitate their escape. Still others enter meiosis with the possibility that a new genetic combination will prove to be more beneficial. Although all eukaryal microorganisms undergo mitosis and meiosis, the specific life cycles of these organisms differ quite dramatically.

Fungi vary widely in their mode of reproduction. Some fungi spend much of their lives as diploid cells and only occasionally enter into haploid states for sexual reproduction. Other fungi spend virtually all of their lives as haploid cells and form diploid cells only briefly. What is the life cycle of *Saccharomyces cerevisiae* (Figure 3.15)? Diploid cells can reproduce asexually via mitosis. Usually during times of environmental stress, these cells undergo meiosis with each diploid cell forming four haploid cells, arranged in a spore case, or **ascus**. These haploid cells are distinguished not by gender—male or female—but instead by mating types; half of the haploid cells are mating type *a* and half are mating type α. These haploid cells can replicate asexually through mitosis, or fuse to form a new diploid cell. Because of structural differences between these cells, type *a* cells can only fuse with type α cells.



A. *Saccharomyces cerevisiae*

B. *Schizosaccharomyces pombe*

Figure 3.16. Budding and fission in yeast **A.** In *Saccharomyces cerevisiae*, or budding yeast, cytokinesis (or cell division) occurs asymmetrically, resulting in what appears to be a smaller cell budding off of the original cell. **B.** In *Schizosaccharomyces pombe*, or fission yeast, cytokinesis occurs symmetrically, resulting in two daughter cells of equivalent sizes.

Fungi show variation even in simple mitosis. *Saccharomyces cerevisiae* is sometimes referred to as the "budding yeast" because it reproduces by forming small daughter cells that bud from the mother cell. *Schizosaccharomyces pombe* is known as the "fission yeast" because cell division results in two daughter cells of approximately the same size (Figure 3.16).

During favorable environmental conditions, motile haploid cells of *Chlamydomonas* replicate asexually, as shown in the left circle of Figure 3.17. When growth conditions deteriorate (as indicated in the right circle of Figure 3.17), these haploid cells differentiate, becoming reproductive cells, or gametes. These haploid cells fuse, forming a diploid cell that quickly loses its flagella and develops a thick cell wall, becoming a spore. This spore can exist, basically inert, for extended periods. When environmental conditions improve, the spore undergoes meiosis, producing four motile, haploid cells.

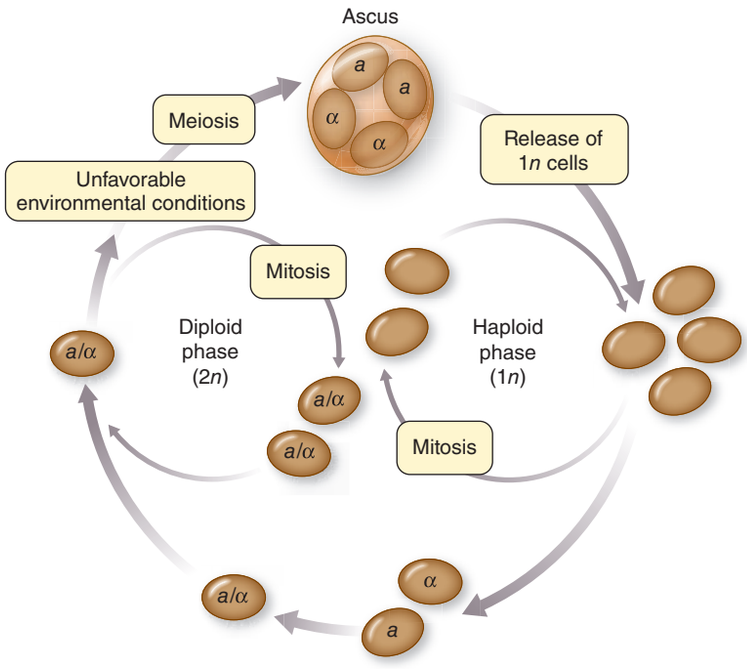


Figure 3.15. Life cycle of *Saccharomyces* Haploid cells, which can be *a* or α mating types, replicate via mitosis. Two haploid cells of different mating types can fuse, producing a diploid cell. This diploid cell also can replicate via mitosis. Under times of stress, diploid cells can undergo meiosis, resulting in the formation of four haploid cells, which remain within a protective spore case, or ascus. When conditions are favorable, the four haploid cells are released from the ascus.

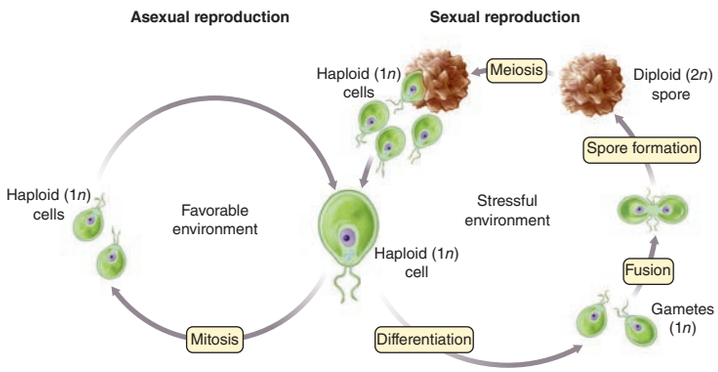

Figure 3.17. Life cycle of *Chlamydomonas* Haploid cells replicate via mitosis, as shown in the left circle. During times of stress, these haploid cells differentiate, becoming gametes that can fuse, resulting in a diploid cell. The diploid cell develops into an environmentally stable spore. When conditions improve, the diploid cell undergoes meiosis, forming four haploid cells, which are released and can replicate again via mitosis.

Among the eukaryal microorganisms, slime molds like *Dictyostelium* may have the most interesting life cycles (see Figure 1.4). Haploid, amoeboid forms of *Dictyostelium* typically feed on bacteria and divide by mitosis. When they begin depleting the existing food supplies, these cells aggregate, forming a multicellular slug. As we mentioned earlier, this aggregation results from a complex and quite fascinating cAMP-mediated cell-signaling mechanism. Once formed, the slug can move short distances. During this period of the life cycle, cell differentiation also occurs. Some cells form a stalk and others form a fruiting body. Spores form within the fruiting body and then are released. The released cells are dispersed and resume the life cycle as amoeboid cells. Two of these haploid amoeboid cells can fuse, engulf neighboring cells, and form a diploid macrocyst. Meiosis occurs within the macrocyst, resulting in the formation of new haploid cells.

3.3 Fact Check

1. What are the results of mitosis and meiosis? For what purposes are they used?
2. How are the processes of meiosis and mitosis involved in the life cycle of *Saccharomyces*?
3. Describe the life cycle of *Dictyostelium*.

3.4 The origin of eukaryal cells

How did eukaryal microorganisms originate?

It is generally thought that *Eukarya* emerged as a new domain of life between 2.1 and 1.6 billion years ago. Thus, the world was exclusively the realm of prokaryotes for the first 2–3 billion years of life. The emergence of eukarya was a new wrinkle in the biological landscape, with the complexity of internal structures making possible an extraordinary diversity of cell morphologies and, eventually, multicellular organisms. It is equally important to remember that eukarya do not necessarily represent an evolutionary step forward. We often consider complexity as a sign of progress (reflections of our own technological focus as humans, perhaps), but in life, evolution selects among varied options through the relative reproductive success of the best-adapted organisms. Those organisms better suited to the time and place will have more offspring. Numerically, bacteria and archaea are much more prevalent than eukarya and are therefore at least as successful, if not more so, than their nucleated cousins.

The endosymbiotic theory

Because we traditionally define eukarya by the presence of a nucleus and other organelles, when we consider the origin of eukaryal cells, we are primarily concerned with understanding how organelles evolved. Most researchers agree that eukaryal microorganisms arose by a process known as **endosymbiosis** (Figure 3.18). The basic theory is that a single cell either engulfed another cell, likely for the purpose of eating it for energy and building blocks, or was invaded by another cell. The internalized cell, however, escaped destruction and set up housekeeping within its new host cell. Each member brought new capabilities to this partnership that enhanced the survival of the new combined cell, giving it evolutionary advantages and thus ensuring its survival. Endosymbiosis thus indicates that the two original cells have an intimate relationship with each other ("-symbiosis"), and one cell is fully inside of the other ("endo"). Endosymbiosis is the best theory for the origins of the mitochondrion and chloroplast within eukaryal cells, and perhaps other organelles as well.

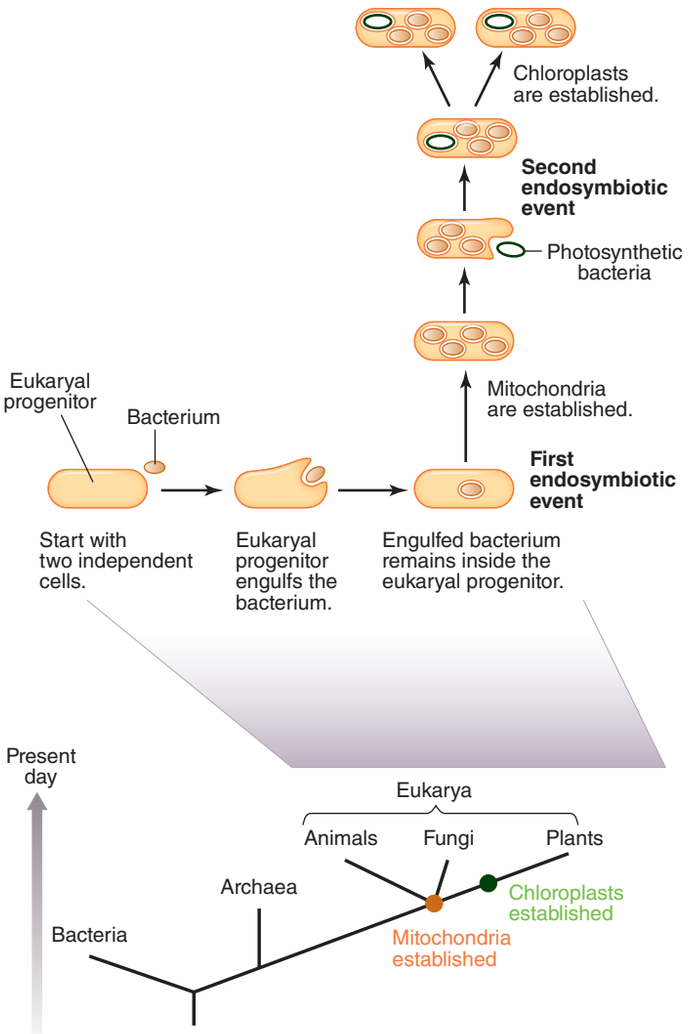

Figure 3.18. Endosymbiosis and the evolution of eukaryal cells. Mitochondria appeared in developing eukaryal cells before animals, fungi, and plants differentiated from each other. The progenitor eukaryal cell engulfed or was invaded by a bacterial cell. Rather than being destroyed, the internalized cell was maintained in a symbiotic relationship, eventually becoming the mitochondrion. In a subsequent event, a photosynthetic bacterium entered a eukaryal cell, and eventually became the chloroplast. Chloroplasts appeared in the plant lineage after plants differentiated from the other eukaryals that had already acquired mitochondria.

CONNECTIONS Endosymbiosis represents just one form of symbiosis. In **Section 17.1**, we will introduce various types of symbiotic relationships. Throughout Chapter 17, we will explore these relationships in more detail.

Because virtually all eukarya contain mitochondria, but only a subset of eukarya contain chloroplasts, it is believed that the first endosymbiotic event was the engulfment of a bacterium that led to the presence of the mitochondrion (see Figure 3.18). Subsequently, a second endosymbiotic event occurred in which a cell that already contained the mitochondrion engulfed a second autotrophic bacterium that gave rise to the chloroplast. In both cases, the benefit to the host cell involved the expansion of energetic capabilities (the mitochondrion permits aerobic respiration and the chloroplast permits photosynthesis) that would have made the host cell more competitive in an environment with scarce energy resources. In parallel, the engulfed bacterium would have benefited from the protection offered by the larger host cell. Note that over time the engulfed cells, today's mitochondria and chloroplasts, have lost so much of their genetic material that they could no longer function as independent cells.

Evidence in Support of the Endosymbiotic Theory

Where can we find evidence to support the theory of endosymbiosis? How do we find evidence for events that are proposed to have taken place over a billion years ago? The key is finding evidence of ancient cellular processes and life-forms that allow us to retrace the paths of evolution. Historically, such evidence has been physical, usually involving fossils of organisms from microbes to dinosaurs. Today, however, scientists look for molecular and cellular evidence. By examining protein structures and DNA sequences, we can identify fingerprints, or leftover remnants, of the predecessors to current cells.

The hypothesis that endosymbiosis is responsible for the origins of the chloroplast and mitochondrion was first proposed, respectively, by the Russian scientist Konstantin Mereschkowsky and the American scientist Ivan Wallin in the early 1900s. However, Lynn Margulis is most closely associated today with the term "endosymbiosis." Her work since the 1970s provided some of the key evidence to move endosymbiosis from a fringe hypothesis into an accepted theory. Indeed, her first book on the topic, *The Origin of Eukaryal Cells,* published in 1970, became a seminal work in shaping our understanding of the evolution of cells.

Three main lines of evidence from Margulis and other researchers support the theory of endosymbiosis. First, mitochondria and chloroplasts resemble bacteria both in shape and size. Both organelles are rod shaped and usually measure between 0.5 μm and 5 μm in length. Second, the arrangement of membranes around these organelles is consistent with the endosymbiotic theory. Transmission electron micrographs clearly show that two membranes surround mitochondria and chloroplasts, while a single membrane surrounds other cell organelles. This observation correlates nicely with a model in which a parent cell engulfed a bacterium during the original endosymbiotic event and the resulting mitochondrion (or chloroplast) retained both the original bacterial membrane as well as the piece of the host cell plasma membrane that surrounded the bacterium when it was engulfed. Moreover, the lipid composition of the membranes of these organelles is bacteria-like, in contrast to the eukaryal-like lipid composition of other organelle membranes.

The third critical line of evidence supporting endosymbiosis came with the discovery that mitochondria and chloroplasts contain their own DNA (mitochondrial DNA is represented as mtDNA, and chloroplast DNA is known as ctDNA). This DNA is essential for the activities and reproduction of the mitochondria and chloroplasts, suggesting a degree of autonomy otherwise unique among cell organelles. Furthermore, the gene sequences and organization of the mitochondrial and chloroplast genomes are much more analogous to those of bacteria than to those of eukaryal cells. Indeed, complete sequencing of mitochondrial genomes and numerous bacterial genomes has indicated that all mitochondria are derived from the endosymbiosis of a particular type of bacteria: an alpha-proteobacterium. Likewise, all chloroplasts are derived from the endosymbiosis of a cyanobacterium. Finally, mitochondria and chloroplasts divide by fission, much like bacteria. Mitochondria and chloroplasts control their own division, dividing on their own timetable, independent of the cell cycle.

Mitochondria and chloroplasts contain only a small subset of genes found in alpha-proteobacteria and cyanobacteria. What happened to the missing genes? The answer is twofold. One likely reason for the missing genes is that these particular alpha-proteobacteria or cyanobacteria live their lives exclusively within a host cell and thus have diminished needs for independent function since the host cell will be providing them with some materials for life. Once a gene product is no longer needed, the extra DNA content becomes a burden during replication and can be lost due to the selective pressure of evolution. In other words, genes that became redundant or obsolete were lost. With a smaller genome the mitochondria can replicate faster. The second, and more important, reason is that the majority of genes (well over 1,000) that originated in the alpha-proteobacterium or cyanobacterium moved during the course of evolution from the mitochondrion and chloroplast into the nucleus. These genes are transcribed in the nucleus, translated on ribosomes in the cytoplasm, and imported post-translationally into the mitochondria.

Several eukaryal microorganisms, termed amitochondriates, lack mitochondria but are not otherwise closely related to each other. Being non-photosynthetic, they also lack chloroplasts. Several medically important eukaryal microorganisms, including *Giardia*, *Trichomonas*, and *Entamoeba,* are amitochondriates. It once was believed that these organisms evolved prior to that first endosymbiotic event that gave rise to the mitochondrion. Two lines of recent evidence, however, cast doubt on this hypothesis. First, certain amitochondriates contain remnant organelles that resemble mitochondria. Second, genes within the amitochondriates' nuclear genome appear to have been derived from a mitochondria-like alpha-proteobacterium genome. Based on these pieces of evidence, one could hypothesize that the amitochondriates once had mitochondria, but that they have been lost through evolution.

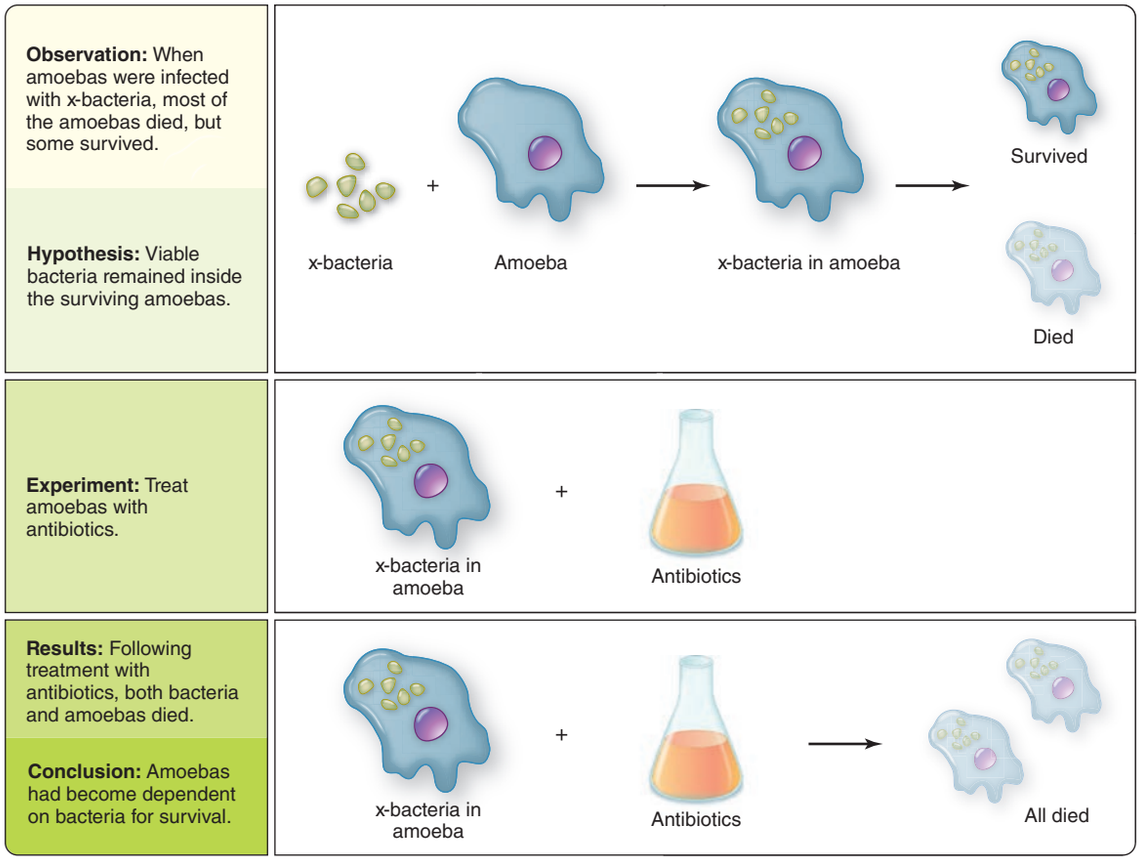

Figure 3.19. Experimental evidence for endosymbiosis: Amoeba and x-bacteria Following treatment with antibiotics targeting the x-bacteria, both the x-bacteria and the amoebas died. What killed the amoebas? Jeon concluded that the amoeba had become dependent upon the x-bacteria. The loss of the x-bacteria deprived the amoeba of some needed substance.

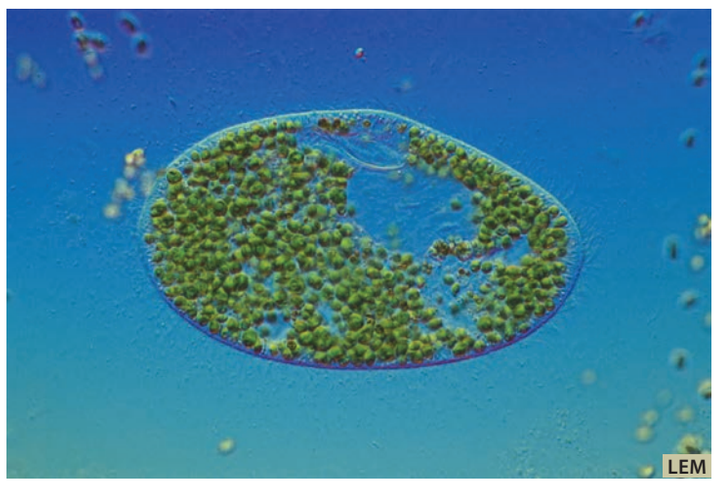
Endosymbiosis in Modern Cells

More experimental evidence supporting the endosymbiotic model is provided by the work of Kwang Jeon at the University of Tennessee. In the mid-1960s, Jeon began investigating a group of amoebas that had become infected with bacteria he termed "x-bacteria." Most of the amoebas died from the infection, but a few survived. Jeon's continued study of the surviving amoebas led to a pair of surprising discoveries. First, he found that the x-bacteria were still living inside the surviving amoebas. Second, when he then treated the amoebas with antibiotics that specifically targeted the bacteria to cure the amoebas of the infection, both the x-bacteria and the amoebas died **(Figure 3.19)**. These results indicated that not only had the amoebas adapted to live with the x-bacteria inside of them, but also that the x-bacteria actually became essential for the survival of the amoebas. Jeon's further research indicated that the x-bacteria alter patterns of gene expression in the amoebas to cause this endosymbiotic interdependence. This example, and its ability to be reproduced and studied in real time in the laboratory, provides evidence that endosymbiosis can give rise to new organisms, though the amoeba-bacteria hybrid falls far short of the extremely complex cell-organelle relationship found in eukaryal cells.

An additional example of a naturally occurring transient endosymbiotic relationship can be found in a common protozoan, *Paramecium bursaria*. This paramecium can derive energy and building blocks from either the ingestion of other cells or organic particles (heterotrophic) or through the use of sunlight (phototrophic). Although it has mitochondria, it doesn't have chloroplasts, so how can it perform photosynthesis? The answer is that, in the presence of sunlight, *P. bursaria* ingests a type of algae known as *Zoochlorella* and maintains the algae within its cytoplasm, a phenomenon sometimes referred to as "algal farming." The algae perform photosynthesis and provide the *Paramecium* with energy and sugars, while the *Paramecium* provides the algae with transportation and safety **(Figure 3.20)**. We can think of this arrangement as a type of secondary endosymbiosis



©Michael Abbey/Science Source

Figure 3.20. Paramecium and endosymbiosis: Algal farming This image shows a *Paramecium bursaria* cell containing numerous *Zoochlorella* algae. The algae perform photosynthesis for the benefit of both cell types.

Perspective 3.2
SECONDARY ENDOSYMBIOSIS: THE ORIGINS OF AN ORGANELLE WITH FOUR MEMBRANES

A wonderfully rich example of the correlation between double membranes and phagocytic events was recently discovered in an organelle of *Plasmodium falciparum*, the protozoan that causes malaria. This organelle, termed the apicoplast, exhibits two surprising features. First, its genome contains genes most like those of chloroplasts in sequence and organization. Second, four membranes surround it. How do you end up with four membranes around an organelle? Scientists now believe that the ancestor of *P. falciparum* engulfed an algal cell that already contained a chloroplast. Thus, the membranes of the apicoplast consist of (from the inside out): the membrane of the cyanobacterium, the membrane from the vacuole surrounding the cyanobacterium after the first endosymbiosis, the membrane of the alga, and the membrane from the vacuole surrounding the alga after the second endosymbiosis **(Figure B3.6)**. This event, logically termed secondary endosymbiosis, was first proposed by Sarah Gibbs more than 25 years ago in her work on *Euglena*, although it took genome sequencing to bring the idea into mainstream biology. Similar evidence for secondary endosymbiosis can be found in diatoms, in which four membranes surround a chloroplast that was originally a cyanobacterium, engulfed by a red alga, which in turn was engulfed by the ancestor of the diatom. Again, the presence of genes homologous to genes found in both cyanobacteria and red algae can be found within the chloroplast genome.

Our understanding of this secondary endosymbiosis may lead to the development of new chemotherapeutics (drugs) to treat malaria. Because of the presence of an algal-derived organelle, the malaria parasite has structures and biochemical processes in common with both bacteria and plants. Research is underway to evaluate the effectiveness of certain antibiotics and herbicides as treatments for malaria.

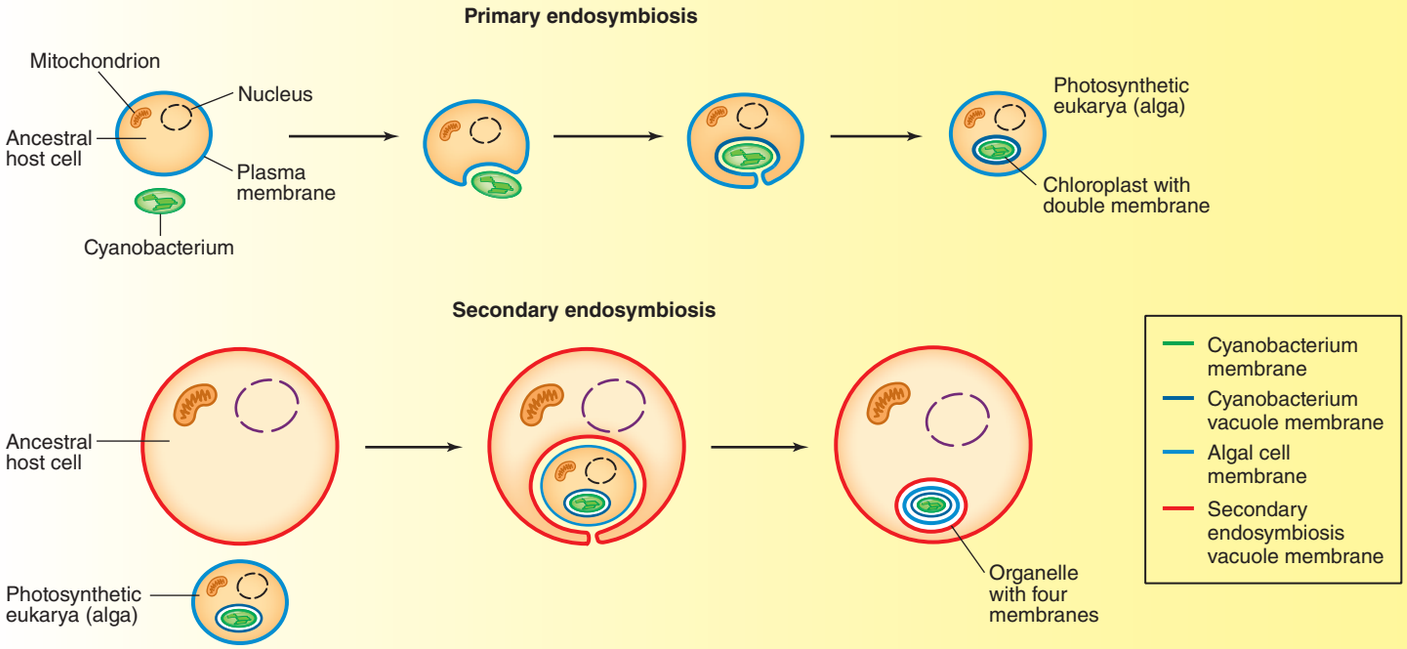


Figure B3.6. Secondary endosymbiosis: Generating an organelle with four membranes The process by which the product of a primary endosymbiosis leads to secondary endosymbiosis and results in the formation of a new organelle with four peripheral membranes.

(Perspective 3.2). Initially, the precursor of the algal cell engulfed a cyanobacterium-like cell, leading to the development of the chloroplast. Now, *P. bursaria* engulfs this eukaryal cell. This arrangement, however, is not permanent. Once the sunlight is gone, *P. bursaria* becomes heterotrophic and digests the algae for energy and food.

Lingering Questions about the Endosymbiotic Theory

The theory of endosymbiosis has good supporting evidence and seems straightforward. Like most ideas in science, however, the deeper you look into the question, the more interesting and complex it becomes. So, while endosymbiosis is a solid theory to explain the origin of eukaryal cells, some surprises and details remain unresolved, awaiting further investigation. Sequence analyses indicate that only two endosymbiotic events have led to the development of organelles: one that gave rise to mitochondria and one that gave rise to chloroplasts. Yet, experiments such as those involving Jeon's amoeba and the *Paramecium bursaria* indicate that endosymbiosis may occur readily. As we will see in Chapter 17, microbial endosymbionts

are plentiful in insects and some plants. Why then have stable endosymbiotic events leading to the development of organelles been so rare in the course of evolution? Another important question remaining is the identity of the original host cell that engulfed the alpha-proteobacterium. Scientists debate whether it was a bacterium or an archaeon that gave rise to the mitochondrion, and look to evidence of gene sequences and biochemical processes for a better understanding.

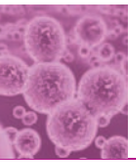
A dilemma comes from our ready use of the term "engulf" when referring to the process of endosymbiosis. We typically envision something like phagocytosis, the process by which cells of our immune system eat infectious bacteria. Phagocytosis requires cells to have both a flexible periphery and a cytoskeleton capable of forming a vacuole. Neither of these properties typically exists in bacteria or archaea that are surrounded by a rigid cell wall. It is possible, of course, to imagine that the engulfing cell lacked a wall. Possibly, this host cell was not the initiator of the endosymbiosis. Maybe it didn't eat the alpha-proteobacterium, but instead the alpha-proteobacterium invaded this cell. In this case, the need for a cytoskeleton to direct the process is less critical, and indeed, researchers have identified a number of disease-causing microbes that force their way inside host cells in a manner that does not involve the host cell cytoskeleton. Another possible scenario is a progenitor eukaryal cell with many attributes we commonly associate with eukaryal cells today (flexible membrane, complex cytoskeleton) was simply missing the full complement of internal organelles.

Might other organelles also be derived from endosymbiotic events? Is it possible that the nucleus itself might be the result of an endosymbiotic event? Remember that it too is surrounded by a double membrane and contains DNA. The origins of other organelles are less clear. Because other organelles lack DNA—the key piece of evidence of a former life as an independent cell—some think that they may be the result of invagination of membranes and subsequent localization of specific cell functions within those isolated compartments. Lynn Margulis believed, and other scientists still believe, that endosymbiosis may have been more widespread, and many are actively seeking evidence that other organelles also might be endosymbiotic legacies.

CONNECTIONS Several lines of evidence support the hypothesis that the eukaryal nucleus may have resulted from endosymbiosis of an archaeon. In **Section 7.2**, we will see that many of the enzymes involved in archaeal DNA replication show a similarity to enzymes utilized by eukarya.

3.4 Fact Check

1. What is the endosymbiotic theory, and how is it related to the origins of mitochondria and chloroplasts?
2. What evidence supports the endosymbiotic theory?



3.5 Interactions between eukaryal microorganisms and animals, plants, and the environment

What harmful and beneficial roles do eukaryal microorganisms play?

Given the vast number and great diversity of eukaryal microorganisms, it should come as no surprise that these organisms play vital roles in our world. In fact, it is hard to imagine what life on Earth would be like without these organisms. Certainly, the ecosystem of the Rio Tinto would be very different! In this last section, we will examine some of the roles eukaryal microorganisms play, focusing first on diseases caused by these organisms and second on the roles they play in the environment.

Diseases caused by eukaryal microorganisms

Eukaryal microorganisms cause a wide array of diseases in both animals and plants. Their role as pathogens raises particular problems because drug treatments normally target cellular structures in the pathogen that are different from those of the host. Such differences are common between bacterial pathogens and their eukaryal animal and plant hosts. As a result, we have many antibiotics for the treatment of bacterial infections. When both the pathogen and the host are eukaryal cells, however, the options for cellular targets are much more limited, and the development of drugs that are both safe for the host and effective against the eukaryal pathogen is more difficult (see Chapter 24).

The list of human diseases caused by eukaryal microorganisms is long and has both historical and contemporary significance **(Figure 3.21)**. One of the top three infectious disease killers in the world today is cerebral **malaria**, a disease caused by the parasite *Plasmodium falciparum* that is transmitted between humans by the *Anopheles* mosquito. Malaria kills around one million people per year. In countries with high rates of infection, largely in sub-Saharan Africa, up to 50 percent of public health costs and hospital visits are attributable to malaria. The parasite has developed resistance to current drug treatments in many regions and no effective vaccine against the disease exists.

Eukaryal microorganisms cause many other insect-borne diseases. Trypanosomatids cause several diseases: African sleeping sickness (caused by *Trypanosoma brucei* and transmitted by the tsetse fly), Leishmaniasis (caused by *Leishmania* and

transmitted by the sand fly), and Chagas disease (caused by *Trypanosoma cruzi* and transmitted by the triatomine insects known as the "kissing bugs"). Disease-causing eukaryal microorganisms also include a number of intestinal pathogens transmitted in food and water: *Entamoeba histolytica* **(Microbes in Focus 3.2)**, *Cryptosporidium parvum*, and *Giardia lamblia*. One eukaryal microorganism, *Toxoplasma gondii*, which is related to *Plasmodium*, causes a common infection typically transmitted via cat feces or raw meat. The infection is most commonly asymptomatic, but if a woman becomes infected for the first time at the beginning of a pregnancy, it can cause significant neurological problems in a small percentage of fetuses. Additionally, the parasite remains within the host and can reemerge to cause neurological damage if the host immune system is suppressed, for example in people with HIV/AIDS or those who have received organ transplants.

The list of fungi that cause diseases in healthy people is quite limited. However, fungi do cause some superficial skin infections **(Figure 3.22)**. Fungal infections can cause athlete's foot, ringworm, or jock itch, depending on the species of fungus. *Candida* infections can also cause different diseases, ranging from an oral disease, termed "thrush," in infants to vaginal yeast infections in adult women. Many groups of fungi, however, can cause disease in people with suppressed immune systems. Indeed, one of the features of HIV/AIDS that first attracted medical interest was the appearance of fungal infections in these patients.

The list of plant diseases caused by eukaryal microorganisms is long and has both historical and modern significance. Although humans more often suffer infections from protozoa, plants are more often affected by fungi. Fungi are particularly well suited to causing plant infections because the durable nature of their spores readily permits them to survive in soil between crops and during inclement weather conditions.

Microbes in Focus 3.2
ENTAMOEBA HISTOLYTICA: THE CAUSE OF AMOEBIC DYSENTERY

Habitat: Infects humans and other primates. Cysts can exist in water, soil, and on foods. Infection occurs by ingestion of cysts. Found worldwide, but infections are more common in developing countries.

Description: Parasitic unicellular microorganism; lacks mitochondria.

Key Features: It was once thought that pathogenic and nonpathogenic strains of *E. histolytica* existed. Now, researchers recognize that these strains are actually two distinct species. *E. histolytica* is pathogenic, *E. dispar* is not.

D. Oral thrush

Figure 3.22. Parasitic fungi cause human diseases. A. The fungus *Epidermophyton floccosum* showing reproductive spore structures. This fungus can cause athlete's foot. Related fungi also can cause athlete's foot, ringworm, and jock itch. **B.** Athlete's foot resulting from a fungal infection. **C.** The fungus *Candida* showing reproductive spore structures. *Candida* can cause a variety of diseases, ranging from oral thrush to vaginal yeast infections. **D.** Oral thrush resulting from a *Candida* infection.

These organisms cause a number of plant diseases, descriptively named rusts, rots, mildews, and smuts, that infect many grains and other crops, exacting a devastating toll on both crop yields and economies. Dutch elm disease, for instance, is a fungal disease of plants that has dramatically altered the landscape of American cities and towns (see Section 23.1). The most famous example of a plant disease is the infection of potato plants with *Phytophthora infestans* **(Microbes in Focus 3.3)**, a water mold (a protozoan most closely related to brown algae and diatoms) responsible for potato blight **(Figure 3.23)**. Infections with *P. infestans* caused widespread famine in Ireland in the mid-1800s, resulting in 0.5–1 million deaths. At least twice as many Irish immigrated to the United States during this famine. Today, in the United States alone, there are more than 50,000 identified infectious diseases of plants with an annual cost of tens of billions of dollars spent on prevention and loss to crop damage.

Certain fungi also infect insects, sometimes with dramatic effects. Often referred to as the "zombie fungus," *Ophiocordyceps unilateralis*, for example, infects a specific type of ant found in tropical locations. Initially, spores attach to and then enter the insect. As the fungus grows within the ant, it affects the central nervous system of the host, altering its behavior. The infected ant leaves its colony in the canopy of the forest and travels to the more humid understory. It then bites a leaf, firmly attaching itself to the plant before dying. Having caused the ant to travel to this new location, the fungus continues to grow within the host, eventually forming a stalk that erupts from the head of the ant **(Figure 3.24)**. Spores disperse from the stalk and can infect other ants. Not surprisingly, the bizarre appearance of insects with fungal stalks growing from their bodies and the behavioral changes caused by the fungal infections have captivated the interest of scientists and science fiction writers alike.

Microbes in Focus 3.3
PHYTOPHTHORA INFESTANS AND THE IRISH POTATO FAMINE

Habitat: A common pathogen of potatoes, especially in cooler, damp climates. Also infects some other plants, including tomatoes.

Description: Forms filamentous hyphae-like structures. Spores develop into flagellated, swimming zoospores.

Key Features: Originally classified as a fungus, *P. infestans* now is considered to be more closely related to the algae and diatoms. *P. infestans* possesses a cell wall made of cellulose, not chitin. Unlike most fungi, it produces swimming spores.

CONNECTIONS *Ophiostoma novo-ulmi*, the causative agent of Dutch elm disease, produces several enzymes that help it degrade the plant cell wall. We will explore the roles of these enzymes in **Section 23.1**.

Beneficial roles of eukaryal microorganisms

As mentioned earlier, not all microbes are associated with disease. Eukaryal microorganisms also play essential beneficial roles. In most ecosystems, eukaryal microorganisms, bacteria, and archaea serve as primary producers and biodegraders, keeping both energy and nutrient cycles going. Indeed, any cupful of water from a pond will reveal a world teeming with an enormous diversity of protozoa, algae, and fungi—a complete and self-sustaining microbial ecosystem. The description of life in the Rio Tinto presents this fundamental point. Photosynthetic algae harvest the energy of sunlight. Protozoa may survive by ingesting these algae or bacteria. Fungi decompose wastes, releasing nutrients. A complete and self-sustaining ecosystem thrives in this apparently hostile environment.

Figure 3.24 Zombie fungus Many fungi infect insects, but perhaps none do so as dramatically as *Ophiocordyceps unilateralis*. Often referred to as the zombie fungus, this pathogenic fungus replicates within an infected ant. Eventually, a stalk forms, erupting from the head of the infected ant, to spread infectious spores to other susceptible individuals.

Our mental image of photosynthesis is usually one of large green trees. In reality, however, it is the open oceans that account for the majority of photosynthesis, followed closely by tropical rain forests. Algae and photosynthetic bacteria play key roles in photosynthesis in the ocean. Thus, photosynthetic microorganisms are essential for maintaining an aerobic atmosphere and for providing energy from sunlight and organic carbon from carbon dioxide.

Eukaryal microorganisms also serve a critical function in biodegradation of organic matter. They are particularly important in the breakdown of cellulose, an abundant structural polysaccharide in plants that is poorly digested by animals. By degrading cellulose, eukaryal microorganisms are vitally important in the decomposition of plant matter and provide a critical step in rendering this plant matter usable for energy and nutrients by other organisms. Eukaryal microorganisms also can be found in great numbers in ruminant and termite digestive tracts, where they facilitate the degradation of cellulose **(Figure 3.25)**.

CONNECTIONS Many animals, like deer, cows, and termites, culture bacteria, fungi, and protozoa in their guts to hydrolyze cellulose for nutrition. See **Chapter 24** for details.

3.5 Fact Check

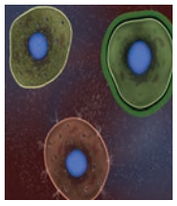
1. Why is it difficult to treat infections by eukaryal microorganisms?
2. What are examples of human infections caused by fungal pathogens?
3. List common fungal infections in plants.
4. What are some beneficial environmental roles of eukaryal microorganisms?

© Michael Abbey/Science Source

Figure 3.25. Termite gut contains a protist that digests cellulose The flagellated protist *Trichonympha* in the gut of the termite is responsible for digestion of cellulose. Despite being a danger to wooden structures, the protist's breakdown of cellulose is ecologically important and difficult chemically. The β-1,4 linkage between the glucose units is more stable to chemical breakdown than is the α-1,4 linkage found in starch. Enzymes capable of degrading cellulose are found in some microorganisms, such as *Trichonympha*.

Image in Action

WileyPLUS Learning Space Some eukaryal microorganisms can use various mechanisms to withstand acidic environments like the Rio Tinto. These mechanisms may include allowing for the flow of protons (white spheres) freely into the cell (yellow, *top left*) and coping with the cytoplasmic acidity, maintaining a thick cell wall to prevent the influx of protons (green, *top right*), or maintaining porous membranes to allow protons to enter the cell, and then pumping them back out (red, *bottom center*).



1. You have been asked to add additional detail to this image to convey to the viewer that these cells are eukaryal cells. What features are already present and what detail or labeling would you add to convey this point? What features might be specifically used to point out that these cells are a type of algae?
2. If a toxin that blocked H^+ pumps in the cell membrane were dumped into the Rio Tinto, predict how this event would affect the metabolism and survival of the cells in this image and, by extension, the overall Rio Tinto ecosystem. Explain your reasoning.

The Rest of the Story

When scientists first discovered the rich diversity of the Rio Tinto ecosystem described in the opening story, they were struck by the dominant presence of eukaryal microorganisms and wondered at their ability to survive in such harsh conditions. In particular, they questioned how the eukaryal cells could survive in very low pH conditions and proposed the three possibilities mentioned earlier. Our understanding of the role of membranes in maintaining homeostasis will illuminate the answer to this question.

Some researchers hypothesized that the eukaryal microorganisms within the Rio Tinto simply let hydrogen ions flow in and, as a result, had a reduced intracellular pH. However, the intracellular pH of one particular species (a new species in the *Chlamydomonas* genus) is close to pH 6.6. Remember that the pH scale is logarithmic, so the hydrogen ion concentration outside the cells, where the pH is around 2.2, is close to 40,000 times higher than inside of the cells! This finding certainly does not support the first option.

It seems, then, that the cells must erect barriers against hydrogen ions or actively defend themselves against the influx of hydrogen ions. To distinguish between these options, scientists turned their attention to a novel set of hydrogen ion ATPases. They found that *Chlamydomonas* grows better at higher extracellular pH than at lower extracellular pH, and they measured the cost at 7 percent more ATP consumed per second by the cell under acidic conditions. Based on these data, it seems that the cells do not simply have a barrier that protects them from the hydrogen ions. Rather, these data provide good evidence that the hydrogen ions are actively transported against a chemical gradient out of the *Chlamydomonas* cytoplasm by using ATP for energy. When the extracellular pH is lower, this chemical gradient is greater and the cell must use more energy to pump the hydrogen ions out of the cell. Thus, the cells maintain homeostasis, but at an energetic cost. Possibly, the protons are pumped from the cytoplasm into an internal organelle. In this case, the H^+ pumps would not be exposed to the acidic extracellular environment and could function just like pumps found in *Chlamydomonas* species that live under less acidic conditions. As we can see from this one example, our understanding of cellular structure helps us to formulate hypotheses about cellular function.

Summary

Section 3.1: What do eukaryal cells look like?

Eukarya possess a membrane-bound nucleus. Additionally, eukaryal cells contain other internal **organelles** and a complex cytoskeleton.

- The **nucleus** contains the genetic material. Within this double membrane-bound organelle, DNA replication and transcription occur.
- The **secretory pathway**, which includes the **endoplasmic reticulum (ER)** and the **Golgi apparatus**, is involved in protein trafficking.
- **Mitochondria** and **chloroplasts** are responsible for cellular energetics. Cellular respiration occurs within the mitochondria. Conversion of solar energy to chemical energy and carbon fixation occurs within the chloroplast. Both organelles generate ATP via **chemiosmosis**. The **amitochondriates** are eukarya that lack mitochondria.
- The **plasma membrane** effectively separates *inside* from *outside*. Even though bacteria and archaea also possess plasma membranes, structural differences in the membranes of these domains do exist. Proteins exist within the plasma membrane and can move within the membrane, which has led to the **fluid mosaic model** of the plasma membrane. Localized pockets of specific lipids, **lipid rafts**, exist within cellular membranes.
- **Cilia** and flagella of eukaryal cells are encased within the plasma membrane.
- The **cell wall** plays a role in cell support. Not all eukarya possess cell walls. Algae have cell walls composed primarily of **cellulose**. Fungi generally have cell walls composed of chitin.

- The **cytoskeleton** provides shape and support to eukaryal cells and is composed of three major types of structures: **microtubules**, **microfilaments**, and **intermediate filaments**. The cytoskeleton directs the movement of material within the cell and the movement of the cell itself.

Section 3.2: What are the different types of eukaryal microorganisms?

Eukaryal microorganisms are very diverse and their classification has been problematic.

- Traditional groupings have been based mainly on morphological features.
- Currently, phylogeny is based on SSU rRNA sequence comparisons. These comparisons demonstrate that some traditional groups, like the fungi, are, in fact, monophyletic. Other traditional groups, like the algae, are much more diverse.
- Phylogenetic trees based on other molecular markers, like Hsp70, reveal somewhat different evolutionary relationships among the eukaryal microorganisms.
- Much of what we know about eukaryal microorganisms is based on studies of **model organisms**.
- The fungi, like *Saccharomyces cerevisiae*, are distinguished by their cell wall, a chitin-based structure. Fungi are all heterotrophs.
- The protozoa, like *Giardia lamblia*, represent a broad and poorly defined group of eukaryal microorganisms. While some are heterotrophic, others are photosynthetic. Some contain a cell wall, while others do not.
- Slime molds, like *Dictyostelium discoideum*, often are classified as protozoa. The slime molds, though, always are heterotrophic and usually exist in multicellular aggregates.
- Algae, like *Chlamydomonas reinhardtii*, contain chloroplasts and are autotrophic.

Section 3.3: How do eukaryal microorganisms replicate?

Unlike bacteria and archaea, eukaryal microorganisms have **haploid** ($1n$) and **diploid** ($2n$) genetic complements at different stages of their life cycles.

- In **mitosis**, genetically identical copies of the parent cell are produced. **Cytokinesis** generally follows mitosis.
- In **meiosis**, a reduction in the genetic complement, from $2n$ to $1n$, occurs, along with a recombination of genetic material.
- Diploid cells of *Saccharomyces cerevisiae* reproduce asexually via mitosis. During periods of stress, the diploid cells undergo meiosis, producing haploid ascospores arranged in an **ascus**. These haploid cells can mate, resulting in the formation of a new diploid cell.
- Haploid cells of *Chlamydomonas* reproduce asexually via mitosis. During periods of stress, these haploid cells undergo morphological changes and become gametes. These gametes can fuse, producing a diploid spore. When conditions improve, this spore can undergo meiosis, resulting in four new haploid cells.
- The slime mold *Dictyostelium* has a very interesting and complex life cycle. Haploid amoeboid cells aggregate when food sources are depleted. The aggregated cells then undergo a type of differentiation, eventually forming spores that are released in the environment.

Section 3.4: How did eukaryal microorganisms originate?

Eukaryal cells originated when one cell engulfed another. The engulfed cell escaped destruction and became a necessary component of this developing eukaryal cell, a process known as **endosymbiosis**. Three main pieces of evidence support the endosymbiotic theory.

- Mitochondria and chloroplasts resemble bacteria both in size and shape and these organelles replicate independently of the cell cycle via fission.
- A double membrane surrounds mitochondria and chloroplasts, which is consistent with phagocytosis.
- Mitochondria and chloroplasts contain their own DNA and this DNA is more analogous to bacterial DNA than it is to the DNA of eukaryal cells.
- Questions about the origins of eukaryal cells, including how organelles other than mitochondria and chloroplasts originated, still remain.

Section 3.5: What harmful and beneficial roles do eukaryal microorganisms play?

Eukaryal microorganisms cause a wide array of diseases in both plants and animals, but also serve many beneficial roles.

- One of the major infectious diseases in humans is **malaria**, which is caused by the parasite *Plasmodium falciparum*.
- Photosynthetic eukaryal algae account for a significant amount of the photosynthesis that occurs in the oceans.
- Eukaryal microorganisms serve a critical function in the degradation of organic matter.

Application Questions

1. Imagine you identify a cell and must characterize it as a eukaryal microorganism, a bacterium, or an archaeon by examining it under the microscope. Explain how you would make this determination.
2. What genes might you look for in the genome of a newly identified cell to identify it as a eukaryal microorganism rather than a bacterium or archaeon? Explain.
3. In the process of studying a given eukaryal microorganism, you have disabled its Golgi apparatus. What would be the functional consequences for the eukaryal cell in this experiment?
4. While examining cellulose synthesis in the green alga *Chlamydomonas reinhardtii*, a researcher has deleted the genes involved in the process. What would be the structural and functional consequences of deleting cellulose synthesis genes in these algae? Explain.
5. The fungus *Candida albicans* causes vaginal yeast infections in women. This microorganism does have a cell wall, but penicillin is inactive against it. Explain why.
6. The bacterium *Escherichia coli* and the parasitic protozoan *Giardia lamblia* both have flagella that help them swim. Although they have the same name, the structure and mechanism of action of the two flagella are quite different. Describe these differences.
7. Kwang Jeon found that when he treated the x-bacteria-infected amoebas with antibiotics, both the bacteria and amoebas died. What is the significance of this finding and how does it support the theory explaining endosymbiotic events that happened billions of years ago?
8. You read about a drug that disrupts the enzyme chitin synthase (involved in synthesizing chitin in cells). What type of microbes would this drug combat? Explain.
9. A scientist is writing a research grant to obtain funds to study the metabolism and activity of the slime mold *Dictyostelium*. He notes that his research could have many applications to understanding both human health and soil health. Explain how studying this one organism could provide information in such different scientific fields.
10. Many cases of disease outbreaks caused by the protozoan *Cryptosporidium parvum* in public pools have been documented, even though the pools were chlorinated. Why doesn't the osmotic pressure or the chlorine in the pools destroy these microorganisms?
11. You accompany scientists on their next trip to the Rio Tinto and carefully scrape a crusty sample from a rock in shallow water at the edge of the river. Upon returning to the laboratory, you are rewarded by the sight of many large oblong cells.
    a. First, describe what cell features you would look for to determine whether these cells were bacterial or eukaryal microorganisms.
    b. Second, assume that you have identified them as eukaryal microorganisms. Now, describe what structures/functions you would examine to determine whether the cells are fungi, algae, slime molds, or protozoa.
    c. Describe how you might use immunofluorescence techniques to determine your answer in part b.

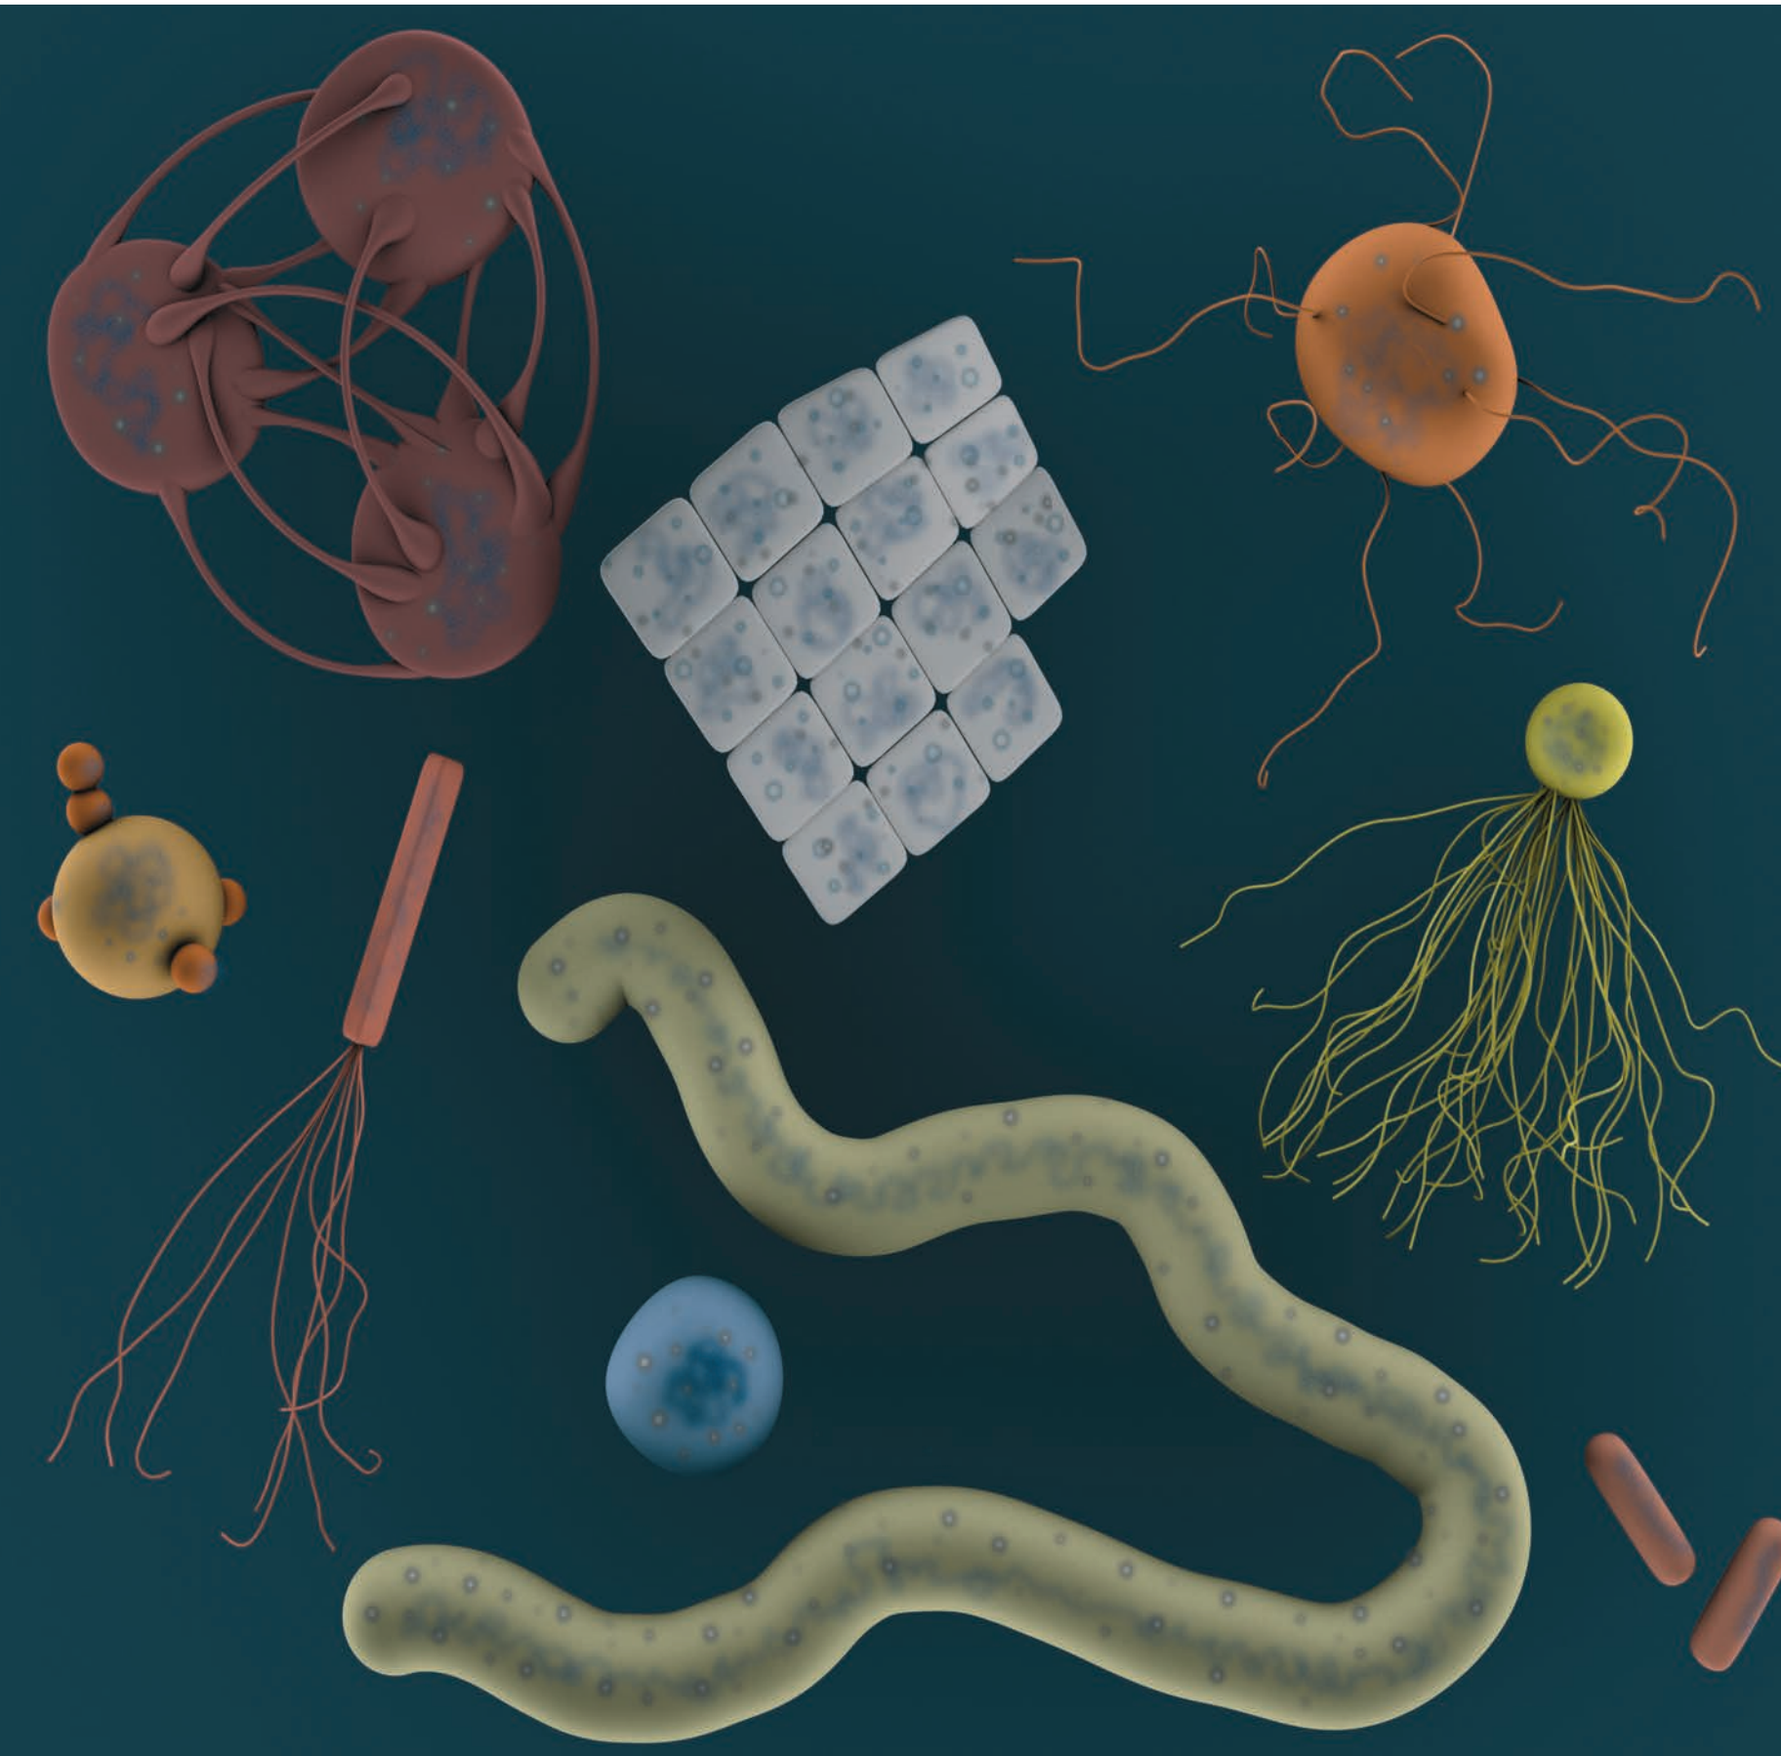
CHAPTER

4 Archaea



During explorations of hydrothermal vents off the coast of Iceland, microbiologists isolated a new microbial species, *Ignicoccus hospitalis*. They discovered that this single-celled, coccus-shaped microorganism lacks a nucleus, like the bacteria that we explored in Chapter 2. This microorganism, however, is not a bacterium. Rather, it is a member of another domain of life: the *Archaea*.

In the laboratory, researchers could cultivate this microorganism, but only under some fairly atypical conditions. Like the only other current members of the *Ignicoccus* genus, *I. islandicus* and I. *pacificus*, this microorganism grows optimally at 90°C. Additionally, these three species all grow best in slightly acidic and somewhat salty environments. They also gain energy by reducing elemental sulfur and, in the process, forming hydrogen sulfide. Structurally, *I. hospitalis*, *I. islandicus*, and I. *pacificus* differ from all other known archaea. For these species, the cell envelope consists of a plasma membrane, a periplasm, and an outer membrane, similar in many respects to the cell envelope of the Gram-negative bacteria that we studied in Chapter 2.

Ignicoccus hospitalis certainly exhibited unusual growth requirements, but another aspect of this microorganism interested the researchers even more. They noticed that very tiny, coccus-shaped cells were attached to many of the *Ignicoccus* cells. This second microbial species, named *Nanoarchaeum equitans*, also is an archaeon and appears to grow only in association with I. *hospitalis*. The exact nature of the relationship between these microorganisms remains a topic of great interest. The cells of *N. equitans* are only 0.4 μm in diameter, and its genome is less than 500,000 base pairs, making it one of the smallest-known living organisms. Additionally, some researchers have proposed that *N. equitans* represents the sole member of an entirely new phylum within the archaeal domain. Studies of this unusual organism may provide us with new insight into life under extreme conditions, interspecies relationships, and the minimal requirements for life.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Microorganisms in this domain are distinct from bacteria and eukarya.

CONNECTIONS for this chapter:

Methane production by archaea **(Section 17.4)**

Penicillin and bacterial cell wall synthesis **(Section 24.2)**

Effects of cell signaling on flagellar rotation **(Section 11.7)**

Industrial uses of microbes **(Section 12.4)**

Proton motive force and ATP generation **(Section 13.4)**

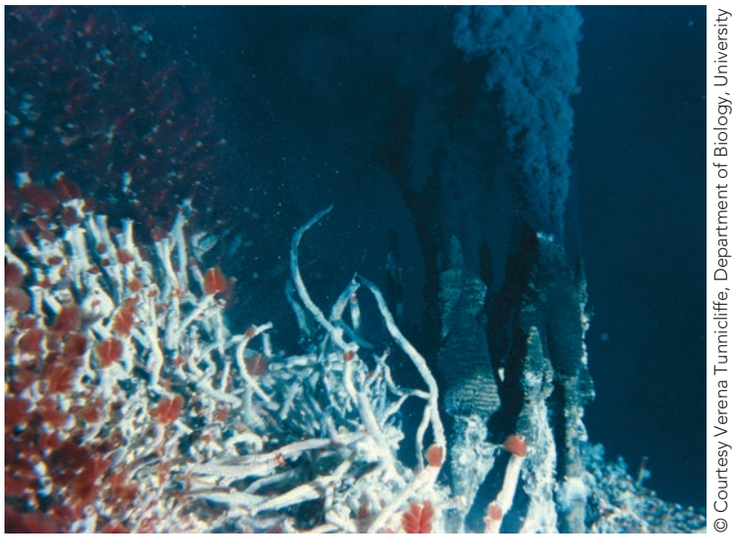
Introduction

In this chapter, we will explore another domain of life: the *Archaea*. Like the bacteria that we examined in Chapter 2, archaea lack a true nucleus. These organisms, however, differ in fundamental ways from both bacteria and eukarya. Although we still know relatively little about archaea, our studies of these microorganisms have shed light on important aspects of how proteins and cells function and future studies promise to provide insight into the evolution of all living organisms. The story of the domain *Archaea* is both exciting and exotic; it begins in some of the most inhospitable environments on Earth.

Since the discovery of the first organisms that grow optimally in environments with extreme chemical and/or physical properties, microbiologists have searched for signs of life in almost every imaginable environment on Earth. Perhaps surprisingly, or perhaps not, we have found living organisms that thrive in every explored environment. From the boiling waters of hot springs to the frigid environments of Antarctica, and from the low-pH, sulfur-rich waters often associated with volcanoes to the high-pH waters of lakes containing sodium carbonate, life, it seems, exists everywhere.

Underwater, hydrothermal vents are no exception. Often referred to as black smokers, these vents actually represent fissures in Earth's crust through which geothermally super-heated water escapes. Often topping 400°C initially, this mineral-laden water cools quickly, causing the precipitation of its mineral contents and the gradual formation of the characteristic rock chimneys. Studies of black smokers in oceans throughout the world have demonstrated that a wonderful array of life calls these very hot environments home **(Figure 4.1)**, including many archaea. We should note, however, that archaea are not relegated solely to these seemingly harsh environments. Current studies show that archaea inhabit myriad environments that we may consider to be more hospitable, such as soils, freshwater, marine water, and even the human body. In fact, archaea are abundant and widespread just about anywhere you might find life on this planet.

Because archaea superficially resemble bacteria, *Archaea* was not recognized as a domain of life until quite recently.



© Courtesy Verena Tunnicliffe, Department of Biology, University of Victoria, B.C.

Figure 4.1. Black smoker in the Pacific Ocean Rising from the seafloor over a mile beneath the surface, black smokers may seem inhospitable. The water emerging from them may be over 400°C and laden with various sulfur compounds. Nonetheless, a rich community of life, including numerous tube worms, grows in the super-heated waters of these 10- to 15-foot-tall formations. Some of the most abundant inhabitants of these environments are archaea that have evolved to survive in these hot waters.

In 1977, Carl Woese and colleagues proposed that these organisms were distinct from bacteria and, in 1990, argued that *Archaea* represents a unique domain of life, separate from *Bacteria* and *Eukarya*. In subsequent chapters, we will explore how archaea differ from bacteria and eukarya. In this chapter, we will address this issue briefly. We also will tour an archaeal cell, much like we toured the bacterial cell in Chapter 2. Finally, we will begin to investigate the diverse groups of archaea. So let's begin by asking a few questions:

How do we know that Archaea is a distinct domain of life? (4.1)
What do archaeal cells look like? (4.2)
What are the major groups of archaea? (4.3)

4.1 Evolution of Archaea

How do we know that Archaea is a distinct domain of life?

It's hard to imagine that a whole domain of life, one of the three domains into which all living organisms now are categorized, was not discovered by biologists until the last decades of the twentieth century. In fact, the entire story of the domain ***Archaea*** is somewhat hard to imagine. For many years, cultured members of this domain were lumped together with bacteria into a single kingdom. Indeed, archaea bear striking similarities to bacteria. Most notably, archaea and bacteria are very similar in size and have chromosomes of similar size and organization. Members of both groups also lack a membrane-bound nucleus. Despite these superficial similarities, genetic studies have revealed that bacteria and archaea form two highly distinct evolutionarily groups. Additional studies have provided more evidence that archaea differ substantially from both bacteria and eukarya. In Section 4.2, we will examine the structure of archaeal cells, focusing on how common structures differ among archaea, bacteria, and eukarya. In this section, we will focus on a more fundamental question. How do we know that *Archaea* is a distinct domain of life?

Phylogeny

The question posed above can best be answered by phylogenetic studies, or studies of the evolutionary relatedness of organisms. The question, then, becomes: How can we determine the evolutionary relatedness of all living organisms? In 1977, while Carl Woese and George Fox were researchers at the University of Illinois at Urbana-Champaign, they answered this question in a most elegant way. In their landmark paper (PNAS 74:5088), the authors noted that:

> Phylogenetic relationships cannot be reliably established in terms of noncomparable properties. …To determine relationships covering the entire spectrum of extant living systems, one optimally needs a molecule of appropriately broad distribution. None of the readily characterized proteins fits this requirement. However, ribosomal RNA does.

In other words, by comparing **ribosomal RNA (rRNA)** nucleotide sequences, we can determine the evolutionary relatedness of all living organisms (see the Mini-Paper in Chapter 1 for more details about this important study). Organisms with closely related rRNA sequences must be closely related evolutionarily. More specifically, Woese and Fox examined the sequence of the 16S or 18S ribosomal RNA molecules, the small subunit rRNA (SSU rRNA). As we will see in Section 7.4, SSU rRNA is a critical component of the ribosome in all cells. Because this molecule is present in all known living organisms and always fulfills the same biological function, Woese and Fox reasoned that it will be highly similar among all organisms. Minor sequence variations, resulting from random mutations, will exist, and the number of differences between the rRNA sequences of two species will reflect the evolutionary distance between those species. In other words, ribosomal RNA sequences can be used to compare all organisms.

The findings of Carl Woese and George Fox were groundbreaking and, quite literally, resulted in the rewriting of biology textbooks. Ribosomal RNA sequence analyses showed that all eukaryal organisms, as Woese and Fox expected, were related. Prokaryotic organisms, however, formed two distinct groups. All of the well-characterized bacteria, like *Escherichia coli* and *Staphylococcus aureus*, formed a distinct group. However, not all prokaryotic organisms were related to these well-characterized bacteria. The rRNA sequence analysis of a then poorly characterized group of microorganisms capable of producing methane were evolutionarily distinct from bacteria **(Figure 4.2)**. As Woese and Fox noted, "These 'bacteria' appear to be no more related to typical bacteria than they are to eukaryal cytoplasms." These methane-producing organisms, Woese concluded, constituted a separate domain of life altogether: the *Archaea*. We now know that the domain *Archaea* includes more than just these methane-producing organisms; they possess diverse metabolisms rivaling metabolic diversity found within the *Bacteria*.

CONNECTIONS Methane-producing archaea remain an important and well-studied group of organisms. Methane-producing archaea live in the gastrointestinal tract of mammals, aiding in the digestion of food. As we will see in **Section 17.4**, cattle produce a substantial amount of methane, thanks to their archaeal partners.

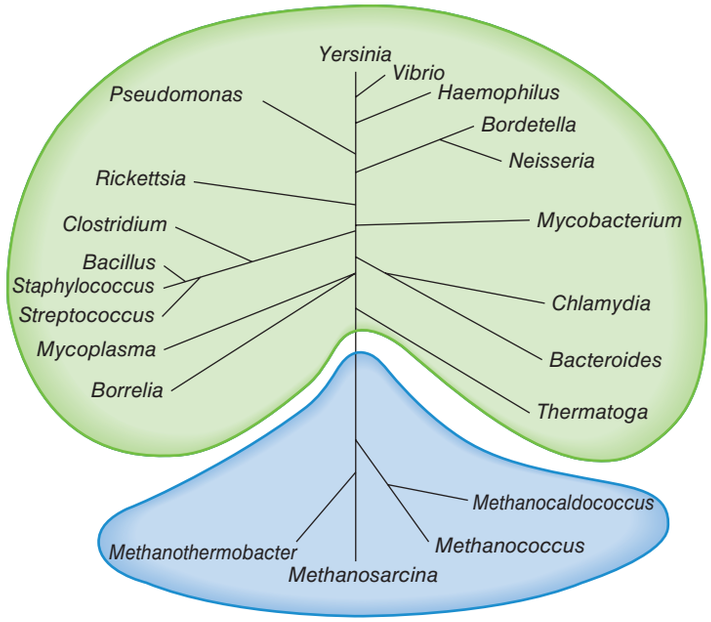


Figure 4.2. Methanogens are genetically distinct from bacteria In 1977, Woese and Fox proposed that methanogens were distinct from all commonly known bacteria. Subsequent SSU rRNA gene sequence analysis has confirmed this hypothesis. As shown in this schematic, when the 16S rRNA sequences of various bacteria and the four methane-producing microorganisms are compared, the methanogenic species form a distinct cluster.

Consistent with the initial discovery of *Ignicoccus* and *Nanoarchaeum* that we highlighted in the opening story, many archaea have been identified in environments that seem extreme to us **(Table 4.1)**. In fact, for quite some time, many scientists assumed that all archaea lived in atypical environments and referred to them as extremophiles. We should note that "extreme" lies in the eyes of the beholder; what may seem extreme to us may be quite normal for other organisms. More recently, archaea have been identified in environments that humans consider less extreme. Indeed, we now know that archaea are quite common in temperate marine, freshwater, and soil environments. Moreover, archaea play a major role in biogeochemical nutrient cycling. Despite inhabiting diverse environments, all of these organisms are phylogenetically related; all of them exhibit significant 16S rRNA gene sequence similarity.

TABLE 4.1 Selected archaea and their preferred growth requirements

Organism	Notable growth requirement(s)	Natural habitat
Halobacterium salinarum	3.0–5.0 M NaCl	Dead Sea, salted foods
Pyrococcus furiosus	100°C	Hydrothermal vents
Picrophilus oshimae	0.7 pH	Sulfur-rich volcanic regions
Methanogenium frigidum	15°C	Ace Lake, Antarctica

Evolution

What do we know about the evolutionary history of archaea, and what can these organisms tell us about the evolutionary history of life? As with so many aspects of the biology of archaea, we still are developing answers to these critical questions. Initially, many people assumed that archaea were ancient organisms, perhaps even the descendants of the first life-forms. After all, the first archaea identified were extremophiles, and conditions on Earth when life arose were quite extreme. However, SSU rRNA gene sequence analyses paint a different picture. These analyses clearly show that the domains *Bacteria, Archaea,* and *Eukarya* form three distinct clusters. These analyses also suggest that *Archaea* and *Eukarya* may share a more recent common ancestor than either of these domains shares with *Bacteria* (see Figure 1.8). In other words, the last common universal ancestor (LUCA) gave rise to both bacteria and another precursor that eventually gave rise to the archaea and eukarya we see today. Some researchers hypothesize that the appearance of **histones**, DNA-binding proteins traditionally considered to be a defining characteristic of eukarya, in a precursor cell led to the evolution of archaea and eukarya. Histones certainly can protect DNA in high-temperature environments and can allow larger amounts of DNA to be packaged into cells. The appearance of histones may have led to a rapid evolutionary burst.

CONNECTIONS As we just noted, archaea, like eukarya, possess histones. In **Section 7.1**, we will see that many archaeal proteins associated with DNA replication, including DNA polymerase, primase, and helicase, show similarities to their eukaryal counterparts.

Any discussion of archaeal evolution faces an even more perplexing issue: the altered plasma membrane found in members of this domain, a topic that we will examine more closely in Section 4.2. We could surmise that the archaeal membrane provides increased thermal stability. Certainly, that would benefit species that live in high-temperature environments. However, many archaea inhabit a wide range of temperate environments. Furthermore, many bacteria also live at high temperatures, which demonstrates that the archaeal membrane structure is not absolutely necessary for survival at elevated temperatures. This fundamental question about the evolutionary history of the domain *Archaea* remains unanswered.

4.1 Fact Check

1. How did Woese and Fox determine evolutionary relatedness, and why did they consider their approach best?
2. How are archaea similar to and different from bacteria?
3. How are archaea similar to and different from eukaryal cells?
4. What do SSU rRNA sequence analyses show about the timing of archaeal evolution? Explain.

4.2 Archaeal cell structure

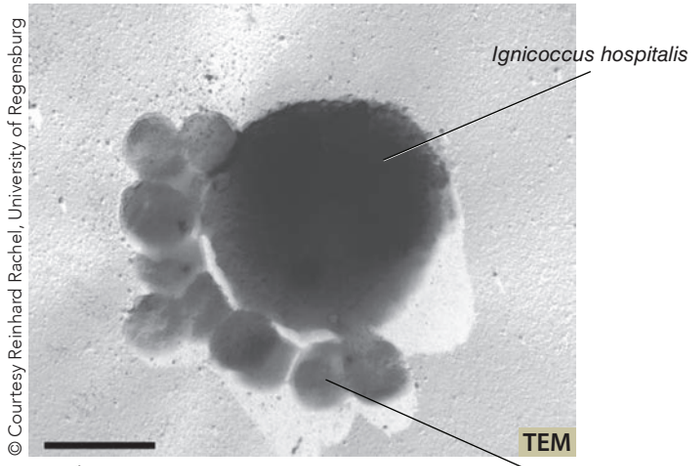
What do archaeal cells look like?

In Chapter 2 and 3, we investigated the structures of bacterial and eukaryal cells, paying particular attention to the functions performed by various structures and the evolutionary relationships of these structures. In this section, we will investigate the structure of archaeal cells, the biological functions performed by these structures, and begin to explore the diversity and evolutionary history of these organisms. We will begin by describing the archaeal cell. Next, we will look at specific parts of these cells, beginning with the cytoplasm and progressing to the plasma membrane, the cell wall, and the cell surface.

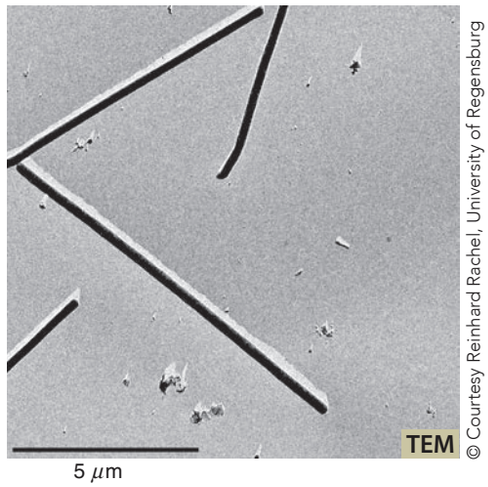
Morphology of archaeal cells

Like bacteria, most archaea range in size from 0.5 micrometer (μm) to 5 μm, about a tenth of the size of typical eukaryal cells. As we saw with bacteria in Chapter 2, though, the sizes of different species of archaea can vary widely. *Nanoarchaeum equitans*, the microorganism we mentioned in the opening story, is only about 0.4 μm in diameter, and its internal volume is only about 1 percent of the volume of an *Escherichia coli* cell. As a result, *N. equitans* ranks among the smallest living organisms. Conversely, species in the genera *Thermoproteus* and *Thermofilum* may have cells up to 100 μm long **(Figure 4.3)**.

Also like bacteria, archaea display various distinct shapes, or morphologies. Many characterized archaea exist as rods or spheres. Additionally, some archaeal species display spiral-shaped cells. Other archaeal species exhibit more unusual shapes. Members of the *Sulfolobus* genus often have an irregular shape. In contrast, members of the *Thermoproteus* and *Pyrobaculum* genera appear to be rectangular **(Figure 4.4)**. Researchers even have identified an archaeal species, *Haloquadratum walsbyi*, in which the cells grow as very thin and flat squares **(Microbes in Focus 4.1)**. Although *H. walsbyi* first was observed in 1980, we still have no direct explanation for how the cells maintain their unusual shape. As studies of archaea continue, we expect to discover other unusually shaped species and, eventually, better understand the basic properties affecting cell morphology.



A. *Nanoarchaeum equitans*



B. *Thermofilum pendens*

Figure 4.3. Size range of archaeal species Like bacteria, archaea can differ dramatically in size. *Nanoarchaeum equitans* cells are only 0.4 μm long, whereas cells of species from the *Thermofilum* genus may be 100 μm long. For comparison, cells of the bacterium *E. coli* are approximately 2 μm in length. **A.** *Nanoarchaeum equitans* (small cells) associated with an *Ignicoccus* cell. Both of these organisms have been isolated from marine hydrothermal vents. **B.** *Thermofilum pendens,* initially isolated from slightly acidic hot springs associated with volcanoes.

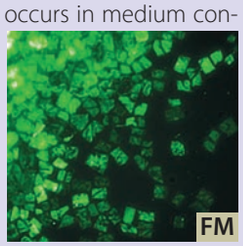
Microbes in Focus 4.1

HALOQUADRATUM WALSBYI: THE SQUARE MICROORGANISM

Habitat: Originally identified in 1980 in a salt pool near the Red Sea; subsequently found in salt pools throughout the world.

Description: Halophilic archaeon in the *Euryarchaeota* phylum. Distinguished by its flat (only 0.1–0.5 μm thick), square (2–5 μm per side) shape. Also contains a large number of gas vesicles.

Key Features: Growth in the laboratory occurs in medium containing 3.3 M NaCl and 2.2 M KCl. Researchers are interested in determining how this microorganism grows in such a high-salt environment and what factors govern its shape. Although the 3.1-Mbp genome was sequenced in 2006, researchers still cannot adequately explain how these cells maintain their unusual shape.

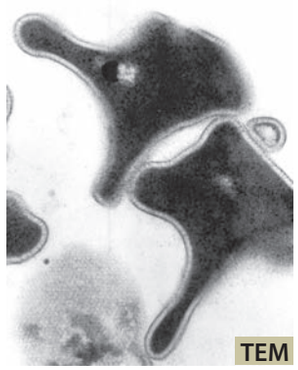


Courtesy Mike Dyall-Smith, University of Melbourne, Australia

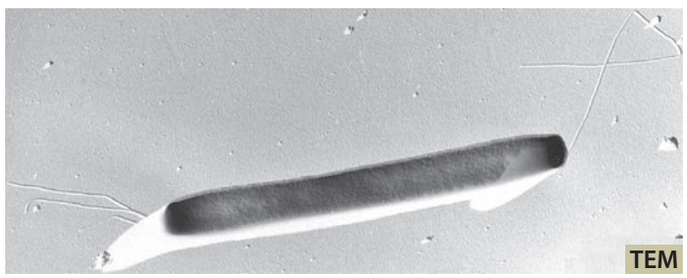
The cytoplasm

Like the cytoplasm of a bacterial cell, the archaeal cytoplasm contains a diverse mixture of molecules. The largest component of an archaeal cell is the nucleoid, which bacteria also possess. Also similar to the bacteria, the DNA of archaea generally exists as a single circular molecule. Unlike bacteria, some archaea contain histones, which serve to condense, or compact, the DNA. Compacted DNA allows more DNA to be packaged within a smaller area.

Histones exist in almost all eukaryal species. Typically, two copies each of four different histone polypeptides (H2A, H2B, H3, and H4) form an octameric complex. Approximately 160 base pairs of DNA wrap around each histone octamer, thereby compacting the DNA. The H1 histone is a separate histone protein that interacts with this octamer and the DNA. In some archaea, histones similar to the eukaryal H3 and H4 histones have been identified. Current research indicates that, in some archaeal species, approximately 60 base pairs of DNA wrap around a tetramer of these polypeptides **(Figure 4.5)**. Until 2005, histones were only identified in one phylum of the *Archaea*, the *Euryarchaeota*. Researchers now have identified histones in members of the archaeal phylum *Crenarchaeota* and in *Nanoarchaeum equitans*, which currently is the only cultivated member of a third archaeal phylum, the *Nanoarchaeota* (see Section 4.3).



A. *Sulfolobus acidocaldarius*



B. *Thermoproteus tenax*

Figure 4.4. Shapes of archaeal cells Although most archaea are rod or coccus shaped, some exhibit more unusual shapes. **A.** *Sulfolobus acidocaldarius* cells often exhibit irregular shapes. This organism grows optimally in high-temperature and low-pH environments. **B.** *Thermoproteus tenax* cells have a rectangular shape. Like *S. acidocaldarius*, this organism grows optimally at high temperatures. Additionally, species in the *Thermoproteus* genus can utilize sulfur compounds for energy.

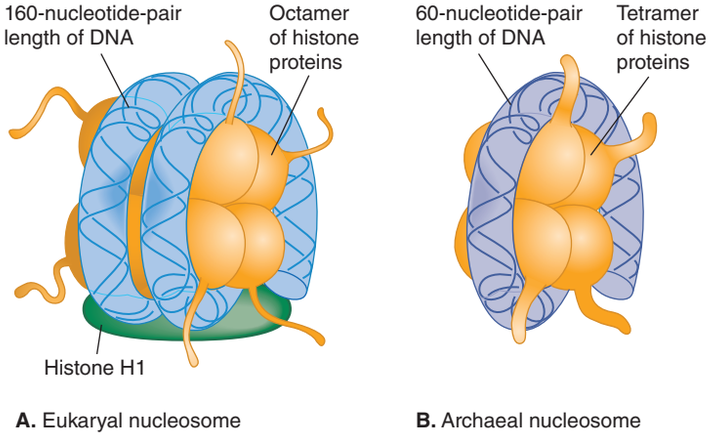


Figure 4.5. Compaction of DNA in eukarya and some archaea by histones Positively charged histone polypeptides interact with the negatively charged DNA, compacting the DNA. **A.** In eukarya, a histone octamer associates with approximately 160 bp of DNA. The H1 histone interacts with this octamer and the DNA. **B**. In archaea, a histone tetramer associates with approximately 60 bp of DNA. The presence of histones in archaea and eukarya, but not bacteria, suggests that histones evolved after the split between bacteria and archaea, but before eukarya evolved.

The existence of histones in species from all known phyla of the *Archaea* has led some researchers to propose that histones, and consequently a method for efficiently packaging DNA, evolved early in the history of life. According to this model, histones evolved after the divergence of bacteria and archaea but before the emergence of eukarya. Furthermore, the existence of histones, and the ability to package DNA, may have been a necessary prerequisite to the increased genomic size that we see today in many eukarya. Macroscopic life, in other words, may exist because of these DNA-binding proteins.

In addition to the nucleoid, the cytoplasm of archaea contains many other molecules that we see in the cytoplasm of bacteria. DNA and RNA polymerases, the enzymes needed for DNA replication and transcription, respectively, exist in the cytoplasm. Ribosomes, the complex structures involved in translation, or protein synthesis, also exist here. Other enzymes needed for various cellular functions reside within the cytoplasm, as do other important molecules, like transfer RNA, ions, and sugars. More complex structures, like gas vesicles, also have been identified in archaea. Although the biochemical nature of some of these components may differ between bacteria and archaea, the types of molecules and their basic functions are remarkably similar.

The archaeal cytoskeleton

Historically, the cytoskeleton, an intracellular framework of proteins, was considered to be a defining characteristic of eukarya. As we discussed in Chapter 2, though, cytoskeleton-like structures exist in bacteria. The bacterial FtsZ, MreB, and ParM proteins show similarity to eukaryal tubulin (FtsZ) and actin (MreB and ParM). Researchers also have identified a cytoskeleton-like element in archaea. An actin homolog, Ta0583, was identified in *Thermoplasma acidophilum* **(Microbes in Focus 4.2)**, a species in the *Euryarchaeota* phylum. Genetic and biochemical studies have shown that Ta0583 may more closely resemble eukaryal actin than bacterial MreB or ParM proteins **(Figure 4.6)**. Conversely, cytoskeletal-like proteins isolated from the archaeal species *Methanobacterium thermoautotrophicum* and *Methanopyrus kandleri* show greater similarity to the bacterial MreB protein. From these results, it should be obvious that

Microbes in Focus 4.2
LIVING IN "HOT VINEGAR": *THERMOPLASMA ACIDOPHILUM*

Habitat: Originally isolated from a coal refuse pile, has now been isolated from a variety of high-temperature and low-pH environments.

Description: Archaeon approximately 1 μm in diameter in the *Euryarchaeota* phylum. Lacks a cell wall and, probably as a result, displays a variety of shapes. Grows optimally at 56°C and pH 1.8.

Key Features: Some researchers have described its preferred habitat as "hot vinegar." The cell membrane of this thermoacidophilic microorganism consists of a tetraether lipid monolayer, rather than a more typical phospholipid bilayer. Presumably, this monolayer arrangement provides increased stability in the presence of elevated temperatures and a low pH.

Figure 4.6. Protein sequence comparison of eukaryal actin, bacterial MreB, and archaeal homologues In this comparative tree, the amino acid sequences of archaeal homologues to MreB were compared to bacterial MreB and eukaryal actin amino acid sequences. The linear distance between two samples reflects the likely evolutionary distance between those samples. The homologue found in the methanogenic archaeon *Methanopyrus kandleri* shows more similarity to a bacterial MreB isolate from *Thermotoga maritima* than to eukaryal actin. Homologues in the thermophilic archaea *Archaeoglobus fulgidus, Ferroplasma acidarmanus,* and *Thermoplasma acidophilum* are more similar to human actin than to bacterial MreB.

much still needs to be learned about the evolution, distribution, and function of cytoskeletal proteins.

The cell envelope

All archaea, like all bacteria and eukarya, contain a plasma membrane, a semi-permeable barrier surrounding the cytoplasm. Most archaea, like most bacteria and some eukarya, also contain a cell wall, a more rigid structure surrounding the plasma membrane that helps provide shape and stability to the cells. However, the chemical compositions of the archaeal plasma membrane and cell wall differ substantially from their bacterial and eukaryal counterparts. These distinct structures are important defining characteristics of the *Archaea*.

The Plasma Membrane

As we have seen in bacterial and eukaryal cells, a membrane surrounds the cytoplasm of archaeal cells. Functionally, the membranes in all of these cells are equivalent. In all cases, the plasma membrane forms a differentially, or selectively, permeable barrier that separates inside from outside. Proteins embedded within the membrane allow both active and passive transport of important molecules. Other integral membrane proteins serve in cell-signaling capacities. Still other proteins control secretory events, facilitating endocytosis and exocytosis events.

Although the functions of the plasma membrane in bacteria, eukarya, and archaea are quite similar, the structure of the archaeal plasma membrane differs from the plasma membranes of bacteria and eukarya **(Figure 4.7)**. The plasma membranes in bacteria and eukarya consist of a phospholipid bilayer. In all cases, this membrane consists of fatty acids linked to glycerol 3-phosphate (G3P) molecules. Instead, the archaeal membrane consists of **isoprenoids**, which are hydrocarbon molecules built from 5-carbon isoprene subunits, attached to glycerol 1-phosphate (G1P). The G1P head group is a **stereoisomer**, or mirror image, of the molecule found in bacteria and eukarya. Moreover, these hydrophobic molecules are linked via ether linkages to the glycerol, as opposed to the ester linkages seen in bacterial and eukaryal phospholipid bilayers.

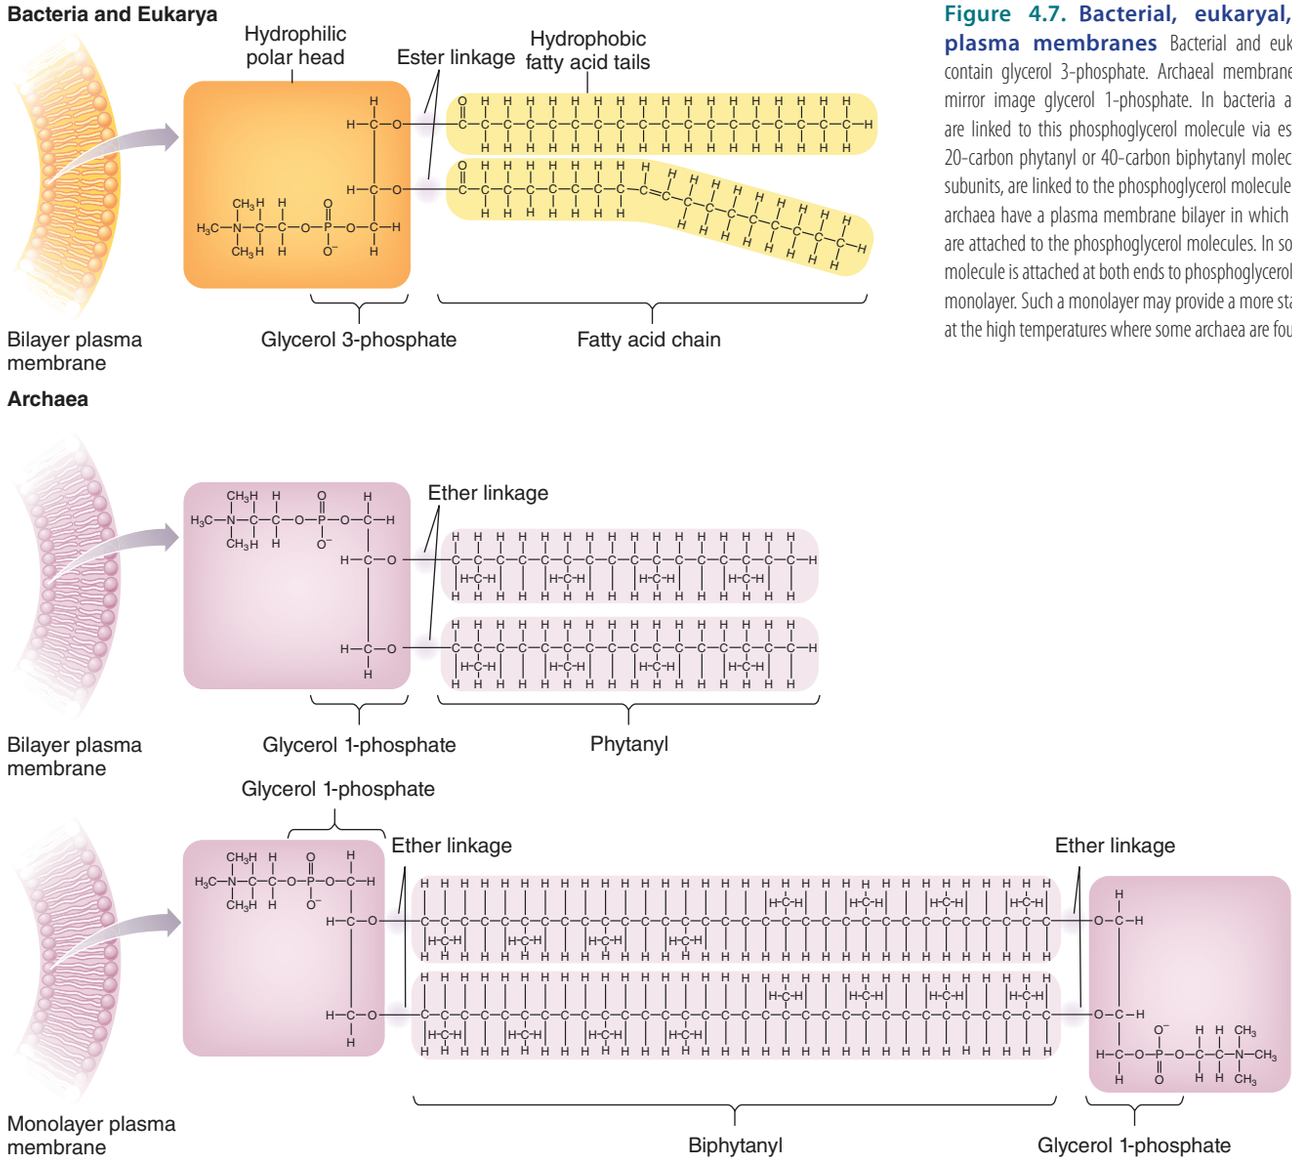

Figure 4.7. Bacterial, eukaryal, and archaeal plasma membranes Bacterial and eukaryal membranes (*top*) contain glycerol 3-phosphate. Archaeal membranes (*bottom*) contain the mirror image glycerol 1-phosphate. In bacteria and eukarya, fatty acids are linked to this phosphoglycerol molecule via ester linkages. In archaea, 20-carbon phytanyl or 40-carbon biphytanyl molecules, built from isoprene subunits, are linked to the phosphoglycerol molecule via ether linkages. Many archaea have a plasma membrane bilayer in which two phytanyl molecules are attached to the phosphoglycerol molecules. In some species, a biphytanyl molecule is attached at both ends to phosphoglycerol molecules, resulting in a monolayer. Such a monolayer may provide a more stable membrane structure at the high temperatures where some archaea are found.

In many archaea, the most commonly used isoprene polymer is **phytanyl**, a 20-carbon hydrocarbon. Alternatively, some archaea contain **biphytanyl**, a 40-carbon hydrocarbon. Among species that contain biphytanyl, a phosphoglycerol molecule often is linked to both ends of the isoprene polymer. This biphytanyl membrane is a phospholipid monolayer, rather than a bilayer (see Figure 4.7). The monolayer formation associates most commonly with archaeal species that live at very high temperatures. The archaeal monolayer is more rigid and is thought to offer increased stability at high temperatures than its bilayer counterpart. Indeed, researchers have demonstrated that monolayer **liposomes**, tiny vesicles made from cell membrane material, are more stable at high temperatures than are bilayer liposomes. Interestingly, researchers are exploring the potential medical uses of archaeal liposomes **(Toolbox 4.1)**.

As we noted in the opening story, species in the *Ignicoccus* genus possess both a plasma membrane and an outer membrane, a cell envelope organization unique among all archaea thus far categorized. In addition, its periplasm appears to be quite large, measuring between 20 and 400 nm **(Figure 4.8)**. In contrast, the periplasms of Gram-negative bacteria like *Escherichia coli* and *Pseudomonas aeruginosa* appear to be only 20–25 nm wide.

The functional role of this outer membrane may be more unusual than its mere existence in these organisms. It appears that *Ignicoccus* species make energy across this outer membrane. In Section 2.4, we briefly examined how bacteria create energy by transporting protons across the plasma membrane. As these protons then travel back into the cytoplasm through ATP synthase molecules embedded in the plasma membrane, ATP forms in the cytoplasm. This same process appears to be utilized by most archaea. Among *Ignicoccus* species, however, evidence suggests that protons are transported across the outer membrane, from the periplasm to the extracellular environment. As these protons flow back into the cell, through ATP synthase molecules embedded in the outer membrane, ATP is generated within the periplasm. The evolutionary significance of this atypical arrangement remains a topic of active investigation.

Figure 4.8. Outer membrane of *Ignicoccus* Like Gram-negative bacteria, archaea in the genus *Ignicoccus* possess a plasma membrane (PM) and an outer membrane (OM). As seen in this ultrathin section transmission electron micrograph, a relatively large periplasm (P) exists between these two membranes, and membrane-bound vesicles (V) appear to exist within the periplasm.

Even though it is intriguing to discuss differences in membrane composition between bacteria and archaea, let's ask a more fundamental question: What is the significance of these differences? As we just noted, a lipid monolayer may offer increased stability at elevated temperatures than does a lipid bilayer. Additionally, ether linkages are more resistant to high temperatures, oxidation, and alkaline degradation than are ester linkages. Overall, the unique chemical nature of the archaeal plasma membrane may be an adaptation to life in extreme environments, reflecting the evolutionary origins of this enigmatic domain.

The Cell Wall

Many archaea also possess a cell wall. Like the cell walls of bacteria, plants, and fungi, the archaeal cell wall gives shape to the cells and provides them with protection from, among other things, osmotic pressure and mechanical stress. Although all cell walls perform these similar functions, the chemical composition of cell walls may differ significantly. In bacteria, the cell wall consists largely of peptidoglycan (see Section 2.4). Plants and fungi have cell walls of cellulose and chitin, respectively (see Section 3.1).

Several different types of cell walls have been identified in archaea. In some species, most notably species in the *Methanobacterium* genus, the cell wall consists of **pseudomurein** (also referred to as pseudopeptidoglycan), which is chemically similar to the peptidoglycan seen in bacteria. Both peptidoglycan and pseudomurein consist of a polymer of alternating sugar derivatives to which are attached crosslinked short peptide chains. Despite these similarities, peptidoglycan and pseudomurein differ in several ways **(Figure 4.9)**. In pseudomurein:

- *N*-acetyltalosaminuronic acid replaces *N*-acetylmuramic acid.
- β-1,3-glycosidic bonds, instead of β-1,4-glycosidic bonds, link the sugar derivatives in pseudomurein.
- All amino acids in pseudomurein are L-stereoisomers, whereas peptidoglycan frequently contains D-stereoisomers (see Figure 2.16).

It is unclear if these chemically distinct yet closely related structures arose through divergent evolution or represent an example of convergent evolution. In other words, the cell walls in archaea and bacteria may represent structures that have evolved and diverged from a structure that existed in a common ancestral organism. Alternatively, the cell walls in archaea and bacteria may have evolved independently.

CONNECTIONS As we will see in **Section 24.2**, penicillin and related β-lactam antibiotics interfere with cell wall synthesis in bacteria. Because of the chemical differences between peptidoglycan and pseudomurein, these agents are not effective against archaea.

Finally, a few archaea, like *Thermoplasma acidophilum* that was mentioned earlier, contain no cell wall. In fact, the absence

Toolbox 4.1
VACCINE DELIVERY STRATEGIES

In Perspective 4.1, we will examine the many industrial uses for enzymes isolated from archaea. A less obvious component of these organisms has generated some medical interest: their lipids. As we noted in this section, the plasma membranes of archaea differ fundamentally from the plasma membranes of bacteria and eukarya. These chemical differences, most notably the ether linkages present in archaeal membranes, confer the archaeal lipids with increased stability. Recently, researchers have explored the use of archaeosomes, liposomes composed of archaeal lipids **(Figure B4.1)**, as vaccine additives and drug delivery vehicles. These archaeosomes serve as strong adjuvants, agents that augment the immune response to a vaccine (see Section 20.4). Additionally, the ether linkages confer increased stability to high temperatures, acidic and alkaline pH conditions, and enzymatic degradation.

To explore the efficacy of archaeosomes as vaccine adjuvants and delivery modules, scientists at the National Research Council of Canada created lipid vesicles from archaeal membrane lipids and lipid vesicles from bacterial membrane lipids. Specifically, they used lipids extracted from the archaeon *Methanobrevibacter smithii* (see Microbes in Focus 4.4). Additionally, these vesicles contained bovine serum albumin (BSA), a protein commonly available in laboratories.

Mice injected with the archaeosomes produced a stronger immune response to BSA than did mice injected with liposomes made from bacterial lipids. Thus, these studies showed that archaeosomes can serve as effective vaccine delivery modules. Because of the increased stability of archaeal lipids, archaeosomes may be particularly useful in resource-limited areas. Their increased stability may mean that vaccines can be stored longer or stored under less than ideal conditions.

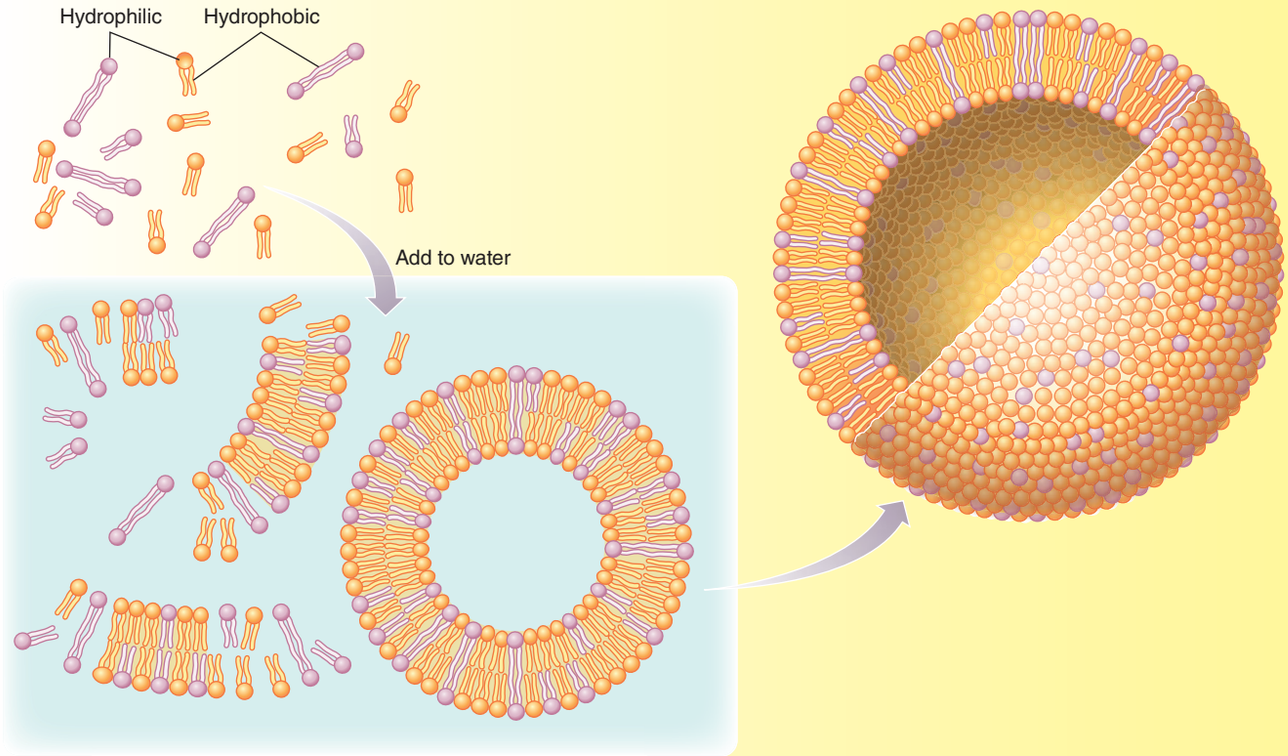

Figure B4.1 Archaeosomes: Liposomes made from archaeal lipids Researchers are exploring the usefulness of archaeosomes, lipid vesicles constructed from archaeal lipids. When bacterial and archaeal phospholipids are combined in water, vesicles form. These lipid vesicles can be used for many purposes. They have proven to be very useful for studying basic properties of cell membranes. Additionally, they are being explored as drug delivery vesicles. Therapeutic agents can be enclosed within the liposome or embedded within the liposome bilayer. Archaeosomes are more stable than liposomes constructed from bacterial lipids. Also, archaeosomes used as vaccine delivery vesicles function as effective adjuvants.

Test Your Understanding

You are asked to develop novel archaeosomes that could be used as vaccine delivery vesicles in tropical countries. From what species might you obtain archaeal lipids? Why?

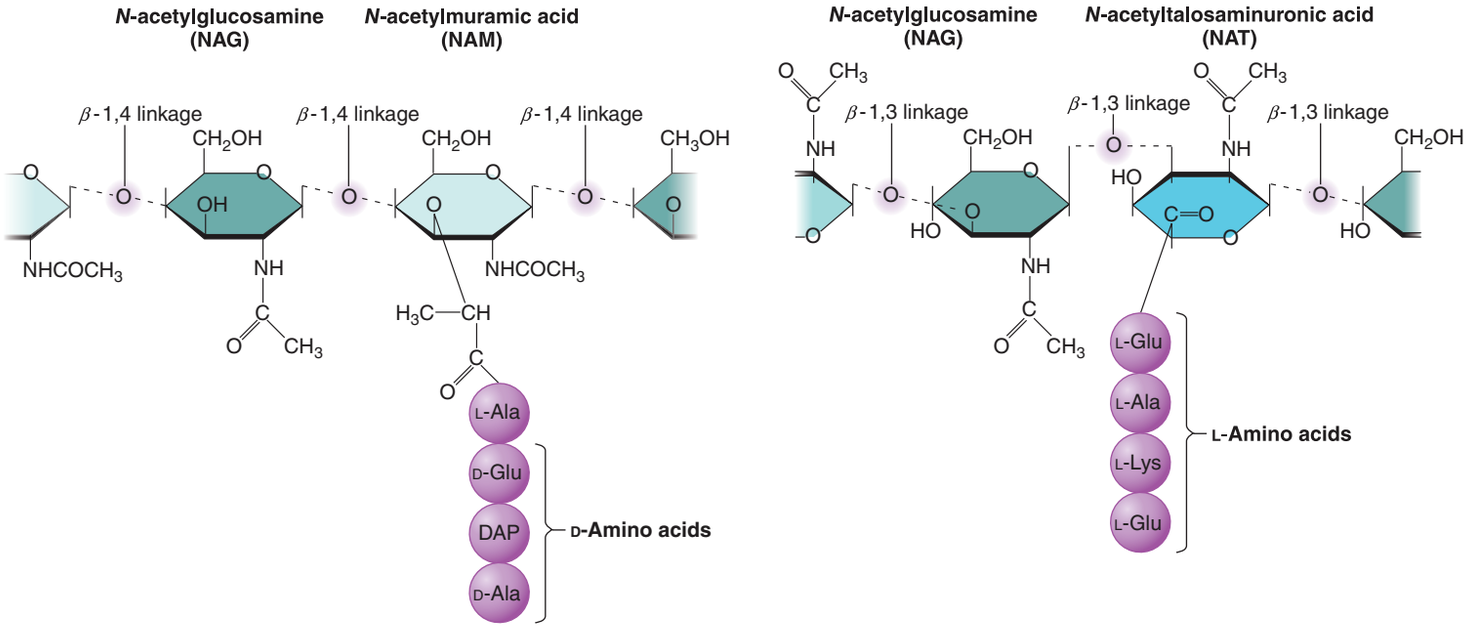

Figure 4.9. Cell walls of bacteria and archaea **A.** The peptidoglycan in bacterial cell walls consists of *N*-acetylglucosamine (NAG) and *N*-acetylmuramic (NAM) acid sugars, linked by β-1,4-glycosidic bonds. **B.** The pseudomurein in archaeal cell walls consists of *N*-acetylglucosamine (NAG) and *N*-acetyltalosaminuronic (NAT) acid sugars, linked by β-1,3-glycosidic bonds.

of a cell wall in these archaea, coupled with their non-spherical, irregular shape, led researchers to postulate that *T. acidophilum* might contain a cytoskeleton. They reasoned that in the absence of a cell wall, a cytoskeleton would be needed to help the cells maintain a non-spherical appearance.

CONNECTIONS As we discussed in **Section 2.4**, bacteria in the genus *Mycoplasma* also lack a cell wall. Again, this lack of a cell wall led researchers to hypothesize that *Mycoplasma* species must contain a cytoskeleton.

The cell surface

As we saw for bacteria and eukarya, archaea interact with each other and with the outside environment in many ways. Archaeal cells must, among other tasks, move around, stick to surfaces, sense the environment, and acquire nutrients. To a large extent, these activities are mediated by structures that exist on the cell surface. Many of these structures, like receptors and channels, may be quite familiar to us. Like many bacteria, some archaea contain a layer of protein, glycoprotein, or a layer of polysaccharide, often referred to collectively as the S-layer. Generally, the S-layer is composed of multiple copies of a single molecule arranged in a crystalline fashion. The exact role of this structure is unclear. This outer shield may protect the cells from viruses, provide environmental stability, protect against desiccation, or aid in adhesion.

Other archaeal surface structures may seem more exotic. Among the *Pyrodictium*, for example, **cannulae**, hollow glycoprotein tubes, connect individual cells together, forming a complex network **(Figure 4.10)**. The function of these tubes, and the resulting network of cells, has not been determined. The network may permit the cells to exchange nutrients. Some evidence indicates that the tubes may extend into the periplasm, but not the cytoplasm, of connected cells.

As we conclude our introduction to archaeal cell structure, we will focus on one particular cell surface structure—the flagella. Like some bacteria, some archaea contain flagella. Like bacteria, some archaea contain a single flagellum, some contain multiple flagella, and some lack flagella entirely **(Figure 4.11)**. Also,

Figure 4.10. Hollow tubes connect *Pyrodictium abyssi* As these cells grow, hollow glycoprotein tubes, called cannulae, are produced that connect the individual cells.

© Eye of Science/Science Source Images

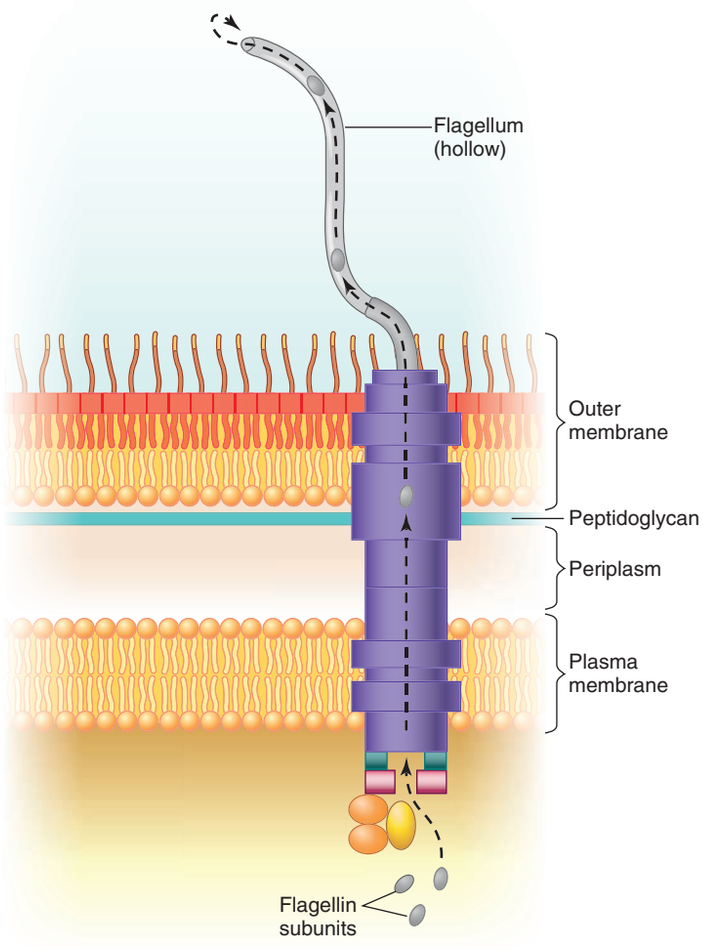
Figure 4.11. Flagella of *Pyrococcus furiosus* Cells of this species may have as many as 70 flagella per cell. These structures may be used for attachment, in addition to motility.

as we saw in bacteria, the flagella of archaea rotate and are used primarily for movement. Despite these outward similarities in appearance and function, bacterial and archaeal flagella display significant structural differences. For this reason, microbiologists sometimes refer to the archaeal flagellum as the archaellum.

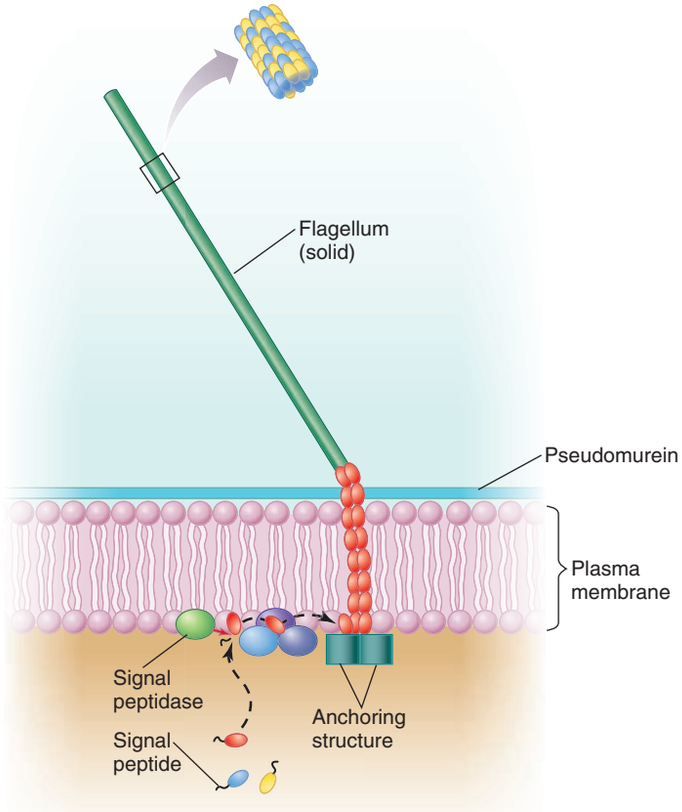
Archaeal flagella tend to be thinner than their bacterial counterparts (10–14 nm versus 20–24 nm). Additionally, archaeal flagella often comprise multiple copies of two or more different versions of **flagellin**, the polypeptide that makes up the shaft of the flagellum. Conversely, multiple copies of a single flagellin species typically compose the flagella in bacteria. Some archaeal flagellins exhibit *N*-linked glycosylation; only *O*-linked glycosylation has been observed among bacterial flagellins. Finally, the assembly of archaeal and bacterial flagella differs. As we noted in Chapter 2, bacterial flagella are assembled via the type III secretory pathway. Flagellin monomers travel through the developing flagellar filament, and assembly occurs at the tip of the growing filament. Current evidence suggests that in archaea, flagellin monomers are added to the base of the growing structure **(Figure 4.12)**.

We should note that this mode of archaeal flagellar construction mirrors the assembly process exhibited by some types

Figure 4.12. Bacterial and archaeal flagellar structure and assembly Functionally, archaeal flagella closely resemble their bacterial counterparts. Structurally, though, these appendages differ. **A.** Bacterial flagella are composed of multiple copies of a single flagellin subunit. During assembly, flagellin monomers travel through the flagella and attach to the tip of the growing flagellum. **B.** Archaeal flagella, in contrast, consist of several different subunits. During assembly, new subunits are attached to the base of the growing flagellum. As shown in this schematic, the yellow and blue subunits first form the flagellum. The red subunits then form the basal hook.



A. Bacterial flagellum



B. Archaeal flagellum

of bacterial pili. Certain bacterial pili also grow from the base rather than the tip. Indeed, genetic and biochemical evidence shows a link between archaeal flagella and bacterial pili. First, the archaeal flagellins and bacterial pili exhibit some amino acid sequence similarity. Second, homologous assembly proteins have been identified in both systems. Conversely, a number of bacterial genes necessary for the assembly of flagella and pili appear to have no homologues in archaea, and several genes essential for flagellar assembly in archaea have been identified that have no homologues in bacteria. Therefore, the exact evolutionary relationship among bacterial flagella, bacterial pili, and archaeal flagella remains unclear.

Although the flagella of bacteria and archaea seem to be evolutionarily distinct, it is interesting to note that they may use related chemotaxis pathways. Bacterial chemotaxis, the process of directed motility in response to a chemical signal, depends ultimately on switching the rotational direction of the flagella (see Figure 2.28). The cell-signaling pathway in bacteria involves several proteins, most notably CheA, CheB, and CheY. The binding of an extracellular signal to a receptor protein on the cell surface can initiate a cell-signaling cascade involving these proteins. In turn, changes in these proteins affect the rotational direction of the flagella (see Figure 11.26). Studies with *Halobacterium salinarum* **(Microbes in Focus 4.3)**, an archaeon that exhibits chemotaxis, have shown that this species contains similar genes. Furthermore, chemotaxis was disrupted when researchers mutated these genes in *H. salinarum*.

CONNECTIONS This cell-signaling cascade involves the phosphorylation or methylation of a series of proteins. In **Section 11.7,** we will see how the flagellar rotation is affected by these molecular changes.

Microbes in Focus 4.3
THE SALTY LIFE OF *HALOBACTERIUM SALINARUM*

Habitat: Found in a variety of high-salt environments throughout the world, including the Great Salt Lake, the Dead Sea, and even salted foods.

Description: Rod-shaped archaeon, approximately 5 μm in length in the *Euryarchaeota* phylum.

Key Features: Blooms of *Halobacterium* species are responsible for the reddish color often seen in hypersaline environments. These microorganisms not only can thrive in high-salt environments, but also they can survive exposure to UV irradiation and desiccation. Researchers currently are investigating their DNA repair mechanisms.

4.2 Fact Check

1. In some archaea, DNA is complexed with histones. What may the presence of histones indicate about the evolutionary history of archaea?
2. How does the archaeal plasma membrane differ from the plasma membrane in bacteria and eukarya?
3. Would the antibiotic penicillin be effective against archaea? Defend your answer.
4. Discuss the similarities between archaeal and bacterial flagella.

4.3 Diversity of Archaea

What are the major groups of archaea?

As we have seen throughout this chapter, we still have much to learn about archaea. Our understanding of the phylogeny of these organisms is no exception. Based on 16S rRNA gene sequence analyses, researchers have grouped most well-characterized archaea into one of two major phyla: *Crenarchaeota* and *Euryarchaeota*. Analyses of 16S rRNA sequences from cultured and non-cultured archaea have led microbiologists to propose at least three other archaeal phyla: *Thaumarchaeota, Korarchaeota,* and *Nanoarchaeota*. This last phylum has only a single cultivated member, *Nanoarchaeum equitans*, the organism we mentioned in the opening story of this chapter. As we learn more about these organisms, and develop better methods of culturing more of them, the current classification scheme of archaea almost certainly will change. For now, though, we will briefly examine these five phyla, emphasizing some unique features of each.

Crenarchaeota

Members of the phylum *Crenarchaeota* are phylogenetically related, but researchers have identified few, if any, structural or biochemical features unique to all members of this phylum. Species within this phylum display a wide range of metabolic properties. It appears that all species in this phylum are **thermophiles** or **hyperthermophiles**, organisms whose optimal growth temperatures are greater than 55°C or 80°C, respectively **(Table 4.2)**. Many of these thermophilic and hyperthermophilic microorganisms have been isolated from thermal

TABLE 4.2 Representative thermophilic and hyperthermophilic crenarchaeotes

Species	Temperature range (°C)	Temperature optimum (°C)
Ignicoccus hospitalis	75–98	90
Sulfolobus solfataricus	50–87	80
Pyrolobus fumarii	90–113	106
Archaeoglobus fulgidus	60–95	83

springs and geysers, such as those in Yellowstone National Park in the United States, and volcanic regions (Figure 4.13). Often, these areas contain large amounts of sulfur and are quite acidic. Unsurprisingly, many of these hyperthermophiles are also **acidophiles**, growing in low-pH environments. For example, *Sulfolobus solfataricus* represents a prime example of a hyperthermophilic acidophile. Isolated from a volcanic crater near Naples, Italy, this archaeon has an optimal growth temperature of approximately 80°C. Additionally, it grows optimally at pH 3.0 (see Microbes in Focus 7.2). Other members of this phylum have been isolated from deep sea hydrothermal vents. These species grow not only at elevated temperatures, but also at high pressure and are referred to as **barophiles**.

Life at high temperatures requires certain adaptations. For most organisms, elevated temperatures lead to the disruption of the plasma membrane. Plasma membranes containing tetraether lipids or lipid monolayers, as we discussed earlier, may provide extra stability at high temperatures, and many crenarchaeotes possess this feature. Additionally, elevated temperatures generally cause the denaturation of proteins. Hyperthermophiles, as a result, must possess proteins that remain functional in extreme environments. It appears that hyperthermophiles may employ two distinct mechanisms to maintain protein integrity.

The proteins in thermophiles and hyperthermophiles differ slightly, but meaningfully, from their mesophilic counterparts.

© Interfoto/Alamy

Figure 4.13. Some crenarchaeotes thrive in hot springs above 55°C
Located over a large volcanic region spread over three states, Yellowstone National Park in the United States is home to a great variety of geysers, hot springs, and mudpots. Numerous thermophilic archaea have been isolated from these locations.

To explore these differences, researchers at the National Cancer Institute in the United States and Tel Aviv University in Israel compared the biochemical properties of proteins isolated from thermophilic organisms with the homologous proteins from mesophilic organisms. They observed a few interesting differences. First, the proteins from thermophiles have a larger percentage of α-helical regions. Second, these proteins contain more salt bridges and side chain interactions. Third, the amino acids arginine and tyrosine are more common in thermophilic proteins than in their mesophilic counterparts, whereas the amino acids cysteine and serine are less common (Table 4.3). The researchers postulate that these differences contribute to the increased thermostability of the proteins isolated from thermophiles. The increased α-helical content and increased proportion of arginine and tyrosine, they note, may lead to strengthened interactions between amino acids. These strengthened interactions allow the protein to maintain its shape at elevated temperatures. On the other hand, cysteine is a thermolabile amino acid. Its decreased usage may diminish the potentially damaging effects of high temperatures.

The hyperthermophiles also rely on a series of **molecular chaperones**, proteins that help fold proteins, or refold denatured proteins, to maintain functionality. Although molecular chaperones have been identified in species from all three domains, the archaeal chaperonins more closely resemble eukaryal chaperonins than their bacterial counterparts. Often referred to as the **thermosome** in hyperthermophilic archaea, this protein complex appears to be quite abundant and instrumental in these organisms. In *Ignicoccus hospitalis*, the host of *Nanoarchaeum equitans*, thermosome proteins are some of the most abundant proteins in the cytoplasm. We should note that the study of these thermostable proteins could have profound effects on our everyday life because enzymes that function under extreme conditions could have many industrial uses (Perspective 4.1).

CONNECTIONS In Chapter 12, we will see that many microbes and their enzymes have been harnessed for industrial purposes. For example, we will investigate how microbes could be used to produce renewable biofuels.

TABLE 4.3 Usage (%) of selected amino acids in mesophiles and thermophiles

Amino acids	Mesophiles (%)	Thermophiles (%)
Alanine	9.2	8.9
Proline	4.2	4.2
Valine	8.2	8.2
Cysteine[a]	1.0	0.6
Serine[a]	5.5	4.0
Arginine[a]	3.6	4.6
Tyrosine[a]	3.7	4.5

[a]Statistically significant difference.

Perspective 4.1
EXTREMOPHILES AND BIOTECHNOLOGY

You should be familiar with one very important enzyme isolated from a thermophilic organism: Taq polymerase. As we learned in Toolbox 1.1, this enzyme was isolated from the thermophilic bacterium *Thermus aquaticus* and is used by researchers for the polymerase chain reaction (PCR). Taq was the first thermostable DNA polymerase to be isolated and used for PCR. Today, other choices are available. Pfu and Vent, DNA polymerases isolated from the hyperthermophilic archaea *Pyrococcus furiosus* and *Thermococcus litoralis*, respectively, are widely used **(Table B4.1)**.

Other enzymes isolated from hyperthermophiles also may be useful commercially. Thermostable proteases, enzymes that degrade proteins, and lipases, enzymes that degrade lipids, are being investigated as detergent additives. The stability of these enzymes at elevated temperatures would allow them to remain active during washing in hot water. Proteases and lipases from alkaliphiles, organisms that grow optimally in high-pH environments, also may prove to be useful detergent additives. Because laundry detergent is basic, the activity of these enzymes in high-pH environments would be ideal.

TABLE B4.1 Thermostable enzymes

Enzyme	Source (species/domain)	95 °C half-life (min)
Taq	*Thermus aquaticus* Bacteria	40
Pfu	*Pyrococcus furiosus* Archaea	120
Tli	*Thermococcus littoralis* Archaea	400

In addition to maintaining the integrity of their proteins, hyperthermophiles must maintain the integrity of their DNA. Some species possess thermostable DNA-binding proteins that increase the melting temperature of double-stranded DNA. More importantly, all known hyperthermophiles possess **reverse DNA gyrase**, an enzyme that increases the supercoiling of the DNA. By increasing the degree of supercoiling, these enzymes greatly increase the temperature at which the DNA unwinds and denatures.

Thaumarchaeota

Since the early 1990s, researchers have reported the isolation of crenarchaeotal-like DNA from a variety of temperate and cold marine and terrestrial environments. Initially thought to be crenarchaeotes, these microorganisms now are classified in a separate archaeal phylum, *Thaumarchaeota*, supported by their overall genetic similarity to one another. These **mesophiles** and **psychrophiles**, literally "intermediate loving" and "cold loving," grow optimally between 15°C and 40°C or at temperatures less than 15°C, respectively. Moreover, they appear to be quite abundant, especially in marine environments.

Given the apparent ubiquitous distributions of the thaumarchaeotes, they may be major contributors to the biogeochemical cycles in the oceans. Several pieces of evidence, including their overall abundance and ability to assimilate inorganic carbon through the process of autotrophy, suggest that these organisms are major contributors to carbon cycling. Analysis of *Nitrosopumilus maritimus*, a marine thaumarchaeote first isolated in 2005, indicates that this microorganism and its relatives also contribute to nitrogen cycling on a global scale. *Nitrosopumilus maritimus* is an ammonia oxidizer, obtaining energy by oxidizing ammonia to nitrite. Genome-sequencing studies have shown that all ammonia-oxidizing archaea (AOA) of the *Thaumarchaeta* contain an ammonia monooxygenase gene (*amoA*), the product of which oxidizes ammonia to hydroxylamine, the first step in the nitrification process. Prior to the discovery of the AOA, only ammonia-oxidizing bacteria (AOB) were thought capable of conducting this reaction.

CONNECTIONS The biogeochemical cycling of nitrogen involves several chemical processes, including ammonia oxidation. As we will see in **Section 14.3**, certain bacterial and archaeal species drive these important steps in the conversion of inorganic N_2 to organic nitrogen compounds and back again.

In 2006, the first complete genome sequence of a psychrophilic thaumarchaeote, *Cenarchaeum symbiosum*, was reported. This species, which still has not been grown in pure culture, was first detected in 1996. It resides within a marine sponge and appears to grow optimally at temperatures between 8°C and 18°C. By analyzing its genome, researchers observed that *C. symbiosum* contains some genes previously identified only in crenarchaeotes and some genes previously identified only in euryarchaeotes, leading to its eventual placement within the phylum *Thaumarchaeota*. Analysis of its genome also revealed homologues of genes normally associated with ammonia oxidation, including ammonia monooxygenase

and urease. While the metabolic properties of this archaeon remain unknown, researchers have hypothesized that it may metabolize nitrogenous waste products generated by its host. Both *C. symbiosum* and the marine sponge may benefit from this interaction. Further studies of this archaeon may shed more light on the intricacies of their symbiotic relationship and provide insight into symbiosis within the context of microbial ecology more generally.

Euryarchaeota

Like members of the phylum *Crenarchaeota*, members of the phylum *Euryarchaeota* share significant 16S rRNA gene sequence homology, but also exhibit quite diverse morphologies and biochemical properties. As with the *Crenarchaeota*, one would struggle to list even a single defining characteristic for this phylum, aside from their phylogenetic relatedness. In this section, we will investigate two major groups of euryarchaeotes, the methanogens and the halophiles.

The Methanogens

The **methanogens**, organisms that produce methane (CH_4), represent one of the more interesting groups of organisms in the living world. Despite the abundant metabolic diversity that exists within biology, very few organisms and only a few members of the phylum *Euryarchaeota* can produce methane. These organisms produce methane from a variety of substrates, such as carbon dioxide (CO_2) or various simple organic molecules like methanol (CH_3OH) and formate ($CHOO^-$). Most commonly, the production of methane involves the reduction of these substrates with H_2 serving as the electron donor.

$$CO_2 + 4\ H_2 \rightarrow CH_4 + 2\ H_2O$$

During the reduction of CO_2 in this reaction, enough free energy is released to drive the fixation of carbon. These organisms, then, are autotrophs, incorporating inorganic carbon into organic molecules.

CONNECTIONS All living organisms require organic molecules. Heterotrophs ingest organic molecules. Autotrophs manufacture their own organic molecules. A more detailed description of photosynthesis, the process by which the energy present in sunlight is captured by organisms and converted into chemical energy, can be found in **Section 13.6**.

Where can we find methanogens? Given their metabolic properties, we can assume that methanogens can be found where their necessary substrates (carbon dioxide and hydrogen, for instance) are found. Moreover, all of the identified methanogens are strict anaerobes, which are organisms that can survive only in **anoxic**, or oxygen-free, environments. We tend to think of the world as replete with oxygen, yet anoxic environments abound. From lake and ocean sediments, to hot springs and the GI tracts of animals, environments lacking oxygen are quite common **(Figure 4.14)**. Methanogens can be found in all of these locations.

One of the first well-documented discoveries of methanogenesis occurred over 200 years ago, well before *Archaea* was recognized as a domain of life. The Italian physicist Alessandro Volta observed that gases stirred up from the bottom of a marsh were capable of being burned **(Figure 4.15)**. He proposed that the gases were "combustible air." That gas was methane. The source of that methane was methanogens living in the anoxic sediment of the marsh.

B. *Methanococcus maripaludis* lives in salt marshes.

Figure 4.14. Anoxic environments and methanogens Because we are aerobic organisms, and spend virtually all of our time in oxic environments, we may think that anoxic environments are quite rare. This thought could not be further from the truth. In fact, anoxic environments are quite common. **A.** The human gut is largely anoxic and houses many anaerobic microorganisms, like the methanogen *Methanobrevibacter smithii*. **B.** Sediments of ponds, swamps, and salt marshes are commonly anoxic and as are house methanogens like *Methanococcus maripaludis*.

© Courtesy John Leigh, University of Washington, Seattle

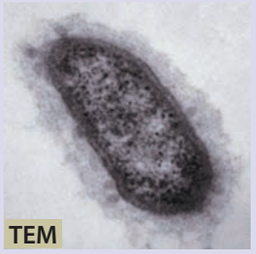
Figure 4.15. The Volta experiment In the eighteenth century, Alessandro Volta observed that gas collected from a swamp burned. We now know that this "combustible air" is methane, produced in the anoxic environment of the swamp by archaeal methanogens. It is possible to repeat Volta's classic observation today. By placing a large, plugged funnel in a wetland and stirring up the underlying decaying material, methane can be trapped in the funnel. When the plug is removed, the methane can be ignited. Be careful!

Microbes in Focus 4.4
METHANOBREVIBACTER SMITHII

Habitat: Anoxic environments, including the GI tract of humans and other animals

Description: Rod-shaped archaeon within the *Euryarchaeota* phylum; mesophilic anaerobe that grows in pairs or short chains

Key Features: *Methanobrevibacter smithii,* a methane producer, is the most abundant archaeon in the human digestive tract. It utilizes H_2 produced as a by-product of fermentation by bacteria. In a 2009 study, researchers observed higher levels of *M. smithii* in the feces of people with anorexia than in the feces of obese or lean individuals. The authors speculated that the increased levels of this methanogenic archaeon might be a response to the extremely low-calorie diet.



TEM

The human gut represents another environment where methanogens can be found. The large intestine contains a great diversity of microbes, including the methanogen *Methanobrevibacter smithii* **(Microbes in Focus 4.4)**. In this location, *M. smithii* uses formate and H_2 produced as fermentation by-products by bacteria in our intestines. *M. smithii*, in turn, produces its own noticeable by-product: methane gas. As we ingest and begin digesting food, certain bacteria further process the food, releasing nutrients needed by this archaeon. Does this microorganism, then, affect our digestive health? Perhaps. In one very intriguing study, researchers detected higher levels of *M. smithii* in the GI tracts of people with the eating disorder anorexia nervosa than in the GI tracts of lean individuals. They speculate that this increase may represent an adaptation to a low-calorie diet. Our gastrointestinal tract certainly is a complex and fascinating ecosystem. The roles of these various bacteria and this particular archaeon on our health are just now being investigated **(Mini-Paper)**.

Methanobrevibacter smithii may affect our ability to use various food sources, thereby affecting our digestive health. Another methanogen, *Methanobrevibacter oralis*, may affect our oral health. Researchers have detected this methanogen in the oral cavity of many people. Moreover, its presence correlates with the existence and severity of gingivitis (gum inflammation) and periodontitis (gum disease). Although the exact role that this microorganism plays in these diseases remains unclear, many investigators now consider *M. oralis* to be a periodontal pathogen.

The anoxic habitats in which methanogens exist can be fairly diverse. Perhaps it should not be surprising, then, that the shapes of various methanogens and their optimal growth temperatures also differ. Some methanogen species, like *Methanothermus fervidus*, are rods. Other species, like *Methanculleus olentangii*, are cocci. Methanogens also thrive in various environments. Some species, like *Methanopyrus kandleri*, are hyperthermophilic. Other species are mesophilic or psychrophilic. Despite sharing a unique metabolic property, the methanogens exhibit remarkable diversity.

The Halophiles

As we just noted, the methanogens share a common metabolic property. In contrast, the salt-loving **halophiles** share a common environmental requirement. These organisms only grow with NaCl concentrations of at least 1.5 M. Many of the identified halophilic archaea require even higher salt concentrations. As a brief introduction to these organisms, we will investigate where we can find these organisms and what adaptations they may have that allow them to survive in these unusual environments.

Whereas environments favored by methanogens are relatively common, high-salt environments are more limited. Probably the two most well-known high-salt environments are the Great Salt Lake in Utah and the Dead Sea, located between Israel and Jordan **(Figure 4.16)**. Because these lakes have no outlets, water leaves only through evaporation. As a result, minerals brought in by the tributaries accumulate to high levels. The specific salinity in both lakes depends on the location within the lake, the season, and the recent weather. On average, the salinity in the Great Salt Lake varies from 5 to 25 percent, and the salinity of the Dead Sea may be as high as 34 percent. The salinity of the ocean, in contrast, is around 3.5 percent, or approximately 0.6 M. Because of these high salt

© Adam Sylvester/Science Source Images

Figure 4.16. The Dead Sea Halophilic archaea are nearly the only life-forms in hypersalinic bodies of water. Located between Israel and Jordan, the Dead Sea is over 1,300 feet below sea level and is one of the world's saltiest environments. It is largely devoid of macroscopic life, but harbors various archaeal species.

concentrations, both the Great Salt Lake and the Dead Sea are largely devoid of macroscopic life, sustaining brine shrimp and some plankton, but no fish.

Other high-salt environments do exist. A number of hypersaline lakes, like Deep Lake, have been characterized in Antarctica. As with the Great Salt Lake and the Dead Sea, the actual salt concentration varies spatially and temporally within these lakes. Additionally, the temperatures are very low. Halophiles isolated from these locations, then, must be psychrophiles, or psychrotolerant. Other locations, like Lake Magadi in Kenya, contain high concentrations of sodium carbonate (Na_2CO_3). The carbonate ions result in an alkaline environment. As expected, the halophiles isolated from these locations grow optimally under high-salt and high-pH conditions.

Life in a high-salt environment presents some interesting challenges. Most notably, these cells must avoid osmotic shock. In a hypertonic environment, such as the Dead Sea, ion concentrations outside of the cell are much higher than ion concentrations inside a typical cell. As a result, water will flow out of the cell, causing it to shrink. Conversely, ion concentrations outside of a cell in a hypotonic environment are lower than inside the cell, causing water to flow into the cell and making it swell (Figure 4.17). To combat this problem, *Halobacterium salinarum*, a well-studied halophile, maintains a high intracellular concentration of potassium ions (K^+). The high intracellular potassium levels provide the cell with a type of osmotic balance, thereby preventing the efflux of water (Figure 4.18).

High-intracellular potassium concentrations, however, present other problems. First, high salt concentrations denature DNA. The increased potassium levels would disrupt the hydrogen bonds that hold together the two strands of a double-stranded DNA molecule. Second, the increased intracellular potassium levels also would adversely affect cytoplasmic proteins. Again, proteins tend to denature when placed in high-salt environments. So how do halophiles avoid these problems?

Studies of *Halobacterium* sp. NRC-1 have provided some answers to this question. This archaeal species grows optimally in medium containing 4.5 M NaCl, which is slightly less salty than the Dead Sea but over seven times more salty than typical ocean water. In 2000, its complete genome was sequenced, making it the first halophile to be sequenced. Computational analyses of its genome have provided interesting insight into life in high-salt environments. First, the genome has a high-GC content. Within the chromosome, approximately 68 percent of the 2 Mbp are GC pairs. Because GC pairs are held together by three hydrogen bonds, as opposed to the two hydrogen bonds that connect AT pairs, a chromosome with a high GC content will be less likely to be denatured by the high intracellular potassium levels. Second, the proteins are highly acidic, containing a large number of aspartic acid and glutamic acid residues. Acidic proteins, biochemists have demonstrated, tend to remain more stable in high-salt environments than do neutral or basic proteins. From these studies of *Halobacterium* sp. NRC-1, it appears that this species possesses several unique properties allowing it to flourish in a very atypical environment.

Perhaps the most interesting feature of *Halobacterium* species is not directly related to their adaptations to high-salt environments. Members of this genus possess a novel means of obtaining additional energy when exposed to low-oxygen

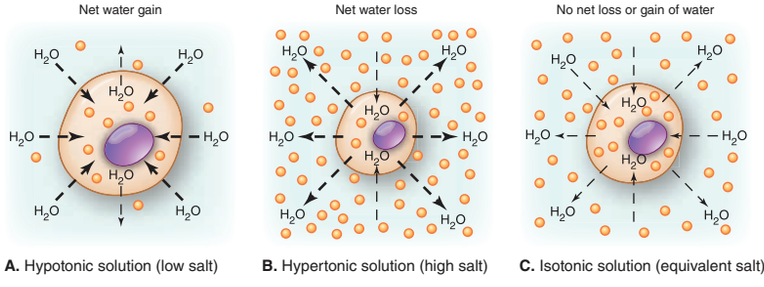

Figure 4.17. Osmotic balance in cells **A.** When cells are placed in hypotonic, or lower salt, solutions, water molecules will move into the cell, causing the cell to swell. In extreme cases, cells lacking a cell wall will lyse. **B.** When cells are placed in a hypertonic, or higher salt, solution, water molecules will move out of the cell, causing the cell to shrink. **C.** When the extracellular and intracellular salinities (indicated by blue spheres) are similar, there is no net movement of water across the membrane.

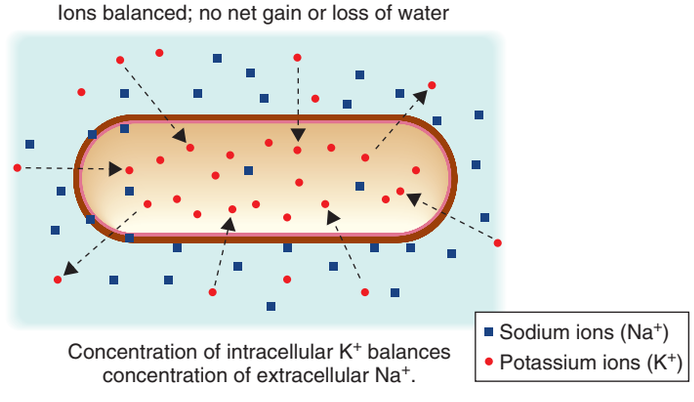

Figure 4.18. Maintaining osmotic balance in halophiles To combat the movement of water out of their cells, some halophilic archaea, like *Halobacterium salinarum*, accumulate high-intracellular potassium (K^+) concentrations. The high levels of intracellular K^+ balance the high extracellular Na^+ concentrations, thereby preventing the efflux of water from the cell. Such maintenance of water balance and cell shape permits normal functioning.

Mini-Paper: A Focus on the Research
THE ROLE OF ARCHAEA IN OUR DIGESTIVE SYSTEM

B. S. Samuel and J. I. Gordon. 2006. A humanized gnotobiotic mouse model of host-archaeal-bacterial mutualism. Proc Natl Acad Sci USA 103:10011–10016.

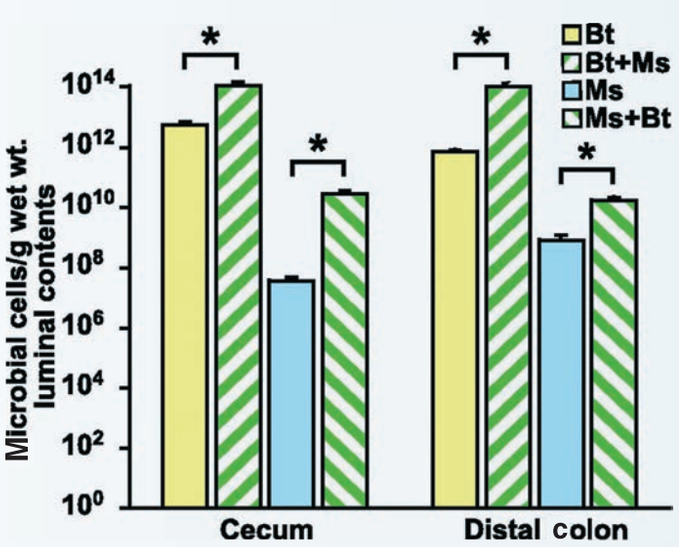
Context

Our intestines contain trillions of microbes. Many of the bacteria residing in our large intestine feed off of indigestible material in our diet, often fermenting fiber, releasing various small organic molecules, H_2, and CO_2. The by-products of these fermentation reactions, in turn, can be absorbed by our cells, contributing to the amount of calories we ultimately derive from the food we eat. Studies with germfree mice, mice raised in sterile environments and lacking microorganisms within their GI tract, have demonstrated the role microorganisms play in this process. When the GI tracts of germfree mice were colonized with microorganisms from another animal, creating gnotobiotic mice (see Toolbox 17.1), the gnotobiotic animals exhibited increased fat deposits, even though their food intake did not change. The microorganisms, then, allowed the host animals to gain more from the food they ate.

The archaeon *Methanobrevibacter smithii* may constitute 10 percent of all anaerobic microorganisms present in the GI tract of humans. Presumably, this organism survives on the H_2 and CO_2 produced by other fermenting organisms. Given this information, the researchers posed an interesting question. Does this archaeon affect how much energy we get from the food we eat?

Experiments

To address the impact of *Methanobrevibacter smithii* on digestion, Samuel and Gordon examined gnotobiotic mice. These mice were colonized with either *Bacteroides thetaiotaomicron (Bt)*, a common bacterial inhabitant of the human GI tract known to scavenge various polysaccharides that we consume, or *M. smithii (Ms)*, or both microorganisms together. At defined times after colonization, the researchers measured the amounts of each species present in the cecum and colon, two portions of the large intestine, of the previously germfree mice **(Figure B4.2)**. In mice that were co-colonized (Bt+Ms or Ms+Bt), the number of microorganisms present was significantly greater than in mice that were colonized with only one species (Bt or Ms), leading the researchers to conclude that the two species forged a "mutually beneficial relationship." Presumably, *M. smithii* allows *B. thetaiotaomicron*



From B. S. Samuel and J. I. Gordon. 2006. PNAS 103:10011–11016. © National Academy of Sciences, USA

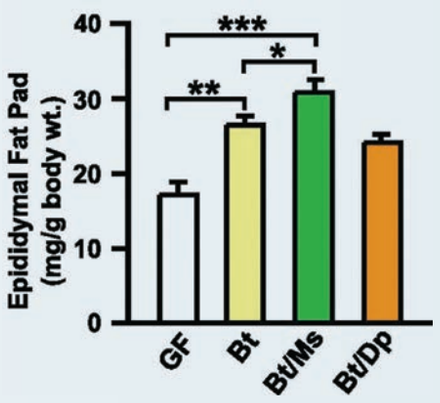
Figure B4.2. Mutually beneficial relationship between *Methanobrevibacter smithii* and *Bacteroides thetaiotaomicron* in the GI tract Following colonization or co-colonization of germfree mice, researchers examined the amount of *B. thetaiotaomicron* (Bt and Bt+Ms bars) or *M. smithii* (Ms and Ms+Bt bars) in the organisms. The colonization of each species was enhanced by the presence of the other organism.

conditions. Species such as *H. salinarum* can obtain additional energy via **phototrophy**, the acquisition of energy from sunlight. However, these organisms do not use a chlorophyll-based form of phototrophy. Rather, the energy present in sunlight is harvested by another molecule—**bacteriorhodopsin**. Initially named before *Archaea* was a generally accepted domain of life, this integral membrane protein, like the rhodopsin protein found in the human eye, surrounds a molecule of retinal. Absorption of light by retinal results in the transfer of a proton by bacteriorhodopsin directly into the periplasm. A proton motive force is generated without an electron transport system. These protons then flow back into the cell through a typical ATP synthase H^+ channel, generating ATP **(Figure 4.19)**. The bacteriorhodopsin molecules also cause a characteristic reddish hue in locations containing significant concentrations of *Halobacterium* species **(Figure 4.20)**.

CONNECTIONS In most living organisms, a proton motive force provides the potential energy needed for the generation of ATP. As the protons flow down their concentration gradient, through ATP synthase, ADP and inorganic phosphate are combined to form ATP. This process is described in more detail in **Section 13.4**.

The Other Euryarchaeotes

The methanogens and halophiles represent the most closely studied groups within the phylum *Euryarchaeota*, but other members of this phylum also exist. Most of these species are thermophiles or hyperthermophiles, and many of them also are acidophiles, growing optimally in very acidic environments. *Picrophilus* species, for example, have been isolated from volcanic areas replete with sulfuric acid in northern Japan and grow optimally at 60°C and a pH of 0.7. Certainly, as we have seen for



From B. S. Samuel and J. I. Gordon. 2006. PNAS 103:10011–11016. © National Academy of Sciences, USA

Figure B4.3. Presence of *M. smithii* and increased fat deposition in co-colonized mice Energy utilization, as measured by fat deposits, was assayed in germfree (GF) mice and mice colonized with *B. thetaiotaomicron* alone (Bt) or co-colonized with *B. thetaiotaomicron* and *M. smithii* (Bt/Ms) or *B. thetaiotaomicron* and *Desulfovibrio piger* (Bt/Dp). Co-colonization with *M. smithii*, but not *D. piger*, significantly increased the energy utilization of the animals.

to ferment polysaccharides more efficiently by keeping H_2 levels low. In turn, *M. smithii* uses the H_2 produced by *B. thetaiotaomicron* for methanogenesis.

To explore the effects of this microbial relationship on the host, the researchers then looked at the amount of fat stored in these animals **(Figure B4.3)**. As shown previously, the amount of energy the host derived from its diet, as evidenced by its fat accumulation, increased significantly when germfree mice were colonized with *B. thetaiotaomicron*. An even greater increase in fat pad weight was observed when mice were co-colonized with *B. thetaiotaomicron* and *M. smithii*. However, this co-colonization-associated increase was not observed when germfree mice were co-colonized with *B. thetaiotaomicron* and *Desulfovibrio piger*, another common bacterial inhabitant of the human GI tract. In other words, the increased fat pad weight was not simply a factor of having two microbial species present.

Impact

These results indicate that a complex relationship exists between the various inhabitants of the GI tract. Not only do the species interact with each other, but they also interact with the host. From this specific set of experiments, it is clear that *Bacteroides thetaiotaomicron* and *Methanobrevibacter smithii* have a relationship with each other and with their host that is mutually beneficial. The authors note that these results could provide insight into preventing obesity or, conversely, allowing underfed people to obtain more calories from the food they ingest. Altering our gut microbiota could affect the nutritional value of the food we eat.

Questions for Discussion

1. How valid is the gnotobiotic mouse model used by these researchers?
2. If specific microorganisms affect our ability to extract calories from food, then how could this information be used therapeutically?
3. Our GI tract, as we noted, contains trillions of microbes, representing a large number of species. How accurately can a two-species model, as described in this paper, shed light on our digestive processes?

the halophiles, these species must be uniquely adapted to their surroundings. For instance, preliminary studies demonstrate that cell membranes of these species actually become destabilized when the pH increases. More detailed biochemical studies of these species will provide us with interesting information about life under extreme conditions.

Korarchaeota

As we noted previously, most well-characterized archaea have been classified as crenarchaeotes or euryarchaeotes. Certainly, though, not all archaea fall into one of these two phyla. Beginning in the early 1990s, researchers analyzed small subunit rRNA sequences isolated from thermal environments in Yellowstone National Park in the United States. Many of these sequences appeared to cluster in a separate group apart from known crenarchaeotes or euryarchaeotes. Such studies led to the proposal of another archaeal phylum, *Korarchaeota*. Today, korarchaeotal sequences have been identified in a number of thermal environments throughout the world. No members of this phylum have been cultivated.

Although uncultivated, the entire genome of one korarchaeotal representative has been sequenced. To achieve this feat, researchers used a continuous enrichment culture technique, a method that we will investigate more fully in Section 15.2. From the enriched culture, they isolated and sequenced the genome of *Candidatus* Korarchaeum cryptofilum (see Appendix C for this designation). Analysis of this genome shows that some genes, like those encoding ribosomal proteins, most closely match homologous crenarchaeal genes. In contrast, others genes, like those encoding DNA repair proteins, most closely match homologous euryarchaeal proteins.

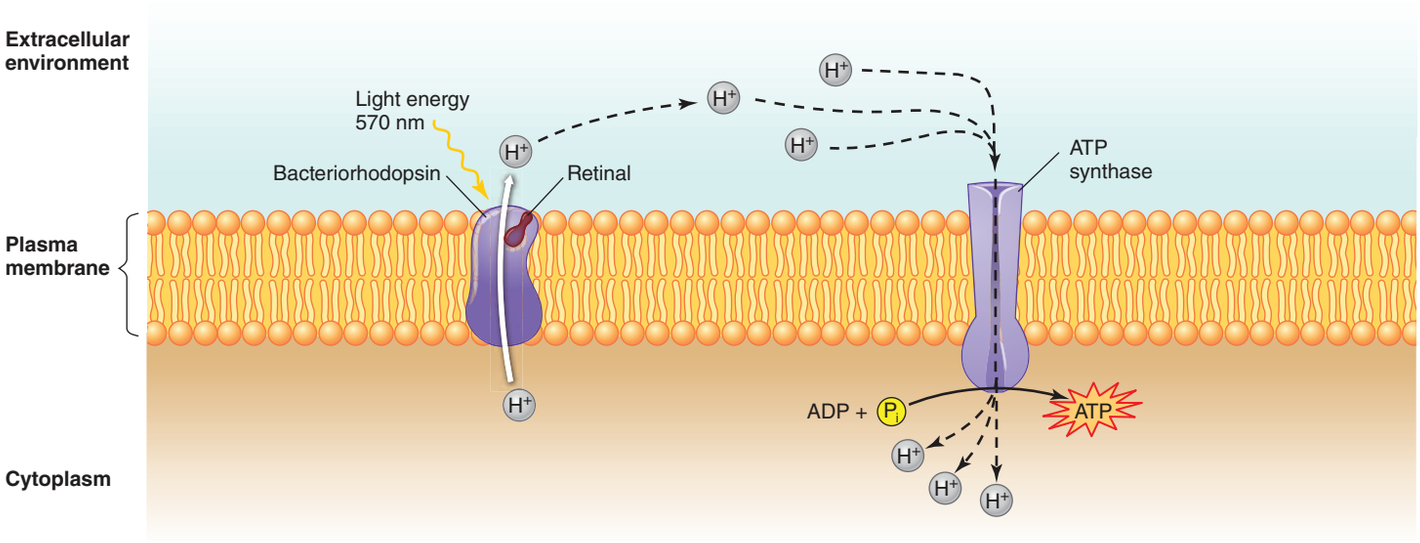


Figure 4.19. Bacteriorhodopsin-based phototrophy Many halophilic archaea can utilize sunlight as an energy source. Unlike plants and most photosynthetic bacteria, these organisms do not contain chlorophyll. Rather, a molecule of retinal, located within the integral membrane protein bacteriorhodopsin, absorbs the energy present in sunlight. Bacteriorhodopsin functions directly as a proton pump, allowing the cell to create a proton motive force. The protons then pass through ATP synthase, resulting in the production of ATP. This process was demonstrated clearly when researchers inserted bacteriorhodopsin and ATP synthase into an artificial lipid vesicle. When this structure was exposed to light, protons accumulated in the vesicle and ATP was produced.

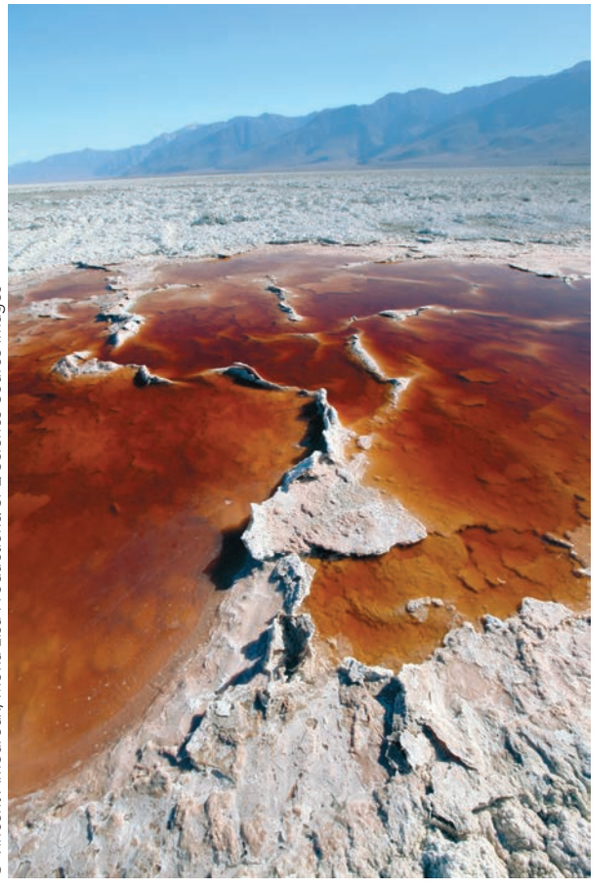

© Vincent Amouroux, Mona Lisa Productions/SPL/Science Source Images

Figure 4.20. Red coloration by *Halobacterium* Because of water diversion for the city of Los Angeles, Owens Lake in eastern California is nearly dry and exhibits a high salt concentration. The large numbers of halophilic archaea that thrive in this hypersaline environment give the lakebed a dramatic red color.

This feature of the *Ca.* K. cryptofilum genome could reflect its distant evolutionary relationship to the other archaeal phyla.

Nanoarchaeota

Nanoarchaeum equitans, the organism we mentioned in the opening story, currently is the only cultivated member of this phylum. The 16S rRNA gene sequence of *N. equitans* indicates that this species is distinct from the other archaeal phyla. With a genome of less than 500,000 base pairs and a diameter of about 0.4 μM, this species also appears to be among the smallest living organisms. Furthermore, it exhibits a fascinating relationship with a host organism.

Nanoarchaeum equitans was first observed attached to another archaeal species, *Ignicoccus hospitalis*, and it appears that *N. equitans* depends on its host for survival. Indeed, all attempts to grow *N. equitans* independently have failed. Furthermore, analysis of the *N. equitans* genome shows that it lacks genes for seemingly essential functions, like the synthesis of nucleotides, lipids, cofactors, and amino acids. Perhaps it acts as a parasite, syphoning needed resources from its host. Members of this phylum may be widespread given that environmental sequencing studies indicate that *N. equitans*-like 16S rRNA genes exist in various high-temperature environments. Future studies of these species may tell us more about the taxonomy of archaea, provide insight into the minimal requirements of life, and help us understand how different microbial species interact.

CONNECTIONS Researchers have been studying the bacterium *Mycoplasma genitalium* (see **Microbes in Focus 10.1**) in attempts to define the minimal requirements of life. Their experimental approaches are described in **Section 10.3**.

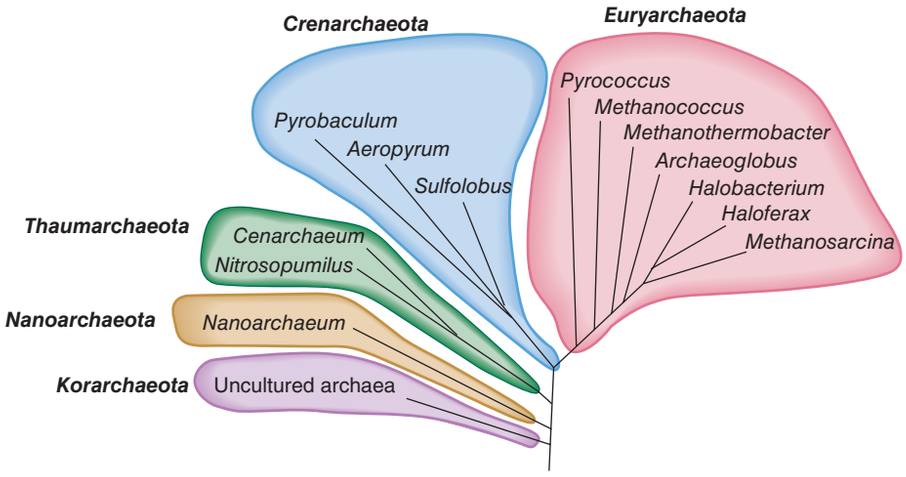

Figure 4.21. Phyla of the *Archaea* Researchers now postulate that the *Archaea* contains five phyla. As more archaeal species are identified and their genomes sequenced, the evolutionary relatedness of members of this domain will become clearer and this phylogenetic tree will continue to change.

4.3 Fact Check

1. What are the two major phyla of *Archaea*?
2. What is the key feature of most known crenarchaeotes?
3. Describe the terms thermophile, hyperthermophile, acidophile, and barophile.
4. Identify and describe several of the chemical adaptations of hyperthermophiles that allow for life at extreme temperatures.
5. Describe an important biogeochemical role that members of the *Thaumarchaeota* are known to contribute.
6. What are methanogens and where are they found?
7. What is bacteriorhodopsin? Describe its role in the generation of energy.

Image in Action

WileyPLUS Learning Space In this illustration, we see the diversity in morphologies present within the domain Archaea. The tiny *Nanoarchaeum equitans* lives with its host, *Ignicoccus hospitalis*. *Pyrodictium abyssi* produces a network of long hollow tubules called cannulae, and *Haloquadratum walsbyi* forms sheets of flat squares. Some archaea are rod shaped. Others are spherical. Some archaea contain many flagella. Others contain few or no flagella.

1. If you were able to examine the archaea in this image more closely, what key features might you expect to find?
2. Several of the archaea in this image may be thermophilic. What adaptations would you expect to find in these organisms?

The Rest of the Story

Since the discovery of *Nanoarchaeum equitans* in 2002, we have learned much more about this unusual microorganism. As we noted in Section 4.3, some researchers have proposed that *N. equitans* represents a member of a new archaeal phylum, *Nanoarchaeota*. Indeed, the SSU rRNA genes of this organism could not be detected by PCR using universal primers, primers thought to recognize all archaeal species. The SSU rRNA of *N. equitans* differs significantly from the SSU rRNA of other known members of this domain.

The relationship between *N. equitans* and its host, *Ignicoccus hospitalis*, has generated a great deal of interest. All attempts to grow this microorganism in the absence of a host have failed. Indeed, the relationship between *N. equitans* and *I. hospitalis* appears to be quite specific; attempts to grow *N. equitans* in the presence of other *Ignicoccus* species also have failed. It also appears that *N. equitans* will grow only when physically attached to *I. hospitalis*. Initially, researchers concluded that the relationship between these organisms was not parasitic. They observed that the growth of *I. hospitalis* was not altered in the presence of *N. equitans*. However, more recent studies suggest that the relationship may be mildly parasitic. In other words, *N. equitans* may harm *I. hospitalis* in some way under certain conditions.

The *N. equitans* genome is approximately 490,000 bp, making it among the smallest genomes of any living organism. It appears to lack necessary genes for amino acid, nucleotide, cofactor, and lipid synthesis. Most likely, it acquires these materials from its host. Indeed, analyses of the lipid composition of membranes from both species indicate that the *N. equitans* plasma membrane may be obtained from its host. Other studies have demonstrated that amino acids are transported from *I. hospitalis* to *N. equitans*.

Recent findings indicate that *N. equitans* may have other close relatives. SSU rRNA sequences closely related to *N. equitans* have been detected in Yellowstone National Park, United States, and Kamchatka, Russia, indicating that related species may be widely distributed. In all likelihood, further microbial ecology studies will help us better understand the relationships between these interacting species and further elucidate their evolutionary history.

Summary

Section 4.1: How do we know that the Archaea is a distinct domain of life?

Historically, all living organisms were divided into two broad groups—the eukaryotes and the prokaryotes—based on presence or absence of a membrane-bound nucleus. However, ***Archaea*** is now recognized as a distinct domain of life.

- To determine the phylogeny of all living organisms, researchers often compare **ribosomal RNA (rRNA)** sequences.
- Small subunit (SSU) rRNA sequence comparisons demonstrated that living organisms form three phylogenetically distinct groups, or domains: *Eukarya, Bacteria*, and *Archaea*.
- Many archaeal DNA replication, transcription, and translation proteins resemble their eukaryal counterparts.
- Current studies indicate that archaea and eukarya may have evolved from a bacterial precursor.

Section 4.2: What do archaeal cells look like?

Archaea, like bacteria, exhibit a multitude of shapes, although most appear to be spherical or rod shaped.

- Most archaea, like most bacteria, are between 0.5 μm and 5 μm in diameter.
- The cytoplasm of archaea contains a mixture of molecules, most notably the DNA, which usually exists as a single, circular chromosome.
- Unlike bacteria, some archaea possess **histones**, DNA-binding proteins that help to package the DNA and may make it more thermostable.
- Some archaea contain cytoskeletons that may help them maintain their shape. The identified cytoskeleton proteins resemble identified eukaryal cytoskeleton proteins.
- The archaeal plasma membrane consists of glycerol 1-phosphate, a stereoisomer of the molecule present in bacterial and eukaryal membranes. Attached to the glycerol molecule are **isoprenoids**, usually **phytanyl** or **biphytanyl**, via ether linkages. Some archaea possess lipid monolayers, rather than bilayers, which can form stable **liposomes**.
- Most archaea possess a cell wall composed of **pseudomurein**, which is similar to, but chemically distinct from, the peptidoglycan seen in bacterial cell walls.
- Some archaea possess **flagellin**. Again, the flagellin proteins in archaea are distinct from the flagellin proteins used by bacteria.
- Some archaea form networks, in which cells are connected by **cannulae**.

Section 4.3: What are the major groups of archaea?

The domain *Archaea* currently is divided into five phyla, *Crenarchaeota*, *Thaumarchaeota*, *Euryarchaeota*, *Korarchaeota*, and *Nanoarchaeota*.

- Members of the phylum *Crenarchaeota* are **thermophiles** or **hyperthermophiles**. Many of these species also are **acidophiles** or **barophiles**.
- Hyperthermophiles possess several adaptations to life at high temperatures, including the presence of **molecular chaperones**, which form a complex referred to as the **thermosome** that facilitates protein folding and refolding, and **reverse DNA gyrase**, which increases the melting temperature of DNA.
- The phylum *Thaumarchaeota* consists of **mesophiles** and **psychrophiles**, which are common in terrestrial and aquatic environments.
- Thaumarchaeotes contribute to biogeochemical cycling, especially the nitrogen cycle by oxidizing ammonia.
- The phylum *Euryarchaeota* contains **methanogens**, which are organisms that produce methane, and **halophiles**, organisms that grow in high-salt environments.
- Methanogens are found in **anoxic** environments throughout the world, including the human GI tract.
- Halophiles possess several adaptations to life in high-salt environments. Some also undergo **phototrophy**, using **bacteriorhodopsin** to harvest the energy of sunlight
- Although no members of the phylum *Korarchaeota* have been cultivated, korarchaeotal sequences have been identified in thermal environments throughout the world.
- One of the smallest known living organisms, *Nanoarchaeum equitans*, represents the only cultivated member of the phylum *Nanoarchaeota*.

Application Questions

1. Many hyperthermophilic organisms will die if exposed to lower temperatures. Why might these lower temperatures be too extreme for these organisms?
2. Thermophilic organisms must maintain the integrity of their proteins at elevated temperatures. Explain what would typically happen to bacterial proteins at elevated temperatures and how thermophilic bacteria are able to avoid this.
3. Imagine you are attempting to isolate and cultivate various extremophiles. What problems might you encounter in trying to accomplish this?
4. You are reading about archaea and their importance in many industrial applications. Explain why enzymes isolated from some archaea can be useful commercially. Provide an example.
5. Why might a cell contain a lipid monolayer as opposed to a lipid bilayer? Explain.
6. A scientist is studying the optimal growth conditions of a unique microbial cell. After testing many conditions, she finds that the cell grows best at 80°C and a pH of 3.0. How would this cell be categorized? Explain.

7. A microorganism's cellular proteins are being analyzed. Nearly all of its proteins have a high percentage of α-helical regions, low levels of the amino acid cysteine, and increased levels of arginine. Based on these unique characteristics, what type of microorganism might this be? Explain.
8. The search for life on Mars has focused on the chemistry of the subsurface as a potential environment for methanogens. Describe the conditions in this environment that might support the metabolic activities of methanogens.
9. You are examining a microorganism that contains a membrane protein with very high similarity to the protein bacteriorhodopsin. Based on this similarity, what would you hypothesize is the function of this protein? Explain how it would function in the cell.
10. A microorganism is observed with a gene that codes for reverse DNA gyrase. What would this enzyme do, and what selective advantage would it provide the organism?
11. You detect what appears to be a new type of archaeon, although it does not live in an extreme environment.
    a. What structural characteristics would you need to observe to officially consider this microorganism an archaeon?
    b. Explain how you would go about determining whether this organism is phylogenetically related to archaea.

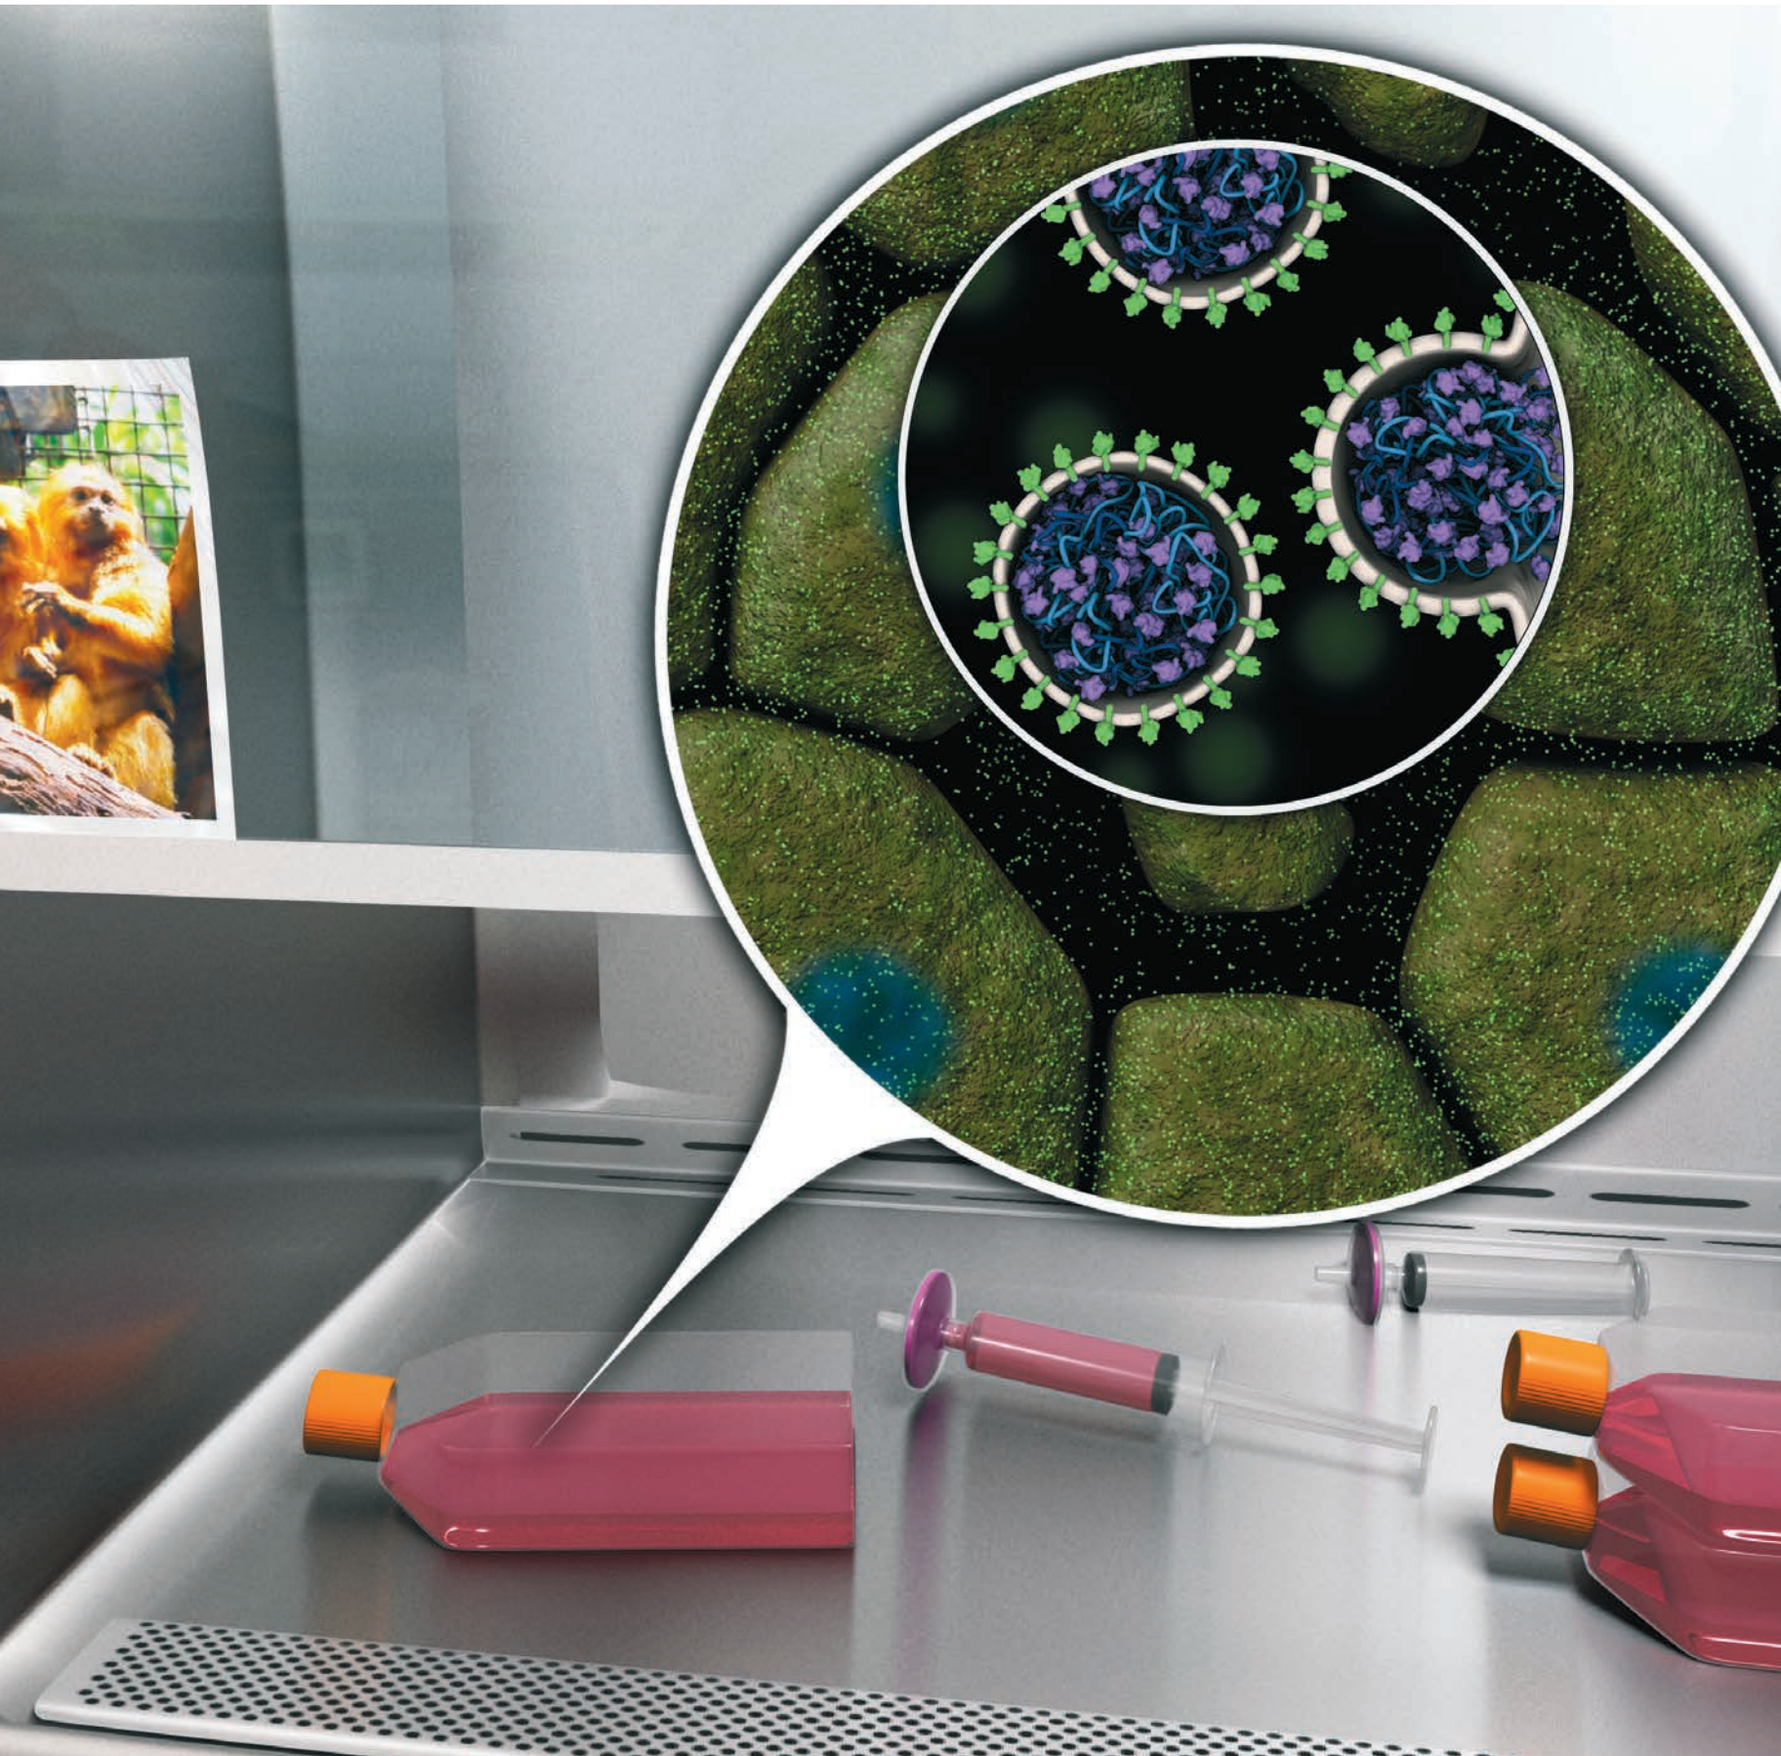
CHAPTER 5

Viruses



In the spring of 1991, Dr. Dick Montali, the chief veterinary pathologist at the National Zoo in Washington, DC, learned about deaths among golden lion tamarins at a zoo in the United States. Similar outbreaks of a fatal hepatitis among these small primates had occurred at various U.S. zoos during the preceding several years. Certainly, the unexplained deaths of any animals at a zoo troubled Dr. Montali, but these deaths worried him more than most because the golden lion tamarins, or GLTs, are endangered.

The brightly colored golden lion tamarins live in the Atlantic coastal forest of Brazil, where they eat various fruits, insects, and small reptiles and amphibians. Because of increased human activity in this area, their habitat has shrunk and their populations have plummeted. Today, researchers estimate that only about 1,500 GLTs remain in the wild. Another 500 live in zoos throughout the world.

To help stabilize the GLT populations, the National Zoo coordinates a program for GLT breeding and reintroduction to the wild. At various zoos throughout the United States, GLTs are bred in captivity. Upon maturation, animals destined for reintroduction first are sent to the National Zoo. There, they become acclimated to life in the wild. The GLTs at the National Zoo live in a non-enclosed wooded area in the center of the zoo, where they are provided with food and nesting boxes. After a short period of acclimation, they are then transported to the Reserva Biologica de Poço das Antas, a protected reserve near Rio de Janeiro. Again, food is provided initially, but over time the released animals learn to forage for themselves. Since 1984, about 400 GLTs have been reintroduced into Brazil.

Obviously the deaths of GLTs could adversely affect the reintroduction program, but veterinarians had a bigger concern: What if an infectious agent was killing these animals? Because zookeepers routinely transported GLTs between various zoos for breeding purposes, an infectious agent could easily be spread to zoos throughout the country. Even worse, if conservation biologists inadvertently reintroduced an infected animal into the Brazilian rain forest, then wild populations could become infected. Rather than saving a species from extinction, the efforts of concerned biologists could actually have deleterious effects. Finally, what if an infectious agent affecting the golden lion tamarins could be transmitted to humans?

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Although quite diverse, all viruses are small, obligate intracellular parasites.

- Figure 5.3: Sizes and shapes of selected viruses
- Table 5.1: Sizes and structural features of selected viruses
- Microbes in Focus 5.1: The many contributions of bacteriophage T2
- Figure 5.12: Process Diagram: General steps in a viral replication cycle

Several hypotheses about the evolutionary history of viruses have been proposed.

- Perspective 5.1: Ribozymes: Evidence for an RNA-based world
- Figure 5.13: Process Diagram: Replication of retrotransposons

Various techniques are used to amplify and quantify viruses.

- Toolbox 5.1: Cell culture techniques
- Microbes in Focus 5.2: Poliovirus and the race for a vaccine
- Figure 5.15: Cytopathic effects (CPE) in virally infected cells
- Figure 5.21: Plaque assay to determine viral titer

Viruses generally are classified based on their structure and replication strategy.

- Figure 5.26: Classification of viruses
- Figure 5.27: Using electron microscopy (EM) to differentiate viruses
- Figure 5.29: Genome sequence analysis of SARS coronavirus

Viruses are not the simplest subcellular particles.

Introduction

"Virus." Many of us associate this word with disease or sickness. Viruses, after all, cause common colds. Viruses such as influenza, smallpox, polio, and HIV have caused immeasurable human suffering and death. Only a very small proportion of all viruses, though, are human pathogens, or disease-causing agents. The air we breathe, the water we drink, and the foods we eat contain millions of viral particles. The vast majority of these viruses do not cause us to become ill. In fact, most of these viruses do not even infect humans at all. Rather, they infect other animals, plants, fungi, protists, bacteria, and archaea. Most likely, there are specific viruses that infect every type of living organism. Additionally, viruses can play an integral role in nutrient cycling in many, if not all, ecosystems. In this chapter, we will discuss the history of virology and basic properties of viruses, explore theories about the origin of viruses, and learn about common techniques for cultivating, purifying, and quantifying viruses. Other topics, including viral classification and identification, will be addressed as well. We will investigate viral replication more thoroughly in Chapter 8. For now, let's focus on these questions:

What is a virus? (5.1)
From what did viruses arise? (5.2)
How can we "grow" and quantify viruses? (5.3)
What are the different types of viruses? (5.4)
Are viruses the simplest pathogens? (5.5)
What's next for virology? (5.6)

5.1 A basic overview of viruses

What is a virus?

Quite simply, **viruses** are small subcellular particles that can replicate only within living host cells. As a result, viruses are **obligate intracellular parasites**; they cannot replicate independently. They consist of an RNA or DNA genome enclosed within a protective protein shell, or **capsid**. Together, the genome and capsid compose the **nucleocapsid**. Some viruses also contain a **viral envelope**, a host cell-derived membrane that surrounds the capsid. During the production of new virus particles, all viruses require host cell enzymes for translation. Many viruses also require host cell enzymes for various aspects of transcription and/or genomic replication. Because of this dependence on the host cell, all viruses have a mechanism for entering a host cell, and newly formed viruses must possess a mechanism for then exiting the cell. As we will see later in this chapter, and in Chapter 8, different viruses carry out these basic activities in very different ways. To begin our investigation of viruses, we will explore the history of virology.

History of virology

In some respects, the history of virology is nearly as old as the history of life itself. We know that different types of viruses exist that can infect all forms of life—plants and animals, fungi, bacteria, and archaea. Some researchers have postulated that all viruses, like living organisms, may have evolved from a common ancestor—what one might call the primordial virus. Although this hypothesis still needs more supportive data, it does raise an interesting question. Are all viruses related? We will examine the question of viral origins in more detail later in this chapter.

Most likely, viruses that infect humans have existed since humans first evolved and have affected human history dramatically. Archeological and anthropological evidence suggests that pathogenic viruses, particularly smallpox virus, have infected humans throughout our history. Smallpox epidemics plagued ancient Egypt and may have caused the death of King Ramses V in the twelfth century B.C. **(Figure 5.1)**. Many historians today agree that the decimation of Native American populations after the invasion of the Europeans was more due to smallpox than warfare. Some historians argue that the outcome of World War I may, at least in part, have been determined by the 1918 influenza outbreak.

Virology as a science, on the other hand, is only a little over 100 years old. Dimitri Ivanovski, in 1892, demonstrated that a disease of tobacco plants (see Figure 1.9D) could be transmitted by extracts of a diseased plant that had been passed through a filter small enough to exclude the smallest known bacteria.

© Patrick Landmann/Getty Images, Inc.

Figure 5.1. Pathogenic viruses and human history This photograph of the mummy of Ramses V, king of ancient Egypt in the twelfth century B.C., shows pustule-like markings on his face, suggesting that a smallpox infection probably led to his death. Smallpox plagued human populations for thousands of years, but the last recorded natural case occurred in Somalia in 1977.

A few years later, in 1898, Martinus Beijerinck described this agent (now known to be tobacco mosaic virus) as *contagium vivum fluidum*, a "soluble living germ." Most virologists see this event as the official beginning of the field of virology.

The advances in this new field have been amazingly rapid. By 1901, Walter Reed and colleagues demonstrated that a human disease—yellow fever—was caused by a virus and could be transmitted by mosquitoes (Figure 5.2). During the early part of the twentieth century, Frederick Twort and Felix d'Herelle described viruses that infect bacteria, termed **bacteriophages** ("bacteria eaters") by d'Herelle. In the ensuing decades, researchers isolated a number of plant and animal viruses and conducted groundbreaking genetic and biochemical experiments with bacteriophages (or phages). Today, viruses that infect all forms of life continue to be identified. Molecular studies continue to provide us with a more detailed understanding of how viruses replicate and the effects that they have on their hosts.

CONNECTIONS If bacteriophages "eat" bacteria, then could they be used clinically as antibacterial agents? Maybe. This idea has been explored for many years. With the increased incidence of antibiotic-resistant bacteria, some researchers are intrigued by the therapeutic potential of bacteriophages. We will explore this topic in **Perspective 24.3**.

Structure of viruses

Although all viruses tend to share several properties, perhaps the most notable characteristic of almost all viruses is their small size. Typically, the diameter of a viral particle is between 10 and 100 nanometers (1 nm = 10^{-9} meters or one billionth of a meter!). Poliovirus, for example, has a diameter of approximately 30 nm, whereas the oval-shaped poxviruses like variola virus, the agent of smallpox, may be over 200 nm long. Bacteria and archaea, in contrast, typically have diameters from 1 to 10 micrometers (1 μm = 1,000 nm), and eukaryal cells generally have diameters from 10 to 100 μm (Figure 5.3).

Not surprisingly, all viruses possess a genome, their genetic material. Even though all bacteria, archaea, and eukaryal organisms possess double-stranded DNA genomes, the genomic material of viruses may be DNA or RNA. Additionally, some viruses possess double-stranded genomes and other viruses possess single-stranded genomes. Some viruses possess circular genomes, while other viruses possess linear genomes. Most viruses possess a single genetic molecule, but a few viruses contain segmented genomes. Influenza virus A, for example, contains eight segments of single-stranded RNA that code for a total of ten different proteins. Despite these structural differences, most viral genomes are relatively small, ranging from a few thousand nucleotides in length for the smallest viruses to about 200,000 nucleotides for the largest

Bettmann/© Corbis

B. Dr. Walter Reed

Figure 5.2. Yellow fever: First human disease linked to a virus In 1901, a team of researchers led by Walter Reed demonstrated that yellow fever was caused by a filterable agent, yellow fever virus, that was transmitted by mosquitoes. The last major outbreak in the United States occurred in 1905. Despite various public health efforts and an effective vaccine, yellow fever remains a significant problem in South America and Africa. **A.** Yellow fever virus is the causative agent of yellow fever. **B.** Walter Reed was head of the team that showed mosquitoes transmit yellow fever.

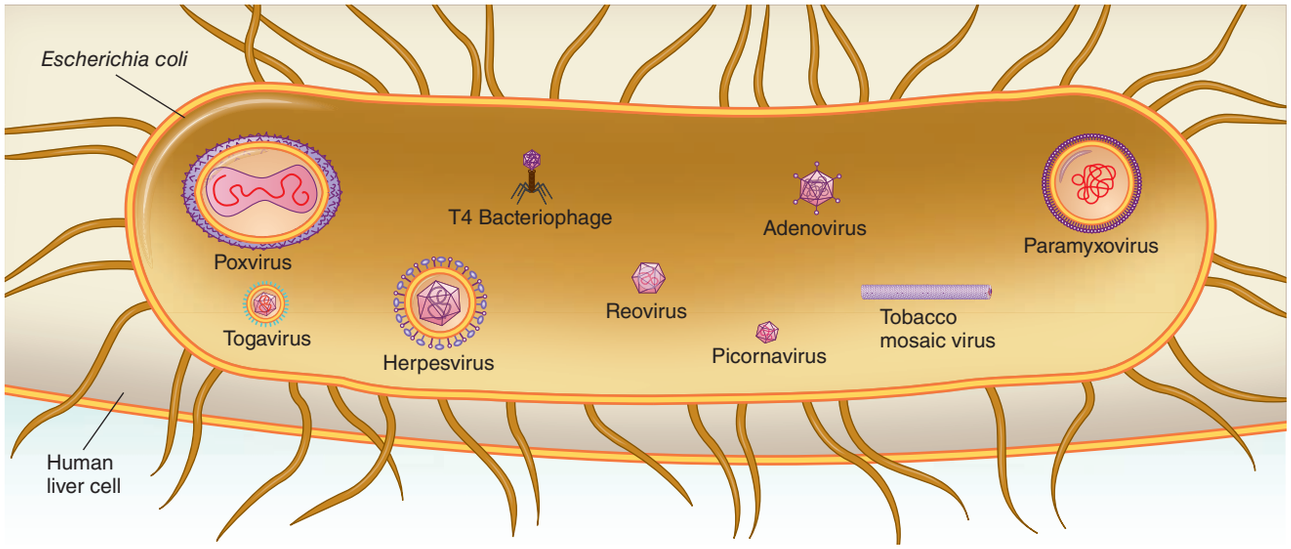

Figure 5.3. Sizes and shapes of selected viruses Specific viruses differ in size. Picornaviruses, like poliovirus, are quite small. Poxviruses, like smallpox virus, are relatively large. Virus structures also differ significantly. The models depicted here represent average sizes and shapes.

viruses **(Table 5.1)**. Contrast this with the genome sizes of the bacterium *Escherichia coli* (4.6 million base pairs) and humans (3 billion base pairs).

CONNECTIONS When two genetically distinct strains of influenza virus infect the same cell, progeny viruses may be produced that contain some gene segments from one of the infecting viruses and some gene segments from the other infecting virus. As we will see in **Section 22.4**, this genetic reassortment can lead to influenza pandemics.

The structures of viruses also exhibit great variation, as we will see in the rest of this section. Some viruses have an almost spherical shape; others are rod-like. Still other viruses, like the bacteriophages, exhibit a combination of structures. Conversely, poxviruses exhibit more complex structures.

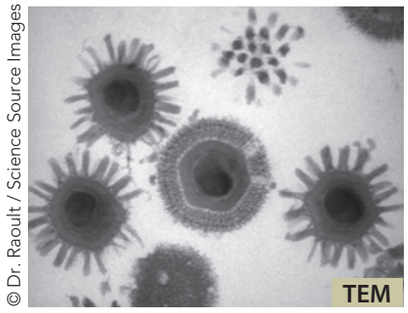
Of course, there are exceptions to every rule, and the general rules about viruses are no different. Since the early 2000s, researchers have isolated and described several viruses whose physical properties certainly stretch the general rule about the size of viruses. First classified as a virus in 2003, Mimivirus, a double-stranded DNA virus that infects amoeba, has a capsid approximately 400 nm in diameter and a genome of 1.2 Mbp (1.2×10^6 bp) that encodes 979 proteins **(Figure 5.4)**. Mimivirus, however, is not the world's largest virus. In October 2011, researchers reported the isolation of an even larger virus, *Megavirus chilensis. This virus* has a genome of over 1.2 Mbp, and also infects amoeba. The current leaders in the giant virus contest, however, are *Pandoravirus salinus*, which has a double-stranded DNA genome of 2.47 Mbp, and *Pithovirus sibericum*, which has a genome of "only" 610,000 bp, but is an incredible 1.5 μm long and 500 nm wide. Like the other known giant viruses, these viruses also infect amoeba.

The genomes of these giant viruses are larger than the genomes of numerous bacteria, including *Mycoplasma genitalium, Treponema pallidum,* and *Chlamydia trachomatis.* Perhaps more astonishingly, the Mimivirus genome contains nearly 2.5 times as many genes as are present in the *M. genitalium* genome! More interestingly, the genomes of these large viruses include genes not typically associated with viruses. For example, genes similar to those needed for the synthesis of nucleotides and amino acids have been identified. No more traditional viruses possess these types of genes. Because of their unusual size and their genetic makeup, these large viruses may force virologists to re-examine the definition of "virus."

TABLE 5.1 Sizes and structural features of selected viruses

Virus	Host	Structure	Size (nm)	Genome size (bp)	Genetic material[a]
Poliovirus	Humans	Non-enveloped, icosahedral	30	7,700	ssRNA
Tobacco mosaic virus	Tobacco and related plants	Non-enveloped, helical	300 × 18	6,400	ssRNA
T4	*Eschericia coli*	Non-enveloped	200 × 90	170,000	dsDNA
Variola virus	Humans	Enveloped, complex	300 × 250	186,000	dsDNA
Mimivirus	Amoeba	Enveloped, complex	400	1,200,000	dsDNA

[a]ssRNA: single-stranded RNA; dsDNA: double-stranded DNA



© Dr. Raoult / Science Source Images

Figure 5.4. Mimivirus: An unusually large and complex virus Generally, viruses are much smaller than even the smallest bacterial cells. Mimivirus is an exception. Mimivirus is approximately 400 nm in diameter, about the same size as the bacterium *Ureaplasma urealyticum*, a mycoplasma that is part of the normal genital microbiota of about 70 percent of sexually active males and females. Mimivirus has not been shown to be pathogenic, but has been associated with cases of pneumonia. The genome of Mimivirus includes genes coding for the synthesis of nucleotides and amino acids. Such genes are unknown in other viral genomes.

A. Tobacco mosaic virus (TMV)

B. Schematic of TMV structure

Figure 5.5. Helical symmetry of tobacco mosaic virus (TMV) A viral capsid exhibits helical symmetry if it can be rotated about its long axis and shows no distinguishing features. **A.** Electron micrograph of TMV, showing the filamentous, rod-like shape of the virus. **B.** Schematic of TMV showing the presence of the RNA genome within the helical protein shell. The helical capsid is composed of multiple copies of a single polypeptide that interact with each other and the RNA genome.

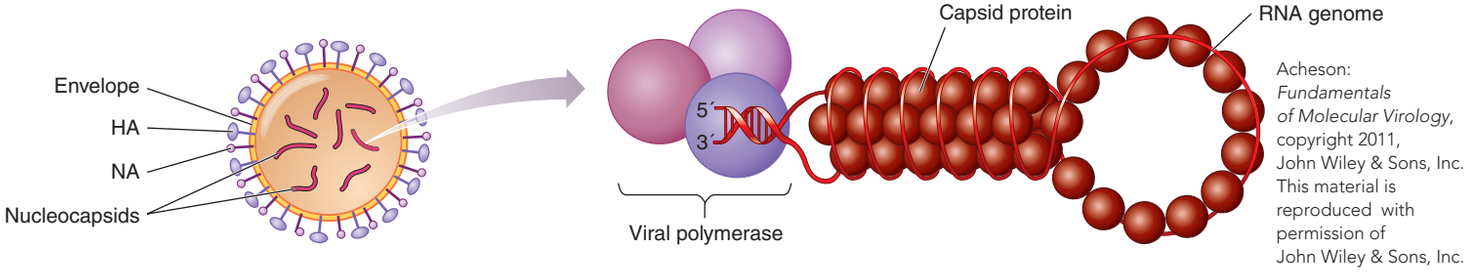
Symmetry

In all viruses, one or more viral proteins surround the genome, forming the nucleocapsid or, more simply, the capsid. Biochemical and genetic studies have shown that the capsid of all viruses consists of many symmetrically arranged subunits, or **capsomeres**. In turn, each capsomere consists of one or more polypeptides. Electron microscopy and X-ray crystallography studies have demonstrated that the capsids of most viruses exist in one of two forms.

The capsids of some viruses, like tobacco mosaic virus (see Figure 5.3), exhibit a **helical morphology**, in which the capsomeres form a helix and the capsid resembles a hollow tube. The capsids of other viruses exhibit an **icosahedral morphology**, in which the capsomeres form an icosahedron, or 20-sided polygon, with each capsomere making up a face of the icosahedron. Many bacteriophages, like T4 (see Figure 5.3), exhibit both helical and icosahedral morphologies, containing an icosahedral "head" and a helical "tail." The giant viruses that we described earlier and a few animal viruses, most notably the poxviruses, have a less well-defined capsid morphology.

Helical Symmetry The simplest structural arrangement found in virus capsids is that of a single polypeptide that directly coats the genome in a repetitive manner, as occurs for tobacco mosaic virus (TMV). The individual capsid proteins interact at regular intervals with the genome and also associate with each other, causing the structure to twist and take on a tube-like coiled form, much like a spiral staircase **(Figure 5.5)**. A similar arrangement occurs in influenza viruses. Multiple copies of a single viral protein, known as nucleoprotein or NP, and a viral polymerase complex associate with each segment of RNA, resulting in eight separate nucleocapsids within each virus particle.

This helical symmetry gives viruses like TMV a filamentous, fiber-like, or rod-shaped morphology. In all viruses with helical capsid symmetry, there is an intimate association between the genome and the capsid proteins. Many phages and plant viruses consist of just helical nucleocapsids. In these viruses, the helical nucleocapsid *is* the **virion**, or complete viral particle. However, all known animal viruses with helical nucleocapsid symmetry, like influenza virus, have an envelope surrounding the nucleocapsid **(Figure 5.6)**.



Acheson: *Fundamentals of Molecular Virology*, copyright 2011, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 5.6. Structure of influenza virus The influenza virus genome consists of eight RNA segments, each of which is enclosed with capsid protein. The viral polymerase is bound to the end of each nucleocapsid. A viral envelope surrounds these nucleocapsids. Embedded in the envelope are two viral proteins, hemagglutinin (HA) and neuraminidase (NA).

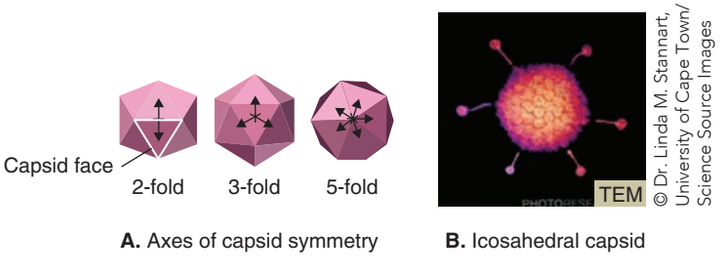


Figure 5.7. Icosahedral symmetry in viruses An icosahedron has 20 faces and 12 vertices. **A.** As seen in this drawing, each face is an equilateral triangle. Icosahedrons exhibit twofold, threefold, and fivefold axes of symmetry. **B.** Adenovirus, depicting icosahedral symmetry, with attachment proteins protruding from the vertices.

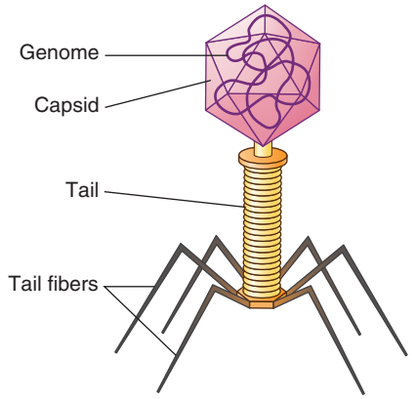

Figure 5.8. Complex structure of bacteriophages Viruses of bacteria typically possess an icosahedral head, which houses the genome, and a helical tail. Attached to the tail are attachment fibers that facilitate binding to host cells.

Most viruses with helical capsid symmetry contain single-stranded RNA genomes. There probably are molecular reasons for this pairing. Single-stranded RNA is quite unstable and subject to rapid degradation; directly coating the genome in protein helps to protect it. In many viruses with helical capsid symmetry, the genome length determines the size of the virus because the capsid proteins faithfully coat the entire length of the new genomes being produced in the host cell. Because of this property, viruses with helical capsids, such as the filamentous TMV and rabies virus, often show diversity in virion size. If the length of the genome varies, then the size of the capsid also will vary. Conversely, viruses with icosahedral capsids have very strict limits on their genome size because of the packaging constraints imposed by the volume of the enclosing capsid. A defined amount of space is available within the capsid.

Icosahedral Symmetry A geometrically perfect icosahedron has 20 faces and 12 vertices forming a closed sphere, and each face of the icosahedron is an equilateral triangle **(Figure 5.7)**. When viewed from different angles, an icosahedron exhibits twofold, threefold, and fivefold axes of symmetry. Proteins, of course, are globular in shape rather than triangular. The only way to make a protein triangle is to use a minimum of three polypeptides per face. As a result, even the smallest icosahedral viruses must use 60 protein units to construct a capsid. In the simplest icosahedral viruses, such as parvoviruses, each face is formed from three identical proteins. Rhinovirus, which causes the common cold, uses three different polypeptides to construct its capsid.

Complex Symmetry Although some viruses of bacteria exhibit simple helical or icosahedral capsid symmetry, most of the known bacteriophages exhibit a more complex structure. These viruses possess an icosahedral head, which contains the genome, and a helical tail **(Figure 5.8)**. This structural arrangement has not been observed among any viruses of plants or animals. As we will see in the next section, this structure is intimately tied to the way in which phages infect their host cells.

Viral Envelopes

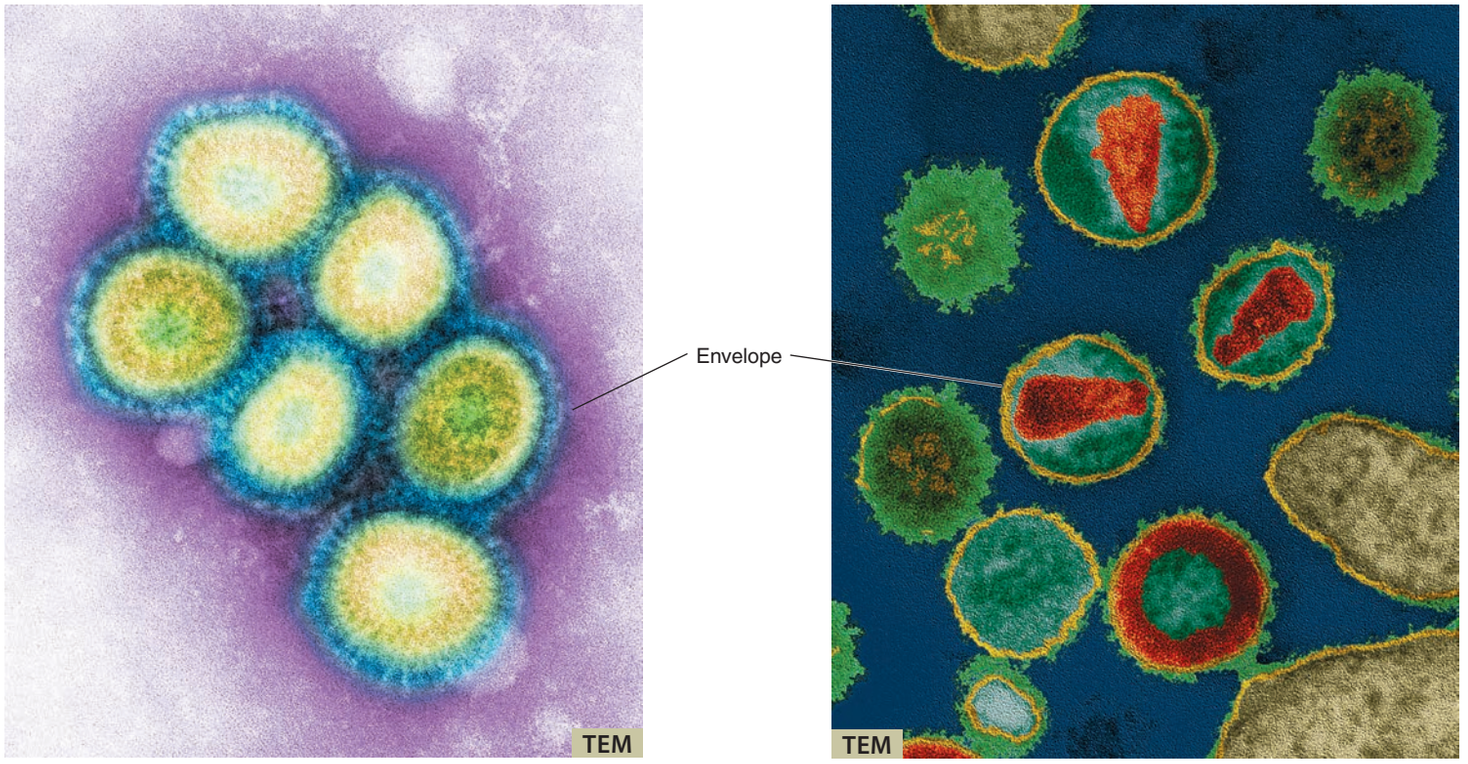
For many viruses, like poliovirus, complete infectious virions consist only of a capsid surrounding a genome and are referred to as non-enveloped, or naked, viruses. For other viruses, a cell-derived membrane, called the viral envelope, surrounds the nucleocapsid. Examples of enveloped viruses include influenza virus and HIV **(Figure 5.9)**. As we will see in Section 8.2, the viral envelope is added as progeny virus particles bud out of cellular membranes on their transit out of an infected host cell. Although many animal viruses are enveloped, very few enveloped viruses of plants or bacteria have been identified.

For enveloped viruses, the viral envelope and its associated proteins usually are required for successful entry into a new host cell. Without an intact envelope, the proteins needed for viral attachment are absent or non-functional, and the virus is rendered non-infectious. These viral attachment and entry proteins are transcribed and translated from the viral genome in the infected host cell and are inserted into the host cell membrane that is destined to become the viral envelope. In acquiring an envelope, the virus also may take with it some host cell-derived membrane proteins. These proteins may help disguise the virus from immune attack by making it appear similar to a host cell, at least on the outside. Even though this strategy has an obvious advantage to the virus, the drawback is that the envelope typically can be degraded in the external environment through desiccation and exposure to chemicals.

As we will see later in this chapter, the classification of viruses depends, to some extent, on these basic structural properties. Virologists used this type of information to begin identifying the infectious agent affecting golden lion tamarins (GLTs) that we discussed in the opening story of this chapter. Electron micrographs of thin liver sections isolated from GLTs that died of the mysterious agent revealed what appeared to be enveloped virus particles approximately 100 nm in diameter exiting the GLT hepatocytes, or liver cells. Furthermore, the envelopes contained very distinct spikes. Based on this simple piece of evidence, virologists began their quest to identify the infectious agent, which appeared to be a virus in the *Coronaviridae* (see Figure 5.25) or *Arenaviridae* family of viruses.

Replication cycle

To enter an appropriate host cell, most animal viruses bind to the cell. Usually, this binding occurs through a specific interaction between the viral **attachment protein**, a protein or proteins present on the surface of the virus that aid in binding to a



A. Influenza virus **B.** HIV

Figure 5.9. Electron micrographic identification of the viral envelope The envelope surrounds the nucleocapsids and contains viral proteins that extend from the envelope. Shown here are **A.** influenza virus and **B.** HIV.

host cell, and the **receptor**, a protein present on the surface of the host cell with which the attachment protein interacts. For enveloped viruses, the attachment protein generally resembles a spike embedded within the lipid bilayer envelope of the virion. For some non-enveloped viruses, like the adenoviruses, the attachment protein exists as a spike protruding from the vertices of the icosahedron (see Figure 5.7B). For other non-enveloped viruses, like poliovirus, the cellular receptor interacts with amino acid residues that exist in an indentation, or canyon, within the capsid.

CONNECTIONS If the virus binds to a host cell through a specific protein–protein interaction, then shouldn't changes in the host cell protein affect the cell's susceptibility to certain viruses? Yes. We will see how in **Section 8.1**.

Once a viral particle has attached to a host cell, some form of the virion, capsid, or viral genome enters the cytoplasm of the cell **(Figure 5.10)**. For non-enveloped animal viruses like rhinovirus, the entire viral particle enters the cell through a type of endocytosis referred to as receptor-mediated endocytosis (see Figure 5.10A). Following endocytosis, conformational changes in the capsid allow the viral genome to enter the cytoplasm.

For some enveloped viruses, entry into the cell is mediated by fusion of the viral envelope and the plasma membrane. To explore this strategy, let's examine HIV. Initially, this virus attaches to its primary receptor—the CD4 molecule. Subsequently, the virus interacts with a secondary receptor, or co-receptor, typically CCR5 or CXCR4. All are integral membrane proteins found primarily in certain cells of the human immune system. The interaction with the co-receptor triggers conformational changes in the viral proteins embedded within the viral envelope. Following these conformational changes, the viral envelope fuses with the plasma membrane, allowing the nucleocapsid to enter the cytoplasm (see Figure 5.10B). In Figure 8.6, we describe this process in more detail.

CONNECTIONS To a large extent, the ability of HIV to infect our cells depends on the presence of these receptor molecules. As we will see later, CD4 molecules can be found on various cells of the immune system, including macrophages **(Section 19.5)** and CD4+ T cells **(Section 20.2)**.

The envelope of influenza virus, on the other hand, fuses with an intracellular membrane (see Figure 5.10C). Again, the process begins with an interaction between the virus and a cell surface receptor. After binding, the virus is endocytosed. The acidic pH of this endosomal vesicle causes conformational changes in the viral proteins. Fusion between the viral envelope and the vesicle membrane then occurs. After entry, the viral capsid usually undergoes a specific set of disassembly, or uncoating, events in the cytoplasm that result in the release of the genome. More detail of this process is shown in Figure 8.5.

Plant viruses often enter cells through disruptions in the cuticle covering of the plant tissue. Farm machinery, grazing animals, or feeding insects, for example, can cause these disruptions. Once inside a cell, the viral capsid undergoes a disassembly process, thereby releasing its genome. The genome

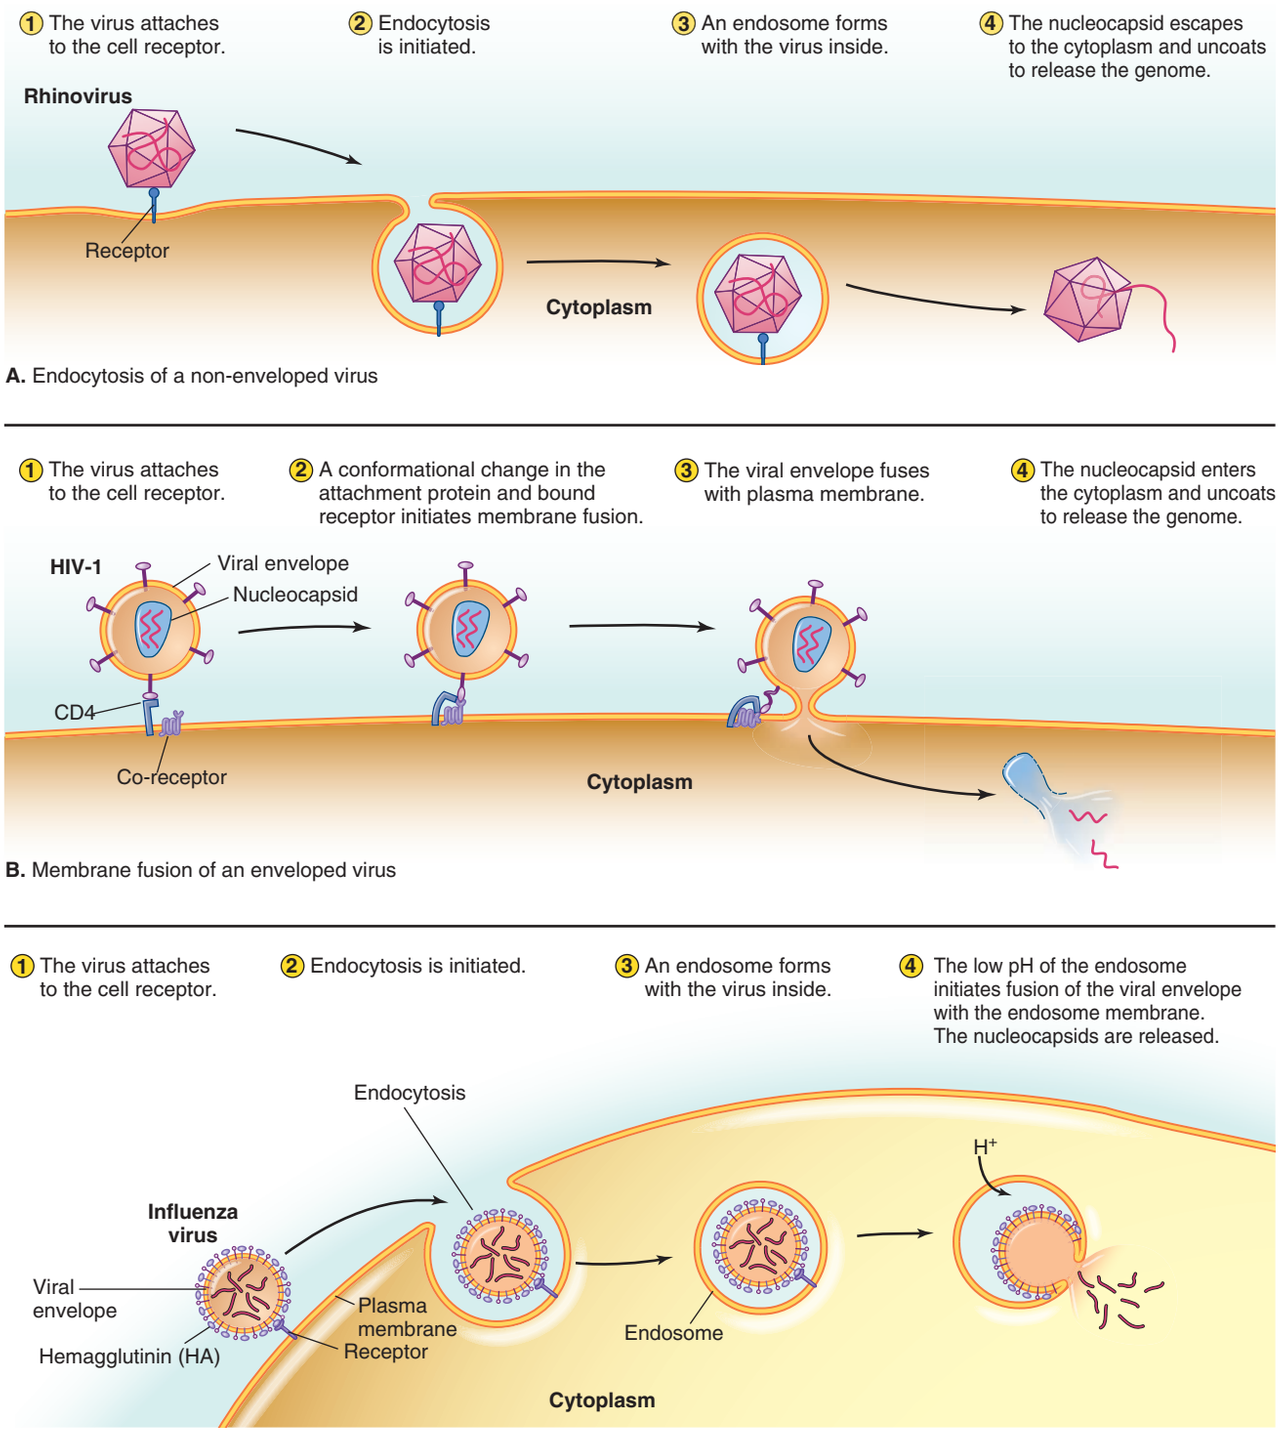


Figure 5.10. Process Diagram: Entry mechanisms of animal viruses Following attachment to a host cell, some part of the virion or viral genome must gain access to the cell. **A.** Non-enveloped viruses like rhinovirus often enter through endocytosis. **B.** Enveloped viruses like HIV undergo a membrane fusion event at the cell surface. **C.** Enveloped viruses like influenza first enter the cell via endocytosis. A fusion event between the viral envelope and vesicle membrane then occurs.

and newly formed virions can spread to other cells within the plant through the plasmodesmata, or small channels, that connect plant cells and serve as conduits for the transport of necessary materials. Unlike animal viruses, plant viruses do not recognize specific cellular receptors on their host cells. We will investigate some of the implications of this in later chapters.

Like animal viruses, bacteriophages interact with various components of the bacterial surface, including specific polysaccharide residues. For the phages T2 **(Microbes in Focus 5.1)** and T4, this initial contact occurs between the tail fibers and, most likely, specific sugar residues on the bacterial cell surface. After relatively stable binding has occurred, a conformational

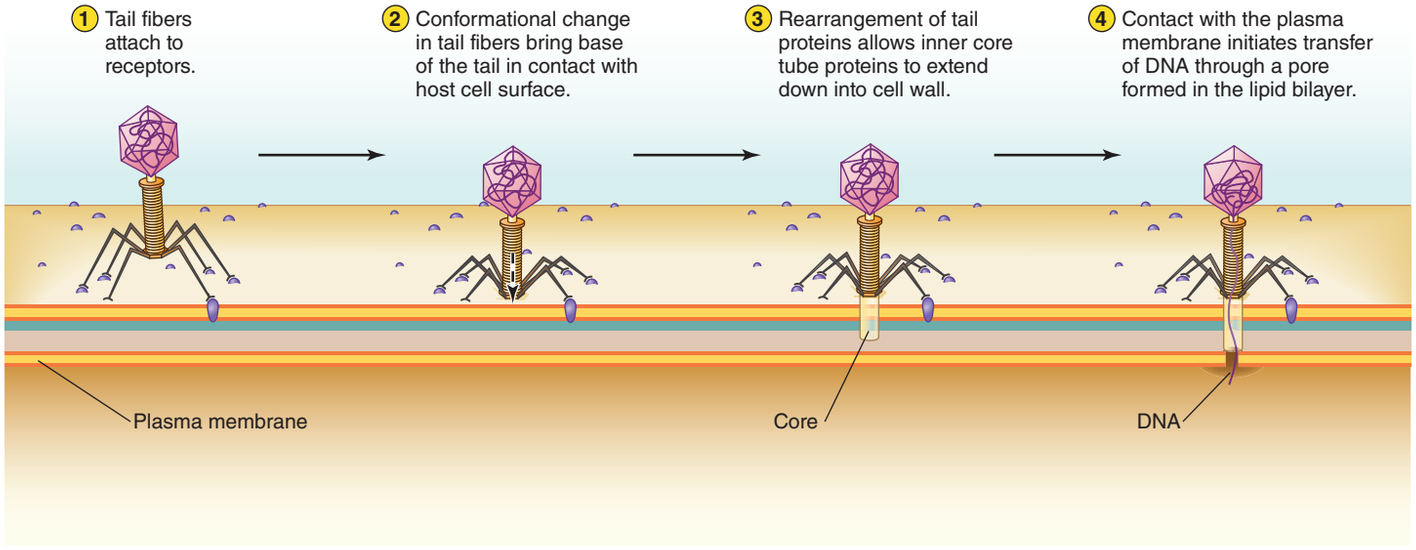

Figure 5.11. Process Diagram: Entry mechanisms of bacteriophages Following attachment to a host cell, a series of conformational changes occur in the protein units of the tail, allowing the DNA to move from the capsid head directly into the cytoplasm of the host cell. The virus particle does not actually enter the host cell.

change results in the contraction of the bacteriophage tail. With the action of specific enzymes, the phage core proteins penetrate the cell membrane, and the bacteriophage injects its genetic material into the host cell, much like a syringe injects its contents. Thus, the viral proteins remain outside the cell, never crossing the cell membrane **(Figure 5.11)**.

For all viruses, replication of the viral genome and production of viral proteins follows attachment and entry. These newly formed components then assemble to form new virus particles, which exit the infected cell **(Figure 5.12)**. This assembly process often is referred to as a sequential and irreversible

Microbes in Focus 5.1
THE MANY CONTRIBUTIONS OF BACTERIOPHAGE T2

Host: *Escherichia coli*

Description: Virus in the *Myoviridae* family with a double-stranded DNA genome approximately 160,000 bp long and a complex capsid with an icosahedral head, helical tail, and tail fibers involved in attachment. Entire capsid is approximately 200 nm in length.

Key Features: T2 played a major role in demonstrating that DNA is the hereditary material. In a classic experiment, Alfred Hershey and Martha Chase infected *E. coli* with T2. They showed that the protein coat of T2 remained outside of the infected cells, while the viral DNA was injected into the cell. Because the infected cell then began producing new viral particles, they concluded that DNA, and not protein, was the hereditary molecule. Today, T2 remains a valuable tool for molecular biologists.

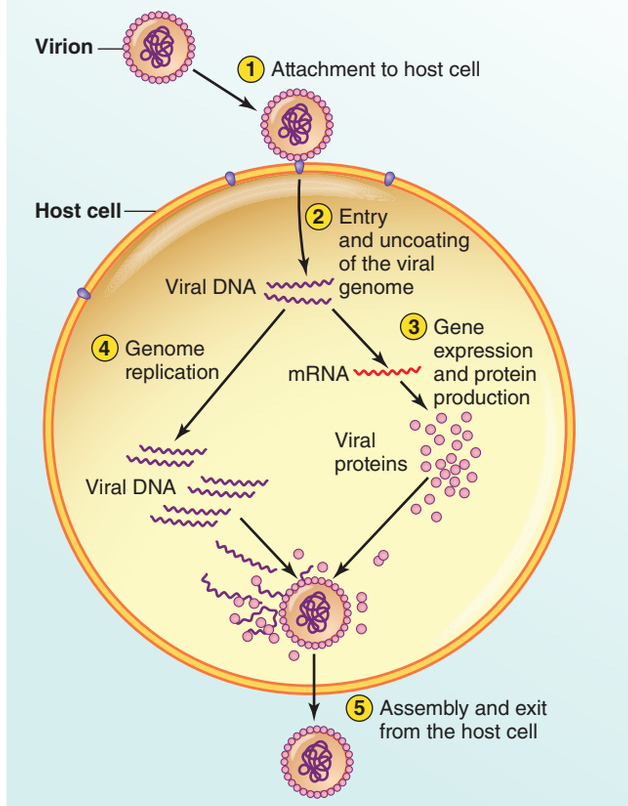

Figure 5.12. Process Diagram: General steps in a viral replication cycle Despite the many differences that exist in viral replication strategies, the underlying process is the same for all viruses. This schematic depicts the replication of a virus with a DNA genome.

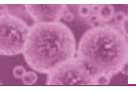
process. The assembly steps occur in an ordered fashion, and once completed, a step cannot be reversed. Recent studies with T4 bacteriophage, however, challenge this simple explanation of viral assembly and further our understanding of the relationship between capsid and genome size **(Mini-Paper)**.

Once new virus particles form, they must exit the cell. Some viruses exit by budding out of the infected cell. Other viruses exit by lysing, or rupturing, the infected cell. In this manner, a single infected cell may produce up to 10,000 new viral particles. These newly released viral particles may bind to another host cell within the organism or be shed from the organism and enter the environment.

Not surprisingly, viruses differ tremendously in their site of host entry, the location of appropriate host cells, and their site of exit. The types of disease associated with different pathogenic viruses also differ. Respiratory viruses, such as human influenza viruses, cause respiratory problems by damaging cells of the respiratory tract. These viruses exit a human host through coughing and sneezing and, if inhaled by another person, may begin a new infection. Enteric viruses, such as rotaviruses, cause intestinal problems by damaging cells of the GI tract. These viruses generally exit a host through fecal material and, if ingested by another person, may begin a new infection. HIV, a blood-borne virus, can be transmitted through bodily fluids such as blood and semen. It causes an immunodeficiency by destroying cells of the immune system.

5.1 Fact Check

1. What are some key properties of viruses?
2. Identify the different types of viral genomes.
3. Contrast the capsid structures of helical and icosahedral viruses.
4. What are the different ways in which viruses attach to host cells?
5. Compare the entry into host cells of enveloped and non-enveloped viruses.



5.2 Origins of viruses

From what did viruses arise?

How did viruses originate? The answer to this basic question remains unresolved. That said, our understanding of the structure of viruses and how viruses replicate allows us to make educated guesses about their origins. In Chapter 8, we will examine in more detail the replication strategies of specific viruses. For now, though, it is sufficient to remember that all viruses replicate within living host cells, using various resources of their host. Thus, the origin of viruses must be tightly interwoven with their host cells.

Given even this limited information about viruses, one still can formulate hypotheses about their origin.

- **Coevolution hypothesis**: Viruses may have originated prior to or at the same time as the primordial cell and have continued to coevolve with these hosts.
- **Regressive hypothesis**: Viruses may represent a form of "life" that has lost some of its essential features and has become dependent on a host.
- **Progressive hypothesis**: Viruses may have originated when genetic material in a cell gained functions that allowed the DNA or RNA to replicate and be transmitted in a semi-autonomous fashion.

Coevolution hypothesis

Perhaps viruses evolved along with their host cells or arose before the first cells. Many biologists agree that life arose billions of years ago when an RNA molecule with enzymatic activity first arose on Earth **(Perspective 5.1)**. At some point, this RNA molecule gave way to a DNA genome capable of directing the synthesis of proteins via an RNA intermediate. With the encapsulation of this DNA:RNA:protein system within a lipid envelope, the ancestor of the first cell arose. One can imagine that the first virus evolved along with the evolution of the first cell. A self-replicating RNA molecule may have evolved to make use of the protein-synthesizing machinery of the nascent cell.

Some researchers have speculated that primordial viruses gave rise to the eukaryal nucleus. According to proponents of this hypothesis, a large and complex DNA virus entered a bacterial or archaeal cell. Rather than replicating within the host, the virus became permanently established in a type of endosymbiotic event. The existence of a specific group of viruses, the nucleocytoplasmic large DNA viruses (NCLDVs), provides some support to this hypothesis. These viruses, which include herpesviruses, poxviruses, and the recently discovered Mimivirus (see Figure 5.4), exhibit a complex DNA genome and some genes associated with translation. Perhaps, the modern nucleus arose from NCLDV ancestors.

Regressive hypothesis

As an alternative to the coevolution hypothesis, one can hypothesize that viruses originated from fully functional cells that became parasites of other cells. Over time, these parasites gradually lost some of their replicating and metabolic capabilities, eventually becoming dependent on the host cells for their complete replication. Several examples of this type of regressive evolution exist within the biological world. As we discussed in Section 3.4, the endosymbiotic theory states that mitochondria and chloroplasts present in eukaryal cells originated when fully functional bacteria invaded or were engulfed

Perspective 5.1
RIBOZYMES: EVIDENCE FOR AN RNA-BASED WORLD

Until the 1980s, enzymes were thought to be solely the domain of proteins. After all, proteins can fold into complex three-dimensional shapes capable of forming a seemingly infinite array of active sites for catalytic activities. RNA, conversely, has only four possible subunits and thus lacks the chemical diversity of proteins. Still, RNA is not locked into a double-helical structure like double-stranded DNA and can fold into more elaborate shapes. When researchers realized in the late 1960s that single-stranded RNA could assume complex shapes, some molecular biologists began to speculate that RNA might be capable of enzymatic activity and thus represent an evolutionary link between genetic information and catalytic function.

In the 1980s, Tom Cech and colleagues at the University of Colorado showed that a purified ribosomal RNA molecule from the ciliated protozoan *Tetrahymena thermophila* can undergo a self-cleavage event, removing a segment of itself without the help of any proteins **(Figure B5.1)**. Simultaneously, Sidney Altman and colleagues at Yale were studying the enzyme RNase P that cuts transfer RNA, or tRNA, precursors, which are initially transcribed as part of a larger RNA molecule, into active tRNAs. RNase P is composed of protein and RNA components, but Altman's group showed that the RNA portion of the *Escherichia coli* enzyme can carry out cleavage on its own. Cech and Altman won the Nobel Prize in 1989 for their demonstration of RNA catalysis.

Since the last decade of the twentieth century, molecular biologists have discovered more catalytic roles for RNA. Non-coding sections of messenger RNA that must be removed by splicing prior to translation, are ubiquitous in eukaryal genes. These regions are removed by the spliceosome, a protein-RNA complex in which RNA components are critical for catalysis. Peptide bond formation during translation also relies on RNA catalysis. Scientists and biotechnology companies have jumped on the catalytic RNA bandwagon, because the activity of synthetic ribozymes can be targeted to specific nucleic acid sequences. One could envision creating an RNA molecule that cleaves a specific target, like the RNA genome of HIV or messenger RNAs from genes associated with cancer. None of these ideas have reached clinical application yet, but research in this exciting area continues.

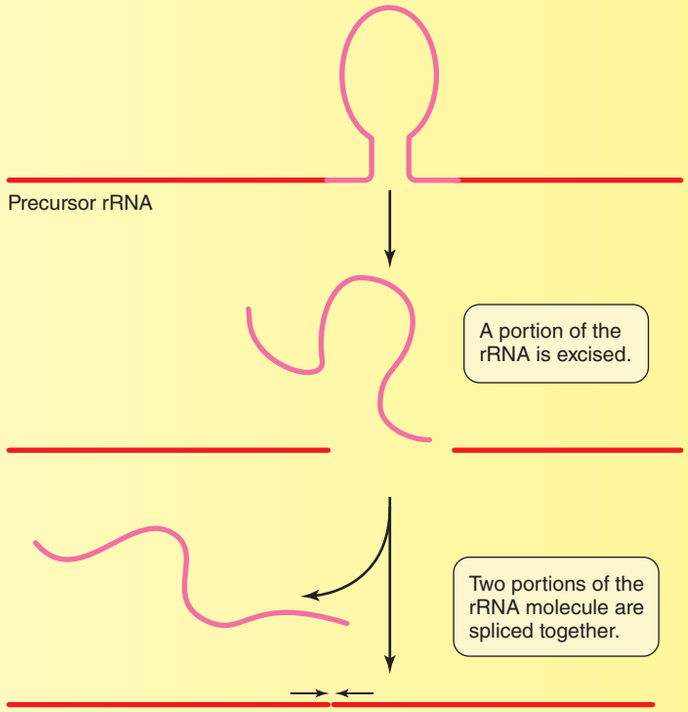


Figure B5.1. Self-splicing RNA molecules As demonstrated by Tom Cech, a ribosomal RNA molecule from the protozoan *Tetrahymena thermophila* undergoes cleavage without the aid of an enzymatic protein. The RNA molecule itself is catalytic. Several different forms of self-splicing have since been observed in various species. As shown in this schematic, two portions of a precursor RNA molecule are spliced together. The intervening sequence is excised and ultimately degraded.

by a developing eukaryal cell. Rather than being destroyed by the larger cell, though, the invading or engulfed cells became permanent residents. Initially, these cells may have remained fully autonomous within their host. Eventually, these engulfed cells lost some of their functions, thus becoming dependent on the host.

Chlamydia represent another interesting example of potential regressive evolution. These bacteria are very small, about the size of some large animal viruses. Like viruses, they are obligate intracellular parasites. Although chlamydia possess DNA, RNA, translational machinery, and some metabolic pathways, they can reproduce only within a host cell. It appears that members of this phylum, the *Chlamydiae*, lack key components of the electron transport chain and, as a result, cannot synthesize ATP. Rather, they depend on the host for energy. Most likely, these organisms evolved from a fully functional organism that, over time, lost some essential features. In some ways, chlamydia can be viewed as intermediates between fully independent cells and viruses. As with mitochondria and chloroplasts, though, the genomes of chlamydia are most definitely bacterial.

The existence of organelles like mitochondria and chloroplasts, and bacteria like chlamydia, provide some support for regressive evolution. Viruses, perhaps, are evolutionary descendents of life-forms that have lost most of their genetic code and now are non-living parasites, completely dependent on a host cell. Although some evidence supports this hypothesis, some discrepancies also exist. Most importantly, sequence analysis of viral genomes reveals that the genomes of animal viruses show great similarity to regions of their host genomes, and almost

no similarity to bacterial genomes. This finding stands in stark contrast to the evidence supporting the regressive evolution of mitochondria, chloroplasts, and chlamydia. The regressive evolution from a fully functional bacterium to a chlamydia-like bacterium to an animal virus thus seems unlikely.

CONNECTIONS To determine the relationships between bacteria and viruses that infect mammals, we need to compare their genomes. This burgeoning field of comparative genomics is explored in **Section 10.3**.

The regressive pathway may be responsible for the NCLDVs that we mentioned earlier. These viruses have a more complex genome than other viruses and possess some genes associated with translation. In fact, Mimivirus contains genes that may encode aminoacyl-tRNA synthetases and translation initiation factors, two key components of the translational machinery. Additionally, the genome of this giant virus contains other genes that show homology to eukaryal genes associated with DNA repair and protein folding. It seems plausible that this virus could have evolved from a previously free-living ancestor.

Progressive hypothesis

According to the progressive hypothesis of viral origins, viruses evolved from existing genetic elements that, over time, gained functions necessary to allow them to be transmitted between organisms and undergo some aspects of replication. Bacteriophages, for example, may have evolved from preexisting and autonomously replicating plasmids. If these plasmids acquired a gene coding for the production of a capsid protein, then a virus-like particle might form.

In a similar manner, retroviruses may have evolved from eukaryal **retrotransposons**, pieces of DNA capable of moving to new locations within a genome. For these mobile genetic elements to move within a genome, their DNA first is converted to RNA. This free-floating RNA then is converted back into DNA by a reverse transcriptase enzyme before being reinserted into the genome **(Figure 5.13)**. Retroviruses also undergo an RNA to DNA conversion, and the genetic organization of retroviruses resembles the genetic organization of retrotransposons.

CONNECTIONS As we will see in **Section 8.3**, the replication cycle of retroviruses is remarkably similar to the steps involved in the movement of retrotransposons. A key component of both processes—reverse transcriptase—is the target of several antiretroviral drugs.

What about DNA viruses? In a 2011 report, researchers from the University of British Columbia presented compelling evidence that some viruses with DNA genomes may be evolutionarily related to transposons, another class of mobile genetic elements (see Figure 9.30). The genome of Mavirus, a small virus associated with CroV, a giant virus first identified in 2010, exhibits significant similarity to the Maverick/Polinton class of transposons. Perhaps, this virus evolved from these transposable elements. Alternatively, the authors note, these transposable elements may have evolved from ancestors of this virus.

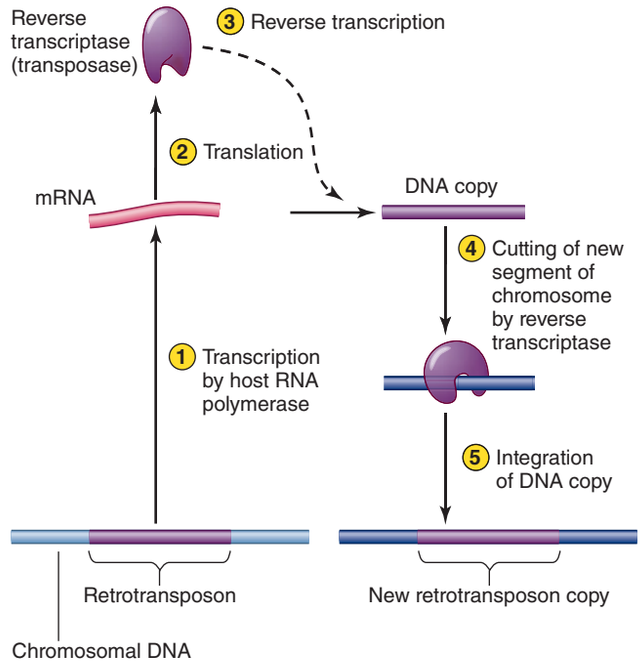

Figure 5.13. Process Diagram: Replication of retrotransposons Although the origin of viruses still is open for debate, the similarities between the replication of retroviruses and the replication of retrotransposons seem compelling. Retrotransposons copy and insert themselves within the genome via an RNA intermediate that is converted into DNA by reverse transcriptase—a mechanism very similar to that used by retroviruses like HIV, whose RNA genome is copied into DNA before replicating their RNA genomes.

Compelling evidence supports the coevolution, progressive, and regressive hypotheses of viral origins. No single hypothesis seems completely adequate. Perhaps viruses have originated repeatedly over the four-billion-year history of life on Earth. All three hypotheses about the origin of viruses may be correct. Maybe other, more compelling hypotheses about the origin of viruses are yet to be formulated.

5.2 Fact Check

1. Discuss the various hypotheses regarding the evolutionary origins of viruses.
2. What evidence does *not* support the regressive evolution of viruses?
3. Under the progressive hypothesis, describe how bacteriophages and animal viruses may have evolved.
4. Differentiate between transposons and retrotransposons.

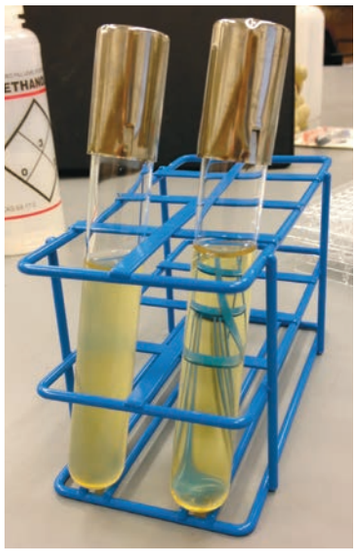
5.3 Cultivation, purification, and quantification of viruses

How can we "grow" and quantify viruses?

Several hallmark features of viruses make working with these particles somewhat difficult. As we discussed previously, viruses only replicate within appropriate host cells. Therefore, the cultivation of viruses requires the availability of these cells. Additionally, the small size of viruses affects our ability to purify and count them. In this section, we will examine some of the techniques used by virologists to cultivate, purify, and quantify viruses. We also will examine the development of cell culture techniques—a major advancement in the field of virology—and the clinical importance of viral quantification.

Viral cultivation

As mentioned previously, viruses only can replicate within appropriate host cells. To cultivate viruses, a researcher must inoculate appropriate cells with the virus and then harvest the resulting progeny viruses. For bacteriophages, cultivation can be achieved by inoculating a liquid culture of actively growing bacteria with a small amount of phage. Upon continued incubation, the phage will replicate in the host cells, eventually lysing, or destroying, the infected cells. When the host cells lyse, the newly produced phage particles are released and can infect other bacterial cells. As more and more bacterial cells in the culture are destroyed, the liquid in the flask containing the bacteria and phage turns from turbid to clear, indicating a decrease in the number of intact bacterial cells (Figure 5.14). After a period of incubation, the solution can be filtered to remove any remaining intact bacteria and relatively large cellular debris. The resulting cell-free filtrate will contain the amplified phage.



© Courtesy David Wessner

Figure 5.14. Cultivation of bacteriophage A small sample of phage can be used to inoculate a tube of actively growing bacteria. As the phage replicates and lyses the bacterial cells, the growth medium may turn from turbid to clear, indicating that intact bacterial cells are being disrupted and scattering less light. After incubation, the medium is centrifuged and the resulting supernatant is filtered through a 0.2-μm filter. This will prevent the passage of bacteria, but allow the passage of bacteriophage. The resulting filtrate is an amplified, cell-free sample of phage.

CONNECTIONS Bacteriophages exhibit various replication strategies. As we will investigate in **Section 8.3**, some bacteriophages always replicate in and lyse infected host cells. For other bacteriophages, the virus can replicate in and lyse the host cell or the viral genome can exist within the host cell without replicating.

Since the advent of mammalian cell culture techniques (Toolbox 5.1), the propagation of many animal viruses has become almost as simple as the propagation of bacteriophages. Typically, virologists add a small amount of virus to appropriate host cells growing in a flask. As each virion infects a cell and replicates, new virions are released from the infected cell into the medium and infect other cells. The replication of many different animal viruses, like poliovirus (Microbes in Focus 5.2), can cause **cytopathic effects (CPE)**, visible changes in cellular morphology often associated with cell damage or death. These morphological changes may involve the rounding and

Microbes in Focus 5.2
POLIOVIRUS AND THE RACE FOR A VACCINE

Host: Humans

Description: Virus in the *Picornaviridae* family with a single-stranded RNA genome of about 7,500 nucleotides that resides within a non-enveloped, icosahedral capsid approximately 27 nm in diameter

Key Features: Poliovirus, the causative agent of poliomyelitis, was a major health concern in the United States throughout the first half of the twentieth century. With the development of the Sabin and Salk vaccines, the number of reported cases of poliomyelitis in the nation dropped from 58,000 in 1952 to 161 in 1961. In 1994, the Americas were declared free of poliovirus. Only 359 cases were reported globally in 2014.

Toolbox 5.1
CELL CULTURE TECHNIQUES

Because viruses only can replicate within living host cells, virologists are presented with an interesting problem; before researchers can effectively study viruses in the laboratory, they must be able to grow appropriate host cells. Prior to the development of mammalian cell culture methodologies, the propagation of animal viruses occurred via serial passage of the virus in animals. A susceptible animal would be inoculated with a small sample of the virus of interest. At a later time, perhaps when the infected animal became sick, virus would be isolated from this animal and a second susceptible animal would be inoculated, thereby allowing the virus to continue replicating. Clearly, this method of viral propagation was not terribly practical; it required the researcher to maintain appropriate animal hosts. As you can imagine, this requirement greatly reduced the study of viruses that infect humans!

During the 1940s and 1950s, this difficulty was overcome with the development of cell culture techniques. In 1949, John Enders, Thomas Weller, and Frederick Robbins demonstrated that poliovirus could replicate in various embryonic tissues. This discovery directly led to the development of the poliovirus vaccine a few years later and earned the three researchers the Nobel Prize in Physiology or Medicine in 1954. George Gey and colleagues cultured the first human cell line in 1952. This cell line, derived from a human cervical carcinoma, was named HeLa, in recognition of Henrietta Lacks, the young woman from whom the cells were isolated. She died of cervical carcinoma in 1951. The HeLa cell line still is widely used by researchers throughout the world, and this contribution of Henrietta Lacks to modern biomedical research is immeasurable. A final important contribution to the budding field of virology came in 1955 when Harry Eagle and colleagues developed a well-characterized nutrient medium that could be used for the maintenance of cells in the laboratory. With the availability of defined growth media and several different cell lines, researchers could propagate animal viruses easily and conduct controlled experiments. Thus, the history of animal virology is inextricably linked to the development of *in vitro* cell culture methodologies.

Today, researchers can use many different types of cultured cells. Mammalian cells typically are incubated at 37°C (normal human body temperature) in an atmosphere containing 5 percent CO_2 (to mimic blood gas levels and maintain an appropriate pH). Once attached to a substrate, the cells will begin to divide. These cells will continue to divide until they completely cover the substrate, or become confluent, at which point most animal cells cease to divide (see Figure 5.15A). For the cells to continue growing, their density needs to be decreased. The growth medium is removed, and trypsin, a protease, usually is added to the cells to dislodge them from the surface. These dislodged cells are diluted in fresh medium and plated, at a lower density, in new cell culture dishes, thereby allowing the cells to continue replicating **(Figure B5.2)**.

Most animal cells can be grown in this fashion, but only for a limited number of rounds of replication, at which point the cells will begin to die. In some cases, though, a few cells within the culture will become immortalized. These cells have undergone genetic changes that allow them to grow indefinitely. At this point, the cells are referred to as a cell line or a continuous cell line. Although these cells can be maintained in the laboratory indefinitely, they do differ significantly from "normal" cells. Immortalized cells often are aneuploid, that is, they possess an incorrect chromosomal complement. For example, HeLa cells usually possess 82 chromosomes, rather than the 46 chromosomes normally found in human cells. These cells also often exhibit other aberrant properties. Thus, although cell lines allow researchers to conduct exquisitely detailed biochemical and genetic experiments, one could argue that the results obtained with cell lines may differ from that which occurs *in vivo*.

Figure 5.15. Cytopathic effects (CPE) in virally infected cells When removed from a living tissue and placed in a flask with well-defined nutrient medium, animal cells can grow rapidly and may form a layer attached to the substrate. **A.** A layer of healthy uninfected cells grown in cell culture showing a uniform, elongated form. The nuclei are stained blue. **B.** Cells infected with virus show fused cells called syncytia (*middle*) containing numerous nuclei.

detachment of the infected cells or the fusion of individual, infected cells into a large, multinucleated mass known as a **syncytium** (Figure 5.15). Researchers often use this CPE as a marker of the extent of viral replication. After a sufficient period of incubation, the medium, containing the released virions, can be harvested.

Techniques similar to those used to propagate viruses can be used to generate clonal populations of viruses. For bacteriophages, the phage is mixed with molten agar, and this mixture then is added to host bacteria growing on a nutrient agar plate. For animal viruses, the virus is added to appropriate host cells growing in a small dish, and a nutrient agar is layered on top of the infected cells. In both cases, the viruses replicate within the host cells. However, as progeny viruses exit an infected cell they are spatially constrained by the agar and can infect only adjoining cells. As a result, a localized area of cell death, called a **plaque**, forms (Figure 5.16).

Each plaque potentially contains thousands of viral particles. Because only a small number of virus particles initially were used to infect the cells, one can assume that each plaque arose from a single virion. Thus, each plaque contains a clonal population of virus. These clonal viruses can be easily isolated. A researcher can use a pipette to extract the plug of agar over a plaque, which contains many viral particles. The particles then can be isolated, providing the researcher with a clonal population of virions.

Viral purification

For many experimental protocols, it may be necessary to obtain purified preparations of a virus. Of course, different levels of purification can be achieved depending on the experimental needs. Most purification strategies make use of the small size of viruses. For simple and relatively crude purifications, a viral suspension can be centrifuged and then filtered through a very small pore filter.

Virologists working with the National Zoo used this very simple technique initially to determine that a virus caused the acute hepatitis affecting the golden lion tamarins (GLTs). They disrupted liver sections from affected GLTs and filtered this cell suspension through a 0.2-μm filter. They then inoculated common marmosets, a species closely related to GLTs, and various cell lines with this bacteria-free filtrate. The marmosets developed an acute hepatitis. Additionally, marmoset and monkey cell lines produced noticeable virus particles when inoculated with this filtrate (Figure 5.17). Thus, the researchers concluded that the infectious agent was a virus.

Filtration, as you can see, may separate the virions from eukaryal cells, large cellular debris, and bacteria, but does not concentrate the virions. The concentration of viruses generally requires some form of ultracentrifugation. In ultracentrifugation, centrifugal forces of up to one million times the force of gravity can be generated. These extreme forces cause particles even as small as viruses to move through the liquid, toward the bottom of the centrifuge tube. In a process known as **differential centrifugation**, virologists subject medium containing virions and cells to centrifugation at a relatively low speed, causing intact cells and large cellular debris to pellet, or collect at the bottom of the tube (Figure 5.18). The supernatant can be harvested and subjected to ultracentrifugation, causing the virions to pellet. Once virions have formed a pellet in the tube, the supernatant can be removed from the tube and the particles can be resuspended in a smaller volume of liquid, thereby resulting in a purified and much more concentrated viral solution.

Viruses also can be purified based on their size and density. In **gradient centrifugation**, medium containing virus particles is added to a centrifuge tube containing a linear gradient of a salt or sugar solution (often sucrose) and subjected to ultracentrifugation. Particles present in the sample will travel through the gradient until they reach a point where the density of the

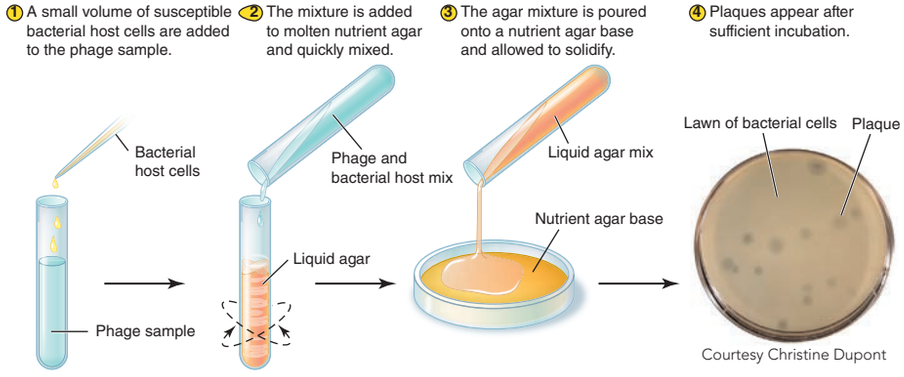

Figure 5.16. Process Diagram: Producing a viral clone Susceptible bacterial cells are mixed with a phage sample. After the phage have attached to the cells, a molten nutrient agar is added to the cells. This mixture then is poured onto a plate containing a nutrient agar base and allowed to harden. The plates are incubated, permitting viruses to replicate and infect neighboring cells. The layer of agar inhibits the free movement of released progeny viruses during incubation. Each virus that infected a cell produces a distinctive visible plaque of dead cells. Each discrete plaque contains the progeny of a single virus and thus is a clone. Such clones are essential to doing viral genetics.

Figure 5.17. Virus-like particles produced in cells inoculated with a bacteria-free liver extract Liver from an infected common marmoset, a species closely related to the golden lion tamarin, was homogenized and filtered through a 0.2-μm filter. Cells then were inoculated with this bacteria-free filtrate. Electron micrographs show virus particles associated with inoculated marmoset hepatocytes.

gradient solvent impedes their downward movement. Even particles of very similar sizes and densities can be effectively separated with this technique. After a period of centrifugation, the tubes can be examined and the band of virions identified within the gradient **(Figure 5.19)**.

Viral quantification

Often, it is useful to know how much virus a specific sample contains. It is necessary for a researcher to know the viral **titer**, or concentration of a virus preparation, in order to accurately plan experiments. If a researcher wishes to repeat a given experiment, then he or she must know how much virus was used initially and be able to accurately measure the same amount of virus when repeating the protocol. For the clinician, knowing the amount of virus present in an infected person may affect the treatment options. When treating people with HIV, for example, clinicians routinely monitor the viral load, or amount of virus in the blood of the infected person **(Perspective 5.2)**. The viral load, it turns out, presents a fairly good indicator of the overall health of the individual.

At first glance, one might think that viral quantification should be very straightforward: simply count the number of viral particles in a given solution. Of course, nothing ever is as simple as it first seems. Let's start by examining a few basic questions. First, how can we "see" viruses to count them? Second, are all viral particles infectious? In other words, if some viral particles do not infect anything, then should they be included in the count? Third, what do we mean by "infectious"? Should we only count viral particles capable of causing an infection in a human being? How could we possibly conduct such a count? As you can see, viral quantification is not that simple. In this section, we will explore some of the various techniques used to determine viral titers.

Direct Count

To determine the absolute number of total viral particles in a sample, a direct counting method can be used. In one procedure, a known quantity of microscopic markers, such as small latex beads, first is added to a sample of the purified virus being tested. This mixture then is placed onto a grid and viewed with an electron microscope (EM). When the sample is viewed, the

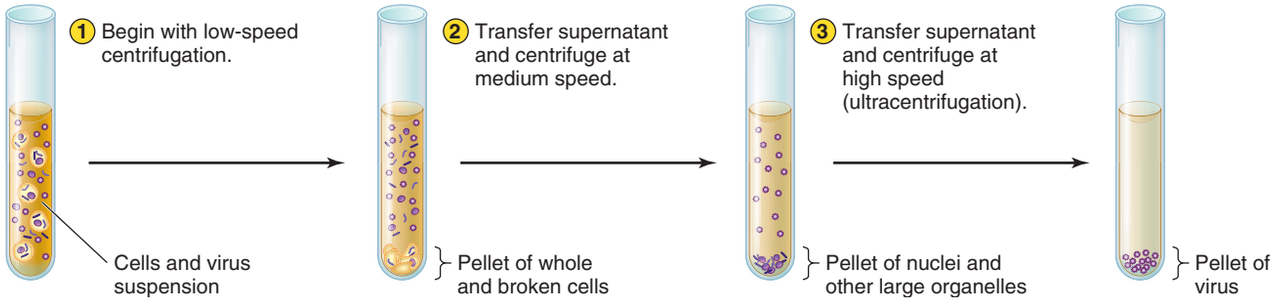

Figure 5.18. Process Diagram: Differential centrifugation to separate particles based on mass A low-speed centrifugation results in the pelleting of large objects, including whole and damaged cells. The supernatant above the pellet can be recentrifuged at a higher spin, resulting in the pelleting of smaller objects, such as cell organelles. With even higher centrifugation rates, researchers can pellet objects as small as viruses. Separated from other cellular components, this purified preparation of a virus can be used for experiments.

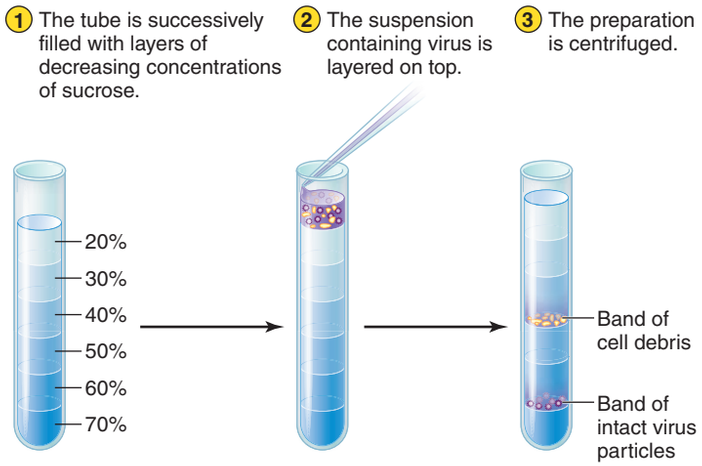

Figure 5.19. Process Diagram: Gradient centrifugation to separate particles based on density A density gradient consisting of sucrose concentrations varying from 20 to 70 percent is formed in a centrifuge tube. The sample is layered on top of this gradient. During centrifugation, the gradient is maintained, but suspended particles will move down the gradient until they encounter a sucrose concentration (density) that is equivalent to their particle density. Particles of different densities form distinct bands at different locations in the tube. The band of particles then can be removed from the centrifugation tube. In this way, a purified preparation of particles is obtained for further investigations.

viral particles and beads are counted. By determining the number of beads on the grid, one can determine the exact volume of the sample applied to the grid and, by extension, the viral concentration. Alternatively, fluorescent microscopy or flow cytometry can be used. In both of these approaches, viruses are stained, usually with a nucleic acid-specific fluorescent dye, and then visualized.

Although direct viral counts seem very straightforward, this method has two major drawbacks. First, it requires the use of a very expensive microscope. Second, it does not allow the researcher to differentiate between infectious and non-infectious viral particles—all particles get counted. However, after a direct count is made initially, it may be possible to estimate the number of viral particles in similar samples using simpler biochemical or spectrophotometric assays. For instance, after doing a direct count of a sample of purified virus, a researcher could measure the absorbance at a particular wavelength of the same sample. Potentially, one could determine a conversion factor that converts the absorbance reading to a direct count value. In the future, then, one simply could measure the absorbance of samples prepared in the same manner and use this information to calculate the virion concentration.

Hemagglutination Assay

Many viruses bind to the surface of erythrocytes, or red blood cells (RBCs), and cause the RBCs to clump together through a process referred to as **hemagglutination**. When a sufficient number of viral particles combine with a specific amount of RBCs, the virus:RBC interactions result in the agglutination, or binding together, of the red blood cells. This hemagglutination event can be seen with the naked eye. In contrast, if too few viral particles are added to the RBCs, then hemagglutination does not occur. Thus, by adding serial dilutions of a viral preparation to constant numbers of RBCs, a researcher can determine the hemagglutination titer of the viral preparation—the maximum dilution of the viral preparation that still results in complete hemagglutination **(Figure 5.20)**.

Again, this technique generally does not allow one to differentiate infectious and non-infectious particles. Additionally, a hemagglutination titer does not accurately reflect the total number of viral particles present in a sample; many viral

Perspective 5.2
MEASUREMENT OF HIV VIRAL LOAD

Determining the amount of virus in a patient, or the viral load, can be very important to the clinician. Today, infectious disease specialists routinely monitor the viral load of people infected with HIV. For the clinician, this information can be vital in determining the best course of treatment.

The human immunodeficiency virus, or HIV, is a retrovirus. Viruses in this family possess several defining characteristics, and their replication will be discussed in more detail in Section 8.3. For now, it is important to know that HIV contains an RNA genome and can be found in the blood of an infected person. To determine the amount of virus present in the bloodstream, researchers use a technique referred to as reverse transcriptase polymerase chain reaction, or RT-PCR (see Toolbox 5.2). Basically, a sample, usually plasma from an infected person, is obtained and treated to disrupt any viral particles, thereby releasing the viral RNA. The enzyme reverse transcriptase is used to convert the HIV RNA into DNA. The viral DNA then is amplified, and the amount of the resulting PCR product is quantified. Usually, the results are presented as copies of HIV RNA per milliliter of blood. Currently, available tests can detect fewer than 50 copies per milliliter (cpm). It follows that these tests have their limits. A person infected with HIV may have undetectable levels of the virus in his or her blood. This result does not mean that the person contains no HIV. Rather, it means that the person contains lower levels of the virus than can be detected.

For someone living with HIV, a low viral load generally correlates with improved health. Additionally, a low viral load reduces the risk of transmitting the virus. In a remarkable study published in 2011, researchers showed that HIV^+ individuals receiving effective treatment and, as a result, having a low viral load, were 96 percent less likely to transmit the virus than someone who was not receiving effective treatment. This finding has led to the current idea that we can think of treatment as prevention.

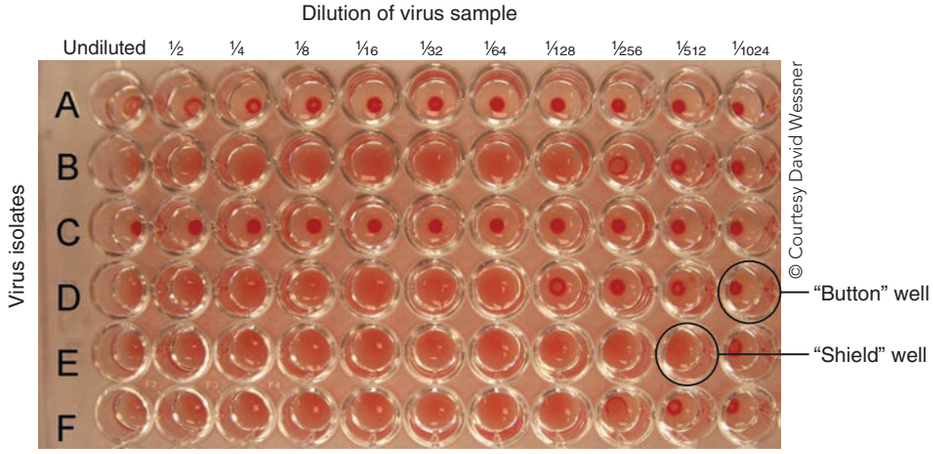

Figure 5.20. Using viral hemagglutination to determine a viral titer Serial dilutions of the virus are mixed with a constant amount of red blood cells (RBCs) and added to wells of an assay plate. When high numbers of viral particles are present, the virions bind to the RBCs and form a diffuse mesh, or shield. When fewer viral particles are present, the RBCs settle to the very bottom of the well, forming a button. In this figure, each row contains serial twofold dilutions of reovirus isolates added to wells containing bovine RBCs. The isolate in row B has an HA titer of 128 (greatest dilution still capable of forming a shield). A titer cannot be determined for the isolate in row C.

particles usually need to be attached to each RBC to result in agglutination. Finally, for some viruses, hemagglutination may occur in the absence of intact viral particles because specific viral proteins alone may foster this clumping of RBCs. Despite these drawbacks, the hemagglutination assay is a simple and affordable assay that can provide useful information about virus concentration, especially when comparing titers between samples.

Plaque Assay

In most instances, it is more useful to determine the titer of infectious viral particles, rather than the total number of infectious and non-infectious particles. The plaque assay commonly is used to determine the infectious titer. As discussed previously, a virologist can inoculate a series of dishes containing appropriate host cells with serial dilutions of the virus and then add a nutrient agar, or gel-like medium, to the cells to constrain the movement of progeny viruses. As a result, newly formed viruses can infect only neighboring cells, and discrete areas of dead cells, or plaques, form. By counting the plaques, the virologist can determine the plaque-forming unit (PFU) titer of the original viral suspension **(Figure 5.21)**. This simple technique provides a good measurement of the infectious viruses. Of course, it does depend on the ability of the virus being studied to lyse available host cells.

A similar type of assay can be used to determine the infectious titer of plant viruses. Briefly, serial dilutions of a viral suspension are applied to previously scarified, or scratched, leaves. The scarification serves to break the cell walls, thereby allowing the viruses to enter the leaf cells. After a sufficient

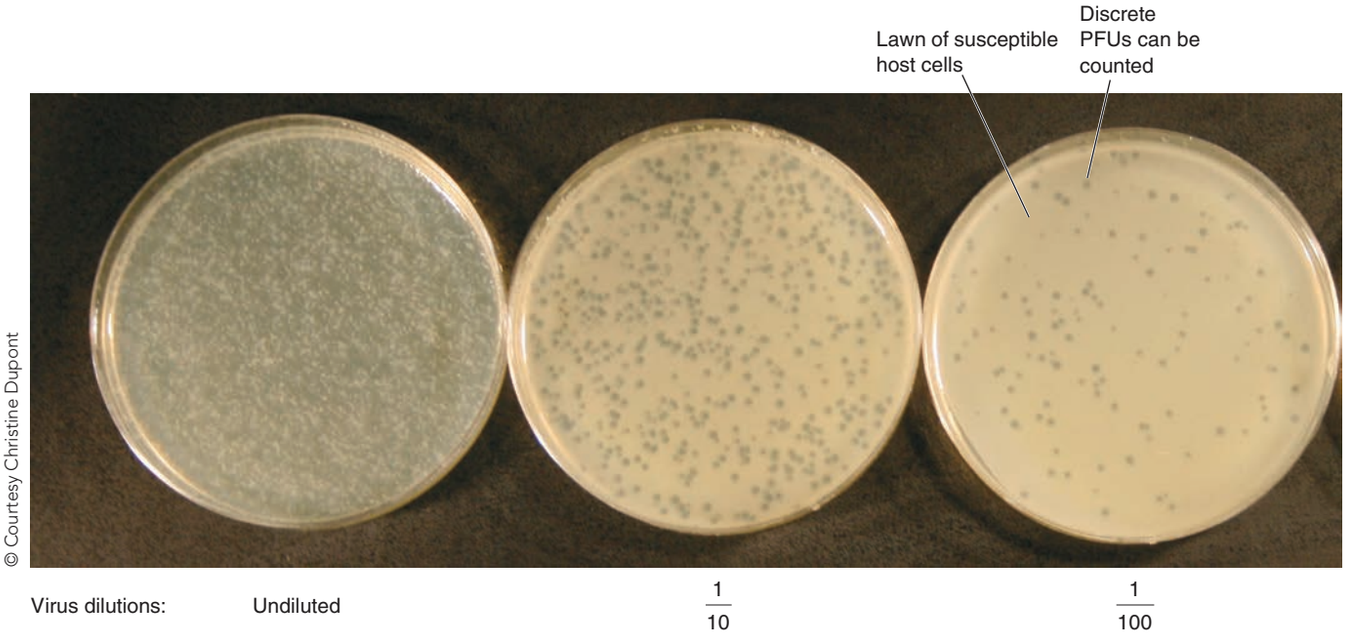

Figure 5.21. Plaque assay to determine viral titer By plating serial dilutions of a virus on susceptible host cells, one can determine the number of plaque-forming units (PFUs) in the original stock. In this assay, tenfold serial dilutions of a virus stock were added to each plate. As you can see, approximately tenfold fewer plaques are observed when the virus is diluted tenfold.

© Nigel Cattlin/Science Source Images

Figure 5.22. Using viral lesions on a leaf to determine the titer of plant virus The plant leaf shows distinct lesions caused by ringspot virus. If a plant leaf is experimentally inoculated with virus, then these areas of localized cell death, analogous to plaques that form in a standard plaque assay, can be counted, thereby allowing one to determine the infectious titer of the virus.

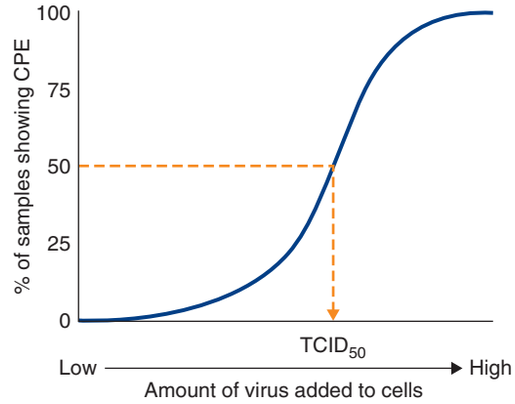

Figure 5.23. Endpoint assays determine tissue culture infectious dose 50 ($TCID_{50}$) In an endpoint assay, the effects of various dilutions of the virus are assayed for a specific outcome, such as cytopathic effects (CPE). To determine the tissue culture infectious dose 50 ($TCID_{50}$), for example, dilutions of virus are used to infect cells growing in culture. The cells then are monitored for CPE. By analyzing the data, one can determine how much virus is needed to cause CPE 50 percent of the time.

period of incubation, the numbers of lesions present on the leaves are counted. If one assumes that each lesion arose initially from the infection of a single cell by a single virion, then the number of lesions can be used to determine the concentration of the infectious viral particles **(Figure 5.22)**.

A plaque assay of a particular viral sample may provide a titer that differs dramatically from a direct count of the same sample. For some viruses, the direct count may yield a value for the number of viral particles that is 100 or 1,000 times greater than the PFU titer. How can we interpret this apparent discrepancy? Let's look at what each assay actually measures. In a direct count, every particle that looks like a virus is counted. In a plaque assay, every virus that results in the death of host cells is counted. In other words, the direct count measures the total number of viral particles, although the plaque assay measures the number of *infectious* particles. So, let's reevaluate our apparent contradiction: if the direct count exceeds the PFU titer by a factor of 100, then we can assume that only one out of every 100 viral particles actually is infectious. For some reason, the other 99 particles are unable to infect cells. These defective viral particles may have been assembled incorrectly, are missing part of their genome, or contain mutations that preclude further replication. As we will see in Chapter 8, viruses, especially RNA viruses, have very high mutation rates, allowing them to evolve at a rapid pace. A large number of defective particles may be the price that viruses pay for this genomic plasticity.

Endpoint Assays

In some instances, viruses do not form plaques in cultured cells and do not agglutinate red blood cells, but do have some observable effect on inoculated cells or animals. These viruses may be quantified by an endpoint assay. Serial dilutions of the virus are examined for their ability to cause the observable effect. A statistical analysis of the data then is used to estimate the amount of virus needed to cause the desired effect 50 percent of the time.

For instance, if a virus can cause the death of a certain type of animal, then it would be possible to determine the amount of virus that kills 50 percent of infected animals, the **lethal dose 50 (LD_{50})** of that virus. Again, serial dilutions of the virus are made. Susceptible animals are inoculated with each of the viral dilutions, the animals are monitored, and the number of animals that died after receiving each dose of virus is recorded. Presumably, high amounts of virus would result in high numbers of deaths, whereas low amounts of virus would result in few deaths. Although this measurement may provide very valuable information about the virus being studied, it also requires the use of a large number of appropriate host animals. Because of concerns about the use of animals in the laboratory, this assay is not typically used. Alternatively, one can determine the **tissue culture infectious dose 50 ($TCID_{50}$)** of a virus. Serial dilutions of the virus would be used to inoculate cells, and these cells then would be observed for cytopathic effects. Statistical analysis would be used to determine the amount of virus typically required to produce an infection 50 percent of the time **(Figure 5.23)**.

5.3 Fact Check

1. Describe how bacteriophages are cultivated in the lab.
2. How are animal viruses cultivated and harvested?
3. What is meant by the term "cytopathic effect"?
4. Explain how filtration and centrifugation can be used to purify viruses.
5. What techniques can be used to quantify viruses?
6. Differentiate between LD_{50} and $TCID_{50}$.

5.4 Diversity of viruses

What are the different types of viruses?

As we discuss in Appendix C, viruses, like bacteria, archaea, and eukarya, are formally classified in a hierarchical system. However, the classification of viruses is problematic. First, the evolutionary history and relatedness of viruses still is poorly understood. Second, no single genetic yardstick, comparable to the ribosomal RNA sequences of bacteria, archaea, and eukarya, exists for establishing relationships between viruses of mammals or between the viruses of mammals and the viruses of plants, insects, eukaryal microorganisms, bacteria, or archaea. No single gene exists in all viruses. Despite these obstacles, it still is useful, perhaps even necessary, for virologists to categorize viruses in some meaningful way. To explore this important topic of viral classification more thoroughly, we will examine how viruses are named and how viruses are classified.

Virus names

Historically, viruses have been named in a variety of ways. Many bacteriophages, such as T2 and λ, have been named with a combination of Roman or Greek letters and numbers. Some mammalian viruses have been named after specific locations, usually related to where the viruses were first isolated. The Ebola virus, for example, was named after the Ebola River in Zaire (now the Democratic Republic of Congo) **(Figure 5.24)**. Other mammalian viruses, such as hepatitis A virus, have been named after the disease they cause. Most plant viruses, such as tobacco mosaic virus (see Figure 1.9D), have been named after the appearance of the infected plant. The names of other viruses are based on the shape of the virus. Coronaviruses, for instance, have characteristic crown-like or corona projections on their envelope **(Figure 5.25)**. In some cases, the names convey useful information about the virus. In other cases, the names reveal an interesting, though not particularly important, factoid. In still other cases, the names are just names **(Table 5.2)**.

For biologists, though, names ideally should reflect the relatedness of organisms. For example, we know that all organisms within the genus *Drosophila* are fruit flies. Similarly, the virus that causes herpes cold sores has the species name *Human herpesvirus* 1 and is a member of the genus *Simplexvirus* and the family *Herpesviridae*. For simplicity, we will use primarily the family name and the species name when referring to viruses in this chapter.

Virus classification

Although a name may be nothing more than a name, a systematic means of classifying entities is very important to biologists. Again, viruses historically have been classified in a variety of ways. In some cases, the mode of spread of a virus (by insect, for example) has played a role in classification. In other cases, the disease caused by a virus (hepatitis, for example) has played a role in classification. These types of classification strategies may have some merit. For the clinician, it may be very logical to group together all the viruses that cause hepatitis, or damage to the liver. Ultimately, such a classification strategy does not have much scientific usefulness. Hepatitis A virus, hepatitis B virus, and hepatitis C virus, for example, share very few attributes other than causing hepatitis.

Figure 5.25. Crown-like or "corona" appearance of coronaviruses The viral attachment proteins, or spikes, extending from the surface of coronaviruses give them a crown-like appearance.

TABLE 5.2 Many different strategies are used to name viruses

Strategy	Example	Notes
Location	Ebola virus	The first recognized outbreak of Ebola occurred in Zaire (now the Democratic Republic of Congo), near the Ebola River. Most subsequent outbreaks have occurred in central Africa.
	West Nile virus	Initially isolated from a person living near the Nile River in Uganda, this virus first appeared in the United States in 1999 and now is firmly established in North America.
Disease	Tobacco mosaic virus	Plants infected with TMV show a distinct discoloration, or mosaic pattern. The disease was first described in the 1880s and still causes significant crop losses today.
	Hepatitis A virus	A number of viruses, including hepatitis A virus, hepatitis B virus, and hepatitis C virus, have been identified. These viruses all cause damage to cells of the liver but differ significantly from each other.
Physical characteristic	*Coronaviridae*	Viruses in this family have projections on their surface that give them a crown-like or corona appearance.
	Picornaviridae	These viruses all have very small, or pico, RNA genomes.

The ICTV Classification Scheme

In 1971, the International Committee on Taxonomy of Viruses (ICTV), a committee of the International Union of Microbiological Societies, developed an official, comprehensive classification system for viruses (see Appendix C). However, it should be noted that the concept of species is poorly defined for viruses. Certainly, the standard definition of a species as a group of interbreeding individuals does not apply to viruses or, for that matter, bacteria or archaea. Instead, the ICTV defines a viral species as a group whose members share several properties and occupy a common ecological niche. More specifically, attributes considered by the ICTV include:

- Virion morphology
  - Size
  - Capsid symmetry
  - Presence or absence of an envelope
- Genome structure
  - Double-stranded DNA
  - Single-stranded DNA
  - Double-stranded RNA
  - Single-stranded RNA
- Biological features
  - Replication strategy
  - Host range
  - Pathogenicity

The Baltimore Classification Scheme

Although the ICTV system represents the official viral taxonomy, many virologists categorize viruses based on a classification scheme developed primarily by Nobel laureate David Baltimore. As we noted earlier in this chapter, all viruses rely on the host cell machinery for translation. All viruses, then, must generate mRNA that can be recognized by the ribosomes of their host cells. Whether the virus has a DNA or RNA genome, or infects bacteria, archaea, or eukarya, the virus must generate usable mRNA molecules. Thus, the generation of mRNA can be thought of as a common feature by which we can compare all viruses. Using this single defining feature, Baltimore has classified all viruses into seven groups **(Figure 5.26)**. We will explore this method of categorizing viruses more extensively in Section 8.3, when we examine methods of viral replication.

Virus identification

Today, researchers employ a number of biochemical and molecular tests to more clearly identify viral isolates. In this section, we will examine two specific techniques: electron microscopy and nucleic acid analyses. Certainly, nucleic acid analyses provide important information about the identity of a virus, but we will start with the more straightforward approach: What does the virus look like?

Electron Microscopy

As we discussed earlier in this chapter, viruses differ a great deal physically. Poliovirus particles, on the one hand, are nonenveloped icosahedrons approximately 30 nm in diameter. In contrast, variola viruses, which cause smallpox, are enveloped, brick shaped, and over 200 nm long. Clearly, these two viruses look different. By viewing virus preparations with an electron microscope, we can see these physical differences **(Figure 5.27)**. It shouldn't come as any surprise, then, that poliovirus virions and smallpox virus virions easily can be differentiated by electron microscopy.

Electron microscopy is not just useful for differentiating vastly different viruses. Many viral groups have distinctive shapes. As a result, electron microscopy can be a fairly useful tool in identifying viruses. Not surprisingly, though, electron microscopy also can be fairly imprecise. Many viruses look

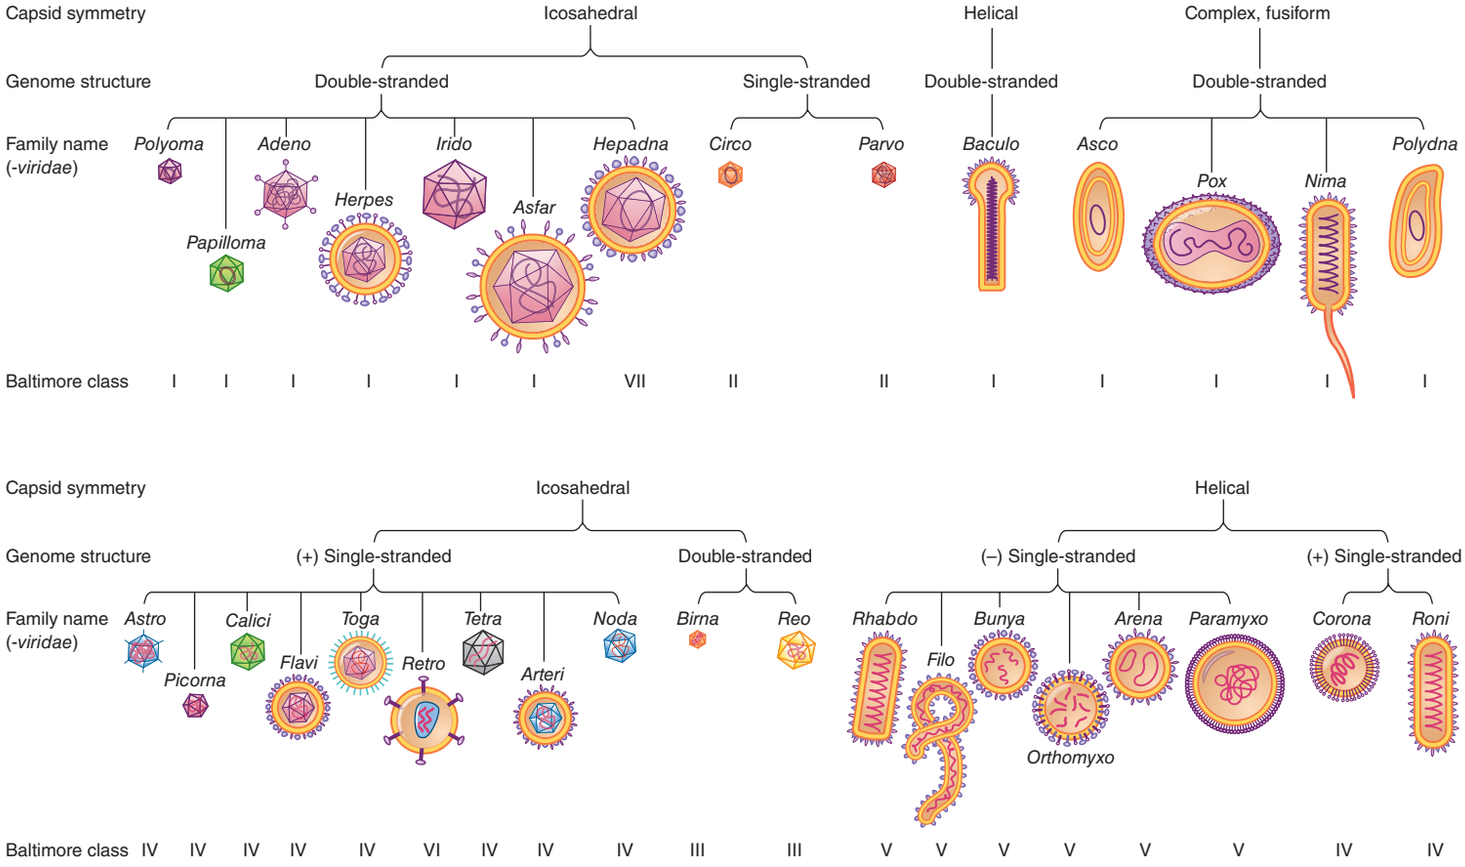

Figure 5.26. Classification of viruses The hierarchy of recognized viral taxa, as recognized by the International Committee on Taxonomy of Viruses (ICTV), is: Order, Family, Sub-family, Genus, Species. Because all viruses do not possess a common gene, a universal classification scheme is problematic. Members of a virus family (with the suffix *-viridae*) share overall virion structure, genome organization, and transcription and replication strategies. Note, not all families are shown here. Criteria used to determine species commonly include host range, cell and tissue tropism, pathogenicity, antigenicity, and nucleic acid sequence relatedness.

similar, at least superficially or to the untrained eye. For example, viruses in both the *Paramyxoviridae* and *Orthomyxoviridae* families are enveloped, spherical, and about 100–150 nm in diameter **(Figure 5.28)**. Paramyxoviruses enter the cell by fusing with the cell membrane and contain a linear single-stranded RNA genome of 16,000 to 20,000 nucleotides. Orthomyxoviruses enter the cell by endocytosis, followed by fusion between the viral envelope and the endosomal membrane. Additionally, orthomyxoviruses possess a segmented genome. These viruses contain eight segments of single-stranded RNA rather than a single RNA molecule. Clearly, the electron microscope cannot be used to observe these important biological features of the viruses.

The severe acute respiratory syndrome, or SARS, outbreak provides an excellent case study in viral identification and demonstrates the advantages and disadvantages of electron microscopy. In the winter and spring of 2003, the world quickly became aware of a threatening new infectious disease. In February 2003, people in Guangdong province of China showed signs of a severe respiratory disease. By the end of March, people with similar symptoms were identified in countries throughout the world, including Vietnam, Hong Kong, Thailand, and Canada. All of these people had SARS.

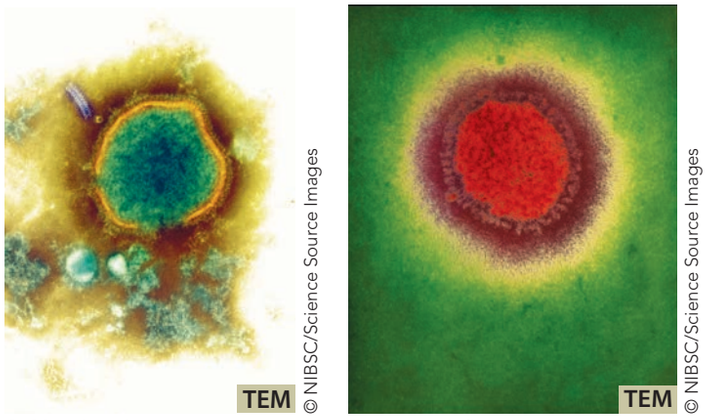
Figure 5.27. Using electron microscopy (EM) to differentiate viruses Although identification of a virus by EM is not always possible, researchers certainly can use EM to differentiate a large, enveloped virus from a small, non-enveloped virus. **A.** Smallpox virus, an enveloped virus nearly 220 nm in diameter. **B.** Poliovirus, a non-enveloped virus approximately 30 nm in diameter.

CONNECTIONS We now know that the SARS virus is a coronavirus. As we will see in **Section 22.4**, researchers hypothesize that strains of this virus that infect bats recombined, giving rise to the human pathogen.



A. Measles virus **B.** Human influenza virus

Figure 5.28. Using electron microscopy (EM) to identify viruses Similarly shaped viruses may be difficult to distinguish by EM. **A.** Measles virus is an enveloped virus approximately 100–150 nm in diameter in the *Paramyxoviridae* family. **B.** Human influenza A virus is an enveloped virus approximately 100–150 nm in diameter in the *Orthomyxoviridae* family.

To identify the causative agent of SARS, clinicians isolated samples from the lungs of people with the syndrome and sent them to electron microscopists. The electron micrographs, images obtained by the electron microscopists, clearly revealed virus-like particles in bronchial washes. These particles appeared to be enveloped virions approximately 100 nm in diameter. Based on these initial electron micrographs, some virologists hypothesized that the causative agent of SARS was a paramyxovirus. Further studies, however, showed that this supposition was incorrect—a coronavirus causes SARS. The initial electron micrographs were not specific enough to allow researchers to distinguish between these similar viruses. More precise tests were needed to confirm the identity of the SARS virus.

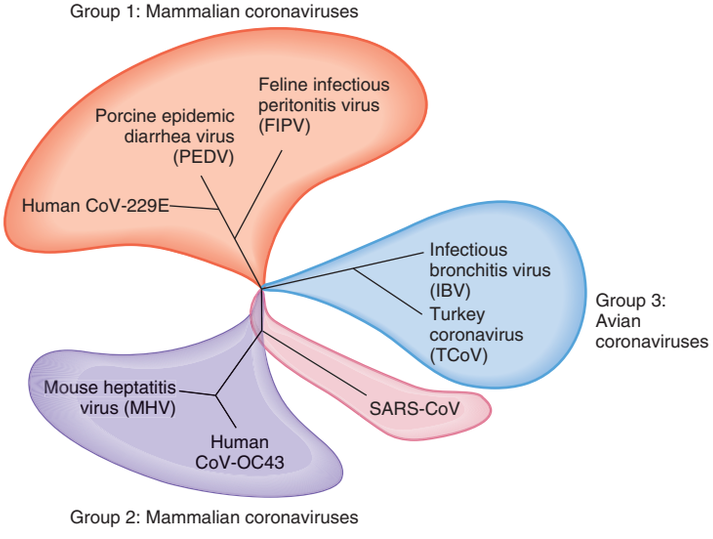


Figure 5.29. Genome sequence analysis of SARS coronavirus As shown in this relatedness diagram based on sequence comparison of the gene encoding the replicase enzyme, the genetic sequence of the SARS genome (SARS CoV) is similar to, but distinct from, the other known groups of coronaviruses.

CONNECTIONS As we have seen in this section, electron microscopy can be a very useful tool for visualizing viruses. More information about electron microscopy and other types of microscopy can be found in **Appendix B: Microscopy**.

Nucleic Acid Analysis

As we have seen previously, sequence analyses can provide us with a wealth of information about bacteria, archaea, and eukaryal microorganisms. The same holds true for viruses. Physical appearances often provide limited information; many viruses have similar shapes. Indeed, various assays may not differentiate closely related viruses within the same virus family. Nucleic acid analyses, however, generally provide more exact information.

To examine the usefulness of nucleic acid analyses, let's return to the SARS outbreak. In May 2003, researchers reported in the *New England Journal of Medicine* that the SARS virus was a novel coronavirus. As part of their analysis, they isolated RNA from cells infected with the SARS virus. Using primers designed to hybridize to sequences conserved among the RNA genomes of all known coronaviruses, they used **reverse transcriptase PCR (RT-PCR)** to generate coronavirus **complementary DNA (cDNA)**, a DNA copy of an RNA molecule (**Toolbox 5.2**). Analysis of this cDNA demonstrated that the SARS virus was a coronavirus.

CONNECTIONS Researchers commonly use a reverse transcriptase enzyme to make DNA complementary to a molecule of RNA. As we will see in **Section 10.2**, the use of reverse transcriptase often is used in microarray studies.

By using RT-PCR, researchers determined conclusively that a coronavirus caused SARS. A more pressing question still remained: What coronavirus was it? To address this question, researchers sequenced the amplified viral cDNA and used sequence comparison software programs to compare the sequence of this unidentified virus to the sequences of other, known coronaviruses. Interestingly, the SARS coronavirus was related to, but definitely distinct from, all other known coronaviruses (**Figure 5.29**). These sequence comparisons led researchers to conclude that SARS was caused by a newly identified coronavirus.

5.4 Fact Check

1. Describe the strategies used to name viruses.
2. What viral attributes are considered by the ICTV when classifying viruses?
3. How does the Baltimore classification scheme categorize viruses?
4. Describe how electron microscopy and nucleic acid analysis are each used to identify viruses.

Toolbox 5.2

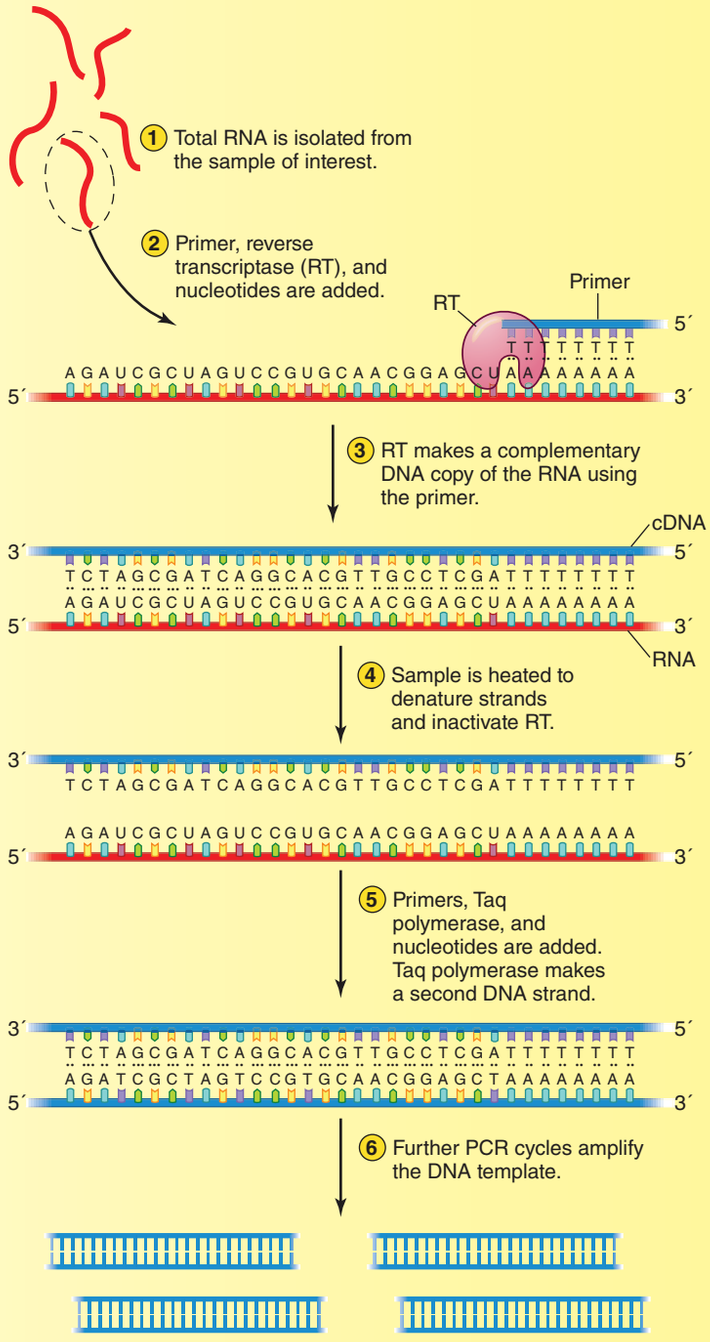
REVERSE TRANSCRIPTASE POLYMERASE CHAIN REACTION (RT-PCR)

As we discussed in Chapter 1, the polymerase chain reaction, or PCR, is a powerful tool for the molecular biologist. By combining a small amount of DNA with thermostable DNA polymerase, nucleotides, and specific primers, we can quickly amplify a specific region of the DNA. Since its development in 1983, PCR has become one of the most widely used molecular biology techniques.

Often, though, a researcher may need to amplify a piece of RNA, rather than DNA. Generally, it is desirable to convert the RNA of interest into DNA. A DNA copy of the RNA is advantageous for two main reasons. First, DNA can be used in further applications such as sequencing or cloning. Second, DNA is more stable than RNA. Obviously, if we can convert our RNA of interest into DNA, then PCR can be used to amplify this newly generated DNA. One important problem remains to be addressed. How can we convert the RNA into DNA?

As happens so often in research, nature already has solved this problem. In 1970, David Baltimore and Howard Temin independently reported the identification and characterization of reverse transcriptase, an enzyme that converts single-stranded RNA into double-stranded DNA (see Mini-Paper in Chapter 8). In retroviruses like HIV, this enzyme converts the single-stranded RNA genome of the virus into double-stranded DNA, which then becomes integrated into the host cell's genome. Researchers can use this enzyme to convert any RNA molecule into complementary DNA, or cDNA. Once cDNA has been generated, then a normal PCR procedure can be used to amplify it.

Like other DNA polymerases, reverse transcriptase cannot simply add nucleotides onto a piece of single-stranded nucleic acid. Rather, it requires a short oligonucleotide primer to which it can add new nucleotides in a 5′ to 3′ fashion. If a specific region of RNA needs to be amplified, then a specific primer, complementary to a short region of the RNA, can be used for the reverse transcription. Alternatively, researchers often use a series of random hexamer primers, which are six nucleotide-long primers of random sequences. These random primers will anneal to the RNA at various locations, thereby allowing the reverse transcriptase to convert all of the RNA into cDNA **(Figure B5.3)**.



Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure B5.3. Process Diagram: Reverse transcriptase PCR Using RT-PCR, DNA can be formed from RNA and amplified. First, reverse transcriptase is used to generate complementary DNA (cDNA) from the RNA. Random primers can be used to form cDNA from all RNA or a specific primer can be used to generate cDNA from a particular RNA species. Following the denaturation of the RNA:DNA molecule and inactivation of the RT, a thermostable DNA polymerase like Taq and specific primers can be used to amplify the DNA fragment of interest.

Test Your Understanding

You are troubleshooting an RT-PCR reaction that did not work and did not produce a DNA product. You realize that you forgot to add one of the reagents: the oligonucleotide primer. Why would this mistake result in a lack of DNA product?

5.5 Virus-like particles

Are viruses the simplest pathogens?

Viruses represent a very diverse set of subcellular particles. Although many different types of viruses exist, they all share some common features. A number of other subcellular infectious agents, which do not share all of these characteristics, also have been identified. Quite possibly, more will be discovered.

Viroids

In 1967, researchers isolated an infectious agent that causes potatoes to grow abnormally **(Figure 5.30)**. Biochemical tests revealed that this subcellular agent, now known as potato spindle tuber viroid (PSTVd), differed significantly from all known viruses. Today, a number of **viroids** that infect plants have been isolated and characterized. All of them share several characteristics and differ from viruses in significant ways. Viroids:

- consist only of naked RNA,
- are extremely small (less than 400 nucleotides),
- exhibit a great deal of internal sequence complementarity,
- exhibit increased resistance to ribonucleases, enzymes that degrade RNA.

Because of the internal complementarity that exists in viroid RNA, certain regions of the genome can form base-pair interactions with other regions of the genome. For example, a string of Gs in the single-stranded molecule could interact with a string of Cs in the same molecule, resulting in a short region of double-stranded RNA. As a result of this intramolecular base-pairing, the molecule exhibits a complex structure **(Figure 5.31)**. This extensive secondary structure probably accounts for the resistance to ribonucleases.

The replication cycle, pathogenesis, and transmission of viroids have been areas of intense research. It appears that viroid genomes do not contain any genes, and consequently, viroids do not produce any proteins. So, what enzymes are involved in the replication of the viroid genome? Several studies, using inhibitors of various cellular polymerases, indicate that one or more of the host cell RNA polymerases may be involved. The pathology associated with these agents may result from this utilization of the host RNA polymerases. It is postulated that replication of the viroids may divert essential resources away from cellular transcription, thereby adversely affecting the health of the plant.

Although this explanation of viroid pathogenesis may be correct, another interesting explanation has been proposed. The genomes of several viroids, including PSTVd, contain a region of nucleotides that is complementary to a sequence found in signal recognition particle (SRP) RNA. The eukaryal SRP consists of several polypeptides and an RNA molecule, referred to as the 7S RNA. This particle directs nascent polypeptides in the cytoplasm into the endoplasmic reticulum. Possibly, the viroid genome can bind to the 7S RNA, interfere with the formation of the SRP, and disrupt the SRP-directed localization of proteins in the infected cell.

CONNECTIONS Following translation, polypeptides may be transported to various areas within the cell, inserted into the plasma membrane, or secreted from the cell. In **Section 3.1**, we investigated the role of signaling sequences in this cell-sorting process.

© Nigel Cattlin/Science Source Images

Figure 5.30. Infectious naked RNA and potato disease Potato spindle tuber viroid (PSTV) contains an RNA genome of less than 400 nucleotides. The genome is not associated with any protein and appears not to code for any protein, but this subviral infectious agent can cause severe pathology. PSTV has caused this potato to be cracked and misshapen.

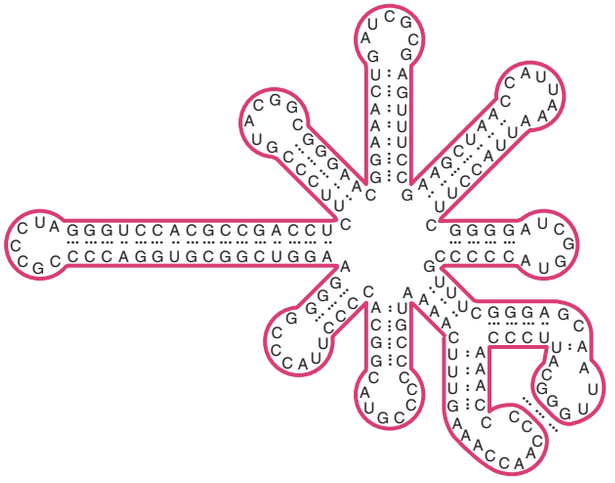


Figure 5.31. Structure of viroid RNA The RNA genomes of viroids are circular and single-stranded, but intramolecular base-pairing results in double-stranded regions.

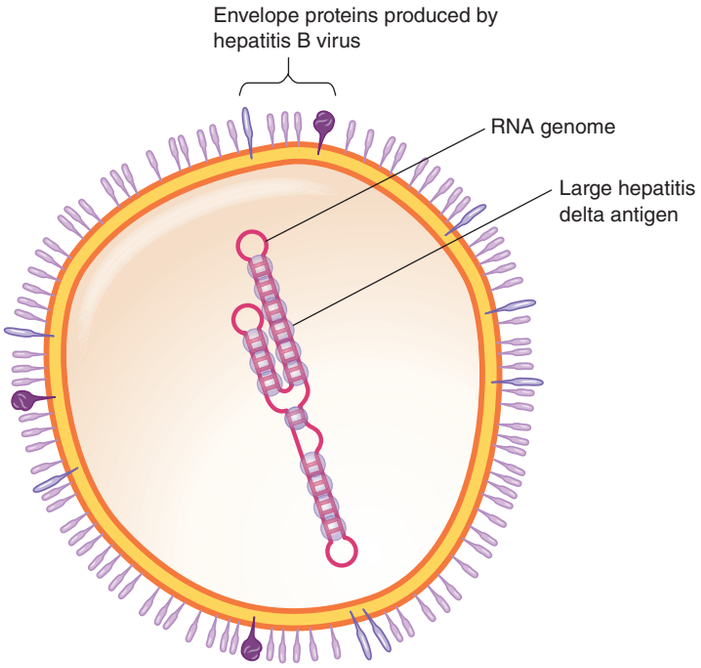

Figure 5.32. Hepatitis delta virus Hepatitis D virus (HDV) is an enveloped virus-like agent with a circular single-stranded RNA genome with extensive base-pairing. The genome is associated with the large form of the hepatitis delta antigen, encoded by HDV. HDV only can replicate in cells that are also infected with hepatitis B virus (HBV). HBV provides the proteins necessary for the HDV envelope.

Finally, transmission of viroids from one plant to another often occurs through insects and may be facilitated by human activities, such as various cultivation practices associated with farming. When an infected plant is pruned, for example, the pruning shears may become contaminated with viroids. When those same shears are used to prune another plant, the integrity of the second plant will be damaged, thereby providing a gateway for the viroids.

Satellite viruses and RNAs

Satellite viruses and **satellite RNAs** represent other classes of subcellular infectious agents. Like viroids, these agents both contain small RNA genomes and infect plants. Satellite viruses and RNAs differ from viroids in two basic ways. First, satellite viruses and RNAs cannot undergo autonomous replication within a host cell. Rather, the replication of these agents depends on functions provided by a helper virus that coinfects the host cell. Second, these agents contain a protein coat that encapsulates the RNA genome. The source of this protein provides the major distinguishing feature between satellite RNAs and satellite viruses. For satellite RNAs, this coat consists of a protein encoded by the helper virus. On the other hand, satellite viruses possess a gene that encodes their own capsid protein.

A human infectious agent very similar to satellite viruses has been identified. Hepatitis delta virus (HDV) contains a single-stranded RNA genome approximately 1,700 nucleotides in length that, like viroids, contains many regions of intrastrand complementarity. HDV only can replicate and form infectious progeny in a cell that is co-infected with hepatitis B virus (HBV). Infectious HDV particles are enveloped, and the envelope contains proteins derived from hepatitis B virus. The HDV genome is complexed with the large form of hepatitis delta antigen, a protein encoded by a gene in the HDV genome. Clinical studies suggest that coinfection with HBV and HDV results in more severe disease than is seen with HBV infection alone **(Figure 5.32)**.

Virophages

Like satellite viruses, **virophages** only replicate in host cells co-infected with a helper virus. Unlike satellite viruses, the replication of these infectious agents is detrimental to the helper virus. Identified in 2008, Sputnik virus, for example, only replicates in amoeba infected with mamavirus, a giant virus related to mimivirus. Sputnik appears to replicate rapidly, possibly using some of the mamavirus proteins in the process. As a result of the co-infection, production of new, infectious mamavirus particles is inhibited. Since 2008, several other virophages have been identified. All of them replicate in amoeba co-infected with a giant virus.

The replication strategy of virophages appears to be quite interesting and unusual. Even more interesting is the role these infectious agents may play in the transfer of genetic material. An analysis of the 18-kbp genome of Sputnik revealed that it possesses genes homologous to genes found in viruses of eukarya, bacteria, and archaea. Based on this finding, researchers have postulated that virophages may play an important role in the lateral transfer of genetic material. Future investigations certainly will tell us more about these unusual agents and their role in the evolution of other microbes.

Prions

Although satellite viruses, satellite RNAs, and virophages may seem a bit unusual, **prions** probably represent the most unusual infectious agents identified to date. Prions, or proteinaceous

© C.E.V./Science Source Images

Figure 5.33. Proteinaceous infectious particles (prions) and transmissible spongiform encephalopathy (TSE) Signs of mad cow disease include various neurological problems, aggressive behavior, and death. It is related to scrapies in sheep and variant Creutzfeld–Jakob disease (vCJD) in humans. Evidence suggests that vCJD can occur as a result of eating beef from affected cattle.

infectious particles, appear to contain no DNA or RNA. Despite the absence of a genome, these agents can replicate, in a manner of speaking, in the host, causing disease. In fact, researchers now recognize prions as the causative agents of several diseases, including kuru and Creutzfeldt–Jakob disease (CJD) in humans, scrapie in sheep, and bovine spongiform encephalopathy (also referred to as mad cow disease) in cattle (Figure 5.33). Collectively, these diseases are referred to as **transmissible spongiform encephalopathies (TSEs)**, progressive neurological diseases characterized by impaired mental functions and sponge-like holes in the brain. In humans, an inherited form of CJD has been observed. An infectious form, vCJD, also has been observed.

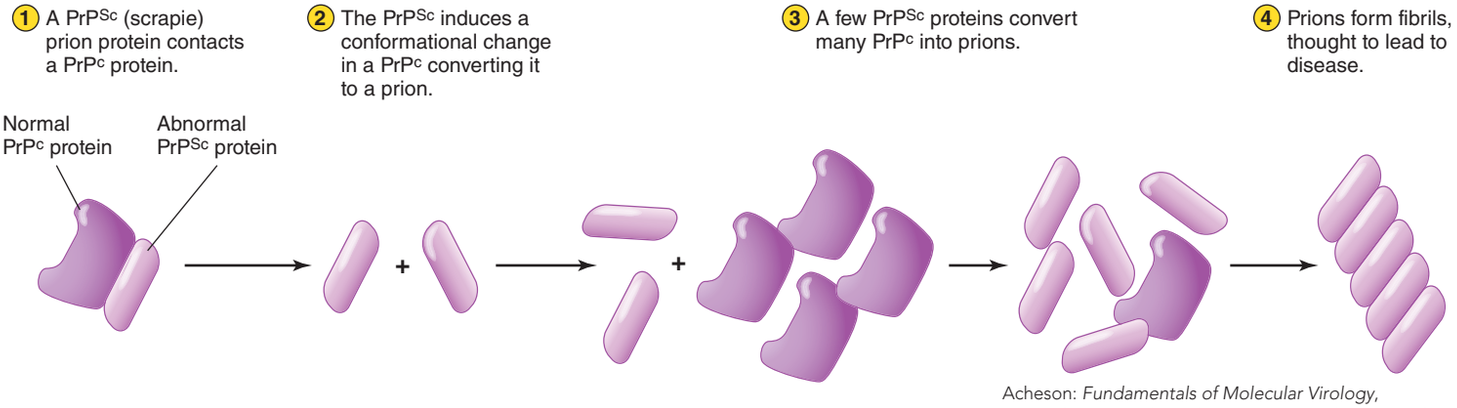
During the initial studies of these diseases, most researchers assumed that the causative agents were viruses. Indeed, these diseases appeared to be caused by viruses. Studies clearly showed that scrapie could be transmitted from animal to animal, indicating that it was caused by an infectious agent. Moreover, brain homogenates passed through a 0.2-μm filter still were infectious, indicating that the responsible agent probably was not a bacterium. Experiments by Stanley Prusiner at the University of California, San Francisco and others demonstrated that treatments that destroy nucleic acids did not alter the infectivity of the agent. Based on these and other experiments, Prusiner concluded that the agent probably consisted of protein but not DNA or RNA. In 1997, he received the Nobel Prize for the characterization of this truly unusual proteinaceous pathogen.

But how can an agent that does not contain DNA or RNA replicate? It appears that prions are misshapen forms of naturally occurring proteins. This protein normally exists on the surface of neurons and can exist in one of two different conformations, the more common PrP^{c} (cellular) form and the pathogenic PrP^{Sc} (scrapie) form. A molecule of PrP^{Sc} can facilitate the conversion of PrP^{c} molecules to PrP^{Sc}. Thus, PrP^{Sc} replicates (Figure 5.34).

Obviously, PrP^{Sc} can be classified as an infectious agent. If PrP^{Sc} is transferred to a susceptible individual, then PrP^{c} molecules within that individual will be converted to PrP^{Sc}. When enough PrP^{c} molecules have assumed the PrP^{Sc} conformation, the encephalopathy associated with prion diseases occurs. Certain mutations in the *PrP* gene make the protein more likely to assume the PrP^{Sc} conformation. Thus, some people develop Creutzfeldt–Jakob disease not because they were infected by PrP^{Sc} molecules but because they inherited a predisposing mutant allele of the *PrP* gene. As a result, prion-associated diseases can be both infectious and hereditary!

5.5 Fact Check

1. How are viroids different from viruses?
2. What are the characteristics of satellite viruses, satellite RNAs, and virophages?
3. What are the key features of prions?
4. What diseases are caused by prions? Describe.



Acheson: *Fundamentals of Molecular Virology*, copyright 2011, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 5.34. Process Diagram: Model of prion replication When pathogenic PrP^{Sc} (scrapie) protein molecules come in contact with PrP^{c} (normal) molecules, they cause the PrP^{c} molecules to change shape, becoming PrP^{Sc} molecules. In this fashion, the prion protein, devoid of any nucleic acid, can replicate and function as an infectious agent.

5.6 Virology today

What's next for virology?

The field of virology has progressed greatly during its relatively brief history. The impact of this explosion of knowledge has affected many disparate areas, including genetics, molecular biology, and medicine. These advances continue to occur at a dizzying pace. Today, virology remains an extremely exciting and dynamic field.

CONNECTIONS Increasingly, researchers are exploring the role of viruses in ecosystems. As we will see in **Section 15.3**, vast numbers of viruses exist, for example, in marine ecosystems. The viruses that infect and lyse marine microorganisms may contribute significantly to nutrient cycling in these locations.

Because viruses are obligate intracellular parasites and, as a result, use various components of the host cell's transcriptional and translational machinery, they represent wonderful tools for studying the inner workings of our own cells. Indeed, since the advent of molecular biology in the 1950s, viruses have been used extensively to further our understanding of DNA replication and gene regulation. In fact, some of our first detailed glimpses into gene regulation came from studies of simian virus 40 (SV40) and the attendant discovery of enhancers, genetic elements that increase the expression of genes. Additional studies with SV40 and other viruses led to a better understanding of promoters, transcription factors, RNA splicing, and translation. Indeed, studies with bacteriophages showed that DNA, not protein, was the genetic material. Clearly, our understanding of genetics owes a lot to studies of these simple particles.

Although molecular studies with viruses have contributed greatly to our understanding of how our cells work, viruses also have proved essential in developing the molecular techniques used to address fundamental questions about cell biology. Indeed, many of the most influential molecular biology experiments initially were conducted with viruses. Studies of viral replication, for instance, led to the discovery by David Baltimore and Howard Temin of reverse transcriptase, the enzyme used by retroviruses to convert RNA into DNA (see Mini-Paper in Chapter 8). Today, this enzyme is used widely in molecular biology, most notably for the generation of cDNA.

Studies with viruses also have led to profound advances in various medical fields. Our understanding of cancer owes a great deal to virology. Studies by Harold Varmus and J. Michael Bishop in the 1970s showed that Rous sarcoma virus, a retrovirus, caused cancer in experimental animals because the virus contained a mutated form of an animal gene. This discovery led to their description of **proto-oncogenes**, genes involved in the normal regulation of the cell cycle, and **oncogenes**, altered forms of proto-oncogenes that can lead to uncontrolled cell growth and the development of tumors. Today, a host of proto-oncogenes and oncogenes have been characterized, many through the study of retroviruses. The characterization of these genes is revolutionizing our approaches to the treatment of cancer.

CONNECTIONS Viruses cause cancer? In some cases, yes. Human papillomavirus infection represents the major cause of cervical cancer. The mechanism of this process is explored more fully in **Section 22.3**.

Not only have viruses been used to further our understanding of cancer, but also they are being investigated as anticancer agents. **Oncolytic viruses** infect and kill cancerous cells without harming normal cells. Recent studies with reovirus have been especially noteworthy. These non-enveloped, icosahedral, double-stranded RNA viruses preferentially infect cells in which the Ras signaling pathway has been activated. Intracellular Ras proteins often become activated in response to an extracellular signal, such as a growth hormone binding to a membrane-bound receptor. Once activated, Ras proteins normally interact with a series of intracellular proteins, eventually leading to increased gene expression and increased cell proliferation. Abnormal activation of the Ras pathway has been observed in a large proportion of human cancers. Because reovirus preferentially infects cells with an activated Ras pathway, cancer cells should be susceptible to reovirus infection. Several clinical trials currently are underway investigating the ability of reovirus to combat different cancers.

The oncolytic potential of other viruses also are being investigated. Researchers have developed a modified version of herpes simplex virus 1 that exhibits preferential destruction of tumor cells. In 2013, researchers from the biotechnology company Amgen announced that this modified virus, known as talimogene laherparepvec, or T-VEC, performed well in a clinical study involving people with melanoma. Meanwhile, scientists led by Dr. Matthias Gromeier at Duke University are investigating the ability of a modified version of poliovirus to combat glioblastoma, a form of brain cancer.

Viruses also are central players in the burgeoning field of **gene therapy**. With gene therapy, researchers and clinicians hope to someday actually correct genetic defects in humans. The idea is simple: if a genetic defect is identified, then one could insert a functional copy of the gene into a person with the defect, thereby eliminating the problem. Of course, the process is not that simple in reality. One big problem involves inserting the correct gene into the defective cells. Again, because viruses naturally enter cells, they are being investigated as potential shuttles of genetic information. In one sense, viruses can be thought of as microscopic containers. The capsid, or container, carries the infectious viral genome—its cargo. With biochemical and genetic manipulations, though, we can alter this cargo. For example, we could remove part of a viral genome and replace it with a copy of the human CFTR gene, which encodes the cystic fibrosis transmembrane conductance regulator protein. In people with cystic fibrosis, this gene is

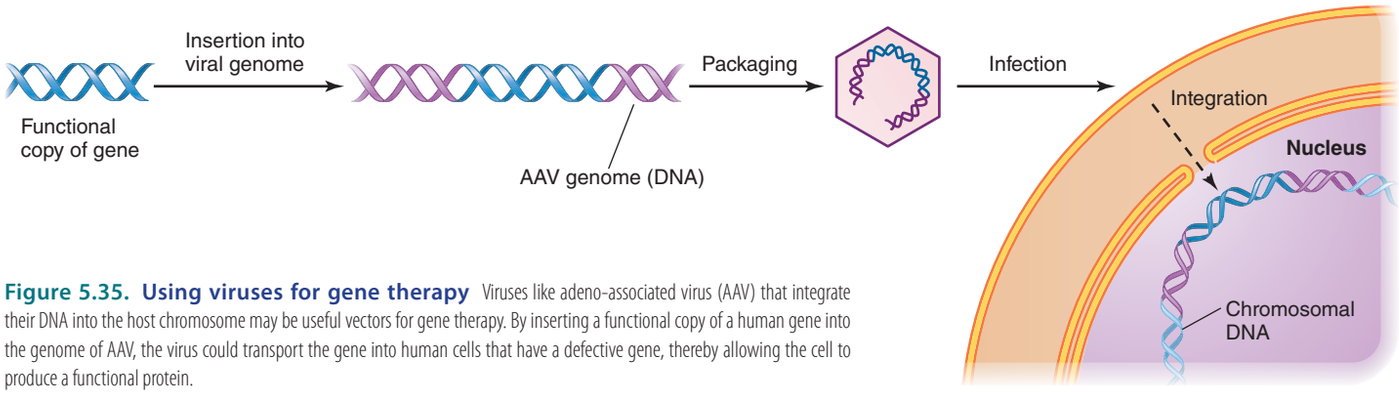


Figure 5.35. Using viruses for gene therapy Viruses like adeno-associated virus (AAV) that integrate their DNA into the host chromosome may be useful vectors for gene therapy. By inserting a functional copy of a human gene into the genome of AAV, the virus could transport the gene into human cells that have a defective gene, thereby allowing the cell to produce a functional protein.

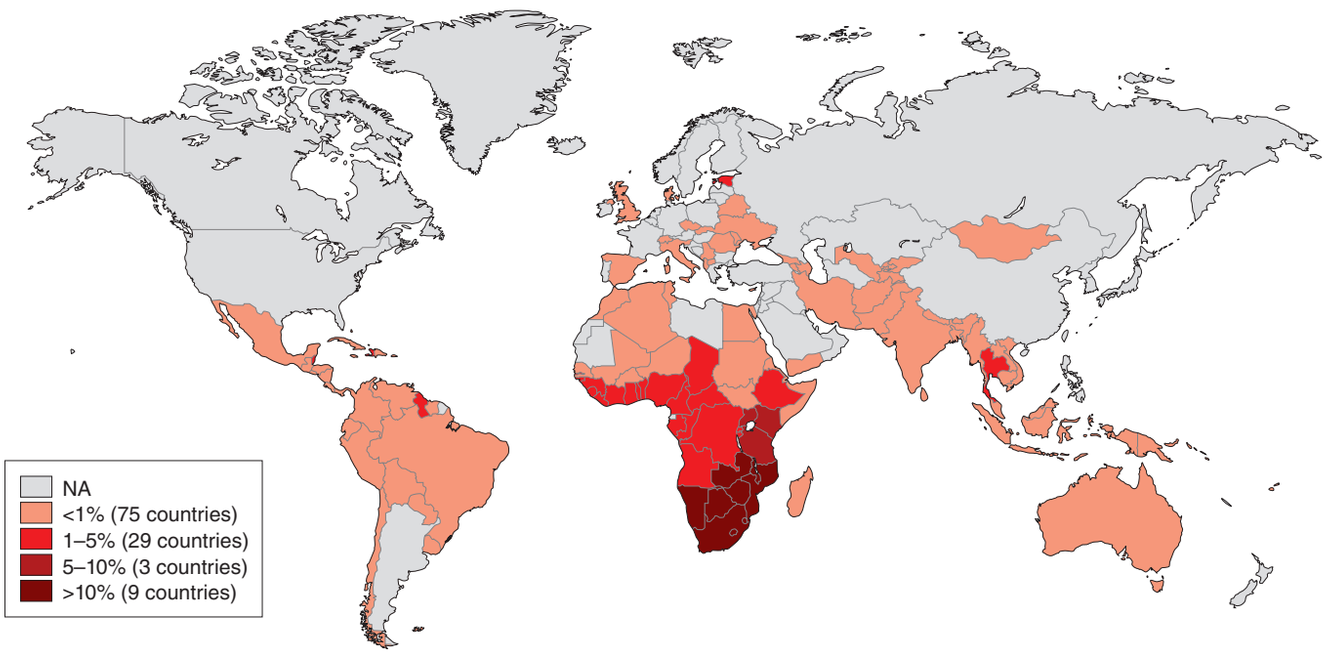
mutated, producing a non-functional protein. As a result of this mutation, thick mucus accumulates in the lungs, leading to respiratory problems and an increased risk of bacterial infections. A virus containing a functional copy of the CFTR gene would house a very beneficial cargo. If this altered virus infects lung epithelial cells in a person with CF, the virus might deliver a new and correct copy of the defective gene, thereby alleviating the underlying genetic problem **(Figure 5.35)**.

As microscopic containers, viruses also are being used in the expanding field of **nanotechnology**. Briefly, nanotechnology involves the development and use of nano-devices—machines that are nanometers in size. So how do viruses fit into this field? Given what we have discussed about viruses, you probably can imagine the viral capsid serving as a container for a desirable cargo. In one recent set of experiments, cowpea chlorotic mottle virus (CCMV), a plant virus, has been used to facilitate the formation of complex inorganic molecules. By slightly altering the CCMV capsid, researchers were able to use the capsid as a nano-staging area for the desired chemical reaction. The capsid not only spatially restricted the precursors but also sequestered them from the host cell. Because of this natural function of the viral capsid as an ultra-small vesicle, viruses certainly will play an ever-increasing role in the exciting field of nanotechnology.

Finally, and sadly, viruses remain a public health threat throughout the world. Currently, HIV infects approximately 35 million people worldwide **(Figure 5.36)**. Millions of people die every year from virally caused diarrheal diseases. Recent outbreaks of SARS, MERS, and Ebola showed everyone that we do, indeed, live in a global village and viruses that infect humans *any*where can infect humans *every*where. But we can be hopeful. Our increased understanding of viruses is leading to the development of new antiviral drugs. New vaccines against pathogenic viruses also are being developed and tested. The research of today will lead to more treatment and prevention options for tomorrow.

CONNECTIONS Our understanding of virus structures and replication strategies has led to the development of antiviral drugs. In **Section 8.5**, we will explore how antiviral drugs, like AZT, function to inhibit the replication of HIV.

Figure 5.36. Numbers of people infected with HIV worldwide Despite the progress we have made in HIV/AIDS research, there still is not a vaccine or a cure. Worldwide, approximately 35 million people are infected with HIV. Most of the people living with HIV are in sub-Saharan Africa.



Mini-Paper: A Focus on the Research

NEW FINDINGS IN THE PACKAGING OF DNA BY THE MODEL BACTERIOPHAGE T4

Z. Zhang, V. I. Kottadiel, R. Vafabakhsh, L. Dai, Y. R. Chemla, T. Ha, and V. B. Rao. 2011. A promiscuous DNA-packaging machine from bacteriophage T4. PLoS Biol 9:e100592.

Context

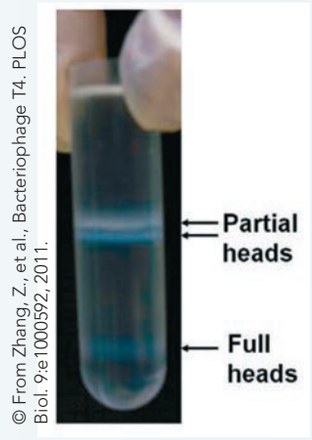
The T4 bacteriophage is widely distributed and abundant in nature. It also has been the subject of extensive genetic and biochemical studies. Indeed, much of our understanding of bacteriophage capsid assembly results from studies of T4. The capsid of T4 includes a head that packages the 170-kb dsDNA genome and a contractile neck and tail that is used to inject the DNA into the bacterial host cell (see Figure 5.11).

A key event in T4 assembly involves the packaging of the DNA into the head, a process carried out by a molecular motor called "terminase." This motor consists of two proteins, gp17 and gp16, and its activity is fueled by the hydrolysis of ATP. When T4 DNA replication occurs, a concatamer, or string of complete genome copies arranged end to end, is produced. This long molecule is stuffed into the bacteriophage head until it becomes full, at which time the terminase cleaves the DNA and then falls off the developing structure. The neck and tail proteins then attach to the filled head to complete the assembly of the infectious virion in a highly ordered process. The gp17 protein is responsible for the ATPase and nuclease activities of the terminase, whereas gp16 regulates the activity of gp17. Because the sequence of events in virion assembly appears to be strictly controlled, researchers thought that the terminase would introduce DNA only into empty heads. In this study, they tested this hypothesis.

Experiments

To determine how DNA enters bacteriophage heads, the researchers examined T4 mutants that could not assemble the neck and tail. Cells infected by these mutants produced bacteriophage heads containing DNA. Researchers observed that two types of heads could be isolated by differential centrifugation—heads that contained genome-length DNA (termed full heads by the investigators) and heads that contained approximately 8 kbp of DNA (termed partial heads) **(Figure B5.4)**.

If these heads have already packaged DNA in the past, then would it be possible for them to package DNA again? To answer this question, the investigators used both the full and partial heads in an *in vitro* DNA-packaging assay. Empty heads that had never packaged DNA were used as a control. Surprisingly, both the full and the partial heads packaged short DNA fragments of 50–766 bp in length, as shown by gel electrophoresis analysis **(Figure B5.5)**.



© From Zhang, Z., et al., Bacteriophage T4. PLOS Biol. 9:e1000592, 2011.

Figure B5.4. Identification of full and partial T4 heads Following infection with T4 mutants unable to produce necks and tails, *Escherichia coli* cells were lysed to release bacteriophage heads. Cesium chloride density gradient centrifugation was used to isolate these structures. Low-density partial heads and high-density full heads were observed.

To ensure that they were detecting DNA that had been packaged, the researchers treated the T4 heads first with DNase I and then with proteinase K. Why? DNase I digests exposed DNA. Treatment with this enzyme, degrades any non-packaged DNA. Proteinase K digests proteins. Treatment with this enzyme degrades the previously added DNase I and also degrades the proteinaceous bacteriophage head, freeing any encapsulated DNA. In other words, this combination of enzymes ensured that the detected bands represented DNA that had been packaged.

When a similar packaging assay was done with 48.5-kb phage λ DNA, the partial heads successfully incorporated this DNA, but the full heads did not **(Figure B5.6)**. Most likely, the full heads contained limited free space and could not accommodate an additional DNA molecule of this size.

5.6 Fact Check

1. How can viruses be used as molecular biology tools? Provide examples.
2. How are the terms "proto-oncogene" and "oncogene" related? How were viruses used to characterize these genes?
3. What are oncolytic viruses and how could they be used as anticancer agents?
4. How can viruses be used for gene therapy? Give examples.

Image in Action

WileyPLUS Learning Space A cell culture hood is being used to study the lymphocytic choriomeningitis virus (LCMV) outbreak in golden lion tamarins. The flasks contain primate cells. The syringes attached to filters help the researchers isolate the viruses. A zoom-in window on the flask reveals cells that are at late stages of LCMV infection. In the second zoom-in window on the cells, a new viral particle is shown budding off a cell (*right*).

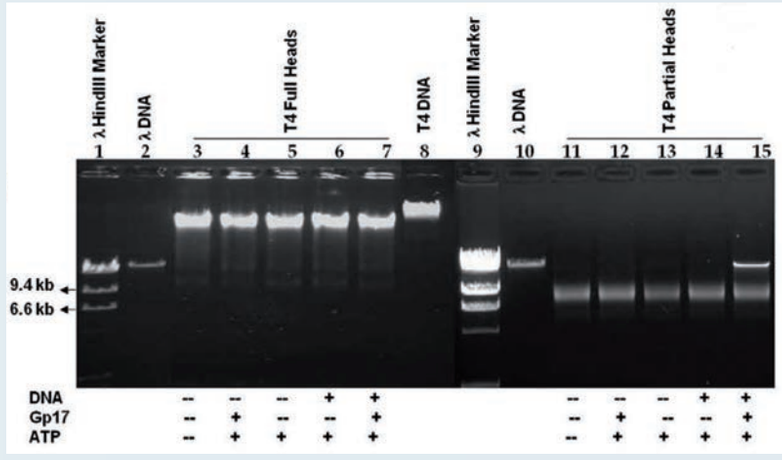
Figure B5.5. Full and partial heads package additional DNA Following *in vitro* DNA-packaging reactions, T4 heads were treated first with DNase I and then with proteinase K to release the encapsulated DNA. Agarose gel electrophoresis analysis demonstrated that both full and partial heads efficiently package a mixture of short fragments of DNA.



© From Zhang, Z., et al., Bacteriophage T4. PLOS Biol. 9:e1000592, 2011.

Figure B5.6. Packaging of λ DNA In a separate *in vitro* DNA-packaging assay, researchers exposed full and partial T4 heads to 48.5-kbp λ DNA. Gel electrophoresis analysis demonstrates that partial heads can package these larger DNA fragments, but the full heads cannot.

Impact

The results of these experiments challenge the central idea that virus assembly occurs sequentially and irreversibly. Virologists long have assumed that virion assembly occurs in a highly ordered fashion where each step depends on the successful completion of the immediately preceding step, and each step is irreversible. After all, the entire assembly of the virion is a very intricate process that occurs rapidly. It stands to reason that each step must be completed before the next step begins. Virologists had assumed that once a bacteriophage T4 head had been filled with DNA and the terminase was released, the developing capsid would not be able to reassociate with terminase and receive more DNA.

The results reported in this article demonstrate that the interaction of a full head with the terminase is not inhibited. Because the terminase appears not to discriminate between empty and full heads, the authors refer to this type of interaction as promiscuous. We now need to re-examine certain assumptions about the assembly of virions. We also need to investigate the possibility of using full or partial heads for *in vitro* packaging reactions. These bacteriophage components could be used to incorporate various types of foreign DNA of potential use for different biomedical applications.

Questions for Discussion

1. This study used differential centrifugation to separate full bacteriophage heads from partial bacteriophage heads. How does this separation method occur?
2. The small DNA fragments that were used in the *in vitro* packaging assay did not have any special qualities. Based on this point, do you think there are any specific DNA sequences that are required for the DNA to be packaged?

1. To isolate viruses from samples obtained from infected animals, a filter is being used. Explain how this technique would aid in the isolation of viruses.
2. The researchers needed to determine which cells in the flask were appropriate to use. What cell characteristics did they need to consider, and what would they look for to determine whether their viral culture attempt was successful?

The Rest of the Story

With the help of several microbiologists using a variety of tools, Dr. Montali at the National Zoo investigated the golden lion tamarin (GLT) deaths. Electron micrographs depicted viral particles within the tissues of the diseased GLTs. Viruses could be purified from these tissues and replicated in the laboratory. All of these findings confirmed Dr. Montali's initial fears—an infectious agent was killing the GLTs.

The research team replicated these viruses in a monkey epithelial cell line. Using antibody binding and nucleic acid hybridization assays, virologists determined that the GLTs were infected by a strain of lymphocytic choriomeningitis virus (LCMV). LCMV, a large enveloped virus with a single-stranded RNA genome in the *Arenaviridae* family of viruses, typically causes mild or no apparent disease in rodent species. When transmitted from rodents to humans, though, these viruses can cause serious disease. For example, both Lassa fever and Bolivian hemorrhagic fever are caused by arenaviruses. LCMV itself has been associated with serious disease in humans.

Researchers considered how rodents were involved in these GLT infections. It turned out that animal keepers often provided GLTs with mice along with their food as a supplemental protein source. Occasionally, these feed mice were infected with LCMV. When the tamarins ingested these mice, they, too, became infected, with dire consequences. The solution to the problem proved to be obvious and very simple—stop providing mice to the GLTs. Quickly, zoo personnel throughout the country were informed of the situation. Just as quickly, zoo personnel stopped providing mice to their tamarins. The outbreaks ended.

Summary

Section 5.1: What is a virus?

Viruses probably have existed since life itself first evolved. We have isolated and characterized viruses that infect every known type of life, from bacteria to plants to humans.

- **Viruses** are small **obligate intracellular parasites**, with diameters typically between 10 and 100 nanometers and genomes typically between a few thousand and about 200,000 nucleotides in length.
- Viruses can contain single-stranded or double-stranded DNA or RNA genomes. They have **capsids** surrounding the genome, forming **nucleocapsids**, which generally exhibit **icosahedral** or **helical morphology**. A **viral envelope** surrounds the capsids of some viruses. The capsids are constructed from symmetrically arranged **capsomeres**. **Bacteriophages** often exhibit a complex morphology, with **virions** containing an icosahedral head and a helical tail. Some large animal viruses have more irregular shapes.
- In enveloped viruses, a lipid bilayer surrounds the capsid. Non-enveloped viruses lack this feature. These various characteristics are used to classify viruses.
- Viral replication typically involves an interaction between the viral **attachment protein** and the host cell **receptor**, penetration of the host cell membrane, disassembly of the capsid (for viruses of eukaryal cells), replication of the viral genome and production of viral proteins, assembly of new virus particles, and exit from the cell of these new particles.

Section 5.2: From what did viruses arise?

Although the evolutionary history of viruses remains unclear, several hypotheses have emerged.

- Viruses may have evolved along with their appropriate host cells. Although this **coevolution hypothesis** is very simple and could explain the origins of the many RNA viruses, there is very little data supporting it.
- Viruses may represent cells that, over time, lost some of their replicative and metabolic capabilities, eventually becoming dependent on host cells. Although examples supporting this **regressive hypothesis** exist in the biological world, this hypothesis does not offer an explanation for the many RNA viruses.
- Most virologists currently think that viruses arose from existing genetic elements that eventually gained the ability to move from cell to cell and organism to organism. The similarities between transposons and certain DNA viruses and **retrotransposons** and retroviruses perhaps provide the best evidence for this **progressive hypothesis**.

Section 5.3: How can we "grow" and quantify viruses?

Because viruses are very small and only replicate within appropriate host cells, various strategies are used to amplify and quantify viruses.

- Viral cultivation only can occur within appropriate host cells. For **bacteriophages**, a culture of bacteria can be inoculated with a sample of phage. After a period of incubation, the phage will replicate within the bacteria.
- For animal viruses, a sample of virus can be added to cells of an appropriate cell line. Many animal virus cause characteristic **cytopathic effects (CPE)** in infected host cells, often resulting in the formation of **plaques** or a **syncytium**.
- Viruses can be purified in several different ways. Filtration can be used to separate viruses from eukaryal, bacterial, and archaeal cells. **Differential centrifugation** or **gradient centrifugation** then can be used to purify virus particles.
- Virus **titers** can be quantified in many different ways. Electron microscopy can be used to count the actual number of particles. Various assays, like the **hemagglutination** assay, **tissue culture infectious dose 50 ($TCID_{50}$)** or **lethal dose 50 (LD_{50})** assay can be used to measure some specific property displayed by the virus particles. Plaque assays allow a researcher to measure the number of infectious virus particles.

Section 5.4: What are the different types of viruses?

Viruses have been classified in many ways. The most useful classification schemes are based on structure and replication strategies.

- Viruses have been named in a variety of ways, ranging from descriptions of the disease caused by the virus, to the location where the virus was first isolated, to simple numbers or letters.
- The ICTV has developed a systematic taxonomy for viruses in which viruses are classified based on a series of shared attributes, including virion structure, genome composition, and host range.
- The Baltimore classification system organizes all viruses based on the process by which they generate mRNA.
- Researchers can begin to identify viruses by examining their structure.
- Techniques like **reverse transcriptase PCR (RT-PCR)** and nucleic acid sequence comparisons provide a more definitive means of identifying viruses.

Section 5.5: Are viruses the simplest pathogens?

A variety of subviral entities have been discovered and characterized.

- **Viroids** consist only of naked RNA; they lack a protein coat. The RNA genome typically is less than 400 nucleotides long and does not encode any proteins. Host cell polymerases probably replicate the genome.

- **Satellite viruses**, **satellite RNAs**, and **virophages** are dependent on a helper virus for replication. These agents contain a protein coat. For satellite viruses, the agent's genome encodes the coat protein. For satellite RNAs, the helper virus encodes the coat protein. Virophages interfere with the replication of their helper virus.
- **Prions** do not contain a genome. These infectious agents, responsible for **transmissible spongiform encephalopathies (TSEs)**, such as mad cow disease, consist only of protein.

Section 5.6: What's next for virology?

The future of virology certainly will include many new advances and, hopefully, an increasing array of treatments to prevent viral diseases.

- Studies of viruses will continue to help us learn more about the normal workings of eukaryal cells and about problems associated with these cells. These studies will continue to lead to the development of new molecular biology techniques.
- Viral research has increased our understanding of **proto-oncogenes** and **oncogenes**.
- Studies of **oncolytic viruses** may lead to new cancer treatments.
- Virologists are becoming actively involved in the burgeoning fields of **gene therapy** and **nanotechnology**. Because of their small size and ability to package a genome, viruses represent ideal tools for these two exciting new areas of research.
- Viruses continue to contribute to human mortality and suffering. Studies of viral pathogenesis remain critically important.

Application Questions

1. Many microbiologists consider viruses to be non-living particles. Explain their rationale for this.
2. Enveloped and non-enveloped viruses enter host cells differently. Why is this, and what are their different approaches for entry?
3. Viral attachment obviously is a key step in a viral infection. What strategies could be employed by an antiviral drug to prevent this step?
4. You are working in the lab and must quantify the viruses in your sample. Which would you consider a better approach to use: a direct count of viral particles or a count of infectious viral particles? Explain your answer.
5. Currently, many different cell lines have been characterized and are available for use by researchers. Why might virologists need many different cell lines to do their work?
6. A connection has been made between helical morphology of the viral capsid and the presence of an RNA genome in a virus. Explain why this might be.
7. When examining a new virus, what characteristics would you need to observe in order to determine the type or classification of that virus?
8. Many chemical biocides (disinfectants) target the lipid envelopes of viruses. Why would the chemical destruction of the envelope render the virus non-infectious?
9. Some viruses cause cancer. Given what you know about viral replication, would the induction of cancer be beneficial to the virus?
10. Phage therapy involves the therapeutic use of bacteriophages to treat bacterial infections in animals. Based on your understanding of bacteriophages, would the phage used for this therapy be able to destroy or replicate inside the animal cells?
11. Examinations of golden lion tamarins (GLTs) that died at zoos in the United States revealed a severe hepatitis, or inflammation of the liver. Electron microscopy of the liver tissue revealed significant tissue damage and the presence of virions.
    a. Initially, how could you use filtration to determine if the liver was infected with viruses or bacteria?
    b. How would you go about isolating and culturing the virus in the lab? What type of cell line would you need to use?
    c. What technique would you use to determine the viral load in the GLTs? Explain.

CHAPTER 6

Cultivating Microorganisms

"Anthrax Tower," otherwise known as Building 470 or the "Pilot Plant," was a seven-story brick building at Fort Detrick, Maryland. Built in 1953 by the Department of Defense, it served as a pilot plant for the production of biological weapons, initiated in response to the perceived threat of biological warfare during the Cold War. Between 1953 and 1965, researchers cultivated *Bacillus anthracis*, the cause of anthrax disease, in two 2,500-gallon, three-story-high fermenters housed within the tower, similar to brewery fermentation vats. To prevent the unintentional escape of pathogens to the outside world, a powerful ventilation system maintained negative pressure in the building. If a door opened, or a crack occurred in the structure, air would rush into the building, not out.

Bacillus anthracis can be cultivated aerobically in rich nutrient medium at 35–37°C. However, when nutrients in the medium become depleted, the cells undergo a morphological change, resulting in the formation of endospores. It is the endospores that are coveted for use as a biological weapon. *Bacillus anthracis* spores are particularly resilient to extreme temperatures, desiccation, harsh chemicals, and sunlight. They can survive for decades in soils. In 1943, the British government tested the viability of anthrax spores on an uninhabited, remote island off the coast of Scotland. In 1980, nearly 40 years after the initial experiments, sheep were moved onto the island and promptly died of anthrax. The endospores had remained viable.

Bacillus anthracis spores germinate rapidly in response to specific environmental conditions found in mucosal surfaces and wounds of mammalian hosts. The infection process can begin with inhalation, ingestion, or contamination of a cut with just a few spores. It seemed to be the perfect biological weapon but, thankfully, never was deployed. Eventually, the Cold War ended. In 1965, researchers stopped production of biological agents at Fort Detrick and Building 470 was sealed. But what to do with a building full of anthrax spores? The very characteristics of the spores that made them once so desirable now became a detriment.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Microorganisms obtain nutrients and energy in diverse ways.

- Figure 6.1: Energy, electron, and carbon sources for metabolism
- Figure 6.2: Incorporation of ammonia into amino acids

Nutritional requirements and environmental factors affect microbial growth.

- Toolbox 6.1: Phenotype MicroArrays for examining microbial growth

CONNECTIONS for this chapter:

Role of iron-binding proteins in pathogens **(Section 21.1)**

Nucleoside acquisition by *Plasmodium falciparum* **(Section 23.1)**

Archaeal adaptations to high-salt conditions **(Section 4.3)**

Metagenomic analysis of non-cultivated microbes **(Section 10.4)**

Process of pasteurization **(Section 16.2)**

Introduction

Microorganisms are capable of reproducing faster than any of the larger forms of life on Earth, and microbial growth has enormous consequences for the biosphere and human health. As we saw in Section 4.3, the archaeon *Methanobrevibacter smithii* may play an integral role in our digestive system. As we will learn in Sections 14.2 and 14.3, microbes play key roles in biogeochemical cycling, transferring important elements like carbon and nitrogen from one molecular state to another. Other microbes, like the bacterium *Streptococcus pyogenes*, can cause various diseases in humans, as we will see in Section 21.2. For us to better understand the actions of these microbes, we need to work with them in the laboratory. To facilitate this research, we need to understand the replication requirements of these microbes.

Understanding how microbes grow can be surprisingly challenging. Like animals in a zoo, some microbes replicate well in the laboratory, but other microbes do not, just as some animals do not thrive in captivity. In this chapter, we will explore how nutritional and environmental factors affect population growth. We also will explore methods for studying these effects. We will learn about methods for isolating and cultivating microorganisms in the laboratory. We also will learn about methods for studying microorganisms that we cannot yet grow. Finally, we will examine methods for preventing the growth of microorganisms, and destroying undesirable microbes. Along the way, we will address the following questions:

What do microorganisms generally need to grow? (6.1)
How do nutritional and environmental factors affect microbial growth? (6.2)
How can different types of microorganisms be grown in the laboratory? (6.3)
How can we measure and monitor microbial populations? (6.4)
How can we eliminate microbes or inhibit their growth? (6.5)

6.1 Nutritional requirements of microorganisms

What do microorganisms generally need to grow?

As we saw in Section 1.1, all living organisms contain certain macromolecules, primarily proteins, nucleic acids, lipids, and carbohydrates (see Table 1.1). These macromolecules, in turn, are composed primarily of carbon (C), nitrogen (N), phosphorus (P), sulfur (S), oxygen (O), and hydrogen (H). Cells also require several elements that are not major components of macromolecules. Potassium, sodium, magnesium, calcium, and iron (K^+, Na^+, Mg^{2+}, Ca^{2+}, and Fe^{2+} or Fe^{3+}) are the most abundant cations in microbial cells. Chloride (Cl^-) is the major anion. The ions K^+, Na^+, and Cl^- have important functions in controlling osmotic balance and in charge-dependent interactions with macromolecules. Adenosine triphosphate (ATP) associates with Mg^{2+}, which also is a key component of many enzymes and protein-nucleic acid complexes, such as the ribosome. DNA polymerases require Mg^{2+} or Mn^{2+} as a cofactor for their activity.

Several enzymes and cytochromes, the membrane-bound electron transfer proteins that have critical roles in energy metabolism, require iron for their activity. Despite its importance, iron frequently is limiting for growth in natural habitats, where soluble iron can be in short supply. The mammalian body goes to great lengths to sequester iron in tightly bound protein complexes, both to minimize iron toxicity and to keep it away from microbial pathogens.

CONNECTIONS Because free iron typically is in short supply, many pathogens possess siderophores—iron-binding proteins. Additionally, many pathogens possess specific mechanisms for getting iron from their hosts. We will explore some of these processes in **Section 21.1**.

Finally, various **micronutrients**, such as zinc, cobalt, molybdenum, copper, and manganese (Zn^{2+}, Co^{2+}, Mo^+, Cu^{2+}, and Mn^{2+}), also are needed for microbial growth. Certain enzymes and electron transfer protein complexes require small amounts of these metals. Most microorganisms need so little of these metals that they often are not intentionally added to culture media. The organism's needs are supplied as these elements contaminate other chemicals used to make media, or leach from glass culture vessels.

To grow microorganisms in the laboratory, we must make the appropriate nutrients available in the appropriate forms. In Section 6.2, we will examine various ways of cultivating bacteria. In this section, though, we first will examine how microorganisms naturally acquire these nutrients. Then, we will explore how microorganisms acquire energy. Finally, we will investigate the electron sources utilized by various microorganisms.

Acquisition of nutrients

Because carbon is the most abundant element in biological macromolecules, acquiring carbon and incorporating it into macromolecules is critical for a growing cell. The general process by which cells import a molecule and incorporate it into cellular constituents is called **assimilation**. **Autotrophs** assimilate carbon from inorganic sources. They convert the carbon present in molecules such as carbon dioxide (CO_2) into organic molecules (**Figure 6.1**), a process known as **carbon fixation**. Autotrophic organisms generate most of Earth's biomass. Additionally, as we saw in Section 1.3, these autotrophic organisms generally are responsible for the oxygen-rich atmosphere

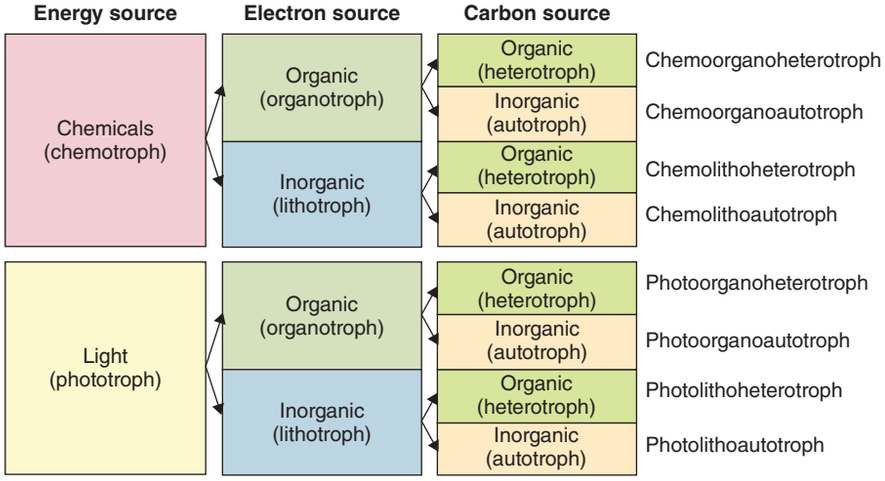

Figure 6.1. Energy, electron, and carbon sources for metabolism Metabolic types of organisms are categorized on the basis of how they obtain their energy, electrons, and carbon. We should note, though, that some microorganisms can be metabolically versatile, using different energy, electron, and carbon sources at different points in time, depending on growth conditions.

that we have today. **Heterotrophs** cannot assimilate carbon from inorganic carbon molecules. They must obtain it in a preexisting organic form (see Figure 6.1). Heterotrophic microorganisms have evolved to acquire carbon from many kinds of molecules—carbohydrates, amino acids, lipids, organic acids, alcohols, and more. It's worth noting, too, that many bacteria exhibit remarkable metabolic diversity. The Gram-negative bacterium *Rhodospirillum rubrum*, for example, can function as an autotroph or a heterotroph, depending on environmental conditions. Because of this metabolic diversity, we see microorganisms growing in every conceivable habitat on Earth.

CONNECTIONS Microorganisms can be categorized on the basis of how they obtain carbon, energy, and electrons. These metabolic categories are described in **Section 13.2** and summarized in **Table 13.1**.

Nitrogen also is abundant in biological macromolecules, and actively growing microorganisms must acquire it in a usable form. As we will see in Section 13.7, certain microorganisms can convert dinitrogen gas (N_2) present in the atmosphere into ammonia (NH_3), through a process known as nitrogen fixation. Other organisms assimilate nitrogen in the form of ammonia (NH_3). Still other microorganisms assimilate nitrate (NO_3^-) and nitrite (NO_2^-), which they then convert to ammonia. Once a cell obtains NH_3, through any of these avenues, it can incorporate the nitrogen into the amino acids glutamate and glutamine **(Figure 6.2)**. These molecules can serve as the precursors for the generation of other amino acids and additional molecules that contain nitrogen.

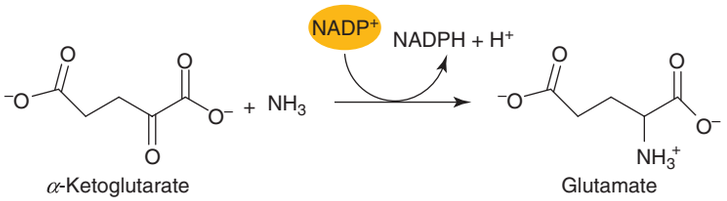

Figure 6.2. Incorporation of ammonia into amino acids Nitrogen can be incorporated into organic molecules through the combination of ammonia (NH_3) with α-ketoglutarate, resulting in the formation of the amino acid glutamate. This amino acid can serve as a precursor for the biosynthesis of other amino acids.

Acquisition of energy

In addition to acquiring nutrients such as carbon and nitrogen for building new biomolecules, cells need energy to drive their metabolism. Microorganisms acquire energy in various ways. As we will see in Section 13.6, **phototrophs** (see Figure 6.1) capture light energy, or photons, to generate chemical energy such as ATP. This ATP, in turn, is used for metabolic processes. Many phototrophs, including certain bacteria, eukaryal algae, and green plants, use the energy generated from phototrophy for carbon fixation, incorporating CO_2 into biological molecules, such as carbohydrates. This two-step process is known as photosynthesis.

In contrast to phototrophs, **chemotrophs** acquire energy through the oxidation of reduced organic or inorganic compounds that they have acquired from the environment. In many cases where organic molecules are used as a source of energy, the same molecule serves as both the carbon and energy source. A good example is glucose, which heterotrophic microorganisms break down through glycolysis and the tricarboxylic acid cycle to provide essential precursors for the synthesis of macromolecules and for powering the production of ATP (see Figure 13.11). Glucose is a common constituent in synthetic media meant for the culture of a wide variety of heterotrophic microorganisms.

Electron sources

In addition to nutrients and a source of energy, all microorganisms require an appropriate source of electrons. Electron donors, or reducing agents, are needed for biochemical oxidation and reduction reactions, which will be covered in Chapter 13. **Organotrophs** acquire electrons from organic molecules, such as glucose (see Figure 6.1). **Lithotrophs** (literally, rock eaters) remove electrons from inorganic reduced molecules, such as ferrous iron (Fe^{2+}), elemental sulfur (S^0), hydrogen gas (H_2), hydrogen sulfide (H_2S), ammonium (NH_4^+), and nitrite (NO^{2-}). Lithotrophic bacteria and archaea make substantial contributions to biogeochemical cycling of sulfur, nitrogen, and other elements, as we will see in Chapter 14.

6.1 Fact Check

1. What roles do ions play in cells?
2. Contrast autotrophic and heterotrophic organisms.
3. From what sources can organisms acquire electrons?
4. How might understanding the natural growth requirements of a microorganism help a researcher?

6.2 Factors affecting microbial growth

How do nutritional and environmental factors affect microbial growth?

Microbial growth rate and yield are determined by the interaction of environmental factors, both physical and chemical, and the genetically encoded traits of an organism. To grow and divide, all organisms must acquire nutrients and use them to build biomass. They also must extract usable energy from their surroundings to drive chemical reactions. The growth of a microorganism in any environment depends on whether, and how quickly, it can capture the necessary nutrients and energy sources. The chemical composition of the environment determines nutrient availability, and can affect cell structure and function. Physical parameters such as temperature, pressure, and illumination also can affect cell structure and function and thereby influence growth rates. In this section, first we will explore how nutritional factors affect microbial growth. Then we will investigate the effects of chemical and physical factors, such as oxygen availability and pH, on microbial growth.

Effects of nutritional factors on microbial growth

When a molecule enters the cytoplasm of a cell, it may contribute to growth if it is used to synthesize cellular components, or it may contribute to ATP production. It may provide another useful function, such as serving as an enzyme cofactor or enhancing the stability of the cell membrane. Ultimately, though, the rate at which a cell can acquire critical nutrients, process them into macromolecular building blocks, and then assemble essential macromolecules determine the cell's growth rate. Before it can divide, a cell must (1) fully duplicate its genome and (2) approximately double its mass, which is largely composed of proteins, nucleic acids, lipids, and carbohydrates. If these tasks are not executed fully and faithfully, then progeny cells will not receive the complete repertoire of genetic information or cellular machinery, or cell size will decrease steadily every generation. Neither result would be sustainable. As a result, cells have regulatory mechanisms linking replication and cell growth to cell division, thereby making sure these critical processes work together.

Nutrient Type

The types of nutrients a microorganism can access profoundly affect its growth rate and yield. **Prototrophs** can synthesize all necessary cellular constituents from a single organic carbon source and inorganic precursors. These organisms possess biosynthetic pathways to build all the macromolecular precursors they need. In contrast, an **auxotroph** cannot build all the precursors that it needs. Rather, certain organic precursors must be acquired from the environment. The growth of these organisms is limited to environments in which the appropriate organic molecules can be found. Determining what nutrients an organism requires **(Toolbox 6.1)** can improve greatly our understanding of the natural ecology of a microorganism.

Although prototrophic organisms can grow in areas with low concentrations of organic nutrients, growth in such habitats is typically slow, or at least slower than in a more organic-rich environment. Why? Synthesis of macromolecular precursors such as amino acids "from scratch," using nitrogen from ammonia and carbon derived from glucose, costs significantly more ATP than using preformed amino acids taken up from the environment. Cells that import amino acids can devote their energy to simply linking them together into proteins. In contrast, a cell that cannot import amino acids must use a great deal of energy, carbon, and nitrogen to synthesize them. The net result is less protein assembled per unit of energy expended and less cellular material produced per unit time.

CONNECTIONS *Plasmodium falciparum*, the eukaryal microbe that causes malaria, cannot manufacture certain nucleosides, important precursor components of DNA. Instead, it possesses a well-characterized mechanism for importing nucleosides from host cells. We will discuss this process in **Section 23.1**.

Nutrient Concentration

Within certain limits, growth rate is sensitive to the concentrations of key nutrients in the environment **(Figure 6.3)**. If the concentration of a critical nutrient is low, then one or more biochemical pathways may operate at less than their maximal potential. The growth rate of the microorganism, as a result, will be less than maximal. To illustrate the relationship between growth rate and nutrient concentration, consider an experiment in which a bacterium such as *Escherichia coli* is inoculated into a medium lacking a carbon source. The initial growth rate would be 0. Glucose is added to the medium at progressively higher concentrations, and the growth rate is measured to generate the curves in Figure 6.3. The growth rate initially increases proportionally to glucose concentration, but this relationship breaks down as the growth rate approaches a maximum. Once the bacteria are dividing as

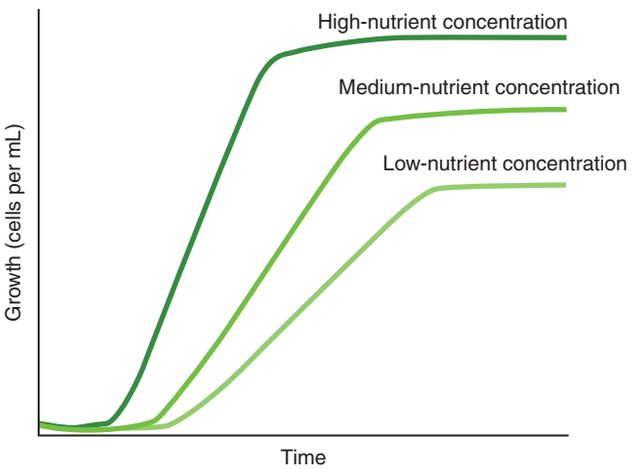

Figure 6.3. Effect of nutrient concentration on growth Increases in nutrient concentrations lead to increases in the growth rate of microbial cells. At high-nutrient levels, growth rate reaches a maximum determined by the rate at which cells can acquire nutrients, the efficiency with which they can use those nutrients, and the space available for cells to occupy.

Toolbox 6.1

PHENOTYPE MICROARRAYS FOR EXAMINING MICROBIAL GROWTH

When investigating a particular microorganism, a microbiologist may want to explore its physiology, such as its ability to metabolize various nutrient sources. Testing potential growth substrates can be very tedious, but the Phenotype MicroArrays (Biolog, Hayward, CA), shown in **Figure B6.1**, allow microbiologists to easily and systematically determine whether a microorganism can utilize hundreds of potential carbon, nitrogen, phosphorus, and sulfur sources. Phenotype MicroArrays also can be used to examine the ability of an organism to tolerate a wide range of chemically distinct environments.

How do Phenotype MicroArrays work? The system starts with a solution containing a standard set of nutrients that support the growth of most commonly cultivated bacteria and fungi. The medium is supplied in a dehydrated form in 96 well plates. To test the ability of a heterotrophic microorganism to utilize various carbon sources, we use a set of plates in which each well contains a different carbon source, along with the basal medium supplying N, P, S, and micronutrients. One of the wells on each plate has no carbon source added, and serves as a negative control. Two different carbon source plates allow the researcher to examine the ability of a microorganism to use 190 different organic compounds. Another plate tests nitrogen sources, and yet another tests phosphorus and sulfur utilization. Additional plates can be used to examine the effects of varying pH, solute concentration, and the presence of potential growth inhibitors in the medium.

To use these plates, a sample of the microorganism being tested is suspended in inoculating fluid and added to each well. The plates are covered and incubated at the organism's preferred temperature. The standard inoculating fluid contains a tetrazolium dye that can be reduced by the electron transport systems of many species. During active metabolism, as electrons flow through the membrane-bound electron transport system, some of the electrons are diverted to dye molecules. Reduction of the dye generates an intense color that can be monitored in a spectrophotometer. By using an electron-sensitive dye like tetrazolium, the investigator can determine if active metabolism is occurring in the wells, even if growth is quite slow.

Phenotype MicroArrays have many uses. They allow a broad assessment of the metabolic capabilities and environmental tolerances of an organism. Is an organism versatile in its nutritional requirements, or finicky? Does it prefer sugars, amino acids, lipids, or other carbon compounds? To what sorts of chemical and environmental conditions can it adapt? Such information can provide insight into the environments in which the microorganism might live, or may be used to improve laboratory media upon which it can grow. It also can provide support for metabolic predictions based on annotated genes in a sequenced genome, a topic that will be discussed further in Chapter 10. Finally, for microorganisms that can be genetically manipulated, Phenotype MicroArrays can be valuable for broadly assessing the effects of mutations on physiology and stress responses.

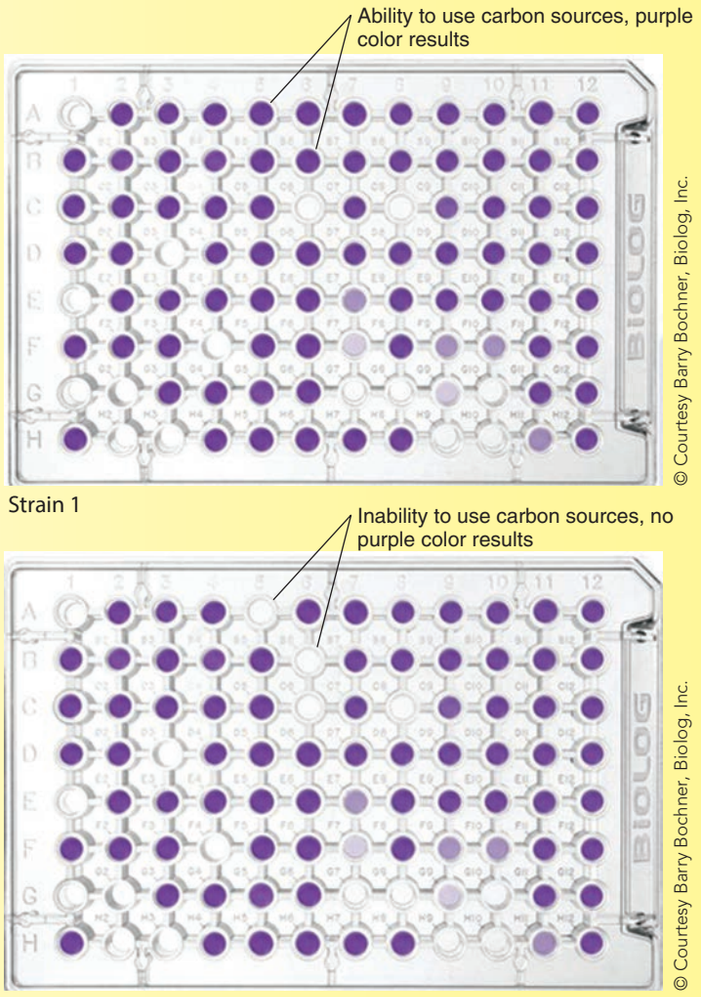

Figure B6.1. Analyzing metabolic properties with the Phenotype MicroArray Two strains of a bacterium were added to wells of Phenotype MicroArray plates to examine their metabolic properties. Cellular activity in a well leads to a purple color change. In the absence of cellular metabolism, wells remain clear. As seen in this example, these strains differed in their ability to grow under two different conditions. Strain 1 grew in the two highlighted wells, but Strain 2 did not.

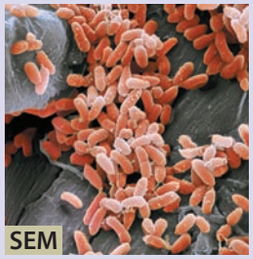
Test Your Understanding

You isolate two new species of bacteria. It appears that one of these newly discovered microorganisms thrives in many different environments. The other one, in contrast, seems to grow only in a limited number of environments. You test both with a Phenotype MicroArray. Predict your results.

Microbes in Focus 6.1
THE METABOLIC DIVERSITY OF *PSEUDOMONAS AERUGINOSA*

Habitat: Normal inhabitant of soil and water, occasionally found on the skin of various animals. A noted opportunistic pathogen of humans, often causing respiratory disease in people living with cystic fibrosis.

Description: Gram-negative, motile rod-shaped bacterium, approximately 1.5–3.0 μm in length



© Steve Gschmeissner/Science Source

Key Features: Members of the *Pseudomonas* genus exhibit metabolic diversity. Although all are capable of aerobic respiration, pseudomonads can utilize many different organic molecules as carbon sources. Because of this metabolic diversity, members of this genus are being investigated as possible bioremediation agents given the potential of some to consume toxic waste materials.

fast as they possibly can, further increases in the nutrient concentration have no effect on growth rate.

Effects of oxygen on microbial growth

Aerobes require oxygen for growth. Molecular oxygen (O_2) is the only electron acceptor that can be used by their respiratory electron transport system. As we will discuss more in Chapter 13, the favorable redox properties of O_2 allow aerobic respiration to extract more energy from oxidative metabolism than any other terminal electron acceptor. In habitats where O_2 is present at substantial levels, the dominant organisms almost always will be aerobes. Organisms that absolutely depend on oxygen are called **obligate aerobes**. Obligate implies an absolute requirement. Common bacterial examples of obligate aerobes can be found in the genus *Pseudomonas*. Growth rates for most obligate aerobes are maximal at or near atmospheric O_2 concentrations and decline as the oxygen concentration decreases. Although many pseudomonads are obligate aerobes, some species, like the occasional pathogen *Pseudomonas aeruginosa* (Microbes in Focus 6.1), can use alternative electron acceptors, such as nitrate (NO_3^-).

Anaerobic growth occurs without the use of oxygen. **Aerotolerant anaerobes** do not use oxygen for respiration, but are not harmed by it. In contrast, **obligate anaerobes** cannot grow in the presence of oxygen. **Facultative anaerobes**, also sometimes called facultative aerobes, can use oxygen for respiration when it is present, but also grow in the absence of oxygen. What accounts for these differences? One important consideration is whether microorganisms possess the molecular machinery for aerobic or anaerobic metabolism. Tolerance to oxic conditions is another important consideration. Molecular oxygen can generate by-products that act as powerful oxidants capable of attacking proteins, nucleic acids, and lipids. These reactive oxygen species include superoxide, hydroxyl radical, hydrogen peroxide, and singlet oxygen, a transient high-energy form of O_2 (Table 6.1). Because reduction of O_2 during respiration generates some of these potentially dangerous by-products, aerobic microorganisms depend on multiple defenses against oxidative damage. Examples of defensive enzymes produced by aerobic microorganisms include catalases, peroxidases, and superoxide dismutases. To live in oxic habitats, even microorganisms that do not undergo aerobic respiration need defenses against toxic oxygen species generated by various biochemical and abiotic reactions. Obligate anaerobes lack adequate defenses.

Molecular oxygen is not ubiquitous in the biosphere. Many habitats have reduced O_2 levels or are completely anoxic. For example, the upper portion of the human digestive tract is oxic, largely due to swallowed air, but quickly becomes anoxic in the intestines. It is impossible for obligate aerobes to grow in the colon, so the colonic microbiota must consist of aerotolerant, facultative, and obligate anaerobes. There are several ways to grow anaerobic microorganisms in the laboratory. One approach is to evacuate the normal O_2-containing atmosphere and replace it with an artificial atmosphere lacking O_2. An alternative small-scale method employs the anaerobic jar used in many diagnostic labs (Figure 6.4). After the agar plates are placed in the bottom of the jar, the gas generator envelope is opened, and water is added to it. A chemical reaction in the

TABLE 6.1 Toxic oxygen species

Hydroxyl radical: OH·	By-products of reduction of O_2 during respiration and other biochemical redox reactions	Antioxidants such as glutathione
Hydrogen peroxide: H_2O_2		Catalase and peroxidase enzymes

© Scott Coutts/Alamy

Figure 6.4. Anaerobic culture system simple sealed container, an anaerobic jar, can be used for cultivating anaerobic microorganisms on agar plates. Chemical reactions within the jar consume virtually all of the O_2, creating an anoxic environment.

envelope generates hydrogen (H_2) and carbon dioxide (CO_2) gases, which escape into the atmosphere of the jar. At this point, the jar is sealed. An airtight gasket prevents atmospheric O_2 from entering and all O_2 in the jar is converted to water by reacting with H_2 gas in the presence of a palladium catalyst.

Microaerophiles show maximal growth rates at O_2 concentrations lower than are typically present in the atmosphere. These species are adapted to relatively stable zones where O_2 is depleted by microbial growth and diffusion of atmospheric O_2 is restricted. Microaerobic habitats can be found in dense soils, aquatic sediments, and relatively deep marine or freshwater zones. An example of a microaerophile is *Magnetospirillum*, the magnetotactic bacterium we introduced in Chapter 2 (see Perspective 2.1).

Effects of pH on microbial growth

The term "pH" expresses the hydrogen ion activity, or concentration of H^+ ions, of a solution. The pH scale is an inverse logarithmic function ($pH = -\log[H^+]$), ranging from 0 to 14. Pure water at 25°C has a pH of 7, which is defined as neutral pH. Solutions with pH values less than 7 are acidic. Solutions with pH values greater than 7 are alkaline, or basic. Because pH is a log function, a solution with pH = 6 has a tenfold higher H^+ concentration than a solution with pH = 7. Microbial growth rates can be affected considerably by pH. Natural habitats span a wide range of pH (Figure 6.5). In addition to affecting macromolecular structures, pH affects the transmembrane electrochemical gradients that are necessary for ATP synthesis and many transport processes.

Neutrophiles grow optimally in environments with pH close to neutrality (5.5–8.5). **Acidophiles** prefer acidic habitats (pH < 5.5). **Alkaliphile** prefer alkaline habitats (pH > 8.5) (see Figure 6.5). The most thoroughly studied acidophilic microorganisms include the lactic acid bacteria (see Section 13.1), Gram-positive bacteria of the genus *Streptococcus* and related species. These aerotolerant anaerobes generate energy through fermentation, often producing lactic acid as a primary fermentation product. Because their fermentative metabolism is so inefficient, these bacteria have many nutritional requirements and grow best in environments with high-sugar concentrations. Under these conditions, lactic acid bacteria produce abundant organic acids that can acidify the medium to pH 4–5. These bacteria often are found in anoxic habitats rich in sugars and other organic materials, such as decaying fruits and vegetables.

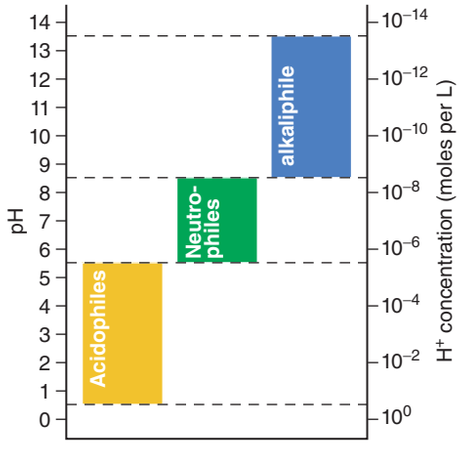

Figure 6.5. Effects of pH on microbial growth The pH scale ranges from extreme acidity (*bottom*) to extreme alkalinity (*top*). Microorganisms can be categorized as acidophiles, neutrophiles, or alkaliphile, based on their pH preferences.

CONNECTIONS Although some lactic acid bacteria may be associated with rotting fruit, other lactic acid bacteria are used in the production of foods. As we will see in **Section 16.3**, various lactic acid bacteria are used in the production of cheeses, sour cream, and yogurt.

Even though geochemical processes determine the pH of many habitats, microorganisms also can play an active role in altering the pH of their environment. In Chapter 3, the extremely acidic environment (pH 1.5–3) of the Rio Tinto results from the metabolism of lithotrophic bacteria such as *Acidithiobacillus ferrooxidans* that oxidize pyrite (FeS_2) and ferrous iron (Fe^{2+}), and in the process release sulfuric acid (H_2SO_4), a strong acid. This process contributes greatly to acid drainage from thousands of abandoned flooded mines around the world.

CONNECTIONS As we have seen in this section, pH can affect the growth of microorganisms. Changes in the pH of an environment affect the microbial inhabitants of a location. In **Perspective 14.4**, we will examine in more depth the effects of pH changes caused by acid mine drainage, and in **Section 15.4** we will examine how soil pH is the most important determinant of soil microbial community diversity and composition.

Effects of osmotic pressure and water availability on microbial growth

Microorganisms inhabit environments with a wide range of solute concentrations. Because cells have semi-permeable membranes, a difference in solute concentration between the cytoplasm and the surrounding environment causes water to move in or out of the cell (see Figure 4.21). If solute concentrations are higher in the cytoplasm as, for example, for microorganisms living in freshwater habitats with low levels of dissolved salts and organics, net water flow will be into the cell, resulting in pressure outward against the cell envelope. It is common for microorganisms to maintain higher solute concentrations in their cytoplasm than in the surrounding environment, so some osmotic pressure is normal. Membranes have some flexibility for expansion, but ultimately a rigid cell wall, whether peptidoglycan in bacteria or chitin or cellulose in eukaryal microorganisms, is critical for withstanding osmotic pressure.

CONNECTIONS The cytoplasm of the halophilic archaeon *Halobacterium salinarium* contains high levels of potassium, which provides the cell with osmotic balance against high-salt concentrations. Additional adaptations to life in salty environments are discussed in **Section 4.3**.

Osmotic pressure is closely affiliated with water availability. For microorganisms to grow, water must not only be present, it also must be accessible. To determine the availability of water, researchers may calculate the **water activity (a_w)** of an environment. This term refers to the vapor pressure of a liquid relative to the vapor pressure of pure water under identical conditions.

Pure water, then, has a water activity of 1.0. When solutes are added to water, they decrease the vapor pressure of the liquid. As a result, the a_w decreases. The a_w of seawater is approximately 0.98. The a_w of honey is approximately 0.6. To grow, most bacteria require an a_w of greater than 0.9. Fungi, in contrast, can be more tolerant of low water activity, which helps to explain the common observation of moldy bread or fungal growth on the surface of jams. The relationship between water activity and food spoilage is discussed more thoroughly in Section 16.1.

Effects of temperature on microbial growth

As we discovered in Section 4.3, microorganisms inhabit environments with a wide range of temperatures. Mesophiles grow at temperatures that we consider "normal"—between 10°C and 40°C. Psychrophiles grow at temperatures below 10°C **(Figure 6.6)**. Thermophiles and hyperthermophiles grow optimally at temperatures above 55°C and 80°C, respectively. What cellular or molecular factors determine temperature tolerance? First, remember that temperature affects the rate of chemical reactions. Increasing temperature raises the thermal energy of molecules, making them more likely to react. Decreasing temperature lowers the available energy. So, in a broad sense, we could expect growth to slow as temperature declines below an organism's optimal growth temperature, as biochemical reactions slow.

Biochemical reactions in cells are not simply reactions between free molecules. Enzymes, complex molecules whose conformations are affected by temperature, catalyze the reactions. Protein folding and activity are important determinants of the upper and lower temperature boundaries of an organism. At lower temperatures, proteins fold more slowly, and dynamic changes in structure that may be necessary for proper function are restricted. Conversely, at higher temperatures, the effects of thermal energy may overcome some of the weaker chemical interactions that help to stabilize protein structure. The cumulative effects of such structural disruptions can change a finely tuned enzyme structure into a non-functional polypeptide chain. Between the upper and lower temperature boundaries lies the temperature range at which an organism's enzyme set has evolved to function at or near maximal efficiency.

Figure 6.6. The psychrophilic alga *Chlamydomonas nivalis* The bright red pigment astaxanthin is concentrated in the spores of this alga and produces a pinkish tinge to snow, known as "watermelon snow." The alga thrives in cold environments, such as glaciers and snow-covered mountain peaks. Astaxanthin is produced under conditions of low nitrogen and high ultraviolet (UV) light. The pigment aids in resistance to UV light damage.

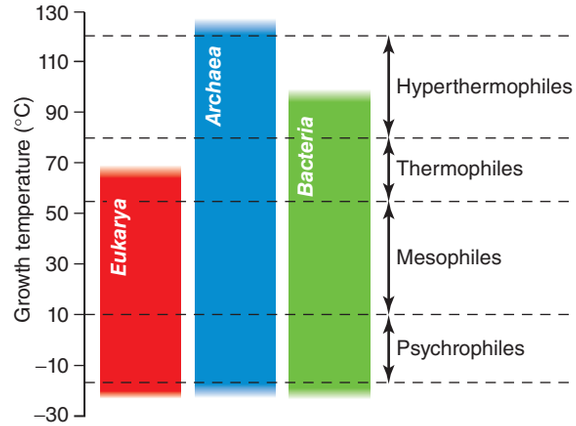

Figure 6.7. Acceptable temperature ranges of organisms in the three domains Growth at elevated temperatures is quite rare among eukaryal organisms. It is more common among bacteria and archaea.

Fluidity of the membrane bilayer also is affected by temperature. Fluidity decreases as the temperature drops. The progressive "freezing" of a membrane can affect critical transmembrane processes negatively, such as nutrient transport, electron transport, and maintenance of electrochemical gradients. A bilayer richer in unsaturated lipids will maintain a higher degree of fluidity at low temperatures than a membrane that is richer in saturated lipids, which pack more tightly. The organization and structural integrity of a membrane bilayer, including its constituent proteins, can also break down at high temperatures. Because the effects of both low and high temperatures on membranes are somewhat dependent on lipid composition, many microorganisms actively adjust lipid composition in response to temperature. Differences in the temperature extremes to which bacteria, archaea, and eukarya can adapt **(Figure 6.7)** may relate to differences in membrane lipid composition.

CONNECTIONS As we discussed in **Section 4.2**, the plasma membranes of some archaea contain tetraether-linked glycophospholipids. These lipids generate a membrane monolayer with enhanced thermostability. Membranes of hyperthermophilic archaea are greatly enriched in such molecules.

6.2 Fact Check

1. How do prototrophic and auxotrophic organisms differ?
2. What are the advantages and disadvantages of growing in an oxygen-rich environment?
3. Why does growing in a salty environment pose a challenge?
4. Name a couple of cellular components or processes that may be affected by changes in temperature.

6.3 Growing microorganisms in the laboratory

How can different types of microorganisms be grown in the laboratory?

As we have seen in the preceding sections, different microorganisms have different physicochemical requirements for growth. Different species grow at different temperatures and utilize different carbon sources, to provide just two examples. To grow a specific microorganism in a laboratory setting, we must understand the growth requirements of that species and also adequately recreate those requirements in the laboratory. In this section, we will examine how we can grow microorganisms. We will focus our exploration of this topic on four main areas. First, we will discuss properties of general microbial media. Second, we will examine the interesting features and uses of some specialized media. Third, we will look at techniques used for isolating pure cultures. Finally, we will investigate how we can characterize organisms that we currently cannot grow in the laboratory.

Media for microbial growth

In the laboratory, **growth medium** consists of a combination of organic and inorganic materials designed to support the growth of microorganisms. Growth media can be prepared in either liquid or solid forms. Liquid growth medium, sometimes referred to as broth, contains dissolved nutrients. A solid growth medium usually contains the same nutrients as liquid medium, but with the addition of a solidifying agent. Today, **agar** is the most commonly used solidifying agent; agar is a polysaccharide purified from red algae (Figure 6.8).

Purified dehydrated agar, typically at a final concentration of 1.5 percent, is mixed with water and other media components. When this solution is heated to a high temperature, the dehydrated agar melts. The high temperature also destroys most, if not all microbes present in the solution, thereby sterilizing it. When this molten agar begins to cool, it typically is poured into Petri dishes. The molten agar will transition to a solid gel when the medium cools to around 40°C. This solidified, hydrated agar provides a smooth, firm, and moist surface on which microorganisms can grow. If the medium contains the nutrients a microorganism needs, and other environmental conditions are acceptable, a cell deposited on the agar surface will divide repeatedly to produce a **colony**, a mound of clonal cells that grows large enough to be seen without a microscope (Figure 6.9).

Pathogenic microorganisms generally are adapted to the complex mix of nutrients available in or on a host organism. In the laboratory, pathogens often prefer, or even require, a rich medium with abundant sugars, amino acids, and vitamins. Media used in clinical laboratories to grow bacteria such as *Neisseria meningiditis* and *Streptococcus pneumoniae*, two species that can cause meningitis, contain blood, in part because hemoglobin is a good source of amino acids and iron. A medium containing blood is considered a **complex medium**, because the chemical components of the medium are not precisely defined in identity or concentration. Other common components of complex media include yeast extract composed of hydrolyzed yeast cells and beef extract composed of beef muscle tissue that has been soaked and boiled and the soluble components extracted. Both of these preparations are rich in amino acids, nucleosides, and various minerals. Peptone is prepared from acid hydrolysis of casein, the major protein in milk, and tryptone is prepared from trypsin treatment of casein. Both are rich in amino acids and peptides. By contrast, the chemical identity and concentration of all of the constituents is known for a **defined medium**. Table 6.2 compares the makeup of a complex medium (lysogeny broth, or LB) and a defined medium (M9), both of which can be used for the growth of *Escherichia coli*.

Specialized media

In some cases, the general media that we have just described may not be sufficient. A researcher, for example, may want to cultivate bacteria under conditions in which some types of bacteria will grow, but not others. Alternatively, a researcher may

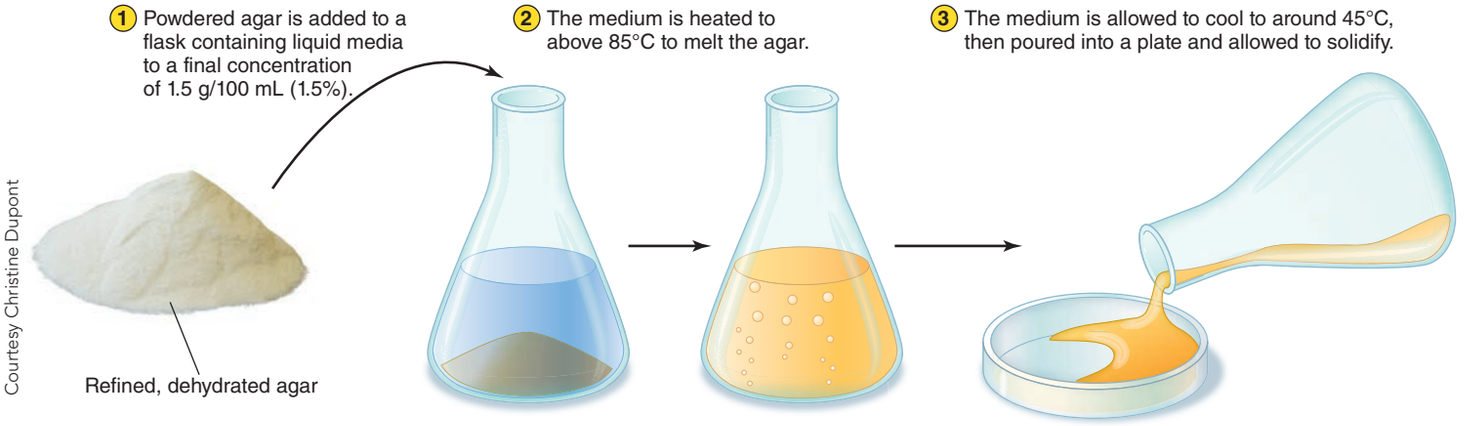

Figure 6.8. Process Diagram: Making agar plates to support microbial growth Agar is a purified polysaccharide used as a solidifying agent for solid media. Dehydrated agar powder is added to microbiological nutrient growth media, typically at a final concentration of 1.5 percent. Following melting, the agar cools to form a stable gel.

C. Variations in form, texture, elevation, and color

Figure 6.9. Colony growth on agar media When plated on an appropriate nutrient agar, microorganisms will grow, eventually forming a colony that is visible to the naked eye. Each colony is derived from a single cell deposited on the agar surface. **A.** Many microorganisms, including *E. coli* shown here, form compact circular colonies on the surface of agar plates. **B.** Some microorganisms, particularly fungi shown here, and soil bacteria, such as the actinomycetes, form colonies composed of filaments that spread across the surface of the agar. **C.** Colonies can have a variety of morphologies and colors. Note that colony morphology is not usually a reliable characteristic for identification.

want several types of bacteria to grow, but be able to distinguish one type of bacterium from another. Perhaps the researcher wants to grow a mixture of bacteria under conditions that allow one specific type to grow more rapidly than other types. In all of these scenarios, to borrow a phrase, there's a medium for that (Table 6.3).

Selective Media

Clinical samples, like samples from any natural habitat, often contain many different species of microorganisms with different growth needs and traits. A scientist interested in one particular type of microorganism could use a **selective medium** designed to allow the growth of only certain target organisms. Selective media could have a limited set of nutrients, an unusually acidic or alkaline pH, unusual solute concentrations, or other chemical components that limit the growth of non-target species. A good example is a medium that contains one or more antibiotics, so that only resistant microorganisms can grow.

Selective media are quite useful in the cultivation of several human pathogens, like *Bordetella pertussis* (Microbes in Focus 6.2),

TABLE 6.2 Complex and defined media for growing *Escherichia coli*

LB broth (per liter)		M9 minimal salts broth (per liter)	
Peptone	10 g	$C_6H_{12}O_6$	2 g (11 mM)
Yeast extract	10 g	Na_2HPO_4	6 g (42 mM)
NaCl	5 g	KH_2PO_4	3 g (22 mM)
(pH adjusted to 7.0)		NaCl	0.5 g (9 mM)
		NH_4Cl	5 g (93 mM)
		$MgSO_4$	1 mM
		$CaCl_2$	0.1 mM
		(pH adjusted to 7.0)	

Microbes in Focus 6.2

A PICKY EATER—*BORDETELLA PERTUSSIS*

Habitat: Respiratory tract of humans

Description: Gram-negative, rod-shaped bacterium, approximately 0.8 μm in length. Expresses several virulence factors.

Key Features: This bacterium causes whooping cough (pertussis), a potentially severe respiratory disease. The availability of an effective vaccine has decreased dramatically the number of cases in developed countries, but it remains a major problem worldwide. It is a fastidious organism and typically is cultivated in the laboratory on solid medium supplemented with horse or sheep blood.

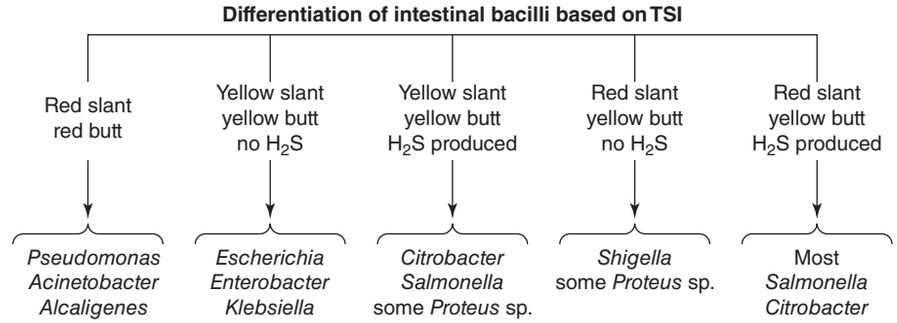
TABLE 6.3 Common specialized media

Medium	Organism(s) identified	Selectivity and/or differentiation achieved
Brilliant green agar  © Fancy/Alamy Limited	*Salmonella*	**Selective** Brilliant green dye inhibits Gram-positive bacteria and thus selects for Gram-negative bacteria. **Differential** Differentiates *Shigella* colonies (which do not ferment lactose or sucrose and are red to white) from other organisms that do ferment one of those sugars and are yellow to green.
Eosin methylene blue agar (EMB)  © Courtesy Christine Dupont	Gram-negative enterics *Enterobacteriaceae*	**Selective** Medium partially inhibits Gram-positive bacteria. **Differential** Eosin and methylene blue differentiate among organisms: *Escherichia coli* colonies are purple and typically have a metallic green sheen; *Enterobacter aerogenes* colonies are pink, indicating that they ferment lactose; and colonies of other organisms are colorless, indicating they do not ferment lactose.
MacConkey agar  © Courtesy Christine Dupont	Gram-negative enterics	**Selective** Crystal violet and bile salts inhibit Gram-positive bacteria. **Differential** Lactose and the pH indicator neutral red (red when acidic) identify lactose fermenters as red colonies and non-fermenters as white or tan. Most intestinal pathogens are non-fermenters and hence do not produce acid.
Triple sugar-iron agar (TSI)  © Courtesy David Wessner  © Courtesy David Wessner	Gram-negative enterics	**Not Selective** **Differential** Used in agar slants (tubes cooled in slanted position), where differentiation is based on both aerobic surface growth (slant) and anaerobic growth in agar at base of tube (butt). Medium contains specific amounts of glucose, sucrose, and lactose, sulfur-containing amino acids, iron, and a pH indicator, so relative use of each sugar and H_2S formation can be detected. **1** Uninoculated tube of TSI. **2** Inoculated: red slant and red butt = no change; no sugar fermented. **3** Yellow slant and yellow butt = lactose and glucose fermented to acid; trapped bubbles in butt indicate fermentation to acid and gas. **4** Red slant (lactose not fermented) and yellow butt (glucose fermented to acid); black precipitate = H_2S produced; sometimes obscures yellow butt. Almost all enteric pathogens produce red slant and yellow butt, with or without H_2S and/or gas.



the cause of whooping cough, and *Neisseria meningitidis*, a potential cause of meningitis. Both of these species require highly nutrient-rich media, but grow so slowly that other bacteria and fungi easily overwhelm them. To avoid this conundrum, clinicians often streak *N. meningitidis* on a selective medium, often referred to as Thayer Martin medium, that contains four antibiotics: nystatin, vancomycin, colistin, and trimethoprim. Nystatin kills most fungi, and vancomycin kills most Gram-positive bacteria. Colistin and trimethoprim are effective against many Gram-negative bacteria, except for *Neisseria*. Trimethoprim is added especially to kill *Proteus* bacteria, Gram-negative bacteria that also happen to be resistant to colistin. In the presence of these antibiotics, *Neisseria* have a chance to grow and be detected. This specialized medium, in other words, allows researchers to grow *Neisseria* species selectively.

Another important application of selective media in the clinical laboratory involves the isolation of possible pathogens from fecal specimens that can contain hundreds of species of bacteria. A clinician interested in determining whether a patient harbors diarrheal pathogens such as bacteria of the genera *Salmonella* or *Shigella* might streak a fecal sample on a selective medium that allows the growth of these species, but inhibits the growth of many other genera. MacConkey agar, a complex medium, is selective because it contains bile salts, steroid-derived compounds that mammals secrete in the small intestine to emulsify, or break up, fats and promote digestion. Bile salts also disrupt membranes and are inhibitory to most microorganisms, but many intestinal bacteria and Gram-negative pathogens have developed resistance to these detergents. This medium allows for the selective growth of *Salmonella* and *Shigella* species.

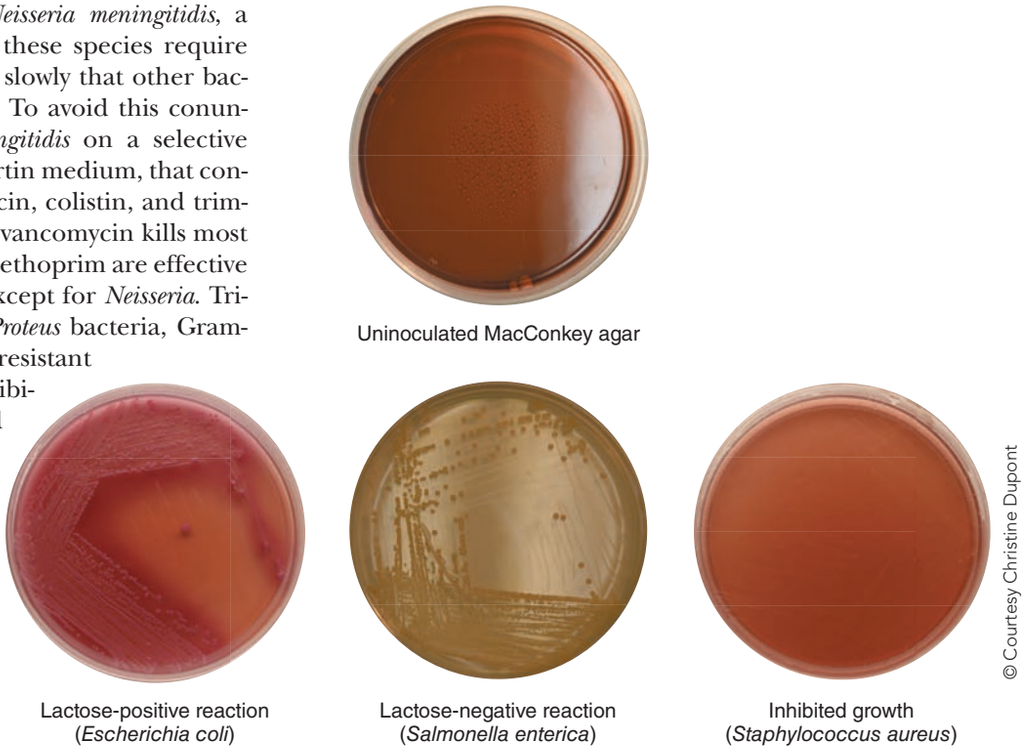


Figure 6.10. Growth on selective and differential media MacConkey agar is both selective and differential. Bile salts and crystal violet dye inhibit the growth of most Gram-positive bacteria, such as *Staphylococcus aureus*. As a result, this medium selects for Gram-negative bacteria. Because of the presence of lactose and the pH-sensitive dye neutral red in this medium, it also can be used to differentiate between lactose-fermenting and non-fermenting bacteria. Bacteria such as *Escherichia coli* ferment lactose and generate acids that lower the pH and convert the dye to its red form. As a result, colonies of lactose-fermenting bacteria appear dark red. Colonies of bacteria that cannot ferment lactose, like *Salmonella enterica*, appear white, gray, or tan.

Differential Media

Whereas selective media allow researchers to cultivate one or more types of bacteria selectively, a **differential medium** allows a researcher to distinguish between two, often related, types of bacteria. We already have been introduced to a differential medium. Indeed, MacConkey agar, the selective agar that we just discussed, also allows some important species to be differentiated by colony color **(Figure 6.10)**. On MacConkey agar, *Escherichia coli* colonies are red because *E. coli* ferments lactose to produce acid, which lowers the pH and causes an indicator dye in the medium to turn red. In contrast, *Salmonella* and *Shigella* species do not ferment lactose and, as a result, produce white or tan colonies. *E. coli* is part of the normal intestinal microbiota, whereas *Salmonella* and *Shigella* are not normally present in the gastrointestinal tract. The clinician would like these related bacteria to be visually contrasted on plates. MacConkey agar, then, is both selective and differential.

Blood agar is an example of a rich medium that is differential, without being particularly selective. In other words, many organisms can grow on the medium, but some can be specifically recognized. The differential property derives from the ability of some microorganisms to release enzymes called hemolysins that attack the cytoplasmic membrane of the red blood cells suspended in the medium, causing the cells to lyse. This hemolysis creates either a clear or a greenish zone around the bacterial colony **(Figure 6.11)**. Hemolytic activity on blood agar is particularly useful for differentiating species of the genus *Streptococcus* (see Figure 21.12). Hemolytic activity is a reliable characteristic of *Streptococcus pyogenes*, a common cause of throat infections ("strep throat"), as well as a few other types of infections in humans. In contrast, other streptococci and related Gram-positive cocci cause partial or no hemolysis on blood agar. Streaking a throat swab on a blood agar plate is a useful initial diagnostic for patients suspected to have strep throat.

Enrichment Media

An **enrichment medium** is one that contains nutrients or other components designed to favor the growth of particular microorganisms. An enrichment medium differs from a selective medium in that it does not necessarily prevent the growth or survival of non-target species, usually because there is no good way to selectively inhibit these other species. Enrichment media are used to help isolate microorganisms that are rare in a population and might be overgrown by other organisms in a non-enrichment culture. If a rare microorganism

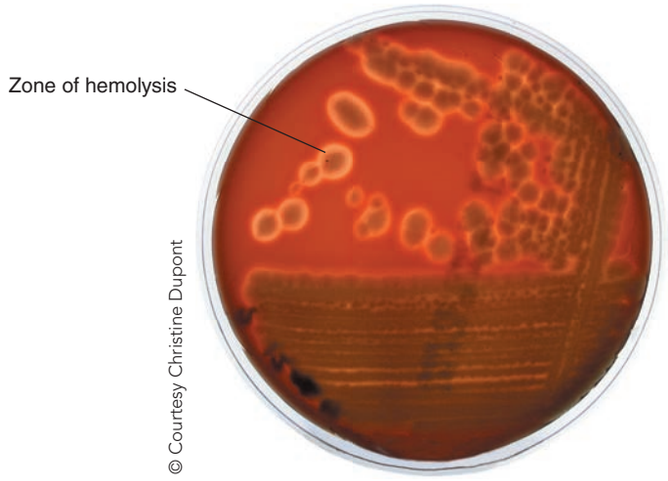

Figure 6.11. Hemolytic activity Many types of bacteria can cause lysis of red blood cells, resulting in a distinctive clear zone around the colonies when cultured on blood agar. Shown here is *Bacillus cereus* on sheep blood agar.

of interest grows better on a particular enrichment medium than other, initially more numerous microorganisms, then the concentration of the initially rare microorganism will increase over time.

CONNECTIONS Enrichment media can be used to isolate bacteria that metabolize a specific carbon source, such as oil. These bacteria, in turn, could be useful in cleaning up oil spills. The use of bacteria in this way will be discussed in **Section 15.4**.

When trying to cultivate microorganisms from environmental samples, microbiologists must recognize that every medium and incubation method is selective and/or enriching in some way. A rich medium does not make every microorganism equally likely to grow. Rich media enrich for microorganisms that are nutritionally versatile, have the fastest and/or highest capacity transport systems, and are adapted to high-nutrient fluxes. But chemicals that are used as nutrients by some species inhibit the growth of others. If we want to grow microorganisms that are adapted to very low concentrations of organic carbon or nitrogen, for example, then we can use a medium with appropriately low concentrations of these materials—as long as we recognize that these species tend to grow very slowly and plan our experiment accordingly.

Aside from nutrient composition, environmental conditions also exert powerful selective forces on microbial growth. Incubating plates under oxic conditions, in a standard atmosphere of 20 percent O_2, selects against anaerobes and microaerophiles. Incubating plates under anoxic conditions does just the opposite. As described in **Perspective 6.1**, lowering the oxygen concentration helped select the pathogen *Helicobacter pylori* from biopsies of gastric ulcers. Any given temperature will enrich for microorganisms evolutionarily optimized for that temperature, and disfavor species optimized for higher or lower temperatures. Incubating in the dark selects against obligate phototrophs. Incubating in the light can enrich the growth of phototrophs and inhibit growth of organisms with inadequate systems to repair cellular damage caused by UV light.

Obtaining a pure culture

To isolate a microorganism on a solid medium, microbiologists can produce a **streak plate** **(Figure 6.12)**. This process involves spreading microbial cells across the surface of the plate so that individual bacterial cells become spatially separated. If these cells can use the nutrients in the medium to grow and divide, then each cell eventually produces a colony (see Figure 6.9). The advantage of a solid medium is that cells are held in place. Isolated colonies should contain a single type of microorganism; all cells within the colony should be descended from a single cell. It takes millions of microbial cells piled together to form a colony that we can see without a microscope. Some microorganisms, such as *Escherichia coli* growing on a rich medium, grow fast enough to form visible colonies overnight. Other species, such as *Mycobacterium tuberculosis*, may take weeks to form visible colonies.

B. Isolated colonies after incubation

Figure 6.12. Streaking plates to isolate cells and separate colonies **A.** Petri plates containing an agar medium are divided into sectors. A loop of a culture is inoculated near the edge of the plate (Streak 1). The loop then is sterilized by flaming to kill any microorganisms remaining on it. The plate is rotated, and the sterile loop is streaked across a second sector that crosses the edge of the previous streak to transfer some cells (Streak 2). This procedure is usually repeated one (Streak 3) or two more times. The loop leaves progressively fewer cells in each sector. **B.** After the plate has been inoculated, it is incubated. Isolated colonies of bacteria should appear in the latter sectors.

Perspective 6.1
THE DISCOVERY OF *HELICOBACTER PYLORI*

In the early 1980s, Barry Marshall was a young physician working at a hospital in Western Australia with Robin Warren, a pathologist. The two men spent endless hours peering into microscopes examining biopsy samples from patients with gastritis, an inflammation of the lining of the stomach. Marshall and Warren frequently saw curved and spiral bacteria **(Figure B6.2)** associated with the gastric mucosa, the layer of mucus-secreting cells lining the stomach. This observation puzzled the researchers; bacteria rarely had been cultured from this site. The pH 2 acidity of the stomach creates a very harsh environment. Exposure to such acidity kills most microorganisms as food passes through the stomach. Could bacteria really colonize this region, and could they be a cause of gastric pathologies? If so, this would be an important discovery. A large number of people lived with debilitating ulcers, and clinicians assumed that stress, diet, and stomach acid were the sole factors involved in stomach ulcer prevalence.

Marshall attempted to culture bacteria from these biopsy specimens on rich media designed for *Campylobacter*, a genus of curved, polarly flagellated bacteria sometimes found in the human intestinal tract, which these bacteria resembled. He also reduced the oxygen concentration in the incubator to the low levels that microaerophilic *Campylobacter* prefers, but still no colonies appeared. A few days later, Marshall had an unexpected surprise when he returned from a long Easter weekend. The plates he had left in the incubator for five days now had colonies on them! Marshall and Warren initially named these slowly growing bacteria *Campylobacter pylori*. The name was later changed to *Helicobacter pylori*, as molecular evidence made it clear that, despite the morphological similarity, these bacteria are not phylogenetically aligned with the *Campylobacter* genus.

Marshall and Warren's discovery turned out to be an enormous breakthrough. Evidence has accumulated that *Helicobacter pylori* is the underlying cause of most gastric (stomach) and duodenal (intestinal) ulcers in humans. This bacterium has been linked to gastric cancers as well. Antibiotic treatment targeted at *H. pylori* is now a routine part of ulcer treatment and is much more effective than simply using drugs that block stomach acid production, as was done previously. Millions of people have benefited from this discovery, for which Marshall and Warren were awarded the Nobel Prize in Physiology or Medicine in 2005.

If Barry Marshall had not been persistent in his attempts to cultivate the bacteria he observed in the microscope, where would we be now? Vast numbers of microbial species on Earth are poorly understood because they have not been cultivated in the laboratory, although molecular tools are changing that. The *Helicobacter* story teaches us not to make too many assumptions about where microorganisms can or cannot grow—and that we must be persistent, patient, and clever in our efforts to study such organisms.

© Juergen Berger /Science Source

Figure B6.2. *Helicobacter pylori* and ulcers These spiral-shaped bacteria were observed in biopsies from patients with gastritis. These acidophilic bacteria survive the highly acidic environment of the stomach (pH 2) on their transit to colonize the more neutral tissues that line the stomach where they contribute to the development of ulcers.

Isolated colonies also can be generated by the spread or pour plate procedures **(Figure 6.13)**. First, dilutions of a bacterial culture are made. In the spread plate procedure, aliquots of each dilution are added to plates containing solidified nutrient agar. The aliquots then are spread evenly over the surface of the plate. In the pour plate procedure, aliquots of dilutions are added to tubes of melted nutrient agar. The tubes then are mixed and added to empty Petri plates. In both cases, following incubation, colonies should be evenly distributed across the plates. As we will see in the next section, this method can be used to quantify the number of bacteria in a sample.

How do these methods compare? Spreading a sample on a plate is easy and does not require molten agar at the right temperature. A defined volume of the sample simply is added to the plate and dispersed over the surface. The disadvantage of this procedure is that colonies may overlap on the surface of the agar, which makes counting difficult and error-prone. The pour plate method embeds colonies in agar, which keeps them smaller and reduces overlap, so that more discrete colonies can be counted. Microorganisms that are particularly sensitive to heat, though, might suffer some mortality after even brief exposure to molten agar.

When attempting to isolate and cultivate microorganisms in the laboratory, or measure microbial populations, researchers often use relatively rich media. After all, if the goal is rapid growth for detection, isolation, or counting, then it seems reasonable to provide lots of food, with perhaps a buffet of different menu items. This approach often works well, but there are

Black, *Microbiology: Principles and Explorations*, copyright 2012, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

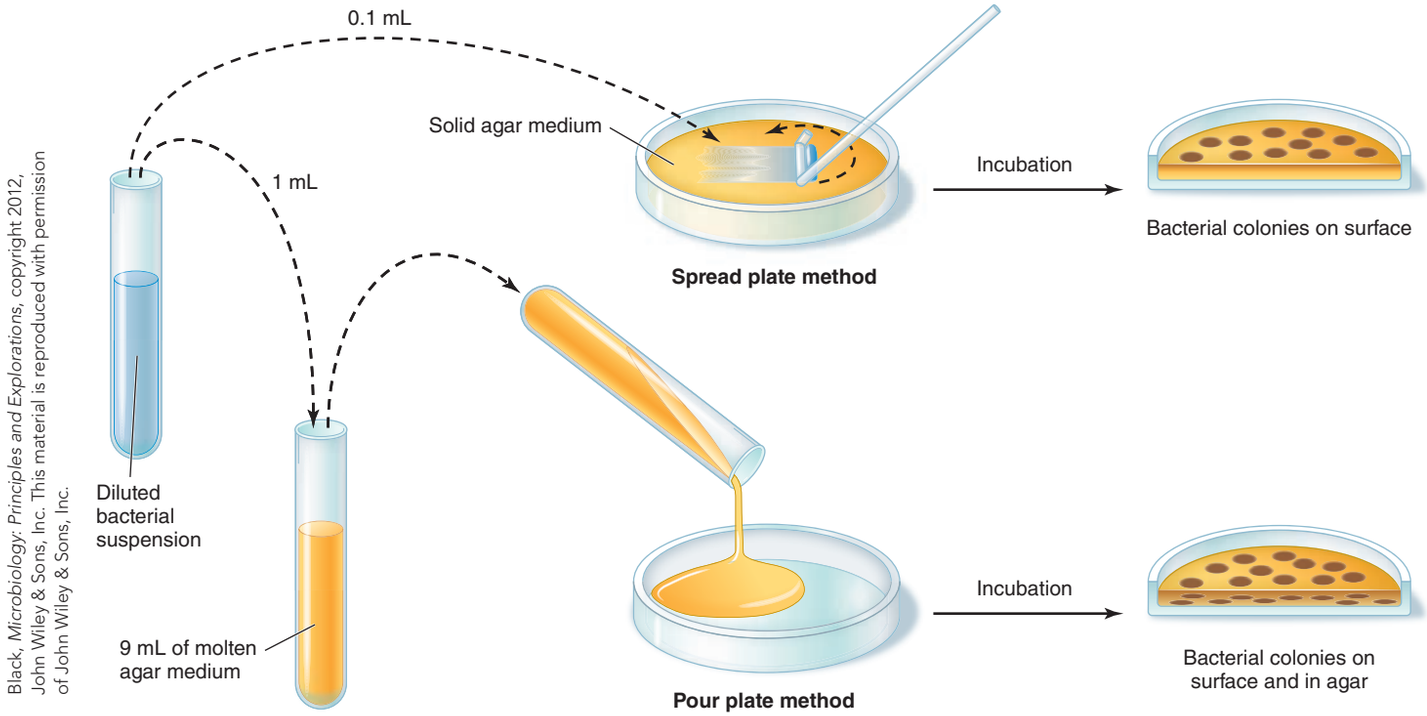

Figure 6.13. Spread plate and pour plate protocols To generate evenly dispersed colonies, aliquots of dilution of a bacterial culture can be grown by the spread plate method (*top*) or the pour plate method (*bottom*). After incubation, individual colonies should be visible on plates inoculated with certain dilutions of the original culture. The number of viable microorganisms in the original culture can be calculated from the colony counts.

situations in which an excessively rich medium can suppress growth or even be lethal. This apparent contradiction is particularly true for microorganisms adapted to life in nutrient-poor environments. The bottom line is that the medium should be well suited to the organism you want to isolate. An important problem, though, still remains. We don't do not know what growth conditions many bacteria prefer.

Uncultured bacteria

When examining microbial communities in environmental samples, microbiologists often note that, based on microscopic observations, there appear to be far more cells present in the sample than can be cultivated as colonies on plates. Often, the difference is extreme, with the apparent density of cells in the sample being 10-, 100-, or 1000-fold greater than the density calculated based on the colonies that grow when the sample is plated on laboratory media. This stark discrepancy has become known as the "great plate count anomaly," a phrase coined by microbiologists James Staley and Allan Konopka in describing their work on aquatic and soil samples. This anomaly applies even to the microorganisms of our own bodies. Only about 30 percent of the microbial inhabitants of the human colon form colonies in the laboratory under anoxic conditions at 37°C, using a variety of media. Under oxic conditions, fewer than 10 percent of cells form colonies.

What accounts for this anomaly? We've discussed many factors that affect microbial growth, from nutrient composition to environmental factors such as pH, osmosis, oxygen, temperature, and light. If critical nutritional needs for an organism are not satisfied, or if one or more environmental parameters are not within acceptable ranges, then growth may not happen at an appreciable rate. For a macroscopically visible colony to arise from a single cell, the starting cell must grow and divide for 20 generations or more. Colony formation seems so simple because it happens readily for the few thousand species of familiar microorganisms. And yet, the evidence is undeniable that even more species elude cultivation because we have not found the right combination of nutritional and environmental conditions. We will discuss this topic more in Chapter 15.

To compensate for the limitations of laboratory cultivation, **cultivation-independent methods** of analyzing microorganisms have been developed. Amplification, cloning, and sequencing of ribosomal RNA genes present in an environmental sample allow researchers to assess microbial diversity without growing the microorganisms in the laboratory (see Figure B1.2). Fluorescent staining methods, like the one shown in **Toolbox 6.2** using labeled DNA targeted to specific microbes, can then be used to further investigate population structure. Recently, such techniques have been used to investigate the microbial inhabitants of hundreds of habitats, from marine environments to the human intestine These surveys reveal the types of microbes present, regardless of which species can be cultivated in the laboratory.

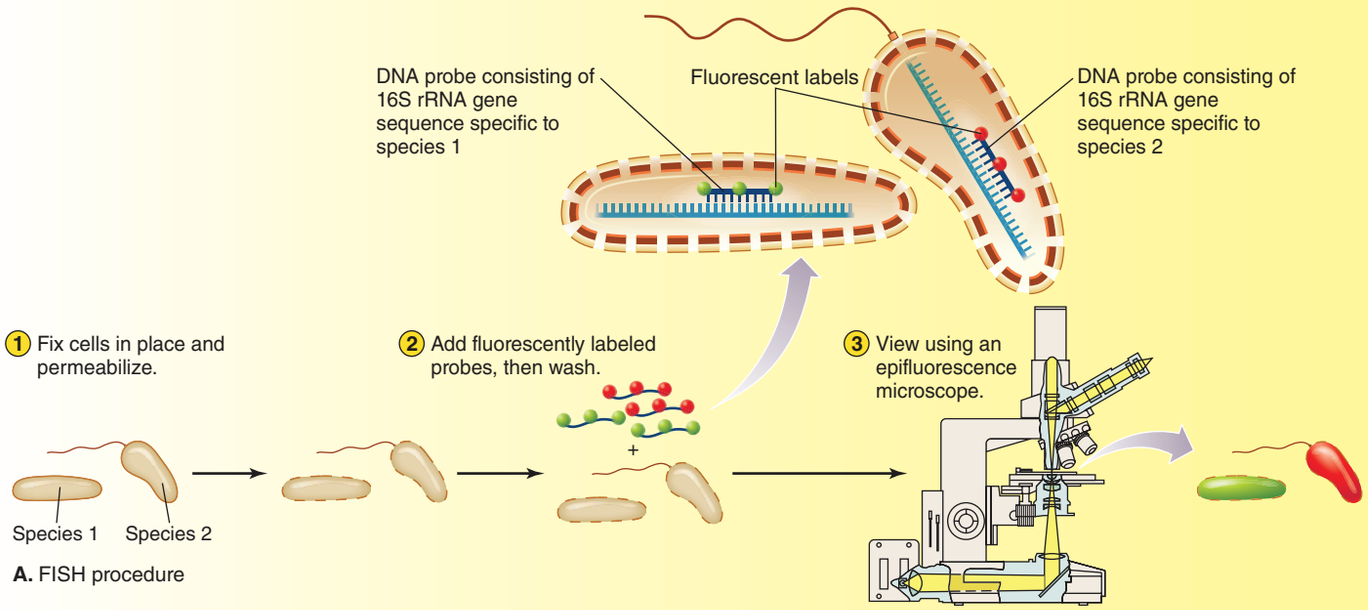
CONNECTIONS Using various culture-independent techniques, researchers in the 1990s proposed that an uncultured bacterium initially named SAR11 made up about a quarter of all microorganisms in some seawater communities. As we will see in **Section 15.3**, researchers in 2002 finally developed a method of cultivating this ubiquitous microbe.

Toolbox 6.2
FISHING FOR UNCULTIVATED MICROORGANISMS

How can we learn more about the identity, physiology, and environmental roles of microorganisms if they cannot be readily cultivated in the laboratory? Many bacteria and archaea look very similar by conventional light microscopy. Identification of uncultivated microorganisms therefore takes advantage of nucleic acid sequences that are both unique and useful for identification. One important method that combines microscopy and detection of specific nucleic acid sequences is FISH (fluorescence *in situ* hybridization). FISH detects particular nucleic acid sequences inside individual cells using fluorescently labeled DNA probes that are detectable by fluorescence microscopy.

FISH probes can assign an organism to a particular phylogenetic group if they are designed to be complementary to ribosomal RNA sequences characteristic of that group. Ribosomal RNA sequences are highly conserved over broad phylogenetic distances, but there are some relatively variable regions within which sequences can be targeted that are only shared by closely related species. The FISH method starts with a sample fixed onto a glass slide, such that cells are physically immobilized. The sample then is treated chemically to make the cell membranes permeable and to denature their DNA. A single-stranded nucleic acid probe complementary to a portion of the 16S rRNA gene is prepared with a fluorescent dye covalently attached to it. The prepared slide is incubated with the probe, under conditions where the probe DNA will hybridize with its target. That is, the probe will bind specifically to the complementary sequence of the denatured DNA in the cells on the slide. The non-bound probe then is washed away, and the slide is viewed by fluorescence microscopy.

Multiple types of microorganisms can be detected simultaneously using this method. The ultraviolet light emitted by the fluorescence microscope excites the compound on the probe to generate light of a particular wavelength, causing the cell to fluoresce. The wavelength, or color, that is produced is unique to the compound. Different probes designed to detect different sequences can be individually labeled with different fluorescent compounds. When used together in a single hybridization procedure, the collection of probes can detect a variety of different organisms in the sample, an example of which is shown in **Figure B6.3**. Digital imaging systems then can be used to photograph the image for subsequent analysis of community composition and organization.



A. FISH procedure

B. FISH image of mixed bacterial sample

Figure B6.3. Process Diagram: Fluorescence *in situ* hybridization (FISH) To distinguish species of microorganisms in a mixture, fluorescently labeled nucleic acid probes can be used. **A.** Cells first are fixed and permeabilized on a solid support. Fluorescently labeled nucleic acid probes, such as those designed to detect 16S rRNA genes specific for particular species, are added to the cells. Non-bound probe is washed away, and the cells are viewed with a fluorescent microscope. If probes specific for different species are labeled with different fluorescent markers (green and red in this example), then cells from these species can be distinguished. **B.** Image of microbial mixture in which three different nucleic acid probes (labeled green, red, and blue) were used.

CONNECTIONS As described in **Toolbox 6.2**, fluorescently labeled DNA probes can be used to identify cells. In **Toolbox 15.1**, we will examine another powerful technique involving fluorescence—flow cytometry. With this technique, researchers can identify and then isolate specific cells for further experimentation.

The use of rRNA sequences for phylogenetic identification of uncultivated microorganisms has practical applications. For example, it can suggest what kinds of genes, metabolic pathways, and structures a microorganism may possess. This information, in turn, could suggest media composition and environmental conditions for cultivation efforts based on what works for related microorganisms that can be cultured.

Scientists have taken an even bigger step toward gaining information from uncultivated microorganisms. In **metagenomics**, DNA isolated from an environmental sample is randomly cloned, and sequences are determined from the cloned DNA fragments. The gene content of microorganisms inhabiting a particular site can be examined, regardless of whether they can be cultivated. Our accumulated knowledge of metabolic genes, nutrient transport, regulation, and cell structure is used as a framework for interpreting the metagenomic data set. This approach gives greater insight into the lifestyles of resident microorganisms than ribosomal RNA profiles alone.

We should note, though, that metagenomics does have limitations. Although metagenomics provides information about the genes present in the uncultivated fraction of microbial communities, and the functions of these genes can be studied in surrogate host organisms, a more complete understanding of the biology of these organisms requires that they be isolated in pure culture. To achieve this goal, it is necessary to devise new methods for cultivation **(Mini-Paper)**.

Before leaving our discussion of uncultured microorganisms, let's address one more factor affecting our ability to grow microorganisms in the laboratory. A microorganism commonly lives in a **community**, a collection of organisms living together in a specified area, interacting with each other and the environment. Often, these communities take the form of a biofilm, a complex community of microorganisms adhered to a solid surface. In situations where communities are stable over long periods, microorganisms may evolve dependent relationships. For example, the by-products of one species' metabolism could provide a nutrient source for another species. Alternatively, the activities of some organisms could affect the pH of a local environment, thereby making the area more hospitable, or less hospitable, to other organisms.

CONNECTIONS The ability to sequence large amounts of DNA is a central requirement of metagenomics. In **Section 10.1**, we will explore different DNA sequencing strategies, including strategies involving high-throughput sequencing. Additionally, metagenomics requires databases of these sequences and tools to analyze them. In **Toolbox 10.1**, we will explore several specific databases, including Basic Local Alignment Search Tool (BLAST), Kyoto Encyclopedia of Genes and Genome (KEGG), and Clusters of Orthologous Groups (COG).

A microbial community in which the growth or survival of members depends on the community is referred to as a **consortium**. Microorganisms adapted to living in consortia may be difficult or impossible to cultivate as isolated species. If we know how the various species interact with each other, though, then clever design of the medium may allow some of the dependencies to be eliminated or chemically substituted. Some members of the community may be eliminated if we can artificially add their contribution to the community. Given that we often do not understand the complex interrelationships in microbial communities, it remains difficult or impossible to grow many members of natural communities and consortia in pure culture.

6.3 Fact Check

1. How do complex and defined media differ?
2. Give examples of selective and differential media.
3. How can a pure culture be obtained?
4. How can we characterize unculturable microorganisms?

6.4 Measuring microbial population growth

3D ANIMATION

How can we measure and monitor microbial populations?

As we have seen in the previous section, various media have been developed to facilitate the growth of microorganisms in laboratory settings. Likewise, several techniques exist for the measurement of microbial growth. First, we will examine techniques that allow us to determine the number of microorganisms present in a specific location. Second, we will explore techniques that allow us to measure the rate at which microbial populations grow. Third, we will examine the mathematical analysis of microbial growth. Finally, we will investigate a specific growth scenario in which nutrients are supplied continuously. Let's begin by examining how we can determine how many microorganisms are present.

Direct counts

There are several ways to measure microbial populations. Most simply, we can count the number of cells that are present. The most direct method is to count cells using a microscope. To convert such data to population density, researchers must count the number of cells in a defined volume. This type of

Mini-Paper: A Focus on the Research

BRINGING TO LIFE THE PREVIOUSLY UNCULTURABLE USING THE SOIL SUBSTRATE MEMBRANE SYSTEM (SSMS)

B. C. Ferrari, S. J. Binnerup, and M. Gillings. 2005. Microcolony cultivation on a soil substrate membrane system selects for previously uncultured soil bacteria. Appl Environ Microbiol 71:8714–8720.

Context

Although advances in microbiology often depend on cultivation of microorganisms, a large proportion of microorganisms in any given habitat have not been cultured. How can we learn about the functions and roles of the uncultured members of microbial communities and why is it so difficult to cultivate these organisms? Many of the uncultured microorganisms do not grow quickly. Also, many of them may be adapted to growth under very low-nutrient conditions. For these reasons, attempts have been made to use low-nutrient agar to successfully grow microorganisms that have been difficult to grow. Often, though, these organisms form microcolonies that are only visible under the microscope, even after several weeks of incubation.

The study presented in this paper describes a method for cultivation of soil bacteria in which non-sterile soil, and the associated natural microbial community, provides nutrients for the growing microcolonies. The microcolonies then can be visualized by microscopy. This method, called the soil substrate membrane system (SSMS), mimics the natural soil environment, allowing the cultivation of microorganisms that have not been successfully cultivated using other methods.

Experiment

These researchers made use of an apparatus that was originally developed for the cultivation of mammalian cells whose growth depends on binding to a solid surface. This apparatus, called a tissue culture insert, consists of a vessel that is sealed with a filter. Garden soil was diluted 1:200 in water and mixed vigorously to prepare the inoculum, which then was collected by filtration onto a membrane. This membrane, containing cells of soil microorganisms on its surface, was placed faceup on top of another membrane on a tissue culture insert apparatus that contained soil. Nutrients were able to diffuse through the membranes, feeding the inoculum that was on the membrane. Incubation was carried out at room temperature, in the dark, for up to ten days.

Following incubation, the membrane containing cells was removed from the apparatus, stained with SYBR Green, which stains DNA within cells, and visualized by confocal laser scanning microscopy

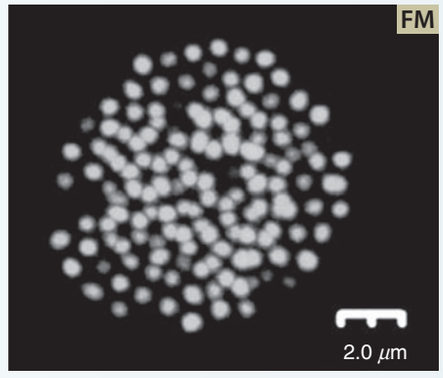
A. Diverse cell morphologies within several colonies



B. Uniform morphology within a single colony

Figure B6.4. Microscopic appearance of microcolonies Following incubation, sections of the polycarbonate filter were stained and viewed with a confocal microscope. **A.** Several different cell morphologies were present. **B.** Clusters of cells exhibiting a common morphology also were evident.

(see Appendix B: Microscopy). Microcolonies, defined as three or more closely associated cells, were clearly observed **(Figure B6.4)**. Many of the microcolonies contained up to 200 cells. Although many different cell types were observed, in most cases each microcolony contained a single cell type. Larger colonies, visible to the naked eye, were not observed on any of the membranes.

To determine the identity of the bacteria in the microcolonies, cells were washed from the membranes, DNA was extracted, and 16S rRNA genes were amplified. Sequence analysis demonstrated that the majority of the sequences were from uncultivated members of the Betaproteobacteria, with some Gammaproteobacteria, Actinobacteria, and TM7. Of particular interest was TM7, a lineage of bacteria that has never been cultivated but has been found in many different habitats, including soil, dental plaque, and wastewater treatment systems. FISH (see Toolbox 6.2) with TM7-specific probes was used to identify TM7 microcolonies on seven-day-old membranes **(Figure B6.5)**. Two TM7 microcolony types were detected. One colony contained short rods. The other colony contained long, filamentous rods.

Could the isolated microcolonies be cultivated in pure culture? To address this question, the investigators cut out eight sections of the membrane containing distinct microcolonies. The cells from each membrane section were suspended in sterile buffer, transferred to a new SSMS apparatus, and incubated. Only one of these subcultures resulted in growth, and this isolate was determined by 16S rRNA sequence analysis to be a member of the Betaproteobacteria. It was not capable of growth on rich medium.

Figure B6.5. FISH analysis of microcolonies FISH was used to tentatively identify microorganisms in microcolonies. A DNA probe specific for TM7 bacteria (red) and a more general DNA probe for most bacteria (green) were used. **A.** Some colonies consisted of short, rod-shaped cells. **B.** Other colonies consisted of long rods in looping chains.

Impact

The microcolony-forming bacteria detected in these studies reflect an interesting growth strategy that is specialized for very low-nutrient conditions. The use of natural soil as a nutrient source ensures not only that appropriate sources of carbon and energy are provided, but also that signaling molecules that might influence growth are present. Further attempts in subsequent studies have resulted in the successful cultivation of many more of the isolated microcolonies on low-nutrient agar media. Although this strategy was demonstrated using garden soil, it could be fairly easily adapted to the cultivation of microorganisms from other habitats. It will be particularly interesting to compare the microorganisms that are cultivated using this approach with the sequences that are discovered through metagenomics.

Questions for Discussion

1. Why do you think non-sterile soil slurry was used as the nutrient source rather than sterilized soil?
2. The isolated microcolonies were not able to form colonies on rich media. What is the significance of this finding?

measurement can be done using a **Petroff–Hausser counting chamber** (Figure 6.14), a specially constructed microscope slide with a chamber of defined depth, overlaid by a coverslip with a grid marking off squares of defined area. When the user counts the number of cells in several grid squares, the average cell density in the chamber can be calculated.

This direct count approach can present several problems. As you might imagine, it can be quite labor intensive. Additionally, the cells counted may not be alive. Generally, a researcher will be more interested in the number of live cells rather than the number of total cells present in a sample. So, how can we identify live cells? With a counting chamber, it is possible to first stain the cells with a viability stain, which binds living and dead cells differently, and then use fluorescence microscopy to identify viable cells while counting. Another common way of counting living cells is to add dilutions of a culture sample to a solid medium that supports microbial growth (Figure 6.15). Following a period of incubation, each viable cell will give rise to a visible colony. We can determine the number of viable cells added to the plate by counting the number of colonies.

Plate count data are used to calculate microbial population density as **colony-forming units (CFUs)** per milliliter of culture. To illustrate this point, let's say a microbiologist wants to examine the growth of *Escherichia coli* in M9 medium with glucose as the carbon and energy source. At several intervals after the initial inoculation of *E. coli* into a flask of M9 medium, she takes a sample and serially dilutes it in tubes of sterile saline solution, as shown in Table 6.4. She then spreads 0.1 mL of each dilution on lysogeny broth (LB) agar plates, and incubates the plates overnight at 37°C. The next day, she observes colonies on all of the plates and attempts to count them. The concentration of cells in the M9 culture, in colony-forming units per milliliter, is extrapolated for each time point using the equation:

$$\text{Culture density (CFU/mL)} = \frac{\text{number of colonies}}{(\text{dilution}) \times (\text{volume plated, in mL})}$$

Samples were taken at the indicated times after initial inoculation. Dilutions were done by initially mixing 1 mL of culture with 9 mL of sterile saline, to give a final volume of 10 mL. This is referred to as a 1:10 dilution, or in mathematical terms a 1×10^{-1} dilution. For serial dilutions, 1 mL of the 1×10^{-1} dilution was added to another 9 mL of sterile saline to give a 1:100, or 1×10^{-2} dilution, and so forth.

Why did the microbiologist use LB agar for plating when the experiment was intended to monitor growth in M9 medium? Although agar plates made with M9 medium could have been used for plating, LB agar was chosen because it is a rich medium and the growth rate on LB is significantly faster than on M9. In addition, complex media, such as LB, are commercially available and much easier to prepare in general. The key point is that each of the colonies growing on the LB agar was derived from a single *E. coli* cell from the M9 culture. When that bacterium was deposited on the agar surface, it stayed there, divided, and formed a colony. The plate counts therefore reflect the population of the M9 culture.

How can we interpret the data in Table 6.4? Within each time point, the calculated viable cell densities vary substantially. These variations may be caused by several factors, including inaccuracies in pipeting or mixing of each dilution and the degree of overcrowding of colonies on each plate. If colonies are too densely packed, then they are difficult or impossible to count accurately. The shorthand TNTC acknowledges this potential problem. The term "confluent" describes a plate on which individual colonies can no longer be distinguished. When colonies are densely packed, many of the apparent colonies probably arose from more than one cell. When multiple cells are deposited close together on an agar surface and their progeny merge to form a single visible colony, subsequent colony counts underestimate the true number of cells plated. But how do you know when colonies are "too dense"? The answer is somewhat arbitrary, but most microbiologists consider more than 300 or so colonies on a standard 100-mm Petri dish to be too many to give reliable data. Plates with less than ten colonies

Figure 6.14. Process Diagram: Counting bacterial cells with a Petroff–Hausser counting chamber
This specialized microscope slide provides a defined volume within which to count cells. The smallest grid squares are typically 50 μm per side, and the chamber is 20 μm deep. Knowing the dimensions of the chamber allows the microbiologist to convert the number of cells observed per grid into cell density (cells/mL^{-1}).

Figure 6.15. Serial dilution of cultures to isolate colonies and determine population density A series of 1:10 dilutions is made from an original bacterial culture. Each sample should have tenfold fewer bacteria than the previous dilution. If a known volume of each dilution is plated, then the number of viable cells per milliliter in the original sample can be calculated.

are often excluded in calculations, unless several plates are counted at that dilution. Why? In statistical terms, small numbers lead to high variability and, arguably, unreliable data, unless the sample size (the number of plates counted) is large.

With respect to data interpretation, let's first apply the data standards discussed above. Plates will be excluded from consideration if they contain more than 300 colonies or fewer than 10 colonies. From the remaining data, the means of replicate samples for each dilution and time point are determined. To calculate CFU mL^{-1}, only one usable dilution exists for the one- and three-hour time points, giving us CFU mL^{-1} values of 8.5×10^4 (at one hour) and 6.3×10^5 (at three hours). For the two-hour time point, both dilutions have valid data, so the mean of the calculated CFU mL^{-1} values is determined for both dilutions, yielding 2.2×10^5 CFU mL^{-1}. As we can see from these data, the number of viable cells in the culture increased over time.

Plate counts of this sort do not work for all microorganisms. If cells tend to grow in filaments or chains, or aggregate into clumps that cannot be separated easily into individual cells, then plate counts will underestimate cell density in the parent culture because a colony could have been derived from multiple cells deposited in a single site on the plate. The fate of the cells after plating also can be an issue. For discrete colonies to form, cells need to remain fixed in place after deposition on the agar. Many microorganisms, though, can move through a film of water remaining after plating or can actively move on solid surfaces. If cells are still moving as they are growing and dividing, then we are more likely to observe either large and/or confluent colonies or more colonies than should be present given the number of cells initially deposited on the plate. If such problems arise, using the pour plate method may work better than spread plates since pour plates trap cells and the resultant colonies inside the agar, where they cannot move or spread as readily.

Environmental samples, such as water samples from a pond, may have low microbial population densities, or low densities of specific species of interest. If the population density is too low to be practical for plate counts or microscopic analysis, then cells can be concentrated in the sample before plating. Membrane filtration is a convenient way to concentrate bacterial cells in liquid samples. A membrane with pores smaller than the diameter of most bacterial cells (0.2 μm or 0.45 μm) will trap the bacteria in the sample as the fluid passes through the filter. The filter then can be placed directly on an agar plate. The colonies that form can be counted **(Figure 6.16)**.

Turbidity

Direct counts, as we just saw, provide us with an absolute number of viable cells within a sample. Microbial populations also

TABLE 6.4 Measuring viable cell density in a bacterial culture by spread plating

Time	Dilution (before plating)	Volume spread on plate	Number of colonies observed (replicate plates)		Calculated CFU mL^{-1}
1 h	none	0.1 mL	TNTC	TNTC	*
	1:10 (1×10^{-1})	0.1 mL	499	518	*
	1:100 (1×10^{-2})	0.1 mL	83	87	8.5×10^4
	1:1,000 (1×10^{-3})	0.1 mL	10	8	*
2 h	1×10^{-1}	0.1 mL	TNTC	TNTC	*
	1×10^{-2}	0.1 mL	190	179	1.85×10^5
	1×10^{-3}	0.1 mL	25	26	2.55×10^5
	1×10^{-4}	0.1 mL	4	2	*
3 h	1×10^{-2}	0.1 mL	408	435	*
	1×10^{-3}	0.1 mL	66	60	6.3×10^5
	1×10^{-4}	0.1 mL	8	10	*
	1×10^{-5}	0.1 mL	1	0	*

TNTC indicates too numerous to count.

* Cell density could not be calculated accurately because plates contained too many colonies to be counted, too many colonies to be counted accurately (>300), or too few colonies to be meaningful (<10)

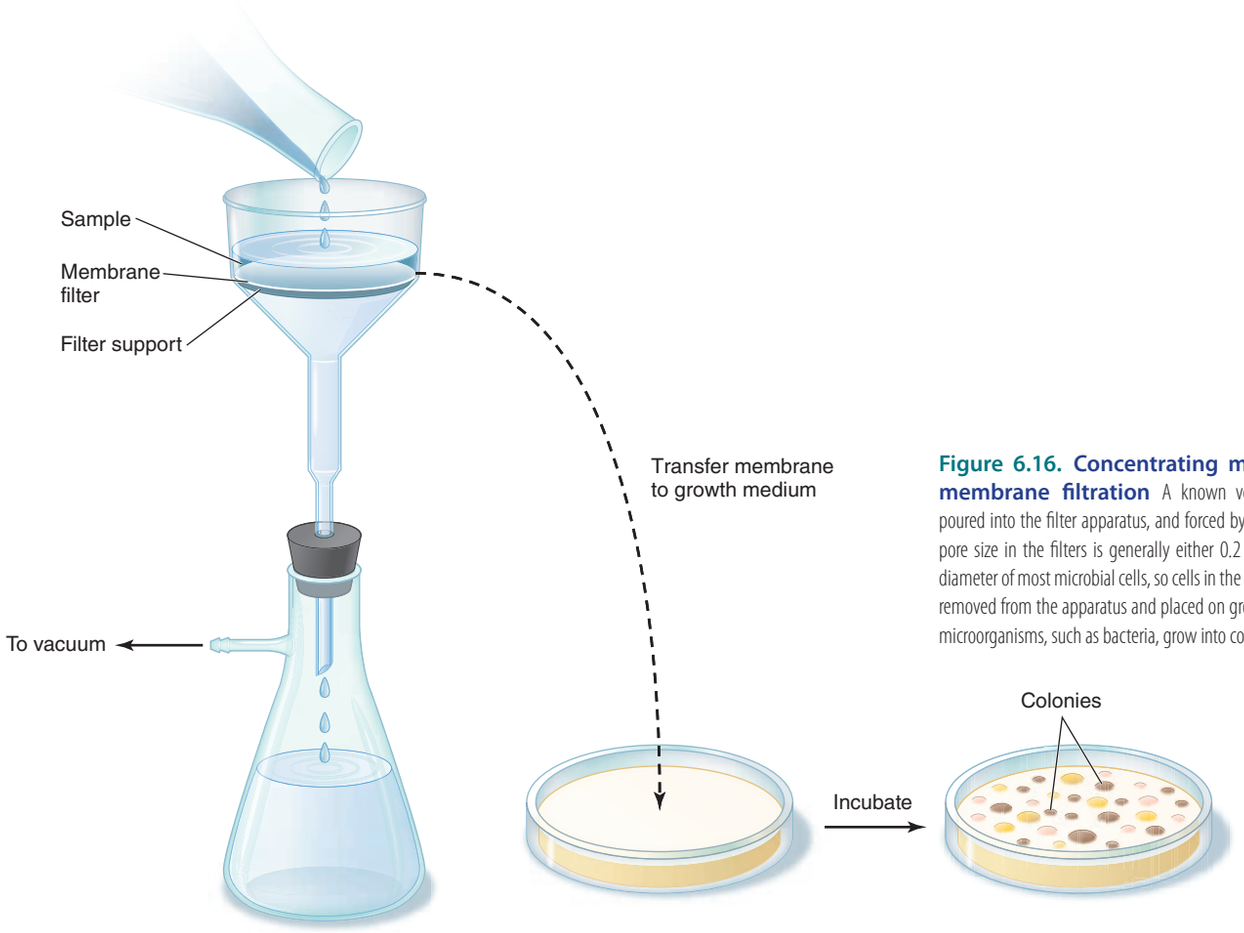

Figure 6.16. Concentrating microorganisms with membrane filtration A known volume of a liquid sample is poured into the filter apparatus, and forced by suction through the filter. The pore size in the filters is generally either 0.2 or 0.45 μm, smaller than the diameter of most microbial cells, so cells in the sample are trapped. The filter is removed from the apparatus and placed on growth medium, so that trapped microorganisms, such as bacteria, grow into colonies.

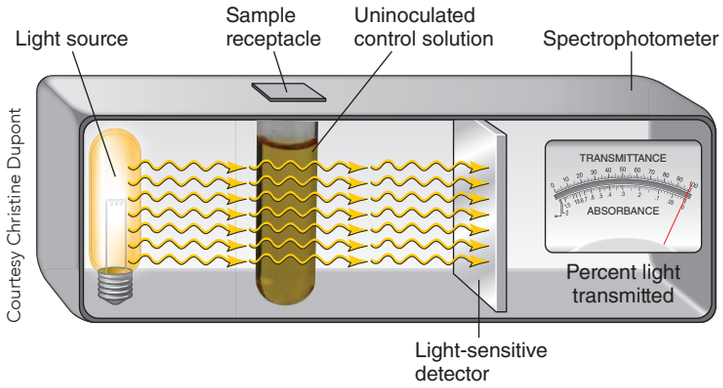
can be monitored by measuring the **turbidity** of a liquid culture using a spectrophotometer set at a wavelength of 550–600 nm (Figure 6.17). As the light beam of the spectrophotometer passes through the liquid, some photons strike cells and are absorbed or scattered and thus do not reach the photodetector. The greater the density of cells, the less light gets through and the higher the **absorbance** or **optical density** reading. Within a certain range, the optical density of the culture is roughly proportional to the population density. Optical density is easy to measure in a spectrophotometer, so this technique represents an easy way to follow population growth in a culture. However, it is only applicable over a relatively narrow range of cell concentrations. For most bacteria, the culture must have at least 10 million (1×10^7) cells per milliliter to see detectable turbidity. Below this concentration, the optical density is so low that an accurate reading is difficult or impossible. When the culture density exceeds roughly a billion (1×10^9) cells per milliliter, the optical density likely will be greater than 1.0. Very little light passes through the fluid, and the linear relationship of optical density to culture density breaks down.

The microbial growth curve

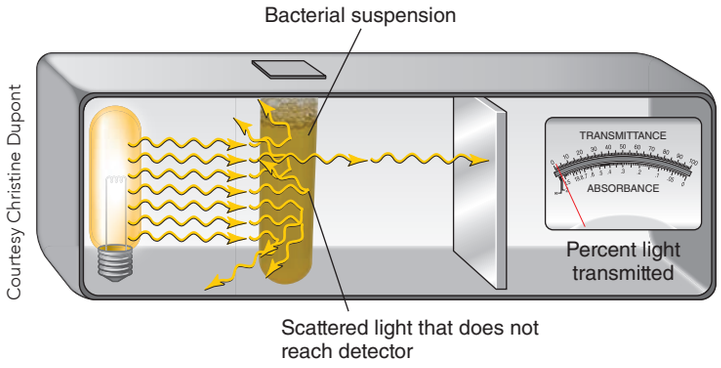
In addition to determining the amount of bacteria in a sample at one point in time, we may instead want to determine how the amount of bacteria in a sample changes over time. In other words, we may want to measure the growth of a population. By analyzing turbidity data obtained with a spectrophotometer, we can track population density over time. Inoculating cells into a vessel containing liquid medium initiates growth. Nutrients are consumed and the microbial population expands, resulting in an increase in turbidity over time. Viable cell density is more difficult to track in real time, but we can take samples periodically and carry out serial dilutions and plating (see Figures 6.13 and 6.15). Once colonies have a chance to grow, the viable cell density can be retrospectively determined. The data from such an experiment generate a **growth curve** that reflects the behavior of the population in a closed system, or **batch culture** (Figure 6.18). Typically, these growth curves display a few common features: a lag phase, an exponential phase, a stationary phase, and a death phase.

Lag Phase

Microbial cultures often grow very slowly immediately after inoculation, particularly if the starting cells had previously slowed or stopped growing, or were in a different medium. During this initial **lag phase** (see Figure 6.18), the cells are adjusting to their new surroundings, which may require altering gene expression, protein content, and membrane composition. New transport systems and metabolic pathways may be needed. Depending on the organism, the medium, and environmental conditions, this lag phase may be virtually absent, or it could last minutes, hours, or longer.



A. Light transmission for uninoculated culture media



B. Light transmission for a bacterial culture

Figure 6.17. Measuring culture turbidity A spectrophotometer can be used to quantify the amount of light passing through a turbid liquid bacterial culture. The light transmitted at various cell densities can be used to measure the number of cells present. **A.** The culture tube is sterile and clear. Almost all the incident light is transmitted. **B.** After bacterial growth, the solution becomes turbid (cloudy) because the microbial cells scatter the incident light and less light is transmitted. Usually, turbidity is reported as absorbance or optical density, which is inversely related to transmittance.

CONNECTIONS A change in gene expression in response to environmental changes isn't just a laboratory phenomenon. As we will discuss in **Section 7.3**, bacteria can alter which classes of genes are expressed by changing which sigma factors the cells produce. Changes in sigma-factor production often reflect changes in environmental conditions.

Exponential Phase

As cells adjust to their new surroundings, intervals between cell divisions become progressively shorter until the population reaches its maximal growth rate. At this point, the average time interval from one division to the next, known as the **generation time**, is constant. The rate at which cells divide is determined by the physiological capabilities of the organism, the nature of the medium, and environmental conditions. When cells are dividing by binary fission—one cell producing two cells by each division—the rate of increase of the population is exponential, and this stage of growth is referred to as the **exponential phase** (see Figure 6.18). We should note that some microbiologists refer to the exponential phase as the "logarithmic phase," but this term is not mathematically appropriate. Because the total number of bacterial cells doubles with each round of cell division, we can calculate the total number of bacteria with the exponential function $y = 2^x$, where y represents the total number of cells after x cell divisions. A logarithmic function ($y = \log_2 x$) does not model bacterial growth.

Stationary Phase

Following the exponential phase, the growth rate slows until net population growth stops completely and the culture has reached **stationary phase**. In a batch culture, the concentration of available nutrients in the medium is continually declining as the number and total mass of cells increases. At some point, the concentration of one or more critical nutrients will drop below the level necessary to sustain the maximal growth rate the culture experiences in the exponential phase. Basically, there will not be enough of some critical nutrient for the cells to keep operating macromolecular synthesis fast enough to sustain rapid growth. As the level of the critical nutrient drops, the culture enters a transitional period in which growth rate declines due to progressively longer intervals between cell divisions.

Besides exhaustion of nutrients, other factors also can contribute to entry into stationary phase. For example, metabolism during exponential growth can produce harmful waste

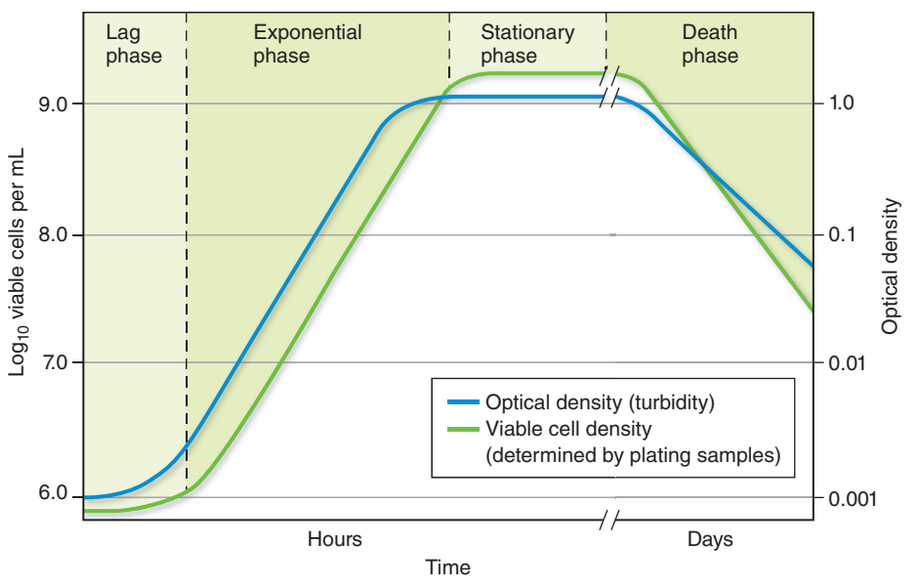


Figure 6.18. Microbial growth curve in a batch culture This graph illustrates growth of a hypothetical microbial population over time in a culture vessel with a fixed supply of nutrients. The *x*-axis shows time on a linear scale. The left *y*-axis shows the population or population density, plotted on a logarithmic scale. The right *y*-axis gives the relative optical density, a measure of the turbidity related to population density. The actual length of each of the four phases of the growth curve (lag, exponential, stationary, and death) depends on many factors—the organism, the nutrient composition of the medium, and various environmental factors.

products. When *E. coli* consumes sugars without enough oxygen for fully aerobic respiration, some carbon is directed into fermentative pathways that generate organic acids, lowering the pH of the medium (see Figure 13.17). The opposite can happen when amino acids are used as the primary carbon source because excess nitrogen is released in the form of ammonia and raises the pH. Although microorganisms can adapt to some variation in pH, a shift away from optimal conditions reduces growth rate, as we will discuss later in this chapter.

Microorganisms have evolved a variety of responses to stationary phase stresses, and most employ multiple strategies for dealing with resource limitations and unfavorable environments. Some stimulate production of flagella for motility, presumably to try to find new nutrient sources. Some Gram-positive bacteria become competent to take up extracellular DNA from other dying cells, which can be consumed for nutrients. Other microorganisms synthesize anti-microbial compounds that kill competitors, which again frees up nutrients. Some bacteria, like *Bacillus anthracis* that we discussed in the opening story of this chapter, radically remodel their cells to form endospores, specialized cells that are metabolically inactive and highly resistant to environmental insults, including high temperatures, dehydration, and chemical damage (see Perspective 2.2).

CONNECTIONS The transfer of DNA between organisms is referred to as horizontal gene transfer. As we will see in **Section 10.3**, comparative genomics studies indicate that this type of genetic transfer may occur quite frequently. DNA may be transferred between closely related organisms and between more distantly related organisms.

Death Phase

If a culture stays in stationary phase long enough, then cells may lose viability. When the concentration of viable cells starts to decline, the culture enters **death phase** (see Figure 6.18). The rate of decline in a cell population during death phase, like the rate of increase during the exponential phase, is an exponential function. The rate of death depends on the organism, the medium, and environmental conditions. To measure cell death, a method such as plate counting must be used that actually tests for viability. Direct counts by microscopy, or culture turbidity measurements, may be misleading if non-viable cells remain intact, at least initially.

Why do cells eventually die in a batch culture? To a certain extent, it depends on why they stopped growing in the first place. If a culture is depleted for an energy source, then several metabolic crises will develop. Transmembrane ion and electrical gradients diminish, and the cell depletes its supply of ATP. Metabolic systems are unable to continue to function normally, and synthesis of macromolecules such as proteins, RNA, DNA, and peptidoglycan (in the case of bacteria) slows drastically. The final fatal blow may come when the cell can no longer repair routine damage to the genome, cell wall, or membrane, either because of insufficient energy or raw materials or because the appropriate enzymes can no longer be produced. The various stress responses induced in stationary phase attempt to stave off these events for as long as possible.

Mathematical analysis of growth

It is important for microbiologists to understand basic methods for quantitative analysis of microbial growth. Comparing **growth rate** and **growth yield** can, for example, provide insight into physiological processes, genetic differences, and interactions between cells and their environments. Let's begin our discussion of growth rate by considering a bacterial population in which cells are dividing with a generation time of one hour. If we start with one cell, then after one hour we would expect two cells. After another hour (two hours total), there would be four cells; after another hour (three hours total), eight cells, and so on. However, cells do not all divide at precise intervals in a real culture. The generation time we calculate for a culture is an average for the entire population of cells over a defined time period. Furthermore, the generation time for the culture is only constant if the culture is in the exponential phase throughout the time period included in the calculation.

To see how we can determine generation time (g), we will introduce a simple equation that describes the growth of a population in the exponential phase:

$$N_t = N_0 \times 2^n$$

where N_t = population at time t
N_0 = initial population at time 0
n = number of generations that have elapsed between time 0 and time t

What if we do not know g or n? Generation time is not a universal constant—it varies between microbial species and strains and is dependent on medium composition and environmental conditions. We can calculate n and g for a culture from experimental data. The first step is to solve for n by transforming the equation $N_t = N_0 \times 2^n$. Taking the logarithm of both sides:

$$\log N_t = \log N_0 + (n)(\log 2)$$
$$(\log 2)(\log N_t) = (\log 2)(\log N_0) + n$$
$$n = \frac{\log N_t - \log N_0}{\log 2} = \frac{\log N_t - \log N_0}{0.301} = 3.32(\log N_t - \log N_0)$$

To calculate g, we can substitute for n in the equation $g = t/n$ as follows:

$$g = t/[3.32(\log N_t - \log N_0)]$$

The value of g also can be approximated by inspection of a semi-logarithmic data plot. From a convenient starting point during the exponential phase, measure the time for the population, or population density, to increase by a factor of 2. To determine g during exponential growth, both points must be during the period when the culture shows a straight line on the semi-log plot.

In some circumstances, it is useful to express growth rate as the number of generations per unit time. This term is referred to as the mean growth rate, k, usually expressed as generations per hour.

$k = n/t$, where t is measured in hours

or $k = 3.32(\log N_t - \log N_0)/t$

Thus, generation time is the inverse of the mean growth rate. In mathematical terms, $g = 1/k$. If g is less than one hour, it can be expressed in units of minutes. For example, for *E. coli* growing in a rich, well-aerated medium at 37°C, g can be described as 20 minutes rather than 0.33 hour. On the other hand, it is more practical to express k as three generations per hour, rather than 0.05 generation per minute.

In the laboratory, it often is faster and easier to measure the turbidity of a culture, rather than the actual number of cells. If all the cells in a population are of similar size and composition over a specified time interval, then they have approximately the same ability to absorb or scatter light, and cell density will have a constant relationship to turbidity. For cultures in the exponential phase, this assumption generally is true. Under these circumstances, turbidity measurements can be used to calculate g and k. To calculate generation time, N_0 is replaced with OD_0, the optical density at a time point early in the exponential phase, and N_t is replaced with OD_t, the optical density at a time point later in the exponential phase:

$$n = \frac{\log(OD_t) - \log(OD_0)}{\log 2} = 3.32[\log(OD_t) - \log(OD_0)]$$

Thus, $g = t/[3.32(\log OD_t - \log OD_0)]$

Rates of growth of microorganisms vary widely, both in the laboratory and in natural environments. The most rapidly reproducing organism known so far is the marine bacterium *Vibrio natriegens*, which can divide in as little as ten minutes! At the other extreme, some bacteria take days to divide even under optimal conditions in the lab. One of the slowest-growing bacteria known is *Mycobacterium leprae*, which takes at least two weeks to divide **(Perspective 6.2)**. *Bacillus anthracis*, by comparison, divides in roughly 20 minutes. Archaea tend to grow more slowly than bacteria. One of the most rapidly growing

Perspective 6.2
MYCOBACTERIUM LEPRAE, AN EXTRAORDINARILY SLOW-GROWING PATHOGEN

Mycobacteria are unusual bacteria, evolutionarily related to Gram-positive bacteria, but lacking the thick peptidoglycan layer characteristic of this group. Instead, mycobacteria have a distinctive thick, waxy, lipid-like layer protecting their cells. Some mycobacteria are well known for the diseases they cause, but these bacteria are exasperating to work with in the lab. Cells of *Mycobacterium tuberculosis*, the cause of tuberculosis (discussed in Chapter 21), take a full day to divide in the laboratory. This slow generation time pales in comparison to *Mycobacterium leprae* **(Figure B6.6)**, the cause of Hansen disease, also known as leprosy, which takes roughly *two weeks* to divide! Furthermore, unlike *M. tuberculosis*, which forms colonies on specialized laboratory media, *M. leprae* has so far only been cultivated in live armadillos and mice.

Why is *M. leprae* so difficult to cultivate in the laboratory? This bacterium normally invades host cells and lives inside them as an intracellular pathogen, slowly growing and dividing where it is largely protected from the immune system. It infects Schwann cells that cover the nerves, but because the bacteria replicate so slowly, the symptoms of Hansen disease are gradual, progressive nerve damage. The bacteria acquire nutrients from the cytoplasm of the host cell, which effectively acts as a rich, complex medium. Adaptation to an intracellular life where it can rely on the host cell for nutrients has allowed the *M. leprae* genome to itself suffer progressive decay by mutation, to the point that it now has less than half the number of functional genes as *M. tuberculosis*. The remaining *M. leprae* genome encodes a limited repertoire of metabolic and energy-generation pathways, severely compromising its growth rate and fitness outside of host cells.

Figure B6.6 *Mycobacterium leprae:* A slow-growing microorganism First discovered in 1873 by Gerhard Armauer Hansen, *Mycobacterium leprae* is the causative agent of Hansen disease, also known as leprosy. It is very slow-growing bacterium, with cells taking about two weeks to divide.

archaea known is *Pyrococcus furiosus*, which has a generation time of just under 40 minutes in ideal conditions. Eukaryal microorganisms also tend to grow more slowly than bacteria. Among the fastest-growing eukaryal microorganisms are yeasts such as *Saccharomyces cerevisiae*, whose generation time under optimal laboratory conditions is around two hours.

Why might a microbiologist be interested in determining growth rate in the laboratory? Let's consider some examples. We could compare the relative ability of a microorganism to utilize various nutrients—which sugars will *E. coli* use as carbon and energy source, and what is its growth rate on each? Which fatty acids support the fastest growth by *Staphylococcus aureus*? What nitrogen-containing compounds support growth of a particular soil bacterium? Experimental answers to such questions could provide insight into what nutrients are available in the environments these organisms inhabit and/or the transport or metabolic pathways utilized. Examining the effect of temperature, pH, or other environmental parameters on growth can generate insight into conditions to which the organism is evolutionarily and physiologically adapted. One could compare the growth of genetically distinct isolates of a species, even genetically engineered strains, to see how particular genes affect growth under various conditions.

Once we understand the mathematics of population growth, the remarkable power of exponential growth becomes clear. Let's look at an example. Assuming unlimited nutrients, and an *E. coli* culture that sustained exponential growth indefinitely with a generation time of 20 minutes, how long would it take to go from a single bacterial cell to a mass of bacteria weighing as much as Earth?

To answer this question, you need to know that an *E. coli* cell has a mass of approximately 1 pg (1×10^{-12}g) and that Earth has a mass of approximately 5.972×10^{27}g. How many bacteria are needed to equal the mass of Earth?

$$(5.972 \times 10^{27}) / (1 \times 10^{-12}) = 5.972 \times 10^{39} \text{ bacteria}$$

How long will it take to generate that many bacteria? Using the following equation,

$$n = \frac{\log N_t - \log N_0}{0.301}$$

we have

$$n = \frac{\log\left(5.972 \times 10^{39}\right) - \log(1)}{0.301}$$

$$= \frac{39.776}{0.301} = 132 \text{ generations}$$

Thus, 132 generations × 20 min = 2,640 min = 44 h.

So, in less than two days, this theoretical population doubling every 20 minutes, which is roughly the maximum growth rate of *E. coli* in rich medium, would have accumulated enough cells to equal the mass of Earth! Clearly, this type of growth does not happen in the real world. Although the mass of microbial cells on Earth is enormous, it is basically stable. No natural population of microorganisms could grow at anywhere near this rate for more than a few hours. Nutrients are virtually always limiting. There may be short periods when a microbial population experiences explosive growth, but these ideal conditions never last long!

When characterizing the behavior of a microbial culture, we also may be interested in growth yield, an expression of the maximum population density achieved and/or the amount of cellular material generated by the culture. This measurement would be particularly important if, for example, we were using a microorganism as an industrial production system for a valuable enzyme or other biological product and wanted to maximize the yield. At the cellular level, growth yield also can indicate the pathways and efficiency with which cells are converting nutrients into macromolecules.

Growth yield can be measured and expressed in several ways, including (1) the maximum optical density of the culture at a specified wavelength; (2) maximum viable cell density, as determined by plate counts; or (3) the dry weight of cells collected from a defined volume of culture. In the latter approach, cells are harvested by centrifugation or filtration and water is removed by evaporation in order to obtain the dry weight of the cellular material.

Continuous culture

So far, our discussion of microbial growth has focused on batch cultures. In such closed systems, there are finite resources, and exponential growth stops when these resources are depleted or when waste products accumulate. For organisms in a batch culture, life is boom and bust—rapid exponential growth when resources are abundant, followed by stasis and perhaps death when resources are exhausted. This pattern is common in dynamic habitats. For example, when an animal or plant dies, microorganisms take advantage of the abundant nutrients in the dead material and proliferate madly as they consume it. The microbial population expands dramatically as the dead material decays, but as more and more microorganisms compete for the declining pool of nutrients, the growth rate of the population as a whole inevitably slows down, and the population eventually crashes.

Microorganisms living in more stable environments may rarely experience boom and bust cycles. Instead, they face constant slow growth under nutrient-limited conditions. This situation can be re-created in the laboratory with a **continuous culture**. A continuous culture is an open system in which nutrients (sterile growth medium) are fed into a culture vessel at a constant rate. To keep the culture volume constant, excess medium is drained at the same rate, removing cells and waste products from the culture. Under such conditions, the microbial population initially will grow exponentially at the maximum rate the medium and environmental conditions will support, until it has nearly exhausted one or more critical nutrients, just as it would in a batch culture. At this point, the growth rate becomes limited by the rate at which new nutrients are added in the form of fresh medium. If the culture is rapidly mixed by vigorous stirring so that input nutrients are quickly distributed throughout the culture vessel, then the culture achieves a state of equilibrium in which nutrient and cell concentrations are stable.

A **chemostat** (Figure 6.19) is a practical continuous culture system in which growth rate and cell density can be manipulated

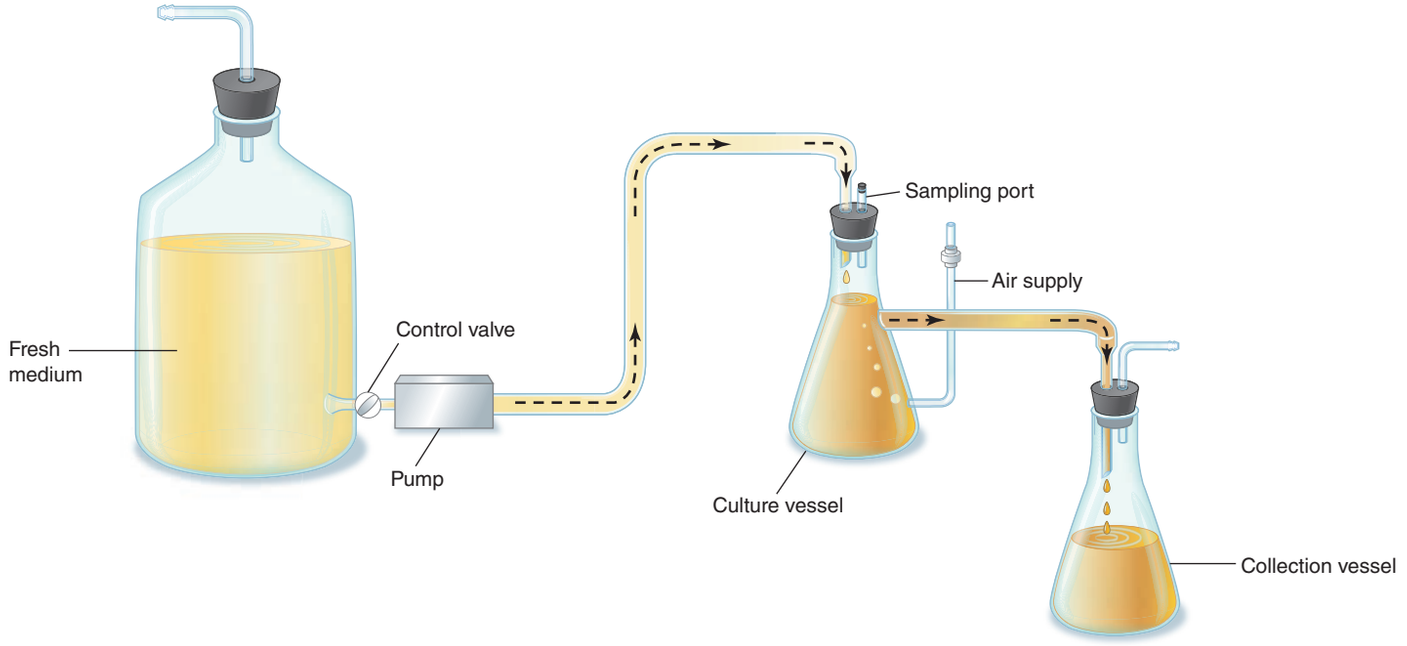

Figure 6.19. A continuous culture system Chemostats provide a means of maintaining exponentially growing cells under constant conditions for the study of microbial physiology. The most basic form consists of a culture vessel with an inlet port for addition of sterile medium and an outlet port for draining culture from the vessel at the same rate as fresh media is added, to keep the culture at a constant volume. The apparatus shown here also has a port for sterile addition of air, a necessity when growing organisms requiring aerobic metabolism.

through the nutrient composition of the medium and the flow rate of fresh medium into the culture vessel. The higher the concentration of nutrients in the medium, the greater the steady-state cell density. Once maximal population density is achieved, growth rate can be manipulated by adjusting the flow of fresh media into the vessel. The mathematical term describing this state is "dilution rate," the time it takes to replace the entire volume of the culture with fresh medium. For example, if fresh medium is added at a rate of 100 mL per hour (accompanied by the same rate of drainage of effluent) into a 1-liter culture, the dilution rate is (100 mL per hour) / (1,000 mL) = 0.1 per hour. If population density remains constant, with new growth balanced by cells lost in the effluent, the average growth rate of cells in this culture is equivalent to the dilution rate. To achieve stability, the dilution rate must be *less* than the maximal growth rate of the microorganism for the medium and environmental conditions. If a microorganism cannot divide fast enough to keep up with the dilution rate, then the chemostat will experience

Perspective 6.3
THE HUMAN INTESTINE—A CONTINUOUS CULTURE

Every day, a human eliminates billions of bacteria in feces. In fact, roughly half of the weight of human fecal material is microbial. Every day, the microorganisms that are lost are replaced through new microbial growth. The colon of a healthy, well-fed person approximates a continuous culture. Nutrients enter in the form of digested food remnants. Microorganisms grow and divide, and waste products and some microbial cells are eliminated. The input of digested food and elimination of feces roughly balance, so the microbial population remains fairly constant.

What is the growth rate of microorganisms in this continuous culture? The rate of transit of materials through the entire gastrointestinal tract is typically 1.5–2 days, most of which is spent in the colon. Let's assume that material spends a day moving through the colon before being eliminated as feces, the "effluent" of this continuous culture. The "dilution rate" of the microbial culture contained in the colon is therefore once per day. So on average, the stable members of the colonic microbiota have generation times of approximately 24 hours when growing in the colon. For a bacterium like *Escherichia coli*, this generation time is very slow; this organism has the ability to divide every 20 minutes in rich laboratory media. What limits the growth rate of microorganisms in the colon? First, nutrients in the biomass passing through the digestive system are continually being absorbed by our intestinal cells or competing microorganisms, so the *E. coli* in the colon are unlikely to have access to optimal nutrient concentrations. Also, by the time ingested material reaches the colon, the molecular oxygen available for respiration has been virtually eliminated, so bacteria must rely on anaerobic metabolism that yields less energy, and utilizes nutrients less efficiently. These two factors greatly limit the generation time of *E. coli* in our colon.

washout, in which cells are flushed out of the vessel faster than the culture can replenish them.

Why would a microbiologist use a continuous culture? Chemostats can be set up so that cultures are monitored and controlled, with pumps to feed media and remove effluent at steady rates. Probes that continuously measure temperature, pH, oxygenation, and other physical and chemical parameters can be coupled to systems for adjusting these parameters when necessary. Ports can be used to sample the culture at any time. For studying microbial physiology, continuous cultures provide more consistent, controlled conditions than batch cultures in which exponential growth is transient, and chemical concentrations are always changing. Constant slow, nutrient-limited growth is characteristic of many natural habitats. Studying the physiological properties of cells growing this way gives us insight into their lifestyle. In industrial microbiology, continuous cultures can be more cost-effective than batch cultures. Products from the culture can be harvested continuously without the downtime or time lag associated with repeatedly starting new batch cultures. **Perspective 6.3** discusses a natural continuous culture, that of the human intestine.

6.4 Fact Check

1. How can we count viable cells?
2. What are the advantages of measuring turbidity?
3. Describe the parts of a typical bacterial growth curve.
4. How can we determine the growth rate of a microorganism?
5. What is a continuous culture?

6.5 Eliminating microbes and preventing their growth

How can we eliminate microbes or inhibit their growth?

So far in this chapter, we've focused primarily on the growth of microorganisms. In many situations, though, we may want to prevent the growth of microbes, kill them, or physically remove them. In the laboratory, we want to be certain that unwanted bacteria do not contaminate glassware and reagents. In a hospital or nursing home, where many patients have limited resistance to microbial infections, it is very important to minimize the exposure of patients to potentially infectious agents. Similarly, it is important to minimize the numbers of microbes in some public places, like swimming pools.

In this section, we will examine methods for removing microbes or limiting their growth. We will focus primarily on removing microbes from inanimate objects, such as liquids, surfaces, and foods. Various ways of preventing infections of our bodies and eliminating microbes from our bodies after an infection will be covered in Chapter 24. For now, we will explore how we can use filtration, heat, electromagnetic radiation, and various chemicals to remove or inactivate microbes from various substances. We also will examine a few practical issues associated with eliminating microbes.

Physical removal of microbes by filtration

It is not practical to physically remove microorganisms from solid materials. Most bacteria, archaea, and eukarya, however, can be removed from liquids by filtering the liquid through a material with pores (holes) that are too small for microbial cells to pass through. You might recall from Chapter 5 that one of the first indications that viruses were distinct from bacteria is that they could pass through porcelain filters known to capture bacteria and larger microorganisms. "Low-tech" water filtration systems made from sand, diatomaceous earth, charcoal, or cloth (or some combination of the above) have been used for centuries to remove sediment and improve the smell, color, and taste of drinking water. Only in the last century have we appreciated that proper filtration could also remove infectious microbes and thus make water safer for human consumption. Modern membrane filters used for microbiological applications are made of tough synthetic materials such as nylon, polyvinylidene difluoride (PVDF), and polytetrafluoroethylene (PTFE, also known as Teflon). Cheaper, less durable filters are made of biologically based materials such as cellulose nitrate or cellulose acetate.

Filters used for sterilization of fluids in the laboratory have an average pore size of 0.2 or 0.45 μm, which is sufficient to trap all eukaryal microorganisms and most bacteria. A 0.2-μm pore still allows many viruses and some very small bacteria, such as *Mycoplasma* and *Chlamydia*, to pass through. Ultrafiltration methods capable of virus removal are used in the pharmaceutical industry. Ultrafiltration pore sizes are reduced to 10–100 nm, the size range of macromolecules. These tiny pores result in very slow flow rates, and high pressure is used to force liquids through the filters. Liquids that are significantly more viscous than water are very difficult to filter. Solutions that contain large particles are also a problem for filtration, because they can easily clog filters. Using a prefilter screen to remove these large particles can solve this problem.

Temperature manipulation

Heating is a simple and effective method for destroying microbes. Elevated temperatures cause proteins to denature—to lose their native structure and become non-functional. Other macromolecules are also sensitive to heat-induced denaturation. Nucleic acids rely extensively on hydrogen bonding to maintain functional structure; double-stranded chromosomal DNA and folded RNA molecules such as ribosomal and transfer RNAs can be structurally disrupted by heat.

Heating to 100°C, the boiling point of water, is sufficient to inactivate most microbes within minutes. Boiling is not sufficient for complete sterilization, as some microbial cells can survive such conditions. Some hyperthermophilic microorganisms, as we discussed in Chapter 4, withstand temperatures above 100°C, but hyperthermophiles are not common outside of specialized habitats like hot springs and thermal vents. Of greater concern are bacterial endospores, the specialized and highly durable cells produced by several common Gram-positive bacteria under stress conditions. Endospores are resistant to heat and other environmental stresses, and some can survive boiling for hours! In order to inactivate endospores, an **autoclave** is used in the laboratory to apply heat to media, instruments, and contaminated waste **(Figure 6.20)**.

An autoclave is essentially a pressure cooker—the chamber fills with superheated steam to reach a temperature of 121°C at a pressure of 15 pounds per square inch. These conditions are well above the boiling point of water at atmospheric pressure, but the elevated pressure in the chamber keeps liquids from boiling away. Like liquid water, steam transfers heat very efficiently. Vegetative cells and endospores rapidly lose viability under these conditions, and 15 minutes of exposure is sufficient for sterilization of small samples or volumes. When autoclaving large volumes of liquids or large masses of solids, longer exposure times are used to ensure that the entire mass or volume reaches 121°C.

Some materials cannot withstand the high temperatures and pressure used in autoclaving, so alternative heating methods, such as pasteurization, have been developed to reduce microbial content. Today, pasteurization is most familiar to the general public as it relates to milk and dairy products. In this process, liquids are heated for a short period of time. This treatment greatly reduces the number of viable bacteria in milk. We should note, though, that mammalian milk is rich in nutrients, and microorganisms that survive pasteurization, or are introduced when a container is opened, will grow if given a chance. Milk turns sour because of a mixture of acidic by-products from bacterial metabolism. If we keep the temperature of milk low, as in a refrigerator set at 4°C, microbial metabolism and growth rates are very slow. Refrigeration inhibits the growth of most microorganisms, and thus is valuable for storage of perishable products subject to microbial degradation, including non-food products such as pharmaceuticals and medical supplies. Refrigeration is *not*, however, a method for disinfection or sterilization.

Figure 6.20. An autoclave for heat sterilization Autoclaves are used in nearly all microbiology laboratories, as well as clinics and hospitals, for heat sterilization of instruments, media, and wastes.

CONNECTIONS Several forms of pasteurization, including high-temperature, short-time (HTST), and ultra-high temperature (UHT), may be utilized. We will learn more about pasteurization in **Section 16.2**.

Freezing can completely stop the growth of microorganisms. It converts liquid water, the aqueous environment in which most biochemical reactions happen, to a crystalline form and dramatically slows the rate of enzymatic reactions. Storing food at temperatures of −20°C or lower is therefore an excellent method for long-term preservation without spoilage. Freezing can be lethal to cells, as ice crystals can cause severe damage to cellular structures, particularly in cells without strong walls. However, it is possible for cells to undergo adaptive changes in cell composition that reduce the formation of ice crystals. Psychrophilic microorganisms in particular express adaptations that increase the likelihood that cells will survive freezing, including synthesis or accumulation of cryoprotectants such as sugars or glycerol that prevent formation of ice crystals. Microbiology laboratories freeze samples of microbes for long-term storage after adding cryoprotectants such as dimethylsulfoxide (DMSO) or glycerol. Thus, freezing can be fatal to cells or it can be a preservative. It's a useful way to shut down microbial growth but, like refrigeration, should not be thought of as a disinfection or sterilization method **(Figure 6.21)**.

Before refrigeration was widely available, people learned to ferment dairy products, juices, and grains—not just because the alcohol produced in some fermentations made them feel good, but because alcohols and acids limited further spoilage! Drying foods eliminates water, thereby inhibiting microbial growth. Adding salt to meat extracts water and increases salinity, both of which reduce microbial growth and slow spoilage. These food preservation strategies were developed through observation and trial and error during millennia of human cultural evolution, long before the microbiology of food spoilage was understood. We will learn more about food microbiology in Chapter 16.

Using electromagnetic radiation to control microbes

Exposure to various forms of electromagnetic radiation can inactivate or kill microbes. Ultraviolet (UV) radiation is

© Courtesy Christine Dupont

Figure 6.21. Cryopreservation of cells For long-term storage of cells, researchers often store vials of cells in liquid nitrogen. To avoid the cellular disruption typically associated with freezing, researchers add cryoprotectants, such as DMSO or glycerol to the cells prior to freezing them.

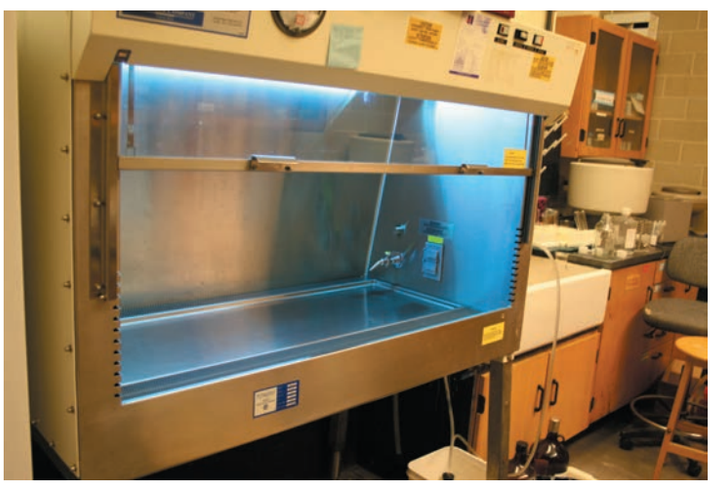
effective for disinfection and sterilization. Photons in the ultraviolet range have wavelengths of 200–400 nm. Ultraviolet radiation at 260–280 nm is strongly absorbed by nucleic acids and induces chemical reactions. The most common form of UV-induced damage in DNA is formation of thymine dimers, in which adjacent thymine bases become chemically linked. These dimers disrupt the normal structure of DNA and prevent its replication, which in turn prevents cell division. Cells have mechanisms for repairing such damage on a small scale, but massive damage to the genome is generally lethal. In the laboratory, UV light, which has little penetrating power in solids, can be used to disinfect surfaces, such as the working areas of specialized laminar flow hoods used for microbiological or cell culture work **(Figure 6.22)**.

CONNECTIONS The bacterium *Deinococcus radiodurans* can withstand extremely high levels of radiation. This radiation resistance may come from its ability to effectively repair double-stranded breaks in its DNA. We will examine this remarkable organism in **Section 7.5**.

Sunlight contains a significant UV component, much of which is absorbed by Earth's atmosphere, although some still penetrates. Small-scale "solar disinfection" of drinking water by sunlight is remarkably effective and useful in rural areas in developing countries, which often lack public water treatment and distribution systems. For solar disinfection, water that is relatively clear of sediment, which blocks UV penetration, is put in clear plastic bottles, shaken for aeration, and exposed to full sunlight for several hours **(Figure 6.23)**. The hotter the water gets, the faster the disinfection. The results are stunning—bacterial counts can be reduced by a million-fold in just a few hours in a warm, sunny area.

Direct UV damage to the microbial cell is not the sole cause of death. UV radiation between 300 and 400 nm interacts with dissolved oxygen in water to generate some of the harmful reactive oxygen species we mentioned earlier in Table 6.1. These oxygen species attack microbes as well, magnifying the killing effect of UV light. In recent years, UV exposure has been increasingly used as a component of large-scale treatment of drinking water as well, in part because it contributes no lasting residual chemicals that alter the taste of the water.

Many types of perishable products, including foods and various medical supplies, cannot withstand high temperatures and cannot be penetrated by UV light. For these products, ionizing radiation has excellent penetrating and sterilizing capabilities. Ionizing radiation, which includes X-rays and gamma rays, are highly energetic photons or other particles that can remove electrons from molecules. Gamma rays are photons with wavelengths from 0.01 to 0.1 nm, much shorter in wavelength and higher in energy than visible and UV light, and thus capable of much greater penetration of solid materials.



© Courtesy Christine Dupont

Figure 6.22. Ultraviolet radiation for disinfection or sterilization Hoods used for cell culture research in the laboratory typically have UV bulbs installed for rapid disinfection of surfaces. These hoods also have laminar air flow systems blowing filter-sterilized air over the working surface.

Figure 6.23. Solar water disinfection (SODIS) In resource-poor areas, sunlight can be used to partially purify water. Water simply is placed in a clear plastic bottle and exposed to sunlight. Over time, the UV irradiation and increased temperature destroy a significant proportion of microorganisms, and hopefully all pathogens, originally present in the water.

The high energy of gamma rays causes breakage of DNA and RNA strands, which leads rapidly to cell death. The overall chemical composition of gamma-irradiated products is basically unchanged. Gamma irradiation is widely used for sterilization in the pharmaceutical and medical supply industries but has not gained traction in the food industry. Irradiation of food is a safe and effective way of improving the microbiological safety of food and prolonging shelf life. The gamma ray source (cobalt-60) never actually comes into contact with the food, and there is no residual radioactivity associated with the product. Nevertheless, the general public does not understand the process well. Even though the irradiated food certainly does not become radioactive, a general fear among the public of all things associated with radioactivity has limited the ability of the food industry to employ this technique.

Chemical methods of controlling microbes

Many chemicals can inactivate microbes or prevent their growth. We will focus on only a few agents commonly used at home, in the microbiology laboratory, or in health care settings. A **disinfectant** is a chemical that is applied to non-living objects to kill potentially infectious microorganisms. Sterilization (the complete destruction or inactivation of living organisms and viruses) accomplishes disinfection, but most chemical disinfectants used for non-medical applications are unlikely to accomplish sterilization of a surface. **Antiseptics** are chemicals that kill infectious microbes and can be used on living tissue, or at least on surfaces such as skin. Most antiseptics are not used internally, because they would be toxic to tissues when ingested. Note that some compounds can be either antiseptics or disinfectants, usually depending on the concentration used. For example, hydrogen peroxide at a concentration of 3% sometimes is used as an antiseptic. At a concentration of 10%, hydrogen peroxide often is used as a disinfectant.

CONNECTIONS To attack microbes within the human body, we use agents that are selectively toxic to microbial targets but spare our own cells. In **Section 24.2**, we will investigate several drugs that are used to combat infectious agents.

What makes a good chemical disinfectant? First, it has to kill or inactivate microbes. It should be able to destroy a wide range of infectious agents: bacteria (Gram-negative, Gram-positive, and endospores), fungi (including spores), other eukaryal microorganism, and diverse viruses. Of course, there are many harsh chemicals that are toxic enough to quickly kill any cell, and destroy viruses as well, so we need additional criteria. For example, we might not want chemicals that are highly corrosive, as they would damage too many of the materials we might need to treat. These chemicals should not leave residues behind, or they should be easily washable with water. They should not smell too bad, or emit toxic fumes, or be overly toxic to handle, unless they are going to be used in highly restricted, controlled settings. An antiseptic must meet an even higher standard of not being toxic, corrosive, or excessively irritating when applied to skin. In this section, we will look at the properties of some commonly used chemical disinfectants **(Table 6.5)**.

Alcohols

Ethanol and isopropanol (rubbing alcohol) are commonly used as antiseptics and disinfectants. Alcohols dissolve and disrupt cell membranes and are effective against many bacteria and viruses, but are less active against fungi and bacterial spores. Although much more potent disinfectants are available, these alcohols have the advantage of being inexpensive, acting quickly but evaporating rapidly, and leaving no residue behind. Ethanol and isopropanol are the active ingredients in most gel or foam-type hand sanitizers marketed to the general public. In the United States, the Food and Drug Administration (FDA) and the Centers for Disease Control and Prevention (CDC) both recommend that hand sanitizers contain at least 60 percent alcohol for maximum efficacy. Although these hand sanitizers do not sterilize skin surfaces, they can reduce bacterial load on the skin surface by 90 percent or more when used properly, and they can inactivate many viruses. Routine use of effective alcohol-based hand sanitizers has been shown to reduce the spread of infectious diseases in schools and day care centers.

Phenolic Compounds

Phenol, known at the time as carbolic acid, was one of the first antiseptics used in medical practice. In the mid-1800s, the surgeon Joseph Lister pioneered the use of the antiseptic and dramatically reduced postsurgical infections as a result. The antimicrobial activity of phenol and derivatives is associated with their aromatic ring (see Table 6.5), which is non-polar and capable of inserting into the hydrophobic interiors of both lipid bilayers and proteins, disrupting their function.

Phenol is prepared as a dilute aqueous solution for use as an antiseptic, since it is quite toxic and corrosive in concentrated form. Because of phenol's historic importance as a disinfectant, it has been used as a standard to which other disinfectants are compared. The term "phenol coefficient" refers to the effectiveness of a disinfectant at killing bacteria, relative to a standard phenol solution. Less corrosive derivatives of phenol include chloroxylenol, an ingredient of antibacterial soaps, and O-phenylphenol, used in some household disinfectants and as an agricultural fungicide.

Triclosan, or 5-chloro-2-(2,4-dichlorophenoxy) phenol, is a structurally complex phenol derivative that is widely used in consumer products because of its stability and its relatively low toxicity to animals and humans. Triclosan can kill bacteria and fungi by the same mechanism as other phenolic compounds, attacking cell membranes. Unlike most other phenolic compounds, triclosan also binds to and reduces the activity of a specific enzyme, enoyl-ACP reductase, which is needed for fatty acid synthesis. As a consequence, triclosan can inhibit microbial growth even at very low concentrations. Mutations in the gene encoding enoyl-ACP reductase, however, can result in bacteria that are resistant to the effects of triclosan. As triclosan has been incorporated into more and more consumer products, some scientists have expressed concern that its excessive use will stimulate the proliferation of

TABLE 6.5 Commonly used disinfectants

Class	Example	Structure	Notes
Alcohols	Ethanol		Routinely used in laboratory settings; also present in most hand sanitizers
Phenolic compounds	Triclosan		Added to numerous products, including some soaps, deodorants, and cosmetics
Oxidizing agents	Sodium hypochlorite		Commonly added to swimming pools and hot tubs to inhibit microbial growth
Others	Benzalkonium chloride	 $R = C_8H_{17} - C_{18}H_{37}$	Major ingredient in Lysol
	Glutaraldehyde		Often used to prepare biological specimens

triclosan-resistant microbes. Additionally, several studies have shown that triclosan present in the wastewater may have estrogen-mimicking activity **(Figure 6.24)**.

Oxidizing Agents

Oxidizing agents strip electrons from cellular molecules, including lipids and proteins. This action leads to their disinfectant properties. A diverse range of chemicals falls into this category. As we noted previously, a 3 percent solution of hydrogen peroxide (H_2O_2) is used as a skin or wound antiseptic. Another oxidizer used for minor skin wounds is iodine, dissolved in a water-alcohol solution ("tincture of iodine"). Iodophores attach iodine to larger carrier molecules such as polyvinylpyrolidone, which are water soluble and eliminate the need for alcohol. An example of this type of agent is Betadine, a topical antiseptic. Iodine also is used to disinfect drinking water, though usually only on a small scale and in emergencies, since it leaves a rather unpleasant taste.

Chlorine-based compounds that act as oxidizing agents also are used for disinfection. Sodium hypochlorite is the active ingredient in household bleaches like Clorox, which in diluted form is an effective disinfectant for household surfaces. Sodium hypochlorite and calcium hypochlorite are added to swimming pools, hot tubs, and fountains to control microbial growth. For larger-scale treatment of drinking water, chlorine gas, chloramines, and chlorine dioxide are all used, depending on the scale, location, and context of the system. Sanitation of water by chlorine treatment, called "chlorination," is fast, effective, and relatively inexpensive, but must be carefully controlled. Chlorine ions are consumed when they react with organic molecules, including proteins in microbial cells, so chlorination is used at a late stage in water treatment, after most organic material has already been removed. Municipal water treatment systems add enough chlorine to ensure that low levels are still present in the water as it enters the distribution system, to provide residual protection from microbial contamination as the water is in transit to the end user.

Ozone (O_3) is another strong oxidizing agent and often is used in wastewater treatment. Ozone treatment is very effective, as it damages cell walls, proteins, and nucleic acids. Ozone is highly reactive and unstable, decomposing to dioxygen (O_2) fairly quickly. Because it is unstable, ozone is generated at the site of application, typically by high-voltage electrical discharge into an O_2-containing atmosphere. The instability of ozone means that it cannot provide the residual protection of water that chlorination does. On the other hand, the fact that

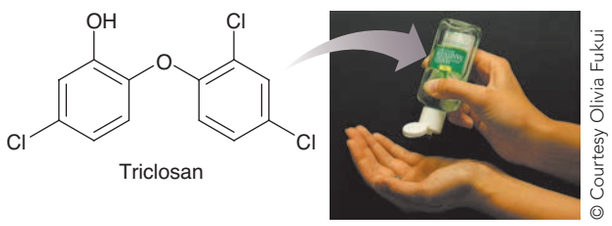


Figure 6.24. Increased use of triclosan in consumer products Since its development in 1972, the phenolic compound triclosan has been used in an expanding range of consumer products, such as liquid hand sanitizer, shown here.

it converts into O_2 is an advantage for applications where the user does not want residual chemicals in the water.

Other Chemical Disinfectants

Quaternary ammonium compounds can act as both detergents and disinfectants. The most common member of this class is benzalkonium chloride, or alkyl dimethyl benzyl ammonium chloride. Benzalkonium chloride is not actually a single molecular species, as the R alkyl group can be from 8 to 18 carbons long (see Table 6.5). Commercial formulations are a mixture of molecules with different R-group lengths. Benzalkonium chloride is the most potent active ingredient in Lysol a widely used household disinfectant and cleaning solution in the United States. Lysol includes other active ingredients as well, including alcohols (ethanol and isopropanol) and a phenol derivative (p-chloro-o-benzylphenol), to enhance its spectrum of disinfectant activity.

Chlorhexidine is the active ingredient of several antiseptics used for skin and oral applications, including toothpastes and mouthwashes. Chlorhexidine has particularly strong antibacterial activity and is thought to disrupt membranes.

Glutaraldehyde is used as a disinfectant on medical equipment. Glutaraldehyde and the related compound formaldehyde react with both proteins and nucleic acids, generating crosslinking chemical bonds that effectively tie macromolecules together. This method of killing cells preserves their structure, which is why glutaraldehyde and formaldehyde are used as fixatives for biological specimens. These chemicals are also used in embalming (along with alcohols) because their toxicity to microorganisms prevents, or at least slows, the ordinary process of tissue degradation by microorganisms. Glutaraldehyde and formaldehyde are too toxic for household use.

Practical issues for destroying microbes or preventing their growth

As we have investigated these various methods of eliminating microbes or inhibiting their growth, you have realized that many practical issues must be considered before deciding which method to use. Some important questions to consider include:

- What microbes need to be controlled? Are bacteria, fungi, protozoa, or viruses present? Are all of these microbes present? Do you need to be concerned about especially durable forms such as endospores?
- How many microbes are present? Do you need to kill them all? If the requirement is for sterilization, the choice of methods will be much different than if a less extreme reduction in microbial load is acceptable.
- What kind of objects, surfaces, and materials are going to be treated? How durable are they to various treatment options? How much collateral damage can be tolerated? Are the target microbes mixed with, or protected inside, organic or inorganic materials that might interfere with treatment?
- If a physical method is applied, how long and how intense must it be? If a chemical approach is considered, how powerful should the active agent be, and how long must it be present?
- Is toxicity to humans or other non-microbial targets an issue?

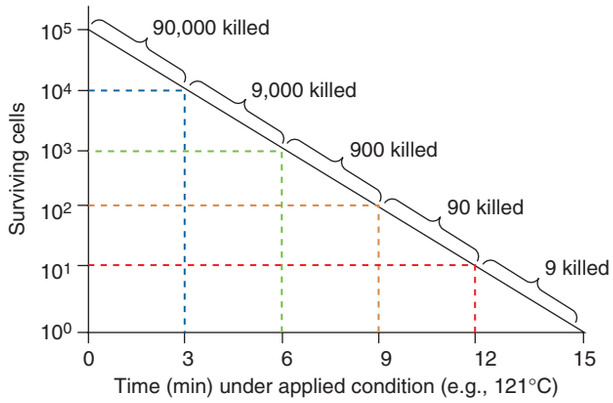

Figure 6.25. Decimal reduction time (D value) The decimal reduction time is the time required to kill 90 percent of the microbial cells under specified conditions. In this example, the population is reduced by 90 percent every 3 minutes (D value = 3 minutes), requiring 15 minutes to reduce the surviving population to one cell.

The answers to such questions are critical for deciding how to apply microbial control methods to particular situations.

In some cases, specific measurements of microbial control effectiveness have been defined. Intense consumer reaction to foodborne botulism outbreaks led to research by commercial canners in the 1920s to establish protocols designed to vanquish endospore survival in canned products. The concept of **decimal reduction time (D value)** arose from this research. The D value is the time required to kill 90 percent of the target organisms under specific conditions. The decimal reduction time is the time needed to reduce the number of microorganisms present by one order of magnitude, that is, by a factor of 10 or by one decimal place. For example, if the D value for an organism under specified conditions is three minutes, then 90 percent of the organisms will be killed in three minutes; 10 percent remains. In the next three minutes, 90 percent of those survivors will be killed, and so on. If the initial population is 10^5 organisms, then it would take five D values or 15 minutes to reduce the population to only one (10^0) organism (Figure 6.25). Knowing the D value for a target organism under set conditions, such as temperature or pH, allows treatment of that product to render it safe for consumption.

6.5 Fact Check

1. What are advantages and disadvantages of removing microbes by filtration?
2. Describe how temperature can be used to eliminate microbes or control their growth.
3. How do oxidizing agents affect microbes?
4. What are some practical issues that must be considered when using disinfectants?

Image in Action

WileyPLUS Learning Space On this laboratory bench, we see different ways of growing bacterial cultures. On the left are two large flasks containing liquid growth media. The flask in the foreground contains a culture in the early stages of exponential growth, and the flask in the background contains a much older culture, with the cells forming endospores. On the right, a nutrient agar plate streaked with bacteria is displayed, in front of two stacks of uninoculated plates. The plates on the left (yellow-green) and on the right (pink) contain different kinds of media.

1. The cells in the flask near the back of the bench are forming endospores. Explain what conditions would cause this change to occur. What other changes might cause the formation of endospores?

2. The yellow nutrient agar may be a general medium. In contrast, the pink agar may be a selective and differential medium. Compare and contrast these two types of media and explain how the growth of common bacteria such as Gram-negative *Salmonella* species and Gram-positive *Staphylococcus* species might differ on these plates.

The Rest of the Story

Following the quarantine of Anthrax Tower, investigators tried three times during the late 1960s and early 1970s to decontaminate the building. The sealed building was flooded with paraformaldehyde gas, and then the army conducted thorough culture testing at about 1,500 locations in the building. In 1971, after finding no evidence of *Bacillus anthracis*, they gave the all-clear for reoccupation, but not destruction; they could not be absolutely sure that spores were not lurking in the cracks and crevices that were not sampled. The building sat unused, a reminder to all of the peril faced in the pursuit of biological warfare. Years went by and the building fell into such disrepair that demolition was necessary. In 2000, experts used culture and PCR to test several hundred samples and confirmed there was no evidence of *B. anthracis*. Anthrax Tower was finally demolished in 2003—but that was not the last of anthrax.

"Amerithrax," as it was called by the FBI, hit the United States in 2001, in the wake of the Al-Qaeda terrorist attacks. Letters containing anthrax spores were mailed to two U.S. senators and several news media offices, killing five people and infecting 17 others. Millions of citizens feared that a new kind of attack was underway, but the letters ended and the cases of anthrax stopped. The cleanup began. Chlorine dioxide (ClO_2), a powerful oxidizing agent, was chosen for the job.

As a result of the letters containing anthrax spores, dozens of buildings needed decontamination. Postal workers at facilities who handled the letters during transit were some of the victims. Spores were found on keyboards in the offices where some of the letters were opened. The cleanup of the Brentwood postal facility in Washington took 26 months and cost $130 million. Decontaminating the Hamilton, New Jersey, postal facility cost $65 million. Decontaminating the Senate office buildings cost $27 million. The affected buildings had to be sealed and disinfected using chlorine dioxide gas that was generated by mixing five separate chemicals: sodium chlorite, sodium hypochlorite, hydrochloric acid, sodium hydroxide, and sodium bisulfite. Exhaustive PCR and culture tests were conducted. It took more than two years to declare some of the buildings safe for occupation.

To preempt the costly cleanup of such future hazards, researchers have begun to develop rapid, cheap, and effective methods for decontamination. A promising mobile sterilization system produces X-rays and ultraviolet-C light. As we have seen in Section 6.5, irradiation is already widely used to sterilize medical equipment and food. Both types of radiation result in irreversible DNA damage. The X-rays can penetrate crevices and many soft materials, such as upholstery. The ultraviolet-C light sterilizes surfaces. Both can penetrate spores, and research has shown the system can kill *B. anthracis* spores in two to three hours. Unlike chlorine dioxide, it leaves no toxic fumes or residues.

What do we know about the perpetrator(s) of these crimes? Sequence analysis of the *B. anthracis* strain delivered in the letters showed it was extremely similar to a strain cultured in Anthrax Tower, called the Ames strain, which now resides in several government facilities. With this information, investigators were able to confirm the strain originated from a government research lab in the United States. The FBI focused their suspicions on a few scientists who worked at the biodefense labs at Fort Detrick, but a conviction was never made.

Summary

Section 6.1: What do microorganisms generally need to grow?

All living organisms need to acquire basic nutrients and energy. Microorganisms have evolved several different strategies for obtaining both of these necessary ingredients.

- All cells need access to carbon, nitrogen, phosphorus, sulfur, and oxygen to build macromolecules.
- Microorganisms also require various **micronutrients**, including several metal ions that have roles in protein structure or enzyme activity.
- Cells must undergo the process of **assimilation** to incorporate nutrients from their surroundings. **Autotrophs** assimilate carbon from inorganic sources, through a process known as **carbon fixation**, whereas **heterotrophs** obtain carbon in organic forms.
- **Phototrophs** capture light energy through the process of photosynthesis. **Chemotrophs** acquire energy through the oxidation of organic or inorganic compounds. **Organotrophs** acquire electrons from organic molecules. **Lithotrophs** acquire electrons from inorganic molecules.

Section 6.2: How do nutritional and environmental factors affect microbial growth?

Microorganisms live in disparate habitats throughout Earth. Their preferred growth conditions depend on how they obtain nutrients and on environmental factors.

- **Prototrophs** can synthesize all the needed macromolecular precursors from a single carbon source and inorganic molecules.
- **Auxotrophs** cannot synthesize all the needed precursors from a single carbon source.
- **Aerobes** grow in the presence of oxygen. **Obligate aerobes** absolutely depend on oxygen. **Microaerophiles** grow optimally at oxygen concentrations lower than atmospheric oxygen.
- **Anaerobic growth** occurs without the use of oxygen. **Aerotolerant anaerobes** do not use oxygen, but are not harmed by it. **Obligate anaerobes** cannot grow in the presence of oxygen. **Facultative anaerobes** can utilize oxygen, but also can grow in the absence of oxygen.
- Different microorganisms grow preferentially at different pHs. **Neutrophiles** grow optimally when the pH is close to neutral (7.0). **Alkaliphile** grow optimally in basic environments ($pH > 8.5$). **Acidophiles** grow optimally in acidic environments ($pH < 5.5$).
- Osmotic pressure, **water activity (a_w)**, and temperature also affect microbial growth.

Section 6.3: How can different types of microorganisms be grown in the laboratory?

Various strategies have been developed for growing microorganisms under controlled conditions in the laboratory.

- Microorganisms can be grown in liquid **growth medium** or solid growth medium that contains **agar**. A **complex medium** or **defined medium** can be used. Under appropriate conditions, a viable cell deposited on solid medium will give rise to a **colony**.
- A **selective medium** allows for isolation of microorganisms with specific properties. A **differential medium** allows certain microorganisms to be recognized based on a visual reaction in the medium. **Enrichment media** are used to increase the population of microorganisms with specific properties.
- The **streak plate** is a simple method for isolating microorganisms in the laboratory.
- **Cultivation-independent methods** based on nucleic acid detection and **metagenomics** can allow identification and characterization of uncultivated microorganisms.
- Members of a microbial **consortium** can evolve obligate dependencies with other members of the **community** that preclude their isolation as individual species.

Section 6.4: How can we measure and monitor microbial populations?

In the laboratory, microbial growth can be controlled and monitored. Such monitoring is instrumental to experimental analysis of microorganisms.

- The actual number of cells in a sample can be determined by a direct count, usually done with a **Petroff–Hausser counting chamber**.
- The number of viable cells can be determined by adding bacteria to an agar medium, either via the spread plate or pour plate method. **Colony-forming units (CFUs)** then can be calculated.
- **Turbidity** can be used to measure the density of a microbial population growing in a liquid medium. As the population density increases, the **absorbance**, or **optical density**, increases.
- Microbial populations growing in a **batch culture** tend to follow a **growth curve** that includes four phases: **lag**, **exponential**, **stationary**, and **death**. By analyzing the growth kinetics, the **generation time**, **growth rate**, and **growth yield** of the microorganism can be calculated.
- **Continuous cultures** operate as open systems. **Chemostats** are practical continuous culture vessels for physiological studies and are sometimes used for industrial production.

Section 6.5: How can we eliminate microbes or inhibit their growth?

Although much research depends on the rapid growth of microorganisms, there also is a need to limit their growth or remove them from certain locations.

- Many microorganisms can be removed from liquids by filtration.
- Microorganisms can be killed by heating. In the laboratory, this destruction occurs in an **autoclave**. Pasteurization uses brief exposure to sub-boiling temperatures to destroy most cells.
- Ultraviolet (UV) radiation, ionizing radiation, and gamma rays profoundly damage DNA and are useful for sterilization.
- **Disinfectants** are chemicals that can be applied to non-living objects to kill microorganisms. **Antiseptics** can be used on skin.
- Antimicrobial compounds can be classified by structure or mechanism of action. Important classes include alcohols, phenolic compounds, and oxidizing agents.
- The **decimal reduction time (D value)** provides a specific measurement of the effectiveness of these agents.

Application Questions

1. The most common autotrophic organisms on Earth are photoautotrophs such as plants, eukaryotic algae, and cyanobacteria. Photoautotrophs, by definition, capture light energy and use it to drive CO_2 fixation to carbohydrates. Is it possible for a non-phototrophic microorganism to be an autotroph?
2. A microbiologist attempting to cultivate bacteria from human feces chooses to use LB agar, rationalizing that it is a rich medium. When he compares microscopic counts of microbial population density to the counts he obtains from cultivation of colonies on agar plates, he realizes he has cultured only a small fraction of the colonic bacteria. What was wrong with his approach? What incubation conditions would you suggest he use to maximize recovery of the colonic microbiota?
3. A scientist takes a water sample and dilutes it 1:1,000. Then 0.1 mL of the diluted sample is plated on an agar plate and incubated, yielding 50 colonies. What was the concentration of bacteria that grew on this medium in the original mixture? How many colonies would you expect to see on a plate on which 0.1 mL from a 1:10,000 dilution was plated?
4. A scientist analyzing the growth of *Escherichia coli* in the laboratory takes a 1-mL culture sample and dilutes it into 99 mL of sterile saline. She then takes a 1-mL sample of the first dilution and mixes it with another 99 mL of saline. She takes a 1-mL sample of the second dilution and mixes it with another 99 mL of saline. She then spreads 200 μL of the final dilution on a nutrient agar plate. The next day, she counts 32 colonies on the plate. What was the cell density (CFU mL^{-1}) in the culture at the time of sampling?
5. What characteristics of microorganisms could make it difficult to get an accurate count using a Petroff–Hausser counting chamber? What steps could be taken to make such counting easier?
6. A microbiologist wants to study microorganisms in groundwater. The first goal is to culture strains from groundwater samples. What are some significant chemical or environmental parameters she should investigate first, in order to develop media and culture conditions likely to give the largest number of viable microorganisms?
7. Laboratory microbiologists almost always prefer working with pure cultures. Scientists working on removal or immobilization of an undesirable compound by microorganisms have sometimes found that degradation of target compounds by pure cultures in the laboratory, even under optimal conditions, is considerably slower and less efficient than degradation by microbial communities in the field. How might this be explained?
8. When preparing microbiological media in the laboratory, why isn't it sufficient to simply boil the medium at 100°C for 15 minutes to sterilize it? Is an autoclave really necessary?
9. Laboratory hoods used for cell manipulations have UV lights built into them. What is the purpose of these lights?
10. Microbiologists studying physiological processes often prefer to study continuous cultures instead of batch cultures. What experimental advantages can continuous cultures offer?
11. Cultures of two very similar bacterial strains were inoculated into fresh medium at a 1:1 ratio. Strain A has a generation time of 20 minutes in this medium, whereas Strain B has a generation time of 21 minutes under the same conditions. Assuming that both strains skip lag phase and immediately start growing and dividing at their maximal rate, and assuming that they are able to maintain constant exponential growth rate over the course of the experiment, what fraction of the total population would Strain A represent after five hours? Ten hours? How long would it take before Strain A constituted 99 percent of the population?

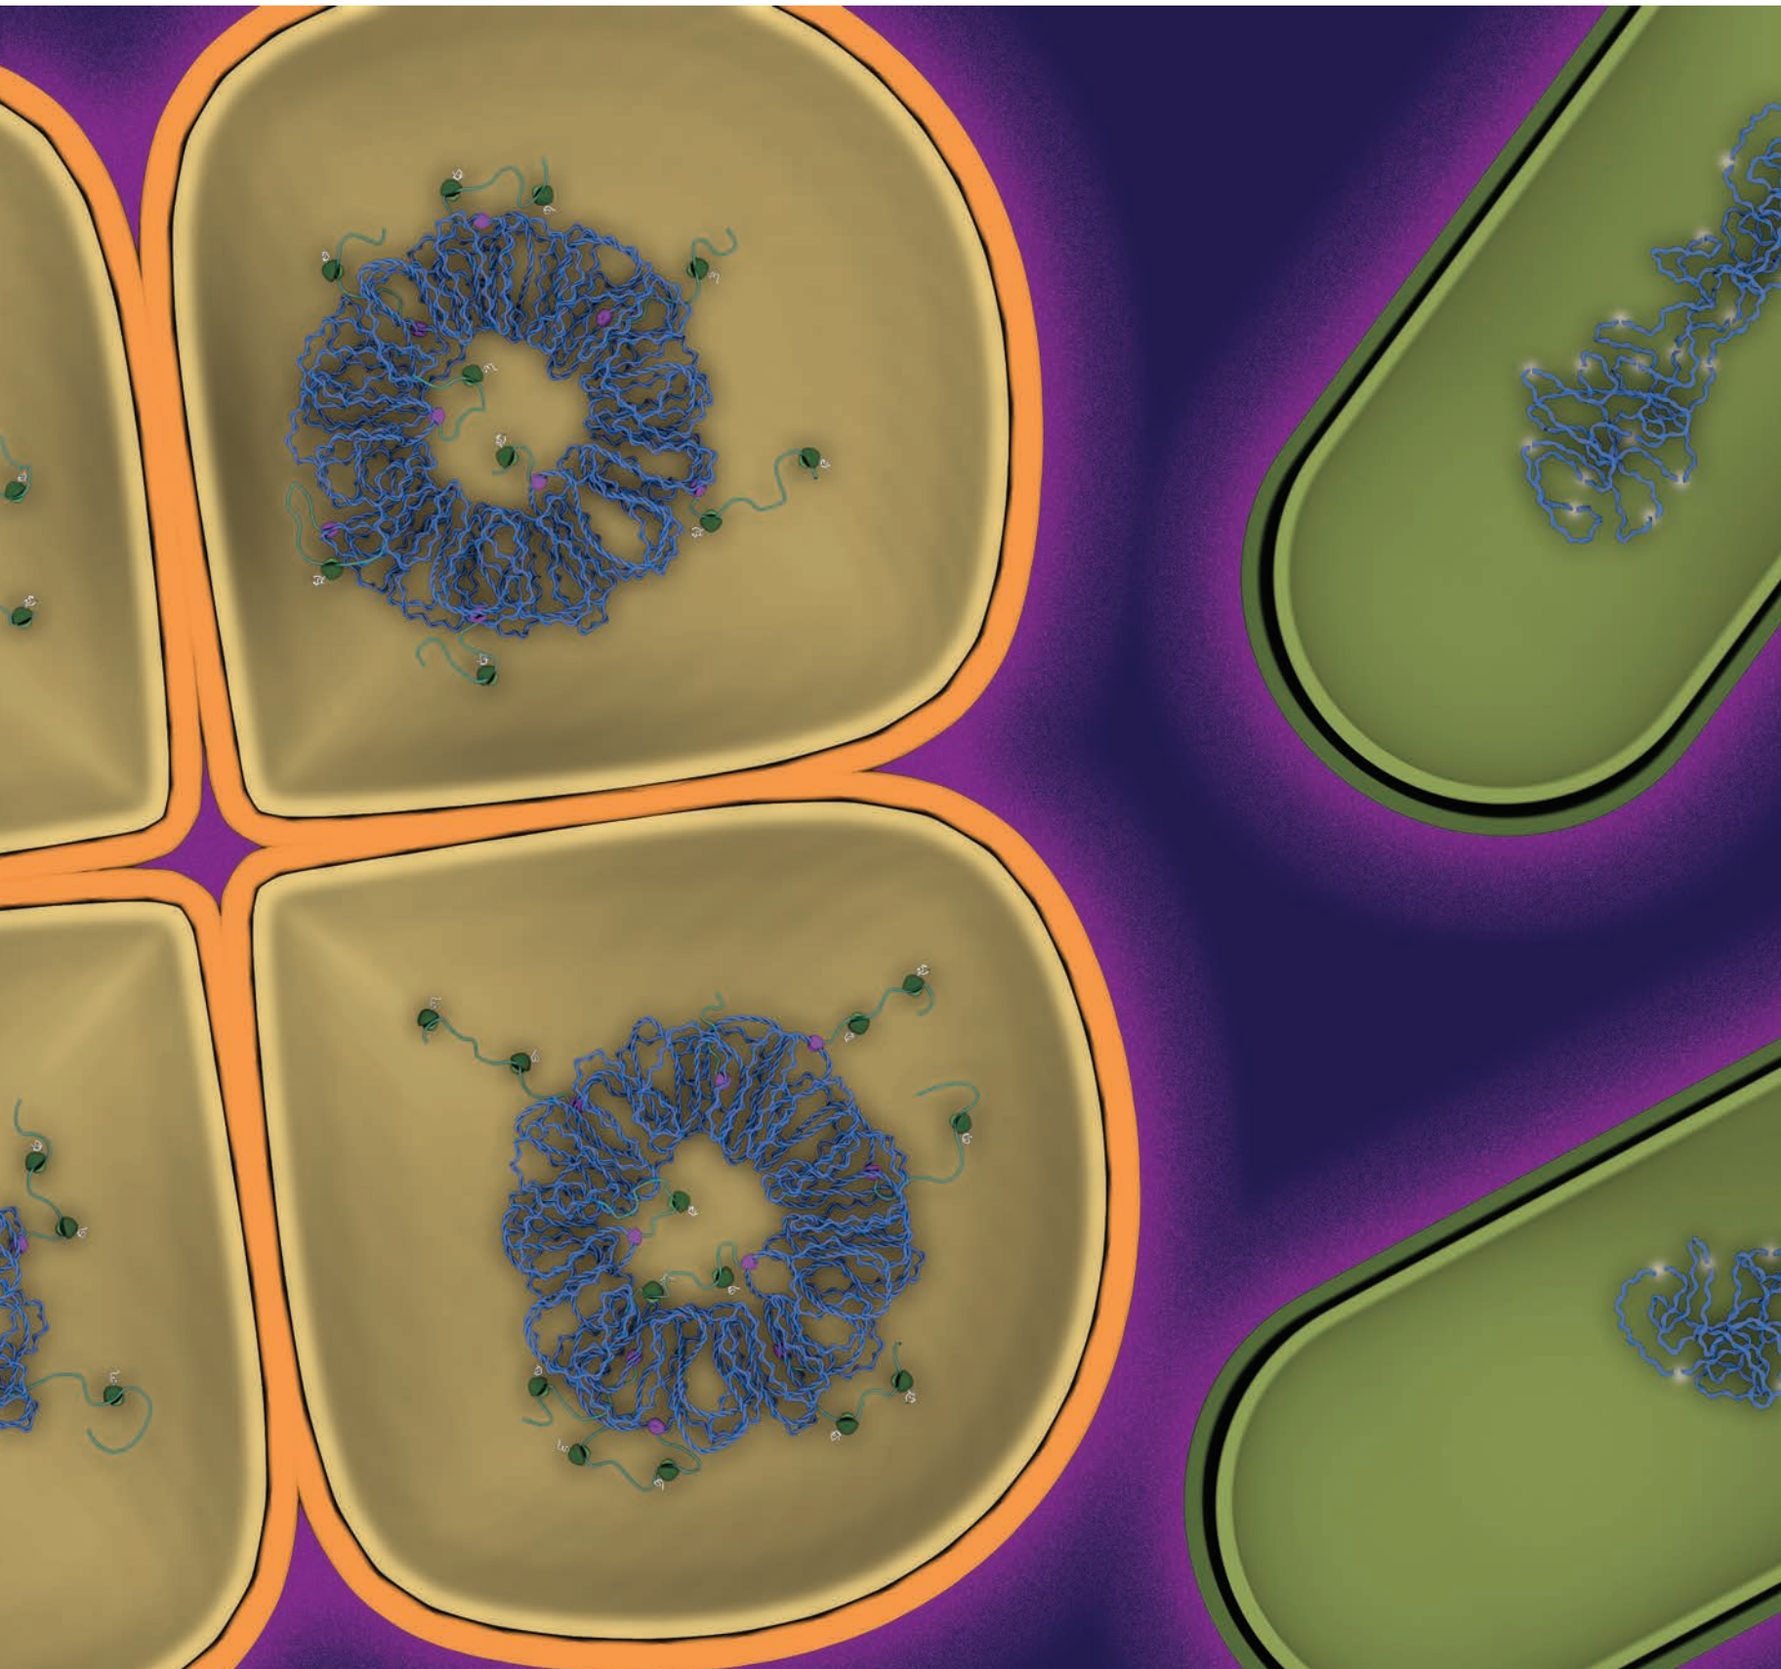
CHAPTER 7

DNA Replication and Gene Expression



What would it take for a microorganism to make it into the Guinness World Records? How about surviving nearly 1,000 times the amount of radiation that would kill a person and 100 times the amount of radiation that would kill *Escherichia coli*? Nicknamed Conan the Bacterium, *Deinococcus radiodurans* can do just that. Oh, and it also can withstand exposure to UV light, hydrogen peroxide, and desiccation.

Researchers first isolated *D. radiodurans* in 1956. Like a surprising number of events in science, the isolation happened quite by accident. Researchers were investigating the use of gamma radiation to sterilize food. A can of meat was exposed to a supposedly lethal dose of radiation. To the researchers' surprise, something survived—a bacterium later classified as *D. radiodurans*. Although this bacterium appears to be Gram-positive when stained, it possesses an outer membrane that is typically associated with Gram-negative bacteria. Cells of *D. radiodurans* often exist in groups of four. The species can be isolated from a variety of environments, including soil, raw meat, and sewage.

High doses of radiation kill organisms primarily by causing extensive damage to DNA. Specifically, ionizing radiation causes double-stranded breaks in the DNA. When the DNA of a cell is extensively disrupted in this way, the cell cannot repair the damage to its genetic material and, ultimately, the cell dies. So how does *D. radiodurans* survive such horrific insults? Perhaps the cells are impervious to radiation through some unknown mechanism. Alternatively, the DNA of this species may be resistant to the effects of radiation. Maybe *D. radiodurans* has developed a novel means of repairing damage to its DNA. Not surprisingly, researchers are investigating the DNA of this species in an attempt to solve this intriguing mystery.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

DNA is the hereditary molecule in all cellular organisms and exhibits a similar composition and structure in all organisms.

Chaperonins and protein folding in hyperthermophilic archaea **(Section 4.3)**

Use of ionizing radiation in sterilizing food **(Section 16.2)**

Introduction

We truly live in a golden era of genetics. Whole genomes can be sequenced and compared. New species can be identified solely on the basis of their sequences. We can use bacterial mutants to explore the inner workings of cells. The DNA of bacteria can be manipulated so that the cells produce useful proteins. In the very near future, bacteria may be engineered to degrade toxic waste or generate a clean form of energy. We also may be able to treat deadly diseases by actually altering the genetic makeup of a person. All of these amazing possibilities have resulted from our understanding of how DNA works. Most of our understanding of how DNA works has resulted from studies done with bacteria and viruses.

In this chapter, we will investigate several key genetic molecules and examine the major steps in the flow and processing of genetic information. We will start by examining DNA, the major genetic information storage molecule in all bacteria, archaea, and eukarya. We will examine the structure of DNA and investigate its replication, focusing on how one double-stranded DNA molecule gives rise to two new, identical, double-stranded molecules. Next, we will investigate how the information contained within DNA is interpreted through transcription, the process by which RNA molecules are generated, using DNA as a template. As we will see, some RNA molecules are functional themselves. Other RNA molecules, messenger RNA (mRNA), serve as templates for the production of proteins, a process known as translation. We will examine this process as well. Finally, we will end this chapter by looking at mutations, how they can occur, and what effects they can have.

Not surprisingly, DNA replication, transcription, and translation are quite complicated. Moreover, despite their general similarities, interesting differences in these processes exist in the various domains of life. Throughout this chapter, we will explore these processes in all three domains of life, highlighting important similarities and differences. We will frame our introduction to genome replication and gene expression around these basic questions:

How do we know DNA is the hereditary molecule? (7.1)
How does DNA replicate? (7.2)
How are genes transcribed? (7.3)
How are proteins made? (7.4)
What effects do changes in the DNA sequence have? (7.5)

7.1 The role of DNA

How do we know DNA is the hereditary molecule?

Today, we all know that DNA is the hereditary molecule of cells. However, our understanding of DNA and its role as the genetic material was not always so clear. During the first half of the twentieth century, many biologists thought that the DNA molecule was too simple to serve as the proverbial blueprint of life. As we mentioned, DNA is a polymer of nucleotides, each of which contains one of only four different nitrogenous bases. Conversely, proteins are composed of at least 20 different amino acids that can be arranged in various orders to produce molecules of myriad shapes and sizes.

Several landmark experiments demonstrated that DNA affected the phenotype of an organism and could direct the synthesis of more complex structures. Researchers made these important discoveries using microorganisms. In this section, we will examine three experiments providing evidence that DNA is the genetic molecule. We also will review the structure of DNA.

The Griffith experiment

The identification of DNA as the genetic material arose from a seemingly odd observation. In 1928, Frederick Griffith published a report in which he examined the virulence, or disease-causing capability, of two strains of the bacterium *Streptococcus pneumoniae*. The strains were referred to as smooth, or S, and rough, or R, based on their colony appearance when grown on agar plates. When live S cells were injected into mice, the mice died. When live R cells were injected into mice, the mice lived. As you might expect, when S cells were heat-killed prior to being injected into mice, the mice did not die. From these observations, one could easily conclude that the S strain was pathogenic, or virulent, and the R strain was non-pathogenic, or avirulent. Griffith did one more experiment. He injected a mixture of both heat-killed S bacteria and live R bacteria into mice. The results were shocking: the mice died. Subsequently, Griffith was able to isolate live S bacteria from the mice **(Figure 7.1)**.

How can we interpret this result? Griffith assumed (understandably and quite correctly!) that the S cells did not come back to life. Rather, he postulated that something released from the killed S cells altered the phenotype of the R cells, converting them, or transforming them, from non-pathogenic R cells into pathogenic S cells. He termed this process **transformation**.

CONNECTIONS Griffith observed natural transformation, which is just one mechanism by which bacteria can acquire new genetic material. In Section 9.4, we will examine all of these processes more closely. We also will see how we can intentionally insert foreign DNA into a bacterial cell.

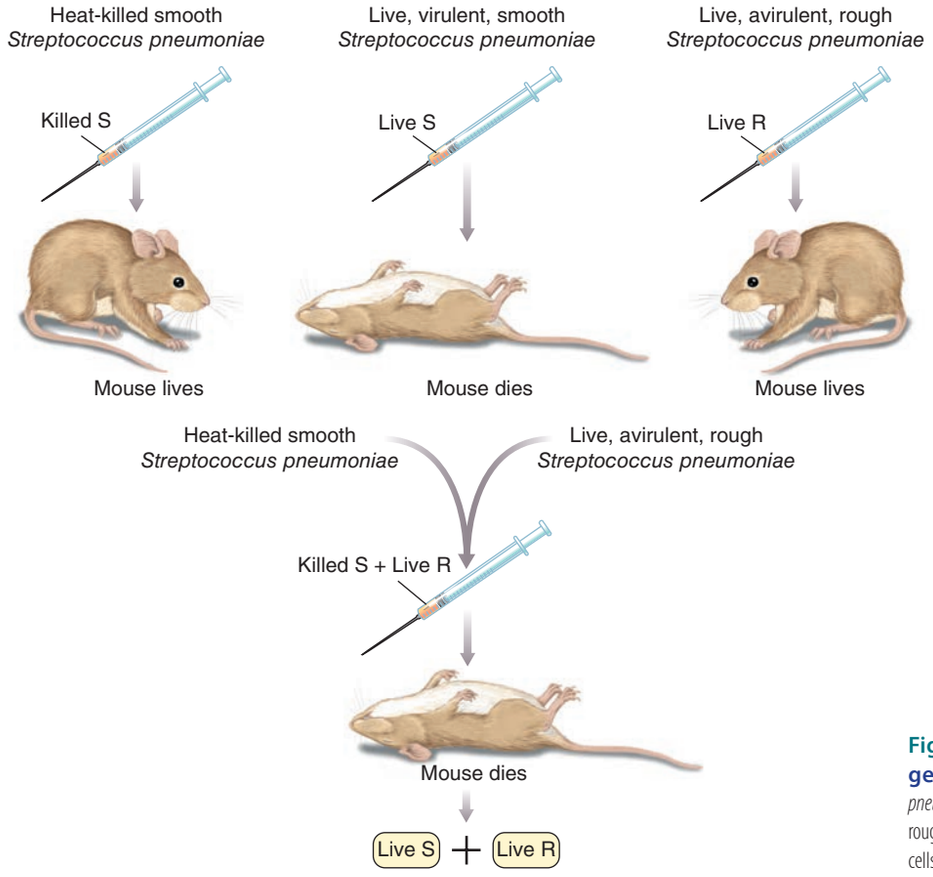

Figure 7.1. Griffith's demonstration of genetic transfer When injected into mice, *Streptococcus pneumoniae* cells from smooth colonies were virulent. Cells from rough colonies were avirulent. When smooth virulent *S. pneumoniae* cells were heat-killed and mixed with live, rough, avirulent cells, a factor from the smooth cells altered (or transformed) the phenotype of the rough cells, producing some smooth cells.

The Avery, MacLeod, and McCarty experiment

Griffith's experiments with *S. pneumoniae* demonstrated that some cellular factor could be transferred to another cell and affect the characteristics of the recipient cell. Of course, Griffith left a major question unanswered: What was this transforming agent? This part of the puzzle was answered in another classic experiment. During the early 1940s, Oswald Avery, Colin MacLeod, and Maclyn McCarty, researchers at the Rockefeller Institute (now known as Rockefeller University) and New York University, investigated this very question. Using various biochemical techniques, they partially purified the transforming factor from S cells and determined that it was mostly DNA. However, the transforming factor they isolated possibly could have contained some protein or RNA. To confirm that DNA was the transforming factor, they demonstrated that the ability to alter the phenotype of the recipient cell was not affected by treatment with proteases (enzymes that degrade proteins) or RNases (enzymes that degrade RNA). However, DNases (enzymes that degrade DNA) did destroy the transforming ability of their isolated factor **(Figure 7.2)**.

Avery described the impact of this finding in a typically understated way:

> If we are right, and of course that is not yet proven, then it means that nucleic acids are not merely structurally important but functionally active substances in determining the biochemical activities and specific characteristics of cells and that by means of a known chemical substance it is possible to induce predictable and hereditary changes in cells. This is something that has long been the dreams of geneticists. (Oswald Avery, 1943)

The researchers published their results in the *Journal of Experimental Medicine* in the spring of 1944.

Today, we have a much better understanding of both this experiment and the Griffith experiment. The pathogenic S strain of *S. pneumoniae* **(Microbes in Focus 7.1)** contains a gene that results in the production of a polysaccharide capsule (see Figure 2.34). This capsule makes the bacterial colonies appear smooth. It also helps the bacteria evade the host immune response, thus making this strain pathogenic. Conversely, the R strain lacks this gene. As a result, R strain cells do not make a polysaccharide capsule, colonies appear rough, and the strain is non-pathogenic. When Griffith combined heat-killed S strain cells with live R strain cells, random fragments of S strain DNA, released from the killed cells, were incorporated by the live R cells. In a few cases, cells incorporated a piece of DNA that included the gene necessary for capsule production. These cells were transformed from rough non-pathogenic cells to smooth pathogenic cells.

The implications of Avery's findings are staggering. First, this experiment provided compelling evidence that DNA was the hereditary molecule. Perhaps more importantly, this

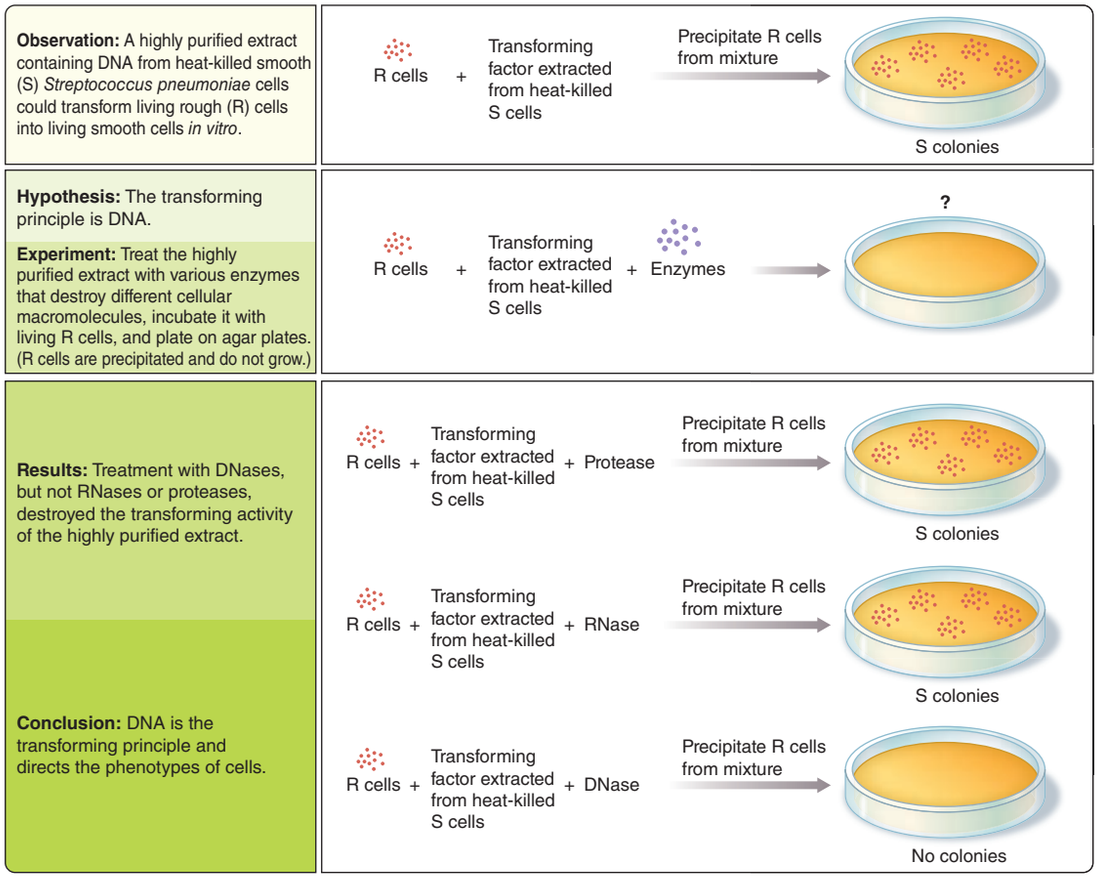

Figure 7.2. Biochemical evidence that Griffith's transforming factor is DNA Avery, MacLeod, and McCarty demonstrate that the transforming factor is DNA. Live R cells were incubated with the transforming factor isolated from heat-killed S cells. Serum that would precipitate and remove R cells was added, and the mixture was grown on agar plates. DNases, but not RNases or proteases, eliminated transformation.

experiment opened the door for the molecular biology revolution. As Avery noted, transformation makes it "possible to induce *predictable and hereditary* changes in cells." If we can identify pieces of DNA associated with specific phenotypes, then we can insert that DNA into recipient cells and alter the characteristics of those cells.

The Hershey–Chase experiment

Although the conclusions drawn by Avery and his colleagues may seem convincing, some biologists still questioned the preeminent role of DNA as the hereditary molecule. All lingering doubts were put to rest by a third classic experiment, the Hershey–Chase experiment. Shortly after Avery, MacLeod, and McCarty published their paper, Alfred Hershey and Martha Chase, researchers at the Cold Spring Harbor Laboratory, used the bacteriophage T2 to investigate the role of DNA in heredity. Their approach was elegant in its simplicity.

CONNECTIONS Replication of bacteriophage T2 begins with a specific binding event between a viral attachment protein and a cellular receptor. Research investigating the molecular determinants of this process is presented in **Section 8.1**.

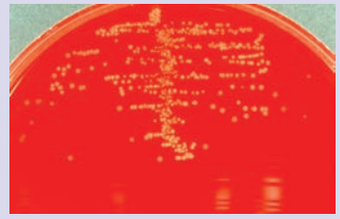
Hershey and Chase knew that the genetic material of viruses entered cells and directed the infected cells to produce more virus particles. They also knew that T2 was composed of just two components—protein and DNA. During the infection process, the capsid of bacteriophage T2 attached to, but did not enter, the infected cell. Biochemical studies had shown that nucleic acids contained phosphorus (P), but not sulfur (S).

Microbes in Focus 7.1
STREPTOCOCCUS PNEUMONIAE IN THE LABORATORY AND THE HOSPITAL

Habitat: Commonly found in the nasopharynx of humans

Description: Gram-positive coccus, approximately 0.8 μm in diameter, that often appears in short chains

Key Features: *Streptococcus pneumoniae* played an integral role in defining DNA as the genetic material. *S. pneumoniae* also is a significant human pathogen, causing not only pneumonia, but also sinus and ear infections and meningitis. Its oligosaccharide capsule interferes with phagocytosis of the bacteria by immune cells, thereby enhancing its virulence.



© Luis M. de la Maza/ Phototake

Conversely, proteins contained lots of sulfur but little phosphorus. Using this information, they developed their experiment. Some phage particles were labeled with ^{35}S, or radioactive sulfur. Because S is present in proteins, these virions contained radiolabeled protein. Other phage particles were labeled with ^{32}P, or radioactive phosphorus. Because P is present in nucleic acid, these virions contained radiolabeled DNA. In separate experiments, labeled phage particles were incubated with *Escherichia coli*, their host cells, for a few minutes and then the mixture was placed in a blender and agitated to remove the capsids from the surface of the bacteria. The mixture then was centrifuged, causing the bacterial cells to pellet, and the amount of radioactivity present in the resulting pellet and supernatant was determined. They found that the ^{35}S was present in the supernatant and the ^{32}P was present in the pellet **(Figure 7.3)**. In other words, the phage capsids, which contained protein, did not enter the cells. Conversely, the DNA was injected into the host cells. The injected DNA directed the production of new phage particles within the cells. Hershey and Chase were able to conclude that the hereditary material of bacteriophage T2 was DNA.

Structure of DNA

Around the same time that Avery, MacLeod, and McCarty and Hershey and Chase were demonstrating that DNA was the hereditary material of cells, many researchers were investigating the structure of this molecule. In 1953, investigations by James Watson, Francis Crick, and Rosalind Franklin solved the puzzle. In the history-making paper by Watson and Crick, they noted that DNA consists of two chains. Each chain is a polymer of nucleotides. Each nucleotide, in turn, consists of the following:

- A five-carbon sugar, *2-deoxyribose*
- A *phosphate group* that covalently links the 3′ carbon of one 2-deoxyribose to the 5′ carbon of the next sugar
- One of four nitrogen-containing, or nitrogenous, bases, attached to the 1′ carbon of the sugar

In contrast, a nucleoside consists only of a nitrogenous base connected to a sugar. The nitrogenous bases are classified as **purines** or **pyrimidines**. The purines, **adenine (A)** and **guanine (G)**,

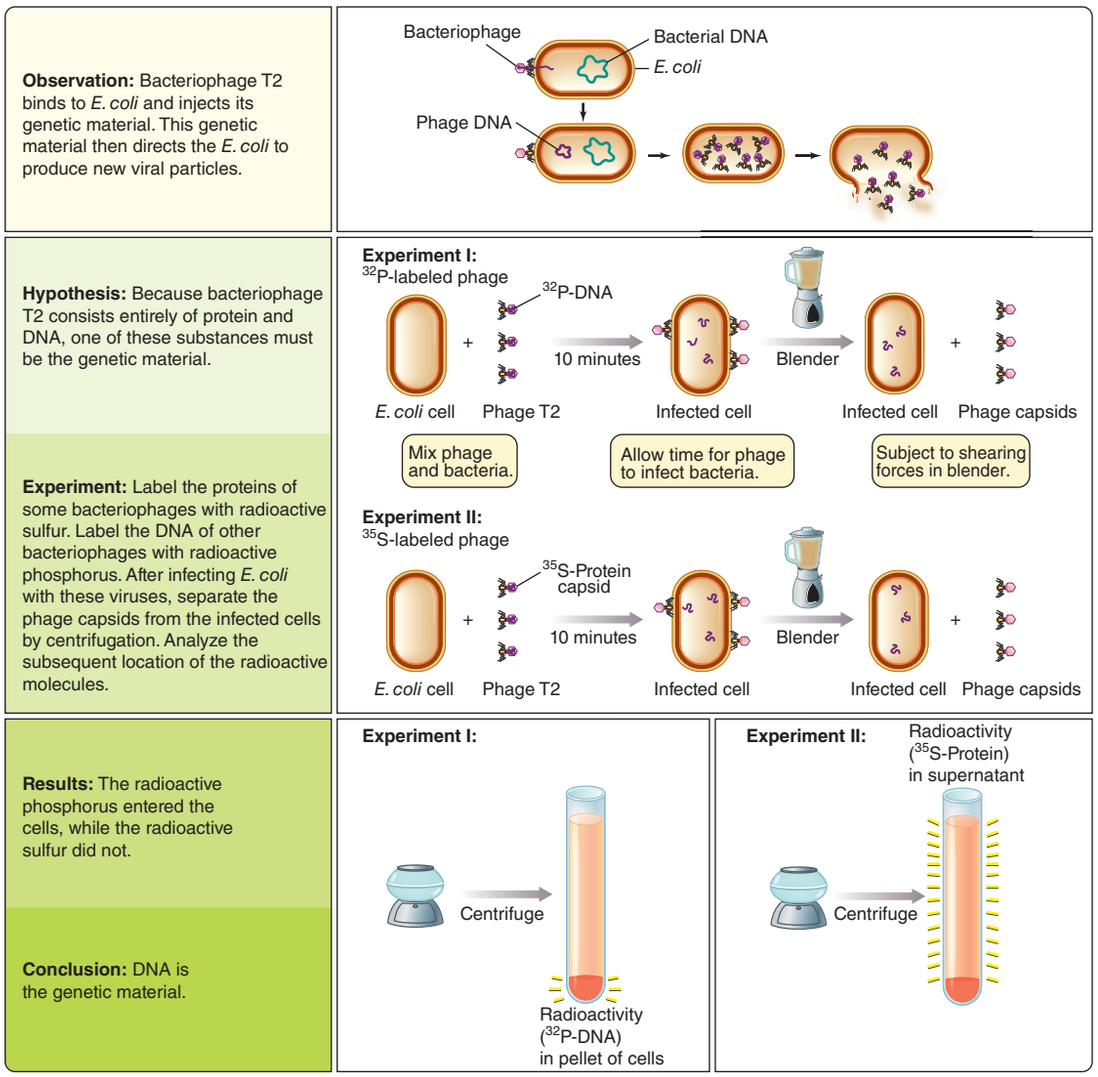


Figure 7.3. Confirmation that DNA is the genetic molecule By separately labeling the proteins or DNA of bacteriophage T2 with radioactive isotopes, Hershey and Chase demonstrated that DNA, and not protein, enters the host bacterium, *E. coli*, and directs the synthesis of new phage particles.

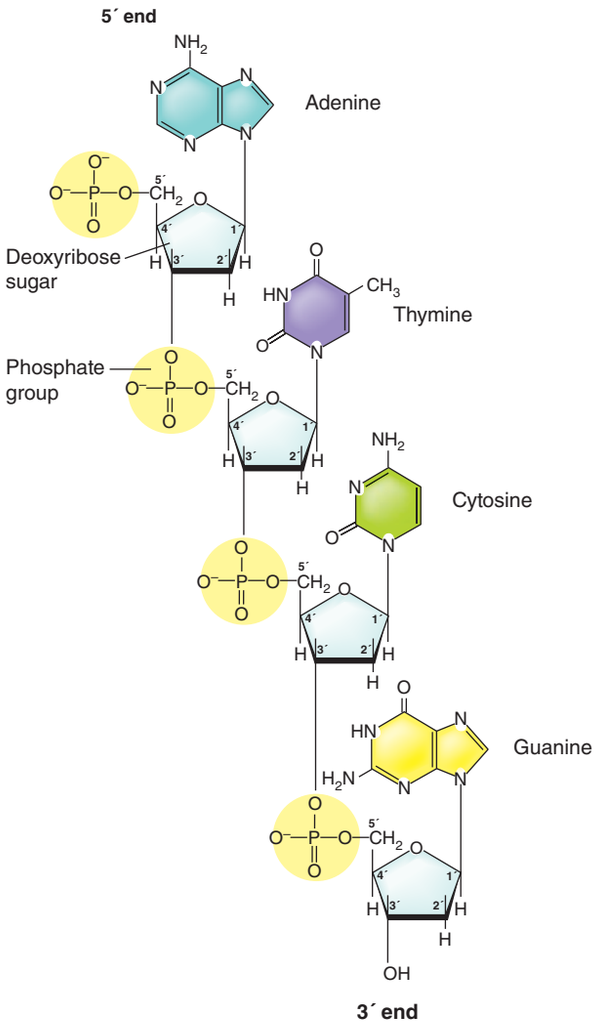
contain a double-ring structure. The pyrimidines, **cytosine (C)** and **thymine (T)**, contain a single ring structure (Figure 7.4). Note the conventional numbering of carbon atoms within the molecules indicated in the figure.

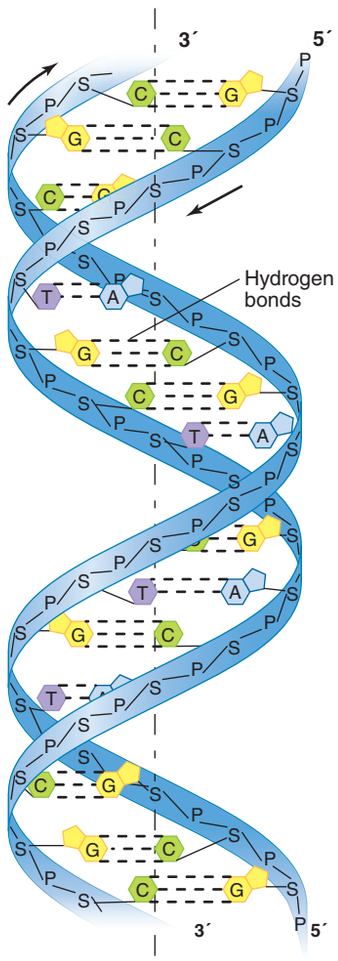
Each linear chain of DNA has a 5′ end and a 3′ end. The two chains of a double-stranded molecule align in an **antiparallel** fashion, with the 5′ end of one chain aligned with the 3′ end of the other chain. More importantly, the nucleotides pair together in a very precise way: A always aligns with T, and C always aligns with G. In this way, the two strands are **complementary** to one another. If we know the sequence of nitrogenous bases in one strand, then we can infer the sequence of bases in the other strand. Hydrogen bonds hold the two chains together, with two H bonds linking A to T and three H bonds linking C to G. The entire double-stranded molecule forms a very precise spiral, or helix. Because of their discovery of the double-stranded structure of DNA, Watson and Crick, along with their collaborator Maurice Wilkins, received the Nobel Prize in Physiology or Medicine in 1962. Sadly, Rosalind Franklin, a coworker of Wilkins who generated most of the data used by Watson and Crick, died of cancer in 1958 and thus could not be recognized by the Nobel committee.

Even though the DNA in all cells is a double-stranded, helical molecule, significant differences in the organization of DNA have been identified (Table 7.1). In bacteria and archaea, DNA usually exists as a single, closed circular molecule. Supercoiling of this circular molecule helps to compact its size, at least in bacteria (Figure 7.5). Because bacteria and archaea usually have a single copy of their chromosome, they also generally have a single copy of all their genes. In addition to this single copy of the chromosome, bacteria and archaea often contain plasmids, small, circular extrachromosomal DNA molecules that typically contain non-essential genes. A bacterial cell may contain multiple copies of a particular plasmid and several different types of plasmids.

Unlike the DNA in bacteria and archaea, the DNA in eukarya usually exists as linear molecules. As we discussed in Chapter 3, eukarya typically have a $1n$ and $2n$ genetic complement at different points in their replication cycle. The eukaryal DNA binds to histones, basic proteins that interact with the DNA. The DNA wraps around these histones in a very precise way, forming nucleosomes (see Figure 7.5B). Again, this level of organization compacts the DNA and also protects it from degradation by various nucleases, enzymes that destroy nucleic



A. Structure of nucleotide polymer



B. Structure of double-stranded DNA

Figure 7.4. The composition and structure of DNA **A.** Each nucleotide consists of a five-carbon deoxyribose molecule, a phosphate group, and a nitrogenous base. The phosphate group links the 3′ carbon of one deoxyribose sugar to the 5′ carbon of the next deoxyribose. Nitrogenous bases are linked to the 1′ carbons of the sugars. **B.** Two strands align in an antiparallel fashion forming a double helix, in which adenine (A) always pairs with thymine (T) and cytosine (C) always pairs with guanine (G). Dashed lines between the nitrogenous bases represent H bonds.

TABLE 7.1 Characteristics of DNA molecules

	Organization	Plasmids	Histones	Representative sizes (kbp)	Notable features
Bacteria	Single, circular molecule	Common	No	580 *Mycoplasma genitalium* 4,600 *Escherichia coli*	Some bacteria, like *Borrelia burgdorferi*, have linear chromosomes.
Archaea	Single, circular molecule	Common	Yes	1,740 *Pyrococcus horikoshii* 3,000 *Sulfolobus solfataricus*	Hyperthermophilic archaea possess reverse gyrase, an enzyme that increases the thermostability of the chromosome.
Eukarya	Linear molecules, 1*n* and 2*n* during replication cycle	Rare	Yes	12,495 *Saccharomyces cerevisiae*, yeast 3,270,000 *Homo sapiens*, humans 17,000,000 *Triticum aestivum*, wheat	Plasmids have been identified in fungi and plants.

Unusual packaging of DNA in *Deinococcus radiodurans* Actively growing cells often possess four to ten copies of the genome. **A.** The DNA in *Deinococcus* cells adopts a doughnut-like conformation. **B.** The DNA is stained with DAPI, causing it to appear blue in this epifluorescence image of *Deinococcus* cells. The plasma membrane is stained red.

acids. In archaea, the DNA also appears to be organized around histones. Recent sequence analysis indicates that the archaeal and eukaryal histones share an evolutionary history.

CONNECTIONS The existence of histones in archaea and eukarya, but not bacteria, raises interesting questions about the evolutionary history of these organisms. As we discussed in **Section 4.2**, some researchers hypothesize that histones evolved after the divergence of bacteria and archaea, but before the emergence of eukarya.

It should be noted that the DNA of *Deinococcus radiodurans*, the radiation-resistant bacterium that we discussed in the opening story of this chapter, differs somewhat from the typical description of bacterial DNA. Rather than possessing a single copy of its genome, cells of *D. radiodurans* typically possess four to ten complete copies of the genome at any one time. Additionally, these DNA molecules appear to be stacked together, forming an unusual doughnut-like conformation **(Figure 7.6)**. Perhaps this stacked packaging of the DNA contributes to the extraordinary stability the DNA of this bacterium shows to radiation and chemical assaults that would severely damage other microorganisms.

7.1 Fact Check

1. Describe the experiments of Griffith and Avery that showed DNA was the hereditary material.
2. How were radioactive sulfur and phosphorus used in the Hershey and Chase experiment?
3. Describe the structure of DNA using the following terms: nucleotide, phosphate group, bases, deoxyribose sugar, antiparallel, complementary, and hydrogen bonds.
4. Compare and contrast the organization of DNA in archaea, bacteria, and eukarya.

7.2 DNA replication

3D ANIMATION

How does DNA replicate?

In their paper on the structure of DNA, Watson and Crick rather slyly noted that their proposed structure "immediately suggests a possible copying mechanism for the genetic material." Indeed, by looking at the structure, one can imagine how this molecule could be duplicated. If A always interacts with T and if C always interacts with G, then each chain of a double-stranded molecule could serve as a template, or pattern, for the production of a new complementary second chain **(Figure 7.7)**. In 1958, Matthew Meselson and Franklin Stahl, researchers at the California Institute of Technology, provided elegant experimental evidence supporting this model. Referred to as **semiconservative replication**, because one strand of the original DNA molecule is conserved in each of the newly formed double-stranded molecules, this mechanism of replication preserves the sequence of the bases. As we will see later in this chapter, maintaining the fidelity of the genetic molecule is critically important.

Of course, the actual process isn't quite as simple as Watson and Crick implied. In this section, we will briefly examine the process of DNA replication. Although the basics of DNA

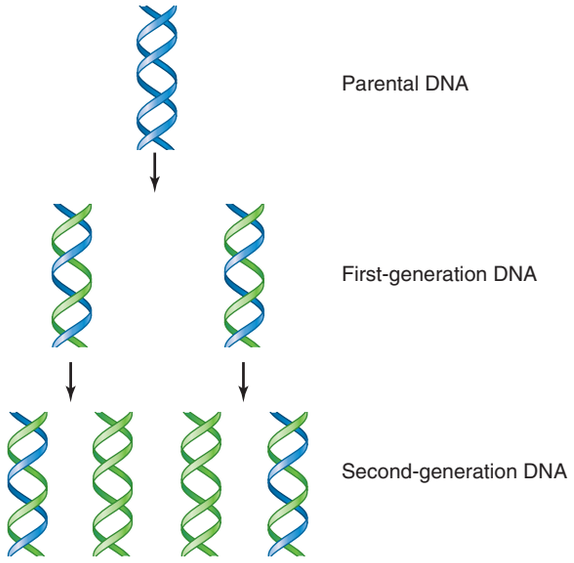

Figure 7.7. Semiconservative replication of DNA As the double-stranded DNA molecule unwinds, each strand serves as a template for the formation of a new complementary strand. As a result, two new double-stranded molecules are formed, each identical to the original molecule. In each new double-stranded molecule, one strand is derived from the original molecule (blue) and the other strand is newly synthesized (green).

replication are the same in all organisms, important and fundamental differences do exist among different groups of organisms. We will look at some of the more notable differences that exist between bacteria, eukarya, and archaea. The replication of viruses will be addressed in Chapter 8.

DNA replication: Origins of replication

Ten years after Watson and Crick described the structure of DNA, Jacob, Brenner, and Cuzin proposed an elegant model for the initiation of DNA replication, which they termed the replicon model. They proposed that the process would require two main components—a replicator and an initiator. They hypothesized that the replicator would be the site on the DNA molecule where replication started. They also predicted that the initiator was a protein that could interact with the replicator, and begin the process.

Subsequent studies with *Escherichia coli* have confirmed the basics of this model. In bacteria, DNA replication begins at a specific site on the chromosome, the origin of replication, or ***oriC***. This sequence, the replicator proposed by Jacob and colleagues, has been very well characterized. In *E. coli*, it consists of roughly 245 base pairs (bp) and contains four repeats of a 9-bp sequence and three repeats of a 13-bp, AT-rich, sequence (Figure 7.8). In other species of bacteria, these same recurring elements, or motifs, also are present, although the number of repeats and their exact positioning within *oriC* may differ. The functional importance of *oriC* can be demonstrated in a simple way. When *oriC* is added to an artificially constructed closed circular DNA molecule, then that molecule can be replicated within an *E. coli* cell. Finally, it appears that every bacterial chromosome contains a single *oriC*. In other words, replication of the bacterial chromosome begins at a single location.

The 9-bp repeats in *oriC*, often referred to as DnaA boxes, serve as binding sites for **DnaA**, a DNA-binding protein produced by the *dnaA* gene. Multiple copies of DnaA, the initiator proposed by Jacob, bind to the DnaA boxes and then interact with the 13-bp repeat regions, resulting in strand separation and the formation of a single-stranded region. Several studies have shown that DnaA is an essential protein. Without a functional DnaA, DNA replication does not begin, and the cell cannot grow and divide. After DnaA begins separating, or "melting," the DNA, a series of other proteins, including DnaB (often referred to as **helicase**) and DnaC (often referred to as a helicase loader), are recruited to this site to aid in the unwinding. **DnaG**, or **primase**, synthesizes short segments of RNA needed to prime DNA replication. **Single-stranded DNA-binding proteins (SSB)** attach to the newly formed single-stranded DNA to keep the strands from reannealing, and a single-stranded **replication bubble** forms (Figure 7.9). DNA polymerases then begin replicating the DNA at both ends of this bubble, the replication forks.

In eukarya, many origins of replication exist in each linear chromosome, in contrast to the single origin of replication present in the circular bacterial chromosomes. In some cases, these origins are within 10 kbp, or 10,000 bp, of one another. In other cases, the origins are over 100 kbp apart. Most likely, multiple origins of replication are needed to replicate the larger genomes of eukaryal cells in a reasonable amount of time. Studies with *Saccharomyces cerevisiae*, a model eukaryal organism introduced in Chapter 3, have identified a eukaryal replicator that shares functional similarities with *oriC*. This element in the yeast genome has been termed an autonomously replicating sequence, or ARS. Like *oriC*, it contains a binding motif for an initiator. In the case of *S. cerevisiae*, the initiator, or origin recognition complex (ORC), is composed of six different proteins (Orc1-6). After binding to the ARS, the ORC recruits additional proteins necessary for replication, including Cdc6, Cdt1, and the minichromosomal maintenance (MCM)

Figure 7.8. Origin of replication in *Escherichia coli* This AT-rich region contains four 9-bp and three 13-bp repeated sequences. Other bacteria contain similar motifs, although the exact numbers and their positioning may differ. In order to replicate in a cell, every circular DNA needs an origin of replication. Note that "N" indicates that any base may be at that location.

Figure 7.9. Process Diagram: Initiation of DNA replication in bacteria
A series of proteins, including DnaA, DnaB, and DnaC, interact with *oriC* to help form a replication bubble. DnaA binds to the 9-bp repeats. Additional molecules of DnaA bind cooperatively, forming a complex with *oriC*, and begin denaturing the DNA. DnaC brings DnaB, also referred to as DNA helicase, to the complex and further unwinding of the double-stranded DNA occurs, forming a replication bubble.

complex, a group of six proteins that functions as the helicase (Figure 7.10). These proteins then begin the important task of unwinding the DNA. An origin of replication also has been identified in *Saccharomyces pombe*, a close relative of *S. cerevisiae*. Surprisingly, the origins in these two species show little similarity to each other. Much less is known about the origins of replication in other eukaryal species.

One might assume that the DNA replication process in archaea more closely resembles the bacterial process than the eukaryal process. After all, the single, relatively small, circular chromosomes common to archaea resemble the chromosomes of bacteria. However, recent evidence indicates that the replication machinery of archaea may more closely resemble the replication machinery of eukarya. In *Pyrococcus horikoshii*, a hyperthermophilic archaeon, a single origin of replication has been identified, much as we see in bacteria. However, the initiator protein appears to be closely related to Orc1 and Cdc6, two of the eukaryal replication complex proteins. *Sulfolobus solfataricus*, another hyperthermophilic archaeon, presents an even more interesting case. The *S. solfataricus* chromosome appears to possess two functional origins of replication, *oriC1* and *oriC2*. Additionally, three *cdc6*-like genes (*cdc6-1*, *cdc6-2*, and *cdc6-3*) have been identified in the genome of this species. It has been hypothesized that the Cdc6-1 and Cdc6-3 proteins may be positive regulators of replication. In contrast, Cdc6-2

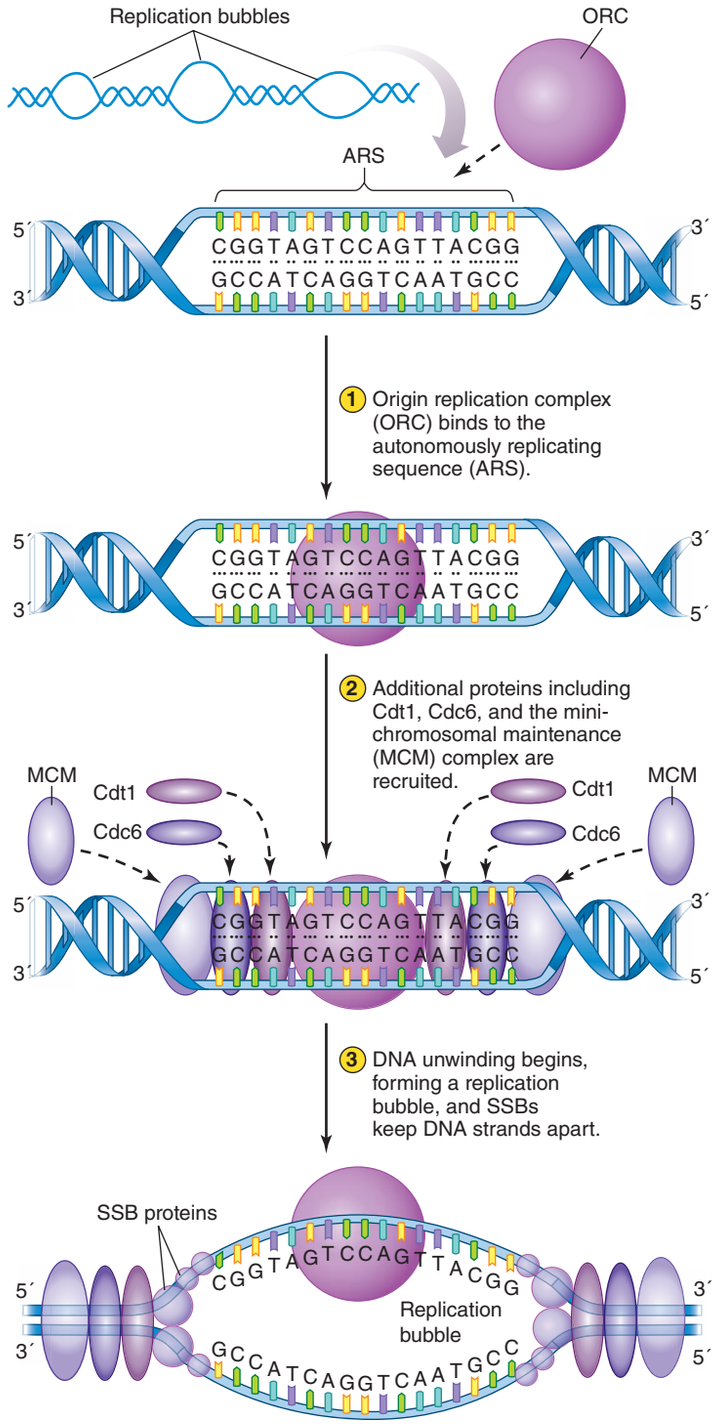

Figure 7.10. Process Diagram: Initiation of DNA replication in eukarya
In eukarya, DNA replication initiates at several spots along the linear chromosome. In *Saccharomyces cerevisiae*, the origin recognition complex (ORC) binds to the origin, or ARS. Additional proteins are recruited, including Cdc6 and Cdt1. The minichromosomal maintenance (MCM) complex also binds and functions as the helicase. Additional proteins then locate to the replication bubble and begin synthesizing new DNA.

serves as a negative regulator, or inhibitor, of replication. Thus, DNA replication in archaea and bacteria exhibit some fundamental differences. This finding provides more conclusive evidence in support of the three-domain tree of life hypothesis. This finding also further supports the idea that archaea may be more closely related to eukarya than to bacteria. The *S. solfataricus* data suggest that archaea may ultimately prove to be useful model organisms for the study of complex eukaryal events like DNA replication.

DNA replication: Initiation and elongation

Following the attachment of the initiator and helicase proteins to the origin of replication, the production of new DNA strands, complementary to the old strands, can occur. A series of enzymes, known as **DNA polymerases**, catalyze this task. However, DNA polymerases cannot simply start synthesizing a new DNA strand using a piece of single-stranded DNA as a template. Rather, these enzymes only can add new nucleotides onto an existing piece of DNA or RNA, using another strand as the template. Furthermore, all DNA polymerases only add new nucleotides onto the free 3′—OH group of a nucleotide. So how does this process ultimately begin? Again, the basic mechanism is remarkably similar in bacteria, eukarya, and archaea.

To initiate DNA elongation, primase, a special RNA polymerase introduced earlier, synthesizes a short piece of single-stranded RNA that is complementary to the exposed single-stranded DNA present at the replication bubble. Once this **primer** has been formed, DNA polymerase then can add new nucleotides onto this fragment in a 5′ to 3′ fashion, using the existing DNA molecule as a template. This elongation occurs bidirectionally, and the helicase proteins described in the previous section continue to unwind the existing double-stranded DNA as the elongation events proceed. Because DNA polymerase can elongate DNA only in a 5′ to 3′ direction, only one strand of single-stranded DNA at each replication fork can be extended continuously **(Figure 7.11)**. These strands are referred to as the **leading strands**. On the opposite strands, new primers must be added as the helicase unwinds more of the DNA. These strands exhibit discontinuous elongation and are referred to as **lagging strands**. These individual pieces of newly synthesized DNA and their corresponding RNA primers often are called **Okazaki fragments** after their discoverer, Reiji Okazaki.

Recall that in bacteria, the DnaG primase synthesizes short segments of RNA that bind to the single-stranded DNA. The major DNA polymerase involved in replication is the DNA polymerase III (DNA pol III) holoenzyme, a large, multisubunit complex. This enzyme adds a deoxynucleotide triphosphate to the free 3′—OH present on an existing nucleotide, removing two phosphates in the process. Elongation occurs at an impressive rate. The *E. coli* DNA pol III can synthesize DNA at a rate of 1,000 bases per second! In the lagging strand, this activity continues until the DNA polymerase and its newly made strand of DNA run into an RNA primer. At this point, a different DNA polymerase, DNA polymerase I (DNA pol I), removes the RNA primer, using a 5′ exonuclease activity. DNA pol I also fills in the resulting short gap. One last step remains.

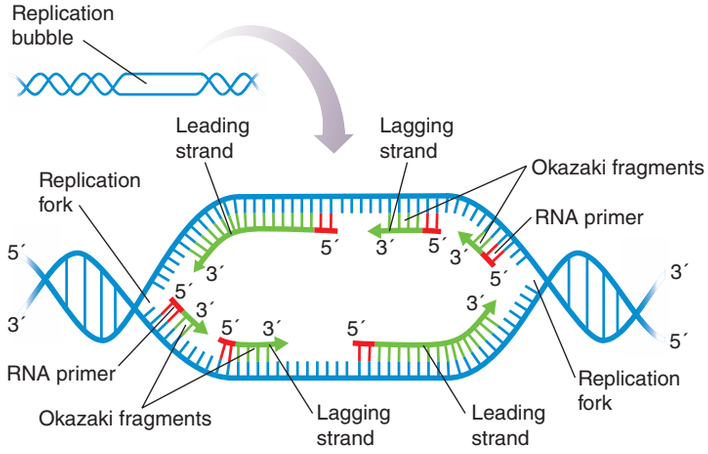

Figure 7.11. Bidirectional replication of DNA As the DNA unwinds, DNA synthesis occurs in a 5′ to 3′ direction, extending from short RNA primers produced by primase. At each replication fork, one strand elongates continuously (leading strand) and the other strand elongates discontinuously (lagging strand).

DNA **ligase** links, or ligates, the final 5′—phosphate and 3′—OH ends. The new DNA strand now is complete **(Figure 7.12)**.

Although it may be easiest to view these events as discrete steps, the entire process occurs in a concerted fashion. Indeed, it has been proposed that many of the enzymes involved in DNA replication, including helicase, primase, and DNA polymerase, interact with each other, forming a large, multisubunit complex referred to as the replisome. The replisome, then, allows for the simultaneous synthesis of the leading and lagging strands of DNA at a replication fork. In order for the replisome to function in this way, researchers have proposed the trombone model of DNA replication. Based on this model, the lagging strand forms a loop, similar in shape to the slide in a trombone. With the DNA in this conformation, the replisome can elongate the opposite sides of DNA while moving in a single direction **(Figure 7.13)**.

Mechanistically, the process of DNA replication in eukarya is very similar to the process of DNA replication in bacteria. Again, a primase adds short stretches of RNA to the single-stranded DNA present at the origin of replication. A DNA polymerase then begins adding nucleotides to the free 3′—OH group on the terminal nucleotide of the primer. Elongation occurs bidirectionally in a 5′ to 3′ direction, with a leading strand and a lagging strand present on each arm of the replication fork. Although the basic steps in the processes are similar, the specific enzymes differ **(Table 7.2)**. In eukarya, for instance, DNA polymerase α, associates with DNA primase, and this complex synthesizes the RNA primer. Also in eukarya, two separate DNA polymerases, DNA pol ϵ and DNA pol δ, respectively, synthesize the leading and lagging strands of DNA at a replication fork. As in bacteria, DNA ligase joins together adjacent lagging strands.

The general process of DNA replication in archaea does not vary much from the standard paradigm described above. However, the specific proteins involved more closely resemble the proteins used by eukarya than bacteria. As in bacteria and eukarya, a primase first adds an RNA primer to the single-stranded DNA at the origin of replication. This enzyme bears

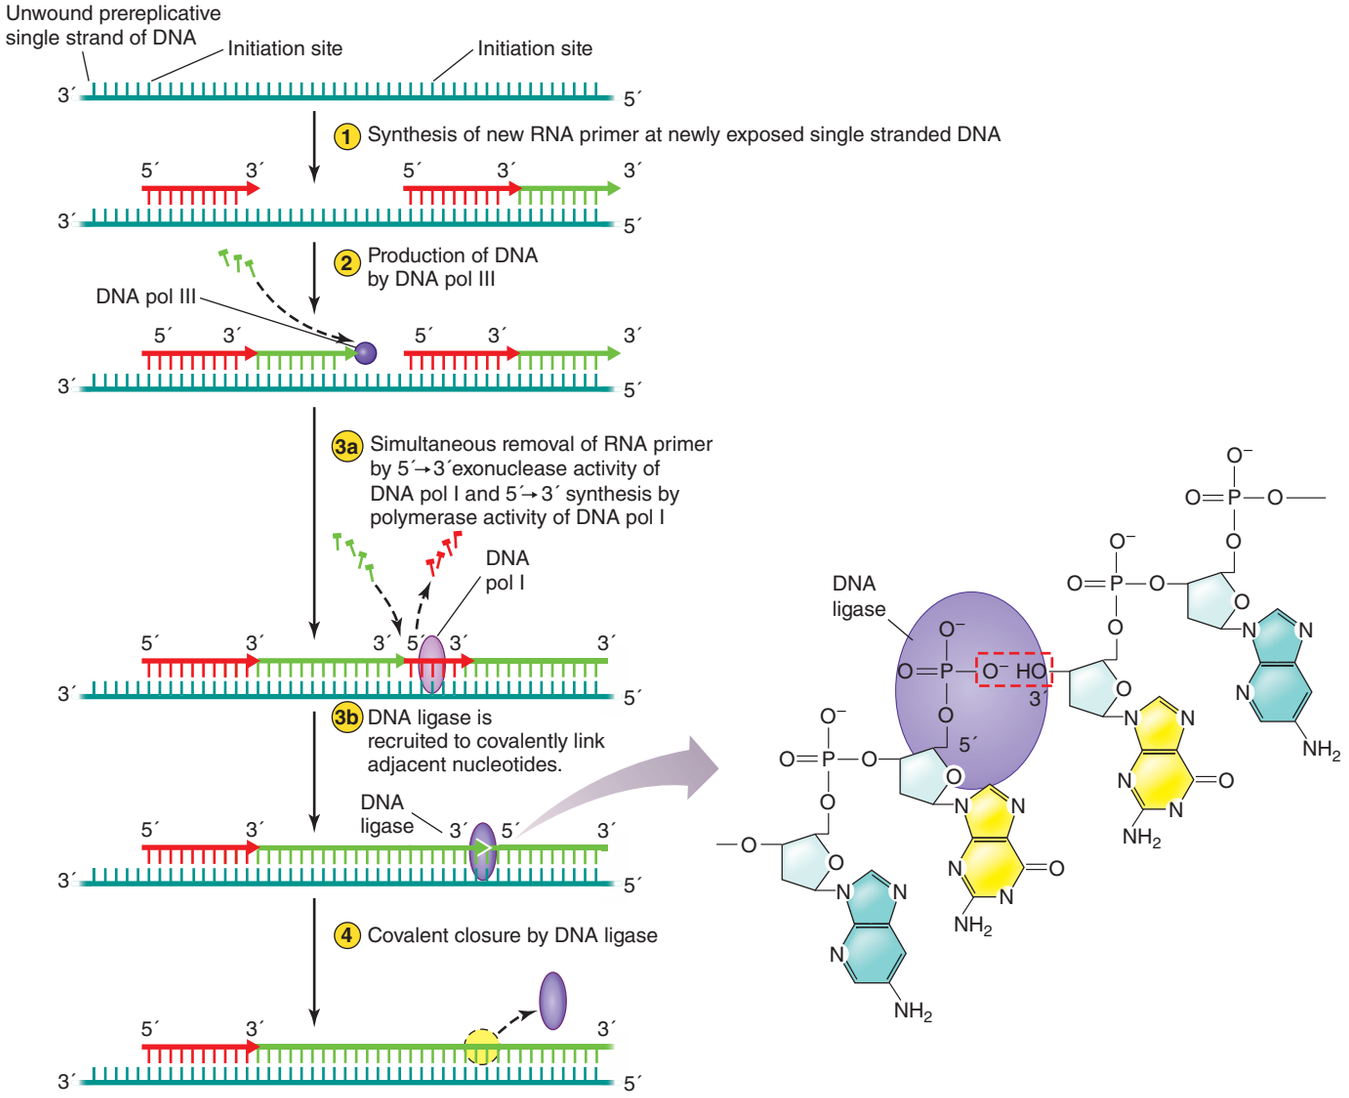

Figure 7.12. Process Diagram: DNA replication of the lagging strand in bacteria After synthesis of an RNA primer by primase, DNA synthesis continues in a 5′ to 3′ direction with DNA pol III, adding DNA nucleotides until the newly synthesized strand of DNA encounters an RNA primer. DNA pol I then removes the RNA primer and fills in the resulting gap with deoxynucleotides. DNA ligase covalently links the DNA fragments.

TABLE 7.2 Major DNA replication enzymes

	Bacteria	Eukarya	Archaea	Function
Origin recognition	DnaA	Origin recognition complex (ORC) proteins 1–6	ORC-like proteins	Site at which replication begins. Typically AT-rich
Primase	DnaG	DNA pol α	DNA pol α-like enzyme	Synthesizes short RNA oligonucleotides to which DNA polymerase adds new nucleotides
		DNA primase		
Helicase	DnaB	Dna2	Dna2-like enzyme	Aids in unwinding double-stranded DNA
Replication enzyme	DNA pol III	DNA pol ϵ (leading strand) DNA pol δ (lagging strand)	Eukaryal-like family B DNA polymerase	Major enzymes involved in synthesizing new DNA
Removal of primers	DNA pol I	FEN1 [Rad2]	FEN1 [Rad2]	Excise short pieces of RNA used as primers
Ligation	DNA ligase	DNA ligase I	DNA ligase	Covalently links adjacent lagging strands

Figure 7.13. Trombone model of DNA replication To facilitate the replication DNA, several proteins, including DNA polymerase III, helicase, and primase, come together to form a structure known as the replisome. The DNA at the replication fork folds, assuming the shape of a trombone. With the DNA in this conformation, the replisome can move in one direction and replicate both the leading and lagging strands of the DNA.

significant sequence homology to the eukaryal protein p48, a component of the DNA pol α/primase complex. The major replicative enzyme in archaea also shows significant sequence homology to the replicative enzymes found in eukarya, suggesting an evolutionary link between the replication machinery of archaea and eukarya.

DNA replication: Termination

As the two arms of the replication fork proceed around the circular bacterial chromosome, they eventually meet on the opposite side of the circle. At this point, DNA elongation stops. In *E. coli*, this termination event is not random. Rather, a series of termination sequences, or *ter* sites, exist on the chromosome, roughly opposite of *oriC*. A Tus protein binds to one of the *ter* sites and stops the forward progress of one of the replication forks. When the other replication fork arrives at this termination locus, the two halves of the newly synthesized DNA are joined, resulting in two identical circular double-stranded DNA molecules. Because these two circular chromosomes are linked together, one more enzyme is needed—topoisomerase. Topoisomerase II forms a transient double-stranded break in the DNA molecules, thereby allowing the two circles to become disentangled **(Figure 7.14)**.

Because chromosomes in eukarya generally are linear, termination of DNA elongation presents a more challenging problem. Think about the scenario described in Figure 7.10. As bubbles of replication along the linear chromosome extend, the replication forks eventually will merge. Through the exonuclease activity of polymerases and DNA ligase, the RNA primers needed to initiate the elongation process will be removed and replaced with DNA. In this manner, the leading strand can extend to the very 5′ end of its complementary template strand. Completion of the lagging strand at the end of the chromosome, however, is not so simple. An RNA primer will remain at the 3′ end of the newly synthesized strand of DNA. The RNA in this RNA:DNA heteroduplex will be degraded by exonucleases, resulting in a short stretch of single-stranded DNA at the end of the chromosome **(Figure 7.15)**. If this stretch of DNA were to remain single-stranded, then it would be degraded, resulting in a shortening of the chromosome with every round of DNA replication, that is, with every cell division. However, filling in this stretch of single-stranded DNA is problematic; DNA polymerase only can add new nucleotides onto the 3′ end of an existing segment of DNA. As shown in Figure 7.15, the single-stranded region at the terminus of a linear chromosome has a 5′ end.

To solve this problem, linear chromosomes of eukarya end in a special sequence known as a **telomere**. Basically, the telomere consists of a short sequence of bases repeated many times. During replication, a unique DNA polymerase, **telomerase**, interacts with the telomere. Telomerase consists of several proteins and a short piece of RNA. The RNA, it turns out, is complementary to the single-stranded DNA that forms at the end of a linear chromosome. Through complementary base-pairing, telomerase attaches to the telomere. It attaches in such a way that part of the telomerase RNA (TER) extends beyond the 3′end of the telomere. Telomerase extends this 3′ end, using TER as a template. In other words, telomerase is an RNA-dependent DNA polymerase. After the 3′ end of the chromosome has been extended, the enzyme moves down the newly synthesized molecule, thereby extending the single-stranded DNA of the telomere and lengthening the chromosome. Eventually, primase can add an RNA primer to this newly created DNA, and DNA polymerases can generate a complementary strand of DNA. Eventually, the final RNA primer will be removed, generating the single-stranded region necessary for telomerase binding during the next round of DNA replication.

Even though the process by which telomerase extends the end of a linear chromosome has been well established, the exact role of telomerase in the life of an individual remains an interesting topic of research. In studies involving various vertebrate species, several groups of researchers have shown that telomerase is active in cells early in development, but not in the somatic cells of adult individuals. In contrast, telomerase is active in tumor cells and immortal cell lines. Based on these pieces of evidence, many researchers now hypothesize that chromosomal shortening that occurs in the absence of telomerase activity may play a role in the aging process.

Let's address one final question before ending our discussion of the termination of DNA replication. What about bacteria with linear chromosomes? Although a vast majority of known bacteria and archaea possess circular chromosomes,

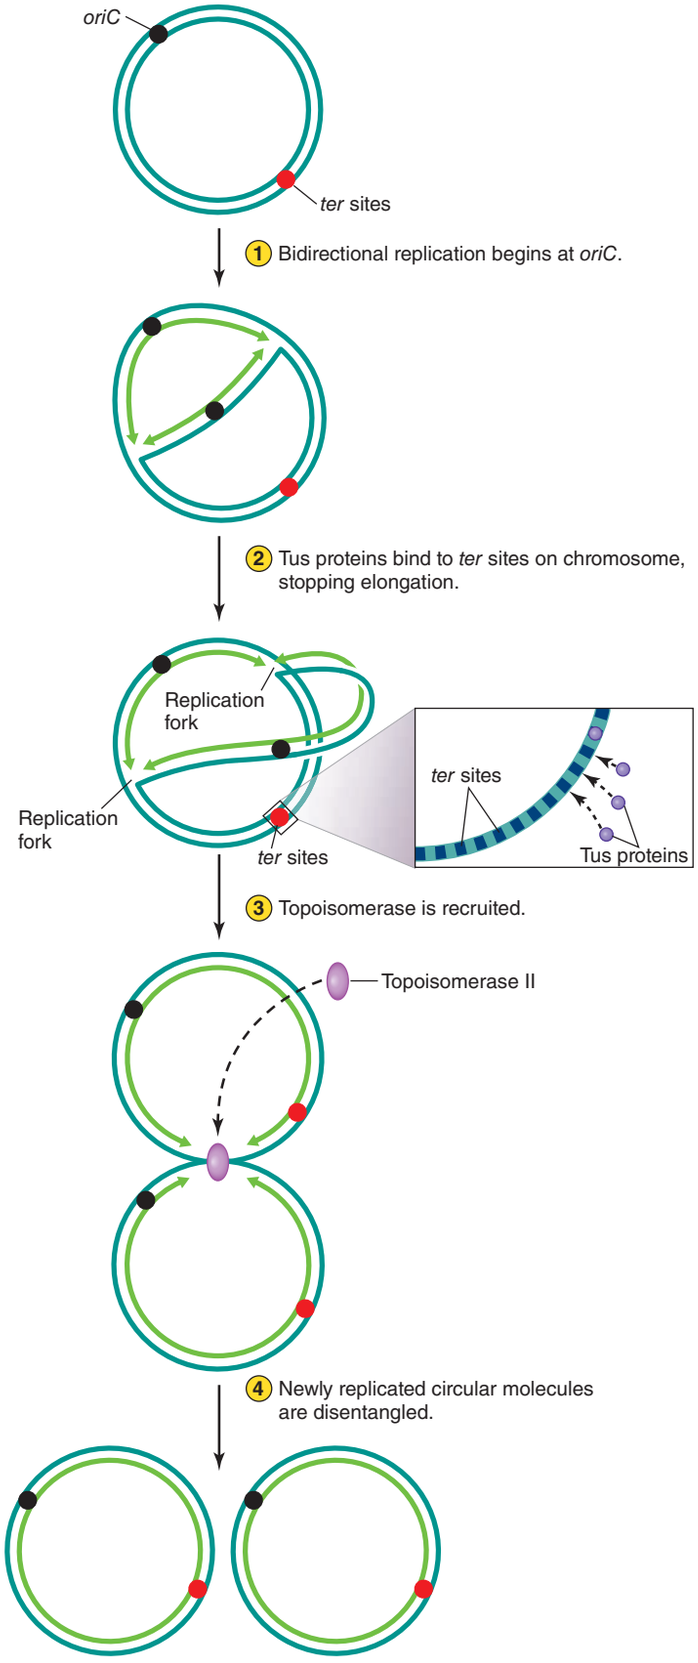

Figure 7.14. Process Diagram: The termination of replication for circular chromosomes In *E. coli*, a series of *ter*, or termination, sites exist roughly opposite the origin of replication (*oriC*). After bidirectional replication begins at *oriC*, the Tus protein binds to these *ter* sites and stops the progress of the replication forks. Topoisomerase II then forms a transient break in the DNA, allowing the two circles to become disentangled.

Figure 7.15. Process Diagram: Role of telomerase in replication of the ends of linear chromosomes On the lagging strand, a terminal RNA primer reaches the very end of the chromosome. After this terminal RNA primer is removed, a short segment of single-stranded DNA will remain. To prevent the degradation of this single-stranded region, the enzyme telomerase interacts with the telomere sequence of the single-stranded DNA. A piece of RNA associated with the telomerase enzyme binds to the single-stranded DNA of the telomere. Telomerase then extends the DNA, using a reverse transcriptase-like activity. The enzyme subsequently moves to the newly synthesized piece of DNA and repeats the process. In this manner, telomerase extends the length of the telomere. An RNA primer attaches to the newly formed piece of DNA, and DNA polymerase synthesizes new DNA, filling in the single-stranded gap.

several bacterial species possess linear chromosomes or linear plasmids. Presumably, replication of these linear DNA molecules presents the same challenge that we just explored with linear chromosomes in eukarya. This issue has been studied most extensively in *Streptomyces* species. *Streptomyces* are Gram-positive bacteria commonly found in soil. Known species within this genus possess linear plasmids and a linear chromosome. These linear DNA molecules end in inverted repeat sequences of differing lengths in different species. Conserved terminal proteins bind to these sequences. This arrangement may sound similar to the telomere/telomerase arrangement we described for eukarya. However, the two systems do not appear to be homologous. Recent research has shed some light on how this unusual bacterial system functions (Mini-Paper).

7.2 Fact Check

1. Why is DNA replication described as semiconservative?
2. Describe the replicon model of DNA replication.
3. Explain how *oriC*, DnaA, helicase, and DnaC play a role in DNA replication.
4. What is the role of the enzymes primase and DNA polymerase?
5. Explain the role of topoisomerase.
6. What is the relationship between telomeres and telomerase?

7.3 Transcription

How are genes transcribed?

As we have seen in the previous section, the structure of DNA clearly determines the mechanism of replication and allows for this replication to produce two new molecules identical to the original molecule. In this section, we will examine **transcription**, the process through which segments of DNA serve as templates for the production of complementary strands of single-stranded RNA. As we will see in the next section, these RNA molecules subsequently perform a variety of functions, most notably serving as templates for the production of proteins. For now, we will focus on the basics of transcription and the differences that exist in transcription among bacteria, eukarya, and archaea. Let's start with a more fundamental question: What parts of the DNA get transcribed?

What is a gene?

A **gene** is any segment of DNA that gets transcribed, or copied, into a piece of single-stranded RNA, as well as the associated DNA regions necessary for transcription. RNA is a polynucleotide, just like DNA. Unlike DNA, the sugar in RNA is ribose, not 2-deoxyribose. Additionally, RNA includes the nitrogenous base **uracil** (U) in place of thymine (T) (Figure 7.16). Like thymine, uracil interacts with adenine.

In bacteria, most of the genome gets transcribed. In contrast, it appears that long stretches of DNA do not get transcribed in eukarya. In all organisms, different types of genes give rise to different classes of RNA molecules, which serve many different functions (Table 7.3). Many genes give rise to **messenger RNA**, or **mRNA**, molecules. As we will see in the next section, mRNA subsequently is translated, producing a polypeptide. Transcription of other genes results in RNA molecules that do not get translated. Two major classes of non-translated RNAs are **transfer RNA (tRNA)** and **ribosomal RNA (rRNA)** molecules, critical components of the translation process. Regulatory RNA molecules constitute yet another category of RNA. These molecules include **micro RNAs (miRNAs)**, small RNA molecules that regulate the expression of genes. Regardless of the ultimate role of the RNA molecule, the process of RNA production remains basically the same.

CONNECTIONS Regulatory RNA molecules, like miRNAs, regulate gene expression by interacting with mRNA molecules. In **Section 11.4** we will see how a regulatory RNA molecule affects the level of RpoS, a protein in *E. coli* that affects gene expression.

Transcription: Initiation and elongation

For every gene, the transcription machinery must identify the beginning and the end of the segment to be transcribed. Once the initiation site has been identified, transcription, much like

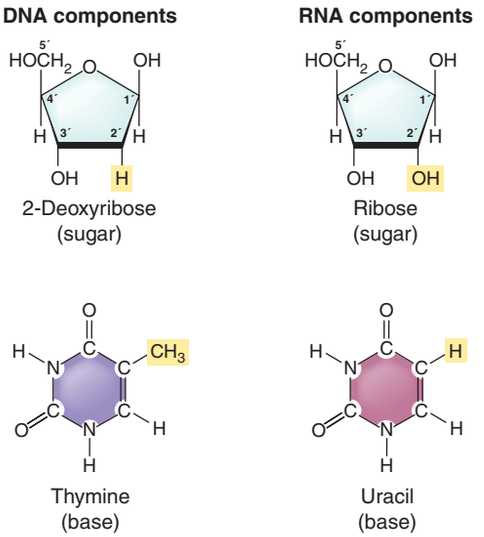

Figure 7.16. Chemical composition differences between DNA and RNA Molecules of DNA and RNA differ in two fundamental ways. First, the sugar in RNA is ribose, not 2-deoxyribose as seen in DNA. Second, the nitrogenous base thymine in DNA is replaced with uracil in RNA.

TABLE 7.3 RNA molecules

Name	Approximate size (nucleotides)	Function(s)
Messenger RNA (mRNA)	500–10,000	Coding molecules translated into proteins
Transfer RNA (tRNA)	75–100	Involved in translation
		Charged with amino acids
Ribosomal RNA (rRNA)	1,500–1,900 (small subunit)	Structural components of ribosomes
	2,900–4,700 (large subunit)	
Micro RNA (miRNA)	<100	Various regulatory functions

DNA replication, begins with the transient unwinding, or melting, of the DNA. As we saw with DNA replication, this unwinding involves specialized proteins and occurs at a very specific location. In all organisms, the enzyme that transcribes DNA is an **RNA polymerase** or, more appropriately, a DNA-dependent RNA polymerase. The transcription process begins at regions of DNA known as **promoters**. Once the RNA polymerase binds to the promoter, it unwinds the double-stranded DNA, much like helicases unwind DNA during DNA replication. The RNA polymerase then makes a strand of single-stranded RNA that is complementary, and antiparallel, to the template strand of DNA. The other strand of DNA is called the coding strand. As shown in Figure 7.17, the sequence of the transcribed RNA is the same as the sequence of the coding strand, except for the substitution of U for T. Like DNA polymerase, RNA polymerase elongates the growing RNA in a 5′ to 3′ direction, adding a new ribonucleotide to the 3′—OH of the previous ribose. Unlike DNA polymerase, however, RNA polymerase does not need a primer. The enzyme can add the first ribonucleotide directly to the template strand of DNA.

Protein synthesis ANIMATION

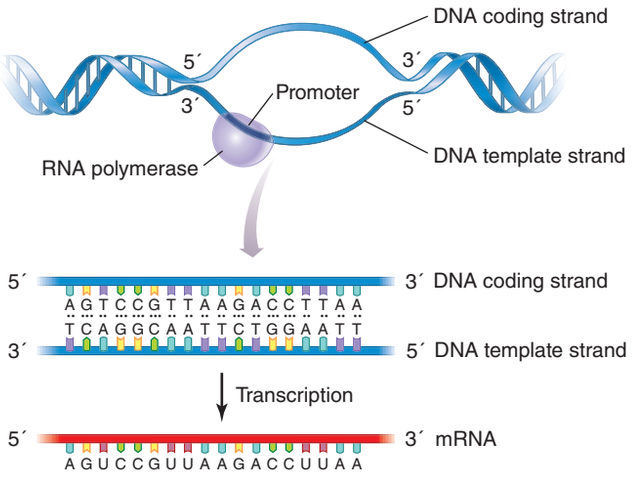

Figure 7.17. Comparison of DNA and transcribed RNA sequences
RNA polymerase binds to the promoter region of the DNA and uses the template strand of the DNA to make an RNA molecule identical to the coding strand of the DNA, except that each T in the coding strand is replaced by U. The RNA is elongated in a 5′ to 3′ direction.

CONNECTIONS As we will see in Section 8.3, viruses use a variety of strategies to replicate. For some viruses, the host cell RNA polymerase generates viral mRNA from the viral genome. For other viruses, the viral genome itself can function as mRNA.

The bacterial RNA polymerase consists of five different polypeptides, α, β, β', ω, and σ. The core enzyme is a complex of β, β', ω, and two copies of σ. The **sigma (σ) factor** combines more weakly with this core enzyme, forming the RNA polymerase holoenzyme, and recognizes promoter sequences on the DNA (Figure 7.18). Once the sigma factor has recognized a promoter and the RNA polymerase has bound, the enzyme

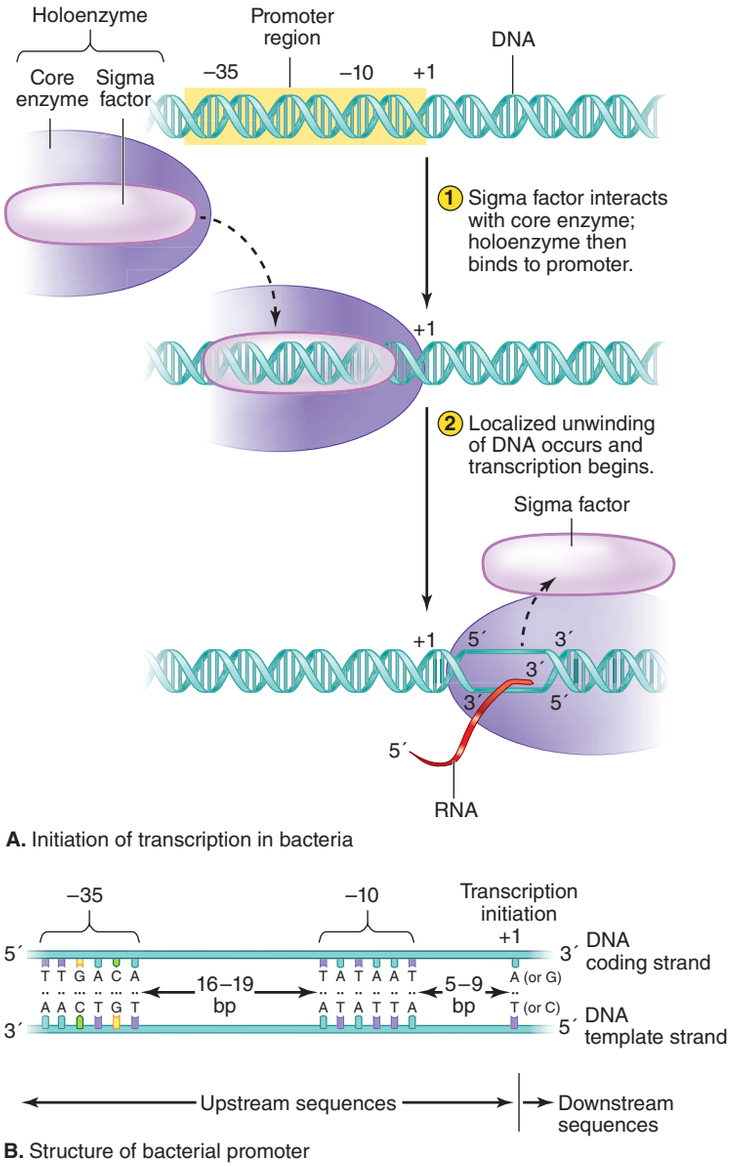

Figure 7.18. Process Diagram: Transcription initiation in bacteria
A. The core enzyme interacts with the sigma factor, forming the functional holoenzyme. This complete enzyme interacts with the promoter, facilitates localized unwinding of the DNA, and creates a molecule of RNA that is complementary to the template strand of the DNA. **B.** To ensure that transcription begins at the correct location, the holoenzyme recognizes a specific region of DNA—the promoter. In bacteria, the promoter consists of several elements, most notably the –10 and –35 elements, which are located 10 base pairs (bp) and 35 bp upstream of transcription initiation. The site of transcription initiation is referred to as the +1 position and, in bacteria, typically is an A or a G.

will begin unwinding the DNA. The sigma factor dissociates, and the core enzyme creates RNA that is complementary to the template strand of the DNA. Transcription, it should be noted, will not begin right at the promoter. Rather, it will start a short distance from this binding sequence. The first transcribed base of the gene is referred to as +1 and, in bacteria, typically is an A or a G. Bases before the transcription start site are said to be upstream and are indicated as –1, –2, and so forth. We can describe these upstream sequences as being 5′ of the transcription start site. Downstream sequences, then, are in a 3′ direction. Shortly after the elongation process has begun, the sigma factor will dissociate from the other subunits and the core enzyme alone will continue the elongation process. As the RNA elongates, it will dissociate from the template strand of the DNA and the two strands of DNA will reanneal.

Many promoters in well-studied bacteria possess two defined regions, one at approximately position –10 and one at position –35, to which the RNA polymerase binds (see Figure 7.18). This binding can be examined in several ways, such as a **gel shift assay** (Toolbox 7.1). Although the specific sequences of these genetic elements may differ between bacterial species, and even between genes within a species, the sequences are fairly well conserved and the "typical" or consensus promoter sequence has been identified. The consensus sequence of *Escherichia coli* for the –10 element, or Pribnow box, in the coding strand of most commonly expressed genes is TATAAT. Because of its sequence, it often is referred to as a "TATA box." The consensus sequence in the coding strand for the –35 element of commonly expressed genes is TTGACA. More recently, additional promoter elements have been identified.

Toolbox 7.1
USING A GEL SHIFT ASSAY TO IDENTIFY DNA-BINDING PROTEINS

We have seen that numerous proteins bind to DNA. Histones bind to DNA in eukarya to facilitate condensing the molecule. DnaA in bacteria and the Orc proteins in eukarya bind to specific sites on the DNA molecule to initiate replication. Sigma factors initiate transcription by recognizing and binding to promoter regions. How do we know that the sigma factor binds to the promoter region of a gene? Or, more generally, how can we identify any DNA-binding proteins? One assay commonly used to address this question is the gel shift assay.

The gel shift, or electrophoretic mobility shift assay (EMSA), often is used to identify proteins that bind to DNA. First, a piece of DNA suspected of containing a protein-binding domain, such as a promoter, is radiolabeled. Second, two aliquots of this labeled DNA are prepared, one that is preincubated with the potential DNA-binding protein, such as a sigma factor, and one that is not exposed to the protein. These DNA aliquots then are run on a non-denaturing electrophoresis gel. Gel electrophoresis allows researchers to separate molecules based on their sizes; small molecules travel farther in a given period of time than do large molecules. Non-denaturing conditions allow weak molecular interactions to remain intact. In other words, protein:DNA-binding interactions would not be disrupted under these conditions. After the DNA samples are run on the gel, their locations on the gel are determined. A piece of DNA with protein bound to it will not migrate as far on the gel as the same piece of DNA without protein bound to it. In other words, protein binding will result in a gel shift (Figure B7.1).

This type of assay can be used to identify proteins that bind to a specific piece of DNA. Similarly, this assay can be used to determine the specific sequence of DNA necessary for protein binding. If a DNA-binding protein and its recognition sequence have been identified, then researchers can experimentally modify the DNA sequence, run a gel shift assay with the altered DNA sequences, and determine what changes in the DNA sequence decrease or eliminate protein binding.

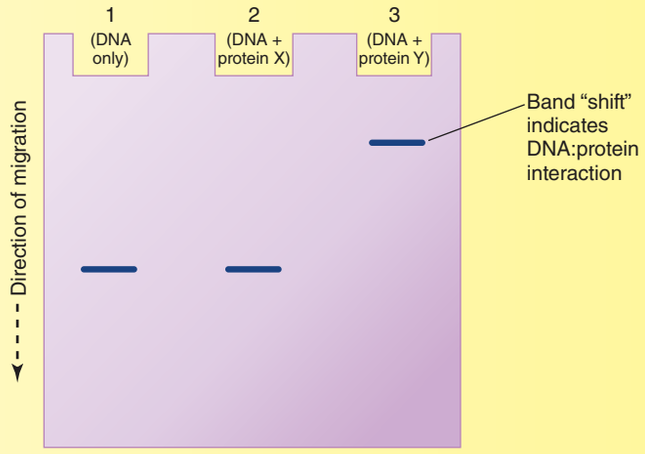

Figure B7.1. Gel shift assay to detect DNA:protein interactions In this assay, DNA or DNA incubated with protein are electrophoresed on a non-denaturing gel. DNA complexed with protein will migrate more slowly than the same fragment of DNA not complexed with protein. In this example, lane 1 contains DNA only, lane 2 contains DNA incubated with protein X, and lane 3 contains DNA incubated with protein Y. In all three cases, the DNA was labeled so that it could be detected. In lane 3, the DNA band did not migrate as far, indicating that it was complexed with protein Y.

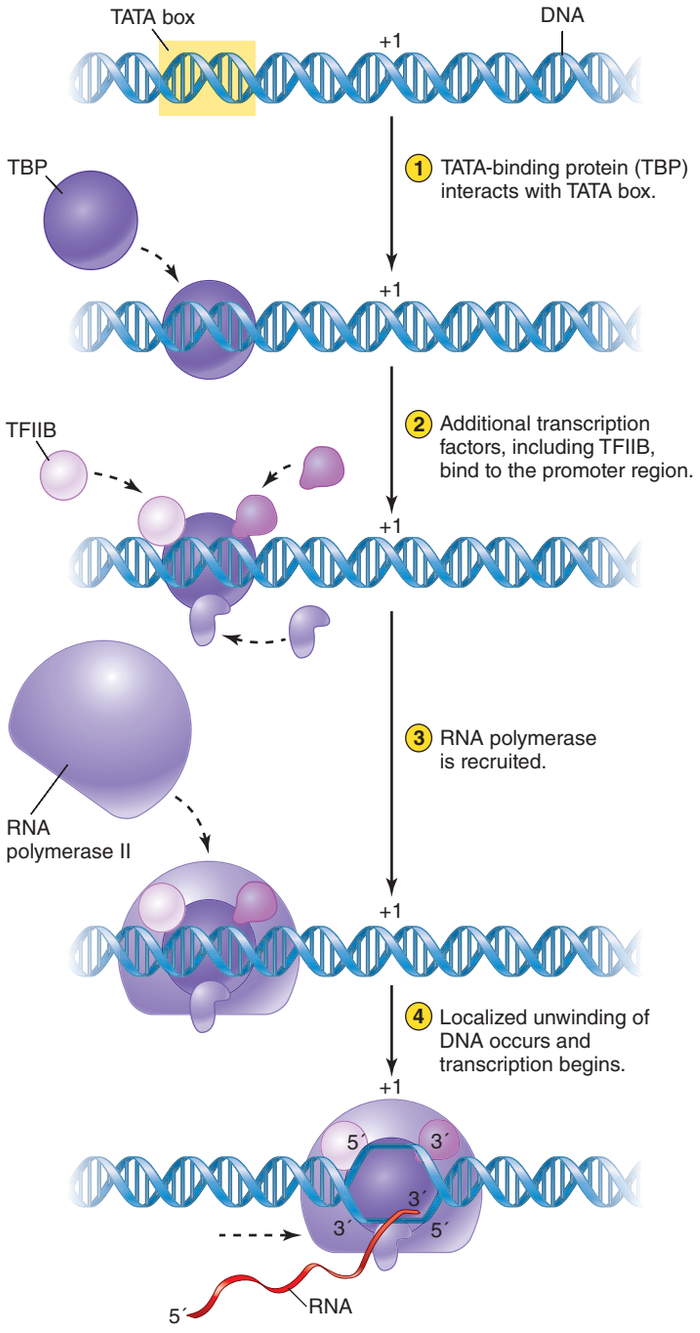
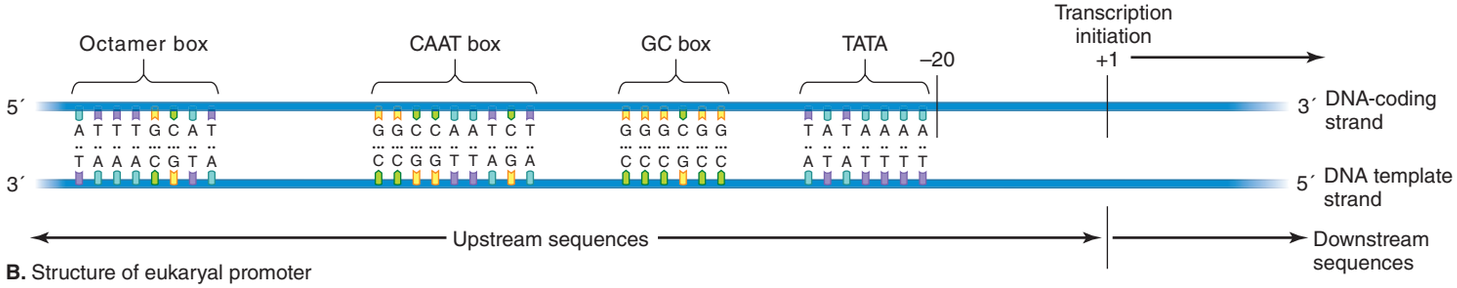
Test Your Understanding

You are trying to determine key bases in a bacterial promoter that are needed for attachment of a sigma factor. You test two different mutant promoters, each with a different single base change, for their ability to interact with the sigma factor using a gel shift assay. What specific results would you see on the gel if mutant A did not allow sigma factor binding, but mutant B did allow binding? Be specific and explain your answer.



A. Initiation of transcription in eukarya



B. Structure of eukaryal promoter

Figure 7.19. Process Diagram: Transcription initiation in eukarya **A.** RNA polymerase II does not bind directly to DNA. Rather, its binding is facilitated by various transcription factors, including TATA-binding protein (TBP) and transcription factor IIB (TFIIB). **B.** The promoters in eukaryal structural genes are complex, consisting of several motifs, including TATA, GC, CAAT, and octamer (eight nucleotide) boxes. Different eukaryal genes contain various numbers of these elements, arranged in various orders. This schematic representation shows the major elements of a eukaryal promoter.

The UP-element is an AT-rich region located upstream of the –35 element. The discriminator is a GC-rich motif located between the –10 element and the transcription start site.

As we mentioned previously, the sequences of promoter elements can vary. Differences in the sequences can alter the affinity of the sigma factor for the promoter, which can alter the level of transcription. If RNA polymerase cannot bind well to a promoter, then it is less likely to initiate transcription of that gene. So, what is the practical importance of this information? Some promoters will interact strongly with sigma factors and undergo relatively high levels of transcription. Other promoters will interact less well with sigma factors and undergo lower levels of transcription. The amount of RNA produced from a gene, in other words, depends to some extent on the sequence of a gene's promoter. However, the story doesn't stop there. Most bacteria can produce several different sigma factors. *Bacillus subtilis*, for example, produces at least 18 different sigma factors under different conditions. These different sigma factors preferentially interact with different classes of promoters. So, by simply regulating which sigma factor it is producing, a cell can regulate which group of genes it will transcribe.

CONNECTIONS When environmental conditions change, bacteria can change the expression of sigma factors. By changing the expression of their sigma factors, bacteria can alter which genes are expressed. More information about how bacteria can regulate gene expression is presented in **Section 11.3**.

In eukarya, the basic process of transcription mirrors the bacterial process. Instead of relying on a single RNA polymerase, though, eukarya possess three different RNA polymerases—RNA pol I, II, and III. RNA pol II is the best studied of these enzymes and transcribes all protein-coding genes. RNA pol I transcribes the ribosomal RNA genes, with the exception of the 5S rRNA. RNA pol III transcribes tRNA genes, the 5S rRNA gene, and genes encoding various other small, non-coding RNA molecules. In eukarya, RNA polymerase II does not bind directly with the promoter. Rather, a series of **transcription factors**, DNA-binding proteins, first must bind to the promoter (Figure 7.19). TATA-binding protein (TBP) binds to the TATA box found in most eukaryal promoters. Other transcription factors, such as TFIIB, also bind, forming a transcription initiation complex. These bound transcription factors then recruit the RNA polymerase and facilitate its interaction with the DNA. As we saw in bacteria, promoters,

located upstream of the transcription start site, mark the locations of genes. Eukaryal promoters contain more elements than bacterial promoters and exhibit more variability than bacterial promoters. Most structural genes contain a TATA box that is approximately 25 bp upstream of the transcription initiation site. The presence, numbers, and locations of the other promoter elements may vary. The sequences shown in Figure 7.19 are consensus, or most typical, sequences. The exact sequences differ somewhat in different genes and different organisms.

Archaea, like bacteria, possess a single RNA polymerase. This archaeal RNA polymerase, however, looks more like RNA pol II of eukarya than the RNA polymerase of bacteria. RNA polymerases characterized from archaea, for example, possess eight or more subunits. Additionally, the archaeal RNA polymerases do not bind directly to DNA. Rather, the enzyme is recruited to the promoter by various proteins, including TBP and transcription factor B (TFB) **(Figure 7.20)**. These transcription factors resemble the eukaryal transcription factors TBP and TFIIB. The archaeal promoter itself is more eukarya-like. We also should note that the RNA polymerase of archaea is not inhibited by rifampicin, an antibiotic that effectively inhibits the RNA polymerase of bacteria.

Transcription: Termination

Not surprisingly, specific mechanisms control the termination of transcription. In bacteria, two main mechanisms of termination have been identified, rho-independent and rho-dependent. Genes that undergo rho-independent, or intrinsic termination, end with a short segment of inverted GC-rich repeats, followed by a string of adenines (A). As RNA polymerase is transcribing the gene, the bases in the inverted repeats of the growing RNA molecule can hydrogen bond to each other, allowing the nascent RNA molecule to adopt a hairpin structure. It is thought that this secondary structure in the RNA molecule causes the RNA polymerase to stall and fall off the DNA. The bases A and U bind weakly to each other. Most likely, then, the A:U interactions at the end of the RNA molecule are too weak to keep the newly made RNA attached to the DNA. As a result, the RNA molecule dissociates from the DNA **(Figure 7.21)**.

Other bacterial genes undergo rho-dependent termination. In these genes, the transcript does not end with a string of uracils and often does not contain the inverted repeats seen in rho-independent termination. A separate protein, the rho factor, mediates transcription termination. This protein binds to the nascent RNA molecule and travels along the molecule. The RNA polymerase will slow down or pause when it reaches a specific termination site. The rho factor then will displace the RNA polymerase, causing transcription to end.

Transcription termination in eukarya is more complex. Termination of transcription by RNA pol I resembles the bacterial rho-dependent termination. Termination of transcription by RNA pol III more closely resembles rho-independent termination. For RNA pol II, the elongating RNA molecule is cleaved by a specific endonuclease, thereby generating the 3′ of the RNA molecule.

Within the nucleus, the RNA pol II products, or pre-mRNA molecules, are modified in three major ways before becoming

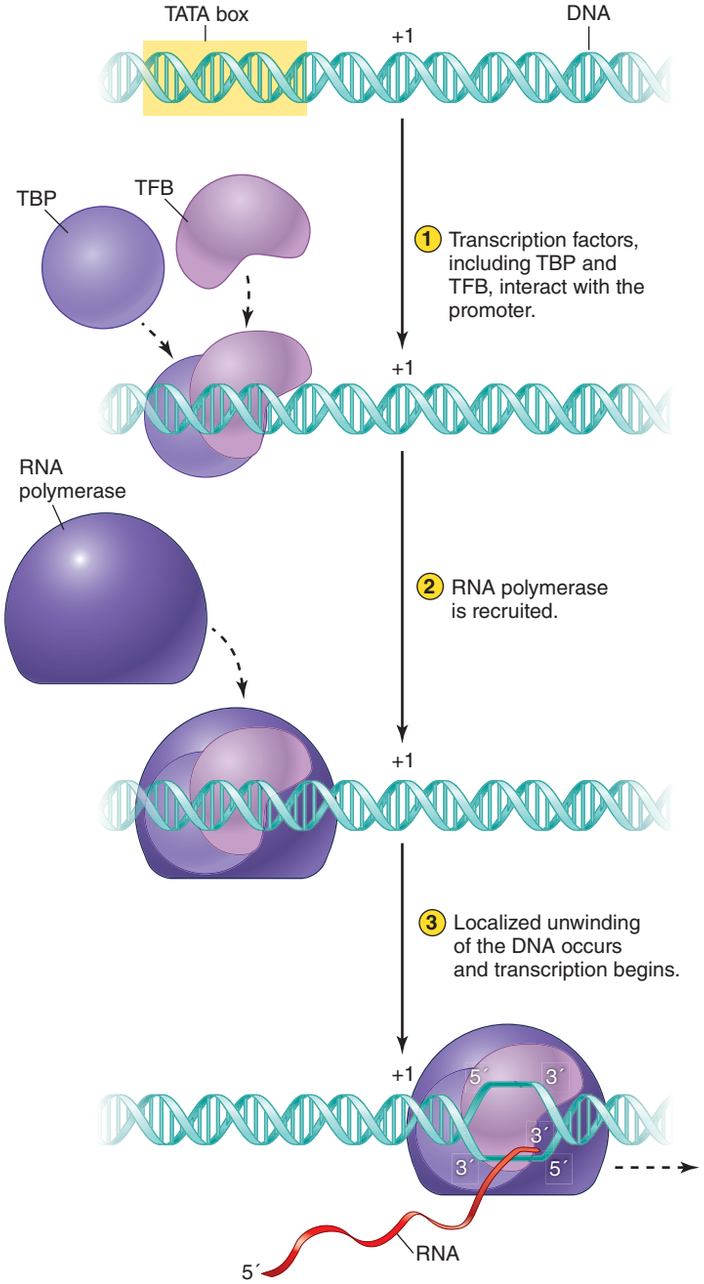


Figure 7.20. Process Diagram: Transcription initiation in archaea As in eukarya, the RNA polymerase of archaea does not bind directly to the DNA. The transcription factors TBP and TFB, similar to the eukaryal TATA-binding protein and transcription factor IIB, respectively, interact with the DNA and recruit the RNA polymerase.

functional messenger RNA (mRNA) molecules. First, a special modified nucleotide, 7-methylguanosine, is added to the 5′ end of the transcript, giving the RNA molecule a **5′ cap**. Not only is this terminal base modified, but also it is connected to the end of the RNA molecule via an atypical 5′ to 5′ triphosphate linkage. Usually, this modification of the RNA occurs soon after elongation has begun. Second, poly(A) polymerase adds a string of adenosine monophosphates to the 3′ end of the RNA molecule. Often, this **3′ poly(A) tail** can be around 200 nucleotides long. Both the 5′ cap and the 3′ poly(A) tail protect

Eukaryal genes contain introns.
ANIMATION

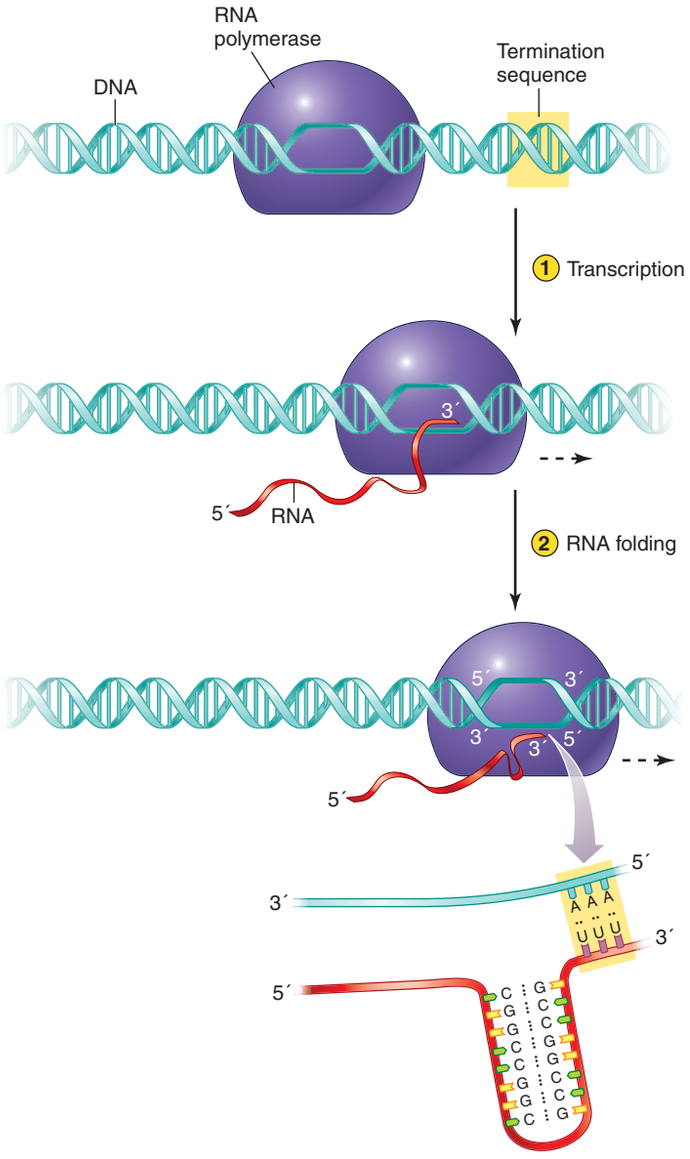

Figure 7.21. Process Diagram: Rho-independent transcription termination in bacteria As RNA polymerase nears the end of the transcriptional unit, GC-rich inverted repeats in the RNA molecule form a hairpin loop. Formation of this loop causes the RNA polymerase to pause and, eventually, fall off the DNA, thereby terminating transcription. The weak A:U interactions at the end of the transcript (highlighted in yellow) facilitate dissociation of the RNA molecule from the DNA.

the RNA from degradation. As we will see in the next section, the 5′ cap also serves as a necessary signal for the start of translation. Third, eukaryal RNA molecules often contain non-protein-coding regions, referred to as **introns** (intervening sequences), which are removed. The coding regions, or **exons**, are spliced together, producing a functional mRNA that contains only protein-coding information (Figure 7.22). Because these processing events occur after transcription, they are referred to as **post-transcriptional modifications**. Only after these modifications occur do the RNA molecules leave the nucleus.

Relatively little is known about transcription termination in archaea. However, several studies suggest that a string of Ts in a transcriptional unit, a region of DNA to be transcribed, represent a termination signal. To test the importance of these oligo(T) stretches, researchers from Ohio State University genetically modified strains of the archaeon *Thermococcus kodakarensis*. They inserted oligo(T) units between a strong promoter and a reporter gene, a gene whose protein product easily can be detected and monitored. If the oligo(T) units served as transcription termination signals, they reasoned, then expression of the reporter gene would decrease when these oligo(T) units were present in the DNA. Indeed, a 5′-TTTTTTTT-3′ (T_8) insertion almost completely inhibited the reporter gene expression. Additional studies will be needed to more fully understand this process and determine how universal it is within archaea.

7.3 Fact Check

1. Contrast the structures of DNA and RNA.
2. Distinguish between the different types of RNA molecules.
3. Describe the role of the RNA polymerase in the process of transcription.
4. What is a promoter, and what are the key regions of most promoters?
5. Differentiate between rho-dependent and rho-independent termination of transcription.
6. What is involved in post-transcriptional modification of eukaryal mRNA?

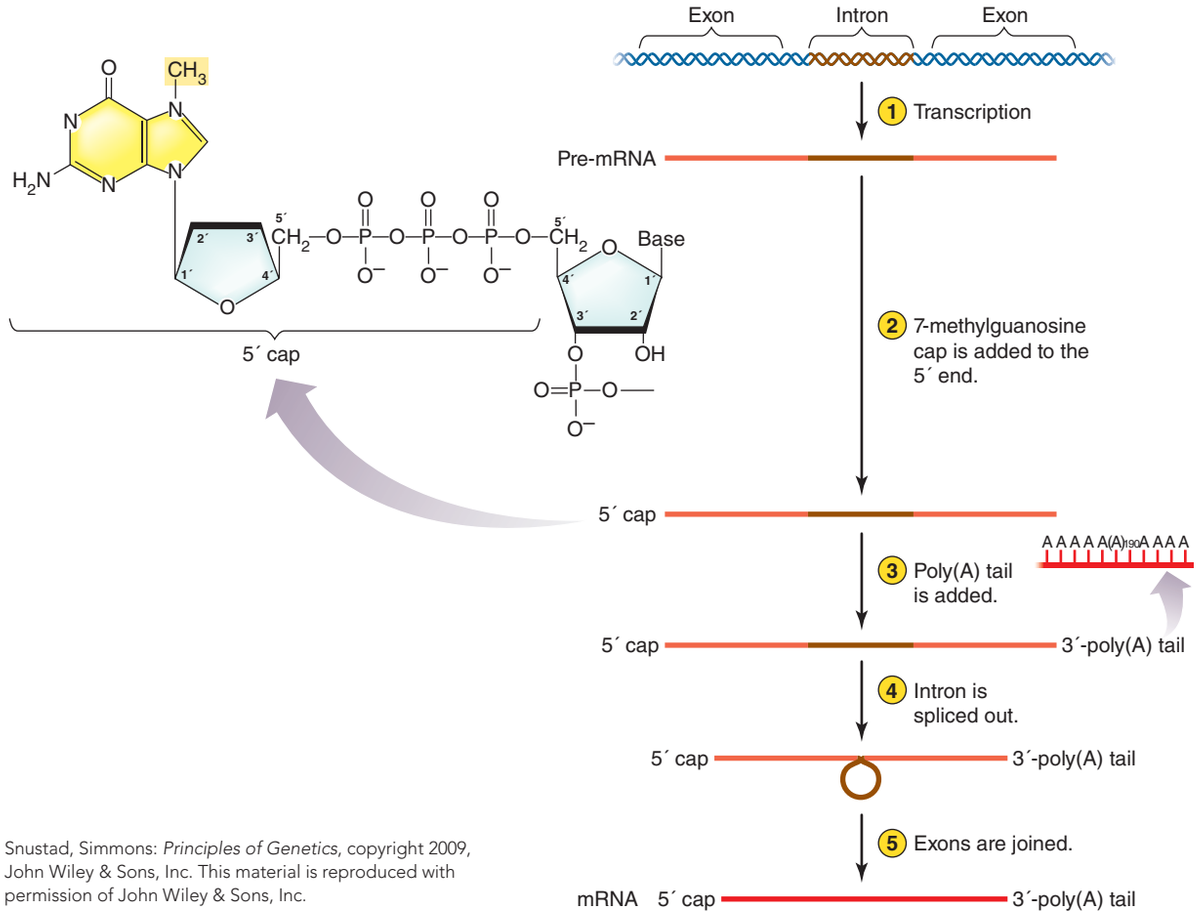
7.4 Translation

How are proteins made?

Translation, the process of protein synthesis, involves using the mRNA sequence as a template to produce a specific amino acid sequence. Again, the basic process is remarkably similar in bacteria, eukarya, and archaea. Briefly, **ribosomes** interact with the mRNA and "read" the mRNA sequence, three nucleotides at a time. These groups of three nucleotides are called **codons**. For every codon, a corresponding transfer RNA (tRNA) exists in the cell that possesses an **anticodon**, three nucleotides complementary to a given codon. A specific **amino acid** is attached to each tRNA. As a result, each tRNA has an amino acid attached to it that is defined by the tRNA anticodon. So, as the ribosome "reads" the mRNA sequence, it recruits a tRNA for each codon. In this fashion, specific amino acids are brought together. Peptide bonds form between these amino acids, and a polypeptide forms (Figure 7.23).

Protein synthesis ANIMATION

With four bases in mRNA, 64 different three-base codons can be formed. Sixty-one of these codons code for the 20 amino



Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 7.22. Process Diagram: Post-transcriptional processing of eukaryal RNA In eukarya, primary RNA pol II transcripts, or pre-mRNA molecules, undergo three major forms of processing before leaving the nucleus. A 7-methylguanosine cap is added to the 5′ end via a 5′ to 5′ triphosphate linkage (shown in enlarged view). Also, a poly(A) tail is added to the 3′ end. Finally, intervening sequences, or introns, are spliced out, bringing together the exons, or coding sequences.

acids commonly found in proteins. As we will see later, one of these codons, AUG, usually serves as the start codon, allowing translation to begin at the correct location. The remaining three codons, as we will see later, do not code for amino acids. Rather, they serve as signals for the termination of translation. Therefore, the genetic code is degenerate; most amino acids are specified by several different codons **(Figure 7.24)**. The amino acid arginine, for example, is coded for by CGU, CGC, CGA, CGG, AGA, and AGG (codons always are written in a 5′ to 3′ orientation). In fact, only two amino acids, methionine and tryptophan, have only one codon each. Additionally, all organisms share the same genetic code. This finding alone provides compelling evidence for the evolutionary relatedness of all living organisms. We should note, however, that interesting exceptions have been identified. In the mitochondria of animals, for example, the traditional stop, or termination of translation codon UGA, codes for the amino acid tryptophan. The evolutionary implications of this and other exceptions remain to be determined.

As we saw for DNA replication and transcription, specific initiation and termination sites for translation must exist. In this section, we will briefly examine the translation initiation and termination events, paying special attention to how these events differ in bacteria, eukarya, and archaea. Finally, we will examine how the presence of the membrane-bound nucleus in eukarya affects the processes of transcription and translation.

Translation: Initiation and elongation

Before we investigate how translation begins, let's first examine two major components of the process, tRNA and ribosomes. Transfer RNA molecules are about 70 nucleotides long. Because of their sequences, these molecules can undergo intramolecular base-pairing, resulting in a molecule with a complex shape often described as a cloverleaf. In one portion of this molecule, several bases remain unpaired. These bases are the anticodon. A specific enzyme, aminoacyl-tRNA-synthetase, adds the amino acid appropriate for the anticodon on that molecule to the other end of the tRNA **(Figure 7.25)**. The specificities of tRNA molecules are indicated by a superscript—$tRNA^{ala}$. This example indicates the tRNA specific for the amino acid alanine. When the amino acid becomes attached to the tRNA, the molecule is referred to as $Ala\text{-}tRNA^{ala}$.

In all organisms, ribosomes consist of two parts, the small and large subunits. Each subunit, in turn, consists of many polypeptides and one or more rRNA molecules. The exact

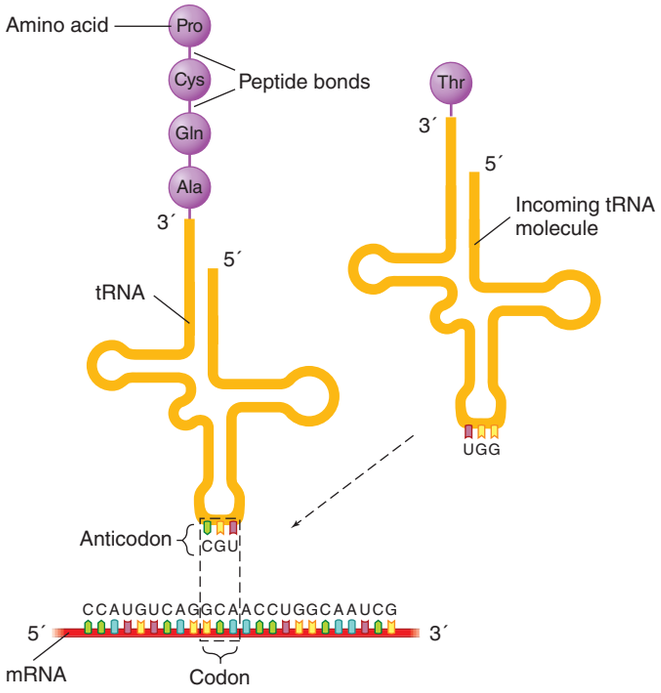


Figure 7.23. Translation of mRNA Ribosomes interact with the mature mRNA and "read" groups of three nucleotides, or codons. Transfer RNA molecules containing complementary anticodons bring in the appropriate amino acids. As shown here, the mRNA codons are read in a 5′ to 3′ direction.

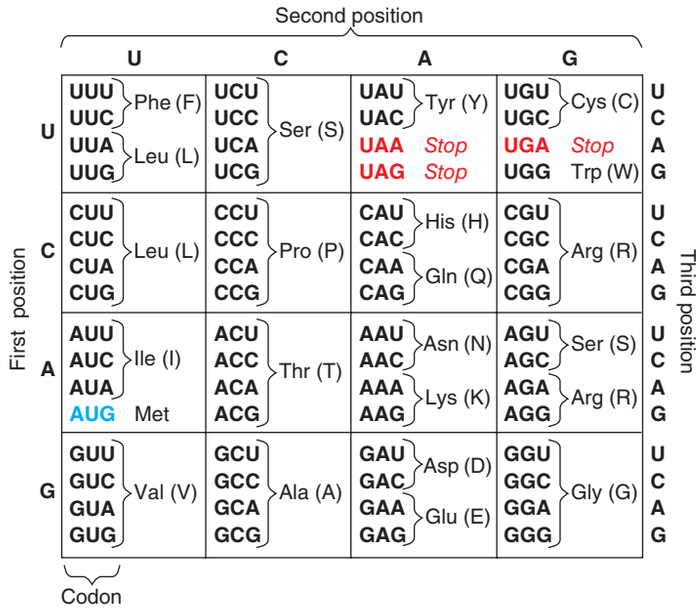

Figure 7.24. The genetic code Each group of three nucleotides, or codon, in an mRNA molecule codes for a specific amino acid. Three codons (UAA, UAG, and UGA) are stop codons that do not code for any amino acid. Rather, they signal where translation should end. In this table, the first letter of each codon is on the left side of the table, the second letter is on the top, and the third letter is on the right side. The three-letter abbreviation and one-letter code for the amino acids are indicated within the table.

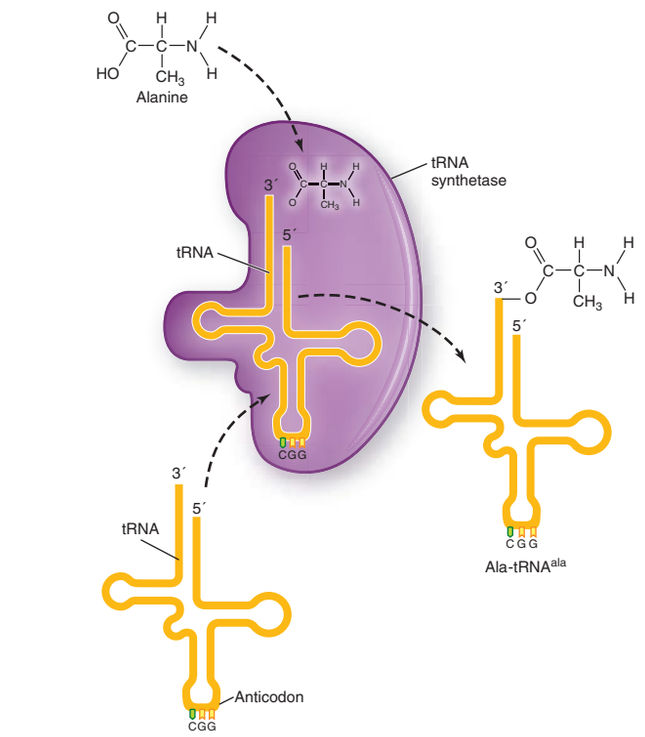

Figure 7.25. Role of transfer RNA Because of intramolecular complementarity, the tRNA molecule assumes a cloverleaf conformation. Three unpaired nucleotides form the anticodon and allow each tRNA to bind to a specific codon on an mRNA molecule. In this case, an aminoacyl-tRNA synthetase specific for both the amino acid alanine and the tRNA with the anticodon CGG attaches alanine to its tRNA.

components of the ribosomes differ in organisms from different domains (Table 7.4). The ribosomes in archaea are similar in size to the bacterial ribosomes. However, the ribosomal polypeptides and rRNA molecules seem to more closely resemble the constituents of eukaryal ribosomes (see Figure 4.2).

The initiation of translation depends on the recognition of mRNA by ribosomes. In bacteria, this initial recognition event involves interactions between a specific sequence in the mRNA, the **Shine–Dalgarno sequence**, or ribosome binding site (5′…AGGAGG…3′), and a complementary sequence in the 16S rRNA, which is part of the 30S small subunit of the ribosome. Translation in bacteria then begins at the first AUG after the Shine-Dalgarno sequence. The 16S rRNA contains a sequence (3′…UCCUCC…5′) that is complementary to this sequence. It seems logical to infer that the 16S rRNA interacts

TABLE 7.4 Ribosome components of *Eukarya* and *Bacteria*

Eukarya	Bacteria
Small (40S*) subunit	Small (30S) subunit
33 polypeptides	21 polypeptides
18S rRNA	16S rRNA
Large (60S) subunit	Large (50S) subunit
49 polypeptides	31 polypeptides
28S rRNA	23S rRNA
5.8S rRNA	5S rRNA
5S rRNA	

*S refers to Svedberg units, a unit of measurement based on a particle's sedimentation rate. Larger particles have greater Svedberg values.

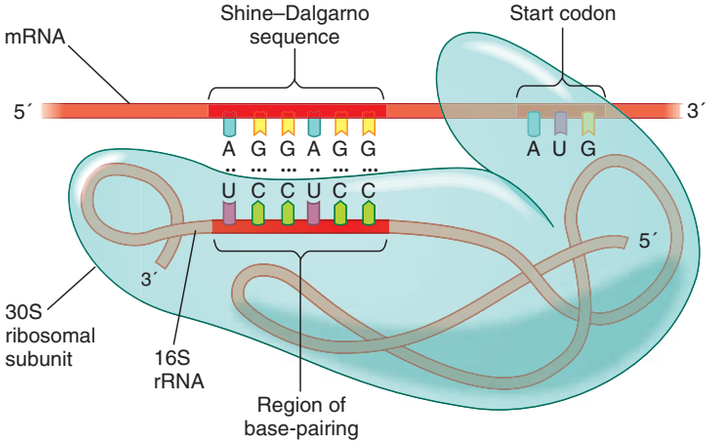

Figure 7.26. Role of the Shine–Dalgarno sequence in bacteria In bacteria, the 30S subunit of the ribosome attaches to the mRNA through base-pair interactions between the 16S rRNA and the Shine–Dalgarno sequence. The 50S ribosome subunit then binds (not shown here), and translation begins at the first AUG after the Shine–Dalgarno sequence. The Shine–Dalgarno sequence and this start codon typically are 6–10 nucleotides apart.

with the Shine–Dalgarno sequence, thereby aligning the ribosome with the mRNA **(Figure 7.26)**.

Three pieces of evidence support this hypothesis. First, mutations within the Shine–Dalgarno sequence can eliminate or greatly reduce the translation of mRNA. Second, mutations within the complementary 16S rRNA sequence can affect overall protein synthesis within a cell. Third, a specific mutation within the Shine–Dalgarno sequence can be "corrected" by a complementary mutation in the 16S rRNA sequence. In other words, if the Shine–Dalgarno sequence is altered from 5′…AGGAGG…3′ to 5′…AGCAGG…3′, then a change in the 16S rRNA sequence from 3′…UCCUCC…5′ to 3′…UCGUCC…5′ will restore translation levels of that mRNA to normal.

A special tRNA, often referred to as the initiator tRNA, interacts with the first codon. The codon AUG, as shown in Figure 7.24, codes for the amino acid methionine. The first AUG after the Shine–Dalgarno sequence, however, interacts with fMet-tRNA^{fMet}. The amino acid attached to this tRNA is a modified version of methionine, N-formylmethionine. All other AUG codons in the mRNA interact with tRNA attached to a non-modified methionine. Initiation factor 2 (IF-2), one of three initiation factors involved in bacterial translation, mediates the interaction between the start codon and fMet-tRNA^{fMet}. After the initiator tRNA has interacted with the start codon, the ribosome "reads" the next codon on the mRNA. Another tRNA is recruited and a peptide bond forms between the two amino acids, linking the amino terminus, or N terminus, of the second amino acid to the carboxy terminus, or C terminus, of the first amino acid. As a result, every polypeptide, has an N-terminus and a C-terminus. The ribosome continues to move along the mRNA, recruiting the appropriate tRNA molecules, and the polypeptide chain continues to elongate **(Figure 7.27)**.

In most respects, the process of translation in eukarya is similar to the process in bacteria. However, three major

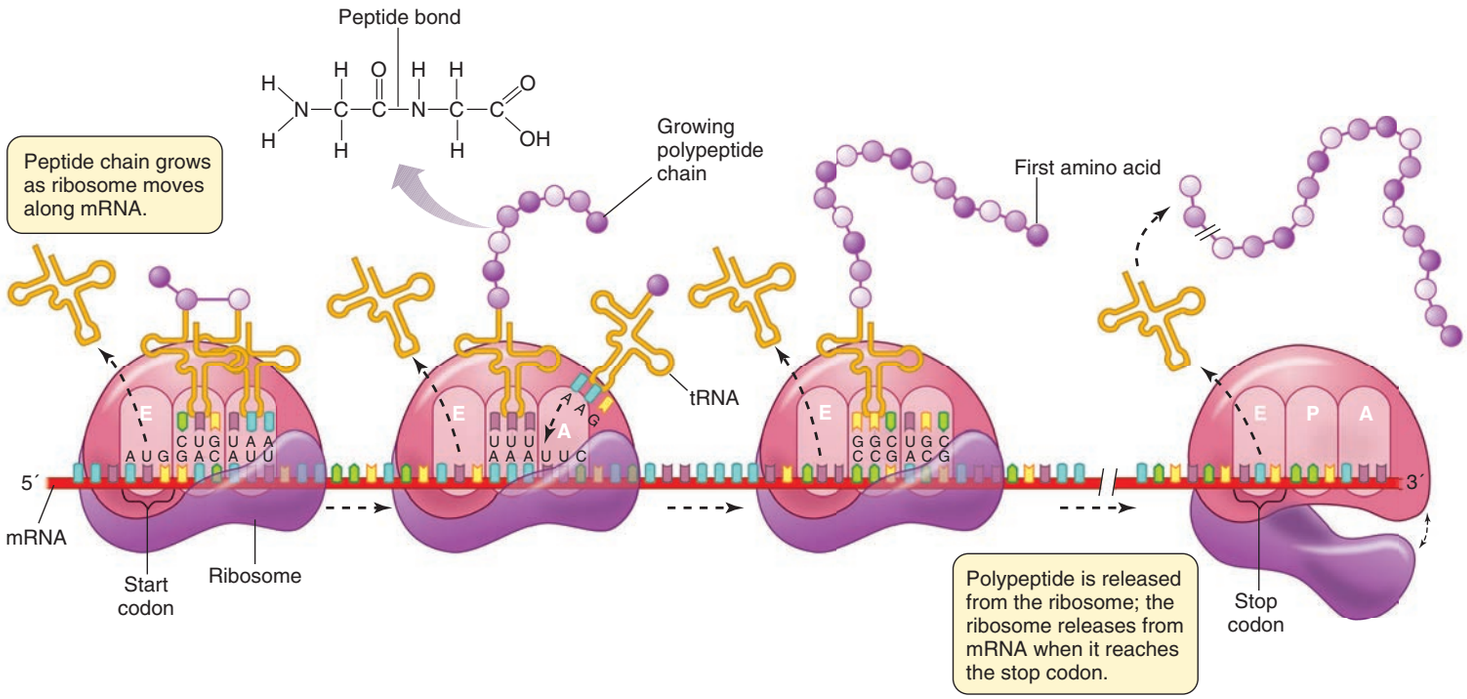

Figure 7.27. Protein synthesis Following the initiation of translation, the ribosome moves along the mRNA, "reading" three base units, or codons. For each successive codon, a tRNA with a complementary anticodon, and charged with the appropriate amino acid, is recruited and enters the aminoacyl (A) site on the ribosome. Peptide bonds form between adjacent amino acids, resulting in polypeptide formation as the tRNA enters the peptide (P) site. After the peptide bonds have formed, the amino acid dissociates from its tRNA and the tRNA leaves the ribosome from the exit (E) site. When the ribosome encounters a stop codon, translation ceases and the polypeptide leaves the ribosome.

differences exist. First, the initial amino acid in eukaryal polypeptides is not f-methionine. Rather, a non-modified methionine is used. A unique tRNA, often referred to as the initiator tRNA, or $tRNA_i^{Met}$, recognizes the AUG start codon. Second, eukaryal mRNAs do not contain a Shine–Dalgarno-like sequence. Rather, the eukaryal ribosome generally initiates translation at the first AUG on the 5′ end of the molecule. Finally, eukaryal cells use many more initiation factors. Recognition of the mRNA by the ribosome requires several different factors. A cap-binding protein, or CBP, first binds to the 5′ cap. Additional polypeptides then bind before the 40S subunit of the ribosome can attach.

Let's think about this process of translation initiation a little more. If translation of eukaryal mRNA begins at the first AUG after the 5′ cap, then how many translation initiation sites can a molecule of eukaryal mRNA contain? One. There only can be one first AUG after the 5′ cap. The situation differs in bacteria. A molecule of mRNA could contain multiple ribosome binding sites. As a result, molecules of mRNA in bacteria potentially can produce several different polypeptides, or be **polycistronic** (Figure 7.28). This process allows the cell to produce two or more different polypeptides from a single mRNA molecule.

Eukaryal mRNA molecules, on the other hand, generally only produce a single polypeptide and are said to be **monocistronic**. Recently, though, it has been shown that a second form of translation initiation can occur in some eukaryal mRNAs. In some cases, the ribosome binds to the mRNA in a 5′ cap-independent fashion, utilizing an internal ribosome entry site, or IRES. These internal ribosome entry sites have been identified in the mRNAs of several viruses of mammals, as well as several mammalian mRNAs. In viruses, the presence of an IRES may facilitate production of viral proteins even when traditional 5′ cap-dependent translation initiation is inhibited. In mammalian mRNAs, the presence of an IRES allows the production of two distinct polypeptides from a single mRNA. The exact mechanism of ribosome binding and the required IRES sequence have not been fully elucidated.

CONNECTIONS With polycistronic mRNA, bacteria can coordinately regulate the production of several polypeptides. We will examine this mechanism of regulation in **Section 11.2**.

Although we know less about translation in archaea, it appears that the process mirrors more closely the process of translation in eukarya. Most of the ribosomal proteins in archaea are closely related to eukaryal ribosome proteins, suggesting that the two systems share an evolutionary link. Additionally, the initiator amino acid in archaea is methionine, not formylmethionine. One particular set of experiments provides compelling evidence for the evolutionary relatedness of the translation machinery in archaea and eukarya. Researchers purified ribosomal subunits from the archaeon *Sulfolobus solfataricus* (Microbes in Focus 7.2), the eukaryal microorganism *Saccharomyces cerevisiae* (yeast), and the bacterium *Escherichia coli*. They demonstrated that combinations of the *S. solfataricus* 30S subunit and *S. cerevisiae* 60S subunit or the *S. solfataricus* 50S subunit and the *S. cerevisiae* 40S subunit resulted in the formation of polypeptides in an *in vitro* translation assay. Combinations of the yeast subunits and *E. coli* subunits, however, were non-functional. These results suggest that parts of the archaeal and eukaryal translation machinery are functionally equivalent.

We mentioned previously that 61 of the possible 64 codons specify amino acids. The other three codons—UAA, UGA, UAG—function as stop codons. When the ribosome reaches a **stop codon**, translation ceases. In *E. coli*, two different release factors, RF-1 and RF-2, recognize the stop codons and facilitate ending the process. A single release factor, eRF, has been identified in eukarya. At this point, the polypeptide leaves the translation complex, the mRNA moves away from the ribosome,

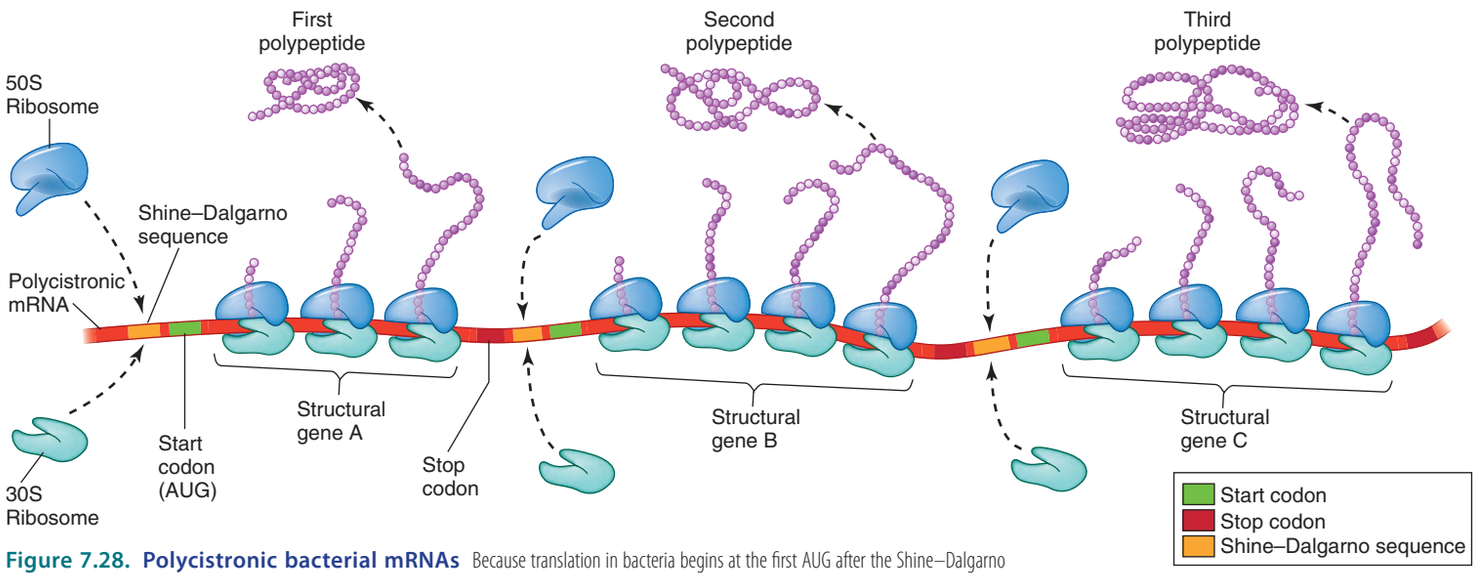

Figure 7.28. Polycistronic bacterial mRNAs Because translation in bacteria begins at the first AUG after the Shine–Dalgarno sequence, more than one different polypeptide can be generated from a single mRNA. If multiple Shine–Dalgarno sequences exist on a molecule of mRNA, then ribosomes will bind at multiple locations on a single RNA molecule and begin translation at multiple sites.

Microbes in Focus 7.2

THE EXTREME LIFE OF *SULFOLOBUS SOLFATARICUS*

Habitat: Found throughout the world, usually in areas of volcanic activity with a temperature of ~80°C, a pH of ~3, and sulfur

Description: Archaeon about 1–3 μm in diameter with a single circular chromosome of approximately three million base pairs in length; cell membrane contains tetraether lipids, making it a monolayer.

Key Features: One of the first extreme thermophiles to be characterized, *S. solfataricus* grows optimally at 80°C and a pH of 3. *S. solfataricus* and related species have been isolated from volcanic hot springs throughout the world.

Figure 7.29. Non-covalent and covalent interactions in the folding of polypeptides Non-covalent interactions between the amino acids, such as H bonds, ionic bonds, and other weak interactions, affect the shape and functional properties of the polypeptides. Covalent disulfide bridges can form between two cysteine amino acids, also affecting the shape and function of the polypeptide.

and the ribosomal subunits themselves dissociate. However, the story doesn't end there.

Protein folding, processing, and transport

The process of making a fully functional protein does not end with the termination of translation. In a way, the polypeptide chain produced during translation represents merely the basic architecture of a functional protein. To complete the process, the string of linked amino acids must be properly folded into a complex three-dimensional shape. Additionally, the polypeptide often is modified in one or more ways. Finally, the protein must be transported to its intended location. We will briefly examine these events in this section.

Protein Folding

A linear string of amino acids produced during translation hardly resembles a protein. As we have noted throughout the preceding chapters, proteins have complex three-dimensional shapes that allow them to carry out their many functions. Chemical interactions between individual amino acids within a polypeptide chain cause the linear chain to assume a specific globular shape. Many of these interactions are non-covalent and include hydrogen bonding and ionic interactions. In some cases, covalent disulfide bonds form between cysteine amino acids **(Figure 7.29)**. Additionally, two or more polypeptides may interact with each other to form a mature functioning protein.

CONNECTIONS When proteins do not fold correctly, disease can result. We saw an example of this in **Section 5.5** when we discussed prions. We will see another example in **Section 23.4** during our discussion of malaria and sickle-cell disease.

Historically, these folding events had been thought to occur spontaneously, but it now appears that the folding process may be more directed. Molecular chaperones, or chaperonins, are proteins identified in species from all three domains of life that aid in the correct folding of polypeptides. Originally referred to as **heat shock proteins** because their levels become elevated when cells are transiently exposed to high temperatures, the chaperonins appear to interact with nascent polypeptides. Most likely, they bind to stretches of hydrophobic amino acids that are exposed only before the polypeptide folds. After binding, the chaperonins then aid in the correct folding of the polypeptide.

CONNECTIONS For microorganisms that survive in harsh environmental conditions, keeping proteins properly folded may be a challenge. As we saw in **Section 4.3**, chaperonins are quite abundant in hyperthermophilic archaea.

Protein Processing

In addition to folding correctly, a polypeptide may undergo other post-translational modifications. Many proteins undergo **phosphorylation**, a process in which a phosphate group (—PO_4) is covalently added to the —OH group present on the amino acids threonine, serine, and tyrosine. Addition or removal of phosphate groups can alter the structure and, as a result, function of a protein. Other amino acid modifications, including the addition of methyl (—CH_3) and acetyl (—$COCH_3$) groups also occurs. **Glycosylation**, the addition of complex sugar residues to polypeptides, appears to be quite

common in eukarya. Again, these modifications alter the function of the non-modified polypeptide.

Protein Transport

Finally, proteins must be correctly located. Many proteins function in the cytoplasm. Other proteins need to be embedded within the cytoplasmic membrane. In bacterial cells, proteins may function within the periplasm. In eukaryal cells, certain proteins may need to get inside specific organelles or become embedded within the membranes of these organelles. For all organisms, some proteins need to be secreted out of the cell entirely.

How do proteins get to their desired locations? Even though the details of this transport process differ between bacteria, archaea, and eukarya, the basic steps are fairly similar. Proteins that need to be embedded within or cross a membrane contain a short stretch of hydrophobic amino acids, known as the signal peptide, at their N-terminus. The signal recognition particle (SRP), a complex ribonucleoprotein, recognizes and binds to the signal peptide as the polypeptide is being translated. The SRP then transports the polypeptide to its appropriate location, based on the specific amino acids present in the signal peptide. The signal peptide, in other words, acts a type of postal code for the protein. Once the polypeptide has arrived at the correct location, a signal peptidase cleaves the signal peptide from the polypeptide.

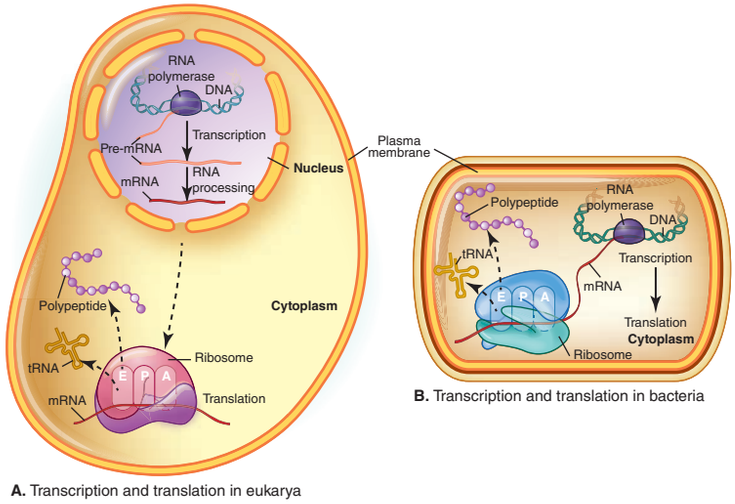
CONNECTIONS Protein secretion in bacteria involves several different polypeptides that facilitate recognition of the protein to be secreted and creation of a membrane channel through which the protein can exit the cell. We examined this process in **Section 2.4**.

The role of the eukaryal nuclear membrane

In the preceding sections, we examined the mechanics of transcription and translation in bacteria, eukarya, and archaea. The details of these events differ, but the basic processes show a great deal of similarity. Before leaving this topic, however, let's consider another question: What role does the nuclear membrane in eukarya play in these events?

The nuclear membrane itself may not be actively involved in transcription or translation, but the presence of a nuclear membrane in eukarya has a profound effect on these two processes. Transcription, of course, must occur where the DNA is located. For eukarya, the DNA resides within the nucleus. However, the ribosomes reside outside of the nucleus, in the cytoplasm. The nuclear membrane separates the locations of transcription and translation. This physical separation also means that transcription and translation must be temporally separated. Transcription must end and the mature RNA molecule must travel out of the nucleus through nuclear pores before translation can occur **(Figure 7.30)**.

As we discussed earlier, there is no nuclear membrane in bacteria and archaea. Transcription and translation are not spatially separated and, as a result, these processes are not temporally separated. The ribosomes exist in close proximity to the DNA. The ribosomes can bind to mRNA even before the transcription process has been completed. In other words, transcription and translation are tightly coupled and can occur almost simultaneously. What does this mean for the organism? In bacteria and archaea, the time frame from DNA to mRNA to protein is shorter. Even if all the transcription and translation enzymes in bacteria, archaea, and eukarya work at equivalent rates, a bacterium or archaeon will be able to produce a protein from a gene more quickly than its eukaryal counterpart because it can begin translation even before completing transcription. This rapid protein production strategy probably benefits bacteria and archaea that may need to respond very quickly to environmental changes.



A. Transcription and translation in eukarya

B. Transcription and translation in bacteria

Figure 7.30. Spatial separation of transcription and translation in eukarya, but not bacteria **A.** In eukarya, transcription occurs in the nucleus. After the pre-mRNA has been modified, or processed, the mature mRNA is transported into the cytoplasm where translation occurs. The two events are separated temporally and spatially, producing a time lag between them. **B.** In bacteria, no physical separation exists between transcription and translation. As a result, translation can begin before transcription ends. This speeds the bacterial capacity to adapt to environmental changes by altering changes in protein production.

7.4 Fact Check

1. How are the following involved in translation: ribosomes, mRNA, codons, tRNA, and amino acids?
2. Compare and contrast translation initiation in bacteria and eukarya.
3. Describe the post-translational modifications made to polypeptides in eukaryal organisms.
4. Why are transcription and translation spatially and temporally separated in eukaryal cells but not in bacteria or archaea?

7.5 The effects of mutations

What effects do changes in the DNA sequence have?

When we discussed the replication of DNA earlier in this chapter, we mentioned that the replication process ensures that each newly produced double-stranded DNA molecule contains the exact same nucleotide sequence as the original molecule. Because A binds to T and C binds to G, each strand of a double-stranded molecule can serve as the template for the synthesis of a complementary strand. The importance of this fidelity now should be obvious. If the DNA sequence of the coding region of a gene changes, then the mRNA sequence will change and the amino acid sequence of the resulting protein may change. A change in the amino acid sequence of a protein may alter the function of that protein. Changes in DNA sequence within non-coding regions, such as promoter regions, or ribosome binding sites, also can alter gene expression. Thus, changes in the DNA sequence may alter the cell's ability to function.

However, changes in the DNA sequence do occur. These changes, or mutations, can arise during DNA replication. The DNA polymerase simply may incorporate the wrong nucleotide. Such spontaneous mutations happen all the time, although at a low frequency. Mutations also may be caused by outside agents, or mutagens, that alter the DNA sequence. As we will see in Chapter 22, viruses sometimes can alter the DNA sequence of the cells they infect. In this section, we will briefly examine different types of mutations, some common causes of these mutations, and ways in which certain errors can be corrected. Before we address these points, let's not forget one very important point—in the grand scheme of things, mutations are not bad. Mutations provide the raw material for evolution. The great diversity of life that we see all around us exists thanks to changes that have occurred in DNA and were acted upon by the natural forces of evolution. Think about life over the 5-billion-year history of Earth if absolutely no mutations ever occurred in the original molecule of nucleic acid. It's a pretty bleak picture, isn't it?

Types of mutations

Probably the simplest type of mutation is a **base substitution**, a mutation in which a single base in the wild-type, or "normal," sequence changes. Transitions involve purine to purine or pyrimidine to pyrimidine changes. In contrast, transversions involve purine to pyrimidine or pyrimidine to purine changes. The effects of these changes can differ dramatically, depending on the bases involved and their location. Changes that alter codons could have an obvious effect on a protein. If a mutation alters the specificity of a codon, then the amino acid sequence of the protein will be altered. Such changes are referred to as **missense mutations**. We should note that even if the amino acid sequence of a protein is altered, the overall shape of the protein and its function may not change. Because of the redundancy of the genetic code, some changes in codons will not alter the amino acid sequence. These changes are referred to as **silent mutations**. Finally, point mutations can lead to the conversion of an amino acid-coding codon into a stop codon. These changes are referred to as **nonsense mutations** (Figure 7.31).

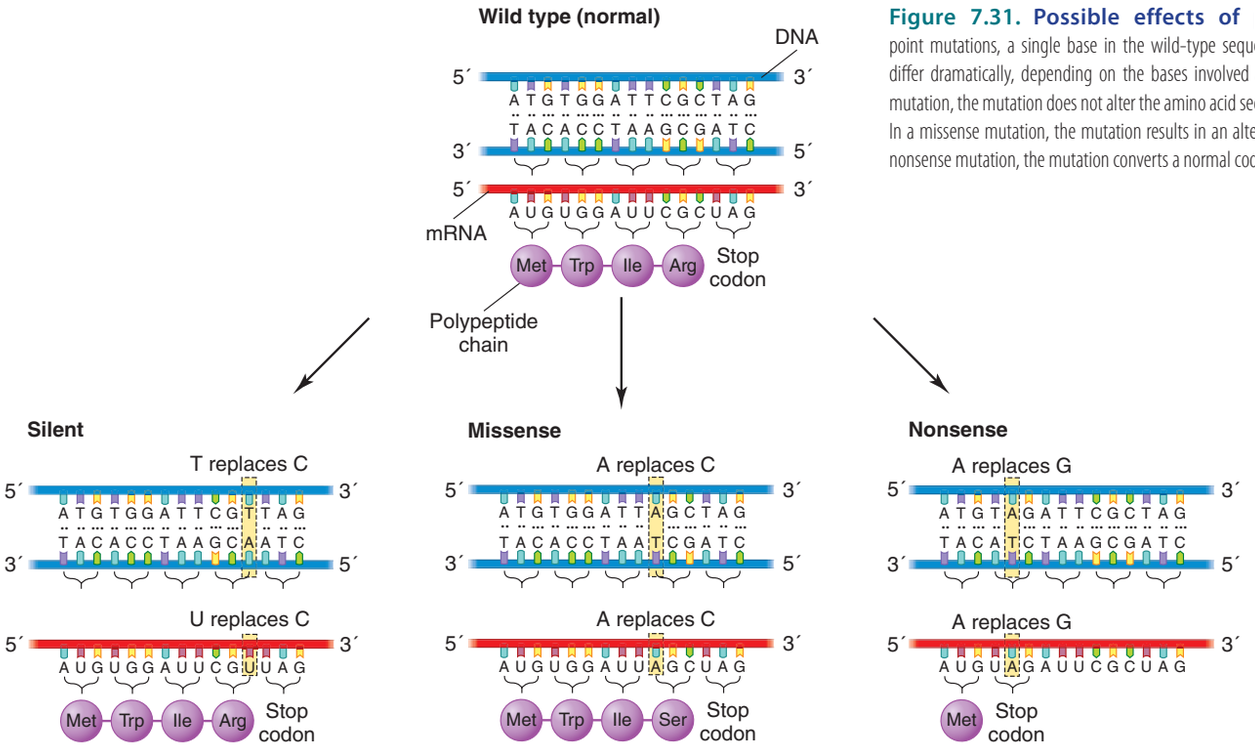


Figure 7.31. Possible effects of point mutations In point mutations, a single base in the wild-type sequence changes. The effects can differ dramatically, depending on the bases involved and their location. In a silent mutation, the mutation does not alter the amino acid sequence of the resulting protein. In a missense mutation, the mutation results in an altered amino acid sequence. In a nonsense mutation, the mutation converts a normal codon to a stop codon.

Substitutions in the non-transcribed regulatory regions of genes also can have profound effects. As we noted during our discussion of transcription initiation, RNA polymerases recognize specific promoter sequences. As a result, mutations in the promoter region could dramatically decrease, or increase, the affinity of the RNA polymerase for that promoter; expression of the gene would be altered. In other words, the structure of the resulting protein would not be altered, but the amount produced would change. Again, this change could have dramatic consequences for the cell.

Instead of substitutions, **insertions** and **deletions** also may occur. With these mutations, one or more bases are added to, or removed from, the original DNA sequence. As with substitutions, the effects of these mutations may be most obvious if they occur within the coding region of a gene. Insertions or deletions within the coding region of a gene may alter the reading frame of the bases. In other words, all the codons after an insertion or deletion could be different. Subsequently, most amino acids after the insertion or deletion probably will be altered. These mutations are **frameshift mutations** (Figure 7.32).

As we saw with substitutions, insertions and deletions also can cause problems in regulatory regions. For example, the −10 and −35 elements of the bacterial promoter need to be about 15 base pairs apart. A lengthy insertion or deletion between these elements could alter the ability of RNA polymerase to bind to the promoter.

Finally, more extensive alterations in the DNA sequence can occur. In **inversions**, sections of DNA literally are inverted and reinserted into the genome at the same location. In **translocations**, a segment of a chromosome breaks off and reattaches to a different chromosome or a different location within the same chromosome (Figure 7.33). The effects of inversions and translocations depend on the sequences involved and, in the case of translocations, the new location of the translocated DNA. For example, a gene could be moved closer to a regulatory element, resulting in increased transcription of that gene.

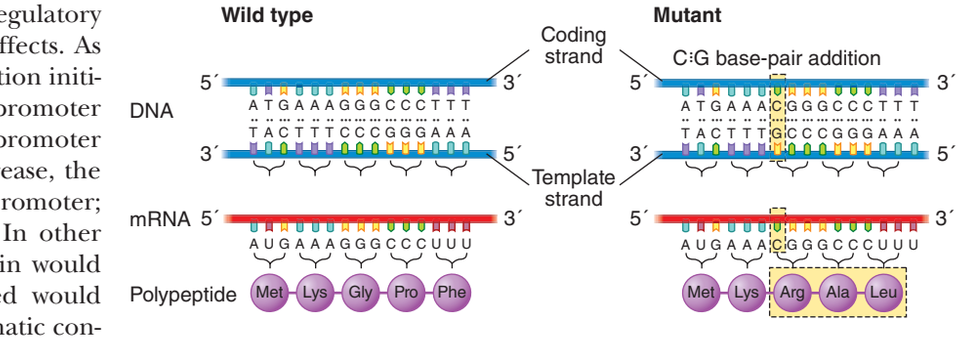

Figure 7.32. Effects of insertions and deletions The insertion or deletion of one or two bases from the coding region of a gene will alter the reading frame of the subsequent bases. As shown here, all codons after the insertion are altered.

Causes and repair of mutations

Because of the importance associated with maintaining the correct DNA sequence, DNA polymerases rarely make mistakes. The DNA polymerase in *Escherichia coli*, as we mentioned before, produces DNA at a rate of about 1,000 nucleotides per second. Yet, it makes a mistake—incorporating the incorrect base into the growing strand of DNA—only about one in every 10^9 bases (10^9 = one billion). Imagine doing that well on your exams! This amazing accuracy occurs due to several processes. First, most DNA polymerases possess a **proofreading** activity. As the enzymes elongate DNA, they also can check their work. Using a 3′ to 5′ exonuclease activity, the polymerase can identify and remove an incorrect base that has just been incorporated into the growing chain. But what happens if DNA polymerase does not immediately detect this mistake? A second mutation correction system known as **mismatch repair** corrects errors that occurred during replication. In *E. coli*, a series of proteins, including MutS, MutL, and MutH, will bind to the mismatched DNA and facilitate the excision of several bases around the mismatched base by exonucleases. DNA polymerase I then fills in the resulting gap and DNA ligase links together the adjoining fragments.

Let's think about this repair process a little more. How can these repair proteins determine which strand of DNA contained the correct base and which strand contained the incorrect base?

Mutations ANIMATION

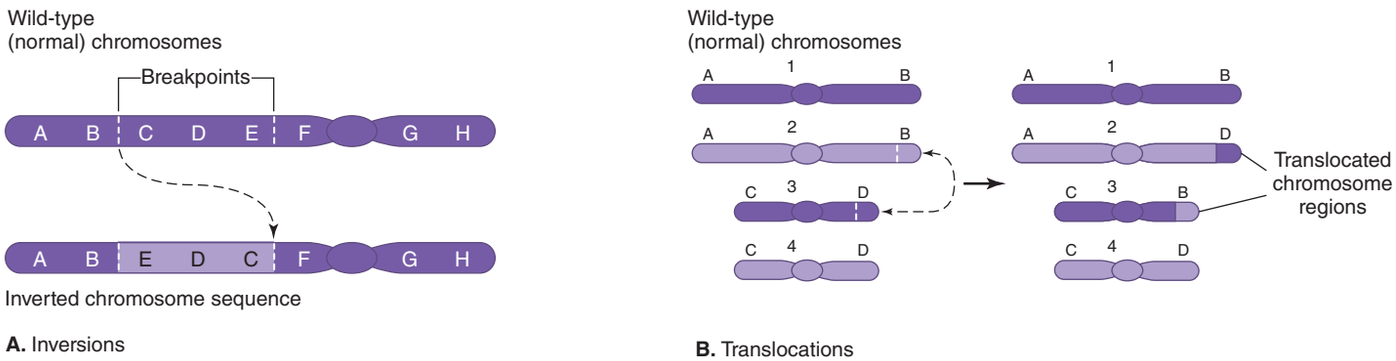

Figure 7.33. Effect of inversions and translocations **A.** A section of DNA becomes inverted, resulting in a different order of genes and other genetic elements. **B.** A segment of one chromosome breaks off and reattaches to a different chromosome or a different location within the same chromosome. This schematic shows a reciprocal translocation, in which pieces of chromosomes 2 and 3 are switched. Note that the letters represent different genes on the chromosomes.

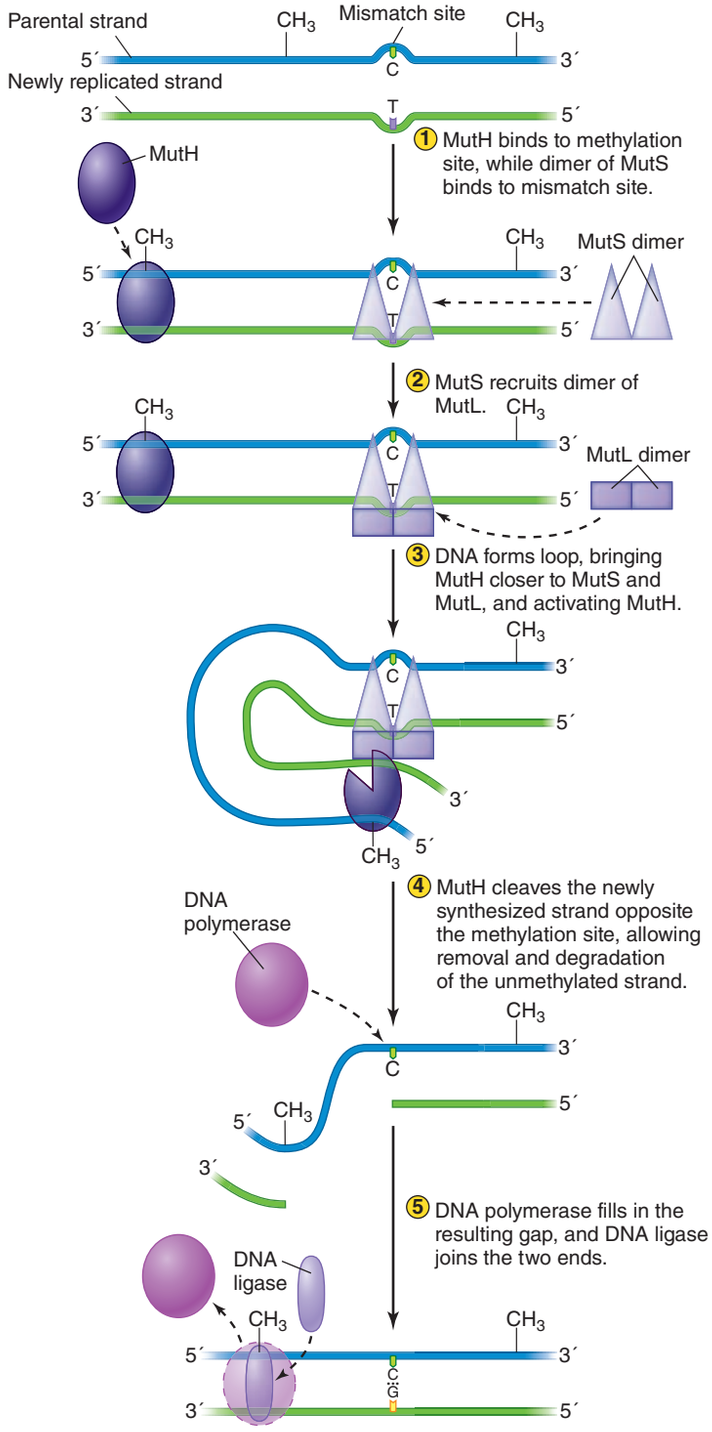

Figure 7.34. Process Diagram: Mismatch repair in *E. coli* If an error occurs during DNA replication and is not corrected by the proofreading ability of DNA polymerase, then a mismatched base-pair results. In this schematic, a TC mismatch is shown as an example. The cell distinguishes the correct (parental) strand of DNA from the mutated (newly synthesized) strand of DNA by detecting the methylation pattern of the DNA. For a brief period following DNA replication, the parental strand is methylated, but the new strand is not. MutH binds to these sites of methylation. A dimer of MutS binds to the mismatched base pair and recruits a dimer of MutL. MutH interacts with the MutS and MutL dimers, which activates MutH, allowing it to cleave the unmethylated strand of DNA opposite the methylation site. The DNA transiently unwinds, and the newly synthesized piece of DNA is degraded from this cleavage site to the mismatch site. DNA polymerase then fills in the resulting gap, and DNA ligase joins the two ends.

The correct "decision" could be vitally important to the cell. As a result, bacteria have evolved a clever solution. After DNA replication occurs in *E. coli*, deoxy-adenosine methylase methylates, that is, adds a methyl group, to A nucleotides found in 5′-GATC-3′ regions. However, this methylation does not occur immediately after replication; a short period of time elapses between replication of the DNA and addition of the methyl groups. As a result, the newly formed double-stranded DNA is hemimethylated, or methylated on only one strand, the original parental strand, for a short period of time. MutH binds to the DNA at this hemimethylated site. If a mismatch occurs, then a dimer of MutS binds to the mismatched base pair and recruits a dimer of MutL. The DNA then forms a loop, resulting in a MutH/MutS/MutL complex. MutH cleaves the unmethylated, or new, strand of DNA at the methylation site, and exonucleases remove a stretch of nucleotides, including the mismatched base. DNA polymerase fills in the resulting gap **(Figure 7.34)**.

Mutations do not arise only from DNA polymerase errors. Mutations also can result from external agents that alter the DNA—**mutagens**. Nitrous acid, for example, chemically alters bases, removing amino groups from them. Deamination of adenine converts it to hypoxanthine, deamination of cytosine changes it to uracil, and deamination of guanine converts it to xanthine **(Figure 7.35)**. During subsequent DNA replication, DNA polymerase will pair a cytosine with the newly created hypoxanthine, an adenine will be paired with uracil, and cytosine will be paired with xanthine, ultimately causing changes in the DNA sequence. Similarly, chemicals like methyl-nitrosoguanidine add methyl ($:CH_3$) groups to bases. When guanine is methylated in

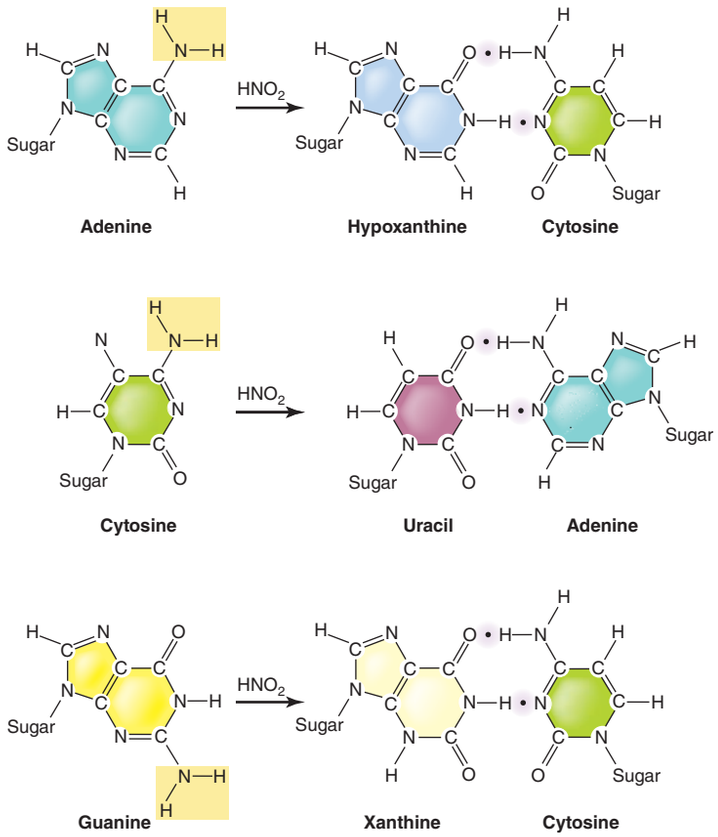

Figure 7.35. Effects of nitrous acid on DNA Nitrous acid removes amino groups (highlighted) from bases. Deamination of adenine converts it to hypoxanthine, the deamination of cytosine converts it to uracil, and deamination of guanine converts it to xanthine.

Y-R. Lin, M-Y. Hahn, J-H. Roe, T-W. Huang, H-H. Tsai, Y-F. Lin, T-S. Su, Y-J. Chan, and C. W. Chen. 2009. *Streptomyces* telomeres contain a promoter. J. Bacteriol 191:773–781.

Context

Unlike most bacteria, the *Streptomyces* are well known for having linear, rather than circular, chromosomes. Attached to the 5′ ends of these linear chromosomes are well-conserved 185 amino acid proteins, called terminal proteins (referred to as TP and Tpg in this paper). These *Streptomyces* linear chromosomes end in telomeres, but telomeres with a different structure than the better-known eukaryal telomeres. The *Streptomyces* telomere sequences are highly conserved, and tend to form complex secondary structures. Each *Streptomyces* linear chromosome contains an internal origin of replication. DNA replication from the origin in both directions toward the telomeres results in single-stranded gaps about 300 bp from the end, leaving 3′ overhangs. TP is responsible for patching these gaps. The mechanism of this end patching is not understood; it is not even known which DNA polymerase is used.

In addition to TP and Tpg, another protein, called Tap, also binds to the telomeres. More specifically, Tap binds to the secondary structure of the 3′ overhangs and is thought to help bring TP to the telomere so that it can patch the single-stranded gap. This study started with the goal of determining what other proteins bind to *Streptomyces* telomeres. Along the way, though, the researchers made another discovery—genes exist within the telomeres. The discovery that the telomere sequences have genes arose naturally from the unexpected finding that RNA polymerase, the enzyme responsible for making mRNA from genes, was one of the proteins that bound telomeres.

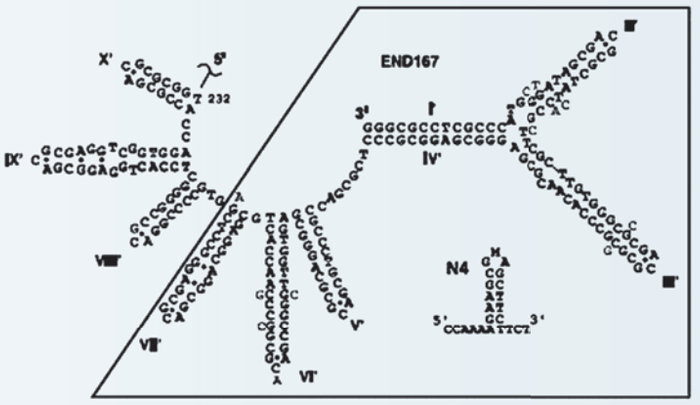
Experiments

To isolate telomere-binding proteins, the researchers first used PCR amplification to prepare double-stranded and single-stranded DNA molecules corresponding to the terminal 167 bp of the *Streptomyces lividans* chromosome. Biotin was covalently attached to one of the primers used in PCR, resulting in the biotin labeling of the resulting PCR products **(Figure B7.2)**.

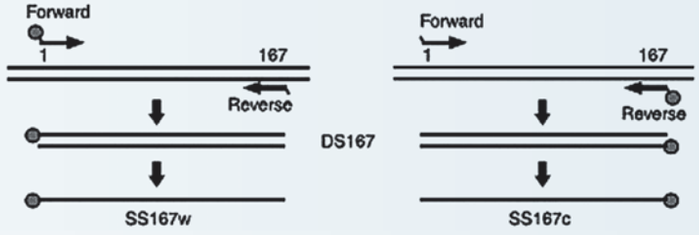
The biotin-labeled DNA fragments were incubated with crude extract from *S. lividans* cells. During this incubation, proteins that interact with the DNA should bind to it. Streptavidin-coated beads then were added to the mixture. Because biotin and streptavidin bind to each other with high affinity, any DNA:protein complexes would bind to these beads. The beads were washed with buffer, and bound proteins were removed from the beads with a salt solution. The liberated proteins then were separated by SDS-PAGE **(Figure B7.3)**. Three proteins attached to the labeled DNA fragments. Note that the bands marked by the * were shown to be due to non-specific binding.

The researchers then tried to identify these three telomere-binding proteins. The proteins, two of 150 kDa, and one of 40 kDa, matched the expected sizes of the proteins that make up the core RNA polymerase subunits β, β', and α_2. Consistent with this finding, the 40-kDa band reacted with an anti-α antibody. Another antibody against a major component of the bacterial RNA polymerase also detected bound proteins that were not visible by SDS-PAGE. In addition to the proteins that bound to all DNA fragments, a 100-kDa protein was found to bind to the double-stranded fragment only, and later was identified as DNA polymerase I.

Taken together, these results suggest that RNA polymerase binds to the telomere of *S. lividans*. If this enzyme binds to these sequences, then the likelihood is strong that it is carrying out transcription, and the telomere region, by extension, contains genes. The researchers tested this hypothesis with an *in vitro* transcription assay using the double-stranded 167-bp telomere fragment as a template and a purified RNA polymerase. In this assay, mRNA transcripts of 100 and 130 nucleotides in length were produced. In other words, the telomere sequences contain genes. Further *in vivo* experiments were conducted, in which the researchers inserted the telomere DNA sequences in front of genes that lacked promoters, the DNA sequences typically required for the initiation of transcription. These telomere sequences led to activity in *Streptomyces* and *E. coli*, and also activated transcription in the yeast *Saccharomyces cerevisiae*.



A. Secondary structure in *S. lividans* chromosome



B. PCR amplification with biotin-labeled primers

Figure B7.3. Isolation of telomere-binding proteins The biotin-labeled DNA fragments were incubated with proteins from *Streptomyces lividans* cells. DNA:protein complexes were isolated with streptavidin-coated beads. Bound proteins were separated by SDS-PAGE.

If you look at the telomere DNA sequences, you will not find sequences typically associated with *Streptomyces* promoters. What is responsible for this promoter activity? Could the secondary structure of the telomere lead to gene expression? Is the promoter activity biologically meaningful? These and other important questions still need to be answered.

Impact

The authors of this paper proposed several ideas about the possible functions of this promoter activity. First, it may be involved in conjugation, a process whereby bacteria can transfer DNA between cells. The F-plasmid promoter of *E. coli* is involved in conjugation, and its activity depends on its secondary structure. Second, the telomere promoter might be involved in the synthesis of the primer of the terminal Okazaki DNA fragment. Third, it might be involved in the transcription of a specific gene. Indeed, a gene called *ttrA*, which is involved in the conjugal transfer of DNA, is located in this region of the telomeres. It will be very interesting to see if the activity of the promoter is subject to regulation and if the promoter activity is affected by whether the telomeres are single- or double-stranded.

Questions for Discussion

1. Although the telomere sequences function as a promoter in bacteria, they do not work as promoters in yeast. However, they do augment gene activity in these eukarya. Are you surprised by this difference? Why or why not?
2. If promoter activity was demonstrated by *in vitro* transcription assays, why was it also necessary to show that it occurred *in vivo*?

this fashion, it may pair with thymine, instead of cytosine, ultimately resulting in a GC to AT transition change.

Physical agents also can damage DNA. For example, ultraviolet (UV) light causes adjacent thymine molecules to bond to each other, forming a T—T dimer **(Figure 7.36)**. These dimers cause a deformation in the double-stranded DNA and can lead to subsequent errors during the next round of DNA replication.

Ionizing radiation, on the other hand, causes double-stranded breaks (DSBs) in the phosphate-sugar backbone of the DNA molecule. In some respects, DSBs may be the most dangerous type of DNA damage. Unless these breaks are repaired, the entire molecule will be non-functional. As we mentioned in the opening story, *Deinococcus radiodurans* exhibits extreme resistance to this type of DNA damage and can withstand the generation of approximately 100 DSBs per genome. Most other bacteria, such as *Shewanella oneidensis*, conversely, can only survive levels of ionizing radiation that result in about one DSB per genome.

CONNECTIONS The effects of ionizing radiation, and its uses in sterilizing food, are discussed in **Section 16.2**. In **Figure 16.9**, we review the electromagnetic spectrum.

As we have seen in this section, various mutagens can cause mutations in a cell's DNA. Researchers use some of these mutagens to intentionally introduce mutations into model organisms. Food safety experts intentionally use mutagens to sterilize foods. Even our own cells use mutagens. Certain intracellular mutagens may help our cells control viral infections **(Perspective 7.1)**.

Individual organisms, however, are not likely to receive direct benefit from having their genomes altered. As a result, all living organisms possess elaborate mechanisms to repair their DNA. As we mentioned previously, the 3′ to 5′ exonuclease activity of DNA polymerases and the methylation-directed mismatch repair mechanism allow cells to correct most of the errors that occur during DNA replication. Other systems exist to repair specific types of DNA damage like the ones we have just explored.

Figure 7.36. Ultraviolet light as a mutagen Ultraviolet light causes adjacent thymines to form covalent bonds, generating thymine dimers that distort the shape of the DNA. If not repaired, these dimers result in DNA damage during the next round of DNA replication.

Perspective 7.1
USING MUTATIONS TO CONTROL VIRAL INFECTIONS

Mutations are necessary for evolution but can be detrimental to an organism. Certainly, a very high level of mutations would alter many genes, change many proteins, and have a severe effect on the organism. So, could we control pathogens by intentionally causing mutations in an infectious agent? It turns out that our cells do just that as a way of controlling some viral infections. Perhaps we can make use of this strategy to develop new antiviral agents.

This story has rather humble beginnings. Quite some time ago, researchers observed that HIV-1, the virus that causes AIDS, does not replicate in all cell lines. These cells were classified as *non-permissive*. A series of experiments demonstrated that these non-permissive cells produced an antiviral factor, later identified as APOBEC3G. In infected cells, this host cell protein can become incorporated in newly formed virions **(Figure B7.4)**.

When these APOBEC3G-containing virions infect other cells, APOBEC3G goes to work. It functions as a cytidine deaminase, removing the amino group from the cytosine base on cytidine nucleotides. This chemical modification affects the replicating viral genome. So why would a cytidine deaminase block viral replication? As we discussed earlier in this section, deamination of cytosine converts it into uracil (see Figure 7.35). When a C is converted to a U on one strand of DNA, the other strand will change from a G to an A in the next round of DNA replication. In other words, a highly active cytidine deaminase would cause a large number of CG to TA transition mutations. Indeed, in cells expressing APOBEC3G, 1–2 percent of all Cs in the viral genome may be changed to Us. This extraordinarily high level of mutations leads to the production of non-functional viruses. As a result, cells induce mutations in the virus as a way of protecting themselves.

The story doesn't stop there. It turns out that HIV-1 produces a protein of its own designed to counteract APOBEC3G. The viral protein Vif, or virus infectivity factor, prevents APOBEC3G from becoming incorporated into the virion, thereby inhibiting the activity of APOBEC3G **(Figure B7.5)**.

It appears that Vif from HIV-1 inhibits only the activity of human APOBEC3G and APOBEC3G from very closely related species. HIV-1 Vif does not inhibit APOBEC3G from more distantly related species. It seems that the *vif* gene in HIV-1 has evolved specifically to interact with the form of APOBEC3G in its host organism.

By analyzing the activity of APOBEC3G, we may learn more about the origins and evolution of HIV. More importantly, we may be able to use this information to design new antimicrobial agents that function by mutating selectively the genomes of specific pathogens.

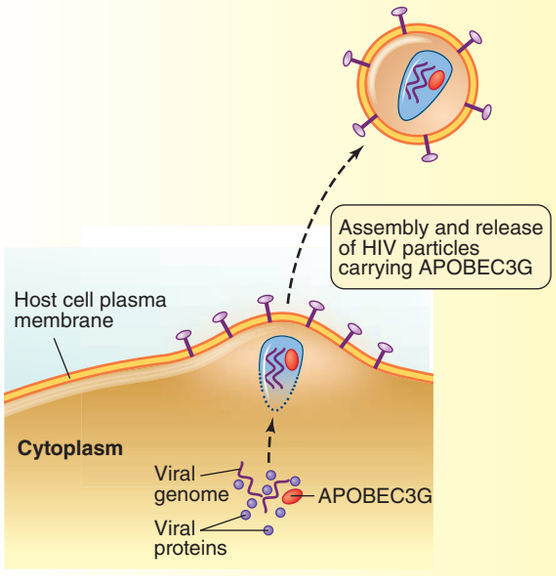

Figure B7.4. Incorporation of the protein APOBEC3G into newly produced virions When a host cell produces the protein APOBEC3G, this protein gets incorporated into newly formed HIV particles, along with the viral genome and key viral proteins. These newly formed virions contain this host protein and transfer it, along with their genome, into newly infected cells.

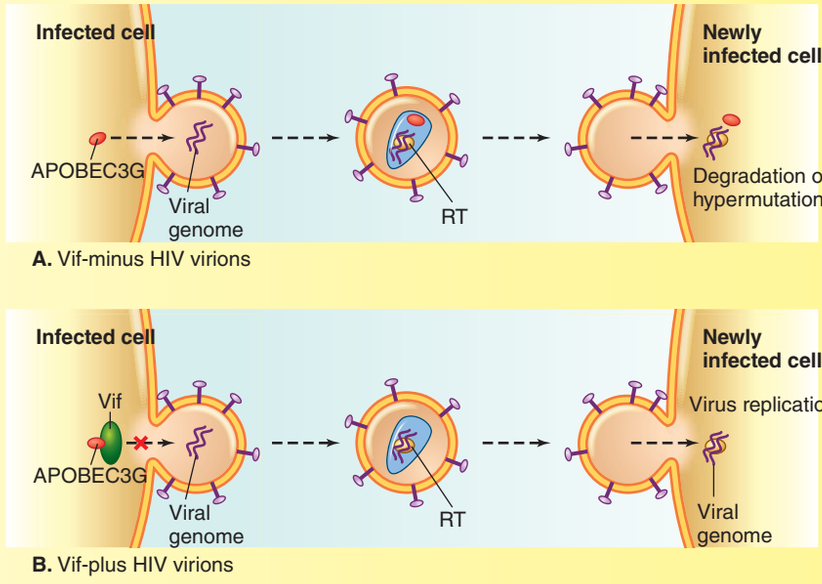

Figure B7.5. The HIV-1 Vif protein counters the action of the APOBEC3G protein **A.** When an HIV-1 virion lacking the *vif* gene replicates within a host cell, the cellular protein APOBEC3G becomes incorporated into newly produced virions. When these virions then infect another cell, the APOBEC3G enzyme deaminates Cs in the replicating viral genome, leading to hypermutations in or degradation of the viral genome, thereby destroying its capacity to effectively replicate. **B.** When an HIV-1 virion containing the *vif* gene replicates within a host cell, the viral Vif protein prevents the incorporation of APOBEC3G into the newly produced virions, thereby preventing the damaging hypermutations or degradation of the viral genome in cells that subsequently become infected by the virus.

Certain types of mutations can be repaired by **DNA glycosylases**. Enzymes in this family recognize damaged bases and initiate a base excision repair mechanism. Uracil-DNA glycosylase, for example, recognizes uracil in DNA and leads to its removal. Various **alkyltransferases** remove methyl groups added to bases by DNA-modifying agents, thereby returning the bases to their normal structure. Indeed, researchers have identified over 100 different alkyltransferases in bacteria, archaea, and eukarya, suggesting that this repair mechanism is quite important to all living organisms. The photoreactivation pathway specifically repairs thymine dimers caused by UV light. **Photolyase** cleaves the covalent bonds linking the adjacent thymines, thereby correcting the error (Figure 7.37). Finally, a series of proteins recognizes and corrects double-stranded breaks, the type of damage caused by ionizing radiation. As a result of these and other repair pathways, the sequence of the genetic material remains fairly constant, yet mutates enough to provide the variation needed for evolutionary change.

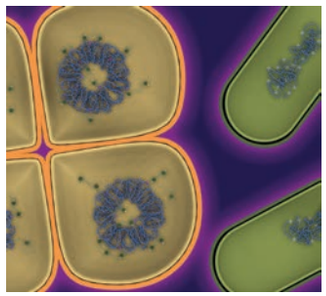
Thymine dimer repair
ANIMATION

7.5 Fact Check

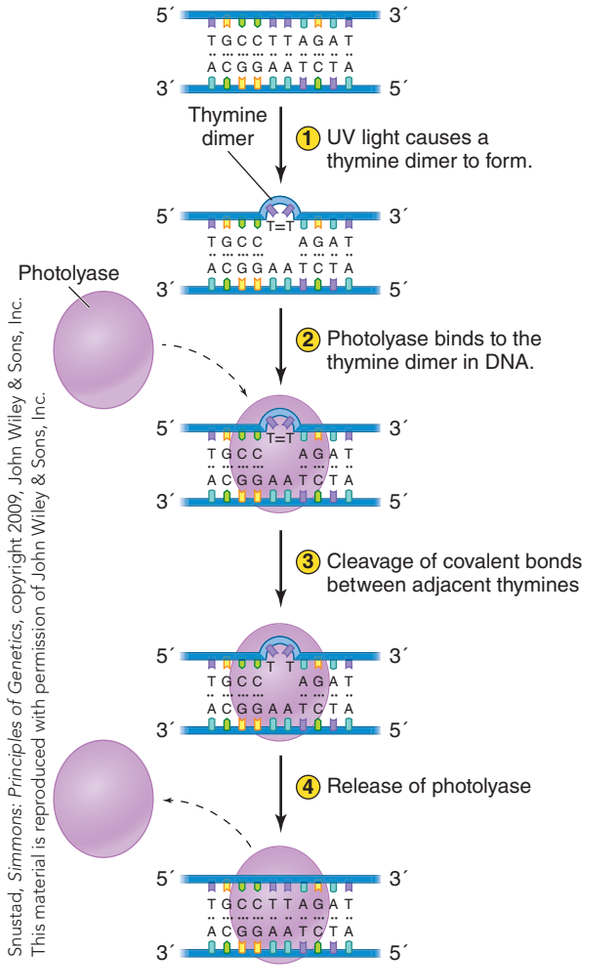
1. Differentiate between the effects of these types of substitution mutations: missense mutations, silent mutations, and nonsense mutations.
2. How would the result of an insertion of two nucleotides differ from that of the insertion of three nucleotides?
3. How can spontaneous mutations that occur during DNA replication be repaired?
4. Provide several examples of mutagens and their effects.

Image in Action

WileyPLUS Learning Space The *Deinococcus radiodurans* cells shown here are exposed to ionizing radiation (pink halo) and still are able to undergo normal cell processes, including transcription and translation. In contrast, the irradiation has caused double-stranded breaks in the genome of *E. coli* cells on the right that cannot be properly repaired.



1. Researchers recognize that the DNA of *D. radiodurans* also is broken when exposed to irradiation. However, the arrangement or packaging of the DNA may play a key protective role. Describe how the DNA is packaged in this organism and how it differs from the *E. coli* DNA shown on the right.
2. Because the DNA of *E. coli* is not packaged the same as *D. radiodurans*, the breakages may result in mutations that can have significant impacts on the cells. Describe some of the mutations that now may occur in the damaged *E. coli* cells in the image.



Snustad, *Simmons: Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 7.37. Process Diagram: Photolyase can correct thymine dimers Living organisms have evolved a complex set of pathways to correct different types of DNA damage. Photolyase cleaves the covalent bonds in thymine dimers, correcting the errors associated with exposure to UV light.

The Rest of the Story

So, how can *Deinococcus radiodurans* survive exposure to extreme levels of ionizing radiation? It seemed very unlikely that *D. radiodurans* was somehow impervious to the effects of radiation. Its structure does not differ dramatically from other bacteria, and the chemical makeup of its DNA does not differ at all from the DNA of any other organism. The DNA of *D. radiodurans* appears to undergo numerous double-stranded breaks when exposed to ionizing radiation, just like the DNA of any other organism. Unlike other organisms, though, scientists determined that *D. radiodurans* must possess a mechanism for repairing this damage.

Sequence analyses of the *D. radiodurans* genome indicated that it contains a normal set of DNA repair genes. A series of experiments demonstrated that DNA repair genes from radiation-sensitive bacteria could restore radiation resistance to several radiation-sensitive mutants of *D. radiodurans*.

So how did this bacterium, with standard DNA repair genes, survive exposure to high levels of ionizing radiation? The answer seemed to first involve the unusual arrangement of its DNA. As was mentioned in Section 7.1, the DNA of *D. radiodurans* appears to exist in a very unusual shape. The doughnut-like arrangement of the DNA provides a mechanism for holding together the many fragments of DNA generated by exposure to radiation. Because the fragments do not disperse, they can be rejoined in the correct order during repair.

More recently, it was observed that *D. radiodurans* contains an unusually high amount of Mn^{2+} and a relatively low intracellular iron concentration. Could the high Mn/Fe ratio account for the radiation resistance? Professor Michael Daly and colleagues at the Uniformed Services University of the Health Sciences hypothesized that the Mn^{2+} may protect critical DNA repair enzymes from damage caused by radiation. As a result, the DNA repair enzymes in *D. radiodurans* can continue to repair the DNA fragments being held together, whereas the corresponding enzymes in other species simply become inactivated.

Summary

Section 7.1: How do we know DNA is the hereditary molecule?

A series of elegant genetic and biochemical studies demonstrated that DNA is the hereditary molecule, and its basic structure is similar in all living organisms.

- Foreign DNA can alter the phenotype of another cell, a process known as **transformation**.
- DNA exists as a double-stranded molecule, with each strand composed of a 2-deoxyribose and phosphate backbone. A **purine** or **pyrimidine** nitrogenous base is attached to the 1′ carbon of each sugar. In a double-stranded DNA molecule, **adenine (A)** always binds to **thymine (T)** and **guanine (G)** always binds to **cytosine (C)**. The two strands of a double-stranded molecule are arranged in an **antiparallel** fashion, and the strands are **complementary** to each other.
- Bacteria usually have a single, circular chromosome that is supercoiled for compaction. Bacteria also commonly contain plasmids, small, circular extrachromosomal pieces of DNA.
- Eukarya usually have linear DNA chromosomes in which the DNA is complexed with histones, forming nucleosomes.
- Archaea usually have a single, circular chromosome, but it often is complexed with histone-like proteins.

Section 7.2: How does DNA replicate?

The replication of DNA is precisely regulated within the cell and occurs with great fidelity.

- DNA undergoes **semiconservative replication**. Each strand of a double-stranded molecule serves as a template for the formation of a new, complementary second strand.
- In *E. coli*, replication begins at the origin of replication, or ***oriC***. A series of proteins, including **DnaA** and **helicase**, interact with *oriC* and initiate replication.
- After a **replication bubble** has formed at the origin of replication, **single-stranded DNA-binding proteins (SSB)** attach to the DNA, and a **DnaG**, or **primase**, adds a short RNA **primer** to the newly formed single-stranded DNA. **DNA polymerase** then adds nucleotides to the primer, replicating the DNA bidirectionally. One new strand, the **leading strand**, elongates continuously. The **lagging strand** elongates discontinuously, forming **Okazaki fragments**.
- The RNA primers are removed by an exonuclease, and a **ligase** links the new fragments into a complete molecule.
- In circular DNA molecules, replication continues until the two replication forks meet. In linear molecules, specialized features, **telomeres**, exist on the ends of the molecules, and a specialized enzyme, **telomerase**, completes the replication process.

Section 7.3: How are genes transcribed?

Like DNA replication, the process of transcription is a closely regulated process. Specific initiation, elongation, and termination processes occur.

- **Transcription** is the process by which **genes** are converted into complementary strands of single-stranded RNA by **RNA polymerases**. These RNA molecules include **messenger RNA (mRNA)**, **transfer RNA (tRNA)**, **ribosomal RNA (rRNA)**, and various regulatory **micro RNAs (miRNAs)**. The RNA contains the sugar ribose and the base **uracil**.
- The transcription process begins at a **promoter**, a specific sequence recognized by the RNA polymerase. In bacteria, **sigma (σ) factor**, a transient component of RNA polymerase, binds to the promoter. In eukarya, **transcription factors** first bind to the promoter and then recruit RNA polymerase. These binding interactions can be observed with a **gel shift assay**.
- Transcription ends at specific sequences. Eukaryal messenger RNAs undergo **post-transcriptional modifications**. A **5′ cap** and **3′ poly(A) tail** are added, **introns** are spliced out, and **exons** are joined together.

Section 7.4: How are proteins made?

In translation, the information within the mRNA molecules is used to make proteins. Again, initiation, elongation, and termination are closely regulated.

- **Translation** is the process of protein synthesis. **Ribosomes** interact with the mRNA, "reading" sequential **codons** and recruiting tRNA with complementary **anticodons**. Each tRNA is associated with a specific **amino acid**.
- In bacteria, translation begins at the first AUG codon after the **Shine–Dalgarno sequence**, a short sequence in the mRNA recognized by the ribosome. In eukarya, translation begins at the first AUG after the 5′ cap. As a result, bacterial genes may be **polycistronic**. Eukaryal genes usually are **monocistronic**.
- Translation stops when the ribosome reaches a **stop codon**—UAA, UAG, or UGA.
- Following translation, nascent polypeptides must be correctly folded and, in many cases, are modified and transported.
- Chaperonins, like **heat shock proteins**, aid in the correct folding of polypeptides.
- Post-translational modifications, such as **phosphorylation** and **glycosylation**, may occur during protein processing.

- In bacteria, transcription and translation occur almost simultaneously. In eukarya, the two events are spatially and, as a result, temporally separated.

Section 7.5: What effects do changes in the DNA sequence have?

Although the DNA replication occurs with great fidelity, mistakes do occur. These mistakes provide the genetic diversity needed for evolutionary change.

- Mutations are changes in the DNA sequence. These changes can alter the coding portion of a gene, resulting in an aberrantly functioning protein.
- Common types of mutations include **base substitutions**, such as **missense**, **silent**, and **nonsense mutations**, **insertions**, and **deletions**. Insertions and deletions within the coding region of a gene will alter the codon reading frame and are referred to as **frameshift mutations**.
- **Inversions**, in which segments of DNA are inverted and reinserted into the genome, and **translocations**, in which pieces of DNA break off and reattach at another location, also can occur, and can have varying effects, depending on the sequences involved.
- Some mutations result from DNA polymerase errors during DNA replication. External agents, or **mutagens**, can cause other mutations.
- Most organisms have evolved complex mechanisms for repairing DNA damage. For example, DNA polymerase possesses a 3′ to 5′ exonuclease **proofreading** activity that allows it to scan newly synthesized DNA and correct most errors. Bacteria often use a **mismatch repair** process to correct errors. Finally, various enzymes, like **glycosylase**, **alkyltransferase**, and **photolyase** exist to correct specific types of DNA damage.

Application Questions

1. The experiments of Griffith and Avery, MacLeod, and McCarty showed that DNA from one organism could alter, or transform, the characteristics of another organism. Using what you have learned in this chapter, explain how this "transformation" actually occurs.
2. You are given macromolecules isolated from a culture of cells. You are asked to determine whether the molecules in the sample are DNA, RNA, or proteins. Using what you've learned in this chapter, how could you go about determining this?
3. Replication of linear DNA encounters problems that are not an issue for circular bacterial chromosomes. Describe these problems and the solution the cell uses to deal with this issue.
4. Do mutations always alter protein function? Explain.
5. A microbe is observed that appears to mutate at twice the normal rate of other similar microbes. Explain how this characteristic could be considered good and bad for this organism.
6. The antibiotic ciprofloxacin (Cipro) inhibits DNA gyrase, a bacterial enzyme involved in DNA replication. What direct effects would this have on a bacterial cell exposed to this drug?
7. As described in Perspective 7.1, APOBEC3G functions as a cytidine deaminase. What effect is implied by this protein's name? How can it be used to render viruses non-functional?
8. Imagine you are attempting to create a collection of mutants that will be used to study and specifically compare to non-mutated strains. How might you use a chemical to generate this collection of mutants? Explain.
9. Researchers isolated *Deinococcus radiodurans* after subjecting canned meat to a supposedly lethal dose of ionizing radiation.
   a. Describe how you might go about isolating from a soil sample a mutant bacterium that exhibits increased resistance to UV light.
   b. How would you quantify this microorganism's level of UV resistance?
   c. After isolating this organism, how could you determine if this microorganism exhibits increased resistance to other chemical or physical agents? (Use this chapter's information on *D. radiodurans* as a guide.)
10. In bacteria, mRNA molecules can be polycistronic. In contrast, eukaryal mRNA molecules generally are monocistronic. What is meant by these terms? What accounts for this difference between bacteria and eukarya?
11. Provide evidence that DNA replication in archaea more closely resembles DNA replication in eukarya than DNA replication in bacteria.

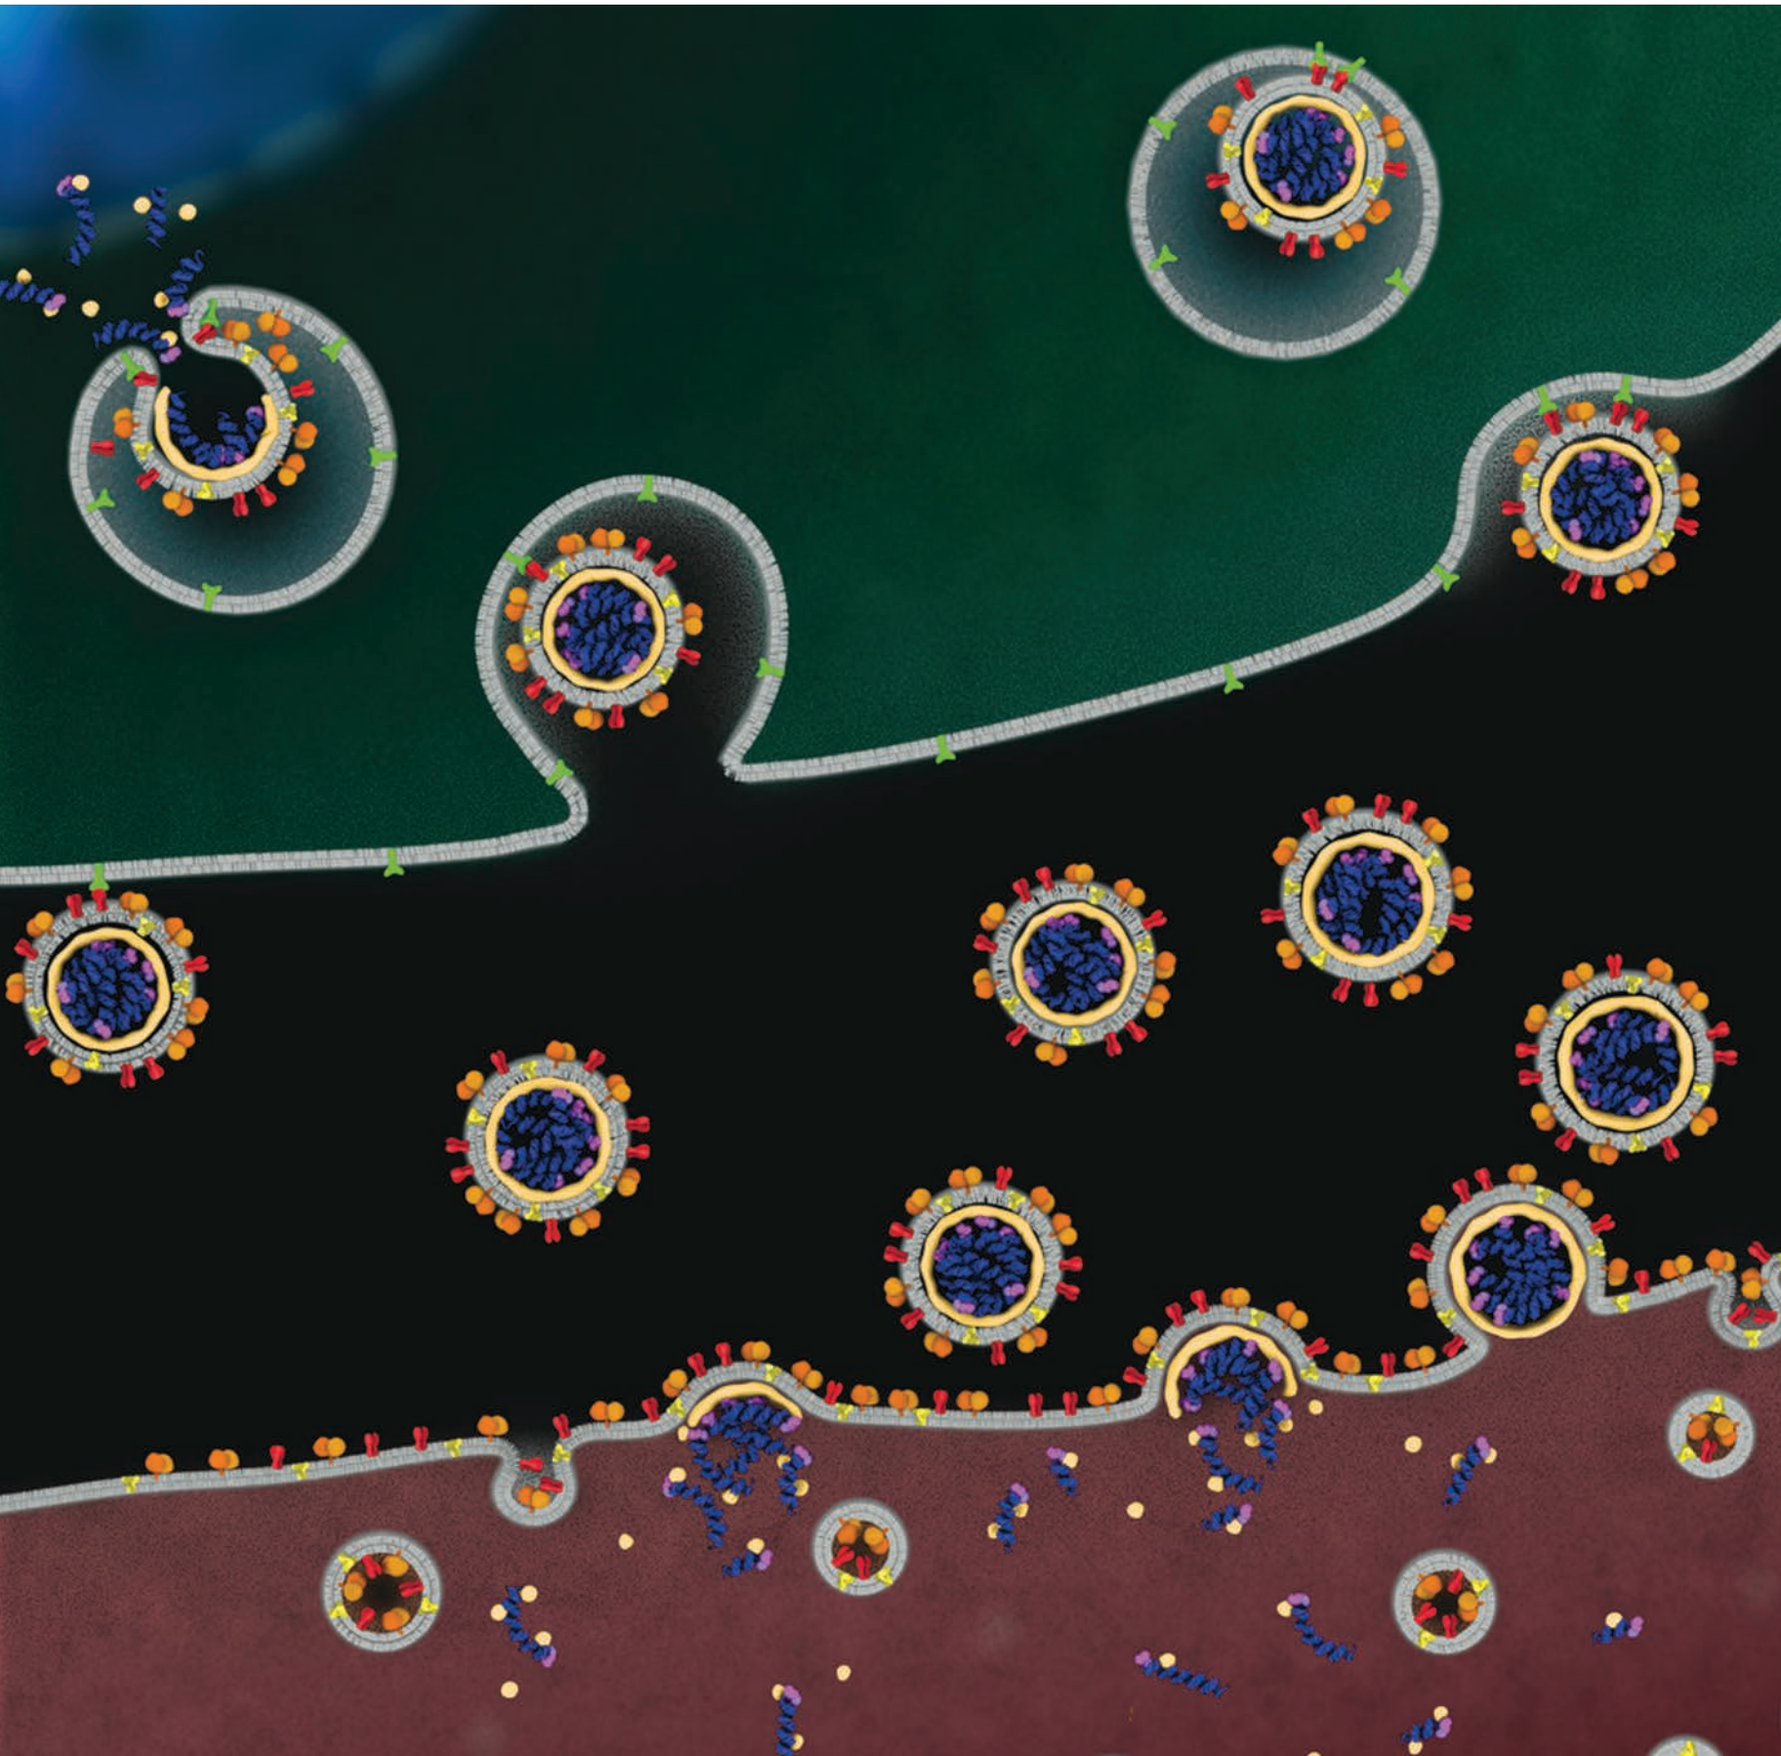
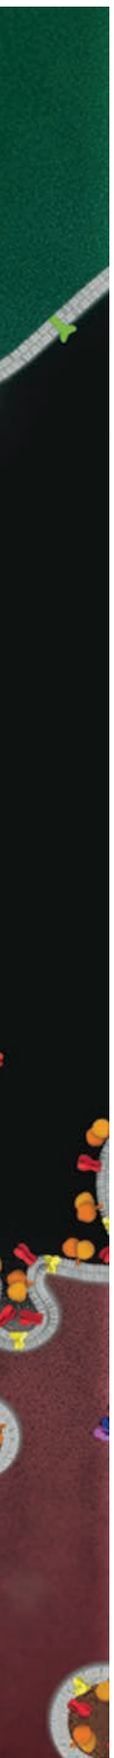
CHAPTER 8

Viral Replication Strategies





In the spring of 2009, outbreaks of a novel influenza virus infection in Mexico were reported. By April 26, 2009, 38 cases (20 in the United States and 18 in Mexico) had been confirmed. By the beginning of May 2009, the World Health Organization (WHO) reported that this new virus had infected 367 people in 13 countries. On June 11, 2009, the WHO reported over 28,000 cases in 74 countries. Also on this date, the WHO declared an influenza virus pandemic.

Initially referred to as swine flu, this strain of influenza virus—officially known as influenza A/California/07/2009 (H1N1)—quickly spread throughout the world. With its spread, fear and uncertainty also spread. During the spring of 2009, many schools were closed to avoid transmission of the virus. In Mexico, soccer matches occurred in empty stadiums when the Mexican government prevented fans from attending. Several countries urged caution to citizens traveling to the United States and Mexico. Common questions were hotly debated: Could this virus cause widespread death throughout the world? Should schools, sporting events, and conferences be cancelled? How can we protect ourselves?

Approximately a year later, on August 10, 2010, the WHO declared an end to the 2009 influenza pandemic. This declaration did not indicate that the H1N1 strain of influenza had disappeared. Rather, the announcement that the pandemic had ended simply reflected that the number of new influenza infections had receded to normal levels. Indeed, the threat of influenza remains. When the 64th World Health Assembly, the annual meeting of the WHO, opened in May of 2011, global influenza preparedness remained a primary topic.

So, how can we protect ourselves? During the height of the 2009 pandemic, many individuals tried to protect themselves from infection by purchasing hand sanitizers and protective masks. Governments made plans for dealing with increased demands on the health care industry. The WHO began distributing the antiviral drug oseltamivir, also known by the trade name Tamiflu to various developing countries.

Numerous studies have shown that Tamiflu can reduce the severity of influenza disease and decrease the duration of the symptoms. The Food and Drug Administration (FDA) also has approved it for use as a preventive drug. But what does it do? To answer this question, we need an understanding of influenza virus and how it replicates.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Viruses generally recognize host cells through specific protein interactions.

- 3D Animation: How do viruses recognize and attach to host cells?
- Figure 8.1: Strain specificity of bacteriophage T2 is dependent on its attachment protein
- Figure 8.3: Strain specificity of mouse hepatitis virus is dependent on the cellular receptor
- Perspective 8.1: DNA microarrays and the SARS virus
- Toolbox 8.1: The Western blot

Viruses enter cells through different mechanisms.

- 3D Animation: How do viruses enter host cells?
- Figure 8.5: Binding and entry of influenza virus
- Figure 8.6: HIV entry
- Figure 8.7: Mechanism of action of Fuzeon
- Figure 8.9: Entry of bacteriophages

Viruses replicate in various ways.

- 3D Animation: How do viruses replicate their genome?
- Microbes in Focus 8.2: Human papillomaviruses (HPVs) and cervical cancer
- Figure 8.13: Classification of viruses
- Figure 8.20: Process Diagram: Replication of retroviruses
- Mini-Paper: The discovery of reverse transcriptase
- Figure 8.22: Phage lambda can undergo a lysogenic or lytic phase of replication, depending on the ratio of two repressor proteins
- Perspective 8.2: Phage therapy: Biocontrol of infections

Newly formed viruses must exit the infected cell.

- 3D Animation: How do replicated viruses exit their host cells?
- Animation: Enveloped virus replication
- Figure 8.23: HIV budding

CONNECTIONS for this chapter:

Segmented genome of influenza virus **(Section 22.4)**

Evolutionary relationship between bacteriophage tail proteins and bacterial secretion apparatus proteins **(Section 2.4)**

Viral replication and the development of cancer **(Section 22.3)**

Development of mode of action of antiviral drugs **(Section 24.2)**

Introduction

Most of us have a pretty good understanding of how plants and animals reproduce. Yes, there are exceptions to the general rules, but most macroscopic organisms reproduce sexually, and sexual replication is fairly standard (at least microbiologists think so!). Bacterial and archaeal replication also is fairly standard. Bacteria and archaea generally replicate via binary fission. The replication of viruses, however, is not uniform.

As we saw in Section 5.4, viruses exhibit a great deal of diversity. Not only do viruses differ in size and shape, but also they differ in the type of genetic material that they contain. Some viruses have DNA genomes, some have RNA genomes, some have double-stranded genomes, and some have single-stranded genomes. This genetic diversity means that the replication strategies employed by viruses are quite diverse.

Perhaps surprisingly, our understanding of how viruses replicate is relatively limited. Despite the fact that viruses outnumber all other biological entities on Earth, most of our knowledge about virus replication is based on studies of only a few species.

It seems clear, though, that all viruses must carry out several other basic functions in order to replicate. All viruses must:

- Recognize appropriate host cells,
- Make their genomes accessible to the host cell machinery,
- Replicate their genomes and make multiple copies of necessary proteins,
- Assemble new viral particles and exit the infected cell.

In this chapter, we will begin to explore how viruses of bacteria (bacteriophages) and viruses of eukarya complete these processes, focusing on the strategies used by several well-studied viruses. Furthermore, we will examine how this information can be used in a clinical setting. Let's start by asking these questions:

How do viruses recognize appropriate cells? (8.1)
How do viruses enter cells and uncoat? (8.2)
How do viruses replicate? (8.3)
How do virus particles form and exit cells? (8.4)

8.1 Recognition of host cells

How do viruses recognize appropriate cells?

For most viruses, replication only occurs within very specific cells. For instance, a plant virus generally can infect certain plant cells, but not human cells. Human hepatitis A virus can infect human liver cells, but not lung cells. To a large extent, this cell specificity is determined by the virus's ability to recognize and bind to the surface of an appropriate cell. To facilitate this binding event, the **viral attachment protein** typically interacts with a **receptor** on the surface of the host cell (Table 8.1). These receptors normally are used by the host cell for communication and signaling purposes but essentially are hijacked by the virus in order to facilitate attachment.

TABLE 8.1 Cellular receptors for selected viruses

Receptor	Cellular function	Virus (family)
CD4	Immune cell interactions	HIV (*Retroviridae*)
ICAM-1	Cell adhesion	Rhinovirus (*Picornaviridae*)
Bgp1[a]	Cell adhesion	MHV-A59 (*Coronaviridae*)
CR2	B-cell activation	Epstein–Barr virus (*Herpesviridae*)
Sialic acid	Various functions	Influenza virus (*Orthomyxoviridae*)
OmpF	Transmembrane channel	T2 (*Myoviridae*)

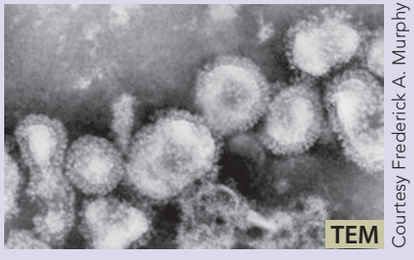
For most bacteriophages, portions of the tail fibers serve as the attachment proteins. The virus, most likely, randomly "bumps" into a potential host cell. When one tail fiber recognizes an appropriate receptor, the virus becomes weakly anchored to

Microbes in Focus 8.1
MOUSE HEPATITIS VIRUS (MHV)

Habitat: Mice

Description: Single-stranded RNA enveloped virus roughly 100 nm in diameter in the *Coronaviridae* family with surface glycoproteins that provide a characteristic crown-like or corona appearance.

Key Features: Several genetically and phenotypically distinct strains of MHV have been identified. Many of these strains are highly transmissible and can easily be spread within laboratory colonies of mice. Recent studies have shown that the causative agents of SARS and MERS are coronaviruses related to MHV.



Courtesy Frederick A. Murphy

the cell. The remaining tail fibers then can bind to additional receptor molecules, thus firmly attaching the virus to the surface of the cell. The bacteriophage T2, which we discussed in Section 5.1, recognizes two molecules on the host cell, lipopolysaccharide and the outer membrane protein OmpF of *Escherichia coli* K12 and related strains. However, T2 cannot infect *E. coli* O157:H7, a strain of *E. coli* associated with severe intestinal disorders in humans. We could hypothesize that T2 does not infect this strain because of strain-specific differences in the receptors. To test this hypothesis, researchers used standard genetic engineering techniques to replace gp37 and gp38, two proteins present at the tips of the T2 tail fibers, with the corresponding proteins from a phage that does infect *E. coli* O157:H7. The altered T2 phage (referred to as T2ppD1) gained the ability to infect O157:H7 and lost the ability to infect K12, its original host (Figure 8.1). Thus, one may conclude that the host specificity, or **host range**, of this phage is determined by the interactions between the viral attachment proteins and the host cell receptors.

Most enveloped mammalian viruses contain a specific protein embedded within the envelope that serves as the attachment protein. Again, this spike interacts with an appropriate host cell receptor, thereby anchoring the virus to the cell. For influenza viruses, like the H1N1 influenza virus that we discussed in the opening story of this chapter, the HA, or hemagglutinin, protein serves as this attachment protein. Non-enveloped mammalian viruses bind to cells in a similar fashion. Some non-enveloped viruses, like adenoviruses, have spikes, or attachment fiber proteins, that extend from the capsid surface. For non-enveloped viruses like poliovirus, the viral capsid interacts with the receptor (Figure 8.2).

The viral attachment protein:cellular receptor interaction also is very specific for mammalian viruses. To understand this specificity more fully, let's examine a particular virus: mouse hepatitis virus, or MHV (Microbes in Focus 8.1). As the name suggests, this

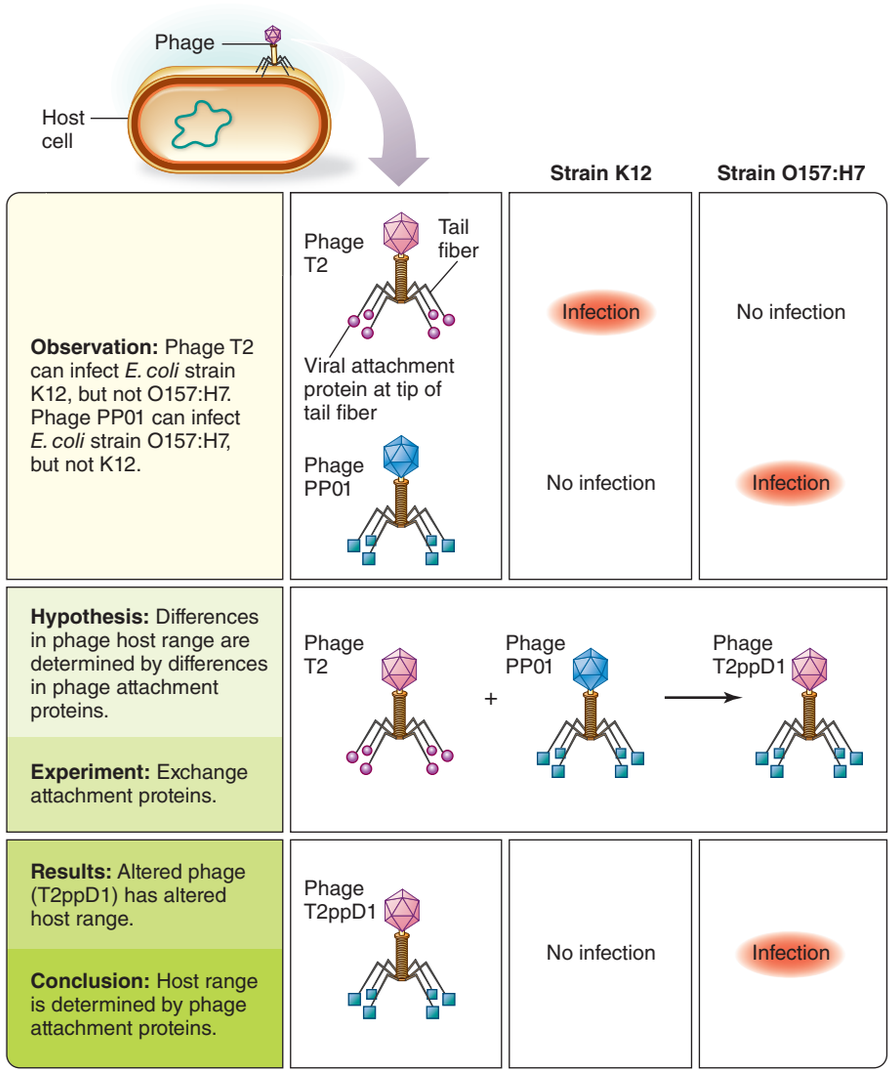


Figure 8.1. Strain specificity of bacteriophage T2 is dependent on its attachment protein. When proteins present at the tips of the T2 tail fibers (●) were replaced by the PP01 versions of these proteins (■), the altered T2 phage (T2ppD1) gained the ability to infect strain O157:H7 but lost its ability to infect strain K12.

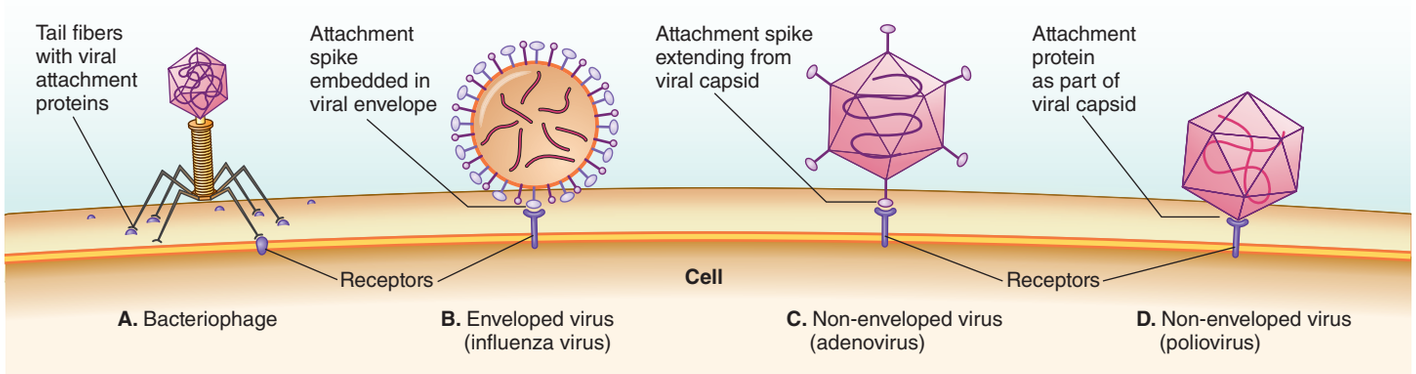

Figure 8.2. Attachment of viruses **A.** Bacteriophages attach to host cell receptors by viral attachment proteins on the tail fibers. **B.** Enveloped viruses attach by a specific viral protein embedded within the envelope. **C.** Some non-enveloped viruses attach by a protein extending from the capsid. **D.** Other non-enveloped viruses attach by a protein that forms part of the capsid itself.

Perspective 8.1
DNA MICROARRAYS AND THE SARS VIRUS

Our ability to identify viruses depends greatly on molecular techniques. From DNA-sequencing studies to PCR to *in situ* hybridization, the identification of viruses increasingly has become a molecular endeavor. Some virologists might even argue that we no longer need to study viruses in animals or cell culture for diagnosis. During the SARS outbreak of 2003, a new molecular technique was added to the list of techniques that can be used to identify viruses: DNA microarray analysis.

The basic concept behind DNA microarray technology is almost deceptively simple. First, a series of specific oligonucleotides, or short segments of single-stranded DNA, is attached to a solid support, forming an array. Then, single-stranded DNA of interest is added to this array. If the DNA of interest is complementary to any of the oligonucleotides,

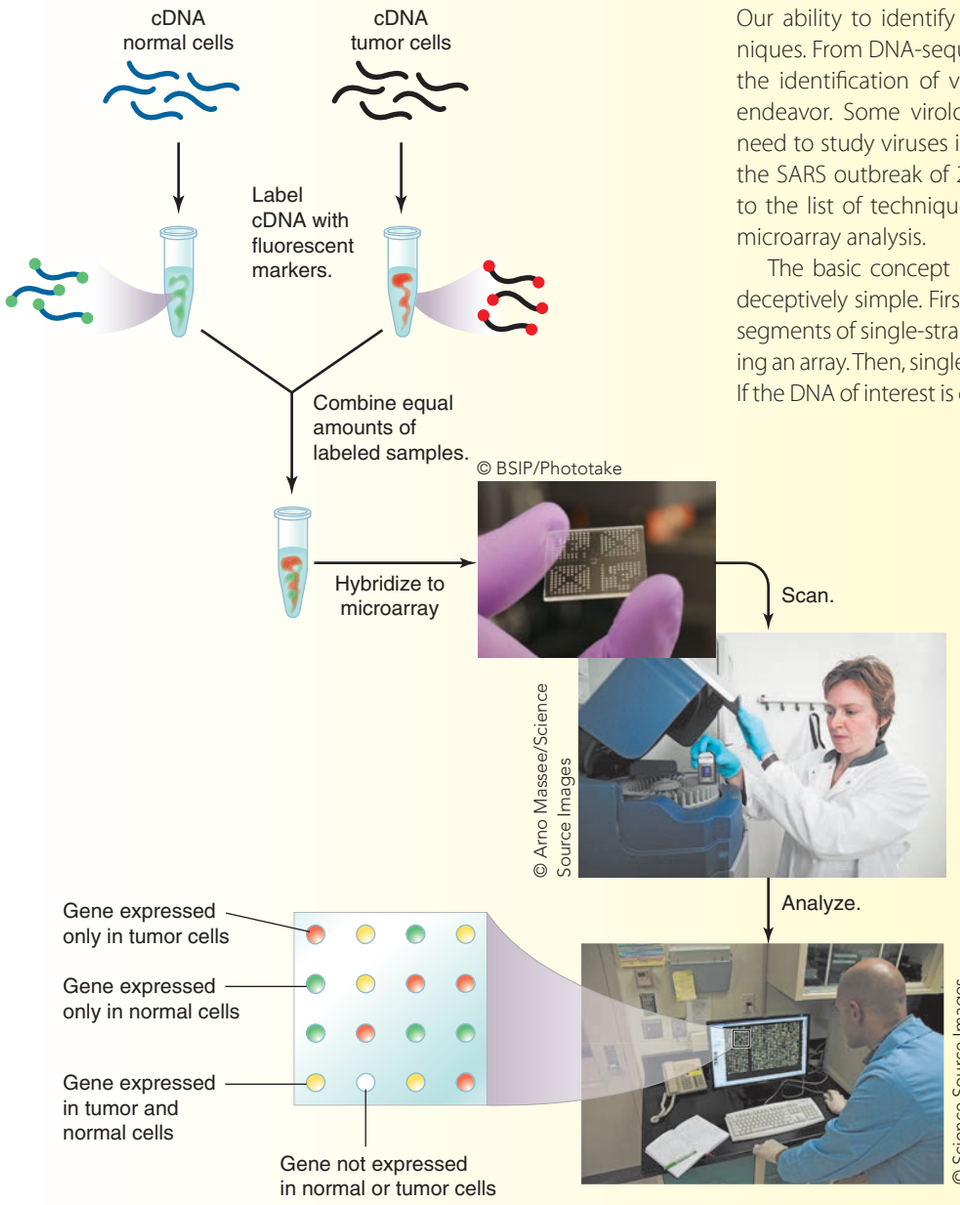

Figure B8.1. Microarray technology can be used to evaluate large numbers of genes simultaneously. First, oligonucleotides representing the target DNA are attached to a slide. In this example, oligonucleotides corresponding to every human gene are placed on the slide. Next, the nucleic acids of interest are fluorescently labeled. In this example, cDNA (corresponding to expressed genes), derived from normal cells, is labeled with a green fluorescent marker. The cDNA derived from tumor cells is labeled with a red fluorescent marker. These tagged cDNAs then are added to the microarray and the microarray slide is scanned. Using software, researchers can analyze the fluorescence associated with each spot on the slide. If both probes bind (yellow spots), then we know that the gene is expressed in both normal and tumor cells. Red spots indicate genes that are expressed only in tumor cells. Green spots indicate genes expressed only in normal cells.

coronavirus infects liver cells of mice, causing severe hepatitis. Virologists have studied MHV for many years in an effort to learn more about viral pathogenesis. More recently, researchers have identified two emerging human viruses, SARS-CoV (Perspective 8.1) and MERS-CoV, which are related to MHV. During their studies of MHV, virologists observed that different strains of mice differed in their susceptibility to the virus. Some mouse strains were very susceptible, but other strains were largely resistant. Subsequent research revealed that differences in the binding affinity between the virus and forms of the receptor determined this strain difference in MHV susceptibility. To conduct these studies, virologists used SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and another technique very similar to a Western blot analysis (Toolbox 8.1). Briefly, they isolated and characterized the MHV receptor from BALB/c mice, a strain of mice susceptible to MHV. A structurally similar protein was isolated from SJL/J mice, a genetically distinct, MHV-resistant strain of mice. Even though these two proteins "looked" similar, their amino acid sequences differed somewhat. More importantly, these proteins differed dramatically in their ability to bind to MHV, presumably because the amino acid differences resulted in slight conformational differences. These observed differences in binding

then it will bind to that specific piece of DNA. By determining to which oligonucleotide the DNA binds, a researcher could gain important information about the DNA of interest **(Figure B8.1)**.

In 2003, researchers at the University of California, San Francisco, Washington University, and the Centers for Disease Control and Prevention demonstrated that this same technique could be used to rapidly identify an unknown virus. To identify an unknown virus, the researchers developed a "pan-viral microarray." This microarray consisted of approximately ten 70-nucleotide-long synthetic DNA oligonucleotides for every viral genome currently referenced in GenBank, the national repository of DNA sequence data. In total, then, the microarray consisted of 10,000 oligomers representing 1,000 different viruses **(Figure B8.2)**.

GenBank WEB

Total nucleic acid was isolated from uninfected cells and cells infected with the unknown virus. These nucleic acid samples then were PCR amplified using random primers and labeled with a fluorescent dye. The outcome of this procedure was that a collection of short pieces of amplified DNA, corresponding to all the DNA and RNA sequences present in the cells, was generated for both the uninfected and infected cells. These sequences were added in parallel to the pan-viral microarrays and allowed to bind, or hybridize, to any complementary oligonucleotides.

Following this hybridization step, the fluorescent intensity associated with each oligonucleotide, or spot, on both microarrays was analyzed. The researchers were most interested in spots for which the infected cell nucleic acid exhibited a much stronger fluorescence than did the uninfected cell nucleic acid. Such a result would indicate that those spots contained oligomers corresponding to the unknown virus. The results were very straightforward; the oligomers that hybridized with infected cell DNA all represented coronaviruses. The unknown virus was a member of the coronavirus family.

To confirm and extend this finding, researchers then isolated the hybridized nucleic acid by physically removing it from the microarray and sequencing it. When they compared the sequence to the existing nucleic acid sequence database, the new sequence was very similar to, but different from, mouse hepatitis virus, a well-characterized coronavirus. The sequence data corroborated their previous finding—the SARS virus was a novel coronavirus.

Using this DNA microarray methodology, these researchers were able to demonstrate the power of this newly emerging technology. Because of recent advances in areas such as bioinformatics, robotics, and fluorescent detection technologies, we now can usually identify a virus in a matter of days.

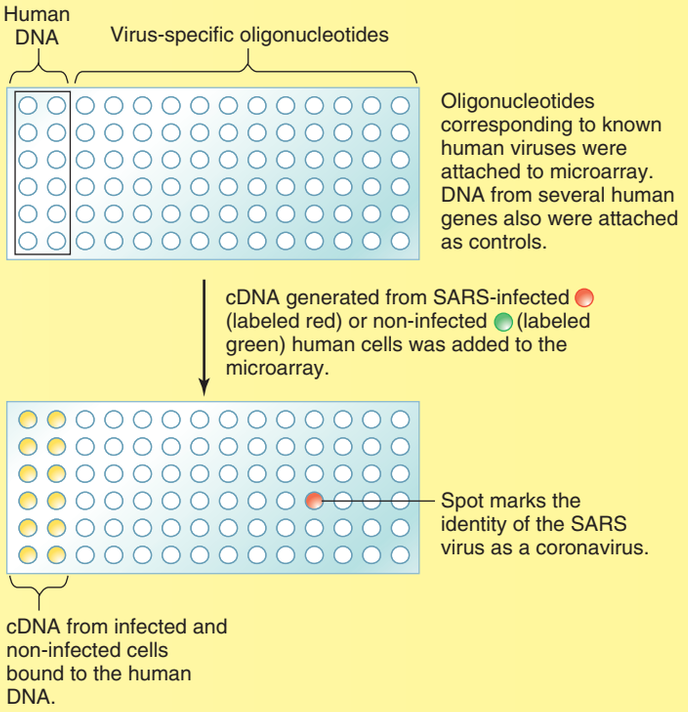

Figure B8.2. Identification of SARS virus with an innovative tool: A pan-viral microarray Synthetic single-stranded DNA oligonucleotides corresponding to all known human viruses were attached to the microarray. Nucleic acid from SARS-infected and uninfected cells was isolated and differentially labeled. The labeled nucleic acid then was added to the microarray. Because the labeled nucleic acid from the SARS-infected cells hybridized to the microarray spot containing coronavirus DNA, the researchers could conclude that the cells had been infected with a coronavirus.

affinities led researchers to conclude that the viral attachment protein:cellular receptor interaction probably determined the susceptibility of these mouse strains to MHV **(Figure 8.3)**.

Before leaving this section, let's address one more question. If the infection of a cell requires binding between that cell and the virus, then shouldn't it be possible to prevent infection by preventing this initial binding event? The answer is yes. As we will see in Section 20.6, our immune system uses this very strategy to prevent or limit the severity of infections. Antibodies, molecules produced by our immune system, bind to viruses and, quite often, block the interaction between the virus and host cell, thereby interfering with the infectious process (see Figure 20.30A). Today, because of our understanding of viral attachment proteins and their cellular receptors, we can design drugs that block the virus:cell attachment event. In April 2007, the Food and Drug Administration approved one such drug. That drug was maraviroc.

Maraviroc is used in the treatment of human immunodeficiency virus (HIV) infection. It blocks the interaction between the viral attachment protein of the retrovirus and CCR5, one of the virus's co-receptors that we mentioned in Section 5.1. Maraviroc (also referred to as Selzentry) binds to CCR5 and

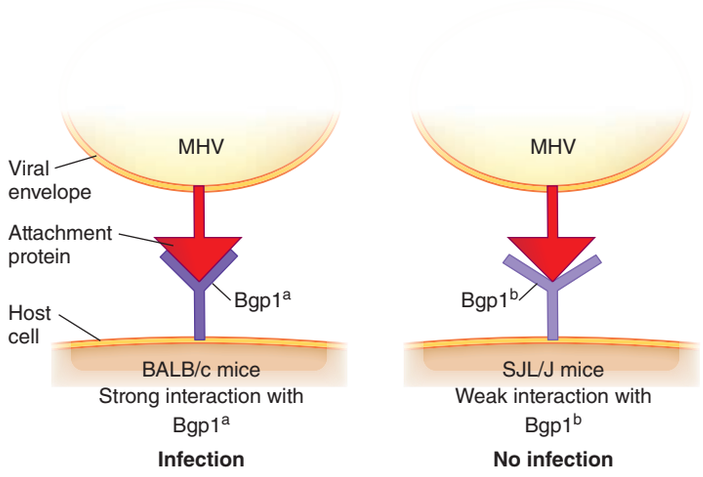

Figure 8.3. Strain specificity of mouse hepatitis virus is dependent on the cellular receptor. Mouse hepatitis virus (MHV) can infect BALB/c mice, but not SJL/J mice. The receptor in BALB/c mice is the cell membrane protein $Bgp1^a$. An allelic variant, $Bgp1^b$, is found in SJL/J mice. Amino acid differences between these two molecules cause MHV to interact strongly with $Bgp1^a$, but only weakly with $Bgp1^b$.

effectively blocks the virus from binding (Figure 8.4). Currently, maraviroc only is used to slow the progression of HIV disease in people already infected with the virus and not as a preventive measure. Additionally, this drug is not effective against strains of HIV that use CXCR4, another co-receptor.

CONNECTIONS In addition to maraviroc, other drugs that inhibit HIV replication have been developed. These and other antiviral drugs are discussed in **Section 24.2**.

8.1 Fact Check

1. What is the relationship between viral attachment proteins and host cell receptors?
2. What is meant by the term host range?
3. How can antibodies and antiviral drugs play a role in blocking viral attachment to host cells?

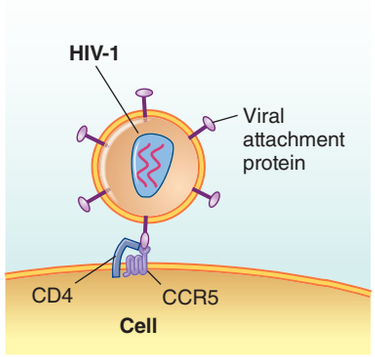

Figure 8.4. Inhibiting HIV infection To enter a host cell, HIV first must bind to its receptor, CD4, and a co-receptor. The drug maraviroc (brand name Selzentry) binds to the co-receptor CCR5, thereby blocking the interaction of some strains of HIV with this co-receptor and inhibiting entry of the virus.

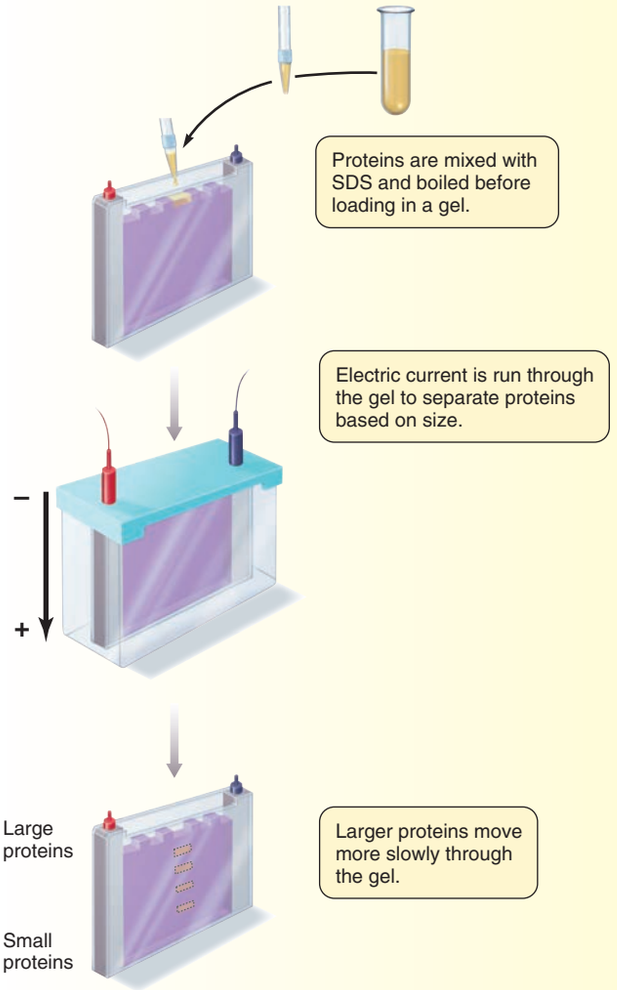
Toolbox 8.1
THE WESTERN BLOT

To investigate the interactions between mouse hepatitis virus (MHV) and the presumptive receptor molecules, the researchers used a modification of a standard molecular biology technique—the Western blot. In this technique, protein samples first are mixed with the detergent SDS, which disrupts their three-dimensional shape and coats them with a negative charge. The protein/SDS mixture generally is boiled, further disrupting any intramolecular interactions and fully denaturing the proteins. The samples then are analyzed by SDS-polyacrylamide gel electrophoresis, or SDS-PAGE. Briefly, the protein samples are loaded onto a polyacrylamide gel and an electric current is applied to the gel. Because the proteins have been coated with the negatively charged SDS, they will migrate toward the positive electrode. The mesh-like consistency of the gel impedes the migration of the proteins in a size-dependent fashion; the migration



Black, *Microbiology: Principles and Explorations*, copyright 2012, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure B8.3. SDS-polyacrylamide gel electrophoresis (SDS-PAGE) To separate proteins based on size, the proteins first are mixed with SDS and boiled. This treatment denatures the proteins and coats them with a negative charge. The proteins then are added to a polyacrylamide gel. An electric current is applied to the gel and individual proteins migrate toward the positive electrode. Their rate of migration is proportional to their size, and separation is achieved.

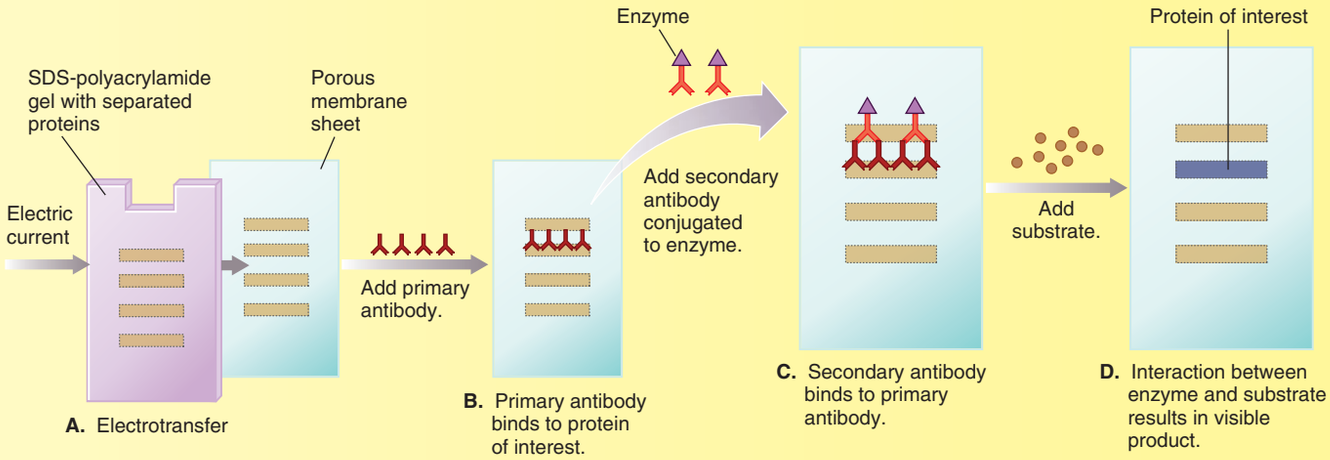


Figure B8.4. After electrophoretic separation, proteins are detected by the Western blot technique.
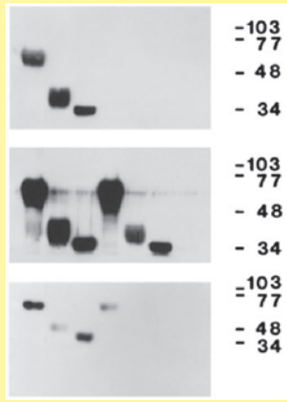
A. Following electrophoresis, the proteins are transferred to a porous membrane, typically composed of nitrocellulose or polyvinylidene fluoride (PVDF). **B.** A primary antibody that specifically binds to the protein of interest then is added to the membrane. **C.** A secondary antibody that binds to the primary antibody and contains a detectable marker, such as an enzyme, is added to the membrane. **D.** A substrate is added next. The enzyme catalyzes the conversion of the substrate to a visible product, thereby permitting localization of the protein of interest.

of large proteins is hindered more than small proteins. Thus, small proteins migrate through the gel more quickly than large proteins. In other words, the proteins separate based on their size **(Figure B8.3)**.

Following this electrophoretic size separation, the proteins are transferred from the gel to a nitrocellulose or polyvinylidene fluoride (PVDF) membrane for the next step, which is the actual Western blotting step. Following this step, the proteins are positioned on top of the membrane, rather than being embedded within the gel. This transfer of the proteins to a membrane makes them more accessible to reagents used in subsequent steps.

The Western blot allows the researcher to detect a specific protein. Antibodies are generally used for this purpose because they bind strongly and specifically to other molecules (see Section 20.6). If a specific antibody is added to the membrane, it will bind to a specific protein—the protein the researcher is interested in detecting. By itself, this primary antibody is not visible to the researcher, so a secondary antibody that attaches to the primary antibody usually is employed. This secondary antibody typically is conjugated to an enzyme so that it can be detected **(Figure B8.4)**.

To study the MHV receptor, the researchers used a slightly different and creative approach to Western blotting. Rather than detecting the receptor protein with an antibody, they detected the receptor protein with the virus (MHV). Cellular proteins from BALB/c mice and cellular proteins from SJL/J mice were separated by SDS-PAGE and then transferred to a membrane. The researchers then added MHV to the membrane, using the virus to identify its own receptor protein. Viral strain MHV-A59 bound very strongly to two differently sized forms of $Bgp1^a$, a protein present in BALB/c mice, but only weakly to $Bgp1^b$, a protein present in SJL/J mice **(Figure B8.5)**.



© American Society for Microbiology.

Figure B8.5. Analysis of MHV receptors Three size variants of $Bgp1^a$ (*left*, lanes 1–3) and $Bgp1^b$ (*right*, lanes 4–6) were separated based on size by SDS-PAGE. The proteins then were transferred to a membrane and probed with an antibody that recognizes $Bgp1^a$ (*top*), an antibody that recognizes $Bgp1^a$ and $Bgp1^b$ (*middle*), or viral strain MHV-A59 (*bottom*). As seen in the bottom panel, the virus strongly bound to the large and small forms of $Bpg1^a$ (lanes 1 and 3) but only weakly bound to the large form of $Bgp1^b$ (lane 4). *Source:* B. D. Zelus et al. 1998. J. Virol. 72:1737–7244.

Test Your Understanding

Based on the result of this experiment, which of these mice would the researchers have concluded to be susceptible to MHV and which of these mice would they conclude to be resistant to MHV? Explain how the data from this technique provided that conclusion.

8.2 Viral entry and uncoating

How do viruses enter cells and uncoat?

Binding to an appropriate host cell represents only the first step in viral replication. After binding, the virus, or its genome, must enter the host cell. As we discussed in Chapters 2, 3, and 4, though, the plasma membranes of bacteria, eukarya, and archaea provide these cells with a fairly tight casing, effectively separating the outside of the cell from the inside. Even small molecules cannot pass freely through the membranes; something as large as a virus or a viral genome certainly will not cross this barrier. So, how do viruses or their genomes get inside cells? Actually, several different mechanisms for entry have been discovered. As might be expected, non-enveloped viruses and enveloped viruses display very different strategies. More surprisingly, bacteriophages do not enter their host cells at all. We will investigate this apparent contradiction shortly.

Entry of enveloped viruses

Consider the entry of an enveloped virus into a host cell. Ultimately, the viral genome must become accessible to assorted host cell molecules. Even after the virus binds to the surface of the cell, though, two lipid bilayers—the plasma membrane and the viral envelope—separate the viral genome from the interior of the cell. For the genome to enter the cell, these membranes must fuse at some point. Some mammalian viruses, like the retrovirus HIV, fuse directly at the plasma membrane. Other mammalian viruses, like the influenza viruses, first undergo **endocytosis**. The viral envelope then fuses with the endocytic vesicle membrane, which is derived from the plasma membrane. Almost always, a viral **fusion peptide**, a short string of hydrophobic amino acids, mediates the actual fusion event.

With influenza virus, the initial interaction between the hemagglutinin (HA) viral attachment protein and the cellular receptor (sialic acid-containing glycoproteins) triggers receptor-mediated endocytosis, resulting in the formation of an endocytic vesicle, or endosome, containing the virus. Normal cellular processes result in the acidification of the vesicle. The resulting low pH of the endosome triggers a conformational change in HA, which exposes a fusion peptide, previously structurally hidden within the HA molecule. This fusion peptide then facilitates the fusion of the viral envelope and the endosomal membrane, thereby allowing the nucleocapsid to enter the cytoplasm (Figure 8.5). Because of its dependence on the low pH of the endosome, influenza entry

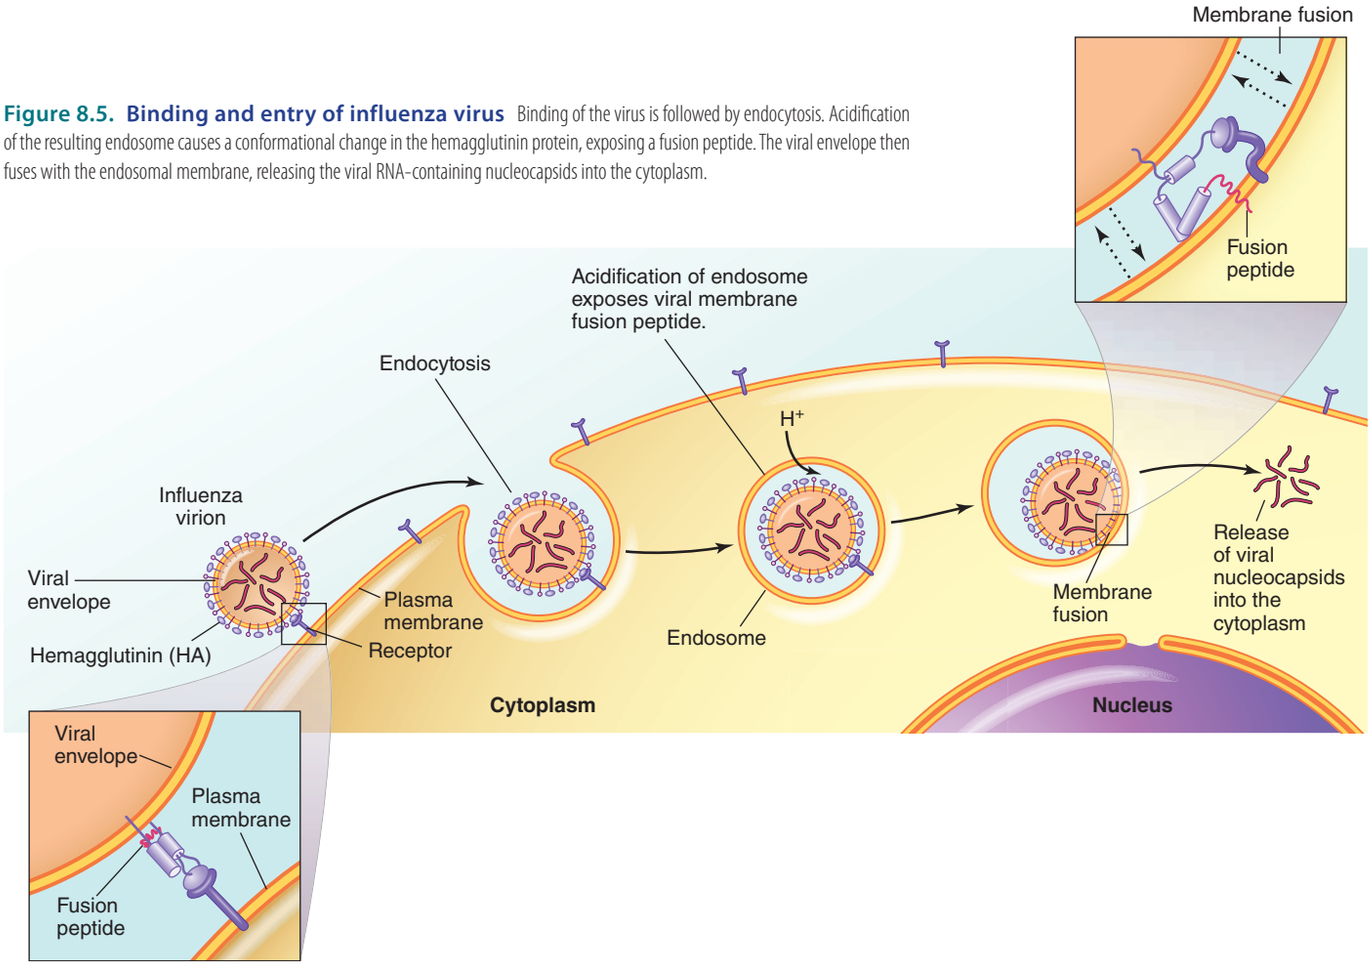


Figure 8.5. Binding and entry of influenza virus Binding of the virus is followed by endocytosis. Acidification of the resulting endosome causes a conformational change in the hemagglutinin protein, exposing a fusion peptide. The viral envelope then fuses with the endosomal membrane, releasing the viral RNA-containing nucleocapsids into the cytoplasm.

often is referred to as being pH-dependent, a common property of viruses that enter cells via endocytosis.

CONNECTIONS As we discussed in **Section 5.1**, the influenza virus genome consists of eight segments of single-stranded RNA, each of which is enclosed within its own helical nucleocapsid. In **Section 22.4**, we will explore how the segmented nature of the influenza virus genome contributes to its virulence.

When HIV binds to a host cell through a specific interaction between gp120, the viral attachment protein, and CD4, the cellular receptor, a conformational change occurs in gp120 that allows it to bind to a co-receptor **(Figure 8.6)**. This binding event causes additional conformational changes, which ultimately expose the fusion peptide on another surface protein, gp41. This exposed fusion domain then facilitates fusion between the viral envelope and the plasma membrane, thereby allowing the viral genome to enter the cell.

As in the previous section, let's end this section by asking an obvious question. If the infection of cells by most enveloped viruses generally requires a membrane fusion event, then shouldn't it be possible to prevent infection by preventing this fusion event? Again, the answer is yes. Again, we can look to HIV for an example. Approved by the FDA in 2003, Fuzeon was the first antiretroviral drug designed to block fusion. It functions by binding to gp41 and preventing the folding of this molecule, thereby effectively blocking fusion **(Figure 8.7)**. Like maraviroc, it is currently used to slow the progression of HIV disease in people infected with the virus.

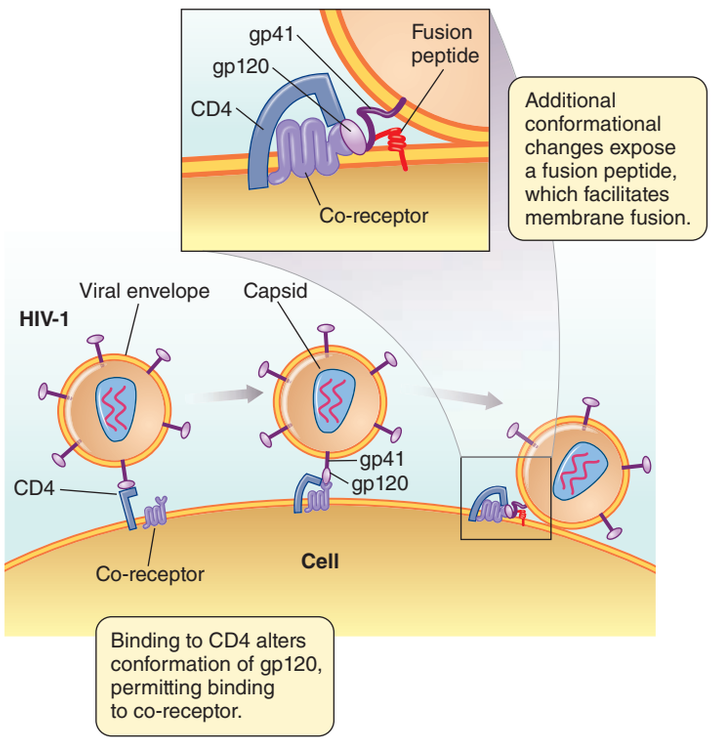

Figure 8.6. HIV entry Entry of HIV requires the binding of HIV to two receptor molecules on the host cell: CD4 and a co-receptor. The initial interaction between the viral polypeptide gp120 and the primary receptor CD4 facilitates a subsequent interaction between the virus and a co-receptor. This interaction then facilitates membrane fusion, which is mediated by the viral protein gp41.

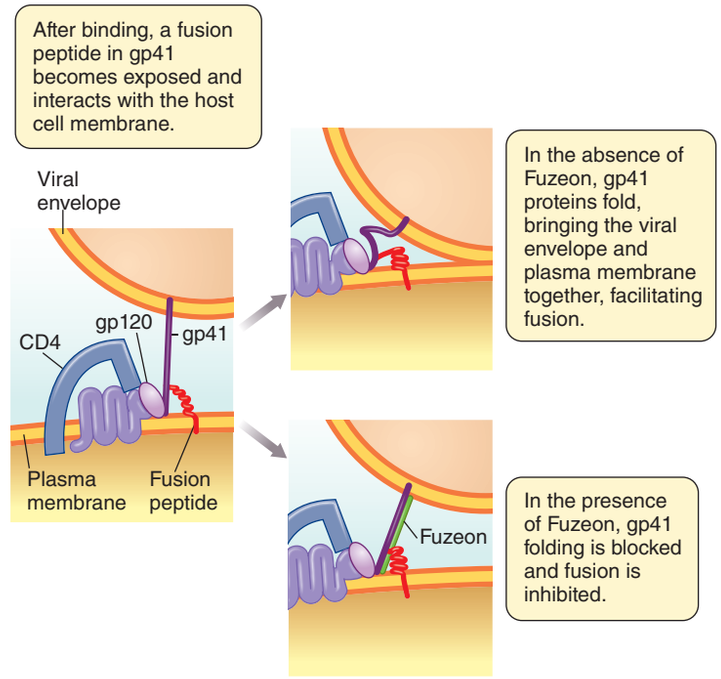

Figure 8.7. Mechanism of action of Fuzeon When HIV interacts with a host cell, a conformational change occurs in the viral gp120/gp41 complex. A fusion peptide in gp41 becomes exposed and interacts with the host cell plasma membrane. Folding of gp41 then brings together the viral envelope and plasma membrane, facilitating fusion. Fuzeon binds to gp41, preventing the conformational change and fusion.

Entry of non-enveloped viruses

Like their enveloped counterparts, non-enveloped viruses ultimately must make their genomes accessible to the replication, transcription, and/or translation machinery of the host cell. Entry for these viruses, though, does not require the fusion of two membranes. Rather, entry of non-enveloped viruses requires direct penetration of a cellular membrane by the virus particle or genome. Again, different non-enveloped viruses achieve this step through a variety of mechanisms. Generally, non-enveloped viruses enter host cells via receptor-mediated endocytosis **(Figure 8.8)**.

A virus particle initially binds to its receptor on the cell surface. This binding event triggers endocytosis, resulting in the

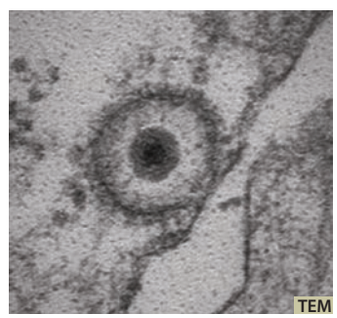

Figure 8.8. Entry of most non-enveloped viruses involves endocytosis. Viral binding to a receptor on the cell surface triggers receptor-mediated endocytosis as with this reovirus. Generally, acidification of the endosome causes conformational changes in the viral capsid that facilitates transfer of the viral capsid or viral genome from the endosome to the cytoplasm. *Source*: From M. Maginnis, T. Dermody, *et al*. 2008. J. Virol. 82:3181–3191, Fig. 6b. © 2008, American Society for Microbiology.

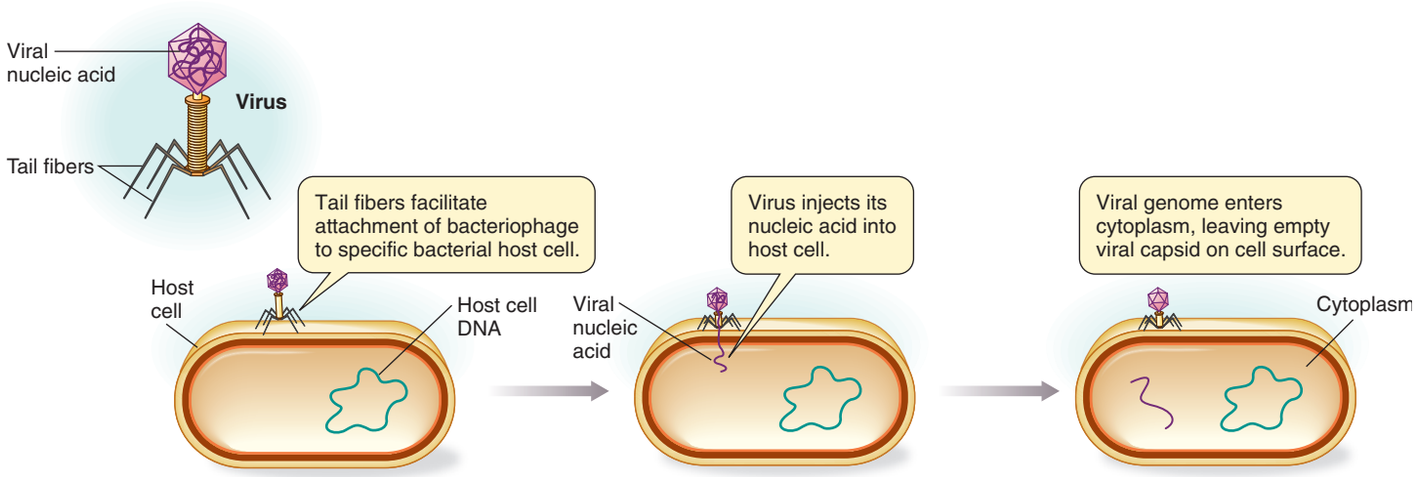

Figure 8.9. Entry of bacteriophages These viruses inject their viral genome into a host cell, but capsids do not enter cells.

internalization of the virus within an endosomal vesicle. For most viruses, the low pH of the endosome causes conformational changes to occur within the proteins of the viral capsid, similar to the changes exhibited by the influenza HA protein. These conformational changes expose a pore-forming domain, which creates a hole in the membrane, thus allowing the viral capsid or genetic material to enter the cytoplasm of the host cell.

Entry of bacteriophages

As we noted previously, bacteriophages do not actually enter their host cells. So, if all viruses are obligate intracellular parasites, then how can bacteriophages replicate without entering host cells? Let's clarify a little. The viral particles do not enter the host cells, but their genomes do. After the phage particle interacts with its host cell receptor, the phage genome is injected through the cell wall and membrane, into the cell. For T4, one of the best-studied phages, the interaction between the phage and its receptor leads to a contraction of the T4 tail. As a result of this contraction, the tail core pushes through the cell wall, bringing the phage DNA into contact with the plasma membrane **(Figure 8.9)**. A specific phage protein, the pilot protein, appears to bind to the phage DNA and assist in allowing the DNA to penetrate the plasma membrane. In this fashion, the viral genome gains access to the interior of the cell, but the viral capsid remains outside.

CONNECTIONS A study published in March of 2009 showed that bacteriophage tail proteins and certain Gram-negative secretion apparatus proteins share a common evolutionary origin. The general process of translocating proteins and DNA across membranes may be conserved. In **Section 2.4**, we examined more thoroughly the mechanisms of bacterial protein secretion.

Entry of plant viruses

Before leaving the topic of viral entry, let's briefly consider plant viruses. Like bacterial cells, plant cells generally contain a sturdy cell wall. Additionally, a cuticle, or thick waxy covering, usually protects plant leaves and new shoots. Like bacteriophages, plant viruses are faced with a major obstacle when entering a host cell. Plant viruses, though, do not inject their genomes into cells as do the bacteriophages. Rather, plant viruses often rely on the help of an outside force. When insects feed on a plant, for instance, they typically damage the cuticle and plant cell wall **(Figure 8.10)**.

When feeding on an infected plant, insects may acquire viruses. When the insect feeds on another plant, it can transmit these particles, thereby infecting a new plant. Once some cells within a plant are infected in this manner, the virus can spread to other cells within that plant through cytoplasmic connections, or plasmodesmata, between the cells.

Viral uncoating

Before viral replication can begin, the virus not only must enter the cell, but also must make its genetic material accessible to at least some components of the host cell. For bacteriophages, this actually represents a false problem. Because most

© Nigel Cattlin/Alamy

Figure 8.10. Entry of plant viruses Damage to plant surface cuticle and cellulose wall is required for viruses to enter plant cell cytoplasm. Whiteflies, shown here, damage cells when they tap into the phloem-carrying vessels of leaves. Through their saliva, they can transmit several different plant viruses, including tomato yellow leaf curl virus.

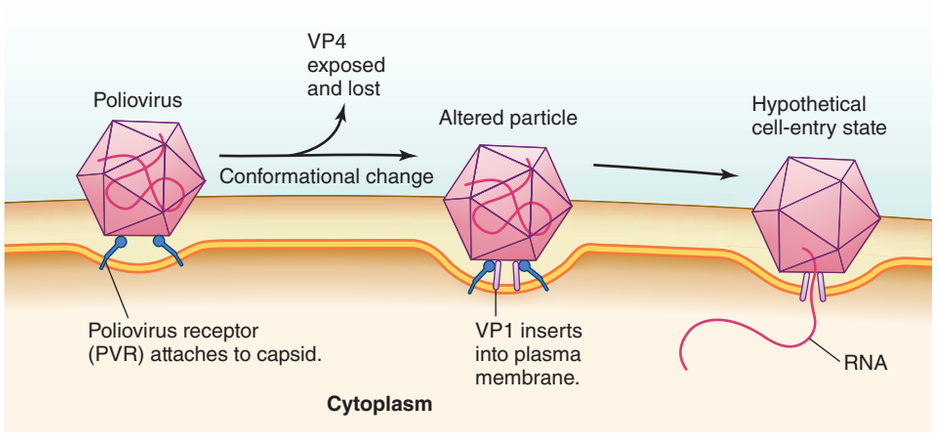

Figure 8.11. Disassembly of poliovirus is necessary for subsequent replication. After binding to the cellular receptor, poliovirus particles undergo a conformational change resulting in the loss of VP4, a capsid protein. This conformational change allows another capsid protein, VP1, to interact with the host cell's plasma membrane, presumably creating a pore through the membrane. The viral RNA leaves the partially disassembled capsid and enters the cytoplasm through the VP1-induced channel.

bacteriophages inject their genome directly into the host cell, the viral genome is immediately accessible. Replication and/or transcription can begin as soon as the genetic material enters.

For most mammalian viruses, some form of **uncoating**, or viral capsid disassembly, must occur to allow the viral genome to interact with the required host cell machinery. This disassembly often involves conformational changes in, or proteolytic processing of, capsid proteins. The capsid of poliovirus, for instance, undergoes an irreversible change after binding to its receptor, the poliovirus receptor (PVR). The native virion, or 160S particle, forms an altered virion, or 135S particle, soon after binding to the receptor. As part of this conversion, lipophilic portions of VP4, an internal capsid protein, and VP1, another capsid protein, become exposed. These domains probably interact with the host cell membrane, forming a channel in the membrane through which the viral RNA is extruded (Figure 8.11). In 2007, researchers provided evidence that this series of events occurs very near the surface of the cell, either in discrete vesicles or plasma membrane invaginations.

Several lines of experimental evidence support this model for poliovirus uncoating. Most notably, altered particles, or A particles, can induce transient pore formation in artificial lipid bilayers. This result supports the hypothesis that the altered particles may form pores in a native lipid bilayer, through which the viral RNA then can enter the host cell cytoplasm. It still is unclear if the viral RNA enters the cell at the plasma membrane or if the viral particle enters the cell via endocytosis and the RNA enters the cytoplasm by passing through the endosomal membrane. In either case, endocytosis does not appear to be absolutely necessary for entry. Evidence comes from studies using drugs that prevent acidification of endosomes. For many viruses that require receptor-mediated endocytosis for entry, such drugs also prevent viral replication. However, these drugs do not inhibit poliovirus replication, indicating that uncoating of poliovirus is not pH-dependent. Additionally, blocking endocytosis itself does not inhibit poliovirus replication. These findings suggest that poliovirus RNA may enter the cytoplasm through either the plasma membrane or an endosomal membrane.

8.2 Fact Check

1. What is membrane fusion and how is it involved in enveloped virus entry?
2. What is receptor-mediated endocytosis and how is it involved in virus entry?
3. Explain why viruses of mammals generally undergo some form of uncoating, but viruses of bacteria usually do not.
4. How do plant viruses overcome the barrier of the cellulose wall and cuticle of plant cells in order to infect?

8.3 Viral replication

3D ANIMATION

How do viruses replicate?

For new virus particles to be produced, what needs to occur? As we noted previously, the viral genome must enter an appropriate host cell, copies of the viral genome and proteins must be made, these pieces must assemble, and newly formed viral particles must exit the cell. For viruses that lyse host cells, we can observe the kinetics of this process by infecting cells in a synchronous fashion and then measuring the amount of virus produced over time. The result is a one-step multiplication curve (Figure 8.12), which allows us to determine the burst size, or average number of progeny virions released per infected cell under specified experimental conditions. Of course, genome replication is a critical step in this process, and how genome replication occurs will depend on the type of genome possessed by the virus. Additionally, mRNA that can be recognized and translated by the host cell must be produced. Again, how this mRNA is produced will depend on the type of genome possessed by the virus. These processes together lead to the production of new virus particles, a process collectively referred to as "viral replication."

As we mentioned in Section 5.4, viruses can be classified based on how they replicate or, more precisely, how they generate

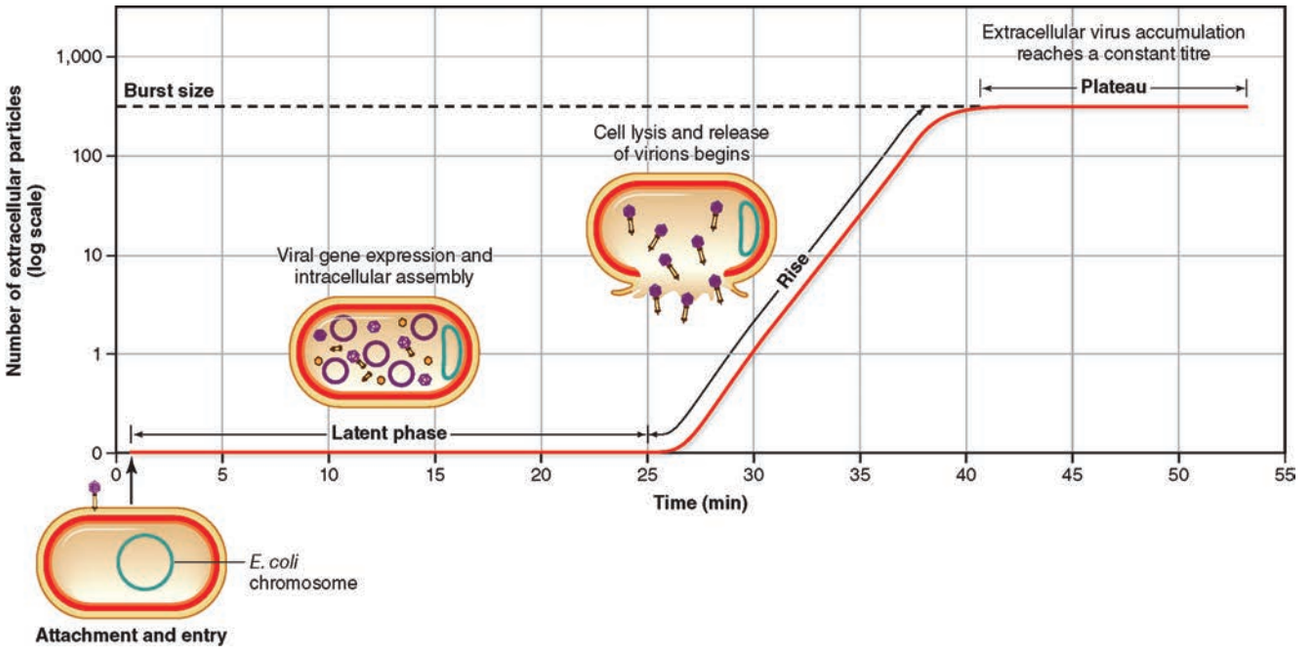

Figure 8.12. One-step virus multiplication curve By experimentally infecting appropriate host cells in a synchronous fashion, we can observe the kinetics of viral replication and determine the viral burst size, or amount of virus produced from a single infected cell. Following a phase of attachment and entry, the virus enters the latent phase, during which genome replication and protein production occur. During the rise phase, cell lysis and the release of virions begins. The number of extracellular infectious virions eventually reaches a plateau. NOTE: Shown here to illustrate these steps are schematics of *E. coli* and lambda phage.

mRNA. In the Baltimore classification scheme presented here, all viruses are categorized into seven distinct classes:

- **Class I: Double-stranded DNA viruses.** DNA serves as a template for synthesis of mRNA. Genome replication usually occurs in the nucleus of the host cell and uses the host DNA-dependent DNA polymerase. Some viruses in this class, like the poxviruses, replicate in the cytoplasm, using viral enzymes.
- **Class II: Single-stranded DNA viruses.** Messenger RNA forms from a double-stranded DNA intermediate. Genome replication occurs as the single-stranded genome becomes converted to double-stranded DNA, which then serves as a template for the production of more genomes.
- **Class III: Double-stranded RNA viruses.** Messenger RNA is generated from one strand of the double-stranded genome. Genome replication generally occurs in the cytoplasm and requires a viral RNA-dependent RNA polymerase.
- **Class IV: Positive-sense single-stranded RNA viruses.** The genome can be recognized by the host ribosomes and thus functions directly as mRNA; it is referred to as positive-sense (same as mRNA). Genome replication usually occurs in the cytoplasm and requires a viral RNA-dependent RNA polymerase.
- **Class V: Negative-sense single-stranded RNA viruses.** The genome serves as the template for formation of mRNA and is referred to as negative-sense (complementary to mRNA). A viral RNA-dependent RNA polymerase produces the mRNA. This enzyme also is required for genome replication, which usually occurs in the cytoplasm.
- **Class VI: Single-stranded RNA viruses that use reverse transcriptase.** The viral enzyme reverse transcriptase, an RNA-dependent DNA polymerase, converts the ssRNA genome into dsDNA, which then becomes integrated into the host genome. Messenger RNA and new genomic RNA is generated from this integrated DNA.
- **Class VII: Double-stranded DNA viruses that utilize reverse transcriptase.** The genome serves as a template for the generation of mRNA and full-length RNA molecules. A viral reverse transcriptase generates genomic DNA from this RNA intermediate.

Figure 8.13 provides a basic overview of the replication strategies employed by these seven classes of viruses.

In this section, we will examine more closely the replication of a few selected mammalian DNA and RNA viruses. We also will examine some features of bacteriophage replication.

CONNECTIONS Researchers have identified several types of viral-like particles, including viroids, satellite viruses, and virophages. The replication strategies of these infectious agents are discussed in **Section 5.5**.

Replication of eukaryal DNA viruses

The genetic material of DNA viruses resembles the genetic material of their host cells. As a result, replication of the viral genome and transcription of viral genes

WWW DNA virus replication ANIMATION

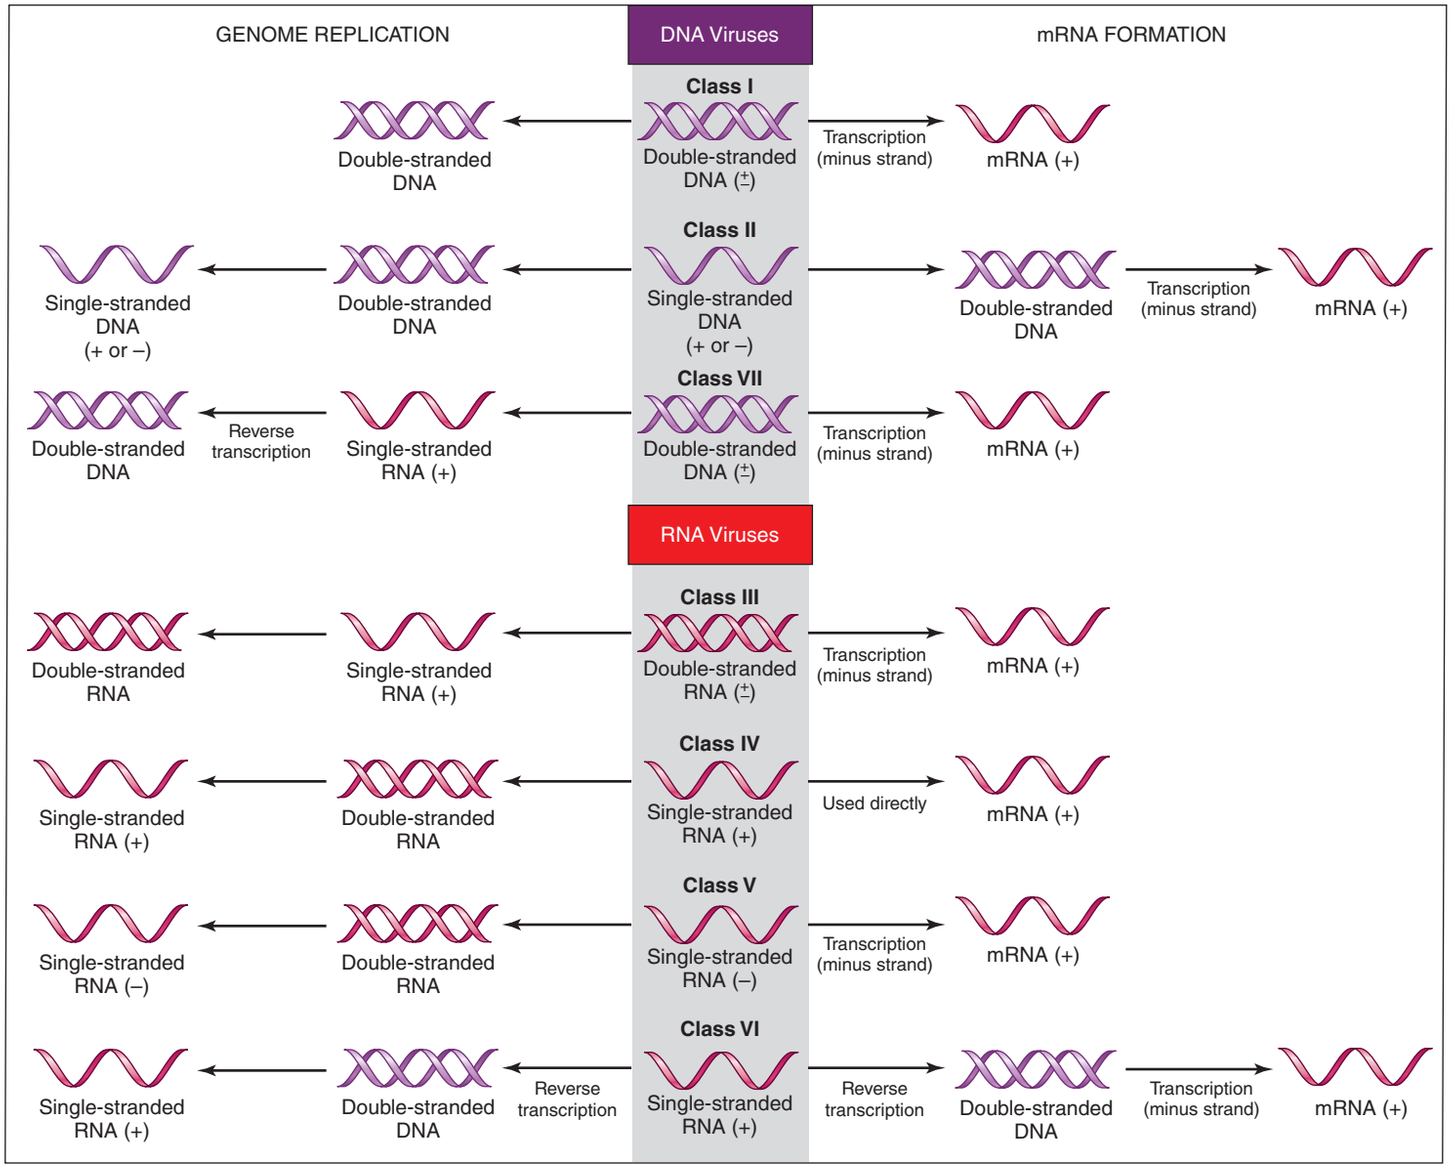

Figure 8.13. Classification of viruses All viruses must both replicate their genome (shown on the *left*) and produce mRNA that functions in the host cell (shown on the *right*). The Baltimore classification scheme is based primarily on how the mRNA of different viruses is generated.

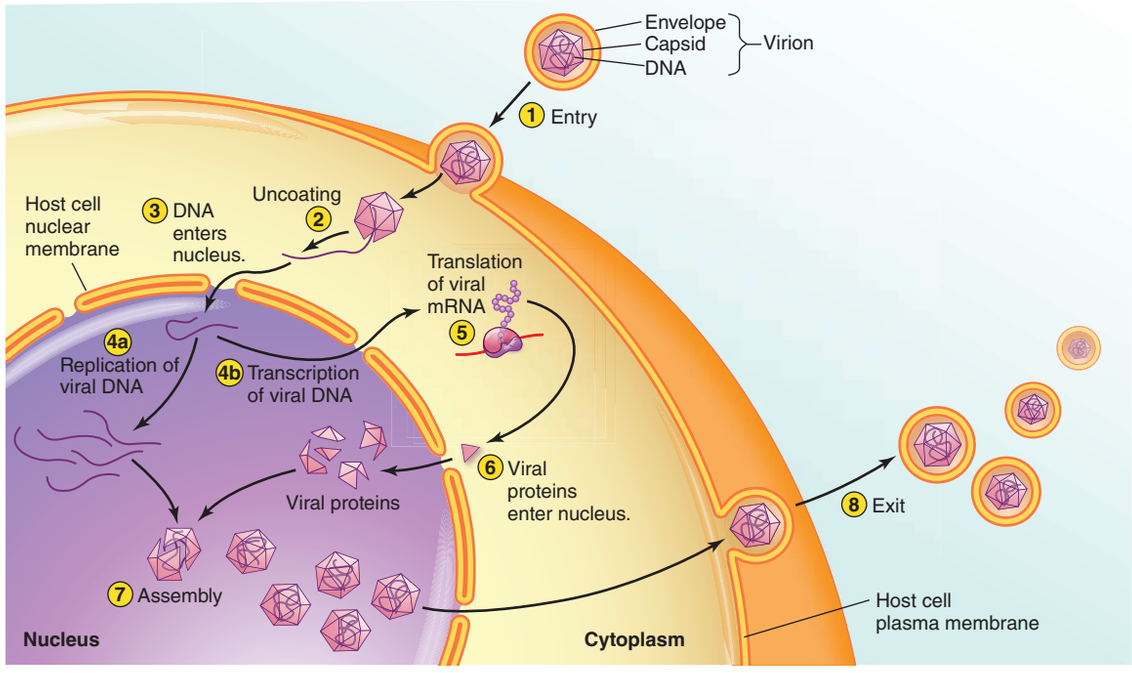
occur much like they do in the host cell. For most DNA viruses, some portion of the viral particle migrates to the nucleus. Here, viral genes are transcribed and the viral genome is replicated **(Figure 8.14)**.

For SV40, a well-studied member of the *Polyomaviridae* family with a small circular DNA genome, the viral protein, called large T antigen, unwinds the viral DNA. Host primases and the host DNA polymerase replicate the viral genome in a bidirectional manner (refer back to Chapter 7 for a refresher on DNA replication). Numerous studies have shown that large T antigen also interacts with cell cycle regulatory proteins and drives the cell toward DNA replication. By priming the cell for DNA replication, the large T antigen also facilitates viral replication. The cell begins producing DNA polymerase and nucleotides, for instance. The virus needs these same materials for viral replication. Thus, by causing the cell to begin DNA replication, the virus ensures that adequate supplies for viral replication will be present. In some cases, this viral "trick" can result in the immortalization of cells in culture; they replicate continuously. Human papillomaviruses (HPVs) also contain specific proteins that drive the cell toward DNA replication and disrupt cell cycle control. Certain strains of these viruses have been strongly associated with cervical cancers **(Microbes in Focus 8.2)**. For polyomaviruses and papillomaviruses, the host RNA polymerase II is responsible for transcription of the viral genes. It appears that high-molecular-weight precursor RNAs are transcribed and then spliced to form individual mRNA molecules that then are translated.

CONNECTIONS A number of viruses have been linked to various types of cancer. In most cases, the viruses alter normal cell cycle controls, thereby leading to altered cell replication. More about the link between viruses and cancer will be discussed in **Section 22.3**.

Figure 8.14. Process Diagram: Replication of DNA viruses
Generally, replication of DNA viruses occurs in the nucleus. Usually, the host cell DNA polymerase is used to produce new copies of the viral genome and the host cell RNA polymerase is used to produce viral mRNA molecules.

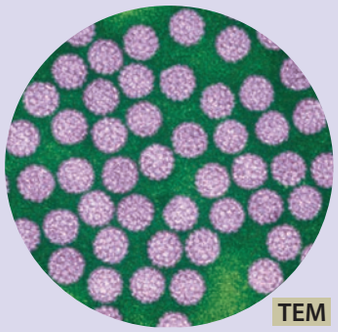


Microbes in Focus 8.2
HUMAN PAPILLOMAVIRUSES (HPVs) AND CERVICAL CANCER

Habitat: Humans

Description: Double-stranded DNA, non-enveloped virus about 50–55 nm in diameter with icosahedral symmetry in the *Papillomaviridae* family. Approximately 130 different strains have been identified.

Key Features: Over 40 strains of HPV are sexually transmitted and infect the genital areas of men and women. In the United States, roughly half of all sexually active men and women will become infected with HPV at some point in their life. Several strains of HPV lead to the development of genital warts, and a few strains have been associated with the development of cervical, vaginal, penile, anal, throat, and mouth cancers. In 2006, the FDA approved Gardasil for use in girls and women. Gardasil is a vaccine effective against the most common strains of HPV associated with genital warts and cervical cancer. This vaccine was approved for use in boys and men in 2009. A second vaccine effective against HPV, Cervarix, received FDA approval for use in girls and women in 2009. Gardasil 9, a vaccine effective against nine HPV strains, was approved for use in December of 2014.



©Kwangshin Kim/Science Source

Although most eukaryal DNA viruses replicate in the nucleus, using the host cell DNA polymerase, members of family *Poxviridae* represent a very interesting exception to this general rule. Poxviruses have a double-stranded DNA genome, but their DNA replication and transcription occur entirely within the cytoplasm of the host cell. Thus, the poxviruses cannot rely on host proteins normally found in the nucleus. Let's look at this problem another way. If the poxviruses cannot rely on any host proteins normally found in the nucleus, then the viral genome must encode all the proteins needed for genomic replication and transcription. In fact, the large poxvirus genome does encode all of these necessary enzymes and associated factors. Because merely possessing genes that encode all the proteins needed for replication and transcription is not enough, how do the necessary viral polymerases get produced initially? To solve this problem, poxvirus particles carry a functional RNA polymerase and their own transcription factors! This polymerase produces eukaryal-like mRNAs, which give rise to the necessary viral proteins **(Figure 8.15)**. Initially, "early" genes are transcribed and translated, producing the DNA polymerase and other proteins necessary for genome replication. "Late" genes encode structural proteins needed for capsid and envelope formation. As we will see in the next section, many RNA viruses follow a similar strategy and bring essential enzymes into the host cell with the genome.

Replication of RNA viruses

For all RNA viruses, the RNA genome presents an interesting problem. Exact RNA copies of an RNA template must be made. All cells can make DNA copies of DNA templates, using DNA polymerase, and all cells can make RNA from DNA templates, using DNA-dependent RNA polymerase. But cells do not routinely make RNA copies of RNA. So, all RNA viruses must employ

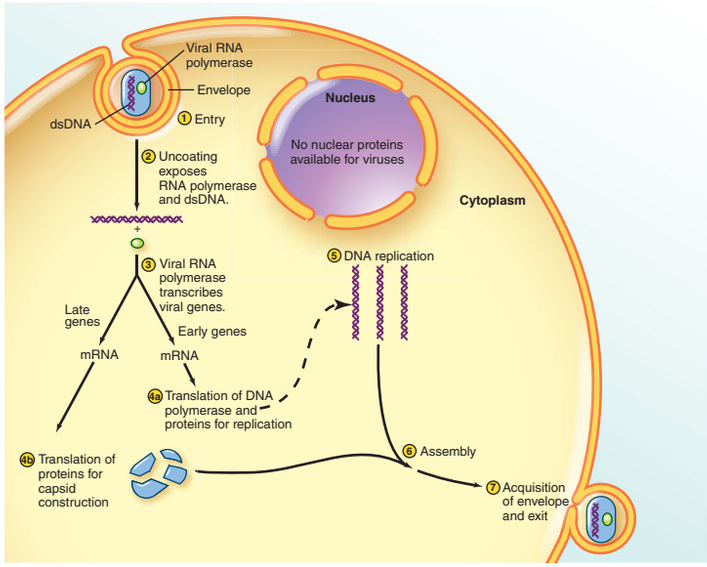


Figure 8.15. Process Diagram: Replication of poxviruses Unlike most DNA viruses, poxviruses replicate entirely within the cytoplasm of host cells. To facilitate this process, the virion brings a viral RNA polymerase and several transcription factors with it into the cell. Viral mRNAs are generated in the cytoplasm and translated by host cell ribosomes. One of the resulting viral proteins is a viral DNA polymerase that replicates the viral genome.

a virally encoded RNA polymerase. For most RNA viruses, this polymerase is an **RNA-dependent RNA polymerase**. In other words, it produces RNA from an RNA template. For many RNA viruses, this RNA-dependent RNA polymerase manufactures not only genomic RNA, but also messenger RNA that can be recognized and translated by the host cell's ribosomes. Thus, replication of RNA viruses occurs independent of host proteins found in the nucleus. It follows, then, that replication of these viruses usually occurs in the cytoplasm. To understand this process a bit more, let's examine three distinct types of RNA viruses: positive-sense single-stranded RNA viruses, negative-sense single-stranded RNA viruses, and retroviruses.

Positive-Sense Single-Stranded RNA Viruses

For some single-stranded RNA viruses, like poliovirus, the genomic RNA "looks" like messenger RNA. In other words, the genomic RNA can be translated directly by the host cell translation machinery. Thus, for these single-stranded **positive-sense RNA**, or **ssRNA (+)**, viruses, the initial production of new viral proteins can occur in the absence of any existing viral proteins within the host cell. An RNA-dependent RNA polymerase can be translated directly from the genome of an ssRNA (+) virus after the virus has entered its host cell. The virus does not need to bring this enzyme with it into the cell. Once the RNA-dependent RNA polymerase is produced, it can produce new copies of the viral genome, using the original genome as a template **(Figure 8.16)**.

Positive-sense RNA virus replication
ANIMATION

For researchers, a positive-sense RNA genome presents many exciting possibilities. Because the viral genome "looks" like mRNA, it can be translated directly by the host cell, resulting in the production of viral proteins. These resulting viral proteins can replicate the viral genome, and new viral particles can be assembled. Let's examine the implications of this process. If a researcher

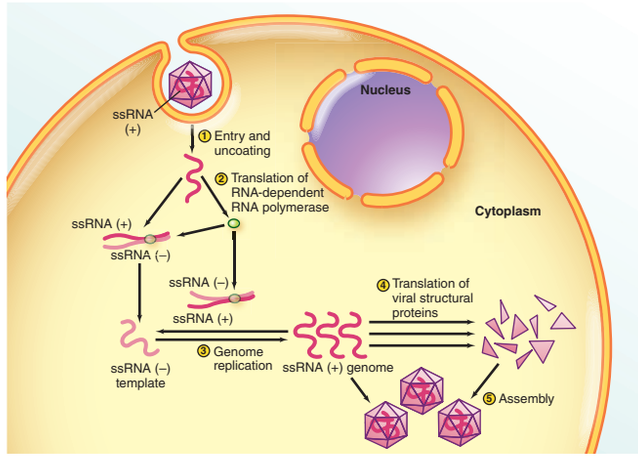

Figure 8.16. Process Diagram: Replication of positive-sense RNA viruses Because the viral genome is positive-sense, it can be translated directly by the host cell. The necessary viral polymerase is not brought into the cell by the virion but rather is synthesized inside the cell.

isolates the RNA from poliovirus and artificially injects it into a host cell, then new viral particles will be produced **(Figure 8.17)**.

The genomes of positive-sense RNA viruses that, when isolated, can lead to virion production in cells, often are referred to as **infectious RNA**. More importantly, researchers observed that if the genomic RNA is converted into double-stranded DNA and cloned into a plasmid, then the plasmid becomes infectious. Using standard molecular biology techniques, researchers

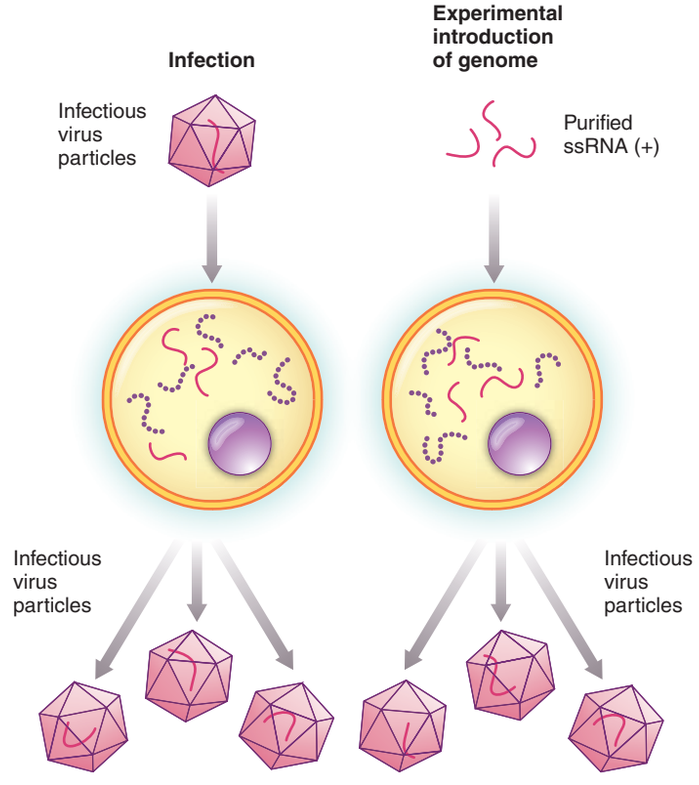

Figure 8.17. Infectious RNA When the RNA genome from a positive-sense RNA virus is isolated and then introduced into a permissive host cell, the host cell machinery can translate the viral RNA. Viral proteins, including the viral RNA-dependent RNA polymerase, are produced. This enzyme can produce new copies of the viral genome, and new infectious viral particles then assemble.

can mutate specific bases within such a plasmid, thus effectively mutating the viral genome. By introducing the mutated plasmid into host cells, virologists can determine the effects of the specific mutations on the virus. These types of studies have provided many insights into viral replication and pathogenesis.

CONNECTIONS As we saw in **Section 7.1**, plasmids are common components of the bacterial genome. In **Section 9.3**, we will explore the use of plasmids in biotechnology.

Negative-Sense Single-Stranded RNA Viruses

In contrast to the genomes of positive-sense single-stranded RNA viruses, the genomes of single-stranded **negative-sense RNA**, or **ssRNA (–)**, viruses are complementary to the viral messenger RNA. In other words, they cannot be directly translated by the host cell. The genomic RNA must serve as a template for the production of messenger RNA. As we've seen earlier, production of RNA from RNA requires a viral RNA-dependent RNA polymerase. Thus ssRNA (–) viruses must carry this enzyme with them, and this polymerase must enter the cell with the viral genome **(Figure 8.18)**.

Retroviruses

Today, the word "retrovirus" has become nearly synonymous with HIV. Indeed, since HIV was determined to be the causative agent of AIDS in 1983, HIV has become the most famous retrovirus. It is important to note, however, that the study of retroviruses has a much longer, and quite interesting, history. Although he didn't know it at the time, Peyton Rous was studying a retrovirus back in 1911 when he described the ability of a virus to cause sarcomas (connective tissue tumors) in chickens. Rous received the Nobel Prize in Physiology or Medicine in 1966 for this discovery of an oncogenic virus, a virus that causes cancer. Until the AIDS pandemic was recognized in the early 1980s, retroviruses were studied primarily because

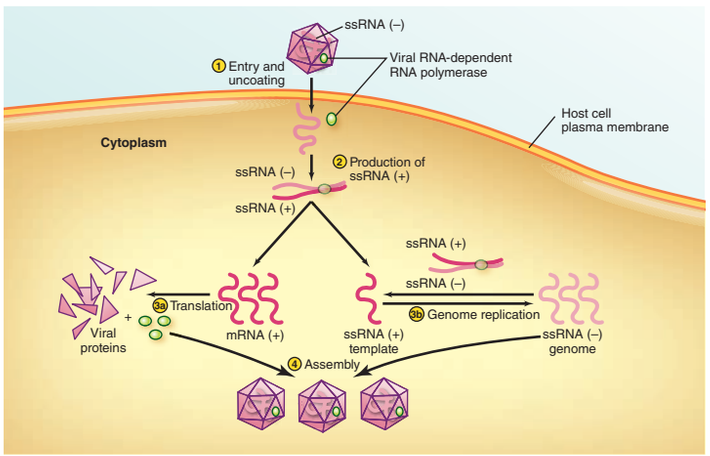

Figure 8.18. Process Diagram: Replication of negative-sense RNA viruses The basic replication strategy employed by negative-sense RNA viruses is very similar to that seen with positive-sense RNA viruses. The major difference, though, is that the negative-sense RNA genome cannot be translated by the host cell. A complementary positive-sense copy first must be made. Because cellular enzymes cannot make an RNA copy of RNA, the virus must bring an RNA-dependent RNA polymerase with it into the host cell.

© Paul Sakuma/AP/Wide World Photos

Figure 8.19. Nobel Prize winners J. Michael Bishop (*left*) and Harold Varmus (*right*) received the Nobel Prize in Physiology or Medicine in 1989 for their work with Rous sarcoma virus, an oncogenic retrovirus.

of their ability to form tumors. In 1976, Harold Varmus and J. Michael Bishop, working together at the University of California, San Francisco, published a series of papers detailing their concept of how retroviruses can convert proto-oncogenes, normal genes typically encoding proteins involved in cell growth, into oncogenes, mutated proto-oncogenes associated with the development of cancer. They received the Nobel Prize in Physiology or Medicine in 1989 **(Figure 8.19)**.

In 1975, Howard Temin and David Baltimore received the Nobel Prize in Physiology or Medicine for their discovery that these RNA tumor viruses converted RNA into DNA through the use of an unusual viral enzyme, **reverse transcriptase (RT)**. More recently, French researchers Luc Montagnier and Françoise Barré-Sinoussi shared the 2008 Nobel Prize in Physiology or Medicine for the discovery of HIV. Seven researchers who studied retroviruses have become Nobel laureates.

The most unusual aspect of retrovirus replication is the multifunctional viral RT, that works as an **RNA-dependent DNA polymerase** (Mini-Paper). Upon entering a cell, this viral enzyme converts the single-stranded RNA retrovirus genome into double-stranded DNA. Initially, the RNA serves as a template for the generation of a DNA:RNA heteroduplex, a double-stranded nucleic acid molecule in which one strand is DNA and the other strand is RNA. This same enzyme then degrades the original RNA molecule, using an endonuclease activity referred to as RNase H. The RT next converts the resulting single-stranded DNA to a double-stranded molecule. This viral DNA is transported to the nucleus where another viral enzyme, **integrase**, integrates it into the host cell genome. The integrated viral DNA is referred to as a **provirus**, or proviral DNA. The host cell RNA polymerase II generates viral mRNA and full-length genomic RNA molecules, which leave the nucleus to be translated or incorporated into newly assembled viral particles **(Figure 8.20)**.

WWW HIV replication ANIMATION

CONNECTIONS Because the HIV reverse transcriptase lacks proofreading activity, it is error-prone. When HIV replicates, mutations occur at a substantial rate. The generation of these mutants within an infected person contributes to the pathogenesis of the virus. We will explore aspect of HIV/AIDS pathogenesis in **Section 22.4**.

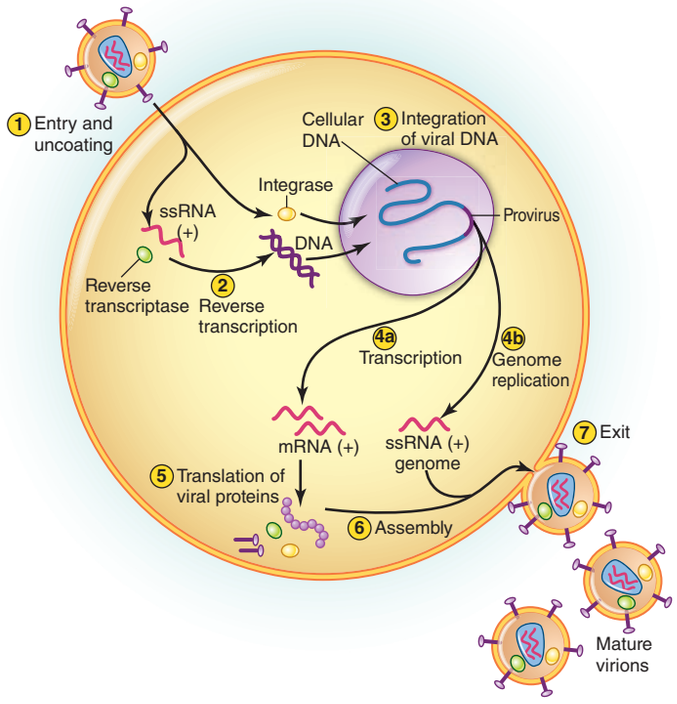

Figure 8.20. Process Diagram: Replication of retroviruses The single-stranded RNA genome is converted to double-stranded DNA by the viral reverse transcriptase. This viral DNA genome then moves to the nucleus of the host cell, where the viral integrase inserts it into the cellular DNA. The host cell RNA polymerase transcribes the integrated viral genome, producing mRNA molecules that are translated to produce viral proteins and new viral RNA genomes.

Replication of bacteriophages

To a large extent, replication strategies employed by bacteriophages mirror the strategies employed by viruses of eukarya. By and large, DNA bacteriophages use host cell DNA polymerase to make new genome copies. RNA bacteriophages, like the RNA viruses of eukarya, generally use a viral RNA-dependent RNA polymerase to make new genome copies. Most RNA bacteriophages currently known have a positive-sense RNA genome. As we discussed earlier, this RNA can be translated immediately upon entering the cell, and as a result, the virus does not need to bring replication enzymes with it into the host cell.

Many viruses of bacteria assemble within their host cell and lyse the cell upon exit, thereby killing it **(Perspective 8.2)**. However, other bacteriophage replication strategies exist **(Figure 8.21)**. Phages whose only mode of replication is to lyse their host cell are referred to as **virulent phages**, or lytic phages. Some bacteriophages, called **temperate phages**, have the option of also existing within the host cell without lysing it. The genome of some temperate phages, such as P1 of *Escherichia coli*, may exist within the host cell cytoplasm as a plasmid, separate from the host cell genome, in a quiescent state. The host cell continues to replicate the viral genome, and thus perpetuate it without the production of new virus particles. Other temperate phages, such as lambda (λ) phage of *E. coli*, can either lyse the cell or integrate their genome into the genome of the host cell, where it is replicated along with the host DNA whenever the host cell divides. Recall from Section 5.3, the quiescent phage genome, which can exist either as a plasmid or

Replication of temperate bacteriophages
ANIMATION

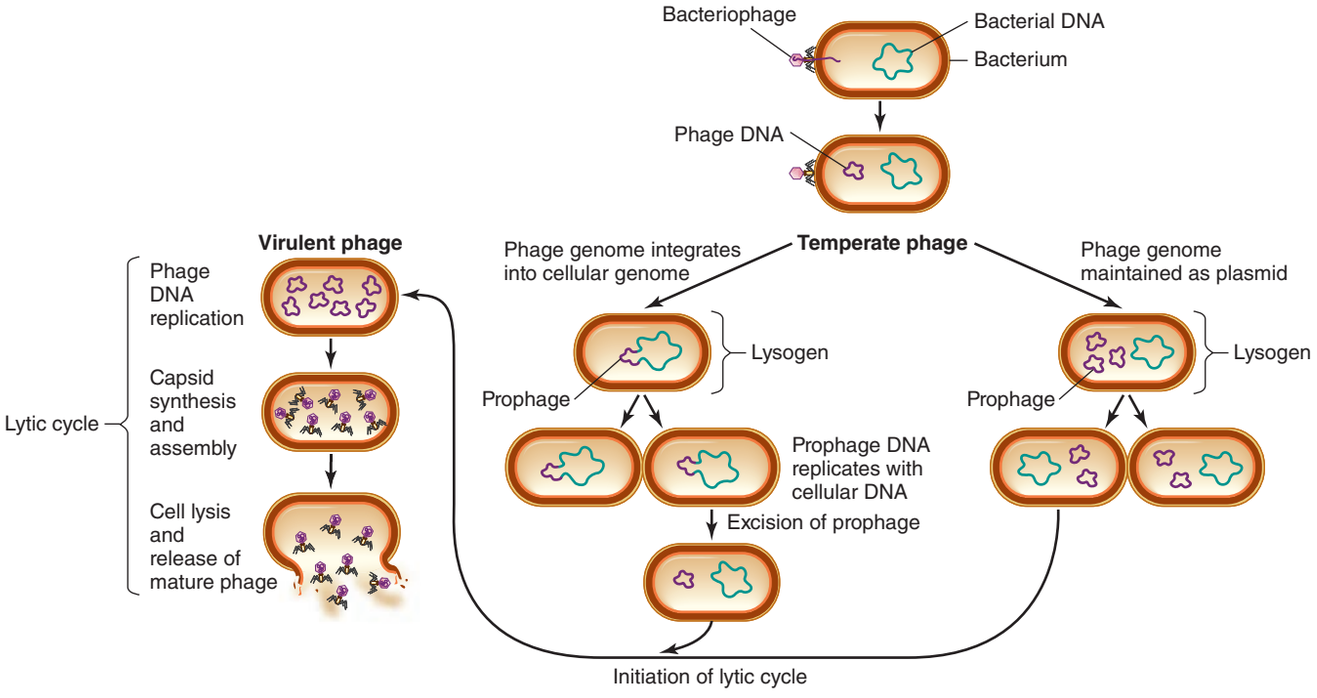

Figure 8.21. Virulent and temperate phages Virulent, or lytic, phages replicate within the host cell, eventually lysing it. Temperate phages can either insert their genomes into the host cell or enter the lytic phase, depending on conditions experienced. In the temperate phase, the viral genome is replicated along with the host, but progeny phages are not made. Some temperate phages integrate their genomes into the host genome, and others maintain the viral genome as a plasmid.

Perspective 8.2
PHAGE THERAPY: BIOCONTROL OF INFECTIONS

Phages can kill bacteria, a fact well-known to microbiologists as early as 1915. If phages can kill bacteria, then could they be used to fight bacterial infections in humans? Perhaps. Indeed, thousands of patients in the early 1900s were treated with phages with apparent success for common bacterial diseases such as dysentery (*Shigella dysenteriae*), cholera (*Vibrio cholerae*), bubonic plague (*Yersinia pestis*), and staphylococcal skin diseases **(Figure B8.6)**. Eastern Europe and Russia were centers for the cultivation of phage stocks to be used by the medical community. In France, L'Oreal, now a famous cosmetics company, marketed several phage remedies, as did Eli Lily in the United States, producing phages in tablet form for easy dispensing and transport.

Phage therapy was pushed aside in the West, as penicillin and other antibacterial agents became mainstream therapies. Despite being widely used for many years, the lack of records and controlled studies has left a checkered history of phage therapy, making it difficult to ascertain just how successful phage therapy was. Recently, the worrisome rise of antibacterial drug resistance has caused researchers to revisit the merits of phage therapy. Phages have several advantages that antimicrobial agents lack:

- They are highly selective for their host, often able to infect only certain strains of a species.
- They remain in the body only as long as the infecting host does.
- They replicate, so repeat doses are not needed.
- Most are easily cultivated in the lab.
- Most can be stored for long periods of time and still retain infectivity.
- Lytic phages are absolutely lethal to their host bacteria.

Many studies using phages have been done in animal models, and the majority of these have confirmed that phage therapy can be highly effective and very safe. Several issues remain to be addressed before phage therapy becomes a mainstream treatment once again. Some of these concerns include:

- Bacterial phage resistance will likely develop, just as it has for conventional antimicrobial drugs, but could be avoided with multiphage cocktails.
- The species or strain of infecting bacteria will need to be identified correctly in order to use the appropriate phage.
- The phage must maintain its selectivity and not infect nontarget microbiota.
- Host production of antibody to the phage may limit its use to topical applications only.

Further study on the efficacy and safety of phages in treating human and animal disease continues, and the production of phages for therapy is making a commercial comeback. Biophage of Montreal, Canada, produces several phage therapeutics for *Salmonella* and *E. coli* infections in farmed animals. In 2006, the U.S. Food and Drug Administration approved a spray-on phage cocktail for treating meat for the bacterium *Listeria monocytogenes*, which causes a serious systemic foodborne illness (see Chapter 16 opening story). Additionally, participants in the Phagoburn project in Europe are testing the efficacy of phages to prevent or treat bacterial infections of burn wounds.

B. During phage treatment

Figure B8.6. Phage therapy **A.** The ulcerated infected leg shown here did not respond to antibiotic therapy, despite over 10 years of treatment. **B.** The leg began to heal with treatment using a phage cocktail containing a mixture of different phage strains against *Staphylococcus aureus*, *Pseudomonas* strains, and *E. coli*. Complete healing was achieved.

integrated into the host genome, is referred to as a **prophage**. A cell containing a prophage is called a **lysogen**, for "lysis generating," and induction back to the lytic pathway is possible in these bacterial strains. To explore this process more fully, let's examine lambda (λ) phage, the most well-studied temperate phage.

When the linear λ DNA enters a host cell, it almost immediately circularizes, and transcription of viral genes begins. A specific viral enzyme, integrase, then facilitates the integration of the viral genome into the host genome through a recombination process. A virally encoded repressor protein, cI, binds to promoters of certain genes, including *cro*, required for lytic replication and prevents their transcription, thereby maintaining the lysogenic state. Under certain circumstances, the cI levels will decline. Usually, the cI levels drop in response to damage to the host cell, perhaps caused by ultraviolet light or chemical mutagens. As the levels of cI drop, another virally encoded repressor protein, cro, binds to and blocks the *cI* promoter, causing an even greater decline in the concentration of cI. Freed from cI repression, other phage genes, such as *cro*, now can be expressed, leading to lytic replication of

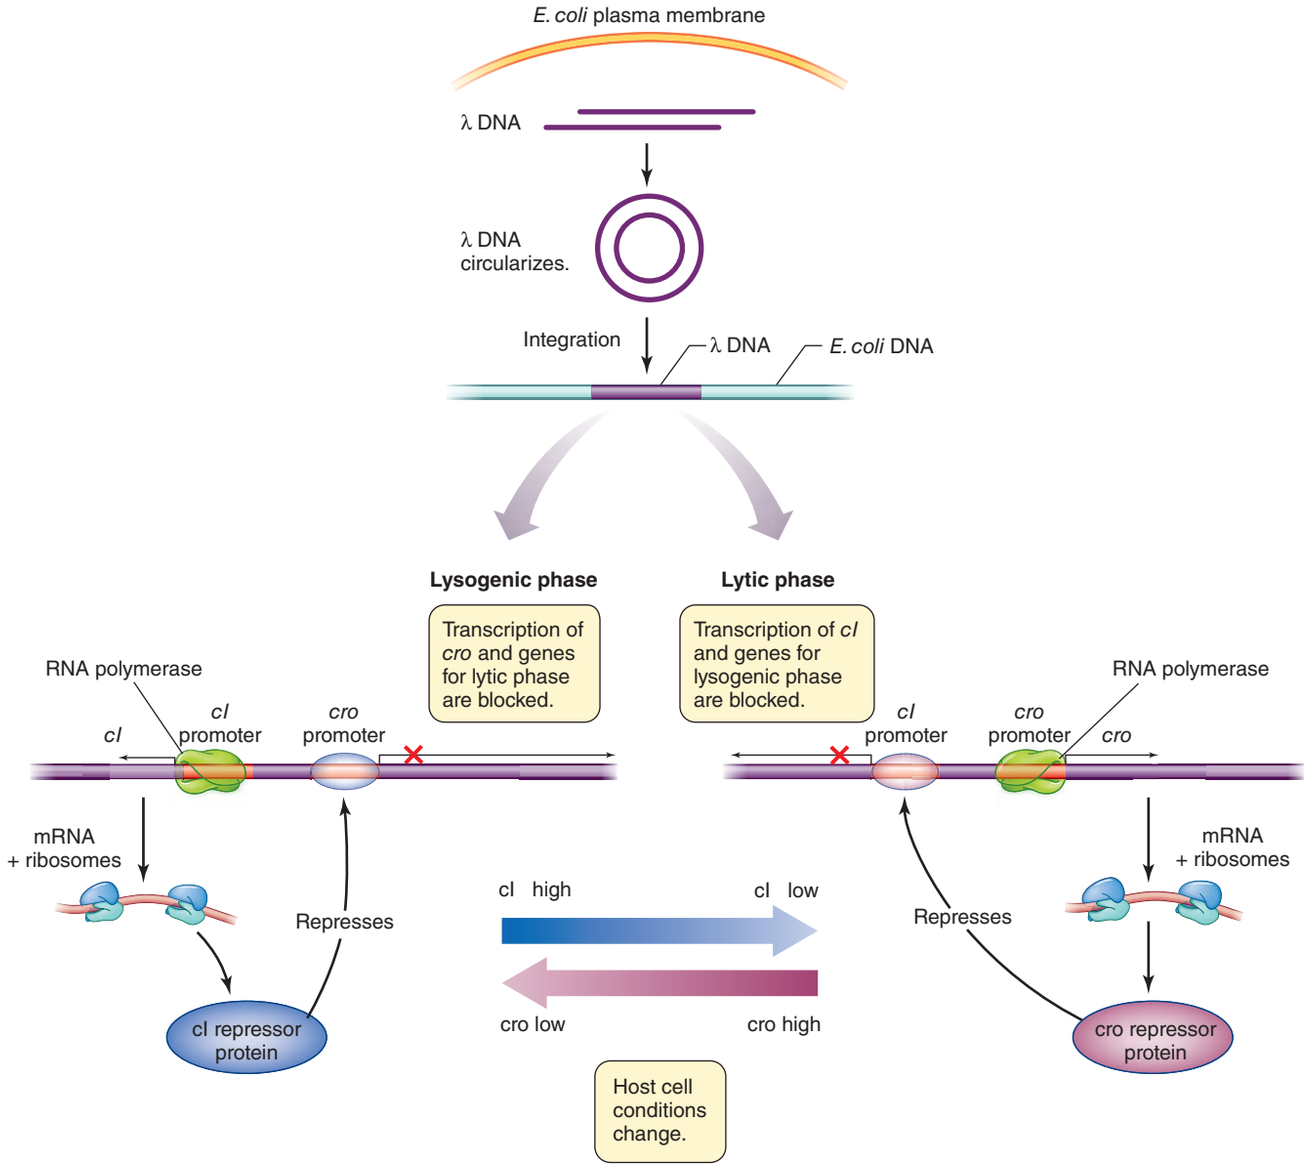

Figure 8.22. Phage lambda can undergo a lysogenic or lytic phase of replication, depending on the ratio of two repressor proteins. The cI repressor protein binds to and represses the *cro* promoter, preventing production of the cro repressor protein and other proteins required for lytic replication, thereby maintaining the lysogenic phase. The cro repressor protein binds to the *cI* promoter, preventing production of the *cI* repressor protein and other proteins required for the lysogenic phase. In the presence of cro, then, the proteins for lytic replication are free to be produced, maintaining lytic replication.

the phage (Figure 8.22). To summarize, when levels of the cI repressor protein are high, genes leading to the lytic phase are blocked. When levels of the cro repressor protein are high, genes leading to the lysogenic phase are blocked. Thus, temperate phages like λ can toggle between lytic and lysogenic replication in response to the overall health of their host cell.

CONNECTIONS As we have just discussed, some bacteriophages can alter their replication strategies within a host cell. Bacteria also have their own means of regulating, or completely blocking, bacteriophage replication. These bacterial defense systems are discussed in **Section 18.2**.

8.3 Fact Check

1. Describe the basis of the Baltimore classification system.
2. How and where do many DNA viruses such as SV40 replicate in the host cell?
3. Contrast the replication strategy of positive-sense RNA viruses with that of negative-sense RNA viruses.
4. How are the enzymes reverse transcriptase and integrase involved in retrovirus replication in host cells?
5. Describe the replication cycles of virulent and temperate bacteriophages.

8.4 Viral assembly and egress

How do virus particles form and exit cells?

Making many copies of the viral genome and all the viral proteins is not the end of the story. New viral particles must be assembled and then leave the infected cell. How do these processes occur? As we saw for viral entry and replication, a few common mechanisms exist. Although assembly and egress are less well studied than entry and replication, it appears that most viruses use one of a relatively few strategies for assembling and then exiting an infected cell. In this section, we will explore the most common patterns.

Assembly

For all viruses, assembly of new viral particles involves a well-orchestrated set of events. Most often, for icosahedral viruses, the individual capsid proteins undergo a self-assembly process. Specific chemical interactions cause individual polypeptides to bind to each other, forming more complex structures like the capsomeres, or faces of the capsid, and eventually the capsid itself. Alternatively, assembly may require the function of specific viral proteins that then do not reside within the mature viral particle. In some cases, such as HIV, a non-infectious precursor form of the viral particle may assemble initially. Certain proteins of this precursor virion then undergo proteolytic processing. Cellular or viral enzymes cleave specific proteins in the precursor virion, causing the virion to undergo some conformational changes. These changes in shape result in the formation of the mature, infectious virion. Not surprisingly, disruption of this proteolytic processing disrupts the formation of infectious viruses. The antiretroviral **protease inhibitor** drugs, agents that block the activity of a proteolytic processing enzyme required for the formation of infectious HIV particles, decrease HIV infection of new cells in exactly this manner.

Viral genomes seem to get into the viral particles in one of two ways. In some cases, the proteins assemble around the viral nucleic acid. For these viruses, often the genomic RNA or DNA possesses a sequence-specific assembly motif, or **packaging sequence.** The viral proteins interact with this sequence, thereby causing the capsid proteins to coalesce around the nucleic acid. The tobacco mosaic virus (TMV), a virus exhibiting helical symmetry (see Figure 5.5), assembles in this manner.

In other cases, "empty" capsids are partially assembled first and then the viral genome is inserted into these capsids. Poliovirus, a virus exhibiting icosahedral symmetry, undergoes this process. Initially, the major poliovirus structural proteins VP1, VP3, and the precursor VP0 assemble into capsomeres, the basic structural unit of the capsid. Groups of five capsomeres then assemble into pentamers, the faces of the capsid. These pentamers coalesce around viral genomic RNA, forming an immature viral particle. Subsequent cleavage of VP0 into VP2 and VP4 results in the formation of a mature, infectious virion.

As we noted in Chapter 5, some viruses possess a segmented genome. Influenza virus, for example, has a genome that consists of eight segments of ssRNA (–). The assembly of new virions possesses an added level of complexity for these viruses. The formation of infectious particles requires that one copy of each segment gets inserted into each virion. Although this genomic feature may present an assembly challenge, it also presents the virus with a different mechanism for generating genetic variability (see Figure 22.29).

Egress

Finally, the newly formed viral particles must leave the cell. For enveloped viruses, this process of egress necessarily involves several steps. First, proteins destined for the viral envelope must be inserted into the cellular membrane. Like the integral membrane proteins of the host cell, these proteins contain a signal sequence that directs them to the appropriate membrane location. Second, the nucleocapsid, formed within the cell, must migrate to the region of the cellular membrane containing the viral envelope proteins. Usually, certain amino acids within the tail region of these transmembrane proteins interact with regions of the nucleocapsid, thereby bringing the nucleocapsid into proximity with the membrane. Third, budding of the nucleocapsid occurs, thus providing the virus with a lipid bilayer that contains the required envelope proteins (Figure 8.23).

In almost all cases, egress of non-enveloped viruses occurs through lysis of the host cell. This lysis event differs somewhat

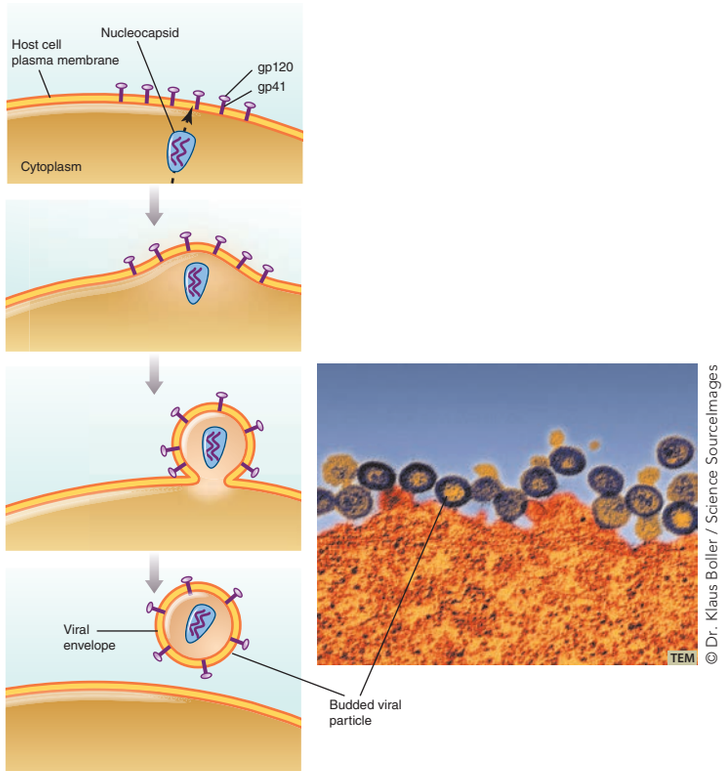

Figure 8.23. HIV budding Viral proteins are inserted into the host cell's plasma membrane. The viral particle then migrates to the membrane and buds off of the cell, thereby acquiring an envelope that contains the viral proteins gp120 and gp41. This electron micrograph shows HIV particles budding from a cell.

between bacteriophages and mammalian viruses. Bacteriophages generally produce specific enzymes that actively destroy the host cell's plasma membrane and cell wall. For instance, T4 produces lysozyme, an enzyme that degrades the peptidoglycan present in the cell wall. Conversely, non-enveloped mammalian viruses rarely produce specific proteins necessary for egress. Rather, the host cell becomes progressively unstable because of the replication of the virus, leading to the destruction of the cell and release of the new virions. Viruses of plants, as we alluded to earlier, do not lyse the host cell. These viruses travel from one cell to another within a plant through the cytoplasmic connections between cells. Spread to a new plant requires the disruption of the cell wall and cuticle by outside forces, such as insects.

CONNECTIONS The insertion of viral envelope proteins into the host cell plasma membrane exposes these viral proteins on the surface of infected host cells. These foreign proteins can be recognized by the immune system. Cytotoxic T cells (**Section 20.2**) are immune cells designed to destroy infected cells.

8.4 Fact Check

1. How can protease inhibitor drugs specifically disrupt viral assembly?
2. Describe two ways that viral genomes can become enclosed within capsids during assembly.
3. How is the egress of new virus particles different for an enveloped virus versus a non-enveloped virus? Explain each process.

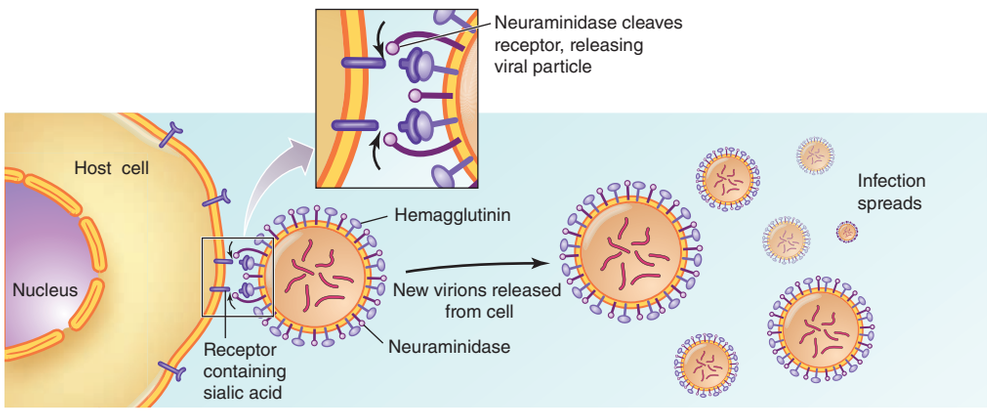
Image in Action

WileyPLUS Learning Space This image depicts the replication cycle of influenza viruses leaving one host cell (*bottom*) and infecting another (*top*).

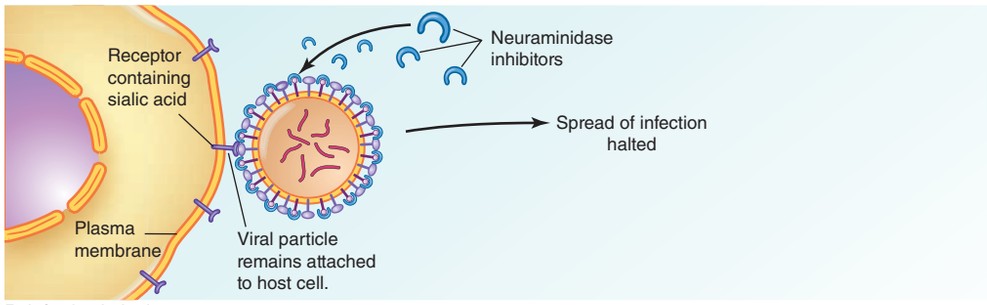
1. Describe the molecular steps that occur when a virus initially interacts with a host cell. Identify and include a description of the specific roles of the green- and red-colored components.
2. Imagine that Tamiflu was administered and is present now in this situation. Describe the antiviral effects of Tamiflu and outline how this image would look different if this drug were present.

The Rest of the Story

As we noted in the opening story, Tamiflu reduces the severity and length of the influenza disease. But how does it work? Tamiflu (oseltamivir) is a neuraminidase inhibitor (NAI). The neuraminidase protein (NA) is located in the influenza virus envelope, along with the hemagglutinin protein (HA). When a virion first encounters a host cell, HA binds to sialic acid, allowing the virus to enter the cell. During budding of newly replicated viral particles, NA cleaves sialic acid residues present on the infected cell's plasma membrane. So? The cleavage of sialic acid residues by NA prevents the newly formed viruses from getting stuck to the infected cell. In other words, NA increases the likelihood that new virus particles will move to other cells **(Figure 8.24)**.



A. Spread of infection



B. Infection halted

Figure 8.24. Action of Tamiflu **A.** Neuraminidase cleaves sialic acid, allowing newly formed virions to disperse from the infected cell. **B.** Tamiflu functions as a neuraminidase inhibitor, preventing the release of virions from infected cells and limiting the spread of the virus to other cells.

Mini-Paper: A Focus on the Research
THE DISCOVERY OF REVERSE TRANSCRIPTASE

D. Baltimore. 1970. RNA-dependent DNA polymerase in virions of RNA tumour viruses. Nature 226:1209–1211.

H. Temin and S. Mizutani. 1970. RNA-dependent DNA polymerase in virions of Rous sarcoma virus. Nature 226:1211–1213.

Context

By the 1960s, several lines of evidence indicated that the replication of RNA tumor viruses, like the tumorigenic virus first described by Peyton Rous in 1911, included a DNA intermediate. First, researchers observed that DNA synthesis inhibitors block replication of these viruses, but only if these inhibitors are added to cells early after their infection. Second, researchers observed that actinomycin D, a drug that inhibits the DNA-dependent RNA polymerase responsible for transcription in mammalian cells, also prevents the formation of new virus particles. Third, several experiments showed that cells infected by RNA tumor viruses contain DNA that hybridizes with, or binds to, viral RNA.

Based on these observations, Baltimore and Temin postulated independently that the replication of RNA tumor viruses proceeds through a DNA intermediate. In other words, the RNA genome is converted into DNA, which later is converted back into RNA genomes. This model would explain the observations previously described. This model also would require the existence of an RNA-dependent DNA polymerase, or an enzyme that could convert RNA into DNA. Such an enzyme had never been observed in any organism. Furthermore, such an enzyme clearly would violate the central dogma of biology: that DNA is converted to RNA, which is converted to protein.

Experiments

To determine if RNA tumor viruses contained RNA-dependent DNA polymerases, the researchers asked two fairly straightforward questions. First, do the viruses produce DNA? Second, what is the template from which this DNA is derived?

To address the first question, both groups started with purified preparations of two RNA tumor viruses: Rauscher mouse leukemia virus (R-MLV) or Rous sarcoma virus (RSV). Refer to Chapter 5 to review how viruses can be isolated, purified, and quantified. Next, they added these viruses to a standard DNA polymerase assay. The ingredients of this assay included the four deoxyribonucleotide triphosphates (dATP, dTTP, dCTP, and dGTP), the precursors of DNA. Additionally, one of the nucleotides, thymidine, was labeled with ^{3}H, a radioactive form of hydrogen. Following an incubation, trichloroacetic acid was added to the reaction and the entire reaction then was filtered through a fine filter. Previous research had shown that DNA was acid-insoluble. In other words, any DNA produced in the reaction would precipitate out of solution when the acid was added and would be retained on the filter. By simply measuring the amount of radioactivity retained on the filter, the researchers could determine if any DNA had been produced.

The reaction did, indeed, result in the formation of an acid-insoluble product. To confirm that this product was DNA, Baltimore then treated the completed reaction with deoxyribonuclease, an enzyme that destroys DNA; ribonuclease, an enzyme that destroys RNA; and micrococcal nuclease, a relatively non-specific nuclease that destroys both RNA and DNA. Deoxyribonuclease and micrococcal nuclease, but not ribonuclease, digested the radioactive product. These two results support the conclusion that purified preparations of R-MLV could produce DNA.

To address the second question, Baltimore and Temin both investigated the sensitivity of the virus to ribonuclease **(Figure B8.7)**. In the absence of ribonuclease, the amount of DNA produced increased over time (line 1). A similar increase was observed when ribonuclease was added after the virus and deoxynucleotides were allowed to incubate together for several minutes (line 2). However, when ribonuclease was included initially in the reaction mixture, the amount of DNA produced decreased markedly (line 3). When the virus was preincubated with ribonuclease before being added to the polymerase assay reaction, the amount of DNA produced decreased even more dramatically (line 4). These results support the conclusion that RNA is the template for DNA production.

By inhibiting neuraminidase, Tamiflu reduces the cell-to-cell spread of influenza virus. Because the spread of the virus is limited, the number of infected cells is limited, and the severity of the disease also is limited. Thus, a very detailed understanding of how influenza virus replicates was essential for the development of this effective antiviral medication.

Influenza viruses can develop resistance to Tamiflu. By October 2009, the WHO had reported 39 oseltamivir-resistant isolates of H1N1 influenza virus. The emergence of these drug-resistant strains of influenza created concern and a need for rapid detection of resistance. Following a significant increase in Tamiflu resistance during the 2007–2008 flu season, researchers have monitored resistance rates closely. The method they use to screen for increased oseltamivir resistance is called the neuraminidase inhibition assay. This assay allows scientists to quantitate viral neuraminidase activity as a means of detecting resistance to the drug. Resistant strains continue to have neuraminidase (NA) activity even in the presence of the drug. Oseltamivir is mixed with varying dilutions of the virus being tested, and a substrate for the neuraminidase enzyme is added to the mixture. When the substrate is degraded, chemiluminescence or light levels are detected by a luminometer. This chemiluminescence allows one to measure levels of neuraminidase activity.

An understanding of the process of evolution indicates that widespread use of Tamiflu increases the probability of Tamiflu-resistant influenza, as those strains will be selected for in the population. Surveillance of Tamiflu resistance will be a key strategy in monitoring and limiting resistance.

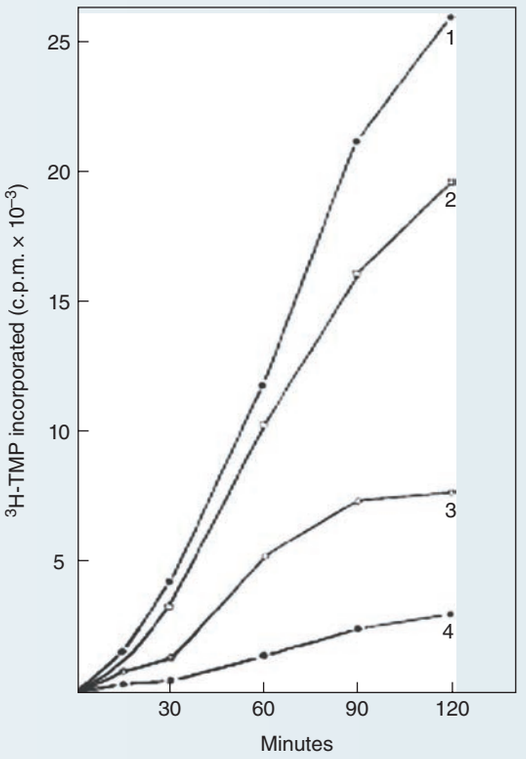


Figure B8.7. Incorporation of radiolabeled dTTP by purified virions
Virus particles were incubated with deoxynucleotides, one of which was radiolabeled. At specified times, the amount of acid-insoluble radioactivity was measured. As seen in line 1, the amount of incorporated radioactivity increased over time. The amount of incorporated radioactivity was greatly diminished if the virus was preincubated with ribonuclease (line 4), indicating that the template for DNA production was the viral RNA. (From D. Baltimore. 1970. Nature 226:1209–1211, Figure 1. Reproduced with permission.)

Impact

The identification of this enzyme that converts RNA to DNA, now referred to as reverse transcriptase (RT), had an immediate and profound effect on the fields of virology and, more generally, biology itself. Indeed, as the editors of *Nature* noted in a comment preceding these two articles, "This discovery, if upheld, will have important implications . . . for the general understanding of genetic transcription." The discovery has been upheld. Today, two classes of viruses, the retroviruses and the Class VII double-stranded DNA viruses, have been shown to encode and use RT. In addition, eukaryal cells use forms of this enzyme both for the maintenance of the ends of linear chromosomes (see Section 7.2) and the movement of certain transposable elements.

Reverse transcriptase also has become an indispensable tool for the molecular biologist. As we saw in Chapter 5, RT is used to convert the RNA of HIV into DNA as part of a standard viral load test. In addition, it is used routinely in the laboratory to convert messenger RNA into DNA. Not only did the discovery of reverse transcriptase change the way biologists viewed the flow of information within cells, but it also changed the way we can do experiments within the laboratory.

Questions for Discussion

1. Given the information presented here, would you hypothesize that retroviruses bring RT into the cell or produce it after infecting a cell?
2. Do you think that RT would be a viable target for antiretroviral drugs? Give reasons why or why not.
3. We mentioned that earlier experiments showed that cells infected by RNA tumor viruses contained DNA that hybridizes with viral RNA. One explanation for this finding is that the viral RNA is converted to DNA within the infected cell. Provide another possible explanation for this initial finding.

Summary

Section 8.1. How do viruses recognize appropriate cells?

Most viruses interact with appropriate host cells through a specific interaction between the viral attachment protein and a cellular receptor. This interaction, in many cases, determines the **host range** of a virus and which tissues within a host a virus may infect.

- For enveloped viruses, this attachment protein generally exists as a spike embedded in the envelope.
- For non-enveloped viruses, the capsid may contain a spike protein, or alternatively, a less-defined component of the capsid may interact with the host cell.
- For bacteriophages, the tail fibers generally serve as the attachment proteins.
- Studies with the T2 bacteriophage have demonstrated that altering the tail fibers of the phage can alter the host specificity of the phage.
- Studies with the mammalian virus mouse hepatitis virus have demonstrated that strains of mice are more or less susceptible to this virus depending on which form of a surface protein they express.
- Information about viral attachment proteins and receptors can be gleaned from two related techniques: SDS-PAGE and Western blotting.

- Drugs that block this initial interaction between the virus and its host cell, like the antiretroviral drug maraviroc, can prevent or slow viral infections.

Section 8.2. How do viruses enter cells and uncoat?

For enveloped viruses, the viral envelope must fuse with a cellular membrane in order for the virus to gain access to the cell. Non-enveloped mammalian viruses usually enter a cell through endocytosis.

- Membrane fusion can occur at the cell surface.
- Alternatively, the virus may undergo **endocytosis**, and fusion then occurs between the viral envelope and the endosomal membrane.
- In both cases, a viral **fusion peptide** facilitates the membrane fusion event.
- Within the endocytic vesicle, low pH initiates conformational changes in the viral capsid generally expose some type of fusion peptide.
- The fusion peptide allows part of the virus or its genome to penetrate the endosomal membrane.
- Bacteriophages do not technically enter their host cells. Rather, they inject their genome through the cell wall.
- Plant viruses often rely on an outside force, such as a feeding insect, to damage the cell cuticle and wall, thereby giving the virus access to the cytoplasm.
- Following entry, some **uncoating** of the viral particle occurs to make the genome accessible to necessary cellular components.

Section 8.3. How do viruses replicate?

DNA viruses usually replicate within the nucleus, using the DNA and RNA polymerases of the host cell.

Most RNA viruses require a virally encoded **RNA-dependent RNA polymerase** to replicate their genome.

- The genomes of **positive-sense RNA** viruses that can be translated directly by the cell are said to be **infectious RNA**.
- The genomes of **negative-sense RNA** viruses cannot be translated directly. These viruses bring a polymerase with them into the cell during infection. The polymerase then makes RNA that can be read by the cellular translational machinery.
- Retroviruses convert their RNA genome into DNA, using an **RNA-dependent DNA polymerase** known as **reverse transcriptase (RT)**. The viral DNA then becomes integrated into the host cell's genome through the action of the viral enzyme **integrase** and is then referred to as a **provirus**.
- **Virulent phages** replicate in and lyse the host cell.
- **Temperate phages** can either replicate in the host cell or exist in a quiescent state. For some temperate phage, the phage genome inserts into the host cell's genome. For other temperate phage, it is maintained in the host cell as a plasmid.
- The quiescent DNA of a temperate phage is referred to as a **prophage**, and a cell containing a prophage is referred to as a **lysogen**.

Section 8.4. How do virus particles form and exit cells?

Newly made viral proteins must assemble with newly made viral genomes within an infected cell to form new viral particles.

- In some cases, proteolytic processing of viral polypeptides is necessary for assembly to occur. The antiretroviral **protease inhibitor** drugs block this step of the assembly process.
- The proteins may assemble around the viral RNA or DNA, attaching to a **packaging sequence**.
- Non-enveloped viruses usually exit the cell through lysis of the host cell.
- Bacteriophages like T4 release lysozyme, an enzyme that degrades the cell wall, thereby aiding in cell lysis.
- Many non-enveloped mammalian viruses disrupt the infected host cell without the use of specialized exit proteins.
- Plant viruses often do not lyse the infected cell, but travel to adjoining cells through cytoplasmic connections between cells.
- Enveloped viruses exit the cell by budding from a cellular membrane, commonly the plasma membrane, thereby acquiring their envelope from the host cell's membrane.

Application Questions

1. Obviously, host cells do not "want" to be infected by viruses, yet they contain receptors that allow viral entry. Why do these receptors exist on the host cells and why can't host cells eliminate the receptors to prevent viral attachment?
2. Rabies virus is somewhat unusual in that it can infect a wide range of mammalian species. Given this information, what conclusions might you draw about the host cell receptor used by this virus? Explain.
3. In the lab, you expose a culture of host cells to ammonium chloride and note that the pH of endosomes within the cells increases. Based on what you learned in Section 8.2, how would this pH change affect the replication of an influenza virus in the cell?
4. A television show highlights the HIV drug Fuzeon, described in Section 8.2. The show mentions that Fuzeon is not a cure for HIV/AIDS, but that it simply "slows down the disease process" by not allowing the viruses to fuse with host cell plasma membranes. Use what you have learned to clarify how this drug will slow down the disease by explaining its effect on the overall viral replication process.
5. You are attending a presentation at your local gardening supply store. The speaker warns that insects such as aphids that infest your garden may cause viral plant infections. Explain the link between insects and plant viruses.
6. After rereading this chapter you notice that some types of viruses must bring along their own RNA polymerase or transcription factors into a host cell, but others do not. Explain this difference.
7. Some viruses manipulate the host cell machinery so that the cell continually replicates DNA and makes additional nucleotides. Explain how this viral manipulation may lead to perpetuations of the normal cell cycle.
8. You are assigned the job of determining whether DNA replication and transcription in a newly discovered virus occur in the cytoplasm or in the nucleus of its host cell. Because you can't see where the processes are taking place, what could you do or look for to determine your answer? Explain.
9. For many viral diseases, diagnosis can be made in the lab by growing host cells in culture and adding a viral sample from a patient. If the virus in question is present in the patient's sample, it will

cause visible changes in the cultured host cells. Based on what you learned in Section 8.4, how would the cultured host cells look different following this process if the patient's sample contained a non-enveloped virus? Explain.

10. Developing drugs against microbes involves finding unique targets that involve only the microbe and are not part of the host organism. Explain why an antiviral drug targeting the translational process of producing new viral proteins is not an ideal target.
11. You are studying a new strain of virus and are in the process of identifying the host receptor protein utilized by that virus. You are told to use the Western blot technique, as described in Toolbox 8.1, to demonstrate that the protein in question is the receptor.
    a. How will the host protein receptor be prepared and analyzed for this Western blot procedure?
    b. What will be the role of the virus in this procedure?
    c. What result will you observe if the protein is in fact the correct receptor?
12. You are assigned the task of determining whether the genome of a newly discovered virus contains infectious RNA. You are given some host cells and a sample of the virus.
    a. What is meant by the term infectious RNA?
    b. What type of virus contains a genome of infectious RNA?
    c. What could you do in the lab with the samples provided to test whether the RNA in this virus is infectious?
    d. What would be the observed result if it is infectious RNA?

CHAPTER 9

Bacterial Genetic Analysis and Manipulation

In 1946, a young Columbia University medical student named Joshua Lederberg took a leave of absence from his studies and joined the laboratory of Edward Tatum at Yale University. Spurred by the question of whether genetic mechanisms operated in bacteria as they did in other organisms, such as plants and animals, Lederberg had been consumed with the idea of determining whether mating and genetic exchange could occur in bacteria. Do bacteria have sex? At the time, bacteria were not recognized as having genes; the evidence for genes depended on the detection and analysis of mating events resulting in progeny whose properties could be compared to the properties of the parents. In multicellular organisms such as corn, pea, or the fruit fly, the tracking of inherited characteristics involved the simple observation of physical traits, or phenotypes, in the progeny. It was not so easy in bacteria. Different physical characteristics were not easily observed. A major breakthrough involved isolating mutants with distinctly different metabolic traits that could be observed and then used to differentiate between the progeny and the parental phenotypes.

In the laboratory, Lederberg's organism of choice was *Escherichia coli*, a common bacterial inhabitant of the human gut. He reasoned that if he were to mix two cell types showing different phenotypes and then observe progeny with characteristics from each of these two cell types, it would be evidence for a type of bacterial mating. The results of his famous experiments provided clear evidence for the ability of bacterial cells to mate. Lederberg was awarded a Ph.D. for this work and went on to an illustrious academic career at the University of Wisconsin, Stanford University, and Rockefeller University, where he served as president from 1978 to 1990. Although the phenomenon of bacterial mating was presumed initially to be similar to sexual crossing in single-celled eukaryal organisms, such as *Paramecium*, it eventually became clear that the process in bacteria was fundamentally different. Lederberg's uncovering of a genetic mechanism used by bacteria for the transfer of genes displaced the prevailing dogma of the time, that bacteria were primitive, simplistic life-forms that could not be used to investigate the genetic basis of life.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Studies of bacterial genetics and bacterial genome structures have been of fundamental importance in microbiology.

- Microbes in Focus 9.1: *Escherichia coli*

Bacterial genome and plasmid origins of replication **(Section 7.2)**

Bacterial toxin genes delivered by phage **(Section 21.4)**

Expression vectors and the production of recombinant proteins **(Section 12.2)**

Introduction

Historically, the study of bacterial genetics focused on microorganisms of practical importance. Scientists were interested mainly in bacteria that caused disease or were associated with the human body, and the bulk of bacterial genetics research was carried out on *Escherichia coli* and *Salmonella*. Researchers were also interested in bacteria used for the industrial production of compounds, like the antibiotic-producing *Streptomyces*, or bacteria that had special properties amenable to genetic study, like endospore-producing *Bacillus*. In later years, systems of genetic analysis were developed in other types of bacteria, such as *Rhizobium*, which forms nitrogen-fixing symbiotic relationships with plants, and *Pseudomonas*, some strains of which can degrade several industrial hydrocarbon contaminants, such as benzene, toluene, and xylene. Much fundamental knowledge and understanding of bacterial genetics is based on studies with such model systems.

Today, bacterial genetics is essential for the study of microbiology. Cell function is determined by gene function and gene regulation, so basic processes in bacteria are often studied at the level of the gene. In this chapter, we will follow the rich development of bacterial genetics from its birth in the mid-twentieth century to the present days of genomics. As we will see, basic research in bacterial genetics has given rise to molecular biology. By understanding the genetic mechanisms that occur naturally in bacteria, researchers have developed powerful tools for molecular biology and genetic research. We will introduce some of these genetic tools in this chapter. In the chapters that follow, we will see how microbiologists use these tools as they address the many questions of microbiology. To get started, let's consider the following questions:

Why study genetics in bacteria? (9.1)
How are mutations used in bacterial genetics? (9.2)
How is DNA cloned? (9.3)
How do bacterial cells transfer DNA? (9.4)

9.1 Bacteria as subjects of genetic research

Why study genetics in bacteria?

The study of bacterial genetics was a bit late in getting started, compared to the study of genetics in organisms like the fruit fly, corn, and pea. However, bacteria present a number of important advantages for genetics research. Each cell is a complete organism, and bacterial growth is measured by the duplication of these cells. Because bacterial cells usually grow rapidly, biomass can increase greatly in a very short time. Although cellular differentiation occurs to generate specialized cell types, such as the endospore, fruiting body, or heterocyst, these changes are relatively simple in comparison to eukaryal differentiation, and details of the processes are generally easier to study.

Bacterial genomes typically are organized in a simple fashion. Usually, bacteria contain only one complete copy of their genome and most genes occur as a single copy within the genome. This arrangement is ideal for genetic studies because a mutation in a gene will often produce a readily observable trait, or phenotype. In contrast, most eukaryal organisms have more than one copy of the genome. When a mutation occurs in one gene copy, the product of the unmutated gene copy often masks the effect of the mutation in the other gene copy. In this section, we will explore the components and organization of bacterial genomes. First, though, we will examine the origins of bacterial genetics.

The origins of bacterial genetics

In the first half of the twentieth century, the science of genetics became well established. However, genetics focused primarily on the study of multicellular organisms. Bacteria were thought to be quite different life-forms, perhaps too simple to have a system of genetic exchange. Although the genetic process of sexual exchange was understood to be an essential part of the life cycle of eukaryal organisms, a similar process had not been demonstrated in bacteria. At the time, genetic experiments with eukaryal organisms involved measuring the inheritance of phenotypes in offspring that arose following a sexual event. In bacteria, no comparable phenotypes clearly demonstrated genetic exchange in these relatively simple organisms.

Returning to our opening story of the discovery of bacterial mating, Joshua Lederberg wondered whether sexual crossing, or some similar mechanism providing for genetic exchange, occurred in bacteria. If it did occur, then how could it be demonstrated experimentally? Lederberg knew that strains of a bacterial species possess slight genetic differences that may result in measurable phenotypic differences. The transfer of genes between different bacterial strains of the same species, he hypothesized, should result in progeny that share the phenotypic characteristics of both parental strains. Lederberg designed experiments to test this hypothesis using strains of the bacterium *Escherichia coli* **(Microbes in Focus 9.1)**.

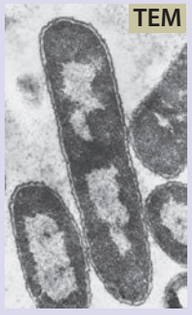
For his experiments, Lederberg used different types of *E. coli* **nutritional mutants**, strains exhibiting altered metabolic requirements. These strains, also known as auxotrophic mutants, or auxotrophs (see Section 6.2), have mutations that disrupt specific metabolic pathways, making them unable to synthesize amino acids or vitamins that are normally produced by the parental strain, a prototroph. Most natural isolates of *E. coli*, for instance, will grow on a simple defined growth

Microbes in Focus 9.1
ESCHERICHIA COLI

Habitat: Originally isolated in 1885 from soiled baby diapers. Commonly found in animal guts, water, soil, research laboratories, and industrial microbiology production facilities worldwide

Description: Gram-negative bacterium in the *Gammaproteobacteria* class of the *Proteobacteria* phylum, approximately 0.5 μm by 2.0 μm. Common member of the normal human microbiota. Some strains can be pathogenic, causing severe gastrointestinal disease and even death.

Key Features: Scientists have used *Escherichia coli* as a model organism for decades to answer many of the basic questions about life, such as the composition of genes, how genes are expressed, and how genes change over time. The first organism used in genetic engineering was *E. coli.* Although many other bacteria have been characterized, *E. coli* remains the champion of molecular biology research.



© Biophoto Associates/Science Source

medium that contains appropriate sources of carbon, nitrogen, and phosphorus, but no added vitamins or amino acids (see Section 6.1). Nutritional mutants grow only if the growth medium contains the appropriate amino acids or vitamins. For example, a methionine-negative (*met*$^-$) strain of bacteria cannot synthesize the amino acid methionine, and a proline-negative (*pro*$^-$) strain cannot synthesize the amino acid proline (Figure 9.1). The *met*$^-$ strain needs methionine but not proline to grow in the medium; this strain can be described as *met*$^-$ *pro*$^+$. The *pro*$^-$ strain requires proline but not methionine and can be described as *met*$^+$ *pro*$^-$.

If we culture two different nutritional mutants together and progeny cells result that can thrive on media lacking nutritional supplements, then we can infer that the transfer of genetic material from one mutant to the other has occurred. As an example, let's look at the two nutritional mutants just described. We could culture *met*$^-$ *pro*$^+$ and *met*$^+$ *pro*$^-$ strains of *E. coli* on growth medium lacking both methionine and proline. Any resulting growth (*met*$^+$ *pro*$^+$) would be evidence that the two parental strains had exchanged genes for synthesis of these two compounds. Lederberg developed an experiment just like this one. In performing these mating experiments, however, a problem became evident. When control cultures of the individual mutant strains were plated separately on unsupplemented media, *met*$^+$ *pro*$^+$ colonies arose. How could this occur? The parent strains spontaneously developed mutations (see Section 7.5) that allowed them to recover the ability to synthesize the missing amino acids. The frequency of this change, or **reversion**, was low, typically a frequency of one cell out of every 10^6 to 10^7 cells. If 10^8 cells were plated, then between 10 and 100 colonies per plate would appear. Thus, the reversion frequency was high enough to mask any gene transfer that might occur.

To avoid the problem described above, Lederberg used strains possessing two or three different nutritional mutations. These double and triple mutant strains would be able to grow on unsupplemented growth medium only if all of the mutations reverted. The frequency of two mutations spontaneously reverting in a single bacterial cell would be the product of both mutations reverting independently, which would be an extremely low number. Instead of a reversion frequency of 10^{-6} to 10^{-7} (10–100 colonies per plate for 10^8 cells plated), the expected reversion frequency in a double-mutant strain would be 10^{-12} to 10^{-14} (0.0001–0.00001 colonies per plate), and the reversion frequency in a triple mutant strain would be 10^{-18}

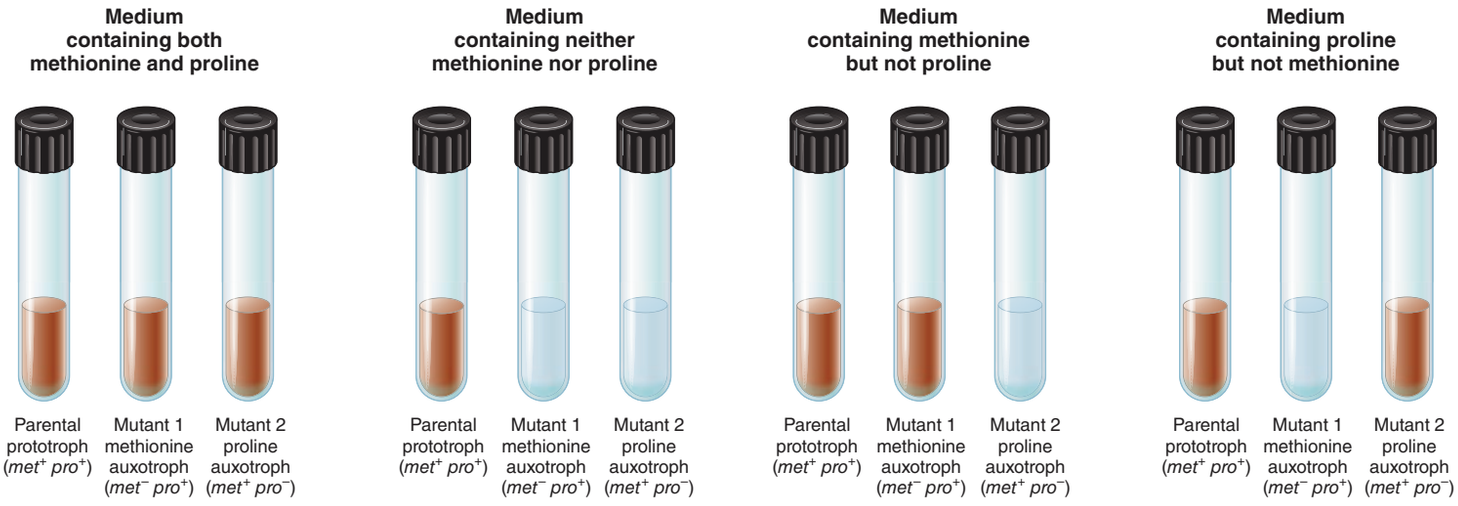


Figure 9.1. Nutritional mutants in defined media The parental prototrophic strain (*met*$^+$ *pro*$^+$) can grow in defined media without supplements. Mutants that lack the enzymes to produce a required nutrient cannot grow unless that nutrient is supplemented in the growth medium. A methionine auxotroph (*met*$^-$ *pro*$^+$) can grow in defined medium supplemented with methionine. A proline auxotroph (*met*$^+$ *pro*$^-$) can grow in defined medium supplemented with proline.

to 10^{-21} (virtually no colonies per plate). Surprisingly, when Lederberg co-cultured two triple mutant strains and plated them on unsupplemented growth medium, colonies appeared! Based on these results, he concluded that the genes required for the synthesis of the missing compounds were transferred from one cell to another. In other words, bacterial mating or gene exchange had occurred.

Lederberg still had to rule out the possibility that DNA liberated by dead cells of one of the mutant strains had been taken up by and incorporated into the genome of the other strain. Therefore, he prepared cell extracts from one strain and added them to the other strain during growth. Very few colonies arose when plated on unsupplemented medium compared to when the strains were grown together. He concluded that uptake of external DNA could not account for the higher frequency of gene transfer.

Lederberg's groundbreaking research is considered a turning point in the development of bacterial genetics as a scientific discipline. In recognition of his contributions, he shared the 1958 Nobel Prize for Physiology or Medicine with George Beadle and Edward Tatum. In the years following the discovery of bacterial mating, bacterial geneticists used this process to determine the relative positions of many genes on the genetic map of the *E. coli* chromosome. This genetic analysis, coupled with the biochemical and physiological analysis of the mutants, resulted in *E. coli* becoming the best-characterized and most intensively studied of all organisms. It paved the way for the genomics revolution.

Organization of bacterial genomes

Compared to the genomes of most eukaryal organisms, bacterial genomes are small. They are also genetically compact. In other words, most of the DNA encodes functional proteins. In contrast, a large amount of DNA typically found in eukaryal organisms does not code for any known products. Early genetic studies suggested that bacteria contain a single circular chromosome. Additionally, many bacteria carry smaller, circular DNA molecules called **plasmids** that replicate independently of the chromosome (see Figure 2.6). Generally, genes carried on the chromosome are required for the basic metabolic processes of an organism. In contrast, plasmids are generally not required for cell viability, but instead contain genes for accessory functions, such as antibiotic resistance and degradation of toxic substances (Table 9.1). Plasmids also may contain genes that allow a bacterium to infect a host cell and cause disease or establish a beneficial relationship. The **genome** is composed of all hereditary material of a bacterial cell, including both the chromosome(s) and any existing plasmid(s).

The configuration of bacterial genomes is much more diverse than originally thought. Examination of the genomes of an ever-expanding range of bacteria by molecular methods (see Chapter 10) has revealed considerable variation in genome architecture (Table 9.2). We now know, for example, that not all bacterial chromosomes are circular. *Streptomyces*, a common group of antibiotic-producing soil bacteria, possesses a linear chromosome (see Section 7.2), as does *Borrelia burgdorferi*, the causative agent of human Lyme disease (see Microbes in Focus 18.5).

TABLE 9.1 Examples of genetic factors carried by plasmids

Plasmid	Trait	Host
R1	Antibiotic resistance	*Salmonella* Paratyphi[a]
pSym	Nitrogen-fixing nodule formation on legume plant roots	*Rhizobium*
pTi	Tumor formation on plants	*Agrobacterium*
pTol	Toluene degradation	*Pseudomonas putida*
pR773	Arsenic resistance	*Escherichia coli*
pWR100	Entry into host cells	*Shigella flexneri*

[a]See Appendix C for nomenclature of *Salmonella* serovars.

Moreover, some bacterial cells contain more than one chromosome. The plant tumor-inducing bacterium *Agrobacterium tumefaciens* (see Section 12.5) contains a circular chromosome, a linear chromosome, and two large circular plasmids.

In bacteria, each chromosome and plasmid can be classified as a **replicon**, a DNA molecule that replicates from a single origin of replication. At this site, the DNA polymerase initiates DNA synthesis. In cells containing plasmids, each cell has a controlled number of plasmid molecules, known as the **copy number**. Different plasmids have characteristically different copy numbers, ranging from one to several hundred copies per cell. Because DNA polymerase synthesizes DNA at a constant rate, initiation of DNA replication controls the plasmid copy number. Mechanisms to control initiation may involve antisense RNA molecules or inhibitory proteins.

CONNECTIONS Bacterial origins of replication, including *E. coli* chromosomal *oriC*, consist of several repeats of a common DNA motif that serve as binding sites for DnaA, a DNA-binding protein that begins melting of the double helix to initiate replication **(Section 7.2)**. Other repeat sequences and AT-rich sequences may also be found in plasmid origins of replication.

TABLE 9.2 Examples of bacterial genome configurations

Bacteria	Chromosome(s)	Plasmid(s)
Vibrio cholerae	Two circular (3.0 and 1.1 Mb)	
Agrobacterium tumefaciens	One linear (2.1 Mb), one circular (2.8 Mb)	Two circular (0.45 and 0.21 Mb)
Burkholderia xenovorans	Three circular (1.5, 3.4, and 4.9 Mb)	
Borrelia burgdorferi	One circular (0.91 Mb)	Nine circular, twelve linear (0.005–0.053 Mb)
Bacillus anthracis	One circular (5.2 Mb)	Two circular (0.095 and 0.18 Mb)
Streptomyces coelicolor	One linear (8.7 Mb)	One linear (0.36 Mb) and one circular (0.03 Mb)

Mb indicates megabases.

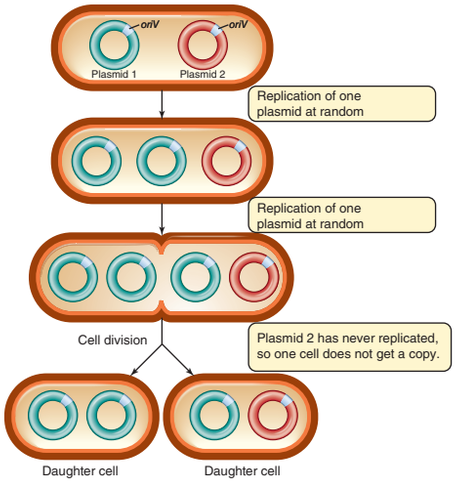

Figure 9.2. Plasmid incompatibility Plasmids that share similar control mechanisms and origins of replication are not distinguished, resulting in eventual loss of one of the plasmids from the population as the plasmids are chosen at random for replication. Plasmids 1 and 2 have a copy number of 4 at cell division. If random initiation results in unequal numbers of the two plasmids when the copy number reaches 4, then one daughter cell does not receive one of the plasmids at cell division. Descendants of the daughter cell on the left will lack plasmid 2.

Much of our understanding of plasmid replication control stems from the investigation of a phenomenon known as plasmid incompatibility. Two different plasmids are incompatible if they cannot exist stably within a population of cells. Plasmid incompatibility occurs when two different plasmids use the same control mechanisms for the initiation of replication, including similar origins of replication. In this case, the controlling machinery is interchangeable, and replication of the plasmid will be initiated at random. The two different plasmids will be treated by the replication control as a single plasmid type, resulting in the cell losing count of how many copies of each of the two plasmids exist within the cell. In these situations, one of the plasmids will always outcompete the other one. Figure 9.2, demonstrates how this random process will eventually result in the loss of one of the plasmids from the population.

Plasmid incompatibility is a consequence of this random selection process. Plasmids that cannot stably co-exist in a cell are assigned to the same incompatibility group. For two or more plasmids to exist in a cell, they must be from different incompatibility groups, using different mechanisms to control initiation of replication. Studying plasmids from different incompatibility groups has provided insights into how plasmids regulate their replication in the cell.

Bacteriophage DNA represents another source of DNA sometimes found in bacteria. The genetic material of viruses can exist for extended periods of time within host cells, either as a circular DNA molecule similar to a plasmid, or as DNA integrated into the bacterial chromosome. Both bacteriophages and plasmids play influential roles in the evolution of bacterial chromosomes by providing mechanisms for moving segments of the bacterial genome from one bacterial cell to another. We will examine some of these mechanisms in Section 9.4.

CONNECTIONS Some human pathogens, like *Clostridium botulinum*, possess toxin-encoding genes that have been delivered by phages. In **Section 21.4**, we will examine further the roles of phages, plasmids, and other vectors of DNA movement in pathogen evolution.

9.1 Fact Check

1. How do the genome arrangements of bacterial and eukaryal cells differ?
2. What are bacterial nutritional mutants, or auxotrophs? Give an example.
3. A bacterial genome typically is composed of what types of molecules?
4. What is plasmid copy number, and how is it controlled in the bacterial cell?
5. Describe what is meant by plasmid incompatibility.

9.2 Mutations, mutants, and strains

How are mutations used in bacterial genetics?

In their studies, bacterial geneticists use large numbers of genetically distinct strains of bacterial species that can be distinguished from other strains of the same species. Each strain can be traced back to a **wild-type strain**, which usually possesses the typical or representative characteristics of the species. In some cases, the wild-type strain may be the original isolate from nature. In other cases, the wild-type strain may be the common laboratory strain from which all of the mutants in a particular study have been derived. For example, *Escherichia coli* K12, isolated from human feces in 1922, is the wild-type strain from which most strains of *E. coli* used in molecular biology have been derived. The most commonly studied wild-type strain of the symbiotic nitrogen-fixing bacterium *Sinorhizobium meliloti* is an antibiotic-resistant derivative of an isolate from an alfalfa root nodule (see Microbes in Focus 13.2). These strains and their mutant derivatives have been cataloged and archived in freezers or in a freeze-dried state in individual research laboratories and in central strain collections. Advances in genetics research require access to and sharing of defined strains by scientists from around the world.

In this section, we will first review basic concepts of mutants and mutations. We will then explore how researchers detect and isolate specific mutants. Next, we will examine how mutations lead to evolution in the laboratory. Finally, we will look briefly at how mutations arise.

C. Carbon utilization mutant phenotype

Figure 9.3. Mutation and phenotype Some mutations cause easily detectable changes in phenotype, as demonstrated by these *Sinorhizobium meliloti* mutants. **A.** A mutant that overproduces exopolysaccharide is far more mucoid than the parental strain. **B.** An auxotrophic mutant is unable to grow on defined growth medium. **C.** A mutant that is unable to hydrolyze a sugar is white on media containing a chromogenic substrate, compared to the blue-green colonies of the parental strain.

Mutants and mutations

The words mutant and mutation appear similar, but the terms are not interchangeable. Mutant refers to a cell or strain possessing a mutation, or a change in its DNA sequence relative to the comparable sequence in the wild-type strain. Change that occurs within the DNA of a mutated gene results in a different **allele** or form of the gene, and in some cases disrupts or changes the function of the gene (see Section 7.5). Mutations may result in loss of gene function, the regaining of function of a previously mutated gene, or modification of gene function, often resulting in a phenotypic change **(Figure 9.3)**. Although mutations arise spontaneously due to errors in DNA replication that are not repaired successfully, bacterial geneticists take advantage of the known mutagenic properties of ultraviolet (UV) light and certain DNA-damaging chemicals to increase the rate of mutation so that fewer colonies must be screened to identify mutations with a desired phenotype.

Researchers use precise genetic terminology to describe strains of bacteria used in the laboratory. Genes are given a three-letter, lowercase, italicized name, often reflective of the associated phenotype. When more than one gene is involved in the same biochemical process, then the different genes are distinguished from each other by adding an uppercase, italicized letter to the designation. We differentiate genes from gene products by changing the italicization and capitalization. For example, the gene *hisC* produces the enzyme HisC. Some gene products have more specific names to describe their biochemical function. HisC is also called by its enzyme name, histidinol phosphate aminotransferase.

The **genotype** describes the alleles within an organism. Because it would be impractical to list each of the alleles in a given organism (*E. coli* has about 4,300 genes, *Streptomyces coelicolor* has about 7,800 genes), we generally describe only the alleles that differ from the alleles of the wild-type parental strain. For example, the alleles of a nutritional mutant strain that contains a disrupted *hisC* would be identical to the alleles of the wild-type organism, except that it does not contain a functional *hisC* gene. So, what is the observable phenotype of this organism? Because HisC is involved in the biosynthesis of histidine, and its function is disrupted, the observable phenotype will be an inability to make histidine. This cell will only grow if histidine is provided, and so will not grow on defined media without supplemental histidine. We can easily differentiate such auxotroph from the prototrophs and then characterize them **(Toolbox 9.1)**. Much of our understanding of biochemical pathways has come from studying auxotrophs.

Detection of mutants

Auxotrophs represent just one example of bacterial mutants useful for investigating biological processes. The study of other phenotypes can be equally as useful. Some examples of other phenotypes are antibiotic resistance, exopolysaccharide capsules involved in virulence, pigment production resulting in colony color, and motility due to the action of flagella. Mutants exhibiting changes in all of these phenotypes can be isolated and studied.

To isolate phenotypic mutants, researchers must be able to quickly and easily detect cells displaying the desired phenotype. Phenotypic selection represents one method of detecting potentially rare mutants **(Figure 9.4)**. This process involves plating bacteria on a selective growth medium that allows only strains with a particular combination of phenotypic characteristics to grow and form a colony. For example, to isolate an antibiotic-resistant mutant from a culture, cells can be plated on media containing the antibiotic. Only the antibiotic-resistant mutants will survive and form colonies. Selection is usually restricted to retrieving mutants with phenotypes that are distinguished by ability to grow or not under specific cultivation conditions. For example, high temperature growth, antibiotic resistance, or phage resistance, would all be suitable for phenotypic selection.

Toolbox 9.1
ISOLATING NUTRITIONAL MUTANTS

As we saw in Section 6.1, many microorganisms have fairly simple nutritional requirements and grow well on defined media containing a source of carbon, nitrogen, phosphorus, and simple salts, without added amino acids or vitamins. Various biochemical pathways enable the microorganisms to synthesize these necessary molecules. The isolation and characterization of auxotrophic mutants helped microbiologists understand these biochemical pathways. These mutants can be used to map the location of genes on the chromosome, and to isolate the wild-type version of the genes for study.

How do investigators isolate auxotrophic mutants? Mutations arise spontaneously, but at a rate far too low for a researcher to reliably isolate mutants with specific phenotypes. Fortunately, we can increase the mutation rate by treating the cells with DNA-damaging chemicals like ethane methanesulfonate (EMS) or nitrosoguanidine (NTG), or with DNA-damaging radiation like ultraviolet (UV) light **(Figure B9.1)**. Auxotrophic mutants can be identified from a population of mutagenized cells. Because auxotrophs cannot grow without a specific nutrient, this identification presents a challenge. Replica plating (see Figure 9.6) overcomes this problem **(Table B9.1)**.

Even with the development of efficient screening methods, isolation of a collection of auxotrophs can be rather tedious. To address this, an auxotroph enrichment strategy called penicillin enrichment was devised. This enrichment is based on the fact that penicillin specifically kills growing cells, as it disrupts formation of peptidoglycan linkages in the cell wall. It is therefore not lethal to cells that are unable to grow when lacking a nutrient that they require. Following mutagenesis, the culture of mutated cells is grown in defined media containing penicillin, but without the nutrient. The penicillin will kill those cells that are able to grow under these conditions, while the auxotrophs will be unable to grow and will therefore not be killed. Subculture into defined media lacking penicillin but containing the nutrient will allow the desired mutants to grow and increase their numbers within the population. Typically, the cycle is repeated a few times, resulting in an overall enrichment of the desired auxotroph type in the population. This method became a widespread technique for isolation of many of the auxotrophic mutations that have been used in bacterial genetics. As Gram-negative bacteria have an outer membrane that inhibits entry of penicillin into the periplasm, increased concentrations of penicillin are used to sufficiently inhibit their growth

Test Your Understanding

Imagine that you have generated what you believe to be a leucine auxotroph. What media would you use to confirm that this mutant is indeed auxotrophic for leucine? Explain the results you would expect on the chosen media.

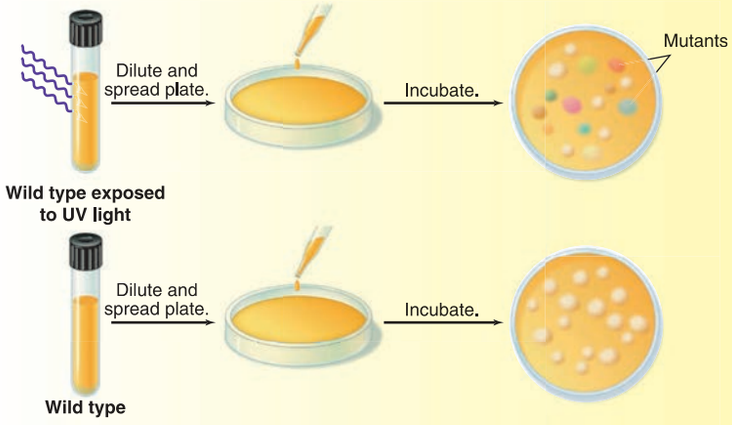

Figure B9.1. Using mutagenesis to increase mutation rates
Cells can be exposed to various mutagens, like UV light, to increase the mutation rate. Following mutagenesis, the culture is diluted appropriately so that spread plating gives rise to single colonies. If there is no mutagenesis, mutants are very rare.

TABLE B9.1 Examples of selection and screening for auxotrophs

Wild-type phenotype	Mutant phenotype	Screen	Selection
Pro–	Pro+	Not applicable	Defined medium lacking proline. All colonies are mutants.
Pro+	Pro–	Replica plates: first, one lacking proline, then one with proline. Collect colonies appearing only on plates containing proline.	Not applicable
Leu–	Leu+	Not applicable	Defined medium lacking leucine. All colonies are mutants.
Leu+	Leu–	Replica plates: first, one lacking leucine, then one with leucine. Collect colonies appearing only on plates containing leucine.	Not applicable

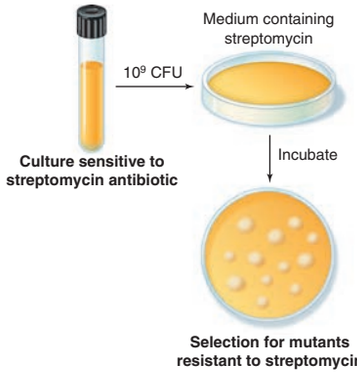

Figure 9.4. Phenotypic selection Very rare events can be detected more efficiently using selection methods. In this example, 10^9 colony-forming units (CFU) from a culture of a streptomycin-sensitive strain are plated on agar medium containing streptomycin. Most of the cells cannot grow, but if a cell contains a mutation conferring streptomycin resistance, then it will form a colony.

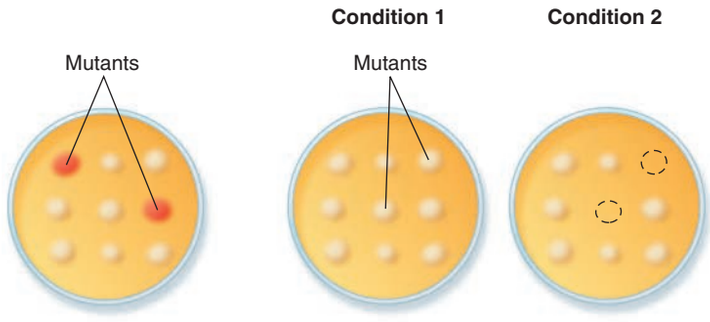

Figure 9.5. Phenotypic screening Phenotypic screening can detect certain mutants. Colonies from a culture that has undergone mutagenesis can be screened on agar plates. **A.** If colonies of mutant cells look different from colonies of wild-type cells, then they can be retrieved directly from the screening plate. **B.** Colonies may be inoculated onto two different types of plates, such as Condition 1, containing complex medium, and Condition 2, containing defined medium with no supplements. Some mutants may be unable to form colonies under Condition 2, but can be retrieved from the Condition 1 screening plate.

The process of screening can also be used to detect mutants (Figure 9.5). Screening does not prevent the growth of cells with the wild-type phenotype, but instead all cells form colonies under the tested conditions. Colonies with the desired phenotype, such as a different colony color, must then be identified by the investigator. Screening is usually less efficient than selection because large numbers of colonies must be screened to find the mutant with the rare phenotype. Screening is usually necessary for recovering mutants for which there are no identified conditions under which they can grow, but the parental strain cannot grow. For example, non-motility, pigment production, or antibiotic sensitivity mutations would be limited to phenotypic screening.

Microbial geneticists frequently employ **replica plating** to screen colonies for phenotypes that cannot be identified by phenotypic selection. In replica plating, colonies are lifted from one plate using a piece of sterile velvet cloth and then deposited onto a fresh plate (Figure 9.6).

Alternatively, some scientists prefer a process in which sterile toothpicks are used to transfer individual colonies to the different types of test plates. Numbered grid templates for the plates are used to keep track of where individual colonies are patched (Figure 9.7). This technique allows more precision than the velvet method and more reproducible results. With a little practice and dedication, researchers can screen several thousand colonies using patching in a single day of work. Indeed, toothpicks and grid templates may be among the most important tools in the bacterial genetics laboratory! More recently, robotic systems have been developed that allow much higher rates of screening, on the order of tens of thousands of colonies per day.

To better understand the usefulness of replica plating, let's investigate the isolation of auxotrophic mutants that cannot synthesize arginine. Following treatment of cells with a mutagen, colonies are first grown on plates containing arginine to ensure the mutants will grow. These colonies can then be replica-plated onto medium not supplemented with arginine. The two plates can then be compared. Any colonies that appeared on the first plate, but not on the second, would be arginine auxotrophs. The selection and screening protocols used for isolating bacterial mutants provided the first crucial insights into adaptation and evolution. We'll investigate this topic next.

Evolution in a test tube

People often perceive mutations as negative changes in the genetic material that have detrimental outcomes, such as genetic diseases. Even though mutations can result in diseases, they can also be beneficial. Indeed, mutations ensure the vitality of all life on Earth. The genetic material in all organisms, including microbes, is constantly changing or mutating. These changes provide the raw material upon which environmental pressures act, continually selecting for those organisms with the most successful life strategies. Consider bacteria. Each bacterial cell is a

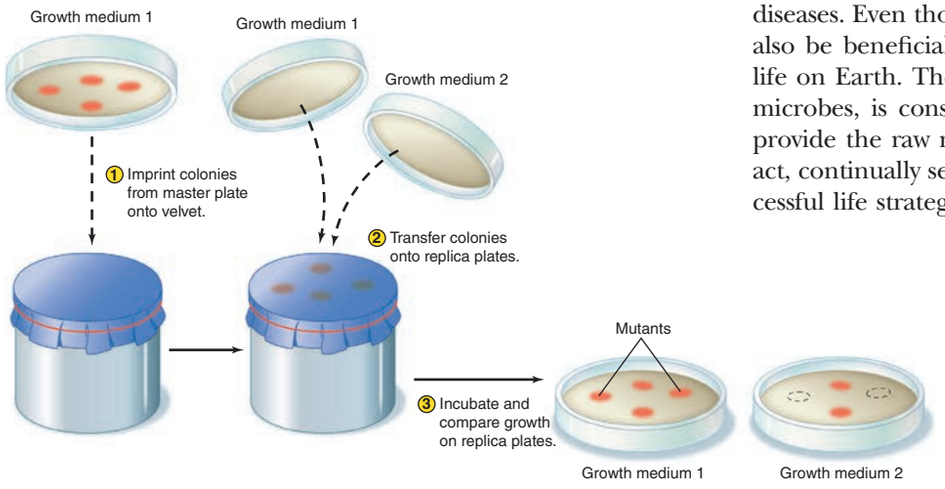

Figure 9.6. Process Diagram: Replica plating Using sterile velvet, researchers simultaneously transfer all of the colonies from an original master plate onto a plate containing defined medium lacking a specific nutrient (Growth medium 2), as well as a control plate that is the same as the master plate (Growth medium 1). By comparing the growth on the defined medium with the growth on the master plate, auxotrophic mutants can be identified and isolated.

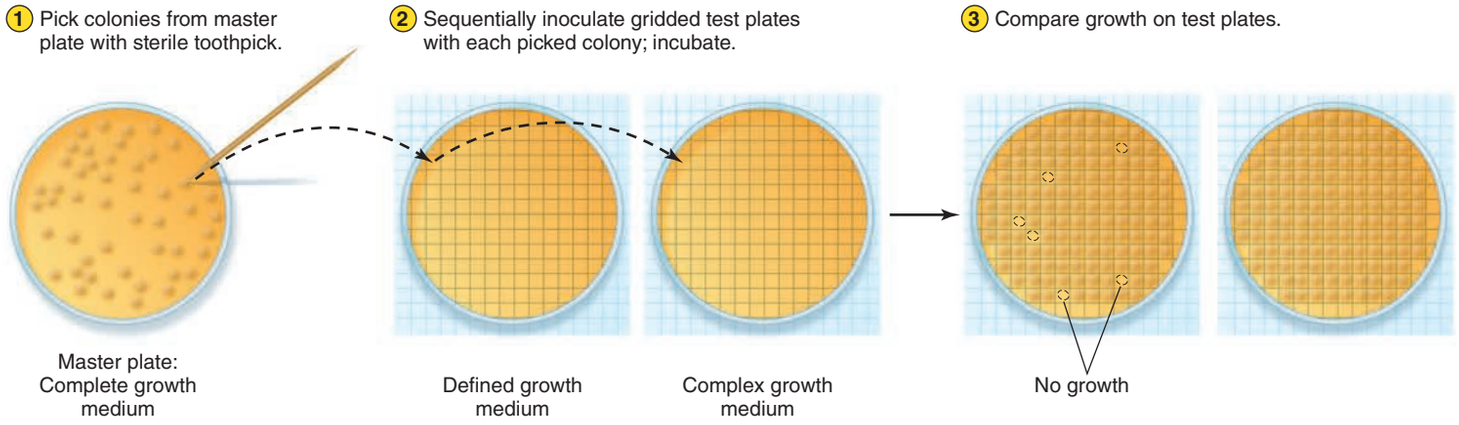

Figure 9.7. Process Diagram: Replica plating using patching Sterile plates are placed agar-side-down on a numbered paper grid and sequentially inoculated with toothpicks, each of which has stabbed a single colony growing on a master plate. This master plate contains colonies plated from a mutagenized culture growing on complex medium. The colonies are transferred to a set of defined growth medium and complex growth medium plates. Those colonies that do not grow on the defined medium plates, but do grow on the complex medium plates, are potential auxotrophic mutants.

complete organism, and bacterial colonies are composed of millions of genetically identical organisms, or **clones**, each of which originated from a single cell. Mutations arising within a single cell in a population of bacteria will be passed on to its progeny. If the mutation confers an advantage to those cells, then the progeny will be able to outcompete cells that lack the mutation, and their representation within the population will increase.

Biology is rooted in the process of evolution by natural selection, for which we have much evidence, including the fossil record and comparative DNA sequence analysis. Although this evidence is compelling, wouldn't it be satisfying to observe evolution in progress? Scientists can, in fact, demonstrate the evolutionary consequences of mutations experimentally by using a microbial system. On February 15, 1988, Richard Lenski established 12 parallel cultures of *E. coli* in defined growth media with glucose as the carbon source. These cultures were subcultured once per day into fresh growth media. Every 75 days, aliquots were removed and frozen for later analysis. After 10,000 generations over about 1,500 days, cell size and survivability of the evolved populations were compared with these same properties in the ancestral cells, which had been prevented from evolving by keeping them in a frozen, non-growing state. Both cell size and survivability, or fitness, increased in the evolved cultures **(Figure 9.8)**.

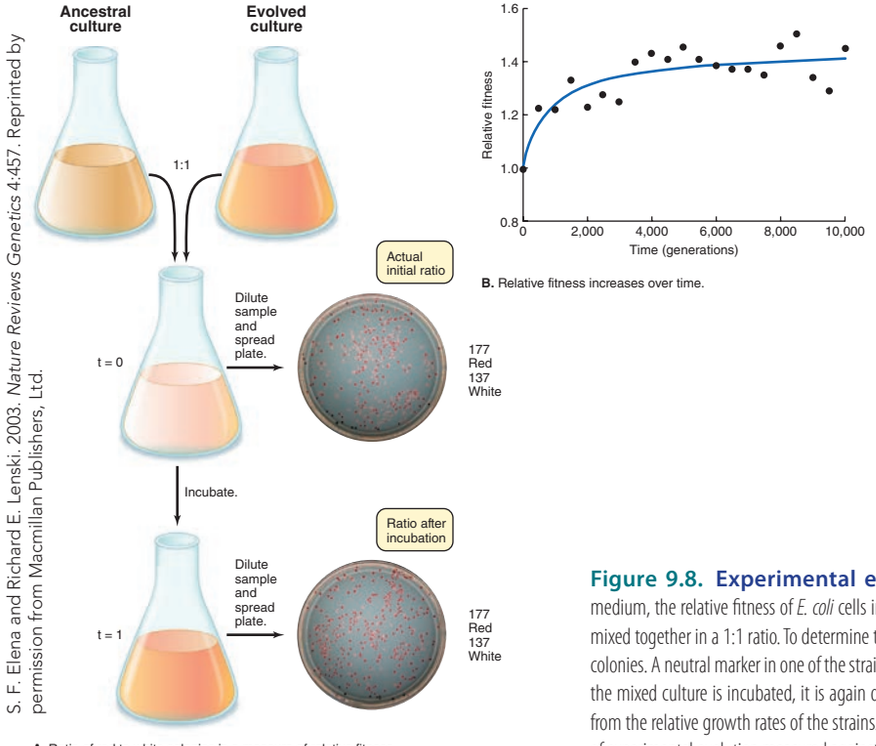

Figure 9.8. Experimental evolution of *E. coli* When subcultured repeatedly in growth medium, the relative fitness of *E. coli* cells increases. **A.** Ancestral and evolved cultures are grown separately, then mixed together in a 1:1 ratio. To determine the actual initial ratios, the mixed culture is diluted and plated for single colonies. A neutral marker in one of the strains allows the two strains to be easily differentiated by colony color. After the mixed culture is incubated, it is again diluted and plated for single colonies. The relative fitness is determined from the relative growth rates of the strains. **B.** Relative fitness in a population of *E. coli* during 10,000 generations of experimental evolution measured against the ancestral strain.

Some of these fitness gains resulted from mutations in genes involved in the cellular stress response. Presumably, these mutations allowed the cells to survive the stresses of growing under laboratory culture conditions. Similar studies have demonstrated that fitness gains are usually specific to given environmental conditions. In other words, a population that has evolved under certain culture conditions will exhibit enhanced fitness under those conditions, but not necessarily under different conditions. These straightforward but carefully conducted experiments showed that it is possible to demonstrate evolutionary processes as a result of mutations in a microbial experimental system. The subculturing continues, and the project, dubbed the Long-Term Evolution Experiment (LTEE), has inspired a number of other studies in experimental evolution that seek to understand the genetic mechanisms by which populations adapt to their environment over the long term. Unsurprisingly, after over 25 years and more than 60,000 generations, this collection of 12 independently evolving cultures continues to be a valuable resource for the study of evolution.

Mutations and selection

Let's now consider how mutations arise in the first place. Do mutations occur in response to selective environmental conditions experienced by the cell, or do they occur spontaneously even in the absence of selective conditions? Scientists observed that if a culture of *E. coli* grows in the presence of an antibiotic such as streptomycin, a few resistant variants appear. When these cells are then grown in the absence of streptomycin, these variants retained their streptomycin resistance phenotype. Was the interaction between the antibiotic and the bacterial cell required to cause the mutation producing streptomycin resistance? A key experiment to answer this question was performed in the early 1950s by Esther Lederberg, who was married to Joshua Lederberg at the time.

Esther Lederberg wanted to know whether streptomycin-resistant mutations arise spontaneously in the absence of selective pressure from the antibiotic streptomycin. She first spread a culture of *E. coli* on an agar plate that did not contain streptomycin **(Figure 9.9)**. Then she used replica plating to transfer these bacteria to an agar plate containing streptomycin. After overnight incubation, only a few colonies were visible on the streptomycin plate.

Lederberg then removed bacterial cells from precisely the region of the antibiotic-*free* plate that corresponded to the regions in which the colonies were growing on the antibiotic-*containing* plate. Because these cell samples were removed from a lawn, they contained a mixture of cells, but Esther Lederberg suspected somewhere in this mix were mutant cells that were resistant to streptomycin. She added these cells to medium containing streptomycin. She also removed bacterial cells from the antibiotic-free plate from a region distant from the areas corresponding to the streptomycin-resistant colonies. She added these cells to medium containing streptomycin. After incubating these samples, she observed that the cells from the region of the antibiotic-free plate corresponding to the streptomycin-resistant colony grew in the presence of streptomycin,

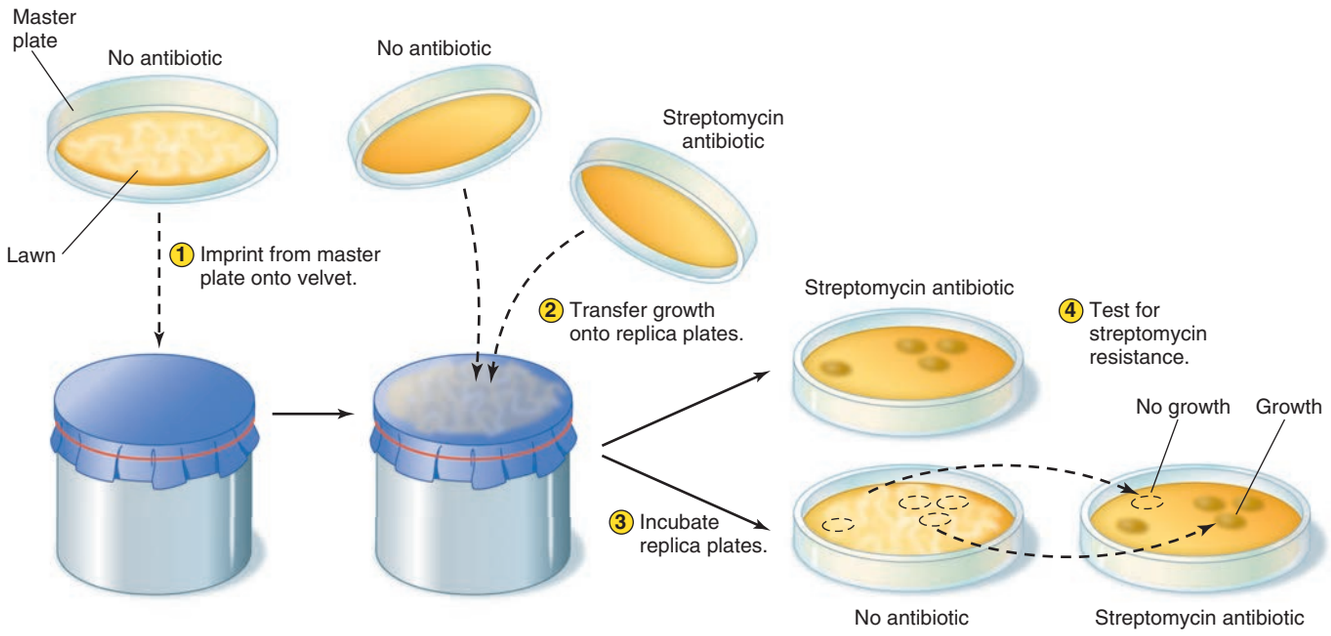

Figure 9.9. Process Diagram: Replica plating to determine if mutations arise spontaneously Esther Lederberg demonstrated that streptomycin-resistant mutations arise spontaneously in the absence of selective pressure from the antibiotic streptomycin. Cells from a master plate were replica-plated on solid medium containing streptomycin and also on another plate containing no antibiotic. Some streptomycin-resistant colonies grew on the streptomycin plate. Cells from the antibiotic-lacking plate corresponding to the location of the resistant colonies grew on plates containing streptomycin, indicating that the mutations existed before exposure to the selective agent.

Figure 9.10. The fluctuation test To determine if mutations occur randomly in the absence of selective pressure, Luria and Delbrück grew phage T1-sensitive *E. coli* in a large volume and plated aliquots on agar medium containing phage T1. They also grew many small cultures of T1-sensitive *E. coli* and plated aliquots from each culture on agar containing T1 phage. Whereas most aliquots from the single, large culture contained similar numbers of phage-resistant bacteria, the number of resistant bacteria varied widely in the small cultures.

whereas the cells from a distant region of the plate did not. From this result, she concluded that mutations can occur in the absence of selective pressure.

Although Esther Lederberg's mutation experiments were convincing, Salvador Luria and Max Delbrück used another approach to investigate whether mutations originate randomly and spontaneously, without regard to selective pressure. They investigated the generation of resistance in *E. coli* to infection with the bacteriophage T1 **(Figure 9.10)**. They reasoned that each random spontaneous mutation imparting phage resistance in a culture would be passed on to the progeny of the cells in which the original mutation occurred. If the mutation occurred early in the growth of the culture, then more progeny containing the mutation would be found in the culture than if the mutation occurred later in the culture.

Luria and Delbrück's experiment, which they called the fluctuation test, compared the frequency of phage resistance arising in independent cultures of *E. coli*. They removed aliquots from several individual cultures and applied these *E. coli* aliquots to agar plates along with bacteriophage. They predicted that random mutations occurring at different times in different cultures would result in different numbers of resistant colonies on the plates, related to how early the mutations occurred in the original culture. When they conducted this experiment, they observed a large variance in the numbers of phage-resistant colonies on the plates from the individual cultures. As a control, a single large culture of cells was grown from initially non-resistant cells, and aliquots from this single culture were applied to several agar plates and subjected to phage challenge. Because the progeny of any phage-resistant mutants would be distributed throughout this culture, they hypothesized that similar numbers of resistant colonies would appear on the different plates. Their results confirmed this hypothesis. Like Esther Lederberg, Luria and Delbrück demonstrated that mutations occur spontaneously and randomly in the absence of selective pressure. The application of high-throughput DNA sequencing methods, which we will describe in Chapter 10, has made it possible to detect extensive rearrangements of chromosomal DNA and provided confirmation that spontaneous mutations accumulate steadily over time.

9.2 Fact Check

1. What is a wild-type strain?
2. Describe how mutant genes and proteins are named.
3. Explain the processes of selection and screening.
4. What is replica plating, and how was it used to show that antibiotic-resistant mutants arise in the absence of selection pressure?

9.3 Restriction enzymes, vectors, and cloning

How is DNA cloned?

As we saw in Section 7.1, Avery, MacLeod, and McCarty experimentally showed DNA to be the heritable material in 1944. By the 1960s, researchers extracted DNA routinely from cells and viruses. Soon after, researchers demonstrated that DNA ligase, an enzyme extracted from *Escherichia coli* infected with T4 phage, could join together DNA fragments. Then, in 1973, investigators used restriction enzymes, first isolated in 1970, to construct the first recombinant plasmid. DNA cloning was born. In this section, we will explore this remarkable achievement. Specifically, we will discuss restriction enzymes and vectors, which have been very important tools in the development of new bacterial genetics techniques.

Restriction enzymes

To create recombinant DNA molecules, researchers must be able to cleave and stitch together pieces of DNA very precisely. The discovery of **restriction enzymes**, bacterial proteins that cleave DNA at specific sequences, allowed microbiologists to fulfill both of these needs. Their *in vitro* use led to the development of molecular biology. Here, we will briefly examine how these enzymes function. We will also investigate their role in molecular biology.

Each restriction enzyme recognizes a specific, short DNA sequence, usually of 4, 6, or 8 base pairs, called a **restriction site**. Because they cut at these precise positions in DNA, restriction enzymes can be thought of as molecular scissors. At these sites, the enzymes make double-stranded cuts, typically generating fragments with single-stranded overhangs called sticky or cohesive ends (Table 9.3). These sticky ends are valuable in making **recombinant DNA**, or DNA generated in the laboratory that does not exist naturally. Note that the name of a restriction enzyme reflects its source. The first letter reflects the genus, the second and third letters reflect the species, and the fourth letter reflects the strain. The Roman numeral refers to its order of isolation from that strain.

TABLE 9.3 Properties of selected restriction enzymes

Restriction enzyme	Source	Restriction site	Cleavage result	
EcoRI	*Escherichia coli*	5′-GAATTC-3′ 3′-CTTAAG-5′	5′-G 3′-CTTAA	AATTC-3′ G-5′
BamHI	*Bacillus amyloliquefaciens*	5′-GGATCC-3′ 3′-CCTAGG-5′	5′-G 3′-CCTAG	GATCC-3′ G-5′
HindIII	*Haemophilus influenzae*	5′-AAGCTT-3′ 3-TTCGAA-5′	5′-A 3′-TTCGA	AGCTT-3′ A-5′
SmaI	*Serratia marcescens*	5′-CCCGGG-3′ 3′-GGGCCC-5′	5′-CCC 3′-GGG	GGG-3′ CCC-5′

Notice in Table 9.3 that the two strands of DNA at restriction sites have the same sequence of bases if both are read in a 5′ to 3′ direction. In other words, the sequences are identical if one strand is read from left to right and the other strand is read from right to left; they are palindromes. Two fragments of DNA that have been cut with the same restriction enzyme, EcoRI, for example, will have single-stranded ends that can anneal with one another (Figure 9.11). The enzyme **DNA ligase** is then added to re-form the phosphodiester bonds between adjacent 5′ phosphate groups and 3′ hydroxyl ends. Blunt-ended fragments, produced by restriction enzymes such as SmaI, can join to any other DNA fragment with blunt ends. Because the ends do not anneal by base-pairing, the sequence of these ends does not matter; any blunt-ended fragments can be joined.

CONNECTIONS The natural function of restriction enzymes is to protect the cell from bacteriophage infection by cleaving introduced foreign DNA, as described in **Section 18.2**. Another bacterial anti-viral defense mechanism called CRISPR-Cas has recently been developed into a powerful genome editing tool, as described in **Perspective 18.1** and **Section 12.2**. These are two great examples of the modification of naturally occurring biological systems for use in molecular biology applications.

Cloning vectors

As we have just seen, restriction enzymes allow researchers to cleave DNA at specific sites and then join together the resulting DNA fragments, thereby creating recombinant DNA molecules. To replicate these recombinant molecules, a process referred to as **molecular cloning** or **DNA cloning**, researchers generally insert the exogenous DNA into a **cloning vector**, a DNA molecule that can be genetically manipulated and replicates within cells. Although many different types of cloning vectors have been developed, plasmids, phages, and cosmids have been used most extensively for DNA cloning. Here, we will examine more thoroughly the usefulness of these entities as cloning vectors. In Section 9.4, we will see how we can use DNA cloned in vectors to mutate specific genes.

Plasmid-Cloning Vectors

Stanley Cohen and colleagues at Stanford University ushered in the age of molecular biology when they performed one of the first DNA-cloning experiments using restriction enzymes and plasmids (Figure 9.12). They began by cleaving a tetracycline-resistant plasmid, pSC101 (named using the initials of the scientist Stanley Cohen), with the restriction enzyme EcoRI. Because this plasmid contained a single EcoRI restriction site (5′-GAATTC-3′), the plasmid became linear following cleavage. Another plasmid, pSC102, conferred resistance to the antibiotic kanamycin and yielded three different fragments when digested with EcoRI, indicating that it contained three

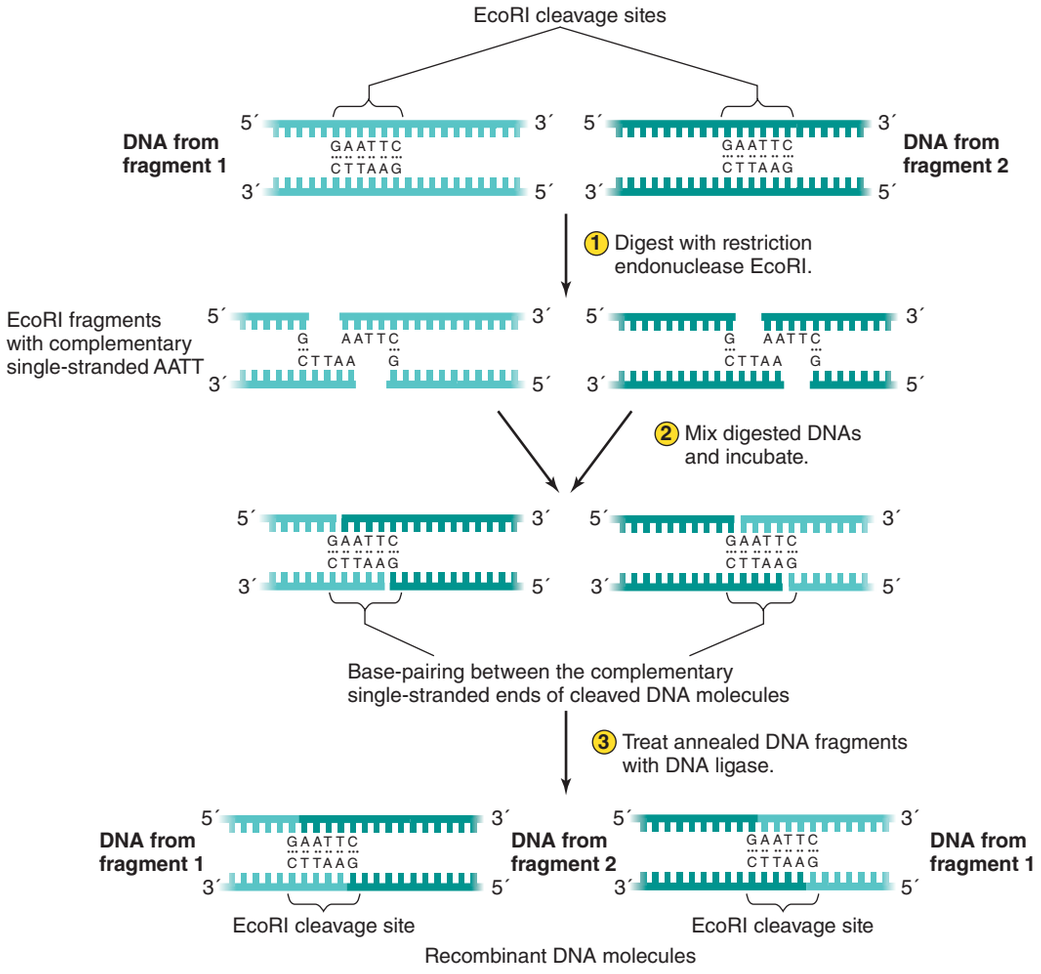

Figure 9.11. Annealing and ligation of sticky ends Sticky ends created by a restriction enzyme are complementary. When fragments generated by the same restriction enzyme are mixed, the sticky ends can anneal. DNA ligase then covalently joins the fragments, creating an intact and double-stranded DNA molecule.

Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

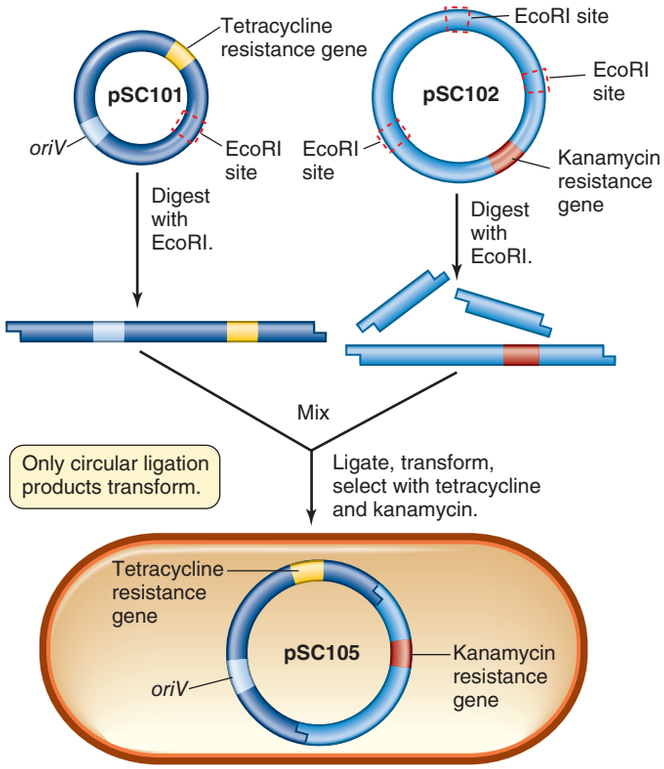

Figure 9.12. The first plasmid-cloning experiment Using digestion with the restriction enzyme EcoRI followed by treatment with the enzyme DNA ligase, Cohen and colleagues combined fragments of pSC101 and pSC102, constructing a new plasmid, pSC105. They then inserted this recombinant DNA into *E. coli*.

EcoRI restriction sites. Researchers combined the restriction fragments of these two plasmids, treated the resulting mixture with DNA ligase, and then introduced the DNA into *E. coli* cells. Cells exhibiting resistance to both tetracycline and kanamycin, they reasoned, received a recombinant plasmid that contained the tetracycline resistance gene from pSC101 and the kanamycin resistance gene from pSC102. The researchers then isolated this recombinant plasmid, which they named pSC105, from these doubly resistant cells. The age of molecular biology was born. Recombinant plasmids have been important tools for genomics and biotechnology, which we will cover in Chapter 10 and Chapter 12, respectively.

One of the first widely used cloning vectors was pBR322 **(Figure 9.13)**. This relatively small plasmid (4,361 base pairs) has unique restriction sites that can be used for inserting fragments of DNA following cleavage with the corresponding restriction enzymes. It also has two different antibiotic resistance genes, one for ampicillin resistance and one for tetracycline resistance. Both of these antibiotic resistance genes contain restriction sites within them.

Let's use this plasmid to illustrate a typical cloning experiment. Suppose we want to clone, or create many copies of the α-amylase gene from a starch-degrading *Bacillus* sp. From previous work, we know that this gene is flanked by BamHI restriction sites in the *Bacillus* genome, but does not contain an internal BamHI restriction site. In pBR322, a single BamHI site exists within the tetracycline resistance gene **(Figure 9.14)**. To insert the α-amylase gene into pBR322, we first can cleave the plasmid with BamHI so that it is cut within the tetracycline resistance gene

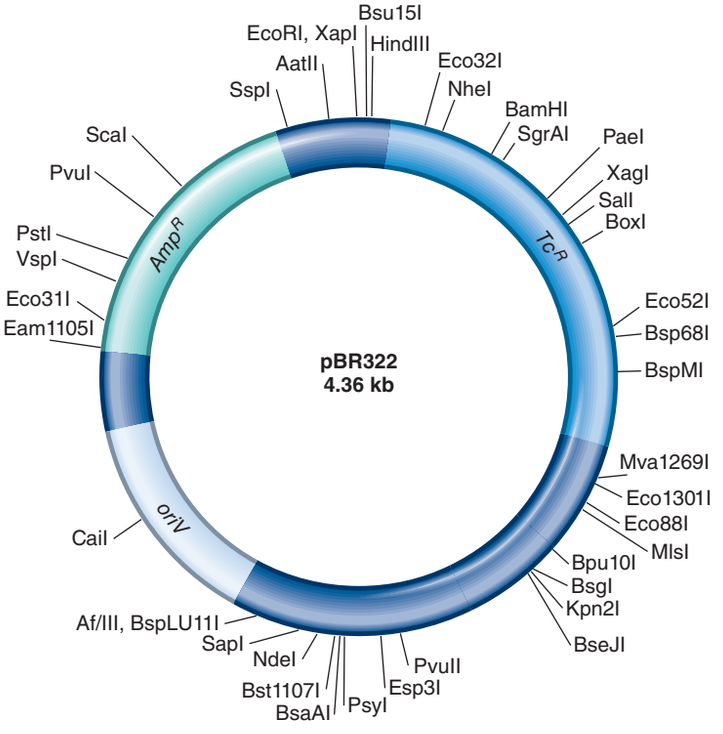

Figure 9.13. The cloning vector pBR322 This plasmid contains several restriction sites for cloning and ampicillin (*Amp*^{R}) and tetracycline (*Tc*^{R}) resistance genes. The *oriV* site indicates the origin of replication. Unique restriction sites exist within the antibiotic resistance genes. Many plasmid vectors used in molecular biology for routine cloning and for production of recombinant proteins are derived from this plasmid.

and becomes a single linear DNA molecule. We can then digest the genomic DNA of the *Bacillus* sp. with this same restriction enzyme, releasing thousands of DNA fragments, each of which contains BamHI sticky ends. These *Bacillus* DNA fragments are combined with the linearized vector DNA, and the mixture is treated with the enzyme DNA ligase to covalently combine pieces of DNA that had joined together by complementary base-pairing. A large number of possible molecules can form by this joining process. Some molecules will be linear, others will be circular, and some will contain multiple pieces of DNA joined together. Many molecules will be made up of the vector alone, re-formed after its two ends have ligated together.

Out of all these molecules that may form, how can we select the one type that interests us: recombinant pBR322 that now contains the α-amylase gene? We can start by adding the mixture of molecules to *E. coli* cells and plating these cells on medium that contains ampicillin. To grow on this medium, cells must express the ampicillin resistance gene present on the pBR322 plasmid DNA. Moreover, the added DNA must be able to replicate within these cells. Only circular plasmid molecules that contain an origin of replication will replicate; fragments of DNA and circular molecules lacking an origin of replication will be degraded and/or lost from the cells. By simply plating our cells on medium containing ampicillin, we can identify cells that have received a functioning plasmid (see Figure 9.14). However, not all circular molecules formed will contain DNA fragments from the *Bacillus*. How can we distinguish between recircularized and recombinant pBR322 molecules? Recircularized pBR322 molecules will contain an intact tetracycline resistance gene. In recombinant molecules, this gene will be disrupted and non-functional. Ampicillin-resistant cells could be screened by replica plating for tetracycline sensitivity. Cells that exhibit resistance to ampicillin, but sensitivity to tetracycline, contain a recombinant pBR322 plasmid in which a DNA fragment has been inserted into the BamHI site.

CONNECTIONS When the genome of an organism is cleaved with a restriction enzyme, all resulting fragments can be ligated into copies of a plasmid cleaved with the same restriction enzyme. A collection of recombinant plasmids, then, could contain all segments of the foreign genome. The generation and use of such genomic libraries will be discussed in **Section 10.2**.

We now have one last challenge. We must identify the recombinant plasmid that contains our gene of interest: the α-amylase gene. To achieve this goal, we can use a functional screen. We can screen each of the ampicillin-resistant, tetracycline-sensitive colonies for the ability to hydrolyze starch, the function of α-amylase. A simple assay using iodine reveals this activity (see Figure 9.14). Although *E. coli* itself possesses a gene encoding α-amylase, it has very low levels of enzyme activity. Cells that exhibit a high level of α-amylase activity contain a plasmid with our gene of interest. Often, DNA sequencing is used to confirm the presence of the gene of interest when there is no convenient functional or phenotypic screen to use for confirmation.

In this example, we were fortunate. The α-amylase gene existed on a single BamHI fragment, and pBR322 has a single BamHI restriction site within its tetracycline resistance gene. Suppose restriction sites for a different restriction enzyme

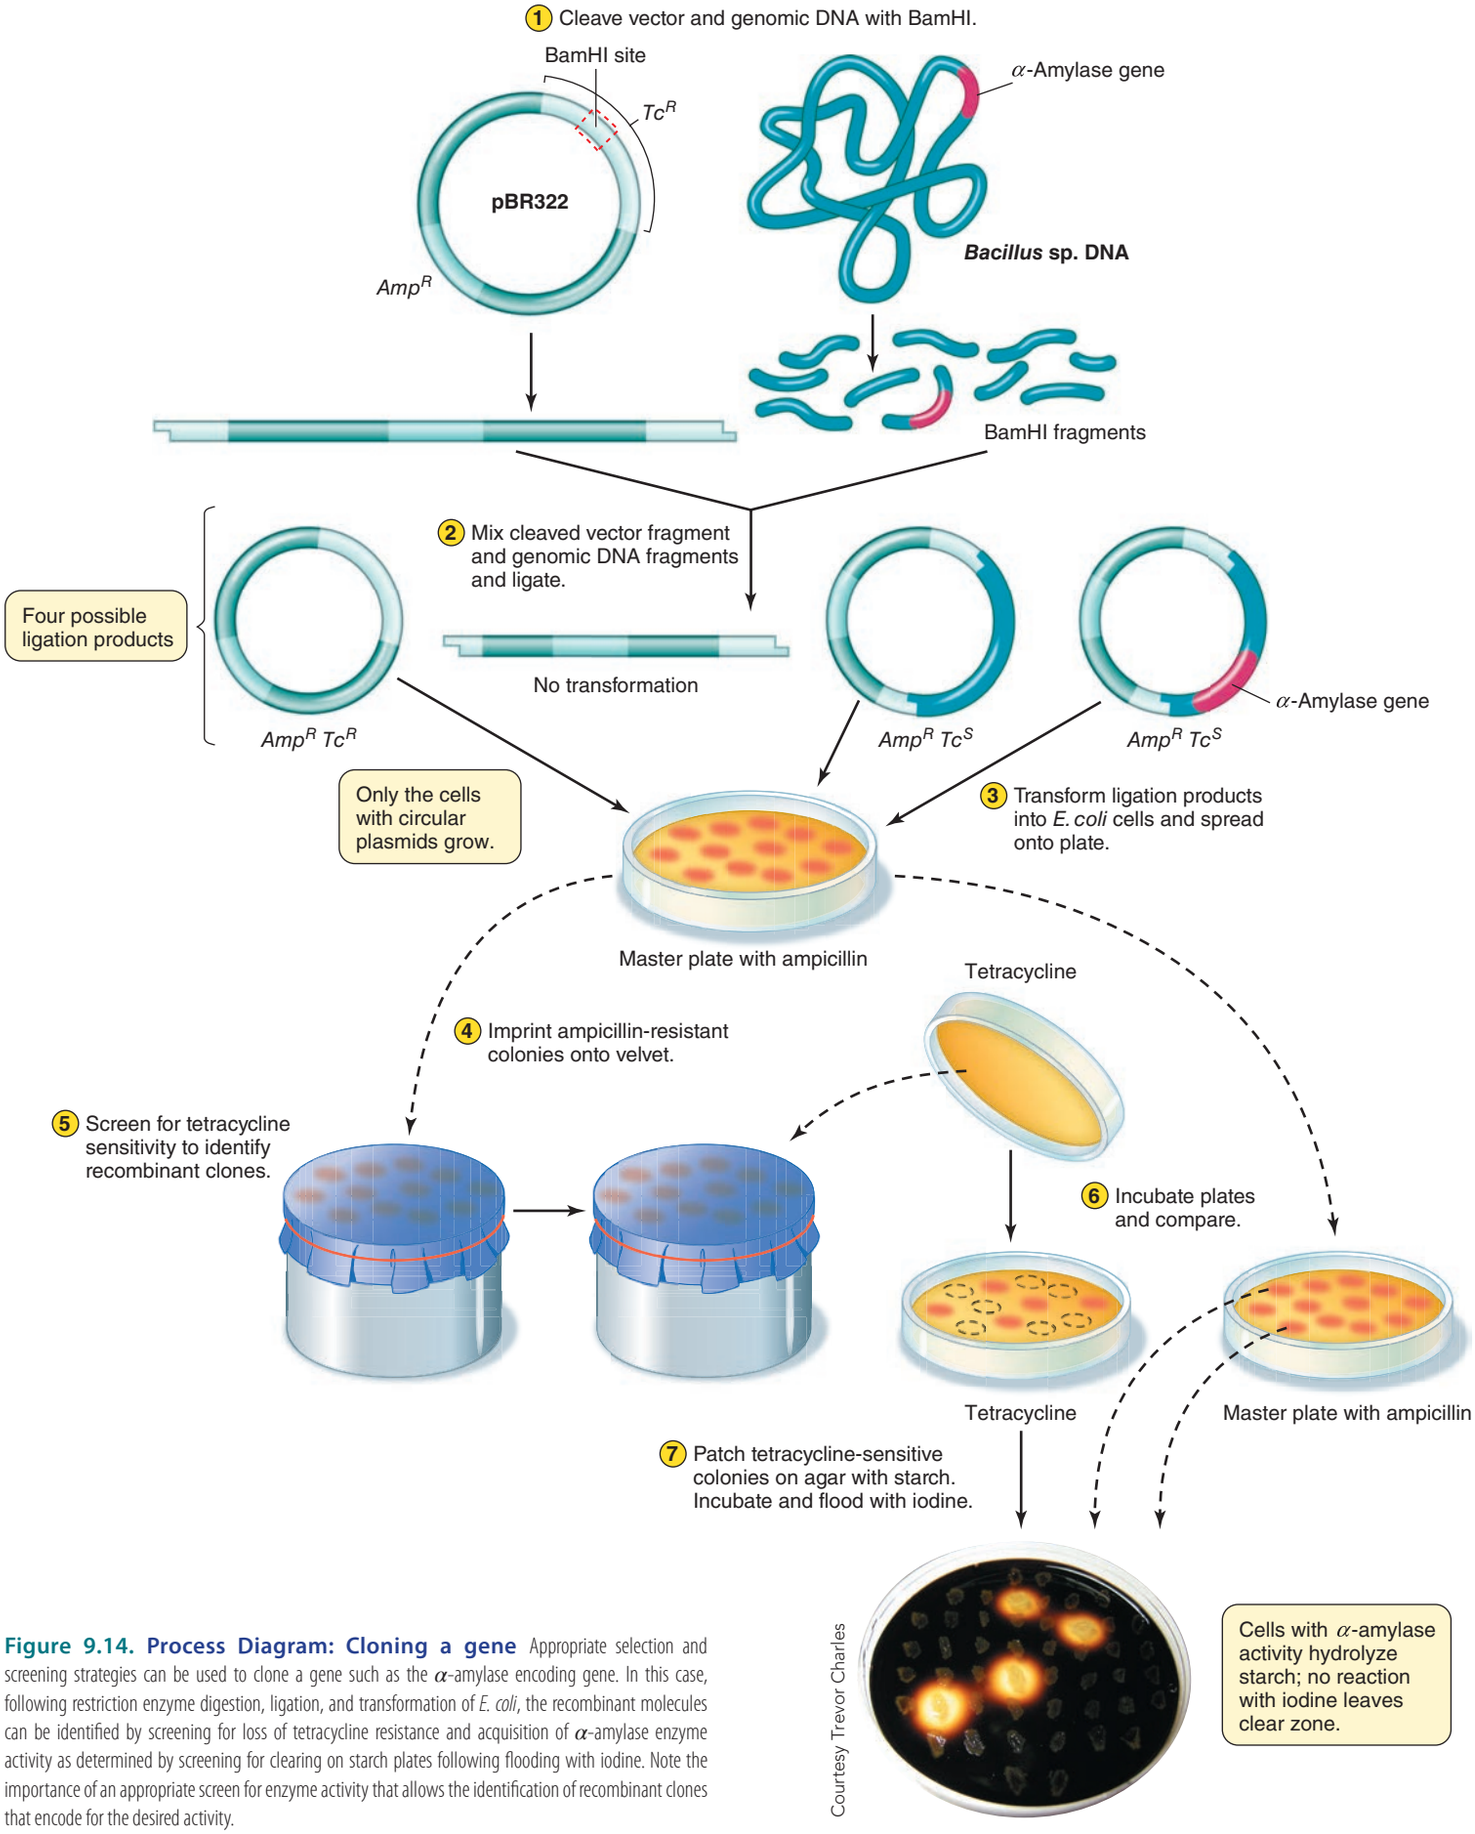

Figure 9.14. Process Diagram: Cloning a gene Appropriate selection and screening strategies can be used to clone a gene such as the α-amylase encoding gene. In this case, following restriction enzyme digestion, ligation, and transformation of *E. coli*, the recombinant molecules can be identified by screening for loss of tetracycline resistance and acquisition of α-amylase enzyme activity as determined by screening for clearing on starch plates following flooding with iodine. Note the importance of an appropriate screen for enzyme activity that allows the identification of recombinant clones that encode for the desired activity.

flanked the α-amylase gene. Even though pBR322 has several unique restriction sites, not all of them reside within the tetracycline resistance gene. If we were to use one of these other sites for cloning, then there would be no easy screen for detecting clones with insertions. How can we circumvent this limitation of pBR322? A major improvement in cloning vectors has been the development of **multiple cloning sites**, which are short segments on the vector that contain a cluster of different restriction enzyme sites that each appear only once in the plasmid. With these plasmids, researchers have greater flexibility in their cloning experiments.

The plasmid pBR322 requires a time-consuming replica-plating step to confirm the presence of an inserted DNA fragment. Wouldn't it be better to be able to detect the presence of a cloned DNA fragment in a single screening step? Blue-white screening probably represents the most commonly used of these screening approaches. Plasmids used for blue-white screening combine antibiotic resistance selection, to eliminate colonies without plasmid, and differential screening, to allow visual differentiation of those colonies that carry inserts from those that do not. This screening is done all on one medium. The plasmids contain an origin of replication and an antibiotic resistance gene, like pBR322. These plasmids also contain part of the *lacZ* gene, coding for the amino-terminal (α) fragment of the enzyme β-galactosidase. When the α fragment is expressed from a plasmid that has been inserted into a strain of *E. coli* that expresses the carboxyl-terminal (ω) fragment of β-galactosidase, the fragments can combine, producing a functional β-galactosidase enzyme. This enzyme breaks down the chromogenic substrate X-gal, causing the formation of blue-colored colonies. The commonly used plasmid pUC18 contains an α fragment-encoding sequence within which a multiple cloning site exists (Figure 9.15). Insertion of foreign DNA into one of the unique restriction sites disrupts the α fragment-encoding

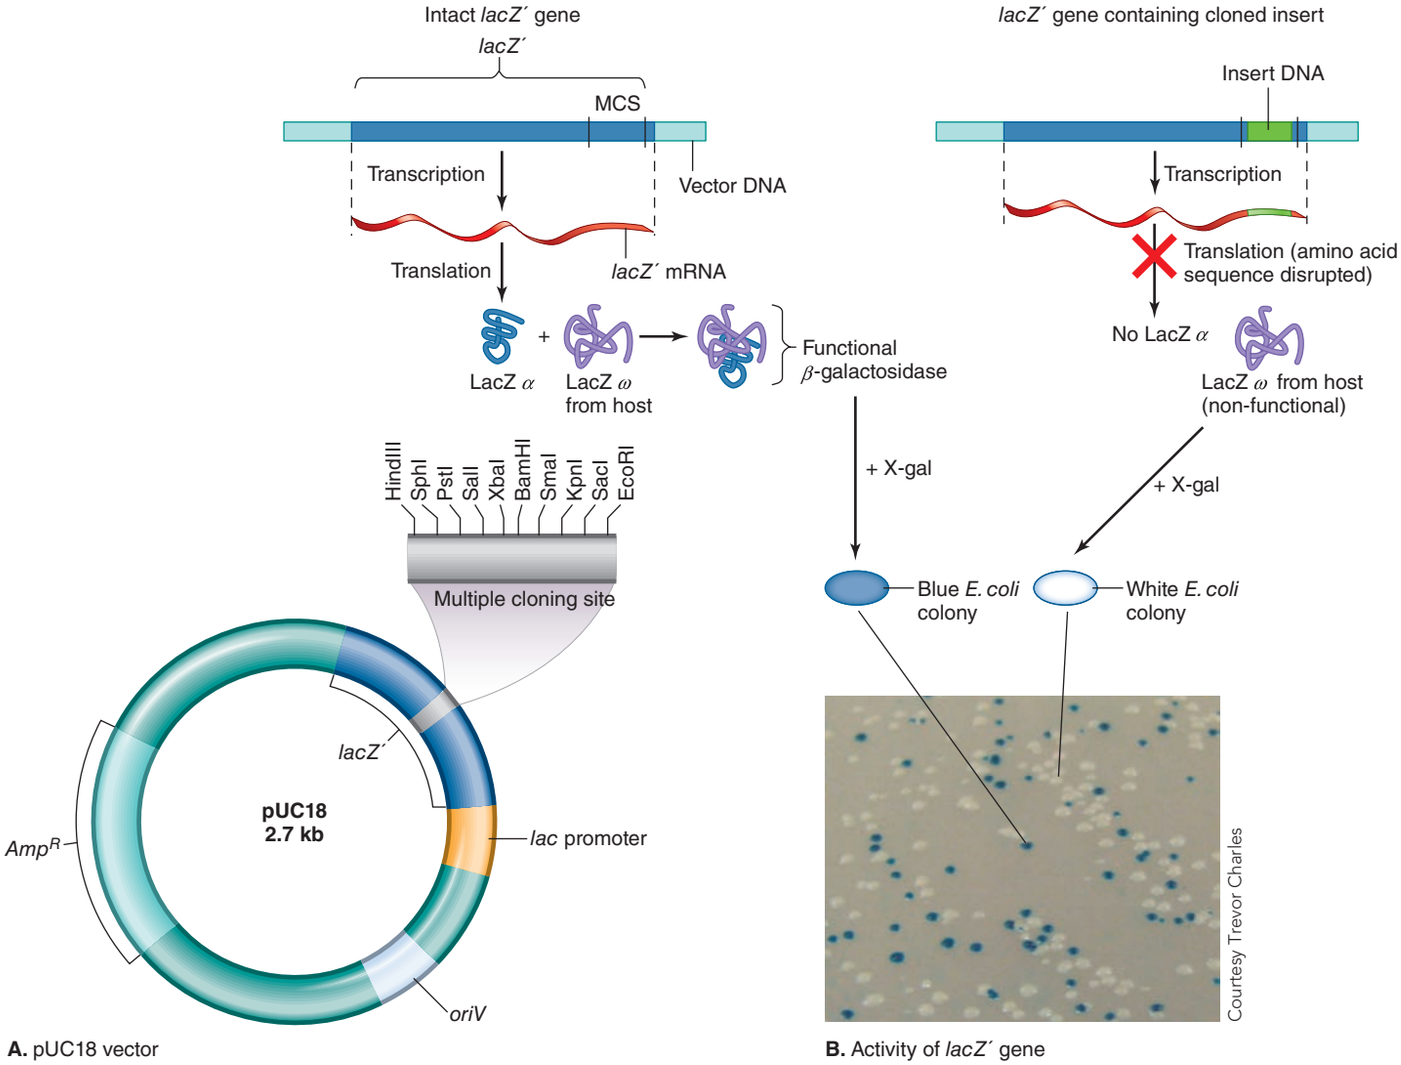

Figure 9.15. Using the *lacZ* gene to improve cloning efficiency **A.** The plasmid pUC18 contains a multiple cloning site within the α fragment-encoding part of the *lacZ* gene (*lacZ′*). Insertion of foreign DNA within this site disrupts *lacZ* expression. **B.** Following ligation, *E. coli* cells that contain recombinant molecules are detected by screening for absence of β-galactosidase activity on agar media containing the chromogenic substrate X-gal and antibiotic. Plasmids that have inserts will give rise to white colonies on X-gal plates. Plasmids that do not have inserts will give rise to blue colonies on X-gal plates.

sequence, thus abolishing β-galactosidase activity. Transformants with inserts therefore appear white when grown in the presence of X-gal, whereas transformants without inserts appear blue. Researchers can easily identify and isolate a white colony growing in the presence of many blue colonies.

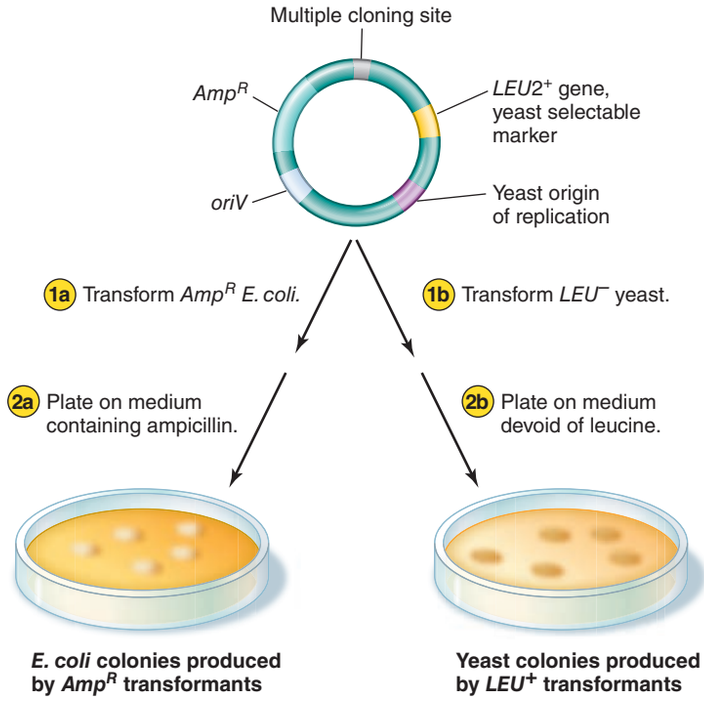
Today, a great number of plasmid vectors for a variety of host cells exist. Many of these vectors are commercially available; others are shared within the scientific community. Regardless of their unique properties, cloning plasmids typically have the following features:

- an *origin of replication* that functions in the host cell(s)
- a *selectable marker* that imparts a phenotype such as antibiotic resistance, so that only cells carrying vector DNA are able to grow under certain conditions
- a *multiple cloning site* that facilitates cloning and allows screening of cells containing cloned DNA
- a *small size* that maximizes transfer efficiency into host cells
- a *high copy number* so many copies of the cloned DNA exist in a small number of cells

Most of the plasmid vectors used in molecular biology are derived from the *E. coli* ColE1 plasmid, which contains the *oriV* origin of replication. Because this origin functions only in *E. coli* and closely related bacteria, these plasmids have a restricted host range. To broaden the usefulness of plasmid vectors, researchers have developed **shuttle vectors**, vectors that can replicate in a more diverse range of hosts. Typically, these vectors contain more than one origin of replication (Figure 9.16), allowing them to replicate in more than one type of host. They also often contain two different selectable markers. In a typical experiment, *E. coli* usually is used for the cloning and amplification steps to construct the recombinant plasmid so one of these origins of replication is able to function in *E. coli*, while the other functions in the organism under study. Shuttle vectors have been used for many disparate purposes, including the *in vivo* assembly of synthesized overlapping oligonucleotide fragments in yeast. Because yeast cells can recombine DNA segments with high efficiency, researchers can insert into yeast cells multiple overlapping DNA fragments and a linearized shuttle vector. Within the transformed yeast cells, the DNA pieces undergo recombination, forming a larger, continuous DNA fragment, which becomes ligated into the shuttle vector. Following growth of the cells, this plasmid can be isolated and transferred to *E. coli*, where it can be further manipulated. The process allows researchers to produce very large segments of DNA with minimal *in vitro* steps.

Phage Vectors

Although researchers use plasmid vectors quite frequently, they also use phage vectors. These vectors take advantage of the natural ability of viruses to infect and efficiently deliver their genomes into cells. DNA fragments of interest and phage DNA fragments are mixed and ligated. The resulting recombinant DNA can be packaged into phage particles *in vitro*, using purified phage head and tail assemblies that are commercially



Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 9.16. Shuttle vectors for cloning in two different cell types
Shuttle vectors typically include two origins of replication, one that functions in *E. coli* and one that functions in the organism being studied, which is yeast in this schematic.

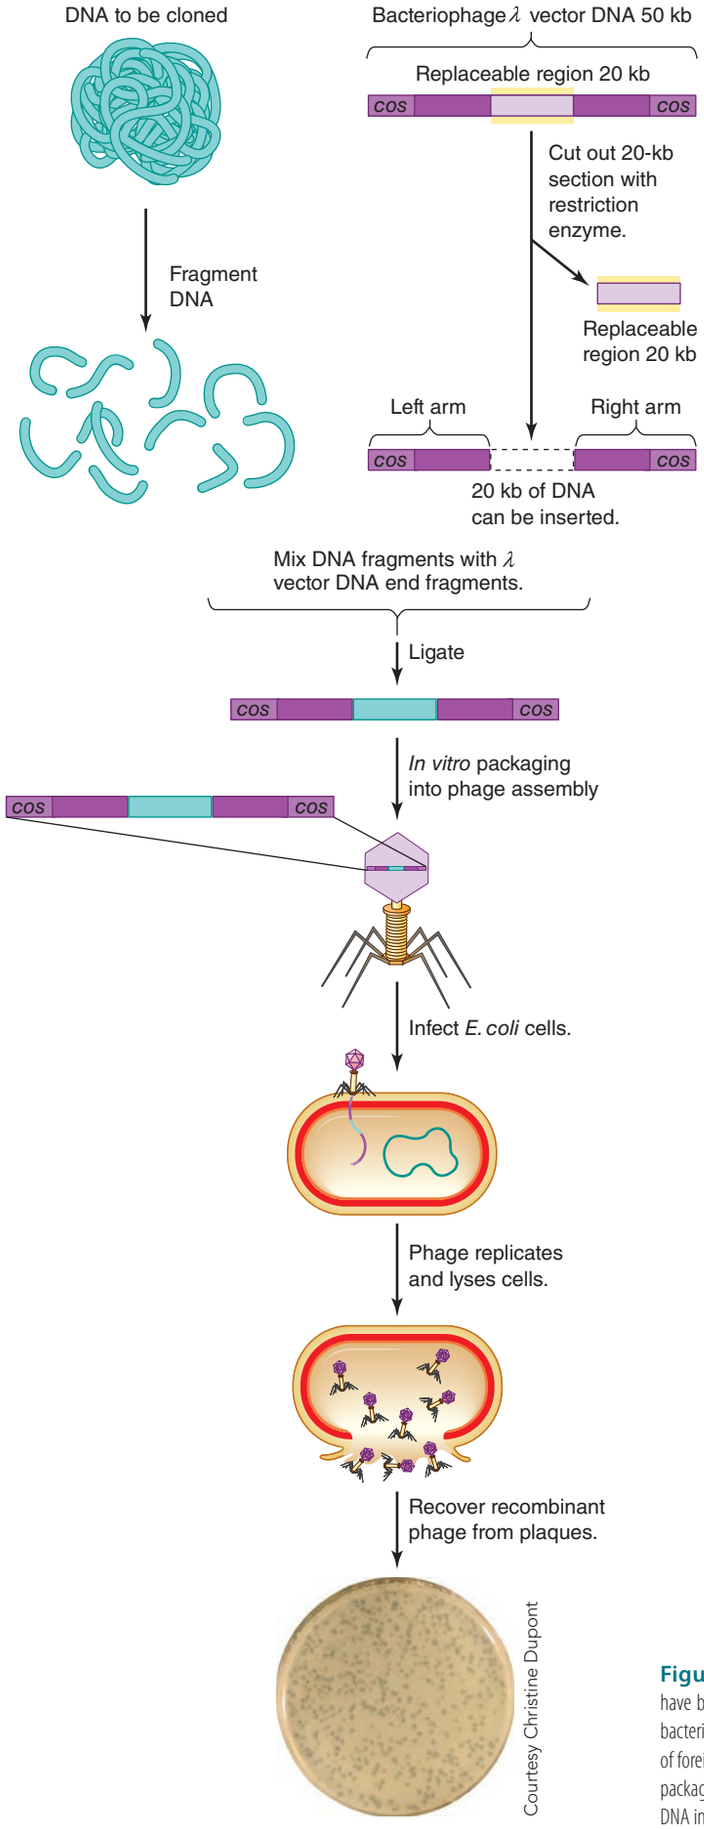
available. The resulting phages can be added to *E. coli*, and then plated on a solid medium to form plaques (see Section 8.3).

The best examples of phage vectors are based on phage lambda (λ), a temperate phage that can integrate into the *E. coli* chromosome (see Section 8.3 and Figure 8.21. When integrated, progeny phages are not produced and, as a result, a cloned fragment would not be amplified. To avoid this obvious shortcoming, researchers have removed from the phage λ genome the genes for integration and excision and genes unnecessary for viral replication (Figure 9.17). Removal of this middle 20 kb of sequence from phage λ leaves left and right arms of linear DNA into which about 20 kb of foreign DNA fragments can be ligated.

To be packaged correctly, the recombinant DNA must contain a phage *cos* site at both ends of the linear fragment. As DNA enters the capsid head, a viral endonuclease present at the entry to the capsid cleaves the DNA at each *cos* site, leaving a single-stranded overhang at each end that can anneal and recircularize the DNA once inside the cell. This circularization is needed for replication of the viral DNA

Cosmid Vectors

As we have just seen, the main advantage of phage vectors is their efficient ability to deliver cloned DNA fragments into host cells. Because packaging of DNA into preassembled capsid heads and tails only requires the presence of *cos* sites, the rest of the phage sequence can be omitted. Hybrid plasmid/phage vectors called **cosmids** have been designed (Figure 9.18). The only remnant of the phage genome left in these cloning vectors is the λ *cos* packaging recognition sites. The rest of the



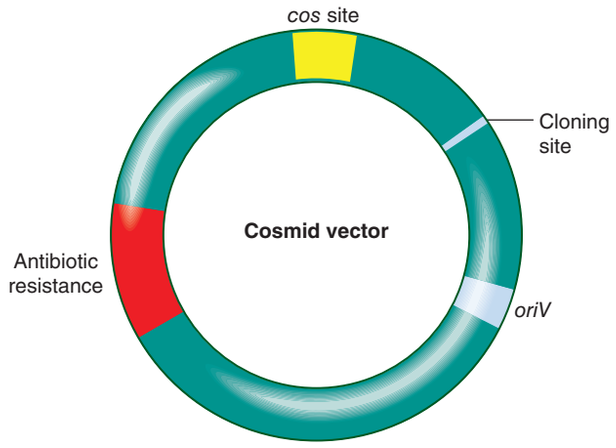


Figure 9.18. Cosmids: Plasmid/phage hybrid vectors Plasmid vectors can be designed to contain the *cos* recognition site, which allows *in vitro* packaging using λ extracts that contain head and tail proteins. These are called cosmid vectors. Just as with the λ phage vectors, only molecules of about 50 kb can be packaged. This allows the selection for clones that contain large DNA inserts, especially if the cosmid vector DNA itself is substantially smaller than 50 kb.

vector DNA typically consists of a multiple cloning site, an origin of replication, and an antibiotic selection marker. Foreign DNA fragments of approximately 35–45 kb can be inserted into cosmids, depending on the vector size, so that the total size of each clone is about 50 kb. After ligation, recombinant molecules containing *cos* are incubated with λ phage head and tail protein mixtures, which will result in the packaging of DNA molecules. The introduction of these packaged clones into an *E. coli* host occurs with very high efficiency. Once in the host cell, the DNA is maintained as a plasmid.

CONNECTIONS One of the reasons to clone a gene in a vector is to produce large amounts of a recombinant protein by expressing that gene in *E. coli* or another host. In **Section 12.2**, we will discuss vectors specially designed for this purpose.

9.3 Fact Check

1. Describe the activity of restriction enzymes.
2. What purpose does a selectable marker play in a plasmid vector?
3. Explain blue-white screening.
4. What is a shuttle vector?
5. What advantages do phage vectors have?
6. What are cosmids?

Figure 9.17. Phage lambda (λ) as a cloning vector A large variety of cloning vectors have been developed based on λ phage. Less than half of the 50 kb λ genome is required for λ to function as a lytic bacteriophage. Cloning vectors can be developed that exclude part of the genome, thereby providing room for the insertion of foreign DNA. These vectors contain *cos* sites, which are required for packing into phage particles. The λ genome is only packaged if the size of the DNA molecule is about 50 kb, and this size constraint is used to select for clones that contain a DNA insert. Following infection of *E. coli*, recombinant phage clones are recovered from plaques.

9.4 Recombination and DNA transfer

How do bacterial cells transfer DNA?

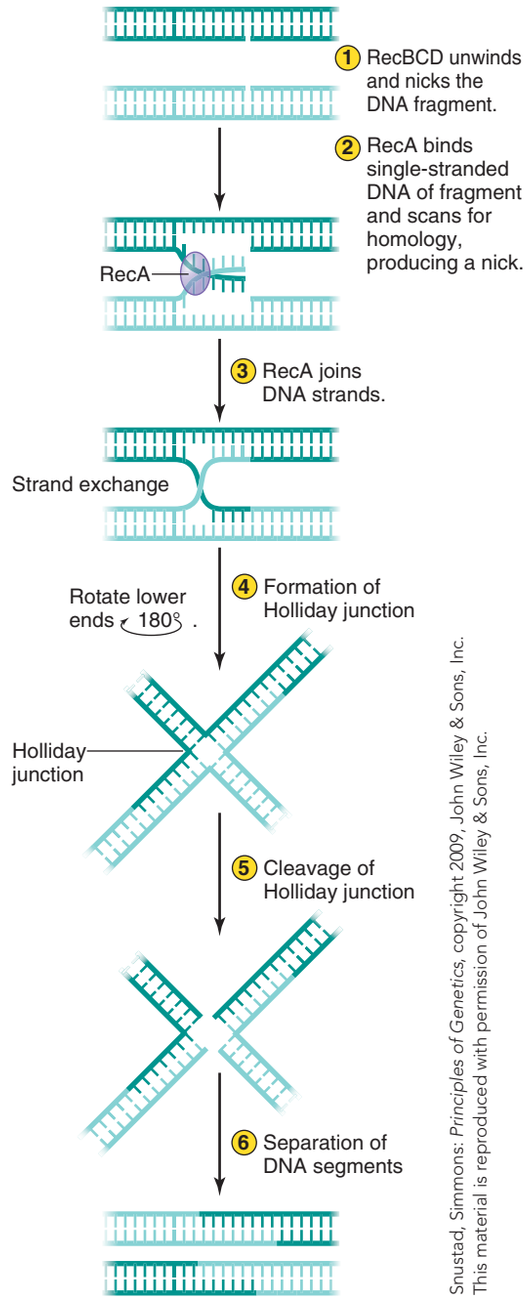
In the opening story of this chapter, the question Do bacteria have sex? was asked, and we will now answer that question with yes—mating and genetic exchange do occur in bacteria. Analyses of bacterial genomes have made it abundantly clear that segments of DNA can move between bacteria. Foreign DNA can become fixed in a new host's genome and confer new traits. Such movement of DNA between microbes is called **horizontal gene transfer** (see Section 10.3), differentiating it from vertical gene transfer, the inheritance of a gene from a direct ancestor. Horizontal gene transfer is a major contributor to evolution in bacteria. Many of the genetic techniques used by microbiologists are based on naturally occurring mechanisms of horizontal gene transfer in bacteria: transformation, conjugation, transposition, and transduction. Regardless of how DNA gets into the cell, some form of recombination commonly occurs to incorporate the foreign DNA into the bacterial genome. In this section, we will examine these four DNA transfer mechanisms. We'll begin by investigating recombination.

Recombination

Once DNA enters a cell, what becomes of it? To remain in the cell, it either must replicate on its own, or it must join with the recipient cell's DNA. In other words, it must have access to an origin of replication or it will not be maintained. Chromosomes and plasmids can replicate on their own, but DNA fragments must be incorporated into the recipient cell's DNA by the process of recombination. This involves breaking and rejoining different DNA strands and may have evolved to repair occasional breaks in DNA that occur during replication. Incorporation of foreign DNA into the bacterial genome appears to be a spin-off of this repair mechanism. Here we examine two forms of recombination: homologous and non-homologous. We will then examine how microbiologists use recombination.

Homologous Recombination

Homologous recombination, also called crossover, is best understood for *Escherichia coli*. After a DNA fragment enters the cell, an enzyme complex, called RecBCD, attaches to an end of the fragment and begins to unwind the strands. The complex eventually nicks the strand, resulting in a long single-stranded end that can pair with complementary DNA **(Figure 9.19)**. The RecA protein then attaches to this DNA and scans the sequence of the second molecule for regions of homology and aligns the single strand by invading and displacing the homologous strand. The displaced strand of the second molecule is then cleaved. This second free single strand can then anneal to the gap left in the DNA fragment, producing the Holliday junction, named for the scientist Robin Holliday, who first proposed this model. To complete the recombination event, two nicks are made in both non-displaced strands at the Holliday junction, and the joining strands are ligated, freeing the two double-stranded molecules.



Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 9.19. Process Diagram: DNA recombination Homologous recombination is initiated by the formation of single-stranded breaks through the action of the RecBCD enzyme. The RecA protein binds to the resulting single-stranded DNA and searches for regions of homology where the DNA can be aligned, displacing one of the strands at that region. A reciprocal event occurs on the other strand. This event produces the Holliday junction, where the two DNA molecules are joined. Cleavage of the junction results in separation of the DNA molecules in a manner that results in recombined molecules.

In bacterial genetics, the most important types of recombination involve single or double crossovers. Single crossovers between two circular molecules, such as a circular chromosome and a plasmid, result in the incorporation of the plasmid

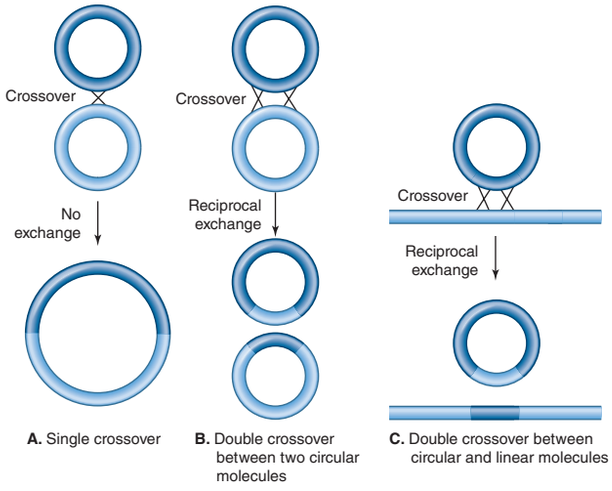


Figure 9.20. Single and double crossovers Single and double crossovers result in different outcomes. **A.** A single crossover between two circular molecules results in a circular molecule. **B.** A double crossover between two circular molecules results in reciprocal exchange of the region between the two crossover events. **C.** A double crossover between a circular and linear molecule results in reciprocal exchange of the region between the two crossover events.

DNA into the chromosome. Double crossovers between one circular and a circular or linear molecule, such as a circular chromosome and a plasmid or DNA fragment, results in the integration of the DNA of the first molecule between the two sites of recombination in the second molecule (Figure 9.20). A single crossover between a circular chromosome and a linear fragment would result in the generation of a single linear molecule, which likely would not be stable.

Non-homologous Recombination

In contrast to homologous recombination, **non-homologous recombination** involves the recombination of DNA pieces that exhibit little or no sequence similarity. This type of recombination occurs in all forms of life and usually involves certain viruses and specialized DNA sequences called transposable elements which we investigate later in this chapter. As we discussed in Section 8.3, temperate bacteriophages can undergo lytic replication, in which new copies of the virus are produced within an infected host cell, or lysogenic replication, in which the phage genome becomes integrated into the host chromosome. This integration occurs via recombination at specific but non-homologous DNA sequences, a type of non-homologous recombination called **site-specific recombination**. Enzymes produced by the viruses cleave host DNA and facilitate insertion of the viral DNA.

CONNECTIONS For temperate bacteriophages like phage λ the switch between lytic and lysogenic replication involves a tightly controlled molecular-signaling pathway for integration into the host genome by site-specific recombination **(Figure 8.21)**. Stressors to the host cell, such as UV light or chemical mutagens, often trigger the switch back to lytic replication.

Uses of Recombination

Naturally occurring recombination occurs, as we have noted, quite frequently and certainly contributes to evolutionary change. Researchers also use this process to intentionally alter the genetic content of cells. The ability to make defined mutations, and to replace segments of the genome with segments that have been altered, is crucial to many genetic manipulations. Researchers also use recombination to disrupt genes, a type of mutation called a **knockout mutation**. The resulting interruption of the gene renders it non-functional. Plasmids and other vector constructs are frequently employed for this work. By disrupting a gene in this fashion, researchers often learn important information about the normal function of the gene. In this section, we will explore this particular use of recombination more fully.

In a single-crossover knockout mutation, the cloned DNA must be an internal fragment of the gene targeted for disruption. Additionally, this fragment must be cloned into a **suicide plasmid**, a specially designed plasmid vector that, once introduced into the target cell, cannot replicate. Often, these plasmids contain an antibiotic resistance selectable marker and an origin of replication that functions in the cloning host but not the target cell.

If we want to knock out a gene in *Bacillus subtilis*, for example, we might use a plasmid that contains an origin of replication that functions only in *Escherichia coli*. The cloning steps could be completed in *E. coli*. Upon transfer of the plasmid to *B. subtilis*, only cells in which a single recombination event has led to the formation of a **cointegrate**, in which the plasmid and chromosome are joined, would remain antibiotic resistant; unintegrated copies of the plasmid would not be maintained. The single-crossover event leads to an antibiotic-resistant cell in which the gene of interest has been disrupted (Figure 9.21).

Gene knockouts using double-crossover events result in more stable insertions than knockouts produced by single crossovers but are more difficult to make. Usually, double-crossover knockouts require the insertion of a selectable marker gene into the target gene to be disrupted. As shown in Figure 9.21B, for example, the plasmid contains a kanamycin resistance gene inserted within the gene of interest, making this gene non-functional. When this suicide construct is introduced into the target organism, a double-crossover event results in the replacement of the functional gene within the target cell with the disrupted gene from the plasmid.

Plasmids used for these types of experiments often also contain a counterselectable marker such as *sacB*, which confers sensitivity to sucrose due to its production of an enzyme called levansucrase, which hydrolyzes sucrose. This produces units of fructose that are polymerized by cells into large levan polymers. Accumulation of levan is lethal to many bacteria. Cells where a single crossover has occurred will be sucrose sensitive and kanamycin resistant. In cells where a double crossover has subsequently occurred, the *sacB* gene is lost. As shown in Figure 9.21B, double crossover recombinant cells would be resistant to sucrose, and resistant to kanamycin. Recombinant cells first can be identified by selecting for kanamycin resistance, followed by selection for sucrose resistance. Kanamycin-resistant, sucrose-resistant survivors have undergone a double-recombination event, resulting in the knockout of the gene of interest.

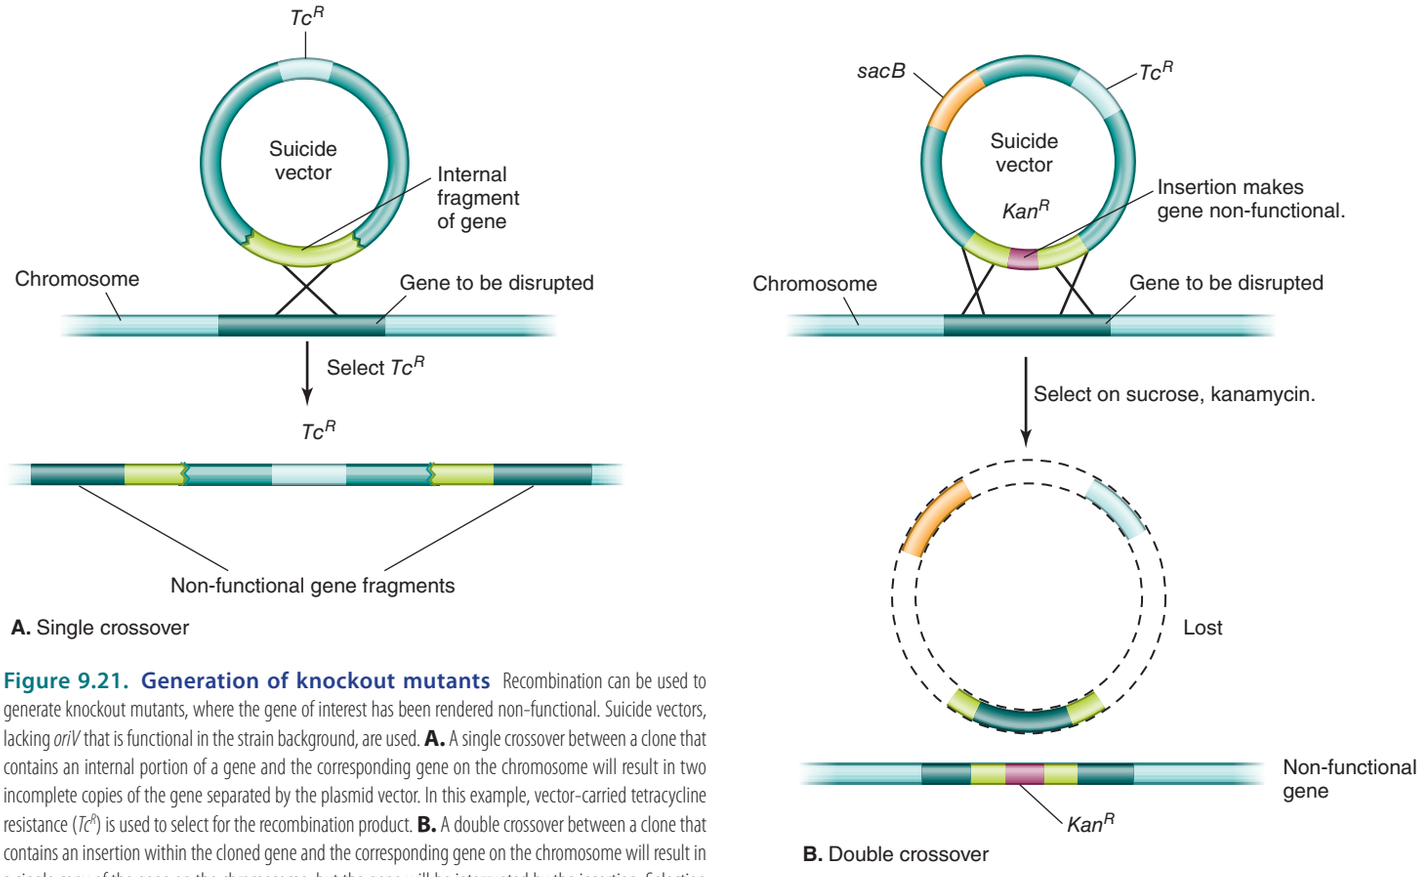

Figure 9.21. Generation of knockout mutants Recombination can be used to generate knockout mutants, where the gene of interest has been rendered non-functional. Suicide vectors, lacking *oriV* that is functional in the strain background, are used. **A.** A single crossover between a clone that contains an internal portion of a gene and the corresponding gene on the chromosome will result in two incomplete copies of the gene separated by the plasmid vector. In this example, vector-carried tetracycline resistance (Tc^R) is used to select for the recombination product. **B.** A double crossover between a clone that contains an insertion within the cloned gene and the corresponding gene on the chromosome will result in a single copy of the gene on the chromosome, but the gene will be interrupted by the insertion. Selection for the double-crossover event is done using the antibiotic resistance that disrupts the gene, in this case kanamycin resistance (Kan^R), and the sucrose sensitivity gene *sacB* carried by the suicide vector.

Transformation

How are plasmids or DNA fragments introduced into host cells? One way, **transformation**, refers to the introduction of extracellular DNA directly into an organism. This process does not require cell-to-cell contact for DNA uptake. Extracellular DNA released from dead cells exists naturally in the environment. Many bacteria, including species of *Streptococcus, Haemophilus, Neisseria*, and *Bacillus* **(Microbes in Focus 9.2)** are naturally **competent**, meaning they can take up free DNA from their surroundings. These bacteria have specialized receptor and transport systems for the uptake of DNA, often involving degradation of one of the strands so that only a single strand is available for entry into the cell **(Figure 9.22)**. This is an active process, involving binding of DNA to receptor proteins on the cell wall, transfer of one strand through a channel formed by specialized pore proteins in the cytoplasmic membrane, and degradation of the strand that is not transferred. One of the driving forces for natural transformation may be that DNA released from other organisms can be used as a nutrient, but in some cases, this DNA is integrated into the chromosome instead of being metabolized.

CONNECTIONS To effectively take up free DNA fragments, competent cells express a series of polypeptides that bind to the external DNA and facilitate its passage across the plasma membrane. Quorum sensing, a process we'll examine in **Section 11.5**, controls the regulation of the genes encoding these polypeptides.

Some bacteria, such as *Escherichia coli*, do not exhibit natural competence; they lack the specialized machinery for DNA uptake. However, cells of *E. coli* can be made competent by treatment with a solution containing cations such as calcium. This treatment probably makes the membrane temporarily more permeable to large molecules, like DNA. Sometimes, researchers use an electric pulse to increase the efficiency of transformation, a process called **electroporation**. In this technique, researchers apply an electric current to cells, which transiently generates holes in cellular membranes through which the DNA can enter. A major advantage of the electroporation technique is that it can be applied to a broad range of bacteria.

The process of transformation has played an important role in the history of modern microbiology. Indeed, transformation made possible the very discovery of DNA as the heritable material. Recall the studies in the 1920s by Frederick Griffith. He investigated the ability of the pneumococcus bacterium *Streptococcus pneumoniae* to cause disease (see Figure 7.1). He provided evidence that a then unknown substance he called the transforming principle, isolated from a heat-killed virulent bacterial preparation, could transform bacteria from non-virulent to virulent. We now know that this phenotypic change resulted from the transfer of DNA from one cell type to the other by transformation. Transformation has also been vitally important to the development of molecular biology. The transformation of bacteria and yeast with plasmids now occurs commonly in research and teaching laboratories. Researchers

Microbes in Focus 9.2
BACILLUS SUBTILIS

Habitat: First isolated and described in the mid-nineteenth century. Common, non-pathogenic inhabitant of soil. Closely related to the human pathogen *Bacillus anthracis*

Description: Gram-positive bacterium approximately 3 μm in length, in the *Firmicutes* phylum. Rod-shaped cells possess flagella, grow aerobically, and can form heat- and desiccation-resistant endospores. The 4.2-Mbp genome sequence of strain 168, encoding 4,100 genes, was reported in 1997.

Key Features: *Bacillus subtilis* has been adopted as a model organism for the study of fundamental processes such as DNA replication and cellular differentiation. Its ease of genetic manipulation has facilitated detailed study of this organism and the developmental processes associated with nutrient starvation. These processes include the development of competence for DNA transformation, the secretion of enzymes such as proteases and amylases, the production of antibiotics, and the formation of endospores. Many of its enzymes, like subtilisin (used in laundry detergents), have been produced commercially, making *B. subtilis* a very important industrial microbe.

continue to use transformation in new and innovative ways, increasing our understanding of biology with the help of this basic bacterial process.

Conjugation

Whereas transformation involves the uptake of free exogenous DNA by competent cells, **conjugation** involves the specialized transfer of DNA from one cell to another via direct cell-to-cell contact. Unlike transformation, the process of conjugation transfers relatively large segments of DNA between cells. Additionally, we now know that conjugation can facilitate the transfer of DNA between diverse organisms, even between organisms in different domains (see Figure 1.21). In some cases, conjugation facilitates the transfer of virulence factors between cells, resulting in the conversion of non-pathogenic organisms into deadly human pathogens **(Perspective 9.1)**. To better understand this important method of DNA transfer, we will first discuss how conjugation occurs. Then, we will investigate some specific uses of conjugation in the laboratory.

Mechanism of Conjugation

When Joshua Lederberg discovered conjugation, he really only studied its end results. In subsequent experiments, William Hayes demonstrated that gene transfer occurs in a single direction. Experiments in *E. coli* showed that certain strains, called donor or F^+ strains (F for "fertility"), could donate DNA, whereas other strains, called recipient or F^- strains, could receive DNA. Hayes mated different F^+ and F^- strains with

Figure 9.22. Process Diagram: Transformation of competent bacterial cells In naturally competent cells, like *B. subtilis*, external DNA first binds to a DNA-binding receptor on the cell surface. This DNA is then transported across the plasma membrane, and one strand becomes degraded. The remaining strand becomes integrated into the host chromosome via recombination.

Perspective 9.1
PLASMIDS THAT PRODUCE PATHOGENS

Since Robert Koch identified *Bacillus anthracis* as the cause of anthrax in the 1870s, this bacterium has remained intensively studied. When inhaled by people, spores of *B. anthracis* germinate and can cause a highly lethal form of anthrax **(Figure B9.2)**. As we saw in the opening story of Chapter 6, terrorists used these spores as a weapon in the United States in 2001. In contrast, *Bacillus cereus* is a common soil microbe that occasionally causes food poisoning in humans, and *Bacillus thuringiensis* causes disease in insects.

What do these three *Bacillus* species have in common? So much, in fact, that a better question might be, "What makes them different?" The *B. cereus, B. anthracis,* and *B. thuringiensis* genomes and ribosomal RNA sequences are so similar that one could argue that they really should be considered the same species, except for the dramatic differences in pathogenic behavior! The pathogenic differences appear to depend on genes present on plasmids that can be transferred via conjugation.

In *B. anthracis*, genes for the anthrax neurotoxin and production of the protective capsule exist on two large plasmids, pXO1 and pXO2. *B. thuringiensis* contains plasmids that express genes that produce a crystalline toxin, which allows the bacterium to penetrate the insect gut and induce spore germination. Different versions of these toxin-encoding genes produce toxins with specificity for different groups of insects. *B. thuringiensis* strains can contain multiple plasmids and produce different combinations of toxins.

The virulence plasmids of *B. anthracis* and *B. thuringiensis* are transferable by conjugation. Therefore, we can envision the generation of virulent *B. anthracis* or *B. thuringiensis* strains from non-virulent *B. cereus* cells by the acquisition of a plasmid expressing virulence-related traits. These bacteria all exist in soil, where conjugation may happen frequently. Because the *B. cereus* genome, even without the virulence plasmids of *B. anthracis* and *B. thuringiensis*, contains a few genes that can contribute to pathogenicity, perhaps it is already an opportunistic pathogen of insects. Plasmid acquisition via conjugation just enhances and targets its virulence toward distinct hosts.

B. *Bacillus cereus*

C. *Bacillus thuringiensis*

Figure B9.2. Closely related *Bacillus* organisms Three organisms in the *Bacillus* genus are very closely related, yet interact with humans in very different ways. **A.** *B. anthracis* causes anthrax, a deadly human disease. **B.** *B. cereus* is a common soil inhabitant that occasionally causes food poisoning in humans. **C.** *B. thuringiensis* can infect insects but not humans.

multiple antibiotic resistance and auxotrophic alleles. Examination of the progeny made it clear that the genetic material moved in a particular direction. Moreover, the F^+ property was infectious; F^- infertile cells frequently converted to F^+ cells following a conjugation event.

We now know that conjugation in *E. coli* requires the fertility factor F, a large (94,500 bp) circular dsDNA plasmid, called the **F plasmid**. When transferred by conjugation from an F^+ cell, the F plasmid converts an F^- cell lacking the plasmid to an F^+ cell. The F plasmid contains all the genes needed for conjugation and plasmid maintenance in the cell **(Figure 9.23)**. More than 30 different *tra* (for transfer) genes encode proteins needed for the production of conjugational structures that link the cells together and transport the DNA. Indeed, loss-of-function mutations in the *tra* genes result in loss of plasmid transfer. Some of the *E. coli* strains used by Joshua Lederberg carried the F plasmid. If this had not been the case, then he might never have discovered bacterial conjugation.

In 1950, Bernard Davis used immersed filters that prevented cellular contact between donor and recipient cultures to show that conjugation requires physical contact. While many researchers have studied the conjugation apparatus, the precise structures involved are still not completely understood. It is known that contact is mediated by special **sex pili** that are encoded by some of the *tra* genes. After contact between donor and recipient cells occurs, a complex of *tra*-encoded proteins called the mating bridge forms. In the donor cell (F^+), an endonuclease associated with the mating bridge makes a single-stranded nick at *oriT* (origin of transfer) of the F plasmid **(Figure 9.24)**. One end of the nicked DNA strand attaches to a protein of the mating bridge, and the remainder of the strand gradually passes to the cytoplasm of the recipient cell (F^-) through the mating bridge. If the mating bridge remains intact long enough, an entire single-stranded copy of the plasmid is transferred into the recipient cell. Once the single-stranded DNA enters the cell, the recipient cell's DNA polymerase synthesizes the complementary strand. A similar process occurs in the donor cell, replacing the DNA strand that has been transferred. Following transfer, the end of the plasmid in both the donor and the recipient cell releases from the mating bridge and attaches to the other end of the plasmid, regenerating the circular form of the plasmid in both cells.

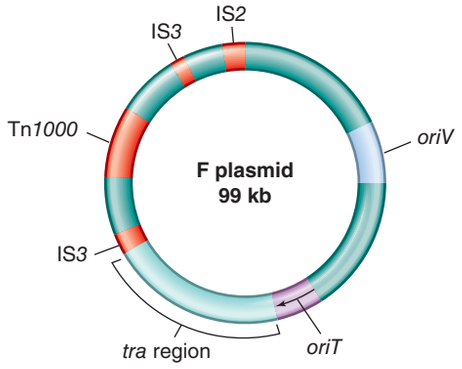

Figure 9.23. F plasmid Nearly 100 kb and self-transmissible, the F plasmid contains an origin of transfer (*oriT*) and *tra* genes, which allow it to conjugate. It also contains two different types of IS elements, IS*2* and IS*3*, and the Tn*1000* transposon. In addition to conjugating on its own, the F plasmid can also cause the transfer of chromosomal DNA. IS and Tn elements are described later in this chapter.

As described in this process, conjugation transfers only the F plasmid without involvement of chromosomal genes. So, how did the chromosomal genes that Lederberg was tracking get into recipient cells? Occasionally, the F plasmid integrates into the bacterial chromosome by a single-crossover event. This event is reversible, so the F plasmid can become extrachromosomal again. Sometimes, though, the F plasmid remains integrated when conjugation begins. When the F plasmid initiates transfer in this integrated state, attached chromosomal genes can be transferred to the recipient cell. Typically, this type of conjugation does not result in the transfer of a complete extrachromosomal F plasmid to the recipient cell. Rather, transferred chromosomal genes integrate into the recipient chromosome by homologous recombination, resulting in a **transconjugant**, a cell that has incorporated DNA from another cell via conjugation. This process produced the prototrophs seen by Lederberg in his crosses between auxotrophic mutants.

On rare occasions, donor strains transfer some chromosomal genes with much higher frequency than other genes. These donors, called **Hfr strains**, for high frequency of recombination **(Figure 9.25)**, form when the entire F plasmid incorporates into the chromosome. Unlike normal F^+ strains, Hfr strains do not convert F^- recipients to F^+ because only part of the F plasmid transfers. When transfer begins, *oriT* is nicked, and only part of the F plasmid is transferred. The rest of the F plasmid remains at the other end of the chromosome. For all the genes of the F plasmid to be transferred, the entire chromosome would need to move into the recipient cell. This extensive transfer rarely happens because mating pairs often separate before the entire chromosome can be transferred. Chromosomal genes closer to the site of insertion transfer at a higher frequency than genes farther away from the insertion site, resulting in a gradient of transfer **(Figure 9.26)**.

The gradient of transfer can be demonstrated experimentally by purposeful interruption of mating during conjugation. Such interruption experiments using crosses with Hfr strains with F inserted at different locations were used to map the position of the genes on the *E. coli* chromosome, long before DNA sequencing was available. The results of such experiments demonstrated that during conjugation, the chromosomal DNA transfers at a constant rate, and it takes 100 minutes to transfer the entire chromosome. The genetic maps thus were marked off in minutes **(Figure 9.27)**. Because the *E. coli* K12 genome contains a 4.6-Mbp chromosome, each minute corresponds to approximately 46 kbp of DNA.

Some donor cells, called **F-prime (F′) strains**, transfer only a limited number of genes in conjugation, but they do so at extremely high frequency. These F′ strains result from rare events in which an integrated F plasmid excises out of the chromosome imperfectly. During excision, sections of chromosomal DNA can be removed with the plasmid. The resulting plasmid/chromosome hybrids can contain large segments of chromosomal DNA **(Figure 9.28)**. When these F′ strains mate with F^- strains, they transfer this modified F plasmid into the recipient. The transferred chromosomal DNA from the donor

B. Conjugation in *E. coli*

Figure 9.24. Process Diagram: Formation of mating pair and transfer of DNA Conjugation occurs between cells that form mating pairs, a donor (F^+) and recipient (F^-). **A.** F plasmid–encoded pili, encoded by the *tra* region, help the cells to form intimate physical contact and facilitate transfer of DNA, which occurs through a mating bridge. **B.** *E. coli* cells undergoing conjugation.

remains part of the F plasmid in the recipient cell. As we will see in the next section, this arrangement has been very useful for studying the genetics of bacteria.

Uses of Conjugation

F′ plasmids were very useful in the early genetic studies of *E. coli*. Using F′ plasmids, researchers can construct strains that carry two different gene alleles or copies of a chromosomal region. One copy exists on the chromosome, whereas the second, different copy, exists on the F′ plasmid. In other words, the cell is a partial diploid, or **merodiploid**; it contains two copies of some of its DNA. Using this system, investigators can characterize genes involved in common cellular processes and learn more about their expression.

Like F plasmids, many other plasmids can be transferred from one cell to another by conjugation. The genetic analysis systems that have been developed for many bacteria have often included the use of broad host range or shuttle-vector recombinant plasmids in which genes of interest are cloned. Once the recombinant plasmid has been constructed, conjugation or transformation can be used to transfer it from *E. coli* to the strain of interest. For some bacteria, conjugation is much more efficient than transformation.

How is conjugation used to transfer recombinant plasmids? Conjugation requires that the plasmid contains both *oriT* and *tra*, but the inclusion of these elements in the plasmid often makes it too large for easy manipulation using recombinant DNA techniques. For this reason, the method of triparental conjugation **(Figure 9.29)** has been devised. In this process, the *tra* genes are provided by a helper plasmid in a mobilizer strain, while the donor strain contains the recombinant plasmid to be transferred to the recipient strain. When cultures of the three strains are mixed, the helper plasmid transfers into the donor strain where the *tra* genes are expressed, causing the recombinant plasmid to be transferred to the recipient strain via conjugation. The recipient strain containing the

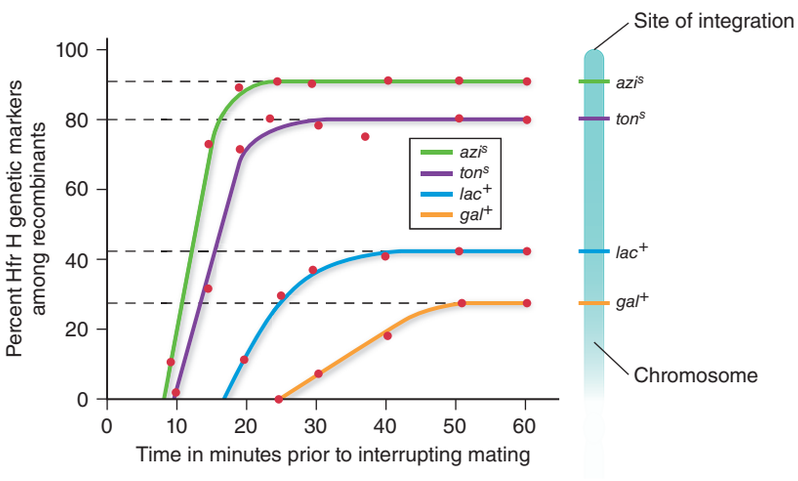
Figure 9.25. Conjugation mediated by integrated F plasmid produces high frequency of recombinants (Hfr). An F plasmid may become integrated into the host chromosome resulting in an Hfr strain. **A.** Recombination between the F plasmid and the chromosome can occur between homologous DNA sequences, located on both the F plasmid and the chromosome. The resulting Hfr is a cointegrate of the F plasmid and the chromosome, which is able to transfer chromosomal DNA because of the F plasmid *oriT*. By convention, the *oriT* arrow points away from the first DNA that is transferred. This particular Hfr is called Hfr H, and *thr* will be one of the first chromosomal genes that it transfers. **B.** The Hfr strain can transfer part of the host chromosome into recipient cells, where it can recombine with the recipient chromosome. Longer matings result in more of the chromosome being transferred, and donor genes near the site of F insertion are transferred at a higher rate than genes that are farther from the site of F insertion.

recombinant plasmid can then be selected by using media on which none of the three original strains can grow.

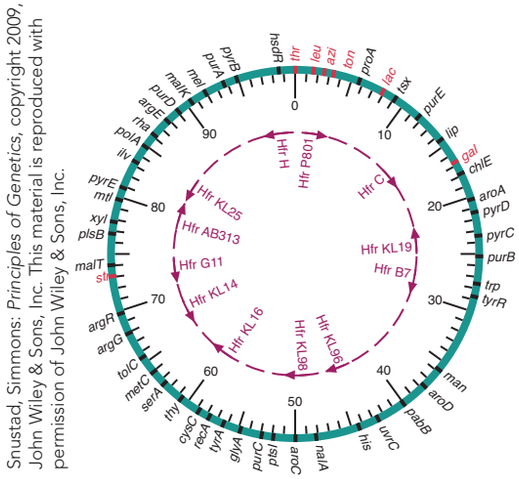
Transposition

Originally a controversial idea, it is now well accepted that some genes are capable of extensive movement from one part of the genome to another. This is due to a third method of genetic transfer in bacteria called **transposition**, the movement of DNA via mobile genetic elements. These mobile genetic elements, or **transposable elements**, mediate genome rearrangements by moving within and between genomes. First detected in corn by Barbara McClintock, transposable elements have generated controversy. To many earlier researchers, they appeared to contradict the principles of Mendelian genetics stating that genes occupy specific points on a genetic map and are passed



Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 9.26. Time and sequence of gene transfer in conjugation between Hfr and F⁻ The time required for the transfer of a given genetic marker from donor to recipient increases with distance from the site of integration of the F plasmid in the Hfr strain. This relationship can be used to determine locations of genes on the chromosome. In this example, the distance from the location of the site of the inserted F plasmid in the Hfr H strain can be deduced by the time of transfer.



Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 9.27. The circular genetic map of *E. coli* (distance in minutes)
Researchers derived the genetic map of *E. coli* by using Hfr-mediated conjugation. The locations and direction of transfer of commonly used Hfr insertions is shown on the inside circle. The total distance of 100 minutes reflects the gradient of transfer during conjugation. Genetic loci are shown on the outside, with those in red having been used in previous figures.

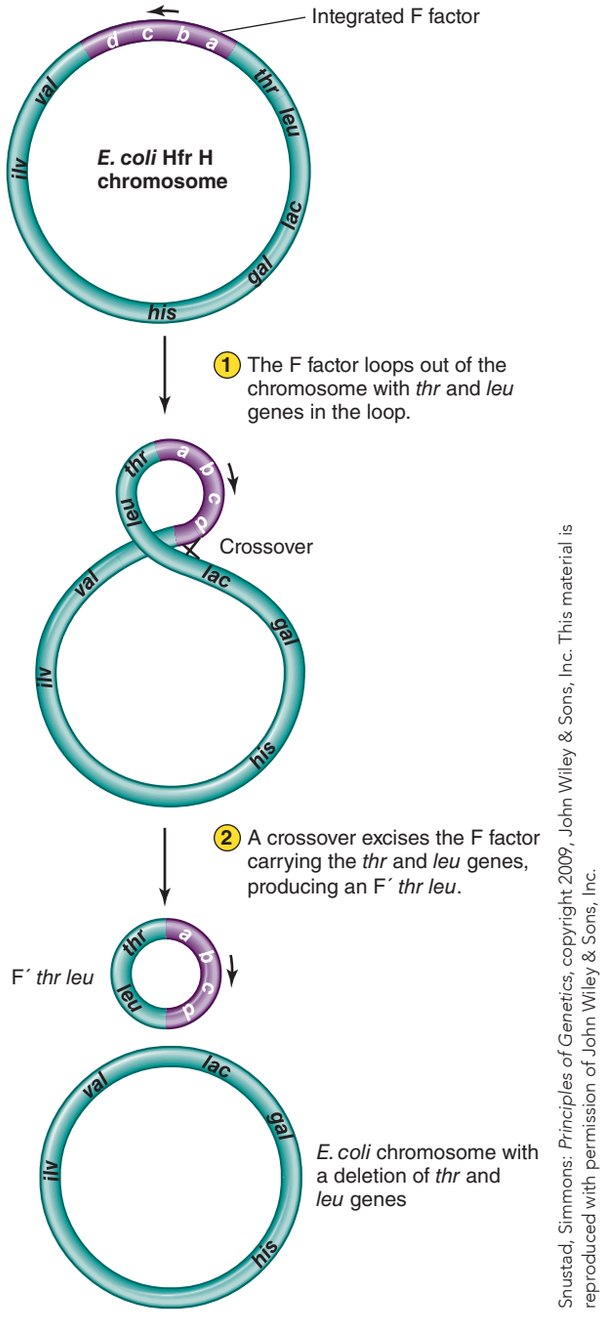
to progeny in a predictable fashion. Today, genome-sequencing data show that transposable elements occur in virtually all genomes (see Section 10.3), and like the other methods of DNA transfer that we have examined, greatly affect evolutionary change. In this section, we will examine simple transposable elements, referred to as insertion sequences, or IS elements, which encode only the proteins necessary for transposition, and more complex **transposons**, abbreviated Tn, which are transposable elements that contain proteins necessary for transposition as well as other genes, such as antibiotic resistance genes.

CONNECTIONS Retrotransposons are transposable elements that move from one location to another via an RNA intermediate, employing the activity of reverse transcriptase. The duplication of these transposable elements resembles the process whereby retroviruses replicate **(Section 8.3)**.

Mechanisms of Transposition

Transposable elements facilitate much of the genome rearrangement and horizontal gene transfer that occur in bacteria. These elements move from one part of the genome to another, using non-homologous recombination. The transposition process requires only the **transposase** enzyme and terminal inverted repeat sequences on the transposon that are recognized by the transposase enzyme. Non-replicative, or cut-and-paste, transposable elements excise from one location and insert into another location. Replicative, or copy-and-paste, transposable elements require a replication step and leave a copy behind at the original site **(Figure 9.30)**. The two copies are separated by the actions of a **resolvase** enzyme, which acts on the *res* sites within the transposon. In both cases, the transposable element may move to a new location within its original DNA molecule or to a different DNA molecule.

The simplest transposable elements generally consist of the transposase gene flanked by inverted repeats, short sequences



Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 9.28. Process Diagram: F′ plasmids F′ plasmids are formed when recombination occurs between chromosomal DNA on either side of the F insertion, resulting in looping out of a substantial segment of the chromosome that also contains the F plasmid. The products of this event are an F plasmid that contains a segment of chromosomal DNA, and a corresponding deletion in the chromosome.

of DNA that exist in an inverted orientation relative to each other **(Figure 9.31)**. Referred to as **insertion sequences**, or **IS elements**, these transposable elements generally are less than 2,500 bp in length. Different inverted repeat sequences, usually between 10 and 40 bp in length, exist in different IS elements. Transposons are more complex transposable elements, including not only the inverted repeats and transposase gene but also other genes not essential for the actual transposition of the element.

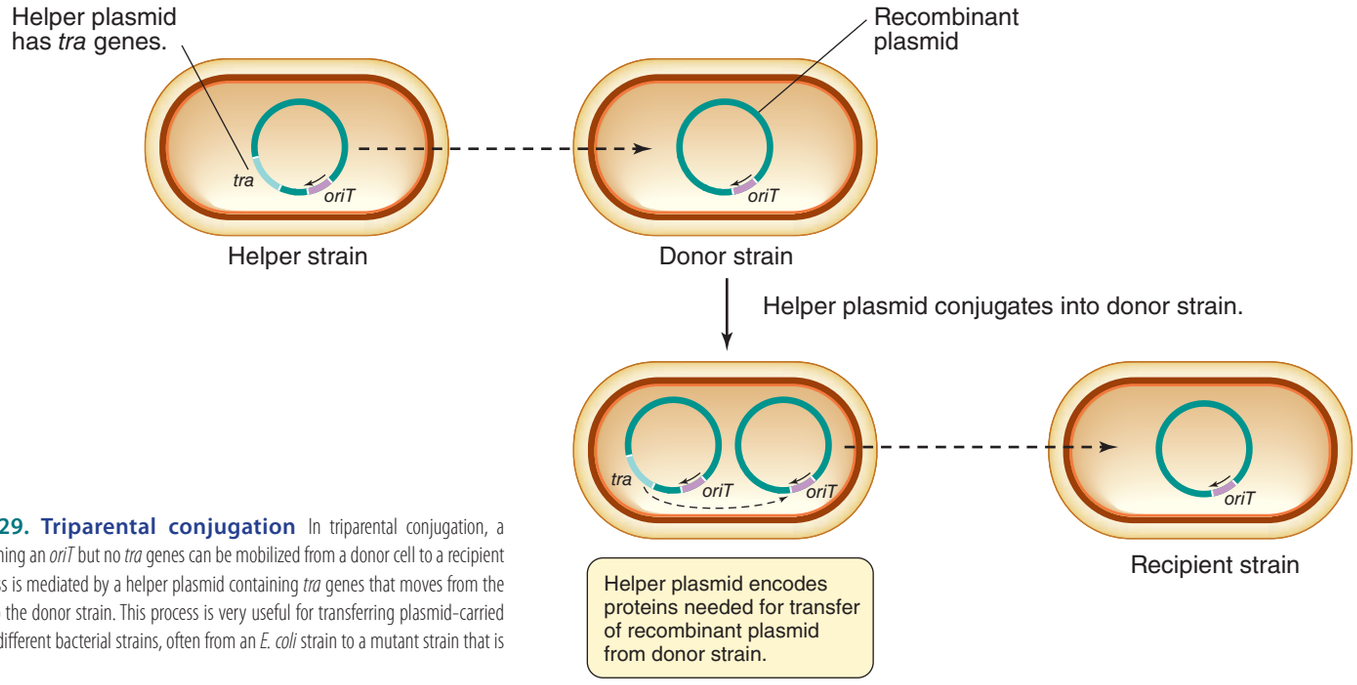


Figure 9.29. Triparental conjugation In triparental conjugation, a plasmid containing an *oriT* but no *tra* genes can be mobilized from a donor cell to a recipient cell. This process is mediated by a helper plasmid containing *tra* genes that moves from the helper strain to the donor strain. This process is very useful for transferring plasmid-carried DNA between different bacterial strains, often from an *E. coli* strain to a mutant strain that is being studied.

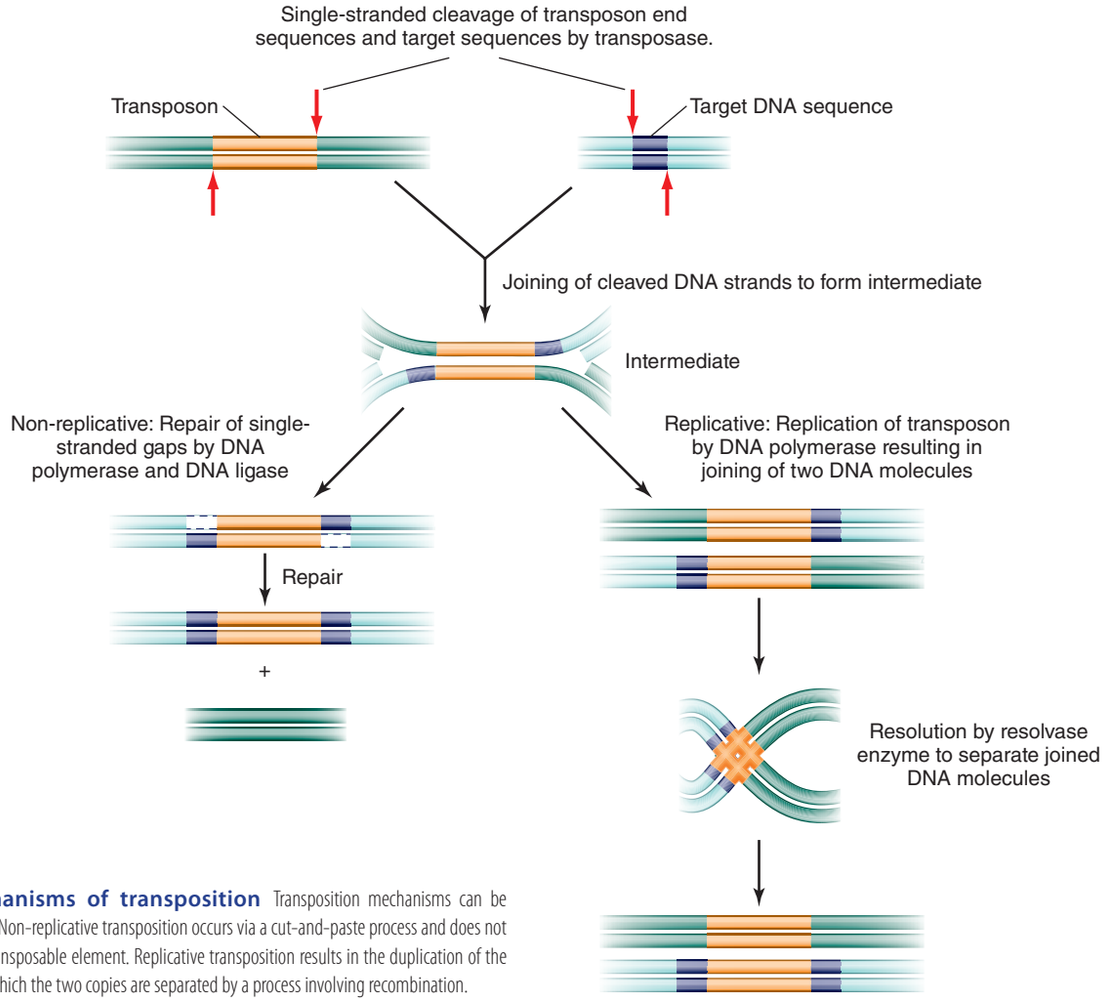

Figure 9.30. Mechanisms of transposition Transposition mechanisms can be non-replicative or replicative. Non-replicative transposition occurs via a cut-and-paste process and does not result in duplication of the transposable element. Replicative transposition results in the duplication of the transposable element, after which the two copies are separated by a process involving recombination.

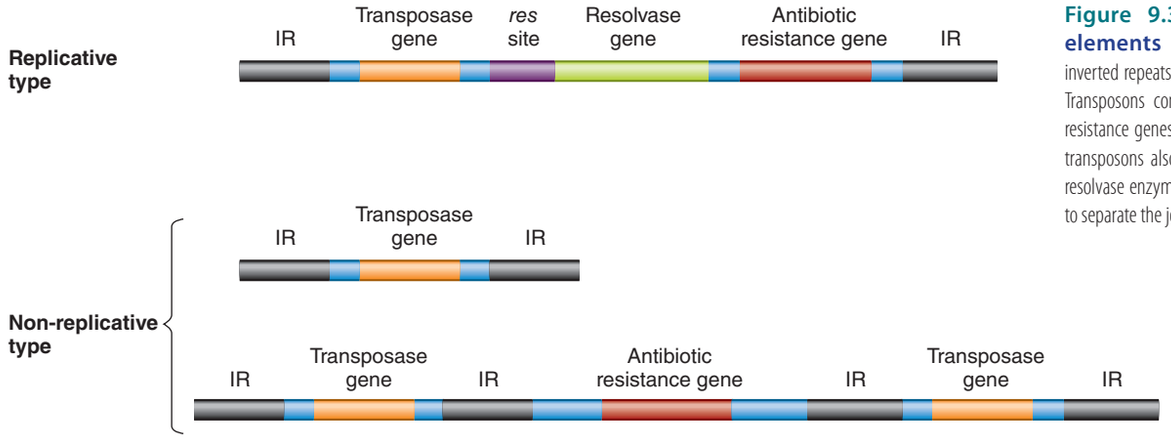

Figure 9.31. Types of transposable elements Insertion sequences, or IS elements, contain inverted repeats (IR), typically flanking a transposase gene. Transposons contain additional genes, such as antibiotic resistance genes, not essential for transposition. Replicative transposons also contain resolvase genes that encode the resolvase enzyme. The resolvase enzyme acts at the *res* site to separate the joined intermediate molecules.

Antibiotic resistance genes have often been associated with transposons. In many cases, the antibiotic resistance genes on plasmids exist within transposons that happen to be on the plasmid. This arrangement provides additional means for the transfer of antibiotic resistance by horizontal gene transfer. In addition to being transferred with the plasmid by, for instance, conjugation or transformation, the transposon-associated antibiotic resistance genes can also move from one plasmid to another plasmid, or from a plasmid to a chromosome. This movement increases the distribution of antibiotic resistance genes throughout bacterial communities.

Typically, transposition does not exhibit any target site specificity; transposable elements can insert anywhere in the genome. Each transposition event results in a short repeat of the host DNA sequence at the site of insertion. Current evidence indicates that the transposase enzyme makes a double-stranded cut at the end of the terminal inverted repeat sequence of the transposon, and it makes a staggered cut at the site of insertion. The DNA molecules are then joined by transposase. DNA polymerase and DNA ligase fill in the gaps and covalently link the free ends, resulting in the formation of the repeats in the host DNA. In replicative transposons, there is no action by DNA ligase, and replication continues, resulting in joining of the two DNA molecules and duplication of the transposon (see Figure 9.30). The joined molecules are then separated into two molecules by resolvase.

When a transposon resides on a plasmid, it can leave the host cell via plasmid conjugation and move to another cell, even to another type of bacteria. Through this process, multidrug antibiotic resistance can spread rapidly (see Section 24.3). Transposons also play a role in evolution by promoting rearrangement of genomes and by mediating the movement of host DNA sequences to new locations. Some transposons exist in multiple copies in a single genome, and homologous recombination can occur between them, resulting in deletions, inversions, and translocations. These types of events have been detected in the LTEE described in Section 9.2,

Uses of Transposable Elements

Transposable elements have been developed as powerful tools for bacterial genetics. These elements often insert randomly in the genome. In many cases, their transposition is regulated such that only a single insertion per genome can occur. If these elements insert within a gene, then they almost always disrupt the function of that gene. For this reason, they can be very useful for generating mutations.

In 2008, scientists at the University of Alabama, Birmingham, published a paper describing large-scale transposon mutagenesis to determine which genes within the *Mycoplasma pulmonis* genome are essential for life. To conduct this study, they examined 1,700 mutants of *M. pulmonis* that contained insertions of Tn4001T, a well-characterized transposon. Because this transposon inserts randomly within the genome, the researchers reasoned that every gene should be a target for insertion. Moreover, because transposon insertion almost invariably leads to the inactivation of the targeted gene, they hypothesized that cells containing insertions within essential genes would not be viable. In other words, only cells containing insertions within non-essential genes could replicate.

When they characterized the mutants, they identified Tn4001T insertions in 321 of the 782 *M. pulmonis* genes. The remaining genes, they concluded, are essential. Disruption of these genes apparently prevents replication of the cells. The functions of these essential genes are now being determined, and they are being compared to essential genes identified in other species.

CONNECTIONS Many microbiologists are interested in defining the essential genes in bacterial genomes. In the **Chapter 12 Mini-Paper**, we will see how researchers used information about essential genes to construct a synthetic genome. Some people have described this accomplishment as the creation of synthetic life.

The isolation of transposon insertion mutants usually involves introducing the antibiotic resistance transposon on a suicide vector into the recipient host cell **(Figure 9.32)**. Recall that a suicide vector cannot replicate in the recipient cell, and as a result, has a very short lifespan within the culture. Thus, antibiotic resistance will arise in the recipient cell only by insertion of the transposon into the host chromosome. Transfer of the plasmid into a target bacterial cell, followed by plating on antibiotic-containing medium, produces colonies that have

Mini-Paper: A Focus on the Research
THE DISCOVERY OF TRANSDUCTION

N. D. Zinder and J. Lederberg. 1952. Genetic exchange in *Salmonella*. J Bacteriol 64:679–699.

Context

In 1948, 19-year-old Norton Zinder embarked on his Ph.D. studies at the University of Wisconsin. He was the first graduate student of the 23-year-old Professor Joshua Lederberg. At this time, scientists were still digesting the implications of Avery's careful demonstration of DNA as the heritable material and Lederberg's description of conjugation in bacteria. Because *Salmonella* was closely related to *Escherichia*, but was a much more dangerous pathogen, Lederberg wanted to investigate conjugation in *Salmonella*. Medical microbiologists had isolated and characterized thousands of different types of *Salmonella*, and these strains were a resource of tremendous potential value. As the topic of a Ph.D. dissertation, the project appeared ideal.

The experiments from Norton Zinder's Ph.D. dissertation were published in the *Journal of Bacteriology*. The paper begins with the following introductory statement:

> Genetic investigations with many different bacteria have revealed parallelisms and some contrasts with the biology of higher forms. The successful application of selective enrichment techniques to the study of gene recombination in *Escherichia coli* (Tatum and Lederberg, 1947; Lederberg et al., 1951) suggested that a similar approach should be applied to other bacteria. This paper presents the results of such experiments with *Salmonella typhimurium* and other *Salmonella* serotypes. The mechanism of genetic exchange found in these experiments differs from sexual recombination in *E. coli* in many respects so as to warrant a new descriptive term, transduction.

Experiment

To investigate genetic transfer in *Salmonella*, Zinder first generated a series of double auxotrophic mutants of *Salmonella* Typhimurium. These mutants were then mixed in different combinations, and he screened the progeny for prototrophs. Initially, no prototrophs appeared, but Zinder did not give up. After almost two years of careful work, he found a combination of strains that yielded prototrophs. One strain, a derivative of strain LT-22, required tyrosine and tryptophan. The other strain, a derivative of LT-2, required methionine and histidine. When Zinder combined these strains, he obtained prototrophic recombinants in frequencies similar to the frequencies observed by Lederberg in his *E. coli* mating experiments. Important differences in the results, however, did exist. First, Zinder found no evidence of linkage or gradient of transfer. Second, the recombinant strains always contained the LT-22 genetic background.

Furthermore, Zinder showed that genetic transfer in *Salmonella* did not require cell-to-cell contact, in contrast to conjugation. To explain this finding, Zinder and Lederberg concluded that the transfer of genetic material involved some sort of filterable agent (FA). Additional studies revealed that FA was only produced when the LT-2 and LT-22 derivatives were co-cultivated. The researchers postulated that FA produced by the LT-2 derivative was induced by the LT-22 derivative. Moreover, they showed that FA was not naked DNA; treatment with a nuclease did not abolish its genetic transfer abilities. How can we explain these results? Although Zinder and Lederberg did not explicitly state this conclusion in their paper, it is now clear that FA is a bacteriophage.

The effect of FA from LT-7 and its derivatives upon LT-7 derivatives

From N. D. Zinder et al. 1952. J Bacteriol 64:679–699. Reproduced with permission from American Society for Microbiology.

Figure B9.3. Conversion of gal⁻ mutants to gal⁺ by filterable agents Several gal⁻ mutants were analyzed. The filterable agent from LT-7 converted these mutants to a gal⁺ phenotype. A filterable agent derived from one mutant could convert other mutants, but not itself, to a gal⁺ phenotype.

Zinder and Lederberg observed that active FA could be produced during co-cultivation of LT-22 derivatives and other *S.* Typhimurium isolates, including LT-7. FA was also induced in several strains by treatment of the cells with penicillin or crystal violet. Crosses carried out using FA from strain LT-7 and a number of auxotrophic derivatives demonstrated the inability to transduce prototrophic markers from the corresponding auxotroph.

Crosses between independently isolated galactose utilization mutants **(Figure B9.3)** revealed that, similar to what was observed for the auxotrophs, they could not be transduced by their own FA. In some cases, they could not be transduced by FA from other galactose utilization mutants. This result was taken to be evidence for the mutations being in the same genes.

Impact

Norton Zinder received his Ph.D. in 1952 and immediately took a position at Rockefeller University in New York City, where he spent his entire career conducting research in bacterial and bacteriophage genetics. Transduction developed into one of the most useful methods for fine structure genetic mapping and for strain construction. Enthusiastic genetic analysis of strain LT-2 resulted in it becoming, after *E. coli* K12, one of the best-characterized strains of bacteria. An extensive collection of mutant strain derivatives has been maintained at the Salmonella Genetic Stock Centre at the University of Calgary. These strains are distributed freely for research purposes.

Questions for Discussion

1. The original crosses involved the transfer of two markers (*tyr*⁺, *trp*⁺) from the LT-2 derivative to the double auxotroph LT-22 derivative. How could this be if the transduction process only transfers single markers?
2. Explain why a prototrophic marker cannot be transduced from a strain that is auxotrophic for that marker.

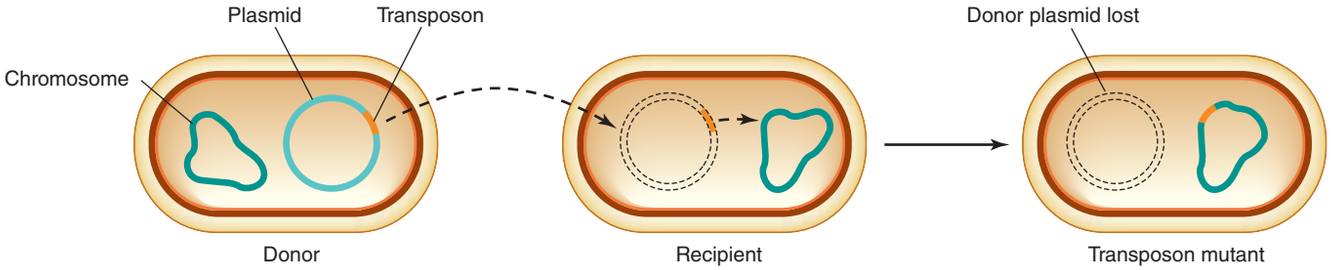

Figure 9.32. Suicide vector for transposon mutagenesis A transposon-carrying plasmid that is unable to replicate in the recipient strain can be used for transposon mutagenesis. Selection for the antibiotic resistance of the transposon will select for the transposition event from the plasmid to the chromosome, allowing the donor plasmid to be lost from the cell.

arisen as a result of the transposon moving from the nonreplicating plasmid into the genome of the recipient cell.

Transduction

As we conclude our survey of DNA transfer in bacteria, let's examine **transduction**, the transfer of bacterial DNA from one cell to another by a bacteriophage. Again, we will begin by examining how this transfer of genetic material occurs. Then, we will look at how this process can be used in the laboratory.

Mechanism of Transduction

As we learned in Chapter 5, bacteriophages infect bacteria and then use the cellular machinery of the cells to copy themselves. Occasionally, in the frenzy to assemble new phage particles, segments of genomic DNA from the infected bacterial cell become packaged into the capsid. This error produces transducing particles, which are phages that carry bacterial DNA **(Figure 9.33)**. Transducing particles are usually defective for infection; they do not contain all the phage genes needed to form infectious viral particles. However, these transducing particles can attach to recipient bacterial cells and inject their DNA into these cells. If this DNA undergoes homologous recombination with the genome of the recipient strain, then a segment of the recipient genome becomes replaced by a segment of the donor genome. A **transductant**, or bacterial cell that contains DNA obtained via transduction, results. Transduction is a very powerful and convenient tool for transferring genes between strains and has also played an important role in the construction of genetic maps. Not all bacteriophages, however, can carry out efficient transduction, and bacteriophages in general have a very restricted host range.

Norton Zinder, a graduate student of Joshua Lederberg, first discovered transduction in *Salmonella typhimurium* (now called serovar *S.* Typhimurium; see Appendix C). He used techniques similar to those Lederberg had used to detect genetic recombination in *E. coli*. He observed that prototrophic recombinants resulted from mixing two auxotrophic strains even when a filter separated these strains. The responsible filtrable agent, then called FA, was later found to be the *Salmonella* bacteriophage P22 **(Mini-Paper)**.

Uses of Transduction

Transduction is one of the most useful genetic tools for those bacteria that have transducing phages. Transducing lysates,

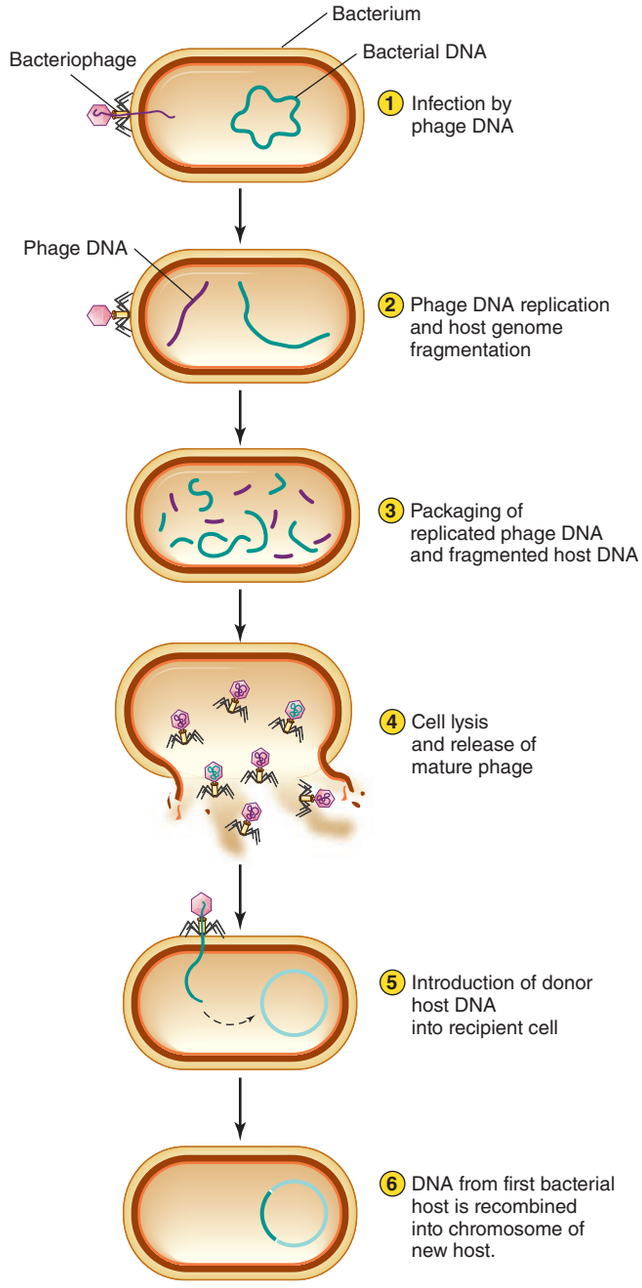

Figure 9.33. Process Diagram: Formation of transducing particles Transducing particles form when bacterial genomic DNA becomes packaged into phage heads. The resulting particles can inject the bacterial DNA into a suitable recipient cell and can be used for strain construction and for genetic-mapping experiments.

cleared cultures that result from phage infection, can be produced easily in the laboratory by infecting a bacterial culture with a small amount of an existing lysate. During a short incubation, the phages will infect the cells and lyse them. A dilution of the resulting lysate, which contains a mixture of virulent phage particles and transducing particles, is then added to a culture of the intended recipient bacterial strain. Both types of particles adsorb to the recipient cells, and inject their DNA into the cells. The cells that have taken up the bacterial DNA-containing transducing particles will have a chance to incorporate that DNA into their genome by double-crossover recombination.

Historically, transduction has been used to map genes by examining co-transduction frequencies. Co-transduction frequency refers to the frequency with which an unselectable marker gene is transduced along with a given selectable marker gene. This frequency depends on the distance between marker genes; close genetic loci are more likely to be transduced together than are genetic loci that are farther apart. By examining the rates of co-transduction between various genetic markers, geneticists were able to develop genetic maps of bacteria.

Today, transduction remains an effective experimental tool. In a paper published in 2010, for instance, researchers from South Africa and the United States hypothesized that transduction of *Lactobacillus* strains could be used to combat HIV/AIDS. The researchers noted that *Lactobacillus* species normally reside within the vagina of healthy women. If these resident bacteria could be genetically altered to express anti-HIV compounds, the investigators postulated that women in whom these bacteria existed might possess some level of protection from HIV. In other words, the resident bacteria would be altered to become a long-lasting guard against HIV.

To engineer bacteria in this way, the investigators used transduction. They constructed cosmids for *Latobacillus gasseria* ADH that contained the genes for CCL3 and CCL5, two human chemokines shown to exhibit some anti-HIV properties, that were then packaged into bacteriophage. They used these recombinant cosmid-containing phages to transduce *L. gasseri* ADH, a bacterial strain commonly found on the vaginal mucosa of women. Following transduction, these bacteria produced the chemokines **(Figure 9.34)**. Although these studies were done *in vitro*, they demonstrate that transduction can be used to genetically alter *L. gasseri* ADH. Much more research

Figure 9.34. Using transduction to genetically alter *Lactobacillus gasseri* ADH To investigate the possibility of developing a bacterial strain that contributes to HIV prevention, researchers used transduction to introduce genes for the chemokine CCL5 into *Lactobacillus gasseri* ADH. Because this chemokine can block entry of HIV into human cells, and because *L. gasseri* ADH is a natural inhabitant of the vaginal mucosa, these altered bacteria may represent a novel HIV prevention strategy.

needs to be done before this strategy can be used clinically. As the authors noted, their approach may lead to a novel means of preventing HIV infection.

CONNECTIONS In humans, the chemokines CCL3 and CCL5 interact with the chemokine receptor CCR5. CCR5 also serves as a co-receptor for HIV **(Section 5.1)**. Increased expression of CCL3 and CCL5 inhibits HIV infection by binding to CCR5 and blocking the attachment of the virus.

9.4 Fact Check

1. Distinguish between horizontal gene transfer and vertical gene transfer.
2. Describe the process of homologous recombination.
3. Distinguish between single- and double-crossover events. How are they used for genetic manipulation in bacteria?
4. What is DNA transformation, and how are competent cells involved in the process?
5. Create a table explaining F^+, F^-, Hfr, and F'.
6. What are transposons?
7. What is transduction? Explain the role of bacteriophage in the process.

Image in Action

WileyPLUS Learning Space Shown are *Escherichia coli* cells undergoing conjugation. The donor cell at the top forms a pilus that can attach to a recipient cell and bring the cells together (second pair of cells from the top). One strand of the F plasmid moves from the donor cell to the recipient cell (third pair of cells from the top). DNA synthesis then occurs in each cell to give rise to a double-stranded DNA plasmid (bottom pair of cells).

1. If this image were to zoom in on the F plasmid itself, identify what genes would likely be shown and explain their roles in the conjugation process.
2. Bisphosphonates are compounds that have been found to inhibit the enzymes that make the single-stranded nick at *oriT* of the F plasmid. Explain how this image would be different if bisphosphonates were present. Why might these compounds be considered as a means of battling the rise in antibiotic resistance?

The Rest of the Story

Earlier, we explored Joshua Lederberg's Nobel Prize-winning research on bacterial mating, or conjugation. Fundamental genetic research, like these early conjugation experiments, has led to the development of applications that have contributed to various aspects of human well-being. The study of conjugation by Lederberg resulted in the widespread use of *E. coli*, which eventually became the workhorse of molecular biology. The study of the F plasmid and λ bacteriophage that existed in strain K12 contributed to the understanding of fundamental genetic mechanisms such as conjugation and transduction. They also led to the development of tools for gene cloning, gene expression, and protein purification.

Applications of bacterial genetic mechanisms have not been limited to molecular biology. More recent applications include bacterial conjugation-based technologies aimed at combating antibiotic-resistant pathogens. For example, genetic information carried on a plasmid can be transferred via conjugation and expressed in a recipient pathogenic bacterium. The transferred plasmids are engineered to carry instructions for destruction of the recipient cells. The approach has proven successful in treating drug-resistant *Acinetobacter baumanii* wound infections in mice, and work continues on perfecting this conjugation-based approach.

Summary

Section 9.1: Why study genetics in bacteria?

Because of their genomic structure, bacteria are ideal candidates for genetic studies.

- Researchers used **nutritional mutants**, also known as auxotrophic mutants or auxotrophs, in some of the earliest genetic studies of bacteria.
- To avoid problems associated with **reversion**, researchers used double and triple mutants, thereby decreasing the probability that spontaneous revertants would arise.

The bacterial **genome** typically consists of a single circular chromosome and a variable number of **plasmids**. However, some bacteria have multiple chromosomes, and some chromosomes can be linear.

- The chromosome and each plasmid is a **replicon**, and the plasmid **copy number** within the cell is closely regulated.
- Plasmid incompatibility refers to plasmids that utilize the same copy number control mechanism and, generally, cannot co-exist stably within a cell.

Section 9.2: How are mutations used in bacterial genetics?

By studying mutants, microbiologists can learn much about the normal workings of bacterial cells.

- By comparing **wild-type strains** and mutant strains of bacteria, scientists can identify **alleles** of genes.

- The **genotype** describes the alleles of an organism.
- Mutants often can be distinguished from wild-type strains by phenotypic selection and phenotypic screening.
- **Replica plating** can be used to isolate mutants with certain phenotypic properties. **Clones** of these mutants then can be analyzed.
- Bacterial strains are described using specific genotypic notation, which ensures that their characteristics are known and understood.
- Several lines of experimental evidence have indicated that mutations arise spontaneously, in the absence of selective pressure, and provide the phenotypic variety on which natural selection acts.

Section 9.3: How is DNA cloned?

With recombinant DNA techniques, specific fragments of DNA can be amplified and modified, a process referred to as DNA cloning or, simply, cloning.

- **Restriction enzymes** cleave DNA at specific **restriction sites**. **DNA ligase** can be used to link cleaved DNA fragments, creating **recombinant DNA** molecules.
- **Molecular cloning**, or **DNA cloning** generally requires a **cloning vector**. Commonly used cloning vectors include plasmids, phages, and cosmids.
- Plasmid-cloning vectors often contain a **multiple cloning site**, a short section of DNA that contains cleavage sites for several restriction enzymes.
- Whereas many plasmid vectors have a narrow host range, **shuttle vectors** can be used in a wider range of organisms.
- Because phages normally transfer genetic material into host cells, phage vectors facilitate efficient cloning and allow the production of high quantities of cloned DNA.
- **Cosmid** vectors, which contain plasmid DNA linked to phage *cos* sites, can be packaged by phage λ, allowing more efficient cloning.

Section 9.4: How do bacterial cells transfer DNA?

Bacteria naturally exchange DNA, a process referred to as horizontal gene transfer, and scientists have exploited these mechanisms of exchange to develop recombinant DNA techniques.

- **Horizontal gene transfer**, in which DNA moves between bacterial cells, contributes to genome changes and rearrangements.
- Transferred DNA molecules can join together via **homologous** or **non-homologous recombination**. Non-homologous recombination may occur via **site-specific recombination**.
- Recombination can be used for many purposes, including the inactivation of a specific gene **cointegrate** formed by a **suicide plasmid**. Such an alteration is referred to as a **knockout mutation**.
- **Transformation** refers to the uptake of DNA by bacterial cells from the surrounding environment. In the laboratory, **competent** cells can be transformed in various ways, including **electroporation**.
- **Conjugation** refers to a specialized method of DNA transfer that requires cell-to-cell contact. The **F plasmid** contains gene-encoding proteins needed to form the **sex pilus**, which forms a bridge between two cells.
- **Transconjugants**, **Hfr strains**, **F-prime (F′) strains**, and the formation of **merodiploids** have been used extensively in gene-mapping studies.
- **Transposition** refers to the movement of DNA by **transposable elements** like **insertion sequences**, or **IS elements**, and **transposons**. Transposition typically requires two enzymes: **transposase** and **resolvase**.
- **Transduction** refers to the transfer of DNA by bacteriophages, leading to the formation of a **transductant**.

Application Questions

1. A strain of *E. coli* is labeled as HB101 *recA*$^-$. Based on this designation, what do you know about the wild-type strain and the phenotype of this strain?
2. You want to determine whether an *E. coli* strain is prototrophic or auxotrophic for histidine synthesis. What agar plates and techniques would you need to make your determination?
3. Scientists observe that antibiotic-resistant bacterial colonies appear when bacteria are grown on agar supplemented with an antibiotic. Does the antibiotic cause the antibiotic resistance mutations to develop? Explain your answer.
4. You are trying to screen a plate of bacterial colonies for resistance to the antibiotic ampicillin. What methods can you use to carry out this screen? Explain each approach to screening.
5. Imagine that a strain of *E. coli* produces a pink pigment. You streak an agar plate with the bacteria, expose it to UV light for one minute and incubate your plate. Following incubation, you observe some colonies that lack the pink pigment. Explain what most likely occurred at the molecular level to produce this result.
6. To extend your findings, you streak an agar plate with the pink pigment-producing bacteria, expose it to UV light for two minutes, and incubate the plate overnight. When you examine the plate the next morning, no colonies are present. How would you explain this result?
7. Why are genes that are nearest the *oriT* of the integrated F in an Hfr strain more likely to be transferred to the recipient cell than genes that are farther from the *oriT*?
8. The evolution of antibiotic-resistant bacteria has presented a major medical problem. A recent development involves administering a drug that prevents conjugation by interfering with the *tra* genes. Explain how this approach might reduce the number of resistant bacteria in a population.
9. In the laboratory, you purify an *E. coli* strain and attempt to cleave its chromosomal DNA with the restriction enzyme that it produces, EcoRI. Electrophoretic analysis shows that the chromosome was not digested at all. Explain what occurred at the molecular level to produce these results.
10. In the laboratory, a group of scientists attempt to generate mutant strains of bacteria that they then can screen for effects. Many tools can be used to generate mutations.
    a. Describe a chemical mutagen you suggest they use and explain its effects.
    b. Explain how transposons could be used to generate the mutants.
    c. How would they screen and select for mutants using the approach described in part b?

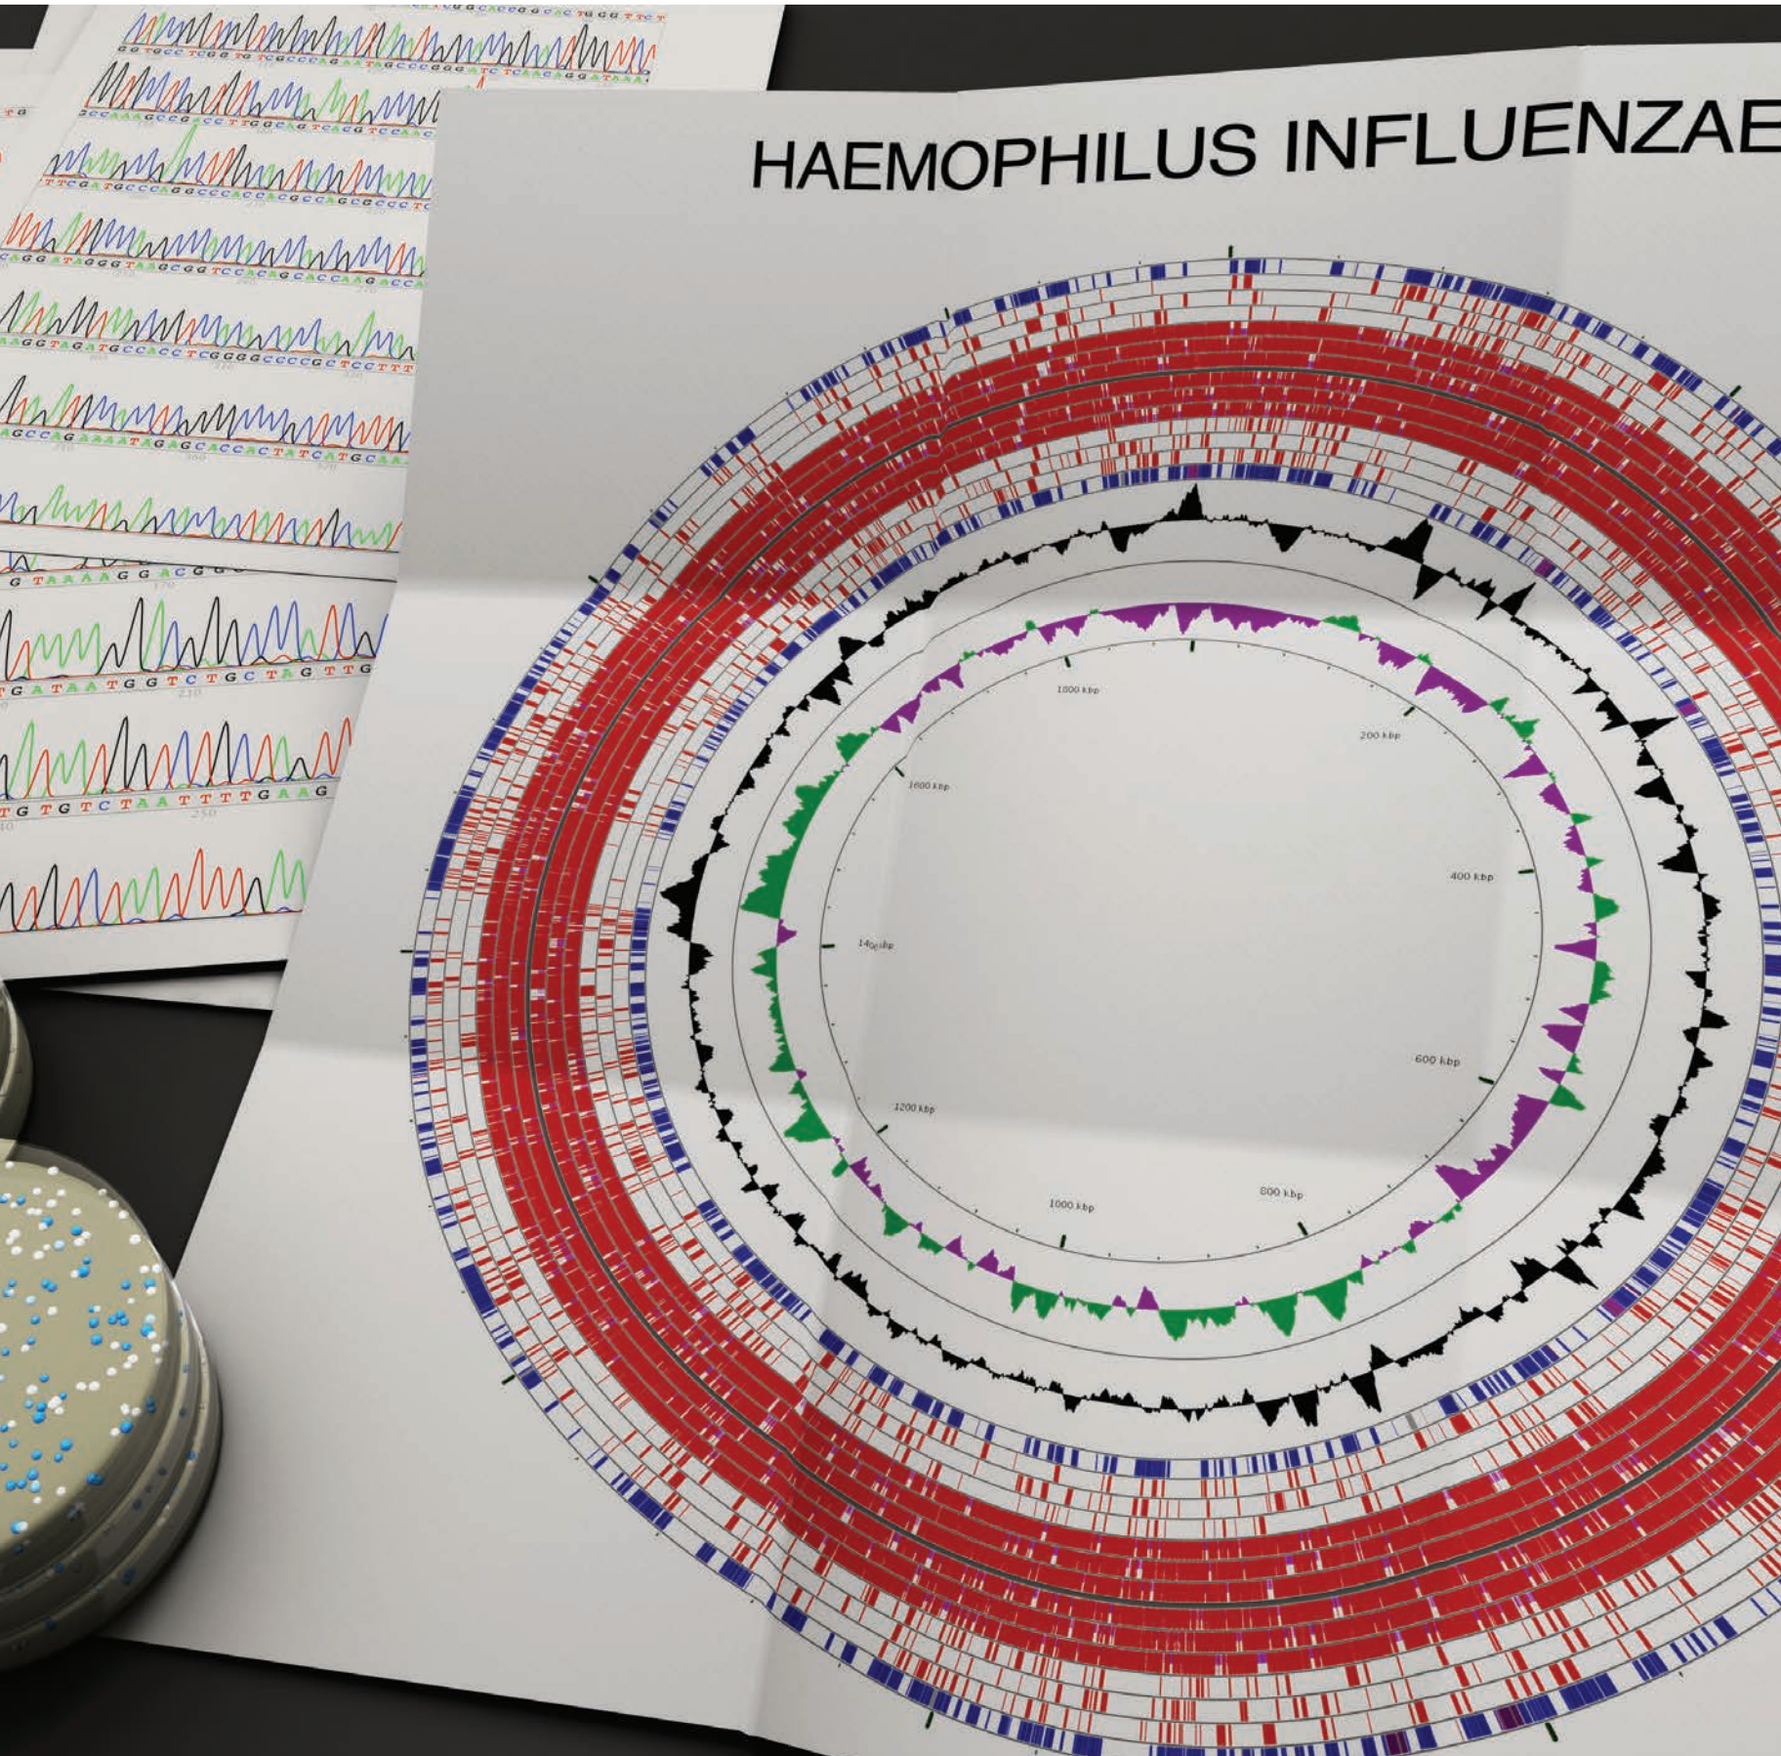
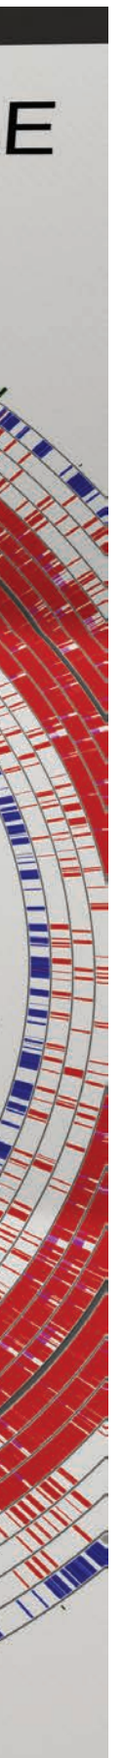
CHAPTER

10 Microbial Genomics





In the summer of 1995, Craig Venter, Hamilton Smith, Claire Fraser, and their team of scientists at The Institute for Genomic Research (TIGR) surprised microbiology and genetics research communities when they announced that they had decoded the complete genome sequence of a bacterium, *Haemophilus influenzae*. Using an innovative strategy called "shotgun sequencing" that took advantage of the speed and efficiency of the newly developed DNA-sequencing instruments and the power of modern computers, they completed the *H. influenzae* genome in a fraction of the time it might have taken using a more traditional approach. They determined the genome sequence after less than a year of work, and finished years ahead of other efforts to sequence the *Escherichia coli* and *Bacillus subtilis* genomes, projects that had begun several years earlier. In fact, they completed the sequencing so quickly that, shortly before they published the sequence, they received word that their grant proposal to do this work had been rejected! Reviewers doubted that the strategy would be successful. Fortunately, Venter and colleagues had received venture capital funding to initiate the sequencing effort. Following the success of this project, shotgun sequencing became the standard method used to sequence microbial genomes.

The work of Venter and colleagues represents an important milestone for bacterial genetics. In just over 50 years, bacterial geneticists progressed from the identification of DNA as the heritable material and the demonstration that bacteria really did have genes, to a detailed description of each of those genes in a single bacterium. Indeed, the development of shotgun sequencing has contributed to the sequencing of genomes of complex eukaryal organisms, including humans, and many microbes. Attesting to the rapid pace of progress in microbial genomics, the complete genome sequences of over 60,000 bacteria and archaea had been reported as of February 2016, compared to approximately 3,000 genomes available in February 2012. We truly live in an age of genomics.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Sequencing techniques and computing power have made whole genome sequencing possible.

- 3D Animation: Measuring gene expression using pyrosequencing
- Figure 10.2: Sanger, or dideoxy, sequencing

Introduction

The genomics revolution has had an important impact on microbiology. Genome sequences allow microbiologists to link genetic characteristics of individual microbes with their physiological properties and ecological roles. Microbiologists can make hypotheses based on genome sequence information and then test these hypotheses experimentally. Comparison of genomes from closely related organisms can reveal the genetic basis of key physiological differences between those organisms. Genome comparisons also provide profound insight into the evolutionary relationships among all living organisms and facilitate medical and epidemiological analysis of infectious disease agents.

In Chapter 9, we introduced a number of genetic tools, such as conjugation, transduction, and transposition, which microbiologists use in their research. We considered the fundamental genetic concepts upon which these tools are based and the mechanisms behind the major genetic processes that occur in bacteria. In the current chapter, we will explore studies of complete genome sequences. Historically, most of the research in bacterial genetics has taken place in a limited number and range of organisms, the so-called model organisms. This approach has resulted in detailed knowledge of genetics and the development of powerful research tools for molecular biology. Indeed, studying model organisms established the fundamentals of the genetics approach. As we explore the unique characteristics that contribute to the genetic, biochemical, and physiological diversity of microbial life, it will be useful to make comparisons to the genetic processes that have been outlined for the model organisms. Given the importance of techniques in microbiology research, this chapter focuses on the experimental and computational methodologies used for studying the biomolecules contained within microbes, from DNA to RNA to protein. We have provided an historical context throughout so that you can appreciate how current techniques arose from those that preceded them. Wherever possible, we emphasize which methods are used less now and which are more commonplace. Let's get started by taking a detailed look at the impact of genomics on microbiology and consider the following questions:

How are genome sequences determined? (10.1)
How can gene expression be measured using genomic tools? (10.2)
What information can be obtained from comparing genomes? (10.3)
Can we apply genomics to study uncultivated microbes? (10.4)

10.1 Genome sequencing

How are genome sequences determined?

The establishment of molecular biology as a discipline was cemented with the advent of recombinant DNA techniques and the development of methods to determine DNA sequences. Initially, the sequencing of single genes required massive and costly efforts. Only specialized laboratories could conduct these experiments. Subsequent technological improvements increased the speed and efficiency of DNA sequencing, while at the same time lowering the cost, until it became possible to determine the complete genome sequence of an organism. Improvements in DNA-sequencing methods continue, and what was once specialized now has become almost routine. Sequencing is a tool for not only microbiology, but also for eukaryal biology. For example, whole genome sequencing is being used to identify rare mutations causing genetic defects in humans. Overall, this dramatic change in DNA-sequencing capacity has impacted the nature of microbiology research.

As we initiate our exploration of **genomics**, the determination and study of complete genome sequences, we will focus on several important techniques. First, we will investigate various DNA-sequencing methods, including the process of shotgun sequencing that we mentioned in the opening story. Then, we will explore the computational tools that have been developed to allow us to analyze the massive amounts of sequence data that are being generated. As we will see, the combination of innovations in DNA-sequencing technologies and advances in computational power has resulted in an explosion of available DNA sequence data.

DNA-sequencing methods

As we saw in Section 9.3, relatively simple molecular biology techniques can be used to clone specific fragments of DNA into plasmid vectors. Such a collection of cloned fragments from an organism's genetic material is called a **genomic library** (Figure 10.1). A genomic library comprises the entire genome of an organism. Traditionally, researchers have relied on genomic libraries for many genetic analyses, including the process of determining the sequences of the cloned fragments. Although we will discuss the applications of genomics, and the computational approaches used to analyze these data sets, an initial discussion of the sequencing methods is critical. This is particularly true because of the incredible rate of recent progress and change in DNA-sequencing methods used for microbial genomics.

In the late 1970s, researchers developed two innovative means of sequencing DNA. Walter Gilbert and his student Allan Maxam at Harvard University developed a chemical degradation method. Around the same time, Fred Sanger and

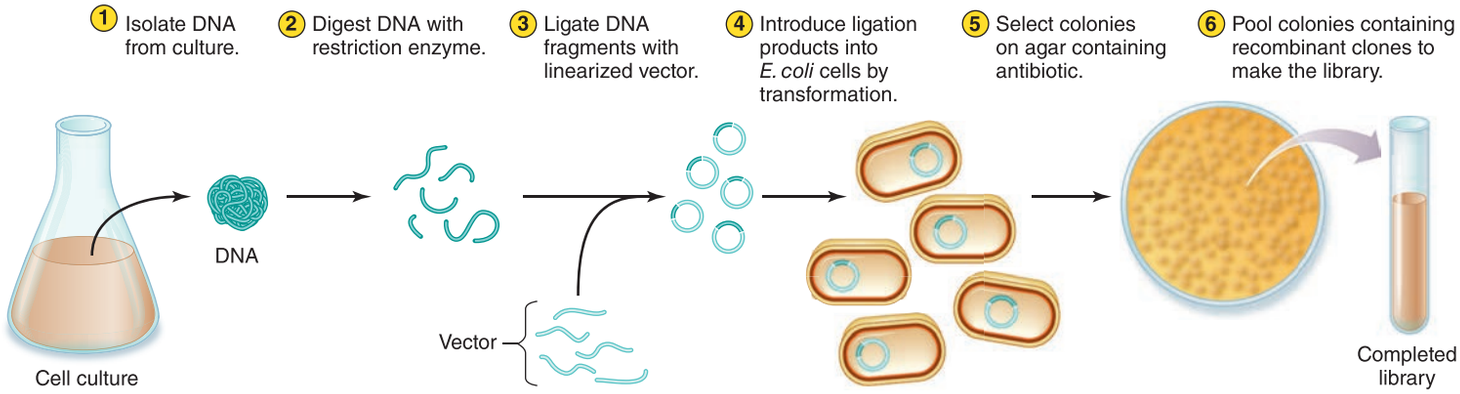

Figure 10.1. Process Diagram: Generating a genomic library To create a genomic library of bacteria, a genome of interest and a plasmid vector are digested with a restriction enzyme. The resulting fragments are mixed and ligated. The ligation products are introduced into suitable host cells, usually *Escherichia coli*. Cells containing a plasmid are selected. Using a mathematical formula, a researcher can estimate the number of clones needed to ensure that every fragment of the original chromosome probably exists in at least one of the clones.

colleagues at Cambridge University developed an enzymatic method using DNA polymerase. Today, many researchers still use some variation of the Sanger method, but this is changing rapidly with advances in sequencing technology. In this section, we will first explore Sanger sequencing. We will then investigate newer sequencing technologies and approaches, which have led to the high-throughput methods used today.

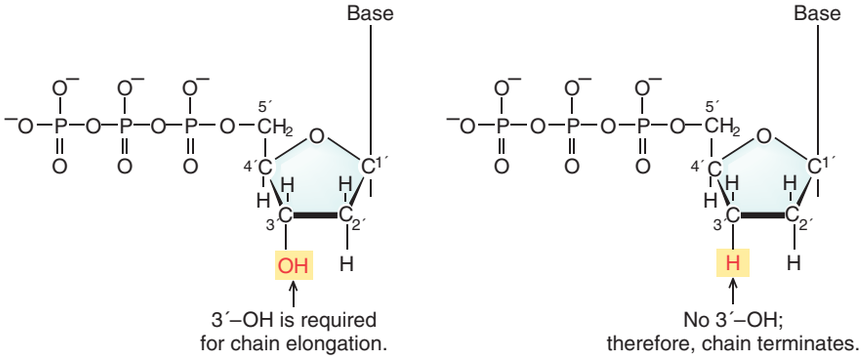
Sanger Sequencing

Sanger, or **dideoxy**, **sequencing** takes advantage of the primer-specific DNA synthesis activity of DNA polymerase (see Section 7.1). Briefly, the procedure usually requires three steps: cloning of the fragment to be sequenced, DNA synthesis, and gel electrophoresis **(Figure 10.2)**. Researchers first isolate the plasmid containing cloned DNA and denature it to provide a single-stranded template. To this template they add a short oligonucleotide primer, DNA polymerase, and the four deoxyribonucleotide triphosphates, collectively referred to as dNTPs, where N refers to the bases G, C, T, and A (deoxyguanosine triphosphate, dGTP; deoxycytidine triphosphate, dCTP; deoxythymidine triphosphate, dTTP; deoxyadenosine triphosphate, dATP). The dCTP added to the reaction is radiolabeled (^{32}P-dCTP), which becomes important for collecting data later in the procedure. The primer, designed to be complementary to the vector sequence flanking one end of the cloned DNA, anneals to the single-stranded template, providing a base-paired free 3′—OH to which DNA polymerase can add additional nucleotides, including ^{32}P-dCTP. As DNA polymerase continues to add new nucleotides, it makes a piece of DNA complementary to the single-stranded template.

Although we described how the DNA polymerase synthesizes DNA in the Sanger method, this basic reaction alone is insufficient to determine the actual sequence of this newly synthesized strand of DNA. To determine the sequence, the *in vitro* production of several truncated strands of DNA complementary to our DNA of interest are made due to the addition of modified nucleotides. Traditionally, the reaction mixture described above is divided into four separate aliquots for the DNA synthesis reaction. To each aliquot, researchers add all four of the deoxynucleotide triphosphates plus a small amount of one of the four *di*deoxyribonucleotide triphosphates (ddNTPs, or dideoxynucleotides.) Each of these dideoxynucleotides lacks a 3′—OH (hence the "di" in dideoxy; see Figure 10.2A). One aliquot receives ddATP, one receives ddTTP, one receives ddCTP, and one receives ddGTP. DNA polymerase occasionally can add a dideoxynucleotide to the growing DNA chain, just as it adds deoxynucleotides. However, once a dideoxynucleotide becomes incorporated, no 3′—OH is available for addition of the next dNTP (see Figure 10.2B). Whenever a dideoxynucleotide is introduced, DNA synthesis stops for that fragment. For this reason, researchers often describe ddNTPs as chain terminators.

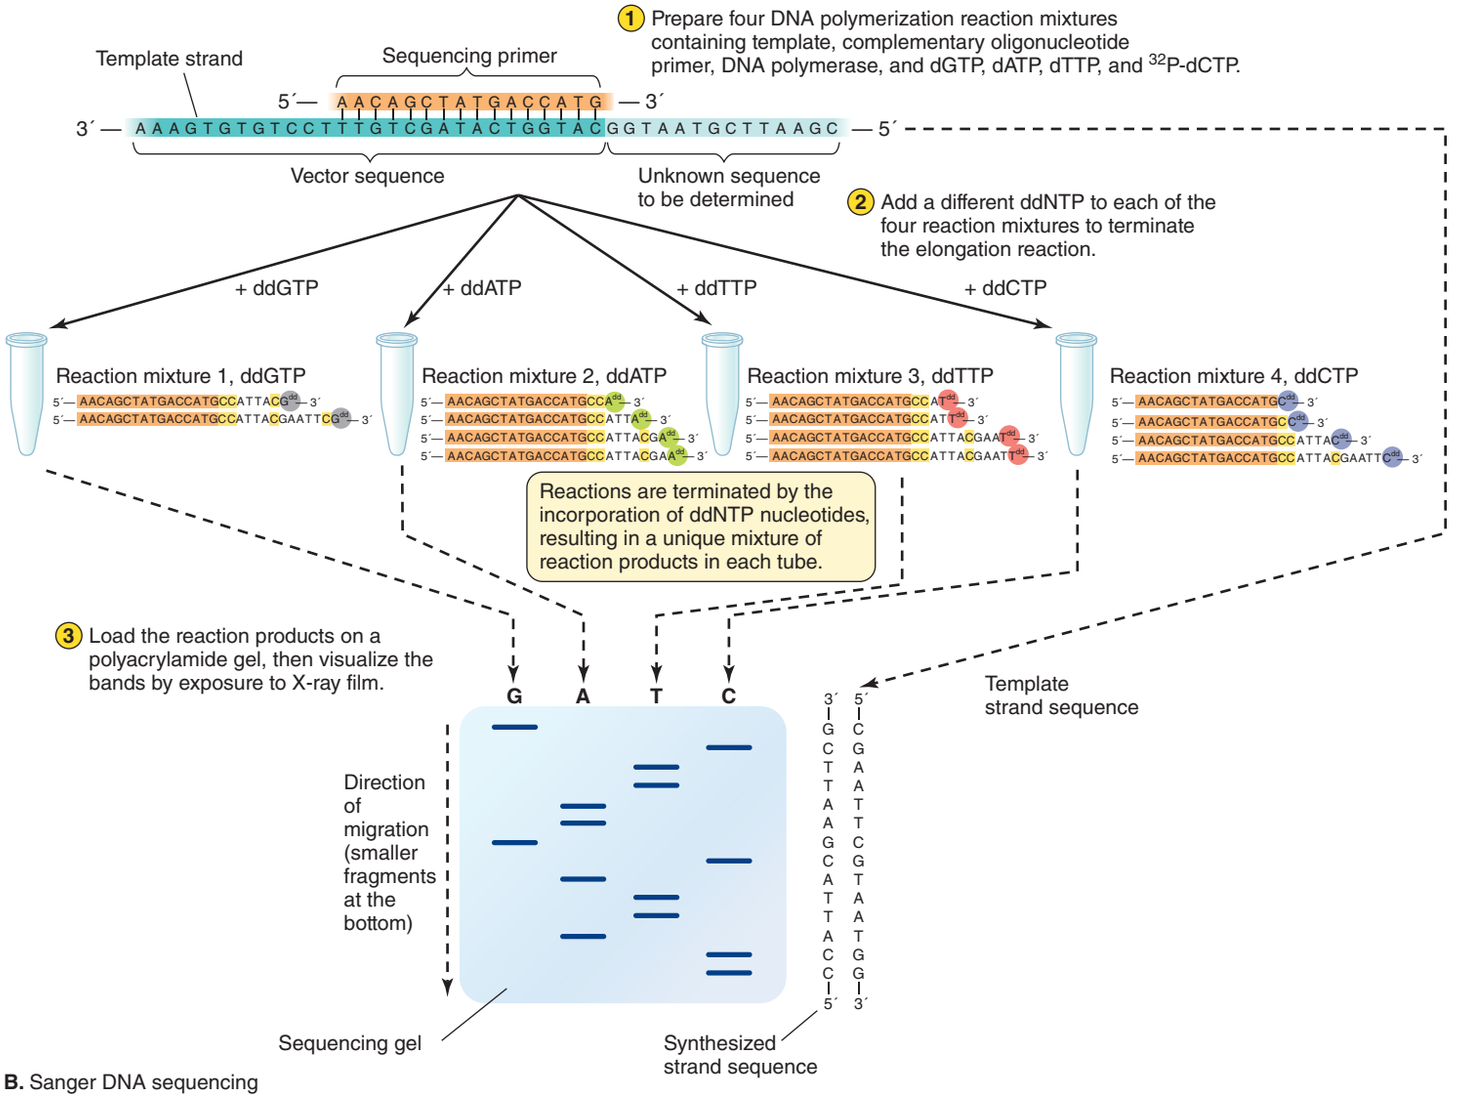
An appropriate ratio of ddNTP:dNTP ensures that a ddNTP is incorporated in the newly synthesized strand during the synthesis reaction. If the ddNTP becomes incorporated at the first opportunity during synthesis, a very short strand is generated. If it is incorporated at the next opportunity, then a longer strand is made, and so on. In this manner, many DNA products of different lengths will be formed in each aliquot, each defined by the site of insertion of the ddNTP. The four reaction sets are then denatured to release the newly synthesized radiolabeled strands from the unlabeled template strands. The mixture is separated by electrophoresis on a high-resolution polyacrylamide gel that can distinguish fragments differing in length by a single nucleotide. The resulting gel is exposed to X-ray film, and the radiolabeled fragments produce a ladder-like pattern that can be analyzed to determine the DNA sequence (see Figure 10.2B). Initially, this method resolved just over 100 nucleotides of sequence in a single run, that is, on a single gel. Subsequent improvements in electrophoresis methods increased this number to greater than 400 nucleotides.

Since its initial development, the Sanger method has had several major improvements. The use of thermostable polymerases, such as the same ones used for PCR (see Toolbox 1.1), allows multiple rounds of synthesis from a single template strand, significantly amplifying the amount of products. The use of fluorescent dyes rather than radioactive labels eliminates the need for X-ray film because the fluorescently labeled



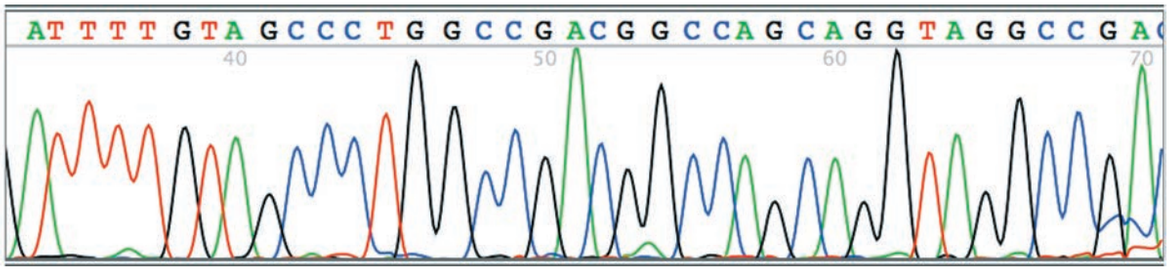
A. Deoxyribonucleoside triphosphate and dideoxyribonucleoside triphosphate

Figure 10.2. Sanger, or dideoxy, sequencing **A.** The Sanger sequencing method relies on the use of special dideoxyribonucleotides that can be inserted into a growing DNA strand by DNA polymerase but block the addition of further nucleotides. **B.** The Sanger sequencing method is based on the synthesis of a DNA strand, using a template strand to guide the insertions of nucleotides. The reaction contains a certain proportion of dideoxynucleotides, which when inserted cannot support the further elongation of the synthesized strand. Because the reaction contains radioactive nucleotides (^{32}P-dCTP, highlighted in yellow), the products of the reaction can be detected by exposure to X-ray film after electrophoresis. For many years, this technique was carried out on thin polyacrylamide gels that were able to resolve fragments that differed in size by a single nucleotide. The fragments visible on the X-ray film were then tabulated by eye and converted into DNA sequence.



B. Sanger DNA sequencing

products can be detected by a laser as they migrate through the gel past the beam. To streamline this procedure even further, each ddNTP can be labeled with a different fluorescent dye, eliminating the need to carry out four reactions; this means that it is no longer necessary to run four separate reactions and run four aliquots on a gel for each sample (Figure 10.3). Reading the sequence is also no longer done manually. Instead, "base-calling" software interprets raw data automatically and provides a direct sequence output and a measure of data quality for each nucleotide in the sequence. Because electrophoresis is continuous, the size of the gel no longer limits the number of fragments read. Larger DNA fragments, not clearly separated by the original Sanger method, undergo longer electrophoretic separation, yielding more sequence data.



Courtesy Trevor Charles

Figure 10.3. Trace from an automated Sanger DNA sequencer Automated methods have improved the efficiency of DNA sequencing and removed the requirement for the researcher to read the gel directly. Fluorescent dye tags are used in place of radioactivity, enabling the automated detection of DNA fragments during electrophoresis. In the resulting output, a different color represents each of the four dideoxynucleotide bases: black for G, green for A, red for T, blue for C. The trace of the peaks can be interpreted by specialized software.

These methods are called **automated sequencing** or **cycle-sequencing methods** and, although they are still based on Sanger's use of dideoxynucleotides, it is now routine to obtain sequences of 700–1,000 nucleotides in a matter of hours for less than a cent per nucleotide.

What happens if a cloned fragment of DNA is longer than a sequencing reaction can measure? The sequence obtained from the first sequencing run can be used to design a new primer that, when subjected to a second run of sequencing, will anneal farther along in the fragment. Consecutive runs of sequencing and primer design allow sequencing of the entire fragment. This technique is called **primer walking** (Figure 10.4).

There is a limit to how much DNA can be cloned into a vector. Most cloning plasmids can hold around 10 kb of cloned DNA, whereas cosmids (see Section 9.3) can hold about 45 kb of cloned DNA. Even one of the smallest bacterial genomes to be sequenced, that of the insect symbiont *Candidatus* Carsonella ruddii (see Section 17.5), consists of 169 kb, which is too big to be cloned in one piece. To sequence a complete genome, many clones must be collected as part of a genomic library and analyzed so that together they capture the entire genome with overlapping coverage. The process involved is repetitive and can now be done without cloning and Sanger sequencing, as you will see later. In this way, the sequencing technology story does not end here because researchers continue to develop new improvements to the process.

High-Throughput Sequencing

During the early days of genomics, few major breakthroughs in DNA-sequencing technology occurred. However, a major cost reduction occurred around 2004 (Perspective 10.1). What caused this abrupt change? New sequencing technologies became available to the scientific community around this time. These were **high-throughput sequencing** methods that were not reliant on gel electrophoresis, also referred to commonly as **next-generation sequencing** methods.

High-throughput sequencing allows the collecting of sequences from many molecules simultaneously instead of collecting information from a single molecule. Originally developed in 1996 by Mostafa Ronaghi at the Royal Institute of Technology in Stockholm, **pyrosequencing** became the basis of the first commonplace high-throughput sequencing method almost a decade later. Like Sanger sequencing, pyrosequencing relies on DNA polymerase-mediated synthesis of the complementary strand of a single-stranded template. It differs from the Sanger method in that instead of using chain-terminating

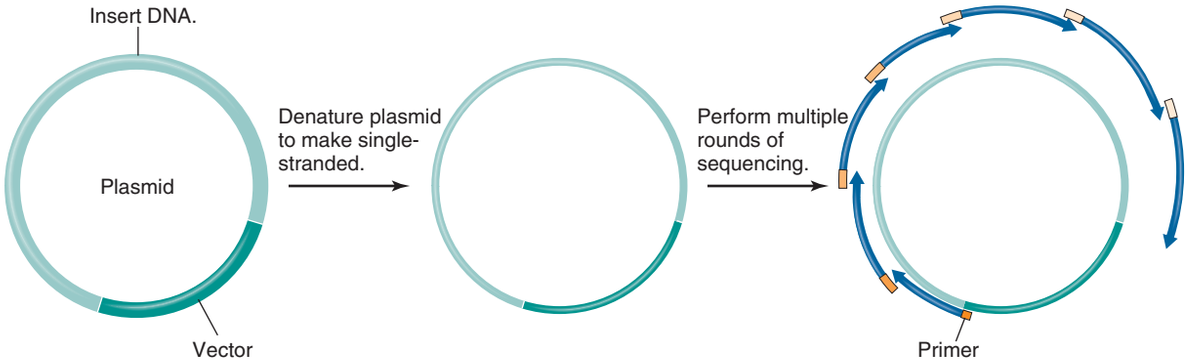


Figure 10.4. Primer walking Sanger sequencing requires binding of a sequencing primer to initiate DNA polymerase activity. As demonstrated in Figure 10.2, the ends of cloned fragments are usually sequenced using sequencing primers complementary to known sequence regions within the vector (in blue). A cloned fragment (insert DNA) of about 3 kb is sequenced using the primer walking method, with each sequencing reaction generating between 500 and 1,000 bases of sequence. The dark blue arrows indicate the sequence that is generated, and the short gold lines at the base of each arrow correspond to the sequencing primers. Starting from the first sequences obtained from the end of the insert using a primer to the vector cloning site sequence, each subsequent sequencing reaction, with the same template, is carried out using primers designed based on the preceding sequence. Note that the primers are all shown as different colors because they are all distinct, designed based on the unique sequence obtained along the DNA template of interest.

Perspective 10.1
RATE OF DNA SEQUENCING

The core principles of dideoxy DNA sequencing have remained the basis for DNA sequencing well into the genomics age. The rate of DNA sequencing, though, certainly has not stayed the same! The number of bases of DNA sequence deposited into public databases has increased exponentially since the mid-1990s **(Figure B10.1)**.

Today, we can sequence genomes more quickly and affordably than ever before. The doubling time for completion of bacterial genomes is 20 months. In other words, about every 20 months, the number of sequenced bacterial genomes (and associated sequencing projects) increases by a factor of two **(Figure B10.2)**. Note that rapid increases are also true for genome projects for archaea, viruses, and metagenomes (metagenomes are discussed in Section 10.4). This exponential increase in throughput has been accompanied by a reduction in cost, which is a result of high-throughput sequencing **(Figure B10.3)**

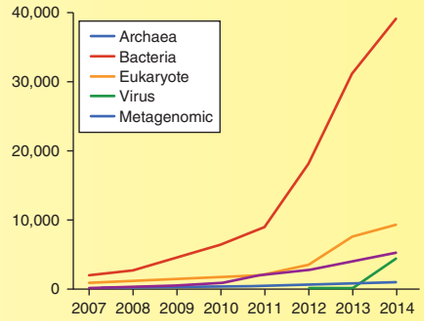

Figure B10.2. Sequencing of bacterial genomes Since the late 1990s, the number of sequenced bacterial genomes has been increasing exponentially, doubling about every 20 months. This rapid increase in genome projects is also evident for other microbes.

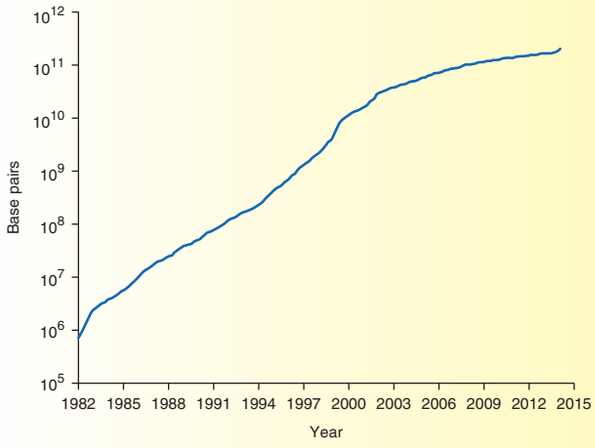

Courtesy of Genbank (NCBI), January 2015

Figure B10.1. Growth in DNA sequencing The amount of sequenced DNA continues to increase rapidly. The number of bases deposited in the GenBank database each year is increasing exponentially.

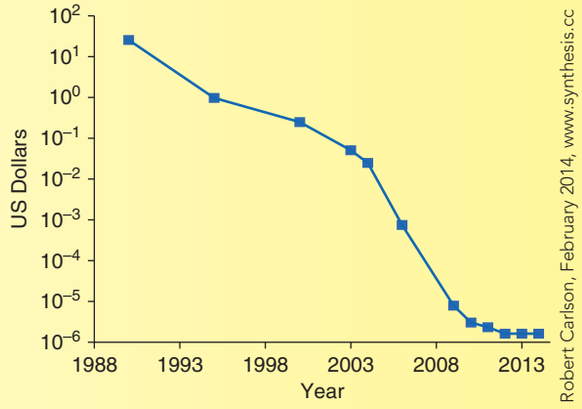

Figure B10.3. Cost of DNA sequencing The cost of DNA sequencing has decreased rapidly over the years. Moreover, the rate of decrease increased dramatically in the first decade of this century. In 1990, an investment of $10 would have yielded a few hundred bases of sequence. In 2015, $10 could purchase hundreds of millions of sequenced bases largely because of advances in sequencing technologies.

ddNTPs, only the four dNTPs are used and the sequence of the strand being synthesized is read in real-time, as it is being created. Each dNTP is added to the reaction one at a time, and only if the dNTP is complementary to the template base, then it becomes incorporated into the growing piece of DNA **(Figure 10.5)**. This incorporation releases pyrophosphate (PPi), which can be converted to ATP by the enzyme ATP-sulfurylase. This ATP will then drive a luciferase reaction, producing light, which can be detected with a charge-coupled device (CCD) camera. This light production gives rise to the name "pyrosequencing." The reaction is repeated sequentially, with multiple steps of adding and removing each dNTP. The removal of unincorporated dNTPs and ATP at each step occurs through the activity of apyrase, which is a nucleotidase enzyme. With every nucleotide added, light will be produced only when an added dNTP is complementary to the next template base.

An adaptation of pyrosequencing—**454 pyrosequencing**—dramatically increases sequencing throughput. Originally developed by Jonathan Rothberg of the 454 Life Sciences Corporation, the name "454" simply originated from the code name of the sequencing technology project. Unlike most applications of the Sanger method, DNA fragments do not have to be cloned into vectors for 454 pyrosequencing. The DNA is fragmented into short pieces, then ligated with nucleotide adapters that facilitate the trapping of these fragments on tiny beads **(Figure 10.6)**. Each bead, containing a single, short DNA fragment, can be separated into its own aqueous PCR mixture droplet within an oil emulsion. PCR is carried out on

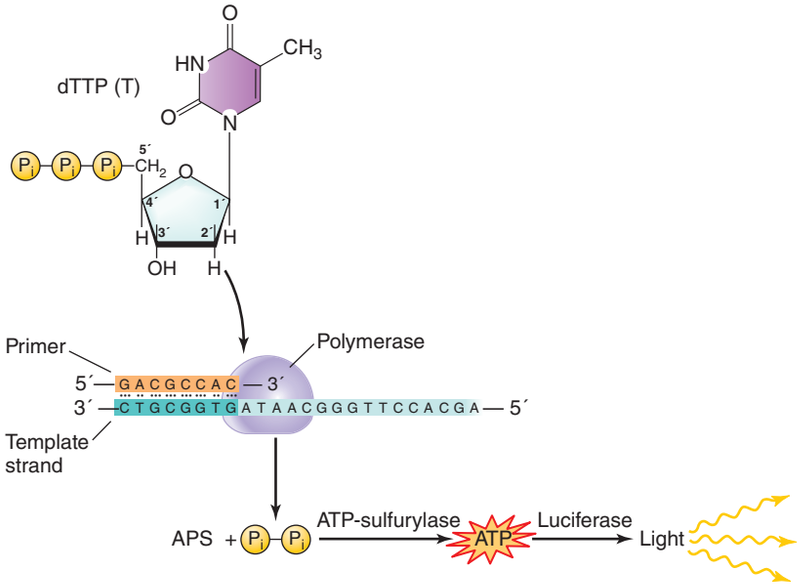

Figure 10.5. Pyrosequencing In the strand shown, DNA polymerase adds dTTP to the growing DNA strand. ATP-sulfurylase reacts with the pyrophosphate that is released upon incorporation with adenosine phosphosulphate (APS), generating ATP. This ATP interacts with luciferase and releases a burst of light. The automated detection of this light by a camera indicates that the nucleotide was added to the growing DNA strand.

the surface of each bead in the emulsion, resulting in thousands of identical DNA molecules on the surface of each bead. Hundreds of thousands of the beads are distributed into individual wells of a flow cell picotiter plate, with each well containing a single bead and its bound DNA. The flow cell picotiter plate is a slide that has almost two million 75-picoliter-volume wells—hence, millions of sequencing reactions will take place simultaneously. The DNA-sequencing reagents are added to each well, and the sequencing reactions are carried out by sequential addition of each of the four dNTPs by horizontal flow over the wells, as is done with pyrosequencing. A CCD camera captures the light. Although short lengths of individual reads initially limited the usefulness of 454 pyrosequencing, subsequent improvements in the technology have led to read lengths greater than 500 bases, which makes it competitive with the Sanger method. Over 500 million bases of sequence data can be generated from a single machine in a 10-hour run.

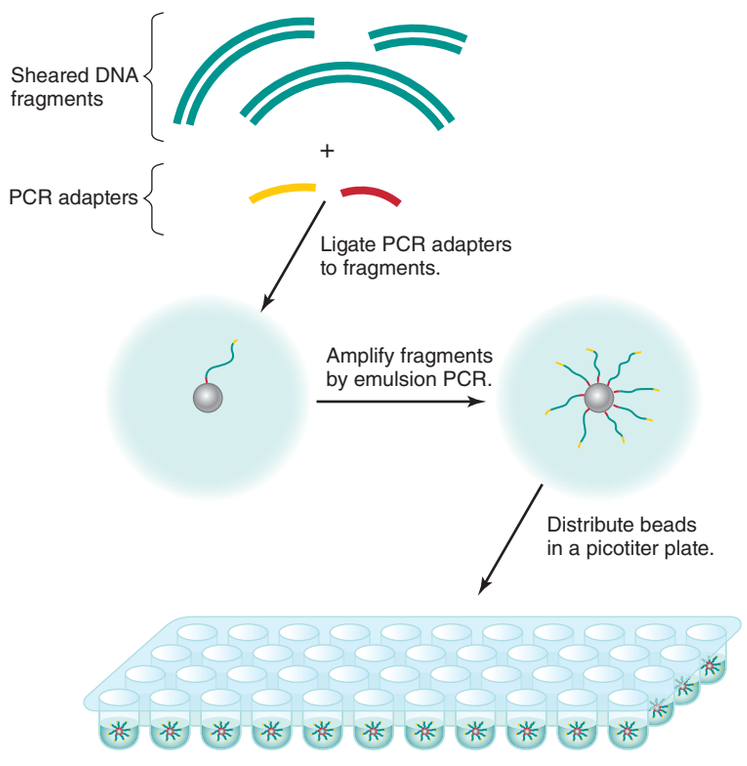

Figure 10.6. 454 pyrosequencing This high-throughput pyrosequencing method starts with shearing of the DNA into fragments. Short adapter sequences are then ligated to the end of each fragment. One of these adapter ends is attached to agarose beads, and the fragment is then amplified by PCR within water droplets, a process called emulsion PCR. Individual beads with the amplification products are distributed in a flow cell, where repeated pyrosequencing reactions are carried out as in Figure 10.5, alternating between each of the four dNTP bases. ATP produced by the DNA synthesis results in light production by luciferase, which can be measured by a CCD camera. Ion Torrent sequencing uses this same overall process but instead measures protons released by the incorporation of nucleotides.

As much as 454 pyrosequencing transformed microbial genomics, other technologies have now largely replaced this platform. Additional high-throughput sequencing methods have been developed that are now more widespread **(Figure 10.7)**. Interestingly, the **Ion Torrent** platform (Figure 10.7A) was also developed by Jonathan Rothberg, the scientist who originated the 454 pyrosequencing platform. The basic principle of Ion Torrent, or ion-semiconductor sequencing, is the same as 454 pyrosequencing. However, instead of measuring light with a CCD camera, a sensor can detect hydrogen ions released each time a particular nucleotide is incorporated. In this way, the system operates like the world's smallest pH meter by measuring protons, with the analysis conducted over millions of wells. In addition to Ion Torrent, another important high-throughput sequencing approach is called **Illumina sequencing** (Figure 10.7B). In Illumina, DNA polymerase adds fluorescently labeled nucleotides to millions of amplified and immobilized fragments of DNA on a glass slide, which is similar in size to a microscope slide. Following imaging, the fluorescent label is cleaved from the terminal nucleotide and another fluorescently labeled nucleotide can be added. The process is repeated until millions of DNA fragments are sequenced in one direction for hundreds of bases, then the process is repeated for the same fragments in the opposite direction if desired. The "paired-end" reads can then be analyzed separately, assembled computationally if they overlap in the middle, or the spatial information used to assist with the assembly of genomes from the millions of reads obtained.

Biologists, chemists, engineers, and mathematicians are working together to develop additional innovative approaches for sequencing DNA. This rapid progress means that new developments are continual while old technologies become obsolete very quickly, such as for 454 pyrosequencing. The most recent developments in high-throughput sequencing include sequencers that deliver extremely long reads of thousands of bases, such as the platform of Pacific Biosciences, commonly shortened to **PacBio**, which can be extremely useful for genome sequencing as described in the next section. Other recent developments include handheld high-throughput DNA sequencers that plug directly into the USB port of a laptop computer!

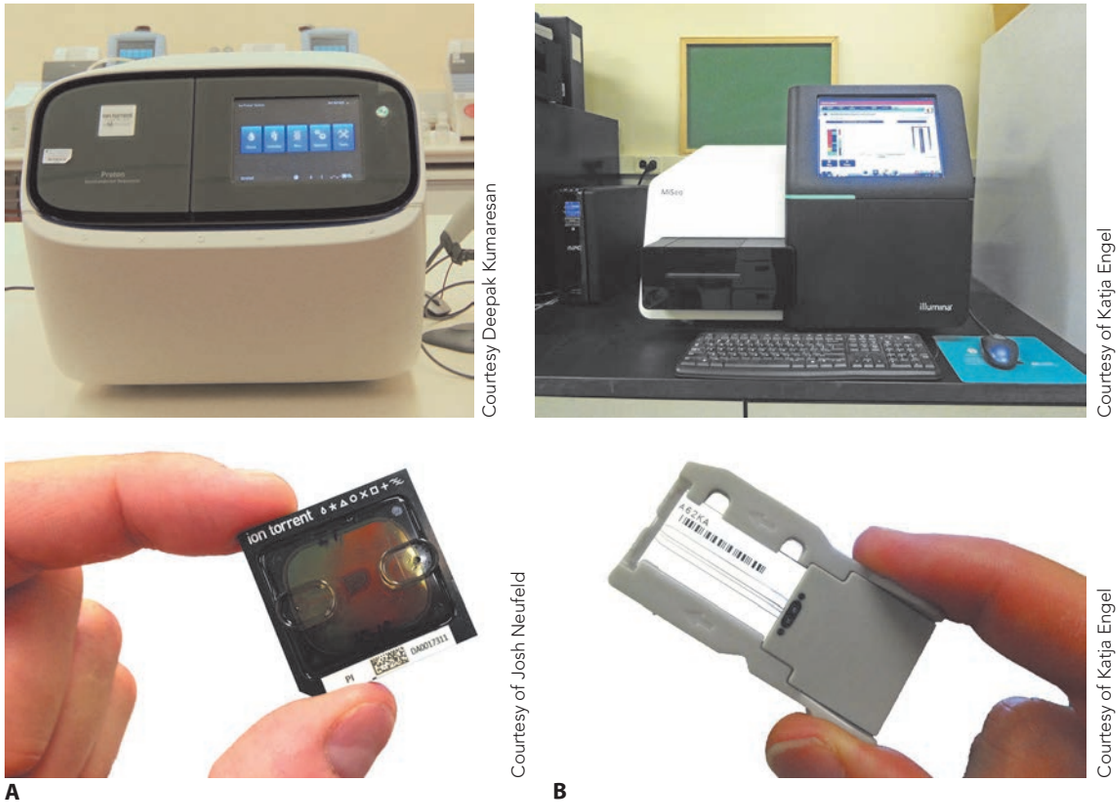

Figure 10.7. High-throughput sequencing technologies Examples of sequencing platforms used to generate millions of reads from DNA fragments, demonstrating the small physical size required for sample analysis. **A.** An Ion PI Chip (*bottom*) and the corresponding Ion Proton system from Ion Torrent (*top*). **B.** A typical flow cell (*bottom*) and the corresponding MiSeq instrument from Illumina (*top*).

Together, these new sequencing platforms, as shown in Figure 10.7, are a far cry from technology that Craig Venter used to generate the first bacterial genome in 1995, which required the use of many Sanger automated sequencers. In fact, a single analysis on any benchtop Illumina instrument now generates far more sequence data than collected by Craig Venter while sequencing the *Haemophilus influenzae* genome, and at a fraction of the cost. What was shocking in its accomplishment and scale decades ago is commonplace and affordable today. Further reductions in cost, coupled with increases in throughput, will continue impacting microbial genomics and microbiology over the next few years.

Shotgun Sequencing

Now that we have explored the methods used to generate sequence data, we can discuss the experimental approaches used to process microbial DNA for genome sequencing. Whether generating high-throughput sequence data with Sanger sequencing, as Craig Venter did, or with alternative sequencing technologies, both leverage **shotgun sequencing** for collecting complete sequences of bacterial genomes. This process involves shearing the DNA into short pieces and then sequencing those fragments from their ends **(Figure 10.8)**. The shearing of DNA can be done by physical methods, such as sonication, or enzymatic manipulations, such as digestions. Generating small fragments from a genome is important for shotgun sequencing because no sequencing methods commonly used today can sequence directly from a large unbroken genome. The sequencing itself can be done by cloning the fragments first, followed by Sanger sequencing, or directly on the sheared and prepared fragments by high-throughput sequencing.

After determining the sequences of individual fragments, researchers use sophisticated computer programs that use algorithms to identify regions of sequence overlap. With this information, individual sequences can be linked together, or assembled, to reconstruct the full genome sequence. Because all of the individual sequences are derived from a random distribution of fragments, the amount of sequence data that must be obtained to ensure complete coverage of the genome is on the order of ten times the genome size. Much more coverage than this is now possible with high-throughput sequencing. More coverage is beneficial because it can help reduce gaps in the final assembly that must be filled in by more time-consuming methods such as primer walking. Another way to reduce the number of gaps in the final genome assembly is to combine data from instruments that produce long, error-prone sequence reads, such as PacBio, with data from instruments that produce many shorter reads, such as those generated by the Ion Torrent or Illumina platforms. In this way, the long reads provide the overall skeleton, referred to as a scaffold, of the assembled genome, and the short reads help to ensure that the final assembled genome does not contain errors.

What is the impact of high-throughput sequencing and shotgun sequencing on microbial genomics? Soon after the development of these DNA-sequencing methods, several research centers established high-throughput genome-sequencing facilities that

could generate data at an astounding pace. Initially, microbiologists began sequencing the genomes of human pathogens because of their fundamental effects on human health. Now, we are determining genome sequences from a broader range of microbes, better representing the diversity and ecology of the microbial world. One outcome is that these genome sequences have reinforced our prediction that wide variation occurs in genome size and complexity among microbes. For example, a 15-fold size difference exists between the genomes of *Mycoplasma genitalium* **(Microbes in Focus 10.1)**, a parasitic bacterium (582,970-bp genome), and *Bradyrhizobium japonicum*, a soil bacterium (9,105,828-bp genome) that forms a symbiosis with the soybean plant. Even within a species, there can be considerable variation in size. For example, *Escherichia coli* genomes may differ in size by as much as 30 percent! Because of this variation, the full complement of all genes within a species of bacteria is called the **pan-genome**. For instance, the pan-genome of *E. coli* includes every gene that is found in all strains of *E. coli*. In addition to the challenges of defining a species and selecting appropriate strains for such analyses, an important challenge is to analyze these increasingly large data sets effectively, using computational tools, which we will explore next.

Microbes in Focus 10.1
MYCOPLASMA GENITALIUM

Habitat: Originally isolated in 1980 from a human urethra. Commonly resides in epithelial cells of human genital and respiratory tracts and is associated with urethritis in humans

Description: Member of the *Mollicutes* class of the *Firmicutes* phylum. Has one of the smallest genomes of any known free-living bacterium, with 582,970 bp encoding 521 genes. Second genome to be completely sequenced, after *Haemophilus influenzae*.

Key Features: Like other *Mycoplasma, M. genitalium* lacks a cell wall and thus is resistant to many antibiotics that target the synthesis of the cell wall. The cells are typically very small, usually less than 1 μm in diameter, and irregularly shaped. Its genetic code differs slightly from the standard genetic code in that TGA codes for tryptophan, rather than a stop codon. Because of its small genome size, it has been studied intensively as part of the Minimal Genome Project (see Perspective 10.2), and its genome is the first genome of a cellular organism to be completely synthesized.

Bioinformatics

As we have seen in the preceding section, high-throughput sequencing methods allow researchers to generate DNA sequence data at a rate unimaginable just 20 years ago. Now,

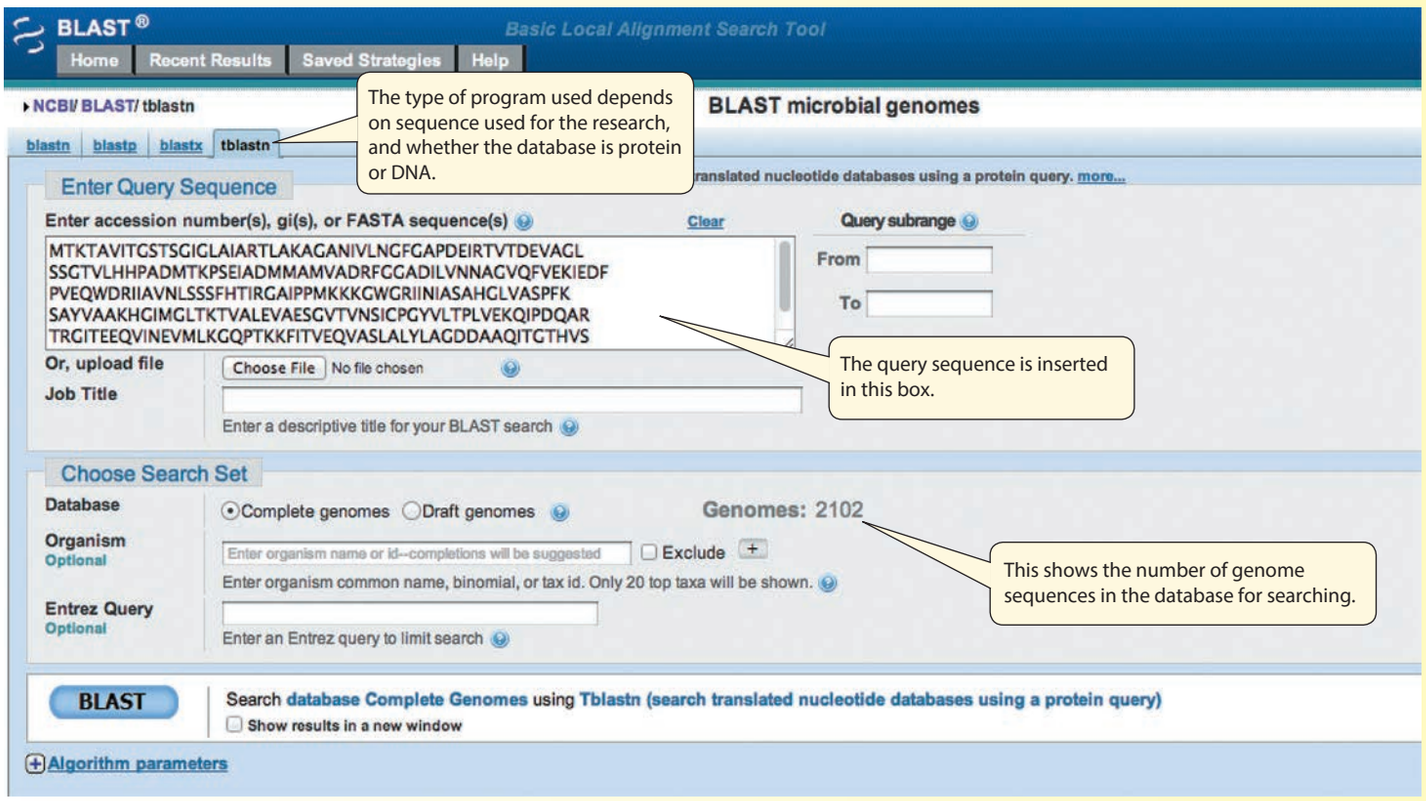
Figure 10.8. Process Diagram: Whole genome shotgun sequencing Whole genome shotgun sequencing is the strategy of choice for determining the sequence of bacterial genomes. It involves the direct sequencing of random clones or DNA fragments. The development of this method was made possible by the improvement of DNA-sequencing methods and the availability of computational power to find overlaps between the obtained sequences.

Toolbox 10.1
GENOME DATABASES

To be most useful to scientists, DNA sequence data should be freely accessible over the Internet. Indeed, three major DNA sequence databases exist: GenBank (National Center for Biotechnology Information; NCBI), the DNA Data Bank of Japan, and the Nucleotide Sequence Database (European Molecular Biology Laboratory; EMBL). Moreover, scientific journals require that DNA sequence data be deposited in one of these public databases before publication in a journal. The databases then share the deposited data, making it readily available to researchers throughout the world.

Although an important function of these databases is to allow distribution of the sequence data, they also serve as portals to a broad range of bioinformatics tools. Using these tools, scientists can query the data in several ways. They can compare sequences at the level of nucleotide or protein, determine whether a gene sequence is similar to any sequences in the database, identify motifs or patterns within DNA and protein sequences, and link to relevant literature in journal databases.

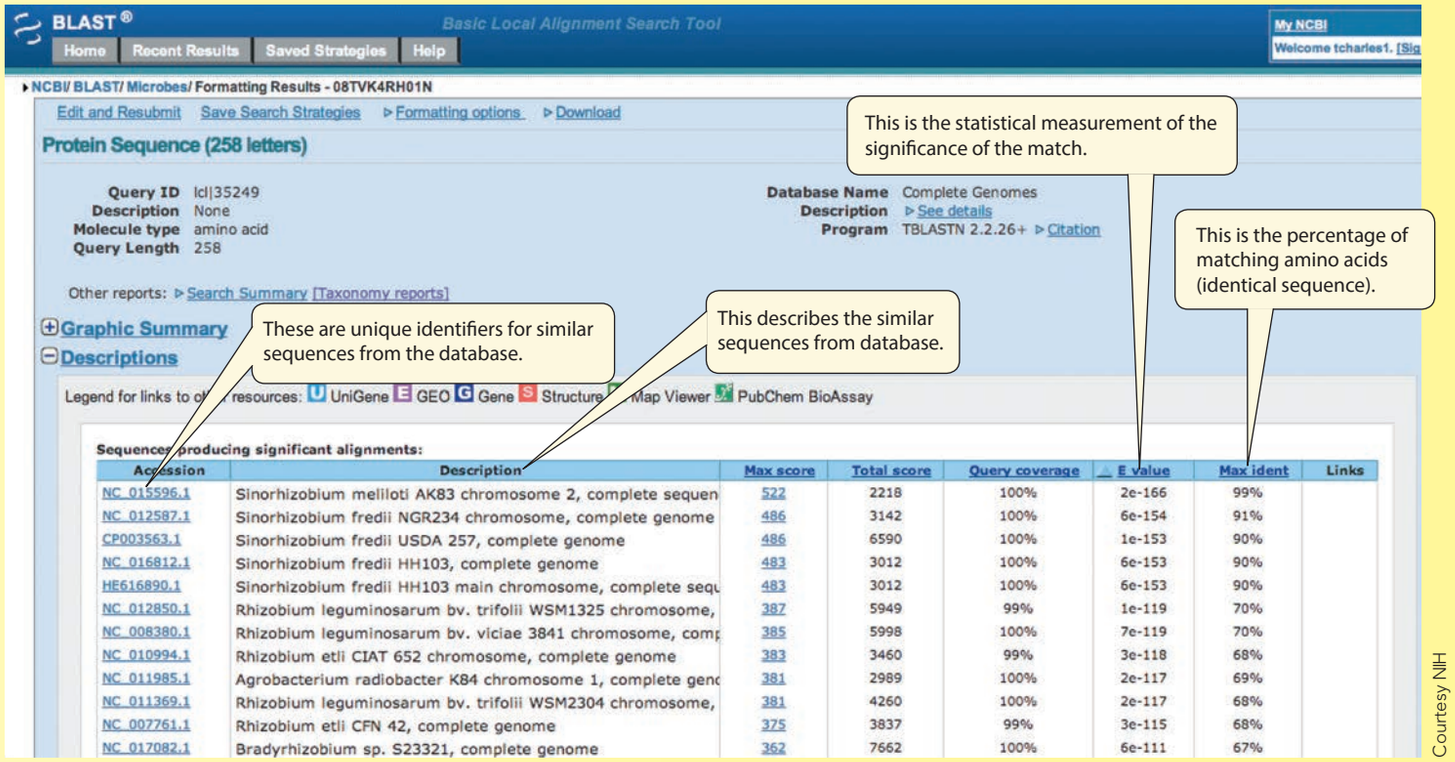
The most widely used search tool is the Basic Local Alignment Search Tool (BLAST) **(Figure B10.4)**. Using the BLAST algorithm, researchers can search nucleotide and protein sequence databases with either nucleotide or protein sequences. An input sequence is compared to previously deposited sequences in the database. A list of the most likely database matches is then generated **(Figure B10.5)**.



Courtesy NIH

Figure B10.4. BLAST Maintained by the National Center for Biotechnology Information (NCBI), the Basic Local Alignment Search Tool (BLAST) allows researchers to enter a query sequence and search for similarities within the existing database. In this example, an amino acid sequence is compared to genomic sequences using the tblastn algorithm, which translates database DNA sequences in all reading frames before comparison with the amino acid query sequence.

the most difficult task in genomics studies is analyzing all of this information. **Bioinformatics**, a burgeoning area within the information technology field, allows us to process large quantities of biological data, and has developed in tandem with advances in DNA sequencing. Many computational tools have been developed that have contributed to the intensity of bioinformatics research. In a process called **annotation**, for instance, researchers use programs employing specific algorithms to predict the beginning and end of protein-encoding sequences or **open reading frames (ORFs)**. Other programs



Courtesy NIH

Figure B10.5. Results of a BLAST search After comparing the query sequence to sequences within the database, BLAST provides the researcher with a list of previously reported sequences that best match the query sequence. In this example, the query sequence matches the sequence of *Sinorhizobium meliloti*.

In addition to the databases listed above and the BLAST algorithm, there are a large number of additional online databases and bioinformatic tools available for exploring microbial genomes. Indeed, over 1,500 of these databases and applications have been catalogued by the journal *Nucleic Acids Research*. Several of these databases are used routinely for categorizing the functionality of new microbial genomes. For example, the Kyoto Encyclopedia of Genes and Genome (KEGG) or Clusters of Orthologous Groups (COG) databases are used commonly to predict broad functional categories for the collection of open reading frames (ORFs) from a sequenced genome. The ORFs are assigned to four categories (e.g., Metabolism) and nineteen subcategories (e.g., Nucleotide metabolism) when using the KEGG database, and to nineteen categories (e.g., Nucleotide transport and metabolism) when using the COG database; often both databases are used to analyze a new genome and the results compared. By assigning functional categories to microbial genomes, a researcher can deduce encoded metabolic and physiological information and compare this information to other previously characterized genomes.

Test Your Understanding

You have sequenced a gene and entered the nucleotide sequence into BLAST. You identify a closely related gene that has been well defined with a very high similarity to your gene sequence. How can you use this information for the next step in your research?

compare the sequences of predicted protein products with the sequences of known proteins available in databases. Based on observed similarities, functions for newly discovered proteins may be suggested. Genome annotation can be a rapid and largely automated process for genomes similar to already analyzed microbes. On the other hand, annotation of genomes from novel microbes can be an extremely laborious task requiring manual verification of potential annotations.

The analysis of sequence data requires access to both the data and the analysis programs. As described in **Toolbox 10.1**,

several repositories of DNA, RNA, and protein sequence data and suites of analysis programs exist that can be accessed via the Internet. Interestingly, these sequence repositories were initiated before the advent of high-throughput sequencing and the widespread availability of the Internet.

Often, sequence analyses can allow researchers to predict the class of protein that a newly discovered gene will produce (Toolbox 10.1). Because of sequence similarities, for example, researchers may predict that a newly identified gene encodes a transcriptional factor, a dehydrogenase enzyme, or a transport protein. However, these predictions are considered tentative until confirmed experimentally and in many cases the ORF sequences cannot even be identified to a general class of protein. In addition, identifying the biological molecules with which proteins interact cannot be predicted reliably. Even for a bacterium as well studied as *E. coli*, many of the genes uncovered by genome sequencing encode gene products whose functions remain unknown. Indeed, as many as a third of the predicted genes in any newly sequenced bacterial genome may be of unknown function. Perhaps more surprisingly, about a quarter of the genes may be unique—present in no other genome that has been sequenced.

What do these "new" genes do? The goal of **functional genomics** is to determine the biological functions of these unknown genes and to gain a better understanding of the functions of all gene products. There are a number of functional genomics projects underway that involve large-scale mutagenesis activities. In these projects, researchers attempt to introduce mutations into each of the genes. They then examine phenotypes of the mutants. Phenotypic changes of mutants can provide important clues about the normal role of the gene and its product.

10.1 Fact Check

1. Describe the Sanger method of DNA sequencing.
2. How does pyrosequencing differ from dideoxy sequencing?
3. What is shotgun sequencing, and how is it used for sequencing genomes?
4. What is bioinformatics and in what ways can it be used for microbial genomics?

10.2 Genomic analysis of gene expression

How can gene expression be measured using genomic tools?

As we will see in Chapter 11, cells will regulate gene expression in response to environmental and metabolic conditions. Most often, the regulation of gene expression occurs at the level of transcription. Some genes may be transcribed under certain conditions, while other genes may be transcribed under different conditions. Similarly, some proteins may be present within a cell under certain conditions, whereas other proteins may be present under other conditions. The production of diphtheria toxin by isolates of *Corynebacterium diphtheriae* and Shiga-like toxin by strains of *Escherichia coli*, for instance, increases when available iron concentrations are low. Other *E. coli* proteins, including iron-binding siderophores, are also produced only when environmental iron is lacking.

CONNECTIONS Why would gene expression be regulated by environmental iron concentrations? As we will see in **Section 19.2**, iron is a limiting nutrient in many environments, including the human body, where it is not freely available because it is bound by other proteins. Pathogens, as a result, have evolved various strategies to acquire it.

Examining mRNA transcripts and proteins present in a cell under specific environmental conditions helps researchers understand the properties and adaptations of microbes. In this section, we will investigate genomic tools that allow us to monitor the abundance of both types of molecules. We will also see what this information tells us about cellular functions. Let's begin by looking at how you might go about measuring the expression of mRNA in a cell.

CONNECTIONS In **Chapter 11**, we will investigate several well-studied gene regulation systems, and delve into their mechanisms. The ability to study these systems using genomic tools provides a much clearer picture of the many regulatory pathways of the cell.

Transcriptomes

Although whole genome sequencing tells us much about the properties of and evolutionary relationships between organisms, understanding the expression patterns of genes allows us to better understand how organisms function under different conditions. Transcription patterns, in other words, can reveal much about an organism. Here, we will see how researchers can analyze the **transcriptome**, or set of transcripts encoded by each of the genes within a genome. How can we analyze the transcriptome of a cell? One answer to this question relies on a fundamental technique in the molecular biology repertoire: nucleic acid hybridization.

Northern Blotting

In 1975, E. M. Southern described a method, now known as the **Southern blot** in honor of the inventor, for detecting specific DNA sequences by hybridization using labeled probes of complementary sequence. This technique involves a gel-based

separation of DNA that was fragmented by restriction enzymes, then is transferred to a membrane for subsequent analysis with DNA probes. The method provided information about the presence or absence of a gene in a genome. A derivation of this technique, termed the **Northern blot**, can be used to measure the transcriptional expression of individual genes (Figure 10.9). In this procedure, researchers first isolate RNA from cells and then separate these molecules by agarose gel electrophoresis. Following electrophoresis, the RNA is transferred to a supportive membrane (usually made of nitrocellulose or nylon) and linked to it, for example by exposure to ultraviolet light. The membrane is then incubated with a chemiluminescent or radiolabeled single-stranded DNA probe. If sufficient sequence complementarity exists between the probe and the RNA on the membrane, then the probe will hybridize with the RNA. The location of the signal on the membrane can then be detected by autoradiography or photography, depending on the nature of the probe. The existence of a signal tells us that a particular gene is being expressed. To some degree, the strength of the signal provides us with information about the level of expression.

Northern blotting still has important applications in the research laboratory. However, solution-based methods of nucleic acid hybridization and PCR (see Toolbox 1.1) have largely supplanted this technique for high-throughput analyses. As we will see in Chapter 11, microbes have evolved complex mechanisms of gene regulation to ensure that specific genes are expressed at specific times. With Northern blotting, tracking the expression patterns of multiple genes becomes quite cumbersome. Other techniques allow us to analyze more easily the expression patterns of many genes at once.

Microarrays

Advances in photolithography, a technique related to computer chip production, and the availability of complete genome sequences have resulted in the development of the **microarray**, a method used to examine the transcriptional activity of all genes in the genome simultaneously. We can think of microarrays as essentially the reverse of Northern blot hybridization. As shown earlier in Perspective 8.1, the process starts with a microarray, which is a glass slide that is spotted with artificially synthesized short single-stranded DNA molecules called oligonucleotides. Researchers convert total mRNA isolated from an organism into complementary DNA (cDNA; see Toolbox 5.2), incorporating a fluorescent label. When more copies of a given transcript exist, then more fluorescently labeled cDNA corresponding to that particular mRNA will be produced. To detect the relative amounts of labeled cDNAs, the cDNA is incubated with the microarray, where it will hybridize to one of the oligonucleotides. A high-resolution scanner generates images of the fluorescent signals on the slide, and specialized software analyzes the resulting data, quantifying the amount of binding to each individual spot. In some systems, cDNAs from two different samples are labeled with different fluorescent labels, and the hybridizations to a single microarray are done simultaneously. By merging the signals, the relative abundance of each transcript can be determined by the color output.

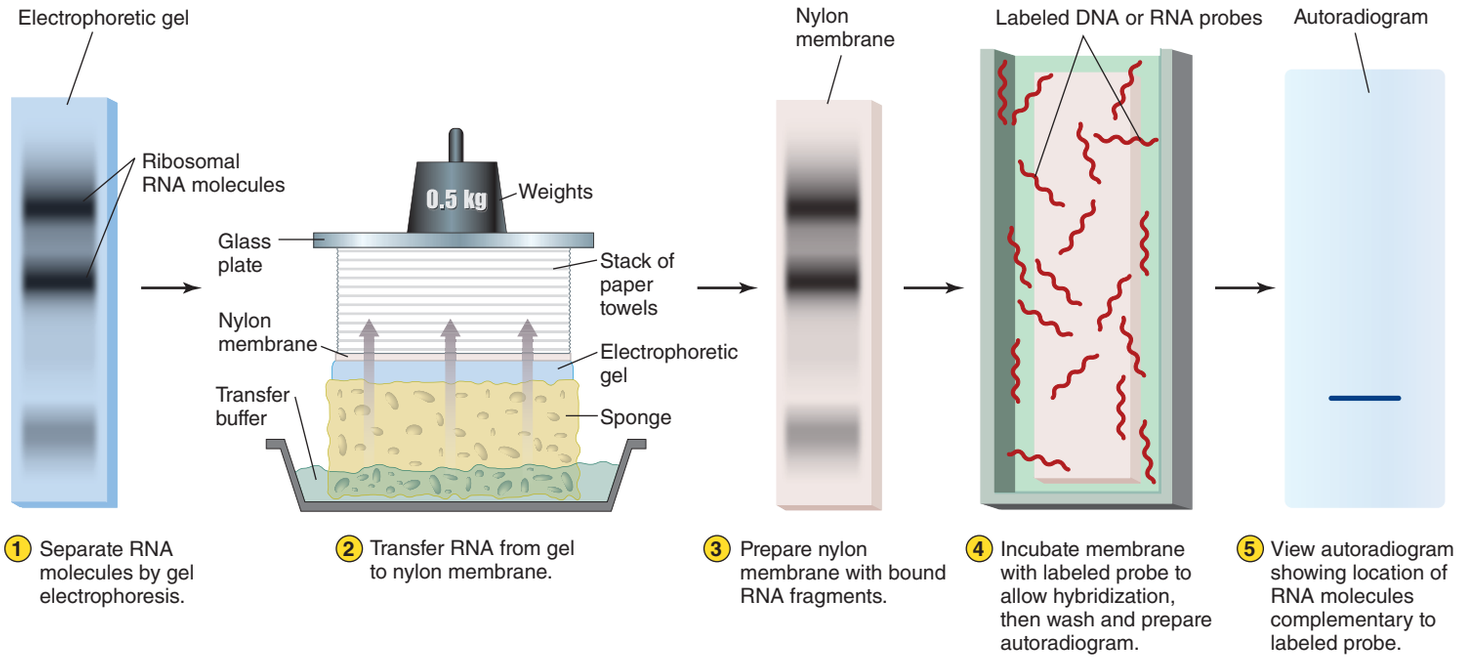


Figure 10.9. Process Diagram: Northern blotting Total RNA is isolated from cells of interest. Electrophoresis is used to separate the molecules by size. The major bands are ribosomal RNA, the most abundant RNA in the cell; the smear represents the collection of other RNA, mostly mRNA. The RNA molecules are then transferred to a nitrocellulose or nylon membrane to provide support for the next process because gels are fragile. The membranes are probed with a labeled oligonucleotide probe that is complementary to the mRNA of the gene whose expression is being examined.

Karp: *Cell and Molecular Biology: Concepts and Experiments*, copyright 2010, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

CONNECTIONS This same technology has been adapted to answer many types of research questions. As we saw in **Perspective 8.1**, investigators used microarrays to identify SARS virus.

To more fully explore the usefulness of microarray analysis, let's consider *Yersinia pestis*, the bacterium associated with the bubonic plague **(Microbes in Focus 10.2)**. Normally, this pathogenic bacterium infects a variety of rodents, including rats, squirrels, and prairie dogs. The bacterium also replicates within fleas, and flea bites serve as the primary mode of transmission between rodent hosts. *Y. pestis* can be transmitted to humans, either via fleas or through contact with an infected rodent **(Figure 10.10)**. We know that humans have a body temperature of 37°C. In contrast, the internal temperature of a flea is much lower, typically below 26°C. *Y. pestis* must be able to survive at these two different temperatures.

We could hypothesize that the temperature shift *Y. pestis* encounters during its transmission from a flea to a warm-blooded host results in a change in gene expression. To test this hypothesis, researchers in China isolated RNA from *Y. pestis* cells growing at 26°C and 37°C (Figure 10.10). Using DNA microarray analysis, they detected over 400 genes, including genes encoding virulence factors and proteins involved in metabolism, that were expressed differently at the two different temperatures. Expression of some genes increased at the higher temperature, while the expression of other genes decreased at the higher temperature. You can see this in Figure 10.10, at the bottom, because some spots on the microarray slide are red (26°C), some are green (37°C), and others are yellow. The red and green spots correspond to genes that may be important determinants of *Y. pestis* pathogenicity because their relative transcript abundances respond differently according to the specific host infected. These genes can be studied further to identify their function, role in pathogenesis, and potential as targets for therapeutic applications.

CONNECTIONS As we will see in **Section 21.1**, virulence factors are studied intensely because they are the specific microbial products that enable or enhance pathogenicity.

Microbes in Focus 10.2
YERSINIA PESTIS

Habitat: Replicates in a wide range of rodent species and can be transmitted between hosts by fleas. Can be transmitted to humans, either by flea bites or by contact with an infected rodent

Description: Gram-negative, rod-shaped bacterium in the *Enterobacteriaceae* family. One of three members of the *Yersinia* genus (along with *Yersinia pseudotuberculosis* and *Yersinia enterocolitica*) that can cause disease in humans

Key Features: During the 1300s, the plague, or Black Death, swept through Europe, killing roughly one-third of the population. Although the plague is uncommon today, it certainly has not gone away. According to the Centers for Disease Control and Prevention (CDC), roughly 10–15 cases of the plague occur annually in the United States, mostly in the rural areas of the Southwest. Annually, 1,000–3,000 cases occur in countries throughout the world.

RNA-seq Technology

RNA sequencing, or **RNA-seq**, represents the most recent advance in studying transcriptomes. In this approach, researchers use high-throughput sequencing to analyze RNA molecules isolated from cells being studied. Briefly, RNA is isolated from cells of interest, the rRNA is removed, and the remaining RNA is converted to cDNA by reverse transcriptase (see Toolbox 5.2). Sequencing linkers, which are short segments of a known DNA sequence, are attached to the cDNA fragments that are then sequenced. The sequences will represent the transcripts within a cell, in addition to smaller RNAs involved in translation (tRNA). Bioinformatic tools then help compare all sequences to known RNA sequences, usually by comparison to the genome of the microbe being studied. In this way, a detailed analysis of the RNA within a cell can be achieved. In many cases, the abundance of RNA transcripts of interest within a cell are confirmed by a separate analysis, such as quantitative PCR (qPCR). In 2008, Michael Snyder and colleagues at Yale University first used RNA-seq to examine the transcriptome of a model eukaryal organism—*Saccharomyces cerevisiae*. Since then, this technique has been used to not only explore the transcriptomes of many other microbes, but also to sequence the genomes of RNA viruses.

RNA-seq can be a valuable tool for comparing gene expression. Indeed, both RNA-seq and microarray analyses are commonly used to compare gene expression for cells grown under different conditions, identify the expression of genes likely under the same regulatory controls (regulons; see Section 11.3), and measure the expression of genes with unknown function, which can yield clues to their roles within cells. Given the increasing affordability of high-throughput sequencing, RNA-seq now is used more frequently in place of microarray technology. Although still in its infancy, the popularity of RNA-seq as a method increases in tandem with advances in sequencing technologies and computational analyses.

Proteomes

Similar to how microbial cells produce different transcripts at different times, microorganisms can also contain different proteins that are a response to specific environmental conditions. The **proteome** refers to this collection of all proteins present in a cell under specific conditions. Differences in protein types and abundance reflect changes in gene expression and/or protein stability. In this way, the proteome is the product of the genome (all genes within an organism) and its corresponding transcriptome (specific genes that are transcribed). Proteomics is important because proteins can vary in stability, in post-translational processing, and in covalent modification

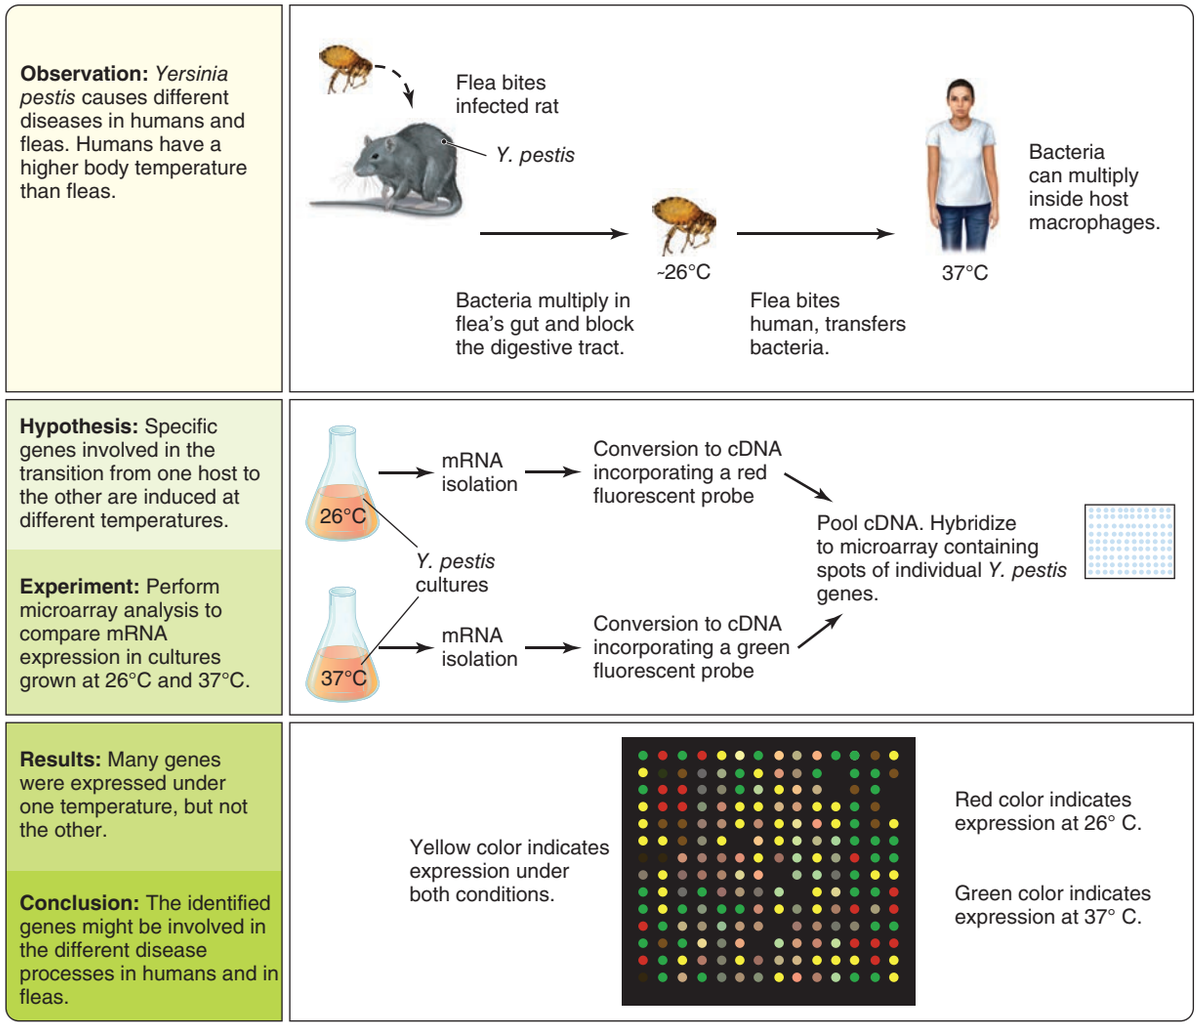

Figure 10.10. *Yersinia pestis* infection cycle and analysis by microarray The hosts that are infected by *Y. pestis* differ in internal temperature, with the human body temperature being much higher than the internal temperature of a flea. To identify possible genes that might be involved in the transition from one host to the other, microarray analysis was performed on *Y. pestis* cultures of different temperatures. The identified genes are candidates for future research because they may be important for causing disease.

states, all of which are relevant to function but won't be detected by analyzing gene expression via mRNA.

Analysis of proteins by gel electrophoresis can be complicated. Different proteins have different overall charges, based on their amino acid composition. Therefore, both the mass and charge of a protein can affect its migration through a gel. In the early 1970s, biologists developed a method for the electrophoretic separation of protein molecules based solely on their molecular mass. As we saw in Section 8.1, inclusion of sodium dodecyl sulfate (SDS) as a detergent in the polyacrylamide gel electrophoresis (PAGE) gel matrix can help separate denatured proteins based on mass. This method is called SDS-PAGE (see Figure B8.1). Although useful for analyzing mixtures of relatively few proteins, many of the bands visible in an SDS-PAGE of an organism's proteome would not resolve properly because they represent multiple polypeptides that have similar molecular masses. Because of this issue, scientists explored using a second dimension of separation of thousands of proteins based on another important property of proteins.

What other property could be used to separate proteins? Remember that SDS-PAGE mitigates the effects of protein charge so that denatured proteins can be separated based on mass alone. In the absence of SDS, each protein has a characteristic pI, or **isoelectric point**, that is a function of its amino acid composition. The isoelectric point is the pH at which the protein contains no net charge. In a pH gradient, to which an electrical current is applied, a protein will migrate to the pH that matches its pI. Using this key property of proteins, researchers developed **2D-PAGE**, a two-dimensional separation method that incorporates separation based on both isoelectric point and mass. With this method, proteins with similar molecular weights can be better resolved over a greater gel surface area.

How is 2D-PAGE used in the lab? Proteins are first subjected to isoelectric focusing. The sample is applied to a pH gradient on a polyacrylamide gel strip. An electric current is then applied to the strip. Proteins migrate along the gradient to the point on the strip where there is no net charge on the protein. In other words, proteins migrate to where the pH equals the pI of

the protein. The strip is then placed along the top of an SDS polyacrylamide gel and the proteins are then electrophoresed in a second direction. This second dimension separates proteins based on their molecular mass. Following these sequential separations, each protein exists as a spot within the two-dimensional matrix (Figure 10.11). Comparing multiple gels, with patterns of spots obtained from cells grown under different conditions, provides a measure of the differences in gene expression. The 2D-PAGE method can also be used to compare proteins expressed by different genotypes of the same microorganism.

Initially, researchers identified pattern differences across multiple gels visually. Today, sophisticated computer programs can compare gel scans, match spots, and indicate significant pattern differences. The 2D-PAGE approach is a powerful method for the identification of genes involved in particular processes. This is because many proteins are often only produced, or are produced at higher levels, under the conditions in which they function or when they are needed by the cell. How does one then identify the proteins and their encoding genes that are differentially expressed? By physically "picking" spots from the gel itself, the identities of proteins within individual spots can be determined using **mass spectrometry (MS)**, coupled with basic knowledge of the corresponding genome sequence (Figure 10.12). With mass spectrometry, one can even determine the amino acid sequences of portions of the polypeptides. Mass spectrometry works by identifying the unique mass-to-charge ratio of proteins, which helps reveal their identity by comparison of similar ratios identified for known proteins.

Instead of 2D-PAGE, mass spectrometry can be preceded by liquid chromatography of the extracted protein mixture in order to separate proteins. This alternative and increasingly commonplace analysis is called **liquid chromatography-mass spectrometry (LC-MS)**, reflecting the combination of liquid chromatography (for separating proteins) and mass spectrometry (for their identification). Although LC-MS and 2D-PAGE

Figure 10.11. Two-dimensional polyacrylamide gel electrophoresis The protein 2D gel electrophoresis method separates polypeptides in two dimensions. The first dimension is based on isoelectric point (pI), determined by pH, whereas the second dimension is based on molecular mass, measured in kilodaltons (kDa). The patterns of spots represent the proteins present in the samples. By comparing the difference in patterns resulting from different strains or culture conditions, inferences can be made regarding the involvement of specific proteins in different processes.

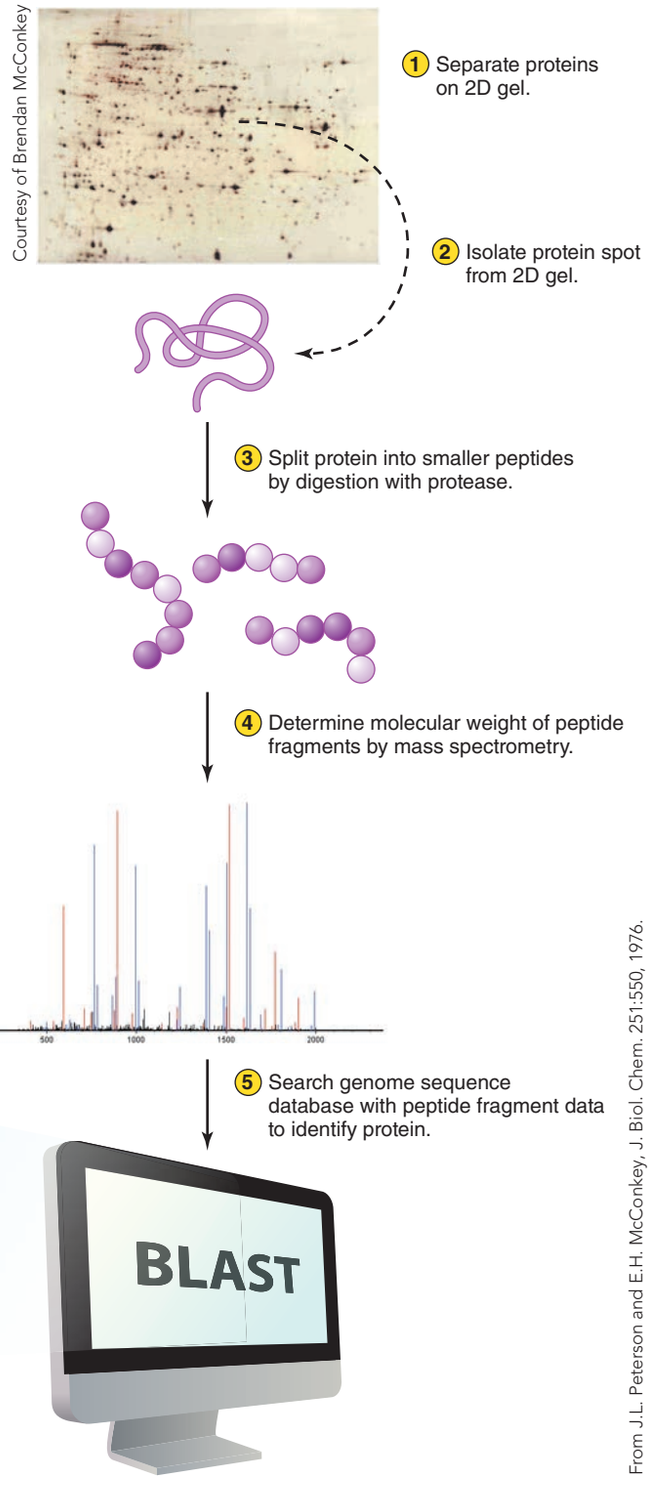

Figure 10.12. Process Diagram: Mass spectrometry to identify proteins The identity of individual spots in a 2D protein gel can be determined using mass spectrometry. This is made possible for organisms with sequenced genomes by comparing the amino acid sequence with the corresponding genome sequence database. In this method, spots are first extracted from the gel and then digested into smaller fragments using proteases. The fragments are analyzed by mass spectrometry to determine the amino acid sequence based on individual mass-to-charge ratios, which can then be compared with the sequence database to identify the corresponding protein.

each have advantages and disadvantages, both methods can enable proteomic profiles, or comparisons, of microorganisms exposed to experimental conditions of interest. Importantly, it is only because of advances in genomics that reference genomes are available for determining the identities of proteins detected by either LC-MS or 2D-PAGE.

Let's examine a specific example of how 2D-PAGE or LC-MS can be used to address a biological question. Perhaps we are interested in the response of an organism to changes in salt concentrations. To address this question, we can compare protein patterns from cells growing under different osmotic conditions **(Figure 10.13)**. This type of analysis often leads to genetic investigations in which the corresponding genes can be mutated, and the phenotypes of the resulting mutants can be investigated to see if their function is actually relevant to the conditions being studied.

Figure 10.13. Proteomic analysis of response to salt concentration In this example, cyanobacterial cultures were prepared in two different types of media that differ in salt concentration. Cell extracts are prepared and proteins then separated by 2D-PAGE. The spots present under one condition, but not under the other, represent genes that are potentially involved in adaptation to the conditions. The corresponding genes can be mutated to further study their function.

Figure 10.14. X-ray crystallography This diagram shows how the diffraction of an X-ray beam by a crystal can be detected. The pattern is used to infer the molecular structure of the molecule.

Whereas 2D-PAGE and LC-MS allow researchers to identify differences in protein production, other powerful tools allow researchers to determine protein structures. Ultimately, the three-dimensional structure of a protein determines its function; knowing the structure of a protein can be valuable for functional analysis of a protein. **X-ray crystallography** and **nuclear magnetic resonance (NMR)** spectroscopy are two primary methods for determining protein structure at the level of individual atoms. X-ray crystallography involves the crystallization of proteins, which is a delicate and often difficult process by which high concentrations of proteins are dried under conditions that favor the generation of tiny crystals. These crystals are then subjected to X-ray diffraction. In this process, an X-ray beam interacts with the protein crystal, resulting in scattering of the beam. A film or detector records the pattern of diffracted X-rays **(Figure 10.14)**. Data from the resulting patterns can be used to infer the structure computationally. One of the difficulties with X-ray crystallography is that most proteins differ substantially with respect to the conditions that will yield crystals of sufficient quality for X-ray analysis. Not all proteins crystallize well, especially hydrophobic proteins that normally associate with cytoplasmic membranes. In contrast to X-ray crystallography, the NMR technique is based on the measurement of distances between atomic nuclei and has the advantage of being able to determine the structure of proteins while in solution. A drawback is that NMR has a maximum size limit of about 30 kDa, which is about the size of an average bacterial protein.

10.2 Fact Check

1. What is a genomic library?
2. Differentiate between the terms "transcriptome" and "proteome."
3. What are the similarities and differences between Southern blotting and Northern blotting?
4. How can researchers use microarrays? Give an example.
5. What is SDS-PAGE? How does it differ from 2D-PAGE?

10.3 Comparative genomics

What information can be obtained from comparing genomes?

We saw in previous chapters how the ability to carry out phylogenetic analyses of organisms based on small subunit rRNA gene sequencing revealed previously unrecognized relationships between organisms. In recent years, these relationships have been further investigated at the whole genome level, a process referred to as **comparative genomics**. Comparative genomics provides us with information about the relationships between different species. In this way, the initial discoveries of the tree of life, including the *Archaea* as its own domain, have been reinforced by comparisons of sequenced genomes. As you will see, comparative genomics provides insight into the phylogeny of all life and the fundamental processes that influence microbial diversity and evolution. In addition to broad surveys of microbial species diversity, comparative genomics can also compare the sequences of different strains of the same species. Altogether, comparative genomics has made it clear that evolutionary relationships among microbes are much more complex than previously realized. As we will see in the **Mini-Paper**, comparative genomics can help us identify genes associated with virulence and pathogenicity. In this section, we will introduce several aspects of this important area of study. We will examine processes by which genetic differences arise. We will also discuss mechanisms by which bacteria can share genetic material. In **Perspective 10.2**, we will investigate an interesting theoretical question: What is the minimal genome necessary for life?

Genetic variability

Let's consider how new genetic capabilities arise in a genome. As we noted earlier, genetic variability ultimately arises from mutations—changes in the DNA sequence. However, analysis of whole genomes reveals that many genes in a given genome belong to related gene families that we assume share a common origin. Such evolutionarily linked genes are referred to as **homologs**.

Some homologs have arisen from gene duplication events. A number of mechanisms can lead to gene duplication, which we do not consider here. Regardless, after such a duplication event, the genome then contains two copies of the gene. One of those copies becomes free to evolve novel functions, leaving the other copy to perform the original function. Homologous

Perspective 10.2
THE MINIMAL GENOME

A fundamental question in biology concerns the core requirements for life. How many genes does a cell require to survive and replicate? In other words, what is the minimal genome for a cell? We can address this question with two different and complementary approaches—the bioinformatics approach and the experimental approach. In the bioinformatics approach, using comparative genomics, orthologs shared in all genomes can be considered to be essential gene candidates. Because they exist in all cells, they may be important for cell viability and overall fitness. Expected in this class of genes would be genes encoding proteins necessary for processes such as transcription, translation, replication, membrane transport, and energy generation.

The first comparative genomics study involved a comparison of the genomes of the first two available bacterial genomes: *Haemophilus influenzae* and *Mycoplasma genitalium* (see Microbes in Focus 10.1). This study revealed 256 shared orthologs between these two genomes. However, researchers later identified only 63 shared orthologs common to one hundred different genomes. Most of these genes encoded proteins involved in transcription and translation. Investigators concluded that comparative genomics probably could not provide a reliable estimate of the minimal genome after all. Most likely, several genes that carry out the same essential functions exist in different organisms. These genes, though, are not sufficiently similar in sequence to be recognized as orthologs.

To further identify essential genes, researchers can also use various methods. For example, gene inactivation experiments reveal a much larger number of genes that can be considered essential. By using a global genome mutagenesis approach, which generates a library of mutants with every gene in a genome disrupted in at least one mutant, we now know that approximately 100 of 482 protein-coding genes in *M. genitalium* are not essential for sustaining life in this microorganism. In addition to the essential protein-coding genes, all 43 structural RNA genes, such as those coding for RNA that occurs within the ribosome, were considered essential. Interestingly, 28 percent of the essential protein-coding genes have unknown function, which underlines the importance of functional genomics for elucidating the roles of essential genes for life.

Researchers can exploit knowledge of the minimal genome to help engineer synthetic microbes. Indeed, a small bacterial genome was synthesized by Craig Venter's team in 2010 and injected into a new host cell. This heralded the first synthetic self-replicating life form, which has been called *Mycoplasma mycoides* JCVI-syn1.0. In addition to better understanding the functions of core genes required for life, an important long-term goal of efforts like these is to engineer new microbial systems with the capacity to carry out "designer" functions of benefit to humans. For example, can you imagine a microorganism that uses light for energy, consumes CO_2, and produces biofuel as waste? We will learn more about this exciting research in Chapter 12.

genes that arise from a duplication event are called **paralogs** (Figure 10.15). Families of paralogs can be quite large. Some paralog families, such as the ABC transporters (see Figure 2.12) and short-chain dehydrogenase families, can have dozens of members in a single genome. Although the gene products of individual family members probably carry out similar functions, the specific substrates of the catalyzed biochemical reactions often differ.

In contrast, homologs with the same function in different organisms that have evolved from the same ancestor through gradual change are called **orthologs** (see Figure 10.15). The evolutionary relationships of orthologs mirror the evolutionary history of their respective genomes. We may assume that genes in two different genomes that encode proteins with high levels of sequence identity are orthologs, but the true test of orthology is the demonstration that they carry out the same functions. For example, the enzymes malate dehydrogenase and lactate dehydrogenase are members of a large family of related enzymes that carry out NAD- or NADP-dependent reactions. Whereas malate dehydrogenases catalyze the conversion of malate to oxaloacetate, lactate dehydrogenases catalyze the conversion of lactate to pyruvate. Typically, each genome encodes several members of this family of enzymes that have resulted from gene duplication events of ancestral genes, followed by evolution of novel substrate specificities. The enzymes that have different substrate specificities and are encoded in the same genome are paralogs. In this way, malate dehydrogenase (malic acid as substrate) and lactate dehydrogenase (lactic acid as substrate) encoded in the same genome would be paralogs. In contrast, malate dehydrogenase encoded in two separate genomes would be considered orthologs.

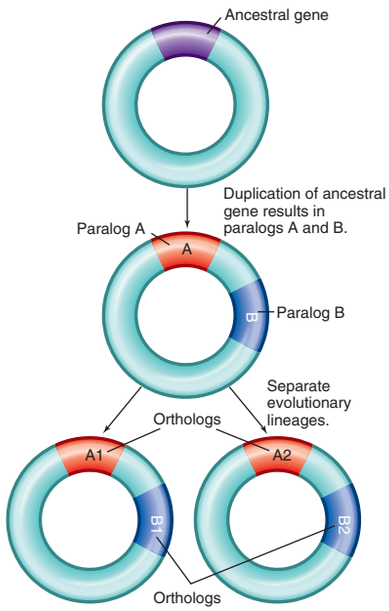

Figure 10.15. Paralogs and orthologs The duplication of genes is important in the evolution of genomes. Two homologous genes that arise via duplication within the same genome, such as A and B in this example (e.g., malate dehydrogenase and lactate dehydrogenase) are called "paralogs," whereas homologous genes that evolve in separate lineages, such as A1 and A2 in this example (e.g., malate dehydrogenase in two different genomes) are called "orthologs."

Horizontal gene transfer

One of the revelations of comparative genomics is the sharing of genetic material by microbes, also known as horizontal gene transfer (see Section 9.4). By comparing the phylogenetic relationships of different genes in different organisms, we can surmise that a substantial amount of horizontal gene transfer occurs among all forms of life. In thinking about how this transfer of genetic material might occur, we can revisit our discussions of gene transfer mechanisms such as conjugation, transformation, transduction, and transposition from Chapter 9. Because of gene transfer events, genomes can be considered as mosaics; extant genomes have arisen from both evolutionary changes and horizontal gene transfers.

CONNECTIONS Most microbes exist in complex communities, as we will discuss in **Chapter 15**. Within these communities, ample opportunities for horizontal gene transfer between species exist. In **Section 24.3**, we will learn that horizontal gene transfer is a major mechanism for transfer of antibiotic resistance genes from one microbial cell to another.

For decades, microbiologists have recognized that bacteria exchange genetic material via horizontal gene transfer. Until the genomics era, many scientists downplayed its importance as an evolutionary mechanism in nature. It is easy to understand this skepticism. Genes from different microbes often have distinct gene regulation features, making it seem doubtful that transferred genes would function very well, particularly if they moved into a distantly related organism. Even if the transfer of DNA occurred, and the DNA segment became fixed in the recipient's genome, such events would have little practical consequence if the recipient could not express the new trait. Acquisition of new DNA might even be deleterious to the organism. The incoming DNA segment could disrupt existing genes or encode a gene that interferes with cellular metabolism. We now know, though, that horizontal gene transfer *does* occur in nature, it *does* have practical consequences, and it *does* play a significant role in microbial evolution.

Several types of evidence demonstrate the process of horizontal gene transfer. Plasmids that can transfer DNA from one cell to another are the most obvious vehicle for horizontal gene transfer, but plasmids do not represent the whole story. Genome sequencing reveals that the genomes of every type of organism contain foreign genes. What is the basis for this conclusion? One indication that a gene or genomic region may have been transferred via horizontal gene transfer is if the base-pair composition of that gene or region differs significantly from the rest of the chromosome. Genomes vary in the frequency of G:C base pairs compared with A:T pairs. Researchers express this value as **percent G+C**, which is the percent of the total base pairs in the genome that are guanines and cytosines. For example, the *Escherichia coli* genome is 50 percent G+C, the genome of the soil bacterium *Streptomyces coelicolor* is 72 percent G+C, and the genome of the yeast *Saccharomyces cerevisiae* is 38 percent G+C. The G+C content usually does not vary much across a single genome, so genes or regions exhibiting a

N. T. Perna et al. 2001. Genome sequence of enterohaemorrhagic *Escherichia coli* O157:H7. Nature 409:529–533.

Context

We all have an intimate association with the intestinal bacterium *Escherichia coli*. It colonizes the human gut shortly after birth. Most *E. coli* strains cause no harm but instead simply exist as low-abundance constituents of the gut microbial community. However, several strains of *E. coli* do cause diseases in humans. Pathogenic strains of *E. coli* cause most urinary tract infections. Even more serious intestinal diseases result from infections with other pathogenic strains. For example, strain O157:H7 can cause a potentially lethal bloody diarrhea in humans. This strain commonly inhabits the gastrointestinal tract of animals such as cattle, although it does not cause disease symptoms in these animals. Unsurprisingly, it is also found in manure from these animals. There have been well-publicized outbreaks related to the consumption of undercooked ground beef, where intestinal bacteria find their way into the meat during processing. Some outbreaks are also linked to vegetables that become contaminated through field applications of manure in addition to improperly maintained drinking water systems contaminated by farm runoff. Surprisingly, this disease was not widely recognized until the early 1980s. In fact, the first known association of O157:H7 with human disease was an outbreak in 1982 involving contaminated hamburgers.

Following ingestion by a human and survival through the acidic stomach, pathogenic O157:H7 cells bind to intestinal epithelial cells, mediated by the bacterial protein intimin. Here, these bacteria produce Shiga-like toxins, which are toxins also produced by related bacteria that cause dysentery. Infection with O157:H7 causes serious damage to the lining of the intestine, resulting in severe abdominal pain and bloody diarrhea. Kidney failure can also develop due to the effects of the toxin.

What causes *E. coli* O157:H7 to be so virulent, whereas other strains of *E. coli* exhibit limited or no pathogenicity? Several genetic factors probably contribute to the virulence and pathogenicity of O157:H7. That said, few virulence factors other than Shiga-like toxin and intimin proteins have been identified. With the aim of gaining a more thorough understanding of how *E. coli* O157:H7 causes disease, Fred Blattner and colleagues at the University of Wisconsin used a comparative genomics approach. They sequenced the

Figure B10.6. Comparison of *E. coli* O157:H7 and K12 genomes The outer ring of this genome map shows a comparison of the O157:H7 and K12 genomes. Light blue regions indicate the genetic material common to both strains. Red regions indicate O-islands (specific to O157:H7), and green regions indicate K-islands (specific to K12). Areas where both O-islands and K-islands exist are indicated in tan. Hypervariable regions are indicated in purple. The second circle (moving inward) shows the percent G+C content data for these two genomes, using the same coloring as the outer circle. Less important for understanding the study, the third circle focuses on the percent G+C content for the third position of each codon. The fourth circle is a scale bar for the positions of bases, moving around the circular genomes, from position 0 to approximately 5.5 million bases. The fifth and final circle indicates information about the orientation and additional features of these two genomes.

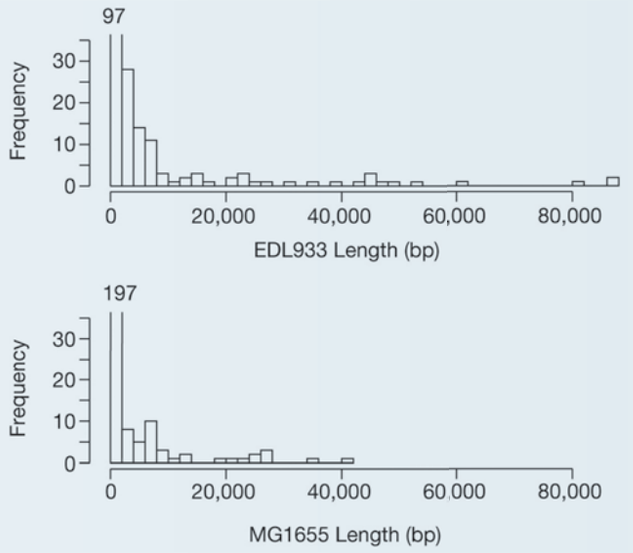

Figure B10.7. Size distribution of O- and K-islands These histograms show the frequency of islands based on size in O157:H7 (labeled EDL933) and K12 (labeled MG1655). More medium- and long-length islands exist in O157:H7.

O157:H7 genome and compared it to the sequence of the non-pathogenic *E. coli* strain K12. A comparison of these genomes, they reasoned, could help them identify other genes associated with *E. coli* O157:H7 pathogenesis.

Experiment

An *E. coli* O157:H7 isolate from ground beef associated with the 1982 outbreak was the chosen strain for this genome sequencing study. This strain contains two plasmids, and the sequence of one of these plasmids was already known. Blattner and colleagues sequenced the chromosome by shotgun sequencing of the whole genome using the Sanger method (see Section 10.1). By comparing this sequence to the non-pathogenic K12 sequence, the researchers quickly recognized that the O157:H7 genome was about 15 percent larger than the K12 genome.

Perhaps more importantly, they determined that large segments of the genome existed in one strain, but not the other. The two strains, which are thought to have diverged from a last common ancestor 4.5 million years ago, share a set of genes, or a common "backbone," consisting of about 4.1 Mb of DNA. These common genes have DNA sequence similarity of at least 98 percent, and 25 percent of the common genes encode identical amino acid sequences. The authors called the unique segments found only in O157:H7 "O-islands," and called the segments found only in K12 "K-islands." They identified 177 O-islands, consisting of 1.34 Mb of DNA, and 234 K-islands, consisting of 0.53 Mb of DNA **(Figure B10.6)**.

The O- and K-islands vary considerably in size. Although most islands are quite short, others are over 80 kb in length. Moreover, the size distribution of these islands differs between the two strains. More medium and long islands exist in the pathogenic strain **(Figure B10.7)**.

The researchers hypothesized that genes associated with pathogenicity would reside within the O-islands and, as a result, analyzed these genes specifically. Unsurprisingly, many of the predicted proteins encoded by O-island genes exhibit similarity to known virulence-associated proteins in other pathogenic *E. coli* strains. These genes include the gene for intimin. Other genes of interest appear to encode virulence factors such as urease enzyme, a type III secretion system, fimbrial synthesis, iron uptake and utilization, and numerous other toxins, including the Shiga-like toxin. Genes predicted to be involved in the catabolism of diverse substrates and genes that confer antibiotic resistance also exist in these O-islands. One could argue that all of these genes might be important for the ability of the bacteria to survive and compete in soil and water habitats and in association with animals.

Impact

Knowing the genome sequence of *E. coli* O157:H7 has provided many opportunities for research that will lead to greater understanding of how this bacterium causes disease. Of direct interest are the genes encoding potential virulence factors that have been identified. To confirm that these genes are related to pathogenicity, it is essential that appropriate experiments be performed. These experiments would include the generation of mutations within each of these genes, followed by testing for effects on the ability to cause disease. Of course, these types of experiments would have to be conducted in suitable animal models that mimic the disease as it occurs in humans. The identification of these genetic factors will provide useful targets for the development of novel treatments for the disease.

This study shows how comparative genomics can be used in the prediction of genes that might be important for virulence. By comparing a pathogenic genome with a non-pathogenic genome, candidate virulence genes can be readily identified. It will be fascinating to see which of these genes are confirmed to be important for causing disease, how this knowledge helps in our understanding of the disease process, and ultimately how this information helps us control this disease.

Questions for Discussion

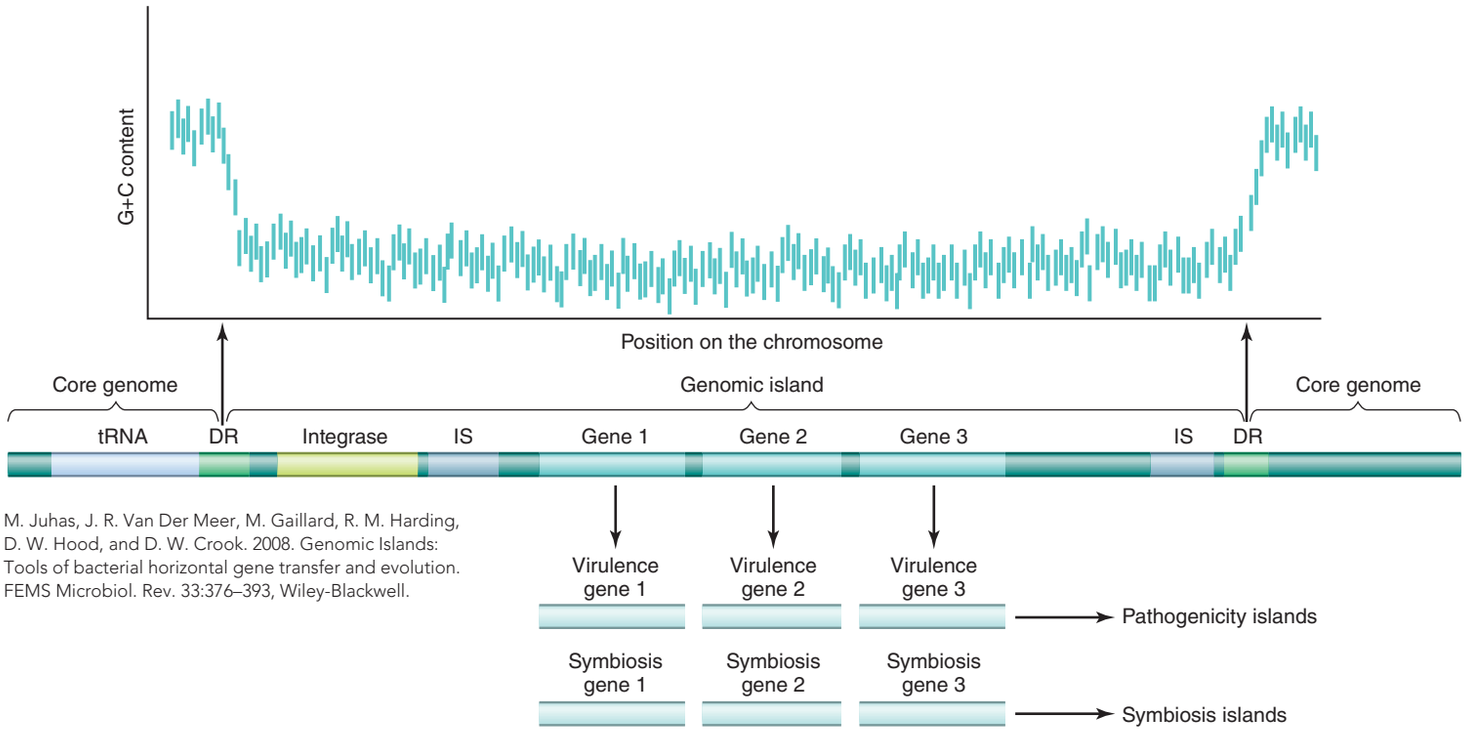
1. This study established that while most of the genes were shared by both genomes and had a very high level of similarity, certain genes were present in one strain and not in the other. These genes were found in clusters called "islands." Discuss some of the genetic mechanisms that might have led to the presence of islands. Where might these islands have originated?
2. Discuss the application of comparative genomics to identify genes that might be important for pathogenicity.

significant difference in G+C content could indicate that the variant DNA had a distinct evolutionary history from the rest of the genome.

To illustrate this point more clearly, let's consider a hypothetical example. Suppose the genome of bacterial strain A has 50 percent G+C content, and the genome of bacterial strain B has 70 percent G+C content. Sequencing studies reveal that gene X in strain B has a sequence that is virtually identical to gene X from strain A, including having a G+C content of only 50 percent. Based on G+C content, then, gene X in strain B more closely resembles the genome of strain A. To explain this observation, we can hypothesize that strain B acquired gene X from strain A. Other clues indicative of horizontal gene transfer include differences in the patterns of nucleotide pairs, codon usage patterns, and presence of repetitive sequences.

Another strong line of evidence for horizontal gene transfer includes gene phylogeny. Horizontal gene transfer is likely involved when evolutionary relationships inferred from sequence analysis for a particular gene, or set of genes, do not agree with the inferred evolutionary relationships of the core genome, as indicated by SSU rRNA sequences, for example. In this case, if the closest related sequences of a gene in the *E. coli* genome are bacteriophage genes, or genes from a Gram-positive bacterium, rather than genes from other *E. coli*, *Shigella*, or *Klebsiella*, it's likely that the gene was acquired horizontally. This can be true even if the G+C content is not anomalous. In fact, horizontal gene transfer is most commonly successful between microbes with similar DNA and G+C content.

By comparing the genome sequences of related microbes, including gene order and location within the genome, it often becomes apparent that large segments of DNA exist in one genome but not in another genome that is otherwise closely related (see Mini-Paper). This observation implies that the introduction or removal of stretches of DNA, presumably by the standard gene transfer mechanisms of transformation, conjugation, and transduction, with the assistance of transposable elements, has occurred. Introduced DNA segments greater than about 10 kb, up to about 200 kb, are called **genomic islands** (Figure 10.16). These islands are commonly associated with tRNA genes, transposable elements, plasmids, or bacteriophages. As mentioned earlier, the pan-genome of any microbial species reflects these complex and widespread processes of genetic exchange, which is an important contributor to the gain or loss of genes and genetic material over time. Indeed, for many microbial species, we now have whole genome sequences of many different isolates, and they can be quite different. For example, there are hundreds of *E. coli* genome sequences available, and many genome sequences of *Staphylococcus aureus* and *Streptococcus agalactiae*. The pan-genome concept reinforces that a single genome sequence does not exist for a microbial species as a result of extensive horizontal gene transfer. In addition, mutations are always occurring to diversify a species.



M. Juhas, J. R. Van Der Meer, M. Gaillard, R. M. Harding, D. W. Hood, and D. W. Crook. 2008. Genomic Islands: Tools of bacterial horizontal gene transfer and evolution. FEMS Microbiol. Rev. 33:376–393, Wiley-Blackwell.

Figure 10.16. Horizontal gene transfer Genomic islands are detected by comparison of genome sequences and analysis of nucleotide composition. They often contain G+C content that is different from the majority of the genome. In addition, genomic islands often integrate at tRNA genes, and contain plasmid or bacteriophage DNA, as well as insertion sequences (IS) and direct repeat sequences (DR). Pathogenicity islands contain virulence genes, whereas symbiosis islands contain genes for symbiosis.

Although it may be possible to identify a core genome common to all strains of a species, genomic analysis has shown that the genome composition within a single microbial species is somewhat open ended.

CONNECTIONS Genomic islands frequently contain genes related to pathogenesis, in which case investigators refer to them as pathogenicity islands. In **Section 21.4**, we will discuss several examples of pathogenicity islands found in human bacterial pathogens.

10.3 Fact Check

1. What are homologs, paralogs, and orthologs?
2. What are some of the ways that genomics can detect horizontal gene transfer events?
3. How can percent G+C be used to detect the possibility of horizontal gene transfer events?

10.4 Metagenomics and related analyses

Can we apply genomics to study uncultivated microbes?

As we have seen in Chapter 9, several approaches exist for analyzing and modifying bacterial DNA. One caveat of such traditional genetic analyses is a requirement that microbes of interest be cultivated prior to their study. Indeed, in almost every introductory microbiology course, instructors stress the importance of working with pure cultures. If cultures become contaminated, then valid conclusions cannot be drawn from any experiments, no matter how good the experimental design. Unfortunately, only a small proportion of microbes from within any given microbial community can be readily cultured on microbiological growth media (see Section 6.4); the remainder can be prohibitively difficult to cultivate and purify. Many of these uncultivated organisms would be fascinating and important to study.

How can we examine a collection of microbes that cannot be cultivated to purity? Fortunately, genomics-based technologies have provided a solution—**metagenomics**—a process in which DNA is extracted directly from microbial communities and analyzed as a composite mixture. The extracted DNA from many microbes can be sequenced directly, as described above, or cloned into vectors to make libraries of this captured DNA for further analysis. Freed from the requirement that a microbe be readily cultured before analysis, metagenomics (also known as environmental genomics) provides unprecedented access to the full extent of microbial diversity. Metagenomics has impacted all areas of microbiological research.

CONNECTIONS Consider the juxtaposition of pure culture microbiology, as discussed in **Chapter 6**, and the natural existence of microbes in complex ecosystems, which we will cover in **Chapter 15**. Metagenomics enables DNA from uncultivated organisms to be examined in detail, thereby providing the means to bring these two worlds together.

To better understand metagenomics' potential, consider several discoveries made possible by applying metagenomics to the marine environment. In the 1990s, Ed DeLong and coworkers at Monterey Bay Aquarium Research Institute began an investigation that would have far-reaching impacts. Studying marine microbial communities, they isolated genomic DNA directly from marine samples, inserting large fragments of this DNA into vectors, and then determined the sequence of these genome fragments. Analysis of these sequences resulted in the discovery of a number of unknown genes, including genes encoding a novel light-harvesting protein, proteorhodopsin. We now know that proteorhodopsins are enormously important to marine organisms, which use them to harness light energy for their metabolism (see Chapter 15). In 2005, Craig Venter and his team (see chapter opening story) sequenced DNA extracted from marine surface-water samples and discovered that members of the domain *Archaea*, specifically the *Thaumarchaeota*, were likely capable of ammonia oxidation under oxic conditions. For a century prior to this metagenomics work, this ability was thought to exist only in a select few ammonia-oxidizing bacteria. Years later, a team from the University of Waterloo analyzed hundreds of ocean metagenomic data sets to discover that these abundant marine thaumarchaeotes are also likely to be important for producing vitamin B_{12} on a global scale, which is essential for the overall productivity of the marine environment. These are a few examples of how sequencing and analyzing mixed-community DNA directly from environmental samples can provide new insight and hypotheses about the many important functions that microorganisms carry out through their individual metabolisms. This is the power of metagenomics!

With the huge diversity of organisms represented in many microbial communities, you can imagine what a Herculean task it is to determine the complete DNA sequences of each of the individual genomes. As a result, usually only a subset of a microbial community is targeted by metagenomics, confined to the analysis of the dominant organisms. In many cases, individual cloned DNA fragments are isolated based on properties of interest, and then those clones are characterized and sequenced. This is referred to as "functional metagenomics," and this approach often involves screening the clones for particular enzyme activities, followed by characterization of the clones. In this way, many new genes have been isolated and characterized from organisms that have never been cultured. The functional metagenomics strategy, pioneered by Jo Handelsman and colleagues at the University of Wisconsin, has transformed many areas of microbiology. Gene libraries constructed from uncultivated microbial communities found

in soil, freshwater and marine environments, wastewater treatment systems, acid mine drainage, and mammalian intestines have yielded new genes encoding novel enzymes and antibiotics, many of which have applications in biotechnology.

As the cost of DNA sequencing continues to decline with a concurrent rise in sequencing capacity, it has become more common to skip the screening step and simply sequence randomly chosen clones of the metagenomic library **(Figure 10.17)** or sequence the metagenomic DNA directly without a cloning step at all. The direct sequencing approach has even resulted in the recovery of assembled genome sequences of the most abundant microbes in the sample, without ever cultivating them. The large amounts of data generated by this type of work can often be overwhelming. For example, a series of publications of metagenomic sequence data from marine environments (again, by Craig Venter's team), produced sequence data equivalent to several times the size of the human genome. These data alone revealed the existence of thousands of entirely new protein families, as well as novel branches of the tree of life. Metagenomics demonstrates that we have only begun to scratch the surface of the knowledge we can gain from exploring microbial communities, as explored further in Chapter 15.

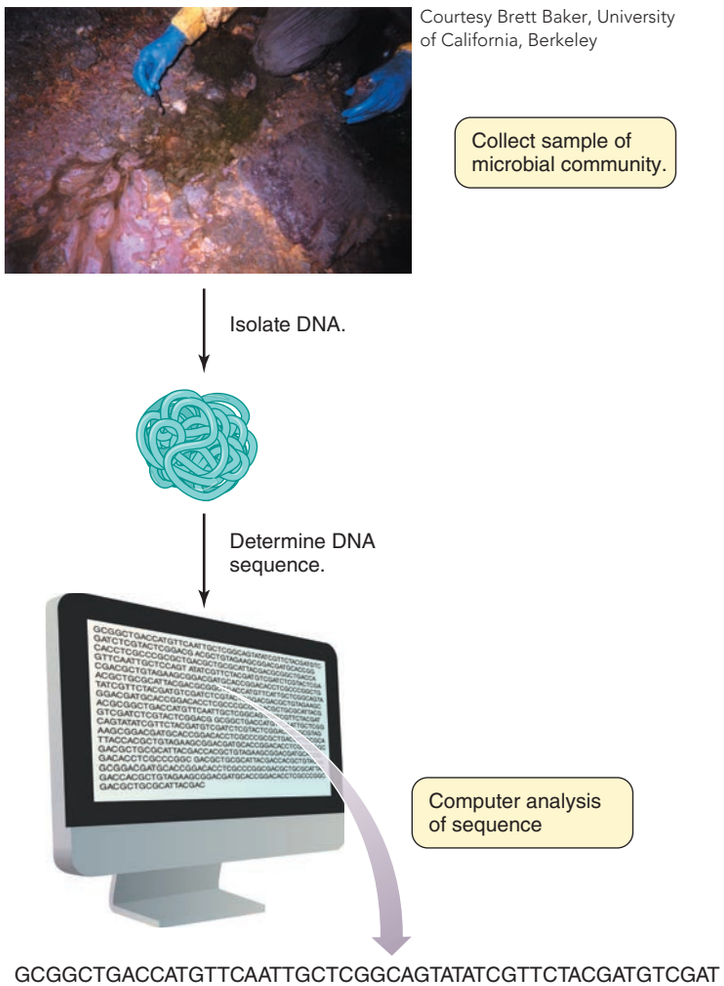


Figure 10.17. Metagenomic analysis Analysis of the genetics of complex microbial communities has been made possible by the development of metagenomic techniques. In sequence-based metagenomics, DNA that has been extracted directly from the community is sequenced directly, and that sequence is then analyzed. A similar analysis would be conducted for metatranscriptomics (analyzing environmental RNA directly) and proteomics (analyzing environmental proteins directly).

You might wonder how a researcher knows the types of microbes that contribute individual sequenced metagenomic DNA fragments. How do we link these sequenced genes to particular microbes? In some cases, comparisons of gene sequences to genomes available in databases can provide an indication of the approximate taxonomic group associated with the recovered DNA (see Toolbox 10.1). In a few cases, such as for Craig Venter and the discovery of ammonia oxidation by marine archaea, the phylogenetic placement of the original organism was readily identified because the metagenomic fragment also contained a small subunit rRNA gene, often abbreviated as SSU rRNA gene. We have seen in Chapter 1 that the widely used tree of life is based on a comparison of these SSU rRNA gene sequences, which greatly facilitates identifying the taxonomic groups.

Even though metagenomics provides direct access to the DNA sequences of microbes in environmental samples, other scientists study microbial communities using related molecular techniques. As we are well aware, microbial communities on Earth occupy an almost limitless diversity of habitats. In many cases, researchers want to quickly survey various communities and catalog the diversity of microbes present. As described further in Chapter 15, the most common approach for surveying microbial communities is to extract genomic DNA directly from samples taken from these habitats, use PCR to amplify the SSU rRNA genes, then sequence these gene fragments directly. The DNA sequences are then compared to DNA sequence databases. In many cases, the sequenced SSU rRNA gene matches existing sequences in the database. Occasionally, though, the newly sequenced SSU rRNA gene does not closely match any known SSU rRNA genes or differ substantially. In these instances, researchers hypothesize that the amplified SSU rRNA genes were recovered from organisms representing branches of the tree of life that had never before been described. Indeed, such gene sequences represent the only information we have about several branches in the tree of life.

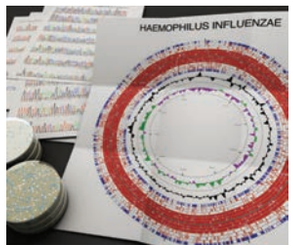
Using these metagenomics and SSU rRNA gene data, the tree of life continues to develop, incorporating information about uncultivated microbes. However, even as this type of research helps us to better understand the diversity of microbes, it has its limitations. Often, researchers cannot make firm predictions about the characteristics of an organism based solely on the available sequence information. Also, the sequence data alone may not provide adequate information about how organisms interact with each other and the environment. One way to gain more functional information about a microbe that has been detected only by single genes, such as the SSU rRNA gene, is to use labeled sequences (probes) in association with permeabilized cells from a complex community to recover single cells. As discussed further in Chapter 15, fluorescently activated cell sorting (FACS) can recover individual uncultivated cells in order to amplify and sequence their

genomes ("single-cell genomics"), gaining new knowledge about the organism and its associated genome.

Just as metagenomics is the adoption of genomics tools for the study of microbial communities, independent of cultivation, other approaches exist for studying additional biomarkers in the same way. For example, metatranscriptomics focuses on RNA extracted directly from environmental samples, and metaproteomics analyzes environmental proteins. Although the methods and bioinformatics used for these meta-analyses are similar to those developed for the analysis of individual organisms, environmental samples pose their own unique challenges for analysis. Co-extracted contaminants can inhibit the analysis of environmental biomarkers, and community complexity can overwhelm the bioinformatics tools commonly used for pure culture analyses. Given the enormous benefits derived from analyzing microbial communities in a cultivation-independent manner, surmounting these challenges is an important research goal for the future of microbial genomics and related analyses.

Image in Action

WileyPLUS Learning Space The laboratory bench of a researcher involved in sequencing the *Haemophilus influenzae* genome is shown. Using the agar plates on the left, the investigator can identify bacterial colonies that have been transformed successfully with plasmids containing fragments of genomic DNA to be sequenced. The printout in the upper left illustrates the results of a Sanger sequencing reaction. The color of each peak indicates the identity of the base in the sequence. The resulting genome map on the right displays open reading frames (red lines) and regions predicted to encode proteins (blue lines), as well as indicating whether the region is G+C-rich (purple) or not (green).



1. Identify and describe the reagents that the researcher used to generate the sequencing results shown in the upper left. How was this process conducted?
2. Now that this stage of the researcher's work has been completed, what would be the next likely step for using these results?

10.4 Fact Check

1. What is meant by the term "metagenomics"?
2. How can metagenomic DNA be linked to a microbe's taxonomy?
3. Describe how the metagenomics approach can affect biotechnology.
4. Compare advantages and disadvantages of metagenomics and genomics.

The Rest of the Story

The successful determination of the genome sequence of *Haemophilus influenzae* was an impressive feat and a springboard into the world of microbial genomics. Looking back on this event, it is clear that it was a landmark on the way to transitioning microbiology into a digital science. Dr. Craig Venter and his research teams have continued to be pioneers in the digital science of genomics and metagenomics research. The J. Craig Venter Institute (JCVI) was formed in October 2006 as a large multidisciplinary genomics-focused organization. JCVI research groups use their genomics tools to explore human genomics medicine, infectious disease, plant, microbial, and environmental genomics, and synthetic biology.

The Institute's Global Ocean Sampling Expedition project has focused on sampling, sequencing, and analyzing the DNA of the microbes inhabiting the world's oceans, many of which were previously unknown. Their work on this project has paved the way for similar analyses of microbes that inhabit the human body, collectively referred to as the human microbiome. The JCVI has played a leading role in the Human Microbiome Project.

In May 2010, the JCVI reported on their successful construction of the first self-replicating, synthetic bacterial cell (see the Mini-Paper in Chapter 12). This synthetic bacterial cell is called *Mycoplasma mycoides* JCVI-syn1.0, and it began as a digitized genome. Progress in sequencing technology and microbial genomics has come a long way in a short time. It is amazing to think that the same scientist can sequence the first bacterial genome, then later demonstrate that genomes can be designed using computers, chemically made in the laboratory, and transplanted into a recipient cell that then is controlled by a synthetic genome!

Summary

Section 10.1: How are genome sequences determined?

- Innovations in DNA-sequencing techniques and information technology have resulted in a rapid increase in DNA sequence data.
- The field of **genomics** was spurred initially by the development of recombinant DNA protocols, improvements in DNA-sequencing techniques, such as **automated sequencing**, **cycle sequencing**, **pyrosequencing**, and the generation of tools for analyzing large data sets.
- Coupling of **Sanger sequencing**, or **dideoxy sequencing**, and **primer walking** allow researchers to sequence large pieces of DNA and close gaps in genome sequences.

- **High-throughput sequencing methods** such as **454 pyrosequencing**, **Ion Torrent**, and **Illumina**, have increased the speed and efficiency with which DNA can be sequenced. These methods are occasionally also referred to as **next-generation sequencing techniques**.
- **PacBio** provides longer sequence reads (with more errors) that facilitate genome assembly.
- **Shotgun sequencing** allows researchers to sequence complete genomes, starting with individual genome fragments.
- **Bioinformatics** facilitates the analysis of genome sequences and the prediction of gene function.
- **Annotation** of genome sequences helps researchers identify **open reading frames (ORFs)**.
- **Functional genomics** determines the biological functions of unknown genes.

Section 10.2: How can gene expression be measured using genomic tools?

- Various techniques allow researchers to analyze the transcripts and proteins within cells.
- A **genomic library** is a collection of cloned DNA fragments that together comprise the entire genome of an organisms, which is particular useful for whole genome studies.
- The abundance of specific cell transcripts can be analyzed by means of the **Northern blot**, a technique similar to the **Southern blot**.
- The entire **transcriptome** of a cell can be assessed by **microarrays**, which analyze the levels of expression of each gene in the genome at a given time.
- **RNA-seq** involves direct sequencing of a cell's transcriptome by using high-throughput sequencing of RNA-derived cDNA.
- **Proteome** studies involve the use of **2D-PAGE**, which separates polypeptides based on both surface charge (**isoelectric point**) and size.
- Individual polypeptides can be identified by **mass spectrometry (MS)**, and this information can be used to determine differences in gene expression patterns.
- **Liquid chromatography-mass spectrometry (LC-MS)** can be combined to separate and identify individual proteins from a protein mixture.
- **X-ray crystallography** and **nuclear magnetic resonance (NMR)** can be used to determine the three-dimensional structure of proteins.

Section 10.3: What information can be obtained from comparing genomes?

- Genome comparisons can reveal much about the evolutionary history of organisms.
- **Comparative genomics** yields new insight into evolutionary processes.
- **Paralogs** are homologs that arise from gene duplication in a single genome
- **Orthologs** encode the same functions but in different genomes.
- Horizontal gene transfer can be detected by comparison of sequence features such as **percent G+C**.
- Comparative genomics can reveal **genomic islands**, which are stretches of DNA transferred from one species to another, and the **pan-genome**, which is the collection of all genes found in all strains of a given species.

Section 10.4: Can we apply genomics to study uncultivated microbes?

- Advancements in DNA sequencing allow us to analyze uncultivated microbes directly.
- **Metagenomics** involves characterization of DNA extracted directly from the complex microbial communities.
- Metagenomic libraries can be analyzed by screening for specific gene function and by large-scale DNA sequencing.
- Marker genes, such as the small subunit ribosomal RNA (SSU rRNA) gene, can help to identify the taxonomic origins of recovered metagenomic sequences.
- Large-scale metagenomic-sequencing projects have resulted in the detection of novel protein families and microbial types.
- Metatranscriptomics and metaproteomics focus on direct analysis of microbial communities, analogous to how transcriptomics and proteomics are used for pure culture analysis.

Application Questions

1. Explain why automated-sequencing results in longer reads than non-automated dideoxy-sequencing methods.
2. In some ways, the dideoxynucleotides used in Sanger sequencing are structurally similar to nucleoside analogs used as antiviral treatments. Explain why.
3. Explain how you could use microarrays to study a pathogenic bacterium before and after it enters the host's lungs.
4. A laboratory technician sets up a sequencing reaction, using the Sanger method. You see him adding several reagents to his reaction tubes. What is he adding, and what will he do next after adding all the necessary reagents?
5. Many complete genomes have been sequenced using a shotgun-sequencing approach. Outline how a researcher can use this approach to sequence a newly discovered soil bacterium.
6. You are asked to determine whether a newly discovered strain of a bacterial pathogen possesses a gene common to many pathogens. Your boss tells you to use the Southern blot to make your determination. Explain what you will need to do and how this process will work.
7. Describe how you could use 2D-PAGE to analyze expression of genes induced at low pH. How would you identify the specific proteins involved in low-pH growth?
8. Eating a hamburger that is cooked rare could be deadly, while eating a steak that is cooked rare is less risky. Discuss what developments would be necessary to make the consumption of a rare hamburger a safe experience.
9. Strains of two bacterial species are being studied to determine if horizontal gene transfer of an antibiotic resistance gene (*bla* gene)

has occurred. What would you conclude based on the results below? Explain your answer.

Percent G+C analysis of strain X and strain Y

DNA sampled	percent G+C
Strain X	57
Strain X *bla* gene	48
Strain Y chromosome	48
Strain Y *bla* gene	48

10. A microbial geneticist isolates a new mutant of *E. coli* and wishes to map and sequence the mutation accurately.
    a. What genomics techniques could she use?
    b. Using what you have learned in Chapters 9 and 10, compare the approach that she might have taken in 1990 with the approach that she could take in 2016. Explain your answer.
    c. What are the pros and cons of the approaches described above?
11. Several patients in a hospital acquire an unknown gastrointestinal illness. All efforts to cultivate the causative agent have failed. What type of experiment might you set up in order to identify the genes and microbes associated with this illness? What would be the advantages and drawbacks of such an analysis?

CHAPTER

11 Regulation of Gene Expression

The second half of the twentieth century witnessed perhaps the greatest series of developments in the history of the biological sciences. In earlier chapters, we learned how researchers determined that DNA was the genetic material, discovered genetic mechanisms in bacteria, and revealed the structure of DNA. They also formulated the idea of gene regulation using this knowledge. Indeed, the 1965 Nobel Prize for Physiology or Medicine was awarded to François Jacob, André Lwoff, and Jacques Monod in recognition of their discoveries regarding genetic regulation in bacteria and bacteriophages.

These French researchers, working at the Institut Pasteur in Paris, struck on a visionary idea: that cells only produced enzymes when they needed to. In their great example, they noted that *Escherichia coli* much preferred to use glucose than lactose, the milk sugar. Furthermore, the enzyme for degrading lactose was only detectable when lactose was present and glucose was absent. In following up on this idea, they proposed the operon concept, which describes a mechanism by which regulatory genes can direct cell metabolism by altering rates of transcription of structural genes. The discovery of gene regulation in *E. coli* had far-reaching impact on the understanding of the living world, as foreshadowed by the famous quote from Jacques Monod, "What is true for *E. coli* is also true for the elephant." These types of insights made the Institut Pasteur a mecca for many young scientists from around the world.

Through a series of elegant genetic experiments, and driven by intuition, these scientists showed for the first time that genes can be turned on and off. By studying the control of metabolism of lactose, and also the control of infection of *E. coli* by the lambda (λ) bacteriophage, they deduced the fundamental nature of gene regulation and discovered genes whose sole role was to regulate expression of other genes. Since these early discoveries, scientists have studied numerous gene regulatory systems in an assortment of microbes. The diversity of these systems is remarkable, although probably not unexpected, given the immense variety of microbes and their habitats.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Enzymes can be regulated in several ways.

CONNECTIONS for this chapter:

Allosteric regulation of enzymes **(Section 13.2)**

Chaperonins in hyperthermophilic archaea **(Section 4.3)**

Chloramphenicol mode of action **(Section 24.2)**

Genetic engineering of plants with *Agrobacterium* **(Section 12.5)**

Introduction

As we have seen in previous chapters, microbes live in diverse, ever-changing habitats. Survival depends upon their ability to utilize the available resources and to respond to changes in environmental conditions. Consider the waterborne human pathogen *Vibrio cholerae*. It can thrive in aquatic environments, but it can also infect humans, causing disease. Or consider rhizobia bacteria. They can live in the soil, but can also live symbiotically in compatible leguminous plants, where they fix nitrogen. How do microbes respond to these dramatic environmental shifts?

Inside the cell, shifts in the activity or availability of enzymes occur in response to these changes in environmental conditions. Fluctuations in enzymatic activity typically result from changes in the structures of the enzymes. Although this type of regulation is quite effective and can occur quickly, it does have a significant downside. The cell has used energy and resources in the transcription and translation of genes coding for inactive enzymes that are activated only when needed.

How can a cell avoid this waste of energy and resources? A more energy efficient way to control metabolic pathways might be to regulate the transcription and/or translation of genes. In other words, the cell could regulate the amount of a protein present by controlling gene expression, rather than by regulating the activity of the protein. As we will see throughout this chapter, control of gene expression plays a central role in governing responses to environmental changes.

In this chapter, we will present a variety of well-researched examples of how microorganisms control gene expression. Some control mechanisms affect one gene at a time, while other control mechanisms affect groups of genes. At the end of the chapter, we will examine three relatively complex bacterial behaviors—quorum sensing, virulence, and chemotaxis—and uncover the roles of both gene expression and protein modification in these behaviors. As we progress through this chapter, we will consider the following questions:

How are gene expression and enzyme activity controlled? (11.1)
How do regulatory proteins control transcription? (11.2)
How does a single environmental stimulus control multiple operons? (11.3)
How can mRNA be controlled? (11.4)
How do bacteria communicate with their neighbors? (11.5)
How do environmental conditions affect gene expression? (11.6)
How can bacterial cells regulate their behavior? (11.7)

11.1 Differential gene expression

How are gene expression and enzyme activity controlled?

In Chapter 7, we learned how the processes of transcription and translation result in the production of gene products with specific functions. As we consider the activities of a cell, though, it should be obvious that not all gene products are required at all times. Cells may need some gene products all the time, such as the enzymes involved in glycolysis, transcription, and translation. After all, these gene products are needed for metabolism and the production of proteins—essential processes of a cell. Therefore, the genes encoding these products are always expressed, a state referred to as **constitutive expression**. A cell may need other gene products only under certain conditions. For instance, a cell requires enzymes to metabolize a particular substrate only when that substrate is available. Similarly, it needs to produce an essential molecule only when sufficient amounts of that molecule are not present in the environment. Expression of genes encoding these products, then, may be turned on or off as needed, a state referred to as **inducible expression**.

How can genes be turned on or off? The answer is quite interesting, and quite complex (Figure 11.1). The binding of RNA polymerase to the promoter controls the initiation of transcription. Enzymatic degradation of mRNA may be regulated, thus influencing the amount of transcript in the cell. Translation of mRNA may be inhibited. The mRNA secondary structure can influence both mRNA degradation and translation. Even after translation, the functions of individual proteins may be activated or silenced. Let's begin our exploration of this topic by examining how the activity of enzymes can be regulated.

Activity of enzymes

Organisms can regulate the activity of enzymes by altering their structure and therefore their binding properties. Enzymes already present in the cell can be turned off rapidly if they are not needed suddenly. In a pathway of many steps, the final product often inhibits the activity of the enzyme at the first step of the product synthesis pathway. The inhibitory product may bind to the enzyme, changing its conformation so that the substrate is unable to bind at the active site. This type of regulation is called **allosteric inhibition**, and it shuts down the pathway (see Figure 13.9B). In other cases, enzyme

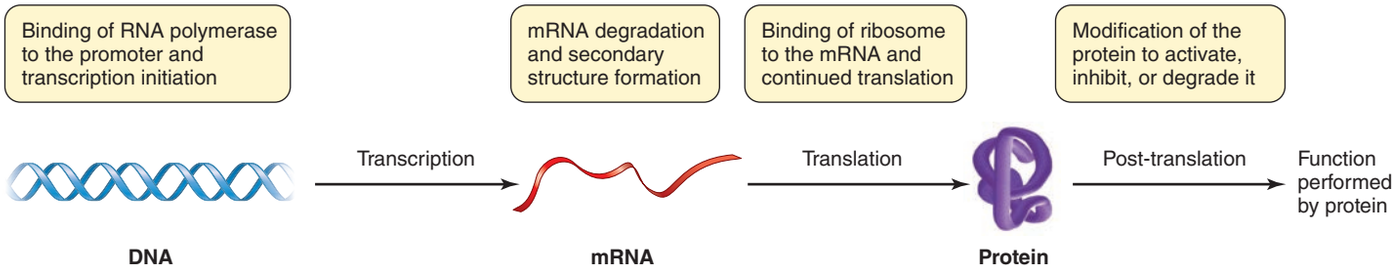

Figure 11.1. Control of gene expression Gene expression can be controlled at several levels, ranging from control of transcription to control of translation to activation or inhibition of the final gene product.

activity can be regulated by **covalent modification**, such as phosphorylation (PO_4) or methylation (CH_3) of the enzyme (Figure 11.2). Bacteria use both of these forms of modulation to control chemotaxis, a topic we will investigate in Section 11.7. Even though enzymes can be quickly deactivated by allosteric or covalent modifications when a rapid response is required, a more efficient way to control metabolic pathways would be to regulate transcription of the genes that encode these enzymes, thus saving energy and resources.

CONNECTIONS In biochemistry, the binding of a molecule to an enzyme resulting in a change of shape and therefore change in activity of the enzyme is referred to as allosteric regulation. In **Section 13.2**, we will investigate allosteric regulation and its role in ATP production.

Production of enzymes

The production of an enzyme begins with gene transcription, resulting in mRNA that is translated subsequently to protein. The initiation of transcription can be regulated in several ways. Often this control involves regulatory molecules and DNA-binding proteins that affect the ability of RNA polymerase to bind to the promoter on DNA. By modulating the ability of RNA polymerase to bind, these molecules affect the amount of transcription that occurs. When transcription is prevented, no mRNA is produced and no protein is made. The amount of transcript can also be affected by factors that influence mRNA stability. Normally, however, mRNA degrades within minutes of its production. Therefore, the window for controlling this mechanism is narrow.

Recall from Section 7.3 that RNA polymerase binds to DNA at the start of a gene, at the promoter. Promoter sequences vary, but the most common sequence is called the **consensus sequence**. For a given gene, RNA polymerase will bind most tightly to the optimal promoter sequence, resulting in a very high basal level of gene expression in the absence of any regulatory proteins. RNA polymerase will bind less well to weak promoters, promoters with sequences that differ from the optimal sequence, resulting in a low basal level of activity. Activator proteins can increase the binding of RNA polymerase to weak promoters, whereas repressor proteins can obstruct the binding of RNA polymerase to promoters.

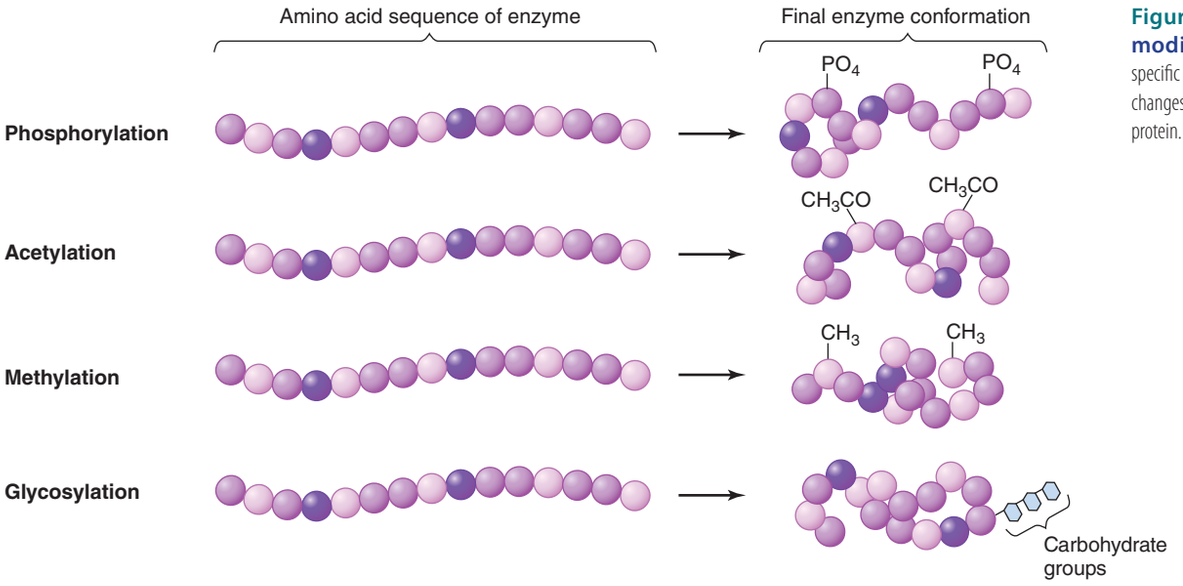

Figure 11.2. Enzyme covalent modification Binding of molecules to specific sites on proteins can cause conformational changes that inhibit or enhance the activity of the protein.

CONNECTIONS In bacteria, the component of the RNA polymerase that actually binds to the promoter is the sigma factor. **Toolbox 7.1** describes how DNA-binding proteins like the sigma factor can be identified using a gel shift assay.

As we will see later in this chapter, other regulatory processes occur after the initiation of translation. In some cases, the mRNA molecule is produced but translation is inhibited. These mechanisms may be the least common regulatory processes; they are neither the most efficient nor the quickest. Nevertheless, mechanisms of translation inhibition involving small RNA molecules are under intense study. We will explore these intriguing molecules in Section 11.4.

11.1 Fact Check

1. Describe the difference between constitutive and inducible genes. What types of genes might be constitutive, and what types of genes might be inducible?
2. Microbial cells can regulate the amount of protein produced. At what level is this control most efficient? At what level is it quickest?
3. Explain the various ways enzyme activity and/or metabolic pathways can be regulated.

11.2 The operon

3D ANIMATION

How do regulatory proteins control transcription?

Although the initiation of transcription can affect the production of a single polypeptide, it may often be advantageous for a cell to coordinately regulate the production of several polypeptides. For instance, if the cell requires polypeptides A, B, and C for a single process, then the production of polypeptides A, B, and C should occur (or not occur) at the same time. Operons facilitate this type of coordinated regulation. The classic definition of an **operon** is a transcriptional unit consisting of (1) a consecutive series of structural genes that code for polypeptides, which are transcribed from a single promoter, and (2) regulatory DNA elements that affect their transcription. Such polycistronic operons, which encode more than one polypeptide, commonly exist in bacteria (see Figure 7.27). They generally are not present in eukarya, where each mRNA transcript typically codes for only one polypeptide. Often, the products of the genes of an operon participate in a single biochemical pathway (Table 11.1). Simultaneous transcription, therefore, facilitates efficient operation of that pathway.

TABLE 11.1 Examples of operons

Organism and name	Function	Number of structural genes
Escherichia coli lac	Transport and catabolism of lactose	3
Escherichia coli trp	Biosynthesis of tryptophan	5
Agrobacterium virB	Virulence genes involved in DNA transfer from bacteria to plant	11
Klebsiella pneumoniae nifHDK	Nitrogenase enzyme involved in nitrogen fixation	3
Conserved throughout bacteria, S10	Ribosome structure	11

To investigate how operons function, let's explore the *lac* operon of *Escherichia coli*, the study of which contributed greatly to the development of the operon concept (Figure 11.3). The *lac* operon consists of three structural genes, *lacZ, lacY*, and *lacA*, and an **operator**, which is a DNA sequence to which regulatory proteins can bind. The product of the *lacY* gene, permease, facilitates the uptake of lactose by the cell. The product of the *lacZ* gene, *β*-galactosidase, facilitates its enzymatic breakdown (Figure 11.4). These genes are encoded on a single transcript, along with the *lacA* gene, which encodes *β*-galactoside transacetylase. The role of this enzyme in lactose metabolism remains unclear.

How can the cell regulate the expression of these structural genes? A single promoter controls the initiation of transcription in an operon. Regulatory proteins that bind the operator, along with associated effector molecules, modulate the ability of RNA polymerase to bind to the promoter and initiate transcription (Table 11.2). The genes encoding these regulatory proteins may be located adjacent to the operon on the chromosomal DNA, or they can be located elsewhere on the chromosome. As we will see in this section, these regulatory proteins can inhibit operon transcription, a process referred to as negative control, or facilitate operon transcription, a process referred to as positive control. Additionally, as we will see in Section 11.3, some regulatory proteins have a number of target genes distributed throughout the genome.

Negative control of transcription

In general, higher rates of transcription initiation result in higher levels of mRNA transcript and higher levels of protein production. **Negative control** refers to regulatory mechanisms involving a **repressor**, which blocks transcription. The repressor binds to the operator as a dimer and inhibits the binding of RNA polymerase to the promoter. **Effectors**, molecules that are often intermediates of the related metabolic pathways, interact with repressor proteins and modulate their ability to bind to

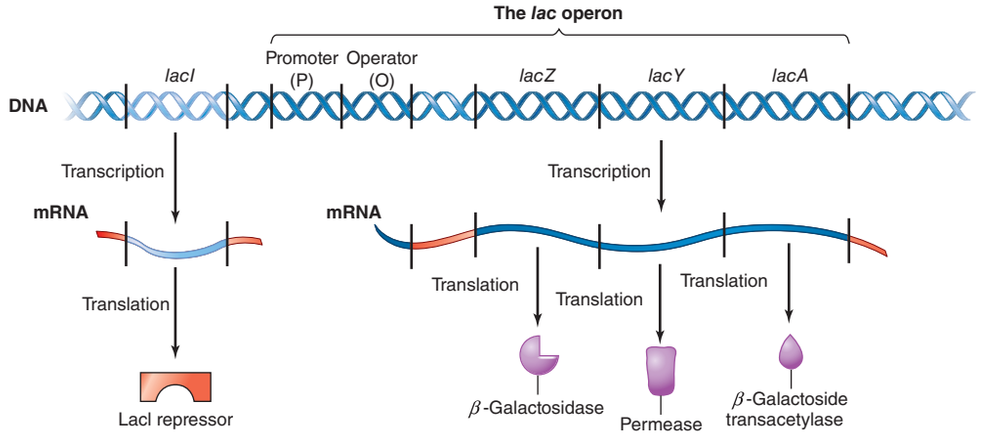

Figure 11.3. The *lac* operon The *lac* operon includes three structural genes (*lacZ*, *lacY*, and *lacA*) along with a single promoter and an operator. A regulatory gene, *lacI*, is located upstream of the operon and encodes the LacI repressor protein, which controls the operator.

the operator. This is an example of allosteric regulation. Binding of the repressor to the operator blocks the path of RNA polymerase, thus inhibiting transcription. Effector molecules can be either **inducers**, which inhibit binding of the repressor protein to the operator, or **corepressors**, which enhance binding of the repressor to the operator.

The *lac* operon of *E. coli* is a good example of an inducible catabolic pathway involving negative control of transcription **(Figure 11.5)**. In the absence of lactose, a repressor binds to the operator as a dimer, blocking the promoter site. When lactose is present in the environment, allolactose, a metabolite of lactose (see Figure 11.4), acts as an effector, binding to the repressor and preventing it from binding to the operator. Allolactose, then, can be classified as an inducer; it counteracts repression and allows transcription of the structural genes that enable the use of lactose. Negative control shuts down the catabolic pathway in the absence of the substrate, lactose.

Now that you are familiar with how the basic system works, one thing that you may have thought about is how lactose enters the cell initially. If transcription of the *lac* operon is off, then we might assume that there would not be any permease in the cell membrane and lactose could not enter. Clearly, this doesn't make sense, and there must be a way to overcome such a conundrum. It turns out that the *lac* operon is a leaky system; it is never completely turned off. Thus, there is always some very small amount of permease being made even when lactose is not present. Additionally, there may be some permease present in the membrane from past expressions. This allows some lactose to enter the cell and turn on the operon. Similarly,

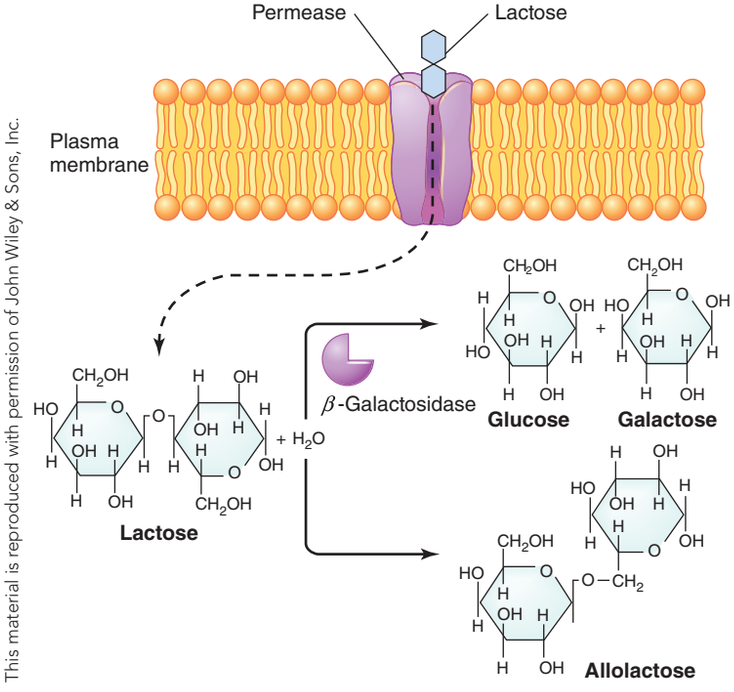

Figure 11.4. Action of β-galactosidase Lactose can be cleaved into glucose and galactose that can be further metabolized by the cell. Lactose can also be converted to allolactose, which can turn on the *lac* operon.

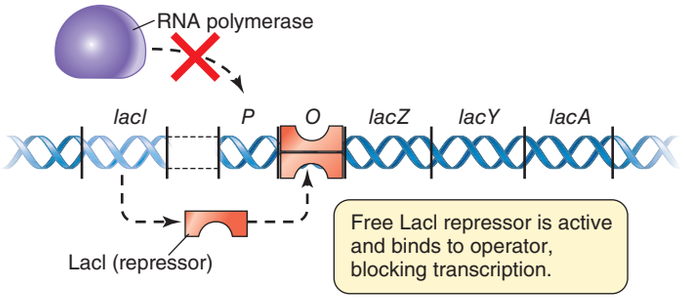
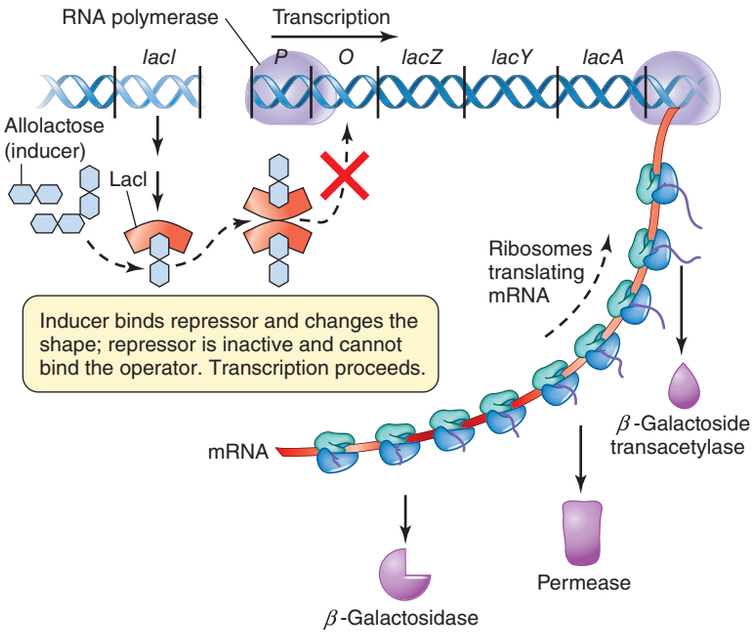
TABLE 11.2 Key components of operons

Feature	Definition
Promoter	Site on the DNA bound by the RNA polymerase; the promoter directs the initiation of transcription.
Activator	Protein that binds to a site on the DNA; the activator assists binding of RNA polymerase to the promoter, resulting in increased transcription initiation.
Activator binding site	Site on the DNA bound by the activator.
Repressor	Protein that binds to the operator on the DNA, inhibiting transcription.
Operator	Site on the DNA bound by the repressor.
Effector	Small molecule that binds to activator or repressor proteins, modifying their gene regulation activity.
Inducer	Effector that increases transcription by enabling an activator or disabling a repressor.
Corepressor	Effector that decreases transcription by enabling a repressor.

Figure 11.5. Inducible expression: The *lac* operon Inducible operons can be repressed in different ways. **A.** When the repressor binds to the operator, it blocks transcription by the RNA polymerase. **B.** When an inducer (allolactose) binds to the repressor (LacI) and prevents the repressor from binding to the operator, transcription proceeds.



A. Absence of inducer: Repression



B. Presence of inducer: Induction

Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

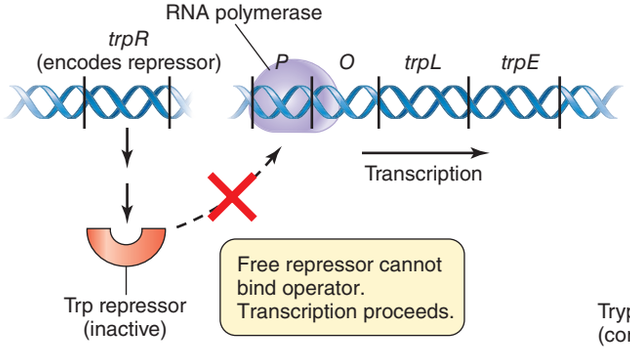
there will always be some β-galactosidase present to convert lactose to allolactose to begin induction.

The anabolic pathway for the production of tryptophan in *E. coli* presents an example of a repressible pathway involving negative control of transcription (Figure 11.6). At relatively low intracellular concentrations of tryptophan, the repressor does not bind to the operator of the tryptophan (*trp*) operon and the cell produces tryptophan. If tryptophan is present in the environment, however, then the tryptophan acts as a corepressor. It binds to the repressor, allowing it to bind to the operator and block transcription. In this example, negative control shuts down the anabolic pathway in the presence of the essential molecule, tryptophan.

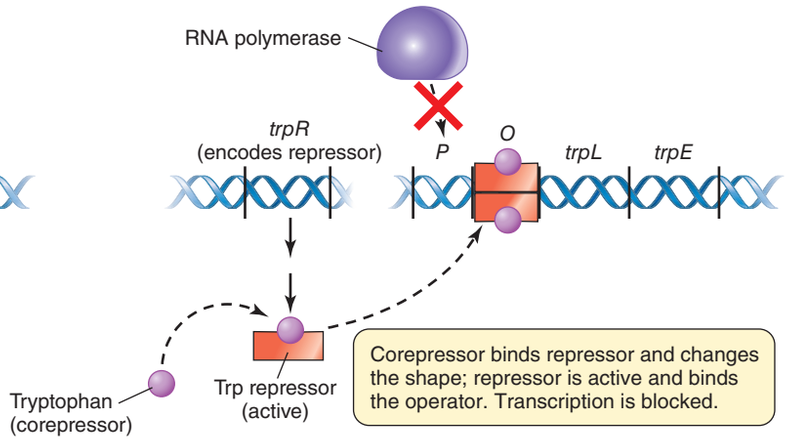
Positive control of transcription

Operons can also be regulated by **positive control**, in which activator proteins lead to increased transcription. An **activator molecule** increases the affinity of the RNA polymerase for promoters that otherwise do not bind them very strongly. An inducer can alter the conformation of the activator protein, changing its ability to bind to an **activator binding site** on the DNA. In this case, the pathway may be shut down either by an inhibitor that removes the activator from the activator binding site on the DNA or removal of the inducer.

To better understand how positive control works, let's revisit the *lac* operon. This operon exhibits both negative



A. Absence of corepressor: Induction



B. Presence of corepressor: Repression

Figure 11.7. Positive control of transcription of the *lac* operon by activators An activator protein (CRP) must bind to the activator binding site for transcription to proceed. **A.** In the absence of coactivator (cAMP), CRP does not bind the activator binding site, the RNA polymerase does not bind well to the promoter, and there is no activation of transcription. **B.** Under low-glucose conditions, the amount of cAMP will increase. When cAMP binds CRP, it is able to bind the activator binding site, increasing the affinity of RNA polymerase for the promoter, resulting in transcription.

and positive transcriptional control. *E. coli* cells grow better using glucose than using lactose. Quite simply, cells expend less energy during glucose metabolism as it enters glycolysis directly. Conversely, lactose must first be converted to galactose and glucose. As a consequence, the presence of glucose overrides the ability of lactose to activate the *lac* operon.

As we noted earlier, the presence of lactose in an *E. coli* cell leads to the removal of a repressor from the operator, allowing RNA polymerase to bind. For transcription of the *lac* operon to occur, however, an **activator protein (cAMP receptor protein,** or **CRP)** must bind to the activator binding site to enhance binding of RNA polymerase to the promoter. Furthermore, CRP requires the coactivator cyclic AMP, or cAMP, before it can bind to the activator binding site. In the presence of glucose, levels of cAMP are low. As a result, CRP does not bind to the activator binding site with great affinity. RNA polymerase, in turn, cannot bind to the *lac* operon promoter, and transcription of the *lac* operon genes does not occur **(Figure 11.7)**. This phenomenon, called catabolite repression, ensures that *E. coli* preferentially utilizes glucose. Conversely, when glucose levels are low, cAMP levels increase, CRP facilitates binding of RNA polymerase to the promoter, and the cell can make the enzymes needed to use lactose (see Figure 11.7B). Of course, in the absence of lactose allolactose would not be present to remove the repressor from the operator site and the enzymes would be produced only in very small amounts **(Figure 11.8)**.

Investigating the *lac* operon

In the preceding two sections, we gained a better understanding of how the *lac* operon is regulated. In this section, we will address a different question about this operon. How do we know that the operon is regulated in these ways? The nature of the *lac* operon has been revealed through the work of many scientists whose experimental analyses have defined the study of genetics in bacteria.

Let's begin by investigating the role of glucose on the *lac* operon. Although wild-type *E. coli* cells can use lactose to support growth, glucose is the preferred carbon source for these cells. When growth medium contains both glucose and lactose, the cells will exhaust the supply of glucose before they start using lactose, resulting in a **diauxic growth curve (Figure 11.9)**. Between the two growth phases, a lag occurs during which *lacZYA* transcription and translation begin. In the first phase, during which the cells metabolize glucose, faster growth occurs than during the second phase, when cells metabolize lactose. How is this preferential use of glucose over lactose coordinated?

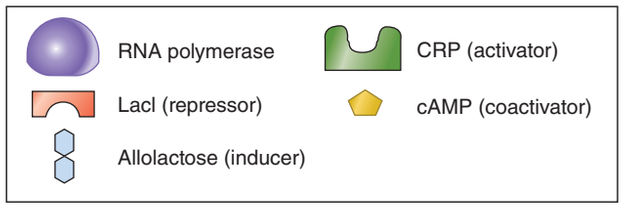
Genetic studies of lactose utilization began with the isolation of a series of mutants that were unable to metabolize lactose. One class of mutants did not exhibit β-galactosidase activity, while another class did exhibit β-galactosidase activity, but still could not grow using lactose. Interrupted mating experiments indicated that the mutations causing these two phenotypes mapped close to each other (*lacZ* and *lacY* in Figure 11.3). The first group of mutants, in which β-galactosidase activity was abolished, was called Z, while the second group of mutants was called Y. Using radioactive lactose, researchers demonstrated that the transport of lactose into the cell required Y, the enzyme now known as permease. We now know that *lacA* is the third gene in this operon, but mutations in *lacA* do not affect lactose utilization or transport.

In subsequent experiments, researchers isolated mutants that exhibited constitutive (constant) expression of β-galactosidase in the absence of lactose. These mutants were designated *i*– for inducer-negative. When a second, wild-type copy of the *lac* region was introduced into this i^- strain using a plasmid, the constitutive phenotype of the *i*– mutants could be complemented; they were now inducible for expression of β-galactosidase **(Figure 11.10)**. This occurred even though the wild-type alleles were expressed from different DNA molecules. Investigators hypothesized that one of the wild-type alleles synthesized a diffusible repressor that is absent in the mutant strain. This repressor, LacI, subsequently was shown to be a protein.

CONNECTIONS **Section 9.4** describes how F-prime plasmids can be used to add a copy of a gene to a cell. This type of genetic manipulation enables researchers to conduct the type of complementation study used to characterize the regulation of the *lac* operon.

Glucose concentration	Lactose concentration	cAMP concentration	Operon status	Level of *lacZ*, *lacY*, and *lacA* transcription	Lactose metabolized?
Low	High	High		High	Yes
Low	Low	High		Low	No
High	Low	Low		Low	No
High	High	Low		Low	No

Figure 11.8. Control of *lac* operon expression The binding of LacI repressor by allolactose and binding of CRP activator by cAMP regulate expression of the *lac* operon so that maximal expression occurs in the presence of lactose and absence of glucose.



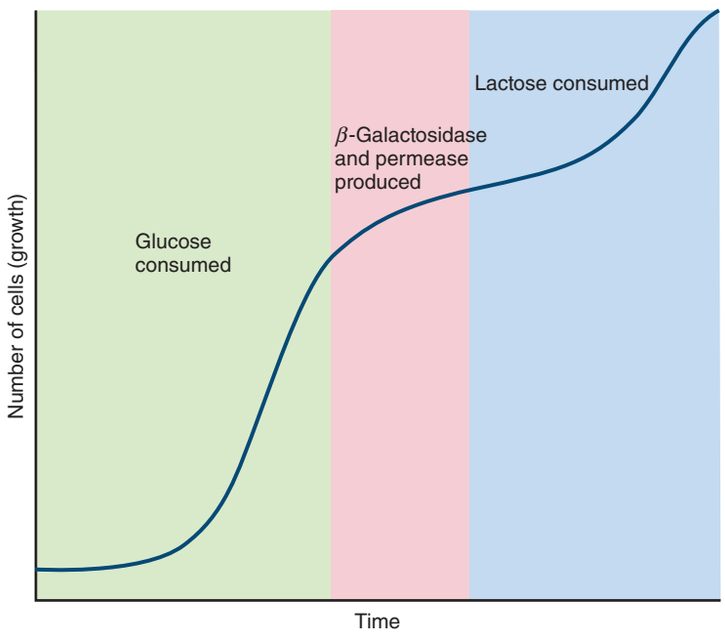


Figure 11.9. Diauxic growth curve of *E. coli* When growing in medium containing glucose and lactose, *E. coli* preferentially uses glucose. When glucose becomes depleted, β-galactosidase and permease must be produced before the cells can begin to use lactose. This requirement results in a lag in growth. When they are using glucose, the organisms do not produce these enzymes.

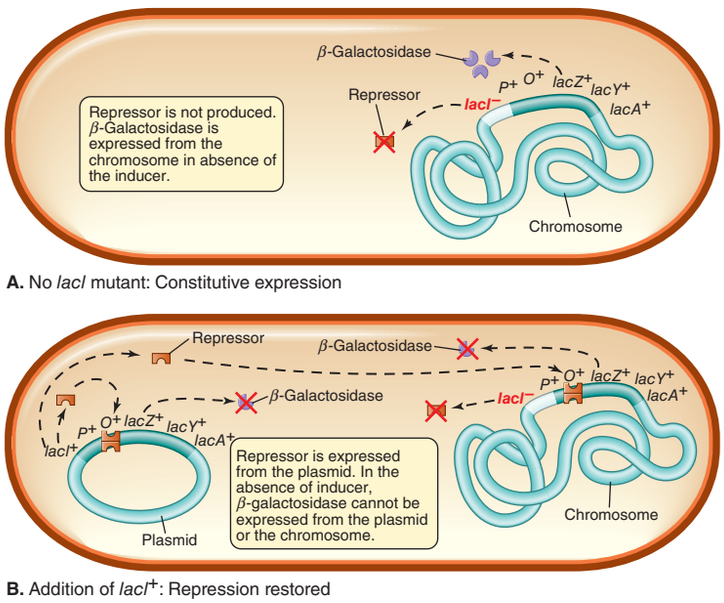

Figure 11.10. Constitutive LacI repressor mutants of the *lac* operon By analyzing constitutive mutant strains, researchers identified mutations of LacI repressor. **A.** In the absence of an inducer, the cell can synthesize β-galactosidase. **B.** The wild-type *lacI* allele carried on a plasmid can interact and repress (complement) a *lacI* mutant (i^-) even though it resides on a separate piece of DNA, indicating that the LacI repressor is diffusible.

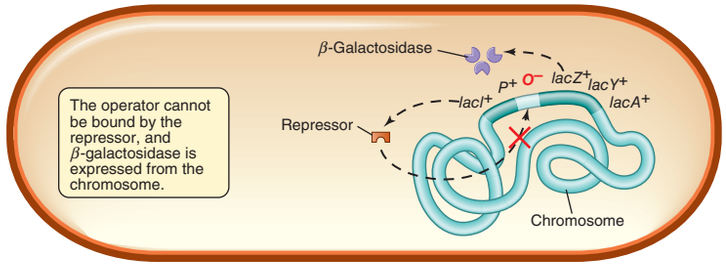
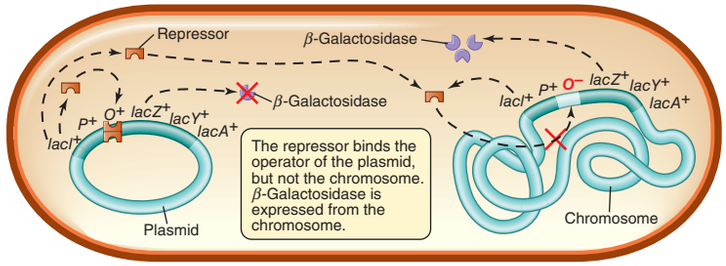
Once researchers identified LacI, another question needed to be addressed. How does the LacI repressor shut down expression of the structural genes? Again, researchers used a series of mutants to answer this question. In this case, the investigators analyzed constitutive mutants in which the constitutive phenotype could not be complemented by the presence of the wild-type allele on another DNA molecule (Figure 11.11). These mutations, the researchers hypothesized, existed not in the gene encoding the repressor, but in the DNA sequence to which the repressor bound. These mutations, in other words, defined the operator. Because the repressor binds specifically to the *lac* operator, changes in the operator sequence would prevent repressor binding and result in constant expression of *lacZ* and *lacY*. During their studies of the *lac* operon, researchers also identified a set of mutants that never expressed *lacZ* or *lacY*. These mutations defined the promoter. Changes in the DNA sequence of the promoter region can prevent binding of RNA polymerase. In the absence of RNA polymerase binding, transcription, of course, does not occur.

These early studies laid the foundation for our current understanding of gene structure and gene regulation. The advances since these initial experiments have been remarkable. As we will see in the rest of this chapter, we now have an even better understanding of gene expression. Perhaps more importantly, we now have the ability to intentionally piece together existing genetic elements, allowing us to modify gene regulation systems in creative and useful ways (Mini-Paper).



A. Operator mutant: Constitutive expression



B. Addition of *lacI*$^+$: Repression not restored

Figure 11.11. Constitutive operator mutants of the *lac* operon By analyzing constitutive mutant strains, researchers identified mutations of the *lac* operator. **A.** In the absence of an inducer, the cell can synthesize β-galactosidase. **B.** The addition of a second copy of the *lac* operon to these constitutive mutants was not able to restore repression, thus distinguishing this class of mutants from the LacI repressor mutants. In these new mutants, the operator is unable to bind LacI repressor.

11.2 Fact Check

1. Describe the process of negative control of gene expression. Explain the role that repressor proteins play in this process.
2. Describe the process of positive control of gene expression. Explain the role that activator proteins play in this process.
3. What role does lactose play in *lac* operon regulation? What role does glucose play in this regulation?
4. What role does the LacI repressor play in *lac* operon regulation?

11.3 Global gene regulation

How does a single environmental stimulus control multiple operons?

As we saw in the previous section, *Escherichia coli*, in the presence of lactose and absence of glucose, begins expressing the genes of the *lac* operon. Other environmental changes, though, may require altering the expression of more than just a few genes. When a cell is stressed, such as being exposed to elevated temperature, for example, it produces a number of heat shock proteins that help to stabilize other proteins in the cell. The heat shock proteins allow the cell to survive. Additionally, the optimal cellular response to some changes in the environment may require the increased expression of some genes and the reduced expression of other genes. The collections of operons regulated in this global manner are called **regulons**.

CONNECTIONS **Section 7.4** explains the role of chaperonins, a group of heat shock proteins, that aid in the correct folding of proteins. These proteins may be particularly important in hyperthermophilic archaea, as discussed in **Section 4.3**.

An example of global control is regulation by glucose. The presence of glucose in the environment lowers the cellular level of cAMP that can bind to CRP and shuts down the production of enzymes that allow utilization of lactose. The effects of glucose are felt far beyond the *lac* operon, which is part of a much larger regulon. Glucose also shuts down operons that produce enzymes for use of other, less preferred nutrients. This phenomenon, called **catabolite repression**, ensures

Mini-Paper: A Focus on the Research
TUNING PROMOTERS FOR USE IN SYNTHETIC BIOLOGY

R. S. Cox III, M. G. Surette, and M. B. Elowitz. 2007. Programming gene expression with combinatorial promoters. Mol Sys Biol 3:145.

Context

The early part of the twenty-first century represents another golden age for microbiology, as molecular biology matures and allows the detailed study of microbial cells and communities at the genomic level. What will the future hold? Today, much excitement surrounds synthetic biology, a developing field in which engineers and biologists are working together to design and build simpler, more predictable, and more reliable biological systems. Investigators hope that this approach can be used to develop useful biotechnology applications.

A central requirement of synthetic biology involves the optimization of gene expression within the system. To accomplish this goal, researchers must have a good understanding of how promoters operate, and have at their disposal a well-characterized collection of promoters to use for the design of novel gene regulatory circuits. To better understand the functions of promoters, one could take the DNA-binding sites of existing promoters, recombine them in different ways, and then examine the regulatory characteristics of the new constructs. Robert Sidney Cox, a graduate student working with Michael Elowitz at the California Institute of Technology (Caltech) and in collaboration with Michael Surette of the University of Calgary, utilized such a combinatorial approach. Their work was published in *Molecular Systems Biology*. Its relevance and potential impact are described next.

Experiment

Many genes respond to more than one transcription factor. These transcription factors can be either repressors or activators. To better understand the mechanism of such gene expression, and to identify rules for the operation of these systems, the investigators designed an experiment in which parts of different naturally occurring promoters could be combined artificially.

They began with 16 naturally occurring promoters of the sigma-70 family with well-defined transcription factor binding sites. These promoters respond to signals through either the AraC or LuxR activators, or the LacI or TetR repressors. To create new, potentially better promoters, the investigators first divided each of these promoter sequences into a 45-bp distal region, corresponding to the region immediately upstream of the −35 box, a 25-bp core region, encompassing the region between the −35 and −10 boxes, and a 30-bp proximal region downstream of the −10 box. They then developed a novel strategy to create new hybrid promoters containing random combinations of these parts.

To engineer new promoters from these parts, the researchers first synthesized complementary oligonucleotides for each of these regions such that after annealing, 5′ overhangs would exist. When these pieces were mixed together, they reasoned, any distal region, core region, and proximal region could interact, forming a new promoter **(Figure B11.1)**. In theory, 16^3 or 4,096 possible combinations could result. After ligation, the constructs were cloned into a luciferase reporter plasmid, which provided a means to easily measure gene expression. A total of 217 of the 288 analyzed constructs were confirmed by DNA sequencing to be unique, and were subjected to further study.

Following the construction of these novel promoters, the investigators then asked the obvious question: Do these synthesized promoter constructs work? Perhaps surprisingly, most of them were functional. Detectable expression of luciferase was seen in 83 percent of the constructs. Half of the constructs responded to one of the four regulating signals with a regulatory range, defined as the ratio of induced-to-uninduced activity, of 10 or more **(Figure B11.2)**. Further analysis resulted in the development of useful rules that can be used in the design of completely synthetic promoters with desired properties. The authors demonstrated that it is possible to remove promoter parts from their original context without losing function.

Impact

The work reported in this paper is pioneering, and it will be interesting to see in the next few years how these advanced methods of DNA manipulation are adopted and adapted in the continuing development of synthetic biology. It soon may become possible to design regulatory systems for specific purposes and applications. Probably more important, though, is the insight that this type of work provides into the function of naturally occurring promoters and the detailed mechanisms that have evolved in nature to carry out complex regulatory processes. Eventually, it may be possible to develop models to predict the behavior of naturally occurring promoters.

that *E. coli* uses glucose preferentially. In *E. coli*, the CRP-cAMP complex regulates well over 100 operons, thus constituting a major regulon.

In this section, we will explore regulons more fully. To start, we will examine how bacterial cells respond to DNA damage, focusing on the experimental evidence for a DNA repair mechanism. We will also examine the use of the *lac* operon and lactose analogs in expression studies. Finally, we will discover how interactions between sigma factors and promoters can affect gene regulation. Throughout this section, we will see how cells can quickly and effectively conduct global changes in their gene expression patterns.

Experimental evidence for the existence of regulons

To understand regulons more fully, let's consider the response of the cell to DNA damage. A number of environmental

Figure B11.2. Activity of novel promoter constructs Luciferase activity of novel promoter constructs was determined. Most engineered plasmids were functional. Half of the constructs led to a 10-fold increase in the induced compared to uninduced activity, in production of luciferase.

Questions for Discussion

1. The paper describes combining parts of different promoters to create novel regulatory units. Can you suggest another level at which such a combinatorial approach might be useful?
2. Discuss the possible evolutionary consequences of the generation of novel promoters by natural combinatorial processes.

stresses, such as ultraviolet (UV) radiation and various chemicals, can damage DNA. If a cell experiences severe DNA damage, then the cell will die. Not surprisingly then, cells possess mechanisms to repair damaged DNA. One type of DNA repair response, the **SOS response**, functions as a final option for rescuing cells whose genomes have been seriously damaged. As might be expected, this mechanism does not become operational until the cell senses the DNA damage.

CONNECTIONS **Section 7.5** explains how various mutagens can damage DNA. For reasons that remain unclear, the bacterium *Deinococcus radiodurans* exhibits extreme resistance to damage from radiation.

Jean-Jacques Weigle, a Swiss physicist who became a phage biologist, performed early studies of the cellular response to DNA damage while working at the California Institute of Technology (Caltech) in Pasadena, California.

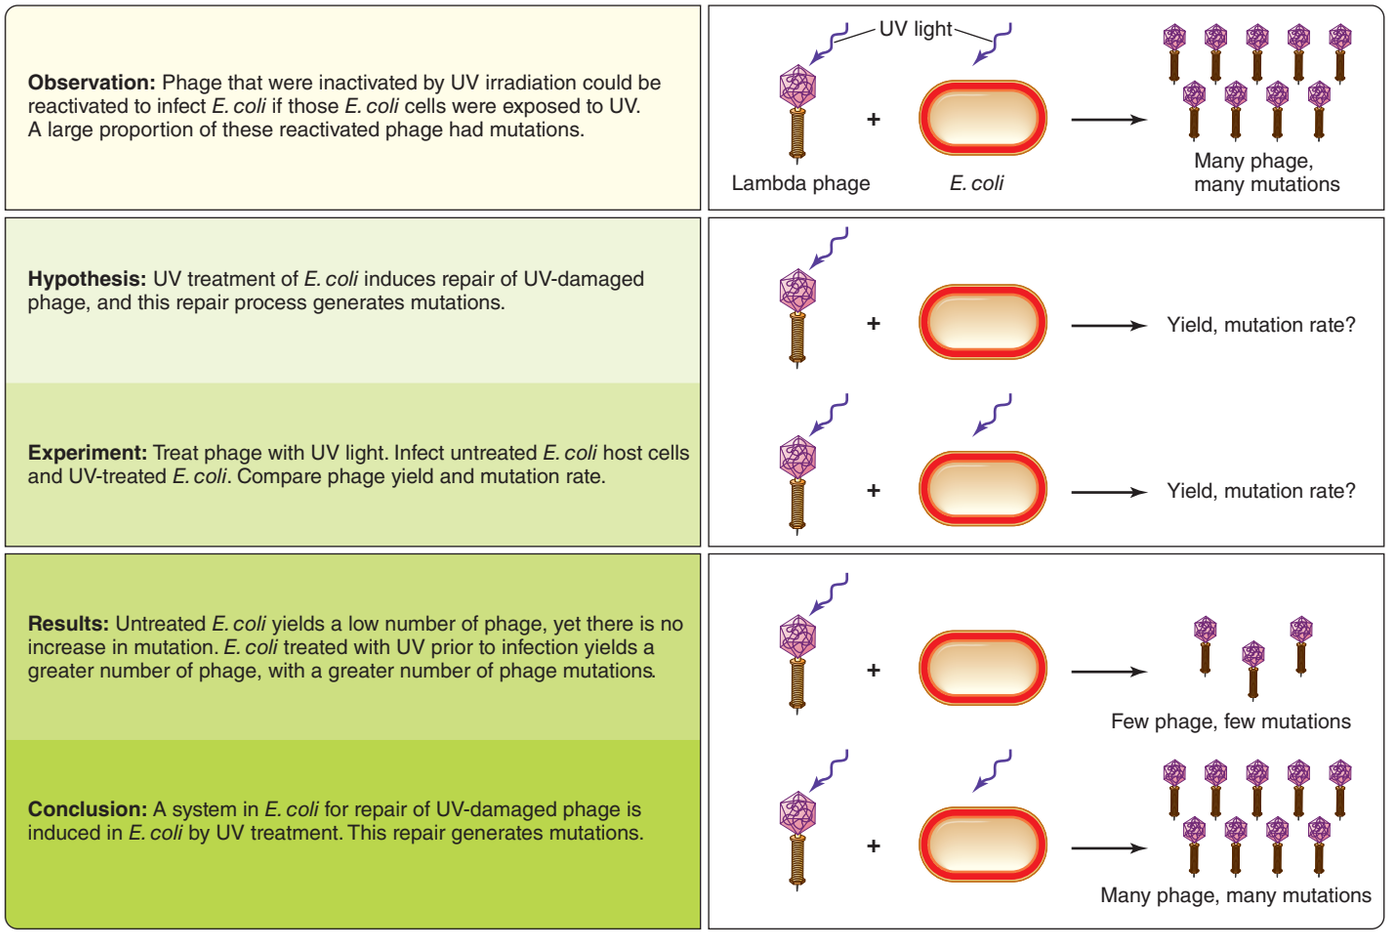

Figure 11.12. Infectivity of lambda (λ) phage particles after UV light treatment Exposure of bacteriophage to UV light causes DNA damage and reduces their ability to infect *E. coli*. If *E. coli* cells are also exposed to UV light prior to infection, then phage infection rates are high, as are their rates of mutation.

He investigated the effect of UV treatment on the infectivity of lambda phage particles (Figure 11.12). After exposure to UV light, the phage particles had a reduced rate of infection of *E. coli* and no increase in phage mutation rate. Presumably, the UV light exposure damaged the phage DNA, making them unable to replicate. However, if both the *E. coli* host cells and the phage were treated with UV light prior to infection, then the rate of phage infection was high, as was the rate of mutations observed in the phage. This correlation between infectivity and mutagenesis of the phage suggested that UV treatment of host cells enhanced their ability to repair the UV-induced damage of the phage DNA, thus allowing the phage to replicate. However, the repair mechanism is error-prone, resulting in an increased number of mutations in the phage.

To investigate the nature of the SOS response, researchers investigated the effects of the antibiotic chloramphenicol on DNA repair. This antibiotic specifically blocks protein synthesis in bacteria. Investigators observed that chloramphenicol also inhibits DNA repair. From this observation, they concluded that DNA repair requires protein synthesis. They then asked an obvious follow-up question: What proteins need to be produced for DNA repair to occur?

To identify which genes must be expressed to produce these DNA repair proteins, the researchers used a *lacZ* promoter-probe transposon to mutate *E. coli*. The promoter-probe transposon contains a promoterless *lacZ* **reporter gene**. With no promoter of its own, the only way the *lacZ* gene will be expressed is if it inserts within an actively transcribed gene. In other words, an active promoter will drive transcription of the inserted *lacZ* gene. The transposon also contained an antibiotic resistance gene used for selection. Recall that the *lacZ* gene encodes the enzyme β-galactosidase, the activity of which is very easy to detect using the chromogenic substrate X-gal (Perspective 11.1). Introduction of the promoter-probe transposon would result in some colonies that are blue on X-gal media because the insertions are in genes that are expressed. White colonies would carry insertions in genes that are not expressed (Figure 11.13).

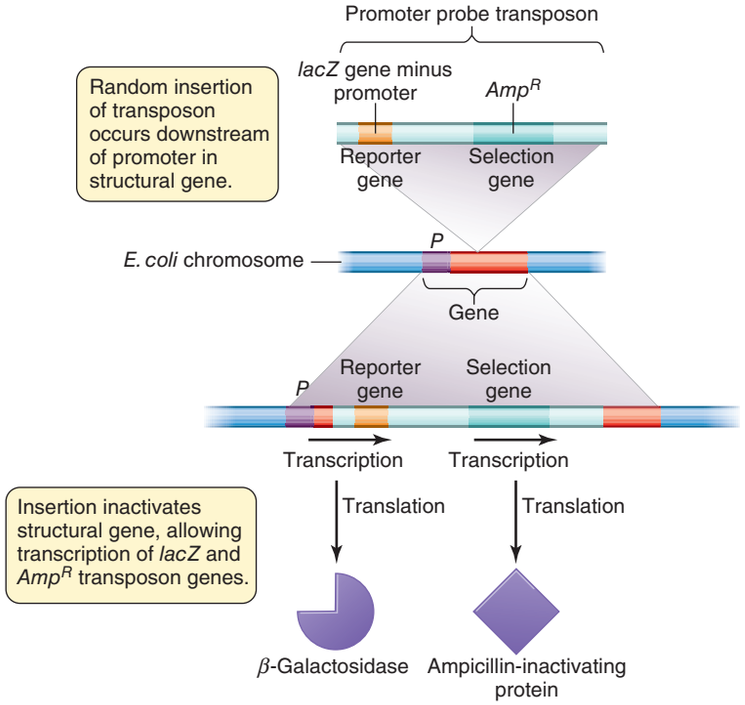
CONNECTIONS **Section 24.2** outlines how the antibiotic chloramphenicol binds to the 23S rRNA of the 50S ribosomal subunit, thus interfering with peptide bond formation during translation. This mode of action makes it a very useful reagent in experiments designed to determine if certain biological processes require protein synthesis.

Investigators used this promoter-probe approach to screen mutant colonies to identify those that exhibited β-galactosidase activity in the presence of the DNA-damaging agent, mitomycin C, but not in the absence of mitomycin C. In other words, these genes were induced by DNA damage. These mutants contained promoter-probe transposon insertions in several different regions of the chromosome, as determined by gene-mapping experiments. The genes, called *din* genes for damage inducible, thus defined the potential set of genes involved in DNA repair. Many of these genes are members of the SOS regulon.

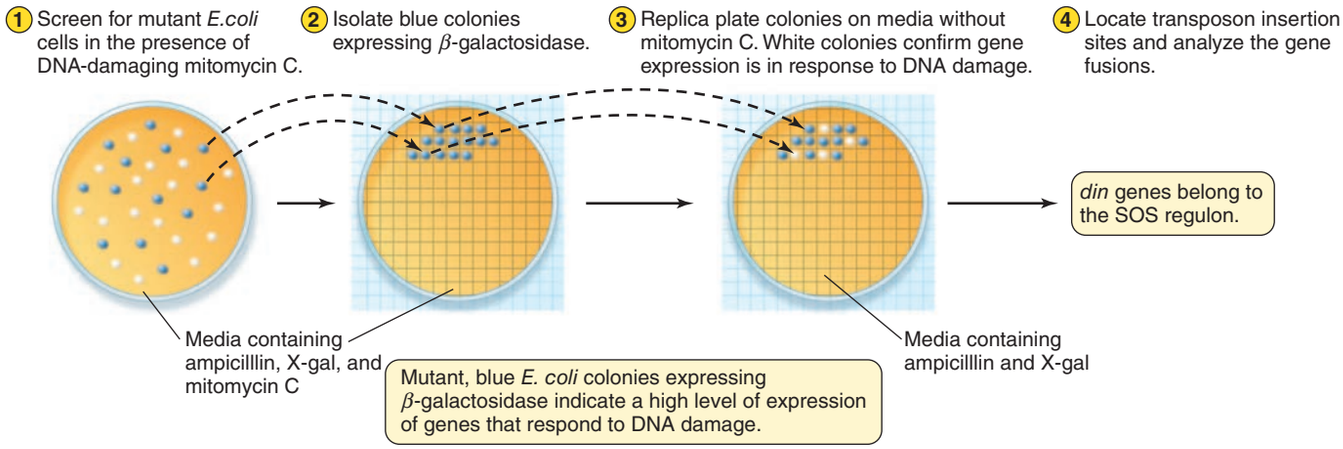
These early experiments that resulted in the discovery of regulons, such as the SOS regulon, relied on classical genetic approaches involving gene fusions. In recent years, with the availability of genomics technology, these types of studies have been largely supplanted by the use of transcriptomics techniques such as those described in Chapter 10. Nevertheless, there are still occasions when the use of gene fusions to monitor gene expression can be very useful.

After identifying genes of the SOS regulon, researchers then addressed another question. How does a cell sense DNA damage? *In vitro* studies using purified proteins showed that bacteria do not actually detect the agent that causes the DNA damage. Any number of different agents can damage the DNA. Rather, the cells detect a molecule that results from DNA damage: single-stranded DNA. The SOS repair system uses alternative DNA polymerases that lack the ability to proofread to fill in missing DNA. This mechanism repairs the structure of the chromosome, but results in a high rate of mutation.

If the SOS genes all respond to the presence of single-stranded DNA, then what detects the presence of this? Using the inducible mutants identified in the previous experiment, researchers identified two genes, *recA* and *lexA*, that could alter the SOS response in these mutants. The *recA* gene had been shown previously to be required for genetic recombination, with its product RecA binding to single-stranded DNA. Later, the LexA protein was shown to be a repressor that binds to operator sequences of members of the SOS regulon. Binding of RecA to single-stranded DNA activates a process, not completely understood, that results in the cleavage of LexA.



A. Creation of *E. coli* mutants using promoter probe



B. Screening process to identify genes involved in the SOS regulon

Figure 11.13. Process Diagram: Monitoring the induction of gene expression in response to DNA damage By using *lacZ* gene fusions, researchers can monitor the expression of genes in the SOS regulon. **A.** A *lacZ* promoter-probe transposon is used to mutate *E. coli*, facilitated by selection for ampicillin resistance. Insertion of the transposon within expressed genes results in β-galactosidase activity, yielding blue colonies on X-gal. **B.** Insertions in *din* genes are strongly induced immediately after the introduction of the DNA-damaging agent mitomycin C. They are identified through a two-step screening process to determine which promoter-probe fusions are expressed in the only presence of mitomycin C and not expressed in the absence of mitomycin C.

Perspective 11.1
THE USE OF LACTOSE ANALOGS IN GENE EXPRESSION STUDIES

Not only was the *lac* operon one of the first operons to be studied and characterized, but it has also been developed as a powerful tool for investigating the function and regulation of other genes. Many experiments that led to our understanding of the nature of genes and gene regulation were performed on the *lac* operon, and the use of synthetic lactose analogs as substitute substrates was instrumental to these studies. The usefulness of the *lac* operon as a genetic tool has been enhanced considerably by the availability of these synthetic lactose analogs, and as a result, components of the *lac* operon have found widespread use as integral parts of cloning vectors, expression vectors, and reporter gene fusions.

In addition to its ability to cleave the glucose-galactose disaccharide lactose, the *lacZ*-encoded enzyme β-galactosidase can break down several synthetic analogs of lactose that contain β-linkages between galactose and chromogenic, lumigenic, or fluorogenic molecules in place of glucose. Cleavage of these molecules causes color change, luminescence, or fluorescence, respectively. **Table B11.1** lists several of these analogs and their properties. ONPG (*ortho*-nitrophenyl-β-D-galactoside) is a particularly useful molecule. Cleavage of this colorless compound results in the release of ONP (*ortho*-nitrophenol), which is yellow in color. The intensity of the color in a reaction can be measured using a spectrophotometer. Greater enzyme activity results in a more intense color. ONPG thus forms the basis for a very sensitive assay for β-galactosidase activity. Because β-galactosidase activity is directly related to the level of expression of the *lac* operon, this analog has become a very convenient method to measure gene expression, especially using plasmid and transposon gene fusion tools.

X-gal (5-bromo-4-chloro-3-indolyl-β-D-galactoside) represents another widely used lactose analog. Upon cleavage, this analog

TABLE B11.1 Artificial lactose analogs used in bacterial genetics

Analog	Characteristics	Structure
Ortho-nitrophenol-β-D-galactoside (ONPG)	Chromogenic substrate, yellow in color; ONPG is used for quantitative measurement of β-galactosidase activity.	5-Bromo-4-chloro-3-indolyl-β-D-galactoside (X-gal)	Chromogenic substrate conferring blue color, non-inducing; X-gal is commonly used for detection of β-galactosidase activity in bacterial colonies.	4-Methylumbelliferyl-β-D-galactoside (MUG)	Fluorogenic substrate, cleavage releases fluorescence; MUG is used for enzyme assays.	Isopropyl β-D-1-thiogalactopyranoside (IPTG)	Inducer, not metabolized; IPTG is used for induction of *lac* operon expression.	Phenyl-β-d-galactoside (Pgal)	Substrate, non-inducing; *lacY* not required for uptake. Pgal is used for the isolation of constitutively expressing *lacZ* mutants.	
releases an indole dye, which leads to the formation of a blue precipitate. On solid media containing X-gal, colonies expressing β-galactosidase appear blue. A number of screens are based on the ability to easily differentiate blue and white colonies. Blue colonies have *lacZ*-encoded β-galactosidase activity, whereas white colonies do not. We have seen in Section 10.1 that this type of screen is particularly useful for the detection of recombinant plasmids in which DNA fragments have been successfully cloned, and it is widely used in cloning vectors.

Less widely used than ONPG or X-gal, 4-methylumbelliferyl-β-d-galactoside (MUG) represents another lactose analog. This compound provides researchers with a fluorogenic measurement of β-galactosidase activity. Upon its cleavage, MUG releases 7-hydroxy-4-methylcoumarin, which absorbs light at 360 nm and then emits light at 449 nm.

The design and implementation of effective, often clever, genetic screens showcases the creative abilities of the bacterial geneticist. Because such screens rely on the phenotypes associated with mutations, they are limited to cases with selectable or easily detectable phenotypes. To overcome this limitation, gene fusion technology often is used, in which reporter genes that do not contain upstream regulatory regions are fused to the genes whose expression is being analyzed. Connecting the expression of a gene of interest to a readily detected reporter gene such as *lacZ* makes it possible to monitor gene expression using the phenotype of the reporter gene. This procedure facilitates screening for factors that influence expression of the gene of interest. Once researchers identify interesting relationships by the X-gal screening, they can then use ONPG to more accurately quantify the gene expression profile.

Some other lactose analogs, such as IPTG (isopropyl β-D-1-thiogalactopyranoside), can induce the expression of the *lac* operon without being subject to degradation by the β-galactosidase enzyme. This feature of IPTG has been important in studies of the regulation of the *lac* operon. As a molecular biology tool, IPTG induction is commonly used in expression vectors to produce large amounts of recombinant proteins. Such expression vectors typically contain the *lac* promoter and ribosome-binding site alongside which the ORF of the gene to be expressed is cloned; activation of the promoter results in expression of the gene. In the presence of *lacI*, the gene will be repressed, and the addition of IPTG will relieve this repression. Variation of the amount and timing of IPTG addition allows careful control of the desired level of gene expression to produce the product. In contrast to IPTG, phenyl-β-d-galactoside (Pgal) can be metabolized by *E. coli*, but does not induce the *lac* operon.

It truly is a testament to the quality of the research undertaken by the early microbial geneticists who unraveled the workings of the *lac* operon that this set of genes continues to find widespread use throughout the life sciences. While artificial analogs of other substrates have been used in microbial genetics, *lac* is still the model. After well over a half century, this icon has found a permanent place in the science of microbiology.

The cleaved LexA protein can no longer bind the operators of the SOS genes, resulting in induction of gene expression **(Figure 11.14)**. Various experiments indicate that the SOS regulon of *E. coli* consists of at least 40 genes distributed throughout the genome. As we might expect, many of these genes encode polypeptides that function in the repair of DNA damage **(Table 11.3)**.

CONNECTIONS Certain antibiotics exert their antibacterial activity by damaging DNA, thereby inducing the SOS response. Many prophages have evolved the ability to detect the induction of the SOS response in their host cells. In **Perspective 21.4**, we will see why this adaptation is advantageous for these temperate phages, and why treating some bacterial infections with DNA-damaging antibiotics may do more harm than good.

Alternative sigma factors

Although regulons effectively allow cells to control the expression of a large number of genes, alternative sigma factors provide another means of global gene regulation. As we saw in Section 7.3, initiation of transcription in bacteria

TABLE 11.3 Members of the *E. coli* SOS regulon

Gene	Function
umuDC	Error-prone DNA polymerase V
dinB	Error-prone DNA polymerase IV
polB	DNA polymerase II, repair of DNA interstrand crosslinks
uvrA	Nucleotide excision repair
uvrB	Nucleotide excision repair
uvrD	DNA helicase, involved in DNA repair
sbmC	DNA gyrase inhibitor
ruvAB	Homologous recombination, Holliday junction resolution
lexA	DNA-binding transcriptional repressor of SOS regulon genes
recA	Recombination and regulation of SOS response, binds single-stranded DNA
dinI	DNA damage inducible protein, regulation of RecA protease activity
recN	DNA recombinational repair protein
ssb	Single-stranded DNA-binding protein
dinG	ATP-dependent DNA helicase
sulA	SOS cell division inhibitor
ftsK	Cell division protein
pcsA	Phosphatidylcholine synthase

Based on Fernández de Henestrosa et al. 2000. Identification of additional genes belonging to the LexA regulon in *Escherichia coli*. Mol Microbiol 35:1560–1572.

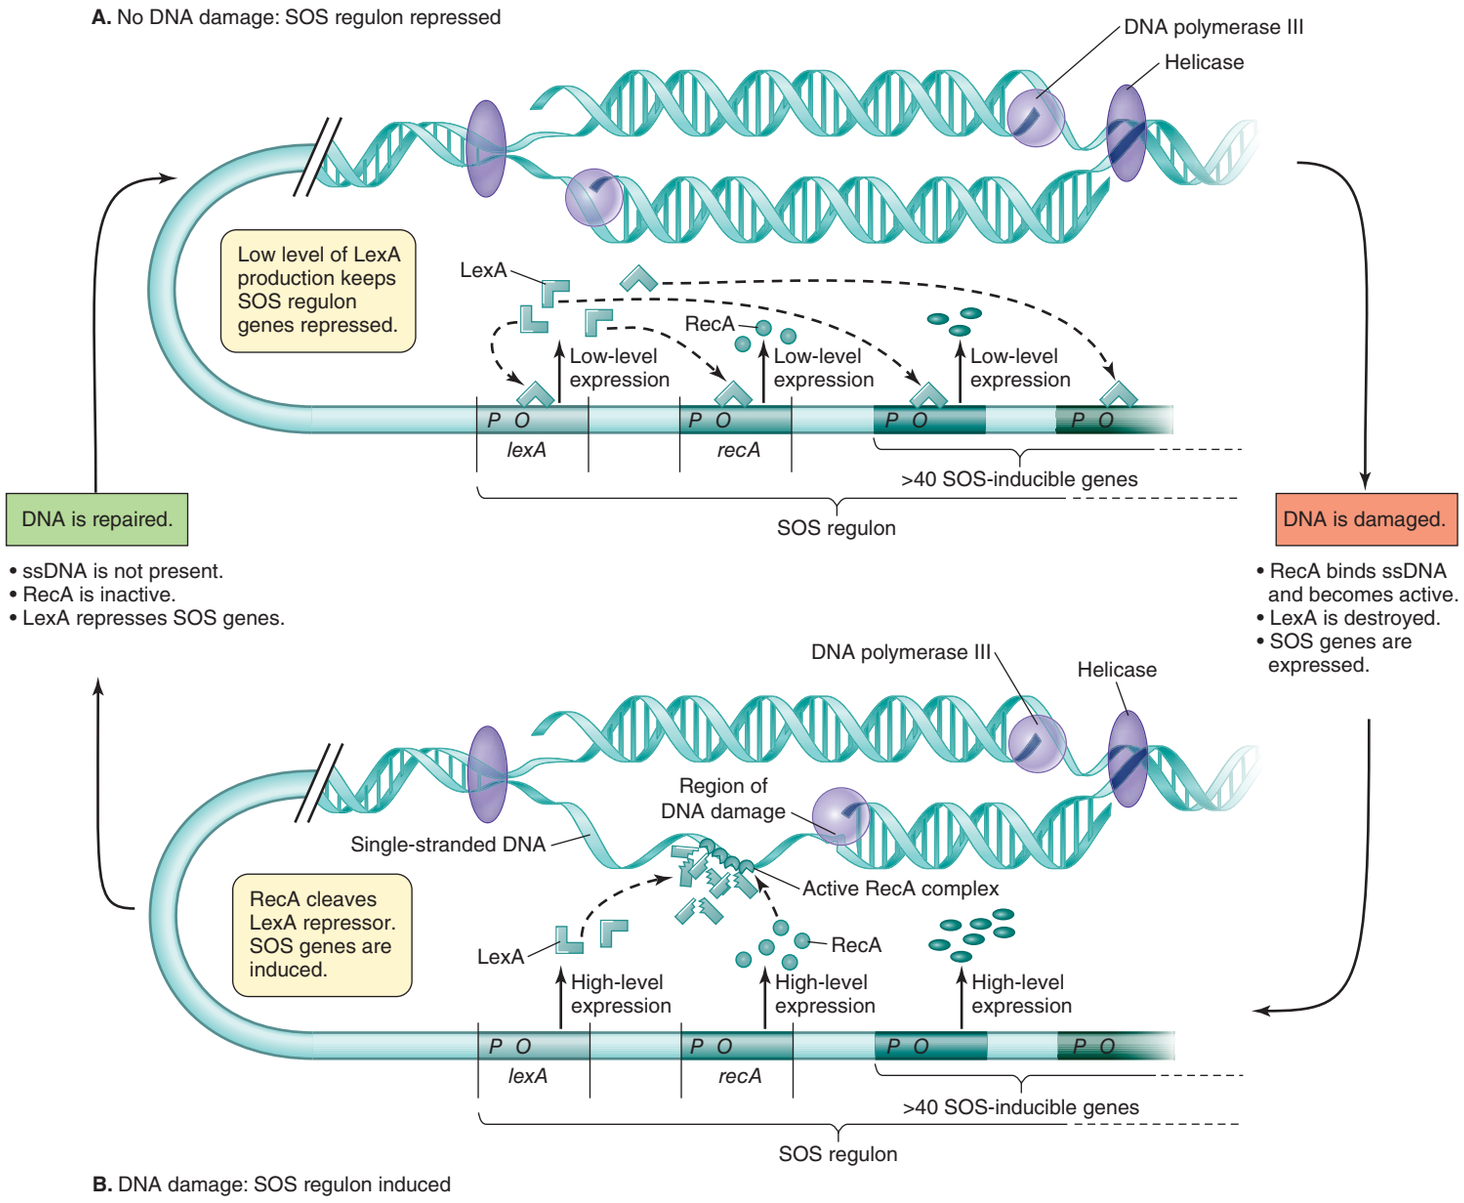

Figure 11.14. The SOS response control and the LexA repressor Expression of the members of the SOS regulon are controlled by LexA. **A.** The LexA repressor inhibits the expression of genes under SOS control. **B.** When DNA damage occurs, the RecA protein interacts with single-stranded DNA produced by damage to DNA, causing it to mediate cleavage of the LexA repressor. This action results in relief of the SOS genes from repression, activating their expression.

requires the sigma factor, a polypeptide that allows RNA polymerase to identify the promoter. The sigma factor responsible for recognizing most promoters, called the primary sigma factor, in *E. coli* is sigma-70 (or RpoD), named according to its molecular weight, which is 70 kDa. Most bacterial genomes encode several alternative sigma factors. Although these alternative sigma factors recognize *different* promoters than sigma-70 does, they are related to sigma-70 and use a similar mechanism for promoting transcription initiation. Increased synthesis of those sigma factors can activate entirely different sets of genes. *Escherichia coli*, for instance, has six alternative sigma-70 family members. *Streptomyces coelicolor*, an antibiotic-producing bacterium with a complex developmental pathway, has over 60 alternative sigma-70 family members.

Some bacteria also have one or two alternative sigma factors in the sigma-54 (or RpoN) family. Most of the approximately 30 *E. coli* promoters recognized by sigma-54 family members deal with some aspect of nitrogen utilization. Members of the sigma-70 and sigma-54 families differ in the mode by which they promote transcription initiation. Members of the sigma-54 family require an activating protein and ATP to initiate transcription; members of the sigma-70 family do not. Sigma-54 family members also recognize promoter regions at different distances from the initiation of transcription, whereas sigma-70 family members do not.

CONNECTIONS **Section 7.3** describes the regions of the promoter recognized by sigma factors to initiate transcription. Although sigma-70 recognizes sequences at regions 10 and 35 upstream from the first transcribed base, sigma-54 recognizes sequences at positions −12 and −24.

Generally, alternative sigma factors are active only under specific conditions and are not required for cell viability. For example, sigma-32, the heat shock sigma factor also called RpoH, recognizes about 30 different promoters in the *E. coli* genome. Normally, RpoH is degraded very quickly after it is synthesized. When the temperature rises, however, other proteins in the cell begin to unfold and compete with RpoH for proteases that will degrade them. As a result, the concentration of RpoH increases. As RpoH accumulates, it initiates transcription of a wide variety of genes that code for proteins that can help the cell to survive temperature increases. Many of these genes encode proteins that assist in the proper folding of proteins.

Another sigma factor that controls expression of a large number of genes is sigma-38, or RpoS, the product of the *rpoS* gene. This sigma factor is responsible for differential gene expression in *E. coli* and related bacteria in response to general stress conditions. Such conditions include high cell density, nutrient starvation, low temperature, high osmolarity, and oxidative stress. Dozens of target genes respond to RpoS, including genes involved in protein processing, general stress adaptation, membrane stability and transport, and metabolism. Expression of these genes depends on the amount of sigma-38 protein present in the cell. The products of these genes result in entry of the cell into the stationary phase as cells prepare for survival over extended periods of time.

Just as sigma factors can control entire regulons, sigma factors themselves are also regulated. For example, proteins called anti-sigma factors can bind to the sigma factor and prevent RNA polymerase from binding to its promoters, thus turning off the genes it controls. These processes are useful in controlling the timing of global gene expression. When the anti-sigma factors are eliminated, then the entire regulon can be quickly and coordinately activated. An example of an anti-sigma factor is the FlgM protein that influences the activity of sigma-28, which is responsible for the timing of expression of the genes involved in assembly of the flagella.

11.3 Fact Check

1. What is a regulon?
2. What is catabolite repression? How is this process involved in the actions of the *lac* operon?
3. Describe the SOS response.
4. How do LexA and RecA control the SOS response?
5. Explain the roles of the two different sigma factors, RpoH and RpoS.

11.4 Post-initiation control of gene expression

How can mRNA be controlled?

Sigma factors and regulatory proteins, like repressors and activators, typically control the initiation of transcription. This type of regulation saves resources and energy used to produce mRNA coding for proteins that the cell does not need. Still, protein synthesis may also be controlled at other points. Transcription may be inhibited after initiation, for example. Enzymatic degradation of mRNA may be regulated, thus influencing the amount of transcript in the cell. Translation of mRNA may be inhibited. Even after translation, the activity of individual proteins may be inhibited, as we saw in Section 11.1. In this section, we will consider some mechanisms of gene regulation that occur after the initiation of transcription. Specifically, we will explore the roles of regulatory RNAs and mRNA secondary structure.

Regulatory RNAs

The genomes of archaea, bacteria, and eukarya contain regions that code for RNA that is not translated into proteins. These regions include genes for rRNA and tRNA molecules, along with a more recently identified class of RNAs with regulatory functions. These small non-coding RNAs, called **sRNAs**, typically are about 50–400 nucleotides in length. Identified by such names as microRNA (miRNA), small interfering RNA (siRNA), and antisense RNA (asRNA), sRNA operates by a variety of methods, but typically affects gene expression very quickly by interacting with existing mRNA. These interactions can prevent transcription from completing, or block translation of existing mRNA transcripts, resulting in decreased production of the corresponding polypeptide.

To see how these regulatory RNAs function, let's examine the regulation of a specific sigma factor: sigma-38, or RpoS. In *Escherichia coli*, this sigma factor activates genes associated with stress. Control at the level of translation of the *rpoS* mRNA has a major influence on the levels of RpoS molecules present in the cell. Molecules of **antisense RNA**, single-stranded RNA that can interact with specific mRNA molecules through complementary base-pairing, direct this control. In the absence of antisense RNA molecules, the secondary structure of a region

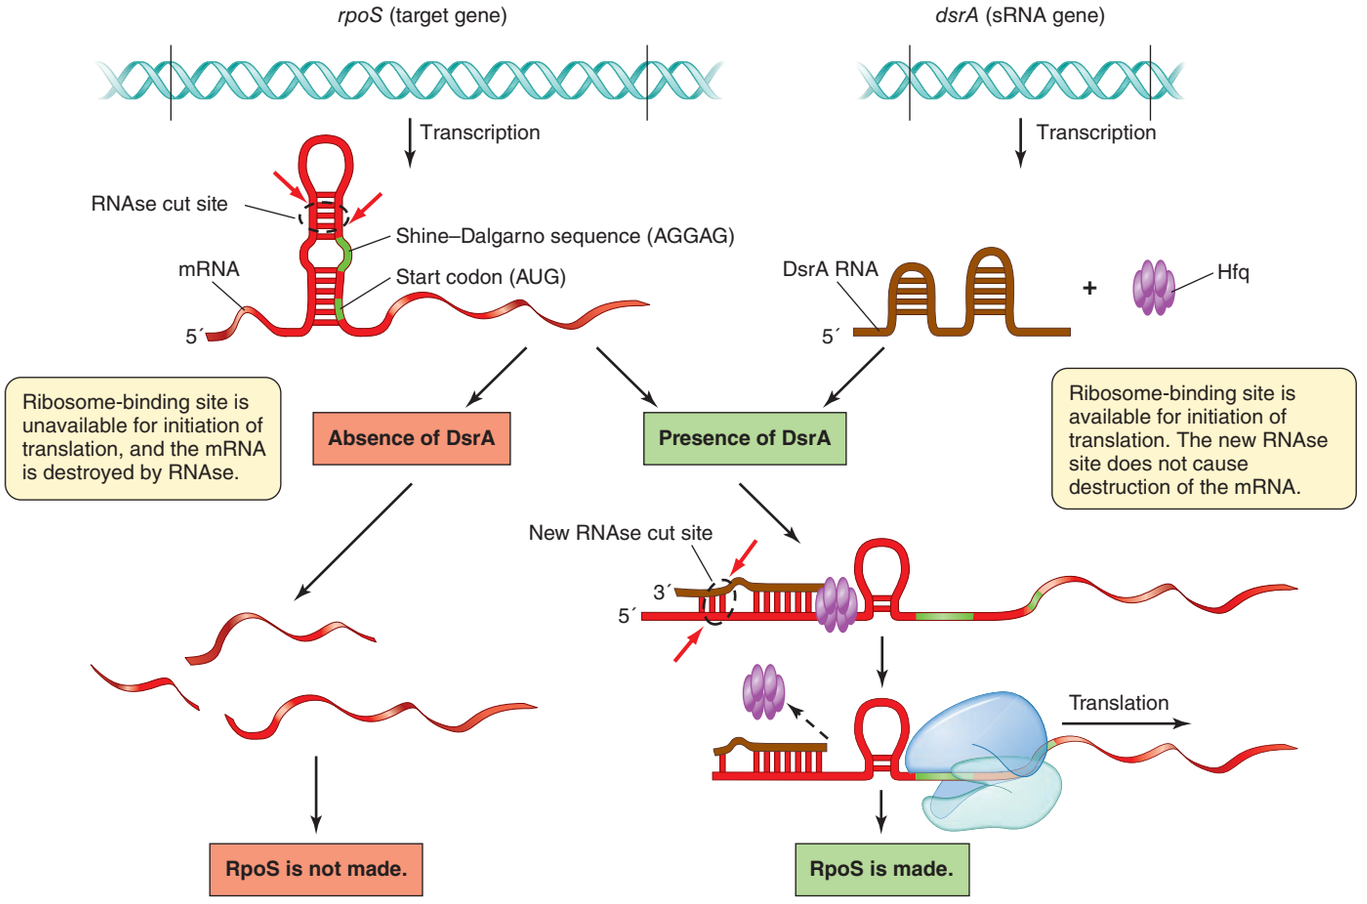

Figure 11.15. sRNA molecules and the regulation of *rpoS* translation The *rpoS* transcript contains a 5′ leader sequence that forms a hairpin stem-loop structure, obscuring the translation start site (shown in green). The Hfq protein promotes binding of sRNA molecules, thus releasing the translation start site so that it can be accessed.

called "the leader" at the 5′ end of the *rpoS* transcript inhibits translation. Certain antisense RNA molecules that interact with the leader, however, accumulate when the cell experiences various stresses (Figure 11.15). The 85-nucleotide sRNA DsrA, for instance, accumulates to high levels in the cells in response to low temperature, whereas the 105-nucleotide sRNA RprA accumulates to high levels in the cell in response to cell surface stresses. In conjunction with the RNA-binding protein Hfq, both of these antisense RNAs bind to the *rpoS* transcript, disrupt the inhibitory secondary structure, and allow translation to proceed. Levels of sigma-38 increase and activate the regulon. The newly produced gene products, in turn, help the cell thrive under these conditions. In this case, the regulatory RNA enhances translation, but in other cases it can inhibit translation. RNA that is complementary to mRNA of a given gene can be used to decrease gene expression (Toolbox 11.1). This technique has become an important tool in molecular biology.

Control of transcription by mRNA secondary structure

In Section 11.2, we saw that a repressor protein blocks transcription of the *trp* operon when tryptophan is present in the environment (see Figure 11.6B). In the early 1970s, scientists observed evidence of another form of regulation of this operon. Deletion mutations in the upstream regulatory region of the *trp* operon resulted in several-fold increases in the level of transcription regardless of the presence or absence of the repressor protein. Further studies revealed this process to be an elaborate type of regulatory mechanism that involves interactions between transcription and translation. This mechanism is called **attenuation**.

Regulation by attenuation occurs after the initiation of transcription, but before transcription of the operon has been completed. Attenuation of the tryptophan biosynthetic operon involves a short translated leader sequence on the mRNA (Figure 11.16). The leader is encoded by *trpL*, found following the operator but before the five structural genes required for the synthesis of tryptophan. Recall that in bacteria and archaea, transcription and translation are coupled, so the 5′ end of a transcript containing the leader sequence can be translated before synthesis of that transcript is complete. The leader sequence contains two tryptophan codons. If tryptophan is abundant, then it will be incorporated into the leader peptide chain and the leader will be translated completely. If tryptophan is scarce, then it will be difficult for the leader peptide to be completely synthesized.

How does this feature of *trpL* affect production of the tryptophan biosynthetic polypeptides? To address this question,

Toolbox 11.1

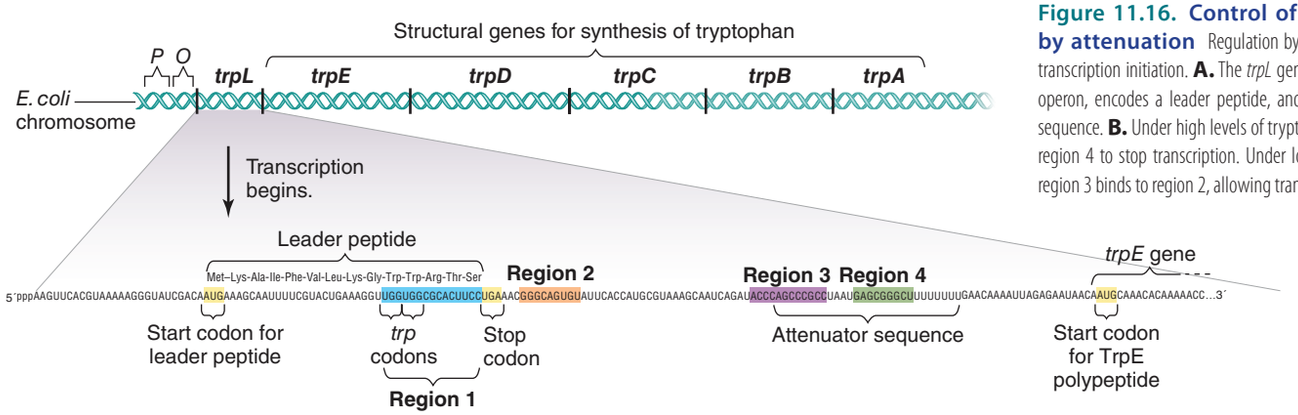
USING RNA MOLECULES TO DECREASE GENE EXPRESSION

Not too many years ago, scientists referred to DNA that did not code for proteins as "junk DNA." Even though some of the non-protein-encoding DNA coded for important RNA molecules, like rRNA and tRNA instead of proteins, researchers generally did not assign a major function to most of the other regions of this DNA. Today, we recognize the importance of these sequences. As we have seen in this section, bacteria frequently use small RNAs to regulate the expression of genes. Moreover, researchers have developed ways of utilizing small RNAs to regulate gene expression experimentally.

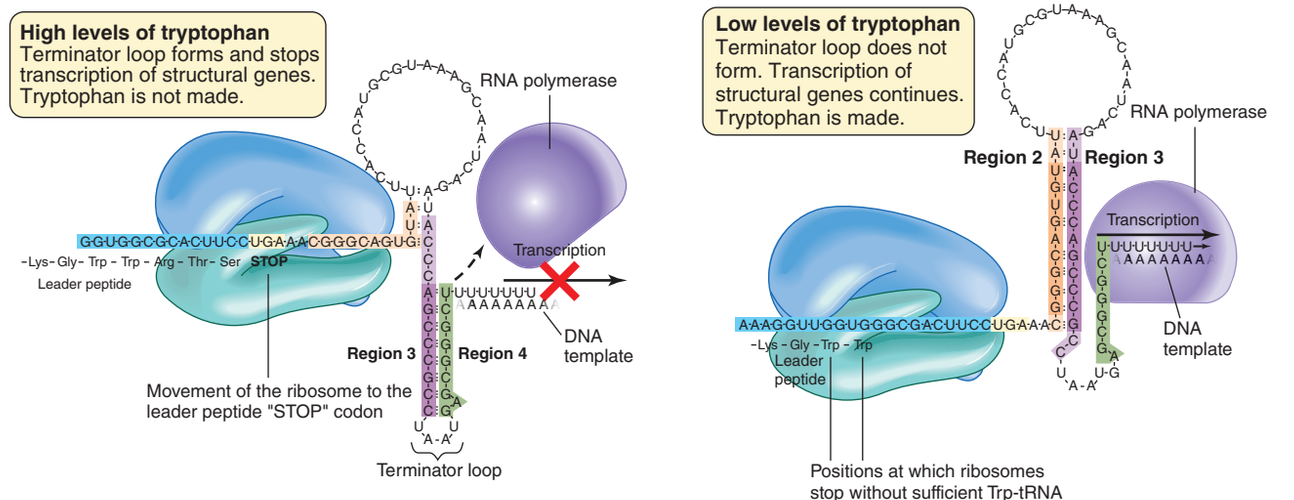
In 1998, Andrew Fire and Craig Mello demonstrated that small pieces of RNA could downregulate the expression of genes, a process they referred to as RNA interference. For this intriguing discovery, they were awarded the 2006 Nobel Prize for Physiology or Medicine. Today, scientists throughout the world are using this discovery to investigate basic aspects of cell biology and to develop treatments for human diseases.

The discovery of RNA interference by Fire and Mello has led to the development of gene knockdown techniques. In these experiments, scientists typically engineer cells to produce a short piece of RNA complementary to the mRNA of the gene being studied. When expressed in the cell, this small RNA interacts with the target mRNA, leading to a decrease in protein production. A knockdown in expression occurs. For researchers interested in basic biology, this technique allows them to better understand the role of the target gene and protein.

This technique may also be clinically relevant. For any case in which the overexpression of a gene results in disease, knockdown technology may provide a mechanism whereby the overexpression is corrected. The first human trials of RNA interference to treat a disease began in 2004 when investigators explored the effectiveness of RNA interference as a treatment for macular degeneration, a debilitating eye disease that results in a loss of vision. Today, researchers are exploring the use of RNA interference as a treatment for a number of human diseases, including Huntington's disease and certain cancers.



A. The tryptophan (*trp*) operon and regulatory region of mRNA



B. Attenuation of transcription by high levels of tryptophan

Figure 11.16. Control of the *trp* operon by attenuation Regulation by attenuation occurs after transcription initiation. **A.** The *trpL* gene is the first gene in the operon, encodes a leader peptide, and contains an attenuator sequence. **B.** Under high levels of tryptophan, region 3 binds to region 4 to stop transcription. Under low levels of tryptophan, region 3 binds to region 2, allowing transcription to proceed.

Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc.
This material is reproduced with permission from John Wiley & Sons, Inc.

we first should note that the leader sequence contains several regions of internal sequence complementarity. Base-pairing among these regions in the leader sequence mRNA results in the formation of double-stranded stem-loop structures affecting the secondary structure of the RNA. If these regions are numbered 1, 2, 3, and 4 from the upstream end, then region 1 contains the tryptophan codons. Region 3 can form a stem-loop with region 2 or with region 4, but not with both. After region 4, a uracil-rich region called the attenuator exists that can interact with a 3–4 stem-loop allowing the formation of a transcription termination structure, causing termination to occur before reaching the structural genes.

If tryptophan is plentiful, the leader sequence will be fully translated, and when the ribosome reaches the stop codon for *trpL*, it blocks formation of a stem-loop between region 2 and region 3. As a result, region 3 binds to region 4, terminating transcription by RNA polymerase after the leader sequence. Hence, tryptophan production stops because the genes are never transcribed.

If tryptophan is scarce, then the ribosome pauses during translation of region 1, waiting for an aminoacyl-tRNA carrying tryptophan. In that position, it blocks region 1 from interacting with region 2. Region 3 then binds with region 2, forming a stem-loop. Under these conditions, region 3 is no longer free to form a stem-loop with region 4, so the attenuator is not activated. Transcription proceeds past the stop codon for *trpL* and transcribes the structural genes for tryptophan synthesis.

The *trp* operon represents an example of the regulation of transcription through the influence of stalled ribosomes on RNA secondary structure. The *trp* operon, though, certainly does not represent the only operon regulated in this fashion. The transcription of a number of other amino acid biosynthesis operons is also influenced by the translation of leader sequences rich in the corresponding amino acid. Computational tools have been developed to scan genome sequences for regions that may encode RNA secondary structures. Based on this type of analysis, it is becoming apparent that attenuation-like mechanisms add considerably to the overall complexity of gene regulation.

The action of antisense RNA and the formation of stem-loops within mRNA show that segments of RNA can bind to one another through complementary base-pairing. We can also extend our definition of effectors to include regulatory molecules that bind RNA. Some mRNA molecules can bind effectors, like the activators and repressors that we examined earlier. These systems of mRNA and metabolite effector molecules, which are usually involved in the biosynthesis and transport of metabolites, collectively have been termed **riboswitches (Figure 11.17)**. Changes in secondary structure of the upstream 5′ end of the mRNA transcript caused by binding or release of an effector are a widespread means of regulating gene expression. Binding of the effector to mRNA may inhibit further elongation of the transcript as we saw in attenuation, or it may block mRNA binding to the ribosome, affecting translation.

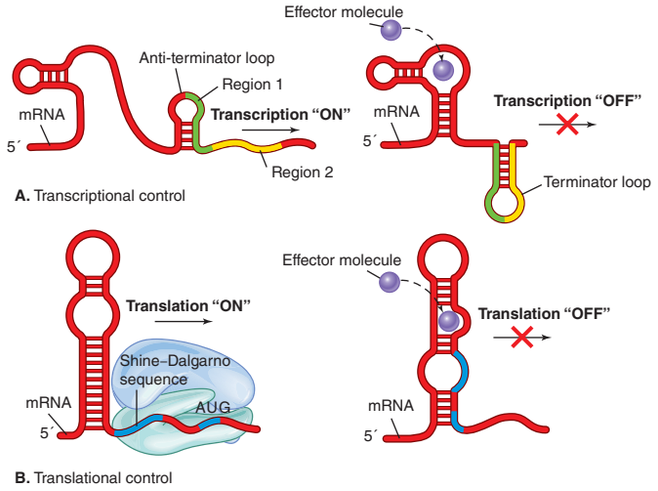


Figure 11.17. Riboswitches Messenger RNA can bind effector molecules such as vitamins or amino acids that regulate gene expression. **A.** Some riboswitches affect transcription. **B.** Some riboswitches regulate translation by inhibiting ribosome binding.

11.4 Fact Check

1. What is sRNA, and what is its role in cells? Give an example.
2. Explain the general mechanism of attenuation and its role in regulation of gene expression.
3. Describe the role of stem-loop structure in the regulation of the *trp* operon.

11.5 Quorum sensing

3D ANIMATION

How do bacteria communicate with their neighbors?

In the laboratory, we usually work with isolated, often clonal, populations of microbes. In the real world, though, microbes usually live in diverse communities, often interacting with other microbes and macroscopic organisms. Information about other organisms in their environment, then, probably would benefit them. In fact, many microbes can detect the presence and number of other organisms in a population by the use of a chemical-signaling system called **quorum sensing** and regulate gene expression in response to this information. The term "quorum sensing" refers to the number of members of a group that must be present in order to conduct business (a quorum). When microbes achieve quorum, enough cells

Figure 11.18. Bioluminescence Some bacteria can use chemical energy to produce light. **A.** *Allovibrio fischeri* colonies on an agar plate photographed in the dark demonstrate luminescence from the bacteria. **B.** The squid contains a light organ that luminesces after it has been colonized by bacteria.

are present to accomplish a task that one cell alone cannot perform.

Quorum sensing involves the release of specific signal molecules, known as **autoinducers**, into the environment by bacterial cells. The amount of autoinducer increases as the density of the bacterial population increases. Therefore, the bacteria can assess their population density by detecting autoinducer concentrations in the surrounding environment. As the population density changes, gene expression may also change. Because different populations employ different autoinducers for this signaling, this communication can be very specific. In this section, we will examine one particular quorum-sensing system and then briefly investigate the prevalence of quorum-sensing systems in the microbial world.

Lux, a prototypical quorum-sensing system

The Lux system in *Allovibrio fischeri* **(Microbes in Focus 11.1)** represents one of the first quorum-sensing systems to be described. The bacterium *A. fischeri* has two distinct lifestyles. It can exist in a free-living state in the marine environment or as a symbiont of the Hawaiian bobtail squid, *Euprymna scolopes*, which likely uses it for camouflage **(Figure 11.18)**. Only within the light organ of the squid do *A. fischeri* cells emit light, in an energy-intensive set of reactions involving the enzyme luciferase. How does *A. fischeri* regulate the production of luciferase? Investigations of this question led to the discovery of bacterial quorum sensing.

It was discovered that luminescence could be induced in free-living *A. fischeri* cells. However, this occurs only when the cultures have been grown to high cell densities, roughly mimicking the population density within the squid light organ. Growth of a colony on solid agar fulfills this requirement. The cells produce a specific molecule, an ***N*-acyl-homoserine lactone (AHL)**, which acts as an autoinducer based on its ability to induce luminescence **(Figure 11.19)**. AHL molecules are used for intercellular signaling by a number of bacteria from the *Proteobacteria* phylum. The LuxI protein, sometimes called autoinducer synthase, catalyzes synthesis of this molecule. Cells living at low cell density also produce the autoinducer, but the molecule diffuses away from the cell as soon as it is produced and never reaches sufficiently high intracellular concentration to induce luminescence. Addition of sufficient amounts of autoinducer to low cell-density cultures results in luminescence.

How do cells detect AHL? A transcriptional activator protein called the LuxR regulator interacts with the autoinducer molecule once the molecule reaches a critical threshold concentration and enters the cell. This complex then binds to the *lux* regulatory site on the DNA, called the *lux* box, situated upstream of the *lux* operon, resulting in activation of the expression of the *lux* structural genes **(Figure 11.20)**. These genes include *luxA* and *luxB*, which encode the luciferase enzyme that catalyzes the production of light. The operon also includes the *luxI* gene, which encodes LuxI, the enzyme that catalyzes the synthesis of AHL. As a result, this system is

Microbes in Focus 11.1
ALLOVIBRIO FISCHERI

Habitat: Found in oceans throughout the world, most often in symbiosis with other marine organisms

Description: Gram-negative rod-shaped bacterium, approximately 2 μm in length

Key Features: A relative of the pathogen *Vibrio cholerae, A. fischeri* is well known for its bioluminescent capabilities. Through a quorum-sensing mechanism, cells of *A. fischeri* can produce light. Presumably, this light production aids its host by camouflaging the host from predators during moonlit nights.

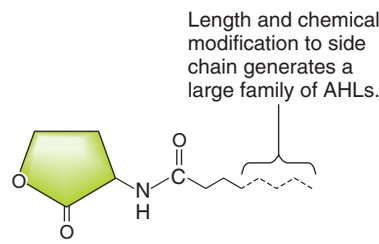

Figure 11.19. *N*-acyl-homoserine lactone (AHL) Versions of this molecule act as autoinducers in a number of bacteria. The length and chemical modifications to the side chain are very important for determining signaling specificity.

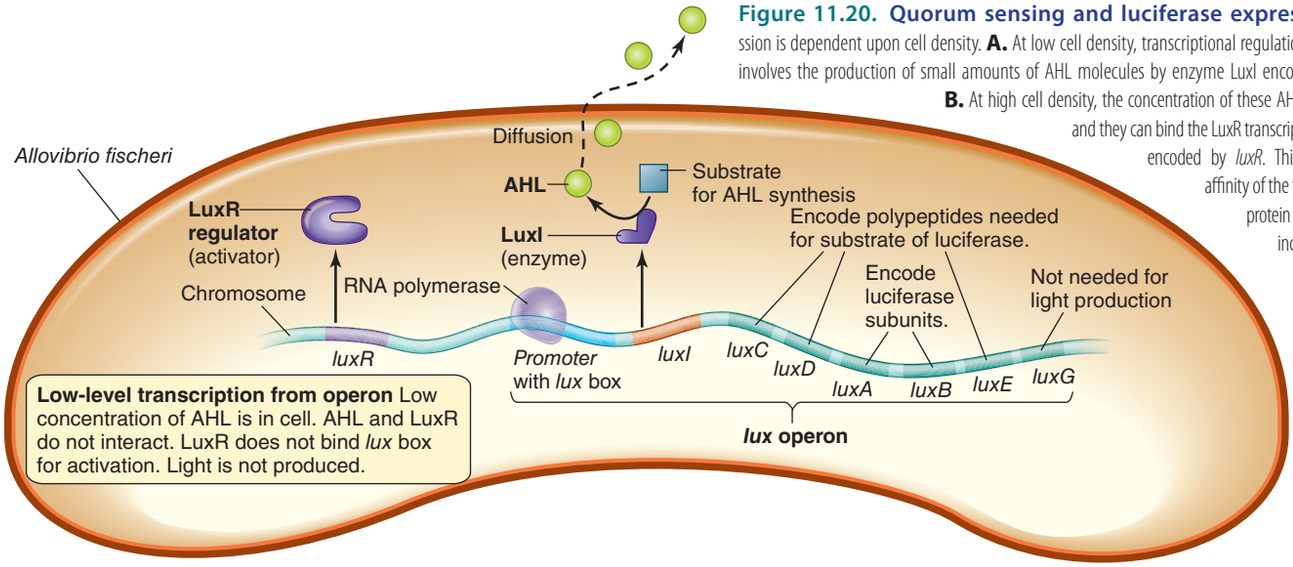
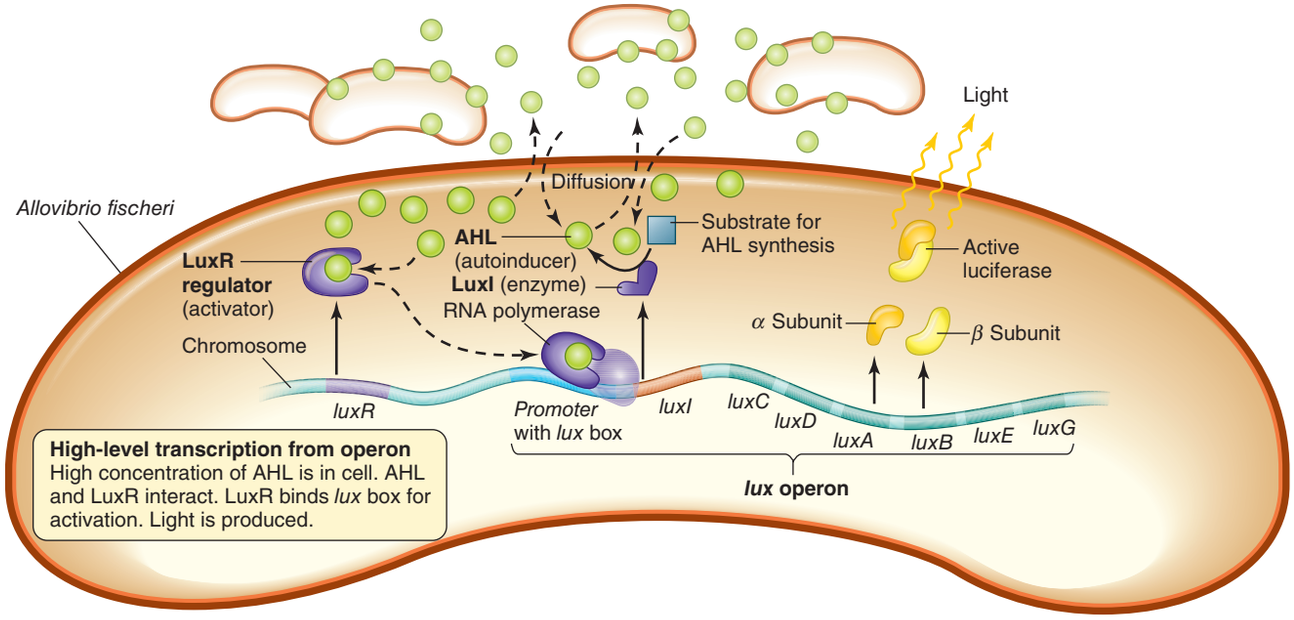


A. Low population density; low concentration of AHL



B. High population density; high concentration of AHL

Figure 11.20. Quorum sensing and luciferase expression Gene expression is dependent upon cell density. **A.** At low cell density, transcriptional regulation by quorum sensing involves the production of small amounts of AHL molecules by enzyme LuxI encoded by the *luxI* gene. **B.** At high cell density, the concentration of these AHL molecules increases, and they can bind the LuxR transcriptional activator protein encoded by *luxR*. This results in increased affinity of the transcriptional activator protein for the *lux* box, and increased transcription of the *lux* operon.

reinforced under high cell densities, resulting in amplified synthesis of the autoinducer, which then results in yet higher gene expression and increased light production.

AHL molecules seem to be used as signaling molecules most frequently in members of the *Proteobacteria*. Gram-positive bacteria, in contrast, utilize small peptides for quorum sensing. Like the AHL molecules we just examined, these peptides are transported out of the cell, into the intercellular environment. There, they can bind to specific cell surface receptors, triggering a cell-signaling pathway that affects gene expression.

Now that we have a general idea of how this system works, let's ask another question. How does this quorum-sensing mechanism benefit the organisms involved? Within the light organ, the squid provides the bacteria with nutrients and a secure habitat. The bacteria require considerable energy and reducing power for the luciferase reaction and for production of the aldehyde substrate for luciferase. In return, the squid's survivability and therefore reproductive success increases because the light produced by *A. fischeri* provides camouflage from predators that cannot detect the illuminated squid from below against a background of the filtered light above. The ultimate advantage to the bacteria remains unclear. The symbiosis may allow the bacteria to grow to very high population densities followed by dispersal of large numbers of cells back into the water. This question is under investigation by several research groups around the world.

Widespread occurrence of quorum sensing

Although quorum sensing was discovered as a result of studying what some might consider a relatively unimportant interaction between a marine microorganism and a squid, quorum-sensing

systems have been discovered in a broad range of microorganisms, controlling a number of different processes. These processes include motility, conjugation, biofilm formation, secondary metabolite production, and pathogenesis. Many of these events involve the colonization or infection of multicellular organisms. For example, one *Vibrio cholerae* cell cannot produce enough toxin to have much effect on a host. In the presence of a sufficient number of other *V. cholerae* cells, however, toxin production might be a worthwhile expenditure of energy and resources. A larger dose of toxin could enable the pathogen to avoid destruction by the host's immune system. Perhaps not surprisingly, then, toxin production in *V. cholerae* is controlled by quorum sensing.

CONNECTIONS **Sections 21.1 and 21.2** describe how successful infection often requires the coordinated production of virulence factors in order to overcome host immune systems. Genes for the production of such virulence factors are expressed in response to environmental conditions consistent with the presence of the pathogen within a suitably susceptible host.

Some organisms contain multiple quorum-sensing systems, which use different signal molecules that have different sets of target genes. In some cases, these systems use AHL molecules with side chains of different lengths and chemical modifications that affect the signaling specificity. In other cases, other types of signaling molecules such as peptides are used. While quorum-sensing systems most commonly regulate gene expression within genetically identical populations, these systems may also affect gene expression in other species. In the formation of biofilms, for example, different types of microorganisms might produce similar autoinducers that stimulate one another. Molecules synthesized by one type of organism could also disrupt a quorum-sensing pathway in another type of organism. These interactions could play an important role in competition between populations or in host resistance against infection by pathogens.

CONNECTIONS As we will see in **Section 24.2**, resistance to today's antimicrobial drugs represent a very serious problem. Quorum-sensing systems involved in some host/pathogen interactions provide the potential for the development of novel antimicrobial medications based on disrupting the quorum-sensing systems of infecting pathogens.

11.5 Fact Check

1. What is quorum sensing, and how are autoinducer molecules involved?
2. In *Allovibrio fischeri*, describe how the autoinducer, the LuxR protein, and the *luxA*, *luxB*, and *luxI* genes are involved in producing luminescence.
3. Provide several examples of the advantages/uses of quorum sensing in bacteria.

11.6 Two-component regulatory systems

How do environmental conditions affect gene expression?

In the preceding sections, we have seen how bacterial cells can regulate gene expression, often in response to changes in their external environment. In some cases, an effector molecule binds to DNA or RNA and directly affects its activity. In other cases, the effects of external conditions on gene expression may be less obvious. Often, these systems involve a **two-component regulatory system** composed of one protein that acts as a sensor and another protein that regulates transcription. Their interaction results in **signal transduction**, or a cellular response to an external stimulus.

Genome analyses reveal two-component regulatory systems to be among the most common regulatory systems in bacteria (Table 11.4). Typically, these systems involve a sensor, commonly **histidine protein kinase (HPK)**, for detecting the environmental stimulus, and a **response regulator (RR)** that regulates transcription (Figure 11.21). Kinases are enzymes that phosphorylate other molecules, usually by adding phosphate from ATP. HPK is so named because it becomes phosphorylated at a specific histidine amino acid. In many cases, the target genes whose expression is regulated by these systems have not been determined, and in most instances the environmental stimulus is also unknown. Despite their name, two-component regulatory systems sometimes include several HPK and RR proteins that support extensive phosphoryl transfer. An example of this is the control of *Bacillus subtilis* endospore formation in response to nutrient limiting conditions that involves at least six different proteins, including two separate HPK proteins.

Another extensively studied example of a two-component regulatory system involves the virulence of the plant tumor-inducing bacterium *Agrobacterium tumefaciens*. This remarkable bacterium functions as a natural genetic engineer, transferring genes from a plasmid, called the **Ti plasmid** (from tumor inducing), into the nucleus of a plant cell. Once these genes have been transferred to the nucleus, they are expressed, and the resulting gene products cause the formation of a tumor by altering the balance of hormones in the plant. *Agrobacterium*-induced plant tumors were once studied as a possible model for human cancer, but it soon became apparent that the mechanisms behind the two types of proliferative growth differed significantly.

Ground-breaking discoveries made in the laboratories of Eugene Nester, Mary-Dell Chilton, and Jeff Schell in the 1970s

TABLE 11.4 Examples of two-component regulatory systems

Sensor	Regulator	Function	Organism

revealed that the plant tumor formed due to the transfer of a segment of DNA, called "T-DNA" (for transferred DNA), from the Ti plasmid in *Agrobacterium* into the plant cell nucleus. This "transfer led to the expression of the T-DNA genes encoding enzymes that direct the production of plant hormones. This system has been extensively developed for the genetic engineering of plants. The system can be manipulated to deliver any gene into the nucleus of a susceptible plant. We now know that the DNA is transferred between the bacterial and plant cells in a manner very similar to bacterial conjugation.

CONNECTIONS In **Section 12.5**, we discuss how scientists have used *Agrobacterium* to introduce genetic material into plants. This technique has been used for improving varieties of crop plants and studying fundamental biological mechanisms.

The transfer of T-DNA from the bacterium to the plant cell nucleus requires the products of a number of virulence genes on the Ti plasmid. These genes, called *vir* genes, are only expressed under conditions similar to those present at a plant wound site. More specifically, acidic pH and the presence of certain phenolic compounds, such as acetosyringone, lead to the expression of the *vir* genes. These are considered to be inducing conditions.

Two regulatory virulence genes, *virA* and *virG*, are required for the expression of the other *vir* genes. VirA is a transmembrane protein of the HPK family that extends into the periplasm. VirG is a transcriptional activator of the RR family (Figure 11.22). Transcription of target *vir* genes by VirG depends on VirA. This observation suggests that VirA perceives an extracellular signal, and transduces the signal to VirG, resulting in transcriptional activation of the other virulence genes. Although there is a low level of expression of *virA* and *virG* under non-inducing conditions, their expression is elevated under inducing conditions.

To better understand the interactions between these proteins, Shougouang Jin, a graduate student working in the laboratory of Eugene Nester at the University of Washington in the late 1980s, conducted *in vitro* experiments using VirA and VirG proteins expressed in and purified from *Escherichia coli* (Figure 11.23). When the proteins were each mixed with radioactively labeled ATP, VirG became phosphorylated, an event he could detect by following the radioactive signal. VirG did not become phosphorylated in the absence of VirA. Phosphorylated VirA was detected only if the reaction was carried out in the absence of VirG. Finally, the addition of phosphorylated VirA to VirG resulted in phosphorylation of VirG.

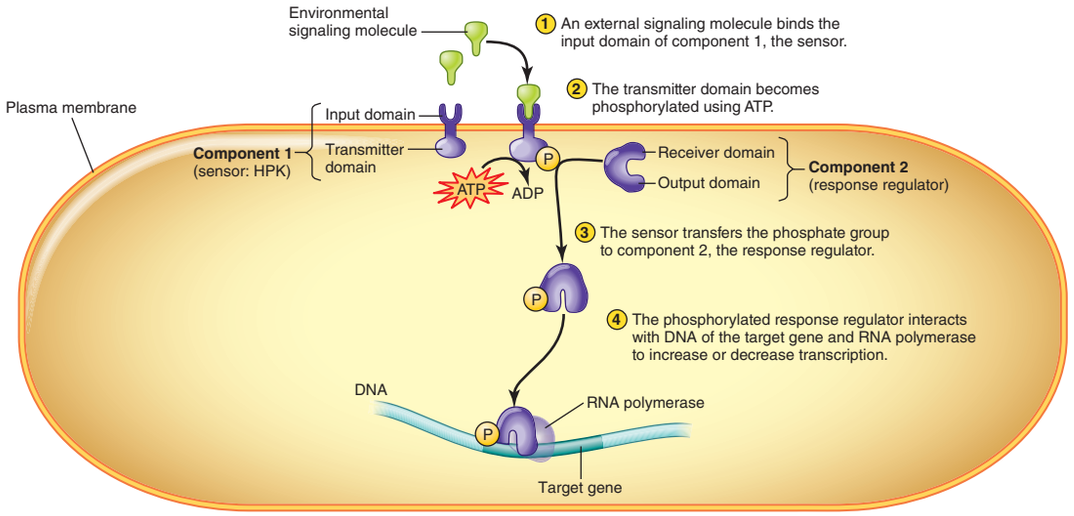

Figure 11.21. Process Diagram: Using an environmental signal to alter gene expression Two-component regulatory systems are composed of two proteins: a sensor histidine protein kinase (HPK) and a response regulator. Upon sensing the input signal, the sensor becomes phosphorylated and then phosphorylates the response regulator. Phosphorylation of the response regulator results in a change in its conformation, often causing activation or repression of the transcription of specific target genes.

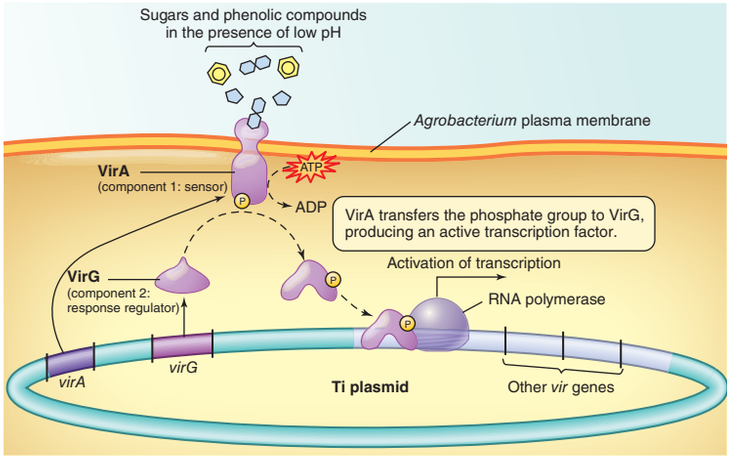

Figure 11.22. A two-component regulatory system and expression of virulence genes The regulation of the *Agrobacterium* signal transduction pathway is mediated by the VirA/VirG signal transduction system. On detection of signal molecules such as sugars and phenolic compounds from the injured plant, as well as acidic pH, the VirA protein becomes phosphorylated. The phosphorylated VirA then phosphorylates VirG, which then activates transcription of the *vir* genes.

Further experiments identified the specific amino acid residues that were phosphorylated within the proteins. For VirA, the histidine residue at position 474 became phosphorylated; for VirG, the aspartate at position 52 became phosphorylated. Using site-directed mutagenesis (see Section 12.2), the researchers then changed the histidine codon to a glutamine and the aspartate codon to asparagine. These mutations abolished the phosphorylation *in vitro* and also abolished the expression of the virulence genes. These experiments demonstrated a signal transduction mechanism in which (1) ATP is hydrolyzed, (2) the phosphate is transferred to the histidine residue, and (3) the phosphate is transferred to the aspartate residue. This same histidine-aspartate phosphotransfer mechanism occurs in many two-component regulatory systems.

The HPK protein can be subdivided into a variable N-terminal sensor module and a conserved C-terminal transmitter module, while the RR protein can be subdivided into a conserved N-terminal receiver module and a variable C-terminal output module. Different two-component regulatory systems differ in the environmental stimulus that causes the phosphorylation of the sensor and the target of the response regulator. Despite the shared signal transduction mechanism, the correct operation of these systems is dependent on a sufficiently high level of specificity. Phosphotransfer, in other words, occurs between certain pairs of HPKs and RRs, but not between other pairs. The basis of this phosphotransfer specificity involves recognition between the protein molecules.

11.6 Fact Check

1. Describe the two types of protein components involved in a two-component regulatory system. What are their roles?
2. What is the role of the VirA and VirG proteins in *Agrobacterium* cells?
3. Explain how phosphotransfer mechanisms play a role in VirA and VirG function.

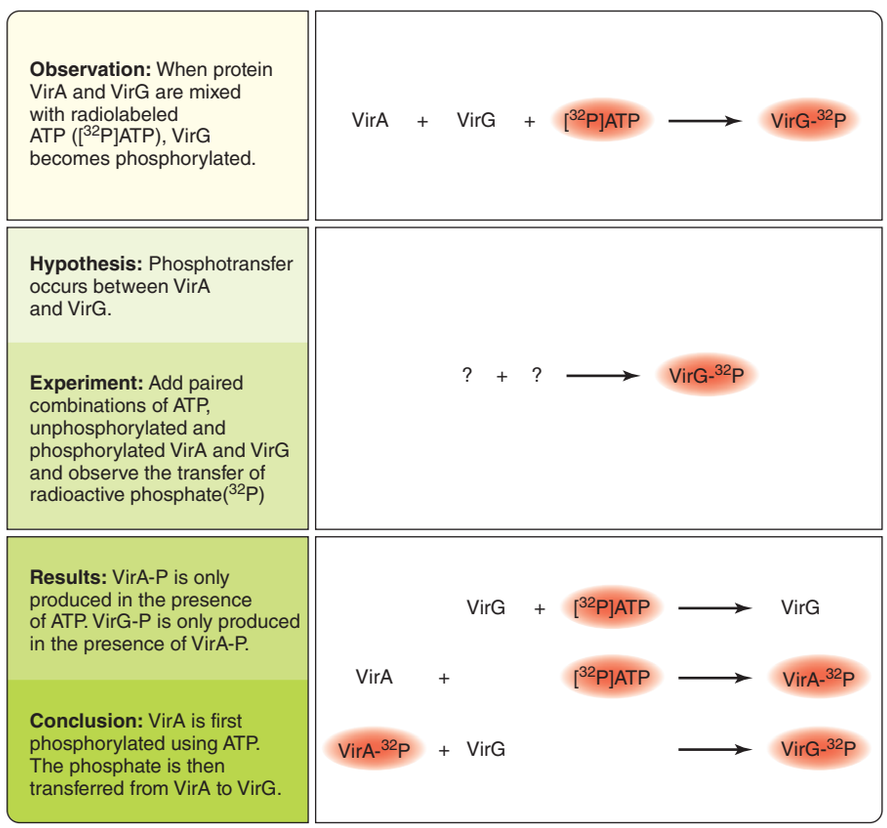

Figure 11.23. Sequence of phosphorylation in the VirA/VirG signal pathway *In vitro* phosphorylation experiments were performed using purified VirA and VirG proteins and radioactively labeled ATP. VirA could be phosphorylated directly by ATP, but VirG could not. VirG was phosphorylated only in the presence of either VirA and ATP, or previously phosphorylated VirA (VirA-P), indicating that phosphotransfer occurred from VirA-P to VirG.

11.7 Chemotaxis

How can bacterial cells regulate their behavior?

One of the most thrilling experiences for the beginning microbiologist involves the use of phase contrast microscopy to observe live bacterial cells. As some cells dart across the field of view, other cells move at a leisurely pace, or not at all. Why are some bacterial cells motile, while others are not? Motility must confer a selective advantage or it would not be worth the effort to expend the required energy. Chemotaxis, introduced in Sections 2.5 and 4.2, involves the movement of motile bacteria toward favorable chemicals, such as preferred nutrients, or away from detrimental chemicals, such as toxins or poisons. A highly modified two-component regulatory system that integrates several additional control systems regulates chemotaxis in bacteria. Unlike most of the regulatory systems that we have explored in this chapter, this system does not involve transcriptional or translational regulation. Regulation of chemotaxis involves protein switches.

The mechanism of chemotaxis

Once again, the regulation of chemotaxis is best understood in *Escherichia coli*. Recall from Section 2.5 that *E. coli* cells have several peritrichous flagella that form a bundle during counterclockwise (CCW) rotation, propelling the cells forward. During clockwise (CW) rotation, the flagella separate and rotate independently. In the absence of attractant or repellent, the cell alternates between CCW and CW rotation of the flagella. This switch occurs on average about once per second. CCW rotation results in smooth swimming or a run. CW rotation causes the cell to tumble end over end, resulting in a change of direction. A combination of runs and tumbles results in a random walk (see Figure 2.28).

In the presence of attractant or repellent, the ratio of CCW rotation to CW rotation changes. If the attractant concentration is increasing or the repellent concentration is decreasing, then CCW rotation is favored, resulting in smooth swimming, or a run. If the attractant concentration is decreasing, or the repellent concentration is increasing, then CW rotation is favored, leading to tumbling and change of direction. A chemical gradient can influence the duration of runs, resulting in net movement up or down the concentration gradient.

How do bacteria detect changes in chemical gradients? To understand the molecular mechanism of chemotaxis, researchers again began with the analysis of mutants. In this case, they analyzed mutants in which chemotaxis was disrupted.

Study of chemotaxis using mutants

Chemotaxis mutants can be isolated using a capillary tube filled with semisolid agar containing a higher concentration of attractant than the surrounding environment. A normal cell that can perform chemotaxis will migrate into the tube **(Figure 11.24)**. A mutant that cannot change the direction of flagellar rotation in response to an attractant concentration will not be able to move up the tube. Such mutants typically exhibit a bias toward either CCW or CW rotation. Mutations in the *cheA*, *cheY*, *cheW*, or *cheR* genes result in CCW rotation, whereas mutations in the *cheB* or *cheZ* genes cause CW rotation.

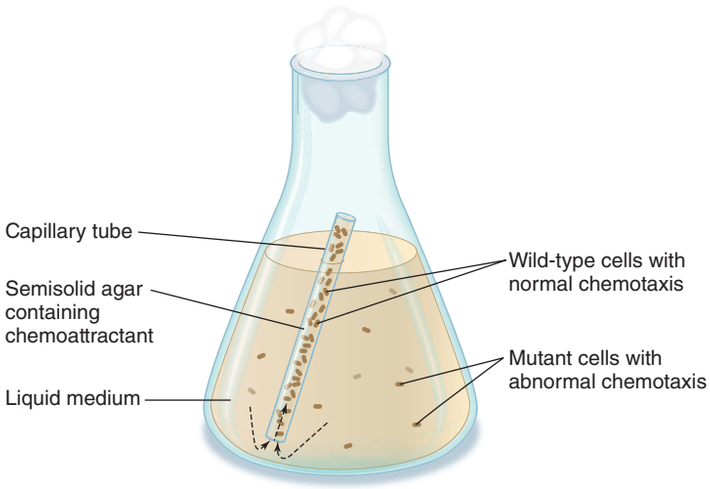

Figure 11.24. Isolating chemotactic mutants A capillary tube filled with semisolid agar and a higher concentration of attractant chemical than found in the surrounding medium is used to screen for mutant bacteria that are deficient in chemotactic ability. In this example, the wild-type strain is attracted to the compound, and it tends to move up the tube to higher concentrations of chemical; the chemotactic mutant does not exhibit this behavior.

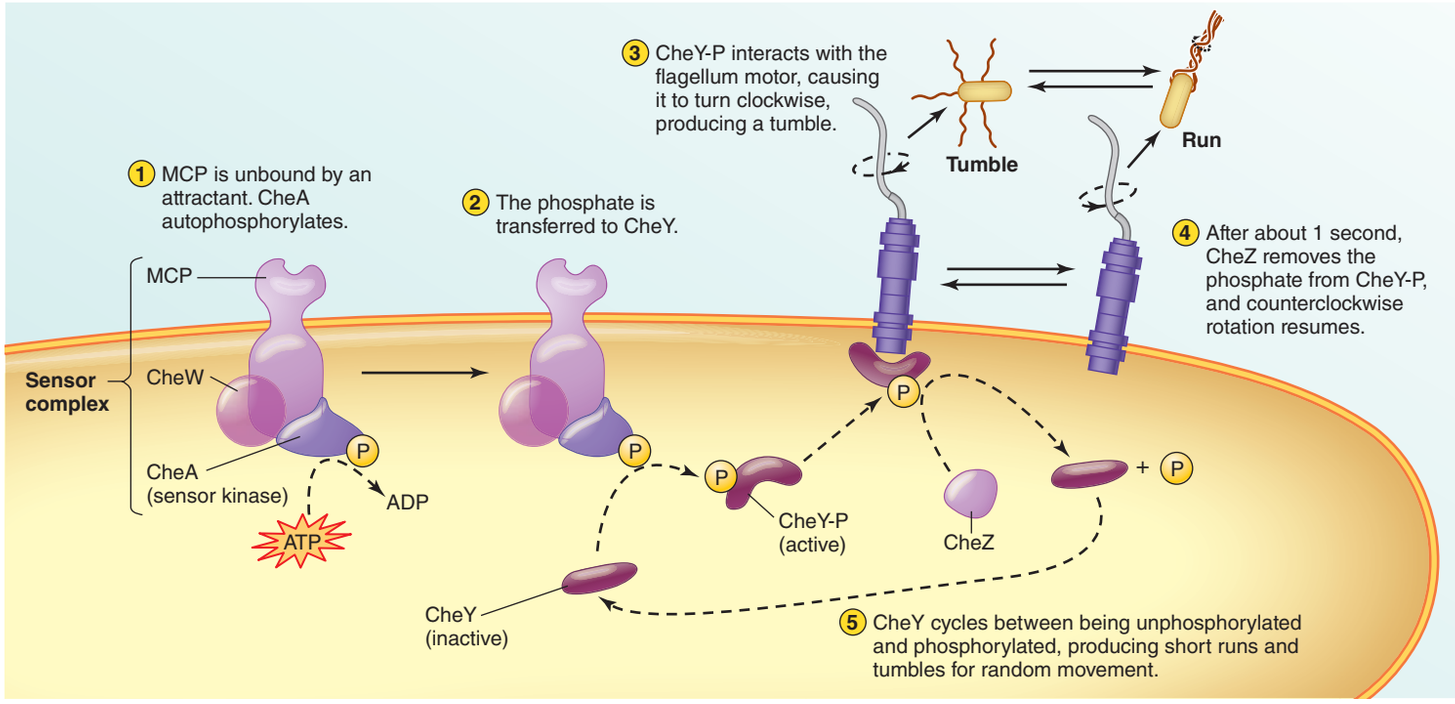
The corresponding Che proteins are involved in a series of signal transduction events that regulate chemotaxis. Their functions are summarized in **Table 11.5**. The central proteins CheA and CheY are present in all chemotactic bacteria. CheA functions as the sensor kinase in the system and is phosphorylated to CheA-P at a specific histidine residue in response to the presence or absence of a particular attractant or repellent. CheA-P then phosphorylates CheY, the response regulator, at a specific aspartate residue to CheY-P, which interacts with the flagellar motor to determine the direction of rotation **(Figure 11.25)**. The phosphorylation circuit is a histidine-aspartate phosphorelay, typical of two-component regulatory systems.

The study of chemotaxis is an excellent example of how combining the approaches of genetics, molecular biology, and

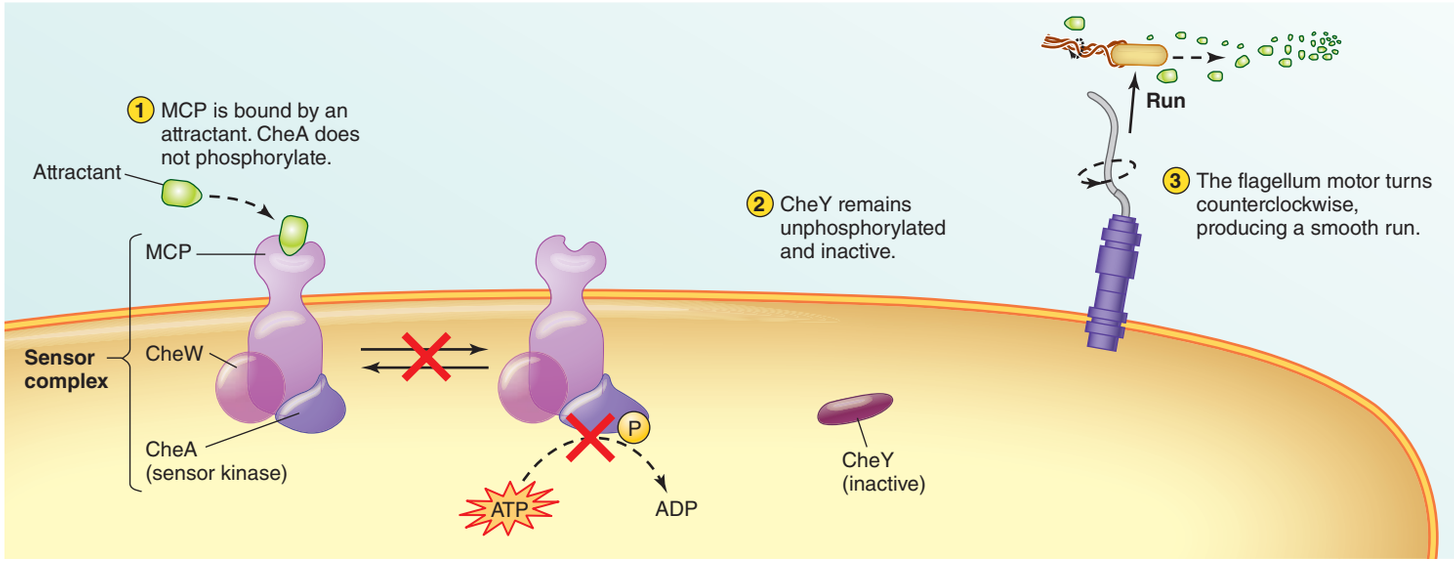
TABLE 11.5 Functions of chemotaxis proteins

Methyl-accepting chemotaxis proteins (MCPs) → sensory proteins or transducers; can be methylated by CheR
CheR → methylates MCPs[a]
CheA → sensor kinase
CheY → response regulator: controls direction of flagellar rotation
CheB → response regulator, demethylates MCP
CheZ → dephosphorylates CheY-P
CheW → involved in transduction of signal from MCP to CheA

[a]Methyl-accepting chemotaxis proteins are sensory proteins or transducers that can be methylated by CheR.



A. Chemotaxis in the absence of attractant



B. Chemotaxis in the presence of attractant

Figure 11.25. Process Diagram: Chemotaxis Phosphorylation patterns can affect chemotactic behavior. **A.** In the absence of attractant, CheW promotes phosphorylation of CheA, which in turn phosphorylates CheY. The resulting CheY-P interacts with the flagellum, signaling it to rotate clockwise (CW), causing a tumble (*left*). Removal of the phosphate from CheY-P by CheZ disrupts interaction with the flagella, resulting in counterclockwise (CCW) rotation, and the cell runs. **B.** In the presence of attractant, phosphorylation of CheA is inhibited, so CheY is not phosphorylated either. The absence of CheY-P results in counterclockwise rotation of the flagella, causing a longer run (*right*).

biochemistry can lead to a deeper understanding of mechanisms than would be possible using any single approach alone. The generation of mutants resulted in the discovery of the chemotaxis genes. Once these genes were cloned and sequenced, scientists realized that the chemotaxis systems shared much in common with the two-component regulatory systems, even though regulation was not carried out at the level of transcription. Using site-directed mutagenesis, scientists identified key functional motifs in the chemotaxis proteins that were involved in the protein switches. *In vitro* biochemical analysis with purified chemotaxis proteins unraveled the phosphorylation and methylation circuits that are described below.

Transmembrane sensory proteins, called **methyl-accepting chemotaxis proteins (MCPs)**, sense the presence of attractant

or repellent molecules. Although mutations in the *che* genes affect chemotaxis in response to all chemical signals, mutations that affect the synthesis of MCPs abolish chemotaxis only toward a specific chemical signal. The MCPs interact with the cytoplasmic protein CheW, and the resulting complex modulates the level of autophosphorylation of CheA. Attractants decrease the level of phosphorylation, whereas repellents increase the level of phosphorylation (see Figure 11.25). The phosphorylated CheA (CheA-P) transfers the phosphoryl group to the protein CheY, resulting in CheY-P. CheY-P causes clockwise rotation and tumbling until CheZ removes the phosphoryl group.

Another level of regulation of chemotaxis, called adaptation, involves methylation of the MCP proteins, hence their name. Adaptation determines the system's sensitivity to attractants and repellents and prevents it from becoming saturated, which would prevent it from responding to changes in chemical concentration. The protein CheR can methylate the MCPs, decreasing the ability of the MCP to respond to attractant **(Figure 11.26)**. Another protein, CheB, is phosphorylated by CheA-P. The resulting CheB-P molecules demethylate the MCPs, increasing their sensitivity to attractant. As an example, the Tsr MCP can respond to a few serine molecules when fully demethylated, but when highly methylated, a response requires thousands of serine molecules. Thus, in the presence of a continually high level of attractant, resulting in lower levels of CheA-P, CheY-P, and CheB-P, the extent of methylation will increase because of a lack of CheB-P-mediated demethylation. Highly methylated MCPs only respond to very high levels of attractant. If these levels are not maintained, then the result will be the phosphorylation of CheA and subsequent phosphorylation of CheB, resulting in eventual demethylation of the MCP.

Recent studies and genome sequence analyses indicate that the basic mechanism of chemotaxis studied in *E. coli* is conserved across bacteria and archaea, as similar genes are found in many organisms. It is becoming clear, however, that *E. coli* possesses one of the simpler systems. As scientists address, through experiments, the diversity in chemotaxis systems revealed by genome sequences, we will understand how the remarkable behavior of these organisms has been shaped through evolution.

11.7 Fact Check

1. Differentiate between CW and CCW flagella rotation in bacteria.
2. How does the presence of attractants and repellents affect flagella rotation?
3. Explain the roles of the CheA and CheY proteins in chemotactic bacteria.
4. How is phosphorylation involved in the activity of CheA and CheY?
5. What is the role of methyl-accepting chemotaxis proteins (MCPs)?
6. How do MCPs work with the Che proteins to regulate chemotaxis?

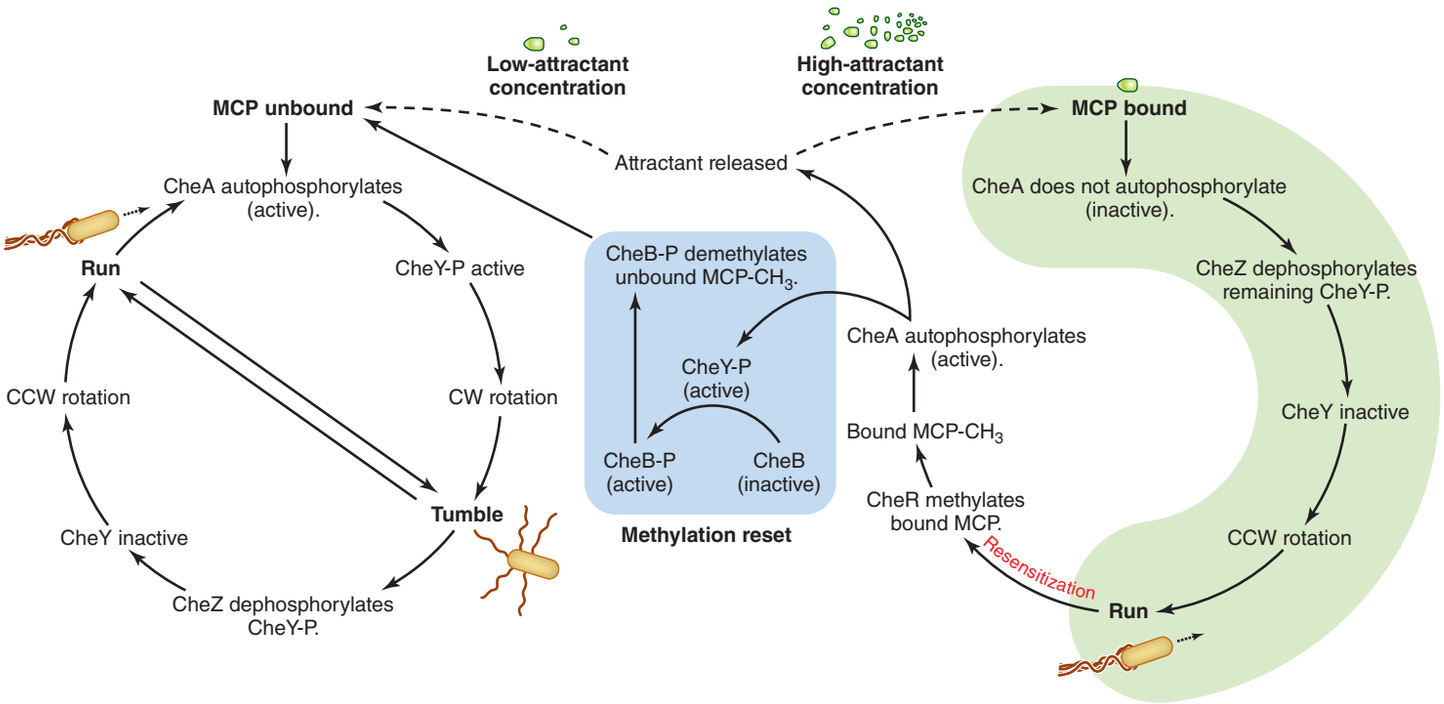


Figure 11.26. Regulation of chemotaxis by methylation In a process called adaptation, the prolonged presence of attractant results in increased methylation of MCP to MCP-CH_3, caused by CheR. This methylation reduces the sensitivity of the MCP to the attractant. Resetting allows it to exit from the run as the signaling proteins are again phosphorylated (*right*). If the concentration of attractant decreases, increased phosphorylation of CheY results in increased phosphorylation of CheB. The CheB-P demethylates MCP-CH_3 (*center*), so that it is once again available to be bound by attractant.

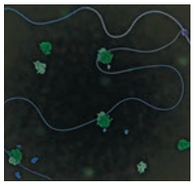
Image in Action

WileyPLUS Learning Space This illustration shows the active transcription and translation of an operon that encodes three distinct polypeptides. The *lac* operon encodes three proteins: LacZ (shown in dark blue), LacY (medium blue), and LacA (light blue). DNA is shown at the top of the screen, with RNA polymerase (purple) moving from left to right. The RNA strand, which is shown twisting from the top right to the bottom left, is undergoing translation by several ribosomes.



1. Imagine that lactose is not present. In what ways would the image differ?
2. Imagine that you wanted to monitor and quantify the gene expression represented in this image. What lactose analogs are available for this purpose, and how would you use them?

The Rest of the Story

In this chapter, we have seen several well-known examples of gene regulatory systems, many of them in the model organism *Escherichia coli*. These systems operate at several different levels and ensure that cells respond appropriately to environmental and nutritional conditions. Microbial metabolism, for example, is a well-regulated and complex process. A microorganism's metabolism is tightly controlled to ensure that enzymes and proteins are only made when they are needed and in the amount they are needed as the available nutrients and surrounding environmental conditions change. From an evolutionary point of view, an overproduction would be a waste of energy and could impact an organism's ability to compete and survive. Genetic regulation ensures that such wastes and inefficiencies are minimized.

The science of metabolic engineering involves manipulating regulatory pathways to override the natural genetic regulatory and efficiency controls so that microbes overproduce desired products. Deregulation of a particular biosynthetic pathway can be accomplished by overexpressing positive regulators or by inactivating repressors. A classic, early example involved optimizing production of the drug penicillin. Researchers carried out random mutagenesis on the organism *Penicillium chrysogenum* using radiation and chemical agents in the laboratory. They then screened for deregulated mutants with the ability to overproduce penicillin. Some of these mutations affected genes related to penicillin biosynthesis; mutants were screened for higher output than parental cells.

As the knowledge of gene regulation and biosynthetic pathways has grown, more rational approaches are also being used to engineer a variety of commercially desirable compounds including amino acids, vitamins as nutritional supplements. These rational approaches involve specific, site-directed mutation and manipulation of the biosynthesis genes.

Indeed, the spirit of Monod's maxim, "What is true for *E. coli* is also true for the elephant," remains true today. Early genetic regulation studies in *E. coli* now apply beyond the realms of the elephant and impact nearly all areas of the biological sciences, encompassing a vast variety of molecular mechanisms. What has been accomplished in the biosciences, medicine, agriculture, and industrial microbiology arguably would not have been possible without having studied this unassuming bacterium, *E. coli*.

Summary

Section 11.1: How are gene expression and enzyme activity controlled?

Many mechanisms for controlling enzymatic activity have been discovered.

- Under a given set of conditions, a cell requires only a small subset of all possible gene products.
- **Constitutive expression** refers to genes that always are expressed, while **inducible expression** refers to genes that are expressed only under certain conditions.
- Gene expression can be regulated at several different levels, from transcription initiation to protein activity.
- Protein activity can be regulated by **allosteric inhibition** or **covalent modification**.
- The sequence that represents the most commonly occurring residues at each position is called the **consensus sequence**.

Section 11.2: How do regulatory proteins control transcription?

The initiation of transcription can be controlled in various ways.

- The **operon** is the unit of transcription, whose expression is under the control of discrete regulatory elements including promoters and **operators**.
- In **negative control**, a **repressor** blocks transcription. **Effectors** can bind to repressors and modulate their activity. These effectors can function as **inducers** or **corepressors**.
- In **positive control**, an **activator molecule** may bind to an **activator binding site**, leading to increased transcription. In the *lac* operon, **activator protein (cAMP receptor protein, or CRP)** serves as an activator.
- In the presence of glucose and lactose, *Escherichia coli* exhibits a **diauxic growth curve**.

Section 11.3: How does a single environmental stimulus control multiple operons?

Larger sets of genes can also be coordinately regulated.

- **Regulons** are coordinately regulated genes that respond to the same regulatory systems.
- **Catabolite repression** and the **SOS response** represent two well-studied regulon systems.
- Members of the SOS regulon initially were identified using *lacZ* fusions as **reporter genes**.
- Lactose analogs have also been instrumental in studies of regulons and gene expression.
- Alternative sigma factors bind to specialized promoters, resulting in transcription initiation.

Section 11.4: How can mRNA be controlled?

Small, non-translated RNA molecules also regulate gene expression.

- Small non-coding RNAs, or **sRNAs**, can control gene expression at transcription or translation.
- **Antisense RNA** regulates translation by complementary base-pairing with mRNA.
- **Attenuation** involves changes in the secondary structure of mRNA.
- **Riboswitches** are a system of mRNA and effector molecules that can increase or decrease the level of gene expression.

Section 11.5: How do bacteria communicate with their neighbors?

Bacteria can regulate gene expression based on their density.

- A chemical-signaling system called **quorum sensing** allows bacteria to communicate population status through the detection of chemical signals.
- Studies on the luminescence system in the squid symbiont *Allovibrio fischeri* provided much of the initial knowledge about quorum-sensing systems.
- The signal for the quorum-sensing system is the **autoinducer**. In *A. fischeri*, ***N*-acyl-homoserine lactone (AHL)** acts as the autoinducer.
- Quorum sensing may be important in the infection of multicellular organisms, the formation of biofilms, and other processes that involve cooperation among bacterial cells.

Section 11.6: How do environmental conditions affect gene expression?

Bacteria can also regulate gene expression in response to environmental signals.

- The activity of **two-component regulatory systems** usually results in **signal transduction**, facilitating cellular response to external stimulus.
- Two-component regulatory systems, composed of sensor **histidine protein kinases (HPKs)** and **response regulators (RRs)**, are among the most abundant regulatory systems.
- In *Agrobacterium tumefaciens*, environmental signals result in the transfer of the **Ti plasmid** from the bacterium to the plant cell nucleus.

Section 11.7: How can bacterial cells regulate their behavior?

Complex bacterial behaviors can be modulated by shifts in protein activity.

- Chemotaxis is controlled at the level of protein activity, rather than by changes in gene expression.
- Chemotactic bacteria sense chemical gradients by detecting changes in concentration over time.
- Key genetic studies that contributed to the understanding of the mechanism of chemotaxis involved the isolation of mutations in the *che* genes, which remove the chemotactic ability of the cell but do not affect motility.
- Chemicals are detected by specific **methyl-accepting chemotaxis proteins (MCPs)**, which ultimately affect the direction of flagellar rotation and thus whether the cell runs or tumbles.

Application Questions

1. You are working as an intern for a researcher who studies housekeeping genes in bacteria, particularly those genes that encode the enzymes required for cell maintenance and energy production. Explain the type of gene expression that most likely occurs in these genes.
2. Certain bacteria have the ability to produce capsules that allow them to hide from a host's defenses. Before bacteria were introduced into a host mouse in the laboratory, the capsule genes were not expressed. Within minutes of being introduced into the mouse's bloodstream, however, the genes were actively expressed. Explain the type of gene expression that most likely is involved in this response.
3. You are performing an experiment in which you monitor expression levels of the enzyme β-galactosidase in *Escherichia coli*. At the beginning of the experiment, the bacteria have large amounts of lactose, but at the end of the experiment, no lactose remains. Describe what happens to the β-galactosidase levels during the course of the experiment.
4. Compounds called furanones show promise as antibacterial drugs in humans. The compounds decrease the virulence or harmfulness of some bacteria by inhibiting their quorum-sensing ability. This inhibition of quorum sensing makes it easier for the bacteria to be cleared from the body. Based on your knowledge of quorum sensing, how could furanones make bacteria less harmful?
5. While watching a nature documentary with a friend, you learn of a Hawaiian squid species with the ability to emit light because a bacterial species that undergoes bioluminescence colonizes it. These bacteria can also be found free-living, outside the squid, but they only luminesce when in the light organ of the squid. Explain the behavior of the bacteria to your friend.
6. Imagine that you discover a new two-component regulatory system. You know that certain aspects of these systems tend to be conserved among different bacterial species. What would you expect to see in your system that also has been described in other systems? What features might be unique to your system?

7. Many bacteria are resistant to the antibiotic ciprofloxacin (Cipro). At the molecular level, ciprofloxacin inhibits DNA gyrase, leading to dsDNA breaks and the activation of the SOS response. Explain how SOS induction could cause drug resistance. What role would the LexA and RecA proteins play in this response?
8. In your study of *E. coli* chemotaxis, you add increasing levels of an experimental repellent. If the repellent is truly effective, what will happen to the Che proteins? Will the addition of the repellent result in running or tumbling of the *E. coli*? How will that action affect its direction of movement?
9. You observe a mutant that is deficient in the CheZ protein, carrying a mutant form of the *cheZ* gene. What specific effect will this mutation have on chemotaxis regulation, and how will this mutation affect the cell's chemotactic response? Explain.
10. You read about a protein that remains attached to an operator site most of the time. When a certain amino acid is present, the protein changes shape and detaches from the operator. What type of gene regulatory system does this behavior describe? Explain.
11. You are assigned the task of describing the chemotactic response of some new *che* gene mutants in the presence of an attractant chemical. You elect to use the capillary tube method described in Section 11.7.
    a. Describe your experimental procedure using a capillary tube and attractant.
    b. What result would be observed in a bacterial cell with normal chemotaxis? What would you conclude?
    c. Imagine that one of the mutant bacteria contains a mutation in the *cheY* gene. What result will you observe in this mutant? What would you conclude?

CHAPTER

12 Microbial Biotechnology

For most of humankind's existence, infectious diseases have been the major cause of mortality. During World War I, many soldiers died not from their battle wounds directly, but from the ensuing infections. Little could be done to treat these patients. Their recovery depended on the ability of their immune systems to clear the infection. Although the link between microbes and disease had been made several years earlier and better public sanitation improved the situation somewhat, infectious diseases remained a serious and largely untreatable problem. In September 1928, a chance observation in the laboratory changed all that.

Alexander Fleming, a Scottish bacteriologist working at St. Mary's Hospital in London, noticed that a fungus was inhibiting the growth of *Staphylococcus* on some culture plates. Many scientists would have thought nothing of this observation. However, Fleming decided to further explore this serendipitous finding. He identified the mold as a *Penicillium*, a filamentous fungus. Culture filtrates of *Penicillium*, which he termed "penicillin," could inhibit the growth of many Gram-positive bacterial pathogens as well as the common sexually transmitted Gram-negative bacterium *Neisseria gonorrhoeae*.

Fleming also demonstrated, using animal tests, that penicillin was not toxic. Despite this finding, the clinical potential of penicillin was not realized until the late 1930s. At that time, a research group at Oxford, led by Howard Florey and Ernst Boris Chain, scaled up production so that sufficient amounts of the penicillin culture filtrate were available for human clinical trials. The results were so successful that the Allied forces in World War II employed the antibiotic, reducing mortality due to infected wounds on the battlefield. This success spurred massive investment in the development of large-scale production methods, resulting in drastic reductions in cost of production by over 100-fold. In recognition of the discovery and development of penicillin as the first clinically useful antibiotic, Fleming, Florey, and Chain shared the 1945 Nobel Prize for Physiology or Medicine.

The discovery of penicillin and its development as an antibiotic to treat infections clearly was a major breakthrough in the medical field. The impact of this breakthrough, though, is not limited to medicine. Work on penicillin led to the design and development of large vessels that enable large-scale growth of microbial cultures under defined conditions. This advance contributed to an explosion of biotechnology products that have enriched human lives and contributed to the improvement of living conditions worldwide.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Microbes used for biotechnology may be obtained from existing collections or isolated from nature.

- Figure 12.2: Microbial culture collections
- Perspective 12.1: Bioprospecting: Who owns the microbes?

CONNECTIONS for this chapter:

Using metagenomics to find potential genes for biotechnology applications in uncultured microbes **(Section 10.4)**

Use of GFP fusion proteins **(Section 3.1)**

Effects of endotoxin on humans **(Section 19.3)**

Interactions between plants and soil microbes **(Section 17.2)**

Introduction

Quite simply, **biotechnology** refers to the use of biological processes or organisms for the production of goods such as antibiotics, or services such as food preservation, wastewater treatment (see Section 16.5), and bioremediation of polluted soils (see Section 15.4). For centuries, humans have relied on biotechnology to support their existence. The rise of agriculture and the domestication of animals were accompanied, perhaps less conspicuously, by the use of microorganisms for the production or preservation of foods. Beer, wine, bread, pickles, sauerkraut, and fermented milk products like cheese and yogurt all were produced using naturally occurring microorganisms. The use of microorganisms for food production and preservation will be discussed in greater detail in Chapter 16. Indeed, the yeast *Saccharomyces cerevisiae* has been used for centuries in the production of wine and beer. It was not until the mid-nineteenth century that Louis Pasteur demonstrated that alcoholic fermentation was not purely a chemical process but was carried out by living yeast cells. These yeasts are found on the skin of grapes and result in a natural fermentation after the grapes are crushed. Even though such natural fermentation is still carried out in some traditional wineries, fermentations are usually inoculated with known yeasts nowadays because this results in a more rapid process and consistent product.

As we will see in this chapter, biotechnology affects virtually all aspects of our lives. This phenomenal growth in biotechnology has been enabled by a basic understanding of microbial genetics. As we saw in previous chapters, we now know much about gene regulation, transcription, and translation. Understanding these basic processes has led to the development of powerful molecular biology tools. These tools, in turn, have made possible the widespread use of biotechnology. Basic research into the genetic machinery of simple microbes, in other words, has revolutionized our world.

As we explore biotechnology, we will examine how our understanding of microbial genetics has improved our ability to use microbes for the production of desired products. We will also examine some of the strategies used for the large-scale production of these products, the tools that are employed for improving product efficiency and yield, and the prospects for the development of new products. Along the way, we will address the following questions:

What microbes and genetic materials are available for biotechnology applications? (12.1)
How can molecular biology tools be used to improve microbial strains? (12.2)
What role do microbes play in pharmaceutical biotechnology? (12.3)
What role do microbes play in industrial biotechnology? (12.4)
What role do microbes play in agricultural biotechnology? (12.5)

12.1 Microbes for biotechnology

What microbes and genetic materials are available for biotechnology applications?

Current applications of biotechnology can be grouped broadly into **red biotechnology** related to medical applications, **white biotechnology** related to industrial applications, and **green biotechnology** related to the agricultural sector (Figure 12.1). The application of biotechnology to the environment is discussed in the context of bioremediation in Chapter 15. Microbes participate in all sectors of biotechnology, and as these represent the major activities of current economies, microbial biotechnology is integral to the workings of modern societies. In this chapter, we will consider each type of biotechnology and the ongoing research in microbiology that is leading to new products and applications. These include replacements for many of the products that are currently derived from fossil fuels (Table 12.1).

Today, our agricultural system depends on animals and plants that have been developed slowly over thousands of years from naturally occurring organisms. For instance, corn grown by farmers worldwide bears little resemblance to teosinte, its native ancestor. Over centuries, farmers selected variants of teosinte that produced larger ears of corn, grew better in local environments, or were resistant to diseases. Similarly, the microbes used in biotechnology applications today are modified versions of naturally occurring organisms. These microbes, taken from ecosystems in which they are optimally adapted, most likely are not optimally adapted for biotechnology processes. To be useful in biotechnology processes, microbes must, at the very least, replicate well under standard laboratory conditions. Additionally, naturally occurring strains may not produce high levels of a desired product.

To combat these problems, microbiologists can employ simple selection strategies. Genetic variants with improved characteristics can be isolated, starting from the original strain. These improved strains may replicate more quickly or produce greater amounts of desired product. Sometimes, though, genetic selection alone is not sufficient. Recombinant DNA technology, coupled with a better understanding of basic microbial genetics, biochemistry, and metabolism, can facilitate the construction of more useful microbial strains. Because microbes have short generation times and can be handled easily, the selection of microbes with superior qualities can be achieved within years, rather than decades, as is the case for livestock and crop plants. With powerful recombinant DNA

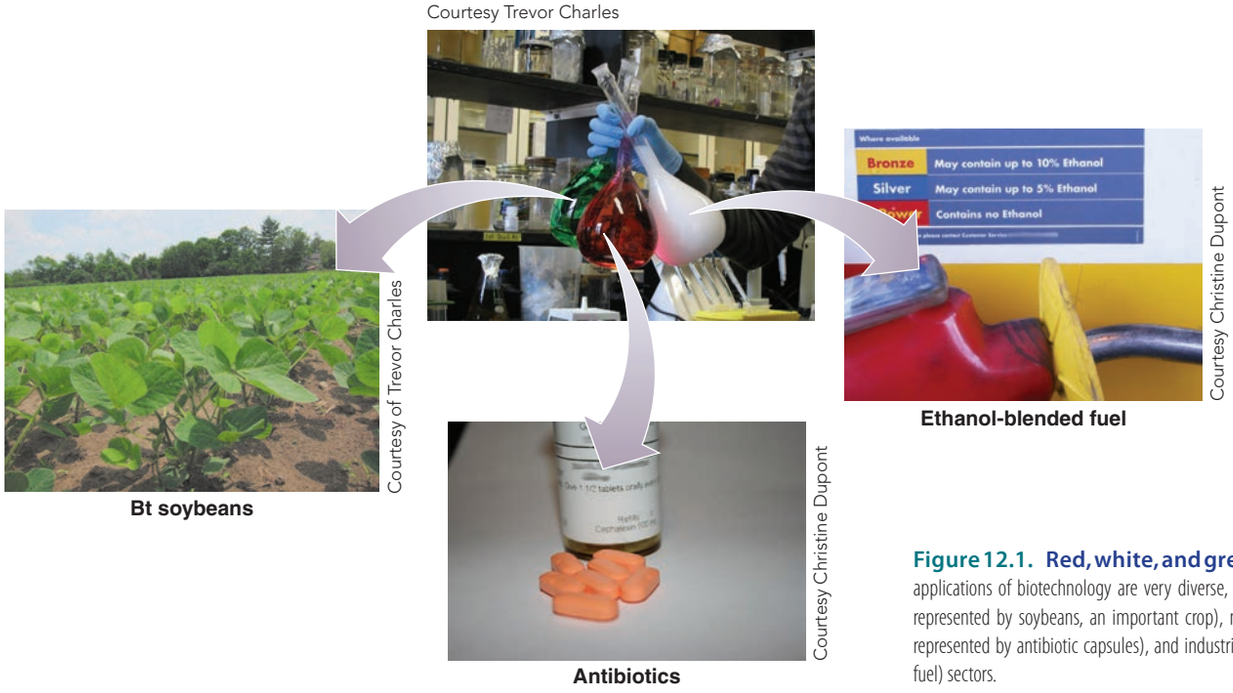

Figure 12.1. Red, white, and green biotechnology The applications of biotechnology are very diverse, including the agricultural (green, represented by soybeans, an important crop), medical and pharmaceutical (red, represented by antibiotic capsules), and industrial (white, represented by ethanol fuel) sectors.

tools at our disposal, we can generate microbes with novel properties in the laboratory.

In this section, we will look at how researchers obtain microbes for use in biotechnology processes. We will then investigate the large-scale use of these microbes.

CONNECTIONS You can review basic recombinant DNA technology and the roles of restriction enzymes and plasmids in **Figure 1.22**.

Sources of microbes

Although many potentially useful microbes certainly exist, we must know about them before we can begin to use them. To facilitate the widespread availability of microbial strains, microbiologists throughout the world deposit microbes that have been isolated and characterized in publicly available archives called **culture collections** (Figure 12.2). These collections, containing freeze-dried, frozen, or otherwise preserved living samples of the microbial cultures, allow scientists from around the world to obtain these organisms at minimal cost. As a result, experimental findings reported in the scientific literature can be confirmed by independent research, and those findings can be extended through additional studies. Note that scientists do not have to always isolate microbial strains directly from the environment. Instead, they can screen strains from culture collections for properties and products of interest. Such an open source model, to which all scientists have access and to which

TABLE 12.1 Examples of microbial products

Microbial product	Examples
Food additives	Amino acids, organic acids, fatty acids, vitamins
Solvents	Acetone, butanol, ethanol
Enzymes	Proteases, amylases, cellulases, lipases
Biofuels	Ethanol, butanol, methane, hydrogen
Agrochemicals	Feed additives, biopesticides
Whole cells	Baker's yeast, crop inoculants, probiotics
Fine chemicals	Antibiotics, chemotherapeutic agents, nucleic acids, proteins, enzymes, biochemicals, optically pure chiral molecules

Figure 12.2. Microbial culture collections Microbiology cultures are archived in international culture collections where they may be obtained for study or use in commercial applications. Depending on the organism, they are usually stored in a freeze-dried or frozen state, and must be revived after shipment to the end user.

they are expected to contribute biological material, is critical for the growth of microbial biotechnology, as it is for all microbial science.

Although it is convenient to obtain microbes that have been previously characterized, in many cases well-suited organisms with the appropriate physiological characteristics for a given biotechnology application may not be available. For example, suppose that a researcher wanted to produce methane at very low temperatures. Initially, he or she could see if any psychrophilic methanogens had been isolated and were available in culture collections. Suppose that no such organisms had been described. The researcher could then search anoxic cold environments for novel organisms that survive at low temperatures and produce methane. Similarly, one might search in a rotting log, or in the gut of a termite or cow to find a microorganism that can produce cellulase, an enzyme that degrades cellulose. To find an organism that produces a new antibiotic, one might search in soils where many organisms, particularly species of *Streptomyces* bacteria, are known to produce antimicrobial compounds that help them compete in these rich ecosystems **(Microbes in Focus 12.1**; see Table 24.1). Termed **bioprospecting**, such searches for novel organisms, biological materials, or biological processes in nature, have fueled innovations in biotechnology **(Perspective 12.1)**.

Using a variety of search strategies, microbiologists can isolate novel microbes from diverse environments and then screen them for specific activities, like the production of methane. Although this process may sound quite simple, the success rate of bioprospecting remains somewhat limited, given that only a small fraction of microbes can be cultivated (see Section 6.3). The uncultivated majority of microbial life is a rich, untapped resource of biological material for biotechnology applications that is now being accessed using metagenomics approaches.

Microbes in Focus 12.1
STREPTOMYCES: A GOLDMINE OF NATURAL PRODUCTS

Habitat: Soil, compost

Description: Gram-positive, obligate aerobes producing a fungal-like branching mycelium with hyphae of 0.5–1 μm in width and spores called "conidia"; member of the family *Actinomycetes*

Key Features: Like fungi, *Streptomyces* have a complex life cycle. Similar to fungi, they have a linear chromosome rather than the circular structure found in most other bacteria. Metabolically versatile, they degrade and metabolize a wide variety of substrates, producing a host of useful natural products including anticancer agents and immunosuppressant drugs used to prevent the rejection of transplanted organs and to treat autoimmune diseases. Most antibiotics used today originate from *Streptomyces*. The genome of *Streptomyces coelicolor* was sequenced in 2002 and, at 8.7 Mbp, is one of the largest bacterial genomes ever decoded.

Courtesy David Capstick and Marie Elliot / McMaster University

CONNECTIONS The discussion of metagenomics in **Section 10.4** considers the application of genome-sequencing technology to determine DNA sequences present in complex microbial communities. By combining DNA sequencing with phenotypic selection and screening of libraries, genes of interest for biotechnology applications are accessible from uncultured microbial communities.

Perspective 12.1
BIOPROSPECTING: WHO OWNS THE MICROBES?

One could imagine a bioprospecting researcher to be the Indiana Jones of microbiology. Looking for enzymes that can function at low temperatures? Then hunt for microbes in Antarctica. Need an enzyme that remains active under high-temperature and high-sulfur conditions? Scale an active volcano in Hawaii and collect microorganisms that live just inches from the molten lava. Just like Indiana Jones scoured the globe searching for valuable antiquities, bioprospectors may scour the globe searching for valuable microbes.

Aficionados of the Indiana Jones movies may remember that Dr. Jones always insisted that the relics he found should be displayed in a museum for everyone to see and not used for any one person's personal gain. This same issue surrounds bioprospecting. Should potentially valuable microbes be made available to everyone, or should they become the property of the person who discovers them?

Bioprospecting can have enormous economic benefits for a company. The discovery of a microorganism that produces a potent anticancer compound, for instance, could increase the revenue of a pharmaceutical company many fold. The question remains: Does the company own that microorganism? Many countries say "No." Since the 1993 United Nations Convention on Biological Diversity statement that nations have sovereignty over their biochemical resources, countries increasingly have implemented benefit-sharing laws. Generally, these laws state that money earned by a private company from biological material obtained within the country must be shared with the government.

Probably the best-known and most successful benefit-sharing agreement exists in Costa Rica. In this country, companies must provide the government with a share of the profits derived from biological materials obtained within the country. However, implementation and enforcement of such agreements can be problematic. Also, what about the academic bioprospector who, much like Indiana Jones, searches for novel microorganisms just because they are interesting? For him or her, the issue of microbial ownership remains murky.

Industrial culture of microbes

In industrial microbiology, **fermentation** refers to any industrial process involving the culture of microorganisms, either aerobic or anaerobic, for the production of desired substances. As we will see in Section 13.3, metabolic or biochemical fermentation refers to specific catabolic reactions that produce ATP without oxygen. For example, in the production of fermented beverages such as wine and beer, yeast produces ethanol only through biochemical fermentation reactions. Industrial use of the term "fermentation" probably arose from such historical use of biochemical fermentations in biotechnology. Many modern industrial "fermentations" are carried out in the presence of oxygen, and biochemical fermentation may not even be occurring. For example, large-scale culture of *Escherichia coli* for recombinant protein production is almost always done in the presence of oxygen. *E. coli* will use cellular respiration rather than fermentation under these conditions. Yet in industry, this large-scale culture is still referred to as fermentation One of the most important challenges in the scale-up from laboratory to industrial culture is the transfer of oxygen and maintenance of adequate mixing at very large volumes.

CONNECTIONS Fermentation in metabolism is defined as the transfer of electrons from a reduced electron carrier, such as NADH, to an organic molecule, such as pyruvate, as shown in **Figure 13.17**. The process of fermentation does not require oxygen, but it is not restricted to anaerobic microorganisms, nor does it require strict anaerobic conditions.

Industrial fermentations take place in large-culture vessels called **bioreactors** or fermenters that are designed to maximize cell density and product yield **(Figure 12.3)**. Bioreactors are specially designed so that environmental conditions, including nutrients, oxygen, pH, and temperature can be controlled precisely. Much of the optimization of production usually involves manipulation of the fermentation conditions.

Courtesy Iogen Corporation

Figure 12.3. Bioreactor This bioreactor at the Iogen Corporation, a biotechnology company located in Ottawa, Canada, has a capacity of 200,000 L.

The most commonly used bioreactors are open systems to which nutrients are continually added. The two basic designs are the fed-batch reactor and the chemostat that was introduced in Section 6.4.

Generally, bioreactors are designed to support maximum production of the desired product. A **fed-batch reactor (Figure 12.4)** supports very high cell densities by providing the culture with a growth-limiting nutrient, such as a carbon source, over time. This process controls the growth rate and can often prevent the production of non-desired side products. In continuous bioreactors, like the **chemostat** shown in Figure 12.4, an equivalent amount of culture is removed as new medium is added. This continuous addition of fresh medium results in a very precisely controlled constant growth rate of the organisms and the maintenance of a physiological steady state. The choice of a bioreactor is very much dependent on the type of microorganism employed and the nature of the desired end product. In practice, the fed-batch reactor is much more dependable and reproducible, so it is used more often than the chemostat in industry.

CONNECTIONS In **Section 6.2**, we looked at many of the critical factors affecting the growth of microorganisms including oxygen availability, nutrient types and concentration, pH, temperature, and osmotic pressure. These variables can be tightly regulated and monitored in a bioreactor.

By controlling the conditions within a bioreactor, scientists can also control the growth of microorganisms within the vessel. Within a closed system, in which no new nutrients are added or cells removed, microorganisms exhibit a characteristic growth curve consisting of a lag phase, an exponential phase, a stationary phase, and a death phase (see Figure 6.19). The metabolic pathways used, and metabolites produced by the cells, can vary significantly depending on the growth phase. As a result, researchers may need to maintain the culture in a

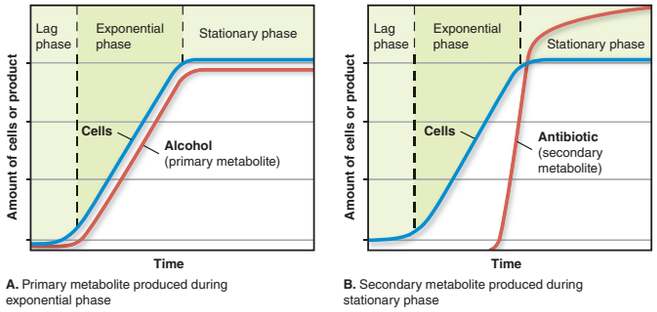
Figure 12.4. Types of bioreactors In the fed-batch reactor (*left side*), concentrated nutrient (feed) is added in a controlled manner until the maximum concentration of cells is reached, and then the biomass is harvested. In the chemostat (*right side*), some amount of biomass is continually removed (effluent) as the same amount of nutrient solution is added (feed). The addition of nutrient solution to the chemostat can continue indefinitely.

particular phase of growth to obtain the optimal production of a desired product. For example, the main source of commercial ethanol is fermentation of sugars by the yeast *Saccharomyces cerevisiae* (see Figure 13.17). To maximize production of ethanol, yeast cells are maintained in exponential phase with low oxygen and with glucose as a carbon and energy source.

For yeast growing under anoxic conditions, ethanol represents a **primary metabolite**, a product of metabolic processes required for anaerobic growth of yeast under anoxic conditions (Figure 12.5). **Secondary metabolites**, such as antibiotics, are not required for growth and are often produced during the stationary phase of the growth curve. Concentrations of primary metabolites may be difficult to increase in a culture. Because they are intrinsically linked to energy-production pathways, high concentrations of primary metabolites frequently interfere with growth by producing toxicity or feedback inhibition. Even production strains of *S. cerevisiae* that have been selected for resistance to higher ethanol levels can tolerate only about 15 percent ethanol before the culture ceases to grow. On the other hand, secondary metabolites can often be overproduced without affecting the growth of the culture.

CONNECTIONS Feedback inhibition **(Section 13.3)** occurs when the product of an enzyme or series of enzyme reactions accumulates in the cell and inhibits the action of an enzyme. Typically, binding of the product causes a conformational change in the enzyme that diminishes its ability to bind or act on the substrate, inhibiting production.



A. Primary metabolite produced during exponential phase

B. Secondary metabolite produced during stationary phase

Figure 12.5. Primary and secondary metabolite production **A.** The production of primary metabolites, such as ethanol in a yeast anaerobic culture, mirrors the increase in biomass. **B.** The production of secondary metabolites, such as antibiotics, is usually induced in stationary phase.

12.1 Fact Check

1. Describe what is meant by red, white, and green biotechnology.
2. How are culture collections used in biotechnology?
3. What is bioprospecting?
4. Explain how bioreactors are used for biotechnology fermentation processes.
5. Distinguish between fed-batch bioreactors and chemostats.
6. Distinguish between a primary and a secondary metabolite.

12.2 Molecular genetic modification

3D ANIMATION

How can molecular biology tools be used to improve microbial strains?

Whether researchers obtain microbes from a culture collection or isolate them directly from the environment, the usefulness of these naturally occurring microbes is often limited. As we noted earlier, the naturally occurring strains may not grow efficiently in the laboratory or may not produce large amounts of a desirable product. How can these inefficiencies be overcome? Production may be improved by altering the genetics of the strain. It may be possible to manipulate the expression of genes for certain enzymes in a pathway, resulting in the enhanced production of desired metabolites. Alternatively, strains might be altered to downregulate competing pathways or pathways that lead to the production of unwanted substances. In some cases, a strain could be altered so that it grows on a lower-cost carbon nutrient. All of these types of genetic alterations in a microbe could lead to the production of more material, more cheaply.

In this section, we will examine several means of improving microbial performance for biotechnology. We will start by investigating two methods of mutating microbial strains, random mutagenesis and site-directed mutagenesis. We will then examine methods for producing recombinant proteins. Finally, we will explore an area that seemed like science fiction only a decade ago, the synthesis of designer organisms.

Mutagenesis

How can we generate beneficial genetic alterations in naturally occurring microbes? We can rely on **random mutagenesis**. As we saw in Section 9.3, the exposure of cells to X-rays, UV light, or DNA-damaging chemicals such as nitrosoguanidine or ethyl methanesulfonate can cause mutations in the DNA of a cell. The resulting mutants can be screened for desired phenotypes, like the increased production of a certain enzyme (Figure 12.6). A major drawback of this approach is that the resulting mutations are undefined. Many mutations will have no effect at all, and others may be detrimental. Additionally, effective screens are often not available for desired phenotypes. Despite these drawbacks, this type of approach is still employed today. The fact that a researcher may not know all of the cellular processes that impact the phenotype they desire to affect actually makes random mutagenesis quite appropriate, as it does not require

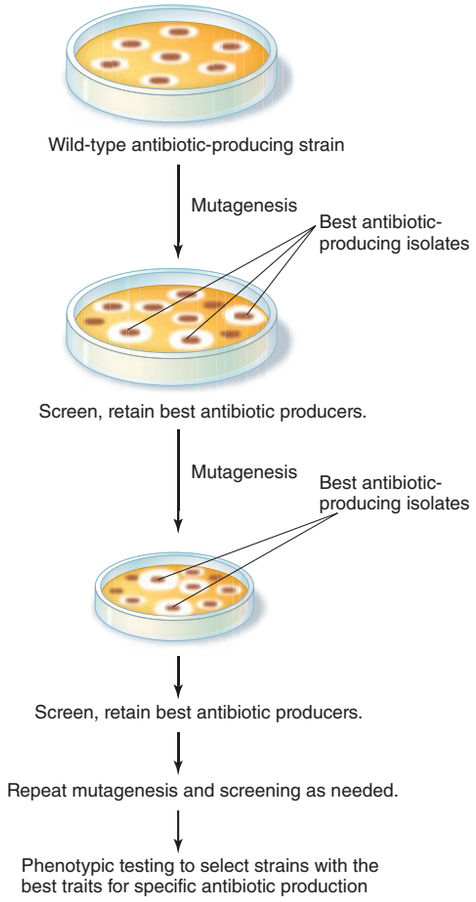


Figure 12.6. Strain improvement by random mutagenesis A random mutagenesis strain-improvement scheme typically involves multiple rounds of mutagenesis combined with screening for superior phenotypic characteristics. The best performers after each round of screening are retained for additional rounds of mutagenesis and screening. These are then subjected to additional phenotypic analysis to identify the strains with the best traits for production of the desired product.

knowing potential targets in advance. Although large numbers of mutants often must be screened, mutagenesis approaches can be very successful in developing more desirable strains.

The history of penicillin production provides a wonderful example of the effectiveness of random mutagenesis. The strain of *Penicillium* isolated by Alexander Fleming, *Penicillium notatum*, produced small amounts of penicillin. Through a type of bioprospecting, researchers identified another naturally occurring strain, *Penicillium chrysogenum*, which produced higher levels of the antibiotic **(Microbes in Focus 12.2)**. This strain was then subjected to X-ray and UV light mutagenesis. Variants that produced even higher amounts of the drug were isolated. Eventually, researchers identified a mutant strain of *P. chrysogenum* that produced much higher amounts of penicillin than Fleming's original isolate of *P. notatum*.

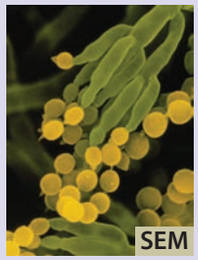
Although random mutagenesis can be used to improve microbial strains, another technique allows researchers to alter microbes in a much more rational way. **Site-directed mutagenesis (Toolbox 12.1)** allows researchers to make specific mutations at specific known sites within a DNA molecule. Because site-directed mutagenesis introduces such precise genetic changes, researchers can change a specific amino acid within a protein.

In recent years, methods have been developed to precisely modify genomes directly, a process called **genome editing**. These methods were first developed using zinc-finger nucleases (ZFN) and transcription activator-like effector nucleases (TALENs). ZFNs are well known motifs that are involved in recognizing and binding specific DNA sequences. TALENS are DNA-binding proteins that are found in plant pathogenic *Xanthomonas* bacteria. Scientists determined that the sequence specificity of the DNA-binding domains could be modified to recognize almost any desired sequence by altering the amino acid sequence of the domain. Pairing up these custom DNA-binding domains with nuclease domains resulted in the ability to introduce DNA cleavage at exact locations in the genome within a living cell. Despite the success of these methods, the design of the specificity of the DNA-binding domains is often tedious. Very recently, another genome-editing tool has emerged that does not rely on DNA-binding protein motifs. This tool is based on a naturally occurring system that has evolved to protect bacterial cells from infecting bacteriophage. This system includes both clustered regularly interspaced short palindromic repeats (CRISPR) and a CRISPR-associated (Cas) enzyme, together abbreviated as "CRISPR/Cas." The CRISPR/Cas system is able to recognize DNA sequences by producing RNA, called "guide RNA," which is able to bind single DNA strands a with complementary sequence. The Cas protein is then guided to that location, aided by the guide RNA, where it is then able to cleave the DNA. Because the sequence of the guide RNA can be easily specified, the precise cleavage site can be determined. In a very short time, CRISPR/Cas has found widespread use for genome editing in many different organisms, from bacteria to plants to animals.

Microbes in Focus 12.2
PENICILLIUM CHRYSOGENUM: THE MOLD THAT STARTED THE ANTIBIOTIC REVOLUTION

Habitat: Wide distribution in nature, preferring moist conditions. Commonly found in soil, and in foods as a contaminant. Also found in large industrial bioreactors

Description: Filamentous fungus forming long, narrow hyphae up to 5-μm wide. Bears conidia in specialized hyphae called "conidiophores." Hyphae provide a fuzzy texture, usually white, blue, or green in color. The 32-Mbp genome was sequenced in 2008.



Key Features: This fungus is best known for its production of the antibiotic penicillin, the first mass-produced antibiotic. It also produces several other antimicrobial compounds as secondary metabolites. It is generally not pathogenic to humans, although the conidia sometimes act as allergens.

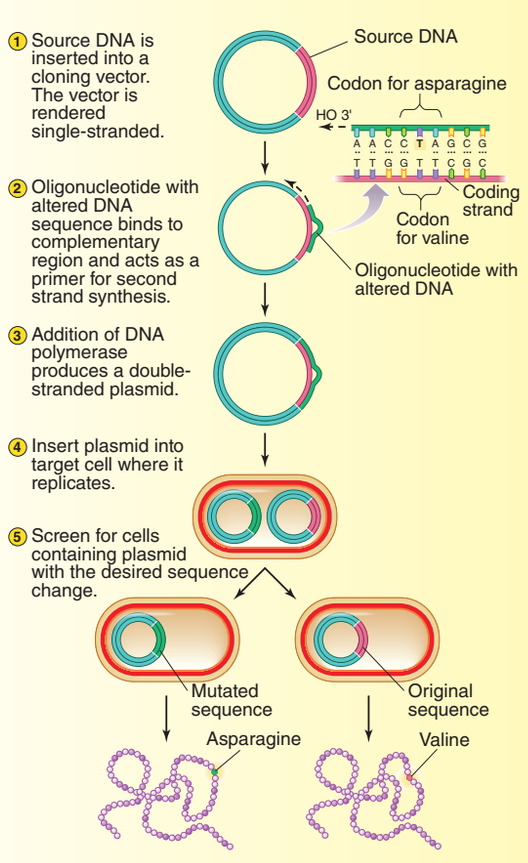
Toolbox 12.1
SITE-DIRECTED MUTAGENESIS

Pioneered by the Canadian biochemist Michael Smith in the late 1970s, site-directed mutagenesis has become a powerful molecular biology tool. In recognition of the significance of this development, Smith shared the 1993 Nobel Prize for Chemistry with Kary Mullis, the inventor of PCR (see Toolbox 1.1). Similar to PCR, site-directed mutagenesis involves the use of a short oligonucleotide primer. In this case, the primer used for the initiation of replication contains an altered, or mutated, DNA sequence. After extension with DNA polymerase, the resulting double-stranded molecule contains this mutation. This fragment of double-stranded DNA can then be introduced into *Escherichia coli* by transformation, where it replicates. This series of steps results in the stable incorporation of the desired genetic change. Designed oligonucleotides can also be used in PCR to introduce the desired alteration in a DNA sequence, a technique referred to as PCR site-directed mutagenesis **(Figure B12.1)**.

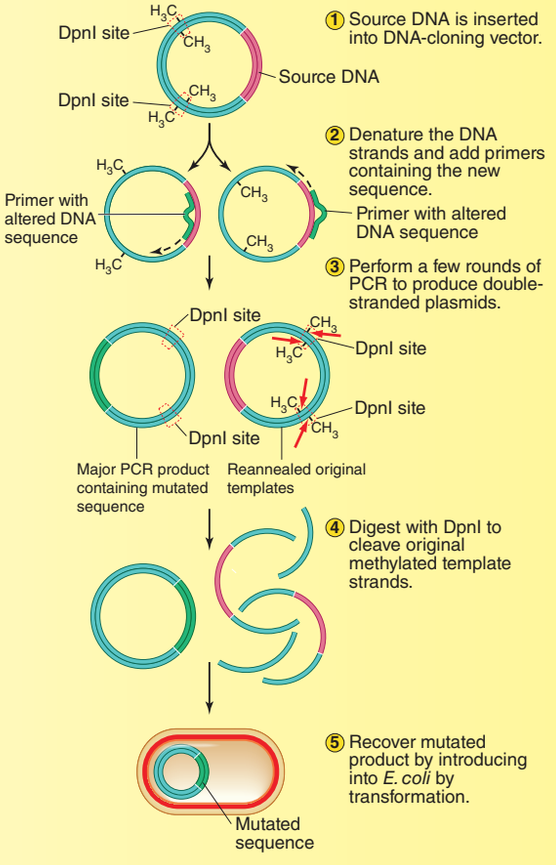
Once the desired sequence changes in genes of interest have been made, the altered genes can be introduced into the production organism. Popular hosts include the bacteria *E. coli* and *Bacillus subtilis*, the yeasts *Saccharomyces cerevisiae* and *Pichia pastoris*, Chinese hamster ovary cells, and insect cells. In some cases, the genes can simply be introduced on a plasmid expression vector that can replicate in the host organism. In other cases, it is desirable to replace the wild-type copy of the gene with the altered gene. This gene replacement requires recombination events between the plasmid vector that contains the altered gene and the corresponding genome region. A number of systems have also been developed based on virus integrase systems that allow site-specific integration within the genome of the host cell.

Test Your Understanding

What is the function of the oligonucleotide primer used in site-directed mutagenesis?



A. Oligonucleotide site-directed mutagenesis



B. PCR site-directed mutagenesis

Figure B12.1. Process Diagram: Site-directed mutagenesis
A. The original oligonucleotide-mediated site-directed mutagenesis procedure required the cloning of the DNA to be mutated into a vector that produces single-stranded DNA molecules. These vectors are modified from bacteriophage, such as M13, that have single-stranded genomes. A complementary oligonucleotide containing the desired sequence change is allowed to anneal, and then DNA synthesis is carried out by DNA polymerase. Once the complementary strand is completed, double-stranded plasmids carrying the desired mutation can be recovered after transformation of *E. coli*. **B.** In PCR site-directed mutagenesis, researchers design complementary primers with the desired mutation and conduct PCR with these primers. The product is subjected to digestion with the DpnI restriction enzyme, which cleaves its recognition site (GATC) only when it is methylated during propagation within an *E. coli* cell. Thus, it will not cleave the DNA that was synthesized outside of the cell in the PCR, only the original template DNA that has been replicated in the *E. coli* cell. This will enrich for the desired mutated product. The products are introduced into a host cell by transformation, and the presence of the correct mutation can easily be confirmed by DNA sequence analysis.

CONNECTIONS Like most molecular biology tools, genome-editing tools are based on naturally occurring biological processes. For example, we will see in **Section 18.2** and **Perspective 18.1** how the CRISPR/Cas genome-editing tool was developed from a bacteriophage defense system.

Let's now ask a more practical question. What types of mutations would researchers want to make? Often, scientists want to improve the activity of an enzyme. Improved functionality may arise from the addition of cysteine amino acids in key positions within the polypeptide to facilitate disulfide bond formation in the final product. Disulfide bonds stabilize proteins, making them less susceptible to denaturing conditions of extreme pH, as might be experienced in drugs taken orally, or high heat, as would be experienced by enzymes produced for washing detergents (Figure 12.7). For example, site-directed mutagenesis has been used to add three disulfide bonds in T4 lysozyme, a bacterial cell wall-degrading enzyme originally derived from phage but now produced in recombinant *Escherichia coli* cells. This enzyme, an effective antimicrobial agent, is used widely as a food preservative. It is also used in infant formula and as sprays on meats and vegetables destined for the grocery store. The increased stability of engineered T4 lysozyme allows it to maintain its enzymatic function longer under various conditions.

Unsurprisingly, the successful alteration of a protein via site-directed mutagenesis usually requires a fairly detailed knowledge of the three-dimensional structure of the protein. Knowing the structure allows researchers to target codons for amino acids in binding or catalytic sites. Additionally, the amino acids targeted for substitution must not be critical for the normal functioning of the protein.

In many instances, insufficient structural information about a protein of interest limits use of site-directed mutagenesis. In these cases, combined methods have been developed to carry out random mutagenesis on a targeted gene. This approach, termed **directed enzyme evolution**, applies rounds of random mutation and selection to achieve stepwise desired changes in a gene of interest (Figure 12.8A). This approach has been used to improve strains by generating more active enzymes and imparting new or broadened ranges of enzyme activities for particular substrates.

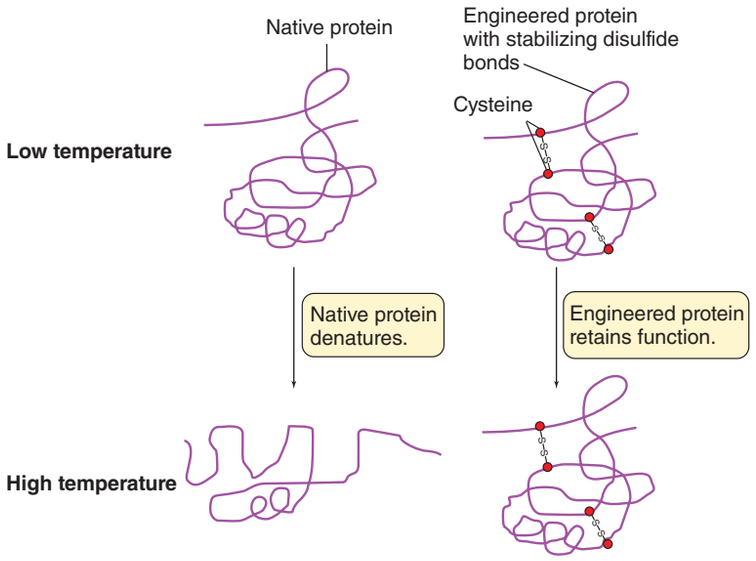


Figure 12.7. Increasing protein stability Site-directed mutagenesis can be used to add disulfide bonds to proteins to increase stability. When the structure of a protein is known, codons in the gene can be purposefully changed to new codons that impart a beneficial characteristic in the protein. As shown in the two-dimensional protein here, changing two sets of amino acids that are near each other in the folded peptide chain to cysteine amino acids allows internal disulfide bonds to form.

As an example, let's consider a dehydrogenase enzyme that catalyzes the oxidation of a substrate such as glycerol in the following reaction:

$$\text{Glycerol} + \text{NAD}^+ \xrightarrow[\text{dehydrogenase}]{\text{glycerol}} \text{dihydroxyacetone} + \text{NADH} + \text{H}^+$$

The product of this reaction, dihydroxyacetone, is the main ingredient in sunless tanning products. From a biotechnology perspective, obtaining a variant of glycerol dehydrogenase that catalyzes this reaction more effectively could be quite profitable. A form of directed enzyme evolution could be used to produce such a variant.

Initially, a collection of glycerol dehydrogenase variants can be constructed using a technique called **error-prone PCR**. In this process, the native glycerol dehydrogenase gene is PCR amplified under conditions that result in a very high error rate. The PCR products, in other words, frequently contain mutations. These amplified fragments are then cloned into a plasmid vector, and the plasmids are introduced into a host strain that does not produce the glycerol dehydrogenase enzyme. The resulting colonies, each containing a glycerol dehydrogenase gene variant, are then screened for enhanced glycerol dehydrogenase activity. Researchers select the best-performing clones and repeat the process. In many ways, this type of process resembles the selective breeding used in animals and plants; only clones producing improved enzymes are allowed to reproduce. Like natural evolution, the improvements typically occur in small steps, making it a time-consuming process.

To improve the efficiency of directed enzyme evolution, **DNA shuffling** can be used. In this approach, groups of mutants generated from directed enzyme evolution, or groups of related genes from different organisms, serve as the starting material (Figure 12.8B). The investigators randomly fragment these gene variants, usually using the enzyme DNase I, which cleaves DNA. The fragments are mixed together, denatured, and reassembled into full-length genes by PCR. The result is chimeric genes, products of recombination between the input fragments. This process provides a way to combine multiple beneficial variations into single clones and can result in dramatically improved phenotypes.

In microbial biotechnology, production is ultimately limited by the genetic and physiological characteristics of the microbial strains that are used. The process can often be improved by making changes to the metabolic characteristics of the strain. This can be accomplished by introducing genes or altering their expression. For example, production costs might be lowered if genes are introduced that allow organisms to use a cheap and readily available source of carbon. Knowledge of metabolic pathways may suggest ways to manipulate

the expression of genes for enzymes in the pathway, enhancing production of the desired metabolites. Alternative strategies might repress competing pathways or pathways that lead to the production of unwanted substances. For example, high cell density of *E. coli* is often hard to achieve during fermentation because of the accumulation of waste products, in particular acetate, which inhibits cell growth and protein production. One potential solution to this problem is to divert the precursor pyruvate from the acetate production pathway. When the gene is added for acetolactate synthase, pyruvate is instead converted to acetolactate, which is then converted to the less inhibitory end product, acetoin **(Figure 12.9)**.

Biosynthetic pathways can also be manipulated. For instance, the production of the penicillin-like antibiotic cephalosporin increases significantly when additional copies of *cefEF* and *cefG*, genes involved in the biosynthesis of cephalosporin, are inserted into the fungus *Acremonium chrysogenum*. With increased copies of these genes in its genome, the recombinant *A. chrysogenum* strain produced more cephalosporin than the non-modified strain. Although this type of approach can be very successful, it requires a certain level of specialization in molecular biology and knowledge of the genetics and physiology of the organism being used.

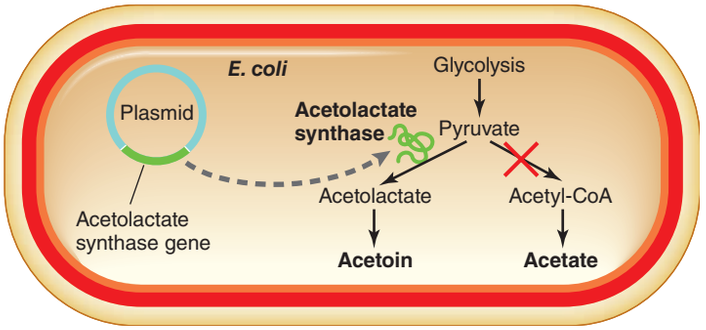

Figure 12.9. Manipulating a pathway Modifying the metabolic pathway reduces production of the inhibitory waste product acetate. Introduction of a plasmid encoding the gene for acetolactate synthase into *E. coli* results in conversion of pyruvate into acetolactate, which is then converted into acetoin. Acetoin is less inhibitory to growth than acetate, allowing cells to reach higher densities in culture.

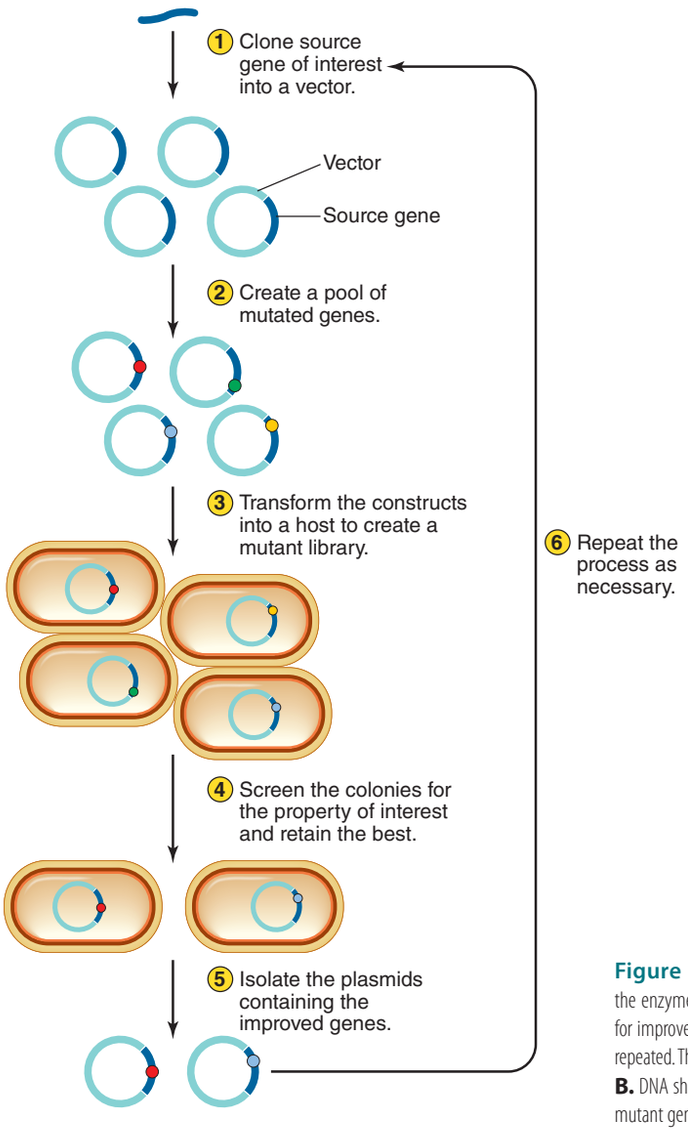
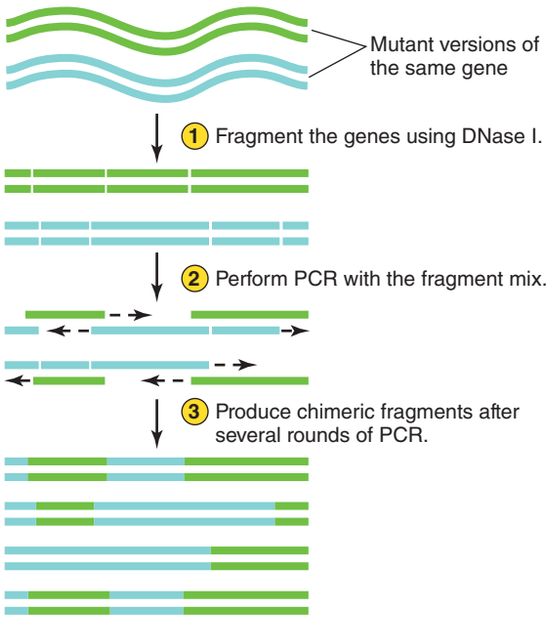
CONNECTIONS Recombinant DNA techniques like restriction enzyme digests, PCR, and ligations have become established tools for molecular biology and biotechnology. These methods are discussed in **Section 9.3**.



A. Directed evolution



B. DNA shuffling

Figure 12.8. Process Diagram: Directed enzyme evolution **A.** Starting with a gene encoding the enzyme of interest, mutagenesis is carried out to generate a library of variant genes. These libraries can then be screened for improved gene function, with the best-performing genes being subjected to mutagenesis again, and the screening process repeated. The process is similar to that described in Figure 12.6, but here it is limited to a single gene rather than the entire genome. **B.** DNA shuffling allows the *in vitro* recombination of multiple mutants of the same gene, dramatically extending the range of mutant genes that can be recovered. In this process, a collection of mutant genes is cleaved randomly by DNase I. The remaining fragments are mixed together and subjected to PCR amplification, which results in recombination of the mutated gene segments.

Production of recombinant proteins

As we have seen, various mutagenesis techniques can be used to alter DNA within a cell. Other molecular biology tools can be used to introduce foreign DNA into a cell (see Section 9.4). Although vectors used for this purpose allow for the amplification of cloned DNA in cells, they may not be designed to express foreign genes. **Expression vectors** are specifically designed to produce recombinant proteins. In *E. coli*, expression vectors can produce recombinant protein to levels of 20 percent or more of the total cell protein. In contrast, even the most abundant native protein in *E. coli* constitutes only about two percent of the total cell protein. These advantages make expression vectors a first choice for commercial production of recombinant proteins.

First designed for use in *E. coli*, expression vectors now exist for a number of different cell types, including yeast, insect, and mammalian cells. These expression vectors are used for production of therapeutic human proteins such as insulin, human growth hormone, antiviral interferons, and interleukin-2. In humans, specialized cells typically produce such proteins, and usually under specific conditions and in very small quantities. Their large-scale, commercial production could not occur without the use of expression vectors.

Expression of a eukaryal protein in a bacterial host cell like *E. coli* will occur only if the foreign gene contains the correct bacterial elements for transcription and translation. The eukaryal gene, in other words, must be reformatted to look like a bacterial gene. To better understand this issue, let's first think about transcription. RNA polymerase binds to a promoter to initiate transcription. However, eukaryal promoters differ significantly from bacterial promoters (see Section 7.3). The RNA polymerase of *E. coli* will not recognize a eukaryal promoter. Instead, the expression vector must contain an *E. coli* promoter **(Figure 12.10)**. Transcription termination also differs between bacteria and eukarya. The *E. coli* expression vectors must also contain a bacterial transcription terminator (see Figure 7.20). If an expression vector contains a bacterial promoter and transcription terminator, then the cloned sequence between these elements can be transcribed to produce an mRNA transcript. Moreover, it should be possible to regulate the promoter so that production of the protein can be controlled. Transcription regulation can be accomplished by adding an appropriate operator sequence to the vector that will respond to inducer or repressor proteins.

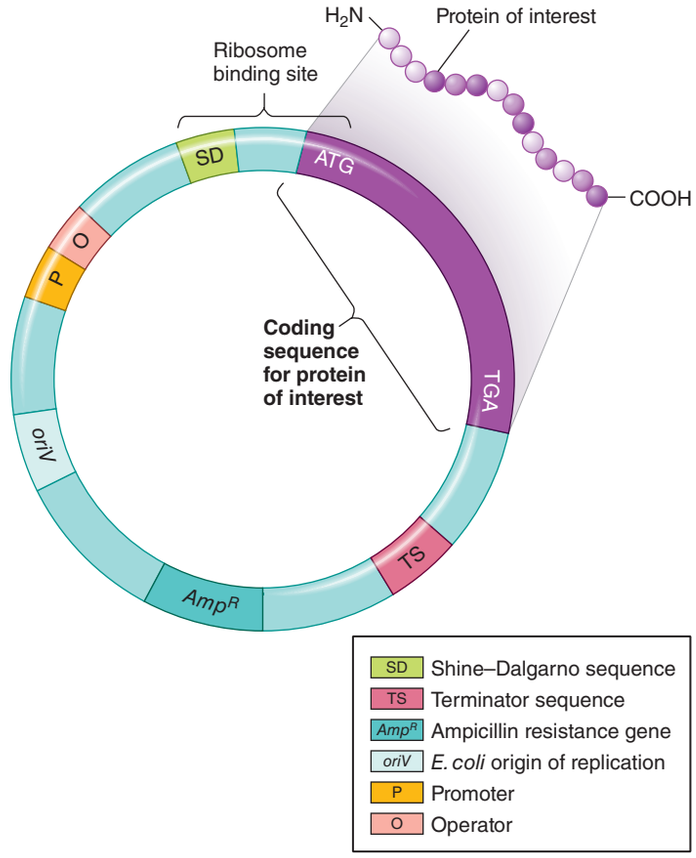


Figure 12.10. Expression vector Expression vectors have customized promoters to drive a high level of transcription. An operator, such as O^{lac} of the *lac* operon, regulates the level of transcription. Expression vectors also contain an optimized ribosome binding site (RBS) including a Shine–Dalgarno (SD) sequence and a start codon ATG. The coding sequence of the protein of interest is inserted 6–10 bases downstream of the SD to maximize initiation of translation. The coding sequence for the protein follows, including the start codon ATG and stop codon TAA, TGA, or TAG. Transcriptional terminator sequences end transcription. Expression plasmids also contain a selectable marker gene, shown here as an ampicillin resistance gene, and an origin of replication for the expression host, shown here as *oriV*. Most cloned protein-coding sequences can be transcribed and translated, including those from eukaryal genes. Note that this figure is not to scale.

CONNECTIONS Understanding how expression vectors work requires a solid understanding of the gene structure of bacteria and eukarya. In **Sections 7.3** and **7.4**, we examined the functions and placement of various transcriptional and translational elements. In **Section 11.2**, we explored the regulation of these processes.

For expression of a eukaryal gene in a bacterial host, the gene itself must also be reformatted. Most eukaryal genes contain introns (see Figure 7.21). Eukaryal cells remove these non-coding regions during RNA processing in the cell nucleus before translation of the mRNA. As a result, the inserted DNA must be free from introns for correct expression of a eukaryal gene in bacteria. How can researchers remove these introns? The intron-free sequence could be artificially synthesized. Alternatively, an mRNA transcript from the eukaryal cell can be used as a template for the reverse transcriptase enzyme (see Sections 8.3 and 10.2) to produce a DNA strand that lacks the introns. This complementary DNA (cDNA) can then be inserted into the expression vector.

CONNECTIONS Recall from **Section 5.4** that the DNA product of reverse transcriptase and single-stranded RNA is called complementary DNA (cDNA). cDNA is double-stranded and can be cloned into vectors.

Let's now consider translation. The ribosomes of *E. coli* recognize the Shine–Dalgarno sequence on the mRNA and initiate translation at the downstream AUG start codon. Will eukaryal genes have this element? No. The Shine–Dalgarno sequence must be contained within the vector, or added to the cloned DNA sequence at the appropriate place. A eukaryal

coding sequence, including the stop codon, can then be cloned so that the translation start codon, ATG, exists approximately 6–10 bases downstream of the Shine–Dalgarno sequence. With the addition of these various elements, the *E. coli* host will recognize the foreign DNA and make the protein.

As we noted in Section 7.3, the sequences of bacterial gene promoter elements vary, altering the affinity of the sigma factor for the promoter. Promoter sequences that interact strongly with sigma factors undergo high levels of transcription. Expression vectors typically contain promoter sequences designed to drive a high level of transcription of the cloned sequence. Bacterial genes also show variation in their ribosome binding sites. These variations affect the level of translation. Bacterial expression vectors therefore contain ribosome binding sites with preferred Shine–Dalgarno sequences and a perfectly placed ATG codon 6–10 bases downstream to maximize initiation of translation.

To facilitate cloning from a variety of sources and make a truly universal expression vector, a multiple cloning site containing an array of several unique restriction sites (see Section 9.3), is often placed directly after the ATG start codon in the vector. As long as the coding sequence of interest is cloned in the correct reading frame for translation, then *E. coli* will produce the recombinant protein. A universal expression vector can often express *any* given coding sequence—eukaryal, bacterial, or archaeal.

Although the expression of recombinant proteins may seem fairly simple, several caveats exist. Proteins often undergo glycosylation in eukarya, which is the addition of complex sugar residues to polypeptides (see Section 7.4). Bacterial hosts often are not capable of carrying out the specific type of glycosylation that many eukaryal proteins require for correct folding and function. For example, many mammalian proteins are glycosylated with sialic acid, whereas bacteria and fungi tend to glycosylate proteins with mannose units **(Figure 12.11)**. If a eukaryal protein requires specific glycosylations to function correctly, then a eukaryal expression system, rather than a bacterial expression system, may be required.

Disulfide bond formation may also be problematic in *E. coli*. Without correctly formed disulfide bonds, proteins may not fold correctly and, as a result, may be inactive (see Section 7.4). Again, if extensive disulfide bond formation is necessary, then a eukaryal host may be needed. Recombinant protein production in insect cells uses modified insect baculoviruses as vectors. Similarly, viruses that infect mammals can be modified for use as vectors to allow production of recombinant proteins in cell lines, such as Chinese hamster ovary cells, and cultured human cells, such as HeLa cells. These host systems are more expensive than bacterial systems and often do not produce as much recombinant protein; a trade-off exists between function and amount.

Vectors designed for expression in eukaryal organisms follow the same general principles as vectors used in bacterial species. They must contain a eukaryal promoter and a transcription terminator that also signals the addition of a polyA tail to the transcript. As we noted earlier, eukaryal mRNAs do not contain a Shine–Dalgarno binding site. Instead, eukaryal ribosomes bind the 5′ cap structure of the mRNA and scan

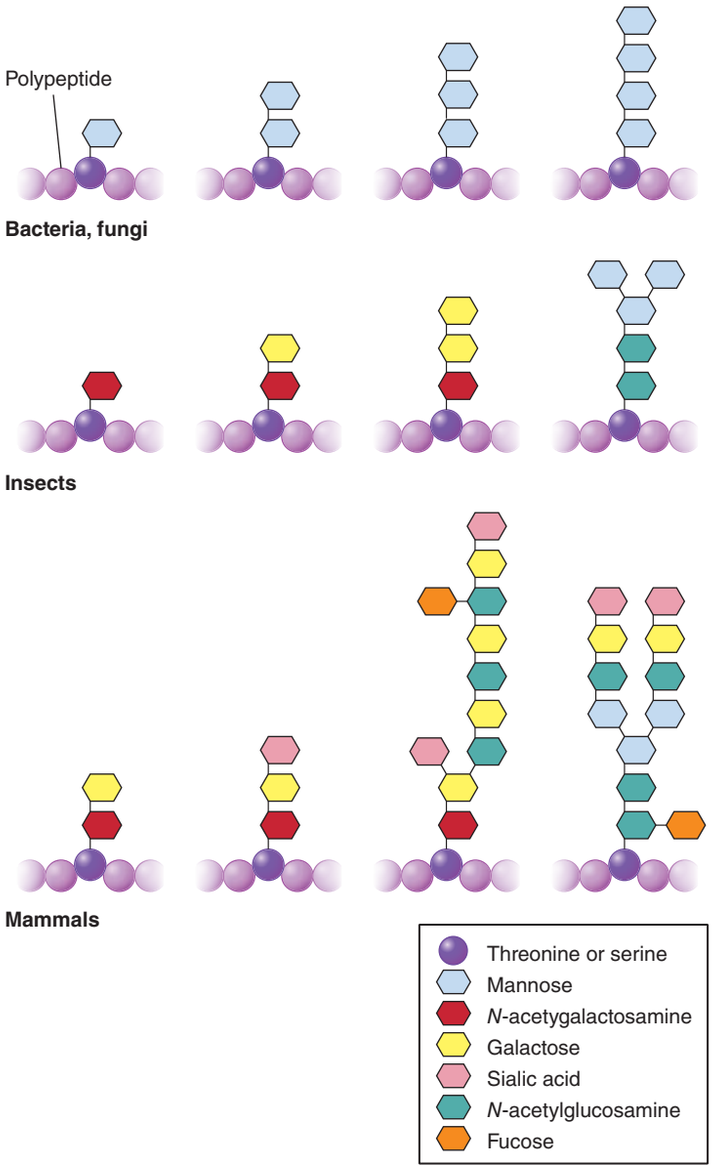

Figure 12.11 Glycosylation These post-translational modifications vary between groups of organisms. The addition of specific sugars to particular amino acids is often required for proper protein folding and function. Shown here are common glycosylations added to threonine or serine amino acids in proteins from bacteria and fungi, insects, and mammals. The choice of host expression system will depend on the requirement for glycosylation.

the mRNA until they reach an AUG codon, where translation begins. As a result, a Shine–Dalgarno sequence is not needed in a eukaryal expression vector.

Although expression vectors can be used to produce individual proteins, expression vectors can also be used to produce **fusion proteins**, which are proteins that contain domains of two or more proteins **(Figure 12.12)**. Sometimes called **tagged proteins**, fusion proteins often contain a protein of interest fused to a portion of another protein that adds a beneficial characteristic to the recombinant protein. For example, an **affinity tag**, a peptide that facilitates purification, can be added to a protein of interest to simplify the selective enrichment of the recombinant protein from the other proteins produced by the cell **(Toolbox 12.2)**. Many affinity tags have been

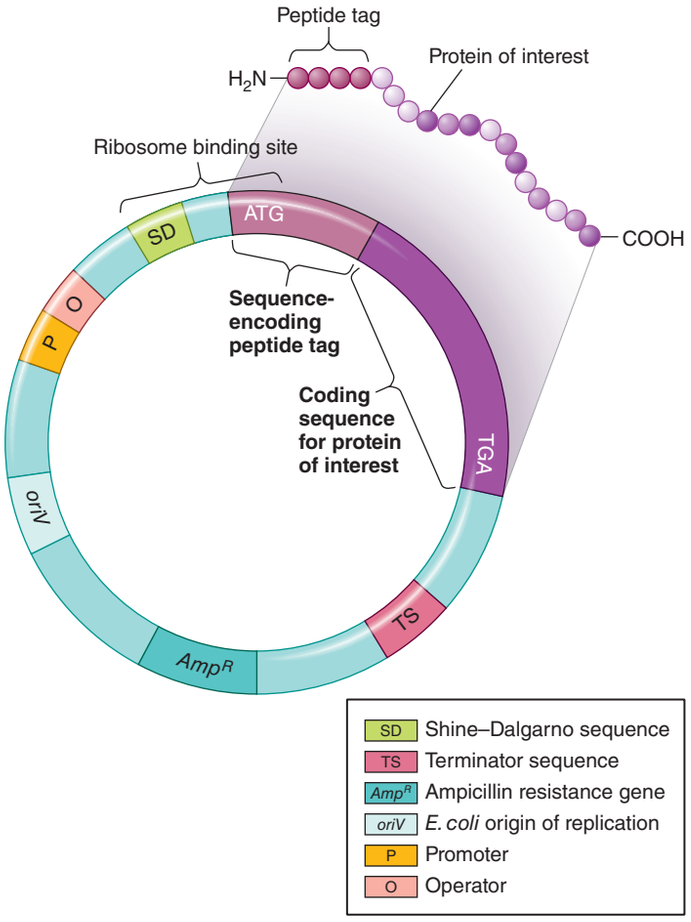

Figure 12.12. Expression of tagged proteins Expression vectors designed for producing fusion or tagged proteins have a built-in coding sequence for a peptide tag that is fused to the coding sequence of the cloned protein of interest. Following translation, the peptide tag will be part of the recombinant protein. Tags may be used for purification of the target protein (see Toolbox 12.2). Note that this figure is not to scale.

developed (Table 12.2). A large number of expression vectors and purification systems employing these affinity tags are available commercially.

CONNECTIONS Not all fusion proteins are designed to aid in purification. As we saw in **Section 3.1**, GFP fusion proteins are often used to monitor the location of a protein within a living cell.

TABLE 12.2 Common affinity tags used to purify fusion proteins

Affinity tag	Receptor used for purification
Protein A	Antibody
Histidine (His) amino acids	Ni^{2+}
Maltose-binding protein (MBP)	Maltose
Glutathion S-transferase (GST)	Glutathion
Strep-tag	Streptavidin

Designer organisms

Although traditional molecular biology techniques involve modifying existing organisms, **synthetic biology** involves constructing novel biological systems from constituent parts. In other words, it is the design and building of biological operating systems with defined specifications to carry out desired tasks. In this section, we will take a brief look at this exciting new field and see how it may affect the future of biotechnology. As we have seen in other sections, PCR and site-directed mutagenesis techniques require the ability to design and produce single-stranded DNA oligonucleotides of specific sequence. When DNA synthesis technology was first developed, university departments often ran their own oligonucleotide synthesizers, shared by several research groups. As DNA synthesis technology has matured, most DNA synthesis is now done commercially. Oligonucleotides can be ordered online. The companies synthesize the oligonucleotides almost immediately, and often ship them by courier within a day. Some companies now specialize in the production of longer, double-stranded (ds) DNA molecules. The dsDNA of a typical 1-kb gene can be synthesized for less than $250. Even larger DNA molecules in the size range of 10 kb can also be constructed, and by connecting these larger molecules, the complete syntheses of first viral and then bacterial genomes have been achieved.

We have entered an age in which novel genomes with desired specifications can be designed and then synthesized. It may become possible to do computer-aided design at the genome level. Once the genome for an organism with the desired specifications is designed, then the genomic DNA could be synthesized. The tricky part is to make the synthetic DNA functional. It must undergo replication, transcription, and translation. For viruses and plasmids this is not difficult; the synthesized DNA can be inserted into a host cell to replicate. Tools based on phage integrase enzymes (see Section 8.3) and their DNA recognition sequences are available for precise and efficient integration of DNA into bacterial host chromosomes, and these could be very useful for the construction of organisms with novel properties. However, to create a truly synthetic organism, the entire microbial genome would need to be synthesized, introduced into a cell, replicate, and replace the preexisting host DNA (Figure 12.13). The resulting cell would be a true synthetic organism, designed for a specific purpose. Today, this approach to creating a designer organism appears to be feasible (Mini-Paper). Scientists have even created a genetically recoded *E. coli* strain in which the stop codon, UAG, now codes for phosphoserine, a novel amino acid not found in nature. In another experiment scientists replaced an A-T base pair with a synthetic nucleotide pair using a plasmid in *E. coli*. When the synthetic nucleotides were added to the growth media, *E. coli* successfully maintained the novel nucleotide incorporation through multiple generations. This developing field, called "xenobiology," focuses on the development of novel biological systems through expansion of the genetic code and incorporation of novel amino acids into proteins. This emerging subfield of synthetic biology has the potential to enhance protein engineering and pathogen resistance in microorganisms used in industry.

In considering the design of microbes for specific functions, such as the synthesis of a valuable secondary metabolite

Toolbox 12.2
FUSION PROTEIN PURIFICATION

Expression vectors can produce large amounts of a desired protein for research and commercial purposes. Following expression of the recombinant protein, the task of separating it from all the other proteins in the cell begins. With tagged proteins, an efficient method for purification involves affinity chromatography. In this process, researchers employ receptors, like antibodies or metal ions, which specifically bind the tag fused to the protein of interest. Using chemical techniques, these receptors are attached to small beads, which are then added to a column. Cells expressing the tagged proteins of interest are lysed, and the cellular lysate is applied to the column. Proteins containing the tag will bind to the receptors. Unwanted proteins will not bind and can be washed through the column **(Figure B12.2)**. With this relatively simple approach, recombinant proteins can often be purified 100-fold, with greater than 90 percent recovery **(Figure B12.3)**.

Following purification, the tag must often be removed from therapeutic recombinant proteins before they receive approval by regulatory agencies for use. This step provides a safeguard against unforeseen reactions the tag may cause in the body. To accomplish this tag removal, vectors can be designed to code for a short amino acid sequence between the tag and protein of interest that is recognized by specific proteases that cleave this sequence following purification. Thus, the tag can be removed from the final product.

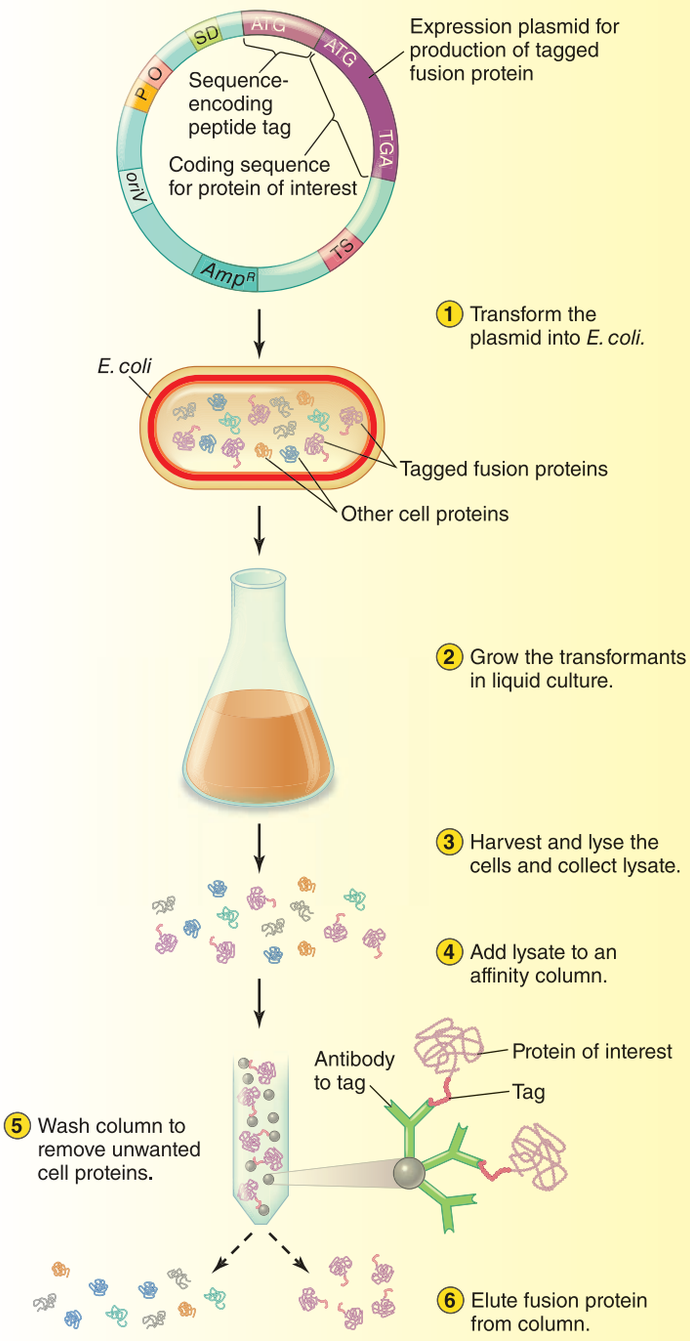

Figure B12.2. Process Diagram: Separation of tagged fusion proteins using affinity chromatography Cells containing the recombinant fusion protein are lysed, and the resulting mixture of proteins is passed through a column containing an antibody to the tag. Tagged proteins will remain bound in the column while other proteins pass through.

Figure B12.3. Polyacrylamide gel electrophoresis shows the purified protein. The successful purification of a his-tagged protein can be visualized by SDS-PAGE, followed by staining with Coomassie Brilliant Blue dye. Lane 1, crude extract of uninduced culture that doesn't contain the expression plasmid; lane 2, crude extract of culture that contains the expression plasmid; lane 3, crude extract of induced culture containing the expression plasmid; lane 4, purified protein following affinity chromatography. Note that the purified protein in lane 4 is present as a single band, whereas the original cell lysate in lane 3, from which the his-tagged protein was purified, contains multiple bands representing various *E. coli* proteins.

Test Your Understanding

How might a protease remove a tag from a therapeutic protein before it is used in humans?

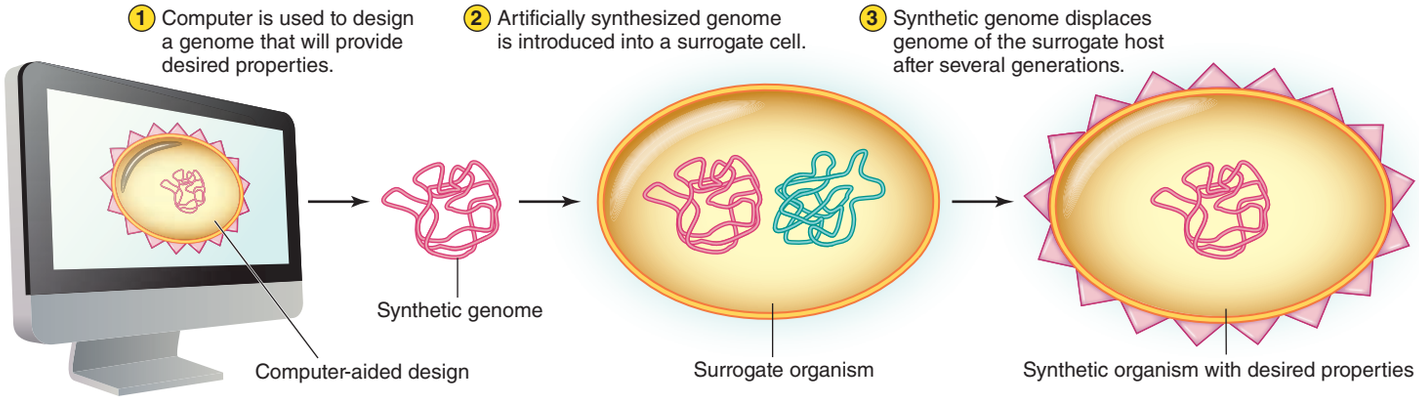

Figure 12.13. Process Diagram: Design and construction of a synthetic organism The synthesis of complete microbial genomes is technically possible, and has been achieved, but the challenge is to reliably generate viable organisms after introduction of the synthesized genome into the surrogate host. Once these problems have been solved, the design and production of synthetic microbes will likely find a multitude of applications in biotechnology.

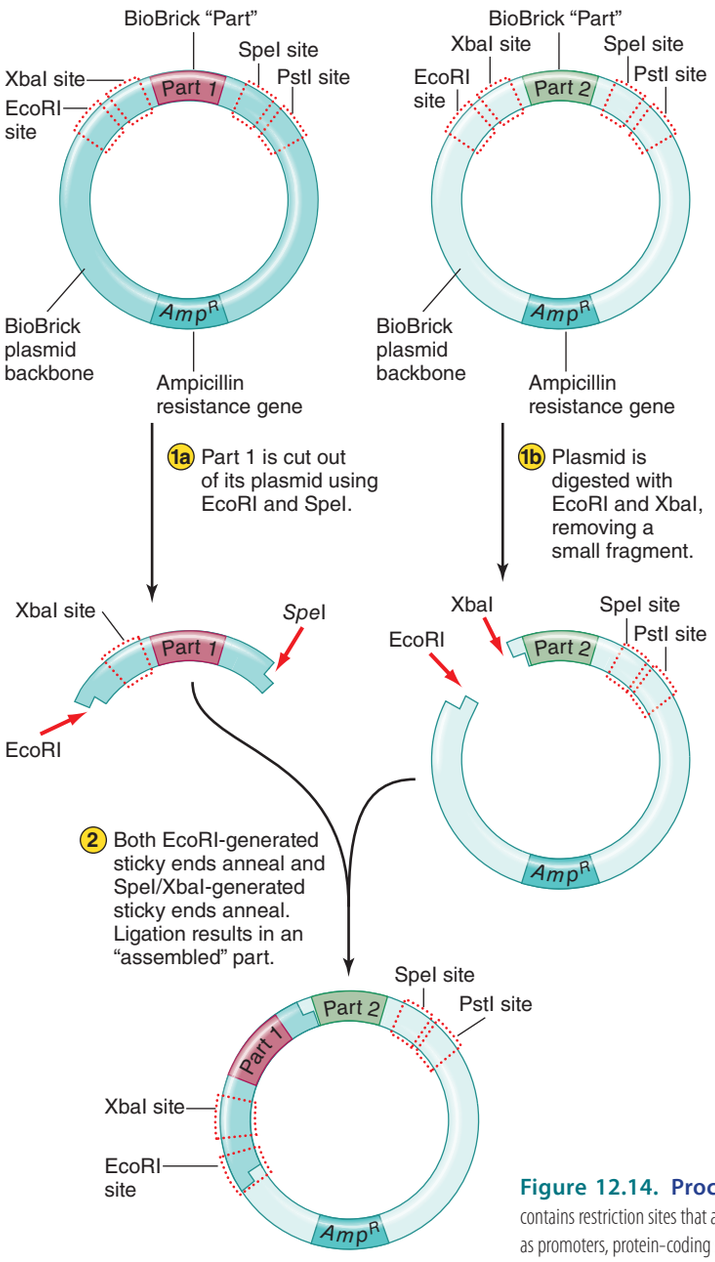


with pharmaceutical properties, the production of an enzyme with a desired catalytic activity, or the degradation of an environmental contaminant, genetic elements must be joined in different combinations and under appropriate regulation. We can consider these genetic elements, whether they are enzyme-encoding genes, regulatory DNA sequences, or genes encoding regulatory proteins, as biological parts. The goal is to use these parts in a reproducible manner so that they can be combined using computer-aided design software, and the corresponding synthesized DNA will have predictable behavior once it is introduced into a cell. Proponents of this vision of synthetic biology are actively working on developing the standards in an open source environment where they share experimental protocols and resources, and provide tools for online collaboration.

The concept of biological parts has its roots in engineering disciplines, where standardized parts may not necessarily be identical, but do adhere to certain specifications. Using these parts, engineers can design objects that will perform predictably without necessarily understanding the details of how each of the individual parts functions. Biology, consisting of collections of natural entities shaped by evolutionary processes, does not adhere to any such standards. As a result, standard molecular genetics research involving the manipulation of genes with tools such as restriction enzymes and PCR can be a very tedious process that often proceeds through trial and error. It is very difficult, if not impossible, to design a biological entity, carry out the construction based on that design, and have the resulting genetic construct behave as initially predicted.

To address this biological reality, researchers have created the Registry of Standard Biological Parts. It contains descriptions of genetic parts such as promoters and gene regulatory elements, ribosome binding sites and protein open-reading frames, and devices that are combinations of parts for protein production, reporter genes, and cell signaling. Each part has been inserted into a vector and is flanked by EcoRI and XbaI restriction sites on one side, and SpeI and PstI restriction sites on the other side (Figure 12.14), in an arrangement

Figure 12.14. Process Diagram: Standard assembly using BioBricks The BioBrick plasmid backbone contains restriction sites that allow removal or insertion of the part from the plasmid backbone. Parts available for assembly include such things as promoters, protein-coding sequences, ribosome binding sites, and transcription terminators.

D. G.Gibson et al. 2010. Creation of a bacterial cell controlled by a chemically synthesized genome. Science 329:52–56.

Context

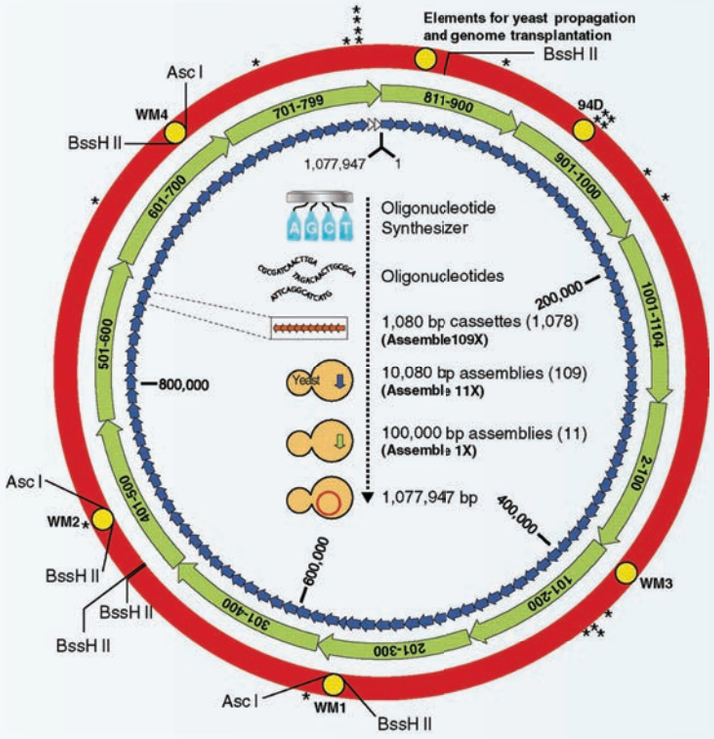
Advances in DNA sequencing and DNA synthesis have made these methods inexpensive and available to most scientists. We now know the complete genome sequences of thousands of microbes, and it is possible to design genes right down to the individual base pair. Genes can be altered at will so that they operate optimally within a given organism and strain. However, there is an upper limit to the length of double-stranded DNA that can be produced reliably, so that only about a dozen or so synthesized genes can be prepared at a time on one double-stranded DNA fragment. What if it were possible to design the complete genome of a microbe, have it synthesized from scratch, and then regenerate a live organism using that DNA? This could allow complete control over each of the details of the designed microbe. Once gene functions are better understood, the biotechnology applications will be vast.

A series of efforts in gene synthesis started with Gobind Khorana's construction of the 72-bp gene for alanine tRNA in 1970. Synthesis of the genes for human insulin in 1978, the 7.7-kb genome of the poliovirus, and the 5.4-kb genome of the ΦX174 bacteriophage in 2003 further extended the lengths of synthetic DNA. Eventually, the construction of a complete bacterial genome could be contemplated. In preparation for this, scientists have tried to determine the minimum genome size required for a bacterial cell to live and replicate (see Perspective 10.2). The genomes of species of *Mycoplasma* are some of the smallest known bacterial genomes, ranging from 400 to 500 Mbp, within the range of a complete synthesis effort. A strategy for piecing together the synthesized DNA fragments into longer pieces just needed to be developed. A strategy involving homologous recombination after transformation of yeast was described in Toolbox 9.2. Now, we describe the use of this strategy to successfully construct a complete bacterial chromosome and have that chromosome replicate after introduction into an existing cell, displacing the preexisting chromosome.

Experiment

This work started with a design for a synthetic genome, designated JCVI-syn1.0. The design was based on the known genome sequence of *Mycoplasma mycoides* subspecies *capri*. Added to the natural sequence were four watermarks, or introduced sequences. One of these watermarks contained the cipher that is required for decoding the other three watermarks. After successful deciphering, those watermarks indicated names of scientists who had contributed to the project, as well as quotations from literature. Note that these watermark sequences were not functional sequences intended to be translated to gene products, but instead were introduced as markers or tags for the synthetic genome to confirm the identity of the cells obtained at the end of the assembly. Including these watermarks, there were 25 sequence differences between the synthesized genome and the original genome.

As indicated in **Figure B12.4**, the genome was assembled in several steps starting from the synthesized oligonucleotides, with yeast being



From Gibson et al. 2010. Science 329:52–56, Fig.1. Reprinted with permission of AAAS and J. Craig Venter.

Figure B12.4. Assembly of a synthetic genome The flow chart shows the progression from synthesis of overlapping single-stranded oligonucleotides to assembly into 1-kb double-stranded cassettes, which are then recombined in yeast to make 10-kb assemblies (blue arrows) and then 100-kbp assemblies (green arrows), which are finally recombined to make the 1-Mb genome. The locations of the four watermarks (WM1–WM4) and relevant restriction enzyme sites are indicated in the outer ring. Asterisks show the locations of other differences in sequence from the wild-type sequence.

used for the *in vivo* recombination steps. The correct assembly had to be checked extensively by PCR to ensure that the correct fragments were present in the correct order. To enable replication in yeast, all fragments were constructed in a vector that contained a yeast origin of DNA replication called an "autonomously replicating sequence," a yeast centromere, a URA3 yeast selection marker, as well as a tetracycline-resistance marker and the *lacZ* gene encoding the β-galactosidase enzyme needed for selection and expression in the final bacterial cell host.

Once the complete synthesized genome had been constructed, the next step was to introduce it into another strain of *Mycoplasma* by transformation and have it replicate and take over control of the cell from the natural chromosome that was already present. The strain that was chosen to receive the synthetic genome was *Mycoplasma capricolum*. Several hurdles had to be overcome to establish the genome transplant. To ensure that the chromosome extracted from the yeast cells remained intact, the cells were broken open only when they were embedded in an agarose plug to reduce the chance of chromosome breakage by shear forces, and the DNA was carefully purified from the agarose. This DNA was then added to competent *M. capricolum* recipient cells, and after a suitable period of incubation, the mixture was placed under selection on agar media containing tetracycline and X-gal. However, initial attempts to transplant the synthetic genome failed. It turned out that *M. capricolum*

Figure B12.5. Identification of transformants **A.** Colonies of successful tetracycline-resistant transformant cells appear blue when grown on an X-gal-containing medium. **B.** Colonies of cells that have not taken up the exogenous DNA appear white.

produced a restriction endonuclease that cleaved the synthetic genome upon transplant. Recall that the synthetic genome was manufactured in yeast, so protective nucleotide methylation was not present. To overcome this, the researchers tried two successful approaches. They methylated the synthetic genome using purified methylase enzymes prior to transplant, and they used a restriction endonuclease gene mutant of *M. capricolum* as recipient. Following transformation, blue colonies were visible within a few days, indicating the presence of the *lacZ* marker of the introduced DNA **(Figure B12.5)**.

Analysis by restriction enzyme digest and PCR were consistent with the inheritance of the complete synthesized chromosome by the blue transformants. The complete genome sequence of one clone, named JCVI-syn1.0, was determined using the Sanger shotgun method (see Figure 10.1). Interestingly, there were 10 minor sequence differences between the designed sequence and the sequence from the transformant. Most of these were single-nucleotide changes, but one was an insertion of the *E. coli* transposable element IS1, which was likely obtained during the 10-kb assembly that included an intermediate passage through *E. coli*. Comparison of the proteomes by 2D-PAGE, as shown in **Figure B12.6**, revealed no discernable differences between the patterns of protein spots between JCVI-syn1.0 and the wild-type strain.

Impact

The announcement of this feat attracted considerable global media attention. Much of the discussion revolved around the implications of synthetic life. There was even talk about the possibility of designer humans! Although this study was certainly an impressive technical accomplishment, it needs to be put into perspective because it is still a very long way to the design and synthesis of complex multicellular organisms. Humans have been synthesizing genes for decades, and individual mutations can be placed into many organisms at will. Genomes can be manipulated with high accuracy by recombination methods. Complete genome synthesis simply demonstrates that this type of work can be done at the genome level. Even though the

Figure B12.6. Proteomes of transformant and wild-type cells Comparison of the proteomes of the synthetic genome transformant and the wild-type strain. There are no readily detectable differences.

Mycoplasma genome is relatively small compared to the genomes of most other microorganisms, it is expected that the technology will be scaled up for use in most microorganisms, especially those most relevant to biotechnology applications.

Questions for Discussion

1. Why was it important to use a restriction endonuclease mutant as the recipient?
2. What is the function of the *lacZ* gene in the transformation experiments?
3. Why do you think these experiments were carried out in *Mycoplasma* rather than an organism that is more relevant to biotechnology?

Perspective 12.2

THE INTERNATIONAL GENETICALLY ENGINEERED MACHINE (IGEM) COMPETITION, STANDARD BIOLOGICAL PARTS, AND SYNTHETIC BIOLOGY

Each fall, over a weekend, teams of undergraduate students from around the world descend on the Boston area for the iGEM World Championship Jamboree. These students represent a number of academic disciplines, from molecular biology to mathematics, computer science, chemical engineering, and electrical engineering. They are there to present the research projects that they have been working on at their home campuses, to share ideas, and to contribute to the growth of synthetic biology. Their aim is straightforward—simplify complex biological organisms so that they can be truly engineered. This synthetic biology movement is a very open culture in which all developed material is made available for sharing, and genetic material that is produced by the teams is contributed to a central repository.

The iGEM Jamboree has grown from a January course at Massachusetts Institute of Technology that spawned a meeting of a small group of five teams in the summer of 2004 to 245 teams comprised of 2,300 participants representing over 30 countries in 2014 **(Figure B12.7)**. There is now even a high school division with 51 teams competing in 2014. Through the various research projects, the participants aim to demonstrate that diverse genetic constructs can be designed and built within living cells **(Table B12.1)**.

TABLE B12.1 The iGEM competition

Year	Number of teams	Grand prize-winning team	Winning project title and description
2004	5	No grand prize	
2005	13	No grand prize	
2006	32	Slovenia	*Engineered Human Cells*: Human embryonic kidney cells were transfected with constructs designed to induce artificial tolerance in the TLR-signaling pathway, thus reducing the chance of sepsis following bacterial infection
2007	54	Peking	*Towards Self-Differentiated Bacterial Assembly Line*: Development of devices that allow genetically identical cells to differentiate so that they perform complementary tasks
2008	84	Slovenia	*Immunobricks*: Production of a designer vaccine against *Helicobacter pylori*
2009	112	Cambridge	*E. Chromi*: Design and construction of novel biosensor systems that respond to the concentration of inducer with different color output
2010	130	Slovenia	*DNA Coding Beyond Triplets*: Development of a system for DNA-guided assembly of functional proteins
2011	160	University of Washington	*Make It or Break It:* Diesel production and gluten destruction, the synthetic biology way
2012	191	Groningen	*Stop the Food Waste Initiative*: Biosensor for detection of spoiled meat
2013	204	Heidelberg	*The Philosopher's Stone*: Recycling gold from electronic waste
2014	245	Heidelberg	*The Ring of Fire*: Circularization of proteins
2015	280	William & Mary	*Noise*: Characterization of promoter-driven transcriptional noise in *E. coli*

called a BioBrick. The 6-base XbaI and SpeI restriction sites share the same core 4-base sequence, but they differ in the flanking nucleotides on either side. Cleavage yields compatible sticky ends, and combination of XbaI and SpeI sites by ligation results in loss of both restriction enzyme recognition sequences.

Although the BioBrick concept is very useful for physical sharing of biological parts, as the cost of DNA synthesis drops, it will become possible to design devices and construct them without needing physical access to the DNA. Eventually, we may be able to use software to design biological systems based on standard biological parts, have the DNA for those systems synthesized, and then expect the resulting organisms to perform exactly as predicted. However, we do not understand fully how even simplified biological organisms operate. As our knowledge continues to increase, and we combine this knowledge with engineering expertise, synthetic biology surely will have a great impact on biotechnology applications **(Perspective 12.2)**.

Now that we have seen how microbes can be modified, let's ask an important question. How can we use these genetically modified organisms? In the next sections of this chapter, we will look at three categories of biotechnology, or "biotech"—red biotech, white biotech, and green biotech. As we will see, all three areas employ similar techniques, but have different foci. Within each category, we will emphasize a few specific examples.

12.2 Fact Check

1. Explain the benefits and drawbacks of using random mutagenesis in biotechnology.
2. What are some of the challenges in the production of recombinant eukaryal proteins in bacterial cells?
3. What is synthetic biology?

12.3 Red biotechnology

What role do microbes play in pharmaceutical biotechnology?

The inexpensive production of antibiotics has revolutionized public health worldwide. As we saw at the start of this chapter, the first antibiotic to be produced in mass quantities and at a reasonable price was penicillin. In less than 10 years during the 1940s, pharmaceutical companies developed processes to manufacture penicillin on a large scale. By the late 1940s, the cost of penicillin production was approximately $5.00 per kg. Production improvements continued and, by the 1970s, the cost of the drug had dropped to an astonishing $0.03 per kg. However, red biotech does not just involve the production of antibiotics. During this introduction to red biotech, we will look at two specific applications—secondary metabolites and human protein therapeutics.

First, a number of other secondary metabolites from microbes, besides antibiotics, have been discovered to have therapeutic effects. However, microbes are not the only original source of useful secondary metabolites. The antimalarial compound artemisinin is extracted traditionally from the plant *Artemisia annua*, but as we will see at the end of the chapter, it can now be produced by recombinant microorganisms. Second, as we have seen, recombinant DNA methods have been used to provide reliable sources of synthetically produced human proteins, such as the hormone insulin. Let's first consider the secondary metabolites, and we will come back to the human proteins later in this section.

Secondary metabolites as therapeutics

Penicillin is not the only antibiotic. In the early 1940s, two other antibiotics, actinomycin and streptomycin, were discovered in culture filtrates of actinomycetes, saprophytic filamentous soil bacteria, sometimes mistaken for fungi because of their filamentous growth and complex life cycle. *Streptomyces* (see Microbes in Focus 12.1), the most widely used actinomycete, produce many antibiotics as secondary metabolites. Recall from Section 21.1 these are compounds produced by an organism but not directly needed for the survival of the organism. In fact, members of this genus produce most of the known antibiotics, including antibacterial and antifungal agents. *Streptomyces* also produce many other medically important compounds, including anticancer agents and immunosuppressants.

CONNECTIONS Antibiotics are compounds derived from microorganisms that inhibit the growth of other microorganisms, although the term is sometimes used to encompass similarly acting synthetic compounds. Many antibiotics are discussed in **Section 24.2**.

Not all drugs based on secondary metabolites are antimicrobial in nature. One of the most profitable classes of drugs on the market today is a secondary metabolite that inhibits the activity of hydroxymethylglutaryl (HMG)-CoA reductase, a key enzyme in the cholesterol synthesis pathway. These HMG-CoA reductase inhibitors, called "statins," were introduced in 1987 as a treatment to lower cholesterol linked to cardiovascular disease. They act by binding to the HMG-CoA reductase binding site, thus blocking interaction with the substrate.

Akira Endo, working for the Japanese pharmaceutical company Sankyo, became interested in the link between cholesterol and heart disease. Many scientists recognized that the ability to specifically inhibit HMG-CoA reductase would be the key to reducing cholesterol production. Endo and his team decided to screen several thousand fungal cultures for their ability to inhibit the enzyme extracted from rat livers. After two years of testing, they found that an extract from a *Penicillium citrinum* strain contained a potent inhibitor of HMG-CoA reductase.

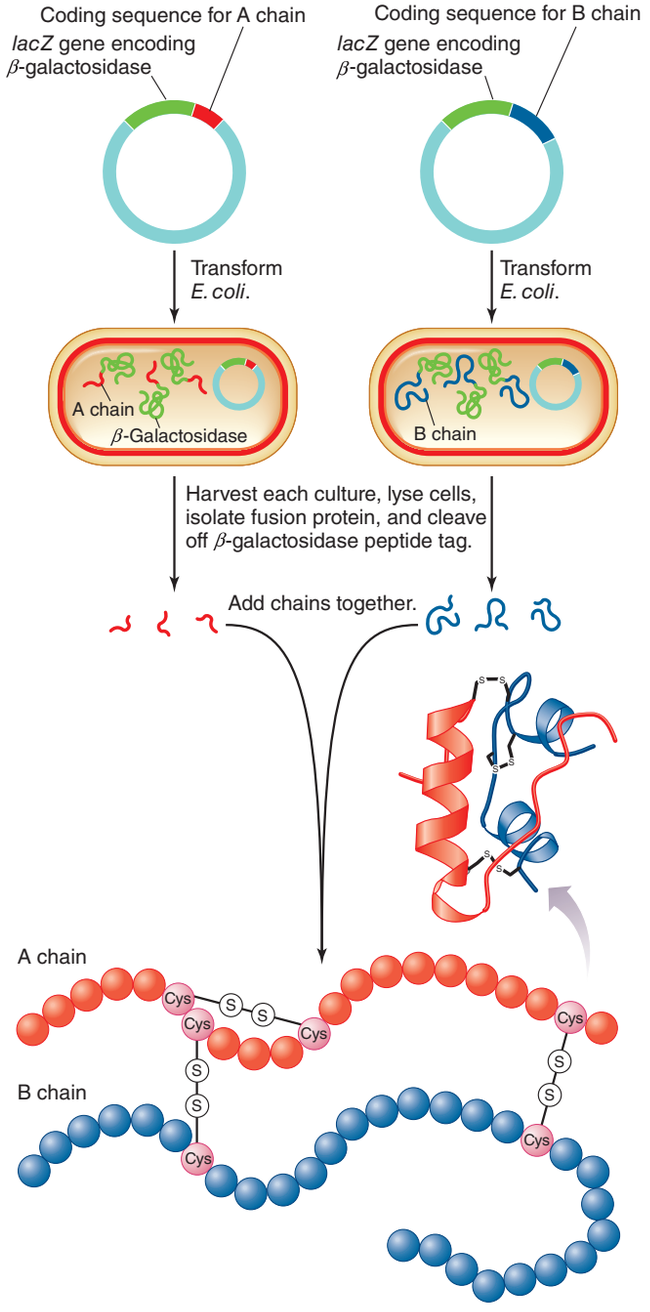

Figure 12.15. Production of recombinant insulin Insulin was the first recombinant human protein to be produced and marketed. The coding sequences for each of the two chains were cloned to make translational fusions with the *lacZ* gene encoding β-galactosidase. Following expression in *E. coli*, the polypeptides were purified and separated, the β-galactosidase tag was removed, and the resulting peptides were combined to make active insulin.

They had identified the first statin. Similar compounds subsequently were found in a number of other fungi, and even in some *Streptomyces* strains of bacteria. Clinical trials showed that these compounds not only reduced cholesterol levels, but also reduced the risk of heart attack. In the United States, roughly one-quarter of all people over the age of 45 take these drugs.

Human proteins as therapeutics

Although secondary metabolites constitute a large portion of red biotech products, various human proteins also constitute a substantial part of the pharmaceutical industry. Examples of these therapeutics include Type I interferons with antitumor and antiviral properties (see Section 19.4), blood coagulation factor XIIIa used for the treatment of hemophilia, and epidermal growth factor that aids in treating burns and organ damage. Some of these human factors may be expressed in bacterial cells. Other factors are expressed in eukaryal cells, as we discussed in Section 12.2.

One of the earliest successes of recombinant DNA technology involved the production of a human hormone. Hormones are signaling molecules that travel through the bloodstream and regulate the activity of target tissues or organs. Insulin, a protein hormone produced by the pancreas, regulates blood sugar. In people with type 1 diabetes, the destruction of pancreatic cells leads to the decreased production of insulin and a corresponding increase in blood sugar levels. Treatment typically involves the administration of exogenous insulin, usually via repeated injections or an insulin pump that provides a more constant supply of the hormone.

Prior to the advent of recombinant DNA technology, the insulin used to treat people with type 1 diabetes was extracted from pigs or cattle. In 1978, shortly after the first demonstrations of DNA cloning using restriction enzymes in 1973 (see Section 9.3), researchers at Genentech announced the cloning and expression of human insulin in *E. coli* **(Figure 12.15)**. This achievement marked a milestone in molecular biotechnology. The recombinant human insulin was safer and more plentiful than the pig- and cattle-derived alternatives. Today, various insulin analogs, versions of human insulin experimentally modified to improve their characteristics, are available for people with type 1 diabetes.

CONNECTIONS Today, most of the world's recombinant human insulin is produced in yeast. Production in yeast reduces the costly purification procedures needed to rid the *E. coli* product of residual endotoxin (lipopolysaccharide, or LPS), which can produce severe inflammatory side effects when injected into patients. See **Sections 19.3** and **21.2** for the effects of endotoxin on the body and **Toolbox 19.2** to learn about the assay for endotoxin in products destined for human use.

12.3 Fact Check

1. Describe how the pharmaceutical industry can use microorganisms to produce drugs that are effective at guarding against disease-causing microbes.
2. How were microbes involved in the development of statin drugs for treating high-cholesterol levels?
3. Identify some of the human proteins produced by microorganisms using recombinant DNA technology.
4. Why would recombinant human insulin be preferred over insulin from animals?

12.4 White biotechnology

What role do microbes play in industrial biotechnology?

White biotech encompasses the many and diverse applications of biotechnology for industrial purposes, from the production of household cleaners, to cosmetics, to fuel for our cars. Currently, the production of many of these products requires the use of fossil fuels. However, fossil fuel reserves are limited and the burning of fossil fuels has environmental impacts. The increased use of microbes in these processes may alleviate some of these obvious problems.

Over the past century, society has transitioned from an agriculture-based economy to a fossil fuel-based economy. The use of coal, oil, and natural gas as fuels or in the production of goods has expanded rapidly, and now forms the basis of modern economies. However, the oil and gas reserves will eventually be depleted. As demand increases and reserves fall, extraction will become more difficult and the cost of extraction will continue to rise. Perhaps more importantly, burning of fossil fuels increases the atmospheric concentration of gases like carbon dioxide (CO_2) and nitrous oxide (N_2O). The resulting greenhouse effect is increasing the temperature of Earth's surface, resulting in human-driven climate change. Of course, billions of years before humans walked Earth, microorganisms radically altered the atmosphere when photosynthetic bacteria began releasing oxygen. That change occurred over millions of years, whereas human industrial activities have added enough greenhouse gases to the atmosphere to affect the global climate in less than two centuries.

Can we alter our society's "energy metabolism" to reduce our dependence on declining oil reserves and reduce the impact of fossil fuel wastes? Scientists hope microorganisms can help. Bacteria, archaea, yeast, and algae are being tapped to produce biofuels that can power transportation or generate electricity, and be used in the production of various chemicals. Perhaps microorganisms can contribute to an energy economy that is more environmentally friendly than the current fossil fuel-based system. In this section, we will first explore the biorefinery concept. Then, we will examine how microorganisms can be used to produce fuels like ethanol and butanol. We will also investigate how microorganisms can be used to produce bioplastics. To end this section, we will explore two other areas of white biotech—the production of industrial enzymes and the production of vitamins and amino acids.

The biorefinery concept

Today, oil refineries convert crude petroleum into a number of more usable products such as gasoline, kerosene, wax, and asphalt. Many of these refined products are used in the production of other materials, like plastics. Despite advances in the technology of petroleum extraction, our supplies of affordable petroleum are dwindling. Furthermore, the refinery process leads to the production of various pollutants.

A **biorefinery** converts biomass, living or recently living biological substance, into a number of products, including chemicals, energy, and materials (Figure 12.16). Unlike crude petroleum, the use of biological materials as a **feedstock**, or raw starting material, is virtually limitless, providing us with a renewable source of starting materials. Moreover, harvesting and processing of biomass generally have fewer associated

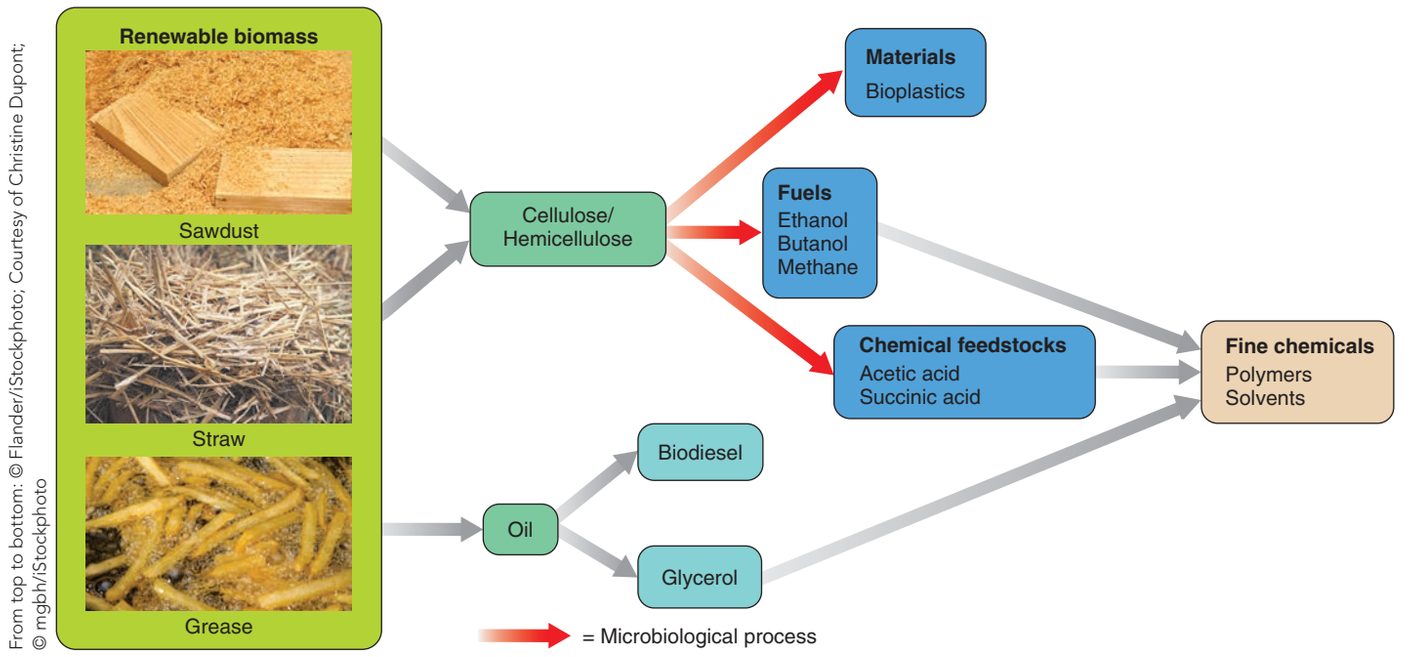

Figure 12.16. The biorefinery The biorefinery concept is modeled on the petroleum refinery; biomass is processed into a number of usable products. In the biorefinery, crude biomass feedstock would be converted to biomaterials, bioenergy, and biochemicals.

environmental concerns compared to drilling for and refining crude oil. The biomass used in biorefineries can include crop plants specifically grown for this purpose, as well as agricultural and forestry waste that otherwise would be discarded and eventually decomposed and even methane in biogas that is generated in landfills and anaerobic digesters.

Crop plants that are specifically grown as biomass feedstock to support the biorefinery industry include the perennial grasses (such as *Miscanthus*), switchgrass, and fast-growing trees like poplar. Within the biorefinery, the cellulose/hemicellulose fraction of plant biomass provides the starting material for the microbiological production of fuels such as ethanol and butanol, basic biochemicals such as succinic acid and acetone, and other biopolymers. Cellulose, a complex polymer of β-1,4-linked D-glucose units, provides structure to the plant cell wall and is the most abundant organic polymer on Earth. This fiber is very difficult to break down and, although some microorganisms produce collections of glycoside hydrolase enzymes that can degrade cellulose to its component sugars, most microbes used for fermentation in the biorefinery cannot break cellulose. Cellulose must be degraded to its component sugars in advance. This degradation can be achieved through physical processes using heat and alkaline treatment or by glycoside hydrolase enzymes.

CONNECTIONS In **Section 15.4**, we will see how natural decomposition is an essential aspect of soil microbiology. In **Chapter 17**, we will examine the symbiotic communities of microbes that can degrade cellulose in animal guts.

Can the products of biorefineries be viable substitutes for fossil fuel-derived products? Perhaps. The efficiencies inherent in the biorefinery concept should contribute to the competitiveness of biofuels and bioproducts, leading to reduced reliance on fossil fuels. Next, we will explore the production of biofuels, biorefinery products that may reduce our dependence on fossil fuels.

Biofuels

Perhaps the largest current pursuit involving biotechnology is the production of renewable biofuels, fuels produced via biomass conversion. These materials could be the key to independence from fossil fuels. While biofuels currently are a hot topic, it might be surprising to know that they are not really new. At the beginning of the twentieth century, as the automobile came into prominence, biofuels actually were the preferred transportation fuels. The original diesel engines ran on biodiesel produced from vegetable oil, and the Ford Model T automobile ran on ethanol produced by fermentation of corn. However, petroleum proved to be a more plentiful and less expensive source of fuel. Gasoline and diesel soon replaced the biofuels. The resulting development of the petrochemical industry eventually formed the basis of much of the industrial expansion throughout the world. As the environmental and climate impacts of fossil fuel consumption have accumulated, the interest in ethanol, biodiesel, and other biofuels as transportation fuels has increased again.

Ethanol as a Biofuel

Ethanol, a 2-carbon organic alcohol, has many uses in the industrial sector, and has garnered much attention in recent years as a biofuel to replace or supplement gasoline as a transportation fuel. Strains of yeast like *Saccharomyces cerevisiae* generate ethanol during the fermentation of sugars during anaerobic growth (see Section 13.3). Humans have exploited this process for thousands of years for the production of alcoholic beverages. Even though our ancestors relied on naturally occurring yeast strains, current commercial production of alcohol is carried out by specific yeast strains that have been chosen for their robustness and their efficient production characteristics. However, even industrial yeast strains can only tolerate a maximum of 15 percent ethanol. Increased concentrations of ethanol require distillation, in which manufacturers heat the culture to evaporate the ethanol, which then condenses around cooling coils in the still and is collected **(Figure 12.17)**.

Figure 12.18. Commercial ethanol production using different feedstocks Commercial ethanol is commonly produced from sugar and starch. Ethanol production from cellulosic biomass is under development, with some demonstration plants in operation. Pretreatment results in the efficient conversion of the cellulose to a form that can be fermented by alcohol-producing organisms, and is central to the successful production of ethanol from biomass.

Because internal combustion engines can burn ethanol with little or no modification, this molecule may be a reasonable alternative to gasoline. The cost of commercial ethanol production depends in large part on the cost of the biomass feedstock that is used (Figure 12.18). In Brazil, sugarcane provides an inexpensive source of sucrose, composed of one glucose molecule and one fructose molecule, and supports a large commercial ethanol industry. Most of the motor vehicles sold in Brazil burn ethanol. In North America, much of the ethanol mixed with gasoline is produced from cornstarch that has been broken down to glucose by the addition of amylase enzymes, another microbially produced commercial product (see high fructose corn syrup later in this section). Nonetheless, the production of ethanol from these starting materials, may have unintended consequences. An increased demand for sugarcane and cornstarch may lead to increased prices for foods containing these products. Additionally, large amounts of fertilizer and land are used to produce crops such as corn, and the environmental costs of this usage may outweigh the benefits of ethanol as a fuel.

To avoid these downsides, waste biomass could be used as feedstock. Most waste biomass from agriculture and forestry operations is composed of a mixture of polymeric cellulose, hemicellulose, and lignin (Figure 12.19), collectively called "lignocellulose." Due to its function as a structural material for the plant cell, this material has evolved to be very resistant to microbial degradation. Although it cannot be metabolized directly by yeast, cellulase enzymes, acid treatment, or physical methods such as steam explosion can be used to liberate sugars from the lignocellulose polymer. These sugars can then be fermented by yeast to produce ethanol. The growth of the

Perspective 12.3
BIOFUELS: BIODIESEL AND ALGAE

Even if ethanol consumption grows dramatically, for the near future it will share the transportation market with diesel fuels. Diesel engines predominate in heavy vehicles and, thanks to more efficient engines and cleaner-burning fuels, are regaining popularity in automobiles. Renewable forms of diesel, "biodiesel," are currently made from plant oils. Soybean, palm, and rapeseed (canola) oils lead the market in different parts of the world. However, the use of plant-derived oils for biodiesel is probably unsustainable using current practices. None of these crops can supply enough oil to significantly reduce global diesel consumption without displacing cropland currently devoted to food crops, or inducing farmers to put more virgin land under cultivation. This is already happening with oil palm in Southeast Asia, where tropical rain forests are being cut for palm plantations and local biodiversity is threatened.

Microbes could offer a more sustainable approach to biodiesel production. Many microorganisms store excess carbon as lipids. Diesel fuel, like gasoline, is simply a mixture of hydrocarbons. The hydrocarbons in petroleum-derived diesel contain 12 carbons on average, whereas plant oils primarily consist of triglycerides with esterified fatty acids of 16 or 18 carbons. Do any microorganisms produce lipids similar to the lipids found in these plants? Yes. The so-called microalgae, photosynthetic unicellular eukarya, can accumulate lipids to tremendously high levels under certain conditions. Some species of microalgae have been shown to accumulate up to 80 percent of their dry weight as lipids. To these cells, lipids are simply a storage depot for photosynthetically fixed carbon. Laboratory-scale experiments have shown that these lipids can be extracted easily from the algae and converted to a fuel mix that is as acceptable for diesel engines as plant-based biodiesel. The potential for algal biodiesel is vast. Like plants, algae require sunlight and atmospheric CO_2, but the lipid yield per unit of land area is up to 15-fold higher for algae (about 100,000 liters of oil per hectare) than for oil palm, the most productive oil crop (about 6,000 liters of oil per hectare). Canola and soybean only yield about 25 percent and less than 10 percent the amount of oil per hectare as palm, so they are far inferior to the potential algal oil yield.

So why don't we see vast ponds filled with algae making biofuels? Much research still needs to be done to scale-up algal growth for oil production and make the process economically competitive with petroleum-based fuels and ethanol. During the oil crises of the 1970s, this field flourished. Oil prices retreated in the next few decades, only to surge again recently as concerns over oil prices and the climate effects of fossil fuel consumption have grown. Techniques for genetically engineering algal strains useful for oil production are still limited, so there must be more investment in studying the basic genetics and molecular biology of these organisms if we hope to improve oil production through biotechnology.

Researchers continue to study many different microalgal species, looking for higher oil yields under different nutritional and environmental regimes. Wastewater is being examined as a possible nutrient source, and CO_2-rich exhaust gases from power plants might turbocharge carbon fixation to boost oil production. Engineers are designing large-scale cultivation systems that maximize light exposure and nutrient availability. Open ponds would be the least expensive growth venue, but would likely experience significant problems with contamination, grazing by protozoa, viral infections, and water evaporation. Closed systems bring those problems under control **(Figure B12.8)**, but are more expensive and are challenging to illuminate with natural lighting. Plenty of work needs to be done before microalgal biodiesel comes to a pump near you, but the problems seem manageable and the potential benefits may be huge.

cellulosic ethanol technology has been rapid **(Perspective 12.3)**, and some cellulosic ethanol biorefineries are already operating in North America.

Butanol and Acetone

Although the development of ethanol as a broadly used transportation fuel is promising, ethanol may not be the best possible biofuel. It only contains about 70 percent of the energy as gasoline and is more corrosive than gasoline, making long-term storage difficult. The four-carbon alcohol, butanol, may be a better and more economically viable transportation biofuel. It has similar physical properties to gasoline and can be used directly as a substitute for gasoline in current internal combustion engines. Butanol currently has a $7 billion to $8 billion per year annual market worldwide, being used primarily for latex, enamels, and lacquers, as an additive to plastics to keep them flexible, and as a solvent in the manufacture of antibiotics, vitamins, and hormones.

In the early years of the twentieth century, the microbial process for butanol and ethantol production involved fermentation by *Clostridium acetobutylicum*, so named for these metabolic products. Certain isolates of this anaerobic bacterium naturally

produce large amounts of these substances and, with improved fermentation methods, production expanded rapidly in the 1920s. Butanol became a valuable solvent for the production of lacquer used to prepare the finish of automobile bodies. Acetone became important in making cordite, the propellant used in military ammunition during World War I and World War II. The production method was first developed by Chaim Weizman, the future first president of the State of Israel, working in England around 1914. The method used strains of *C. acetobutylicum* and a cooked corn mash or molasses feedstock. Fermentation occurred in large bioreactors with capacities of 200,000 to 1,000,000 liters. Carbon dioxide was bubbled through the culture to ensure that O_2 was excluded. Fermentation was typically biphasic, with the first phase being acidogenic, forming acetate, butyrate, hydrogen, and CO_2. The cells then use these acids to produce butanol, acetone, and ethanol **(Figure 12.20)**. After 40 to 60 hours, a typical yield was 12–20 g L^{-1} of solvent, in a ratio of 6:3:1 (butanol:acetone:ethanol). The solvent was removed by distillation, and the remaining microbial dried solids were used as high-nutrient animal feed. Although this process was robust and relatively efficient, production declined during the 1950s and 1960s because it was outcompeted by solvent production from the petrochemical industry. However, as the cost of fossil fuels rises, renewed interest in the biological production of butanol has spurred new research to further improve the process.

Bioplastics

The twentieth century witnessed a tremendous increase in the use of plastics, which are versatile polymers with a wide range of physical characteristics. Even though these synthetic materials have many disparate uses, they share one important characteristic—their resistance to biodegradation. As a result, they accumulate in the environment, often with detrimental effects on wildlife and ecosystems **(Figure 12.21)**. To combat this problem, many municipal governments worldwide have banned the use of plastic shopping bags or have begun charging people for their use.

© FabioFilzi/iStockphoto

Figure 12.21. Non-biodegradable plastics washed up on a beach The increasing use of plastic and its resistance to degradation has led to a growing problem with plastics waste. The increased production and use of biodegradable plastics would go a long way toward solving this problem.

Imagine if naturally biodegradable plastics could replace these non-degradable plastics. Microbes may help us obtain this ideal. In the mid-1920s, researchers discovered that the bacterium *Bacillus megaterium* produces **polyhydroxybutyrate (PHB)**, a natural polyester. We now know various microbes can produce an assortment of polyesters, collectively known as **polyhydroxyalkanoates (PHAs)**, that are similar in many ways to the synthetic polyester used today in everything from clothes to plastic bottles to sleeping bags. PHB is the simplest and most common of these polymers formed by microbes. It subsequently has been shown that bacteria store these hydrocarbon polymers under conditions of carbon abundance **(Figure 12.22)**. The cell can use them as sources of carbon and energy under environmental conditions where they would otherwise starve. The short chain-length PHAs are made up of carbon monomers with 3 to 5 carbon atoms, while the carbon monomers of medium chain-length polymers range from 6 to 16 carbons. Interest in the commercial

Figure 12.20. Figure 12.22. Structures of bacterial polyhydroxyalkanoates (PHAs) PHA deposits are accumulated within bacterial cells as carbon storage polymers. Diverse structures of the PHAs result in a broad range of physical properties that are similar to those of existing petroleum-based plastics.

promise of these bioplastics has led to intensive investigation of the biochemistry and genetics of PHA synthesis.

Industrial PHA production is well established, with several companies involved in large-scale fermentation. Because PHA is accumulated under conditions of carbon abundance, high levels of PHA can be achieved by supplying limiting amounts of nutrients such as phosphorus or nitrogen, simultaneously providing ample amounts of carbon. This can be done in either batch or continuous culture and is an example of using physiological manipulation to improve production of the desired end product.

CONNECTIONS We encountered PHB granules in **Section 2.2** because they are an example of an inclusion body in the cytoplasm and can represent over 50 percent of a cell's dry weight.

One of the factors making fossil fuel-derived plastics so ubiquitous is the large variety of physical properties associated with these materials. Fortunately, such variety also exists in PHAs. Although PHB is relatively hard and brittle, alterations in the length of the polymer molecule or the nature of the monomeric constituents can introduce tremendous variability in the physical characteristics. For example, longer chain-length PHAs exhibit more elasticity and have lower melting temperatures. Copolymers that contain more than one type of monomer exhibit even more variation in their physical properties. Indeed, almost every major fossil fuel-derived plastic probably could be replaced by a corresponding PHA bioplastic.

The key enzyme for the synthesis of PHA molecules is PHA synthase. This enzyme incorporates monomers into the growing polymer. Genes encoding PHA synthase enzymes have been characterized in a number of bacteria, including cyanobacteria, and some halophilic archaea. For PHB, metabolism of sugars forms two-carbon acetyl-CoA molecules. When excess acetyl-CoA molecules are formed, two are combined to make the four-carbon acetoacetyl-CoA **(Figure 12.23)** by a ketothiolase enzyme. The acetoacetyl-CoA is then reduced to form the monomer 3-hydroxybutyryl-CoA by an acetoacetyl-CoA reductase enzyme. The monomer is polymerized by PHA synthase into intracellular PHA granules. Bacterial mutants in any of the three genes encoding these enzymes cannot synthesize the polymer. Introduction of these three genes into some bacteria that do not produce PHA granules naturally, such as *Escherichia coli*, results in PHA production.

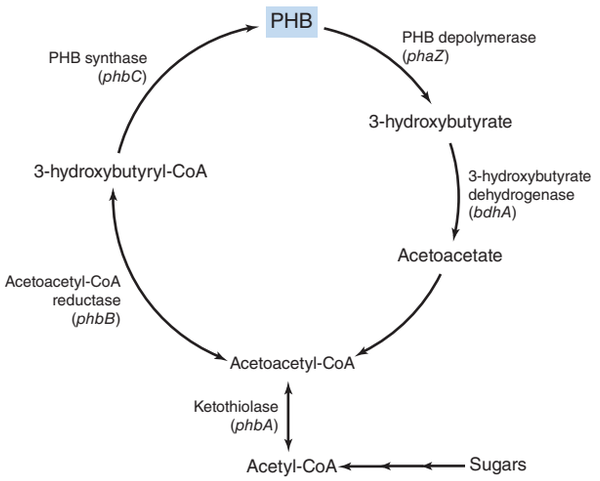

Figure 12.23. The poly-3-hydroxybutyrate (PHB) synthesis cycle Knowledge of the genetics of PHA biosynthesis is important for the production of polymers with desired properties. This figure shows the pathway for synthesis of the most common PHA, poly-3-hydroxybutyrate (PHB). The enzymes ketothiolase and acetoacetyl-CoA reductase are responsible for building the CoA-activated form of the monomer; synthase carries out the polymerization reaction. The substrate specificity of the PHB (or PHA) synthase enzyme influences the final form of the polymer. The polymer within the cell can be broken down and used as a source of carbon and energy.

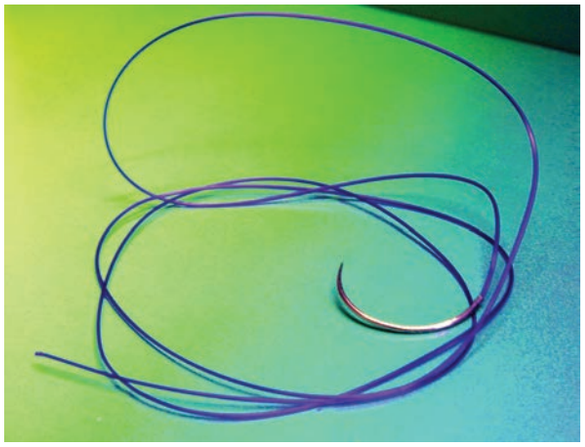
Figure 12.24. Biodegradability of PHA plastic Extracellular PHA depolymerase is active on polymer that has been released from dead cells in the environment. Production of this enzyme by environmental microbes is responsible for the biodegradable nature of the PHA bioplastics.

Another aspect of the PHA cycle deals with degradation. Materials constructed of PHA are naturally biodegradable **(Figure 12.24)**. Remember, cells normally stockpile PHA in preparation for future starvation conditions that the cell might experience. For the cell to benefit from the accumulated deposits, it must be able to degrade the polymer and catabolize the resulting breakdown product. The key degradative enzyme is PHA depolymerase, which degrades PHA to D-hydroxyalkanoates. These are further oxidized to acetyl-CoA, which can enter the energy-generating TCA cycle (see Figure 13.20). In contrast, fossil fuel-derived plastics are not subject to this type of biodegradation.

The main goals of PHA bioplastics research have been (1) to lower the costs of production to make it competitive with fossil fuel-derived plastics and (2) to produce plastics with properties appropriate for specific uses. Several companies around the world are now developing such products. More specialized products, such as medical devices like sutures, vascular stents, and scaffolds for tissue engineering have an inherently high commercial value, making their cost of production less significant **(Figure 12.25)**. Other materials, like shopping bags, must be produced as cheaply as possible. The banning of plastic shopping bags in a number of jurisdictions around the world should promote the adoption of biodegradable PHA bioplastic bags, even if they may be more expensive to produce.

The sun can be a source of energy to produce bioplastics. Photosynthesis in photoautotrophic organisms harnesses the



Courtesy Tepha, Inc.

Figure 12.25. Surgical suture made from poly-4-hydroxybutyrate High-value specialty polymers, such as this surgical suture, are more likely to be cost competitive with petroleum-based plastics because the raw material cost has relatively little impact on final cost of production.

sun's energy, which is then used to reduce atmospheric CO_2 to sugars (see Section 13.6). Some photosynthetic bacteria, most notably cyanobacteria, naturally accumulate large quantities of PHA deposits during photoautotrophic growth. Unsurprisingly, researchers have expressed considerable interest in harnessing these microorganisms for the commercial production of bioplastics. Terrestrial plants might also be able to produce PHA bioplastics efficiently. Being eukaryal organisms, they are unable to naturally produce PHA granules, but bacterial PHA synthesis pathway genes have been successfully introduced into and expressed in a number of different types of plants. These **transgenic plants** (see Section 12.5) containing DNA from another type of organism, successfully produce bioplastics. The amount of production has been relatively low in most cases, so the process is not yet commercially viable, but the results of ongoing research show promise. It will be especially valuable to target PHA production to specific parts of the plant, such as the seed, leaf, or stem. It might even be possible to produce the PHA as a coproduct of a food crop. As the cost of fossil fuel plastics increases due to the inevitable dwindling of oil supplies, and the cost of PHA production by microbial fermentation on waste biomass and by photosynthesis in transgenic plants decreases, we may indeed find that the use of environmentally friendly biodegradable plastics becomes widespread.

Industrial enzymes

The production of many commercial products, including foods, detergents, textiles, and paper, requires the use of enzymes. Many of these enzymes, often referred to as **biocatalysts**, originate from microbes. In the production process, these microbial enzymes have several advantages over organic chemistry alternatives. The biocatalysts quite frequently exhibit high specificity and high efficiency. Additionally, they are biodegradable. Some examples of these enzymes are lipases, proteases, glycosidases, hydroxylases, nitrilases, acylases, and amidases.

How exactly do these enzymes affect our day-to-day lives? Well, the next time you quench your thirst with a soft drink (Figure 12.26), reflect on the fact that it contains a sugary mix of glucose and fructose called high fructose corn syrup (HFCS). This HFCS is produced by the action of amylase enzymes on cornstarch to make corn syrup, followed by treatment with glucose isomerase to adjust the ratio of glucose to fructose. The amylase enzymes are purified from cultures of *Bacillus* sp., whereas glucose isomerase is purified from cultures of *Streptomyces* sp. The HFCS is much cheaper than sugar, and about 10 megatonnes of high fructose corn syrup is produced each year in the United States alone.

When you do your laundry, note that the detergent likely includes a potent mix of lipases, amylases, proteases, glycosidases, and oxidases that work together to remove dirt and stains at lower wash temperatures. In fact, the detergent industry represents the largest single market for microbial enzymes, with other key markets being baking, beverage, and dairy. Because of these applications, the enzymes themselves are valuable products, and considerable effort is expended in finding new enzymes with improved properties such as higher substrate turnover rates and desired substrate and product specificity. Sometimes, companies find better enzymes through bioprospecting. Other times, researchers at these companies try to improve existing enzymes through directed and random mutagenesis approaches like the ones described in Section 12.2.

Figure 12.26. Common consumer products based on industrially produced enzymes HFCS is found in soft drinks and many other foods. A number of different enzymes are used in household detergents to enhance the stain removal properties.

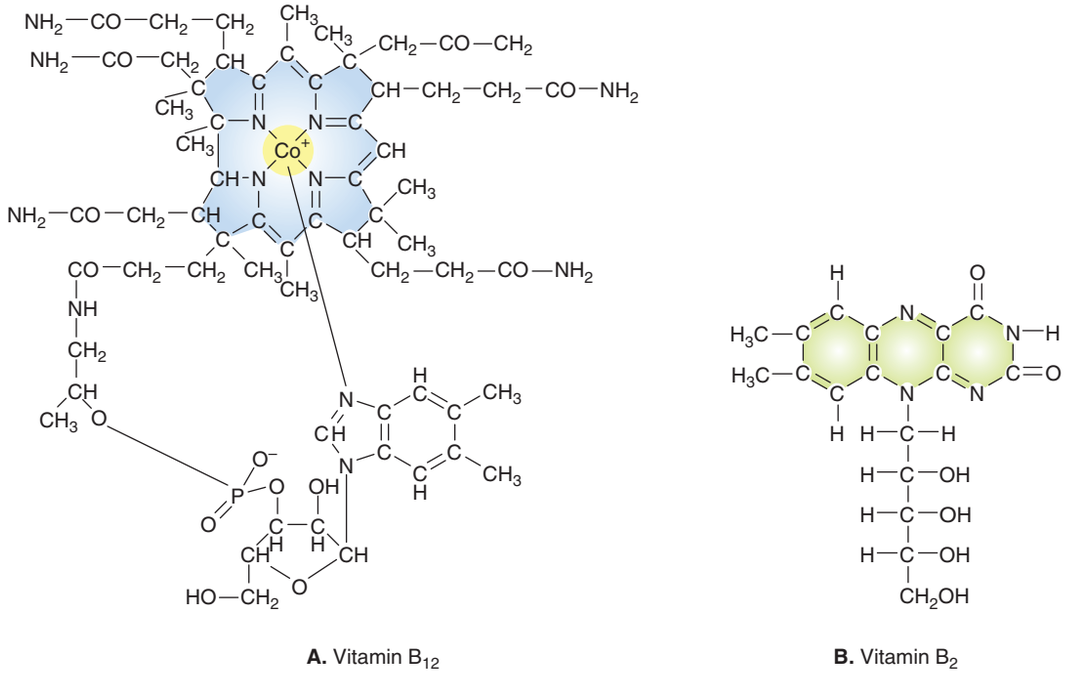

Figure 12.27. Vitamin B_{12} and vitamin B_2 A. Vitamin B_{12} (cyanocobalamin) and **B.** vitamin B_2 (riboflavin) are two examples of vitamins produced from microbial cultures for supplementing the human diet.

Vitamins and amino acids

As we conclude this section, let's explore another group of white biotech products—vitamins and amino acids. Today, manufacturers often fortify processed foods during production by adding nutritive compounds, like vitamins. The reasons for this fortification may be several-fold. The nutritive compounds may be lost from the raw food during processing, or the processed food may be unbalanced in its nutritive value. This strategy of adding nutritive compounds is gaining popularity with the introduction of functional foods that provide specific health benefits beyond their nutritional value. Many breads, pastas, and cereals, for instance, have folic acid (vitamin B_9) added to them to help prevent neural tube defects in the developing fetus. Many individuals also attempt to balance their nutritive intake by supplementing their diet with daily vitamin doses. Most vitamins used for these purposes are synthesized chemically, but several are synthesized as secondary metabolites using microbial culture **(Figure 12.27)**.

To explore the role of biotechnology in vitamin production, let's first look at vitamin B_{12}. Plants do not synthesize or require this compound. Conversely, animals need vitamin B_{12}, which is also known as cobalamin. Although the active forms of this essential enzyme cofactor are adenosylcobalamin and methylcobalamin, the ingested form is usually cyanocobalamin, which can be converted to the active forms by the body. Normally, we obtain a sufficient supply of this vitamin through our food intake and the activities of our gut microbiota. However, a deficiency of vitamin B_{12} in humans can lead to an illness called pernicious anemia. Such a deficiency often results from malabsorption in the gut, as occurs in intestinal disorders like Crohn's disease and inflammatory bowel syndrome. People with these disorders often take supplemental vitamin B_{12}, and manufacturers also add this vitamin to certain fortified foods and multivitamin pills. However, the chemical synthesis of vitamin B_{12} is extremely complicated. Instead, almost all of the commercially produced vitamin B_{12}, some 10 tons per year, is produced by *Pseudomonas* or *Propionibacterium* bacterial strains.

Unlike vitamin B_{12}, vitamin B_2, or riboflavin, can be chemically synthesized relatively easily. Indeed, most commercial vitamin B_2 production occurs via chemical synthesis. However, it can also be synthesized in a microbial process that can be economically competitive with the chemical synthesis. Vitamin manufacturers typically maintain the capacity to do both chemical and microbial synthesis. Cultures of two fungi, *Ashbya gossypii* and *Eremothecium ashbyii*, can yield as much as $20\,g\,L^{-1}$ of vitamin B_2 over a seven-day growth period. In both instances, natural fungal isolates have been selected over the years to develop industrially useful overproducing strains.

In addition to vitamins, amino acids can also be harvested from microorganisms. In fact, the industrial production of a wide variety of amino acids amounts to millions of tons per year **(Figure 12.28)**. These products have many uses in the food, animal feed, and nutritional supplement industries, and in the production of synthetic chemicals. L-Glutamic acid, for instance, is used as a flavor enhancer, whereas DL-methionine and L-lysine are used as animal feed supplements. Microbial synthesis contributes to much of this production. An advantage of microbial production of amino acids is stereospecificity (see Figure 2.16). Amino acids produced by microorganisms are always L-isomers that can be used by the human body, rather than D-isomers, which cannot be used. For example, the common sugar substitute aspartame consists of chemically combined L-aspartic acid and L-phenylalanine, produced by *Bacillus flavum* and *Clostridium glutamicum*, respectively.

Most of the microbial strains used in industrial processes for the production of metabolic products have been

genetically manipulated and are metabolically compromised. They cannot survive and compete in the natural environment because their normal metabolic processes have been biased toward producing one or a few metabolites. However, growing as pure cultures within the highly controlled bioreactor environment, they produce relatively large amounts of the desired product. As an example, consider L-lysine synthesis by overproducing strains of *Corynebacterium glutamicum*. Lysine is one of a family of amino acids synthesized from the precursor aspartate (see Figure 13.45). In the cell, aspartate kinase is a key regulatory enzyme in the pathway to lysine and, in wild-type *C. glutamicum*, aspartate kinase is subject to feedback inhibition, as shown in **Figure 12.29**. Regulatory mechanisms such as this are important in controlling the relative amounts of amino acids present in the cytoplasmic amino acid pool. Should lysine begin to accumulate in the cytoplasm, its further synthesis would be prevented. However, maintenance of cellular balance is not useful in commercial amino acid production. Accordingly, a good lysine-producing strain is one in which the regulatory allosteric site of aspartate kinase is non-functional, but the catalytic active site remains functional (see Figure 13.9). Under these conditions, lysine will be made continuously as long as the substrate for its synthesis, aspartate, is present in the culture medium. Directed enzyme evolution using error-prone PCR can be used to produce such a strain (see Section 12.2).

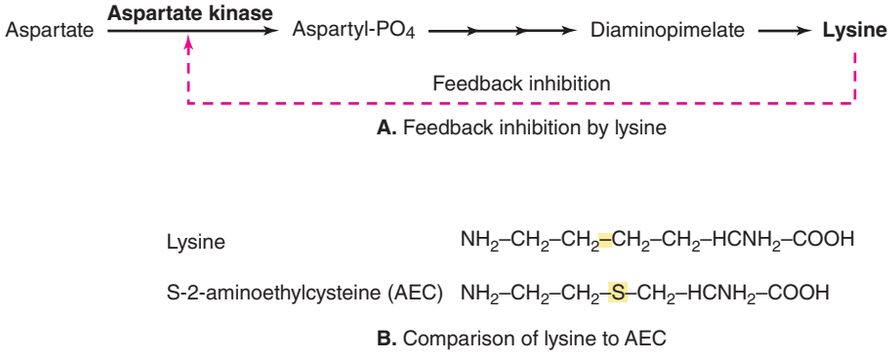

Figure 12.29. Biosynthesis of lysine **A.** The production of lysine is enhanced in mutant cells that possess an aspartate kinase enzyme that is no longer subject to feedback inhibition by lysine. **B.** S-2-aminoethylcysteine (AEC) is an antimetabolite lysine analog that will bind to aspartate kinase and shut down the pathway. Mutants of *Corynebacterium glutamicum* that overproduce lysine are obtained by screening for AEC-resistant cells. Such AEC-resistant mutants overproduce lysine because feedback inhibition is abolished.

To select mutants capable of such high production, an **antimetabolite** of lysine is used. An antimetabolite is a compound that closely resembles the structure of a natural compound. In other words, it is an analog, and it interferes with physiological reactions (see Figure 12.29). The regulatory site of aspartate kinase can recognize and bind to the lysine analog S-2-aminoethylcysteine (AEC) as if it were the true lysine, shutting down activity of aspartate kinase. The strategy used to isolate overproducers entails inoculation of lysine-free, AEC-containing growth medium with large numbers of *C. glutamicum* cells. Wild-type cells are unable to grow under these conditions because they cannot produce lysine in the presence of AEC, and they starve because lysine is not in the medium. However, a cell that has an altered aspartate kinase regulatory site will be unaffected by AEC and will grow in the medium because they are capable of synthesizing lysine. These mutant cells will synthesize lysine continuously because their aspartate kinase enzyme is no longer subject to feedback inhibition. Several other modifications have also been made to lysine overproducers to maximize the amount of cellular carbon flux devoted to lysine synthesis.

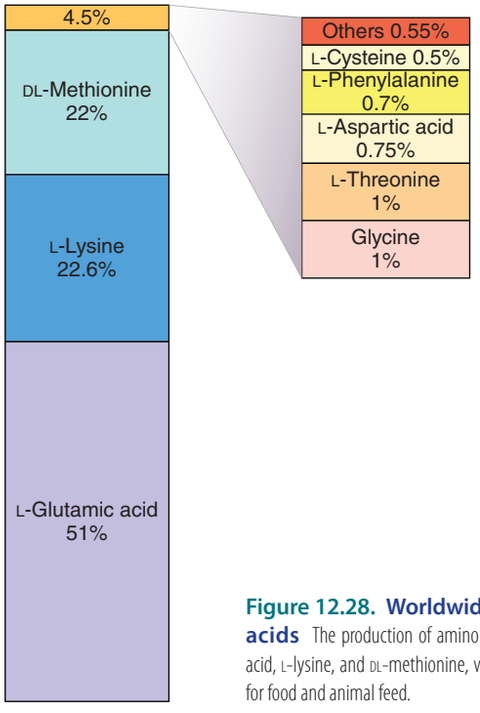

Figure 12.28. Worldwide production of amino acids The production of amino acids is dominated by L-glutamic acid, L-lysine, and DL-methionine, which are used mostly as additives for food and animal feed.

12.4 Fact Check

1. What is a biorefinery and how can it be used?
2. Describe how waste biomass can be used as feedstock.
3. Explain why butanol may be a better biofuel than ethanol.
4. How was *Clostridium acetylbutylicum* used originally to produce acetone, butanol, and ethanol?
5. What are PHAs, and why is there interest in them?
6. Describe a role for photosynthesis in bioplastic production.
7. What are the advantages of using microbial enzymes for commercial applications?
8. Explain how AEC serves as an antimetabolite.

12.5 Green biotechnology

What role do microbes play in agricultural biotechnology?

So far, we have examined the importance of biotechnology in industrial and pharmaceutical settings. Biotechnology is also critically important to modern agriculture. Green biotech refers to the use of biotechnology in this setting. Today, modern agriculture involves the use of large amounts of insecticides, herbicides, and synthetic fertilizers. In addition to being economically costly, this type of intensive agriculture poses human health concerns and environmental repercussions. Green biotech can benefit plant agriculture in several significant ways. The soils that support the growth of plants are complex microbial ecosystems (see Section 15.4). An understanding of the interactions of these microbes with each other and with the subterranean parts of the plant is crucial to our ability to improve plant productivity. Additionally, bacterial systems can be used to introduce genes into plants that impart desired properties to the plants. In this section, we will first look at the use of bacteria to alter the genetic makeup of plants. We will then examine the usefulness of these transgenic traits.

CONNECTIONS In **Section 17.2**, we will investigate the intimate associations that many plants have formed with soil microorganisms that live as endosymbionts inside the plant. Some of these bacteria can fix nitrogen, and the cultivation of several important crops takes advantage of this bacterial capability. Because of these bacteria, the application of nitrogen fertilizer is not required for optimal crop yield. The agricultural inoculant industry provides cultures of endosymbiotic nitrogen-fixing root nodule bacteria, as well as free-living bacteria and fungi with plant growth-promoting properties such as phosphate solubilization.

Agrobacterium—Nature's genetic engineer

Crop plants have been bred for centuries, resulting in the modern forms of plant-based foods that are consumed throughout the world. The application of biotechnology to plant breeding broadens and extends the traits that can be introduced or changed. These traits include taste, yield, nutritional content, pest and pathogen resistance, and shelf life. The introduction of traits depends on the ability to introduce DNA into the plant genome and then have it expressed. The different methods used to achieve this are all called "transformation," but should not be confused with the same term used in bacterial genetics, which refers to the uptake of exogenous DNA by cells. One of the most efficient ways to introduce DNA into plants is transformation by *Agrobacterium*.

At the beginning of the twentieth century, the researchers Erwin Smith and C. O. Townsend demonstrated that a bacterium they called *Bacterium tumefaciens* caused crown gall disease **(Figure 12.30A)**, which produces tumors in many dicot plants. Scientists later changed the name of this plant pathogen to *Agrobacterium tumefaciens*. Active research over the years demonstrated that the bacterium was required for the initiation of the tumor. However, the bacterial cells could be killed after tumor initiation without interfering with tumor growth. In other words, the tumors continued to grow in the absence of bacteria.

Researchers began to understand the basis of crown gall tumor formation in the 1970s and 1980s. First, they showed that tumorigenic bacteria contain a large plasmid. This plasmid was necessary for tumor formation; removal of this plasmid from the bacteria prevented tumor formation. The plasmid was named pTi for "tumor-inducing plasmid." The plasmid could move between strains of *A. tumefaciens* by conjugation, and this conjugation was induced by opines, which are amino acid-like compounds produced by *Agrobacterium*. The real breakthrough in understanding the tumor formation process was made when researchers showed that part of pTi, called "transfer DNA" or "T-DNA," as shown in **Figure 12.30B**, was transferred from the bacteria and integrated into the plant's genome **(Figure 12.30C)**. Eventually, it became clear that the expression of genes on T-DNA in the plant nucleus resulted in the production of opines, as well as plant hormones (also referred to as phytohormones) like auxins and cytokinins. These materials result in plant cell proliferation. In essence, the bacteria are natural genetic engineers. They provide the plant with the genetic ability to produce a tumor, within which the bacteria then reside. Moreover, the tumor cells produce large amounts of opines that the bacteria can use as nutrients due to the presence of opine catabolism genes on the pTi.

The mechanism of tumor formation by *A. tumefaciens* is fascinating. It represents one of the first demonstrated examples of *trans*-kingdom genetic transfer, mediated by the products of the *vir* genes that act on the regions near the ends of the T-DNA **(Figure 12.30B)**. In fact, tobacco and sweet potato plants naturally contain T-DNA sequences integrated into their genome, presumably from one or more natural transformation events that occurred several millennia ago. Even before this was known, experiments quickly showed that the opine and phytohormone biosynthetic genes within the T-DNA in the bacteria could be replaced by other genes, and the T-DNA could still be transferred to the plant nucleus, carrying with it these foreign genes. Following this observation, researchers immediately realized that novel traits could be introduced into plants through T-DNA-mediated DNA transfer. These investigators quickly developed methods for *Agrobacterium*-mediated plant transformation. From the transformed cells, transgenic plants, genetically engineered to contain foreign DNA, can be generated. Such transgenic crops are now widely grown in North America. We will examine the technique of *Agrobacterium* transformation as a biotechnology tool in **Toolbox 12.3**.

Even though *Agrobacterium*-based transformation systems can introduce foreign DNA into the cells of some plant types, the cells of other plants cannot be readily transformed. Unfortunately, plants in this resistant group include agriculturally important crops such as wheat, barley, and rice. These monocots are not naturally susceptible to crown gall. Diligent research, often

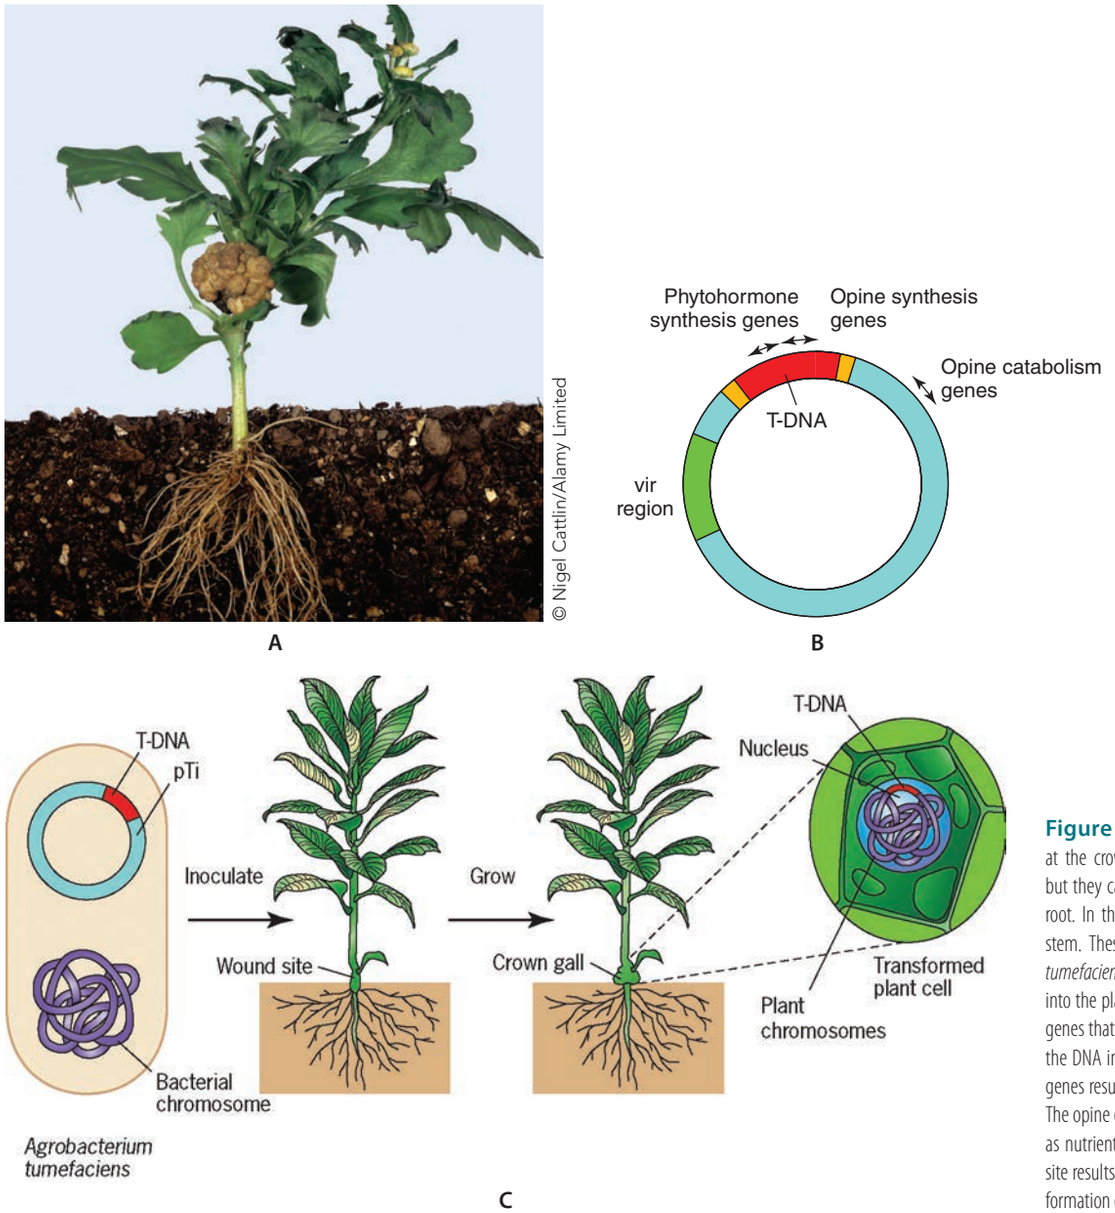

Figure 12.30. Crown gall **A.** Tumors can form at the crown of the plant, where the roots meet the stem, but they can also form elsewhere, even below ground on the root. In this photo, the tumor has formed higher up on the stem. These tumors result from infection by *Agrobacterium tumefaciens*. **B.** The pTi contains T-DNA that is transferred into the plant cell through the action of the products of the *vir* genes that act on the ends of the T-DNA. Once in the plant cell, the DNA inserts into the plant genome, and expression of the genes results in the production of phytohormones and opines. The opine catabolism genes confer the ability to use the opines as nutrient. **C.** *Agrobacterium* cells inoculated into a wound site results in transfer of the DNA into the nucleus, causing the formation of the crown gall tumor.

focused on immature embryos, has resulted in the optimization of *Agrobacterium* transformation for some of these plant species. Other methods of introducing DNA into plant cells include protoplast transformation, in which the cell wall is removed prior to introduction of DNA, and particle gun biolistics transformation, in which metal fragments coated with DNA are fired into the cells. Once inside the cell, foreign DNA can be taken up by the nucleus and then integrated into the genomic DNA.

Applications of transgenic plants

Once it had been demonstrated that transgenic plants could be generated, researchers then considered which traits to introduce into the major crop plants such as corn, soybean, cotton, canola, and rice. Two traits targeted for engineering into crop plants were tolerance to nontoxic herbicides and resistance to insect pests. In both cases scientists turned to microbes to find useful genes for these traits. Here, we will briefly examine both of these examples.

Herbicide Tolerance

Weeds are the bane of all farmers, big and small. For the home gardener, weeds can be physically removed by plucking them one at a time. That approach certainly will not work for farmers who oversee crops covering hundreds or thousands of hectares! To make the large-scale farmers' job a bit easier, several companies produce a broad-spectrum herbicide marketed as Roundup. The active ingredient in this herbicide, glyphosate, is a derivative of glycine (*N*-phosphonomethyl-glycine; **Figure 12.31**). Plant tissues absorb glyphosate efficiently, which then inhibits the activity of the plant 5-enolpyruvylshikimate-3-phosphate (EPSP) synthase, an enzyme in the aromatic amino acid synthesis pathway. Inhibition of EPSP synthase blocks the production of the aromatic amino acids phenylalanine, tryptophan, and tyrosine.

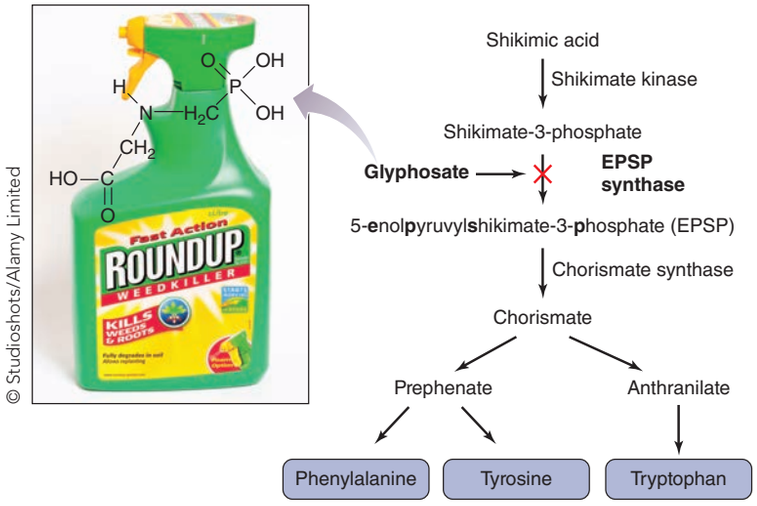

Figure 12.31. Glyphosate Glyphosate is a specific inhibitor of the EPSP synthase enzyme, which catalyzes a key step in the synthesis of aromatic amino acids. It is a very effective herbicide. Humans and other mammals do not contain the aromatic amino acid synthesis pathway because they do not produce these amino acids. This greatly reduces the likelihood of human toxicity.

No longer able to produce these amino acids, plants treated with Roundup die. Humans and other mammals do not possess this biosynthetic pathway and, as a result, must acquire these essential amino acids from their diet. The lack of this aromatic amino acid synthesis pathway also means that glyphosate is not toxic to mammals, a very desirable trait for any pesticide.

Unfortunately, glyphosate is toxic to most crop plants, which meant that farmers could spray it on their fields to kill weeds only before planting crops. Scientists tried for many years to isolate glyphosate-tolerant plants by selection so they could use glyphosate after planting as well. These efforts met with little success. Then microbes came into the picture. Several soil microbes exhibit resistance to glyphosate and actually metabolize it, rapidly removing it from the soil. Scientists at the Monsanto company isolated the EPSP synthase gene from one of these bacterial isolates, *Agrobacterium* sp. CP4, and confirmed the resistance for the expressed enzyme to glyphosate. Next, they attempted to introduce this gene into plants. Because plant EPSP synthase enzymes localize to chloroplasts, the researchers fused the *Agrobacterium* version of the EPSP synthase gene to DNA encoding the chloroplast transit portion of the petunia EPSP synthase gene **(Figure 12.32)**. When expressed in plant cells, they reasoned that the resulting fusion protein would be transported to the chloroplast. The investigators then introduced the gene fusion construct into soybean cells using particle gun biolistics transformation and generated transformed plants successfully. Screening of these transgenic plants identified lines exhibiting glyphosate tolerance. In other words, these plants exhibited tolerance to Roundup. Since the development of these first "Roundup Ready" plants, glyphosate tolerance has been incorporated into several major crop plants including corn, cotton, soybean, and canola. Farmers planting these herbicide-resistant transgenic plants can now use Roundup to control weeds throughout the growing season. Glyphosate tolerance is not the only herbicide tolerance engineered into crop plants using microbial means.

Toolbox 12.3
PLANT TRANSFORMATION USING BACTERIA

Known for its efficiency, *Agrobacterium*-mediated transformation involves replacing the normal genes within the T-DNA with genes to be introduced into a plant. This can be done using a binary vector system. One *Agrobacterium* strain houses a modified pTi with *vir* genes that encode the DNA transfer ability but from which the T-DNA region has been deleted **(Figure B12.9)**. A separate plasmid contains the 25-bp borders of the T-DNA between which the DNA to be transferred is cloned. This plasmid can be easily maintained in *Escherichia coli* until the desired gene is transferred to a plant. At that time, the plasmid containing the gene is introduced into the *Agrobacterium* strain containing the vector with the *vir* genes. Transfer and expression of the modified T-DNA does not cause tumor formation because the tumor formation genes have been deleted. The modified T-DNA does include genetic markers such as genes encoding antibiotic resistance and β-glucuronidase enzyme activity. Transformed cells can easily be identified using these markers.

The process of *Agrobacterium*-mediated transformation starts with the preparation of leaf discs using a standard office single-hole puncher **(Figure B12.10)**. The discs are then immersed in a suspension of *Agrobacterium* cells that have been pretreated with an appropriate phenolic compound such as acetosyringone to ensure induction of the *vir* genes. This step is done under partial vacuum, which helps the *Agrobacterium* cells enter the plant tissue in a process called "infiltration." The leaf discs are then placed on solid plant growth regeneration medium supplemented with phytohormones to promote plant growth and antibiotics to inhibit the growth of *Agrobacterium* and non-transformed plant cells. Cell masses called "calli" that grow out of the disc and are stained blue by X-glucuronide due to β-glucuronidase activity are candidate transformants. Subsequent PCR and Southern hybridization methods can confirm that the introduced DNA is integrated into the plant genome. Because plant cells are totipotent, meaning that complete organisms made up of different cell types can develop from individual mature plant cells, fully functioning plants can be generated from the calli. These plants can then be analyzed to confirm the traits encoded by the introduced genes and bred with other varieties to combine the introduced genes with different genetic backgrounds.

Test Your Understanding

Imagine you forgot to add antibiotics to the leaf discs' growth regeneration medium. Explain why your *Agrobacterium*-mediated plant transformation process would not be successful.

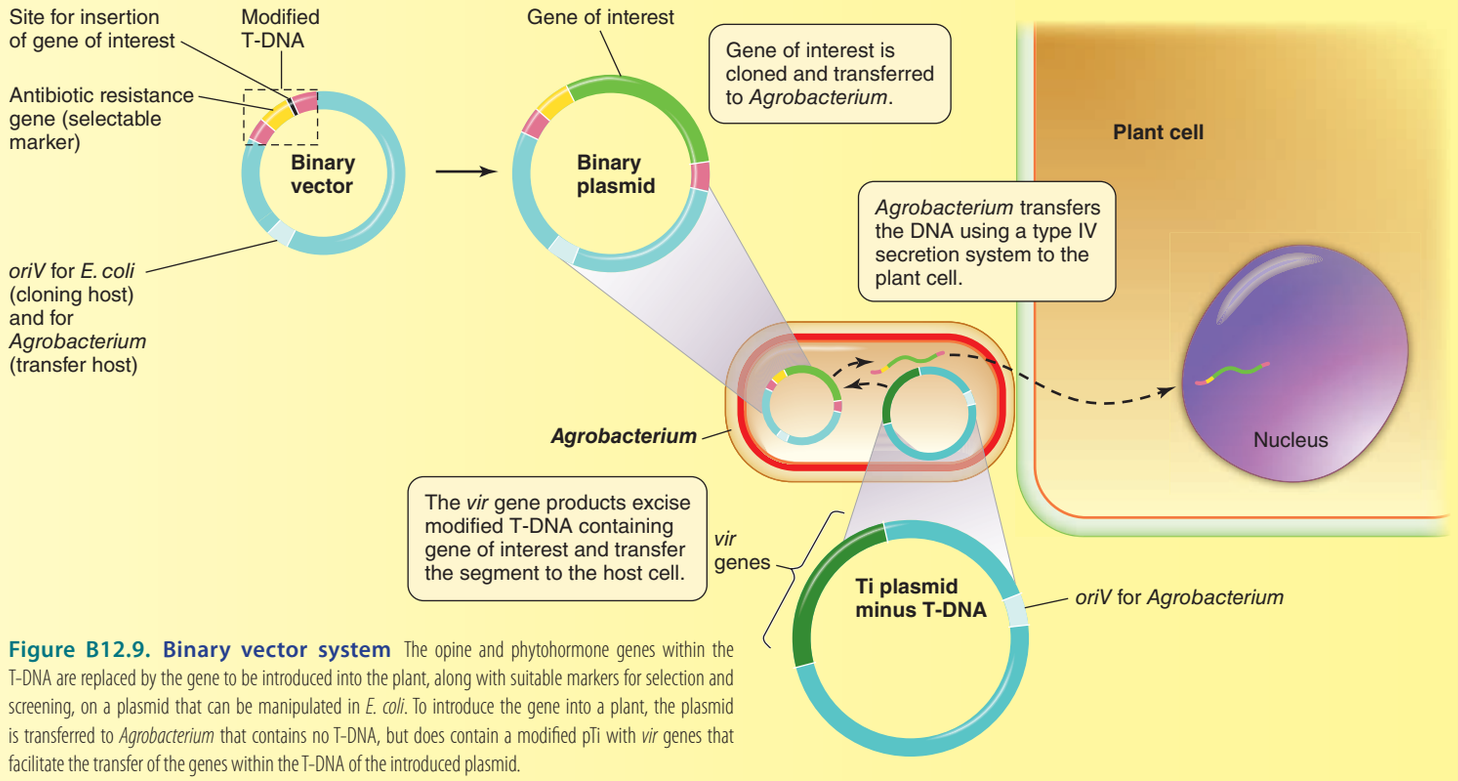

Figure B12.9. Binary vector system The opine and phytohormone genes within the T-DNA are replaced by the gene to be introduced into the plant, along with suitable markers for selection and screening, on a plasmid that can be manipulated in *E. coli*. To introduce the gene into a plant, the plasmid is transferred to *Agrobacterium* that contains no T-DNA, but does contain a modified pTi with *vir* genes that facilitate the transfer of the genes within the T-DNA of the introduced plasmid.

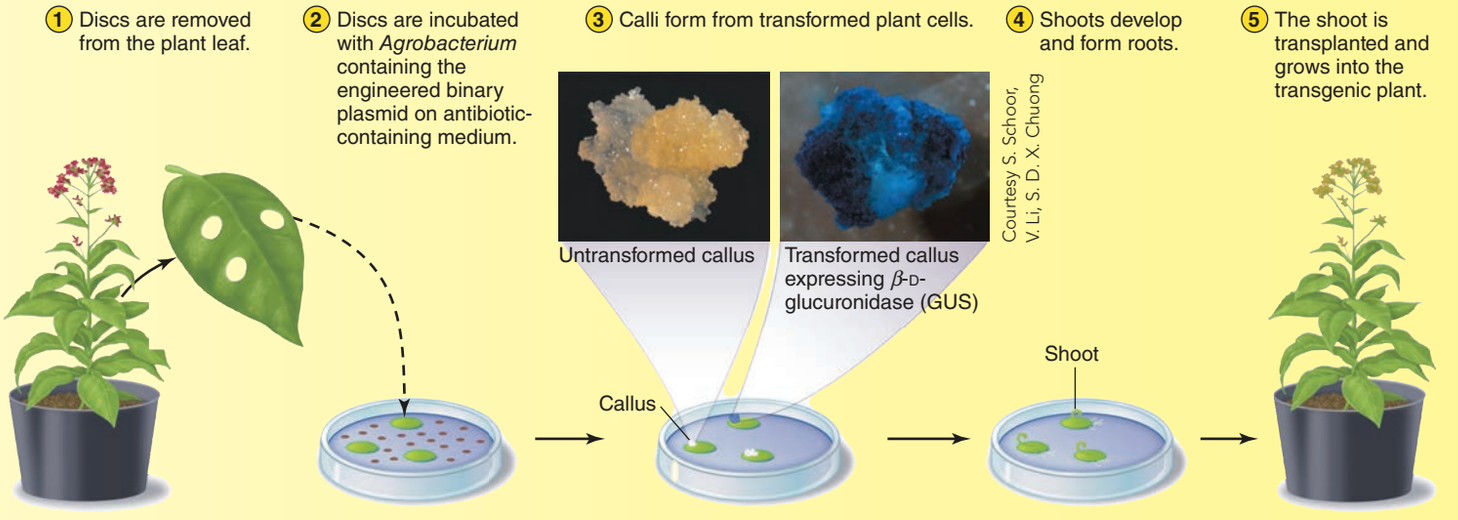

Figure B12.10. Process Diagram: *Agrobacterium*-mediated transformation After their formation, calli are transferred to media that promote the growth of shoots and roots.

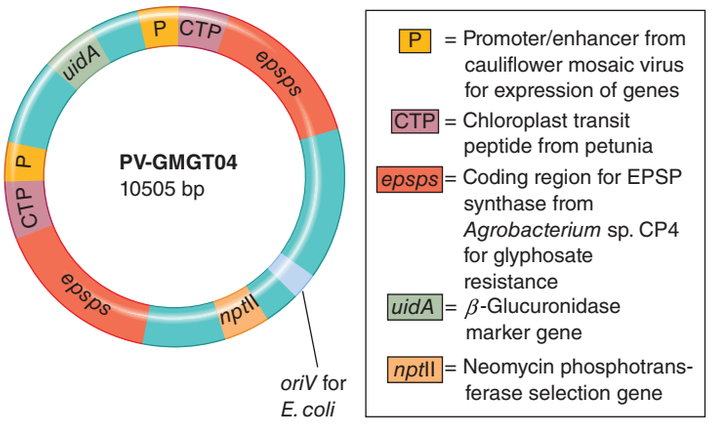

Figure 12.32. Plasmid for transferring glyphosate tolerance The plasmid construct used to introduce the *Agrobacterium* sp. CP4 EPSP synthase gene into soybean plants contains two copies of EPSP synthase gene fused to petunia chloroplast transit peptide (CTP) and under the control of plant virus promoters. The *uidA* gene from *Escherichia coli* provides a marker for the detection of successful transformation events.

Other companies have introduced genes that provide tolerance to herbicides such as glufosinate, an inhibitor of the glutamine synthetase enzyme, and 2,4-dichlorophenoxyacetic acid (2,4-D), a synthetic version of the auxin phytohormone.

Insect Resistance

Like weeds, insect pests are also a bane of farmers. To prevent extensive crop loss due to insect pests, farmers typically spray various insecticides on their fields. Although insecticides reduce insect damage to the crops, thereby increasing crop yields, this increased yield comes at a cost. Many of the chemical insecticides used in agriculture are potent neurotoxins and may have detrimental health effects on humans, livestock, and wildlife. Additionally, many of these insecticides affect non-pest species of insect as well. For these reasons, numerous groups sought alternative strategies for the management of insect pests. In particular, the study of eco-friendly insect pathogens increased in intensity during the mid-twentieth century.

One bacterial species, *Bacillus thuringiensis* **(Microbes in Focus 12.3)**, has received considerable interest. This spore-forming soil bacterium produces intracellular protein crystals called "δ-endotoxins," or "Cry proteins," associated with its spores **(Figure 12.33)**. These Cry proteins, often referred to as **Bt toxin**, have highly specific insecticidal activity against lepidopteran (moths and butterflies), dipteran (flies and mosquitoes), or coleopteran (beetles) larvae. The full-length Cry proteins are not active, but upon ingestion by the larvae, the protein crystals dissolve in the alkaline conditions of the insect midgut, where they are cleaved by proteases. The resulting active polypeptides bind to specific receptors on the gut epithelial cells, producing pores in the cell membrane, thus disrupting the osmotic balance and killing the insect. In a natural setting, killing of insect larvae by *B. thuringiensis* likely provides a source of nutrients for vegetative growth of the bacteria. When it was found that some *B. thuringiensis* strains contained multiple Cry proteins of differing specificities, scientists could target specific agricultural pests while keeping the level of human toxicity extremely low. Spores of *B. thuringiensis* or the crystals themselves have been used in a spray since the 1920s as a natural biological insecticide in forestry and agriculture.

Microbes in Focus 12.3
BACILLUS THURINGIENSIS: THE NATURAL, SAFE INSECTICIDE

Habitat: First isolated and described in Japan in 1902; soil bacteria are pathogenic to insects but not mammals. Often found in insect guts and on plants

Description: This rod-shaped member of the *Firmicutes* phylum has a typical Gram-positive cell structure, averaging about 1 μm in width by 5 μm in length. Heat and desiccation-resistant endospores are formed, as well as spore-associated crystal proteins called δ-endotoxins, which are insecticidal. The genome size ranges between 5.3 and 6.2 Mb, depending on the strain.

Key Features: Commonly known simply as Bt, the major distinguishing feature of this bacterium is the production of δ-endotoxins. Upon ingestion by an insect, the high pH of the insect midgut activates the toxin. The toxin then binds to the intestinal epithelial cells, forming pores that cause cell lysis. Each toxin affects a defined range of insects. Bt is used as an insecticide spray and the toxin genes have been expressed in transgenic plants, resulting in resistance of the plants to insect pests.

© SciMAT/Science Source

CONNECTIONS We saw in **Perspective 9.1** that *B. thuringiensis* is closely related to the animal pathogen *Bacillus anthracis*. Both of these pathogens appear to have arisen from the common soil bacterium *Bacillus cereus*. The major difference between these species is the presence or types of virulence plasmids, which are transferable by conjugation.

Soon after discovering the genes that encode the Cry proteins, researchers successfully expressed these genes in other bacteria, like *Pseudomonas fluorescens*, which is a bacterium that commonly interacts with plants. Some of these recombinant bacterial strains were cultured for use as sprays for plant protection. As methods for making transgenic plants were developed, the introduction of insect resistance via the *B. thuringiensis* Cry proteins became an obvious priority. In 1987, scientists published the first reports of successful generation of Bt toxin transgenic plants using *Agrobacterium*-mediated T-DNA transfer. Scientists at the biotech companies Plant Genetic Systems in Belgium, and Agracetus in Wisconsin, worked with transgenic tobacco, a commonly used experimental model crop plant. Scientists at Monsanto in St. Louis, Missouri, worked with transgenic tomato. When the transgenic plants were challenged with lepidopteran larvae, not only was there a reduction in damage, but larvae that fed on these plants were killed within a few days **(Figure 12.34)**.

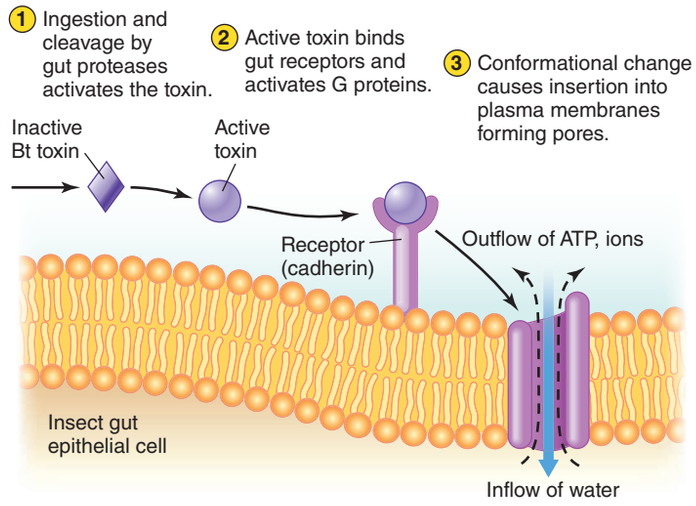
B. Cry protein (Bt toxin) crystals



C. Action of Bt toxin

Figure 12.33. Process Diagram: *Bacillus thuringiensis* crystals and mode of action **A.** Bt crystals are commercially produced and widely marketed for insecticide use. **B.** This electron micrograph shows intracellular protein crystals that are produced during sporulation and have insecticidal activity that is only activated after ingestion by the larvae. **C.** After the toxin is activated, it binds to cadherin receptors in the membranes of gut epithelial cells, where it forms a pore that increases permeability to water, cations, and ATP, resulting in cell lysis.

Following these demonstrations, scientists soon introduced Bt toxin genes into major crops, such as corn and cotton. These insect-resistant transgenic crops gained popularity very quickly, currently accounting for over 80 percent of the acreage planted in the United States. Despite this success, which drastically reduces the use of insecticide spray, there is some concern that Bt toxins could affect closely related non-target insect species. The biological significance of this non-target species toxicity remains a topic of active debate. Also, we know that insects tend to evolve resistance to conventional insecticides, and not surprisingly, resistance to Bt toxin has been reported for some insect species. Management of such resistance commonly involves planting a certain amount of non-Bt crop alongside the Bt crop, which slows the rate at which Bt resistance in the target insect pest arises.

Figure 12.34. Transgenic tobacco expressing Bt toxin The expression of Bt toxin in transgenic plants such as transgenic tobacco (*left*) showing resistance to tobacco hornworm larvae, compared to the non-transgenic leaf (*right*), can be very effective at preventing major crop losses due to insect predation while avoiding the use of chemical insecticides.

12.5 Fact Check

1. Describe the process of using *Agrobacterium tumefaciens* and its pTi for plant transformations.
2. Explain the process that was used to generate Roundup Ready plants.
3. What is Bt toxin, and how is it used in agriculture?

Image in Action

WileyPLUS Learning Space The Petri dishes on the lab bench have a thick white lawn of *Staphylococcus* bacteria growing on them, as well as large colonies of *Penicillium chrysogenum* (green with white edges). *Penicillium* produces an antibiotic that inhibits the growth of *Staphylococcus*, resulting in a clear halo that surrounds the colonies. The structure of penicillin, the antibiotic derived from *Penicillium*, is shown in the ball-and-stick model above, and a prescription bottle filled with penicillin tablets is shown in the lower left.

1. Explain why the bacterium in this image would naturally produce a secondary metabolite that inhibited bacterial growth and why this understanding leads bioprospectors to continue searching for antimicrobial compounds in nature.
2. Imagine you are asked to use mutagenesis techniques to improve the penicillin production in this mold. Identify and explain some mutagenesis options that are available to you for this task.

The Rest of the Story

After the commercialization of penicillin, the antibiotic industry blossomed. Several classes of antibiotics were discovered, mostly produced by actinomycetes of the genus *Streptomyces*. Currently, though, the discovery of new antibiotics has slowed. Given the increasing incidence of pathogenic bacteria that exhibit resistance to all existing antibiotics, the need for new classes of antibiotics has become critical.

Malaria is one of the most serious human diseases in the world. Transmitted by the bites of infected mosquitoes, it is caused by the *Plasmodium falciparum* parasite (see Section 23.2). The parasite multiplies in the liver and then infects red blood cells. Symptoms, including fever, headache, and vomiting, appear 10–15 days after infection, and if not treated, can become life threatening by disrupting blood supply to vital organs. Half of the world's population is at risk for malaria. The disease causes 1–3 million deaths annually, and accounts for 20 percent of all childhood deaths in Africa. The main therapeutic in use is chloroquine, which interferes with the parasite's ability to detoxify the heme by-product of its hemoglobin breakdown. While this treatment is quite effective, resistant strains of the parasite pump the chloroquine back out of the cell.

In searching for an alternative therapy, researchers observed that extracts from the sweet wormwood plant *Artemisia annua*, as used in traditional Chinese medicine, cleared the parasite effectively. However, extraction of artemisinin, the active ingredient, is very labor intensive and not very reproducible. In a heroic effort, using the principles of synthetic biology, Jay Keasling and coworkers at the University of California at Berkeley and Amyris Biotechnologies re-engineered the pathway for artemisinin synthesis in bacteria, and then yeast, using mostly bacterial and yeast genes. For one of the key last steps, they cloned the key cytochrome P450 encoding gene from the sweet wormwood plant and introduced it into their production strain to complete the pathway. The resulting recombinant yeast efficiently produced artemisinic acid, from which artemisinin can be obtained by a one-step chemical conversion. Using biotechnology, researchers generated a microorganism that could produce a life-saving biological compound that is difficult to obtain in nature. Building on this success, this company has gone on to apply similar strategies to the biotechnological production of molecules for applications such as cosmetics, fuels, and lubricants.

Summary

Section 12.1: What microbes and genetic materials are available for biotechnology applications?

Microbes that are used for biotechnology applications are all derived from isolates that originate in natural environments. Most of them have been improved by mutagenesis, screening for enhanced properties, and genetic engineering.

- Beginning with agriculture, over thousands of years humans have taken organisms from the wild and used them for production of food and materials.
- Microbes originating from natural environments are the basis of **biotechnology**, but they are not optimized for biotechnology processes; molecular biotechnology involves genetic engineering of organisms for the production of commercial products.
- **Red biotechnology** is related to medical applications, **white biotechnology** is related to industrial applications, and **green biotechnology** is related to the agricultural sector.
- **Culture collections** provide sources of different types of microbes that can be used in biotechnology.
- **Bioprospecting** is often necessary to obtain microbes with characteristics that are useful or critical for specific biotechnology applications.
- Because most organisms have not been cultivated, the use of cultivation-independent methods such as metagenomics can provide rich sources of genetic material that can be useful in biotechnology applications.
- **Fermentation** in biotechnology refers to the conversion of biomass from one form to another by microbial cell cultures.
- **Bioreactors** are production systems in which cell growth is closely regulated through control of culture conditions.
- **Fed-batch reactors** add a growth-limiting nutrient over time, controlling the growth rate and resulting in very high cell densities.
- **Chemostats** are continuous bioreactors in which an equivalent amount of culture is removed as new medium is added, resulting in very precise control of growth rate and maintenance of physiological steady state.
- **Primary metabolites** are produced during exponential growth; **secondary metabolites** are produced in stationary phase.

Section 12.2: How can molecular biology tools be used to improve microbial strains?

Random mutagenesis, followed by phenotypic selection or screening, can be very effective at yielding strains that are better producers. Because detrimental mutations can also accumulate, this often results in strains that have reduced vigor. The use of molecular biology allows the genetic changes to be targeted to a particular gene, or collection of genes, reducing the chance of creating unwanted genetic changes.

- **Site-directed mutagenesis** allows the construction of precise sequence changes in a gene or in an organism's genome.
- **Directed enzyme evolution**, using methods such as **error-prone PCR** and **DNA shuffling**, is used to improve strains by limiting mutations to a particular gene of interest.
- **Expression vectors** have been developed for several different types of cells, ranging from bacterial to mammalian cells, and have been developed as popular host organisms to be used as the basis of production systems.
- Expression of a eukaryal gene in a bacterial host often uses complementary DNA (cDNA), produced from an mRNA

transcript using reverse transcriptase, inserted into an expression vector.

- **Fusion** or **tagged proteins** contain domains of more than one protein, often including an **affinity tag** that helps in protein purification.
- **Synthetic biology** is an emerging discipline in which the goal is to design and build novel organisms with defined specifications to carry out desired tasks.

Section 12.3: What role do microbes play in pharmaceutical biotechnology?

The pharmaceutical industry is heavily reliant on microorganisms as production organisms. Although some of the products are derivatives of natural products, others are based on human proteins that can be produced in microorganisms using genetic engineering methods.

- The two major uses of microbes in the pharmaceutical industry are as the producers of secondary metabolites with therapeutic properties and as hosts for the production of recombinant human proteins such as hormones.
- Antibiotics that are produced naturally by bacteria and fungi have been major contributors to improved public health.
- Improvements of strains and fermentation techniques have resulted in drastic reductions in production costs for antimicrobial drugs.
- Statins, produced by several fungi, are an important class of drugs that inhibit cholesterol synthesis.
- *Streptomycetes*, which are filamentous bacteria, are the major producers of antibiotics.
- Several human proteins have been produced using recombinant methods and are used as therapeutic drugs.

Section 12.4: What role do microbes play in industrial biotechnology?

Most industrial biotechnology is based on microbial conversion of low-cost biomass to products that have higher value. Biotechnology is likely to become more important as society transitions to an economy that is based more on biomass than on fossil fuels.

- In **biorefineries**, a broad range of chemicals and **feedstocks** can be produced through fermentation of biomass feedstock.
- A key to successful fermentation of biomass feedstock is the ability to break down cellulose, which is very resistant to microbial degradation, but it can be achieved with the help of cellulose-degrading enzymes.
- Production of ethanol from lignocellulosic biomass rather than from cornstarch would result in greater environmental and energy benefits, but this requires the conversion of lignocellulose to fermentable substrate.
- Butanol and acetone fermentation was well established in the early part of the twentieth century, but this production was supplanted by petrochemical sources, although there is renewed interest as fossil fuel costs rise.
- Bioplastics based on **polyhydroxyalkanoates (PHAs)**, such as **polyhydroxybutyrate (PHB)**, represent natural storage compounds within bacterial cells that are used as biodegradable replacements for fossil fuel-derived plastics.
- **Transgenic plants** have been engineered to produce bioplastics.
- Enzymes, as **biocatalysts**, are used in many industrial processes due to their high-specificity and low-energy requirements.
- **Antimetabolites**, which interfere with physiological reactions due to their similar structure to natural compounds, can often be used to select for mutants that overproduce desired products.

Section 12.5: What role do microbes play in agricultural biotechnology?

The use of biotechnology to improve crop plants has resulted in the introduction of traits such as yield increase, insect resistance, and resistance to nontoxic herbicides that can then be used for enhanced weed control without harming the crop plant.

- One of the most effective methods to introduce genes into plants is through the natural genetic engineer, the bacterium *Agrobacterium tumefaciens*.
- Other methods of plant transformation, such as protoplast transformation and biolistics transformation, have also been developed and are widely used.
- Crop plant resistance to the herbicide glyphosate, based on introduction of the bacterial EPSP synthase gene, allows the use of glyphosate throughout the growing season to control weeds.
- **Bt toxin** has been used for several years as a spray insecticide, and genes for Bt toxin are now used extensively for the production of crop plants that are resistant to insect damage.
- Hundreds of different crop plant species have been produced by transformation methods, and this has revolutionized plant biology research and the ability to produce improved breeds of crop plants.

Application Questions

1. The Nature Conservancy reports that 70 percent of the plants identified by the U.S. National Cancer Institute as useful in the treatment of cancer are found only in rain forests. Explain how a bioprospector might have played a role in determining this statistic. Next, explain how biotechnology would play a role after the bioprospecting stage is completed.
2. Imagine you are taking part in an online discussion about the safety of rBGH (recombinant bovine growth hormone). One person comments that he's heard recombinant proteins are bad but he doesn't even know what they are. Explain what a recombinant protein is and why his blanket statement isn't completely true by describing an example of a recombinant protein used in medicine.
3. Bioplastics are biodegradable, while fossil fuel-derived plastics are resistant to degradation by microorganisms. Explain what is thought to account for this difference.
4. A novice researcher is doing research on ethanol production using a strain of yeast. She gives her yeast strain the right conditions, and they begin producing ethanol, but ethanol production always stops at a certain point and no more is made. Explain to the researcher why this is happening. How could she use biotechnology methods to get around this?

5. You are working for a new biotechnology company as a lab technician. Because the company is competing with others, their work is proprietary and kept secret. As a technician, you are given individual tasks but are not always sure what they will be used for. You are currently working on cloning the gene for PHA polymerase and expressing it in a new strain of *Escherichia coli*. What is this enzyme used for, and what does this tell you about the goals of this start-up company?
6. High fructose corn syrup (HFCS) is a widely used sweetener produced from cornstarch. Your lab partner has heard of this chemical but doesn't understand what it is or where it comes from. Explain to her how it is produced, including enzymes used in its production, what reactions those enzymes catalyze, and how microbes are involved in the process.
7. Explain the action of an antimetabolite. Then explain how one might be used as an antimicrobial treatment.
8. Imagine you are asked to use an antimetabolite in a biotechnology lab that is attempting to overproduce a specific vitamin by altering the synthesis pathway. What role might the antimetabolite play in this situation?
9. Although there are those who oppose the use of transgenic crop plants, there are also arguments that they have the potential to reduce the amount of synthetic chemicals used in plant agriculture. Describe an example to illustrate this point.
10. A research team is attempting to develop an edible vaccine. Their overall strategy is to get certain microbial proteins expressed in a tomato plant (specifically, the tomato fruit itself). Outline and explain how *Agrobacterium tumefaciens* could be used to introduce these microbial proteins into the tomato plant.
11. The enzyme glutaminase may be a possible cancer treatment, as it has some ability to inhibit tumor growth. Outline and describe steps you would use to carry out directed enzyme evolution to produce an improved cancer-fighting glutaminase enzyme. Be specific in describing your mutagenesis and screening approaches.
12. A microbiologist has isolated a *Streptomyces* strain with a novel antimicrobial activity. You have identified a unique enzyme in this strain responsible for the activity.
    a. You believe the activity could be increased to improve the antimicrobial. Outline several biotechnology approaches you could use to increase the efficiency of this enzyme's action.
    b. Explain how you would go about producing this enzyme using biotechnology methods.

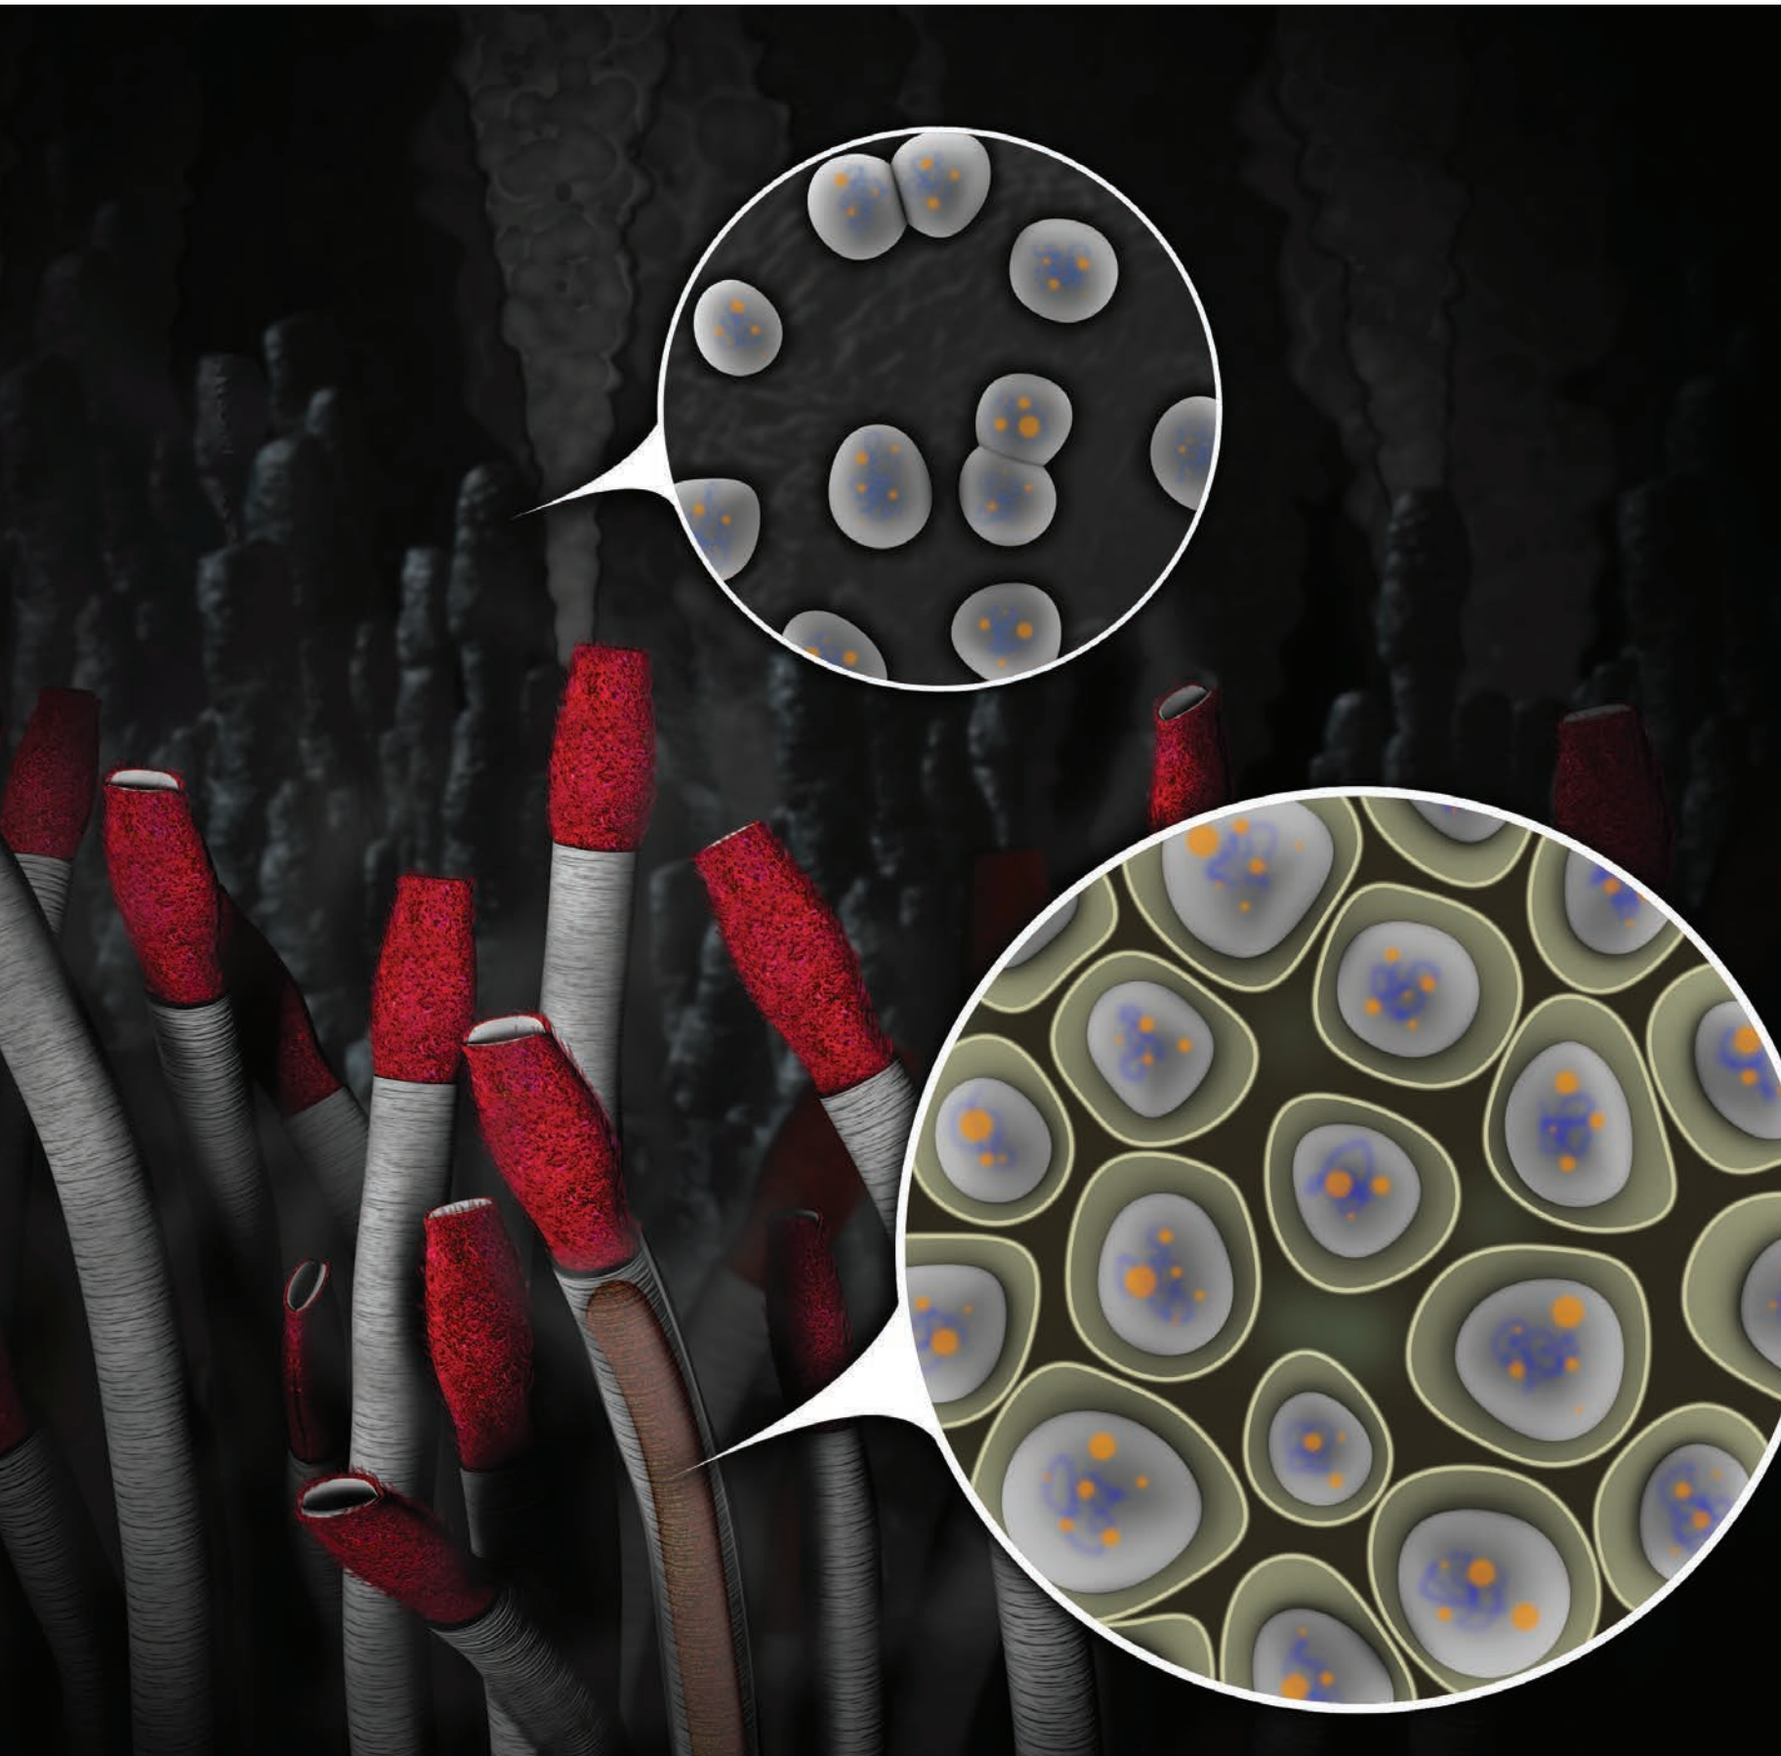
CHAPTER

13 Metabolism



In the depths of the ocean, several kilometers below the surface, there are places where volcanic gases spew from Earth's crust into the dark, cold water. These hydrothermal vents release hydrogen sulfide and methane, deadly toxins for most forms of life. When deep sea submersibles first discovered and explored such sites in the late 1970s, to the initial astonishment of the scientific community, rich communities of invertebrates, fish, and microorganisms were revealed, thriving in a harsh environment largely disconnected from the biosphere far above. The most striking residents of this ecosystem are giant tube worms, *Riftia pachyptila*, averaging 2 meters in length and estimated to live 250 years.

Closer analysis of the tube worms, using samples returned by submersibles such as the *Alvin*, found that they have no mouth and no digestive tract! Unlike their smaller, shallow-water relatives, these giants are totally dependent on chemolithoautotrophic bacteria living inside their bodies for their nutrition. Chemolithoautotrophs are microorganisms that can fix inorganic carbon, carbon dioxide in this case, to make organic molecules using chemical energy obtained through the oxidation of inorganic reduced compounds, such as hydrogen sulfide (H_2S). The chemolithoautotrophs harbored by the tube worms support this unique ecosystem in complete darkness.

This remarkable relationship between the tube worms and the bacteria begins with tube worm larvae, which do have digestive tracts and feed on microorganisms in the water surrounding the vents. As the larvae develop and settle, they become infected with a single species of free-living bacteria from the surrounding area. The bacteria move through the tube worm's skin into deeper tissue. The infected tissue organizes into a specialized organ called the trophosome. This organ virtually fills the central core of the tube worm's body. Once the bacteria are established, the worm's gut and mouth degenerate as they commit to an intimate partnership with the bacteria. The worms depend completely on the bacteria to supply compounds for the biosynthesis of all their sugars, fatty acids, and amino acids, as well as oxygen for cellular respiration. How do the bacteria produce compounds to feed their host in the absence of light for photosynthesis? The answer is not completely known because the tube worms do not survive in the laboratory, but molecular biologists have started to analyze the genome and proteome of both the tube worm and the bacteria to uncover the genes involved in metabolism.

Many intriguing questions surround the tube worm and bacteria relationship. For example, the tube worm captures H_2S, a compound that is toxic to most animal cells, from the surrounding waters and delivers it to the bacterial partner for oxidation. Shouldn't this activity kill the tube worm? Even more curious is the fact that the concentration of H_2S in the waters of the ecosystem is not sufficient to support the large number of bacteria found in the tube worms. How then do these bacteria maintain an adequate supply of H_2S? Are the worms somehow not only able to tolerate but *concentrate* this toxic compound for the bacteria?

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

ATP transfers energy from catabolism to reactions needed for biosynthesis.

Antimicrobial drugs that target nucleic acid synthesis **(Section 24.2)**

Introduction

The diversity of microbial metabolic pathways is truly astonishing. Indeed, the ability of microorganisms to live in extraordinarily diverse habitats on Earth depends on their ability to use a wide variety of energy and nutrient sources. The reactions any organism can carry out are ultimately limited by the set of enzymes that are encoded in the genome. Many, perhaps most, of the enzymes that *could* be synthesized from the set encoded in any microbial genome are *not* produced in appreciable amounts at any given time because they are useful, and therefore expressed, only in a limited range of environmental conditions.

Macromolecule synthesis consumes most of a cell's metabolic resources during active growth. However, the metabolic diversity of microorganisms truly manifests itself in the variety of ways that cells acquire nutrients, extract energy, and generate the precursors for macromolecular synthesis. The number of metabolic pathways collectively available to microorganisms means they can utilize a vast array of molecules unavailable to most multicellular organisms. This allows microorganisms to operate in environments that most multicellular organisms cannot tolerate, such as anoxic environments.

All organisms must use energy sources available in their environment to produce adenosine triphosphate (ATP), which is needed for all mechanical and biosynthetic processes in the cell. The source of energy needed to synthesize ATP in animals is limited to preformed organic matter, such as carbohydrates and proteins, obtained by consumption. In animals, these molecules are also the sole source of carbon. Microorganisms are not so limited. Collectively, they have a multitude of metabolic pathways that allow them to use inorganic as well as organic sources of energy. Like plants, many can use the energy of light and carbon dioxide (CO_2) to generate chemical energy and carbon compounds, respectively. A large number of bacteria and archaea obtain all their energy needs from inorganic molecules found in their environment, such as hydrogen sulfide (H_2S), ammonia (NH_3), and ferrous iron (Fe^{2+}). This independence from preformed organic molecules for energy and carbon assimilation means that many microorganisms can exploit habitats that other forms of life cannot.

A single chapter cannot possibly provide full coverage of microbial metabolism. Instead, we will try to provide a useful overview, present metabolic principles that microorganisms abide by, and showcase some of the most important metabolic processes and pathways of the microbial world. This chapter will address the following questions concerning microbial metabolism:

What are the basic principles of catabolism and energy that control metabolism? (13.1)
How do cells make ATP? (13.2)
How do microorganisms utilize organic carbon? (13.3)
What becomes of the electrons generated by glycolysis and the TCA cycle? (13.4)
How do microorganisms get nutrition from compounds other than glucose? (13.5)
How do microorganisms capture light energy for ATP synthesis and carbon fixation? (13.6)
How do microorganisms use nitrogen and sulfur? (13.7)
How do microorganisms synthesize new cellular components? (13.8)

13.1 Energy, enzymes, and ATP

What are the basic principles of catabolism and energy that control metabolism?

Metabolism encompasses all the biochemical reactions occurring in a living cell. Most aspects of metabolism can be categorized as **catabolism** or **anabolism**. Catabolism refers to the breakdown and oxidation of larger molecules, yielding energy needed for anabolism, the biosynthesis of macromolecular cell components from smaller molecular units. In cells, nearly all these metabolic functions rely on enzymes to facilitate the multitude of chemical reactions necessary for metabolism. An enzyme is a molecule or complex that catalyzes the conversion of specific reactants called **substrates** into products. As a catalyst, an enzyme may participate in the reaction and, once the reaction is completed, it is returned to its prior state. Like all catalysts, an enzyme is not consumed in a reaction and can be used repeatedly.

Thousands of biochemical reactions have been identified that occur in microbial cells. Of course, not all of these reactions happen in every microorganism. The energy and nutrient sources that different microorganisms use depend on the specific enzymes that they can produce. An enzyme increases the rate of a specific chemical reaction. Without the enhancement of biochemical reaction rates provided by enzymes, life could not exist. Let's explore why this is.

Energy

Enzymes must obey the **laws of thermodynamics** that govern all energy conversions. Enzymes can only catalyze reactions that are thermodynamically possible. The first law of thermodynamics states that energy is always conserved; it cannot be created or destroyed. However, energy can be converted from one form into another. The second law of thermodynamics states that in all energy exchanges, where no energy enters or leaves the system, the potential energy of the resulting state

will always be less than that of the initial state. This means that energy will spontaneously flow from a more ordered state to a less ordered state. This is referred to as entropy, and is a measure of disorder. Large molecules will naturally break down into smaller molecules, and some energy will dissipate as heat in the process of energy transfer. The flow of energy maintains life. Cells must take in energy to maintain their organized state by building more ordered molecules from less ordered molecules. For example, nucleic acids and proteins are synthesized from simple sugars and ammonia, respectively. When cells cease to take in energy, entropy increases, metabolism cannot be maintained, and they die.

As governed by the laws of thermodynamics, in order for the reaction A + B → C + D to proceed, the products of the reaction (C and D) must have a lower "free energy" content than the reactants (A and B). When this is true, the conversion of A and B to C and D releases energy. The amount of free energy released in a chemical reaction is represented by the **Gibbs free energy**, ***G***, with the International System of Units given in joules or kilojoules per mole (kJ mol^{-1}). Calories, or kilocalories per mole, can also be used. The change in free energy in a reaction is represented as ΔG, where $\Delta G = G_{product} - G_{reactants}$. Usually, the ΔG of a reaction is measured under standard conditions of temperature, concentration, pressure, and pH, in order to make comparisons between reactions. This is indicated as $\Delta G^{\circ\prime}$. An energy-yielding chemical reaction is termed **exergonic**, and has a negative $\Delta G^{\circ\prime}$ value. An energy-absorbing reaction is termed **endergonic** and has a positive $\Delta G^{\circ\prime}$ value. The value of $\Delta G^{\circ\prime}$ must be negative in order for a reaction to proceed spontaneously.

Spontaneity implies nothing about the rate at which a reaction will occur. Reaction rate is determined by a property called **activation energy (E_A)**. We can think of E_A as the energy that must be invested before a reaction can occur. For example, to bring the chemical bonds in the substrates to a transition state where they can be broken, E_A must be invested before bonds can be re-formed in a new way to generate the product. No matter how favorable the reaction may be, getting to the products requires a transient increase in energy—the E_A—in order to break and rearrange bonds. The greater E_A, the more slowly a reaction will proceed. For most biochemical reactions to occur in the absence of an enzyme, the E_A needed for reactants to move to a transition state to form the final products is greater than the kinetic energy of the reactant molecules as they collide randomly. Even if the reaction has a very negative resulting $\Delta G^{\circ\prime}$ value, the reaction will almost never occur spontaneously. This is where enzymes are involved.

Enzymes and activation energy

The secret to the effect of enzymes on chemical reactions is that they bind the reactants, called substrates, in specific ways to lower the activation energy barrier (Figure 13.1). Conceptually, one can think of E_A as a dam separating water in two reservoirs. Reservoir 1 represents the reactants and reservoir 2 the products. The difference in height between the two reservoirs illustrates ΔG. When reservoir 2 is lower than reservoir 1, ΔG is negative, and water should flow spontaneously from reservoir 1 to reservoir 2—reactants are converted to products.

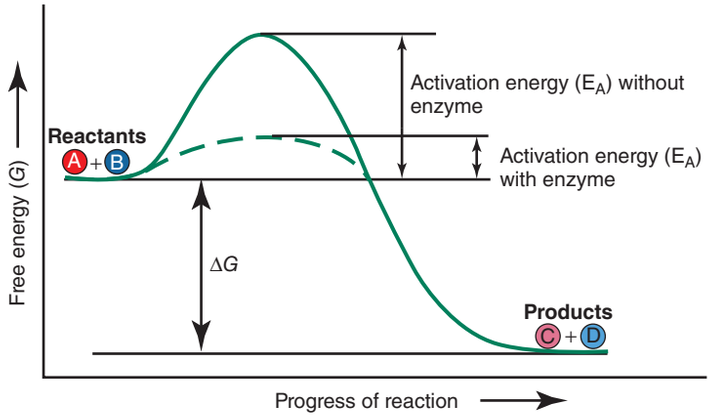

Figure 13.1. Enzymes lower activation energy In an enzyme-catalyzed reaction, the activation energy is substantially reduced compared to the energy required to form the products in the absence of the enzyme. Reducing the activation energy favors the production of products from substrates, thus enhancing the reaction rate.

What about the dam? It represents the E_A that must be supplied before water can move from reservoir 1 to reservoir 2. When the dam is high, water is less likely to move. By lowering the dam (that is, the required activation energy), an enzyme increases the rate at which products are formed.

Enzymes have many ways of enhancing reaction rates through their **active site**, the physical location where the substrates bind to the enzyme (Figure 13.2). One mechanism for increasing reaction rate is to physically position substrates properly for the desired reaction to occur, but enzymes generally function beyond this. In principle, chemical reactions proceed through a transition state between the structures of the reactants and the structures of the products. Enzymes often bind substrates in ways that move them toward the transition state. Enzymes can also provide chemical groups such as acids and bases to participate in reaction mechanisms that would otherwise be virtually impossible under physiological conditions.

Many enzymes require specific **cofactors**, which are small chemical components that are essential for catalytic activity. These cofactors participate in enzyme reactions by assisting in the transfer of functional groups (Figure 13.3). Often, the required cofactor is a tightly bound inorganic ion, such as Mg^{2+}, Fe^{2+}, Zn^{2+}, or Mn^{2+}, but it can also be a small loosely associated organic molecule called a **coenzyme**. Many coenzymes are made from precursor molecules, such as vitamins. Vitamins are broadly defined as organic compounds whose functions are essential for normal cell growth, but cannot be synthesized in sufficient quantities by the organism and must be either consumed in the diet or produced by microorganisms harbored by the host (Perspective 13.1). A vitamin is not an enzyme or a nutrient because it is not metabolized for energy, nor does it provide raw materials for biosynthesis. The availability of cofactors, such as metals and vitamin coenzymes, is one way enzyme activity can be regulated.

We can surmise that enzymes increase the rate at which substrates possessing a high potential free energy content become products with a lower potential free energy content. In this process, energy is released, resulting in a negative $\Delta G^{\circ\prime}$ value.

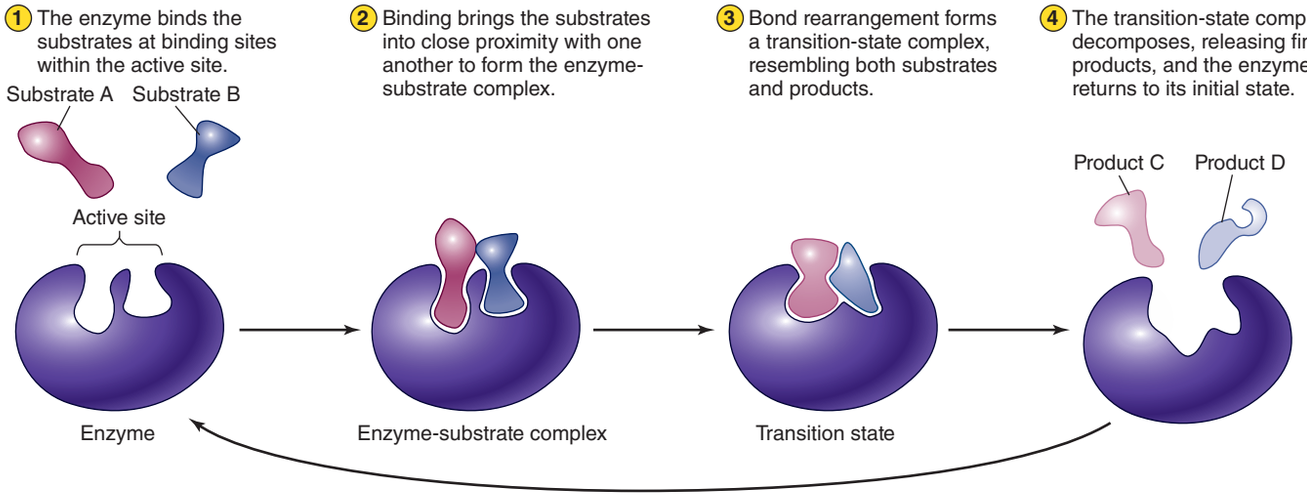

Figure 13.2. Process Diagram: Enzyme-catalyzed reaction Production of products from substrates happens in a series of steps.

However, many anabolic chemical reactions that cells carry out require energy, such as those involved in synthesizing DNA and proteins. They produce positive $\Delta G^{\circ\prime}$ values and are endergonic. How then do endergonic reactions in cells occur? In our dam analogy, this would be equivalent to reservoir 2, containing the product, being higher than reservoir 1, containing the reactants, and water still moving from 1 to 2! This cannot happen directly, but it can happen if two reactions are connected or coupled together by an enzyme so that one reaction releases energy to drive another. This is analogous to someone carrying water from reservoir 1 up to 2, expending their own energy in the process. To carry out anabolic processes, cells must use enzymes that couple endergonic reactions with exergonic reactions. When the energy released from the exergonic reaction is greater than that needed to complete the endergonic reaction, the endergonic reaction will be driven to completion.

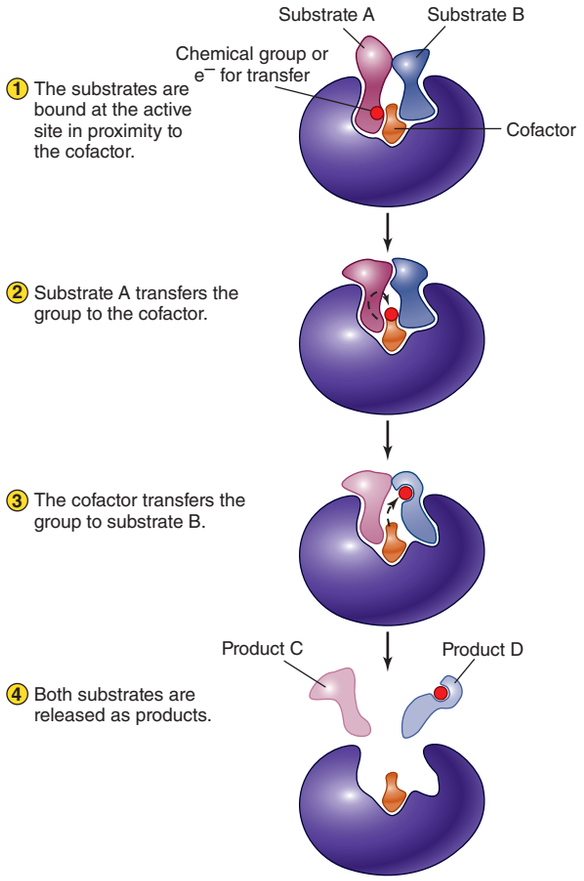

Figure 13.3. Process Diagram: The function of cofactors The cofactor is associated with the enzyme. Substrate A has a chemical group or electron to be transferred by the cofactor to substrate B.

ATP—Energy currency of the cell

We can see that cells need some internal source of energy to drive these biosynthetic coupled reactions. What is this energy source? The most widely used form of energy in the cell is **adenosine triphosphate (ATP)** (Figure 13.4). ATP contains two phosphoanhydride bonds that can be broken to allow transfer of one, or sometimes two, phosphate groups to drive endergonic reactions. The phosphate group of adenosine monophosphate (AMP) is bound by an ester linkage to the sugar and cannot be easily transferred.

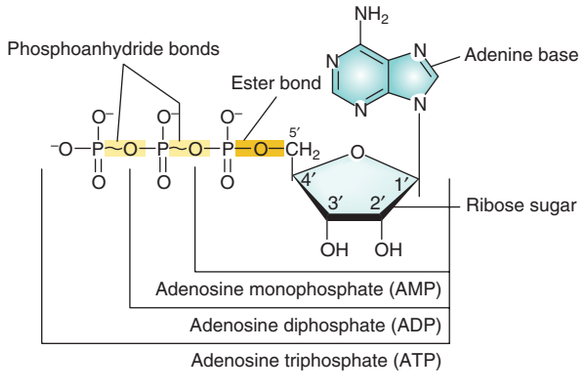

Figure 13.4. Structure of adenosine phosphate molecules ATP, ADP, and AMP all consist of a ribose sugar and an adenine base covalently bound to one (AMP), two (ADP), or three (ATP) phosphate groups.

Perspective 13.1
WHO NEEDS VITAMINS?

Growing up, your parents might have impressed on you the importance of vitamins in your diet through eating the "right" foods and taking vitamin pills. Do microorganisms need vitamins like people do? If so, why? In addition to their protein units, many enzymes require coenzymes, and several important coenzymes are derived from vitamins.

Different organisms require different vitamins in their diet, the most common of which are listed in **Table B13.1**. Humans need 13 distinct dietary vitamins, but most microorganisms need far fewer, and many have no dietary vitamin requirements, being capable of synthesizing all required coenzymes from simpler nutrients. In fact, our intestinal bacteria usually produce and excrete enough extra biotin and vitamin K_2 (menaquinone) that we do not need these compounds directly in our diet. At the other extreme, lactic acid bacteria (see Section 13.3) need nearly as many vitamins as humans and are therefore limited to habitats rich in complex organic nutrients.

In microbiology, vitamins are often referred to as "growth factors." When planning media, the need for growth factor supplements depends on the particular species and strain being used. The use of complex media components, such as yeast extract, often eliminates the need for supplemental vitamins, because the extract contains enough growth factors to support most microorganisms. When needed, vitamins are typically added to media at concentrations of 0.1 mg L^{-1} or less.

TABLE B13.1 Common coenzymes produced from vitamins and their functions

Vitamin	Coenzyme	Function
Biotin (B_7)	Biocytin	Used in carboxylase enzymes involved in fatty acid synthesis and glucose production
Cobalamin (B_{12})	Adenosylcobalamin or methylcobalamin; coenzyme B_{12}	Used in synthesis of folic acid, required for reactions involving methyl group transfer, including nucleotide and methionine synthesis
Folic acid (B_9)	Tetrahydrofolate	Used in reactions involving methyl group transfer, such as during purine and thymine synthesis. Paraminobenzoic acid (PABA), a precursor of folic acid, can also be used as a growth factor
Nicotinic acid (niacin, B_3)	Nicotinamide adenine	NAD and NADP are major electron carriers in cells.
Pantothenate (B_5)	Coenzyme A	Critical in carbon and energy metabolism, and in lipid synthesis and catabolism
Pyridoxine (B_6)	Pyridoxal phosphate	Used for enzymes involved in transamination reactions during amino acid biosynthesis, and certain deamination and decarboxylation reactions
Riboflavin (B_2)	Flavin adenine dinucleotide (FAD) and flavin mononucleotide (FMN)	Used for enzymes catalyzing numerous redox reactions
Thiamine (B_1)	Thiamine pyrophosphate	Used by enzymes that catalyze dehydrogenation and decarboxylation, including pyruvate dehydrogenase

All cells produce enzymes that allow them to convert energy sources they receive from their environment, such as glucose, to produce ATP for biosynthesis and to carry out mechanical work, such as transport of molecules across membranes or movement of flagella. One can think of ATP as the common chemical currency of the cell. In metabolism, ATP transfers energy from exergonic reactions, resulting from catabolism, to endergonic reactions needed for anabolism **(Figure 13.5)**. Anabolism uses products of catabolism, or precursor molecules acquired from the environment, for the assembly of cellular constituents that ultimately lead to the production of new cells. This is analogous to individuals (cells) earning money (ATP) to purchase needed goods (DNA, RNA, and proteins). In some

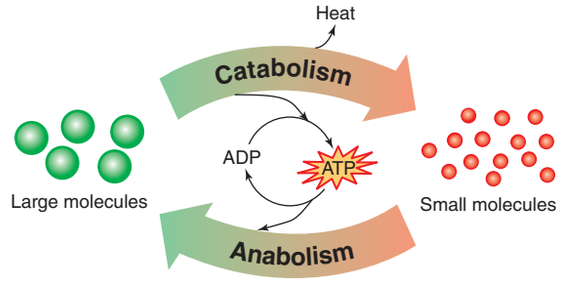

Figure 13.5. Metabolism: Energy transfer between catabolism and anabolism by ATP Catabolism is the breakdown of larger substrate molecules to generate energy and smaller metabolic products. Some energy is released as heat. Energy from catabolism can be used to synthesize ATP, which can be used for anabolism, the biosynthesis of molecules useful to the cell.

instances, functionally equivalent molecules are used to transfer energy, as in the example of guanosine triphosphate (GTP).

The potential free energy content of ATP is much higher than the potential free energy content of its hydrolysis products adenosine diphosphate (ADP; see Figure 13.5) and inorganic phosphate (P_i). This is evident from the resulting large, negative $\Delta G^{\circ\prime}$ value when ATP is hydrolyzed:

$$ATP + H_2O \rightarrow ADP + P_i \qquad \Delta G^{\circ\prime} = -30.5\,kJ\,mol^{-1}$$

Enzymes can use this energy to drive otherwise unfavorable endergonic reactions, such as the biosynthesis of macromolecules from smaller precursors. As long as there is more energy released in the conversion of ATP to ADP and P_i than is necessary to achieve the endergonic reaction, an overall negative ΔG will result, which drives the reaction strongly forward toward the products. We can look at the conversion of glucose to glucose 6-phosphate, the first step in the catabolism of glucose. The reaction can be written as follows:

$$\text{Glucose} + P_i \rightarrow \text{glucose 6-phosphate} + H_2O \qquad \Delta G^{\circ\prime} = +13.8\,kJ\,mol^{-1}$$

As can be seen from the positive $\Delta G^{\circ\prime}$ value, this reaction is not thermodynamically favorable, but if it is carried out together, that is, *coupled*, with hydrolysis of ATP ($\Delta G^{\circ\prime} = -30.5\,kJ\,mol^{-1}$), the overall reaction results in $\Delta G^{\circ\prime} = -16.7\,kJ\,mol^{-1}$. The reaction will now favor the formation of glucose 6-phosphate. We can write the combined reaction as follows:

$$\text{Glucose} + ATP \rightarrow \text{glucose 6-phosphate} + ADP \qquad \Delta G^{\circ\prime} = -16.7\,kJ\,mol^{-1}$$

Coupled reactions are commonly illustrated as shown in **Figure 13.6**, which more clearly show how two reactions interact.

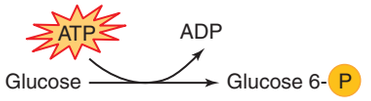

Figure 13.6. ATP-coupled endergonic reaction The conversion of glucose to glucose 6-phosphate is endergonic, but is favorable when coupled to the highly exergonic conversion of ATP to ADP. The reaction results in the transfer of a phosphate group from ATP to glucose.

It is important to note that in the enzyme-coupled reaction, the two reactions do not occur separately. If ATP were hydrolyzed to ADP, all the energy would immediately be released as heat and could not drive a chemical reaction. The enzyme that couples the reaction facilitates the stepwise transfer of the phosphate group from ATP to the substrate glucose, raising its free energy potential, and releasing the remaining free energy as heat. The products ADP and glucose 6-phosphate are then displaced and released from the enzyme.

13.1 Fact Check

1. Distinguish between the terms "metabolism," "catabolism," and "anabolism."
2. Enzymes must obey the laws of thermodynamics. Describe the laws.
3. Differentiate between exergonic and endergonic reactions and identify their relative $\Delta G^{\circ\prime}$ values.
4. Describe how enzymes enhance reaction rates.
5. What are cofactors and coenzymes, and what are their roles in enzymatic reactions?
6. What is the role of ATP in a cell?

13.2 Central processes in ATP synthesis

How do cells make ATP?

Adenosine triphosphate (ATP) is the primary energy currency used to power virtually every activity of cells from bacteria to humans. Although we have been discussing ATP as having a major role in driving endergonic chemical reactions, the potential free energy in ATP is also used to do mechanical work. How then is ATP produced by cells? Cells must carry out exergonic reactions that release even greater amounts of energy to drive the synthesis of ATP from adenosine diphosphate (ADP) and inorganic phosphorus (P_i), as shown below:

$$ADP + P_i \rightarrow ATP + H_2O \qquad \Delta G^{\circ\prime} = +30.5\,kJ\,mol^{-1}$$

As can be seen from the large positive $\Delta G^{\circ\prime}$ value, the formation of ATP is a strongly endergonic reaction. Where does the energy to synthesize ATP come from? The simplest way to produce ATP is by harnessing the potential free energy of a high-energy phosphate group from a phosphorylated intermediate molecule. This is called **substrate-level phosphorylation**.

Substrate-level phosphorylation

Substrate-level phosphorylation is an enzyme-coupled reaction that produces ATP by the transfer of a phosphate group from a reactive intermediate generated during catabolism to ADP. This reaction can occur because the transfer of the phosphate group from a molecule with high potential free energy (the intermediate) creates one of lower potential free energy (ATP). In cells, substrate-level phosphorylation occurs in chemoorganotrophs in the cytoplasm under both oxic and anoxic conditions, and begins with the breakdown of an organic molecule. Although chemoorganotrophs can use a wide variety of molecules to generate energy, one that is used by many is

glucose. We will use the catabolism of glucose to illustrate how ATP can be produced by substrate-level phosphorylation.

CONNECTIONS Recall that we were introduced to the different metabolic types of microorganisms, including chemoorganotrophs in **Section 6.1**. Chemoorganotrophs use preformed chemicals as an energy source, and organic molecules as a source of electrons. We will revisit these types in some detail later in this section.

A commonly used pathway that begins glucose catabolism for ATP production is **glycolysis** (Figure 13.7). Glycolysis, the details of which will be examined in Section 13.3, involves the catabolism of glucose to pyruvic acid (pyruvate) and can produce a total of two ATP molecules from each glucose molecule. One of the intermediate molecules generated during glycolysis is 1,3-bisphosphoglycerate. The production of 1,3-bisphosphoglycerate is one point where ATP is generated by substrate-level phosphorylation because 1,3-bisphosphoglycerate has an even greater potential free energy than ATP. From the reaction below, we can see that the transfer of the phosphate group from 1,3-bisphosphoglycerate to ADP is thermodynamically favorable in a coupled reaction:

$$\text{1,3-bisphosphoglycerate} + H_2O \rightarrow \text{3-phosphoglycerate} + P_i \qquad \Delta G^{\circ\prime} = -52\ \text{kJ mol}^{-1}$$

$$\text{ADP} + P_i \rightarrow \text{ATP} + H_2O \qquad \Delta G^{\circ\prime} = +30.5\ \text{kJ mol}^{-1}$$

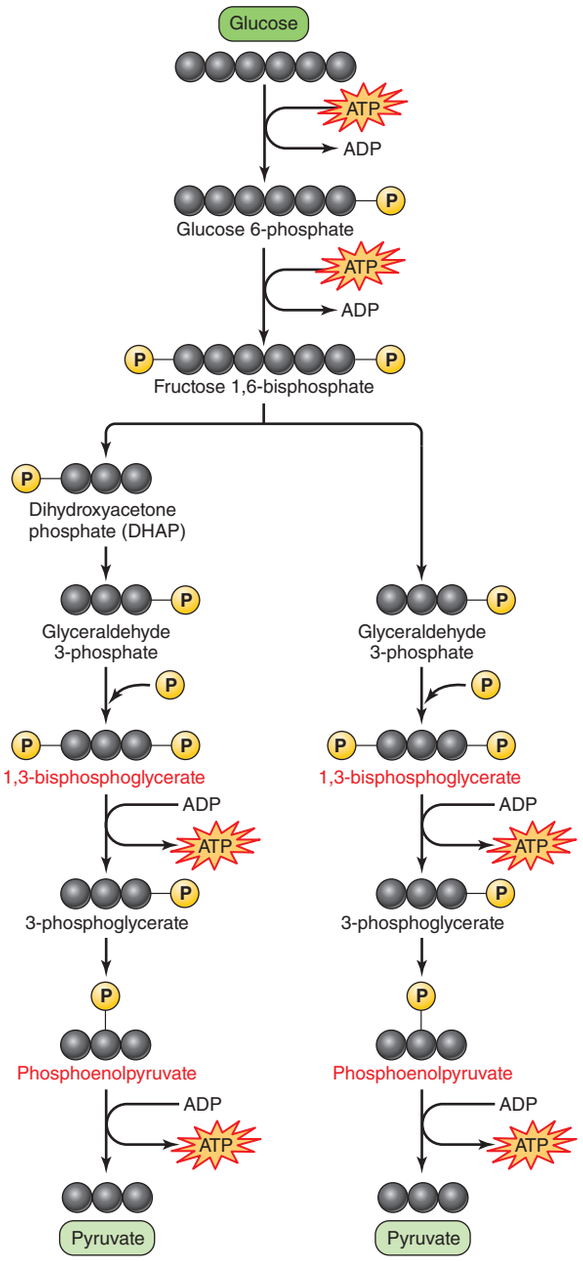
Overall reaction:

$$\text{1, 3-bisphosphoglycerate} + \text{ADP} \rightarrow \text{3-phosphoglycerate} + \text{ATP} \qquad \Delta G^{\circ\prime} = -21.5\ \text{kJ mol}^{-1}$$

In the above reaction, the catabolism of 1,3-bisphosphoglycerate releases P_i and produces 3-phosphoglycerate. The energy released, indicated by the negative $\Delta G^{\circ\prime}$ value, is used to produce a covalent bond between P_i and ADP to produce ATP. It costs energy to synthesize ATP, but as can be seen from the overall negative $\Delta G^{\circ\prime}$ value of this reaction, more energy is supplied than is needed, ensuring the reaction is driven forward to completion to produce ATP. The excess energy is released as heat. The molecule 1,3-bisphosphoglycerate is a very high-energy molecule, meaning that it has a high potential free energy, enough to drive the endergonic reaction of making ATP, itself a high-energy molecule.

Phosphoenolpyruvate represents another intermediate molecule in glycolysis that can be used to generate ATP by substrate-level phosphorylation. The enzyme that catalyzes the coupled reaction to produce ATP using phosphoenolpyruvate in the cell is pyruvate kinase. We can look in more detail at how this enzyme carries out the coupled reaction between phosphoenolpyruvate and ADP to produce ATP through substrate-level phosphorylation. Kinases are a group of enzymes that transfer phosphate groups from high-energy donors to substrates of lower potential free energy. Specific kinases are used extensively during biosynthesis to transfer phosphate groups from ATP in coupled reactions.

As shown in Figure 13.8, pyruvate kinase has two specific active sites, one for binding the substrate phosphoenolpyruvate and the other for binding the substrate ADP. Notice how the enzyme binds the substrates in close proximity to one another to facilitate transfer of the phosphate group. There is a third binding site, the allosteric site, for fructose 1,6-bisphosphate.



Compound	Energy (kJ/mol^{-1})
High energy	
1,3-bisphosphoglycerate	–52.0
Phosphoenolpyruvate	–51.6
ATP	–30.5
ADP	–30.5
Low energy	
AMP	–14.2
Glucose 6-phosphate	–13.8

Figure 13.7. Generation of ATP during glycolysis
Glycolysis is a common first step in the pathway of glucose catabolism, producing two molecules of pyruvate from one molecule of glucose. Phosphoenolpyruvate and 1,3-bisphosphoglycerate are intermediate molecules produced during glycolysis. Both molecules produce very high free energy upon hydrolysis to release a phosphate group (see table insert). This energy can drive the formation of ATP from ADP in a coupled reaction.

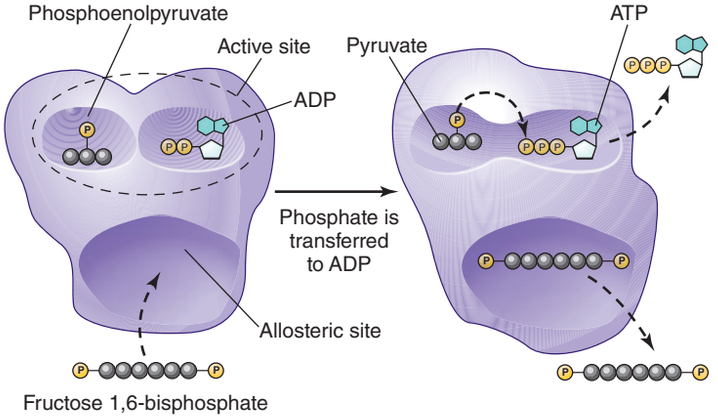


Figure 13.8. Enzymatic activity of pyruvate kinase The active site of pyruvate kinase binds the substrate phosphoenolpyruvate at one binding site and ADP at an adjacent binding site. A third site, the allosteric site, binds fructose 1,6-bisphosphate. When fructose 1,6-bisphosphate is bound, the conformation of the enzyme is modified and the two substrates are brought together, lowering the activation energy required to transfer the phosphate group from phosphoenolpyruvate to ADP to produce ATP. Fructose 1,6-bisphosphate is not changed in the reaction and its binding is reversible.

When bound, fructose 1,6-bisphosphate changes the conformation of the enzyme, bringing the two substrates even closer, lowering the activation energy required to transfer the phosphate group from phosphoenolpyruvate to ADP to produce ATP. Fructose 1,6-bisphosphate is an effector molecule in this reaction; it is not changed in the reaction and its binding to the enzyme is reversible. In biochemistry, this is referred to as **allosteric regulation**—the regulation of an enzyme's activity by binding an effector molecule at the allosteric site (Figure 13.9). The term "allosteric" is derived from the Greek word *allos*, meaning "other" and *stereos*, meaning "solid," interpreted as "other molecule" since it is bound at a site distant from that of the active site. Effector molecules that increase an enzyme's activity are known as allosteric activators, such as fructose 1,6-bisphosphate. Allosteric inhibitors can decrease activity. One such example is inhibition by ATP of the enzyme phosphofructokinase, discussed in Section 13.3 (see Fermentation). Regulation of enzyme activity is critical for microorganisms as they compete with each other for survival and growth.

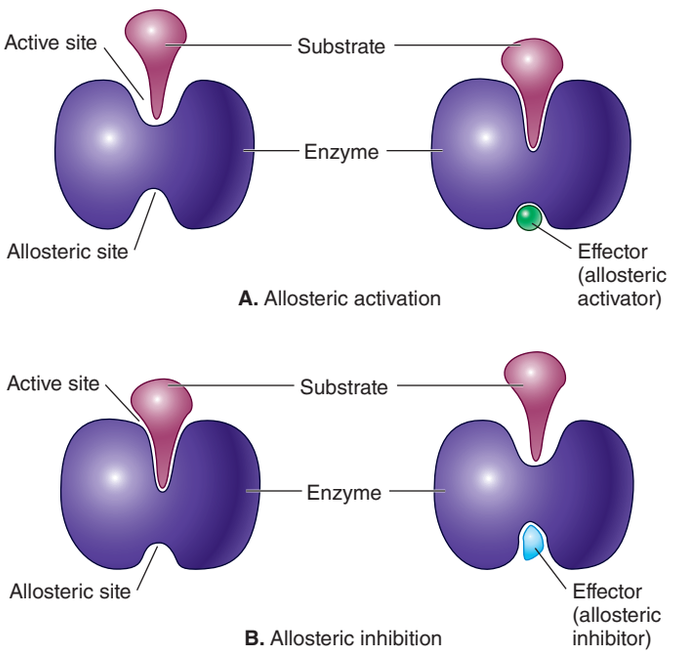

Figure 13.9. General scheme of enzyme allosteric regulation **A.** Allosteric activation requires binding of an effector molecule (the allosteric activator) to the allosteric site. Binding causes a conformational change in the enzyme that results in increased ability to bind or act on the substrate. **B.** Allosteric inhibition requires binding of an allosteric inhibitor to the allosteric site. The resulting conformational change diminishes the enzyme's ability to bind or act on the substrate.

At this point, it will be useful to have a brief overview of the process of ATP generation from the complete catabolism of glucose. In the next sections we will discuss the details and variations on this central theme. Catabolism of glucose begins with glycolysis, producing two ATP molecules and two pyruvate molecules from each molecule of glucose (Figure 13.10). Each pyruvate proceeds through the **tricarboxylic acid (TCA) cycle**, a series of reactions that further dismantles the carbon intermediates into six carbon dioxide (CO_2) molecules (see Section 13.3). Substrate-level phosphorylation in the TCA cycle produces two more ATP (one for each pyruvate), for a total of four ATP molecules. This is a minor contribution compared to the total number of ATP molecules, up to 38, that can be produced from the complete catabolism of glucose ($C_6H_{12}O_6$), as shown by the equation below:

$$C_6H_{12}O_6 + 6\,O_2 + 38\,ADP + 38\,P_i \rightarrow 6\,CO_2 + 6\,H_2O + 38\,ATP$$

Where do the other 34 ATP come from?

The chemiosmotic model

The complete catabolism of glucose into carbon dioxide and water generates a very large amount of free energy:

$$C_6H_{12}O_6 + 6\,O_2 \rightarrow 6\,CO_2 + 6\,H_2O \quad \Delta G^{\circ\prime} = -2{,}840\,kJ\ mol^{-1}$$

Investigators originally postulated that the large number of ATP molecules produced from glucose in cells occurred at membrane sites through substrate-level phosphorylation. However, for this to occur, there had to be another high-energy phosphorylated intermediate molecule generated, other than phosphoenolpyruvate and 1,3-bisphosphoglycerate, which were intermediates of glycolysis only. None was ever found. In 1961, Peter Mitchell proposed an alternative hypothesis for the production of ATP. It stated that ATP generation occurred at membrane sites where electrons were transferred along a chain of molecules, and this was coupled to the translocation of protons in a process called **chemiosmosis**, which could be used to produce ATP from ADP and P_i in the cell. Today, we know many details of this chemiosmotic process. Unlike substrate-level phosphorylation, this method of ATP generation is a complex process, rather than a simple reaction. It involves synthesis of ATP from free ADP and P_i using energy and electrons to create a proton gradient across a membrane. The flow of protons back across the membrane releases energy that is harnessed to produce ATP. As we will see later in Section 13.6,

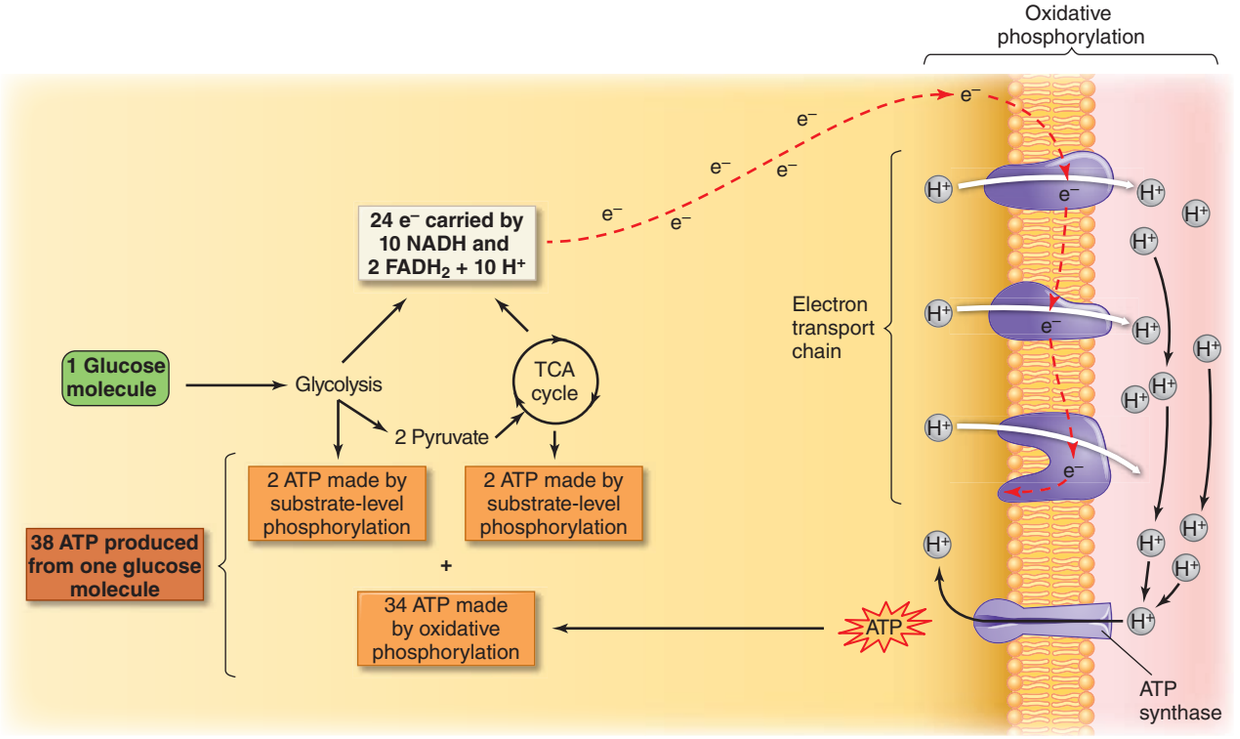

Figure 13.10. ATP production from glucose As glucose undergoes complete catabolism, four ATP molecules are generated by substrate-level phosphorylation. Oxidative phosphorylation produces 34 ATP using electrons removed from the catabolic intermediates of glucose. The electrons are transported by the electron carriers NADH and reduced FAD ($FADH_2$) to the membrane electron transport system. The energy released by the transfer of electrons is used to pump protons across the membrane. ATP synthase uses the inward flow of H^+ ions to synthesize ATP.

phototrophs use light energy for chemiosmosis, and this method of ATP generation is termed **photophosphorylation**. In chemotrophs, the energy is derived from the oxidation of chemical substrates and is termed **oxidative phosphorylation**.

The components for the generation of ATP via the chemiosmotic process varies in different organisms but is accomplished through coordination of three interconnected steps or processes, which we will examine later. For now, a preview of these processes used in oxidative phosphorylation is as follows:

- Electrons are transferred to an electron carrier molecule, such as the coenzymes **nicotinamide adenine dinucleotide (NAD)** (Figure 13.11) or flavin adenine dinucleotide (FAD).
- NAD transports electrons to a chain of electron-transporting molecules in the membrane, called the **electron transport system**. The electron transport system transfers electrons in a series of steps, yielding energy to move protons (hydrogen ions, H^+) across the membrane.
- The protons flow back across the membrane at sites containing the enzyme **ATP synthase**. The kinetic energy of the flowing protons is converted by ATP synthase into chemical energy, and ATP is synthesized from free ADP and P_i.

In organotrophs, electrons for transfer are made available when organic nutrients, such as glucose, are dismantled in small steps through metabolic pathways that carry out oxidation

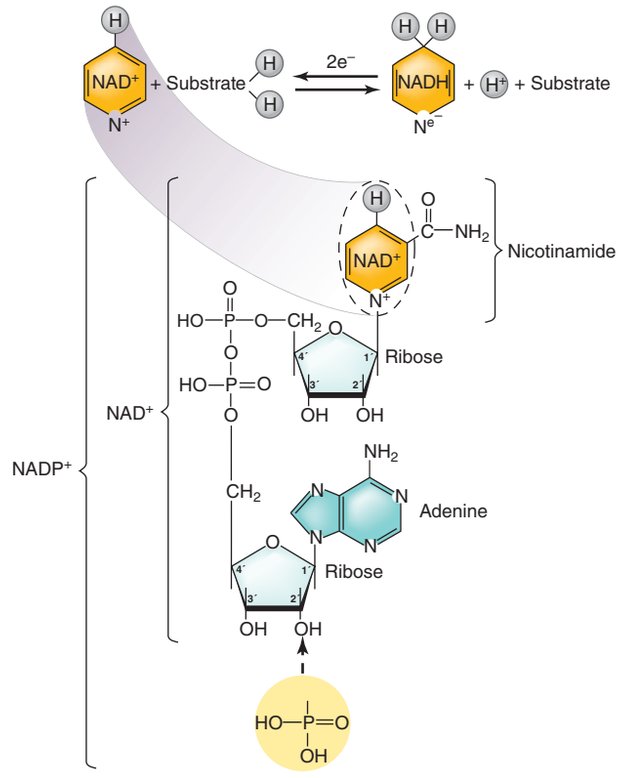

Figure 13.11. Electron carriers NAD and NADP NAD^+ and $NADP^+$ can accept two electrons and a proton on the nicotinamide ring (circled). Using a substrate as an electron source, NAD^+ accepts two electrons and a proton, producing NADH and a proton (H^+). NADH can donate electrons to an electron acceptor to convert back to NAD^+.

and reduction reactions. Electrons can also be generated using light absorption in phototrophs, the subject of Section 13.6. To understand how energy is yielded through transfer of electrons, we need to examine reduction and oxidation reactions.

Reduction and oxidation (redox) reactions

Reduction and oxidation reactions involve the transfer of electrons from one molecule to another and are commonly referred to as **redox reactions**. Electron transfer reactions are a fundamental mechanism by which energy can be liberated or captured in cells. As we have just seen, this energy can be used to generate ATP. By definition, an electron donor—the molecule that *loses* electrons—is said to be *oxidized*. An electron acceptor—the molecule that *gains* electrons—is *reduced*. A simple mnemonic device to help remember the difference between oxidation and reduction is "LEO the lion says GER," representing Loss of Electrons is Oxidation, Gain of Electrons is Reduction. **Oxidation** of a molecule results in loss of an electron and **reduction** of a molecule results in a gain of an electron. Examples:

$$\underset{\text{oxidized}}{2\ H^+ + 2\ e^-} \rightarrow \underset{\text{reduced}}{H_2}$$

$$\underset{\text{oxidized}}{NAD^+ + 2\ H + 2\ e^-} \rightarrow \underset{\text{reduced}}{NADH + H^+}$$

NAD is an important electron carrier molecule in the cytoplasm of cells (see Figure 13.11). Reduction of NAD^+ to NADH is important for many catabolic reactions, not just oxidative phosphorylation. A closely related molecule, reduced nicotinamide adenine dinucleotide phosphate (NADPH), is used typically as an electron donor for biosynthetic (anabolic) reactions. Having two distinct electron carriers may help the cell to organize reducing power, in order to allocate it to catabolism or anabolism in a physiologically optimal manner.

The tendency of a molecule to acquire electrons is its **reduction potential** or **redox potential**, ***E***, which is measured in units of volts (V). Molecules with more negative redox potentials are therefore better electron donors than those with more positive redox potentials. The acceptor and donor pair in a redox reaction is called a "redox couple." Redox potentials for many biologically relevant redox couples are shown in **Figure 13.12**. For purposes of comparison, redox potentials are measured under standardized conditions. The standard reduction potential is indicated as E_o'. Conventionally, redox couples are shown with the number of electrons transferred and the oxidized form of the molecule, or acceptor, on the left, and the reduced donor on the right.

$$\underset{\text{acceptor/oxidized}}{\mathbf{NAD^+} + H^+ + 2\ e^-} \rightarrow \underset{\text{donor/reduced}}{\mathbf{NADH}}$$

The redox couples in Figure 13.12 are organized into a tower with more negative E_o' values near the top and more positive E_o' values below. The more positive a redox potential, the greater its affinity for electrons, and it will have a higher tendency to become reduced. Another way to think of this is that a positive redox potential means that the oxidized molecule

Reduction potentials for common redox couples

Redox couple	E_o' (volts)
$2\ H^+ + 2e^- \longrightarrow H_2$	–0.42
Ferredoxin (Fe^{3+}) + $e^- \longrightarrow$ Ferredoxin (Fe^{2+})	–0.42
$NAD^+ + H^+ + 2e^- \longrightarrow$ NADH	–0.32
$NADP^+ + H^+ + 2e^- \longrightarrow$ NADPH	–0.32
$S + 2\ H^+ + 2e^- \longrightarrow H_2S$	–0.28
Acetaldehyde + $2\ H^+ + 2e^- \longrightarrow$ Ethanol	–0.2
$Pyruvate^- + 2\ H^+ + 2e^- \longrightarrow Lactate^{2-}$	–0.19
$FAD + 2\ H^+ + 2e^- \longrightarrow FADH_2$	–0.18
$Oxaloacetate^{2-} + 2\ H^+ + 2e^- \longrightarrow Malate^{2-}$	–0.166
$Fumarate^{2-} + 2\ H^+ + 2e^- \longrightarrow Succinate^{2-}$	–0.031
Cytochrome *b* (Fe^{3+}) + $e^- \longrightarrow$ Cytochrome *b* (Fe^{2+})	–0.075
Ubiquinone + $2\ H^+ + 2e^- \longrightarrow$ Ubiquinone H_2	+0.100
Cytochrome *c* (Fe^{3+}) + $e^- \longrightarrow$ Cytochrome *c* (Fe^{2+})	+0.254
Cytochrome *a* (Fe^{3+}) + $e^- \longrightarrow$ Cytochrome *a* (Fe^{2+})	+0.29
$NO_3^- + 2\ H^+ + 2e^- \longrightarrow NO_2^- + H_2O$	+0.42
$NO_2^- + 8\ H^+ + 6e^- \longrightarrow NH_4^+ + 2\ H_2O$	+0.44
$Fe^{3+} + e^- \longrightarrow Fe^{2+}$	+0.77
$½\ O_2 + 2\ H^+ + 2e^- \longrightarrow H_2O$	+0.82

Tendency to donate electrons

Tendency to accept electrons

Figure 13.12. Reduction potentials for redox couples Redox couples, indicated in bold, are arranged in a tower with those near the top having large negative reduction potentials and those near the bottom having large positive reduction potentials. Electrons will flow from donors near the top to acceptors near the bottom.

"wants" to accept electrons and become reduced, as the reaction arrow pointing to the right indicates. A negative E_o' value for a couple indicates that the equilibrium is in the other direction; under standard conditions, the reduced form gives up electrons in an energetically favorable reaction. Reduction potential determines which way electrons will flow as they are transferred from one molecule to another. Electrons will move toward molecules with a higher redox potential. In doing this, electrons are moving from a higher potential energy to a lower potential energy, according to the laws of thermodynamics. As a result, free energy is released. For example, NADH will donate electrons to oxygen (O_2) to form water (H_2O), releasing free energy. Chemotrophs can use this available energy to synthesize ATP.

An electron transfer in the cell always involves *two* redox couples because electrons are never found free in the cytoplasm. The reduced form of the couple with the more negative reduction potential donates one or more electrons to the oxidized form of the couple with the more positive E_o'. The energy released by the reaction is proportional to the difference in reduction potential ($\Delta E_o'$) between the couples. For transfer of a pair of electrons from NADH to O_2, the relevant redox couples are as follows:

$$\mathbf{NAD^+} + H^+ + 2\ e^- \rightarrow \mathbf{NADH}$$

$$E_o' = -0.32\text{V}$$

$$\mathbf{½O_2} + 2\ H^+ + 2\ e^- \rightarrow \mathbf{H_2O}$$

$$E_o' = +0.82\ \text{V}$$

The first reaction has a much more negative reduction potential than the second, so the reduced form of the first couple, NADH, will donate a pair of electrons to the oxidized form of the second couple, O_2. The overall reaction will be as follows:

$$NADH + H^+ + \tfrac{1}{2}\, O_2 \rightarrow NAD^+ + H_2O \qquad \Delta E_o' = +1.14 \text{ V}$$

The large *positive* $\Delta E_o'$ indicates the redox reaction is energetically favorable and a great deal of energy is released. You will recall from earlier in this section that a *negative* $\Delta G^{\circ\prime}$ also indicated that the reaction is favorable. The mathematical relationship between $\Delta E_o'$ and $\Delta G^{\circ\prime}$ is as follows:

$$\Delta G^{\circ\prime} = -nF(\Delta E_o')$$

where n = number of electrons, F = Faraday's constant (96.5 kJ mol^{-1} volt), and $\Delta E_o'$ = the difference in reduction potential between the two couples. A *positive* $\Delta E_o'$ translates into a *negative* $\Delta G^{\circ\prime}$, reflecting the release of energy.

The large $\Delta E_o'$ for the transfer of electrons from NADH to O_2 is the basis for energy generation for ATP synthesis during aerobic respiration and accounts for 34 of the 38 ATP molecules that can be generated from the complete oxidation of a molecule of glucose. However, the transfer of electrons from NADH to O_2 proceeds through several intermediates, with incremental $\Delta E_o'$ values for each transfer. These intermediate electron transfers occur within the membrane electron transport system and are coupled to proton movement across a membrane that can be used to drive ATP synthesis. We can briefly compare the energy produced by the transfer of electrons from NADH to O_2 with that of a microorganism that oxidizes hydrogen sulfide (H_2S; the electron donor), producing ferric iron (Fe^{2+}; the electron acceptor is Fe^{3+}). Using Figure 13.12, you should calculate that the $\Delta E_o'$ value for this metabolic reaction is +1.05 V. Less energy is derived from this respiration strategy than by using the previous aerobic respiration reaction. Later, in Section 13.4, we will meet some of the bacteria, such as *Shewanella* and *Geobacter*, that carry out the reduction of iron.

CONNECTIONS Recall from **Section 2.4** that, in cellular respiration, organic molecules are oxidized, and the released energy is used to drive the synthesis of ATP. Aerobic and anaerobic cellular respiration will be detailed in Section 13.4. Aerobic respiration employs an electron transport chain that specifically uses O_2 as a terminal electron acceptor and can be carried out only under oxic conditions. In anaerobic respiration, electron acceptors other than O_2 are used.

Metabolic groups of microorganisms

Microorganisms can be categorized based on the source of energy and the source of electrons they use for redox reactions to produce ATP. As we saw in Section 6.1, chemotrophs acquire energy through oxidation of preformed chemicals that they obtain from their environment. Conversely, phototrophs acquire energy by capturing photons of light to raise electrons to higher energy levels that can drive otherwise unattainable redox reactions (see Figure 6.1). Organotrophs remove electrons from organic molecules, such as glucose, whereas lithotrophs remove electrons from inorganic reduced molecules, such as hydrogen sulfide (H_2S), hydrogen gas (H_2), or elemental sulfur (S^0).

The source of carbon an organism uses is another major consideration when classifying metabolic types. Heterotrophs obtain carbon from organic molecules, such as sugars, obtained from their environment. Autotrophs use inorganic carbon compounds, usually CO_2. As shown in **Table 13.1**, combining information on energy and electron sources with the source of carbon used for biosynthesis gives an overall metabolic profile of a microorganism. In many cases, chemoorganotrophic heterotrophs use the same molecule as the carbon, energy, and electron source. Sometimes the shortened term "chemoorganoheterotroph" or just "heterotroph" is used to describe this combined use of a molecule. Glucose is an example of a molecule used this way by many heterotrophs. As we will see in the following sections, glucose catabolism through glycolysis and the TCA cycle provides essential precursors for macromolecular synthesis *and* powers ATP synthesis. In contrast, chemolithotrophic autotrophs oxidize inorganic compounds, such as ferrous iron (Fe^{2+}), S^0, H_2, H_2S, ammonia (NH_3), and nitrite (NO_2^-) to yield energy and obtain electrons. Their principal carbon source is CO_2. At the end of the chapter, we will see that the bacterium associated with the giant tube worm described in the opening story is an example of a chemolithotrophic autotroph. It uses H_2S from its environment as an electron donor to generate energy to produce ATP in order to synthesize organic molecules from CO_2.

TABLE 13.1 Major metabolic groups of microorganisms

Metabolism	Energy source	Electron source	Carbon source	Microorganisms
Chemoorganoheterotrophy	Chemicals	Organic e^- donor (same as carbon source)	Organic carbon	Most non-photosynthetic microorganisms
Chemolithoheterotrophy	Chemicals	Inorganic e^- donor	Organic carbon	Some sulfur-oxidizing bacteria
Chemolithoautotrophy	Chemicals	Inorganic e^- donor	Carbon dioxide	Some sulfur-oxidizing bacteria, iron-oxidizing bacteria, methanogens, nitrifying bacteria
Photolithoautotrophy	Light	Inorganic e^- donor	Carbon dioxide	Cyanobacteria, purple and green sulfur bacteria
Photoorganoheterotrophy	Light	Organic e^- donor	Organic carbon	Purple non-sulfur and green non-sulfur bacteria

13.2 Fact Check

1. Compare and contrast ATP generation by substrate-level phosphorylation, oxidative phosphorylation, and photophosphorylation.
2. Distinguish differences of oxidation and reduction.
3. Describe the mathematical relationship between $\Delta E_o'$ and $\Delta G^{\circ\prime}$.
4. Explain how glycolysis, the TCA cycle, and the electron transport system are involved in ATP generation in a cell.
5. Describe chemotrophs, phototrophs, organotrophs, lithotrophs, heterotrophs, and autotrophs.

13.3 Carbon utilization in microorganisms

How do microorganisms utilize organic carbon?

Carbon is the most abundant element in biological macromolecules and acquiring it is critical for cell growth and replication. The general process by which cells import a molecule and incorporate it into cellular constituents is called assimilation (see Section 6.1). As mentioned in the previous chapter, most of Earth's biosphere is built on carbon that was assimilated originally by autotrophic organisms. The organic molecules they produce, through mechanisms that will be covered in Section 13.6, are consumed and assimilated by heterotrophs (see Table 13.1). Heterotrophic microorganisms have adapted to transport and incorporate carbon from many kinds of organic molecules—carbohydrates, amino acids, lipids, organic acids, alcohols, and more. Our overview of carbon utilization will focus on what happens when glucose—a sugar assimilated by many cells—is used as a source of carbon and energy.

Glycolysis

Glucose is one of the most abundant organic molecules in the biosphere. It is the building block for cellulose, the main polymer in plant cell walls, and modified forms of glucose are major contributors to bacterial and fungal cell walls. In Section 13.1, we introduced glycolysis as the catabolism of glucose to pyruvate. There are several ways this can be done, and different chemoorganoheterotrophs use different glycolytic (sugar-splitting) pathways for breaking down glucose to obtain energy and carbon compounds for biosynthesis.

The Embden–Meyerhof–Parnas Pathway

The most common glycolytic pathway is the **Embden–Meyerhof–Parnas (EMP) pathway**, named for the German biochemists Gustav Embden and Otto Meyerhof, who worked out this pathway in the early twentieth century. The name of Russian biochemist Jakub Parnas is sometimes also added. This pathway, shown in **Figure 13.13**, generates pyruvate, ATP, and NADH. The overall reaction is as follows:

$$\text{Glucose} + 2\,\text{ADP} + 2\,P_i + 2\,\text{NAD}^+ \rightarrow 2\,\text{pyruvate} + 2\,\text{ATP} + 2\,\text{NADH} + 2\,\text{H}^+$$

The EMP pathway can be divided into two phases. In Phase I (Steps 1 through 5 in Figure 13.13), ATP is used to phosphorylate the six-carbon backbone of glucose to form glucose 6-phosphate. Another ATP molecule is invested after isomerization to fructose 6-phosphate to produce the high-energy molecule fructose 1,6-bisphosphate, which is cleaved into two 3-carbon compounds (Step 4). Dihydroxyacetone phosphate is converted into another molecule of glyceraldehyde 3-phosphate by triose phosphate isomerase (Step 5), resulting in two identical three-carbon units that proceed through Phase II (Steps 6 through 10). Catabolism of the two glyceraldehyde 3-phosphate molecules will produce even more potential free energy; four ATP molecules are synthesized by substrate-level phosphorylation. The investment of two ATP molecules for the initial phosphorylation of glucose results in a net profit of two ATP for the cell. Before any energy earnings can be made, energy must be invested.

Phase II generates energy in the form of electrons as well as ATP and begins with the first oxidation (Step 6). Electrons are removed in a coupled reaction that produces NADH and adds another phosphate to each 3-carbon glyceraldehyde 3-phosphate to generate 1,3-bisphosphoglycerate. Notice that this phosphate does not come from ATP. Instead, the electron removal is coupled with formation of a phosphate bond from a free inorganic phosphate.

In Step 7, a phosphate group is transferred from 1,3-bisphosphoglycerate to adenine dinucleotide (ADP), yielding ATP. You should recognize this as a substrate-level phosphorylation reaction (see Section 13.1) because a phosphate is being transferred to ADP from a high-energy molecule (1,3-bisphosphoglycerate). As there are two molecules of 1,3-bisphosphoglycerate from each glucose molecule, the cell has now recovered its initial investment of ATP during the preparatory phase. The key accomplishment is to capture the energy from the redox reaction in Step 6 as an ATP molecule in Step 7.

Steps 8 and 9 reconfigure and dehydrate the three-carbon molecule to increase the potential energy in the covalent bond attaching the phosphate group of phosphoenolpyruvate. A second substrate-level phosphorylation generates another ATP in Step 10, along with pyruvate. This final step, carried out on

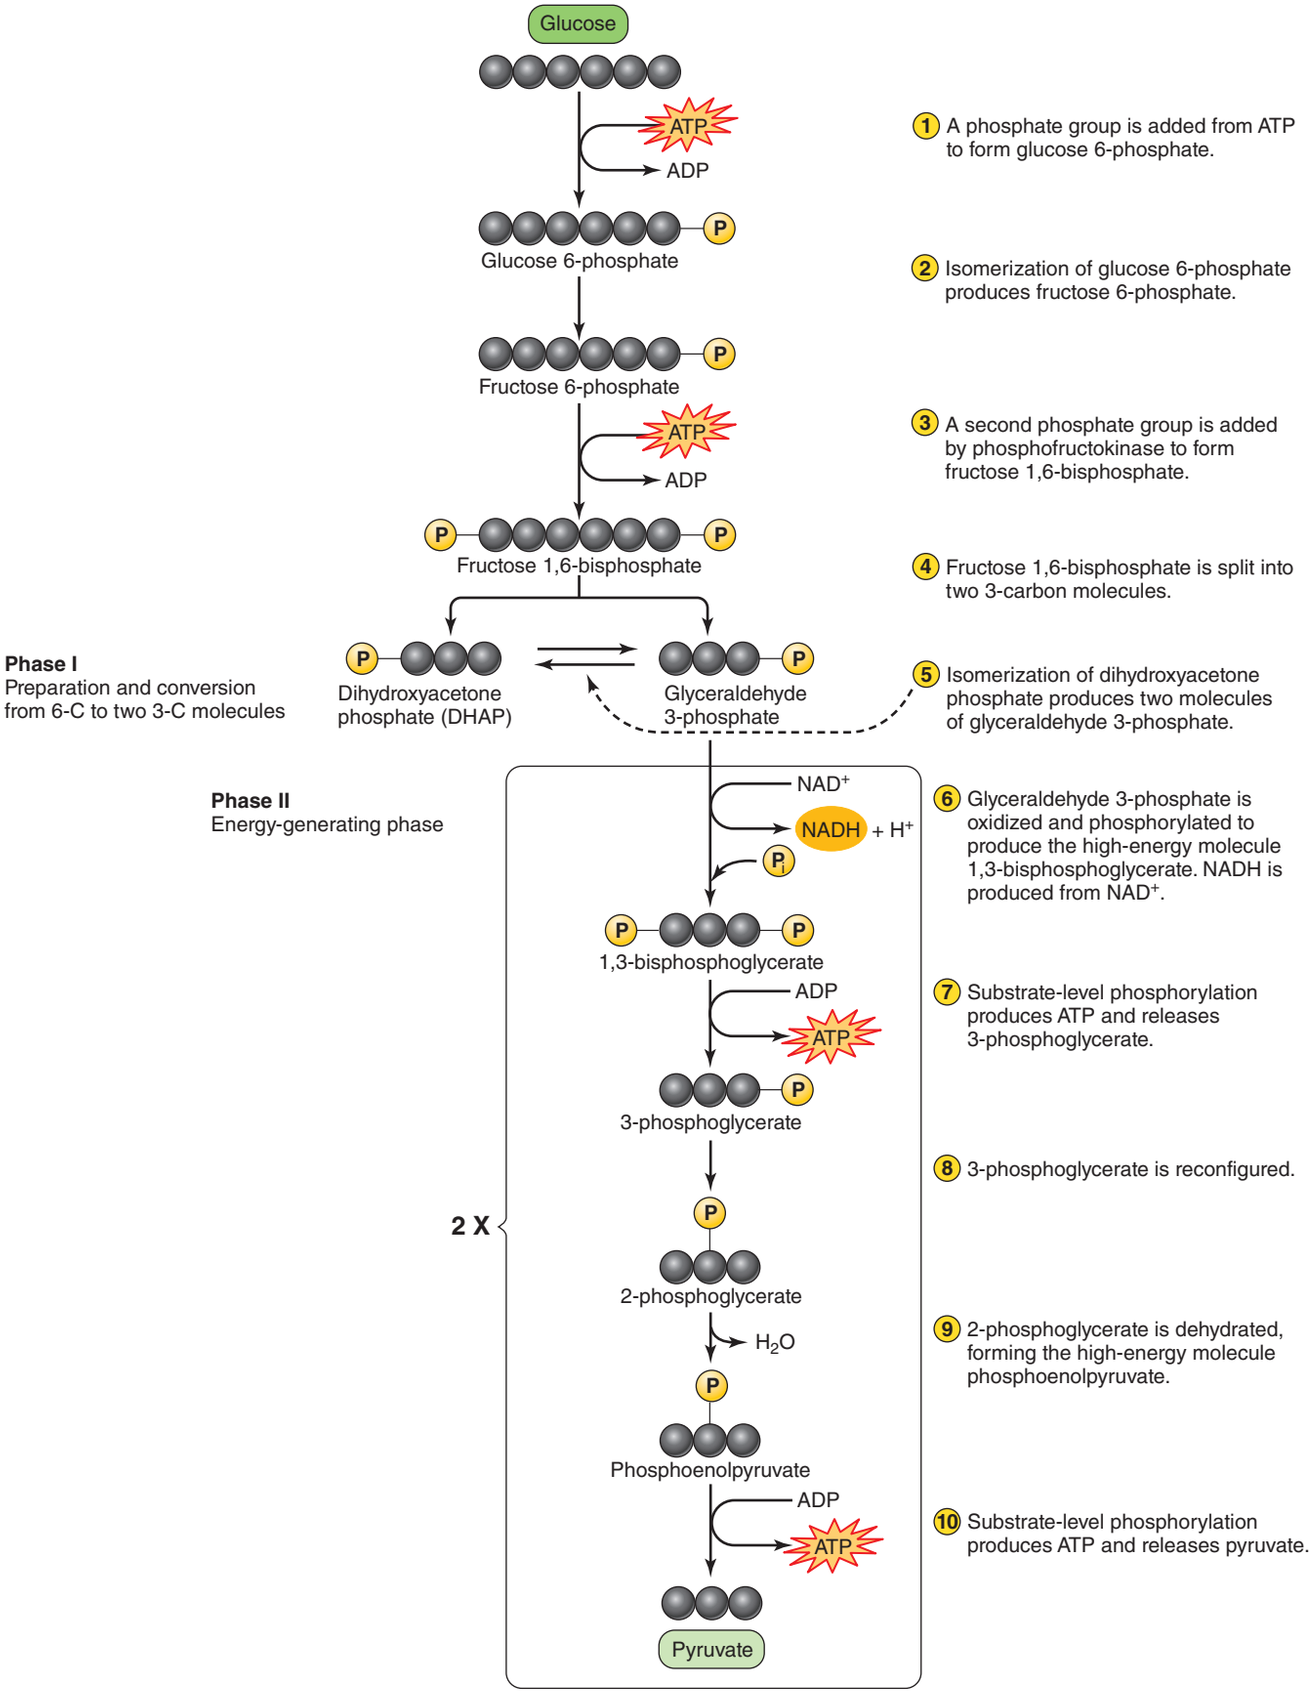

Figure 13.13. Process Diagram: The Embden–Meyerhof–Parnas (EMP) pathway of glycolysis
Glucose is converted to two molecules of pyruvate. Glucose is prepared for dismantling in Phase I, which consumes two molecules of ATP. Phase II generates four molecules of ATP by substrate-level phosphorylation. This results in a net gain of two molecules of ATP from each glucose molecule.

each of the three-carbon units produced from a glucose molecule, gives the EMP pathway a net yield of two molecules of ATP per molecule of glucose. It also yields two NADH molecules per glucose molecule.

The EMP pathway is found in many bacteria, archaea, and eukaryal microorganisms. It is thought to have originated very early in the history of life, prior to the divergence of the three domains. Later, we will see that the pyruvate resulting from glycolysis can be further oxidized in other pathways, such as the TCA cycle, to provide more energy. The EMP pathway is not used just for energy metabolism. Several intermediates, including glucose 6-phosphate, fructose 6-phosphate, glyceraldehyde 3-phosphate, phosphoenolpyruvate, and pyruvate, serve as precursors for synthesis of other key molecules, such as amino acids (see Section 13.8). Because of this, the EMP pathway is of central importance as replenishing **anaplerotic reactions** for the production of intermediates for other metabolic pathways.

The Entner–Doudoroff Pathway

The **Entner–Doudoroff pathway** is less commonly used for glucose catabolism but is often used for catabolism of other carbohydrates containing aldehyde groups, such as gluconate, which cannot be readily processed by the EMP pathway. The pathway, shown in **Figure 13.14**, begins with Step 1, like the EMP pathway, with the ATP-driven conversion of glucose to glucose 6-phosphate. Step 2 oxidizes glucose 6-phosphate to 6-phosphogluconate and generates NADPH. Recall that NADPH is a common electron donor for biosynthetic reactions. At Step 3, dehydration of 6-phosphogluconate generates 2-keto-3-deoxy-6-phosphogluconate. This molecule is then split (Step 4) into two 3-carbon units, pyruvate and glyceraldehyde-3-phosphate, which can proceed through Steps 6 through 9 of the EMP pathway to generate a second pyruvate, along with two ATP molecules and an NADH. Because only one of the three-carbon units generated by Step 4 yields ATP directly, the ATP yield of the Entner–Doudoroff pathway is less than the EMP pathway.

$$\text{Glucose} + \text{NADP}^+ + \text{NAD}^+ + \text{ADP} + \text{P}_i \rightarrow 2\,\text{pyruvate} + \text{NADPH} + 2\,\text{H}^+ + \text{NADH} + \text{ATP}$$

Bacteria known to use the Entner–Doudoroff pathway include *Pseudomonas*, *Caulobacter*, *Rhizobium*, and *Azotobacter* species. Why this strategy evolved is unclear. These species are obligate aerobes that gain most of their ATP from glucose metabolism by conveying NADH to the electron transport system, so the lost ATP molecule has a fairly minor effect on overall yield. Some facultative anaerobic bacteria, such as *Zymomonas,* use the Entner–Doudoroff pathway for fermentation under anoxic conditions.

The Pentose Phosphate Pathway

An alternative to the EMP and Entner–Doudoroff pathways for processing glucose is the **pentose phosphate pathway** **(Figure 13.15)**, so named because it produces five-carbon sugar intermediates. This is technically not glycolysis, as it does not form pyruvate, but we will include it here as an important glycolytic pathway for processing glucose. The pathway is of significant importance as it generates NADPH for biosynthetic

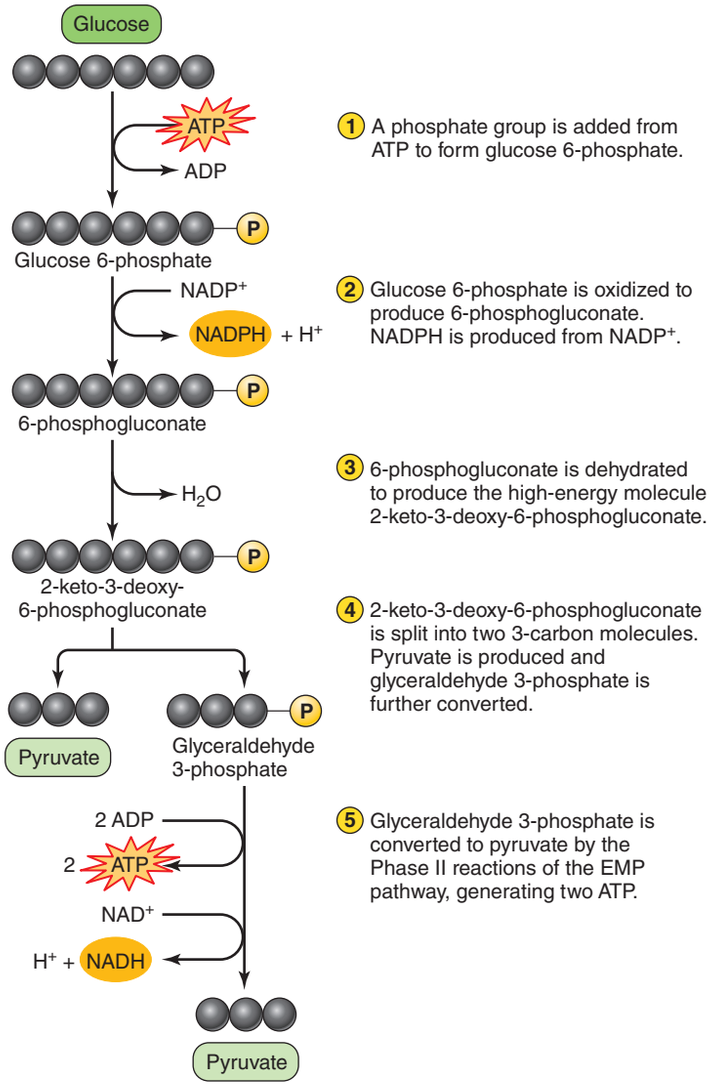

Figure 13.14. Process Diagram: The Entner–Doudoroff pathway of glycolysis Steps 1 through 4 convert glucose to pyruvate and glyceraldehyde 3-phosphate, with the consumption of one ATP. Glyceraldehyde 3-phosphate enters the Phase II reactions of the EMP pathway to produce a second molecule of pyruvate and two ATP. The pathway results in one molecule of ATP from each glucose molecule.

reactions. The pentose phosphate pathway works with the EMP pathway, rather than replacing it. Its primary use is in generating the electron donor NADPH and essential precursors for biosynthesis. As such, it is a pathway with important anaplerotic reactions. For example, a microorganism operating with glucose as its sole carbon source must convert some of it into the five-carbon ribose molecule to make the ribonucleotides for RNA synthesis and deoxyribonucleotides for DNA synthesis. Erythrose 4-phosphate is also an essential precursor for synthesis of the aromatic amino acids tryptophan, tyrosine, and phenylalanine, as well as other aromatic metabolites. Most microorganisms execute some version of this pathway.

The pentose phosphate pathway starts with the intermediate product glucose 6-phosphate, generated by Step 1 of the EMP pathway (see Figure 13.13), and so begins with the same investment of ATP to phosphorylate glucose. Glucose 6-phosphate is oxidized to 6-phosphogluconate and generates NADPH

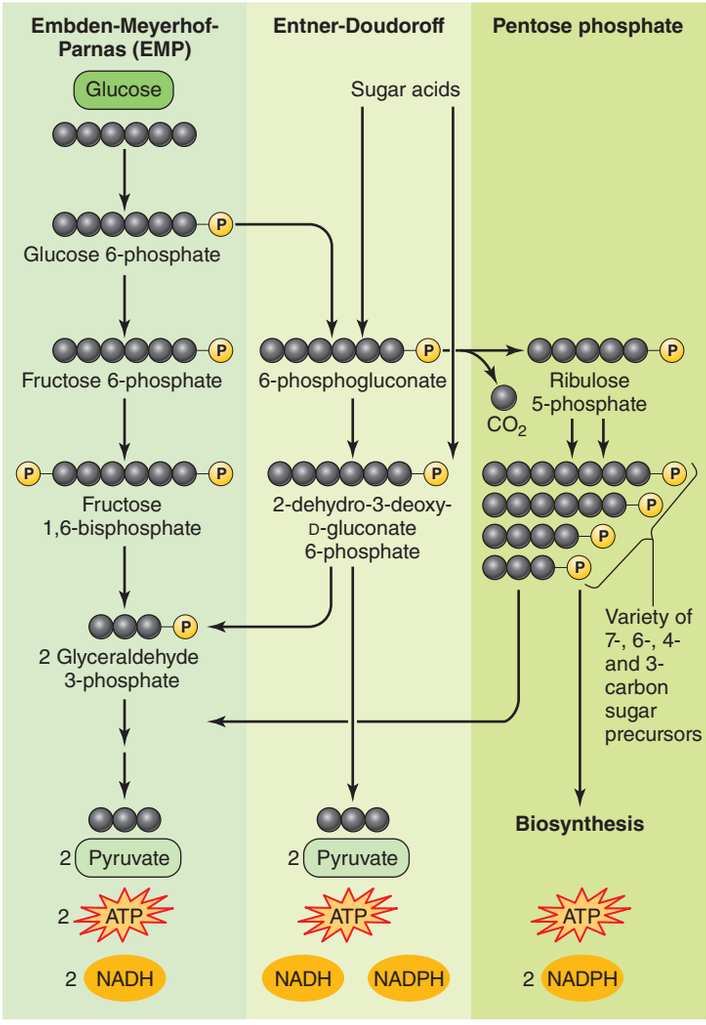

Figure 13.15. Glycolytic pathways The EMP pathway is most useful for generating ATP and NADH. The pentose phosphate pathway produces NADPH, a source of reducing power often used for biosynthetic reactions, as well as a number of seven- to three-carbon compounds that can be used as precursors for biosynthesis. The intermediate product, glucose 6-phosphate from the EMP pathway, can be routed to the Entner–Doudoroff pathway to provide NADPH. The pathways are interconnected and can be used to meet metabolic demands.

in the process. A second oxidation step generates NADPH, and simultaneously decarboxylates the six-carbon molecule to yield the pentose ribulose 5-phosphate. The ribulose backbone is converted to two different pentoses, ribose and xylulose. These are rearranged to produce three-carbon (glyceraldehyde) and seven-carbon (sedoheptulose) units, which in turn recombine to give six-carbon (fructose) and four-carbon (erythrose) units. Erythrose phosphate can be combined with xylulose phosphate to generate fructose 6-phosphate and glyceraldehyde 3-phosphate. The latter molecule can enter the EMP pathway to generate pyruvate, ATP, and NADH. The result, shown in the equation below, is the conversion of three molecules of glucose to two molecules of fructose 6-phosphate and one glyceraldehyde 3-phosphate, with the production of six molecules of NADPH.

$$3\,\text{glucose 6-phosphate} + 6\,NADP^+ + 3\,H_2O \rightarrow 2\,\text{fructose 6-phosphate} + \text{glyceraldehyde 3-phosphate} + 3\,CO_2 + 6\,NADPH + 6\,H^+$$

The fate of the electrons carried by NADH, or other reduced electron carriers generated from glycolytic pathways, depends on the genetic capacity of the organism and the conditions it experiences. As discussed in Section 13.2, the electrons can be used to generate ATP by oxidative phosphorylation, but other options, such as fermentation, are also used by some microorganisms. At this point, we will look at a summary of these options and examine them in more detail in later sections.

Fermentation

There is a finite pool of NAD^+/NADH in a cell. As glycolysis proceeds, NADH would accumulate and the supply of NAD^+ would be exhausted if NADH weren't converted by oxidation back to NAD^+. What would happen to glycolysis if there was no NAD^+ in the cell? Enzymes that require NAD^+ for coupled reactions would cease to function. As a result, glycolysis would stop, and cells might die. Recycling of NADH to NAD^+ must happen for the cell to continue consuming carbohydrates, so there must be an acceptor to take electrons from NADH. Chemoorganoheterotrophs do this conversion by either of the following:

- **Fermentation**, where electrons are passed directly to an organic terminal electron acceptor and the TCA cycle and the electron transport system is not utilized
- Cellular **respiration**, where the electrons are passed through an electron transport system and on to an inorganic or sometimes an organic terminal electron acceptor

Microorganisms can live as long as they have a nutrient source with more energy than the terminal electron acceptor they are capable of using. They can use a multitude of metabolic pathways to achieve this. Fermentation involves fewer processes than respiration, and we will cover it first. Fermentation can be defined as the transfer of electrons from NADH, or some other reduced electron carrier, to an organic molecule, commonly pyruvate **(Figure 13.16)**. As oxygen is not used during

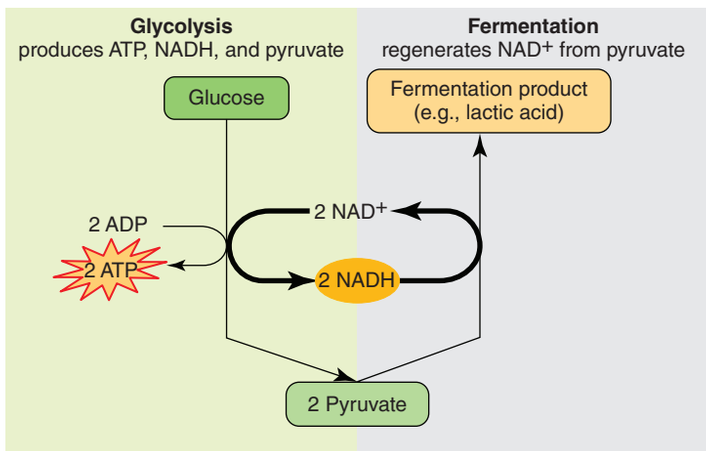

Figure 13.16. Recycling of NADH by fermentation For each molecule of glucose catabolized by the EMP glycolysis pathway, two ATP and two NADH are generated from two ADP and two NAD^+. Fermentation recycles NADH by reducing pyruvate, or a similar organic acid, which accepts electrons from NADH, replenishing NAD^+ for continued glycolysis and releasing a reduced waste product, such as lactic acid.

fermentation, it is an anaerobic process, but many organisms can carry out this process in the presence of oxygen. In other words, fermentation is not restricted to obligate anaerobic organisms. For example, *Escherichia coli* and members of the genus *Streptococcus* can carry out fermentation in the presence of oxygen. The process of fermentation begins with glycolysis and the resulting fermentation products, such as lactic acid (lactate) or ethanol, become waste to be eliminated. The purpose of fermentation is to replenish NAD^+ stocks so that glycolysis can continue to produce a small, but constant stream of ATP from glycolysis.

Lactic Acid Fermentation

Lactic acid fermentation is a very common process in fermenting bacteria and protists. Lactic acid is produced from pyruvate in a very simple process requiring only lactate dehydrogenase (Figure 13.17). Lactic acid is the reduced product of the transfer of an electron from NADH. In solution, lactic acid loses a proton to become the negatively charged counterpart lactate, which is transported from the cell as a waste product.

CONNECTIONS Lactate may be a waste product for some fermenting bacteria, but as described in **Section 17.4**, can be a nutrient for other microorganisms living in the gut of herbivorous animals, such as cows.

The lactic acid fermentation pathway is the dominant route of glucose catabolism in a large group of Gram-positive bacteria known as **lactic acid bacteria (LAB)**, which includes genera such as *Streptococcus*, *Lactobacillus*, and *Bifidobacterium*. The streptococci include several important pathogens of humans (see Microbes in Focus 17.2). In contrast, various lactobacilli and bifidobacteria are commensals of the human intestinal and genitourinary tracts that are known to have beneficial functions (see Section 17.3). Lactic acid bacteria are used in the food industry for the fermentation of milk to produce yogurt and sour cream.

CONNECTIONS The production of lactic acid in foods inhibits other microorganisms that would otherwise cause food spoilage in carbon-rich foods. See **Section 16.3**.

Lactic acid fermentation can occur using one of two pathways from glucose ($C_6H_{12}0_6$), either homolactic fermentation or heterolactic fermentation. Homolactic fermenting LAB use the EMP pathway to make pyruvate and then reduce it directly to lactate ($C_3H_6O_3$), as can be seen in the brown pathway of Figure 13.17. The overall reaction is as follows:

$$C_6H_{12}O_6 + 2\,ADP + 2\,P_i \rightarrow 2\,C_3H_6O_3 + 2\,ATP$$

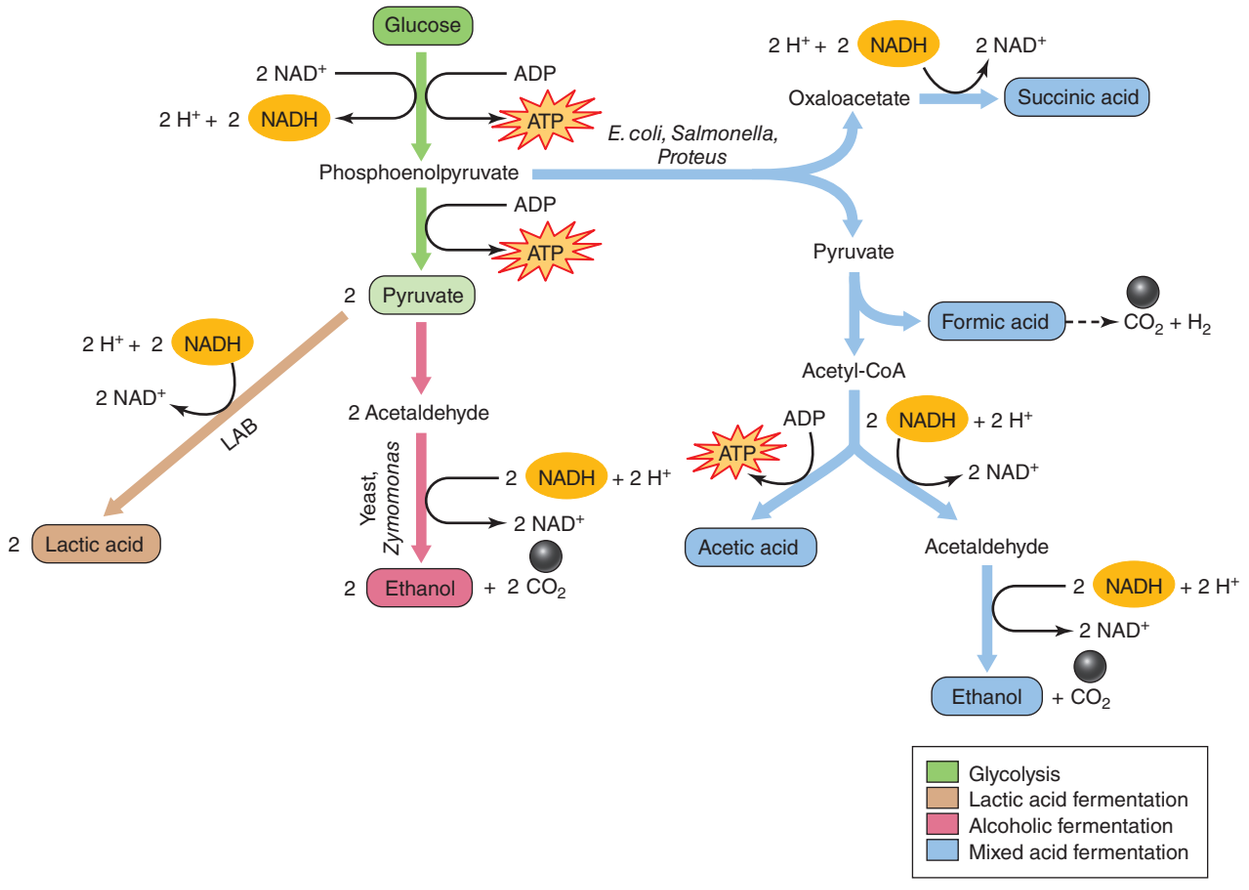

Figure 13.17. Various products of glucose fermentation Glycolysis (green pathway), produces pyruvate, which can be converted to lactic acid through lactic acid fermentation (brown pathway) or to ethanol by alcoholic fermentation (pink pathway). Mixed acid fermentation (blue pathway) produces a mixture of ethanol, and various acids. Some bacteria can convert formic acid into CO_2 and H_2.

Recall that the balance of NAD^+/NADH is restored and does not appear in the final equation.

Some LAB, such as *Leuconostoc*, undertake a more complex process of heterolactic fermentation that generates both lactic acid and ethanol **(Figure 13.18)**. Initial reactions of this pathway are identical to the pentose phosphate pathway (see Figure 13.15). The five-carbon sugars are then further oxidized into lactic acid and ethanol. Note that a total of only one ATP is produced by heterolactic fermentation. Diverse strategies have evolved for anaerobic sugar metabolism, and mixtures of fermentation products from the same microorganism are quite common, depending on the carbon substrates used.

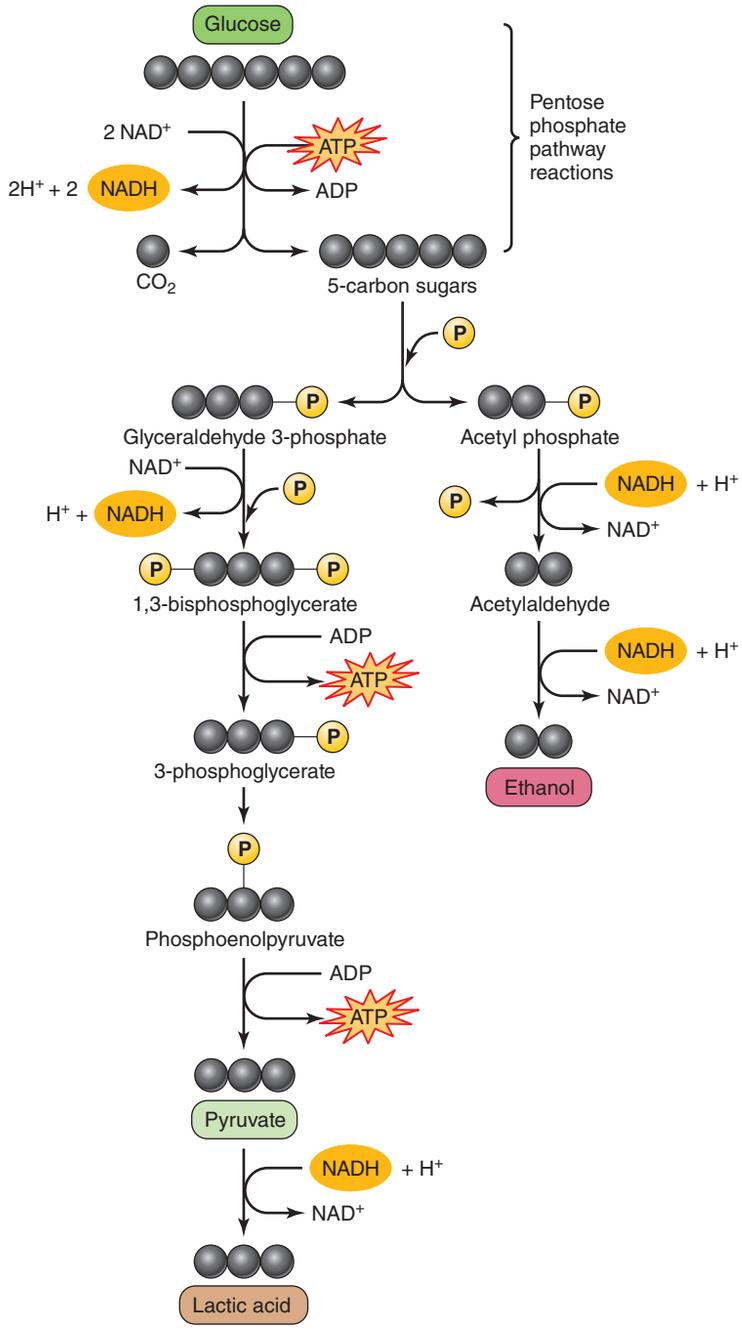

Figure 13.18. Heterolactic fermentation Five-carbon compounds from the pentose phosphate pathway are converted into lactic acid and other products. Shown here are lactic acid and ethanol.

Perhaps the most fascinating aspect about the metabolism of LAB is that although they lack respiration pathways and are restricted to fermentation, they are able to carry out fermentation under oxic conditions. They are classified as aerotolerant anaerobes. Given the energetic advantages of respiratory metabolism, it seems perplexing that they would forgo this option completely. Let's consider this issue from another perspective. In light of their extensive nutritional requirements, LAB are adapted and limited to habitats rich in organic material, such as soil, decaying vegetation, and digestive tracts. They have fairly small cells and small genomes, and they turn out prodigious amounts of lactic acid as a metabolic by-product. Because they are acid-tolerant, this characteristic alters the environment to favor their growth and inhibits the growth of non-acid-tolerant competitors. Dental cavities are a common outcome of this activity, described in detail in Section 17.3. Their restriction to fermentative metabolism, streamlined genomes, and small cells may enable LAB to reproduce quickly and compete effectively with other microorganisms in carbohydrate-rich habitats with limited oxygen.

CONNECTIONS Recall from **Section 6.2** that non-respiring aerotolerant anaerobes, such as LAB, must possess defenses against toxic oxygen species, such as superoxide anions, that are generated in an oxygenated environment. Without protection, these oxygen species can damage enzymes and nucleic acids. Obligate anaerobes lack adequate defenses to such damage.

Alcoholic Fermentation

Some microorganisms produce ethanol and carbon dioxide (CO_2) as major fermentation products. This is known as alcoholic fermentation. Many types of yeast and certain bacteria use this process (see Figure 13.17). Pyruvate, a three-carbon molecule, is first split to CO_2 and acetaldehyde by pyruvate decarboxylase. Acetaldehyde is then reduced to ethanol by alcohol dehydrogenase to accomplish the desired oxidation of NADH to NAD^+. Ethanol is a small, weakly polar molecule that rapidly diffuses across the plasma membrane as a waste product. The overall reaction beginning with glucose is as follows:

$$C_6H_{12}O_6 + 2\ ADP + 2\ P_i \rightarrow 2\ C_2H_5OH + 2\ CO_2 + 2\ ATP$$

Alcoholic fermentation has been used by humans for the production of beer and wine for several thousand years, long before people knew that microorganisms, such as yeast, were responsible for this activity. In the brewing of beer, starch from grains is broken down to glucose to be used as a substrate for fermentation. During the wine-making process, sugars such as fructose and glucose in the juice of grapes or other fruits are fermented. The yeasts that carry out fermentation are present naturally in fruit, although specific strains of yeast, commonly strains of *Saccharomyces cerevisiae*, are typically used in the modern wine and beer industries. These yeast are capable of aerobic respiration if sufficient O_2 is available and will use fermentation under anoxic conditions. They are facultative anaerobes (see Section 6.2). Beer and wine fermentation must be carried out in sealed containers to exclude air. The yeast

initially consumes the dissolved oxygen, then switches to fermentative metabolism and starts producing alcohol. Growth and metabolism naturally stop when the fermentable carbon sources are exhausted or when the ethanol concentration becomes so toxic (12–15 percent range) that metabolic processes stop.

Mixed Acid Fermentation

Other fermentation pathways have been identified in various bacteria and fungi that yield a variety of organic end products from pyruvate or a similar organic acid. Many bacteria belonging to the family *Enterobacteriaceae* use the mixed acid fermentation pathway (see Figure 13.17). Under anoxic conditions, glucose is converted to a mixture of ethanol, acetic, formic, and succinic or lactic acids, as well as CO_2 and hydrogen gas (H_2). In the gut of many animals, including humans, the products of mixed acid fermentation from the activity of intestinal microorganisms can be absorbed through the intestinal wall and used as nutrients that can be converted to acetyl-coenzyme A (acetyl-CoA) and oxidized through the TCA cycle.

In addition to these products, microbial fermentations can produce butanol, butanediol, butyric acid, acetone, propanol, propionic acid, and other compounds. Several fermentative microorganisms have been adapted for commercial chemical manufacturing, including the bacterium *Clostridium acetylbutylicum,* which has been used extensively for industrial production of the solvents acetone and butanol (see Section 12.4).

CONNECTIONS **Sections 17.3** and **17.4** focus on the importance of fermenting communal microorganisms in human and animal health. The fermentation products acetate (acetic acid), propionate (propionic acid), and butyrate (butyric acid) are especially important in providing calories in herbivorous animals, such as rabbits, cows, and sheep.

Metabolic Regulation of Fermentation

Although diverse fermentation pathways can be used by different microorganisms, one unifying outcome is that fermentation does not generate substantial amounts of ATP. Substrate-level phosphorylation during glycolysis is the *only* process of ATP formation in fermentation, and glucose cannot be completely catabolized. Only two molecules of ATP per molecule of glucose are formed by this reaction, about 5 percent of the energy yielded through aerobic respiration. To compensate for this, organisms using fermentation consume large amounts of substrate to sustain their metabolic needs.

Fermentation is much less energetically efficient than respiration, but it is a common mode of metabolism in facultative anaerobic microorganisms that routinely experience anoxic conditions. Yeast, such as *Saccharomyces cerevisiae,* can produce energy using either aerobic respiration or fermentation. Louis Pasteur observed that aerating a culture of yeast led to a reduction in the amount of glucose consumed. Under low-oxygen conditions, much more glucose was consumed. The effect, known as the "Pasteur effect," is due to an increase in the rate of glycolysis during fermentation. When oxygen concentrations increase, aerobic respiration takes place, producing 38 moles of ATP per mole of glucose. Thus, a high rate of glycolysis is not needed to provide the cell's energy needs in aerobically respiring cells.

What is the molecular mechanism that regulates the rate of glycolysis? The enzyme phosphofructokinase, a key enzyme in glycolysis (see Figure 13.13, Step 3) is subject to allosteric regulation (see Section 13.2) by ATP. Phosphofructokinase has two ATP-binding sites, one in the active site and one in an allosteric site. ATP preferentially binds to the active site along with fructose 6-phosphate. During low levels of ATP, experienced during fermentation, ATP binds only to the active site, allowing production of fructose 1,6-bisphosphate and the continuation of glycolysis for fermentation. High levels of ATP experienced during aerobic respiration also enables ATP to bind the allosteric site. In so doing, ATP becomes an allosteric inhibitor, causing a conformational change in the enzyme, shutting down its ability to convert fructose 6-phosphate. This reduces the amount of fructose 1,6-bisphosphate available for glycolysis and explains the decreased rate of metabolism of glucose observed during respiration. Regulation of this key enzyme in glycolysis allows the cell to balance ATP production with its energy needs. This is an example of **feedback inhibition** of a metabolic pathway (Figure 13.19), where the product of an enzyme(s) in a pathway inhibits the reaction of an earlier enzyme through allosteric inhibition (see Figure 13.9). In this case, the accumulation of ATP produced later in the respiratory pathway inhibits glycolysis, a much earlier step in the energy-generating pathway. Some metabolic pathways use **precursor activation** when a substrate in an enzyme pathway increases the activity of one or more enzymes further on in the series.

End product inhibition
ANIMATION

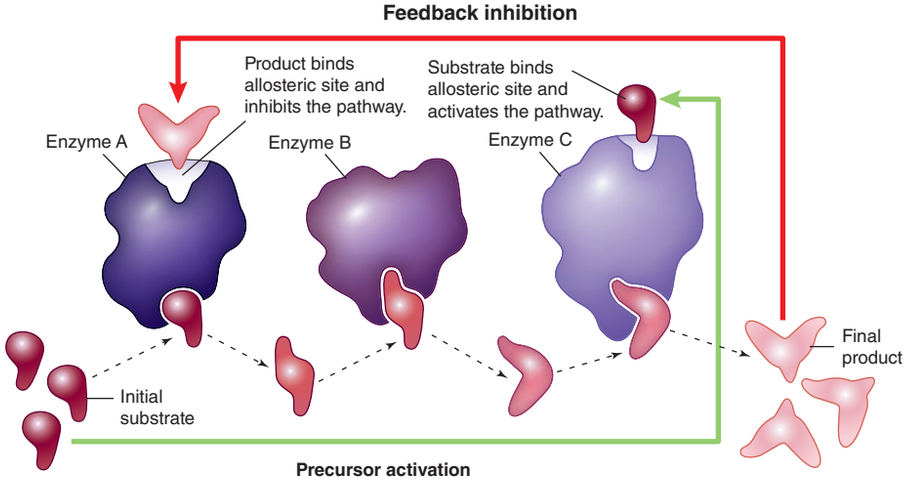

Figure 13.19. Feedback inhibition and precursor activation Feedback inhibition occurs when the product of a series of enzyme reactions accumulates in the cell and inhibits the action of an enzyme earlier in the pathway. Further production of the product is halted. Precursor activation occurs when there is an abundance of an early substrate that can specifically increase the action of an enzyme further along the pathway. Continued use of the substrate ultimately reduces its concentration in the cell. Both mechanisms rely on allosteric regulation of enzymes to control their activity.

Microorganisms may have over a thousand biochemical reactions occurring in the cell at any given time. If these reactions are not carefully controlled, chaos and waste would ensue. Generally, microorganisms regulate metabolism to avoid making enzymes for which substrates are not available and to ensure that enzymes are only active when their products are needed so that substrates are not wasted and excessive products are not generated. In general, enzyme activities are adjusted so that the product concentration is near optimal for growth in the current habitat. Metabolic regulation is accomplished in the following ways:

- *Regulation of gene expression:* Synthesis of macromolecules consume cellular resources. If an enzymatic activity is not useful in a particular environment, it makes sense to reduce or eliminate gene expression (see Chapter 11).
- *Control of enzyme activity:* For enzymes that have already been synthesized, activity can be increased or decreased by allosteric regulation. Enzyme activity can also be affected by regulating the stability of the protein.

As a general principle, metabolic pathways are regulated at the first "committed" step, where an intermediate is produced that has no other function. This is logical in terms of energy efficiency. By controlling the first step of the pathway, the cell can restrict unnecessary metabolite flux into the pathway. The signal for regulation varies depending on the process being regulated, as we saw in Chapter 11. For catabolic pathways dedicated to the breakdown of a particular molecule, it may make little sense to express the enzymes of the pathway in the absence of that molecule.

Respiration

In microorganisms using fermentation, the electrons carried by NADH are essentially waste that must be eliminated to recycle NAD^+. In microorganisms capable of respiration, these electrons can be used to fuel more ATP production using oxidative phosphorylation. Recall that respiration is the process by which electrons generated from the oxidation of an energy substrate are transferred through the electron transport system to yield energy. Cellular respiration can be either aerobic or anaerobic. **Aerobic respiration** uses oxygen (O_2) as a terminal electron acceptor. **Anaerobic respiration** uses some other organic or inorganic molecule as a terminal electron acceptor. We will investigate anaerobic respiration options later in Section 13.4, but for now let's continue looking down the energy-generating pathway of an aerobically respiring chemoorganotroph. This entire respiration process is depicted in Figure 13.10. Respiration is a large three-step process that begins first with glycolysis to generate pyruvate, which is further oxidized to CO_2 in the TCA cycle. Finally, the electrons generated during glycolysis and the TCA cycle are passed to an electron carrier, such as NAD, and down the electron transport system to generate more ATP by oxidative phosphorylation. Ultimately, the electrons are passed to a terminal electron acceptor. Again, the electron acceptor used depends on the microorganism; those that carry out aerobic respiration use O_2, but microorganisms that carry out anaerobic respiration use alternative inorganic molecules, such as CO_2 and nitrate (NO_3^-), or organic molecules, such as fumarate. In the next section (Section 13.4), we will see that the biggest advantage of respiration is that pyruvate is further metabolized to generate substantial amounts of ATP.

The tricarboxylic acid (TCA) cycle

Pyruvate is a central intermediate in glycolysis pathways. At the end of glycolysis, most of the chemical energy of glucose is still trapped in pyruvate with only a maximum two molecules of ATP and two NADH released so far. Fermenting microorganisms lose out on this potential energy because pyruvate or a similar derivative is used as an electron acceptor, not to be further oxidized. However, many microorganisms can further oxidize pyruvate to yield a large amount of energy. The tricarboxylic acid (TCA) cycle is a central pathway in respiration for doing this. The TCA cycle consists of a series of reactions that generate a large number of reduced electron carriers and is an important source of small carbon molecules for use in biosynthesis. The TCA cycle is also called the citric acid cycle or Krebs cycle, after the 1953 Nobel Prize winning biochemist Hans Krebs who described the biochemical reactions of the cycle in mitochondria. Most microorganisms capable of respiration use some version of the TCA cycle, but we will examine only the most commonly used pathway here **(Figure 13.20)**.

Prior to entering the cycle, pyruvate is first oxidized to produce acetyl-CoA. This reaction is sometimes referred to as the transition reaction. Pyruvate dehydrogenase (see Figure 13.20, Step 0) catalyzes a complex, multistep reaction in which pyruvate is both oxidized and decarboxylated, meaning that a molecule of CO_2 is lost. The overall reaction is deceptively simple:

$$\text{Pyruvate} + NAD^+ \rightarrow \text{acetyl-CoA} + NADH + H^+$$

Not shown in this equation are the *five* separate enzymatic steps that occur in the course of this reaction. Pyruvate dehydrogenase contains multiple active sites to accommodate the mechanistic complexity of the reaction. In fact, this is the largest enzyme, other than the ribosome, in most microbial cells. In addition to NAD^+, pyruvate dehydrogenase depends on coenzymes such as flavin adenine dinucleotide (FAD), an electron carrier related to NAD, and lipoamide that are not in the final equation. Lipoamide was the main target of organic arsenic-containing drugs such as Salvarsan, an early antimicrobial drug used to treat syphilis caused by the bacterium *Treponema pallidum* (see Section 1.1). Coenzyme A (CoA), a complex cofactor based on adenine, like NAD and FAD, is also required. Coenzyme A becomes covalently linked to the two-carbon acetyl group remaining from pyruvate. The acetyl group is attached via a thiol linkage to CoA **(Figure 13.21)**, making acetyl-CoA a high-energy molecule, ready to transfer its acetyl group to oxaloacetate.

The TCA cycle, as shown in Figure 13.20, includes four redox reactions (Steps 3, 4, 6, and 8), two decarboxylations (Steps 3 and 4), and a substrate-level phosphorylation to generate guanosine triphosphate (GTP; Step 5), which can be

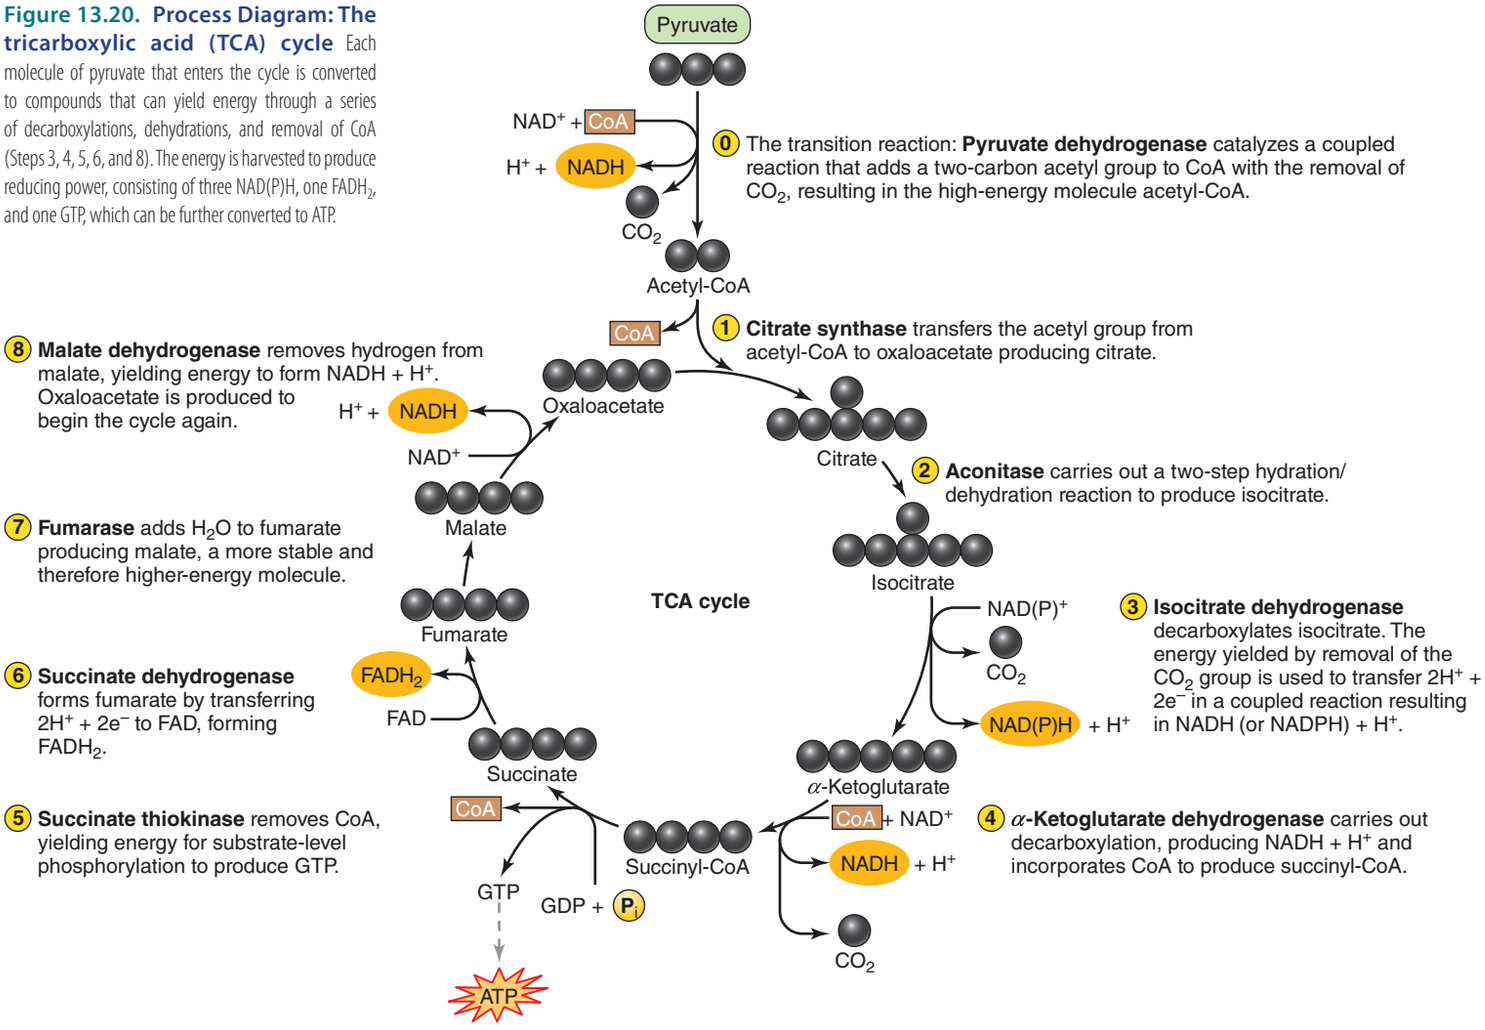

Figure 13.20. Process Diagram: The tricarboxylic acid (TCA) cycle Each molecule of pyruvate that enters the cycle is converted to compounds that can yield energy through a series of decarboxylations, dehydrations, and removal of CoA (Steps 3, 4, 5, 6, and 8). The energy is harvested to produce reducing power, consisting of three NAD(P)H, one $FADH_2$, and one GTP, which can be further converted to ATP.

converted to ATP. The initial step joins a two-carbon acetyl unit to oxaloacetate to generate citrate, a six-carbon molecule. The overall reaction for the complete catabolism of pyruvate is as follows:

$$\text{Pyruvate} + 4\,\text{NAD} + \text{FAD} + \text{ADP} + P_i \rightarrow 3\,CO_2 + 4\,\text{NADH} + \text{FADH} + \text{GTP (ATP)}$$

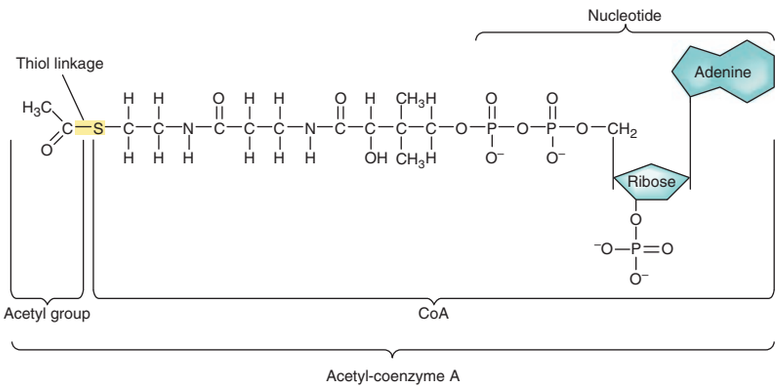

Figure 13.21. Acetyl-coenzyme A (acetyl-CoA) The acetyl group is easily transferred to other molecules by the enzyme-catalyzed hydrolysis of the thiol bond.

The TCA cycle completes the oxidation of glucose, in the form of two pyruvate molecules, to six CO_2. Note that two turns of the TCA cycle are required for the complete oxidation of one molecule of glucose, one for each pyruvate. The majority of the oxidative reactions applied to the original six-carbon skeleton of glucose occur during the TCA cycle and generate large amounts of reduced electron carriers (NADH and $FADH_2$). This is a prime function of the TCA cycle because transfer of these electrons to the electron transport system fuels ATP production. We will examine this in more detail in Section 13.4.

Anaplerotic Reactions and the TCA Cycle

The TCA cycle is critical for generating macromolecular building blocks **(Table 13.2)**.

This use of TCA cycle intermediates raises an interesting question: How can a "cyclic" pathway be sustainably operated when intermediates are diverted continuously for other purposes? Every molecule of α-ketoglutarate, succinyl-CoA, or oxaloacetate that gets consumed by a reaction *outside* the TCA cycle means one less molecule of oxaloacetate is available to combine with acetyl-CoA to keep the cycle going. For this to be sustainable, a cell must have an alternative strategy to generate oxaloacetate. Two replenishing anabolic reactions, or anaplerotic reactions, are shown below:

TABLE 13.2 TCA cycle intermediates used for anabolism

Cycle intermediate	Reaction step in cycle	Anabolic use	Products
α-Ketoglutarate	3	Amino acids	Glutamate, proline, arginine
Succinyl-CoA	4	Porphyrins	Photosynthetic pigments
Oxaloacetate	8	Amino acids, nucleotides	Aspartate, asparagine, threonine, lysine, isoleucine, methionine, cytidine, thymidine, uridine

Pyruvate carboxylase reaction:

$$\text{Pyruvate} + \text{ATP} + CO_2 \rightarrow \text{oxaloacetate} + \text{ADP} + P_i$$

Phosphoenolpyruvate carboxylase reaction:

$$\text{Phosphoenolpyruvate} + CO_2 \rightarrow \text{oxaloacetate} + P_i$$

Both reactions take a three-carbon compound from glycolysis (pyruvate or phosphoenolpyruvate) and add a carboxyl group derived from CO_2 to produce oxaloacetate. These reactions require energy, which is provided by either ATP hydrolysis, or breakage of the high-energy phosphate bond of phosphoenolpyruvate. Microorganisms generally use one or the other of these reactions, but not both, to maintain a sufficient minimum pool of oxaloacetate to keep the TCA cycle flowing while intermediates are being diverted for anabolism.

Regulation of the TCA Cycle

The TCA cycle is regulated through several enzymes. Isocitrate dehydrogenase is one of these (see Figure 13.20, Step 3). It links the TCA cycle with the electron transport system (see Section 13.4) by being the first point of NADH production from the TCA cycle. Isocitrate dehydrogenase is regulated allosterically through both feedback inhibition and precursor activation (see Figure 13.19). Feedback inhibition occurs by the allosteric inhibitors ATP and NADH. Precursor activation is carried out by the allosteric activators ADP and NAD^+. When the concentration of NADH, and correspondingly ATP, in the cell is low, the precursors NAD^+ and ADP are high and the TCA cycle operates to feed electrons into the electron transport system to produce more NADH and ATP for its energy needs. As NADH and ATP stores accumulate, NAD^+ and ADP diminish and the cycle shuts down and stops formation of α-ketoglutarate, a substrate needed for continuation of the TCA cycle. Consequently, NADH and ATP are not made. Regulation of the TCA cycle balances NADH and ATP production with the availability of precursor production.

In *E. coli*, the TCA cycle operates fully under oxic conditions. However, under anoxic conditions, the cycle is suppressed. Instead, Steps 3, 4, and 5 of Figure 13.20 are not utilized, and isocitrate, the product of Step 2, is converted to succinate and glyoxylate. Glyoxylate is converted to malate, and Step 8 of the cycle continues to oxaloacetate. The result of bypassing Step 4 is that less NADH is produced by this cycle under anoxic conditions.

13.3 Fact Check

1. Compare and contrast these three glycolytic pathways: Embden–Meyerhof–Parnas (EMP) pathway, Entner–Doudoroff pathway, and pentose phosphate pathway.
2. Differentiate between fermentation and cellular respiration.
3. Describe an overview of lactic acid fermentation and provide examples of lactic acid–fermenting bacteria.
4. Provide an overview of the process of alcoholic fermentation, including examples of microorganisms that carry out this process.
5. Describe how the following are involved in the TCA cycle: pyruvate, CO_2, NADH, $FADH_2$, and ATP.

13.4 Respiration and the electron transport system

3D ANIMATION

What becomes of the electrons generated by glycolysis and the TCA cycle?

In the previous section, we learned how oxidation of organic compounds such as glucose can generate adenosine triphosphate (ATP) through substrate-level phosphorylation during glycolysis and the TCA cycle. In addition, both the TCA cycle and, to a much lesser extent, glycolysis generate a considerable amount of the reduced electron carriers, nicotinamide dinucleotide (NADH) and flavin adenine dinucleotide ($FADH_2$). The electrons carried by these molecules still have a great deal of potential energy, as indicated by their negative $\Delta E_o'$ values (see Figure 13.12), and can be used to reduce other molecules to generate further energy. As you will recall, cellular respiration is the process by which electron carriers, such as NADH, generated from the oxidation of an energy substrate, transfer electrons through the electron transport system to yield energy.

Respiration allows the recycling of NAD (NADH to NAD^+) to be used again and the generation of ATP.

In fermentation, ATP and NADH are generated through glycolytic pathways. NADH is converted back to NAD^+ by donating an electron to an organic end product, such as pyruvate. Fermentation does not produce additional ATP because the TCA cycle and electron transport system are not used. Therefore, respiration is more energetically beneficial. Cellular respiration can be either anaerobic, where O_2 is not used as a terminal electron acceptor, or aerobic, where O_2 is used as the terminal electron acceptor. Aerobic respiration produces a maximum of 38 molecules of ATP for each molecule of glucose versus a maximum of two molecules of ATP from fermentation. **Figure 13.22** shows the possible catabolic fates of glucose and the pathways to fermentation and aerobic and anaerobic respiration. Some microorganisms, such as *Escherichia coli*, can use all three options for generating ATP. Which option is used depends on the availability of suitable electron donors and acceptors. Central to the process of cellular respiration is the electron transport system, which is our next topic.

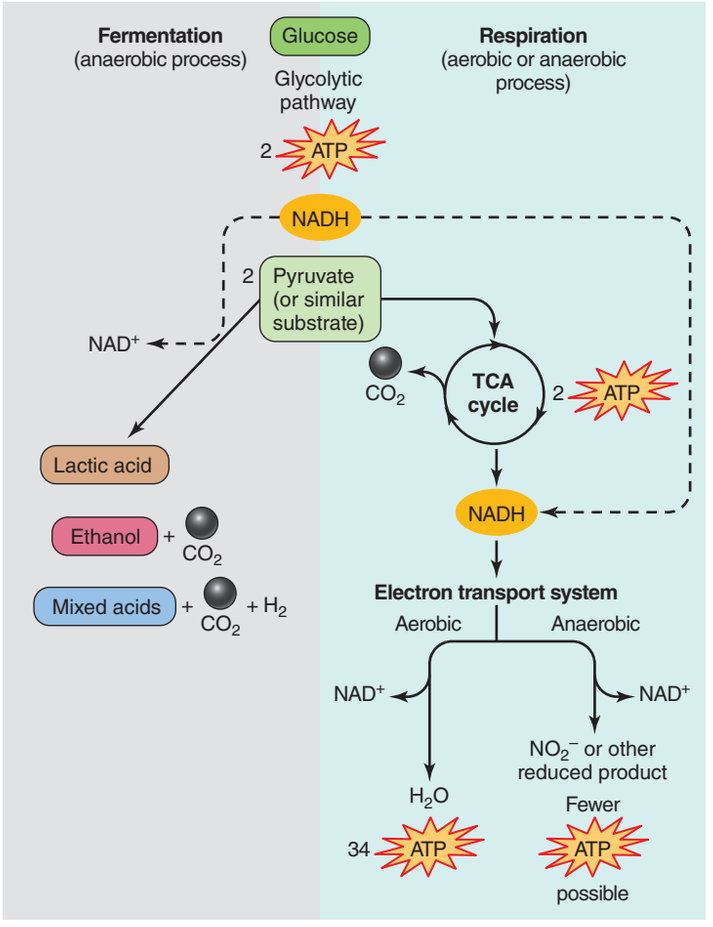

Figure 13.22. Possible catabolic fates of glucose for generating energy Glucose is catabolized in a glycolytic pathway under oxic or anoxic conditions to form pyruvate or similar molecules and a maximum of two ATP. Microorganisms using fermentation (*left*) to reduce glycolytic products form organic waste molecules, CO_2 and H_2. The TCA cycle is not used. Microorganisms using cellular respiration (*right*) use the TCA cycle to catabolize pyruvate in a series of oxidation reactions resulting in CO_2 and NADH. Electrons carried by NADH enter the electron transport system and are used to generate a proton motive force and, ultimately, ATP. Under oxic conditions, glucose can be completely catabolized to carbon dioxide and produce 38 ATP. Some microorganisms are capable of using anaerobic respiration when O_2 is not available, which generates fewer ATP. The number varies with the electron acceptor used.

The electron transport system

The ultimate purpose of respiration is to facilitate the formation of ATP through oxidative phosphorylation by using the energy carried by the electron carriers generated during glycolysis and the TCA cycle. The transfer of electrons from NADH to a terminal electron acceptor, such as O_2, produces a very large difference in reduction potential (~1.1 volts). The use of an incremental series of redox reactions in the electron transport system ensures that the energy released by electron transfers is captured with maximal efficiency. This energy is used to drive the energetically unfavorable movement of protons across the membrane to be used for ATP production or to do mechanical work. To accomplish this, the electron transport system is used. Electrons are progressively passed down a chain of electron acceptors with increasing redox potentials, much like water flowing down sets of rapids. As the electrons move from one acceptor to the next, protons are pumped out of the membrane at multiple sites along the chain **(Figure 13.23)**. This creates a strong potential difference across the membrane, which forms the **proton motive force**. Recall from Chapter 2, the proton motive force drives a flow of H^+ through ATP synthase to produce ATP.

Respiratory electron transport systems are composed of integral membrane proteins and lipids and their associated cofactors. To recap, a cofactor is a molecule that binds to an enzyme, either stably or transiently, and is needed for the activity of the enzyme. The cofactors of enzymes involved in the electron transport system participate directly in electron transfer reactions. The major groups of electron carriers are shown in **Table 13.3**.

In bacteria and archaea, the electron transport system is located in the plasma membrane. In eukaryal microorganisms, it is located in the inner mitochondrial membrane. There are differences in the composition of the electron carriers between archaeal, bacterial, and eukaryal microorganisms, but the function is fundamentally the same in all. There are also variations in the aerobic and anaerobic respiration electron transport systems, but again, they all function to yield energy from the transport of electrons.

Aerobic Respiration

Recall from the previous section that aerobic respiration specifically uses O_2 as a terminal electron acceptor and can only be carried out under oxic conditions. Molecular oxygen is a strong oxidant and excellent terminal electron acceptor (see Figure 13.12), allowing the release of a great deal of energy as electrons move from NADH to O_2. We can examine some of the details of the electron transport system by following the example of aerobic respiration as it occurs in mitochondria, which has been relatively well-studied. The system is organized into four membrane complexes (see Figure 13.23). The pair of electrons carried through the mitochondrial matrix by NADH is transferred to Complex I, also known as NADH dehydrogenase or NADH:coenzyme Q oxidoreductase. The NADH

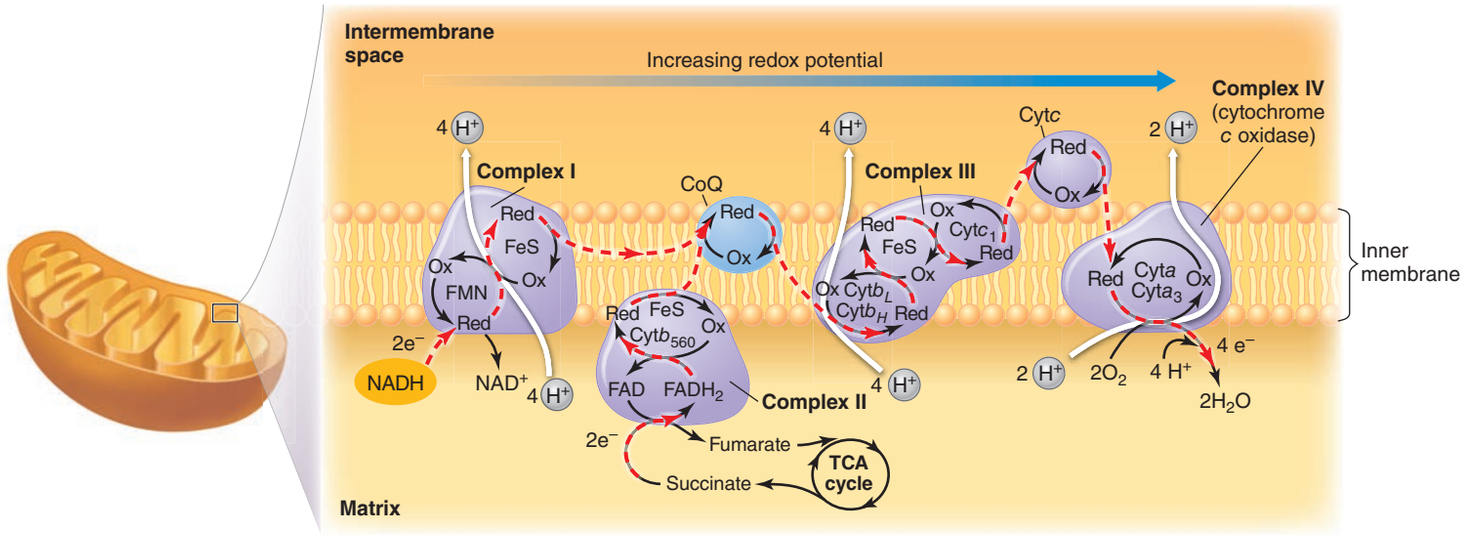

Figure 13.23. The aerobic electron transport system of mitochondria Electrons are passed from NADH and $FADH_2$ to a series of membrane-associated molecules and complexes that are arranged in close proximity to one another in order of increasing redox potential to move the electrons along. At points along the chain, protons are transferred across the mitochondrial inner membrane, creating a force that can be used to synthesize ATP. The red dashed line shows the flow of electrons ending with the reduction of O_2 forming H_2O.

dehydrogenase is a complex containing a flavoprotein with a bound cofactor called flavin mononucleotide (FMN) that accepts the electrons from NADH and passes them to iron-sulfide (FeS) centers of the iron-sulfur proteins, also contained in the complex. As the transfer occurs, four protons are ejected from Complex I to the opposite side of the mitochondrial inner membrane. This is the first step in building a proton concentration gradient across the membrane.

Complex II, the succinate dehydrogenase complex, accepts electrons carried by $FADH_2$, which was generated from the TCA cycle. Complex II is associated with succinate dehydrogenase, which you may recall from the TCA cycle (see Figure 13.20, Step 6), and is the site of a redox reaction generating the reduced cofactor $FADH_2$. Succinate dehydrogenase is the only enzyme of the TCA cycle that is physically associated with the plasma membrane, or inner mitochondrial membrane of eukaryal cells. The fumarate produced by this enzyme continues in the TCA cycle. Electrons carried by $FADH_2$, which is covalently attached to the enzyme, are fed directly into the electron transport system by transferring them to coenzyme Q. Because these electrons do not go through Complex I, they miss the proton-pumping event it carries out. Thus, the yield of ATP from electrons entering the chain from Complex II only is reduced.

Electrons from Complex I and/or Complex II are passed to the carrier coenzyme Q (CoQ). CoQ, also known as ubiquinone, belongs to a class of lipids called quinones. Quinones are mobile in membranes and carry hydrogen and electrons from Complexes I and II to Complex III of the electron transport system. After reduction, ubiquinone becomes ubiquinol, which then passes the electrons to Complex III, the ubiquinol:cytochrome *c* oxidoreductase, sometimes called the cytochrome bc_1 complex. This is the second proton-pumping step. Cytochromes are electron-transporting proteins that contain heme groups, complex organic ring structures with an iron (Fe) atom bound in the center. The iron atom alternates in its oxidation state between Fe^{3+} and Fe^{2+} as it accepts and transfers an electron. Three types of cytochrome proteins are involved in aerobic respiratory electron transport, cytochromes *a*, *b*, and *c*. Each of these contains a slightly different type of heme group, heme *a*, *b*, or *c*, and there are multiple variants of each cytochrome type, indicated by a subscript number following the letter. Electrons passed to Complex III move through two *b*-type

TABLE 13.3 Major groups of electron carriers of the electron transport system

Name	Description	Examples
Flavoproteins[a]	Proteins composed of two different subunits that bind the riboflavin-derived cofactor FAD or FMN	Exists as a subunit of NADH dehydrogenase and succinate dehydrogenase
Quinones[a]	Non-protein, cyclic molecules derived from aromatic compounds	Ubiquinone (coenzyme Q),[b] plastoquinone
Iron-sulfur proteins	Proteins containing iron-sulfur clusters usually consisting of four iron atoms arranged in a tetrahedral structure with sulfur atoms	Ferredoxin[b]
Cytochromes[c]	Proteins containing a heme group with a central metal ion	$Cytc_1$, $Cyta_3$

[a] Can also carry H^+.
[b] Can be found as individual proteins or as subunits of larger complexes, such as NADH dehydrogenase and succinate dehydrogenase
[c] Can be found as individual proteins or as subunits of larger complexes, such as Complex III and IV of mitochondria.

heme groups, an iron-sulfur center, and a *c*-type cytochrome before being transferred to a separate cytochrome *c* associated with the external surface of the membrane. From cytochrome *c*, electrons are transferred to Complex IV, also called cytochrome *c* oxidase, which catalyzes oxidation and reduction reactions using O_2 as the terminal electron acceptor to produce two H_2O molecules using electrons and H^+ (see Figure 13.23). Complex IV contributes to proton motive force generation by catalyzing the transfer of two protons from the cytoplasm across the membrane. Note that the number of protons transferred at each point is not precisely known. Approximately eight to ten protons are pumped for each NADH oxidation along with transfer of four electrons through the chain.

The mitochondrial respiratory electron transport system is functionally similar to that of many aerobically respiring bacteria and archaea under normal atmospheric levels of oxygen (approximately 21 percent). However, the proteins and carriers of the electron transport system used by various microorganisms can vary considerably. Many microorganisms can fine-tune their electron transport system by switching proteins and cofactors in response to the environment. For example, the bacterium *E. coli* has two terminal oxidases, one of which has a significantly higher affinity for O_2, and is expressed most highly under low-oxygen conditions. Some bacteria encode four or more terminal oxidases, allowing them to adapt to changes in the availability of oxygen and other terminal electron acceptors.

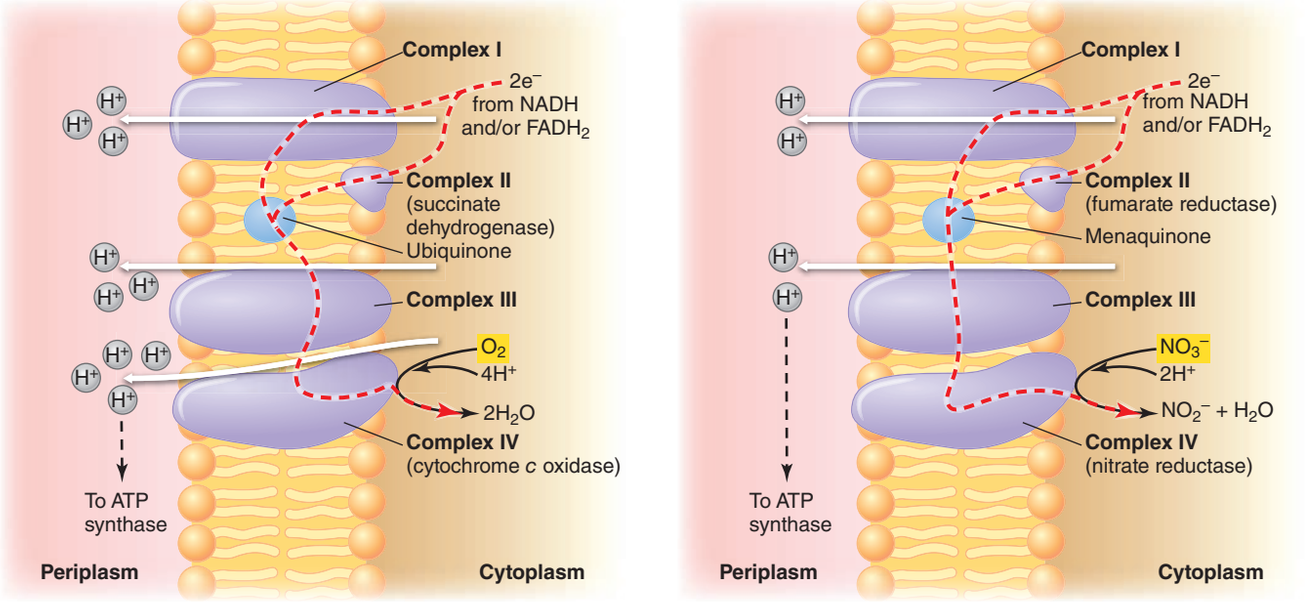
Cell respiration ANIMATION

Anaerobic Respiration

Anaerobic respiration, previously defined as the use of electron acceptors other than O_2, is the oldest form of cellular respiration, evolving during Earth's early anoxic, reducing atmosphere. Bacteria that use anaerobic respiration include the sulfate-reducing bacteria, obligate anaerobes commonly found in aquatic marine sediments. The importance of sulfate reduction in ecosystems is highlighted in Chapter 15. For facultative anaerobes, if the concentration of O_2 is sufficiently low to severely limit aerobic respiration, they can use alternative electron acceptors for anaerobic respiration. Some facultative anaerobes, donate excess electrons to unusual electron acceptors under anoxic conditions. As **Perspective 13.2** describes, this can result in conducting an electrical charge to surrounding metal surfaces.

CONNECTIONS Methanogens, introduced in **Section 4.3**, are obligate anaerobes using anaerobic respiration, exclusive to the domain *Archaea*, that exist in carbon-rich environments, such as swamp sediments and intestinal tracts of animals. Many methanogens use H_2 as an electron donor and CO_2 as an electron acceptor, producing methane (CH_4). The metabolic diversity of methanogens and their role in nutrient cycling are explored in **Section 14.2**

The enzyme complexes in the anaerobic transport chain have different cytochromes and quinones than are found in the aerobic transport system. Enzyme complexes involved in reduction of the terminal electron acceptor are called reductases, rather than oxidases, because oxygen is not the terminal acceptor. One of the most common alternative acceptors is nitrate (NO_3^-), which is reduced to nitrite (NO_2^-), as shown in **Figure 13.24**. Some bacteria stop at nitrite, whereas others employ additional enzymes to further reduce nitrite to



A. *E. coli* aerobic electron transport system

B. *E. coli* anaerobic electron transport system

Figure 13.24. Comparison of aerobic and anaerobic respiration in *E. coli* **A.** Aerobic respiration uses an electron transport system that transfers electrons to O_2, the terminal electron acceptor. **B.** Anaerobic respiration uses an electron transport system composed of similar but not identical molecules. The terminal electron acceptor is not O_2, and the cytochrome *c* oxidase complex (Complex IV) is replaced by a reductase enzyme. Shown here is nitrate reductase, which transfers an electron to nitrate to produce nitrite. Compared to aerobic respiration, fewer protons are pumped per electron, resulting in less ATP generation.

Perspective 13.2
ELECTRICIGENIC BACTERIA AND MICROBIAL FUEL CELLS

In 1911, British microbiologist M. C. Potter reported a fascinating application for *Escherichia coli*. Observing that "the disintegration of organic compounds by microorganisms is accompanied by the liberation of electrical energy," Potter managed to generate a small electrical current from an *E. coli* culture and, in doing so, created the first microbial fuel cell. As Potter realized, oxidation of organic compounds such as glucose initiates a flow of electrons. Depending on the microorganism, there are many possible destinations for these electrons, including being transferred to O_2 during respiration. Construction of a microbial fuel cell simply required redirecting the electrons to an external anode, from which they could flow through an electrical circuit. Potter's culture generated miniscule electrical currents with no practical utility. However, contemporary microbiologists are revisiting the microbial fuel cell concept in the hope of generating a useful, real-world device.

Bacteria have been identified that are far more adept than *E. coli* at transferring electrons from organic electron donors to insoluble external acceptors and generating usable current in the process. Such bacteria, which include members of the Gram-negative genera *Shewanella* and *Geobacter*, are called "electricigens." In anoxic environments, these microorganisms look for a place to dump electrons obtained from oxidation of organic compounds. When soluble electron acceptors are not available, insoluble metals such as Fe^{3+} and Mn^{4+}, which have relatively positive reduction potentials, can provide this service. Note that this is distinct from lithotrophy, where metal ions serve as electron *donors*, rather than *acceptors*. The structural challenge that electricigens face is to transfer electrons from redox centers in the plasma membrane to insoluble metal oxides beyond the cell wall and cell surface.

In 2005, Derek Lovley's lab at the University of Massachusetts–Amherst discovered that one of the best-studied electricigens, *Geobacter sulfurreducens*, produces pilus-like structures that serve as nanowires to conduct electricity from the bacterium to metal surfaces **(Figure B13.1)**.

Other labs soon demonstrated that *Shewanella oneidensis* also depends on conductive pilus-like appendages for electron transfer to insoluble ferric oxide. Precisely how these structures connect with the electron transport system and serve as efficient electrical conductors is not yet known, but the goal seems clear—conductive nanowires expand the physical reach of the cell for electron transfer reactions and eliminate the need for direct cell surface contact with an acceptor. There is still much to learn about this phenomenon. With respect to applications, results so far have been modest. The highest current generated was roughly 50 watts for a cubic meter of fuel cell volume, about enough to power a lightbulb. However, scientists and engineers are intrigued by the potential to develop improved microbial fuel cells that generate electricity while consuming organic wastes. Perhaps such systems could be used for bioremediation of organic pollutants in anoxic sediments or groundwater. Even if large-scale applications do not become a reality, microbial fuel cells could be useful in more limited contexts, such as powering devices in remote, harsh environments where solar cells are not appropriate.

dinitrogen (N_2) in a process called **denitrification**. Denitrification is harmful to soil productivity as it converts nitrate that can be used by plants into N_2 that diffuses into the atmosphere (see Section 14.3).

Other potential respiratory electron acceptors include CO_2, sulfate (SO_4^{2-}), elemental sulfur (S^0), Fe^{3+}, and organic molecules such as fumarate. Fumarate can be generated internally by the TCA cycle. These molecules all have less positive reduction potentials than O_2, but significantly more positive reduction potentials than NADH, so energy is still released by letting electrons flow to them. Recall that the energy released by a redox reaction is proportional to the difference in reduction potentials between the donor and acceptor. **Figure 13.25** shows some examples of terminal electron acceptors used by various microorganisms. Compared to aerobic respiration from glucose ($\Delta G^{\circ\prime} = -28{,}842$ kJ), less energy is released during anaerobic respiration. For example, the $\Delta G^{\circ\prime}$ values for anaerobic respiration using electron acceptors NO_3^-, SO_4^{2-}, and S^0 are –1,796 kJ, –453 kJ, and –333 kJ, respectively. This means fewer protons are pumped per electron, and less ATP is generated.

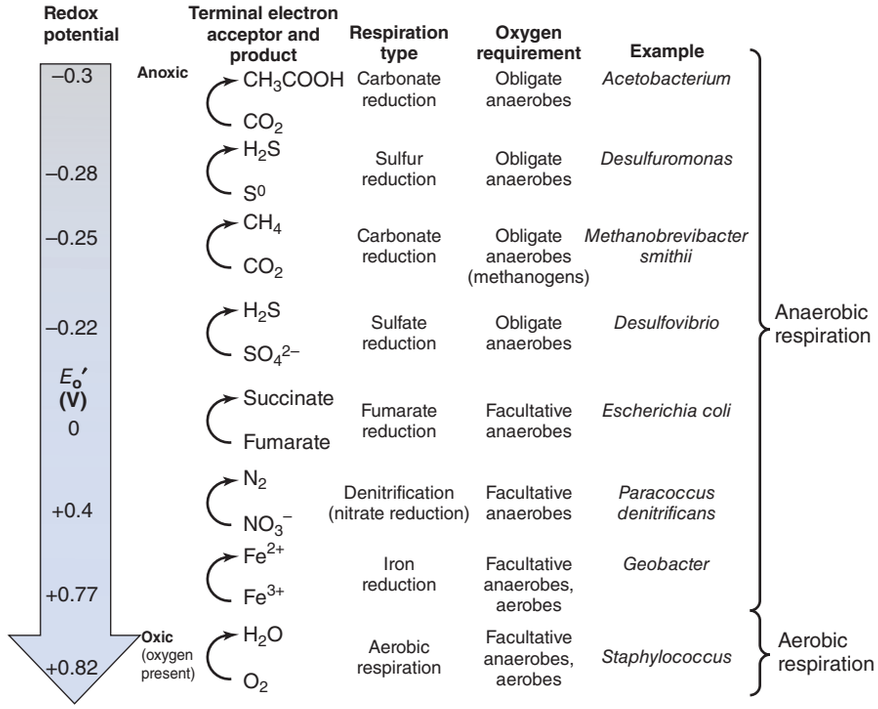

Figure 13.25. Redox potentials of various electron acceptors Molecular oxygen, used only in aerobic respiration, has the highest redox potential and is capable of generating much more energy than the alternative acceptors used in anaerobic respiration.

Microorganisms capable of both aerobic and anaerobic respiration prefer to use O_2 when it is available. Expression of terminal reductases for anaerobic respiration is generally repressed under oxic conditions. Only under anoxic conditions is expression of an alternative terminal reductase induced by the presence of its substrate. We can look at *E. coli* for an example. *Escherichia coli* can alter the composition of its electron transport system to suit the conditions it experiences. Under anoxic conditions, it expresses reductases and represses expression of oxidases. Fumarate reductase and nitrate reductase are alternatives that can be used to allow *E. coli* flexibility depending on what terminal electron acceptor is available. If you compare the redox potentials of fumarate and nitrate in Figure 13.12, you will see that nitrate is a preferred electron acceptor for anaerobic respiration as its reduction yields more energy than fumarate. If both compounds are present, nitrate reductase will be preferentially expressed. *Escherichia coli* ensures this by employing a nitrate detection system that, when nitrate is detected, induces expression of transcription factors that upregulate transcription of nitrate reductase and actively represses genetic expression of fumarate reductase. Finally, if a suitable terminal electron acceptor for anaerobic respiration is not available, or is of low concentration, then fermentation is used to generate small amounts of ATP to sustain growth until conditions change. To facilitate this, pyruvate dehydrogenase, the enzyme that converts pyruvate to acetyl-CoA, is repressed under anoxic conditions. Instead, pyruvate will be converted to mixed acid fermentation products through the combined action of other enzymes (see Figure 13.17).

We must distinguish between transfer of electrons to acceptors for energy metabolism versus assimilation. An example is the use of nitrate and sulfate as electron acceptors. When nitrate and sulfate are used as respiratory electron acceptors, the process is known as dissimilatory reduction. Assimilatory reduction occurs when these molecules are reduced so they can be incorporated into biomolecules such as amino acids. Dissimilatory electron transfer reactions are carried out by membrane-bound reductases linked to the electron transport system and generate large amounts of reduced waste products, such as N_2 or hydrogen sulfide (H_2S), that are eliminated from the cell. Assimilatory electron transfer reactions occur in the cytoplasm using soluble electron donors such as NADPH or $FADH_2$, and produce only as much product as is needed by the cell. We will return to assimilatory processes in Section 13.7.

Chemolithotrophy

So far we have focused on the energetics of chemoorganotrophs, which use organic molecules as an electron source and generate ATP either by fermentation or respiration. However, there are many bacteria and archaea that use inorganic sources of electrons. Recall that this is lithotrophy (see Figure 6.1). Photolithotrophy uses light as the energy source for ATP production, and it will be covered in Section 13.6. Chemolithotrophs include archaea and bacteria, such as the giant tube worm bacteria, that can use reduced inorganic sources from their environment for electrons and energy to produce ATP. These sources include metals such as Fe^{2+}, non-metals such as S^0, and gases such as H_2, ammonia (NH_3), and H_2S. Since inorganic compounds cannot supply these organisms with carbon compounds, most chemolithotrophs are autotrophs and synthesize carbon compounds from CO_2 and, in some cases, methane (CH_4). Consequently, respiration in chemolithoautotrophs does not use glycolysis and the TCA cycle to generate reducing power and ATP. However, some chemolithotrophs can also use heterotrophy, utilizing

glycolytic breakdown of glucose and the TCA cycle when suitable carbon substrates are present—a metabolism sometimes called "mixotrophy."

Chemolithotrophs directly couple ATP synthesis by oxidative phosphorylation to oxidation of the inorganic source. Like chemoorganotrophs, they pass electrons down an electron transport system to generate ATP via the proton motive force (see Figure 13.26). This type of respiration can be aerobic, using O_2 as a terminal electron acceptor if it is present in sufficient quantities, or it can be anaerobic, using other terminal electron acceptors. Of course, the use of O_2 is energetically preferred as it gives the highest free energy yield and thus will generate the most ATP.

The respiratory electron transport system of chemolithotrophs contains specific membrane-bound enzymes to facilitate the removal of electrons directly from the inorganic source. For example, microorganisms that oxidize hydrogen gas have a large hydrogenase enzyme, in addition to a collection of cytochromes. Consequently, electron carriers like NADH are not required for ATP generation in chemolithotrophs. The major respiration differences between chemolithotrophy and chemoorganotrophy are shown in **Figure 13.26**.

The proton motive force

As the electron transport system moves electrons from one acceptor to the next, protons are pumped out of the membrane at sites along the chain (see Figure 13.24). This creates a potential difference across the membrane, which forms the proton motive force. The proton motive force drives a stream of H^+ through ATP synthase to produce ATP, but can also be used to do mechanical work for the cell. How are these activities achieved?

First, let's look at how the proton motive force works. During respiratory electron transport, there is a net movement of H^+ across a membrane **(Figure 13.27)**. The topology of this movement differs among microorganisms. In archaea and Gram-positive bacteria, protons move from the cytoplasm out of the cell. In Gram-negative bacteria, the movement is from cytoplasm to periplasm. In the mitochondria of eukaryal cells, protons start in the mitochondrial matrix, and move to the intermembrane space, between the inner and outer mitochondrial membranes (see Figure 13.23). A proton motive force is also generated during photosynthesis, as we will see in Section 13.6.

Transmembrane proton pumping results in both an H^+ concentration difference *and* a charge difference between the two sides of the membrane. The "outside" to which protons have been pumped has an acidic pH, that is, a higher H^+ concentration relative to the inside, and a more positive charge. Together, these factors yield the proton potential (Δp), a quantitative expression of the force pushing protons to reenter the cell or mitochondrial interior. Protons outside of the membrane cannot simply diffuse back into the cell because their charge forbids them from crossing to the hydrophobic interior of the membrane.

Cell respiration ANIMATION

One of the most important uses of the transmembrane proton gradient is to drive ATP synthesis through the membrane ATP synthase, the focus of the next section. In bacteria, the proton motive force has other applications as well. Rotation of the flagellar filament to propel cells is driven by H^+ influx through the flagellar motor in the membrane. The proton motive force also energizes many transmembrane transport systems. In *E. coli*, proton symporters—channels that mechanistically couple the inward movement of H^+ to simultaneous import of another molecule—are used to transport several

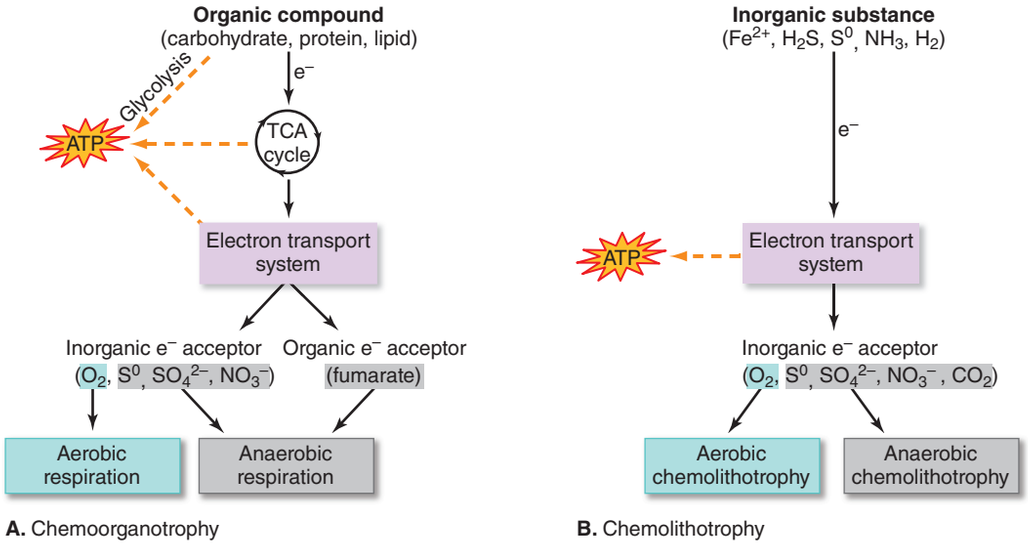

Figure 13.26. Comparison of respiration in chemoorganotrophs and chemolithotrophs **A.** In chemoorganotrophs, respiration involves the removal of electrons through oxidation of an organic compound, such as glucose, via glycolysis and the TCA cycle. ATP is generated at each of these steps by substrate-level phosphorylation. The electrons are carried by electron carrier molecules to the electron transport system to generate further ATP by oxidative phosphorylation. The final electron acceptor is O_2 in aerobic respiration. Anaerobic respiration uses an alternative inorganic or organic electron acceptor. **B.** Bacteria and archaea that use chemolithotrophy remove electrons from a reduced inorganic substance and pass the electrons directly to an electron transport system. Production of ATP occurs only through oxidative phosphorylation. Most chemolithotrophs can use O_2 as a terminal electron acceptor for aerobic chemolithotrophy. In anaerobic chemolithotrophy, some other oxidized inorganic molecule is used.

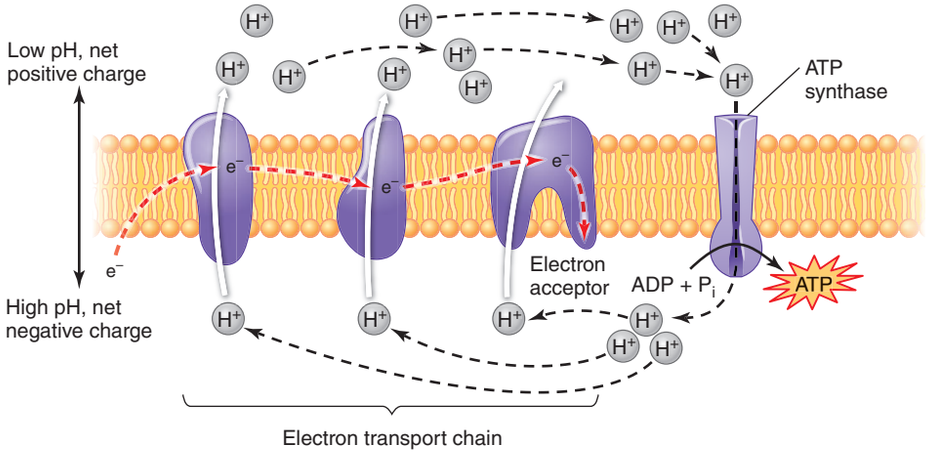

Figure 13.27. Generation of the proton motive force The electron transport system pumps protons across the membrane. This creates a pH and charge differential due to a net increase in protons in the mitochondrial intermembrane space compared to the matrix. In bacteria and archaea, the proton increase occurs outside the plasma membrane compared to the cytoplasm. The differentials across the membrane create a motive force that compels protons to flow back across the membrane. The flow of protons is channeled through the ATP synthase complex to produce ATP from ADP and P_i.

amino acids, lactose, xylose, arabinose, galactose, citrate, and sucrose, as well as other nutrients (see Figure 2.11).

The H^+ gradient is functionally replaced in some microorganisms by a sodium gradient, or sodium motive force (SMF), which is likewise used for ATP synthesis, flagellar motor rotation, and nutrient transport. SMF-dependent processes and transporters for the most part utilize proteins that are evolutionarily homologous to proton motive force-dependent systems. Several *Vibrio* species, including the pathogen *Vibrio cholerae* (see Microbes in Focus 21.7), rely extensively on SMF, at least in marine environments. There's clearly more to learn on this subject, which is made even more intriguing by a theory that the use of sodium gradients for energy metabolism actually preceded the use of H^+ gradients and that the change in ion specificity occurred many times independently during the evolution of various microbial lineages.

ATP synthase

The potential energy of the proton motive force is captured by allowing protons to flow back down their charge and concentration gradient through ATP synthase **(Figure 13.28)**. The ATP synthase enzymes are remarkably similar in structure and function in all organisms, having been conserved through evolution. ATP synthase functions as a rotary motor. The F_0 portion is embedded in the membrane and is composed of an "a" subunit and a rotor composed of "c" subunits. The F_0 portion provides the path through which protons cross the hydrophobic interior of the membrane. The F_0 portion is held to the cytoplasmic F_1 portion via the b and δ subunits. The F_1 portion consists of pairs of α and β subunits arranged around a central γ spindle. The ε subunit is also part of F_1. A proton first contacts the a subunit, then moves on to contact a c subunit. This causes the c subunit to rotate, and the proton is ejected to the cytoplasm. Rotation of a c subunit turns the entire rotor assembly including the large γ spindle of the F_1 component. The movement of approximately three protons turns the rotor and the spindle 120°, which is enough to produce one ATP molecule. The actual mechanism of ATP production involves changes in conformation of the F_1 β subunits with rotation. With one 120° turn of the spindle, the affinity of one of the three β subunits for the substrates ADP and P_i increases significantly and ATP is made. The β subunit then returns to its low-affinity conformation. Movement of the next three protons acts in turn on the next β subunit.

The ATP synthase system can run in reverse to pump H^+ out of the cell, via the F_0 portion, at the expense of ATP. If ATP is present in the cytoplasm and there is no proton motive force pushing inward, proton pumping to the outside can happen spontaneously, simply because the hydrolysis of ATP becomes energetically

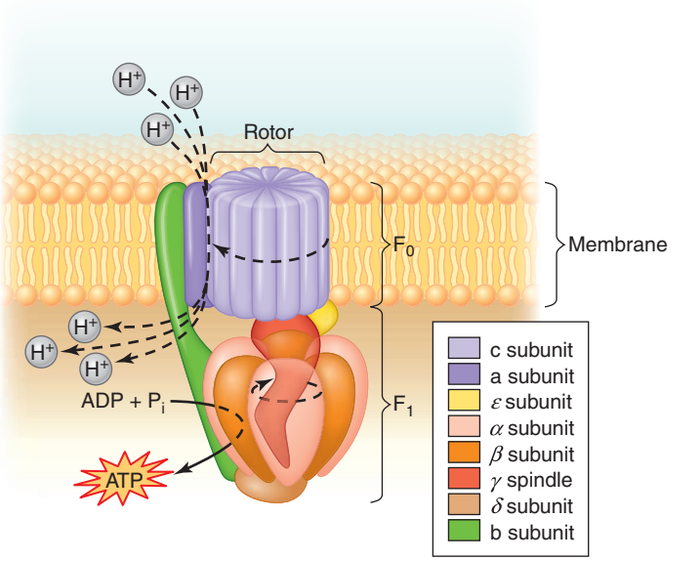

Figure 13.28. ATP synthase function The flow of three protons through F_0 causes rotation of the γ spindle and conformational changes in the β subunits. Each rotation causes a change in a β subunit from a weak to a strong affinity for the substrates ADP and P_i, resulting in the production of ATP. After ATP is released, the conformation cycles back to a weak affinity and the process repeats for the next β subunit upon passage of the next three protons.

favorable. Some bacteria intentionally use F_1F_0 as a proton pump to generate proton motive force to drive the cytoplasmic accumulation of ADP and P_i and to maintain ionic balance.

Eukaryal cells often use related systems called V-type ATPases as dedicated ATP-driven proton pumps. The V-type ATPases are important for generating acidic conditions in organelles such as lysosomes. Recall from Chapter 3 that lysosomes are important for breaking down engulfed food particles and "old" organelles. The various hydrolase enzymes responsible for digesting these materials, including proteases and nucleases, only function under acidic conditions in order to protect the more neutral cytoplasm should they escape.

CONNECTIONS Lysosomes are also important for destroying microorganisms that have been taken in by phagocytic cells such as macrophages, which we will encounter in **Chapter 19**.

13.4 Fact Check

1. What are two main results or benefits of respiration?
2. Describe the flow of electrons in the electron transport system of organisms using cellular aerobic respiration.
3. What is anaerobic respiration, and what can serve as terminal electron acceptors in this process?
4. Differentiate between dissimilatory reduction and assimilatory reduction.
5. What is the proton motive force, and what is it used for in a cell?
6. Describe the role of ATP synthase.
7. Describe the differences in ATP generation between chemolithotrophs and chemoorganotrophs.

13.5 Metabolism of non-glucose carbon sources

How do microorganisms get nutrition from compounds other than glucose?

So far we have focused our discussions on metabolism in the context of glucose catabolism. Through this, we have covered ways of generating ATP through glycolysis, fermentation, and respiration, including the TCA cycle and the electron transport system. Although glucose is used by many microorganisms as an energy, carbon, and electron source, and is very abundant in the biosphere, particularly as a component of cellulose, there are many other carbohydrates. How are these compounds metabolized?

Sugars other than glucose

Rather than evolve completely new metabolic pathways for metabolizing non-glucose sugars, most organisms simply add a few enzymatic steps to convert alternative sugars into glucose or a glycolytic intermediate, at which point the product can enter an established glycolytic pathway. For example, fructose, a component of sucrose and a common hexose (a six-carbon sugar) found in fruits, is phosphorylated by the enzyme fructokinase to produce fructose 6-phosphate, an intermediate in the EMP pathway of glycolysis (see Figure 13.13).

Another sugar commonly encountered by bacteria that live in mammalian intestines is the disaccharide lactose, the major sugar in milk. In Section 11.2 we learned about the *lac* operon in *Escherichia coli*, which contains genes encoding enzymes essential for transport and metabolism of lactose. Disaccharides such as lactose are first split by hydrolysis or phosphorolysis into monosaccharides, which are handled separately. Lactose is split by β-galactosidase into galactose and glucose. Glucose immediately enters glycolysis, whereas galactose is phosphorylated, then converted through additional reactions to glucose 6-phosphate. Other common disaccharides include sucrose, maltose, trehalose, and cellobiose.

Pentose sugars are common in many habitats and are readily consumed by many microorganisms. In plant cell walls, xylans and arabinogalactans composed of the pentoses D-xylose and L-arabinose make up hemicellulose, which is nearly as abundant as cellulose. As with glucose metabolism, there are diverse approaches to pentose metabolism. In *E. coli* and many other bacteria, xylose is isomerized to xylulose, which is then phosphorylated to xylulose 5-phosphate, an intermediate in the pentose phosphate pathway. Arabinose undergoes a similar process, being isomerized to ribulose then phosphorylated to ribulose 5-phosphate, another intermediate in the pentose phosphate pathway. Some bacteria, including *Caulobacter* and *Pseudomonas* species, take an alternative approach, metabolizing xylose and arabinose through a modified version of the Entner–Doudoroff pathway. Yeasts take yet another approach, reducing xylose to xylitol using the enzyme xylose reductase. Xylitol is then converted to xylulose and phosphorylated.

CONNECTIONS Complex carbohydrates are abundant in plant structural material, and many of these carbohydrates are present in the waste products of agriculture, such as corn and wheat stalks. Recall that **Section 12.4** described microbial approaches to biofuel production using cellulose, hemicellulose, and lignin.

Polysaccharides

Polysaccharides are abundant in the biosphere. They are used as structural components of cell walls in many organisms, as structural components of multicellular organisms, such as insect exoskeletons, and as carbon storage deposits. Polysaccharides are typically enormous molecules, too big to be

transported intact across the plasma membrane. The solution for microorganisms is usually to secrete enzymes that carry out preliminary degradation of the polymer to smaller subunits, usually mono- or disaccharides. The microbial cell secreting such enzymes is usually in direct physical contact with the polymer being attacked, attempting to capture as much as possible of the breakdown product.

Proteins and amino acids

Proteins are rich nutrient sources; their amino acid constituents can provide carbon, nitrogen, sulfur, and energy. Polypeptide chains must be broken down into small polypeptides or individual amino acids to be transported into microbial cells for catabolism. Catalysis is accomplished by secreting enzymes called proteases. Not all proteases are used to acquire nutrients; some pathogens secrete proteases to defend themselves from attack by host proteins, such as antibodies. The first step in the breakdown of most amino acids inside the cytoplasm is deamination in which the amino group is removed by transfer to glutamate (transamination) **(Figure 13.29)**. The organic acid that remains after deamination, such as pyruvate, is often used in the TCA cycle, although this depends on the amino acid. Not surprisingly, synthesis of many amino acids works in the opposite direction, with TCA cycle intermediates as the starting point, to which the amino group is added as the final step. We will return to this in Section 13.8.

The profile of carbon sources a microorganism is capable of using can assist in its identification. Rapid bacterial identification systems, described in **Toolbox 13.1** allow simultaneous detection of a microorganism's metabolic functions using a variety of media contained on a single strip or tube. These tests require very small quantities of media, reagents, and culture and are simple to use and reliable.

Lipids

Lipids are highly reduced carbon molecules that are rich in potential energy and are actively catabolized by many microorganisms. Phospholipids and triglycerides are initially attacked by enzymes called lipases that separate fatty acid chains of various lengths from the glycerol or modified phosphoglycerol backbone. The backbone unit is then metabolized independently for carbon and energy, but the big energetic payoff is from the fatty acids as they can donate many electrons to fuel oxidative phosphorylation. The primary pathway for fatty acid degradation is called the ***β*-oxidation pathway**, so called because oxidation and cleavage between carbon 2 and 3 (the β carbon) occurs **(Figure 13.30)**. Each fatty acid chain of varying length is first linked to coenzyme A (CoA), forming an acyl-CoA molecule that then enters the pathway. Each acyl-CoA is progressively degraded into two-carbon acetyl-CoA units with each pass through the pathway. Reduced electron carriers are generated in the pathway, and the acetyl-CoA products enter the TCA cycle for production of more reduced electron carriers and ATP. All that generated reducing power can be harvested in the electron transport chain for ATP production. For example, β-oxidation of a 16-carbon fatty acid in mitochondria can yield 130 molecules of ATP. For each carbon atom, 48 ATP are yielded compared to 38 ATP for glucose. Of course, the catabolic products and reduced electron carriers can also be used for biosynthesis of other carbon compounds, such as proteins.

Catabolism of fats and proteins
ANIMATION

Microorganisms require lipids for membranes. Even when lipids or fatty acids are available for uptake from the environment, lipid synthesis and modification still occurs to tailor a cell's lipid content to its needs. Lipid metabolism must be tightly controlled to ensure that lipids can be used as carbon and energy sources when appropriate, but prevent inappropriate degradation of a cell's own membrane constituents or lipid precursors. Most microorganisms limit the expression of enzymes for lipid catabolism to times when exogenous lipids are available. Another way that catabolic and anabolic fatty acid metabolism are separated is by linking fatty acids to distinct carriers for synthesis or degradation. Fatty acid chains undergoing degradation are linked to coenzyme A, whereas chains being synthesized are linked to acyl carrier protein (ACP). ACP-linked chains are not subject to attack by the β-oxidation pathway.

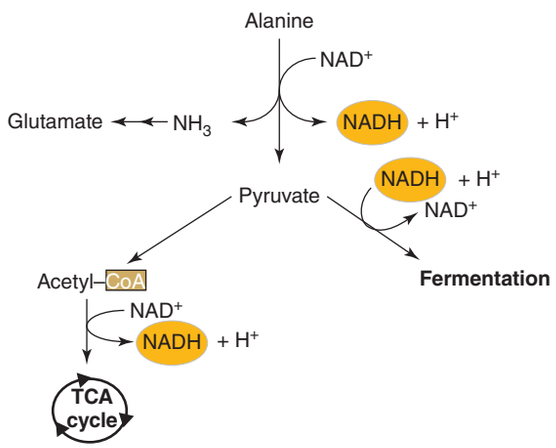

Figure 13.29. Amino acid degradation The amino group of an amino acid, such as alanine (shown here), is removed to form glutamate. Pyruvate is produced, which can enter into further reactions, such as fermentation reactions or the TCA cycle.

13.5 Fact Check

1. Describe how sugars other than glucose are metabolized.
2. How are large polymers, including polysaccharides, proteins, lipids, and nucleic acids, used as nutrients by microbial cells?
3. How are amino acids typically broken down for use in the TCA cycle?
4. What is the β-oxidation pathway, and how does it yield energy?

Toolbox 13.1
METABOLISM AND RAPID BACTERIAL IDENTIFICATION SYSTEMS

Many features differentiate microbial species, including genome content, metabolism, and cell structure. Although genome sequencing and analysis is becoming increasingly routine, clinical microbiologists still commonly use a series of biochemical tests to indirectly uncover specific genes or sets of genes that are expressed under controlled conditions in order to identify a suspected bacterial pathogen. They often start with a Gram stain (see Toolbox 2.1), then turn to metabolic traits. Commercial rapid identification systems are widely used for the identification of some groups of bacteria, including Gram-negative *Enterobacteriaceae*, which includes *Escherichia coli* and relatives such as *Salmonella*, *Shigella*, and *Proteus,* and Gram-positive staphylococci, streptococci, and corynebacteria. As an example to see how these systems work, we will use the API Coryne system **(Figure B13.2)**, manufactured by BioMerieux. This simple microsystem works to identify (within 48 hours) medically important members of *Corynebacteria,* such as toxin-producing strains of *Corynebacterium diphtheria*e (see Microbes in Focus 21.3) *Actinomyces, Listeria,* and *Rhodococcus,* and *Gardnerella vaginalis*.

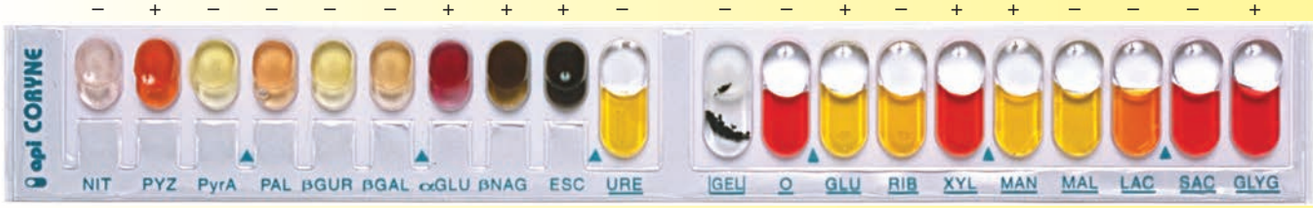
Before using this system, a clinician must determine that the isolate is a Gram-positive rod by performing a Gram stain and microscopic examination. The API Coryne strip has 20 small wells, each of which contains dehydrated media for assaying a specific biochemical activity. The strip is inoculated with a suspension of the isolated bacteria. The first 11 wells examine a variety of enzymes (shown in order: nitrate reductase activity, pyrazinamidase, pyrrolidonyl acrylamidase, alkaline phosphatase, β-glucuronidase, β-galactosidase, α-glucosidase, *N*-acetyl-β-glucosaminidase, aesculin, urease, gelatinase). Catalase activity is examined by adding one drop of 3 percent hydrogen peroxide after reading the aesulin test. The presence of catalase is indicated by production of bubbles after 1 minute. The ninth well is a negative control for the fermentation reactions that follow in the last eight wells. These wells contain a pH indicator that assesses acid production from fermentation of specific sugars and sugar-alcohols (shown in order: glucose, ribose, xylose, mannitol, maltose, lactose, sucrose, and glycogen). The pH indicator starts out red at neutral pH, and shifts to yellow if the pH drops substantially below 6, indicating that the organism is capable of fermenting the particular substrate. Identities can be obtained by converting the profile of results of the unknown organism to a seven-digit code that is then matched with a bacterial species using a manual.

Variation in metabolic capabilities is a reflection of genetic composition and thus can be used to determine the identity of microorganisms. These enzymes and pathways were chosen for analysis specifically because they are variable between different genera and species. Activity profiles for these reactions, and optional tests such as for nitrate reduction, have been generated for thousands of known strains to generate a database.

There are drawbacks to this approach. Depending on the tests used, not every isolate of a particular species will yield precisely the same profile. There is extensive genetic variation within most microbial species, and the various enzymes and pathways examined by such systems vary as well. For example, there are hundreds of profiles associated with *E. coli.* It's even possible for strains from different species to have identical API profiles, which is why the database readout often indicates multiple possible species, and provides an estimate of the likelihood of each based on previous data. If such ambiguity is a problem, there are many alternative identification methods. Fatty acid profiles can be examined by commercial laboratories, and rapid DNA sequence-based genetic tests, using PCR for example, are also available. Nonetheless, streamlined kits based on metabolic traits offer a fast, affordable, and reliable approach to the identification of many clinically important bacteria.

Test Your Understanding

Your lab partner has used an API strip, but her results were inconclusive. She later realized that she did not have a pure culture of the test organism. Specifically explain how and why she got an inconclusive result.



Courtesy BioMarieux

Figure B13.2. API Coryne biochemical results for a Gram-positive *Corynebacterium* isolate Each well contains a medium designed to detect a metabolic function. After inoculation and incubation, the test can be read and the isolate identified. Results for the various reactions are shown.

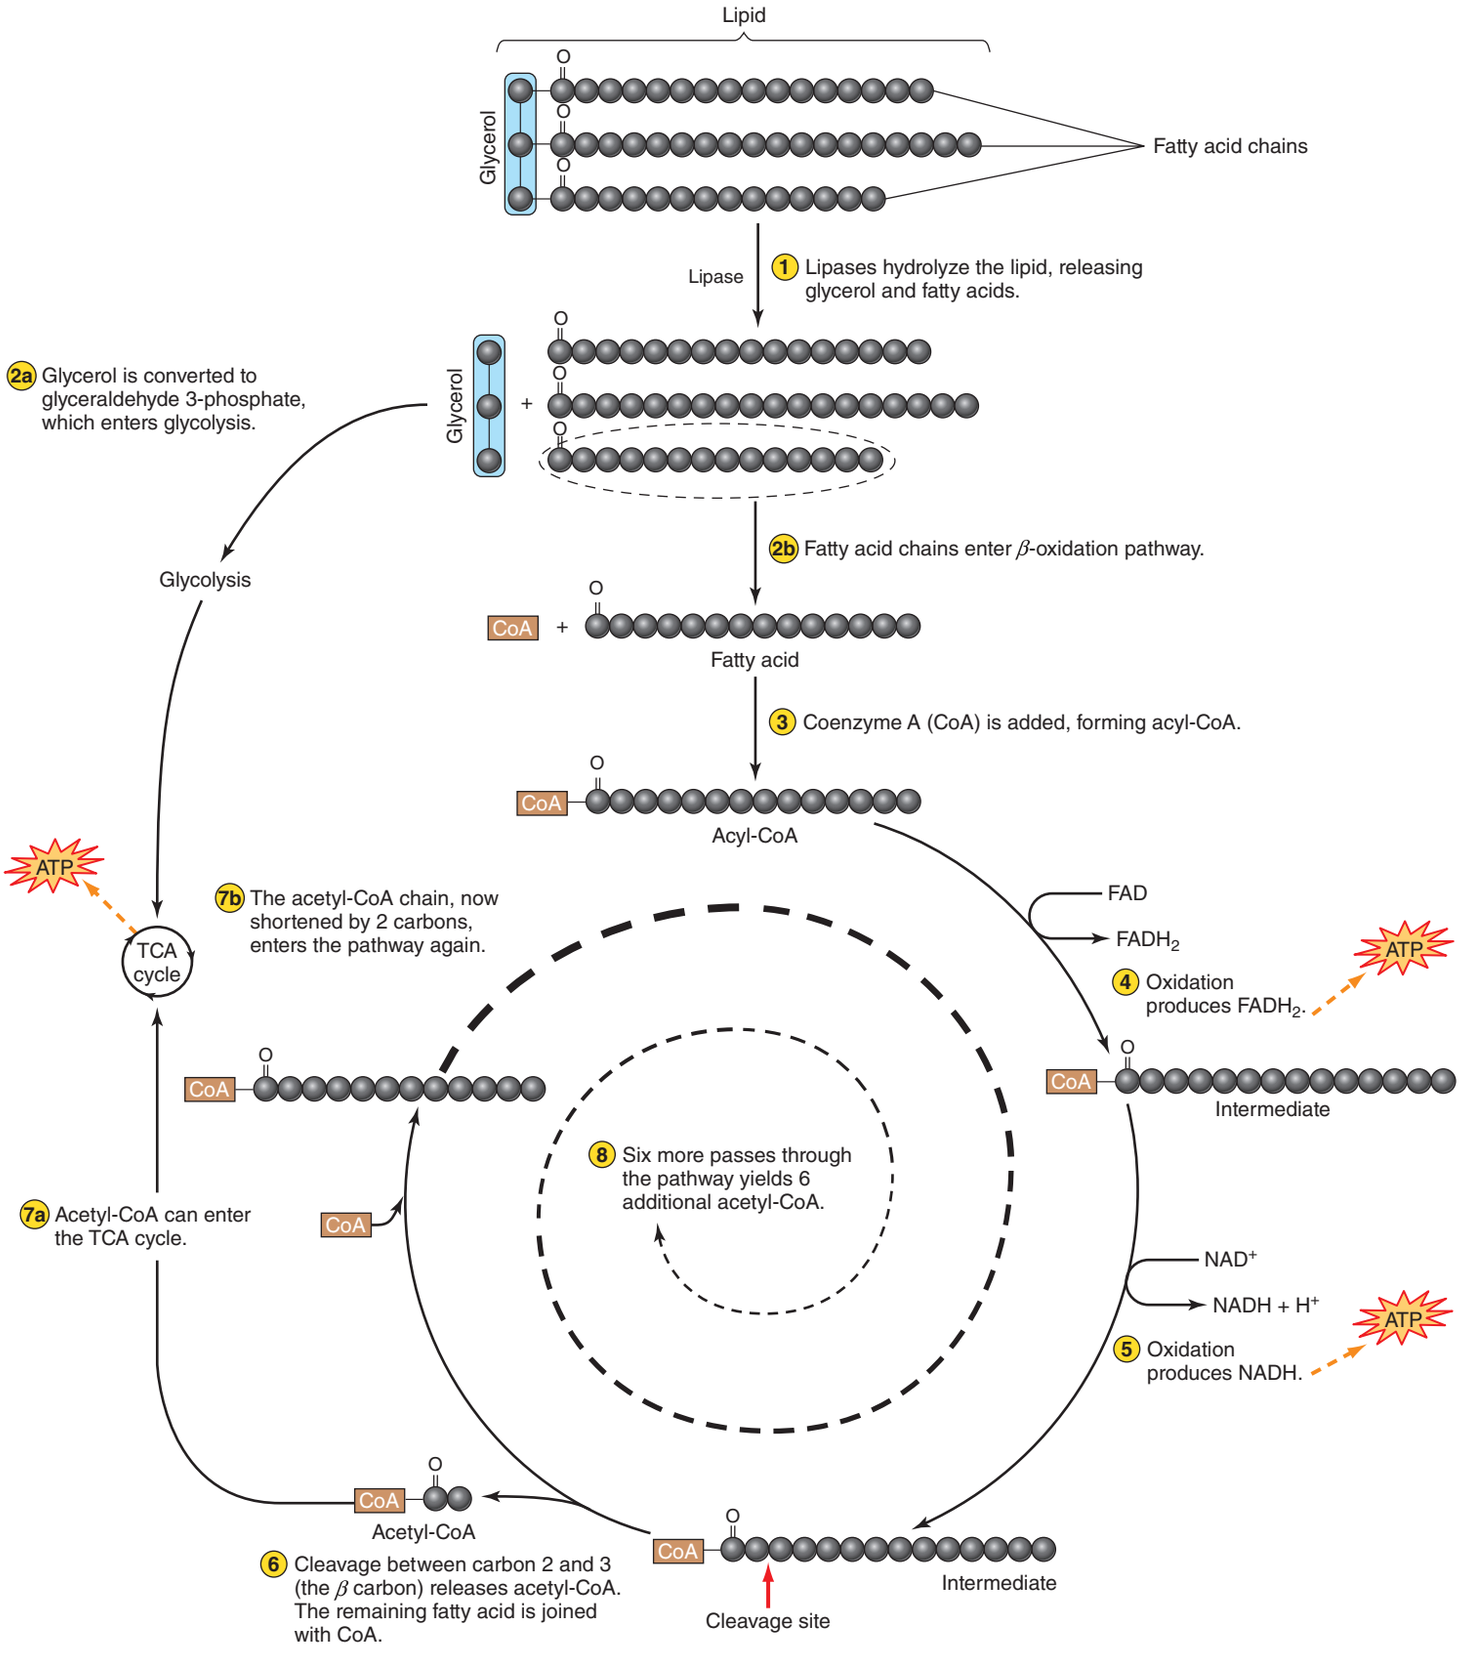


Figure 13.30. Process Diagram: Lipid degradation and β-oxidation of fatty acids Lipids are first hydrolyzed by lipases. The resulting glycerol backbone can enter glycolysis and the TCA cycle to ultimately generate ATP. The released fatty acid chains are joined to coenzyme A (CoA), forming acyl-CoA molecules that enter the β-oxidation pathway. Each pass of an acyl-CoA molecule through the pathway removes two carbons from the chain, producing the two-carbon molecule acetyl-CoA. The dashed arrow indicates successive passes of the remaining acyl-CoA through the pathway. The released acetyl-CoA units can enter the TCA cycle to produce ATP. With each pass, NADH and $FADH_2$ are also produced, which can be used for oxidative phosphorylation to produce more ATP.

13.6 Phototrophy and photosynthesis

How do microorganisms capture light energy for ATP synthesis and carbon fixation?

Previous sections have focused on energy generation by catabolism of chemical substrates such as glucose by chemoorganotrophs or inorganic molecules by chemolithotrophs. Oxidation of these substrates is the source of energy and electrons for generation of ATP. Phototrophs use light energy, or photons, instead of preformed chemicals as an energy source to produce ATP (see Figure 6.1 and Table 13.1). Recall from Section 3.1 that phototrophy involves generating ATP by photophosphorylation using captured light energy, an electron transport system, and the chemiosmotic process in conjunction with ATP synthase. Recall from Section 2.4 that photosynthesis captures light energy and uses this energy to reduce inorganic carbon to form organic molecules. Photosynthesis is therefore a two-step process used by photoautotrophs. The first step of photosynthesis is photophosphorylation. The next step uses the ATP produced by photophosphorylation for carbon fixation, defined in Section 6.1 as the assimilation of inorganic carbon, such as carbon dioxide (CO_2), to make carbohydrates. It is important to distinguish between photophosphorylation and photosynthesis as some photoorganoheterotrophs, such as *Heliobacterium*, can carry out photophosphorylation to make ATP but do not use it for carbon fixation (see Table 13.1), instead obtaining carbon from organic sources.

Chlorophyll-based photosynthesis is a bacterial invention that has found its way into eukaryal algae and plants thanks to endosymbiotic cyanobacteria that evolved into chloroplasts. The biomass generated by photosynthesis forms the foundation of the food chains that sustain nearly all life on Earth. We will consider modern cyanobacterial and chloroplast photosynthesis together in the section on oxygenic (oxygen-producing) photosynthesis because they share mechanisms and machinery. Other bacteria carry out anaerobic, or anoxygenic, photosynthesis. Oxygenic (oxygen-generating) photosynthesis is important both historically and on contemporary Earth. As discussed in Section 1.2, rising levels of oxygen in Earth's atmosphere began about 3.5 billion years ago, thanks to oxygenic photosynthesis by ancestors of modern cyanobacteria, and radically altered the evolutionary trajectory of life on the planet. We now depend on oxygenic photosynthetic organisms for oxygen *and* food. In this section, we will see how light energy is absorbed and transformed into chemical energy that can be used to drive the synthesis of carbon compounds by photosynthetic microorganisms.

CONNECTIONS Recall from **Section 3.4** that phototrophic bacteria brought solar power to eukaryal cells through endosymbiotic events. Evolution resulted in algae and plants.

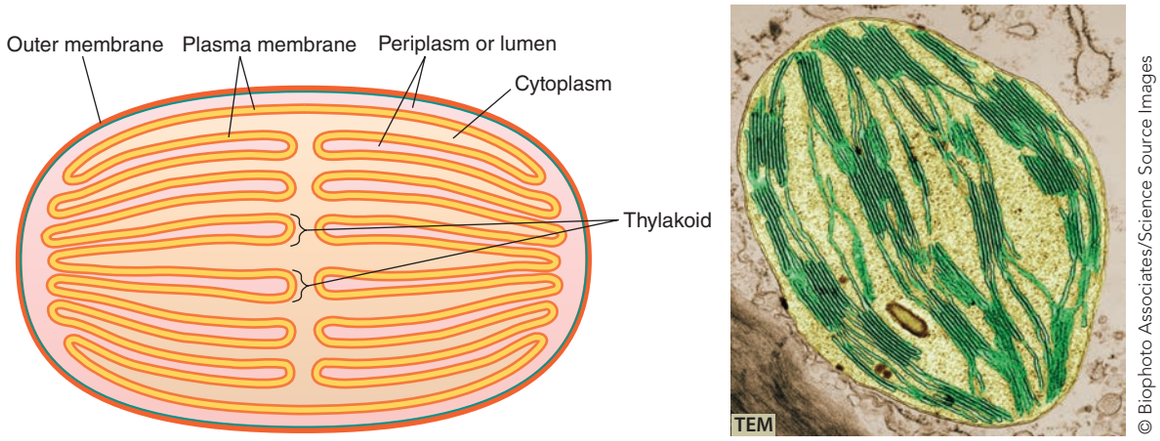
Phototrophy is found in six distinct lineages within the domain *Bacteria*. Five of these phyla are Gram-negative: *Cyanobacteria*, *Proteobacteria* (*Alphaproteobacteria*, or the purple non-sulfur bacteria, and *Gammaproteobacteria*, or the purple sulfur bacteria), *Chlorobi* (green sulfur bacteria), *Chloroflexi* (green non-sulfur bacteria), and a phototrophic member of the *Acidobacteria* (*Candidatus* Chloracidobacterium thermophilum). The only Gram-positive group is the genus *Heliobacterium*, belonging to phylum *Firmicutes*. Of the bacteria, only cyanobacteria carry out oxygenic photosynthesis. Other bacteria do not generate oxygen (O_2) from photosynthesis. We will discuss this in more detail in the section on anoxygenic photosynthesis.

Photophosphorylation: ATP synthesis and the "light" reactions

Photophosphorylation converts light energy to chemical energy that can be used by the cell. The reactions are often referred to as the **light reactions** because they require the presence of light. The light-absorbing machinery is always located in a membrane given that one of the primary functions of the light reactions of photosynthesis is to generate a transmembrane proton concentration gradient. The photosynthetic membrane is folded inward to expand the surface area for light absorption, forming disk-shaped or layered structures called **thylakoids (Figure 13.31)**. In chloroplasts, the photosynthetic membrane is continuous with the inner membrane (see Figure 3.4). The space outside the thylakoid is called the "stroma" in chloroplasts. The inner chamber of a thylakoid is called the "lumen." Bacteria do not contain chloroplasts. Instead, the thylakoids are formed by extensive inward folding of the plasma membrane. In Gram-negative bacteria, the lumen is an extension of the periplasm.

Photopigments

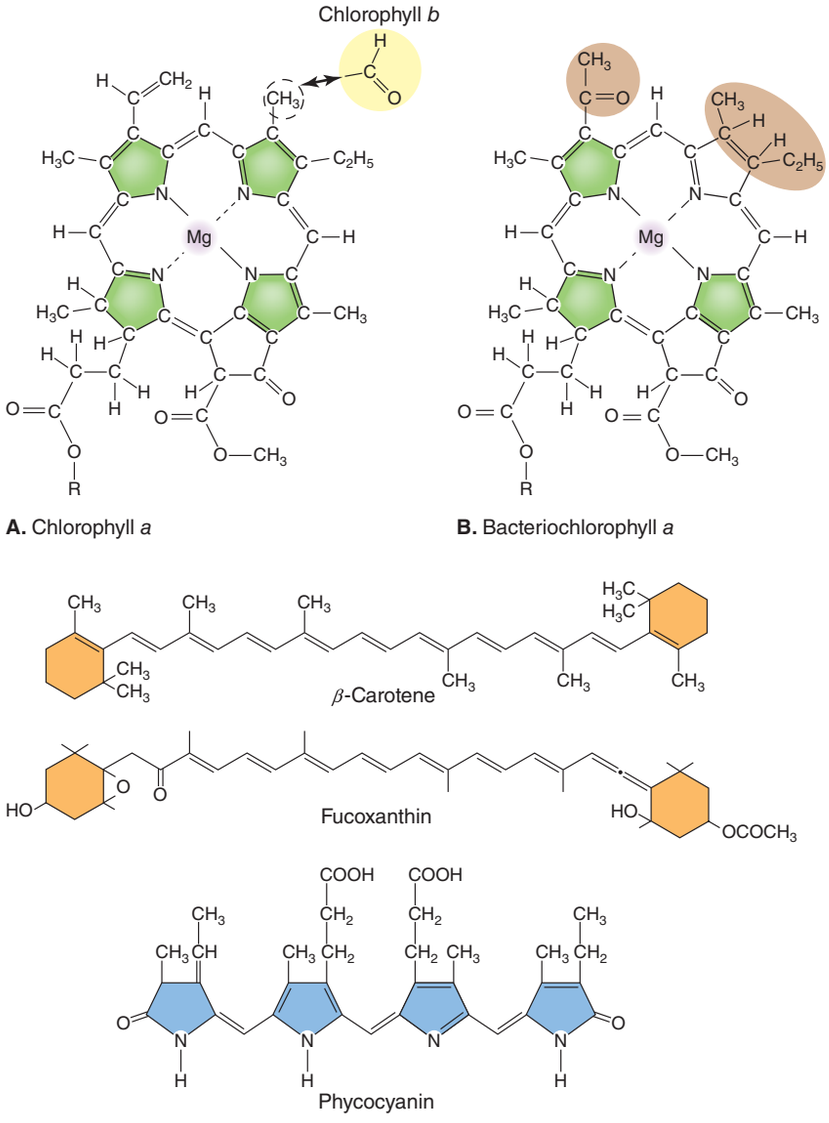
Photophosphorylation depends on light-absorbing photopigments to capture photons. The primary pigment used by cyanobacteria and chloroplasts is **chlorophyll (Figure 13.32)**, which consists of a hydrocarbon component linked to a chromophore that absorbs photons. The chromophore is based on a flat, porphyrin ring structure very similar to the heme component of cytochromes, with the notable exception that chlorophyll holds a central magnesium (Mg^{2+}) ion instead of iron. Most cyanobacteria produce only chlorophyll *a*, but the chloroplasts of most eukaryal algae and plants produce both chlorophyll *a* and a slightly different version called chlorophyll *b*. The slight chemical difference between these chromophores alters the wavelengths of light they absorb best. Chlorophyll *a* absorbs maximally in two peaks centered at 430 nm (blue/violet) and 662 nm (far red). Chlorophyll *b* absorption is shifted to peaks centered at 453 (blue) and 642 nm (near red). The presence of both pigments in algae and plants expands the light absorption spectrum. The green/yellow region of the spectrum is transmitted and reflected most effectively. This is why cultures of actively photosynthesizing cyanobacteria appear green, similar to plant leaves containing chloroplasts packed with chlorophyll.



A. Thylakoid structure in Gram-negative bacteria

B. Algal cell with photosynthetic membranes

Figure 13.31. Thylakoids **A.** In bacteria, the stacked thylakoids are composed of membranes that are continuous with the plasma membrane. The lumen is an extension of the periplasm in Gram-negative bacteria. **B.** Color-enhanced chloroplast of the alga *Nitella* showing interconnected thylakoids appearing as stacked membranes.



A. Chlorophyll *a*

B. Bacteriochlorophyll *a*

C. Accessory pigments

Other versions of chlorophyll, called **bacteriochlorophylls**, are produced by anaerobic photosynthetic bacteria (see Figure 13.32B). Compared to cyanobacterial chlorophylls, bacteriochlorophylls tend to absorb most strongly in more extreme regions of the visible spectrum, below 400 nm, approaching the ultraviolet region, or greater than 750 nm, the infrared region. These microorganisms tend to inhabit aquatic sediments where oxygenic phototrophs do not commonly exist. This includes sediments of deep waters and thermal springs. Their photopigments have evolved to function with light wavelengths not absorbed effectively by cyanobacteria and chloroplasts.

Chlorophylls are not the only light-absorbing pigments used by photosynthetic microorganisms. A variety of accessory pigments help absorb light over a broader range of wavelengths than are captured by the primary chlorophylls, particularly in the green-yellow-orange region from 500 to 620 nm (see Figure 13.32C). Carotenoids exhibiting absorption maxima around 500 nm are found in cyanobacteria and photosynthetic eukaryal protists. Cyanobacteria and various eukaryal algae also produce phycobiliproteins containing pigments such as phycoerythrin and phycocyanin. Phycoerythrin absorbs most strongly in the greenish-yellow range that escapes chlorophylls, whereas phycocyanin absorption is shifted more to orange-red light (620–640 nm). These accessory pigments are regulated by the wavelength of light to which the organism is exposed to maximize the efficiency of light capture and minimize the production of photopigments that cannot operate

Figure 13.32. Photopigments The light-absorbing chromophore structure of chlorophylls contains four pyrrole rings (green) and a central magnesium ion. **A.** Chlorophyll *a* contains a methyl group (dashed circle). Chlorophyll *b* has an ester group substitution (yellow). **B.** Bacteriochlorophyll *a* has two group substitutions (brown). **C.** Accessory pigments β-carotene and fucoxanthin (a carotenoid) and phycocyanin (a phycobiliprotein).

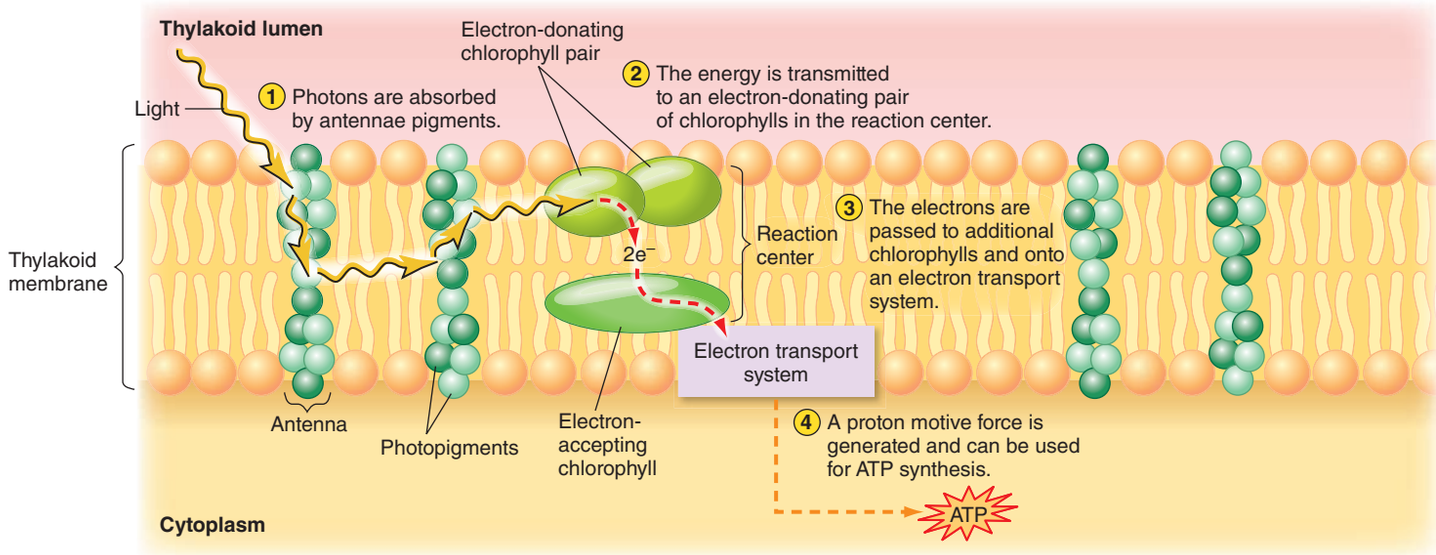


Figure 13.33. Process Diagram: General structure and function of a photosystem A photosystem is composed of many antennae containing photopigments that surround a reaction center. Photons are absorbed by the antenna photopigments, and the energy is transferred from pigment to pigment to the reaction center containing a pair of electron-donating chlorophyll molecules. The electrons are passed to a chlorophyll electron acceptor and onto an associated electron transport system for ATP production.

effectively with the available light spectrum. Microorganisms that rely on bacteriochlorophyll and accessory pigments such as carotenoids, phycoerythrin, and phycocyanin usually appear red, brown, or purple, depending on the mix of photopigments they produce at any given time.

Photosystems

The light reactions depend on an organized structure called the **photosystem** that absorbs energy from photons of light and transfers the generated electrons to an associated electron transport system (Figure 13.33). A photosystem consists of numerous antennae containing photon-absorbing pigments and a reaction center containing electron-donating chlorophylls.

An antenna is composed of an array of chlorophylls or bacteriochlorophylls and accessory photopigments. When an antenna pigment absorbs a photon, the energy excites electrons, but antenna pigments do not directly transfer these electrons. Instead, the excitation energy is shared with other antenna molecules, and eventually the energy makes its way to a reaction center. The reaction center is surrounded by a number of antennae that funnel the energy from the photons to a special pair of chlorophyll molecules. The received excitation energy causes the redox potential of chlorophyll to become very negative, causing it to donate an electron to a nearby chlorophyll molecule in the reaction center. The fate of the electron differs depending on the design of the photosystem. Ultimately, the electron is passed to an electron transport system and a proton motive force is produced across the photosynthetic membrane, which can be used to synthesize ATP.

There are two basic types of photosystems: photosystem I (PS I) and photosystem II (PS II). Chloroplasts and cyanobacteria have both PS I and PS II. Other bacteria have one or the other (Table 13.4). Photosystems I and II have similarities in component parts, indicating they have evolved from a common ancestor. To illustrate how these photosystems function, we will start with PS I from the anaerobic green sulfur

TABLE 13.4 Some characteristics of phototrophic bacteria

Group	Common group name	Photosystem present	Common electron donor	O_2 production	Carbon source
Heliobacterium (genus)		PS I	Organic	Anoxygenic	Organic
Chlorobi (phylum)	Green sulfur	PS I	H_2S, S^0, H_2, $S_2O_3^{2-}$	Anoxygenic	CO_2, organic
Chloroflexi (class)	Green non-sulfur	PS II	H_2S[a] H_2[a], organic[a]	Anoxygenic	CO_2, organic
Chromatiaceae (family)	Purple sulfur	PS II	H_2S[a], H_2[a], S^0[a]	Anoxygenic	CO_2
Rhodospirillaceae (family)	Purple non-sulfur	PS II	H_2[a], organic[a]	Anoxygenic	CO_2, organic
Cyanobacteria (phylum)	"Blue-green algae"[b]	PS I and PS II	H_2O	Oxygenic	CO_2

[a] Not electron donors for photosynthesis reactions, but are used as a source of electrons to make NADH or NADPH through the electron transport system.
[b] The use of the word "algae" is a former, incorrect reference to these photosynthetic bacteria.

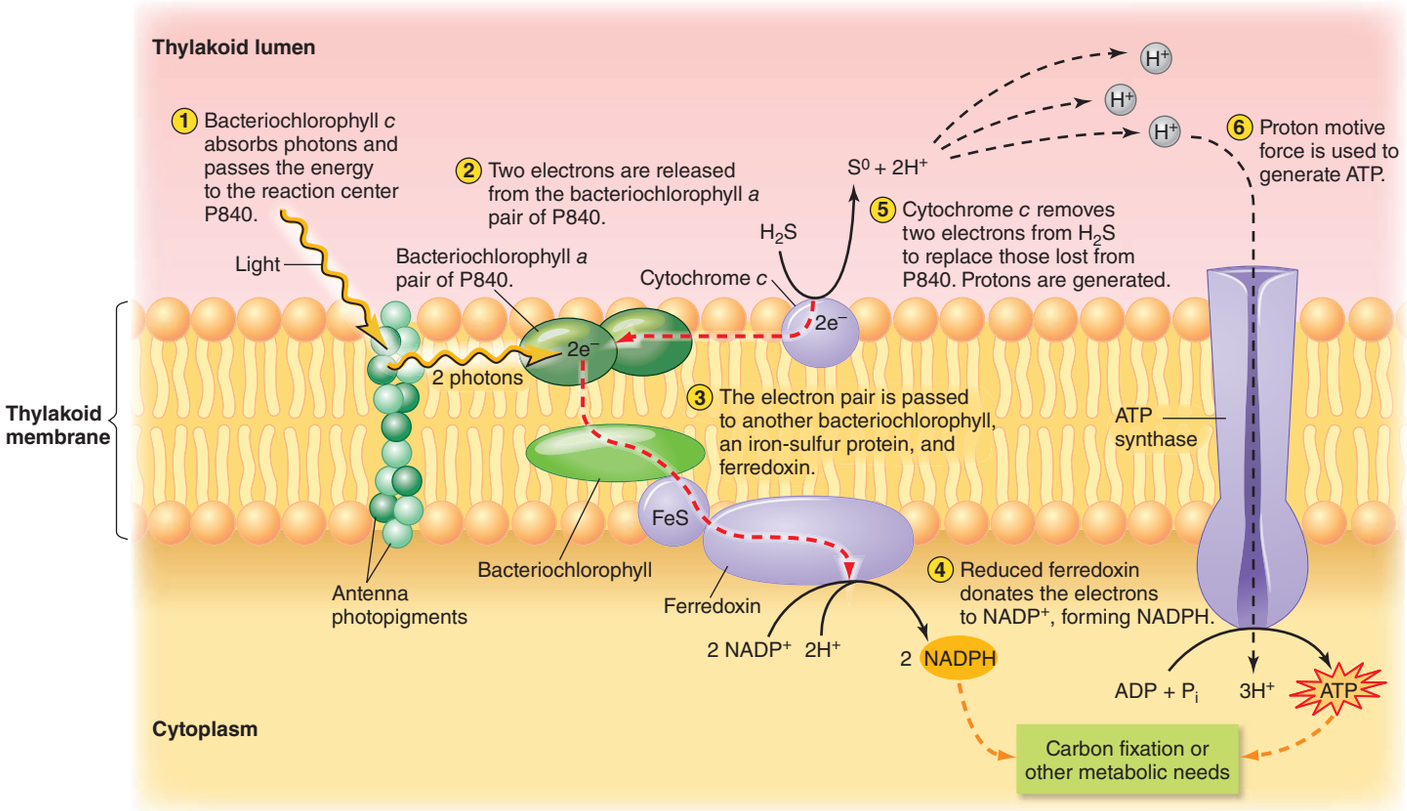

Figure 13.34. Process Diagram: Function of photosystem I of *Chlorobium* Absorption of two photons excites two electrons that are released from the P840 reaction center. The electrons pass through a series of carriers to produce two NADPH. This provides reducing power to carry out metabolic needs, such as carbon fixation. The electrons lost from P840 are replaced using an external source of electrons. Shown here is the oxidation of H_2S to elemental sulfur (S^0) and two protons, which are expelled outside the membrane, creating a proton motive force that can be used to drive ATP synthesis.

bacterium *Chlorobium tepidum*, which carries out anoxygenic photosynthesis **(Microbes in Focus 13.1)**.

Anoxygenic Photosynthesis

Bacteria that can carry out **anoxygenic photosynthesis** that does not produce O_2, evolved much earlier than those using oxygenic photosynthesis, corresponding with the initial anoxic atmosphere of Earth. Photosystem I is the sole photosystem in anaerobic photosynthetic heliobacteria and green sulfur bacteria (see Table 13.4). The informal grouping of sulfur bacteria is due to their ability to produce elemental sulfur (S^0) globules (see Figure 2.5). The green sulfur bacteria possess carotenoids that make them appear green, yellowish, or orange. The purple sulfur bacteria have carotenoids that make them appear purple or reddish brown. The bacteriochlorophyll *c* associated with PS I antennae in *Chlorobium* best absorbs long wavelength (infrared) photons, with an absorption maximum around 750 nm. As shown in **Figure 13.34**, two photons are absorbed to excite two electrons in the reaction center, called P840, containing the electron-donating bacteriochlorophyll *a* pair. The electrons are passed from P840 to a different bacteriochlorophyll *a* electron acceptor and, finally, to the iron-sulfur protein ferredoxin. Here, the enzyme ferredoxin reductase uses electrons from ferredoxin to reduce either NAD^+ to NADH, or $NADP^+$ to NADPH. Thus, light energy is converted to reducing power. The reduced carrier (NADH or NADPH) can then be used for other metabolic needs including, for *Chlorobium*, carbon fixation for synthesizing of sugars and other carbon compounds. Carbon fixation occurs in the "dark" reactions described at the end of this section.

To keep PS I operating, the electrons separated from the bacteriochlorophylls of P840 must be replaced from an external source. Thus, the electron transport pathway in PS I is noncyclic. Green sulfur bacteria such as the photolithoautotroph *C. tepidum* oxidize electron sources such as hydrogen sulfide (H_2S), elemental sulfur (S^0), and hydrogen (H_2). The bacteriochlorophyll of the PS I reaction center is exposed to the periplasmic side of the photosynthetic membrane, but the electrons are passed to carriers on the cytoplasmic side. As replacement electrons are obtained from H_2S, for example, S^0 is produced and protons are released into the periplasm, increasing its acidity and net positive charge. Meanwhile, on the cytoplasmic side, reduction of $NADP^+$ is accompanied by incorporation of a proton. Thus, H^+ ions are liberated to the periplasm and consumed from the cytoplasm, creating a concentration differential across the membrane. As in other bacteria, the resulting proton motive force is used to support ATP synthesis and other proton motive force-dependent processes, such as nutrient transport.

Microbes in Focus 13.1
CHLOROBIUM TEPIDUM: THE BACTERIUM THAT DOES IT ALL

Habitat: Hot springs and thermal mud pools and other warm bodies of water that contain sufficient hydrogen sulfide (H_2S); often forms dense mats

Description: Gram-negative, thermophilic photolithoautotrophic bacterium with small ovoid-shaped cells 5–8 μm in length that grow in long chains; belongs to the green sulfur bacteria group

Key Features: *Chlorobium tepidum* carries out carbon (CO_2) fixation via a reductive TCA cycle, and anoxygenic photosynthesis using sulfides, such as H_2S, as electron donors. Elemental sulfur is a waste product deposited in granules outside the cell. It also fixes atmospheric nitrogen. *Chlorobium tepidum* possesses a unique combination of bacteriochlorophylls and carotinoid pigments that allow it to carry out photosynthesis in low light conditions, avoiding exposure to UV radiation. The characteristics of *C. tepidum* are thought to be like those possessed by the first phototrophs when Earth was much hotter, the atmosphere was anoxic, and organic compounds were scarce.

Photosystem II is used for anoxygenic phototrophy in certain members of the *Proteobacteria*, including the purple non-sulfur *Rhodospirillum* and *Rhodopseudomonas*. The molecular structure of the *Rhodospirillum* PS II reaction center has been intensively studied. In the PS II reaction center called P870, a bacteriochlorophyll *a* pair absorbs photons, and the excited electrons are transferred first to chlorophyll-like bacteriopheophytin, then to a quinone carrier (Figure 13.35). As the quinone is reduced to quinol, two protons are incorporated from the cytoplasm. These protons are shed to the lumen as the electrons are passed to cytochrome *bc*, generating a proton motive force. The electron pair is transferred next to a soluble cytochrome *c*-type carrier protein in the lumen, then back to the PS II reaction center. Because the electron transport pathway is cyclic, no external electron donor is needed. This is a major difference from the non-cyclic electron transport in PS I, where replacement electrons came from an external source. Another outcome of cyclic electron transport is that reduced electron carriers NADH or NADPH are not produced. The sole function of PS II is to serve as a light-driven proton pump. However, all cells need reducing power to carry out metabolic reactions, such as CO_2 fixation, so microorganisms employing PS II must generate NADH or NADPH by other mechanisms. The mechanisms vary, but one way is to reverse the electron flow in the photosynthetic electron transport chain, at the expense of ATP production, by removing electrons from iron-sulfur proteins. The electrons are replaced using other inorganic or organic electron donors, depending on the organism.

Oxygenic Photosynthesis

Cyanobacteria and chloroplasts combine PS I with PS II in **oxygenic photosynthesis**, a non-cyclic process that obtains electrons from water and produces both reducing power and proton motive force (see Table 13.4). On the electron-acquisition side of the process, the generation of one dioxygen (O_2) molecule requires the splitting of two water molecules:

$$2\ H_2O \rightarrow 4\ H^+ + 4\ e^- + O_2$$

The structure and function of PS II in oxygenic photosynthesis differs from *Rhodospirillum* in that, instead of the excited electrons ultimately flowing back to the PS II in a cyclic pathway, they are passed to PS I (Figure 13.36). For this to work, PS II must have an exogenous source of electrons to replace the electrons it sends to PS I; H_2O is used as an electron donor and O_2 is released as a product. It is hard to overstate the practical significance of being able to use water as an electron donor—it covers most of the surface of Earth, at high concentrations, and is thus far more widely available than alternative electron donors. As a result, accessing electrons from this nearly limitless supply represents a metabolic and biogeochemical triumph for the cyanobacteria, which forever transformed Earth from its early reducing atmosphere to one that is hospitable to aerobic life today.

The combined pathway makes several contributions to proton motive force. Protons are released into the lumen of the chloroplast or cyanobacterial thylakoid when PS II splits the electron donor H_2O. The excited electrons of PS II pass from an electron-accepting chlorophyll to a quinone carrier, which incorporates two H+ from the cytoplasmic, or stromal side as it is converted to a quinol. The quinol donates electrons to reduce the complex containing cytochrome *b*, an iron-sulfur center, and cytochrome *f*. This transfer is accompanied by translocation of two protons to outside the membrane. The cytochrome *bf* complex transfers electrons to a plastocyanin carrier, which uses them to replenish the reaction center of PS I. At that point, the electrons can be excited again by photon absorption, and travel through essentially the same pathway discussed earlier for *Chlorobium* PS I. The electrons end up incorporated into NADPH, along with two protons released to the cytoplasm or stroma. Bacteria other than cyanobacteria do not generate O_2 from photosynthesis, either because the electrons used in their photosystem follow a cyclic pathway back to the original reaction center, as in PS II, or because the electron donor for PS I non-cyclic pathways is a molecule other than water. An overview of phototrophic energy capture pathways is shown in Figure 13.37.

As far as we know, there are no photosynthetic archaea. However, some halophilic (salt-loving) archaea, including *Halobacterium* spp. (see Microbes in Focus 4.3), employ the non-chlorophyll pigment bacteriorhodopsin that function as light-powered proton pump to create a proton motive force to produce ATP (see Figure 4.19). These archaea are phototrophs, but not photosynthetic. They do not fix CO_2,

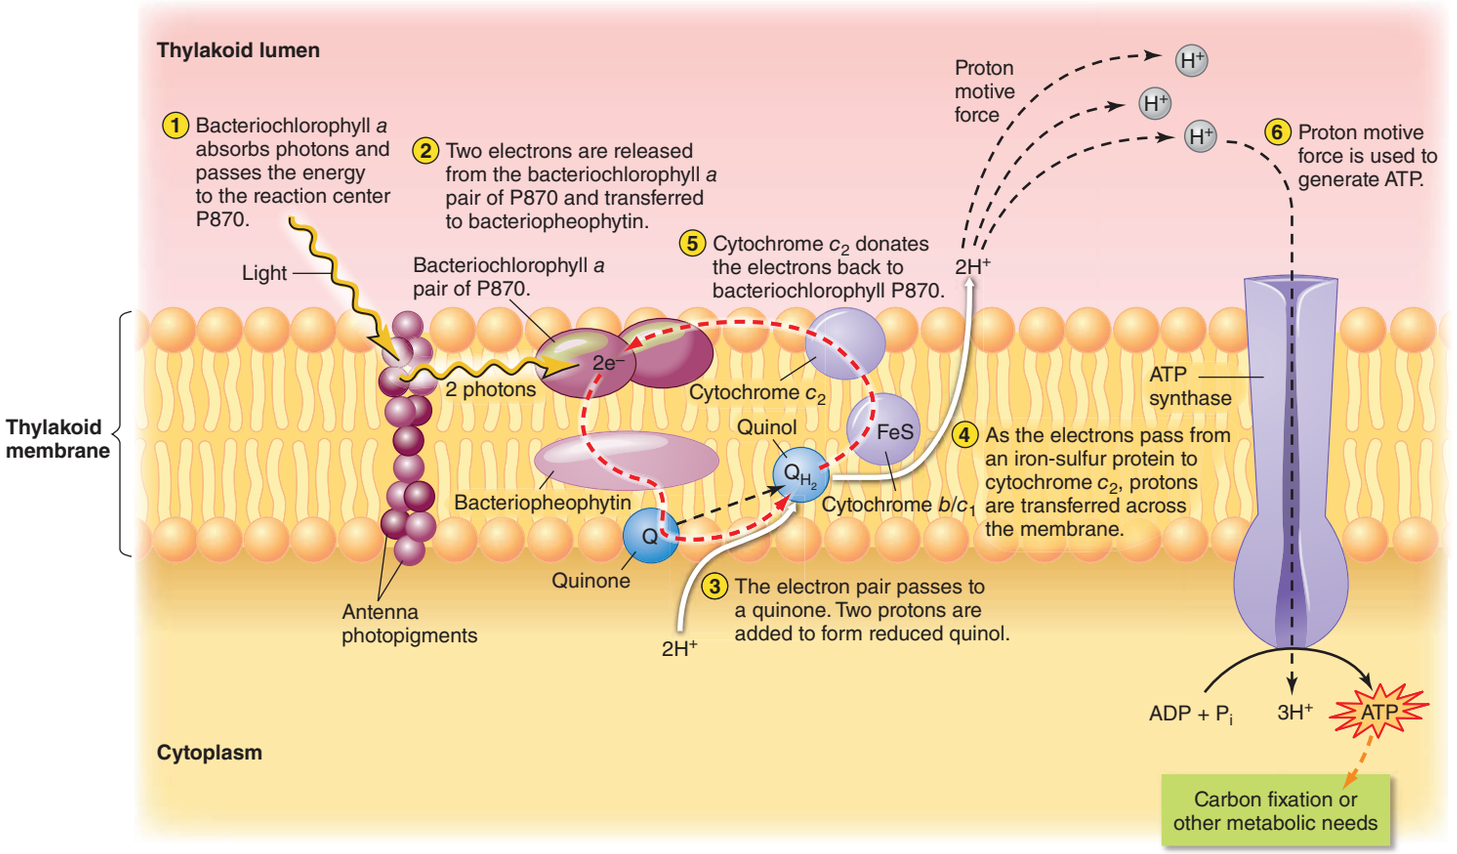

Figure 13.35. Process Diagram: Photosystem II of *Rhodospirillum* Absorption of two photons excites two electrons that are released from the P870 reaction center. The electrons are passed to bacteriopheophytin, then to quinone, reducing it to quinol with the removal of two protons from the cytoplasm. As the electrons pass from an iron-sulfur protein, the protons are transferred across the membrane. The electrons lost from P870 are replaced internally through oxidation of a cytochrome *c* molecule in the transport system. The transferred protons create a proton motive force that can be used to drive ATP synthesis.

instead they use the energy of light as a survival mode, rather than a central metabolic function, but that makes it no less interesting.

The Calvin cycle and carbon fixation: The "dark" reactions

The ability to carry out carbon fixation, gave microorganisms a tremendous opportunity to exploit new habitats. It is no surprise that photoautotrophs, both microorganisms and plants, dominate the illuminated biosphere. In this section, we will look at how photosynthetic organisms use the ATP and reducing power produced by the light reactions of photosynthesis to turn CO_2 into useful carbohydrates. The reactions that convert CO_2 into organic carbon compounds are collectively referred to as the **dark reactions**, as they do not require light, nor do they require darkness, to operate.

Although there are several known pathways for autotrophic carbon fixation, in global terms the most important is the **Calvin cycle** used by cyanobacteria and chloroplasts **(Figure 13.38)**. The Calvin cycle is also called the reductive pentose phosphate pathway because it shares many intermediates with the pentose phosphate pathway (Section 13.3). The essential distinction is that the Calvin cycle is used for assimilation of CO_2, and consumes NADPH and ATP, whereas the pentose phosphate pathway is used for dissimilation of glucose and produces NADPH and, eventually, ATP. The main purpose of the Calvin cycle is making the three-carbon compound glyceraldehyde 3-phosphate. This product is then converted into a variety of macromolecules, such as hexose sugars and amino acids.

CONNECTIONS Autotrophic carbon fixation is not just a feature of photosynthetic organisms. Recall from **Section 4.3** that many archaeal methanogens can also fix CO_2. For this, they use the acetyl-CoA pathway, which incorporates carbon from CO_2 into acetate that can be used for biosynthesis. Similarly, bacterial methanotrophs described in **Section 14.2** can also fix carbon derived from methane (CH_4).

The key reaction of the Calvin cycle is carried out by the enzyme ribulose bisphosphate carboxylase, often referred to as Rubisco. This enzyme is probably the most abundant protein on Earth. In cyanobacteria and plant leaves, it is certainly

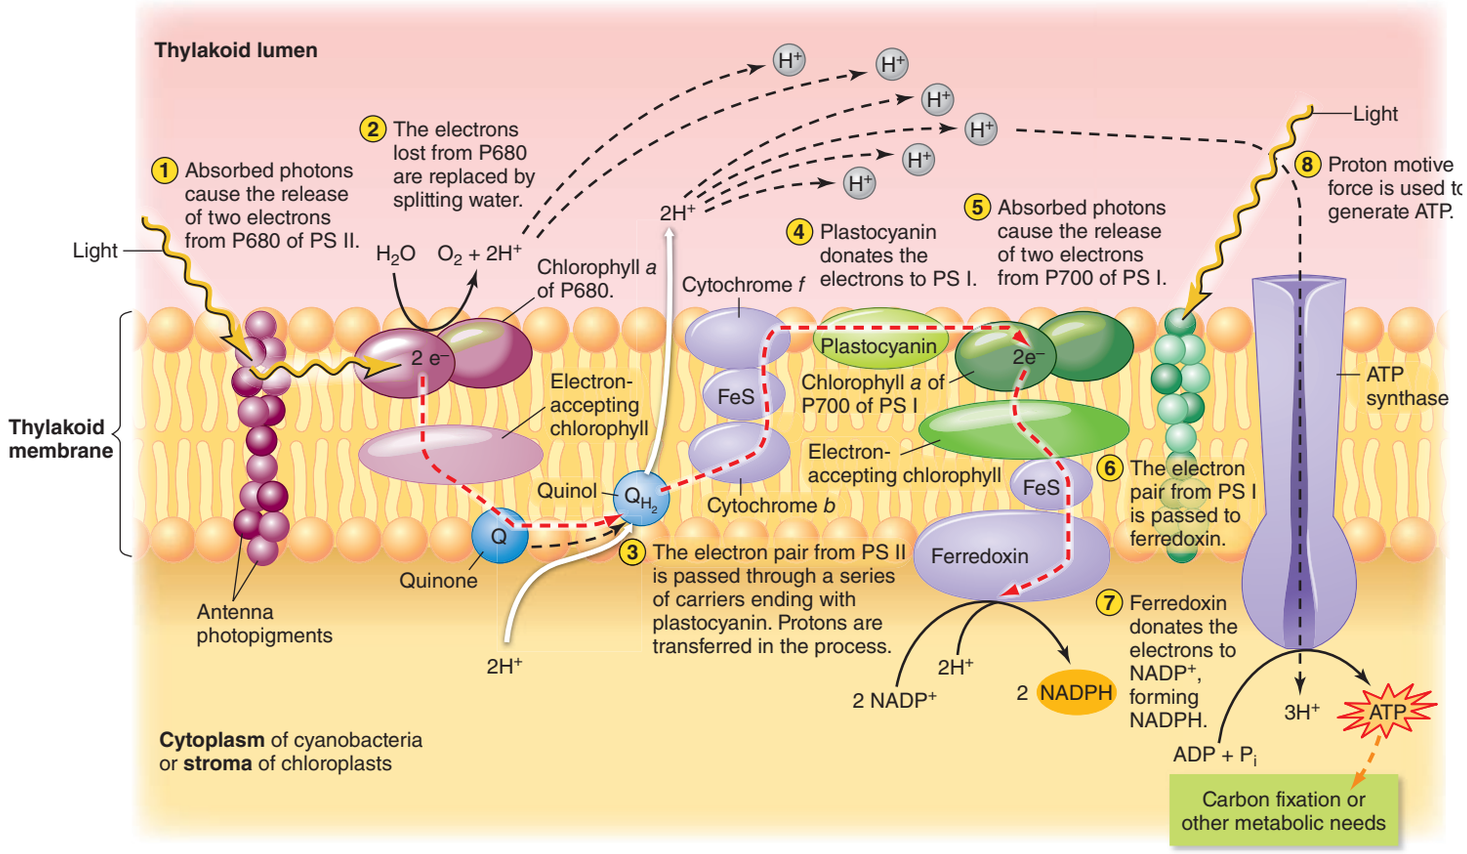

Figure 13.36. Process Diagram: Oxygenic photosynthesis in cyanobacteria and chloroplasts Both PS I and PS II are present, and electrons are passed from PS II to PS I. Water is used as a donor for electrons resulting in the production of O_2. Protons are released to the lumen at two points in the system, efficiently generating a proton motive force used for ATP synthesis. The presence of PS I means reducing power is simultaneously generated and can be used for carbon fixation or other metabolic processes.

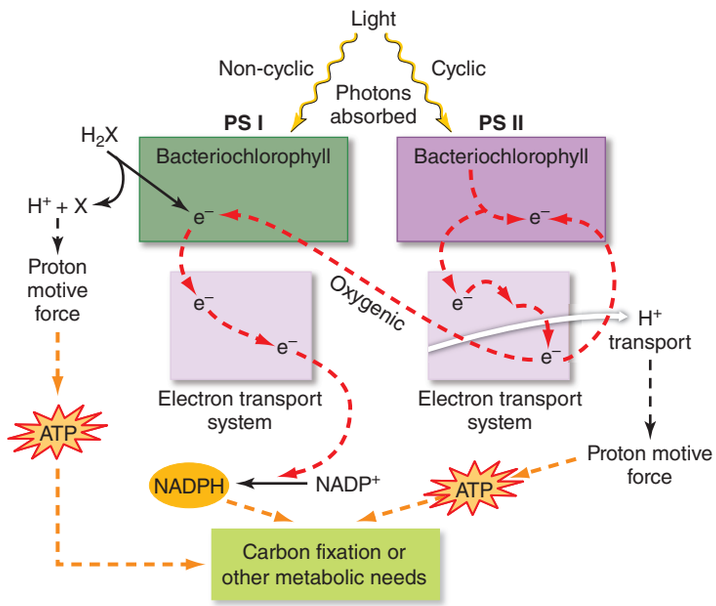

Figure 13.37. Overview of phototrophy Anoxygenic photosynthesis is carried out by PS I or PS II using bacteriochlorophyll. PS I produces reduced electron carriers and a proton motive force that can be used to generate ATP. Electrons are replaced through oxidation of an electron source, represented by H_2X. PS II does not generate reduced electron carriers as electrons are cycled within the system. A proton motive force is still produced. Oxygenic photosynthesis combines PS I and PS II and uses chlorophyll. Water is used to supply electrons to the system.

the most abundant protein. It has been estimated that four *billion* tons of this protein are synthesized by photosynthetic organisms each year. Rubisco catalyzes the addition of CO_2 and water to the five-carbon molecule ribulose 1,5-bisphosphate, which is split in the process to yield two molecules of 3-phosphoglycerate, a three-carbon compound. This is the actual fixation step and is referred to as the *carboxylation phase* of the Calvin cycle. The overall reaction is energetically favorable ($\Delta G^{\circ\prime} = -35$ kJ mol^{-1}), but it is a complex reaction that occurs very slowly.

In the second phase of the Calvin cycle, the *reduction phase*, ATP and NADPH generated by the light reactions are consumed. A molecule of 3-phosphoglycerate is phosphorylated to generate 1,3-bisphosphoglycerate, which is then reduced to glyceraldehyde 3-phosphate. These reactions are essentially the reverse of reactions 6 and 7 of the EMP glycolytic pathway (see Figure 13.13). NADPH serves as the reductant in the Calvin cycle, whereas NAD^+ is the oxidant in the EMP pathway, illustrating the partitioning of these electron carriers between catabolic and anabolic processes.

After glyceraldehyde 3-phosphate generation, the Calvin cycle gets more complicated, just as the pentose phosphate pathway does. Rather than going through the reactions in detail, suffice it to say that roughly five out of every six

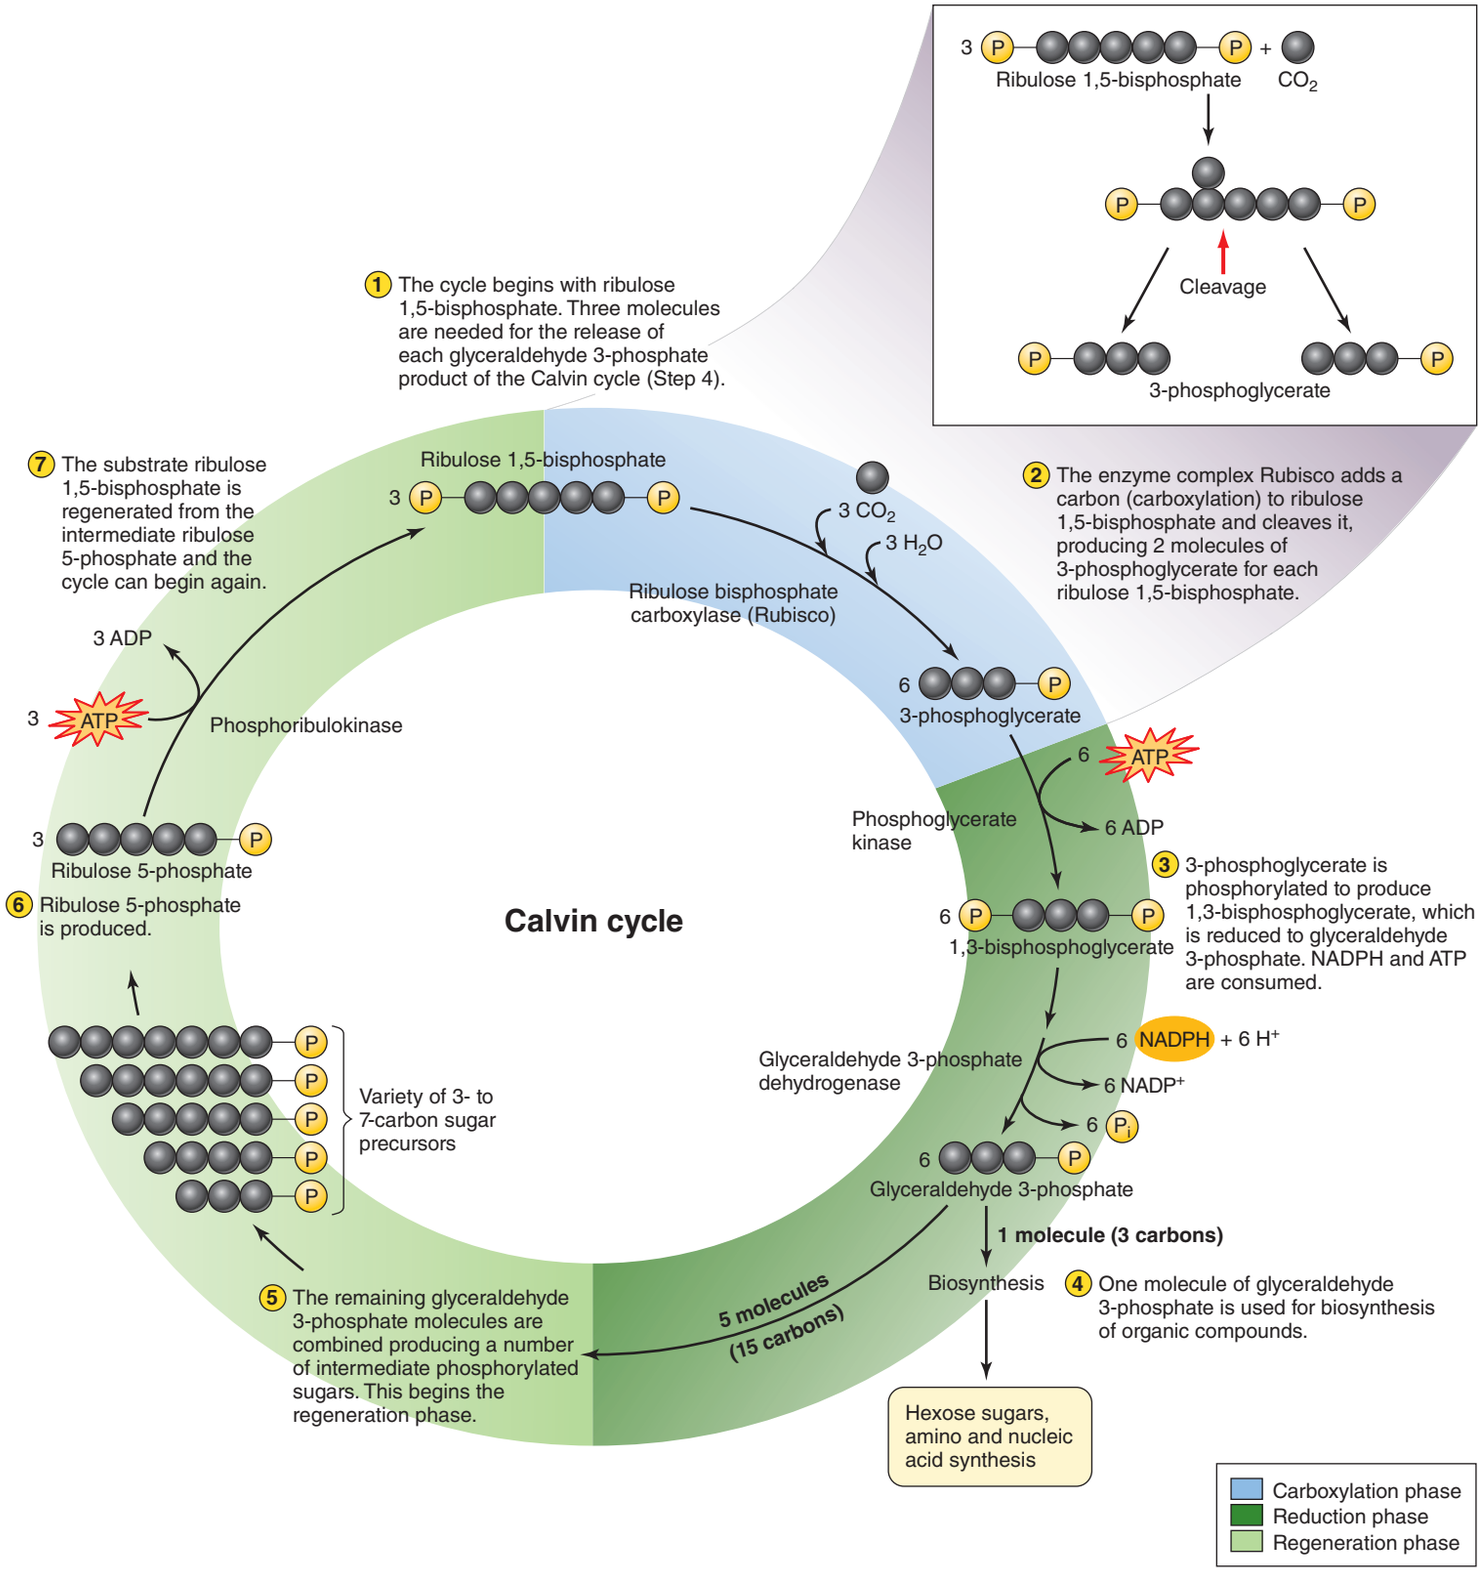

Figure 13.38. Process Diagram: The Calvin cycle Many phototrophs use the Calvin cycle to produce organic carbon compounds from CO_2. The carboxylation phase is catalyzed by Rubisco and incorporates CO_2 into a five-carbon ribulose 1,5-bisphosphate molecule that is cleaved into two 3-carbon molecules. A detail (*upper right*) of the reactions carried out by Rubisco on ribulose 1,5-bisphosphate is shown. The reduction phase uses ATP and NADPH to produce the product glyceraldehyde 3-phosphate. One molecule of glyceraldehyde 3-phosphate is available for other biosynthetic processes, including production of glucose. To continue the cycle, ribulose 5-phosphate is regenerated through a complex series of reactions that use five out of every six glyceraldehyde 3-phosphates made and produces various intermediate sugars.

glyceraldehyde 3-phosphate molecules generated continue in the cycle. Only one glyceraldehyde 3-phosphate is available to leave the cycle for other biosynthetic reactions. The processing of three ribulose 1,5-bisphosphate molecules by the cycle is required in order to regenerate the Rubisco substrate ribulose 1,5-bisphosphate. If this is not remade in the cycle, the Calvin cycle cannot actually function as a cycle. Counting carbons will help show this requirement. We will start with the entry of one ribulose 1,5-bisphosphate. One five-carbon molecule plus one CO_2 yields six carbons. The three-carbon product (glyceraldehyde 3-phosphate) exiting the cycle leaves only three carbons—not enough to remake the five-carbon substrate ribulose 1,5-bisphosphate. Similarly, two five-carbon molecules plus two CO_2 gives twelve carbons. Removing a three-carbon product leaves only nine carbons—not enough to remake two five-carbon molecules (10 carbons). Three ribulose 1,5-bisphosphate molecules (15 carbons) join with three CO_2 to produce a total of six 3-carbon glyceraldehyde 3-phosphate molecules (18 carbons). Three carbons exit, and 15 carbons remain—enough to regenerate three molecules of ribulose 1,5-bisphosphate.

To make one molecule of glucose, or any other hexose sugar, six "turns" of the Calvin cycle are required. Total reactions are as follows:

$$6\,CO_2 + 18\,ATP + 12\,NADPH + 12\,H^+ + 12\,H_2O \rightarrow C_6H_{12}O_6 + 18\,ADP + 18\,P_i + 12\,NADP^+$$

The regeneration of ribulose 1,5-bisphosphate involves numerous reactions, producing a variety of three- to seven-carbon intermediates. Many of these molecules serve as precursors for biosynthesis, including erythrose 4-phosphate used for aromatic amino acid synthesis, and ribose 5-phosphate used for nucleotide synthesis (see Section 13.8).

The reductive TCA cycle

Although the Calvin cycle is used by chloroplasts and cyanobacteria, some autotrophic microorganisms, including both phototrophs and non-phototrophs, use pathways other than the Calvin cycle for incorporation of CO_2 into organic molecules. We have seen that the TCA cycle takes various organic carbon molecules and oxidizes them to produce CO_2 (see Figure 13.20). Some organisms can run the cycle in reverse to consume CO_2 to produce carbon compounds at the expense of ATP and electrons, usually in the form of NADH. This turns the cycle into a reductive (electron-consuming) pathway, known as the **reductive TCA cycle** (Figure 13.39). A product of the reductive TCA cycle is acetyl-CoA, which can be fed into lipid synthesis, or used for glucose production, called "gluconeogenesis." Intermediates of the reductive cycle can also be used for biosynthesis, just like the TCA cycle operating in the oxidative direction. Some autotrophs, such as *Sulfolobus* (see Microbes in Focus 7.2), a non-photosynthetic archaeon, and photosynthetic green sulfur bacteria, such as *Chlorobium* (see Microbes in Focus 13.1), use simple inorganic compounds present in their environments, such as hydrogen or sulfates, as electron donors to run the reductive TCA cycle. As you will recall, *Chlorobium tepidum* uses photosystem I for anoxygenic photosynthesis. The ATP and NADPH that result are used to drive carbon fixation via the reductive TCA cycle.

The reductive TCA cycle goes in the opposite direction of the TCA cycle, beginning with oxaloacetate. The entry of CO_2 is shown in Figure 13.39, as are the steps where an investment of ATP and electrons, carried by reduced molecules such as NADH, are necessary to force the cycle in reverse. Most of the enzymes used in the reductive TCA cycle are the same enzymes used in the normal TCA cycle. How can this be? Reactions that have small $\Delta G^{\circ\prime}$ values can be driven in one direction or the other simply by availability of the reactants. To make this clearer, consider the following reaction:

$$\mathbf{X} \overset{\text{enzyme}}{\Longleftrightarrow} \mathbf{Y}$$

If this reaction has a very small $\Delta G^{\circ\prime}$, it is reversible for practical purposes. Consider that under "normal" physiological conditions, this reaction occurs in the context of a metabolic pathway, where X and Y are produced sequentially. X is produced first in high concentrations by a metabolic pathway and then converted to Y, which is rapidly consumed by another reaction or even multiple reactions. With respect to this particular reaction, the net conversion of X to Y will dominate under these conditions because there is much X and very little Y. If circumstances change so that the other reactions producing X are shut down, and Y instead is produced by other reactions, the X↔Y reaction will run in the opposite direction. That is basically what happens with the reverse TCA cycle. Three enzymes from the oxidative version of the TCA cycle are replaced with new enzymes: fumarate reductase, α-ketoglutarate oxidoreductase, and ATP citrate lyase. The replacement enzymes execute the energy-demanding reactions of the reductive version of the TCA cycle, so that it *incorporates* two molecules of CO_2 to form a new molecule of acetyl-CoA each time around. The dependence of the giant tube worms on the ability of the chemoautotrophic bacteria to use a reductive TCA cycle to supply them with carbon compounds is supported by metagenomic analysis, described in this chapter's **Mini-Paper**.

13.6 Fact Check

1. What is the process of photosynthesis, and why is it considered important for all life on Earth?
2. Differentiate between chlorophyll, bacteriochlorophyll, carotenoid, and phycobiliprotein.
3. Describe the key features of PS I and PS II in anoxygenic phototrophy.
4. Compare and contrast oxygenic photosynthesis and anoxygenic photosynthesis.
5. Provide an overview of the Calvin cycle.
6. What is the reductive TCA cycle, and how is it used by microorganisms?

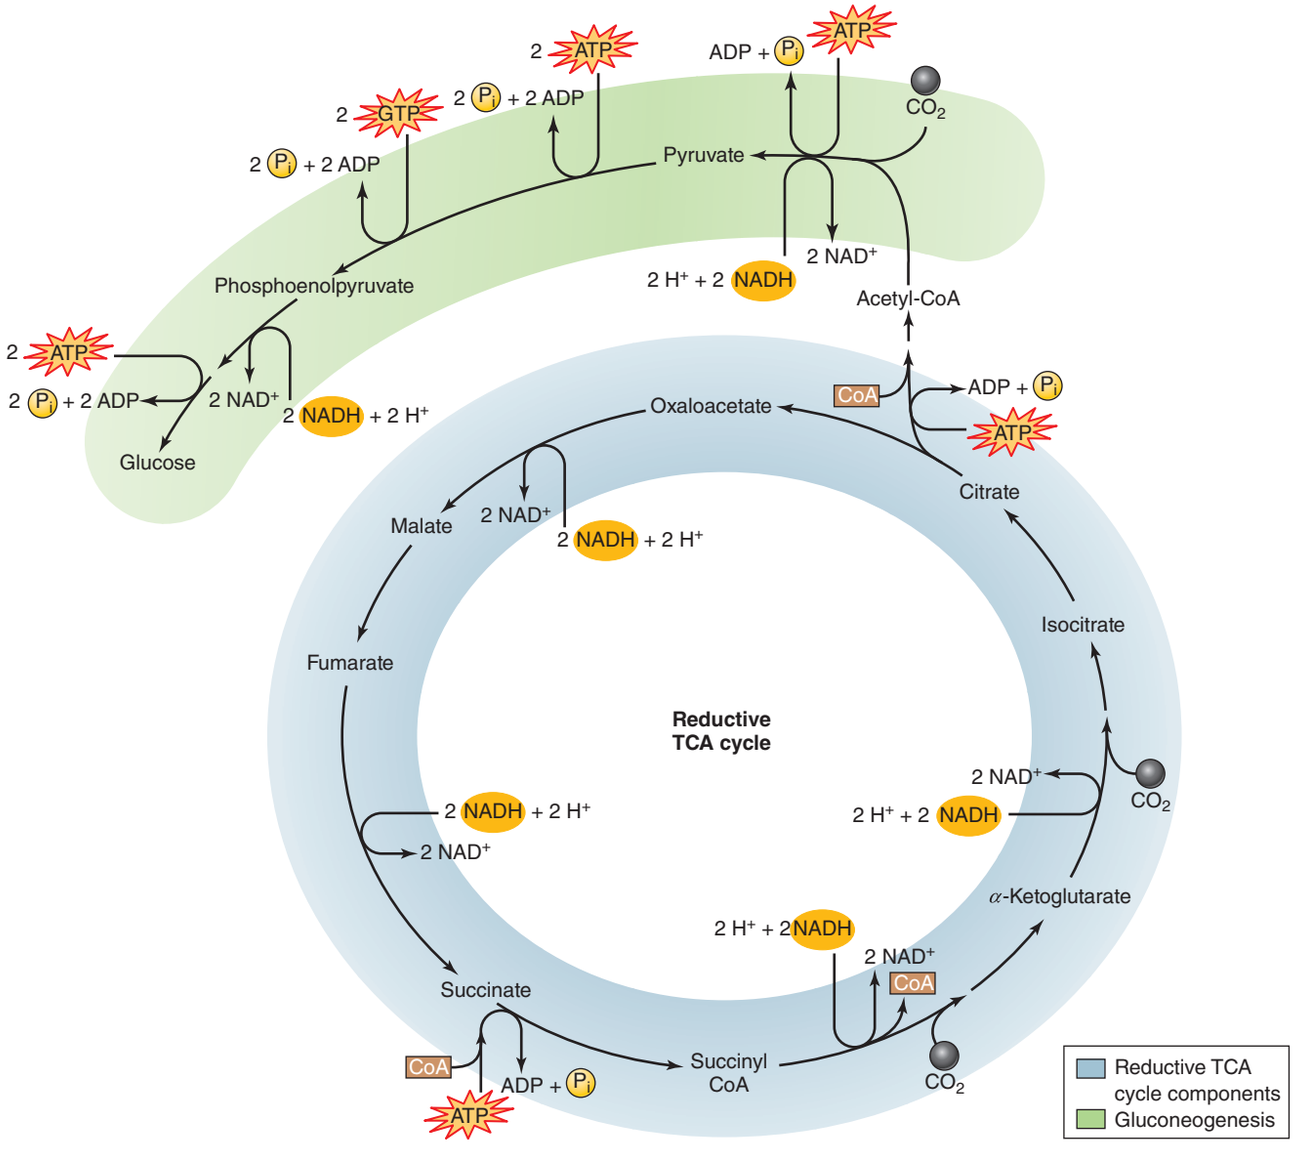

Figure 13.39. The reductive TCA cycle The cycle (blue) begins with the reduction of the four-carbon compound oxaloacetate by using electrons donated from a reduced compound, such as NADH. A product is the two-carbon compound acetyl-CoA, which enters into further biosynthetic reactions (green), depending on the metabolic capabilities of the organism. Shown here are some of the steps in gluconeogenesis, the production of glucose.

13.7 Nitrogen and sulfur metabolism

How do microorganisms use nitrogen and sulfur?

Organic carbon sources needed by heterotrophs or carbon dioxide (CO_2) needed by autotrophs are essential for building organic molecules needed by all cells, such as such as polysaccharides, lipids, proteins, and nucleic acids. In addition, all organisms need access to nitrogen and sulfur to build critical biomolecules. Nitrogen is an essential part of the chemical structure of amino acids and nucleotides, and sulfur is required for the amino acids cysteine and methionine, and for other components, such as the iron-sulfur centers used in many electron transfer reactions. Assimilation of nitrate (NO_3^-), dinitrogen (N_2), sulfate (SO_4^-), or elemental sulfur (S^0) requires an investment of energy and electrons to reduce these compounds to the oxidation state at which they will be incorporated into biomolecules. We will start our discussion of nitrogen metabolism with nitrogen fixation, and move to other methods of assimilation, before touching briefly on sulfur metabolism.

Mini-Paper: A Focus on the Research

GENOME SEQUENCE OF A DEEP SEA SYMBIONT

J. C. Robidart, S. R. Bench, R. A. Feldman, A. Novoradovsk, S. B. Podell, T. Gaasterland, E. E. Allen, and H. Felbeck. 2008. Metabolic versatility of the *Riftia pachyptila* endosymbiont revealed through metagenomics. Environ Microbiol 10:727–737.

Context

The giant tube worm *Riftia pachyptila* is a specially adapted animal associated with deep sea hydrothermal vents. The high temperatures coupled with the unique chemical constituents of the surrounding water make for very specialized communities in these ecosystems deprived of light and carbon substrates. Tube worms have no mouth or digestive tract. They rely solely on a sulfide-oxidizing member of the *Gammaproteobacteria* that lives inside them for their metabolic needs. The bacteria have no contact with the external environment and thus rely on the host for providing certain growth substrates and removal of waste products. These bacteria, known as *Candidatus* Endoriftia persephone, have never been cultivated outside of the host but do survive in a free-living state in the sediments surrounding the vents. To better understand the metabolism of *Candidatus* E. persephone, this study took a metagenomic approach to obtain its complete genome sequence.

Experiments

Tube worm samples were collected near hydrothermal vents from a depth of 2,550 m at the East Pacific Rise, latitude 9°N. The East Pacific Rise is a ridge that formed at the junction between the Pacific tectonic plate and the North American and Rivera tectonic plates. Microorganisms were collected from the internal body tube, the trophosome, of two worms. The DNA was extracted, cleaved with restriction enzymes, and cloned into vectors. The DNA of individual clones was then sequenced using the Sanger method, yielding 14-fold coverage of the estimated 3.2-Mb genome. The resulting sequence was assembled into 2,472 contiguous or non-overlapping fragments, which were then analyzed. One of the first questions was whether the collective sequence represents the genome of a single genome, or if it includes DNA from other organisms that might also be present in the trophosome. Only a single 16S rRNA gene sequence was detected, and very little sequence variation was detected in the overlapping sequence data; *Candidatus* E. persephone appeared to reside in the trophosome as a pure culture.

The sequence was next examined for information about the physiology of *Candidatus* E. persephone. All of the enzymes for the reductive TCA cycle, including the signature genes coding for fumarate reductase, α-ketogluterate oxidoreductase, and ATP citrate lyase, were present. This strengthened the hypothesis that *Candidatus* E. persephone is able to fix carbon dioxide (CO_2) for the benefit of the tube worm host. Although this paper noted that two key enzymes for the Calvin cycle were missing, further research has since confirmed the presence of a functioning Calvin cycle by both genomic and proteomic analyses. For operation under largely anoxic conditions, the oxygen-sensitive reductive TCA cycle is more efficient than the Calvin cycle. Use of the Calvin cycle may occur under higher oxygen levels and is just one example of the metabolic diversity of this microorganism. Genes encoding enzymes for the complete TCA cycle, fructose degradation, and glycolysis were identified, supporting the ability of *Candidatus* E. persephone to survive as a free-living heterotroph. It appears that CO_2 fixation is active in the trophosome of the worm, whereas organic carbon is assimilated in the free-living state. Finally, the genes for sulfide oxidation using a reverse sulfate reduction pathway and dissimilatory nitrate reduction were identified.

Impact

The inability to cultivate the symbiont of giant tube worms limits the investigation of the physiological relationship between these organisms. It also restricts investigation of the transition between the symbiotic and free-living life of *Candidatus* E. persephone. Although the genome sequence obtained through cultivation-independent means provides a window on the metabolic potential, its greatest contribution might actually be that it helps to develop strategies for the cultivation of this unique bacterium so that it can be thoroughly studied in the laboratory.

Questions for Discussion

1. What changes in gene regulation would you expect to find as *Candidatus* E. persephone moves from a free-living state to a lifestyle inside the worm?
2. What advantage do you think *Candidatus* E. persephone gains from being in the trophosome?

Nitrogen fixation

The largest source of nitrogen in the biosphere is atmospheric nitrogen gas, N_2. The problem for living organisms is that N_2 is extremely stable. The triple covalent bonds holding N_2 together must be broken in order to incorporate nitrogen atoms into biological molecules, but reducing this molecule takes a major investment of energy. "Diazotrophic microorganisms" (nitrogen fixers) are rewarded for their efforts with a significant competitive advantage in environments where there is little biologically available nitrogen (ammonia, nitrate, nitrite, or organic molecules such as amino acids). Because of its energetic cost, the enzymatic machinery for fixing nitrogen is highly regulated and is only expressed when alternative forms of nitrogen are exhausted or unavailable.

We were first introduced to nitrogen fixation in Section 1.3. It is the assimilation of N_2 into compounds for cell use.

Nitrogen fixation is purely a microbial process, carried out only by bacteria and archaea. Many phototrophs can fix nitrogen, including cyanobacteria and anoxygenic phototrophs such as *Heliobacterium* spp., *Rhodospirillum,* and *Chlorobium* spp. (see Microbes in Focus 13.1). Non-phototrophic diazotrophs include bacteria with agricultural significance, such as species that form symbiotic partnerships with plant roots. These bacteria fix nitrogen to supply their own and their host plant's nitrogen needs. In return, they receive organic compounds from their host to supply their carbon and energy requirements. Given that gene sets for nitrogen fixation have been shared between many bacterial species through horizontal gene transfer, it's a bit mystifying that no eukaryal organism seems to have acquired this ability.

CONNECTIONS Symbiotic nitrogen-fixing bacteria are crucial to the survival of many plant species, including agriculturally important soybeans, peas, and alfalfa. The bacteria invade the cells of the plant roots where they remain safely encased to carry out nitrogen fixation. This partnership is further discussed in **Sections 14.3** and **17.2**.

The key enzyme for nitrogen fixation is **nitrogenase**, which catalyzes the reaction:

$$N_2 + 8\ H^+ + 8\ e^- \rightarrow 2\ NH_3 + H_2$$

This reaction is accompanied by hydrolysis of at least 16 ATP molecules. The stoichiometry of the reaction is unusual because only six electrons and six protons are actually incorporated into the two ammonia molecules produced. Why H_2 is generated is not clear, but it is thought that N_2 may displace formed H_2 in the enzyme active site. The hydrolysis of ATP reflects the investment of energy necessary to reduce the highly stable N_2 molecule.

Nitrogenase is a large multi-subunit enzyme whose core consists of two types of subunits: dinitrogenase reductase, which provides dinitrogenase with reducing power, and dinitrogenase, which actually reduces N_2. The active sites of both subunits contain metal-bound organic cofactors involved in electron transfer. The dinitrogenase cofactor contains iron and molybdenum, and is referred to as "FeMo-co" **(Figure 13.40)**. Complete reduction of N_2 to ammonia is a multistep process. First, a pair of electrons combines with two protons to form H_2. Then three pairs of electrons are transferred from the electron transport chain in sequential steps through the dinitrogenase reductase subunit, which gets them from donor proteins such as flavodoxin or ferredoxin, depending on the microorganism. Dinitrogenase reductase must be activated by ATP binding, in order for the active site to reach a conformation with a sufficiently negative reduction potential to transfer electrons to the dinitrogenase FeMo-co cofactor. Reinforcing the energy-intensive nature of nitrogen fixation, two ATP molecules are hydrolyzed for *each electron* transferred.

The FeMo-co cofactor, located near the surface of the enzyme, is extremely sensitive to oxidation, which makes it very difficult to operate in an oxic environment. This is a conundrum for diazotrophic microorganisms that live in oxic habitats and use aerobic respiration, or that produce O_2 during photosynthesis. Such microorganisms must take special precautions to protect nitrogenase when they need to fix nitrogen. One adaptation has been studied extensively in the filamentous cyanobacterium *Anabaena*. Nitrogen fixation in *Anabaena* occurs in specialized cells called heterocysts **(Figure 13.41)**. In the presence of ammonia or nitrate, chains of *Anabaena* have no heterocysts. Nitrogen limitation induces the formation of heterocysts, which are recognizable by microscopy in filaments because they thicken and expand their cell walls to limit inward O_2 diffusion. Heterocysts are spaced roughly every 10 to 15 cells, and provide fixed nitrogen to the surrounding cells.

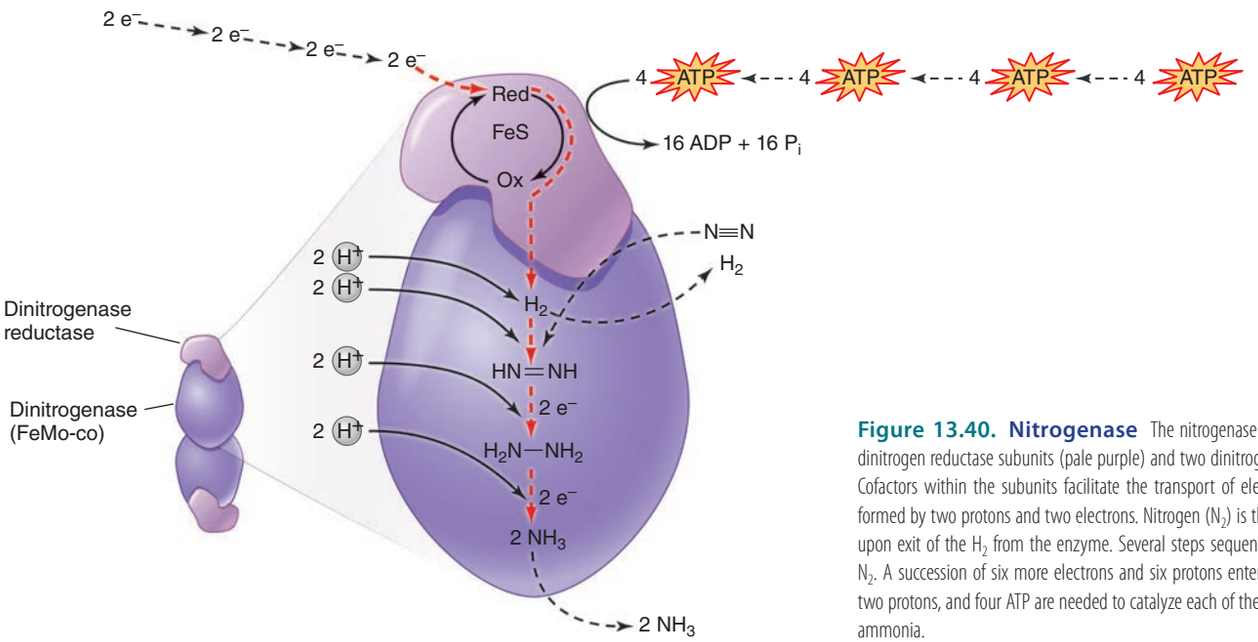

Figure 13.40. Nitrogenase The nitrogenase complex is composed of two dinitrogen reductase subunits (pale purple) and two dinitrogenase subunits (dark purple). Cofactors within the subunits facilitate the transport of electrons. Hydrogen (H_2) is first formed by two protons and two electrons. Nitrogen (N_2) is thought to enter the active site upon exit of the H_2 from the enzyme. Several steps sequentially break the triple bond of N_2. A succession of six more electrons and six protons enters the enzyme. Two electrons, two protons, and four ATP are needed to catalyze each of the three reduction steps to form ammonia.

Figure 13.41. Nitrogen-fixing heterocysts in *Anabaena* filaments
The large brownish heterocysts shown here (5–6.5 μm diameter), are developed in the absence of ammonia or nitrate for N_2 fixation. The thickened cell walls of the heterocysts limit exposure to O_2 to protect oxygen-sensitive nitrogenase. The heterocyst cells do not have a functioning PS II system, ensuring O_2 is not generated in the cell.

Microbes in Focus 13.2
SINORHIZOBIUM MELILOTI

Habitat: Free-living *Sinorhizobium meliloti* are found in soil but form a symbiotic partnership with alfalfa (*Medicago sativa*), in which the bacterium forms specialized cells called bacteroids in small nodules that emerge from the plant roots (shown here).

Description: Gram-negative, rod-shaped bacterium from the *Gammaproteobacteria* with aerobic metabolism, but in the bacteroid state tolerates a near-anoxic environment to carry out nitrogen fixation. In soil, rods are 1–2 μm long, but enlarge to 5–10 μm once inside the plant host.

Key Features: Molecular communication between the plant and bacteria ensures specificity of symbiosis. Bacteroids fix nitrogen and provide ammonia to the plant root tissue, which in turn provides carbohydrates and oxygen to the bacteria.

© Inga Spence/Science Source

Heterocysts cannot divide—they sacrifice their reproductive potential to provide an essential nutrient to their compatriots in the filament.

Heterocysts induce a new program of gene expression in which genes for nitrogenase production are highly expressed, and many genes for photosynthetic activities are turned off. PS II is degraded so that O_2 will not be generated. PS I is not degraded, but instead shifts to a cyclic electron transport pathway, like that used by purple bacteria with PS II. This cyclic pathway pumps protons to generate proton motive force for ATP synthesis. Heterocysts also increase expression of glycolytic enzymes to metabolize carbohydrates such as sucrose from adjacent cells. In return, the heterocysts share nitrogen in the form of amino acids. Sugars and amino acids are readily transported between cells. This is a fascinating example of cooperation among microbial cells, and considerable research has gone into understanding the elaborate regulatory system that allows *Anabaena* cells to communicate and decide which cell will differentiate into a heterocyst.

Other aerobic diazotrophs take different approaches to protecting FeMo-co. *Azotobacter* cells increase respiratory metabolism so that O_2 is consumed rapidly and also add a protective redox-active protein to the nitrogenase complex that counteracts oxidants such as O_2. Symbiotic nitrogen-fixing rhizobia, a group of bacteria detailed in Section 17.2, are partially protected by the plant tissue surrounding them, which lowers O_2 concentration through respiration, and by physically slowing diffusion. **Microbes in Focus 13.2** presents a member of the *Rhizobiaceae* family. Despite their need to protect the nitrogenase complex from O_2, these bacteria must maintain aerobic respiration. To accommodate their bacterial partners, leguminous plants such as soybeans that host rhizobia in root nodules produce an oxygen carrier in root tissue called leghemoglobin.

CONNECTIONS Leghemoglobin, described in **Section 17.2**, is structurally similar to mammalian hemoglobin and sequesters O_2 in the microbial cell, dramatically lowering the free O_2 concentration and protecting nitrogenase. The rhizobial respiratory cytochrome oxidase apparently has a high enough affinity for O_2 that it can operate under these conditions.

Ammonia assimilation

Ammonia (NH_3) and its protonated form, ammonium ion (NH_4^+), are the only forms of inorganic nitrogen incorporated directly into biological molecules. Other forms of nitrogen are first converted to ammonia before they are used for biosynthesis. When free ammonia/ammonium is available in the medium, it is transported into the cytoplasm. Uncharged NH_3 moves relatively freely across membranes. However, in water at neutral pH, equilibrium favors the protonated NH_4^+ form, which is *not* membrane permeable and must enter the cell through a transport system. Once in the cytoplasm, ammonium is incorporated into glutamate or glutamine. There are two common microbial pathways for incorporation of ammonium: the GS-GOGAT pathway and the GDH pathway.

The GS-GOGAT pathway uses a combination of two enzymes: glutamine synthetase (GS) and glutamate synthase **(Figure 13.42A)**. GOGAT is an abbreviation for an alternative name for glutamate synthase: glutamine oxoglutarate aminotransferase. The GS reaction is driven by hydrolysis of an ATP molecule, and GOGAT uses NADPH as an electron donor. The GDH pathway uses the enzyme glutamate dehydrogenase, for which it is named, to add ammonium to α-ketoglutarate

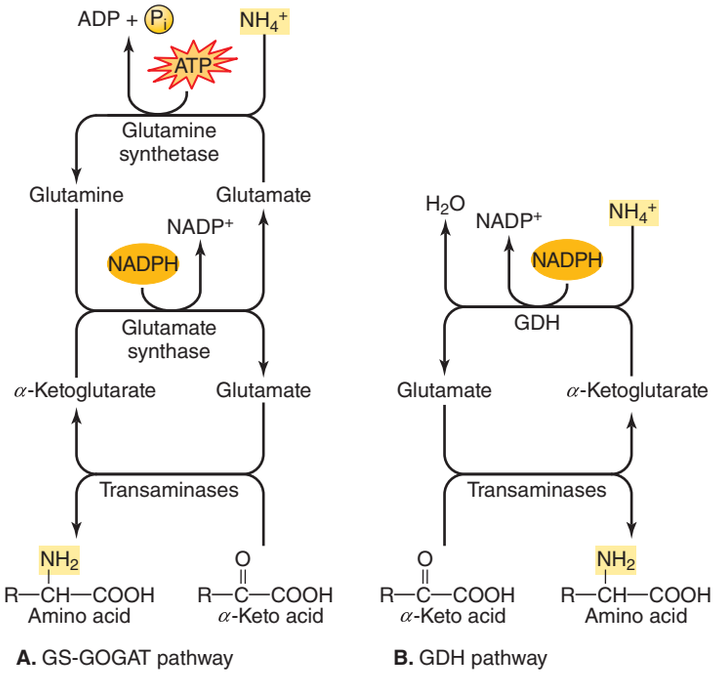

Figure 13.42. Ammonia assimilation **A.** The GS-GOGAT pathway uses dissolved ammonium to incorporate nitrogen into amino acids using a sequence of reactions catalyzed by glutamine synthetase and glutamate synthase. This pathway consumes ATP. **B.** The GDH pathway features glutamine dehydrogenase (GDH), which does not require ATP to produce glutamate from ammonium. Both pathways produce glutamate, which is a substrate for specific transaminases that transfer the amino group onto α-keto acid amino acid precursors, forming all common 20 amino acids. Note R represents the various side chains of specific amino acids.

(see Figure 13.42B). This reaction requires NADPH as an electron donor, but does not consume ATP.

Both of these pathways for ammonium incorporation are found in many microorganisms. Why? It is not known for sure. In general, glutamate dehydrogenase is preferentially used at high NH_4^+ concentrations, and GS-GOGAT is used during low ammonium availability. GS has a higher affinity for ammonium ($K_m < 0.2$ mM for *Escherichia coli* GS) than glutamate dehydrogenase ($K_m \approx 3$ mM for the *E. coli* enzyme), so GS is more active at submillimolar NH_4^+ concentrations. In many microorganisms, these differences are reflected in the regulation of the enzymes, with GDH expression repressed and GS-GOGAT induced in low-nitrogen medium, and the converse when ammonium is more abundant. However, other factors affect these enzyme activities as well. For example, experiments have shown that when *E. coli* is stressed for carbon and energy, GDH takes on a more important role in ammonia assimilation, even if ammonium concentrations are quite low. This makes sense in light of the fact that GS directly requires ATP to function, whereas GDH does not.

The amino group added to glutamate by GDH or GS-GOGAT can be donated to other molecules by enzymes called "transaminases." There are many transaminases in microorganisms, such as those used for synthesis of amino acids by amination of α-keto acid precursors, as we will see in Section 13.8. The GDH reaction is reversible, so the enzyme can function for catabolic deamination of glutamate, generating NADPH and α-ketoglutarate. In mammalian cells, GDH is largely found in mitochondria, where it operates primarily as a deaminase, and is regulated by energy metabolism. Mutations that cause defective regulation of GDH appear to result in excessive insulin secretion through a complex cascade of physiological changes emanating from mitochondria of pancreatic cells.

Utilization of nitrate and nitrite

As well as being assimilated into biomass, ammonia from nitrogen fixation can be oxidized into nitrate in a two-stage process called **nitrification**. The first step in nitrification is the conversion of NH_3 to nitrite (NO_2^-), and the second step coverts NO_2^- into NO_3^-. Each step is carried out by distinct groups of lithotrophic nitrifying bacteria (see Figure 14.11). Their genus names typically begin with "Nitroso" for ammonia oxidizers and "Nitro" for nitrite oxidizers, as for *Nitrosomonas* and *Nitrobacter*, respectively. They are obligate aerobes, and most can fix CO_2. They can be found wherever ammonia is present and are especially important in wastewater treatment (see Section 16.5), and soils where they are key to allowing the nitrogen contained in fertilizer to be made available to plants (see Section 14.3).

Nitrate produced by nitrification can be used as a terminal electron acceptor for anaerobic respiration (see Figure 13.24). This process is called "dissimilatory" nitrate reduction because the products are not incorporated into cellular material. More common is the process of "assimilatory" nitrate reduction, in which NO_3^- is reduced to NH_3 **(Figure 13.43)**. In the cytoplasm, ammonia becomes ammonium and is then

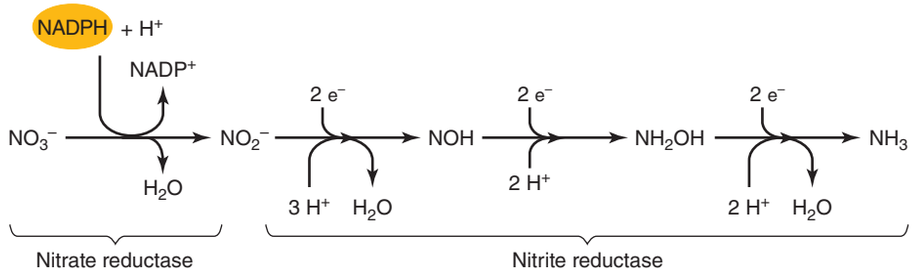

Figure 13.43. Assimilatory nitrate reduction When ammonium is not available for biosynthetic needs, nitrate (NO_3^-) is reduced to ammonia (NH_3) in a series of reactions that begins with nitrate reductase and is completed by nitrite reductase.

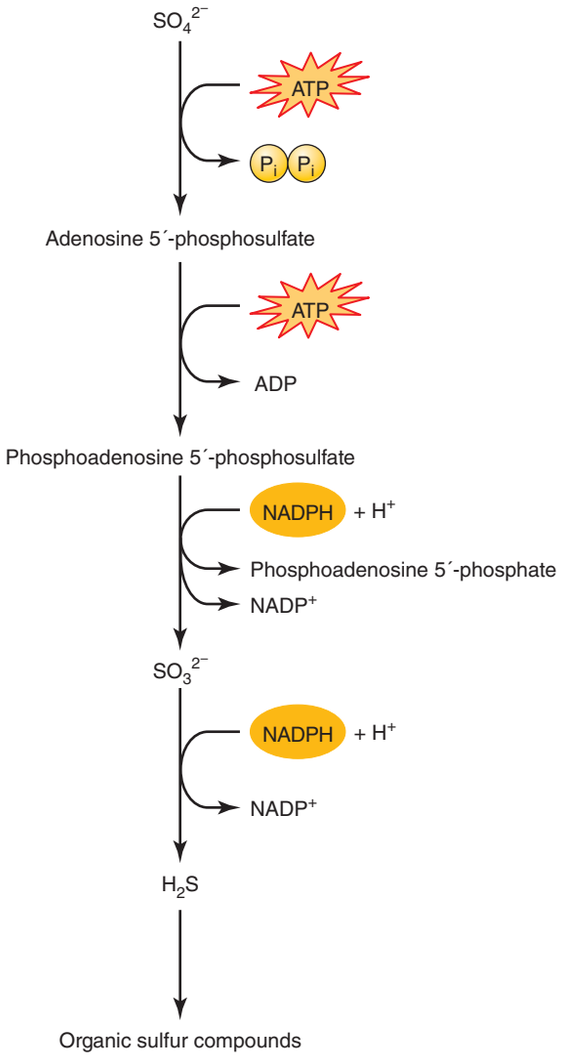

Figure 13.44. Sulfate assimilation Sulfate is a poor electron acceptor and must be converted to adenosine 5′-phosphosulfate in an ATP-consuming reaction. A second phosphate is donated by another ATP, forming phosphoadenosine 5′-phosphosulfate. Reduction to H_2S then occurs through a series of reactions. Hydrogen sulfide is then incorporated into sulfur-containing molecules, such as the amino acid cysteine.

incorporated into biomass by routes illustrated in Figure 13.42. Assimilatory nitrate reduction occurs in the cytoplasm and is not linked to energy metabolism. Cytoplasmic nitrate reductases usually use NADH or NADPH as electron donors, although there are other electron donors. The expression of assimilatory nitrate reductase is generally dependent on the presence of nitrate in the medium and on the nitrogen needs of the cell. Ammonia/ammonium is preferred as a nitrogen source, since it needs no further reduction; if ammonia/ammonium levels are adequate to supply the biosynthetic needs of the cell, little or no nitrate reductase is expressed even if nitrate is present in high levels.

Nitrate reduction to nitrite is the first step in making ammonia/ammonium for assimilation. Nitrite reductases used for nitrogen assimilation catalyze sequential transfer of three pairs of electrons, using reduced ferredoxin as electron donors. Each transfer is accompanied by uptake of two protons. The end result is ammonia that is incorporated into glutamate as described above. Again, it is important to distinguish assimilatory and dissimilatory processes. Denitrifying bacteria also generate nitrite from nitrate, but the dissimilatory nitrite reductase instead generates nitric oxide (NO), which is further reduced to nitrous oxide (N_2O) and ultimately to dinitrogen (N_2), none of which are incorporated into biomass.

Sulfur metabolism

As with nitrogen, biological molecules contain sulfur in a reduced oxidation state. The most common inorganic form of sulfur in most environments is sulfate ion (SO_4^-), which is highly oxidized and must be extensively reduced before it can be incorporated into cysteine. There are exceptions to this, of course. Some habitats are rich in elemental sulfur, or even hydrogen sulfide, in which case microorganisms undertake different assimilatory strategies. We will only discuss sulfate reduction here. As with nitrate, assimilatory sulfate reduction, which occurs in the cytoplasm and is used to incorporate sulfur into cellular components, is distinguished from dissimilatory sulfate reduction, which is a form of respiration coupled to energy metabolism. Assimilatory sulfate reduction is very common in microorganisms; dissimilatory sulfate reduction is rare.

Sulfate (SO_4^{2-}) is a stable molecule to which it is difficult to add electrons. To make it a better electron acceptor, sulfate is covalently attached to ATP by the enzyme ATP sulfurylase, generating adenosine 5′-phosphosulfate (APS), as shown in **Figure 13.44**. APS is used for both dissimilatory and assimilatory sulfate reduction. In the assimilatory system, APS is converted to phosphoadenosine 5′-phosphosulfate (PAPS). From PAPS, the sulfate group is reduced to sulfite (SO_3^{2-}) with electrons from NADPH, and released from the rest of the molecule. The sulfite is reduced further to hydrogen sulfide (H_2S), a potentially toxic intermediate that is quickly used to displace acetate in acetylserine to generate cysteine. The dissimilatory process also proceeds through a sulfite intermediate to H_2S, which is excreted as a waste product from the cell. Sulfate reducers that use the dissimilatory pathway for energy metabolism can supply other microorganisms with reduced sulfur and often live in close proximity to anaerobic phototrophs that consume H_2S as an electron donor for photosynthesis.

13.7 Fact Check

1. Why are nitrogen and sulfur necessary for cells?
2. What is nitrogen fixation, and what role does nitrogenase play in the process?
3. Differentiate between these two microbial pathways: GS-GOGAT pathway and GDH pathway.
4. Describe the process of assimilatory sulfate reductions.

13.8 Biosynthesis of cellular components

How do microorganisms synthesize new cellular components?

Most of the dry weight of a microbial cell is composed of macromolecules, which include proteins and nucleic acids, plus some lipid and cell wall material of varying amounts and composition. These macromolecules are built from just a few subunits: twenty amino acids, four ribonucleotides, four deoxyribonucleotides, and some fatty acids and carbohydrates for the lipids and cell walls. A central theme of this section is that these macromolecular subunits are themselves synthesized from a common pool of precursors. The precursors in this pool are drawn from the EMP pathway (see Figure 13.13), the TCA cycle (see Figure 13.20), and the pentose phosphate pathway (see Figure 13.15). In this section, we will provide an overview of the pathways for synthesis of amino acids, nucleotides, lipids, and peptidoglycan, and try to show how these anabolic pathways are linked. We will not go into much detail on the biochemistry or regulation of these pathways, but students interested in exploring this fascinating field in more depth are encouraged to investigate microbial physiology and biochemistry references.

Amino acid synthesis

The biosynthetic pathways that build amino acids in microorganisms start with one or more of the common precursor pool **(Figure 13.45)**. We will start with the glutamate family. Glutamate has broad significance for amino acid synthesis, since it is the amino group donor for several transaminases used in the synthesis of other amino acids. In Section 13.7 (see Figure 13.42), we mentioned two reactions for synthesizing glutamate, which serve as the entry point for ammonia into organic molecules. The GS-GOGAT and GDH pathways generate glutamate by addition of amino groups to α-ketoglutarate, a product of the TCA cycle. Glutamine is produced by glutamine synthetase, the first enzyme of the GS-GOGAT system. Glutamate also gives rise to the cyclic amino acid proline through a three-step pathway. Finally, arginine is the product of a long, nine-step and energy-intensive pathway starting with glutamate. The arginine pathway is also important because one of its intermediates, carbamoylphosphate, is a precursor for the synthesis of pyrimidine bases for nucleotide synthesis. Some enzymes involved in arginine synthesis are regulated by the demand for pyrimidines as well as arginine to ensure an appropriate distribution of carbamoyl phosphate.

The aspartate family of amino acids begins synthesis with oxaloacetate, another intermediate of the TCA cycle (see Table 13.2). Oxaloacetate receives an amino group from glutamate to produce aspartate, which also serves as a precursor for synthesis of five more amino acids. Pyruvate, the terminal product of glycolysis, is the starting point for making three relatively small

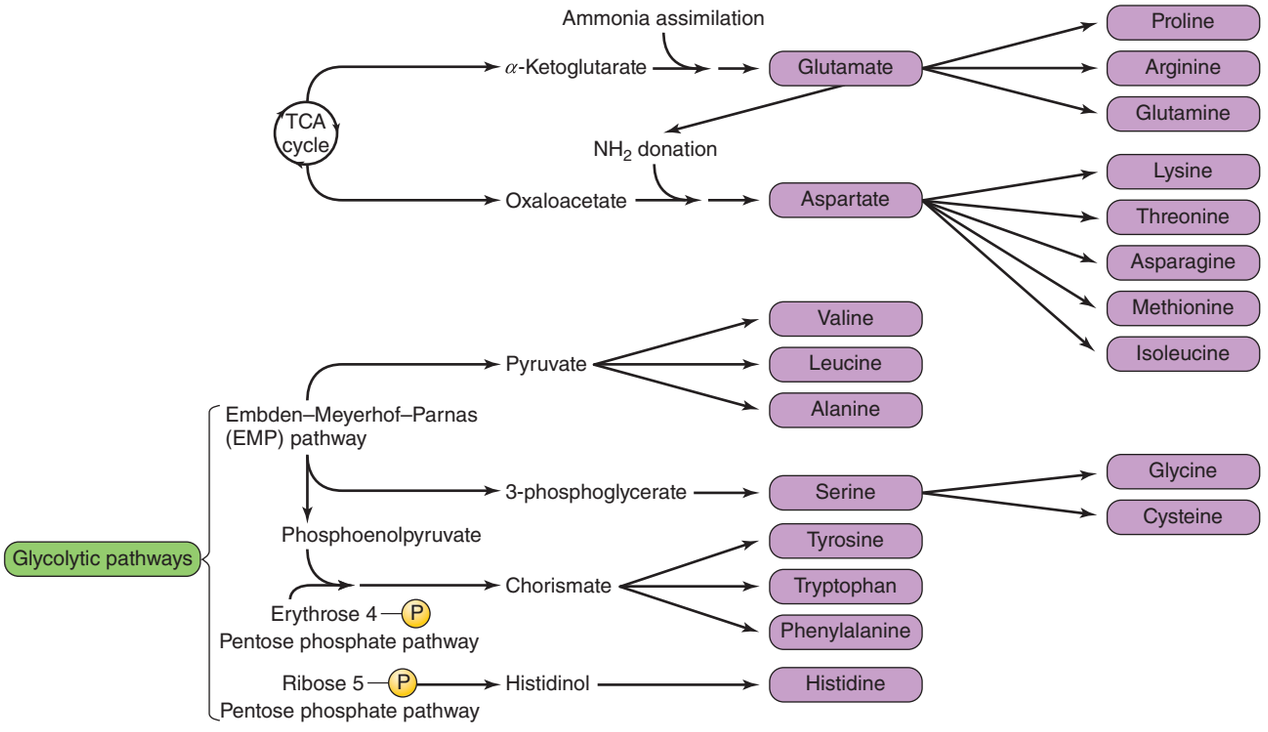

Figure 13.45. Anabolic precursors and pathways to amino acid synthesis The top two synthesis pathways use products of the TCA cycle as precursors for amino acid synthesis. The glutamate family uses ammonia assimilation to produce glutamate from α-ketoglutarate. Glutamate is a precursor for the synthesis of proline, arginine, and glutamine. Glutamate also donates an amino group to oxaloacetate to produce aspartate, which is a precursor for several other amino acids. Glycolytic pathways provide precursors for the other amino acids.

amino acids, alanine, valine, and leucine. The molecule 3-phosphoglycerate, an intermediate of the EMP pathway, initiates production of serine. Serine gives rise to glycine and cysteine, a sulfur-containing amino acid produced by the action of O-acetylserine sulfhydrylase, noted earlier in sulfur assimilation. Cysteine then serves as the sulfhydryl donor for methionine synthesis, another sulfur-containing amino acid. Cysteine also serves as the sulfur donor during synthesis of sulfur-containing cofactors such as biotin and lipoic acid (see Table 13.1).

The last major family of amino acids is the aromatic amino acids: tryptophan, tyrosine, and phenylalanine. Aromatic amino acid synthesis is a long, complex process that starts with phosphoenolpyruvate (from the EMP pathway) and erythrose-4-phosphate, a four-carbon molecule derived from the pentose phosphate pathway. These precursors are combined to generate a seven-carbon molecule that proceeds through several additional steps to generate chorismate. From chorismate, three separate pathways branch out to generate the individual aromatic amino acids. The overall process for making these three amino acids is energy intensive, and is subject to multilayered regulation. The common intermediate, chorismate, is also the starting point for synthesis for folic acid and quinones. Lastly, synthesis of the amino acid histidine uses the precursor ribose 5-phosphate, a product of the pentose phosphate pathway.

Nucleotide synthesis

Nucleotides are the precursors for RNA and DNA synthesis. Given the importance of gene expression and chromosome replication, microbial cells must go to great lengths to maintain adequate nucleotide pools. This is complicated by the fact that nucleotides are not just used for RNA and DNA synthesis. One of the pyrimidine nucleotides, adenosine triphosphate (ATP), also serves as the primary energy currency in the cell (see Section 3.1). The other, guanosine triphosphate (GTP), provides energy for polypeptide synthesis. Derivatives of uridine participate in some biosynthetic processes as carrier molecules, including peptidoglycan synthesis. Cyclic adenosine and guanine nucleotides are used in cellular signaling processes. Considering these demands, maintaining and regulating nucleotide pools is quite complex.

Nucleotides, first mentioned in Chapter 7 (see Figure 7.4A), have three components—a nitrogenous base, a sugar (ribose in RNA, deoxyribose in DNA), and a phosphate group **(Figure 13.46)**.

Cells must either synthesize or acquire five bases: two purines (adenine and guanine) and three pyrimidines (cytosine, thymine, and uracil; see Figures 7.4 and 7.15). Purine and pyrimidine nucleotides are built in distinct ways. Pyrimidine bases are constructed as a cyclic precursor first, then linked to ribose 5-phosphate. In contrast, purines are built up from precursors already linked to ribose 5-phosphate **(Figure 13.47)**.

All nucleotides start as *ribo*nucleotides. The *deoxy*ribose sugar is generated by reduction of the 2′ carbon of the ribose, which replaces the 2′—OH group of the ribose component with a hydrogen atom (see Figure 7.15). This reaction is carried out on all four ribonucleotide triphosphates, despite the fact that deoxyribouridine triphosphate (dUTP) is not intended to be used in DNA synthesis. In the cell, dUTP is quickly converted to the monophosphate dUMP, which cannot be added to a DNA chain by DNA polymerases. The enzyme thymidylate synthetase then methylates the uracil ring to generate the thymidine, in the form of deoxythymidine monophosphate (dTMP). This is then phosphorylated twice to give dTTP, the appropriate precursor for DNA synthesis. Inherent in the pathway to adenosine, guanine, and thymidine synthesis is the donation of carbons from tetrahydrofolic acid, a derivative of folic acid.

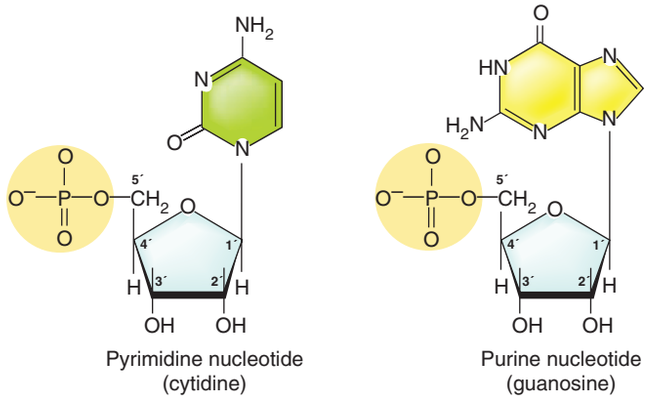

Figure 13.46. Nucleotide structure Nucleotides are composed of a nitrogenous base covalently bound to the 1′ carbon of a ribose sugar. The 5′ carbon is bound to a phosphate group.

CONNECTIONS Sulfonamides and trimethoprim are antimicrobial drugs that act on two separate reactions in the pathway to tetrahydrofolic acid synthesis. They are used together to synergistically block DNA and RNA synthesis by diminishing pools of thymidine, guanine, and adenine. Antimicrobial drugs targeting tetrahydrofolic acid synthesis are discussed in **Section 24.2**.

Microorganisms do not always need to synthesize nucleotides *de novo*. Intact nucleotide triphosphates are rare outside of cells, but ribose and free nitrogenous bases are more common, at least in habitats rich in organic nutrients. Consequently, many microorganisms possess salvage pathways through which they can construct nucleotides from preformed bases and ribose. When a microorganism is grown on rich media containing components such as yeast extract in the laboratory, they largely use salvage pathways for nucleotide synthesis.

Lipid synthesis

Lipids are hydrophobic molecules that are the foundation of cellular membranes. There are a variety of lipids in microorganisms, as we noted in Chapters 2 to 4. We will briefly cover the most common classes of membrane lipids. Phospholipids are the most abundant class of lipids in bacteria and eukaryal microorganisms. They are built from fatty acids linked to glycerol phosphate derivatives. Fatty acids are essentially hydrocarbon chains with a carboxyl group at one end. Within this general description, there is diversity in terms of chain length

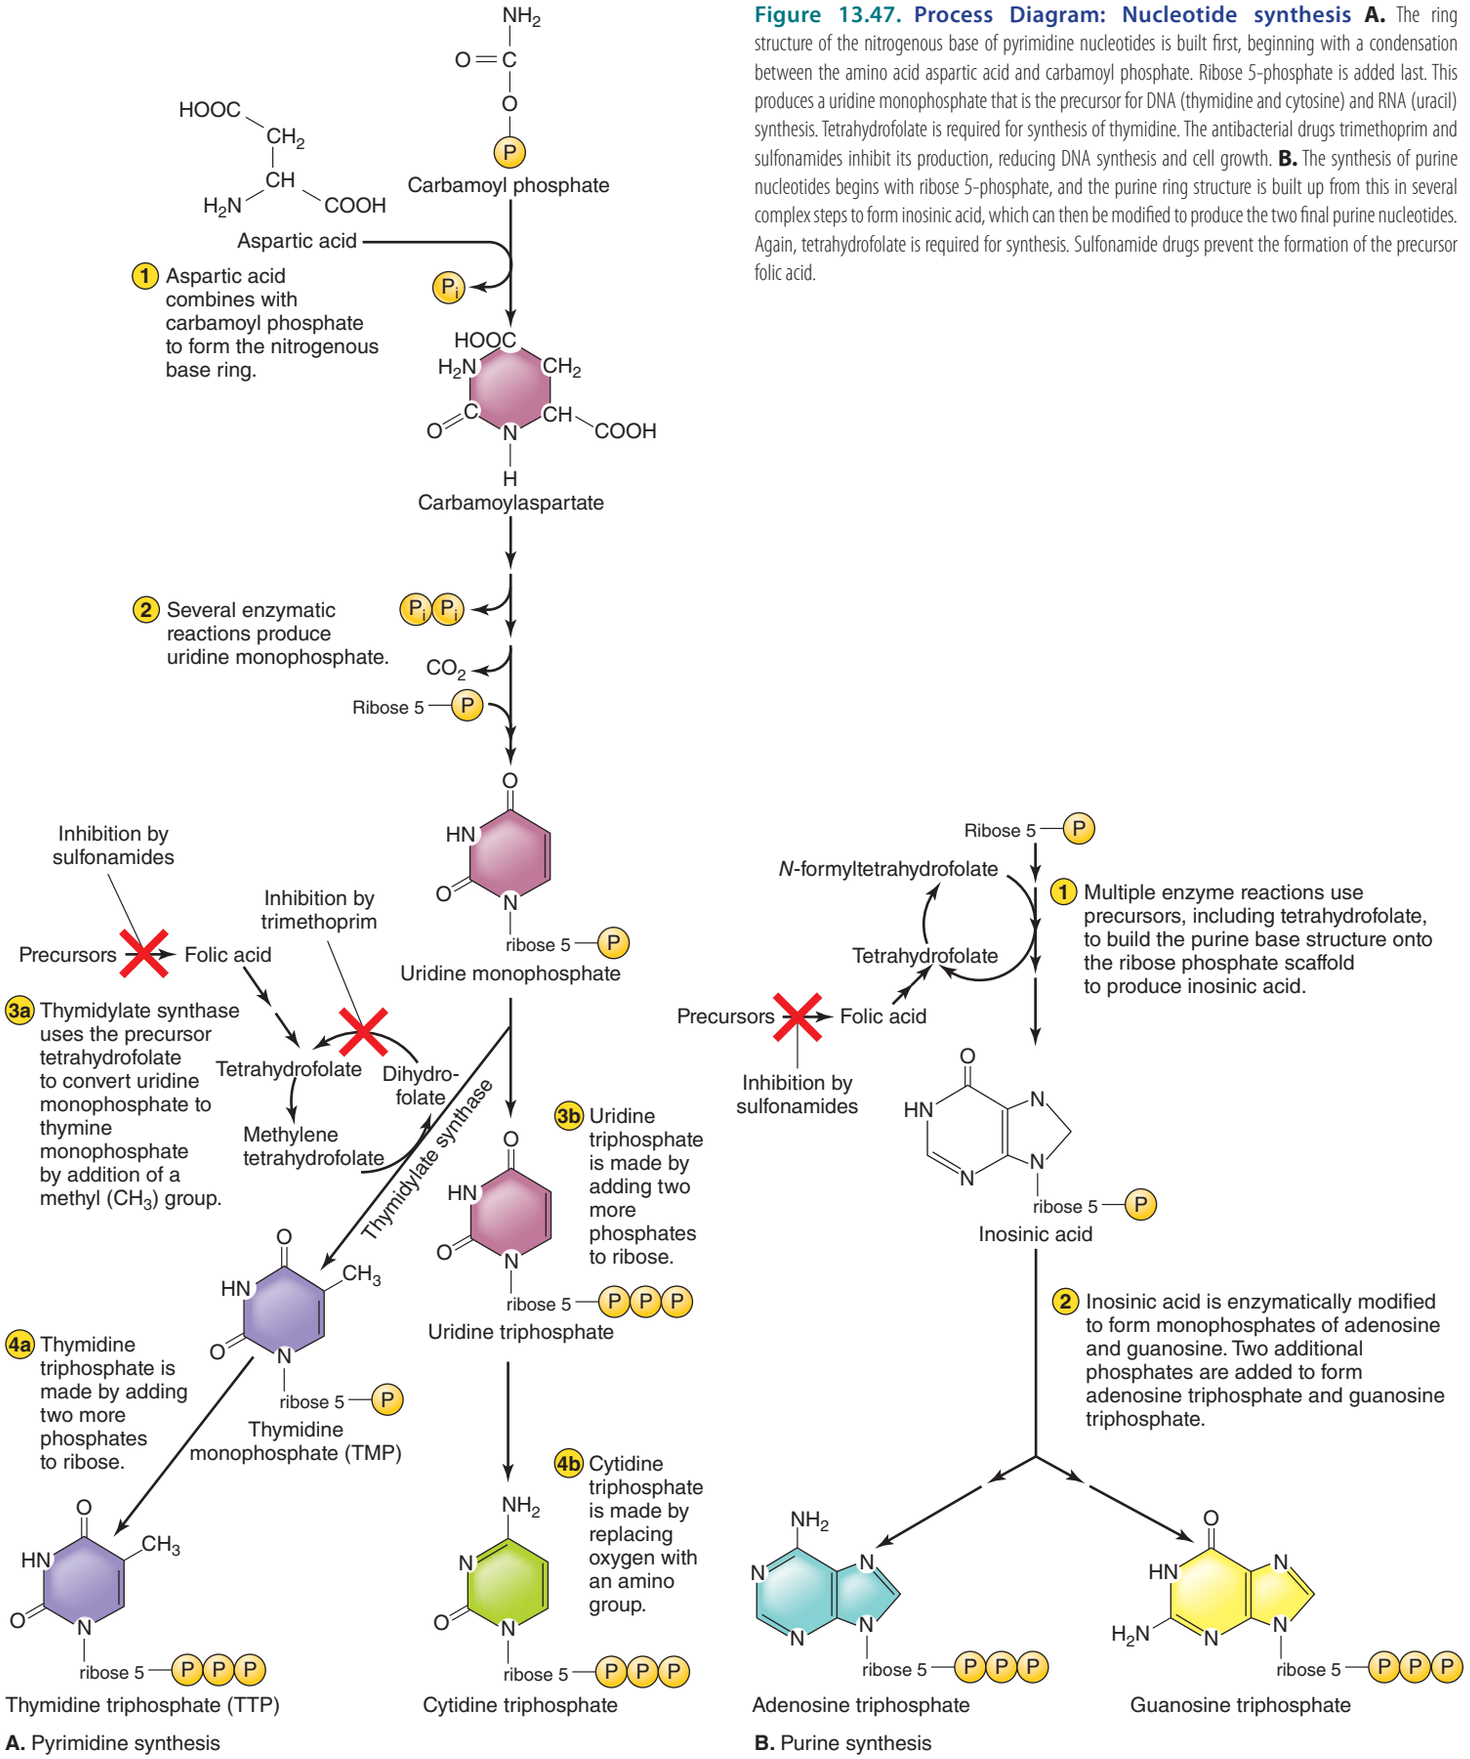

Figure 13.47. Process Diagram: Nucleotide synthesis **A.** The ring structure of the nitrogenous base of pyrimidine nucleotides is built first, beginning with a condensation between the amino acid aspartic acid and carbamoyl phosphate. Ribose 5-phosphate is added last. This produces a uridine monophosphate that is the precursor for DNA (thymidine and cytosine) and RNA (uracil) synthesis. Tetrahydrofolate is required for synthesis of thymidine. The antibacterial drugs trimethoprim and sulfonamides inhibit its production, reducing DNA synthesis and cell growth. **B.** The synthesis of purine nucleotides begins with ribose 5-phosphate, and the purine ring structure is built up from this in several complex steps to form inosinic acid, which can then be modified to produce the two final purine nucleotides. Again, tetrahydrofolate is required for synthesis. Sulfonamide drugs prevent the formation of the precursor folic acid.

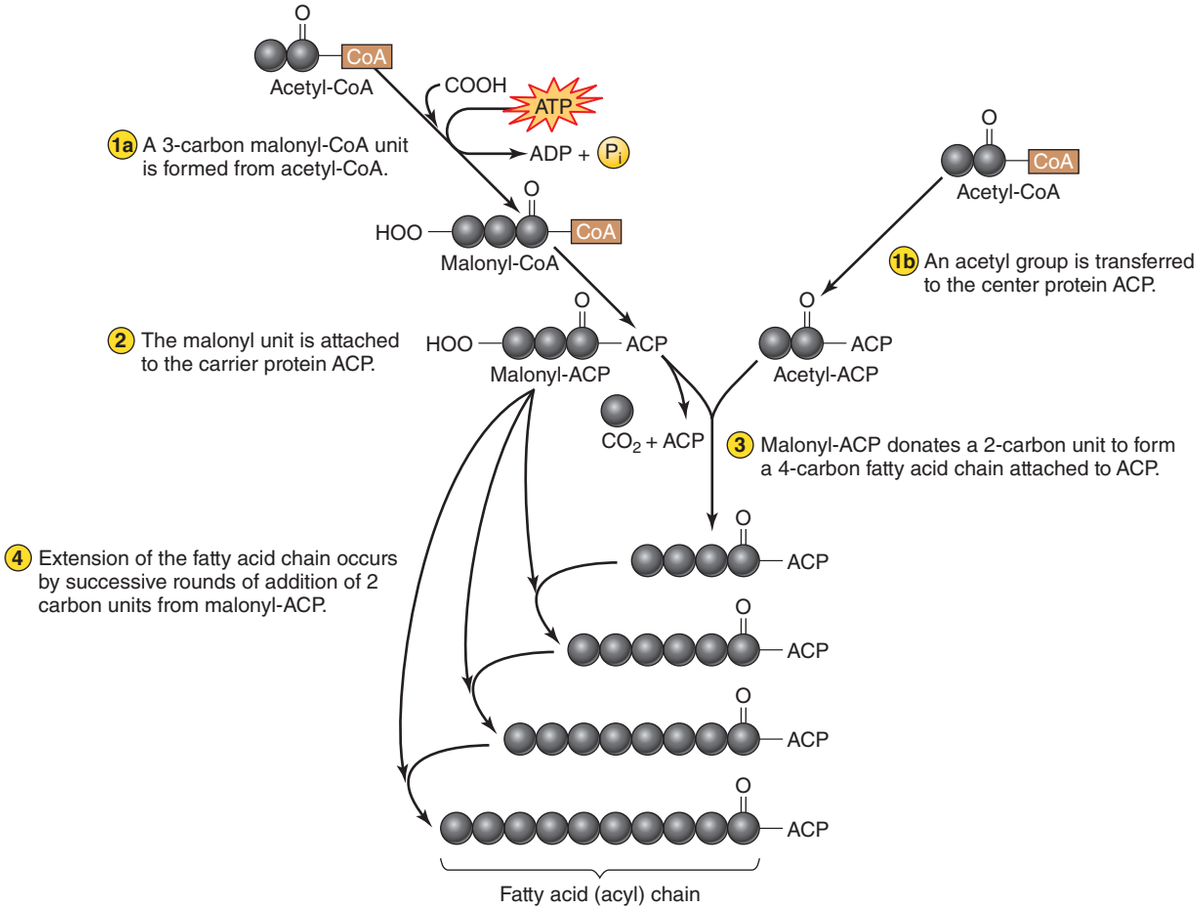

Figure 13.48. Process Diagram: Fatty acid synthesis Fatty acid chains are formed by successive rounds of additions of two carbons from malonyl-ACP until the required chain length is obtained. Carbon dioxide and ACP (acyl carrier protein) are released with each addition to the chain.

(16–18 carbons being most common in bacterial membranes), whether double bonds are present (an *unsaturated* chain), and whether branches are present.

Fatty acid synthesis occurs in the cytoplasm. The process starts with ATP-dependent addition of a carboxyl group to acetyl-CoA to generate malonyl-CoA (Figure 13.48). The CoA cofactor is then displaced by acyl carrier protein (ACP), creating a three-carbon malonyl-ACP. ACP can also displace CoA from acetyl-CoA to make acetyl-ACP. Malonyl-ACP then combines with the two-carbon acetyl group from acetyl-ACP, removing the newly added terminal carboxyl group from the malonyl unit in the process. The result is a four-carbon unit attached to ACP. Successive reactions dehydrate and reduce the bond between the chain and the newly added two-carbon unit to produce an acyl-ACP, a fatty acid linked to ACP. The cycle begins again by donation of two more carbons to the fatty acid chain from malonyl-ACP. The growing fatty acid is covalently linked throughout synthesis to ACP. The final acyl chain length is not completely uniform, but is fairly tightly controlled. How the fatty acid synthetic machinery controls chain length is not well understood.

Fatty acid chains are eventually transferred by membrane-bound enzymes to a glycerol 3-phosphate backbone to form lipids for carbon and energy storage (triglycerides) or for cell wall synthesis (phospholipids) (Figure 13.49). The glycerol 3-phosphate comes from NADH-dependent reduction of dihydroxy-acetone phosphate (DHAP), an intermediate from glycolysis. Two fatty acids are added to each glycerol 3-phosphate molecule to generate phosphatidic acid, which is then a substrate for enzymes that modify the polar end of the molecule. The enzyme CDP diglyceride synthase activates the phosphate group by addition of cytosine triphosphate (CTP) to generate CDP-diacylglycerol. The CDP moiety can then be replaced with other chemical units such as serine to generate phosphatidylserine, which in turn can be decarboxylated to make phosphatidylethanolamine. These are two of the most common phospholipids in *E. coli* and many other bacteria.

13.8 Fact Check

1. Cellular macromolecules are synthesized from a pool of precursors in the cell. Describe the sources of these precursors.
2. What nitrogenous bases must cells be able to synthesize and why?
3. Describe how fatty acids are synthesized.

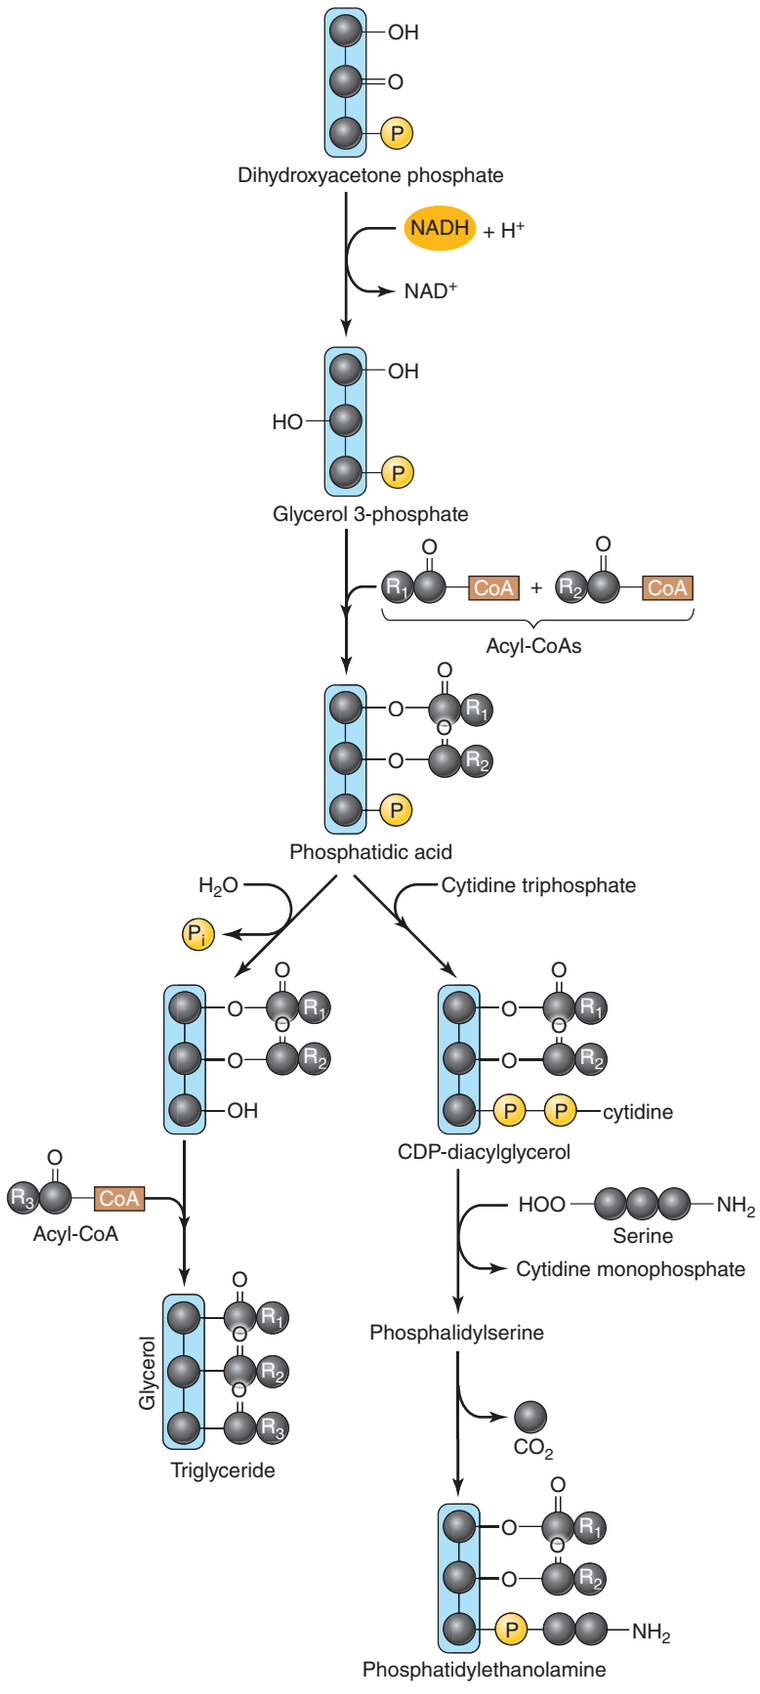

Figure 13.49. Triglyceride and phospholipid synthesis Fatty acids are added to a glycerol 3-phosphate backbone to form triglycerides for storage or to form phospholipids for cell wall synthesis. With each fatty acid (in the form of an acyl-CoA), added to the glycerol backbone, CoA-SH is released (not shown). R_x represents a fatty acid carbon chain of variable length.

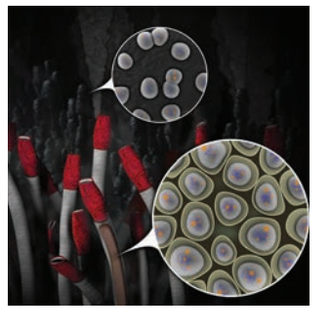
Image in Action



WileyPLUS Learning Space Giant tube worms are found living near hydrothermal vents on the seafloor. The trophosome of one of the tube worms is shown (cylindrical mass in the tube), and a zoom-in shows the bacterial endosymbionts with small orange vesicles containing elemental sulfur, each encased in its own host-derived membrane. A close-up of the vents in the background shows free-living forms of the bacteria on the surface of the vent.

1. Imagine that you are attempting to culture these bacteria in the laboratory. Why would you need to provide H_2S? Explain how H_2S would be used by the bacteria.
2. If this image were to have a zoom in to highlight the metabolic processes of the bacteria, it would show them using the reductive TCA cycle to supply the worms with carbon compounds. Explain this process and how it could be depicted.

The Rest of the Story

In the opening story of this chapter, we were introduced to a very unusual relationship between the deep sea giant tube worm and its tiny inhabitant, *Candidatus* Endoriftia persephone, a bacterial chemolithotrophic autotroph. Metagenomic analysis, as described in the chapter Mini-Paper, confirms the bacterium has the genetic capability to obtain electrons from the oxidation of hydrogen sulfide (H_2S) and transfer these to the electron transport system, generating adenosine triphosphate (ATP). The ATP and reducing power generated is used by the bacterium to fix carbon dioxide (CO_2), a product of tube worm respiration, to produce organic carbon compounds using the reductive TCA cycle and, alternatively, the Calvin cycle. As you will recall, whereas the TCA cycle, found in the majority of life-forms, uses oxidation to break down organic carbon compounds to produce ATP and CO_2, the reductive TCA cycle functions in the opposite direction, using ATP and CO_2 to produce carbon compounds and oxygen (O_2), both of which are used by the worm.

The tube worm has evolved several unusual characteristics in order to cultivate its indispensable bacterial inhabitants. Its digestive system converts to a growth chamber (the trophosome) for the microorganism, and the tube worm produces a unique form of hemoglobin containing zinc instead of iron that can bind both O_2 and H_2S. The hemoglobin is also extracellular, so bound H_2S cannot enter cells. This is an important adaptation because H_2S is toxic to animals, inhibiting the electron transport system in mitochondria. The massive hemoglobin-filled feathery red plumes of the

adult tube worm are used like gills to efficiently collect and concentrate H_2S from the surrounding waters and deliver it to the bacteria inside, as well as deliver O_2 to the tube worm cells. It is incredible to realize that bacterial oxidation of H_2S is the source of energy that provides for all of the nutritional needs of the amazing giant tube worm. Other large citizens that exist in the complete darkness of the tube worm forests include eel-like eelpout fish and pure white vent crabs. They, like the tube worms, depend on the metabolic activities of the microorganisms that harvest chemical energy provided by the released products of the vent, converting it to energy stored as organic molecules.

Summary

Section 13.1: What are the basic principles of catabolism and energy that control metabolism?

Metabolism includes **catabolism** of larger molecules to obtain energy and obtain smaller precursor molecules for **anabolism** of macromolecular cell components.

- Enzymes catalyze nearly all biochemical reactions in cells, when the **active site** binds to specific **substrates** and converts them into products.
- For a chemical reaction to occur spontaneously, the **laws of thermodynamics** dictate that the products of the reaction must have a lower free energy content than the reactants. The free energy released in a chemical reaction is the **Gibbs free energy (*G*)**. The change in free energy during a reaction measured under standard conditions is $\Delta G^{\circ\prime}$.
- An energy-yielding chemical reaction is **exergonic** and has a negative $\Delta G^{\circ\prime}$ value.
- Energy-absorbing **endergonic** reactions will have positive $\Delta G^{\circ\prime}$ values.
- An endergonic reaction in a cell must be coupled with an exergonic reaction that supplies enough energy to drive the coupled reaction to completion.
- Enzymes increase the rate of a reaction by lowering its **activation energy (E_A)**.
- **Cofactors**, such as organic **coenzymes**, assist in transferring functional groups from a substrate to a product.
- The most widely used form of chemical energy in the cell is **adenosine triphosphate (ATP)**.

Section 13.2: How do cells make ATP?

ATP can be synthesized by three processes in cells. These are substrate-level phosphorylation, oxidative phosphorylation, or photophosphorylation.

- **Substrate-level phosphorylation** occurs by transfer of a phosphate group from a reactive intermediate generated during catabolism to ADP. This occurs during **glycolysis** and the **tricarboxylic acid (TCA) cycle**.
- **Oxidative phosphorylation** uses **chemiosmosis** and requires the transfer of electrons through the **electron transport system**, which generates a proton gradient. The energy from the flow of protons can be used to synthesize ATP from ADP and P_i using **ATP synthase**. Oxidative phosphorylation is used by chemotrophs.
- **Photophosphorylation** also produces ATP using a proton gradient and an electron transport system. It requires light energy and is used by phototrophs.
- Many enzymes are controlled through **allosteric regulation**, involving molecules that induce a conformational change in the enzyme.
- **Redox reactions** involve the transfer of electrons from one molecule to another.
- **Oxidation** of a molecule results in loss of an electron, and **reduction** of a molecule results in a gain of an electron.
- The tendency of a molecule to acquire electrons is its **reduction potential** or **redox potential (*E*)**.
- Energy is released when electrons flow from donors with more negative redox potentials to acceptors with more positive redox potentials.
- Electron carrier molecules, such as **nicotinamide adenine dinucleotide (NAD)**, are a source of reducing power used by cells to drive macromolecular biosynthetic reactions and provide energy for ATP synthesis by oxidative phosphorylation.
- The TCA cycle is a major producer of reduced electron carriers in chemoorganotrophs.
- Microorganisms can be grouped based on how they obtain energy (chemotrophs or phototrophs), electrons (organotrophs or lithotrophs), and carbon (heterotrophs or autotrophs).

Section 13.3: How do microorganisms utilize organic carbon?

Heterotrophs use many kinds of organic molecules for assimilation of carbon. Glycolytic pathways that catabolize glucose are important **anaplerotic reactions** that generate precursors for other metabolic pathways, including fermentation and respiration.

- Different glycolytic pathways can be used by different organisms. The pathways are interconnected and can be used depending on the demands of the cell. These are the **Embden–Meyerhof–Parnas (EMP) pathway**, the **Entner–Doudoroff pathway**, and the **pentose phosphate pathway**.
- Many organisms, such as **lactic acid bacteria (LAB)**, are capable of using fermentation under low-oxygen conditions.
- **Fermentation** uses pyruvate, or a similar organic derivative, to accept electrons from NADH generated by glycolysis. Fermentation regenerates NAD^+, allowing glycolysis to continue to produce ATP.
- Fermentation produces only 2 moles of ATP for 11 mole of glucose.
- To keep up with energy needs, glycolysis occurs at a much faster rate during fermentation than during respiration. Allosteric regulation of phosphofructokinase by ATP controls the rate of glycolysis.
- **Respiration** is an alternative to fermentation that is used by chemoorganotrophs for regenerating NAD^+, which allows glycolysis to continue. Electrons of NADH are passed to an electron transport system and on to an inorganic acceptor.
- The TCA cycle is used during respiration to further catabolize and oxidize pyruvate into CO_2. The TCA cycle yields a large

amount of energy and generates carbon intermediates needed for biosynthetic reactions.

- Microorganisms avoid making enzymes when substrates are unavailable or products are not needed or are in excess. Metabolic pathways are commonly regulated through **feedback inhibition** or **precursor activation**.

Section 13.4: What becomes of the electrons generated by glycolysis and the TCA cycle?

Respiration captures the energy in organic molecules by transferring electrons through the electron transport system. Two formats of respiration are **aerobic respiration**, which uses O_2 as a terminal electron acceptor, and **anaerobic respiration**, which uses some other electron acceptor.

- Nitrate (NO_3^-) is a common terminal electron acceptor used in anaerobic respiration. **Denitrification** occurs when microorganisms reduce NO_3^- to gaseous nitrogen (N_2).
- In chemoorganotrophs, the aerobic electron transport system, in conjunction with glycolysis and the TCA cycle, can generate 38 ATP from each glucose molecule.
- Anaerobic respiration produces less ATP because available terminal electron acceptors have less positive redox potential than oxygen, therefore less energy is available to create a **proton motive force**.
- The proton motive force allows protons to flow down the charge gradient back across the membrane through ATP synthase, which couples this proton flow to the production of ATP by oxidative phosphorylation.
- Chemolithotrophs get energy and electrons by oxidizing inorganic molecules, which are directly passed down the electron transport system to generate a proton motive force for ATP production.

Section 13.5: How do microorganisms get nutrition from compounds other than glucose?

Monosaccharides other than glucose can be converted into substrates suitable for processing in glycolytic pathways. This is also true for polysaccharides, proteins, lipids, and nucleic acids, which must all first be broken down into smaller units that can be transported into cells.

- Inside the cell, deamination of amino acids produces pyruvate as a product, which can enter the TCA cycle or fermentation reactions.
- Fatty acids are processed through the ***β*-oxidation pathway** and can be used to generate significant amounts of ATP through production of NADH and $FADH_2$, as well as acetyl-CoA that can enter the TCA cycle.

Section 13.6: How do microorganisms capture light energy for ATP synthesis and carbon fixation?

Phototrophs convert light energy to chemical energy by photophosphorylation.

- Photosynthesis combines phototrophy and carbon fixation for production of carbon compounds.
- The **light reactions** capture light energy and convert it to excited electrons that are passed to an electron acceptor. A proton motive force is generated that can be used to synthesize ATP.
- The site of light capture is the **photosystem** located in specialized **thylakoids**.
- **Chlorophyll** and **bacteriochlorophyll** are the major photopigments that capture photons in the photosystem. Accessory pigments are also used.
- Photosystem I (PS I) requires an external electron donor to replace the electron removed from the reaction center. Reduced electron carriers, NADH or NADPH, and a proton motive force for ATP synthesis are produced.
- In photosystem II (PS II), electrons are replaced internally by the photosystem. PS II generates a proton motive force, but no NADH or NADPH.
- **Oxygenic photosynthesis** uses both PS I and PS II and is carried out in chloroplasts and cyanobacteria. Water is used as an electron donor and O_2 is generated. All other bacteria use **anoxygenic photosynthesis** and possess either PS I or PS II. Oxygen is not produced.
- The reducing power and ATP that is generated during photosynthesis can be used by photoautotrophs to carry out the **dark reactions** for carbon fixation.
- The **Calvin cycle** used by plants and cyanobacteria is a dark reaction that consumes NADPH and ATP for production of glyceraldehyde 3-phosphate, which is used for the synthesis of sugars.
- The **reductive TCA cycle** is an alternative reaction used by some autotrophs and for carbon fixation. It is a reversed version of the TCA cycle that consumes NADH (or NADPH) and ATP.

Section 13.7: How do microorganisms use nitrogen and sulfur?

Nitrogen is required for amino acids and nucleotide synthesis. Sulfur is required for the amino acids cysteine and methionine and the iron-sulfur centers used in proteins of electron transfer systems.

- Nitrogen fixation converts N_2 into compounds, such as ammonia, and is carried out by **nitrogenase**, produced by some species of bacteria and archaea. Nitrogenase must be protected from exposure to oxygen, which inactivates it.
- The triple bond of dinitrogen gas is extremely stable, and an enormous amount of ATP must be consumed to separate the atoms.
- **Nitrification** is the process of conversion of ammonia to nitrate (NO_3^-), which can be used as a terminal electron acceptor for anerobic respiration, or can be reduced to ammonia for incorporation into biomass.
- Ammonia, or its charged ion ammonium, is incorporated into glutamate or glutamine and, from here, into amino acids. When ammonium is unavailable, nitrate is first reduced to ammonia, which consumes ATP.
- The sulfate ion (SO_4^-) is a common inorganic source of sulfur and must be reduced before it can be used in biosynthesis.

Section 13.8: How do microorganisms synthesize new cellular components?

Proteins, nucleic acids, lipids, and various cell wall materials are built from a small number of common subunits that can be synthesized from precursors in the cell.

- Amino acids are built from intermediates of the TCA cycle and glycolysis.
- ATP is the primary energy currency in the cell and must be replaced when it is incorporated into nucleic acid.

- The ring structure of pyrimidine nucleotides are built first using the amino acid aspartic acid, which is then linked to ribulose 5-phosphate of the pentose phosphate pathway. Purine nucleotides begin with ribulose 5-phosphate and the ring structure is added.
- Fatty acid synthesis begins with actyl-CoA, produced from pyruvate, to which carboxyl groups are added. Fatty acids are then added to glycerol 3-phosphate, an intermediate of glycolysis, to make triglycerides for storage or phospholipids for cell wall synthesis.

Application Questions

1. When preparing culture media in the lab, it is important that components such as Mg^{2+}, Fe^{2+}, and Mn^{2+} are available. Explain why these components are necessary in order for the microorganisms to grow on the media.
2. In a biochemistry lab, a researcher is closely examining a microbial chemical reaction. During her experiment, she determines that the value of $\Delta G^{\circ\prime}$ is approximately +38 kJ mol^{-1}. Explain what this value tells her about the reaction being examined.
3. You are examining a microorganism that is growing under anoxic conditions with no available electron acceptors for NADH. Describe how this organism will go about catabolizing glucose under these conditions.
4. Imagine a microbial cell that normally carries out aerobic respiration has encountered a low-O_2 environment and may die if the O_2 levels do not increase. Describe the key role that O_2 plays for this microorganism in the aerobic respiration process and what will occur differently without oxygen that could lead to death.
5. Some microorganisms, such as *Escherichia coli*, have flexible metabolic systems that allow them to generate energy under oxic and anoxic conditions. If *E. coli* is growing in the presence of O_2, nitrate, and fumarate, explain its metabolic processes, including which of these it will use first and why.
6. Soil ecologists are very interested in the process of denitrification. Explain how denitrification is linked to anaerobic respiration, and why it is an important consideration in soils.
7. Fluoride and triclosan are compounds that inhibit the oral pathogen *Streptococcus mutans*, which causes cavities (dental caries). These compounds have been shown to inhibit pyruvate kinase. Describe the direct metabolic effect of inhibiting this particular enzyme and how this could then lead to a reduction in cavities.
8. Sometimes cells are left without oxygen and cannot carry out aerobic respiration to produce large amounts of ATP. These cells may then utilize fermentation that produces much smaller quantities of ATP but also allows for the very important recycling of NADH to NAD^+. Explain why this recycling is so important to the cell.
9. You are watching a movie in which a meteor is headed toward Earth and is predicted to cause a dust cloud that will block the sun for months. The main character declares that this could destroy life on Earth! Explain the impact this dust cloud would have on the light and dark reactions of photosynthesis. Specifically, what would still occur and what would no longer occur without the sunlight? Could this effect destroy life on Earth?
10. The enzyme Rubisco has been described in this chapter as the most abundant protein on Earth. Imagine a toxin entered the atmosphere that inhibited this enzyme. Describe the specific effects this toxin would have on photosynthetic cells.
11. A newly discovered microorganism has been studied and is being called a chemolithotrophic autotroph.
    a. Dissect this term to explain what it means about the microorganism's metabolism.
    b. Imagine that this microorganism cannot be cultured. How could you use metagenomic analysis to determine these characteristics of the microorganism?
    c. Postulate what genes may be found during a metagenomic analysis to characterize the microorganism in this way. Explain your answer.

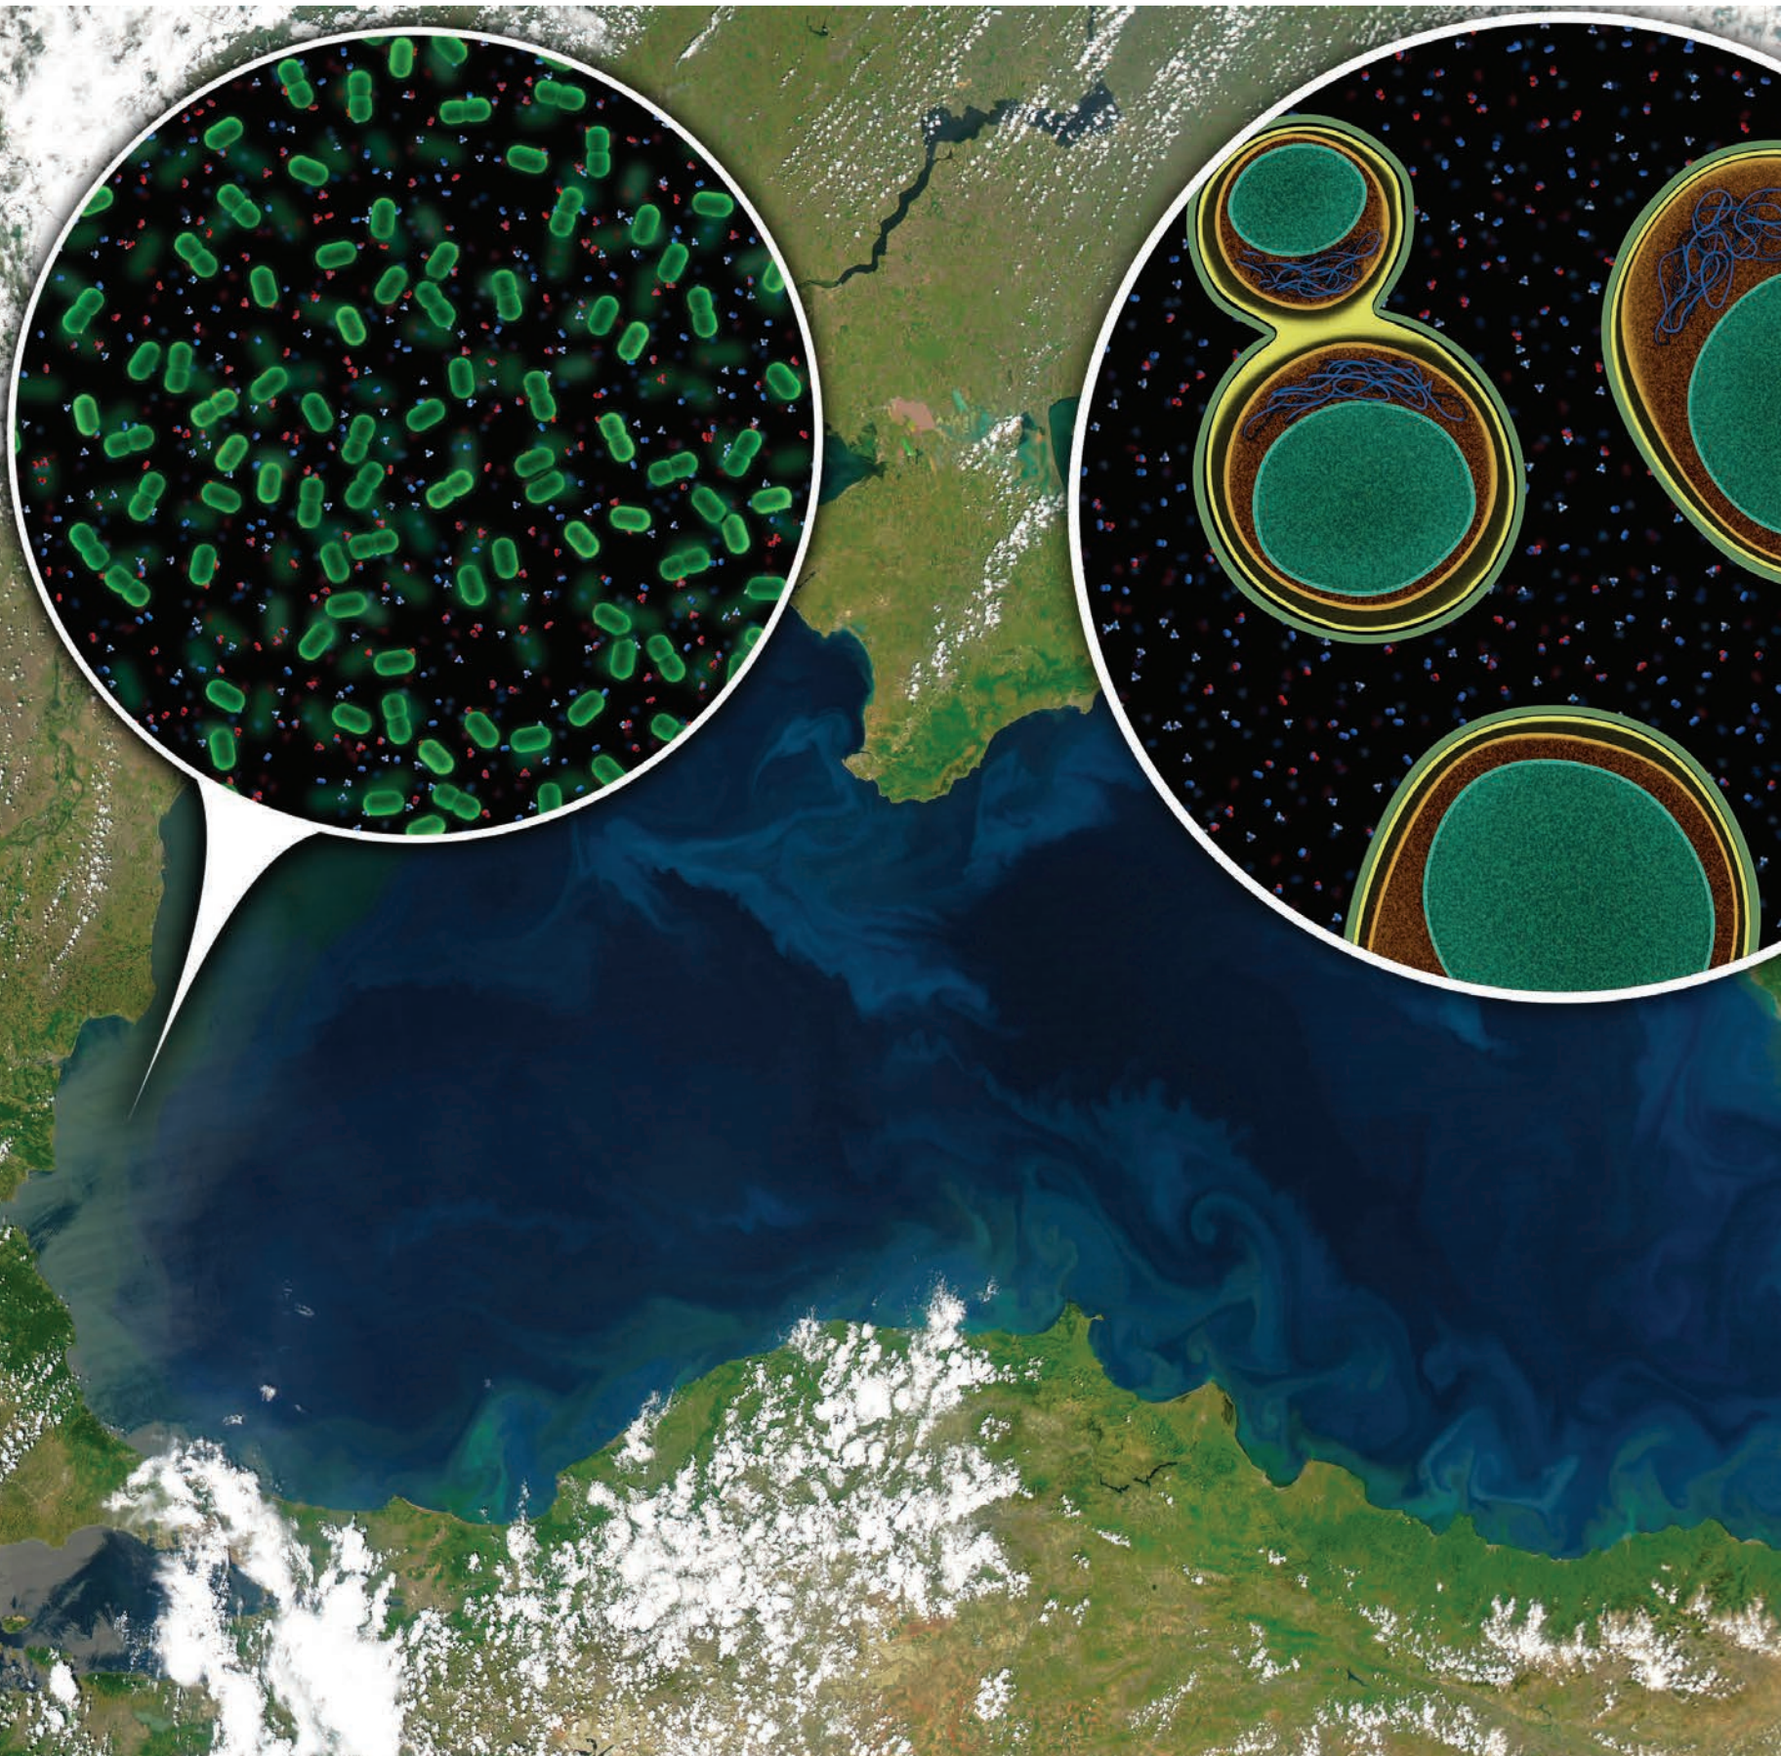
CHAPTER

14 Biogeochemical Cycles



Shortly after microbiology became a discipline, microbiologists learned that microbes play fundamental roles in the transformation and recycling of matter. The study of these transformations has formed the core of environmental microbiology research over the years. Toward the end of the nineteenth century, the Ukrainian microbiologist Sergei Winogradsky discovered that certain aerobic bacteria could oxidize ammonia to nitrite. This conversion proved to be a key step in the nitrogen cycle and appeared to occur only in the presence of oxygen (O_2). For about a hundred years, microbiologists assumed that the oxidation of ammonia only occurred aerobically.

The assumption that ammonia was oxidized solely under oxic conditions changed in the 1970s. Based on thermodynamic evidence, the Austrian chemist Engelbert Broda predicted that ammonia oxidation should be possible in the absence of O_2, even though microorganisms able to perform this task had not been isolated. Additionally, oceanographers observed that the amount of ammonia predicted to be present in anoxic basins, like the Black Sea in Europe, greatly exceeded the amount actually measured, suggesting that the ammonia was being removed. Despite these hints, it was not until 1995 that researchers unequivocally documented a type of ammonia oxidation that occurs under anoxic conditions. Interestingly, this first demonstration occurred not in a natural ecosystem but in an anaerobic reactor designed to treat wastewater.

Microbiologists have explored details of this unexpected ammonia oxidation activity since its initial discovery. We now recognize that this so-called anammox reaction, for anaerobic ammonium oxidation, probably contributes to a large proportion of global ammonia oxidation as part of the nitrogen cycle. Indeed, nearly half of nitrogen loss from the oceans by the formation of dinitrogen (N_2) gas may be due to the anammox reaction! Despite the global importance of anammox, the microorganisms responsible for this reaction have never been isolated in pure culture. Given the challenge of cultivating the majority of Earth's microorganisms, many other processes driving our planet's biogeochemical cycles probably still await discovery.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Nutrients that fuel microbial cells are cycled through the biosphere.

Methane-producing archaeon *Methanobrevibacter smithii* in the human gastrointestinal tract **(Section 4.3)**

Nitrification and denitrification during wastewater treatment **(Section 16.5)**

Introduction

Do you ever wonder what would happen if all microbes on the planet were to disappear? How long would humans survive? What would we notice first? In the article, "Life in a World without Microbes," these questions were explored as a thought experiment. The article indicates that initial disruptions that humans would notice first would include a failure of industries linked to fermented food production and wastewater treatment. That said, these initial challenges would represent relatively minor disruptions for humans in comparison to countless catastrophic consequences associated with a failure of global biochemistry. As we discuss Earth's microbiology in this chapter, pause periodically to ask yourself what might happen if the microbes we discuss, and the reactions that they catalyze, were to disappear suddenly. Revisiting this idea at the end of this chapter, we will discover that many metabolic functions of microorganisms have an irreplaceable global impact, ultimately determining the physical and chemical properties of this planet as a whole and supporting life as we know it.

All living organisms consist of chemical elements bound together to form biological molecules. Normal metabolic processes result in the production and degradation of biomass. During these processes, the atoms of various elements cycle continually through the biosphere, the part of Earth that supports life. Although all organisms participate in this cycling, microbes play crucial roles in moving atoms between living organisms and the physical environment. The resulting linked sets of cycles are termed the **biogeochemical cycles** (Figure 14.1). Without the microbial contributions to these essential cycles, most other life on Earth would not exist for long; the elements would not be recycled efficiently to forms that can be used as nutrients by other cells.

How do microbes contribute to these cycles? In most instances, they do so simply by conducting their normal metabolic activities. Their diverse physiological capabilities, and the rapid rates of their enzymatic reactions, drive these cycles. Although individual microbes may not be directly visible, their collective activities can move substantial quantities of material, and certain groups of microbial species perform important and unique reactions that no other living organisms can.

In this chapter, we will begin by considering the use of nutrients by cells and how we can measure this use. We will then focus on the major cycles of carbon and nitrogen. To conclude, we will briefly examine additional cycles and their interconnectedness. As we investigate these topics, we will address the following questions:

How are the nutrients used by cells cycled in the biosphere? (14.1)
How do microbes influence the cycling of carbon? (14.2)
How do microbes influence the cycling of nitrogen? (14.3)
How are various biogeochemical cycles connected? (14.4)

Figure 14.1. Major reactions involved in biogeochemical cycles Microbial metabolism drives biogeochemical cycles. These important microbial processes include oxygenic photosynthesis, anoxygenic photosynthesis, nitrogen fixation, fermentation, methanogenesis, and respiration involving iron, sulfur, oxygen, and nitrogen. The electron acceptors are arranged according to capacity to accept electrons, increasing from left to right. The cycles are interconnected because individual microorganisms catalyze reactions and transform elements from multiple cycles.

14.1 Nutrient cycling

How are the nutrients used by cells cycled in the biosphere?

Most elements have a cycle that may involve various biological transformations and chemical reactions, as well as changes in physical state between gas, liquid, and solid. Some cycles are complex, like the ones for carbon and nitrogen, whereas other cycles are relatively simple, like the one for iron. Ultimately, all microbial involvement in biogeochemical cycles is simply a scaling up of microbial metabolism from the level of a single cell to the scale of the entire planet. In this section, we will review some basic information about nutrient cycling. We will also look at how investigators study these processes.

Cycling of elements

As we begin to explore nutrient cycling, we should remember that all known organisms require approximately the same suite of elements. All biomass consists of these essential **biogenic elements** in roughly similar proportions. Consider a pure culture of *Escherichia coli* that has been recovered by centrifugation, washed, and then dried, resulting in a concentrated pellet of biomass. As shown in **Figure 14.2**, an elemental assay of this cellular material reveals the cellular mass to consist of carbon (~50 percent), oxygen (~20 percent), nitrogen (~15 percent), and hydrogen (<10 percent), with lesser amounts of phosphorus, sulfur, potassium, calcium, iron, magnesium, and chlorine. Other elements, including sodium, manganese, cobalt, copper, zinc, nickel, and molybdenum, would be found in trace amounts, comprising less than 0.3 percent of the cell dry mass combined. As we saw in Chapter 6, organisms require carbon, nitrogen, phosphorus, and sulfur in relatively large amounts as components of macromolecules, and cell growth is ultimately limited by insufficient quantities of one or more of these elements. Potassium, sodium, magnesium, calcium, iron, and chloride ions are the most abundant ions in the cell. These ions are involved in several cellular functions, such as control of osmotic stability and enzyme activity.

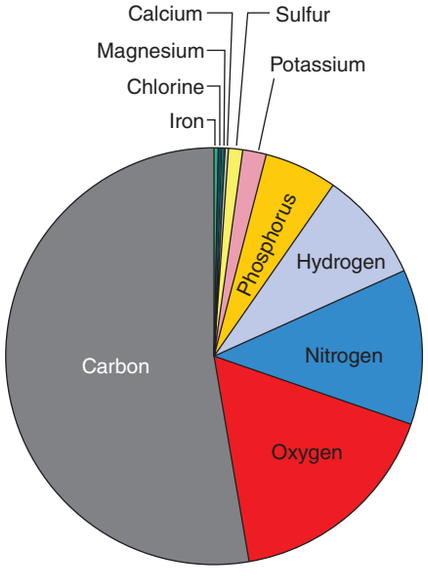

Figure 14.2. Elemental composition of a bacterial cell About half of the mass of a typical bacterial cell consists of carbon, followed in order by oxygen, nitrogen, and hydrogen as the most abundant elements.

Cycling of these elements usually involves changes in the oxidation state. Living organisms contribute to these changes by conducting redox reactions, as discussed in Chapter 13. These reactions involve the transfer of electrons between chemical elements, resulting in changes to the oxidation state of the atoms. To better understand this concept, let's examine the oxidation states of carbon **(Table 14.1)**. During photosynthesis, carbon dioxide (CO_2) has an oxidation state of +4, but carbon in the photosynthesis product—glucose—has an oxidation state of 0. These changes in oxidation state often alter the physical characteristics of the element and may affect whether that form of the element is metabolically available to cells. To understand the cycling of an element, we also need to determine the sizes of the major **reservoirs**, or pools, of the element on the planet. On a global scale, Earth can be divided into four major reservoirs: terrestrial (lithosphere), aquatic (hydrosphere), atmospheric (atmosphere), and living (biosphere). In addition to these major reservoirs, we can also refer to more specific locations of elements as reservoirs as well. Examples include the marine reservoir, sediment reservoir, soil reservoir, and plant reservoir. Importantly, global reservoirs are interconnected. For example, the biosphere associates closely with other global reservoirs and various elements transition between these linked pools. As we will see later in this section, the terrestrial reservoir contains an enormous amount of carbon, which exists both in the physical soil matrix itself and in its associated microbes, plants, and animals. In addition, the terrestrial reservoir acts as a significant source of inorganic carbon to the atmosphere because decomposition of dead organic matter by soil microorganisms releases CO_2. Overall, this movement between reservoirs can be expressed as **flux**, which is the amount of material flowing through a unit area or volume per unit of time. Recipient reservoirs receiving a flux of an element, from a source, is referred to as a sink. A reservoir is said to be in steady state when sources and sinks of elements are equivalent to one another.

TABLE 14.1 Oxidation states for carbon

Oxidation state	Example compound
−4	CH_4 (methane)
−2	CH_3OH (methanol), $[-CH_2]_n$ (hydrocarbons, e.g., C_8H_{18}, octane)
0	$[CH_2O]$ (carbohydrates, e.g., $C_6H_{12}O_6$, glucose)
+2	HCOOH (formic acid)
+4	CO_2 (carbon dioxide), HCO_3^- (bicarbonate ion)

The flux of elements between reservoirs has shifted enormously over Earth's history. We know that the first phototrophs producing oxygen gas (O_2) arose approximately three billion years ago, and their activities over the ensuing 600 million years led to a change in Earth's atmosphere from its original reducing condition to the current oxidizing state (see Section 1.2). The liberation of O_2 by these phototrophs eventually exceeded terrestrial and aquatic reservoir sinks for O_2, leading to a gradual accumulation of this powerful electron acceptor in the atmosphere. Now, oxygen and other elements tend to cycle and they are much closer to steady state within most reservoirs.
