Evidence indicates that these cycles have maintained a dynamic equilibrium over the long-term. With the rise of industrialization, human activities have perturbed this longstanding equilibrium, most evidently in the carbon and nitrogen cycles (Figure 14.3). With respect to carbon, fossil fuel combustion and changes in land use, such as deforestation and conversion of natural grasslands to agriculture or urban use, have had a marked influence on atmospheric CO_2. The high-energy requirements for the manufacture of fertilizers and cement, and the production of lime by heating limestone, are examples of industrial activities that have contributed to increasing levels of atmospheric CO_2. Furthermore, increased warming due to climate change has the potential to impact CO_2 and methane (CH_4) emissions to the atmosphere, particularly from Arctic tundra. Because permafrost contains enormous amounts of labile carbon, permafrost melting releases carbon that can be acted on by anaerobic and aerobic microbial processes highlighted in the carbon cycle section below. These examples underline the critical importance of studying the responses of the overall carbon cycle to anthropogenic perturbations.

How do we assess the capacity of a microbial community to transform Earth's elements through biogeochemical cycles? To assess activity directly, many techniques can be used to measure the concentrations of elements and their conversion from one form to another. These analytical techniques can be used in the field to detect elemental fluxes directly or on samples brought to the lab for short-term incubations. Other approaches involve establishing small- or medium-scale replications of a habitat of interest in the lab or field in order to test experimental manipulations and assess microbial community responses. Such experimental manipulations are referred to as **microcosms** or **mesocosms** for small (bottles, tubes) or mid-size (such as columns in the ocean, containers of soil and plants) habitat replications, respectively, and are important for assessing biogeochemical cycling in response to changes, such as climate change. Later in this chapter, we will look at how microcosms can be used to study the sulfur cycle. In addition to direct measurements of elements and their fluxes, microbial communities can be assessed for their potential to carry out reactions of interest. For example, molecular techniques such as the GeoChip (Toolbox 14.1), or metagenomics (see Chapter 10), provide valuable insight into the metabolic potential of microbial communities as they relate to biogeochemical cycles.

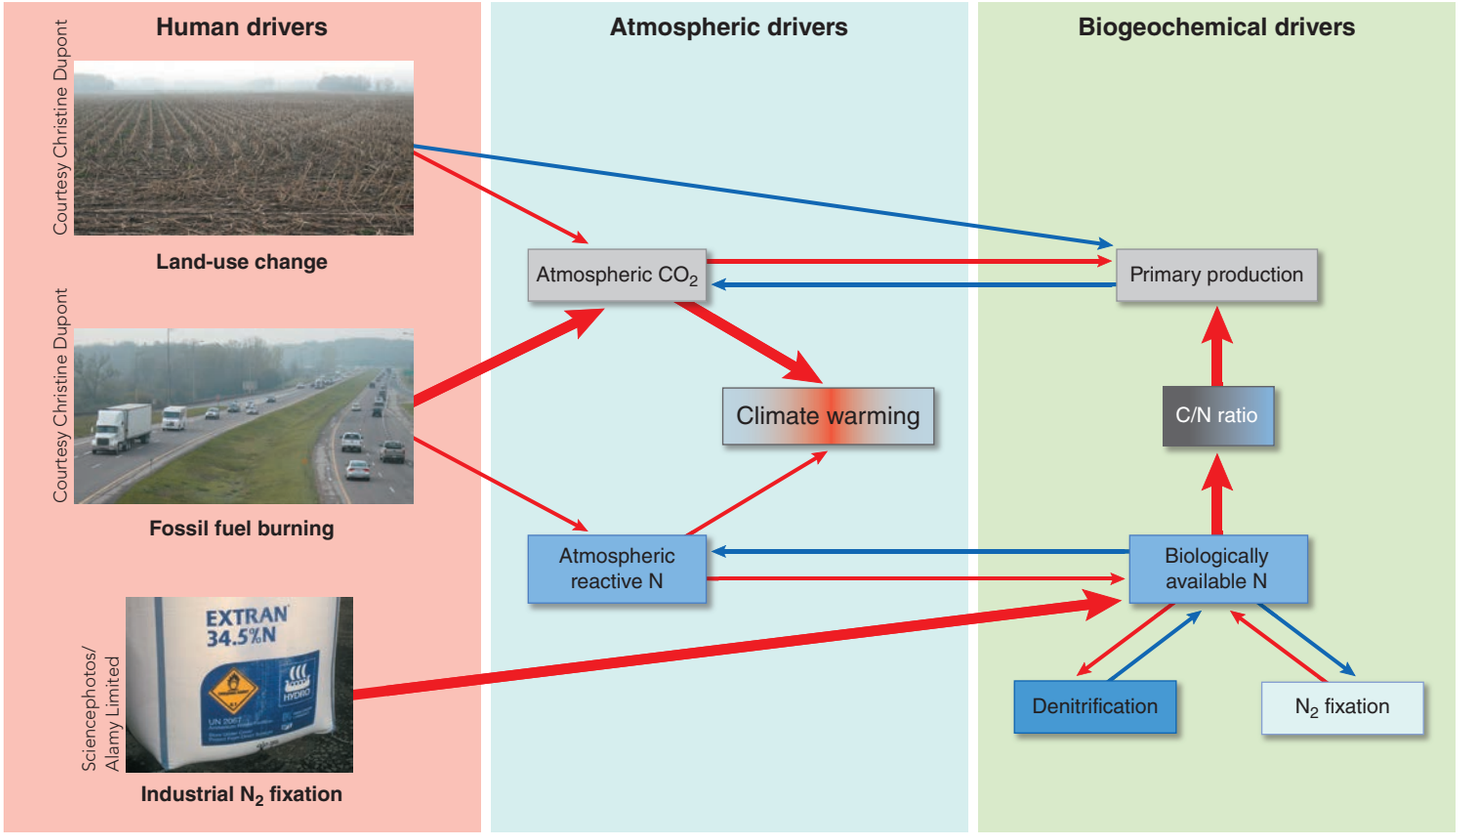

Figure 14.3. Disruption of carbon and nitrogen cycles by human activities Changes in land use, burning of fossil fuels, and industrial N_2 fixation result in perturbations in the carbon and nitrogen cycles. The most noticeable effects are increases in atmospheric CO_2 and biologically available N.

Toolbox 14.1

USING MICROARRAYS TO EXAMINE MICROBIAL COMMUNITIES: THE GeoChip

Microarrays have been used extensively to analyze the transcriptional activity of genes. As we saw in Perspective 8.1, this technique can even be used to identify viruses. Microarray technology can also be used to study the composition of microbial communities. With the vast amount of sequence information available, and the capacity of microarray chips, researchers can design probes to functional genes that represent the possible metabolic processes that are being carried out in a given environment. The GeoChip, designed and produced by Jizhong Zhou and colleagues at the University of Oklahoma, exemplifies this type of approach.

GeoChip 4.0, described in 2014, contains 82,000 50-nucleotide probes, representing genes involved in carbon, nitrogen, phosphorus, and sulfur cycles, as well as energy metabolism, resistance to antibiotics and metals, and degradation of organic contaminants **(Figure B14.1)**. The probes span the sequence diversity of known genes for these processes, from bacteria, archaea, and fungi.

To use the GeoChip, researchers first isolate DNA from an environmental sample and label it by a random primer method. In this process, DNA polymerase synthesizes single-stranded fragments using the isolated DNA as a template, incorporating fluorescently tagged nucleotides to label the newly produced DNA. In the hybridization step, the resulting single-stranded labeled DNA is then incubated with the microarray slide to allow binding to the probe, after which the unbound labeled DNA is washed off. The microarrays are imaged in the microarray scanner to determine which spots were bound, and how strongly. The data are analyzed, presenting investigators with a picture of which genes occur within the microbial community. By extension, this information provides investigators with clues about the metabolic potential of the community.

An advantage of this technique is that it provides information about not just the phylogenetic diversity, but also the genes that actually determine the metabolic characteristics of the organisms present in the community, especially with regard to biogeochemical cycles. It is also a very rapid analysis, much faster than metagenomic DNA sequence analysis. Because functional genomics (see Chapter 10) provides increased knowledge about the functions associated with gene sequences, future designs of the GeoChip and similar microarrays will contain that much more information.

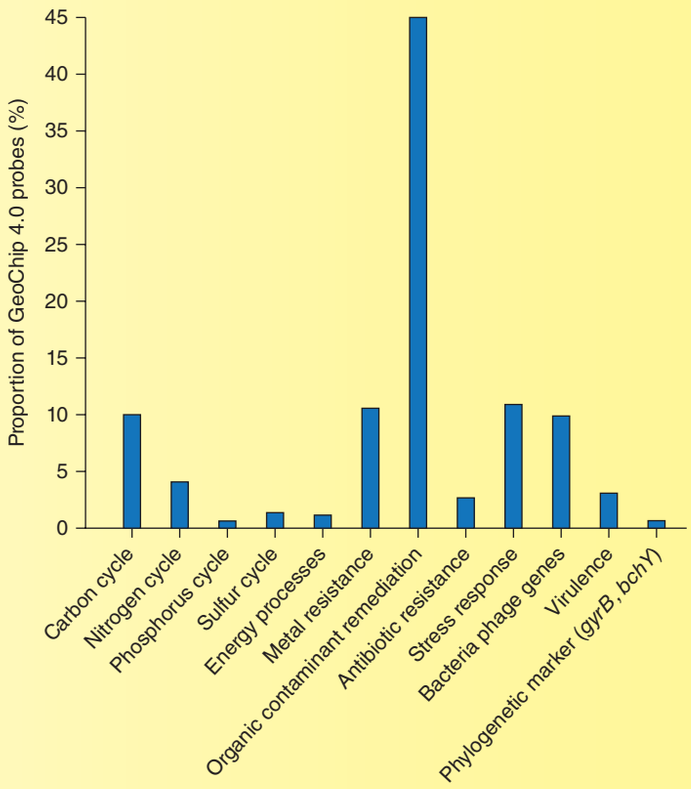

Figure B14.1. Categories of designed probes and covered gene sequences Genes for probe design were chosen to ensure good representation of different gene categories.

Test Your Understanding

You use the GeoChip 4.0 to analyze microbial communities and possible metabolic properties of two different soils. The results indicate that 95 percent of the genes you identify are found in both soils. What does this result suggest to you about the soils?

14.1 Fact Check

1. What four key elements make up most of the cellular mass of *E. coli*, and what additional elements are also found in the cell?
2. Define these terms: reservoir, sink, source, flux, and steady state.
3. In what four major reservoirs is Earth divided when considering biogeochemical cycling?
4. How can microarray technology and metagenomics inform studies of biogeochemical cycles?

14.2 Cycling driven by carbon metabolism

How do microbes influence the cycling of carbon?

Life on Earth is carbon-based. From DNA to sugars to proteins, carbon represents the backbone of biological molecules. However, despite the importance of carbon to life, few of us contemplate the biogeochemical cycling of large amounts of carbon within terrestrial, aquatic, atmospheric, and living reservoirs. The main stores of carbon include biomass, soil organic matter (SOM), atmospheric carbon dioxide (CO_2), fossil fuels, sedimentary rock deposits, calcium carbonate-containing shells, and dissolved CO_2 in the oceans. Today, there is keen interest in potential reservoirs where CO_2 might be stored, and how that carbon may cycle, due to the recognition that atmospheric CO_2 serves as a **greenhouse gas** that causes thermal absorption **(Perspective 14.1)**.

Carbon cycling can be considered in terms of long-term (hundreds of thousands to millions of years) and short-term (months, years, to thousands of years) cycling. Short-term carbon cycling tends to be most tractable and interesting for microbiologists, and will be the primary focus of this section. After examining the global carbon cycle, we will examine several processes affecting short-term carbon cycling, including the related processes of photosynthesis, respiration, and decomposition. We will also explore the microbial processes of methane (CH_4) formation and degradation that drive the contribution of CH_4 to the carbon cycle.

The global carbon cycle

To better understand long-term global cycling of carbon, let's examine the various carbon reservoirs and the flux of carbon between these reservoirs **(Figure 14.4)**. Atmospheric CO_2 exchanges relatively freely and with high turnover rate with the planet's living organisms, the soil, and the upper reaches of the oceans. In contrast, carbon in carbonate-based sedimentary rocks, marine sediments, and fossil fuels cycles very slowly, and constitutes by far the largest carbon reservoirs on Earth, and these cycle over the long-term. An exception to this

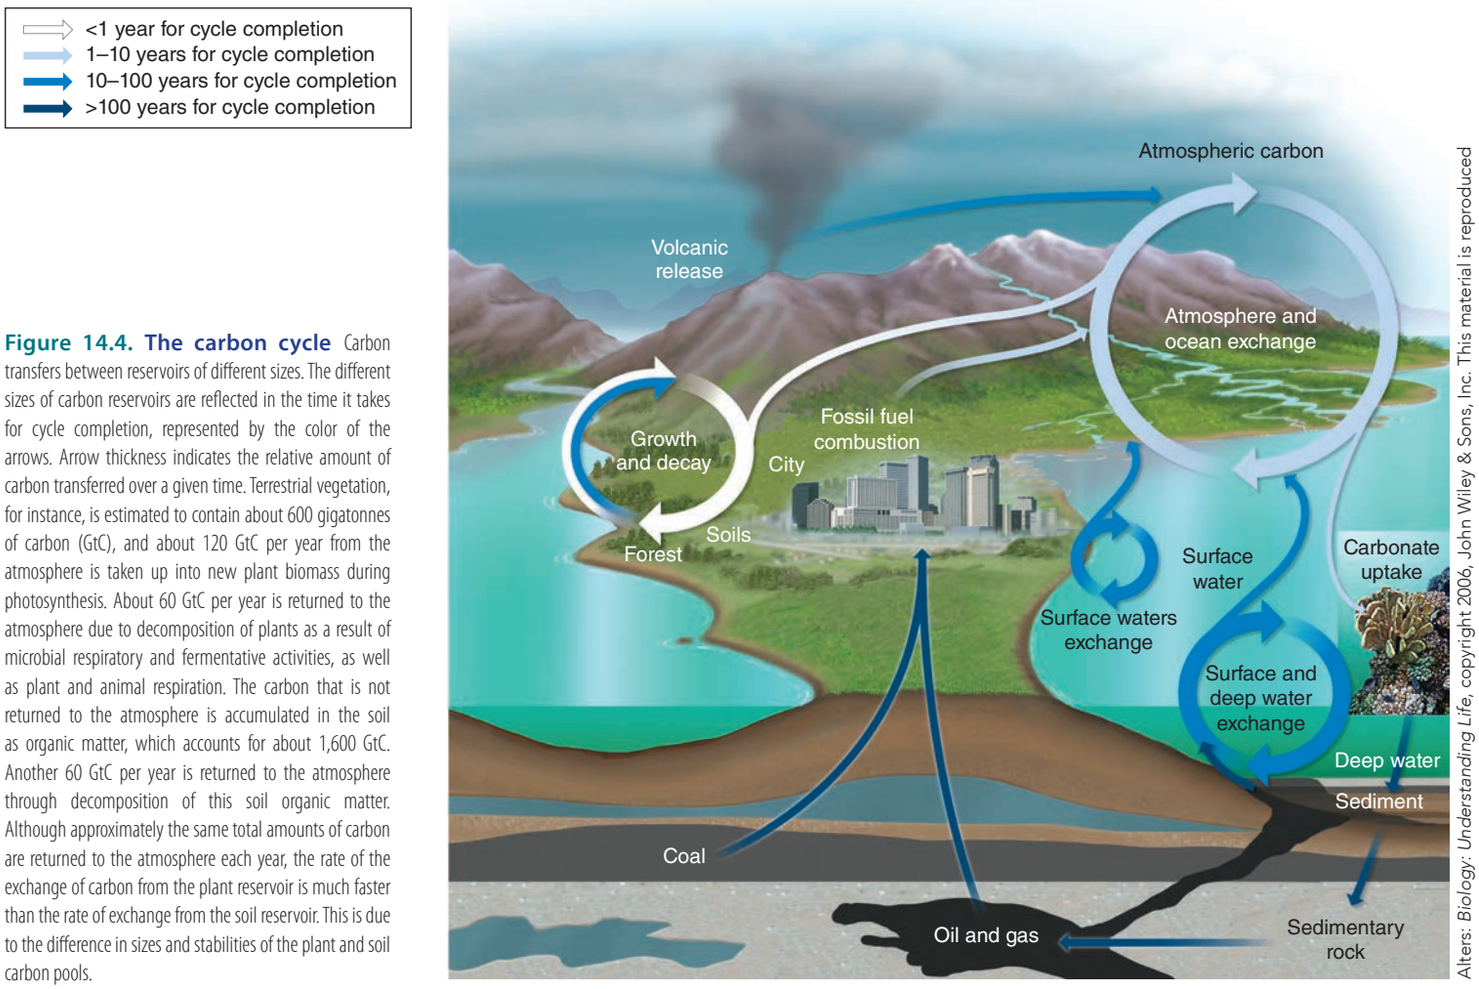

Figure 14.4. The carbon cycle Carbon transfers between reservoirs of different sizes. The different sizes of carbon reservoirs are reflected in the time it takes for cycle completion, represented by the color of the arrows. Arrow thickness indicates the relative amount of carbon transferred over a given time. Terrestrial vegetation, for instance, is estimated to contain about 600 gigatonnes of carbon (GtC), and about 120 GtC per year from the atmosphere is taken up into new plant biomass during photosynthesis. About 60 GtC per year is returned to the atmosphere due to decomposition of plants as a result of microbial respiratory and fermentative activities, as well as plant and animal respiration. The carbon that is not returned to the atmosphere is accumulated in the soil as organic matter, which accounts for about 1,600 GtC. Another 60 GtC per year is returned to the atmosphere through decomposition of this soil organic matter. Although approximately the same total amounts of carbon are returned to the atmosphere each year, the rate of the exchange of carbon from the plant reservoir is much faster than the rate of exchange from the soil reservoir. This is due to the difference in sizes and stabilities of the plant and soil carbon pools.

generalization, of course, involves the recovery and combustion of fossil fuels by humans, which sends carbon from a normally static reservoir into the atmosphere.

Deep ocean water links to the upper waters, then to additional reservoirs, but the exchange of deep ocean carbon with the more rapidly cycling surface water carbon takes place only over hundreds of years. Atmospheric CO_2 dissolves into marine waters. Here, it can be incorporated into corals, clams, protozoa, and other organisms in the form of calcium carbonate ($CaCO_3$), as discussed in Perspective 14.1. When these organisms die, the carbonate structures sink, contributing to the eventual formation of sedimentary carbonate rock such as limestone. Over millions of years, this rock may be drawn into Earth's crust and undergo metamorphosis into calcium silicate rock. This reaction releases CO_2, which can find its way back to the atmosphere via volcanic release. Photosynthesis by land plants and chemolithoautotrophic microbial metabolism captures atmospheric CO_2. In these ways, inorganic carbon becomes incorporated into new plant and microbial biomass (see Figure 14.4).

As we can see from this introduction to global carbon cycling, carbon moves between various reservoirs via a series of interconnected processes. Big picture representations such as this one are useful when focusing on geological or environmental perspectives. We can also focus on the relatively short-term cycling of carbon associated with various microbial activities. Elemental processing by microbes has had a profound effect on Earth over geological time spans. As we will see in the next section, many interesting biological questions involve the relatively rapid transfers of carbon through living reservoirs.

Photosynthesis, respiration, and decomposition

A brief overview of the global carbon cycle illustrates the balance between incorporation of carbon from the atmosphere into new plant biomass during photosynthesis, and the release of carbon into the atmosphere through the decomposition of this biomass. The metabolic activities of organisms are paramount in short-term carbon cycling. The bulk of the action is composed of the complementary activities of photosynthesis and respiration, which are activities detailed in Chapter 13. Photoautotrophic organisms use light-derived energy to fix inorganic carbon into organic matter through the process of photosynthesis. In the terrestrial reservoir, plants dominate this conversion of CO_2 to organic carbon [CH_2O], although microorganisms such as terrestrial algae, cyanobacteria, and lichens also contribute.

In aquatic environments, microorganisms dominate photosynthetic activity. Phytoplankton are the primary producers within the water column. Macroscopic aquatic plants and macroalgae, such as kelp, thrive only in near-shore habitats where the water is shallow enough to enable them to attach. Within these aquatic environments, oxygenic phototrophs such as plants, eukaryal algae, and cyanobacteria dominate photosynthesis. Conversely, anoxygenic phototrophic bacteria predominate in specialized habitats such as non-mixing lakes or other places where light is available along with suitable electron donors, such as hydrogen sulfide (H_2S) or other forms of reduced sulfur.

In addition to primary production via photosynthesis, chemolithoautotrophy contributes to the formation of new organic matter by fixing CO_2 at the expense of inorganic energy sources. Some specialized communities on Earth thrive in the absence of sunlight by relying on primary production by chemolithoautotrophic microorganisms. However, this form of carbon fixation represents a very minor component of primary production in most environments.

CONNECTIONS In **Section 15.5**, we will explore ecosystems, such as deep sea hydrothermal vents, that are driven by non-solar forms of energy. In these ecosystems, the oxidation of inorganic molecules, such as H_2S and Fe^{2+}, drives the generation of energy.

As we discussed in Chapter 6, respiration involves the release of CO_2 and water from the oxidative metabolism of organic compounds, resulting in energy generation. When the total production of organic material and community respiration are in balance, no net gain or loss of organic matter occurs in the community. However, when the organic matter produced via photosynthesis exceeds the amount of organic carbon converted back to CO_2, positive **net community productivity** occurs. In other words, organic matter accumulates and the reservoir is not in a steady state. In contrast, when the amount of organic carbon converted back to CO_2 exceeds the amount of organic material produced, then negative net community productivity occurs. This situation could occur if an external source of organic matter enters a community. For example, leaves falling into a stream could supply additional organic carbon to heterotrophic stream microorganisms.

An important component of the photosynthesis-respiration interaction shown in Figure 14.4 is the decomposition of organic material by chemoorganoheterotrophic microbial activity. Like respiration by plants and animals, microbial respiration has the ultimate effect of converting organic carbon back to CO_2. This CO_2 represents the major natural source of CO_2 to the atmosphere and again becomes available to autotrophic organisms, which are the primary producers. In an idealized food web, decomposition of organic material by microorganisms occurs via aerobic respiration, with O_2 serving as the terminal electron acceptor. In the absence of oxygen gas (O_2), anaerobic respiration may occur if suitable alternative electron acceptors are available, such as sulfate (SO_4^{2-}), nitrate (NO_3^-), or ferric iron (Fe^{3+}). Fermentation (see Section 13.3) often occurs more frequently than anaerobic respiration in O_2-limited environments. Fermentative activities generate partially oxidized organic end products like acids and alcohols, as well as CO_2. In turn, these compounds may serve as nutrients for other microorganisms.

Eventually, organic material decomposes to its inorganic constituents of water (H_2O) and CO_2 through decay processes, although this complete conversion may take quite a long time. Relatively labile molecules, like sugars and free amino acids, degrade readily, but insoluble polymers such as cellulose, hemicelluloses, and lignin (see Figure 12.19) are more recalcitrant and are typically susceptible to attack by a relatively small proportion of microorganisms. As a result, they degrade more slowly.

Perspective 14.1

CO_2 AS A GREENHOUSE GAS AND ITS INFLUENCE ON CLIMATE CHANGE

Since the Industrial Revolution began in the nineteenth century, human activities have increased the atmospheric carbon dioxide (CO_2) concentration by about 30 percent. **Figure B14.2** illustrates this consistent upward trend in atmospheric CO_2 level over the past half century. Fuel combustion accounts for about three-quarters of the increase, and land-use changes, such as clearing of land for agricultural activities that disrupts the carbon reservoir of the natural vegetation, account for the other quarter.

Why should we be concerned about this increase in atmospheric CO_2? Carbon dioxide and other greenhouse gases, such as water vapor, nitrous oxide, methane, and fluorinated compounds, strongly absorb radiation in the infrared range, although they are transparent to visible light. When visible sunlight strikes Earth, a portion irradiates back toward space as longer-wavelength infrared radiation **(Figure B14.3)**. Gases like CO_2 act as a sort of thermal blanket, trapping this infrared radiation and thereby influencing the planetary climate. Accumulating atmospheric CO_2 therefore most likely contributes to climate change and has shaped the climate on Earth throughout its history, including its very recent history. Indeed, recent research demonstrates how the arrival of the Europeans to the Americas, the deaths of millions of native Americans, increased trade, and expansive reforestation of previously farmed land resulted in a decrease in atmospheric CO_2 and a corresponding decrease in global temperature during the "Little Ice Age" (1594–1677). Today, global CO_2 levels exceed 400 parts per million, which is higher than it has been at any other time in human history.

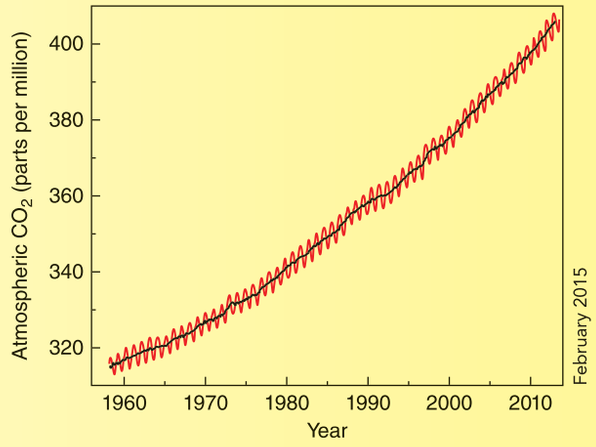

Figure B14.2. Atmospheric CO_2 at Mauna Loa Observatory in Hawaii
The black line represents a steady rise in CO_2 since 1958 when measurements began. The annual up-and-down pattern occurs because primary producers take up relatively more CO_2 during the growing season in the forested Northern Hemisphere. During winter in the Northern Hemisphere, primary producers in the relatively smaller land masses in the Southern Hemisphere take up less CO_2, and the atmospheric level rises.

Given the recent documented perturbation in atmospheric CO_2 by human activities linked to industrialization, we need an accurate accounting of global carbon, and we need to understand what regulates carbon transfer between terrestrial, aquatic, atmospheric, and living reservoirs. This is necessary so that strategies can be devised

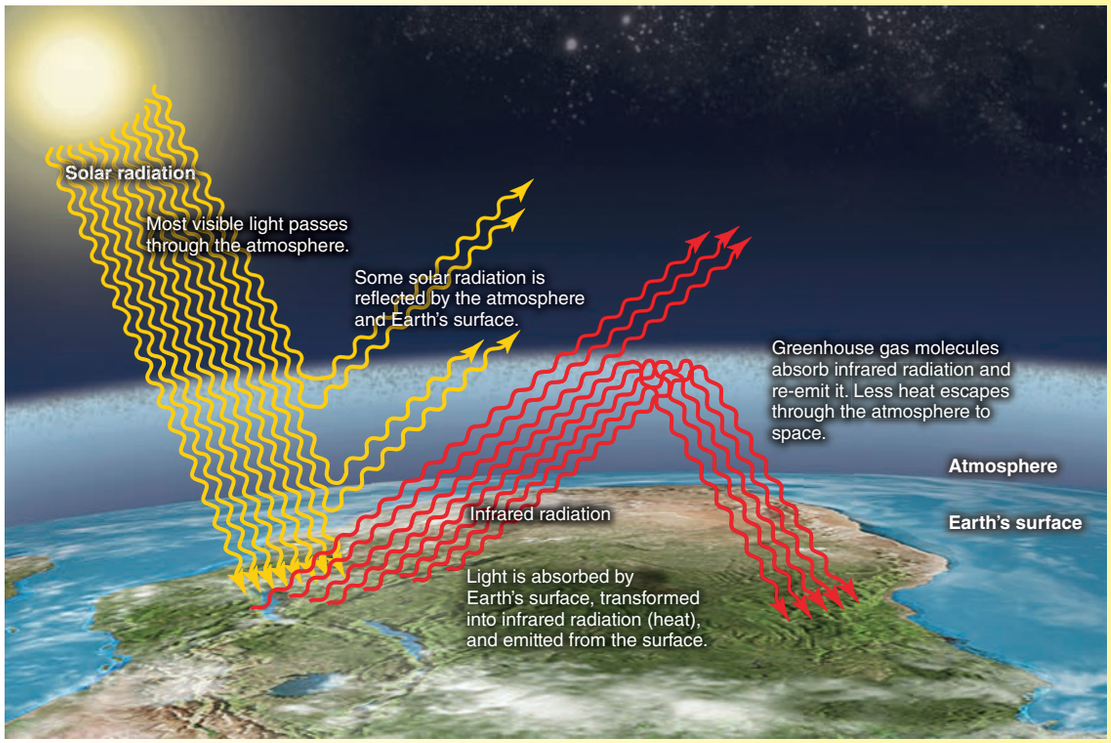

Figure B14.3. The greenhouse effect The absorption of infrared radiation by greenhouse gases prevents some of it from escaping to space, contributing to the warming of Earth's atmosphere and surface.

to deal with a shifting carbon cycle. Although we know quite a lot about how carbon cycling operates today and how it has worked in the past, we still do not have enough quantitative data to construct an accurate global carbon budget. For instance, current models of global carbon cycling show that some carbon appears to be missing. In other words, less carbon exists in the atmosphere than can be accounted for. Perhaps some of the data are inaccurate or some carbon reservoir remains uncounted.

Several possible scenarios could allow us to account for the apparent missing carbon. Scientists at the Woods Hole Oceanographic Institution have used data from the 1990s to summarize the global carbon cycle as follows:

Atmospheric increase = emissions from fossil fuels
+ net emissions from changes in land use
− oceanic uptake − missing carbon reservoir

3.2 (± 0.2) GtC = 6.3 (± 0.4) GtC + 2.2 (±0.8) GtC
− 2.4 (±0.7) GtC − 2.9 (±1.1) GtC

When using estimated values for each of the first four categories, the cycle remains unbalanced unless the *missing* category of about 2.9 GtC is added to the right side of the equation. The unidentified reservoir is required to balance estimates of global releases with global accumulations of carbon over about 150 years **(Figure B14.4)**. Researchers are reasonably confident in their fossil fuel combustion data, land-use-related data, and the atmospheric accumulation data, but there are considerable uncertainties in the understanding of microbe-controlled global photosynthesis and respiration rates and carbon storage. For example, we know that the ocean serves as a "biological pump" for the capture of CO_2 into sinking biomass and carbonate shells of phytoplankton, sequestering carbon to the deep sea and mitigating increases in atmospheric CO_2 levels. We also recognize that viruses help to prevent or delay the biological pump by lysing cells and releasing nutrients that can be more readily assimilated by actively growing organisms. In this way, viruses act as a "viral shunt," sending carbon and other nutrients back into active biomass rather than being pumped to the deep sea through sinking particles. The extent to which these two competing processes occur requires further study. Furthermore, could undiscovered microbial carbon metabolism be responsible for the unaccounted carbon in the models? The answer to this question will only come once we have much better knowledge of the microbial control of the biogeochemical cycles.

Throughout this chapter, other greenhouse gases, such as methane (CH_4) and nitrous oxide (N_2O), will be mentioned in the context of microbial metabolism. These greenhouse gases are important as well, with each deserving consideration as provided here for CO_2. This is the ultimate importance of biogeochemical cycles within the context of microbiology: microbial metabolism must be studied carefully in order to better model the influence of their collective activities on our planet. Furthermore, **Figure B14.5** demonstrates that the collective metabolic role of microbes is an important biological variable that must be considered alongside additional biological and climate variables, all of which are changing due to anthropogenic influences. Biogeochemical microbiology has never been a more urgent research focus than it is today!

Figure B14.4. The global carbon budget Estimated global releases and global accumulations over the past 150 years balance only if an unidentified reservoir is included. The reservoir is most likely due to microbial photosynthesis and respiration, which are not completely understood and quantified.

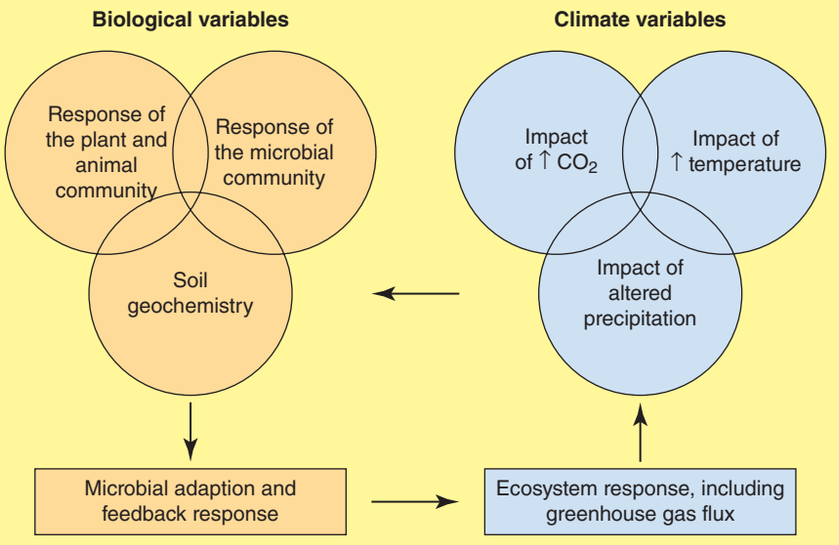

Figure B14.5. Theoretical terrestrial context for future research in biogeochemistry The biological and climate variables shown here are interconnected, and changing temporally. An integrated approach is required for understanding the potential for future climate change and potential measures for its mitigation.

Soil organic matter (SOM), primarily derived through the breakdown of plant and animal biomass, constitutes a significant reservoir of stored carbon. Like the insoluble polymers, it degrades slowly (see Figure 14.4). Soil humus, organic material remaining after microbial attack on the more readily biodegradable components of dead biomass, composes a large part of the SOM. Indeed, studies based on ^{14}C dating have shown that the average age of SOM ranges from 150 to over 1,500 years. Together, respiration and the decay processes account for most of the carbon removed from the atmosphere by photosynthesis.

As we noted earlier, atmospheric CO_2 diffuses into the aquatic reservoirs on Earth, where it can remain as dissolved CO_2, or be converted into bicarbonate (HCO_3^-) or carbonate (CO_3^{2-}). This source of inorganic carbon is fixed into organic material by the oceans' phytoplankton community (algae, cyanobacteria), and subsequently, this organic carbon is subject to respiration and eventual decay by heterotrophic microorganisms. However, the marine biota constitutes a much smaller carbon pool than terrestrial biota (see Figure 14.4). As a result, activities of the terrestrial microorganisms have a relatively greater influence on biological carbon cycling than aquatic microorganisms. However, the huge volumes of the world's oceans means that the aquatic reservoirs store vast amounts of dissolved inorganic carbon.

Methanogenesis

As we saw in the preceding section, CO_2 represents a major end product of organic matter breakdown. However, another gaseous end product can result from the biodegradation of organic carbon in anoxic environments: CH_4. In Chapter 4, we introduced how several archaea from the *Euryarchaeota* conduct a type of metabolism called **methanogenesis**. These archaea are referred to as **methanogens**, and they produce CH_4 as an end product. The methanogen *Methanococcus maripaludis* is profiled in Microbes in Focus 14.1. The actions of these euryarchaeotes are important for global carbon cycling. The gaseous CH_4 they produce in environments devoid of O_2 may diffuse into adjacent oxic habitats where it can be metabolized by other microorganisms. This movement of CH_4 prevents carbon from becoming irreversibly trapped in anoxic environments.

CONNECTIONS In some superficial respects, archaea resemble bacteria. However, as we saw in **Chapter 4**, archaea differ in fundamental ways from both bacteria and eukarya. For this reason, the *Archaea* represents one of the three domains of life.

The reactions below compare the conversion of six-carbon sugars to end products through aerobic (top reaction) and methanogenic mechanisms (bottom reaction):

$$C_6H_{12}O_6 + 6\ O_2 \rightarrow 6\ CO_2 + 6\,H_2O;\ \Delta G^{\circ\prime} = -2{,}840\,\text{kJ mol}^{-1}$$

$$C_6H_{12}O_6 \rightarrow 3\ CO_2 + 3\ CH_4;\ \Delta G^{\circ\prime} = -390\,\text{kJ mol}^{-1}$$

In both reactions, the Gibbs free energy values ($\Delta G^{\circ\prime}$; see Chapter 13) are negative, indicating energy-releasing reactions. However, the reaction under methanogenic conditions releases only about 15 percent as much energy as does the aerobic biodegradation. This difference demonstrates that considerable energy remains stored within the CH_4 molecule. On a related note, it also means that relatively little biomass can be produced per molecule of CH_4 evolved. Generally, biomass yields under anoxic conditions are small compared to the yields under oxic conditions; many metabolic end products of anaerobes remain incompletely oxidized.

Now that we have some understanding of how methanogenesis occurs, let's ask another question. Where does this reaction occur? Methanogenesis occurs in habitats that contain plenty of organic matter but little or no oxygen. Specific locations include freshwater sediments, swamps and bogs, waterlogged soils including rice paddies, and in the anoxic components of sewage treatment systems, such as anaerobic sludge digesters. Because methanogenesis represents the final process of organic matter degradation pathways in such O_2-restricted habitats, methanogens rely on other organisms to process complex organic materials and provide them with substrates. Methanogens use only a restricted range of substrates (Table 14.2). Consequently,

Microbes in Focus 14.1

***METHANOCOCCUS MARIPALUDIS*: A METHANE PRODUCER**

Habitat: Commonly found in marine environments, often in salt marshes, where it produces methane. Also fixes N_2

Description: Coccus-shaped archaeon with a cluster of flagella, known for its rapid growth. The 1.66-Mbp genome sequence, encoding 1,722 protein-encoding genes, was reported in 2004.

Key Features: This microorganism can grow autotrophically on H_2, CO_2, and N_2. It is a popular experimental organism, with a well-developed genetic system, including methods for introduction of DNA by transformation and construction of mutants.

Pyruvate	CH_3COCOO^-
Trimethylamine	$(CH_3)_3N$

methanogenesis involves a **consortium**, or interacting community, of interdependent microorganisms. These organisms form **syntrophic partnerships** in which the metabolic activities of the organisms are mutually dependent; only in combination are they thermodynamically favorable. Probably, much of the biodegradation in oxic environments is also community driven, but unlike anaerobes, many aerobic microorganisms possess metabolic pathways enabling them to completely mineralize carbon-containing compounds to CO_2 and H_2O.

The decomposition of organic compounds in a methanogenic environment occurs in three stages (Figure 14.5). First, organisms hydrolyze polymers such as cellulose and proteins. The resulting monomeric sugars and amino acids are then fermented to fatty acids, organic acids, and alcohols. This stage, sometimes termed "primary fermentation," is carried out by primary fermenter organisms. In the second stage, the fatty acids, organic acids, and alcohols are used as substrates for secondary fermentation, which may result in the formation of hydrogen, acetate, formate, and other related compounds. These reactions are carried out by secondary fermenters, or syntrophs. In the third stage, methanogens metabolize these products, producing CH_4 and CO_2. **Hydrogenotrophic methanogens** produce CH_4 from CO_2 and H_2, whereas **acetotrophic methanogens** produce CH_4 from acetate. The outcome of the overall, three-stage process is the conversion of polymeric carbon-containing organic materials to the simple end products

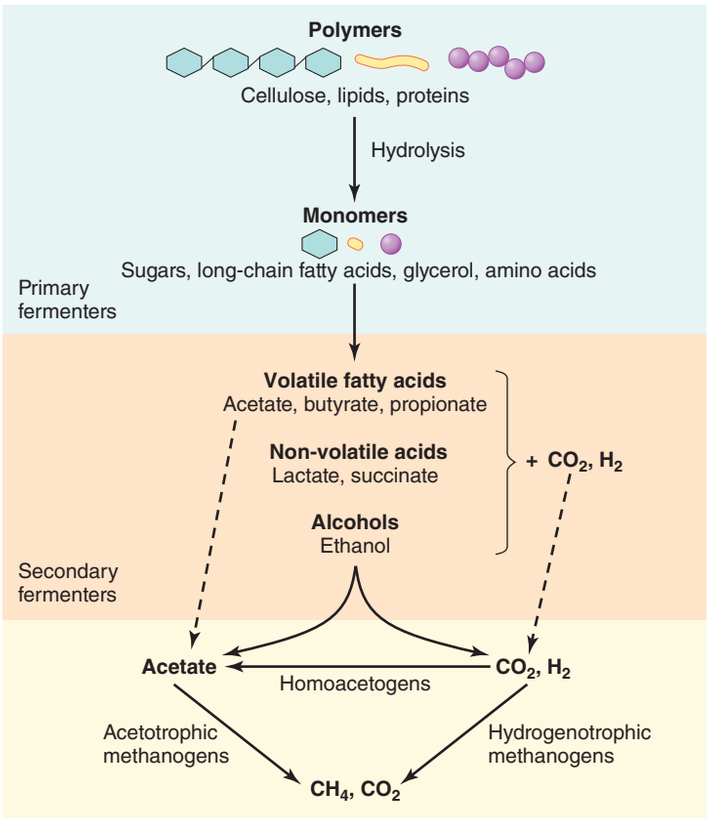

Figure 14.5. Decomposition of organic compounds in anoxic methanogenic environments This process requires different types of microorganisms working together in syntrophic partnerships. Primary fermenters produce fatty acids, organic acids, and alcohols that syntrophic bacteria degrade to acetate, H_2, and CO_2, the substrates of methanogenesis.

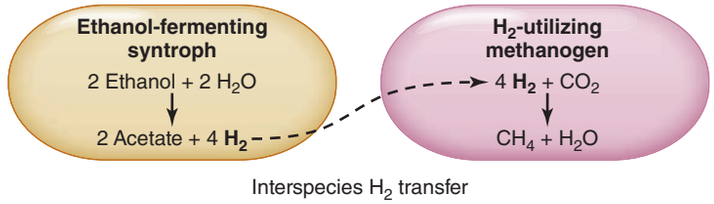

Figure 14.6. An example of a syntrophic partnership In a syntrophic partnership based on interspecies H_2 transfer, the consumption of H_2 by the methanogen keeps the concentration of H_2 low. This makes the oxidation of ethanol thermodynamically favorable. The physiological processes of the two organisms are interdependent.

of CO_2, CH_4, and H_2O. The degradation of proteins, phospholipids, and nucleic acids leads to the generation of these products, as well as ammonia (NH_3), phosphate (HPO_4^{2-}), and sulfate (SO_4^{2-}).

Importantly, the microbial activities of decomposition depend on one another. Each stage in the upper portion of Figure 14.5 also relies on the occurrence of the stage below. In particular, a tight syntrophic association exists between H_2-producing microorganisms and methanogens, involving a process known as "interspecies hydrogen transfer." In this type of relationship, H_2 produced by one organism is used by a hydrogenotrophic methanogen (Figure 14.6). The H_2-producing microorganisms carry out oxidation reactions such as the following:

$$\underset{\text{(butyrate)}}{CH_3CH_2CH_2COO^-} + 2\,H_2O \rightarrow 2\,CH_3COO^- + H^+ + 2\,H_2; \quad \Delta G^{\circ\prime} = +48.1\,\text{kJ}$$

$$\underset{\text{(propionate)}}{CH_3CH_2COO^-} + 3\,H_2O \rightarrow CH_3COO^- + HCO_3^- + H^+ + 3\,H_2; \quad \Delta G^{\circ\prime} = +76.1\,\text{kJ}$$

$$\underset{\text{(ethanol)}}{CH_3CH_2OH} + H_2O \rightarrow CH_3COO^- + H^+ + 2\,H_2; \quad \Delta G^{\circ\prime} = +9.6\,\text{kJ}$$

Each of the above reactions is thermodynamically unfavorable under standard conditions (solutes 1 M, gases 1 atm, 25°C, pH 7.0), as indicated by the positive Gibbs free energy value ($\Delta G^{\circ\prime}$). How then can these organisms gain energy by conducting such reactions? They do so by living in a close, mutualistic relationship with other microorganisms that use the H_2.

Let's examine the benefits of this partnership more closely. The H_2-utilizing microorganisms consume H_2 as soon as it is produced by the H_2-producing microorganisms, thereby keeping the partial pressure of H_2 in their immediate environment very low (~10^{-4} atm or less). The low-H_2 partial pressure pulls the above reactions toward H_2 production. In bioenergetic terms, the actual ΔG of the H_2-producing microbe's reaction under the environmental conditions in which the microorganisms are living is negative, or energy-yielding, and not positive. The oxidation of butyrate shown above, for instance, would have an actual ΔG of about −17.6 kJ in a typical anoxic freshwater ecosystem with ~1 mM butyrate, ~0.6 atm CH_4, and ~10^{-4} atm H_2 present. In the community depicted by Figure 14.5, the methanogens and the homoacetogens play the role of H_2 utilizers. Without these H_2-utilizing groups at the end of the anaerobic microbial food chain, the earlier reactions could not occur. Thus, all the organisms in the process are interdependent.

Because of its high carbon and low oxygen requirements, methanogenesis also occurs in the gastrointestinal tract of animals. Although hydrogenotrophic methanogens are important members of animal guts, including those of humans, production of CH_4 by acetotrophic methanogens is less important in this environment. In fact, the acetotrophic microorganisms grow too slowly to maintain themselves in the gut to any extent. Instead, acetate and the other incompletely degraded organic molecules, such as fatty acids, are absorbed by the animal, thus serving as energy and carbon sources. In Chapter 17, we will investigate the importance of these processes in ruminant animals.

CONNECTIONS Methanogenesis plays an important role in our gastrointestinal tract. As we saw in **Section 4.3**, the archaeon *Methanobrevibacter smithii* represents a major inhabitant of the human GI tract. This microorganism produces CH_4, probably using H_2 and formate as substrates.

Methanotrophy

As we have seen in the previous section, methanogens can convert organic material to CH_4. Let's now ask a closely related and quite important question. What happens to this CH_4? Approximately half of the organic carbon degraded in the absence of O_2 ends up as CH_4, and organisms that rely on aerobic metabolism require the eventual return of this carbon to the oxic side. The fate of CH_4 is also important to consider because of its high-infrared absorbance. Methane is about 30 times more potent than CO_2 as a greenhouse gas.

Only a small fraction of biologically produced CH_4 ever reaches the atmosphere. Most of the CH_4 produced by methanogens is used efficiently by **methanotrophs**, which are bacteria that can oxidize CH_4. These microorganisms are a subgroup of the **methylotrophs**, members of the *Proteobacteria* that can oxidize organic compounds that do not contain C—C bonds such as CH_4, formate, and methanol. Some methylotrophs cannot use CH_4 and thus are not methanotrophs, and some methylotrophs are also able to metabolize compounds that do contain C—C bonds. Note that methylotrophs do not fit neatly into the usual heterotrophic/autotrophic and organotrophic/lithotrophic classifications of carbon and energy metabolism. As you will see, they have unique metabolic capabilities of their own.

Methanotrophs oxidize CH_4, capturing energy from CH_4 oxidation as adenosine triphosphate (ATP) and converting the carbon in this molecule into forms that can be assimilated by themselves or by other organisms. As a result, methanotrophs allow the carbon present in CH_4 to be cycled fully from biomass, to methane, then back to biomass again. In this section, we will examine two specific forms of methanotrophy—aerobic and anaerobic.

Aerobic Methanotrophy

Aerobic methanotrophs oxidize CH_4 to CO_2 as follows:

$$\underset{\text{(methane}}{CH_4} \rightarrow \underset{\text{methanol}}{CH_3OH} \rightarrow \underset{\text{formaldehyde}}{CH_2O} \rightarrow \underset{\text{formate}}{HCOO^-} \rightarrow \underset{\text{carbon dioxide)}}{CO_2}$$

Carbon is assimilated from formaldehyde (CH_2O) and CO_2 via either of two different pathways that contain certain enzymes unique to aerobic methanotrophs **(Figure 14.7)**. The serine pathway produces two-carbon units as acetyl-CoA from CH_2O plus CO_2 in a reaction sequence that requires two ATP and reducing power. The ribulose monophosphate pathway produces three-carbon units (glyceraldehyde 3-phosphate) from three formaldehyde molecules, using one ATP per glyceraldehyde 3-phosphate molecule synthesized. The produced two- or three-carbon units feed into central metabolic pathways, enabling anabolic metabolism and the production of new

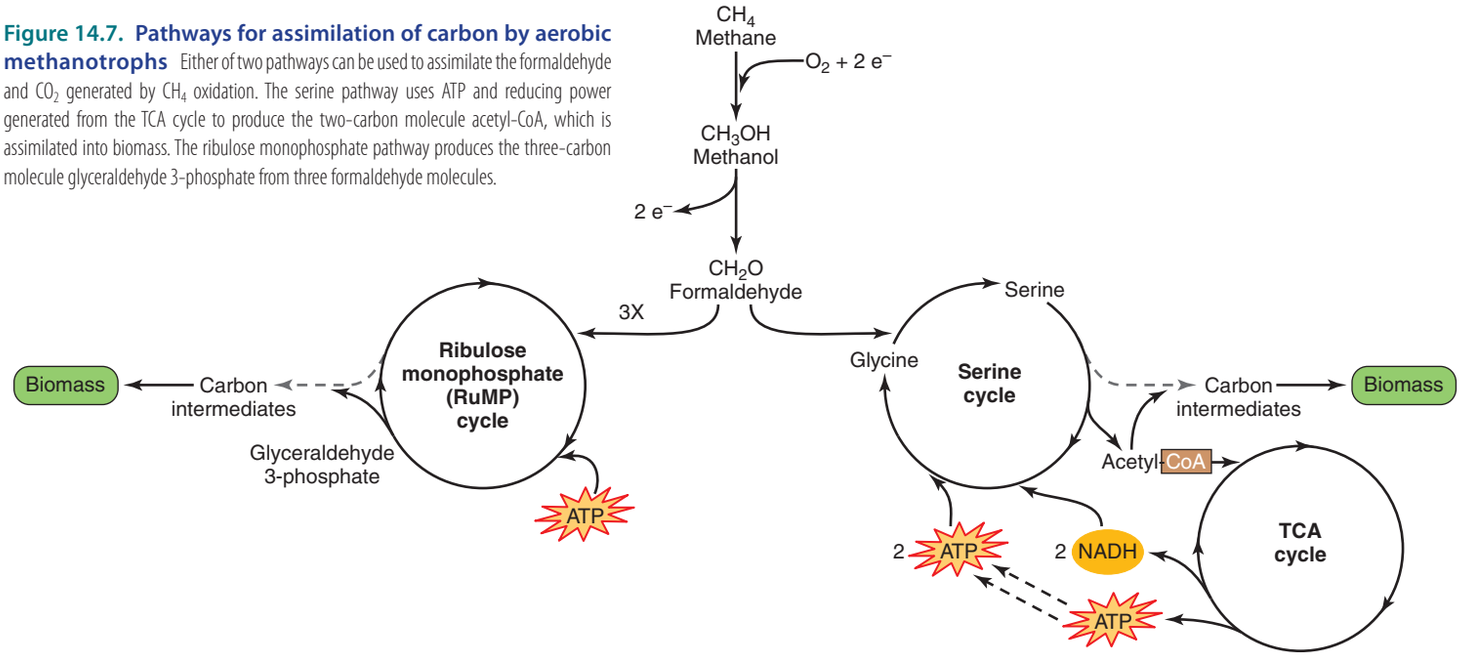

Figure 14.7. Pathways for assimilation of carbon by aerobic methanotrophs Either of two pathways can be used to assimilate the formaldehyde and CO_2 generated by CH_4 oxidation. The serine pathway uses ATP and reducing power generated from the TCA cycle to produce the two-carbon molecule acetyl-CoA, which is assimilated into biomass. The ribulose monophosphate pathway produces the three-carbon molecule glyceraldehyde 3-phosphate from three formaldehyde molecules.

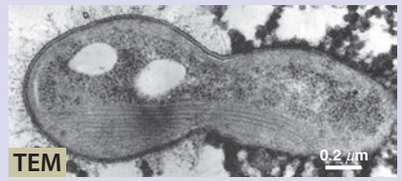
biomass. Reducing power in the form of NADH reduces CO_2 to the oxidation level of cell biomass in the serine pathway. Conversely, formaldehyde is already at the same oxidation state as cell biomass. That, and its lesser ATP requirement, make the ribulose monophosphate pathway the more efficient of these two routes for incorporating carbon.

The ability of aerobic methanotrophs to oxidize methane depends on methane monooxygenase (MMO), the enzyme responsible for converting CH_4 to CH_3OH (methanol). Accordingly, non-methanotrophic methylotrophs lack the MMO enzyme. MMO is a very interesting enzyme, renowned for its ability to act on a broad range of substrates, including aromatic molecules and halogenated hydrocarbons. In a reaction requiring a reductant **(Figure 14.8)**, MMO adds an O atom derived from O_2 to CH_4, producing CH_3OH plus H_2O. In the later oxidative steps of the pathway, electrons are gained from oxidizing formaldehyde (CH_2O) to CO_2 and enter the electron transport chain, generating a proton motive force that permits ATP synthesis. The requirement for O_2 as a reactant in the MMO reaction is the reason these bacteria are obligate aerobes; O_2 is also the terminal electron acceptor in their energy metabolism. Methanotrophic cells possess extensive internal membrane structures, which are readily visualized by electron microscopy (see Figure 14.8 and **Microbes in Focus 14.2**). These internal membranes host the membrane-associated MMO enzyme, which is also called the particulate MMO, or pMMO. Additionally, some methanotrophs produce a soluble MMO, or sMMO, that is not membrane associated. Instead, the sMMO enzyme is found in the cytoplasm.

Microbes in Focus 14.2
METHYLOSINUS TRICHOSPORIUM: A METHANE EATER

Habitat: First isolated and described in 1970 by Roger Whittenbury. Common inhabitant of soil and water that subsists on methane gas or methanol as sole source of carbon. Plays an important role in the consumption of methane gas produced by methanogens in anoxic environments

Description: Strictly aerobic member of the *Alphaproteobacteria*. Rod-shaped with a polar tuft of flagella, a Gram-negative cell wall structure, and an extensive network of intracellular membranes. Forms heat- and desiccation-resistant exospores that bud off one end of the vegetative cell, accumulates intracellular PHB, and can fix N_2



From W.M. Reed, et al., J. Bacteriol. 141:908, Fig. 4. Reproduced with permission from American Society for Microbiology

Key Features: The main distinguishing feature of this bacterium is its ability to oxidize methane due to its possession of the methane monooxygenase enzyme. This enzyme has very broad substrate specificity, making it useful for the degradation of a range of toxic contaminants such as chlorinated organic compounds.

Figure 14.8. Methane oxidation carried out by methane monooxygenase (MMO) The reaction catalyzed by MMO, oxidizing CH_4 to methanol, requires O_2. This direct involvement of O_2 accounts for the obligate aerobic nature of CH_4 oxidation. Oxygen is also required for the generation of ATP via the electron transport chain and ATPase. Extensive internal membranes of methanotroph cells that support the MMO enzyme are also depicted here.

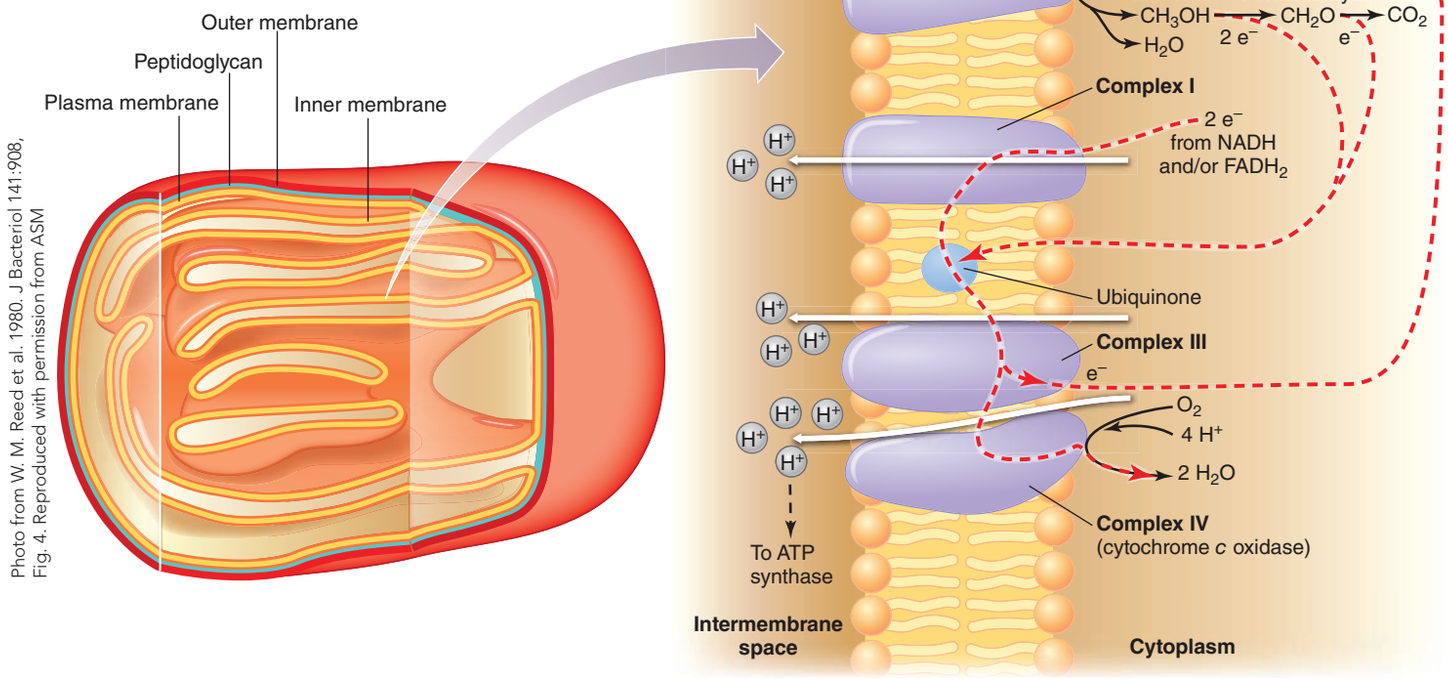


Photo from W. M. Reed et al. 1980. J Bacteriol 141:908, Fig. 4. Reproduced with permission from ASM

Methanotrophs exist in widely distributed areas. They have been isolated from muds, swamps, peat bogs, sediments, fresh and saline waters, rice paddies, sewage sludge, and soils. Not surprisingly, populations of methanotrophs exist in locales where CH_4 accumulates as a result of methanogenesis or from a geologic or human source. Examples of such sites include flooded soils, wetlands, soil overlays on landfills, and near hydrocarbon seeps or natural gas pipeline leaks. Methane oxidation by methanotrophs reduces the amount of CH_4 that these sources ultimately release to the atmosphere. Methanotrophs can be isolated simply by inoculating a mineral salts medium with a soil or water sample, then adjusting the headspace of the closed flask to contain up to ~80 percent CH_4. Evidence also suggests that readily culturable aerobic methanotrophs may not be representative of the complete spectrum of natural methanotroph populations. Methanotroph distributions can be surveyed by probing for the *pmoA* gene using molecular techniques. This gene is recognized as a robust marker for this group of methanotrophs, encoding a conserved 24 kDa subunit of the membrane-associated pMMO.

Methanotrophs can optimize substrate availability by positioning themselves along chemical gradients at the interface between anoxic and oxic environments. At this location, they can obtain CH_4 from anaerobic methanogenic activity and O_2 from the atmosphere or aerated water. Methanotrophic populations in lakes with methane-emitting sediments tend to occupy a relatively narrow band of water where the CH_4 rising up through the water column meets O_2 diffusing downward from the lake surface.

Locations of natural hydrocarbon release represent another habitat favored by methanotrophs. Cold gas seeps occur in certain near-shore locales in the Atlantic and Pacific oceans, and deep sea hydrothermal vents situated in the vicinity of the mid-oceanic ridge can emit geologically derived methane. Some methanotrophs live independently within these habitats, while other species live in symbiotic relationships with various invertebrates, including mussels, sponges, and tube worms. Type I methanotrophs have been identified near cold gas seeps in the Gulf of Mexico where they live as intracellular endosymbionts within mussel gill tissue, taking up dissolved CH_4 and O_2 from seawater passing over the gills. The use of radiolabeled $^{14}CH_4$ to track the flow of carbon has demonstrated that methane-derived carbon is incorporated into mussel tissue. Therefore, these symbioses appear to be similar in concept to the mutualistic relationship between sulfur-oxidizing bacteria and tube worms that is studied in deep sea hydrothermal vent environments. In fact, several research groups have described the co-occurrence of methanotrophic and sulfur-oxidizing bacteria as symbionts within the same deep sea mussels, demonstrating how multiple biogeochemical cycles can overlap even within relatively simple systems, such as tube worm tissue.

CONNECTIONS The relationship between giant tube worms and their bacterial symbionts is described in the opening story and The Rest of the Story in **Chapter 13**. Microbial biogeochemistry is sufficiently important to the tube worm's survival that the worm helps concentrate toxic H_2S to enable oxidation by their chemolithoautotrophic bacterial partners.

Figure 14.9. New Zealand hot spring Methane-rich geothermal springs such as this are prime locations to search for novel methanotrophs.

Until recently, methanotrophs were characterized as unique groupings of aerobic, obligate users of reduced C_1 substrates, such as CH_4, that belonged to either the *Alphaproteobacteria* or *Gammaproteobacteria*. However, novel acidophilic methanotrophic bacteria were independently reported in 2007 and 2008 by the research groups of Arjan Pol, Peter Dunfield, and Nils-Kåre Birkeland. These bacteria were isolated from a solfatara volcano mud pot near Naples (Italy), a geothermal methane-rich area in Hell's Gate New Zealand, and an acidic hot spring in the Uzon Caldera, Russia. These newly discovered methanotrophs were highly similar to one another, and all belonged to the poorly characterized phylum *Verrucomicrobia*, not to the *Proteobacteria* **(Figure 14.9)**. They can grow on CH_4 at pH of less than 1, far below the pH optimum of other known methanotrophs, and appear to possess an autotrophic metabolism rather than assimilating carbon from methane. Intriguingly, very similar environmental 16S rRNA gene sequences have been obtained from thermophilic habitats in Yellowstone National Park, suggesting that these newly discovered methanotrophs are widespread in extreme habitats.

Anaerobic Methanotrophy

Although aerobic methanotrophy is an important sink for methane, CH_4 can also be processed in the absence of oxygen. Over the past quarter century or so, microbiologists have realized that **anaerobic oxidation of methane (AOM)** occurs and is of great significance to the global carbon cycle. In particular, AOM influences the fate of CH_4 produced in near-shore marine sediments. Nearly all of the CH_4 produced globally every year in anoxic marine sediments undergoes anaerobic oxidation. As a result, relatively little of this CH_4 reaches the atmosphere. The microorganisms responsible for AOM have yet to be isolated, but culture-independent molecular and biogeochemical tools have enabled us to learn much about how they accomplish AOM. Clearly, the oxidative reaction sequence catalyzed by aerobic methanotrophs, involving MMO, cannot be at work here because no O_2 is available. An alternative mechanism for oxidizing CH_4 must be involved.

TABLE 14.3 Potential reactions performed by archaea and bacteria involved in anaerobic oxidation of methane

Proposed reaction mechanisms for the CH_4-consuming archaea	
$CH_4 + 2\,H_2O \rightarrow CO_2 + 4\,\mathbf{H_2}$	(a)
$CH_4 + 4\,HCO_3^- + 2\,H^+ \rightarrow CO_2 + 4\,\mathbf{HCOOH\ (formate)} + 2\,OH^-$	(b)
$CH_4 + CO_2 \rightarrow \mathbf{CH_3\,COOH\ (acetate)}$	(c)
$2\,CH_4 + 2\,H_2O \rightarrow \mathbf{CH_3COOH} + 4\,\mathbf{H_2}$	(d)
Associated reactions catalyzed by SRB (syntrophic partners)	
$SO_4^{2-} + 4\,\mathbf{HCOOH} \rightarrow S^{2-} + 4\,CO_2 + 4\,H_2O$	(e)
$SO_4^{2-} + 4\,\mathbf{H_2} \rightarrow S^{2-} + 4\,H_2O$	(f)
$SO_4^{2-} + \mathbf{CH_3COOH} \rightarrow 2\,HCO_3^- + H_2S$	(g)

Source: D. L. Valentine. 2002. Biogeochemistry and microbial ecology of methane oxidation in anoxic environments: A review. Antonie Van Leeuwenhoek 81:271–282.

The organisms capable of AOM include archaeal **anaerobic methane oxidizers (ANME)**. Three phylogenetically distinct groups of these organisms have been recognized: ANME-1, ANME-2, and ANME-3. Organisms in all three groups carry out "reverse methanogenesis". Rather than producing CH_4, these archaea consume CH_4 by running the methanogenic reactions backward. Exactly how they do this remains to be determined. Sequencing of SSU rRNA genes has shown that ANME-2 archaea are closely related to the *Methanosarcinales*, a group of largely methylotrophic methanogens that includes all known species able to produce CH_4 using acetate as substrate.

In addition, the *mcrA* gene, which encodes a subunit of the methanogen-specific enzyme methyl coenzyme M reductase, has been identified in ANME-1 and ANME-2 enrichments. The ANME archaea occur in close association with sulfate-reducing bacteria (SRB) such as *Desulfobacterium autotrophicum*. Together, these microorganisms accomplish AOM in anoxic zones where areas of sulfate reduction and methanogenesis intersect. In these locations, CH_4 released from methanogenesis encounters available sulfate (SO_4^{2-}). Contributions from the partners in this syntrophic association lead to the net chemical reaction associated with AOM:

$$CH_4 + SO_4^{2-} \rightarrow HCO_3^- + HS^- + H_2O$$

How the microbial association accomplishes this conversion has not been firmly established. Proposed mechanisms assume that the archaeal oxidation of CH_4 is coupled to the generation of reduced intermediates (H_2, formate, acetate) that are then oxidized by syntrophic SRB (Table 14.3). The carbon of the CH_4 molecule eventually cycles back to CO_2, which can be fixed into organic compounds by phototrophs, thus closing the carbon cycle. This is an example of how biogeochemical cycles are difficult to study in isolation given how the microorganisms and their metabolisms catalyze reductions and oxidations of intermediates from multiple distinct processes.

The reactions in Table 14.3 reflect the potential syntrophic interspecies transfer of hydrogen, formate, or acetate. Reactions (a) and (d) are thought to be the most viable mechanisms for CH_4 consumption. Reactions (e) through (g) are known metabolic reactions found in sulfate-reducing bacteria.

14.2 Fact Check

1. What is the global carbon cycle, and how is it influenced by long- and short-term cycling?
2. Distinguish between positive net community productivity and negative net community productivity.
3. What is methanogenesis, and in what environments does it occur?
4. How can methanotrophy occur with oxygen or without oxygen?

14.3 Cycling driven by nitrogen metabolism

How do microbes influence the cycling of nitrogen?

Before humans began to exert influences on Earth's biogeochemistry, microbes controlled the planet's nitrogen cycle almost entirely. Microbial processes remain key to processing the nitrogen vital to all living organisms. Today, human actions affect the nitrogen cycle profoundly, especially through fossil fuel utilization. As shown in Figure 14.10, Earth's atmosphere comprises the largest reservoir of nitrogen, mostly in the form of highly inert dinitrogen gas (N_2), which makes up about 79 percent of atmospheric gas. Living biomass accounts for about one-millionth of the nitrogen found in the atmosphere,

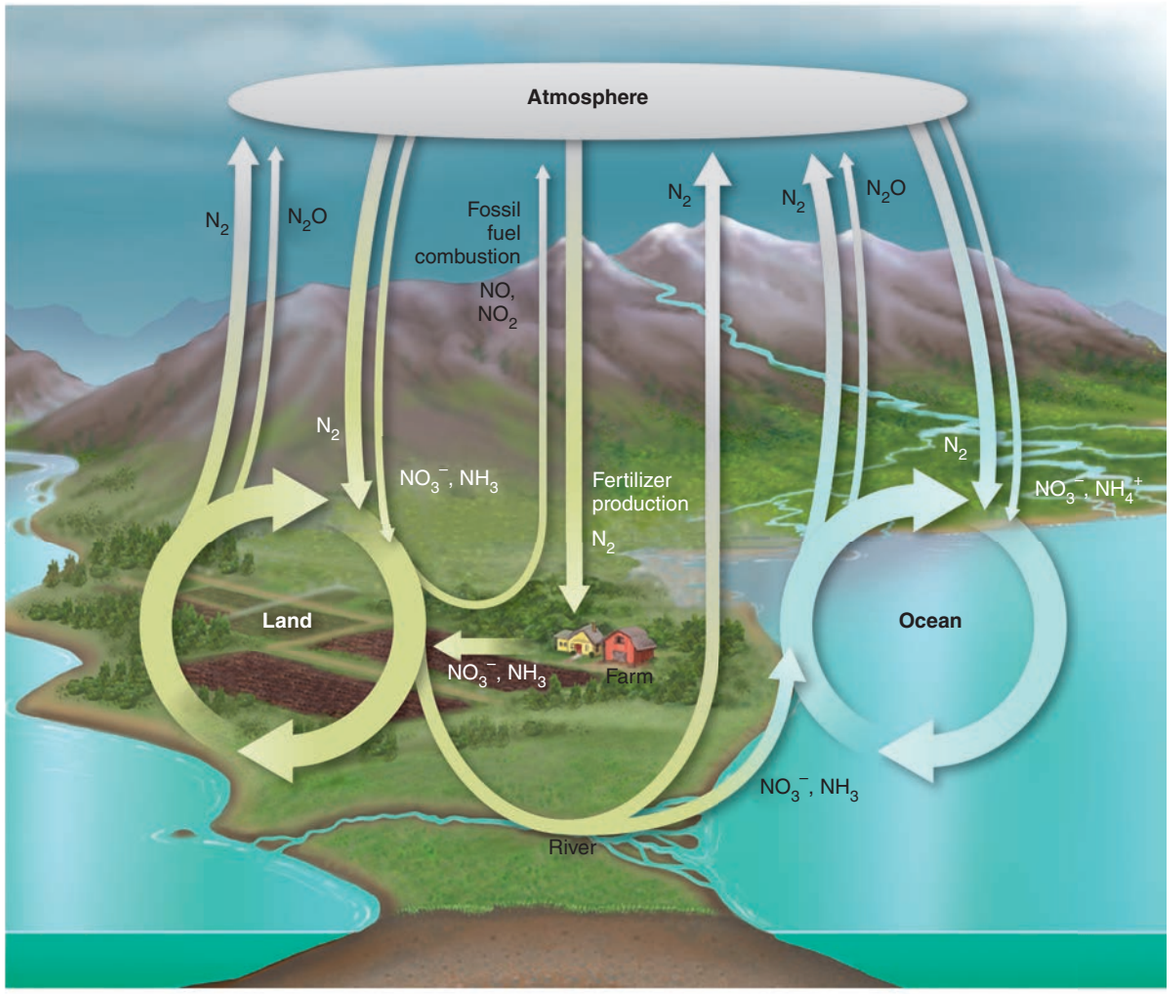

Figure 14.10. The nitrogen cycle Only a very small amount of the N on Earth is biologically available. This diagram demonstrates how the N cycles on land and in the oceans are connected by rivers and atmospheric deposition. Anthropogenic input is mostly from burning of fossil fuels and industrial N_2 fixation for fertilizer production.

Alters: *Biology: Understanding Life*, copyright 2006, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

mostly in terrestrial plant material, but also in land animals and marine plants and animals. The soil reservoir is of roughly the same magnitude as the biomass reservoir.

Within these various locations, major forms of nitrogen include organic nitrogen within biomass and inorganic nitrogen such as NH_3/NH_4^+ (ammonia), N_2 (dinitrogen), NO_3^- (nitrate), NO_2^- (nitrite), and N_2O (nitrous oxide). As we saw with carbon in the preceding section, these molecules contain nitrogen in different oxidation states (Table 14.4). In addition, these molecules may or may not be metabolically available to cells.

The nitrogen cycle consists of several key steps (Figure 14.11), each carried out by specific organisms with unique metabolic characteristics. In **nitrogen fixation**, or N_2 fixation, atmospheric N_2 is reduced to NH_3. Some of the NH_3 becomes incorporated into biomass through assimilation, whereas some of it is oxidized in a process called **nitrification** into nitrite (NO_2^-) and then nitrate (NO_3^-). Nitrate can be directly assimilated by plants and a number of microorganisms, thus becoming incorporated into biomass, or it can be converted back to N_2 in a process called **denitrification**. In this section, we will look more closely at the processes of N_2 fixation, nitrification, and denitrification. The nitrogen cycle has a couple of other pathways, including the pathway highlighted in our chapter opening story, that we will also consider. Finally, we will examine the effects of human activities on nitrogen cycling.

TABLE 14.4 Oxidation states of nitrogen

Oxidation state	Typical compounds
+5	HNO_3, NO_3^-
+4	NO_2, N_2O_4
+3	HNO_2, NO_2^-, NO^+, NCl_3
+2	NO
+1	N_2O, $H_2N_2O_2$, $N_2O_2^{2-}$, $NHCl_2$
0	N_2
$-\frac{1}{3}$	HN_3, N_3^-
−1	NH_3OH^+, NH_2OH, NH_2Cl
−2	$N_2H_5^+$, N_2H_4
−3	NH_3/NH_4^+

Nitrogen fixation

As we noted previously, N_2 composes approximately 79 percent of the atmosphere. Yet the vast majority of living organisms cannot use N_2 directly in their biochemical reactions. Rather, they depend on a select group of microorganisms that can convert N_2 into a more biologically

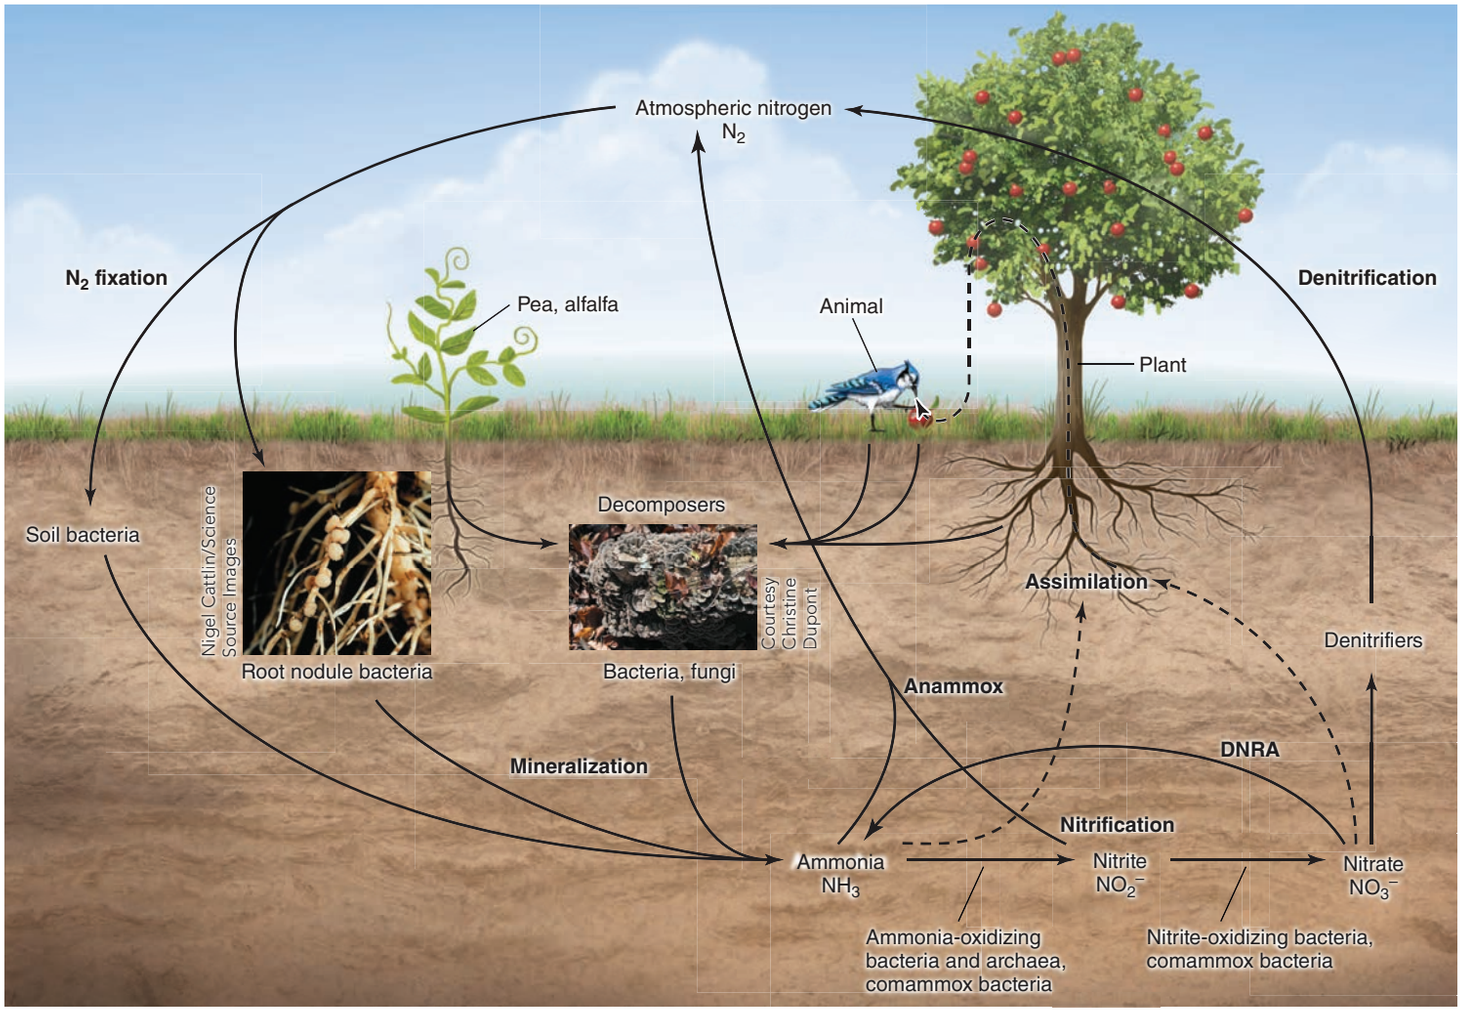

Figure 14.11. The biotic nitrogen cycle Major steps in the nitrogen cycle controlled by living organisms are depicted, including N_2 fixation, mineralization, nitrification, denitrification, anaerobic ammonium oxidation, and dissimilatory nitrate reduction to ammonium (DNRA). Each of these steps is carried out by organisms with characteristic metabolic properties.

useful form through the actions of an enzyme complex called the **nitrogenase complex**. Currently, all known N_2-fixing microorganisms are either bacteria or archaea, and the nitrogen-fixation genes are highly conserved (see Section 13.7). Despite the conservation of the N_2-fixation system itself, the N_2 fixers exhibit incredible diversity, both physiologically and phylogenetically. They may be free-living or they may live in symbiotic relationships with plants, most notably legumes (see Section 17.2). Some of them are aerobes, whereas others are anaerobes. They may be phototrophs or chemotrophs, either heterotrophic or autotrophic. They may be terrestrial or aquatic. In all cases, O_2 inactivates the nitrogenase enzymes irreversibly. This is because O_2 acts as an electron acceptor, removing electrons from the metal-sulfur reaction center of the complex. As a result, N_2-fixing microorganisms have evolved strategies to deal with this limitation. As discussed in Table 14.4, these strategies include the limitation of N_2 fixation to anoxic conditions, the formation of specialized cells such as heterocysts in cyanobacteria, that physically separate oxygenic photosynthesis from the N_2-fixation reaction, and the formation of plant root nodules that protect the bacteria from the harmful effects of O_2.

CONNECTIONS In **Section 17.2**, we will take a look at the use of symbiotic N_2-fixation bacteria with legume crop plants as a major part of the agricultural inoculant industry.

Nitrification, denitrification, anammox, and dissimilatory reduction of nitrate to ammonium

Following the conversion of N_2 to NH_3 by N_2 fixers, nitrification can occur. In this two-step process, NH_3 is oxidized to NO_2^-, which is then oxidized to NO_3^-. Both steps are

chemolithoautotrophic processes, usually carried out by different sets of well-studied bacteria. Collectively, aerobic ammonia and nitrite oxidizers are called **nitrifiers**. Ammonia oxidizers, such as members of the betaproteobacterial *Nitrosomonas* and gammaproteobacterial *Nitrosococcus* genera, are nitrifiers that convert NH_3 to NO_2^-, as shown in the equation above. Two enzymes are involved in this process. First, ammonia monooxygenase (AMO), a three-subunit enzyme evolutionarily related to pMMO, catalyzes the oxidation of NH_3 to hydroxylamine (NH_2OH). Hydroxylamine is then oxidized to NO_2^- by the heme-containing enzyme hydroxylamine oxidoreductase. As we will see in the **Mini-Paper**, some archaea also serve as ammonia oxidizers. In fact, these less-well-studied archaeal ammonia oxidizers are likely more important than their bacterial counterparts for oxidizing NH_3 in most terrestrial and aquatic environments.

Other nitrifiers, such as the alphaproteobacterial *Nitrobacter winogradskyi* **(Microbes in Focus 14.3)**, carry out nitrite oxidation, the second step of nitrification. The key enzyme in this process is nitrite oxidoreductase (NOR), located on the inner face of the cytoplasmic membrane. Although most characterized nitrifiers oxidize either NH_3 to NO_2^- or NO_2^- to NO_3^-, populations of *Candidatus* Nitrospira inopinata ("inopinata" means *unexpected* in Latin) are capable of complete ammonia oxidation (**comammox**), from NH_3 through to NO_3^-, with NO_2^- as an intermediate.

Nitrifiers are widespread in the environment. In particular, nitrifiers become particularly abundant in oxic environments that contain high ammonia concentrations such as agricultural fields to which ammonia fertilizer has been applied, wastewater treatment systems, and aquariums. Nitrifiers are particularly important in wastewater treatment systems for nitrogen removal. In these engineered systems, the produced nitrate may then be processed by denitrifiers, resulting in N_2 that returns to the atmosphere.

The process of denitrification completes the nitrogen cycle, causing nitrogen to be lost from a habitat. The ability to carry out denitrification is widespread within the *Bacteria* and, as we saw in Chapter 13, is usually a heterotrophic process in which an organic substrate is oxidized with nitrate as a terminal electron acceptor under anoxic conditions. Dinitrogen is eventually formed through a series of reduction steps that are carried out by reductase enzymes:

$$NO_3^- \rightarrow NO_2^- \rightarrow NO \rightarrow N_2O \rightarrow N_2$$

The key enzymes in this process are the corresponding reductase enzymes for each step, that is, nitrate reductase, nitrite reductase, nitric oxide reductase, and nitrous oxide reductase.

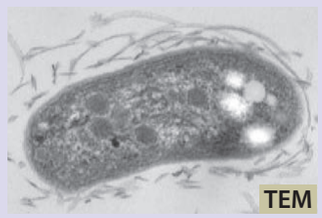
Although removing nitrogen from wastewater and surface waters by denitrification is considered beneficial because it reduces the accumulation of oxygen-depleting microbial biomass in these waters, high denitrification activities in agricultural fields can reduce the effectiveness of nitrogen fertilizer applications. Denitrification can be minimized by ensuring adequate soil aeration, thus preventing anoxic conditions. Another approach to limiting denitrification is to use nitrapyrin [2-chloro-6-(trichlormethyl) pyridine], an inhibitor of ammonia oxidation. Application of this chemical to soils can prevent the production of substrate for denitrification, resulting in more of the applied nitrogen remaining in the soil and available to plants.

Microbes in Focus 14.3
NITROBACTER WINOGRADSKYI

Habitat: Originally isolated by the great pioneering microbial ecologist Sergei Winogradsky in 1892. Widely distributed in the environment due to its diverse metabolic capabilities

Description: Alphaproteobacterial microbe. Short, rod-shaped cells. Divides by asymmetric polar budding. Contains intracellular polyhydroxybutyrate (PHB) granules and microcompartments, called carboxysomes, where CO_2 fixation takes place

Key Features: *N. winogradskyi* can grow chemolithoautotrophically, obtaining energy for CO_2 fixation by oxidizing nitrite to nitrate, using the nitrite reductase enzyme located within extensive intracellular membranes. It can also grow as a chemoorganoheterotroph, and anaerobically use nitrate as a terminal electron acceptor. Researchers are interested in this organism because of its key role in the nitrogen cycle, its potential for removing harmful nitrogen compounds from aquatic habitats, and the generation of the potent greenhouse gases, nitric oxide (NO) and nitrous oxide (N_2O). The 3.4-Mbp genome encodes 3,143 predicted proteins.



Courtesy William J. Hickey

CONNECTIONS **In Section 16.5**, we will examine the use of nitrification and denitrification and how both processes are typically required for complete conversion of dissolved nitrogen to N_2 during wastewater treatment.

For many years, denitrification was thought to be the dominant nitrogen sink for marine nitrogen. In other words, the loss of nitrogen from the ocean, in the form of N_2 gas, was attributed to denitrification. However, research described in the opening story and the Rest of the Story helped reveal the importance of anaerobic oxidation of ammonium (anammox) as an additional sink for marine nitrogen. All known anammox bacteria are phylogenetically distinct within the *Planctomycetes* phylum, falling within five *Candidatus* genera: *Brocadia, Kuenenia, Anammoxoglobus, Jettenia*, and *Scalindua*. In the marine environment, *C.* Scalindua dominates. The overall anammox reaction is:

$$NH_4^+ + NO_2^- \rightarrow N_2 + 2H_2O$$

Attesting to the global importance of anammox, this process is thought to account for nearly half of all N loss from the marine environment alone, with denitrification associated with the balance. Why does it matter whether anammox or

denitrification dominates in a given location at a specific time? It matters because of the fundamentally different metabolisms of denitrifiers and anammox bacteria. We discussed earlier how denitrifiers are chemoorganoheterotrophs, coupling oxidation of organic carbon to sequential reduction of nitrate to N_2 gas. In contrast, anammox bacteria are obligate chemolithoautotrophs. You'll notice how these differences are enormously important for the abundance of greenhouse gases. Denitrifiers produce N_2O and CO_2, whereas anammox bacteria produce neither; in fact, anammox bacteria consume CO_2! For this reason, climate modelers seek information from microbiologists to better understand the distributions and controls on anammox bacteria and denitrifiers, improving models to gain a better understand of future impacts of these bacteria on global biogeochemistry. In addition, nitrogen exists in very low abundance in much of the ocean, which limits marine productivity. As a result, anammox and denitrification activities impact marine life profoundly.

Although we have discussed how ammonia can be oxidized and eventually lost from a system through various microbial processes, you will notice another pathway in Figure 14.11 that must be discussed: dissimilatory reduction of nitrate to ammonium, or DNRA. The first step of the DNRA pathway is the same as for denitrification, with nitrate reduced to nitrite by nitrate reductase. The subsequent step is very different. In a variety of fermentative chemoorganoheterotrophs, and even some chemolithoautotrophic bacteria, nitrite is further reduced directly to ammonium, without any intermediates, by a pentaheme cytochrome *c* nitrite reductase. The DNRA pathway has been linked to bacteria in the *Proteobacteria, Planctomycetes, Bacteroidetes,* and *Firmicutes*, demonstrating a broad phylogenetic distribution for this pathway. The lack of intermediates indicates that the greenhouse gas N_2O is not produced by this pathway. Both denitrification and DNRA compete for nitrate and organic carbon in anoxic environments; multiple ecological, temporal, and chemical factors contribute to determining which pathway will dominate at any given time.

Human impact on the nitrogen cycle

Just as with the carbon cycle, very large changes in the nitrogen cycle have occurred in a very short time, primarily due to human activities such as burning of fossil fuels and the use of synthetic fertilizers. One of the major advances in modern agriculture that has enabled food production to keep pace with human population growth has been the development of the **Haber–Bosch process** for the industrial production of synthetic nitrogen fertilizer (Figure 14.12). This process relies on a series of chemical reactions that extract H_2 from natural gas, which is mostly CH_4, so that it can be combined with N_2 under high temperature and pressure to form ammonia (NH_3).

Incredibly, fertilizer production now accounts for a major portion of all biologically available nitrogen (Figure 14.13). Burning of fossil fuels also affects the nitrogen cycle, resulting in formation of large amounts of N_2O, a potent greenhouse gas. As we will see in Chapter 15, where we discuss the aquatic dead zones that are becoming increasingly widespread on a global basis, the input of large amounts of biologically available nitrogen into the biosphere can change the nutrient balance with drastic consequences for ecosystems whose productivity we depend on to provide our food. It is the biochemical activities of the microorganisms that keep the biogeochemical cycles running efficiently, even in the face of massive influences from human activities.

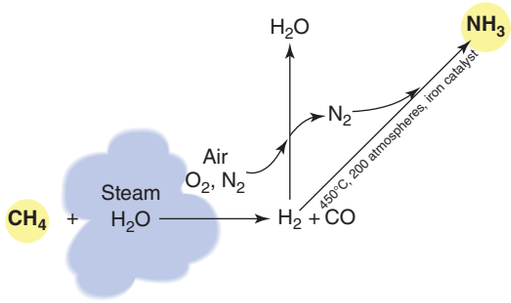


Figure 14.12. Industrial synthetic nitrogen fertilizer production The production of synthetic nitrogen fertilizer was a major stimulus for advances in agricultural productivity in the past half century. The Haber–Bosch process uses CH_4 to generate hydrogen, which is then reacted with N_2 and an iron catalyst at high temperature under high pressure, yielding NH_3.

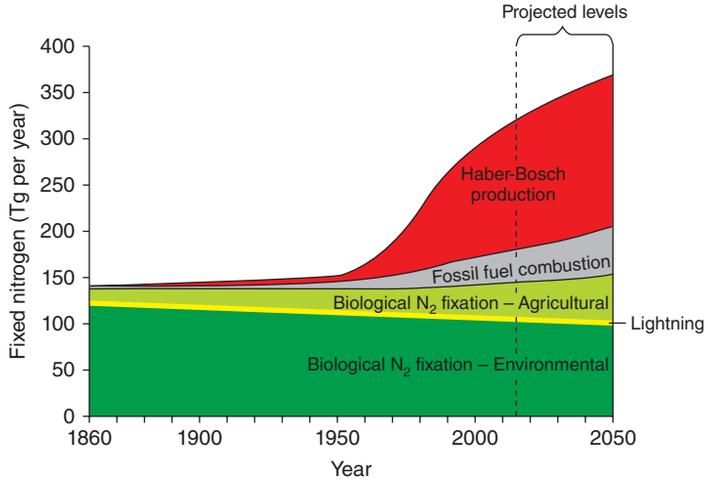
14.3 Fact Check

1. In what major forms can nitrogen be found on Earth?
2. Describe each of the following three processes and explain how they are part of the nitrogen cycle: nitrogen fixation, nitrification, denitrification.
3. Explain the steps of the ammonia oxidation process.
4. Where would you sample to find anammox bacteria? How would you grow them?
5. What is the Haber–Bosch process, and how is it used?



From R. W. Nielsen. 2005. *Can we feed the world?*

Figure 14.13. Impact of synthetic nitrogen production Comparison of the sources of fixed nitrogen indicates that production of ammonia by the Haber–Bosch process is responsible for the largest input of biologically available nitrogen worldwide. It is increasing at a tremendous rate, challenging the total amounts of nitrogen fixation by all biological processes. The production of the greenhouse gas N_2O through the burning of fossil fuels is also increasing rapidly.

Mini-Paper: A Focus on the Research
THE FIRST ISOLATION AND CULTIVATION OF A MARINE ARCHAEON

M. Könneke, A. E. Bernhard, J. R. de la Torre, C. B. Walker, J. B. Waterbury, and D. A. Stahl. 2005. Isolation of an autotrophic ammonia-oxidizing marine archaeon. Nature 437:543–546.

Context

In the opening story of Chapter 15, we will revisit the remarkable discovery of the marine *Crenarchaeota* in the early 1990s. These organisms are now recognized as dominant members of microbial communities within cold ocean waters, accounting for up to 40 percent of the microbial community in the deep ocean, and are widely distributed throughout the diverse habitats on Earth. Through small subunit (SSU) rRNA gene sequence surveys, microbiologists estimated that these organisms comprise approximately 20 percent of all microorganisms in the Earth's oceans. Once we realized that these marine organisms were so abundant, numerous questions arose. What are the physiological characteristics of these organisms? How do they affect biogeochemical cycles? Are they autotrophic or heterotrophic? Despite their global importance, these non-thermophilic *Crenarchaeota* (now reclassified as *Thaumarchaeota*) had never before been isolated in pure culture. This prevented important research into their physiology.

Because SSU sequences of the *Crenarchaeota* were commonly found in nitrifying environments, such as estuary sediments and aquariums, researchers hypothesized that they are involved in nitrification. Indeed, marine metagenomic studies revealed the presence of sequences for *amoA* genes encoding one subunit of the key nitrification enzyme ammonia monooxygenase in archaeal DNA. Could members of the marine *Crenarchaeota* be driving nitrification in the oceans by carrying out the first step, ammonia oxidation? To address this question, and to properly study the physiology of these organisms, researchers needed pure cultures for examination and experimentation. In this paper, members of David Stahl's group at the University of Washington in Seattle describe their successful efforts to cultivate these marine archaea.

Experiment

Starting with the hypothesis that the organisms were capable of ammonia oxidation, investigators developed enrichment growth media by taking Seattle Aquarium water, filtering it to remove existing cells, and supplementing it with 1 mM NH_4Cl. This medium was then inoculated with gravel from a tropical marine aquarium in which crenarchaeotal sequences had previously been detected. The resulting cultures were incubated in the dark, and subcultures were repeatedly made into fresh growth media. After six months, examination of SSU rRNA gene sequences indicated that the resulting enrichment cultures contained approximately 90 percent *Crenarchaeota*, and they were able to oxidize ammonia to nitrite. These cultures were then used to inoculate defined medium that contained bicarbonate and ammonia as sole carbon and energy sources. Through a series of dilutions, a pure culture was obtained, and it was designated *Nitrosopumilus maritimus* strain SCM1. The purity of this culture was supported by the lack of detectable bacterial SSU rRNA gene sequences, and the inability to promote heterotrophic growth by adding yeast extract and peptone. PCR amplification of the SSU rRNA gene sequences, followed by sequence analysis, confirmed the purity of the population. A comparison to other known crenarchaeotal sequences indicated high similarity with other marine *Crenarchaeota*, less similarity with the soil *Crenarchaeota*, and even less with thermophilic *Crenarchaeota*.

Electron microscopic examination indicated that the cells were uniformly straight rods, $0.17 - 0.22\,\mu$m in width, $0.5 - 0.9\,\mu$m in length **(Figure B14.6)**. The maximum density obtained by the cultures was 1.4×10^7 cells per mL, with a minimum generation time of 21 h, and the addition of organic compounds apparently inhibited growth. The growth of the cultures was accompanied by reduction in NH_4^+ concentration and increase in NO_2^- concentration, indicating conversion of NH_4^+ to NO_2^- **(Figure B14.7)**. PCR was used to amplify AMO-encoding genes, and subsequent sequence analysis confirmed that the genes were very similar to other crenarchaeotal sequences and of low similarity to the bacterial AMO-encoding genes.

14.4 Other cycles and their connections

How are various biogeochemical cycles connected?

Although individual biogeochemical cycles are presented separately for clarity, we should reinforce that these cycles are interconnected. For instance, consider how aerobic respiration results in the release of carbon dioxide (CO_2) from organic compounds like glucose ($C_6H_{12}O_6$), while also reducing oxygen (O_2) to water (H_2O). Or consider how the production of new organic material during photosynthesis by algae or cyanobacteria involves the formation of O_2 from H_2O. These complementary reactions of respiration and photosynthesis involve cycling of carbon, oxygen, and hydrogen. Moreover, these same photosynthetic organisms assimilate CO_2 as a carbon source, and some of the cyanobacteria can fix dinitrogen (N_2) into their biomass. This means that each individual microorganism catalyzes reactions that impact several biogeochemical

Figure B14.7. Conversion of ammonia to nitrite by *Nitrosopumilus maritimus* strain SCM1 The culture was grown with ammonium chloride as sole energy source and bicarbonate as sole carbon source. Growth was followed by microscopic detection of cells stained with the fluorescent dye DAPI (4′, 6-diamidino-2-phenylindole). Consumption of ammonia was balanced by nitrite production.

Impact

Nitrosopumilus maritimus strain SCM1 is the first known chemolithoautotrophic nitrifier in the domain *Archaea* and the first mesophilic crenarchaeotal isolate. Prior to this work, known nitrifying organisms belonged solely to the *Betaproteobacteria* and *Gammaproteobacteria*. The significance of the NH_4^+-dependent chemolithoautotrophic growth is that a large amount of primary production in the oceans is carried out by ammonia oxidation in oligotrophic environments, without sunlight or organic sources of energy, and that ammonia oxidation maintains the concentration of ammonia at low levels. These organisms are therefore key players in the cycling of both carbon and nitrogen and help control the primary production within the marine environment. The ability to work with pure cultures opened the door to detailed genetic, genomic, biochemical, and physiological studies of these environmentally important organisms.

Questions for Discussion

1. After reading this paper, what do you think are the main characteristics of the marine *Crenarchaeota* that have contributed to their difficulty in cultivation?
2. The isolation of *N. maritimus* strain SCM1 in pure culture confirms that at least some of the non-thermophilic *Crenarchaeota* are chemolithoautotrophic organisms. Do you think that they are all chemolithoautotrophs, or might some of them be other metabolic types?
3. Since *N. maritimus* strain SCM1 was isolated from an aquarium, rather than from a natural environment, are you concerned that it might not be representative of the abundant oceanic *Crenarchaeota*? How did the authors of the paper address this concern?

cycles through their basic metabolism. In other words, when considering a world without microbes **(Perspective 14.2)**, removing even one group of bacteria would have widespread and unforeseen impacts on several other cycles and processes. We will revisit the way microbial communities and the processes they catalyze fit together within the context of microbial ecosystems in Chapter 15.

In this section, we will explore the interconnectedness of cycles more fully within the context of additional biogeochemical cycles. First, we will look at the oxygen cycle, then we will examine the cycling of phosphorous and sulfur, and finally we will look briefly at iron, manganese, and mercury cycles.

Cycling of oxygen

Actively cycled reservoirs of oxygen include atmospheric and dissolved O_2, which is produced via photosynthesis and is the terminal electron acceptor used in aerobic respiration. These reservoirs also include CO_2 produced via respiration and decomposition of organic matter and fixed by autotrophs. Water (H_2O), an end product of many metabolic activities, including respiration, some methanogenic reactions, and aerobic and anaerobic CH_4 oxidation, represents another major source of oxygen. Living and dead biomass constitute yet another reservoir of actively cycled oxygen atoms.

Perspective 14.2
LIFE IN A WORLD WITHOUT MICROBES

In 2014, researchers at the University of Chicago and the University of Waterloo performed a unique thought experiment for the journal *PLoS Biology*. The question they asked was, "If someone were to wave an antimicrobial wand and eliminate all bacterial and archaeal life on the planet, what would happen?"

The authors explored this question at multiple levels, including all life associated with our human body, all bacterial and archaeal life on the planet, then all microbes on the planet, including fungi, protists, and viruses. Beginning with the disappearance of the human microbiome, the impacts on human physiology and psychology are poorly understood for humans living without their microbes. It would be problematic living without the services microbes provide for us, as described in Chapter 17. Although humans could likely survive for a time without our microbiome, especially if we could synthesize or acquire the vitamins we cannot produce ourselves, it is a world without microbial biogeochemistry that would be particularly dire for remaining life on Earth.

Earth's biogeochemical cycles are critical for sustaining most eukaryotic life. In particular, nitrogen would become an immediate problem. Because microbial N_2 fixation accounts for approximately half of all nitrogen used for growing crops and raising livestock, supplying food for humans would become an immediate problem. Removing this single biogeochemical reaction, N_2 fixation, would drastically reduce the human population within a few short years. Non-agricultural plant life would fail to survive long in a microbe-free world, which means that most natural wildlife would perish relatively quickly.

And although nitrogen itself would be critical, other cycles would be impacted as well. Decomposition of dead bodies would cease, and biomass would accumulate without microbial contributions to the carbon cycle. Oxygen production by single-celled marine algae and cyanobacteria would cease. Carbon dioxide production would increase, largely unchecked, affecting the greenhouse gas effect and climate warming. Phosphorous would cease to cycle within living material and accumulate in ocean sediment way out of reach of terrestrial life. And this is only the beginning.

The interconnectedness of biogeochemical cycles are reinforced by asking such "what would happen" questions, and we encourage you to continue the experiment. Ask yourself what would happen without other microbes we covered in this chapter, including fermenting bacteria, methanogens, anammox bacteria, methanotrophs, nitrifiers, and viruses. To demonstrate how others have explored these questions, Tom Curtis of the University of Newcastle once wrote, "I make no apologies for putting microorganisms on a pedestal above all other living things. For if the last blue whale choked to death on the last panda, it would be disastrous but not the end of the world. But if we accidentally poisoned the last two species of ammonia-oxidizers, that would be another matter. It could be happening now and we wouldn't even know. . . ."

Oxygen is also involved in anaerobic respiration. Sulfate-reducing bacteria, for instance, use sulfate (SO_4^{2-}), which contains oxygen, as the terminal electron acceptor in their electron transport chain. This process releases oxygen as CO_2, as well as the rotten-egg-smelling hydrogen sulfide (H_2S) gas, which dissociates in water to the weak acid HS^-. Sulfate minerals are plentiful on Earth, so the oxygen in sulfate cycles through the biosphere relatively slowly. The utilization of nitrate (NO_3^-) as a terminal electron acceptor results in the production of nitrite (NO_2^-). Compared to sulfate, nitrate is a small and rapidly cycled oxygen reservoir. Connections can be made between the various cycles: carbon and oxygen, carbon and nitrogen, oxygen and nitrogen, and sulfur and oxygen, to name just a few. Sometimes, human activity also plays a role in the interactions of these cycles, as seen in **Perspective 14.3**. These interconnections should be expected. They occur in a shared biosphere and involve organisms with extensive histories of coevolution.

Cycling of phosphorous and sulfur

Although carbon, nitrogen, and oxygen represent three abundant elements in biomass, sulfur and phosphorus also represent crucial elements in all cells. Unsurprisingly, some microorganisms actively acquire these elements from inorganic sources, whereas others aid in the return of these elements from organic stores to the environment. As we saw for carbon, nitrogen, and oxygen, microorganisms play an active role in the cycling of sulfur and phosphorus. As we have also seen while examining the oxygen cycle, these cycles are interconnected in many ways.

Unlike carbon, nitrogen, and oxygen, very little phosphorus or sulfur exists in the atmosphere. Instead, the major reserves of these elements exist in rock or are dissolved in the oceans. Weathering of rocks can release phosphate ions (PO_4^{3-}, HPO_4^{2-}, $H_2PO_4^{1-}$, or H_3PO_4, depending on the pH of the environment) from phosphorus-containing minerals like apatite. In the absence of biological activity, these phosphate ions will be transported to the oceans, eventually settle to the ocean floor, and become part of newly formed rock, thereby completing the cycle. This entire process—from mineralized phosphorus to soluble phosphate to mineralized phosphorus—takes millions of years.

Along the journey, phosphorus can cycle between living organisms over and over again. As we have seen in earlier chapters, phosphorous is an essential element for cells, existing in DNA, RNA, ATP, and a host of other molecules. How do cells acquire this essential element? Phosphate ions released from rocks into the soil and water can be taken up by plants. Once incorporated into organic molecules, phosphorus can be transferred between organisms by processes of ingestion and decay.

The normal concentration of usable phosphate in the soil is typically quite low. To counteract this paucity of usable

Perspective 14.3
THE MICROBIOLOGY OF ENVIRONMENTALLY TOXIC ACID MINE DRAINAGE

A natural phenomenon that occurs worldwide is the oxidation of the abundant mineral pyrite, FeS_2, yielding sulfuric acid. This process occurs following exposure of pyrite to oxygen and water. As you can imagine, this reaction causes a drastic reduction in the pH of the water, which becomes stained orange as a result of the iron hydroxide that forms. What can live in these acidic aqueous habitats? Microorganisms can! In fact, microorganisms contribute to the acidification process. In the absence of sources of fixed carbon, acidophilic autotrophic iron-oxidizing bacteria, such as *Thiobacillus* and *Leptospirillum*, and the archaeon *Ferroplasma*, use Fe^{2+} as the electron donor in their efforts to obtain energy. The resulting Fe^{3+} contributes to the further oxidation of pyrite, releasing even greater amounts of sulfuric acid. Because these microorganisms are acid loving, they thrive in this environment, often forming thick biofilms.

Pyrite oxidation and the resulting acidification have been exacerbated by mining activities that expose previously buried pyrite to water and oxygen. Referred to as acid mine drainage, or AMD, the acidic water flowing from these mines also results in the leaching of heavy metals such as zinc, copper, cadmium, and arsenic from the surrounding rocks. The combined toxicity of the acidification and increased heavy metal concentrations can be severe. Contamination of adjacent waterways can decimate non-microbial life, and also poses threats to sources of drinking water. The AMD conditions can remain long after the mines are abandoned, a nasty legacy of civilization's extraction of metals from the ground.

Courtesy Brett Baker, University of California, Berkeley

Figure B14.8. Collection of biofilm samples Metagenomic studies found five types of iron-oxidizing bacteria at Iron Mountain Mine and one group that can fix nitrogen.

The microbiology of AMD from one abandoned mine, the Iron Mountain Mine near Redding, California, has been studied intensively. Iron Mountain was active from the 1860s until the early 1960s, being mined for iron, silver, gold, copper, and zinc. A half century after the mine closed, AMD still threatens the sources of drinking water for the surrounding human populations. The pH of some samples has been recorded to be an astounding −3.6! In the dark depths of the mine, pink biofilms growing in green pools of highly acidic water were studied in one of the first applications of microbial community sequencing **(Figure B14.8)**. This study was carried out by Gene Tyson, then a graduate student in Jillian Banfield's lab at the University of California, Berkeley, and involved a number of collaborators.

By applying the random shotgun-sequencing method (see Chapter 10) to samples collected in 2000, Tyson and colleagues demonstrated that the community was relatively simple, consisting mostly of five types of known iron-oxidizing bacteria, *Leptospirillum ferriphilum* (Group II), *Leptospirillum* Group III, *Sulfobacillus, Ferroplasma* Type I, *Ferroplasma* Type II, and traces of eukaryal sequences. The dominant bacterium was *Leptospirillum ferriphilum* (Group II). They even regenerated near complete genome sequences for two of the organisms, *Leptospirillum ferriphilum* (Group II) and *Ferroplasma* Type II, and mapped out their metabolic processes based on those sequences. They confirmed that both organisms had the genetic capacity for carbon fixation, but not for nitrogen fixation.

Nitrogen fixation is essential to AMD biofilm communities; no source of fixed nitrogen exists in these acidic habitats. Neither *Leptospirillum ferriphilum* (Group II) nor *Ferroplasma* Type II have genes for N_2 fixation, but N_2-fixation genes were found in sequences associated with *Leptospirillum* Group III. This observation led to further studies in which *Leptospirillum* Group III was successfully isolated in pure culture based on knowledge of its likely metabolic characteristics. It is likely to be an essential member of these biofilms, providing the other biofilm microorganisms with a source of fixed nitrogen.

Today, AMD sites remain a serious environmental concern. Understanding of microorganism-controlled biogeochemistry is essential for cleanup of these toxic sites, and also for prevention of their formation in the first place. They are also fascinating examples of the connections between the biogeochemical cycles.

phosphate, farmers often apply large amounts of phosphate-containing fertilizers to their fields, thereby increasing the growth of their crops. Evidence suggests that bacteria may be able to aid in this process. Some strains from several genera of bacteria, including *Pseudomonas, Bacillus,* and *Rhizobium,* have the ability to solubilize inorganic phosphate compounds. Moreover, these same bacteria can improve the growth of plants, representing a type of natural fertilizer. Their use could decrease our need to produce usable phosphate from natural stores.

In some ways, the sulfur cycle resembles the phosphorus cycle. Very little sulfur exists in the atmosphere. In the absence of biological cycling, sulfur leaves rocks via weathering and travels to the ocean, where it exists primarily as SO_4^{2-}. Volcanoes and other geothermal features release other forms of sulfur, most notably sulfur dioxide (SO_2) and H_2S into the atmosphere **(Figure 14.14)**. Marine algae also contribute to atmospheric sulfur. Algae accumulate osmolytes in the form of dimethylsulfoniopropionate (DMSP), which degrades to dimethylsulfide

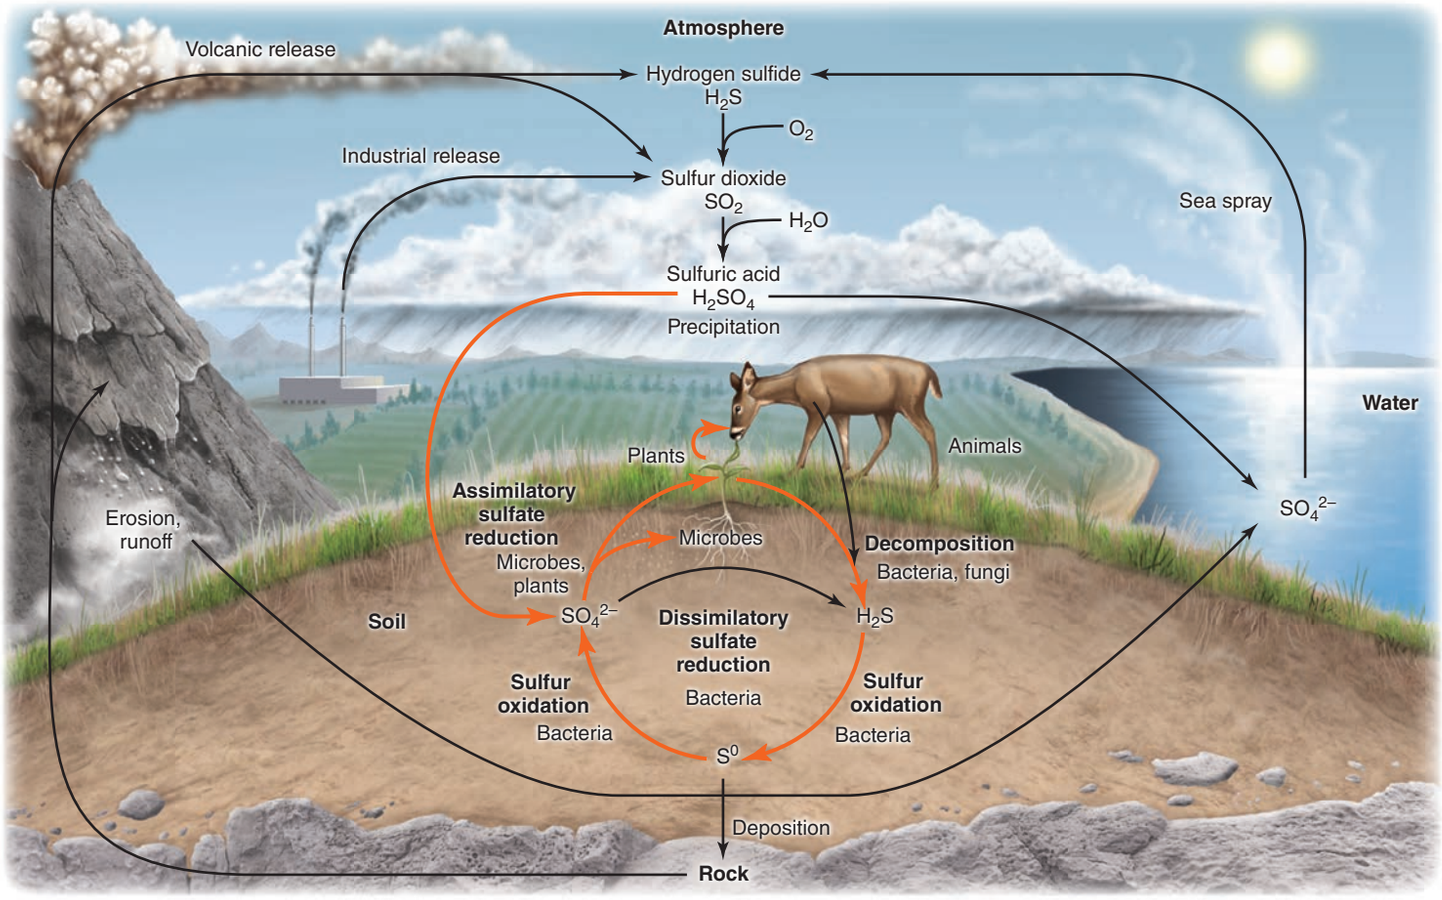

Figure 14.14. The sulfur cycle Microbes play central roles in the biotic parts of the sulfur cycle.

(DMS) through microbial metabolism. Produced DMS aerosolizes to the atmosphere where, along with other forms of sulfur, it can react quickly with O_2 and H_2O and return to Earth through precipitation. Note that this atmospheric interaction of sulfur in the atmosphere increases cloud cover, which has the net effect of cooling the planet by reflecting more solar radiation (see Perspective 14.1).

Plants and microorganisms can assimilate some of these sulfur-containing products. Additionally, microorganisms can use molecules like H_2S or SO_4^{2-} as a source of electrons or as an electron acceptor, respectively. Other sulfur compounds, such as elemental sulfur (S_0), can be used as an electron acceptor, donor, or both, depending on the organism and situation. For example, anoxygenic photosynthetic bacteria such as the purple non-sulfur bacteria (*Rhodomicrobium* of the *Alphaproteobacteria* and *Rhodoferax* of the *Betaproteobacteria*), the purple sulfur bacteria (e.g., *Chromatium* of the *Gammaproteobacteria*), and the green sulfur bacteria (*Chlorobium* of the *Chlorobi*), use H_2S as a source of electrons, producing S^0 and SO_4^{2-} through this process. The S_0 is often stored in periplasm or externally, and can be seen as globules through a microscope. See Figure 2.5 for an example of these globules in *Thiomargarita namibiensis*, which is the largest known bacterium.

Like several other giant sulfur bacteria, *T. namibiensis* uses sulfur as an electron donor and nitrate as an electron acceptor. However, sulfide and nitrate are usually not found in high concentration together. As a result, these bacteria must move physically between their sources of electrons donors and acceptors. Some giant sulfur bacteria (e.g., *Thioploca*) collect nitrate in large vacuoles (accounting for their large size!) and then move vertically through sediment within sheathes to their electron donors where they can then "breathe." In contrast, *T. namibiensis* seems to rely on sediment disruptions to move physically between its donors and acceptors. Recently, a new type of bacteria was discovered, called "cable bacteria" (*Desulfobulbaceae* of the *Deltaproteobacteria*). These bacteria form very long chains of cells that can span centimeter distances through sediment. They function as electrical wires, with electrons released from H_2S oxidation travelling up the cables to their ultimate electron acceptor, O_2, at the sediment surface! In this way, aerobic cable bacteria use an electron acceptor thought to be largely restricted to anaerobic metabolism.

Sulfate can be used as an electron acceptor for sulfate-reducing bacteria (*Deltaproteobacteria, Firmicutes*, and others, including some *Archaea*), which associate with fermentative bacteria. For the anoxygenic phototrophs, bacteriochlorophylls and carotenoid pigments determine the wavelengths of light that are used for photosynthesis, and these light-harvesting molecules are housed on extensive intracytoplasmic membranes.

The purple and green sulfur bacteria associate with anoxic zones of lakes, as well as in aquatic sediments where H_2S is produced. Because of the widespread and abundant distributions of sulfur-cycling microorganisms, the sulfur cycle and its connections to other biogeochemical cycles can be explored through the use of a Winogradsky column. By following the instructions found in **Toolbox 14.2**, you will see how carbon and

Toolbox 14.2

BIOGEOCHEMISTRY IN A BOTTLE: THE WINOGRADSKY COLUMN

In the 1880s, Sergei Winogradsky (see Chapter 1) invented a simple technique for enriching and visualizing specific phototrophic bacteria involved in the biogeochemistry of sulfur. More than this, the Winogradsky column offers a visual demonstration of the interconnectedness of the sulfur, carbon, nitrogen, and oxygen cycles. Indeed, this small-scale enrichment culture (see Chapter 15) represents one of the most valuable tools for teaching biogeochemical cycles, appreciating the connectivity of these cycles, and providing a hands-on visual demonstration of microbiology.

You can prepare a Winogradsky column by placing mud from a swamp or creek in a glass or plastic cylindrical container. When left in a brightly lit location in your house or office, the result is a gradually changing habitat that can be monitored for many years. The development of colors in the Winogradsky column corresponds to the growth of specific microorganisms involved in catalyzing multiple biogeochemical cycles.

The specific procedure for making your own column is straightforward:

1. Find a clear plastic bottle (~500 mL) and cut off the top. Any cylindrical bottle or container will work well—be creative.
2. Collect ~2–3 liters of mud from a marsh, swamp, or stream. Any water-saturated (and preferably stinky!) sediment should work well.
3. Divide the mud in half. To one half, add an egg yolk (crushed from a hard-boiled egg; sulfur source), a teaspoon of baking soda (carbonate), and a handful of shredded newspaper or grass clippings (organic carbon source) for cellulolytic cells. Mix well and remove any stones.
4. Fill 1/3 of the bottle (or a little less) with the amended mud and pack it well. Fill another 1/3 (or a little more) of the bottle with the unamended mud. Fill up most of the remaining space with water taken from the same sampling location.
5. Seal the top with clear film and an elastic band (for a drink bottle) or with a loosely fitted lid. Do not make an air-tight seal.
6. Place in a well-lit area, not necessarily receiving direct sunlight. Colors will form gradually within 1–3 months and will be most impressive after 1–3 years.

Over time, microorganisms initially present in relatively low numbers will proliferate in different sections of the tube **(Figure B14.9)**. Near the top of the tube, in the oxygenated water, cyanobacteria proliferate. Oxygen levels decrease as the distance from the surface increases. In the oxygen-poor regions, green sulfur bacteria and purple sulfur bacteria proliferate. At the bottom of the column, anaerobic sulfate-reducing bacteria thrive along with cellulose degraders and fermentative bacteria. Each of the aerobic and anaerobic phototrophic bacteria have their own distinct color within the tube, providing a visual cue that enrichment of different species has occurred.

With access to a microscope, sample your Winogradsky column. The oxic sediment surface will amaze you with its incredible diversity of oxygenic photosynthetic cyanobacteria, algae, diatoms, protists, rotifers, and countless bacteria of various shapes and sizes. Each organism you see has its own unique metabolism, which impacts multiple biogeochemical cycles. Imagine all of these metabolisms scaled up to the entire column, then to the many global terrestrial and aquatic environments. By doing this, you will begin to appreciate how individual microbial metabolisms can influence Earth's atmosphere over billions of years, eventually enabling the evolution of humans who now study our microbial cousins in Winogradsky columns!

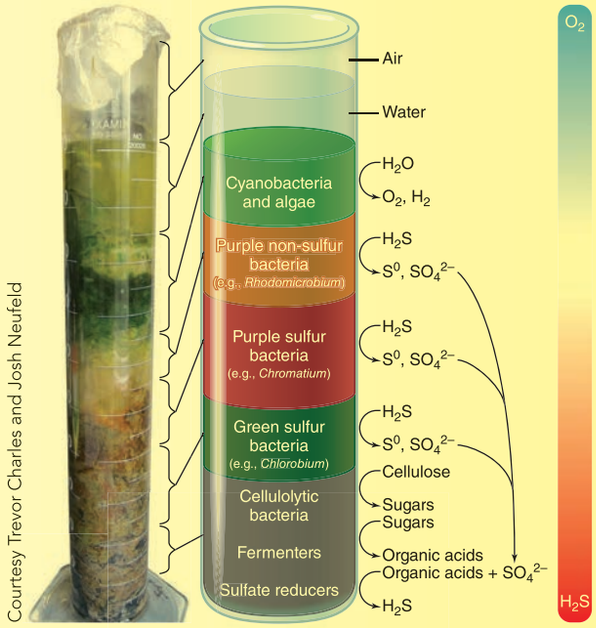

Figure B14.9. A Winogradsky column and its dominant microbial metabolisms Distinct colors develop at different column depths, reflecting the sulfide and oxygen tolerances of different phototrophic bacteria. Green sulfur bacteria prefer the highest sulfide concentrations whereas purple non-sulfur bacteria prefer the lowest sulfur concentrations. The cyanobacteria require oxygen and only grow in the uppermost layers, conducting oxygenic photosynthesis. Note that the black bottom layer results from chemical precipitation of hydrogen sulfide (H_2S, produced by sulfate-reducing bacteria), with iron present in the sediment. The precipitate is ferrous sulfide (FeS), which will slowly disappear through microbial metabolism.

Test Your Understanding

Depending on the source of mud, amendments used, and location of the column, the outcome of a Winogradsky column experiment is unpredictable. Sometimes the purples, reds, and greens are vibrant, other times the coloration can be subtle and difficult to identify. If interested in studying column development, what factors would you vary for each column you prepare and what would you hypothesize as outcomes for these modified conditions?

sulfur cycling results in an interconnected system, with both oxic and anoxic zones, and visual evidence of microorganisms working to manage diverse energy and chemicals. The Winogradsky column is not unique in any way – coordination of biogeochemical cycles is the way in which microorganisms interact every day, and on a global scale, exploiting Earth's elements for energy and nutrition.

Cycling of metals

Metals are distributed in natural environments and can play important roles in biogeochemical cycles. As seen in Perspective 14.1, metal waste resulting from mining activity can result in environmental consequences partly through microbial activity. You also saw how iron present in swamp mud can react chemically with sulfur, forming a black precipitate at the bottom of a Winogradsky column (Toolbox 14.2). We will now look briefly at the iron cycle and then consider aspects of manganese and mercury cycling. Importantly, these cycles are united by these metals serving as oxidants and reductants for microbial metabolism and, in some cases, can be assimilated into cellular components.

The iron cycle involves the oxidation of ferrous iron (Fe^{2+}) to ferric iron (Fe^{3+}), as a source of electrons, or the reduction of Fe^{3+} to Fe^{2+}, using Fe^{3+} as a terminal electron acceptor. In oxic pH-neutral environments, most free iron is oxidized ("rusted") and insoluble. In fact, microorganisms that require iron for incorporation into enzymes or other biomolecules must acquire it through the use of siderophores, which are small organic molecules that bind free iron for transport into the cell. That said, Fe^{2+} can be oxidized in both oxic and anoxic environments. We have already discussed how acidophilic iron oxidizers can act on iron in oxic acid mine drainage conditions (Perspective 14.1), but several *Proteobacteria*, such as *Marinobacter, Leptothrix*, and *Gallionella*, can also oxidize iron at neutral pH. Under anoxic conditions, nitrate can serve as an electron acceptor for iron oxidation by a variety of microorganisms.

Many different bacteria and archaea can use Fe^{3+} as an electron acceptor. These microorganisms include members of *Euryarchaeota, Crenarchaeota*, all classes of *Proteobacteria*, and many others. Why might the ability to "breathe" with Fe^{3+} be so widespread? As discussed in Section 1.2, the origin of life on Earth may have been associated with iron pyrite (FeS_2), including the possibility of primitive membranes forming around fragments of these minerals. As a result, many consider iron to be an important element in early Earth biogeochemistry. Indeed, anoxic lakes can be found today that contain high concentrations of iron and low concentrations of sulfur. These lakes are considered research hot spots, potentially serving as modern day analogues for life during the Archaeon Era.

Like iron, manganese can be oxidized, from Mn^{2+} to Mn^{4+}, and this occurs typically at the interface of oxic and anoxic zones in hydrothermal vents, in well-stratified lakes, and in swamps and bogs. Many microorganisms catalyze this reaction, including *Leptothrix* (also important for iron cycle, see above), using oxygen or nitrate as the electron acceptor. To complete the cycle, several anaerobic chemoorganoheterotrophs, such as *Shewanella*, and *Geobacter*, reduce manganese once again.

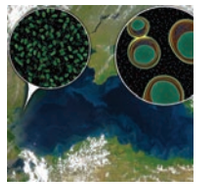
The environmental presence of mercury is largely a result of human industrial activity, which can now be acted upon by microorganisms. Mercury is a good example of a metal that can be methylated. Inorganic mercury contamination found in sediments can be methylated by anaerobic sulfate-reducing bacteria such as *Desulfovibrio*. In this way, the sulfur cycle overlaps with the mercury cycle. The danger of this process is that methylated mercury can be solubilized into animal biomass, finding its way up the food chain, eventually into humans. This further demonstrates the connectivity of biogeochemical cycles and the importance of understanding microbial metabolism for its potential impacts on humans and on our environment.

14.4 Fact Check

1. How is the cycling of oxygen connected to the cycling of other elements?
2. What is acid mine drainage, and how does it demonstrate the connections between cycles?
3. In what ways do the cycling of S and P differ from the cycling of C, O, and N?
4. What are the challenges of examining cycling of individual elements in isolation? Explain.

Image in Action

WileyPLUS Learning Space In the background is a NASA satellite image of the Black Sea that reveals large, swirling algal blooms. On the right, a zoom-in window shows *Candidatus* Kuenenia stuttgartiensis showing its unusual cell organization containing a typical cell wall (green) and cytoplasmic membrane (yellow), as well as an additional intracytoplasmic membrane (dark orange), which contains the genetic material (blue), and a membrane-bounded compartment called the anammoxosome (teal), where the anammox reaction occurs. Behind the cells, molecules of ammonia, nitrite, and dihydrogen are shown. On the left, cells of *Synechococcus*, a type of N_2-fixing cyanobacteria, are illustrated.



1. If in the laboratory you grew the nitrogen-fixing *Synechococcus* shown in this image, what products would you expect it to generate in your culture? Explain.
2. Imagine you are able to more closely examine the environmental conditions and the metabolism of the *Candidatus* Kuenenia stuttgartiensis shown in this image. What conditions would you expect to be present (and need to provide *in vitro*), and as you begin your examination, what chemical compounds would you hypothesize to find in the anammoxosome?

The Rest of the Story

Interestingly, no microbiologist has yet successfully obtained pure cultures of anammox bacteria in the laboratory. This difficulty is partly a result of their extremely slow growth, with doubling times of about 11 days under ideal laboratory condition, and two to three weeks or longer in their natural habitats. However, we have learned a lot about these bacteria through the use of specialized enrichment culture procedures and molecular approaches to probe their metabolic capabilities. Using these approaches, researchers first determined the complete genome sequence of one anammox bacterium, *Candidatus* Kuenenia stuttgartiensis. This genome sequence was reconstructed from the metagenomic sequence data of the community of an anaerobic laboratory bioreactor where the anammox reaction was taking place and in which this organism composed approximately 75 percent of the cells. This accomplishment has now been repeated multiple times, with genomes similarly available for representatives of other anammox genera including *Candidatus* Brocadia, *Candidatus* Jettenia, and *Candidatus* Scalindua.

These bacteria have proven to be very unusual. In general, members of the *Planctomycetes* do not have a peptidoglycan-containing cell wall and divide by budding rather than by binary fission. Their cytoplasm contains different membrane-enclosed compartments, rather like the membrane-bounded organelles we associate with eukarya. These compartments seem to be devoted to different cellular functions. In the case of the anammox bacteria, anaerobic ammonium oxidation takes place in a compartment called the anammoxosome. An important intermediate of the oxidation reaction is hydrazine, N_2H_4, an extremely toxic component of rocket fuel and a molecule not previously known to be a biological product. Another peculiarity of the anammox bacteria is their possession of ladderane lipids, which are cyclobutane-containing molecules not found in other known organisms. The ladderane lipids consist of a mix of ester- and ether-linked lipids. In other words, these lipids possess bacterial and archaeal characteristics. Researchers who work with the bacteria speculate that this lipid characteristic may reflect the early divergence of these species in the bacterial lineage. Ladderane lipids are difficult to produce synthetically but may have applications in the future. Perhaps one day, the unique properties of anammox bacteria will contribute to biotechnology.

Summary

Section 14.1: How are the nutrients used by cells cycled in the biosphere?

As microbial cells use nutrients, the associated metabolism causes the transformation of molecules. The **biogeochemical cycles** are interconnected due to the interdependence of chemical reactions and transformations during metabolism.

- All biomass is composed of essential or **biogenic elements** in similar proportions.
- Earth can be divided into **reservoirs**, or pools, with elements stored and moving between them.
- The movement of elements between reservoirs, or **flux**, is an important part of cycling, and the cycles have achieved equilibrium over the long-term.
- Human activities threaten to perturb the equilibria that have been established.
- Redox reactions carried out as part of cellular metabolism directly support several of the biogeochemical cycles.
- **Microcosms** and **mesocosms**, which replicate ecosystems under controlled conditions, can be used for experimental study of ecosystems.

Section 14.2: How do microbes influence the cycling of carbon?

- The carbon-based nature of life is reflected in the direct influence of the abundant microbial biomass on the carbon cycle.
- The global carbon cycle maintains a balance between organic and inorganic carbon through the complementary metabolic activities of photosynthesis and respiration and decomposition.
- Human activity has disrupted these cycles, causing an increase in the atmospheric levels of **greenhouse gases**.
- The metabolic activities of photosynthesis, respiration, and decomposition contribute to the short-term cycling of carbon. Organic matter can accumulate if CO_2 fixation exceeds respiration, resulting in a positive **net community productivity**. Fermentation results in the production of partially oxidized organic end products that can serve as nutrients for other organisms.
- CH_4 represents a major biodegradation end product under anoxic conditions.
- **Methanogens** produce CH_4 through a type of metabolism referred to as **methanogenesis**.
- **Hydrogenotrophic methanogens** produce CH_4 from CO_2 and H_2. **Acetotrophic methanogens** produce CH_4 from acetate (CH_3COO^-).
- CH_4 production from biomass often involves a **consortium** of metabolically interdependent microorganisms that form **syntrophic partnerships**.
- In some anoxic environments, inorganic electron acceptors other than CO_2 may be used by microorganisms.
- CH_4 can be efficiently oxidized by **methanotrophs**, a subgroup of the **methylotrophs**, under oxic conditions.
- **Anaerobic oxidation of methane (AOM)** is now recognized as an important part of the global carbon cycle, even though the responsible archaeal organisms—**anaerobic methane oxidizers (ANME)**—are only known by DNA sequence and have not yet been cultured.
- Other elemental cycles linked to the carbon cycle include oxygen, sulfur, and nitrogen.

Section 14.3: How do microbes influence the cycling of nitrogen?

Each of the key steps in the nitrogen cycle involves transformations mediated by or influenced by microbial metabolism.

- The atmosphere, made up of almost 80 percent N as dinitrogen gas, is by far the largest reservoir of nitrogen.
- **Nitrogen fixation**, carried out only by certain bacteria and archaea, is essential for converting atmospheric dinitrogen to forms in which it can be incorporated into biomass.
- The nitrogen-fixation process is O_2 sensitive due to irreversible activation of the **nitrogenase complex** by O_2.
- **Nitrification**, the conversion of ammonia to nitrite and then nitrate, is carried out by the sequential activities of **nitrifiers**, which include ammonia and nitrite oxidizers.
- **Denitrification** involves the conversion of nitrate to dinitrogen gas through a series of reduction steps carried out by reductase enzymes during anaerobic respiration.
- Synthetic nitrogen fertilizer, often produced via the **Haber–Bosch process**, now represents a major source of biologically available nitrogen on Earth, and although microorganisms are able to keep the nitrogen cycle running, the changes in nutrient balance can sometimes have adverse effects on ecosystems.

Section 14.4: How are various biogeochemical cycles connected?

By briefly examining the cycling of oxygen, phosphorus, and sulfur, we can see that all biogeochemical cycles are interconnected.

- Major forms of oxygen within Earth's reservoirs include O_2, CO_2, and H_2O. All of these molecules are involved in photosynthesis and aerobic respiration.
- Acid mine drainage leads to the oxidation of FeS_2, yielding sulfuric acid.
- Sulfur and phosphorus cycle mainly through terrestrial and marine reservoirs.
- Microorganisms aid in making sulfur and phosphorus available to living organisms.
- Metals such as iron, manganese, and mercury can serve as electron donors and acceptors for microbial metabolism.

Application Questions

1. Imagine that you present information on the carbon cycle to a class of eighth graders. Explain how CO_2 in the atmosphere is connected to CO_2 in the oceans and the role this connection plays on Earth.
2. When studying and calculating global carbon cycling, scientists find a "missing sink" that doesn't allow their equations to balance. Some researchers theorize that uncultivated or uncharacterized microbes might explain this phenomenon. Explain what this means.
3. What role does plant and animal respiration play as a "natural" way of providing CO_2 to the atmosphere? Describe an "unnatural" way of adding CO_2 to the atmosphere.
4. A biogeochemist graduate student wants to study methanogens in more detail. Based on the conditions needed to support methanogenesis, what habitats would be best for collecting samples? Explain why.
5. Your new research advisor studies interspecies hydrogen transfer in a biofilm community. Describe what she is studying and what is occurring in the biofilm.
6. A high school student hopes to do a research project to survey a site for the presence of methanogens using a molecular tool. As a mentor for the student, explain what gene or genes the student could use for this molecular survey.
7. Why do some farmers inoculate their soil with nitrogen-fixing bacteria when planting their crops?
8. At a tour of your local wastewater treatment facility, you learn that they use different microorganisms at various stages of the treatment process. You hear that at one stage they use nitrifiers. Why might they be using nitrifiers, and what would the nitrifiers do in the treatment process?
9. You learn in a soil ecology class that a chemical is often added in agriculture to inhibit ammonia oxidation. What does this chemical do, and why might it be useful for the soil and the crops?
10. You recently read about the cultivation of crenarchaeotal nitrifiers from the Seattle Aquarium, and you suspect that the nitrifiers in your tropical fish tank are archaea rather than bacteria.
    a. What would you need to look for to determine if the microorganisms were nitrifiers and were indeed archaea?
    b. What lab techniques might you use to make these determinations?

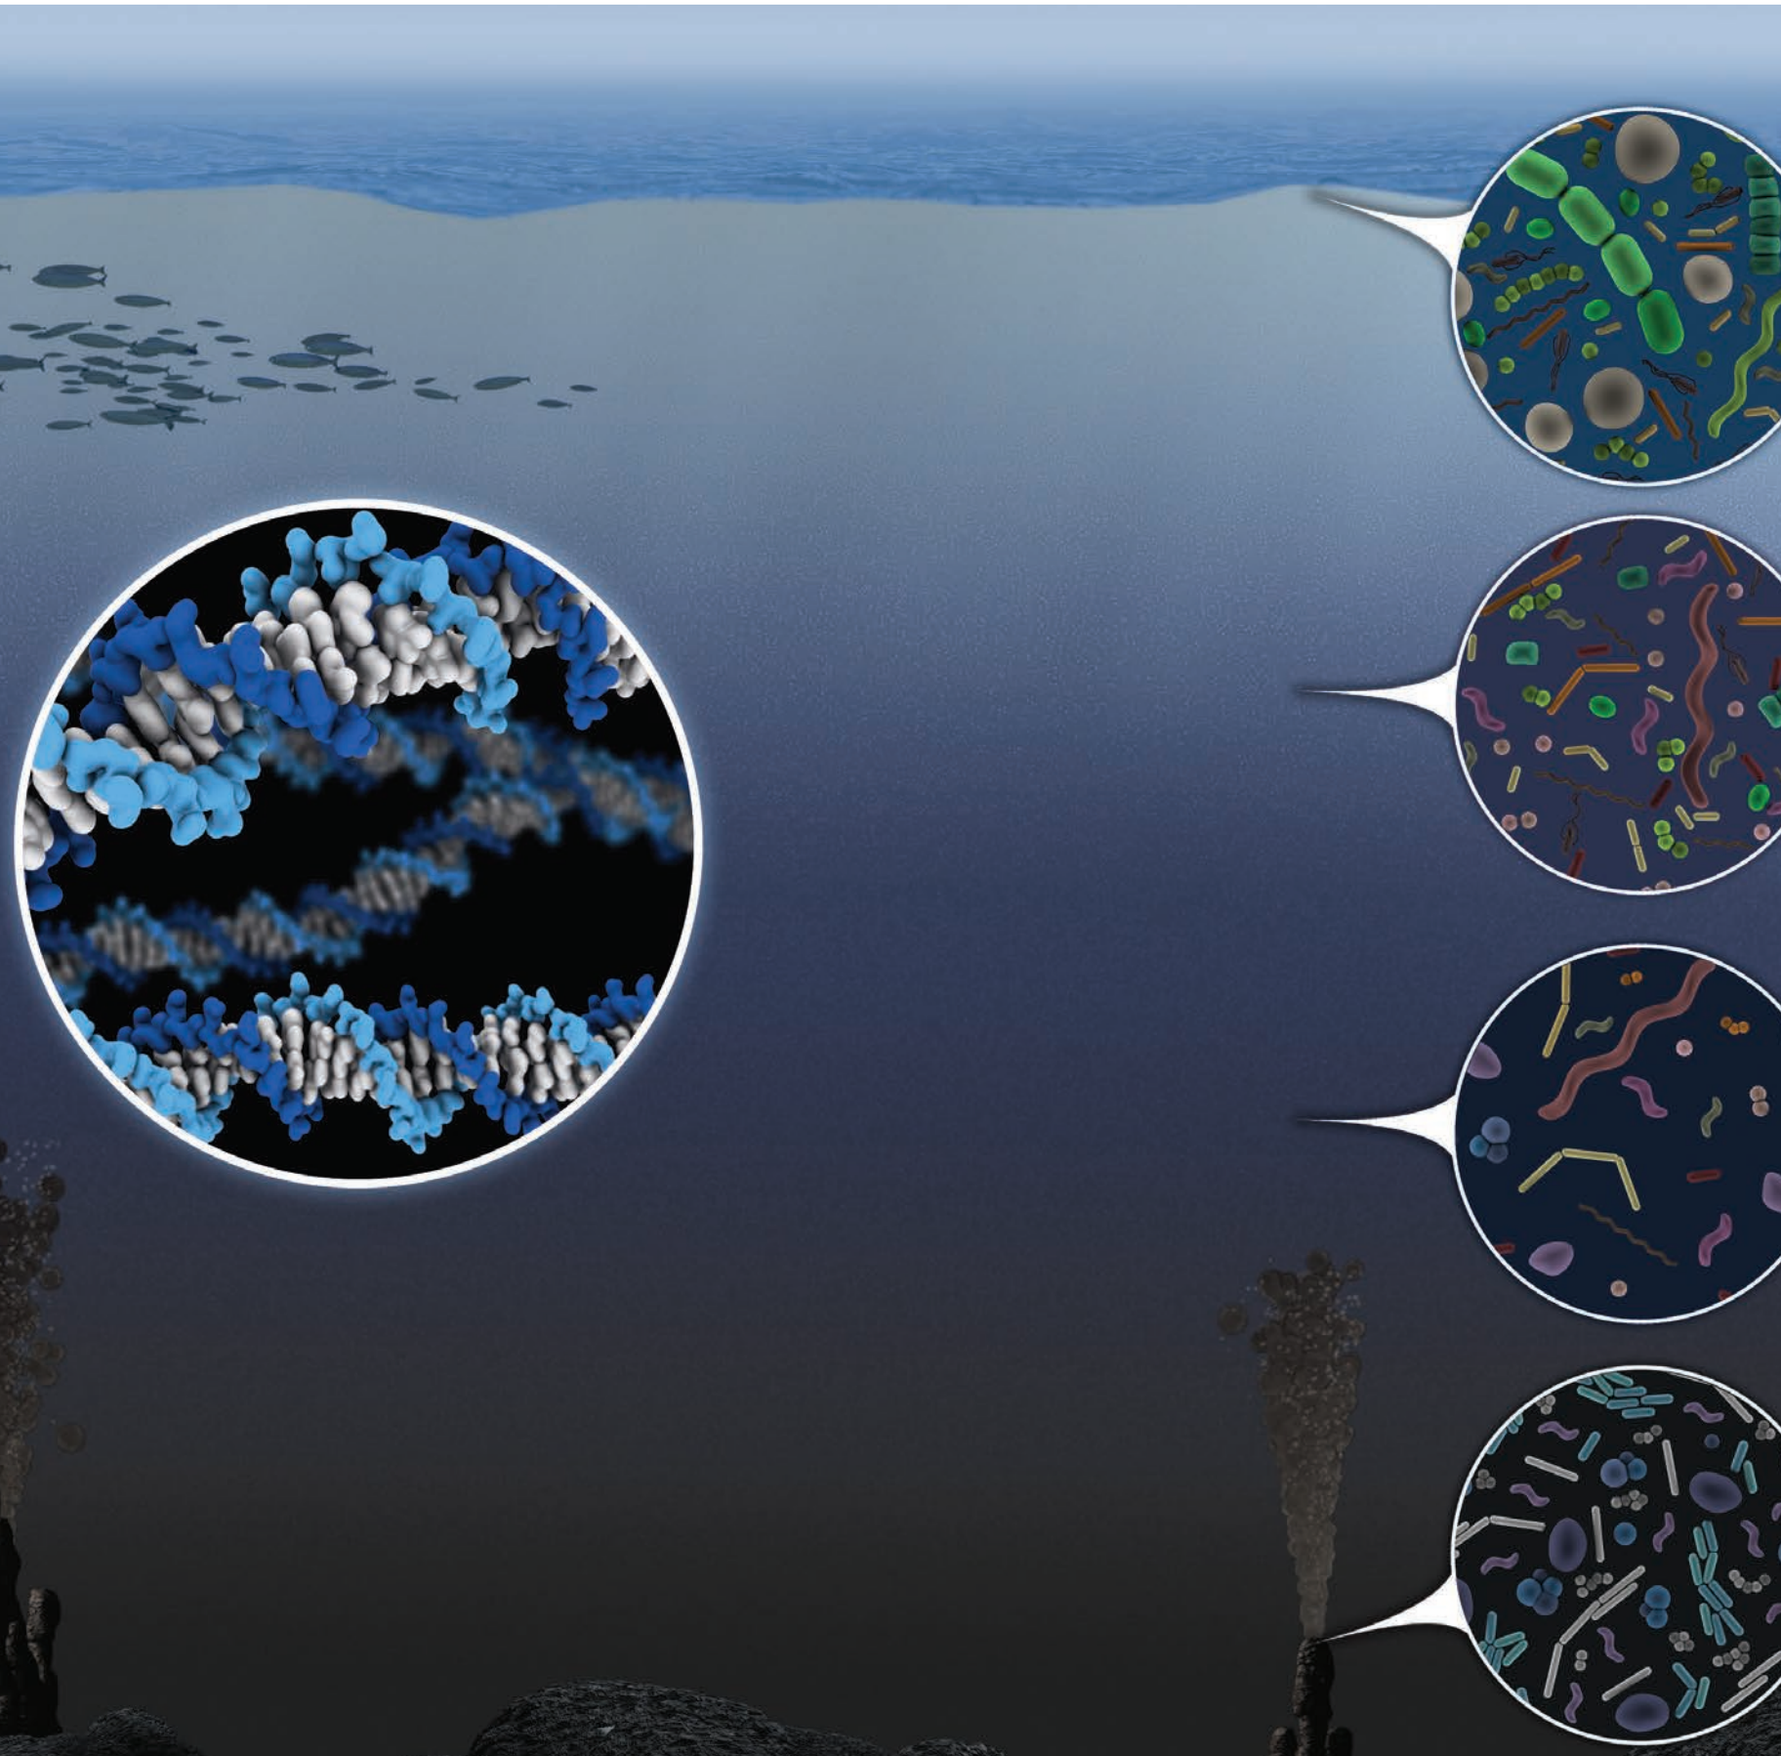
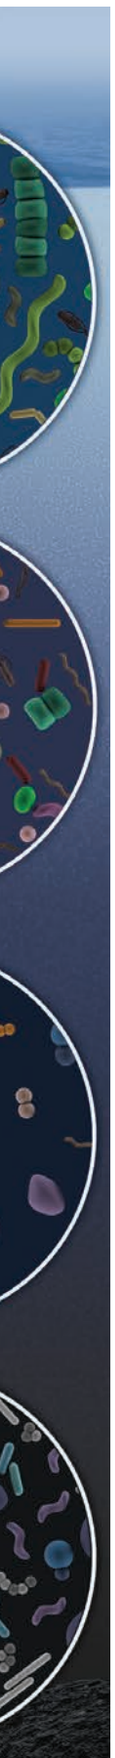
CHAPTER

15 Microbial Ecosystems





In the early 1990s, Ed DeLong, a microbiologist working at the Woods Hole Oceanographic Institution in Massachusetts, made a striking discovery. He detected archaea in oxygenated coastal waters off the coast of North America. As we noted in Chapter 4, archaea were historically considered to be "extremophiles." Indeed, until DeLong's discovery, almost all archaea found in the ocean were either thermophiles or hyperthermophiles living near deep sea hydrothermal vents or were methanogens living in anoxic sediments, which are habitats quite different from oxic surface waters. Based on DeLong's work, microbiologists began to reassess their views of archaea. Perhaps they weren't relegated to environments that we consider extreme. Although this discovery of archaea in coastal waters may have been unexpected, the way in which DeLong and colleagues identified these organisms is also an interesting story.

You may recall that we first encountered Ed DeLong in Section 10.4 during our discussion of metagenomics. He and his colleagues showed that they could analyze marine microbial communities in a culture-independent fashion. By isolating and then sequencing genomic DNA obtained from the environment, the researchers began to understand what types of bacteria were present. DeLong decided to use these same techniques to look at the composition of microbial communities in coastal marine surface waters. Using a series of PCR primers designed to amplify archaeal small subunit ribosomal RNA (SSU rRNA) genes, he detected two very different types of archaeal DNA in several surface seawater samples. Phylogenetic analysis showed that some sequences belonged to the phylum *Euryarchaeota*, as expected for methanogens (see Chapter 4), whereas other sequences belonged to the phylum *Crenarchaeota*. Moreover, these archaeal species appeared to account for a substantial number of the microorganisms in both Atlantic and Pacific coastal marine surface waters. In some cases, archaeal sequences accounted for over 2 percent of the total SSU rRNA genes found.

The discovery of archaea in the marine environment raised many questions at the time. What roles do they play alongside marine bacteria and eukarya? Are they also found deeper in the ocean and away from the coasts? Do similar archaeal species exist in different habitats, such as soils, or were they limited to the marine environment? These are only a few of the questions that resulted from this relatively simple application of molecular methods to microbial ecology. What else was in store? Much more than anyone predicted.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Microorganisms live within ecosystems and perform specialized functions.

- Figure 15.3: Process Diagram: Formation of biofilm

Nucleic acid-based methods are used to examine microbial community composition.

- Figure 15.10: Process Diagram: Using metagenomics to characterize microbial communities
- Mini-Paper: Insights into the phylogeny and coding potential of microbial dark matter

Microbial life in aquatic habitats is governed by light and nutrient availability.

- Perspective 15.2: Dead zones
- Figure 15.12: Comparison of the relative abundance of bacteria and archaea in ocean water
- Figure 15.18: Discovery of new light-harvesting systems in the ocean by sequence analysis of microbial communities
- Microbes in Focus 15.1: *Synechocystis* sp. PCC6803—From unpleasant cyanobacterial blooms to science and biotechnology workhorse

Microbial life on land is intimately linked to the life of plants.

- Figure 15.21: Global map of terrestrial biomes
- Figure 15.22: Soil horizons
- Table 15.3: Rhizosphere influence on soil microbial communities

Some ecosystems are not dependent on photosynthesis for primary production.

CONNECTIONS for this chapter:

Gene expression in response to environmental changes **(Section 11.3)**

Biofilms in the treatment of sewage and the purification of drinking water **(Section 16.5)**

Growth in the rhizosphere **(Section 17.2)**

Metabolic categories of microorganisms based on sources of energy and carbon **(Sections 6.1** and **13.2)**

Introduction

Earth is very much a microbial planet, and its microbial residents have been evolving for about four billion years. In the preceding chapter, we learned how microbial metabolism controls the development and maintenance of the biosphere. In this chapter, we will consider the interactions of microbes with their surroundings, which is a scientific discipline known as **microbial ecology**. Microbes naturally interact with other organisms, both directly and indirectly. In some cases, their own metabolic activities depend on the metabolic activities of their neighbors. In other cases, they compete with their neighbors for common resources. In the process of making a living, microbes often greatly modify their environments. In the study of microbial ecology, links can be made between genetics, physiology, ecological roles, and how the evolution of microbial capabilities and characteristics results from genetic selection within the environment. Whether we consider a wastewater treatment system (see Section 16.5), the human gut (see Section 17.3), an acid mine drainage system (see Perspective 14.2), the open ocean, or fertile agricultural soil, the interactions between individual members of any microbial community are considerable.

Although the many environments on Earth that support life are diverse, we can group them within major geographic divisions of marine, terrestrial, and subsurface. In this chapter, we begin by examining microbial communities and the factors that shape their composition and diversity. We will then look at techniques used by microbiologists to study these communities. Finally, we will investigate several specific types of environments. As we investigate several aspects of microbial ecology, we will focus on the following questions:

What factors affect microbial communities? (15.1)
How can microbial communities be studied? (15.2)
What is the nature of life in water? (15.3)
What is the nature of life on land? (15.4)
Can life exist in the absence of photosynthesis-driven primary production? (15.5)

15.1 Microbes in the environment

What factors affect microbial communities?

Microbial ecosystems have enormous impacts on this planet by virtue of the astounding collective biomass of microbes. By extrapolating direct measurements of microbial cells from the representative major habitats of aquatic, soil, and subsurface environments, current estimates suggest that the number of bacteria and archaea on this planet may be an impressive 92–317 $\times$ 10^{28} cells, representing 52–265 $\times$ 10^{15} g of carbon (Table 15.1). Total microbial carbon is anywhere from 10 to 50 percent of the carbon that exists in all plants on this planet combined. And if you thought that humans were an impressive presence on this planet, think again. Assuming an average human is 136 pounds (62 kg) and that we represent a total population size of 7.3 billion people, we weigh in at approximately 0.45 $\times$ 10^{15} g. This means that Earth's microbial biomass exceeds human biomass somewhere between 115- and 590-fold! Although these numbers might seem surprisingly high, perhaps more surprising is the amount of nitrogen and phosphorus contained within Earth's microbes. For these life-essential elements, bacteria and archaea possess several-fold more nutrients than found in all plant life, partly because of how carbon-rich plant biomass is in relation to nitrogen and phosphorous.

TABLE 15.1 Microbial cell numbers and biomass in different environments on Earth

Environment	Number of bacterial and archaeal cells $\times$ 10^{28}	Grams of carbon $\times$ 10^{15}	Diversity ("species" per milliliter or gram)
Aquatic habitats (freshwater and marine)	12	2.2	160
Oceanic subsurface (sediment and beneath)	29	1.5–22	?
Soil	26	26	6,000–40,000
Terrestrial subsurface (beneath soil layer)	25–250	22–215	?
Total	92–317	52–265	?

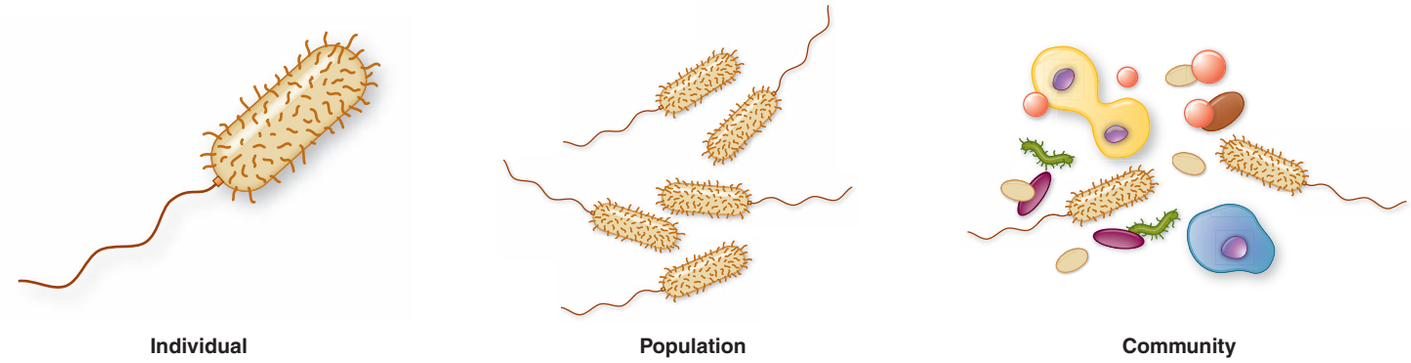

Figure 15.1. Different levels of a microbial community Microbial cells can be considered at several different levels, including individual cells, populations of similar cells, and communities of diverse populations.

Given the enormous biomass of microbes on this planet, coupled with high species diversity (Table 15.1), how can we begin to study their interactions and functions? In Chapter 6 and 13, we examined the concept of microbial growth and explored the incredible metabolic diversity in which microbes make a living in Earth's diverse environments. That said, most studies that have led to our understanding of microorganisms were conducted on cells growing in pure culture, often in mid-log phase. In fact, pure culture studies have been the foundation of the science of microbiology. However, in nature, microorganisms do not grow under ideal laboratory conditions. Microorganisms live in complex communities where they exchange nutrients, waste products, and genetic material with their neighbors in their continual quest to grow and divide. For example, let's look at *Escherichia coli*. You may be working with a specific strain of *E. coli* in the laboratory right now, growing it in LB broth at 37°C. Do you think that a Petri dish in the laboratory is the natural habitat of *E. coli*? Of course not. We know that this bacterium normally resides, among other places, in our gut alongside numerous other microbes. In the gut, *E. coli* is subject to variations of our diet, our overall health, a complex microbial community, and many other external factors.

To understand *E. coli* fully, we should investigate how it survives in a more natural habitat. Moreover, we should investigate how it interacts with other species. As we will see throughout this chapter, these goals can be quite difficult to achieve. Despite our focus on cultivation-based microbiology, it has become widely accepted that readily cultured microorganisms represent a small proportion of the organisms in most microbial communities. We will address this conundrum in Section 15.2. For now, let's begin our study of microbial ecology, in relation to microbial ecosystems, with a brief exploration of ecosystems as a concept.

Ecosystems

Life on Earth represents a collection of **ecosystems**, a term first used in the 1930s to describe the interactions and exchanges of materials between organisms and their surrounding environment. An ecosystem thus consists of a community of organisms living in a specified area, interacting with each other and the environment. An ecosystem includes both biotic factors, such as other organisms, and abiotic factors, such as minerals, gases, and water. The interactions typically are quite dynamic. As environmental conditions change, organisms react to the changes. Changing physiological activities of the organisms in turn influence the environmental conditions. As an example of this, we will discuss later in this chapter how mixing of lake ecosystems can redistribute nutrients and result in microbial blooms, which can have enormous impacts on aquatic life. As we discuss the role of microbes in ecosystems, we can consider several different levels within a microbial community (Figure 15.1), ranging from individual cells through populations of similar cells, and finally the complete community that typically consists of a diverse collection of different microbial populations.

How can we categorize the various members of an ecosystem? We can focus on the roles different organisms within an ecosystem play in the context of energy flow. Familiar primary producers, like plants and photosynthetic microorganisms, capture energy through photosynthesis. This captured energy drives the incorporation of inorganic carbon, usually from carbon dioxide (CO_2), into organic molecules. As we will see in Section 15.5, non-photosynthetic primary producers also exist, primarily in habitats devoid of sunlight. In contrast to primary producers, heterotrophic organisms function as **consumers**, ingesting the stored photosynthetic energy. **Decomposers** break down dead organic matter and recycle the components back into the environment.

In many cases, it may be useful to further separate organisms into functional **guilds**, which are groups of organisms that carry out similar processes. For instance, the guild of anoxygenic phototrophs harvest light energy under anoxic conditions without producing oxygen (O_2), whereas thermophilic methanogens all produce methane (CH_4) under high-temperature conditions. Although members of a guild play similar roles in a given ecosystem, they do not need to be genetically related. Nonetheless, the degree of genetic similarity to other organisms can provide a rough guide to the likely characteristics of an organism.

Within a community, each individual organism must obtain nutrients to support the energy and material needs of the cell. In most ecosystems that have been studied, energy

for metabolism and organic carbon for cell growth originates from sunlight and CO_2 through photosynthesis carried out by the producers. The harvested energy and carbon is then channeled to the heterotrophic consumers. Some ecosystems, such as those on the ocean floor or in the deep subsurface below the seafloor or soil surface, do not have direct access to light energy. Instead, they rely on other sources of energy and organic carbon. For example, the giant tube worms introduced in Chapter 13 rely on chemolithotrophic bacteria that oxidize hydrogen sulfide (H_2S) for energy, producing organic carbon (CH_2O), elemental sulfur (S^0), and water (H_2O) from the process. This type of process is often termed **chemosynthesis**, as shown here:

$$CO_2 + O_2 + 4\ H_2S \rightarrow CH_2O + 4\ S^0 + 3\ H_2O$$

Other organisms obtain energy in different ways. To fully understand the intricate workings of an ecosystem, we not only need to know what guilds are present, we must also understand how individual species obtain nutrients. In other words, we need to more fully understand the physiology of an ecosystem.

Ecosystem physiology

To fully understand the workings of an ecosystem, we need to know more than simply which producers, consumers, and decomposers exist there. We must also ask how each organism interacts with the environment. A fundamental concept of ecology is that of the **niche**, which describes the specific functional role of an organism within an ecosystem. An organism's niche includes its physiological interactions with its physical habitat and with other co-existing organisms. For a particular organism, the type, quality, and quantity of sustaining resources defines the niche. The evolutionary pressures of selection and competition result in the specialization of organisms for their prime niches, and ensure that all niches are occupied. In addition, it is a general rule in ecology that no two populations of organisms can occupy the same niche and coexist together sustainably. One population will always outcompete the other if they occupy identical niches. In contrast, populations that occupy distinct niches can coexist and even complement one another. For an example, consider two microorganisms that we discussed earlier, *Methanobrevibacter smithii* (see Microbes in Focus 4.4) and *E. coli* (see Microbes in Focus 9.1). This archaeal and bacterial pair can coexist stably within the same gut habitats, partly because they occupy completely different niches. In the colon, *E. coli* is a fermenter and *M. smithii* is a methanogen, with distinct requirements for energy and growth. However, just because they occupy distinct niches does not mean that they do not interact with each other. Indeed, we saw in Section 14.3 how the end products of fermentation serve as substrates for methanogenesis; thus, these two co-existing populations occupy distinct niches yet are mutually beneficial to one another.

When characterizing microbial habitats and the potential for competition, we need to think of microenvironments. For example, gradients of O_2, pH, light, or nutrients may exist over very short distances, and these gradients can have substantial effects on different microbes. Metabolic activities of the inhabitants can also have profound effects on local physical and chemical conditions. Conditions also change with time. Although individual microbes might be specialized for a prime niche, their ultimate survival and fitness depends on their ability to adapt to changes in their habitat and to exploit the available resources better than competing organisms. Through gene regulation, microorganisms can modify their metabolism according to external conditions.

CONNECTIONS In **Chapter 11**, we learned about several mechanisms by which microbial cells modulate their gene expression in response to changes in environmental conditions. The resulting metabolic changes are critical in determining the cell's ability to survive when competing for resources.

Although an astounding number of niches exist on the planet, and innumerable combinations of environmental and physiological factors affect microbial growth and success within every niche, certain basic environmental conditions need to be considered when investigating any given niche. Within ecosystems, factors affecting the primary production of organic matter by photoautotrophs and chemolithoautotrophs (see Section 13.2), the decomposition of organic matter by chemoorganotrophs (see Section 14.2), and the associated reactions that drive the biogeochemical cycling of elements that were described in Chapter 14, are probably the most important. When studying microbes in nature, we typically focus more on which metabolic types are present rather than the taxonomic identities of the organisms. Nevertheless, there is often some correlation between the taxonomic identity of an organism and its metabolic capabilities. For example, all known species within the *Desulfovibrio* genus are sulfate-reducing bacteria, whereas all known bacteria within the *Azotobacter* genus (*azote* is "nitrogen" in French) are aerobic nitrogen (N_2) fixers. These correlations between function and phylogeny can be weak for some organisms and attributes. For example, denitrifying bacteria conduct the same basic respiratory metabolism, and yet denitrification is distributed across many bacterial phylogenetic groups, often inconsistently distributed even within individual genera. Nevertheless, the types of microbes and corresponding metabolisms present in a given habitat can often be predicted by prevailing environmental conditions, such as the likely presence of methanogens in anoxic sediments and the intestinal tracts of animals (see Section 17.4).

CONNECTIONS Recall from **Chapter 14** that the major nutrients required by microorganisms are carbon, nitrogen, phosphorus, and sulfur and that these are required for the generation of energy and for growth. Other elements are also important, such as Fe, Mg, Mn, K, Ca, Na, and Cl.

To understand how some microbial populations succeed in different environments, it is often best to consider the elements found in a particular niche and examine how microorganisms

obtain these different nutrients. To put it very simply, microorganisms generate metabolic energy by oxidizing (removing electrons from) certain compounds, and then reducing (passing electrons to) other compounds. The oxidized compound can be thought of as an electron donor, and the reduced compound as an electron acceptor, as was discussed in Chapter 13. In this way, a microbial cell works like a living catalyst, facilitating the transfer of electrons between different compounds, while at the same time harvesting energy released by these reactions.

Biofilms

As we noted in Section 2.5, microbes tend to accumulate and grow on solid surfaces as biofilms, structured communities held together by extracellular polysaccharide (see Figure 2.35). Microbes in biofilms are all around you, from the "ooze" inside your shower drain, plaque on the surface of your teeth, slime on rocks in a stream, and marine "snow" in the ocean water column. Even lichens, which are a fungal symbiosis with algae or cyanobacteria (see Chapter 17), are a form of microbial biofilm. Arguably, most microbes on Earth exist within biofilms.

In general, biofilm growth provides an advantage for microbes because nutrients often bind to these solid surfaces, supporting higher cell concentrations than typically exist in bulk fluid. Moreover, the members of a biofilm interact with and support one other. Demonstrating the importance of biofilms for supporting microbial growth, the formation of a biofilm can be initiated within minutes of placing an object within a microbe-containing fluid. Mature biofilms can be very complex microbial communities, in which the majority of the cells have good access to nutrients and protection from environmental stresses **(Figure 15.2)**. Because some of these stresses are from human activity aimed at reducing microbial numbers, such as the application of antimicrobial agents, the formation of biofilms is often of practical concern.

CONNECTIONS Harnessing microbial biofilms for applications such as sewage treatment or drinking water purification, as discussed in **Section 16.5**, is a good example of engineering and microbial ecology intersecting for human benefit.

During natural biofilm formation **(Figure 15.3)**, the first microorganisms adhering to a surface are often appendaged bacteria, such as *Caulobacter* (see Figure 2.33) or *Hyphomicrobium*; these are specialists in attaching to surfaces in aquatic environments. As these primary colonizers divide and form microcolonies, other microorganisms, the secondary colonizers, join the growing biofilm. Together, they secrete exopolysaccharides (EPS), which are also referred to as extracellular polymeric substances. As discussed in Section 2.5, exopolysaccharides are important for biofilm formation because they produce a gel-like matrix around the microcolonies (Figure 15.3). Other microbial compounds can also contribute to this sticky matrix, including extracellular proteins and DNA. This matrix aids in the formation of water-filled channels that, in turn, facilitate the transport of nutrients and waste through the biofilm.

Several researchers have demonstrated the importance of EPS production for biofilm development. Roberto Kolter and colleagues at Harvard University examined EPS production by *Escherichia coli* K12 for biofilm formation. Specifically, this bacterium produces colanic acid during biofilm formation. To investigate the importance of this EPS, the researchers examined *E. coli* K12 mutants that were defective in the production of colanic acid. When grown in the presence of a solid surface, these bacteria attached to the surface normally but did not form a complex three-dimensional biofilm like the wild-type strain. From these results, the scientists concluded that, under their experimental conditions, *E. coli* requires EPS for biofilm development **(Figure 15.4)**.

It's worth noting that colanic acid is produced by *E. coli* only during biofilm formation. In other words, this essential biofilm

Figure 15.2. Biofilms Biofilms are microbial communities that are often found on solid surfaces within aquatic environments, such as on this rock in a stream. As shown in the light micrograph, the biofilm is made up of a community of microbes. Members of the biofilm benefit by improved nutrient acquisition and avoidance of antimicrobials. Biofilms are usually held together by exopolysaccharides (EPS) produced by their inhabitants.

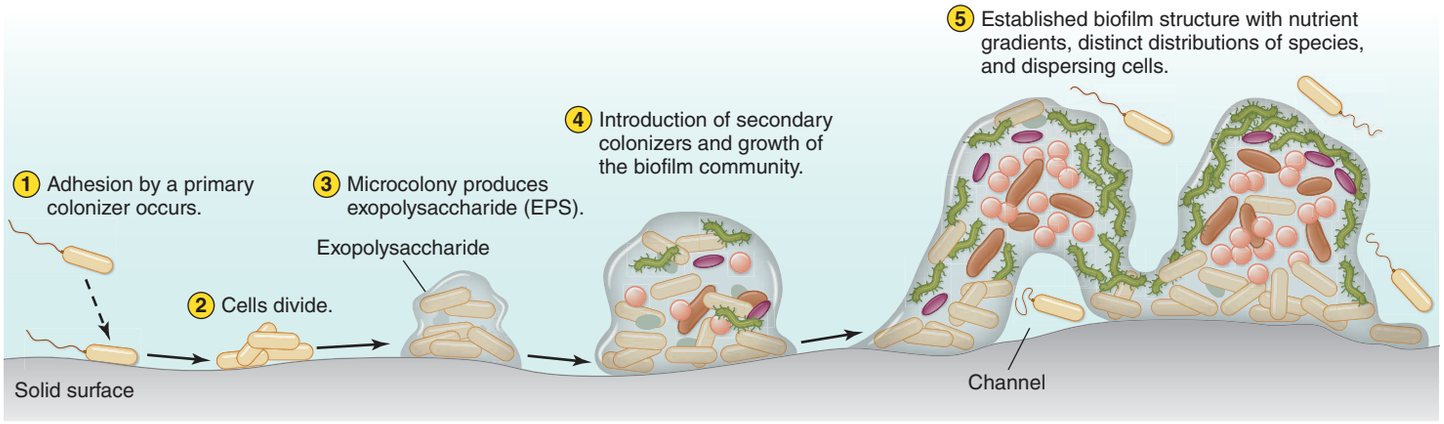

Figure 15.3. Process Diagram: Formation of biofilm Biofilms typically form through a stepwise process. First, the surface is populated by adhesion of the primary colonizers. Growth results in the formation of microcolonies that produce exopolysaccharide (EPS). Secondary colonizers are introduced as the biofilm matures. Throughout this development, intercellular communication occurs through molecular signaling known as quorum sensing.

EPS is only produced when needed. How might this form of regulation occur? It appears that cells within a growing biofilm community communicate by quorum sensing (see Section 11.5). Chemical signaling allows the cells to assess their population density and induce specific gene expression profiles, such as those required for biofilm formation, in response to changes in cell density. Indeed, quorum sensing is thought to be of critical importance for both the formation of biofilm communities and in their eventual dispersion. Because of this, quorum sensing is critical for the dynamic nature of microbial communities inhabiting biofilms, including for pathogenic bacteria.

To get a better understanding of the practical concerns associated with biofilms, let's look at the bacterium *Pseudomonas aeruginosa*. Some strains of this environmental bacterium represent a major threat to people with cystic fibrosis or chronic lung damage by colonizing the lung in a biofilm and causing substantial tissue damage. The bacteria adhere to epithelial cells, form microcolonies, and secrete alginate, an EPS. The resulting biofilm offers protection from the immune system and antibiotics. Thus, biofilm formation by *P. aeruginosa* affects its virulence directly. As with *E. coli*, quorum sensing is essential for the ability of *P. aeruginosa* to form a biofilm by controlling

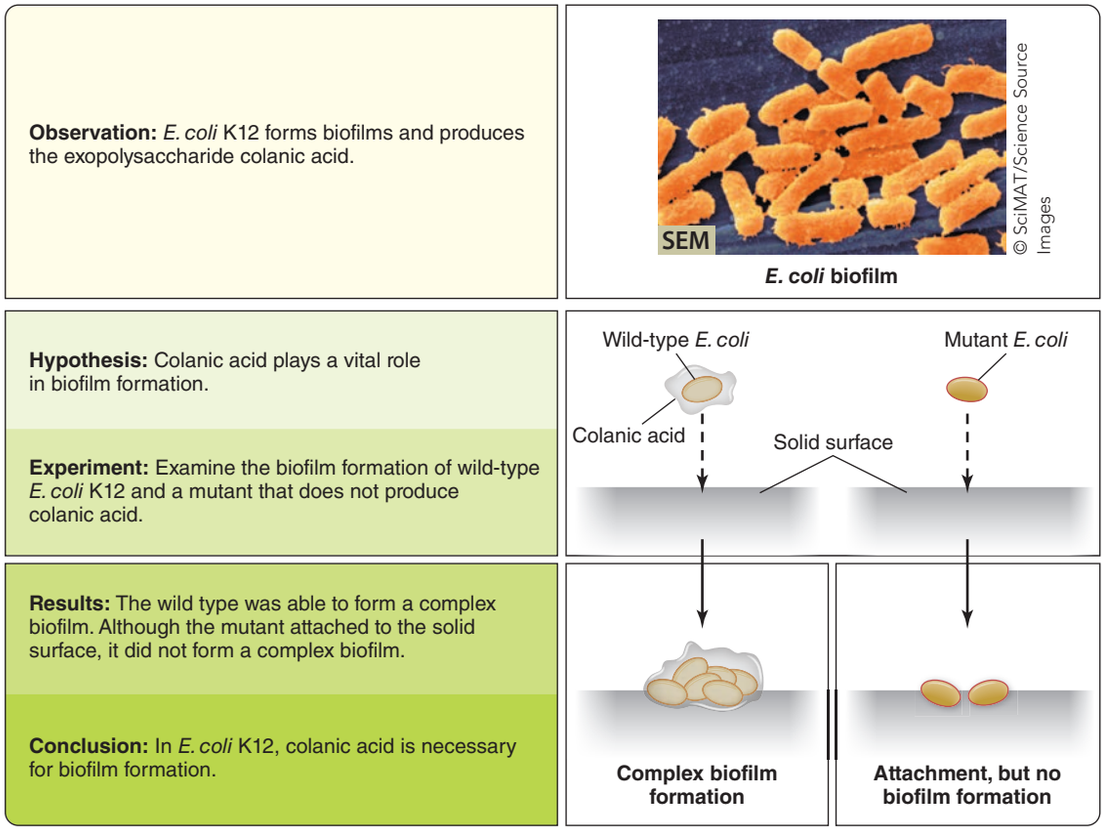

Figure 15.4. Role of exopolysaccharide (EPS) in *E. coli* biofilm formation To test the role of colanic acid production on biofilm formation by *E. coli* K12, researchers isolated a mutant that did not produce this EPS. When exposed to a solid surface, cells of this strain attached to the surface but did not form a complex biofilm. In contrast, wild-type cells that did produce colanic acid attached to the surface and formed a biofilm.

the production of EPS, and this enables the infection to spread through eventual dispersal from the biofilm matrix. Can you appreciate how targeting quorum-sensing molecules may be a possible strategy for the development of novel antimicrobial therapies?

CONNECTIONS *Pseudomonas aeruginosa* possesses several virulence factors, including fimbriae for attachment and a cytolysin. The roles of these and other virulence factors are discussed in **Sections 21.1** and **21.2**.

15.1 Fact Check

1. Describe how the following concepts are related: ecosystem, community, individual cells, population.
2. Differentiate between primary producers, consumers, and decomposers.
3. When studying ecosystems, what basic physiological activities are important to consider?
4. What is a biofilm, and where can biofilms be found?

15.2 Microbial community analysis

How can microbial communities be studied?

Researchers studying microbial ecology pursue two broad objectives. First, they want to understand the biodiversity of microbial life in nature. Second, they want to determine the activities of these microorganisms and explore the effects of those activities, individually and collectively, on communities and ecosystems. Given these objectives, how do microbial ecologists characterize microbial communities and capture their diversity? Until recently, we did not even have a clear view of what microbes existed in most communities nor of their incredible abundance (Table 15.1). This is because cultivation-dependent approaches, used for over a century by microbiologists, usually detect only those organisms that grow well under laboratory conditions, which is widely considered to be the minority of all living microorganisms **(Table 15.2)**.

We introduced this challenge of cultivation in Section 6.3 and referred to it as the "great plate count anomaly." When relatively fast-growing microorganisms, like *Escherichia coli*, grow on plates, it often turns out that these species are not very active nor abundant in a microbial ecosystem at the time of their isolation. In other words, they may simply be better suited to lab culture conditions than other microorganisms. Moreover, as we saw in Section 15.1, individual species do not live in isolation in nature. Even if we can grow a particular microbe in the laboratory, its activity in culture may not reflect its activity in nature. Uncertainties about exactly which organisms are active in the environment, and the nature of those activities, have severely limited our understanding of microbial ecosystems.

In this section, we will explore techniques used by microbial ecologists to describe microbes that exist within microbial communities. First, we will discuss microbial cultivation strategies as they are used for exploring microbial ecosystems. Second, we will explore culture-independent techniques used to identify microbes that cannot be readily cultivated. Although we will focus primarily on cultivation-independent techniques, combining cultivation-dependent and cultivation-independent approaches can be an extremely powerful way to leverage these techniques for increased understanding of complex microbial communities.

TABLE 15.2 Bacterial culturability

Habitat	Culturability (%)[a]
Seawater	0.001–0.1
Freshwater	0.25
Unpolluted estuarine waters	0.1–3
Activated sludge	1–15
Sediments	0.25
Soil	0.3

[a] Cultured bacteria are measured as colony-forming units (CFUs) in relation to cells observed by microscopy.

Cultivation-dependent techniques

How do we culture microbes for understanding microbial ecosystems? Let's consider two general cultivation-dependent approaches, beginning with enrichment culture and followed by more traditional microbial isolation strategies. Enrichment culture, using culture medium and conditions designed to favor the growth of particular microbes (see Section 6.4), can be very effective at enriching the numbers of specific groups of microbes with particular physiological properties. Let's use N_2 fixation as an example, which we discussed originally in Section 14.3. *Azotobacter* and other aerobic N_2-fixing bacteria can be enriched and eventually isolated from soils, even if they are not very active in those soils at the time of culture. The success of this enrichment approach is a result of *Azotobacter* being able to convert N_2 into biologically available molecules. Therefore, unlike most microbes, it can grow in the absence of a source of nitrogen-containing organic material. If we simply inoculate a nitrogen-free liquid medium with soil, then only organisms that can assimilate nitrogen from the atmosphere will grow. Nitrogen fixers, like *Azotobacter*, will increase in number, becoming enriched. We can then plate a small amount of this enriched broth

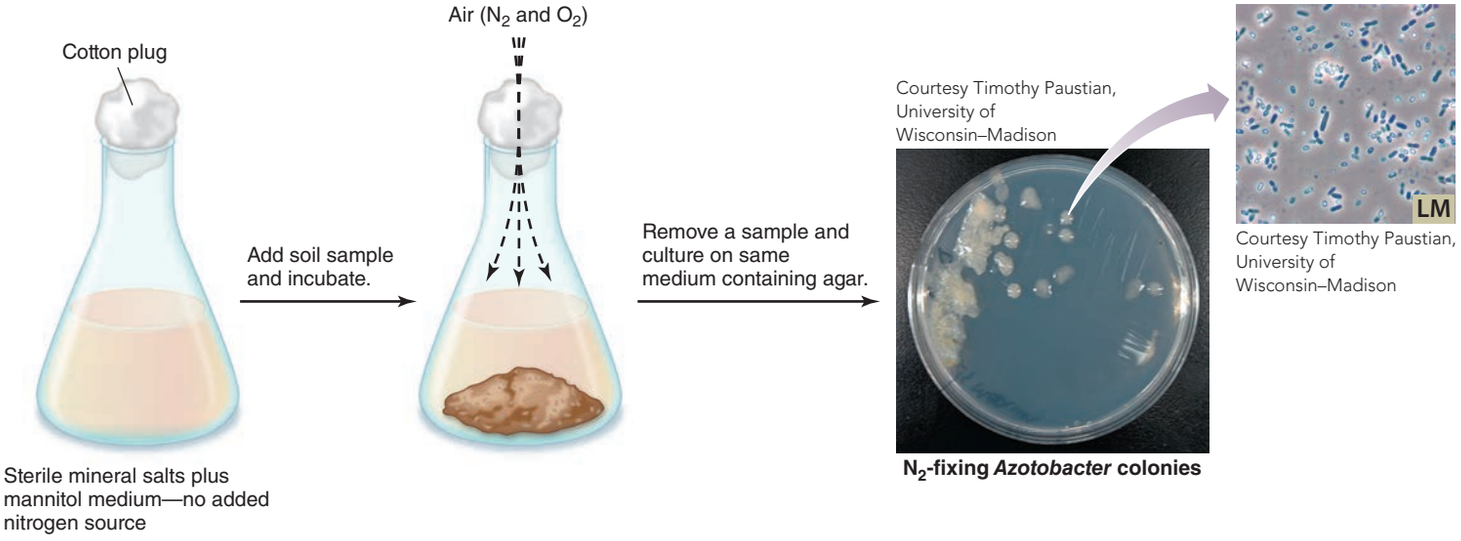

Figure 15.5. Enrichment culture for nitrogen-fixing bacteria To isolate N_2-fixing bacteria, soil can be added to liquid medium that lacks any biologically available nitrogen sources like ammonium (NH_4^+) or nitrate (NO_3^-). During incubation in the presence of air, N_2-fixing bacteria will become dominant in the culture. An aliquot of this enriched culture can then be plated on solid medium that lacks biologically available nitrogen. Again, only N_2-fixers will grow.

on an agar plate. Again, if the solid medium does not contain any biologically available nitrogen, then only N_2 fixers like *Azotobacter* will grow. Individual colonies growing on the plate can be isolated, grown in pure culture, and studied further **(Figure 15.5)**.

Enrichment cultures can also be a useful introduction to microbial diversity and biogeochemistry. Named after the Russian biologist Sergei Winogradsky, the Winogradsky column allows students of microbiology to watch enrichment occur. As shown in Toolbox 14.2, making a Winogradsky column is quite simple, involving the addition of mud from a swamp or pond to a clear cylindrical container that is then exposed to sunlight. Over time, microbes that were present initially in relatively low numbers will proliferate in different sections of the tube. From aerobic cyanobacteria near the top of the tube, to green sulfur bacteria and purple sulfur bacteria that use hydrogen sulfide (H_2S) as an energy source in the middle, to anaerobic metabolism and sulfur-reducing bacteria at the bottom, each of these types of bacteria display a distinct coloration within the tube. As shown in Toolbox 14.2, these colors are evidence that specific types of microbes have been enriched from an enormous background of extensive microbial diversity.

CONNECTIONS Green sulfur and purple sulfur bacteria are Gram-negative photolithoautotrophs, as described in **Table 13.1** and **13.3**. In light-exposed anoxic sediments, they oxidize inorganic sulfur compounds and H_2 to obtain electrons needed to drive photosynthesis.

Traditional cultivation approaches, as introduced in Section 6.3, can still be extremely useful for characterization of individual populations from within microbial communities. Indeed, the use of carefully selected growth media and cultivation conditions can bring many (or most?) microorganisms into culture that might previously have been considered unculturable (Table 15.2). These "tricks" for microbial cultivation have included the addition of key compounds that might be needed for growth. For example, addition of quorum-sensing molecules can stimulate growth of some microorganisms, the addition of siderophores helps microorganisms that cannot produce their own siderophores acquire iron, and the inclusion of vitamin mixtures can enable cultivation of vitamin auxotrophs. Importantly, many bacteria and archaea in microbial ecosystems may divide only once every few weeks, months, or even longer. As a result, lab cultivation strategies must adjust accordingly for some of these slow-growing microorganisms. For all of these reasons, many extant microorganisms should simply be considered uncultured rather than unculturable, and a degree of skepticism should be brought to often-cited statistics, such as that only 1 percent of all microorganisms can be cultured from the environment. Unculturable microorganisms may, in fact, be very rare, and ingenuity of microbiologists has allowed for many microorganisms from microbial ecosystems, including those in soil (see Mini-Paper in Chapter 6) and seawater (see Section 15.3), to be recovered in culture in recent years.

Despite immense progress in cultivating microorganisms, cultivation remains a challenging, time-consuming, and inadequate experimental approach for rapid and routine characterizations and comparisons of complex microbial communities. As we will now explore, cultivation-independent techniques have circumvented some of these challenges.

Cultivation-independent techniques

How can we characterize all inhabitants of microbial ecosystems, including those organisms that we cannot grow readily? In recent years, the application of powerful molecular tools to microbial ecology has helped us answer this question. Here, we will investigate several molecular techniques used to analyze microbial communities. These methods build on sequencing and analysis of nucleic acids extracted from environmental

samples, as we introduced in Chapter 10. Within the context of microbial ecosystem analysis, many of these techniques focus on the analysis of small subunit ribosomal RNA (SSU rRNA) genes amplified by PCR or by capturing DNA extracted directly from environmental samples by metagenomics. Let's begin by looking at SSU rRNA gene analysis.

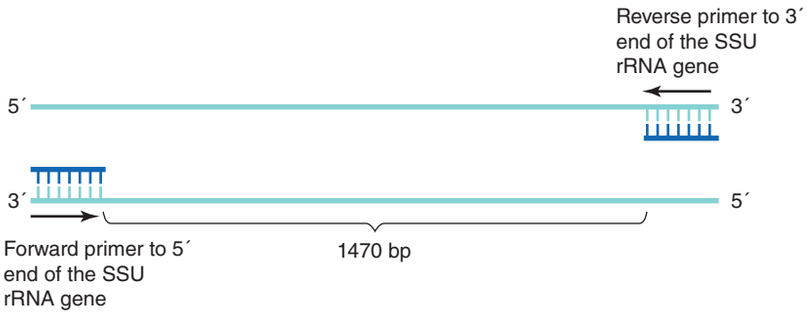
Analysis of SSU rRNA genes, which code for the SSU rRNA itself, has made it possible to learn an enormous amount about the types of microbes present in microbial ecosystems and their relationships to one another, regardless of whether or not they can be cultivated (see Toolbox 1.1). The extensive secondary structure of rRNA molecules, with hairpins of partially double-stranded RNA **(Figure 15.6)**, results in several highly conserved regions and highly variable, or "hypervariable," regions. The dissimilarity in the hypervariable regions allows determination of the phylogenetic relationships among organisms, whereas the conserved regions enable the design of oligonucleotide primers with different levels of specificity to the SSU rRNA genes of different microorganisms. Stretches of sequence specific to different taxonomic levels are found within SSU rRNA gene sequences. For example, universal primers (see Figure 15.6) amplify SSU rRNA genes from all organisms, theoretically, whereas other primer sets can be designed to amplify SSU rRNA genes from bacteria, or archaea, or microbial eukaryotes.

Although most cultivation-independent methods highlighted below focus on the collection of SSU rRNA gene sequences as a sort of barcode to determine the types of microorganisms that exist in environmental or clinical samples, direct extraction and sequencing of nucleic acids for the analysis of microbial ecosystems are becoming increasingly commonplace.

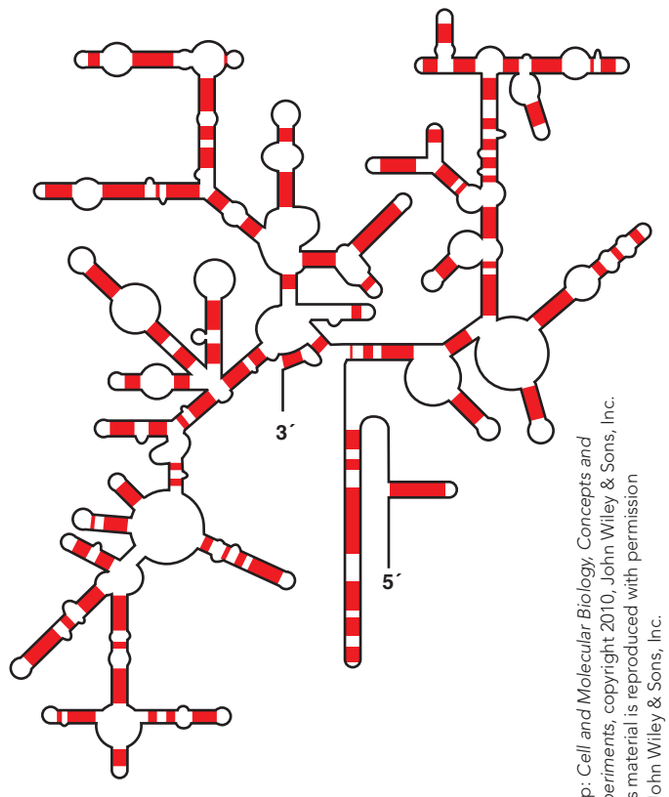
Direct Sequencing of Ribosomal RNA Genes

An effective technique for surveying a microbial community involves direct extraction of DNA from a microbial community. A typical analysis would start with collection of the sample from the environment, followed by transport and storage of the sample under refrigeration to minimize changes to the microbial community in transit. In the laboratory, DNA can be extracted from the sample. A useful targeted approach, especially when many samples must be compared based on the presence of specific populations, is to use extracted sample DNA as template for PCR using SSU rRNA gene primers (see Toolbox 1.1). The resulting amplified DNA molecules are sequenced directly by high-throughput sequencing (see Chapter 10). With some of the newer sequencing methods (see Section 10.1), hundreds or thousands of SSU rRNA gene sequences can be generated easily from hundreds or thousands of samples, all within a single experiment.

Comparison of the DNA sequences to the collection of sequences in publicly available databases, such as the Ribosomal Database Project at Michigan State University, or GenBank, provides a determination of the identity of each SSU rRNA gene sequence or at least indicates the most similar sequences in the databases. Many online tools are available to sort and analyze high-throughput sequence data to allow for organization of community profiles. Such analyses provide detailed information about the diversity and composition of organisms present in the community. The results can also allow estimates of the relative numbers of each type of organism in the community. If, for instance, 500 out of 1,000 SSU rRNA gene sequences from a given environment correspond to *Bacillus subtilis*, then one would predict that roughly half of the organisms in that environment are *B. subtilis*. We will explore how SSU rRNA gene sequence data are interpreted as community composition and diversity a little later in this chapter.



A. Amplification of the bacterial SSU gene using universal primers



B. Structure of the bacterial SSU rRNA molecule

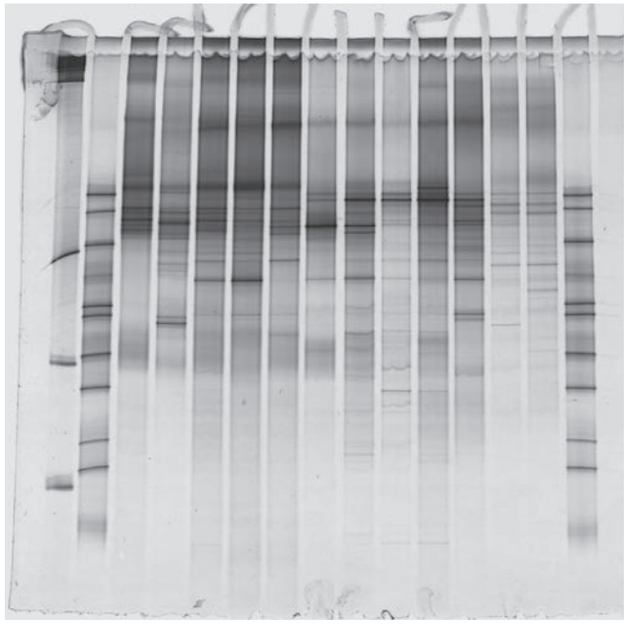
Figure 15.6. Small subunit ribosomal RNA (SSU rRNA) molecule **A.** Universal primers can be used to amplify the entire SSU rRNA by PCR. **B.** The secondary structure, involving intramolecular base-pairing shown in red, results in different degrees of sequence conservation within the SSU rRNA. The design of oligonucleotide primers for PCR amplification and probes for DNA and RNA hybridization studies can provide different levels of specificity.

Note that the SSU rRNA gene sequencing approach, although extremely useful, has its own biases and caveats. In addition to the challenge of extracting DNA quantitatively from all microbes in an environmental sample, the primers used for targeting different microbial groups are imperfect, developed largely based on available pure cultures. In addition, the number of copies of SSU rRNA genes within a single microbial genome can vary across different microbial species, usually ranging from 1 to 15 copies per genome, which means that quantitative estimates of microbial abundance will be approximate. As a result, focusing on SSU rRNA gene PCR products, as well as using other methods considered below, are all biased assessments of microbial community composition. That said, these biases are considered minimal relative to the bias associated with cultivation-based surveys of microbial communities.

Denaturing Gradient Gel Electrophoresis

Historically, large-scale sequencing projects were very expensive. In addition, rapid screening of low-diversity environments or monitoring of samples in real time are both applications that are poorly suited to high-throughput sequencing. As a result, researchers can use less costly and indirect methods of comparing molecules. **Denaturing gradient gel electrophoresis (DGGE)** represents one common indirect method for characterizing microbial ecosystems. This technique can be used to separate small PCR-amplified DNA fragments of 200–700 base pairs that have been obtained from an environmental sample. The separation is based on the variability of DNA sequences in different microbes. The SSU rRNA genes of bacteria and archaea contain blocks of sequence that are unique to particular species. No matter what gene sequence is chosen for analysis, sequence differences of even one base pair can influence how tightly the double-stranded DNA molecule is held together by hydrogen bonding.

Unlike more traditional gel electrophoresis, DGGE employs a high-temperature polyacrylamide gel electrophoresis of PCR products in a gradient of the chemical denaturants urea and formamide. As the DNA fragments migrate through the gel during electrophoresis, they encounter increasingly harsh denaturing conditions. When individual double-stranded DNA fragments begin to separate, or denature, into two single strands, the open DNA structure no longer migrates in the gel. Note that the structure remains partially double stranded because one of the primers used in the initial PCR for DGGE is designed with an extra 40-base region of guanine and cytosine nucleotides, a "GC-clamp," which is extremely strong because of triple hydrogen bonds for each base. The gel position at which partial denaturation happens depends entirely on the overall DNA sequence. The resulting banding patterns (Figure 15.7), or "fingerprints," can then be analyzed for diversity, represented by the number of bands in a single pattern, or for community comparison between different samples, indicated by the band pattern commonality between lanes. Other information, such as the relative abundance of the various bands in a sample, can also be deduced.



Courtesy Josh Neufeld

Figure 15.7. The DGGE method DNA fragments that differ in sequence by as little as a single nucleotide can be resolved as a "fingerprint" in a polyacrylamide gel. This method can be used to compare microbial communities by patterns of amplified SSU rRNA genes. In this gel, molecular marker lanes can be seen in the first two lanes on the left side and in the rightmost lane. These help to orient the remaining sample lanes to enable lane-to-lane pattern comparisons.

One advantage of DGGE is that individual bands can be physically removed from the gel and sequenced to determine their taxonomic identities if using a phylogenetic marker gene, such as SSU rRNA genes, or potential physiological capabilities if targeting a particular functional gene, such as a gene required for photosynthesis or N_2-fixation. The technique can uncover the presence of a multitude of microorganisms from a single sample or from multiple samples processed in parallel, many of which may be uncultured and not previously identified.

Terminal Restriction Fragment Length Polymorphism

Terminal restriction fragment length polymorphism (T-RFLP) represents another indirect method of comparing DNA. In this technique, researchers profile microbial communities by examining the position of a restriction site closest to a labeled end of an amplified gene, which is usually the SSU rRNA gene. Initially, PCR is performed on the target gene using one or both primers labeled with a fluorescent molecule on their 5′ ends. Then, the mixture of PCR-amplified variants of the gene is digested with a restriction enzyme. The resulting fragment mixture is separated by electrophoresis. Because only the terminal fragments contain the labeled primer, only they will fluoresce. Fragment sizes can be determined by a fluorescence detector, which is the same instrument used for reading DNA sequence fragments in cycle sequencing (see Section 10.1). The result is an intensity graph presenting the sizes of the fragments on the *x*-axis and their fluorescence intensity on the *y*-axis (Figure 15.8). Each DNA fragment is represented as a peak, the size of which represents the quantity of that type of organism present. The T-RFLP method provides a profile

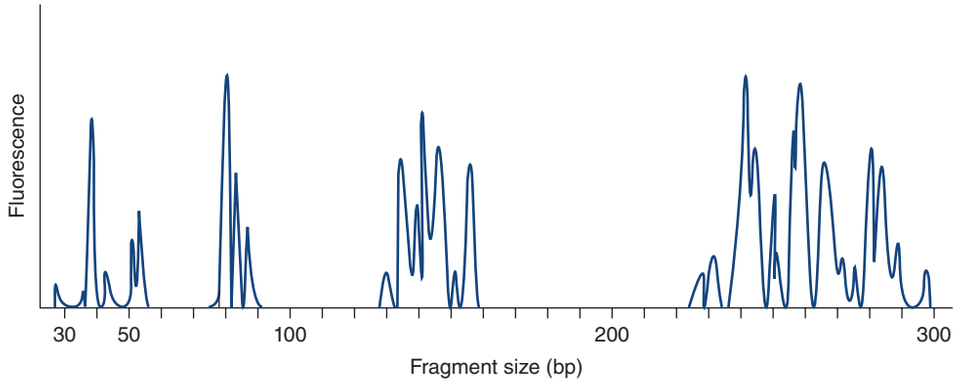


Figure 15.8. T-RFLP data Different terminal fragment sizes are detected. The fluorescence intensity of each peak represents the relative abundance of individual fluorescently labelled fragment ends in the sample.

of the diversity and relative abundance of different microbes present in the sample.

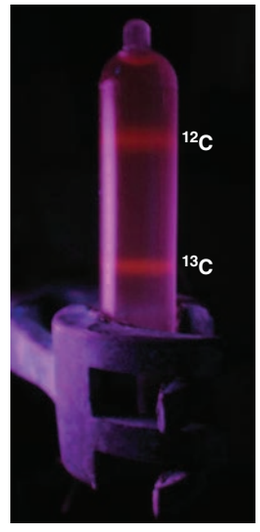
Although the SSU rRNA gene has become the standard for microbial community analysis, either via direct sequencing, DGGE, or T-RFLP, researchers may also examine genes that code for proteins of interest. For example, *pmoA* genes encoding methane monooxygenase could be amplified from methanotroph-containing ecosystems, or *nif* genes encoding the subunits of the nitrogenase enzyme could be amplified from ecosystems in which N_2 fixation is taking place. The conserved sequences of any of these genes can also be used directly as probes to detect their expression microscopically, or their presence, in cells by using fluorescently labeled oligonucleotide probes in a technique called **fluorescent *in situ* hybridization (FISH)** (see Figure B6.3). Multiple differently labeled probes can be used for simultaneous detection of cells with different genetic characteristics. This powerful technique can be used to examine the interactions of organisms at the cellular level. Fluorescence can also be used to screen cells by a technology called **flow cytometry**, which can be used for **fluorescence-activated cell sorting (FACS)** (Toolbox 15.1).

Stable-Isotope Probing

The inability to cultivate many members of microbial communities poses difficulties in determining the metabolic roles of different organisms. We can address this issue by examining microorganisms capable of metabolizing a given compound by using stable isotopes. Two complementary nucleic acid-based variations of the **stable-isotope probing (SIP)** method use either DNA (DNA-SIP) or RNA (RNA-SIP). In DNA-SIP, environmental samples are exposed to small amounts of ^{13}C- or ^{15}N-labeled growth substrates, which have one neutron extra in comparison to ^{12}C- or ^{14}N-native substrates, respectively. Microorganisms that assimilate the compounds will incorporate the heavier ^{13}C or ^{15}N from these molecules into their DNA, thus labeling their DNA and making it heavier. Heavier DNA from these active microorganisms can be separated physically from unlabeled DNA by cesium chloride gradient ultracentrifugation (Figure 15.9). The purified heavy DNA can then be used for amplification of SSU rRNA genes or recovery of metagenomes for analysis of the encoded functions associated with DNA from these active and uncultivated microorganisms. RNA-SIP follows a similar protocol where labeled RNA is recovered and analyzed for SSU rRNA, mRNA-SIP recovers labeled mRNA, and phospholipid fatty acids SIP (PLFA-SIP) analyzes labeled PLFA; all of these SIP techniques provide a novel way to link uncultivated microorganisms with their function, in this case the ability to assimilate a metabolic substrate of interest.

Metagenomics

As discussed in Section 10.4, DNA extracted from environmental samples can be sequenced directly as a metagenomic analysis, which provides access to all genetic potential present within a community. Metagenomics has also become a core tool for microbial ecologists, and this approach involves the construction of gene libraries from DNA extracted directly from the environment (Figure 15.10). Such libraries represent the total set of genomic information within the community. Genes can be isolated based on their function by screening for activity in surrogate hosts, or plasmid inserts can be partially sequenced to identify inserts that possess DNA of interest for further sequencing and analysis. An advantage of this functional approach is that it may result in the isolation of genes encoding proteins with the given activity that might be missed by sequence comparison studies alone. Alternatively, and more commonly now, metagenomics involves the use of high-throughput DNA-sequencing methods, such as pyrosequencing or Illumina (see Section 10.1), for direct analysis of community DNA, without a cloning step (Figure 15.10). As the costs of such analyses continue to decrease and the computational approaches for analysis continue to develop, metagenomics-based surveys of complex microbial communities are becoming increasingly routine approaches for exploring the composition and function of microbial ecosystems.



Courtesy Josh Neufeld

Figure 15.9. DNA stable-isotope probing (DNA-SIP) The spiking of microbial habitats with key nutrients labeled with heavy nitrogen or carbon molecules results in those molecules being incorporated into the DNA of the organisms that take up and metabolize those molecules. The labeled DNA can be separated from non-labeled DNA, and through sequence analysis of that DNA, it is possible to determine the identity of the metabolically active members of the community. Note the separate bands of ^{13}C- and ^{12}C-labeled DNA that have been resolved by ultracentrifugation on a CsCl gradient. In this case, the DNA bands are visible because ethidium bromide, a DNA-binding fluorescent dye, was added to the tube that is being exposed to ultraviolet light.

Toolbox 15.1
FLOW CYTOMETRY

Cells can be labeled fluorescently in a number of ways. Fluorescent dyes coupled to antibodies that recognize specific molecular structures on the outside of the cell can be used. The production of fluorescent proteins, such as green fluorescent protein (GFP), also results in fluorescence. The use of promoterless fluorescence protein genes such as the GFP gene makes it possible to couple the gene expression to promoters of interest so that the cells will fluoresce only when those genes are expressed. The technique of flow cytometry was developed to detect cells by their fluorescence. As shown in **Figure B15.1**, labeled cells in a liquid pass by a laser beam. Fluorescence-activated cell sorting (FACS) involves the use of flow cytometry and detectors for measuring the fluorescence and scatter of light from individual cells. On this basis, it is possible to determine whether the cells are labeled fluorescently, the nature of the fluorescence, and even the volume of the cell. These determinations happen very quickly, with thousands of cells passing the laser per second. Once past the laser, the flow can be adjusted so that each droplet carries a single cell. Moreover, each cell-containing droplet can be sorted out to a container, based on the detected properties. Cells that fluoresce one color, indicating a certain property, can go in one container, while cells that fluoresce another color, indicating another property, can go in another container. Depending on the protocol used, flow cytometry can be non-destructive, such that viable cells can be recovered from the different sorted batches. The live cells in these sorted batches can then be used in additional experiments.

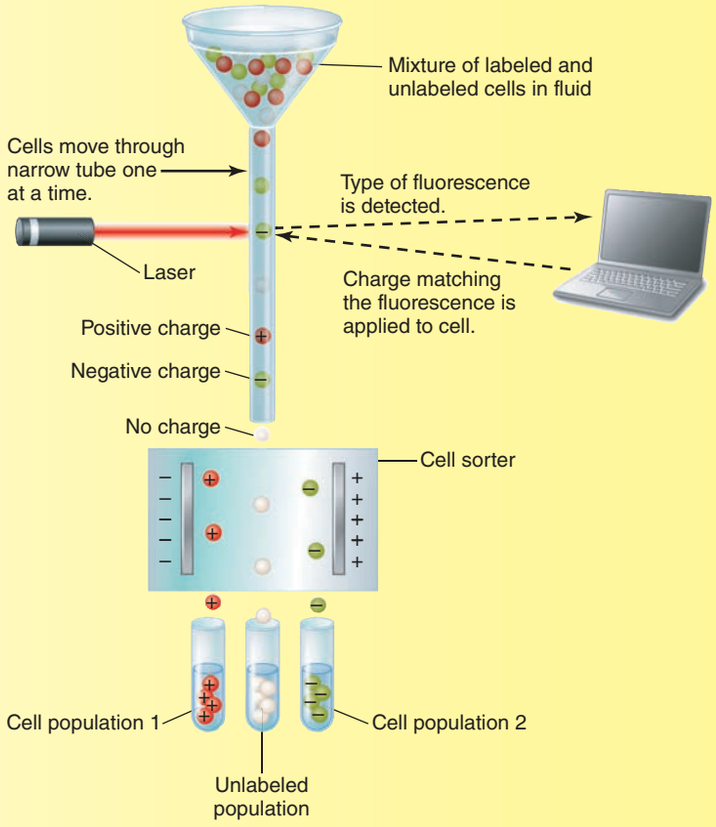


Figure B15.1. Flow cytometry Fluorescence-activated cell sorting (FACS) is a special type of flow cytometry that can sort cells according to their fluorescence. In this example, the differentially labeled cells are separated into two different populations.

Test Your Understanding

Suppose that you want to determine the presence of *Methylosinus trichosporium*, a Gram-negative alphaproteobacterium capable of methane oxidation, in a soil sample. How could you use this technique to find cells that might be your organism, and what types of experiments would you perform next to confirm its identity?

Microbial diversity

As we have seen in this section, molecular techniques allow us to detect many more microbial species than do culture techniques alone. So, what have we learned from these molecular studies? Quite simply, we've learned that we share this planet with a lot of microbes! Four billion years of microbial evolution on Earth, with microbes actively contributing to the development of the planet's biosphere, has resulted in the astonishing breadth of genetic and metabolic diversity within today's microbial world. However, the extent of this diversity is not well understood, as reflected in the question marks shown in Table 15.1. Cultivation-independent techniques are now telling us more about this diversity. Categorizing this diversity represents the next problem.

Outside of the microbial world, the standard measure of diversity is the number of species. Division of organisms into different types, culminating in the reproductively isolated species, or naturally interbreeding populations, has been central to the formulation and understanding of evolutionary processes. Microbiologists also use the species designation but, because of the absence of true sexual reproduction, a

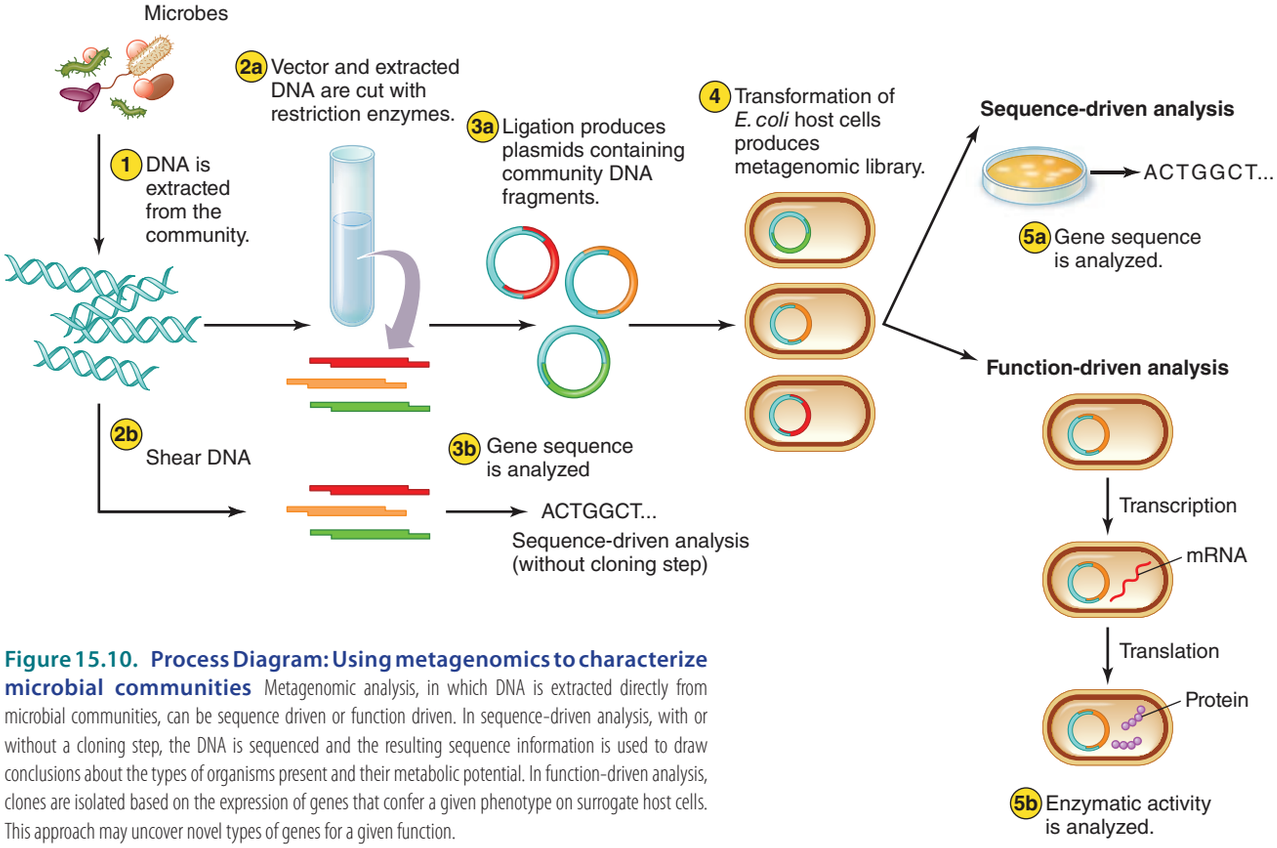

Figure 15.10. Process Diagram: Using metagenomics to characterize microbial communities Metagenomic analysis, in which DNA is extracted directly from microbial communities, can be sequence driven or function driven. In sequence-driven analysis, with or without a cloning step, the DNA is sequenced and the resulting sequence information is used to draw conclusions about the types of organisms present and their metabolic potential. In function-driven analysis, clones are isolated based on the expression of genes that confer a given phenotype on surrogate host cells. This approach may uncover novel types of genes for a given function.

bacterial or archaeal species clearly is not equivalent to a plant or animal species.

Because the species concept may be difficult to apply to microbes, and bacteria and archaea in particular, the term **operational taxonomic unit (OTU)** has become commonplace. By convention, an OTU is any group of organisms that shares at least 97 percent SSU rRNA gene sequence identity. This threshold was chosen because, originally, a 97 percent identity across the full SSU rRNA gene correlated relatively well with a 70 percent identity between two genomes, based on DNA:DNA hybridization (see Appendix C). This somewhat arbitrary OTU measurement has nonetheless been used as an approximate microbial equivalent of a species. For context, we should note that if this same measure were applied to the class *Mammalia*, then a single OTU would include all members of the class, from rats to cats to chimpanzees!

In 2002, Thomas Curtis and colleagues famously reported their calculations showing that more species exist in a ton of soil than in all the oceans combined, using the OTU as the definition of a microbial species. Most of these species still have not been cultured. Only a small bit of DNA sequence data was known, usually just a portion of the 16S rRNA gene. Although the total global diversity of bacterial and archaeal species might be in the millions or hundreds of millions of individual OTUs, or species, the nature of the sequence data used for generating such estimates is inherently problematic. For example, many or most of the OTUs generated in sequence-based surveys occur at very low relative abundance. Some of these sequences are background "noise" inherent in sequence data, and some are genuine. Regardless, sequence data reveal that there are many more OTUs that are not yet detected even by high-throughput sequencing of SSU rRNA gene surveys. We simply know that there are enormous numbers of microbial OTUs in most environmental samples and that we are only scratching the surface of this diversity. And, with such incomplete surveys, should we classify all of these organisms as species with so little information? Should these bacteria even be given names? **Perspective 15.1** and Appendix C give some insight into the naming systems used for uncultured and uncharacterized microbes.

Importantly, because we now have information about the types of microbes that have not yet been cultivated or characterized, novel approaches can be used to recover entire genomes from these poorly explored microbes, which have been called microbial dark matter. As you will see in the **Mini-Paper**, information from SSU rRNA gene surveys and metagenomics data can help identify the most phylogenetically novel microorganisms that can be recovered by flow cytometry for genome sequencing and analysis. The ability to collect genomes from uncultivated microbes was unthinkable just a few years ago: this is an exciting time for microbial ecology!

Mini-Paper: A Focus on the Research

INSIGHTS INTO THE PHYLOGENY AND CODING POTENTIAL OF MICROBIAL DARK MATTER

C. Rinke et al. 2013. Insights into the phylogeny and coding potential of microbial dark matter. Nature 499:431–437.

Context

Global microbial ecosystems are comprised of complex microbial communities. Because most microbes are challenging to cultivate, relatively little is known about the full extent of metabolic and phylogenetic diversity. The majority of cultured bacteria and archaea are associated with a small number of phyla and sequenced genomes are similarly biased. Over 88 percent of microbial genomes are derived from members of only four bacterial phyla: *Proteobacteria*, *Firmicutes*, *Actinobacteria*, and *Bacteroidetes*. There are greater than 60 known bacterial and archaeal phyla, and half of these do not yet have a single culture for study. These uncharacterized phyla are detected by high-throughput sequencing of SSU rRNA genes, which is how they are known to exist, and thus these phyla are referred to as "candidate" phyla. Given the enormous diversity of functions associated with cultivated microbes, reinforced by known genomes, one wonders how many more surprises remain hidden in the uncultivated microbial majority, the "dark matter" microbes that remain unstudied.

Although cultivation-independent approaches, such as metagenomics, collect genomic information from uncultivated microbes, including those from dark matter, the challenges associated with analyzing data from so many mixed genomes can be enormous. How might one specifically target dark matter microbes that exist at low relative abundance? Rinke and coworkers applied a clever strategy for targeting genomes from phylogenetically novel bacteria from a wide range of microbial ecosystems. In doing so, they discovered new microbes, functions, and genetics during this single excursion into dark matter microbes.

Experiment

The recovery of genomes from phylogenetically novel microbes required a careful strategy **(Figure B15.2)**. The researchers began by scanning a range of microbial ecosystems, using high-throughput sequencing of SSU rRNA genes (see Sections 15.2 and 10.1), to identify

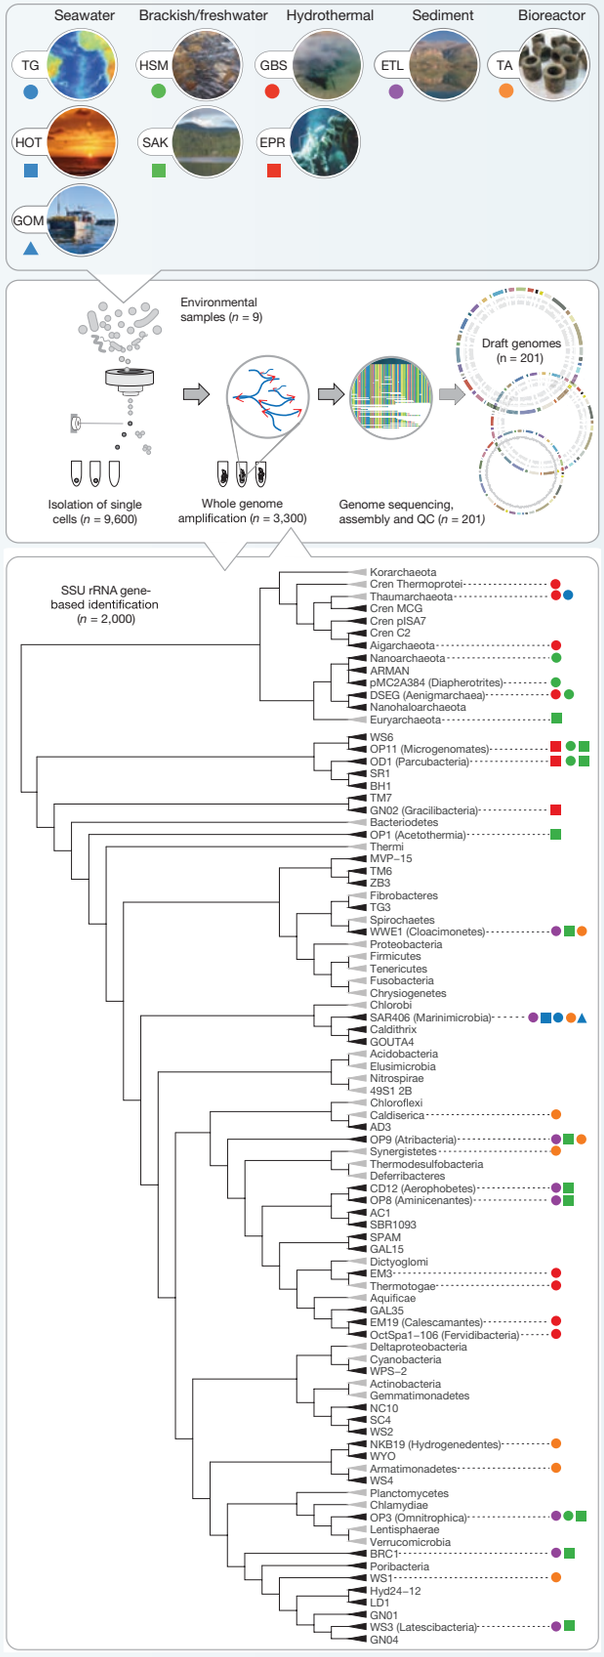

Figure B15.2. Sampling and analysis protocol for genome recovery The upper panel demonstrates a wide range of microbial ecosystems selected because of enriched novel microbe populations. EPR, East Pacific Rise; ETL, Etoliko Lagoon; GBS, Great Boiling Spring; GOM, Gulf of Maine; HOT, Hawaii Ocean Time-series Project; HSM, Homestake Mine; SAK, Sakinaw Lake; TA, terephthalate degrading reactor; TG, tropical gyre in the South Atlantic. The middle panel demonstrates how cells were isolated from samples before genomes were amplified, sequenced, and assembled (QC is quality control). The bottom panel is a cladogram based on SSU rRNA gene sequences from archaea (top) and bacteria (bottom). Black designates the candidate phyla and gray represents known phyla. Note that the symbols link single amplified genomes to their microbial ecosystem (*top panel*), and many of the single amplified genomes corresponded to candidate phyla, or microbial dark matter.

nine samples most likely to contain microorganisms from novel phyla. They then extracted all cells from these samples and subjected them to flow cytometry (see Toolbox 15.1), separating individual cells into separate tubes. They amplified the genomic material from each sorted single cell using a DNA polymerase from phage Phi29, which can replicate large fragments of DNA from a single copy to many millions of copies, a process known as whole genome amplification. They were then able to screen each of the single amplified genomes to identify genomes from novel bacteria and archaea and then selected 201 single amplified genomes for high-throughput sequencing using Illumina technology, followed by genome assembly and annotation (see Chapter 10).

Attesting to the success of this targeted metagenomic approach, these 201 partial genome assemblies were associated with 21 bacterial and 8 archaeal lineages that were poorly characterized or candidate phyla. Because of the additional phylogenetic information from these new genomes, the researchers were able to generate a more robust phylogeny than previously available, helping to resolve bacterial and archaeal phyla into even larger "super phyla," even proposing two new super phyla in the process. They were also able to use these genomes from poorly characterized microorganisms to help with "phylogenetic anchoring" of ~340 million metagenomic reads present in the public databases. This means that future metagenomic studies will be better able to identify environmental sequences because of the information gained by this study.

In addition to gaining a better understanding of bacterial and archaeal phylogeny through this process, the researchers studied the genome fragments associated with the 201 genome assemblies for novel functions. In doing this, they discovered several previously unknown features and functions. From the bacterial genomes, these features included the recoding of a known stop codon (UGA) to code for the amino acid glycine in the *Gracilibacteria* genome, and evidence for lateral gene transfer (see Chapter 10) of an archaeal enzyme for purine biosynthesis into the bacterial superphylum *Patescibacteria*. The archaeal genomes revealed a few secrets as well. A nanoarchaeote genome possessed an oxidoreductase most closely related to the slime mold *Dictyostelium discoideum* (see Section 3.2), which is the first evidence of lateral gene transfer between a microbial eukaryote and an archaeon. Although sigma factors are associated with the regulation of gene expression in bacteria, the researchers discovered sigma factors in several archaeal genomes, suggesting lateral gene transfer from bacterial donors. Other archaeal discoveries implicating lateral gene transfer included the presence of a bacterial response system to limiting nutrients in archaeal genomes and the presence of a lytic murein transglycosylase, which is a bacterial enzyme for degradation of peptidoglycan, in archaea. The latter suggests a possible archaeal defense system against bacteria.

Impact

Given that this study generated surprising phylogenetic and functional discoveries from genomic information derived from only 201 individual cells, the potential for future discovery is enormous. This is especially true given that the most complex microbial communities on Earth are found within soils. You will notice that this study did not focus on soils at all, and as a result, the observations made in this study are likely only the tip of the iceberg when it comes to uncovering the myriad functions hidden within microbial ecosystems for discovery.

Questions for Discussion

1. All methods for studying microbial communities have bias. What sorts of bias do you think influenced this study and the types of microorganisms and genes explored by the researchers here?
2. Annotations of open reading frames suggest functions for the proposed genes of interest. What might the authors need to do to confirm these initial observations?
3. This targeted metagenomics study provides insight into uncultured bacteria and archaea. How might we use the information they obtained to help with developing a strategy for culturing some of these microorganisms? What additional benefits would pure cultures of dark matter microorganisms provide?

Perspective 15.1
NAMING THE UNCULTURED AND UNCHARACTERIZED

Classification of living organisms is based on phylogeny—their evolutionary relationships, ideally based on their genetic relatedness or "phylogenetics." For microorganisms, SSU rRNA genes can be used to assign evolutionary relatedness (see Chapter 1 Mini-Paper), but assigning a formal taxonomic name—a genus, a species, sometimes a subspecies—to a new bacterium ideally requires that the bacterium be isolated, cultured, and thoroughly described in the *International Journal of Systematic and Evolutionary Microbiology*, the official journal of record for new bacterial taxa. A culture of the bacterium should then be deposited in a culture collection for others to study. One of the largest culture collections of microbes is the American Type Culture Collection (ATCC), which maintains and distributes cultures of bacteria as well as protozoa, fungi, algae, viruses, plants, animal, and human cells, and even genomic DNA, DNA probes, and antibodies.

Newly discovered uncultured bacteria or archaea that lack some of these characterizing details are not assigned a formal name. Yet, there is often a practical need for some sort of designation so that scientists can compare results and build information regarding new isolates. A system for naming such putative new taxa has been recommended by the International Committee on Systematics of Prokaryotes (ICSP) in the International Journal of Systematic and Evolutionary Microbiology (IJSEM). The designation "*Candidatus*," meaning "candidate," is used to identify uncultured bacteria or archaea that are characterized only partially or those enriched in culture but not yet purified and characterized. For *Candidatus* designation, information, such as structure, metabolism, reproduction, and the environment in which the organism is naturally located, must accompany genetic data. The names usually are written with the category *Candidatus* in italics and the unique proposed genus not italicized. If a species name is proposed, then this name is added and not italicized. An example of a proposed species name is *Candidatus* Carsonella ruddii (see Section 17.5). For a more in-depth look at microbial taxonomic nomenclature, including the *Candidatus* status, see details presented in Appendix C.

So what do we call microbes that have been identified only by a stretch of nucleic acid sequence? These putative species, based on SSU rRNA gene sequences, are commonly referred to as "phylotypes" or operational taxonomic units (OTUs), which are used to designate a group of SSU rRNA genes that show very close phylogenetic relationships to one another. These terms are used in the recognition that limited sequence data identifies these microbes as similar or distinct from one another, but that little else is known about them.

15.2 Fact Check

1. Describe how SSU rRNA gene sequences are used as a phylogenetic tool.
2. What is an operational taxonomic unit (OTU), and what gave rise to the term?
3. Contrast the strengths and limitations of cultivation-dependent and cultivation-independent approaches for characterizing microbial ecosystems.
4. Explain how the stable-isotope probing method is used for studying microbial metabolism.

15.3 Aquatic ecosystems

What is the nature of life in water?

Earth is very much an aquatic planet, with over 70 percent of its surface covered by water. Although most of that water exists in the oceans, freshwater environments represent important and distinct microbial ecosystems. In this section, we will explore microbial life in aquatic habitats. We will begin by examining marine environments, then investigate freshwater environments. Along the way, we will look at how microbes survive in these aquatic habitats and how they interact with the environment.

Marine ecosystems

Earth's oceans are home to some amazing creatures. Blue whales, great white sharks, and the elusive giant squid all capture our imagination. However, the vast majority of life in our oceans consists of microorganisms. Viruses, bacteria, archaea, and eukaryal microbes constitute over 98 percent of the marine biomass. Ocean water typically contains about 35 grams of salt per liter, with about two-thirds of the salt consisting of Na^+ and Cl^- ions, and comparatively minor amounts of Mg^{2+}, Ca^{2+}, K^+, SO_4^{2-}, and HCO_3^-. In general, conditions are oxic, so aerobic respiration can occur, but levels of available nitrogen, phosphorus, and iron are low. As a result, microorganisms are often in a state of **oligotrophy**, or using nutrients at very low concentrations. Increasing the nutrient concentration in marine waters increases microbial growth, which quickly can lead to anoxic conditions. The ecological impacts of anoxic conditions can be devastating for marine ecosystems **(Perspective 15.2)**.

B. Dead zones worldwide (dots)

Figure B15.3. Dead zones **A.** The Mississippi River Dead Zone in the Gulf of Mexico is a coastal region that is impacted heavily by chemical fertilizer runoff. **B.** Dead zones around the world tend to be found in coastal regions at the outfall of rivers flowing through heavily fertilized agricultural regions.

Productive fisheries, many of them in coastal regions, have been important contributors to the sustenance of human populations for thousands of years. However, massive disappearances of fish and other macroscopic sea life in coastal regions have been reported increasingly, especially in areas where rivers flow into the ocean. A prominent example of this problem is the Gulf of Mexico at the mouth of the Mississippi River **(Figure B15.3)**. These areas have been called "dead zones." Over 400 of these dead zones have been documented worldwide, and the numbers are increasing rapidly. Marine animal life cannot survive because of hypoxia, or low O_2 levels.

What causes the appearance of these dead zones? Within the oceans, the scarcity of key nutrients like nitrogen and phosphorus generally limits photosynthesis. As the Mississippi River flows through the intensively farmed and fertilized land of the American Midwest, runoff from the land deposits nitrogen and phosphorus into the river. As the river water enters the Gulf of Mexico, it brings with it a high dose of nutrients. Nitrogen and phosphorus are deposited in the Gulf of Mexico, converting the oligotrophic conditions to a nutrient-rich eutrophic state. Primary producers proliferate. The resulting massive input of energy and organic carbon into the marine ecosystem supports the increased growth of aerobic heterotrophic microorganisms. The aerobic respiration of these heterotrophs consumes oxygen (O_2), causing hypoxia **(Figure B15.4)**.

If the soils of the Midwestern United States have been farmed for hundreds of years, then why are dead zones only now becoming such a problem? The answer can be linked directly to the increased use of synthetic and mined inorganic fertilizers that easily leach from the soil, instead of organic fertilizers like manure and compost and the bacterial symbiotic N_2 fixation in root nodules of legume crop plants (see Section 17.2). This increased use of synthetic fertilizers has become necessary to support intensive cultivation of crops like corn and wheat.

Of course, the dead zones are far from dead. They contain active communities of microorganisms. However, we know relatively little about how the microbial populations in these communities cause hypoxia and how they then respond to the resulting low-O_2 conditions. How might they adapt to life in the absence of O_2? How do their activities affect the cycling of marine nutrients and greenhouse gases such as carbon dioxide (CO_2)? Do these hypoxic events have long-term effects on the microbial communities? We now have tools needed to address these questions and the answers almost certainly will be extremely interesting.

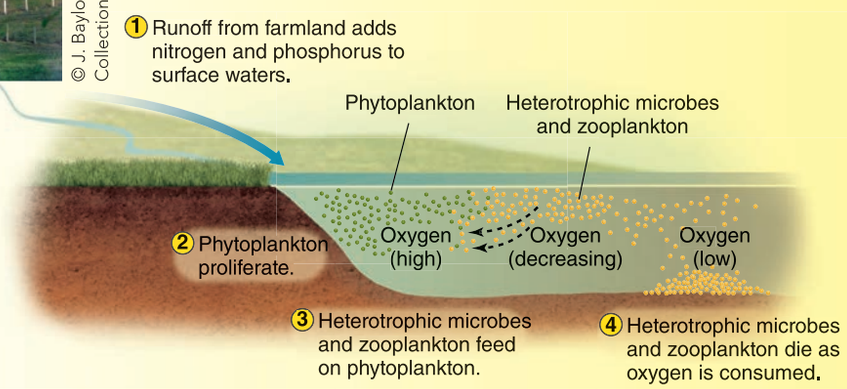

Figure B15.4. Process Diagram: Dead zone formation There is a direct connection between dead zones and agricultural activities. Runoff from farmland increases the amounts of nitrogen and phosphorus in surface waters that empty into marine waters. The resulting increased eutrophication causes phytoplankton blooms that support increased growth of aerobic heterotrophic microbial populations. Degradation and consumption of phytoplankton cells by bacteria and zooplankton can reduce the level of oxygen in the water.

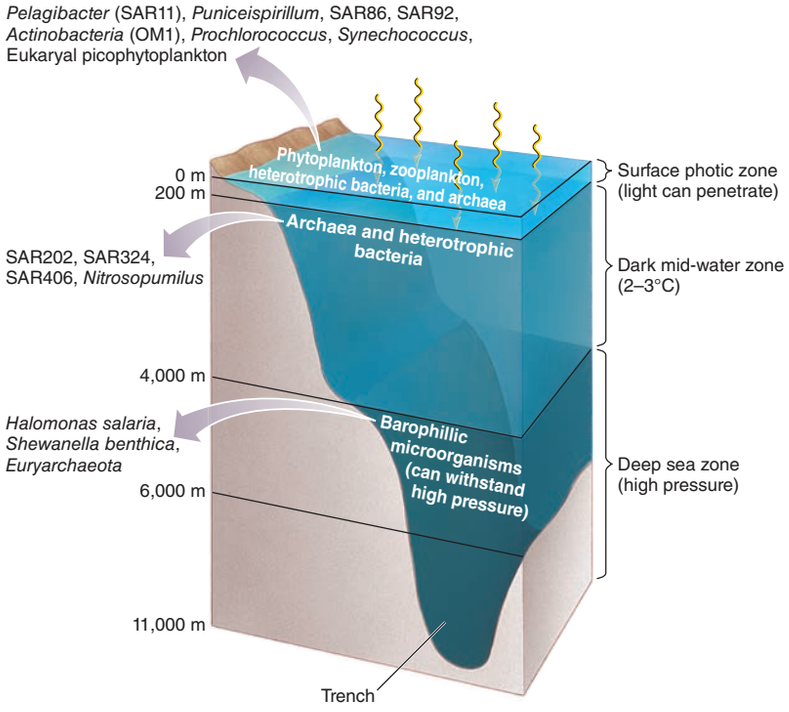

Berg, Hager, Hassenzahl: *Visualizing Environmental Science*, copyright 2011, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 15.11. Ocean zones The oceans can be divided into zones based on depth. These zones are characterized by amount of light, temperature, and pressure. Sampling and DNA sequence analysis of oceanic waters has revealed the major groups of organisms found in different zones. Most of these microbes have not been cultivated, so their physiologies are unknown and their roles are not well understood.

The oceans are not uniform with respect to physical and chemical characteristics. We can divide the ocean **(Figure 15.11)** into the surface zone, which includes the top few hundred meters where light can penetrate, the dark mid-water zone, where the temperature remains a constant 2–3°C, and the deep sea zone where extremely high pressures exist. Sequencing of SSU RNA genes from marine water samples reveal that the distribution of microorganisms changes as a function of depth **(Figure 15.12)**.

Within the ocean, microbial abundance declines with depth as distance from the site of primary production increases. However, the proportion of archaeal cells increases with depth. Indeed, for much of the ocean volume, the biomass consists of more archaea than bacteria, with upwards of 10^{29} microbial cells in all of the oceans combined. As large as this number seems, it has been estimated that the numbers of virus particles are an order of magnitude greater than this **(Figure 15.13)**. We will investigate the role of marine viruses at the end of this section. For now, let's briefly investigate the three major zones of the ocean.

Surface Zone

When you gaze out at crystal blue waters on a tropical beach, probably the last thing that comes to mind is that each teaspoon of water is teeming with hundreds of thousands of microbial cells. Despite the oligotrophic nature of the oceans, the typical cell counts in coastal marine environments can reach 10^8 cells per milliliter, and can be even higher in marine sediment. The oceans are perhaps the most intensively studied, and yet surprisingly not very well understood, ecosystems on the planet.

Photosynthetic microbial inhabitants of the surface waters of the oceans support all other life in the ocean, from other microbes to blue whales. Of course, the primary producers in the oceans are not higher plants like they are on land, but phytoplankton**,** photosynthetic microorganisms like the cyanobacteria *Prochlorococcus* and *Synechococcus*, diatoms like *Thalassiosira* **(Figure 15.14)**, and dinoflagellates like *Ceratium*. During photosynthesis, these organisms contribute to the oxygenation of the water. Many of the cyanobacteria can also fix N_2, increasing nitrogen available in the system. Analysis of SSU rRNA genes indicates that a diverse collection of other, presumably heterotrophic, bacteria and archaea accompany these phototrophs. Because most of these organisms have not been cultivated, their roles in the ecosystem remain unclear. Non-photosynthetic **zooplankton**, many of them protists and small crustaceans, graze on the primary producers and the other microbes in the surface zone, thus distributing the carbon and energy throughout the ecosystem.

Dark Mid-water Zone

Despite the seemingly inhospitable environmental conditions of the dark mid-water zone where photosynthesis is not possible, a wide variety of microbial life exists here, being fed by the

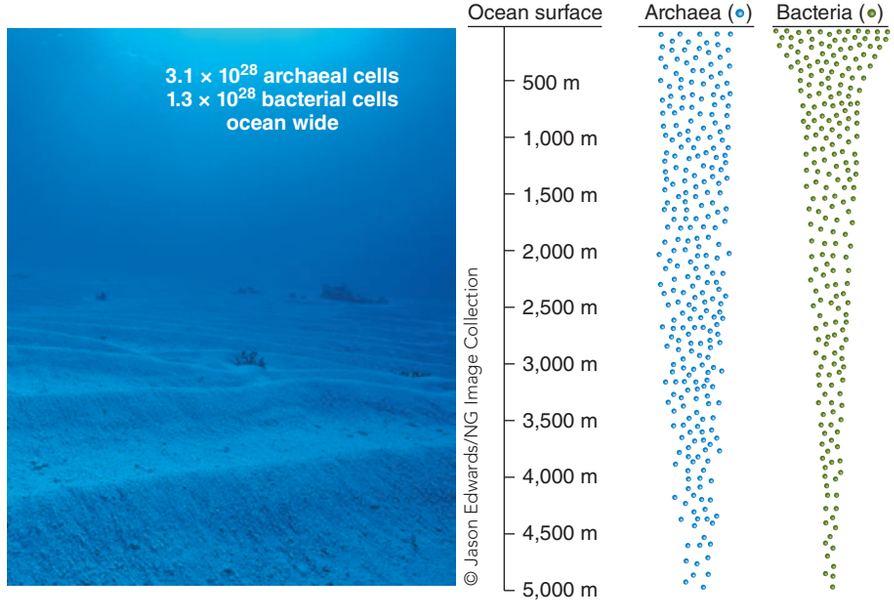

Figure 15.12. Comparison of the relative abundance of bacteria and archaea in ocean water DNA sequence analysis of samples collected from ocean depths has suggested that the proportion of archaea increases with depth, and that there might actually be more archaeal cells than bacterial cells in the world's oceans.

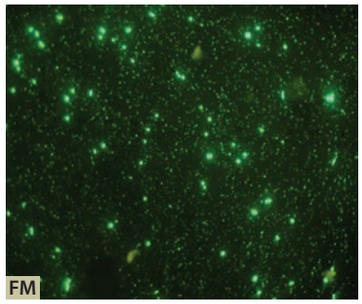

Figure 15.13. Viral particles and microbial cells in a seawater sample The number of viral particles found in ocean waters is at least an order of magnitude higher than the number of cells. This figure shows the visualization of bacterial and/or archaeal cells and viral particles using fluorescence microscopy. The larger points are the cells whereas the smaller points are viral particles.

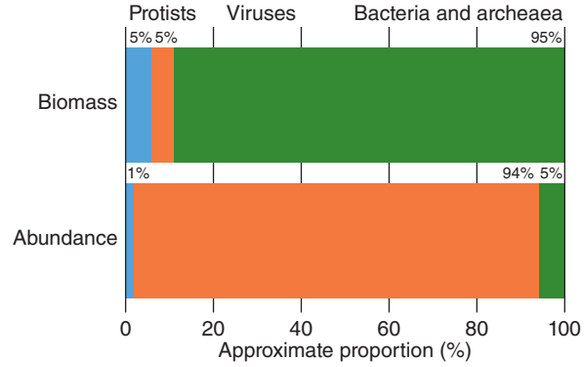

Figure 15.15. Comparison of marine microbial biomass and cell abundance Although viruses compose approximately 5 percent of the total biomass of the marine environment, with the majority being bacterial and archaeal, viral particles outnumber all other cells combined.

organic matter produced in the upper surface waters. Organic carbon, released by viral lysis of the phytoplankton becomes available to support the growth of heterotrophic bacteria and archaea. This released carbon tends to fall, often attached to small particles, and supports the heterotrophic microorganisms in the dark mid-water zone as well. It has been estimated that about 1 percent of the primary production reaches the seafloor, where anoxic conditions contribute to its slow breakdown and accumulation. Over hundreds of millions of years, this raining detritus has resulted in the formation of extremely rich organic sediment on the seafloor that contains very high cell numbers. Many of the oil and gas resources that our economies rely on originate from such sediments.

Deep Sea Zone

The average depth of the seafloor is about 3,500 meters, but trenches can reach much greater depths. Indeed, the deepest point known, the Mariana Trench in the western Pacific, reaches to 11,000 meters below the sea surface. The atmospheric pressure there is about 1,000 times that at sea level. Microorganisms that can reside at these depths and withstand extremely high atmospheric pressures are called **piezophiles**, or barophiles. Some of them are obligate piezophiles that must be kept under pressure in order to grow at all.

Life under extreme pressure presents several challenges. For example, high pressure causes the plasma membrane fluidity to decrease. Enzymes also tend to work less well at high pressures. To combat these problems, piezophiles often have high levels of polyunsaturated fatty acids in their plasma membranes. These polyunsaturated fatty acids probably improve the fluidity of the membranes. Other adaptations of these microorganisms are still being investigated.

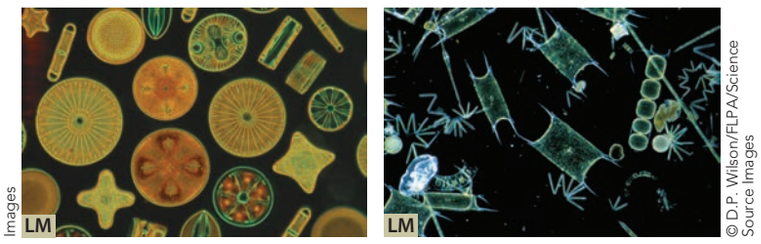

Figure 15.14. Micrographs of different diatom species A collection of diatom cells, demonstrating the uniquely patterned cell walls composed of silica and pectin.

Viruses of the oceans

There are probably greater than ten times more virus particles than all other microbial cells in the oceans **(Figure 15.15)**, amounting to approximately 10^{30} total virions. Despite their enormous dominance, we know relatively little about viruses and their roles in the marine ecosystem. However, our level of knowledge is increasing. In August 2011, researchers at the Bermuda Institute of Ocean Science, the University of South Florida, and the University of California, Santa Barbara, reported the results of a ten-year-long study of viruses in the ocean. Over this time period, they regularly monitored viruses present at various depths within the North Atlantic's Sargasso Sea. Although they sampled only the top 300 m of the ocean, their results demonstrate very definite temporal and spatial variations in the types of viruses present. Perhaps not surprisingly, viruses of cyanobacteria appear to dominate in the surface zone.

What role do marine viruses play? Ultimately, viruses play an important role in controlling the microbial communities that exist with the marine water column. For example, viruses of cyanobacteria replicate in, and typically lyse, cyanobacteria. When these cells lyse, fragments of the plasma membrane, DNA, proteins, and nutrients are released into the environment. Other microorganisms can then acquire these organic molecules. In other words, viruses supply the marine ecosystem with nutrients. We still know very little about how these viruses interact with the environment. However, it is becoming clear that viruses play an integral role in the normal functioning of the complicated marine ecosystem. Viruses probably play a similarly important role in the functioning of other ecosystems as well.

CONNECTIONS In **Chapter 14**, we discussed how microbial metabolism impacts biogeochemical cycles and that understanding these cycles informs how human activities impact the Earth's climate. As introduced in **Perspective 14.1**, viruses in the marine environment play an important role, serving as a "viral shunt" for organic carbon that can reduce carbon sinking to the oceans' depths as part of the "biological pump."

Cultivation of oligotrophic microorganisms from seawater

The science of microbiology was founded on the ability to isolate and maintain pure cultures from single cells. The introduction of solid growth media that supports the growth of discrete colonies was central to pure culture. The development of microbial ecology was based on the application of enrichment culture techniques involving the design of conditions aimed at isolating cells that have particular physiological characteristics and metabolic abilities. We discussed the challenges of cultivating microorganisms earlier in this chapter and highlighted some of the reasons why this is so. Some grow too slowly to form colonies in a reasonable amount of time without being overwhelmed by the faster-growing microorganisms in the community. Some rely on the presence of multicellular organisms or other microorganisms with which they form obligate symbiotic associations (see Chapter 17). Others, like many marine microorganisms, are optimized for low-nutrient, oligotrophic conditions. Let's explore oligotrophic marine microorganisms as an example of how creative experimental design can eventually overcome the difficulties of bringing microorganisms into pure culture.

The study of microbial communities in marine environments provides a particularly good explanation for the imprecise view provided by the use of traditional cultivation and enrichment-based approaches. Standard commercially available marine isolation media contain elemental profiles similar to seawater, except that carbon, nitrogen, phosphorus, and iron are typically present at levels several orders of magnitude greater than the levels found in seawater. Although these media are very good for isolating some marine organisms, such as *Vibrio fischeri* and *Vibrio harveyi*, they do not accurately replicate the growth conditions of the natural habitat. Seawater generally contains extremely low levels of dissolved organic carbon, often less than 1 mg of carbon per liter, whereas common marine media can contain orders of magnitude more carbon than this. Many marine microorganisms cannot assimilate much of this carbon easily. New media formulations, or those that are based on marine water itself, can help address these problems.

Physiological studies require the availability of pure cultures. Efforts to obtain cultures of marine oligotrophs are hindered because low levels of nutrients do not yield large amounts of biomass, and certainly do not support the formation of visible colonies on solid growth media. So, how do we isolate and grow the predominant but cultivation-resistant cells? We should start by recognizing that these cells might be obligately oligotrophic and unable to withstand high concentrations of carbon. We should also separate them from cells that may be less abundant but also less sensitive to higher levels of carbon. In the presence of higher carbon levels, these cells would quickly outgrow the obligate oligotrophs. The standard method of separating the cells for cultivation, developed in the laboratory of Don Button at the University of Alaska in the early 1990s, involves **dilution to extinction**. Seawater samples are diluted so that very few cells remain in each aliquot. Inoculations are then made from these dilutions into autoclaved seawater, rather than a "rich" medium, followed by incubation. Pure cultures of obligate oligotrophs have been isolated using this approach (Figure 15.16). Titers are usually limited to about 10^6 cells per milliliter, which corresponds to the total cell concentrations in a typical natural seawater community.

In 2002, Stephen Giovannoni and coworkers at Oregon State University used the dilution to extinction method to isolate the widespread SAR11 type of microorganism from the Sargasso Sea in pure culture (Figure 15.17). This bacterium, now known as *Pelagibacter ubique*, has been estimated to make up 25–50 percent of the cells in seawater microbial communities. Prior to growing it in the laboratory, researchers knew little about the role of *P. ubique* in the ocean. The availability of pure cultures has allowed microbiologists to determine its genome sequence, study its growth, biochemistry, and physiology, investigate its role in biogeochemical cycles, and learn more about its connections with other organisms.

Figure 15.16. Process Diagram: Dilution to extinction method This method involves first using a microscope to count the cells, then diluting the sample in small volumes of autoclaved seawater so that there is less than one cell per starting culture on average. Cultures that show growth are subcultured to large volumes of autoclaved seawater and incubated. If cultures grow, they can be harvested by centrifugation and analyzed further.

Figure 15.17. Successful cultivation of members of SAR11 The dilution to extinction method was used to cultivate these previously uncultivated but abundant marine bacteria. The phylogenetic tree compares the SSU rRNA sequence of one of the cultures, strain HTCC1062, with SAR11 SSU rRNA gene sequences that had previously been determined from seawater samples without cultivation. The latex bead in the TEM image is ~0.5 μm and was included for scale. These are among the smallest known bacterial cells in culture.

Ocean community genomics

The extremely low culturability of marine microorganisms (see Table 15.2) has led to many sequence-based metagenomics studies of marine ecosystems (see Figure 15.10). In these experiments, researchers collect samples of seawater and recover the biomass by filtration. DNA is extracted from the cells and sequenced. The resulting DNA sequence data can then be compared to DNA sequence databases. Craig Venter and other investigators have used this approach to catalog the genomic information in marine surface waters. Their studies have revealed new organisms and proteins, suggesting new types of metabolic activities. One surprising finding was the apparently widespread occurrence of proteorhodopsin in marine bacteria (Figure 15.18), which is related to bacteriorhodopsin and halorhodopsin of the archaea. Proteorhodopsin commonly functions as a light-driven proton pump to create a proton motive force used to drive ATP synthesis (see Section 13.6). It may also have sensory functions in some bacteria. Given that the widespread and abundant marine bacterium, *Pelagibacter ubique*, uses this form of energy capture, this process likely contributes substantially to ocean carbon and energy levels.

Even with all the new sequence data, scientists have only begun to understand the complexity of ocean ecosystems. The functions of newly determined sequences often cannot be inferred because they are not similar enough to genes in characterized organisms. Although the widespread use of DNA-sequencing studies has greatly furthered our knowledge, cultivation of oligotrophic members of seawater communities remains necessary and continues to present a unique challenge. The study of *P. ubique* remains one of the best examples of how combining cultivation-independent approaches, informing about "who is there," with cultivation-based approaches, informing about "what they do," can help microbiologists with a more comprehensive understanding of microbial ecosystems and their community members.

Freshwater ecosystems

Freshwater ecosystems, including lakes, rivers, and streams, differ in many ways from their marine counterparts. In general, freshwater environments contain much higher nutrient levels than marine environments. They receive higher levels of organic matter due to runoff from land, rather than relying on biomass production by photosynthetic microorganisms.

Figure 15.18. Discovery of new light-harvesting systems in the ocean by sequence analysis of microbial communities One of the major discoveries of microbial community sequencing is the widespread occurrence of proteorhodopsin light-harvesting systems.

In deep lakes, stratification into separate oxic and anoxic zones can occur (Figure 15.19). This stratification results from the temperature-dependent density of water. Typically, an upper layer of warmer low-density water, called the **epilimnion**, is separated from bottom high-density colder water, called the **hypolimnion**. Between the layers is a thin zone called the **thermocline**, which is a region of rapid temperature and density change. Oxic conditions are common in the upper layer, whereas anoxic conditions may exist in the lower layer. Primary production through oxygenic photosynthesis occurs in the uppermost zone and supports aerobic heterotrophic activity directly below it. Just below the thermocline, anoxic conditions can allow anoxygenic photosynthetic bacteria to contribute to primary production. The deepest layers contain considerable methane (CH_4) oxidation and nitrate (NO_3^-) reduction. The sediments support substantial methanogenesis and sulfate (SO_4^{2-}) reduction.

Many deep tropical lakes and relatively few temperate lakes have permanent stratification, with no mixing of the layers. In contrast, thermal stratification occurs seasonally in colder regions, becoming established in the spring and lasting throughout the summer. During autumn, the top warm layer cools until the lake is isothermal and mixes. At 4°C, the density of water is maximum and further cooling results in a surface cold layer that may freeze at the surface. This new "inverse" stratification lasts until the ice melts in spring and the surface water warms above 4°C, causing the "spring turnover." Some lakes may mix one or more times in a year, and others have prolonged thermal stratification and mix more or less continually when not covered by ice. Mixing of the layers results in the redistribution of nutrients from the lower layers, and this can result in algal and cyanobacterial blooms because nutritional

Microbes in Focus 15.1

SYNECHOCYSTIS SP. PCC6803—FROM UNPLEASANT CYANOBACTERIAL BLOOMS TO SCIENCE AND BIOTECHNOLOGY WORKHORSE

Habitat: Isolated from a Berkeley, California, freshwater lake in 1968; has become one of the best studied of the cyanobacteria and a model system for oxygenic photosynthesis

Description: Unicellular, with spherical cells ranging in size from 2 to 7 μm. The genome sequence, determined in 1996, consists of a 3.57-Mb chromosome and seven plasmids ranging in size from 120 kb to 2.3 kb.

Photo provided by Trevor Charles. Courtesy Bithi Eshaque

Key Features: The organism can carry out oxygenic photosynthesis and can grow either autotrophically or heterotrophically. It can also fix nitrogen in the dark. It is easily transformable by DNA, can act as a conjugation recipient, and can be mutated by transposons or through homologous recombination methods. Researchers are studying this organism to gain insight into the fundamentals of oxygenic photosynthesis, as well as for the development of systems for the light-driven production of biofuels and bioproducts. *Synechocystis* sp. PCC6803 was the first photosynthetic organism to have its genome completely sequenced.

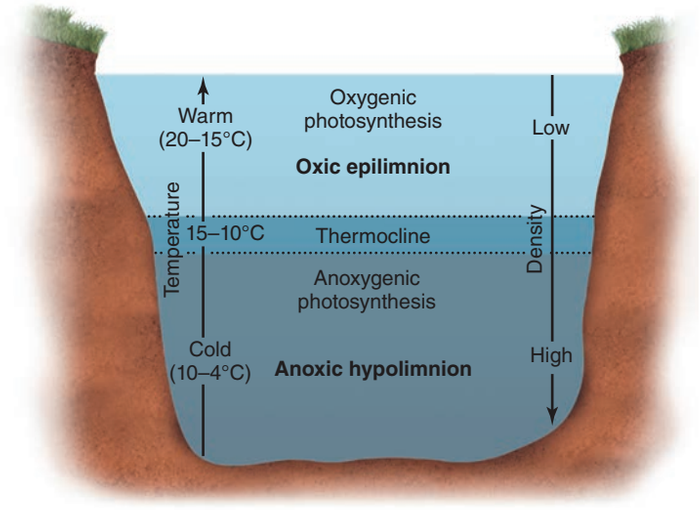

Figure 15.19. Structure of a stratified lake Deep lakes can form discrete layers. Typically, oxic upper zones are separated from anoxic lower zones by the thermocline. The surface waters support oxygenic photosynthesis; below that is a region of aerobic heterotrophic activity. At the thermocline, anoxygenic photosynthesis by hydrogen sulfide (H_2S)-oxidizing organisms occurs. The deeper regions support anaerobic heterotrophic activity and nitrate (NO_3^-) reduction. Anaerobic decomposition takes place in the sediment.

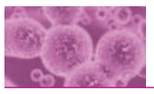
Figure 15.20. Cyanobacterial bloom Overgrowth of cyanotoxin-producing *Microcystis aeruginosa* within Conestogo Lake in Ontario.

limitations to growth are relieved. One common cyanobacterial bloom former, *Microcystis aeruginosa* **(Figure 15.20)**, is often in the news for its ecological and economic consequences. This bacterium, along with several other types of cyanobacteria, can produce cyanotoxins, which can impact drinking water supplies, cause toxicity to aquatic life and humans, and result in beach closures. Freshwater blooms can lead to anoxia and fish kills. However, the organisms in blooms are not all bad. *Synechocystis* sp. **(Microbes in Focus 15.1)**, a common component of cyanobacterial blooms, has been intensively studied as a model organism for photosynthesis and the photosynthetic production of biofuels and bioproducts. The relatively easy genetic manipulation of this microbe lends itself very well to this type of application.

15.3 Fact Check

1. What is oligotrophy?
2. Describe the conditions found in the three main zones of the ocean.
3. What are phytoplankton, and what is their role in ocean waters?
4. Explain the role of zooplankton and viruses in surface ocean waters.
5. Describe the layers and associated microbial life found in freshwater ecosystems.



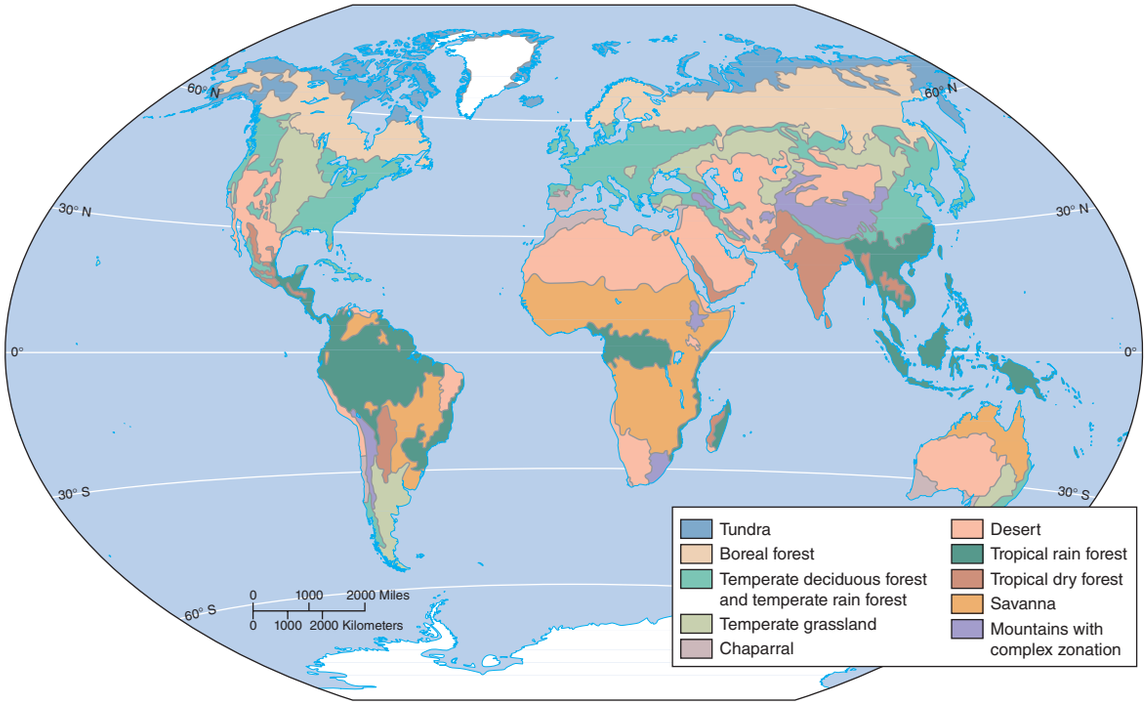
15.4 Terrestrial ecosystems

What is the nature of life on land?

The various terrestrial ecosystems on Earth have been divided into several **biome** types, categories based on vegetation characteristics **(Figure 15.21)**. Temperature and precipitation distinguish these biomes, and these factors are influenced by latitude, elevation, and geological features. In terrestrial biomes, photoautotrophic plants play central roles as the dominant primary producers, providing nutrients to the soil via microbial decomposition and photosynthesis-derived root exudates. Because the health of soils is a key determinant in the functioning of terrestrial ecosystems, we will begin this section by examining soils. Then we will investigate the rhizophere, look at microbial communities of soils, and examine how successful bioremediation relies on our knowledge of these communities.

Soils

Soil is a relatively thin band over the terrestrial surface of Earth, and it contains more microbial diversity and activity than any

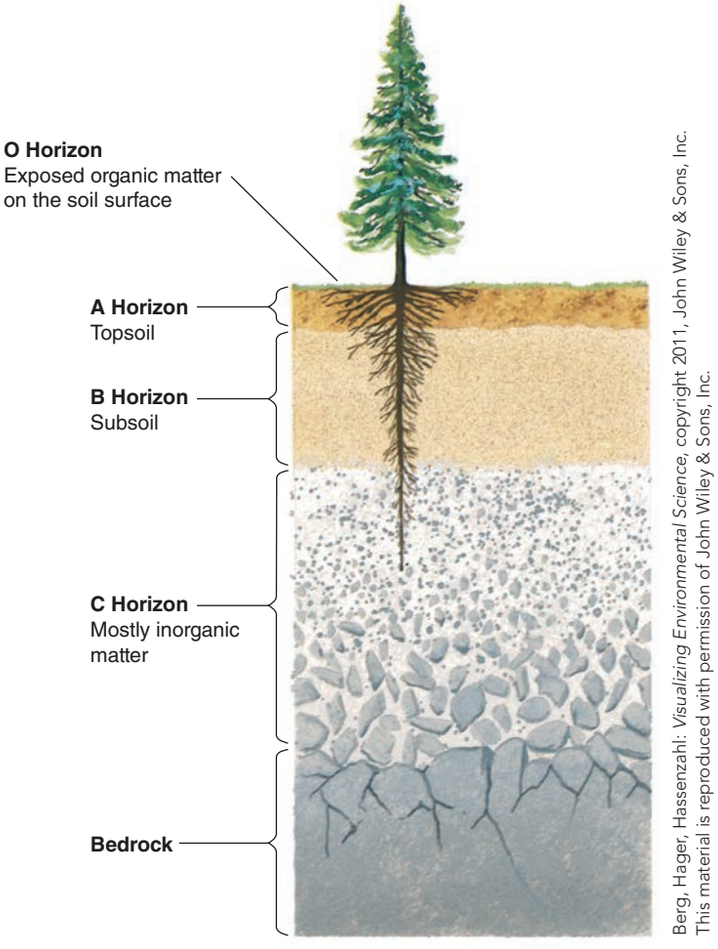


Berg, Hager, Hassenzahl: *Visualizing Environmental Science*, copyright 2011, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 15.21. Global map of terrestrial biomes Terrestrial ecosystems are divided into biome types based on vegetation characteristics.

other microbial ecosystem. Soils form through the microbial decomposition of plant and animal matter. This material then combines with abiotic material, such as minerals from weathering of rocks. Plants also contribute to the soil by excreting nutrients from their roots that encourage the growth of diverse microbial communities, especially communities of ammonifiers and denitrifiers. Many of these microorganisms benefit the plant directly by transforming various chemical compounds to forms that can be better assimilated by the plant. This interplay between plants and their microbial partners is central to the development of soils.

Due to the importance of soils in agriculture and forestry, soil scientists have developed extensive systems for categorizing soil types. Soils, much like oceans, are divided into distinct zones. A typical temperate zone soil can be divided into visibly distinct layers, or **horizons** (Figure 15.22), based on certain characteristics. The deepest layer, close to the bedrock and composed primarily of inorganic material, is called the C horizon. Directly above this layer is the B horizon, sometimes called "subsoil," that contains some organic matter. The A horizon, representing the uppermost surface layer, is known as "topsoil." The organic matter on the surface of the soil composes the O horizon. The topsoil has more organic material than the lower layers due to its proximity to plant roots and decomposing biomass. Accordingly, microbial activity and numbers, like that in oceans, are highest near the surface.



Berg, Hager, Hassenzahl: *Visualizing Environmental Science*, copyright 2011, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 15.22. Soil horizons Soils are divided into layers based on depth. The amount of organic matter is highest in the upper levels and decreases with increasing depth.

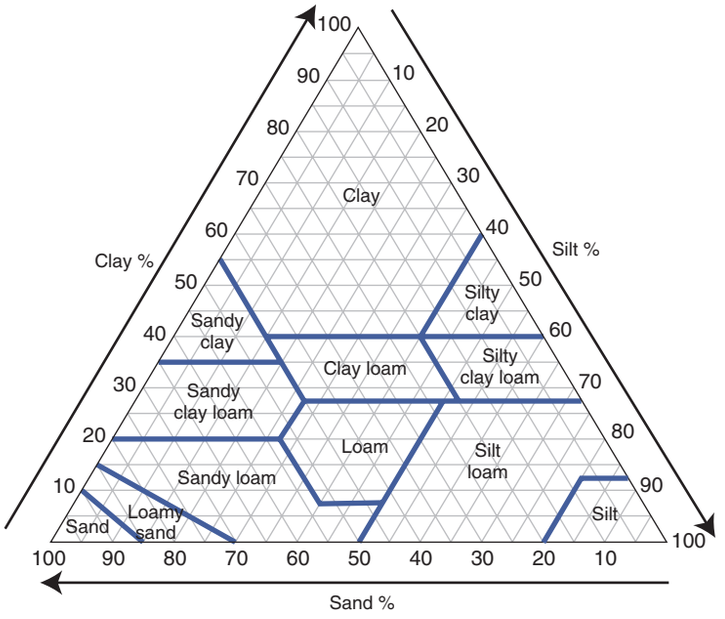


Figure 15.23. Textural classification of soils Soils textural classes are categorized based on the relative amounts of clay (<0.002 mm particle size), silt (0.002–0.05 mm particle size), and sand (0.05–2 mm particle size). When classifying a soil sample using this soil texture triangle, you would find the point of intersection where three lines correspond to three measured textural proportions, which always add up to 100 percent. For example, a soil with 15 percent clay, 25 percent silt, and 60 percent sand would be classified as a sandy loam.

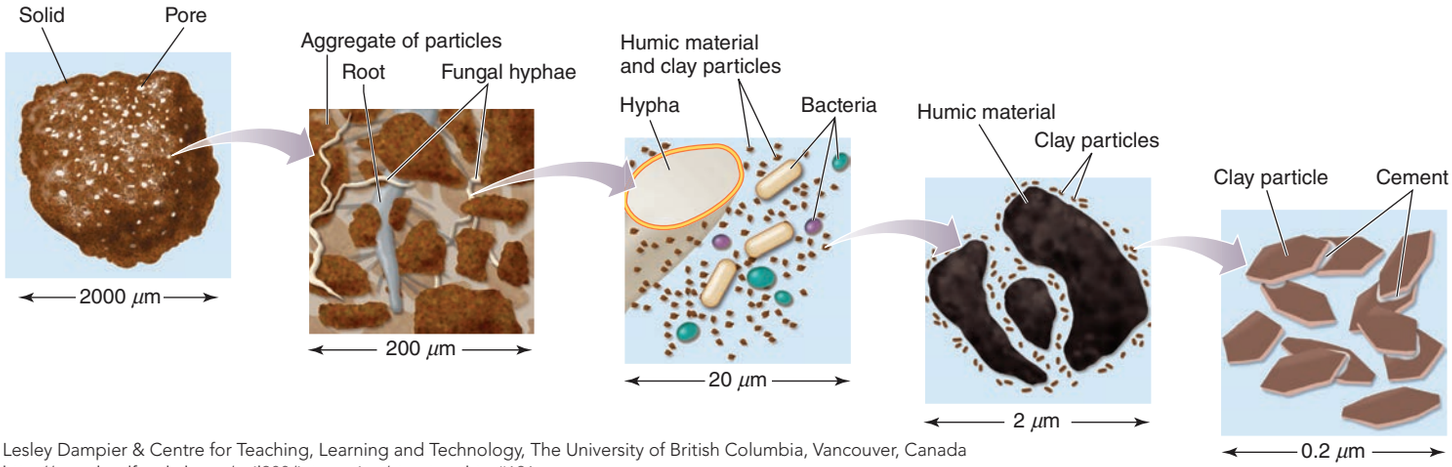
In addition to the soil horizons, soils are classified according to a soil taxonomy. The soil taxonomy system of the United Nations Food and Agriculture Organization describes 26 different soil classes based on physical characteristics. These include soil classes such as gleysols (very wet soils, but not organic), histosols (organic soils), yermosols (desert soils), and many others. Texture represents an important soil physical characteristic and is defined by the proportion of particle sizes that make up the mineral components of the soil. Sand particles range from 0.05 to 2 mm in diameter, silt from 0.002 to 0.05 mm, and clay less than 0.002 mm. Twelve textural classes can be defined based on the combination of particle sizes (Figure 15.23). Soil texture plays an important role in water retention and the potential concentration and interconnectedness of soil microbial communities. Soils with larger particle sizes tend to host fewer microbes per unit volume, yet microbial diversity may be increased for those communities because of increased spatial separation. Although not fully understood, soil texture is nonetheless considered an important factor governing the amount of microbial biomass and its diversity.

Aggregation of soil is its tendency to form clumps. Soil aggregation determines its structure, with the main binding agents being substances derived from microbial cells, as well as from **humic material** that results from incomplete breakdown of plant biomass (Figure 15.24). Although found at very high concentrations in soils, typically on the order of 10^9 cells per gram, microbes are not evenly distributed in the soil, nor



Lesley Dampier & Centre for Teaching, Learning and Technology, The University of British Columbia, Vancouver, Canada
http://www.landfood.ubc.ca/soil200/interaction/structure.htm#121

Figure 15.24. Model of soil aggregate formation mediated by microbial cellular material In a typical soil from lower magnification (*left*) to higher magnification (*right*), it is apparent that microbial cells and microbial debris hold the clumps together and influence the overall structure.

are they crowded. Microbes typically cover much less than 1 percent of the available organic or mineral surface available for growth. Instead of being evenly distributed, soil microbes tend to accumulate in biofilm within or near soil pores, enabling access to the movement of air, water, and nutrients **(Figure 15.25)**.

The organic compounds found in soils mostly result from the decomposition of plant matter. Soluble components, such as sugars and amino acids, can be assimilated and metabolized by various organisms. Extracellular enzymes must break down high molecular weight lignocellulose molecules consisting of cellulose, hemicellulose, and lignin. The resulting breakdown products can then be assimilated, resulting in formation of energy and new organic matter within the microbial cell. Cellulase and hemicellulase can degrade cellulose and hemicellulose, respectively. Lignin, a complex macromolecule composed of covalently linked phenolic-alcohol molecules, is quite resistant to degradation by all but a few types of microorganisms. As a result of this resistance to degradation, the relative proportion of lignin increases during decomposition as the soil forms and becomes a major component of humic material.

Figure 15.25. Accumulation of microbial cells near soil pores Microscopic examination of soil indicates that, rather than being evenly distributed throughout the soil, microbial cells tend to accumulate on soil particles near pores. In particular, note the higher concentration of bacterial cells, shown here in blue, near the bottom-right pore in this fluorescence micrograph of an agricultural soil sample.

Rhizosphere

Besides contributing their biomass to the microbial decomposers, plants influence soil microbial communities in other important ways. The **rhizosphere**, that part of the soil immediately surrounding plant roots, represents a distinct and important ecosystem. In comparison to the non-root-associated **bulk soil**, the rhizosphere contains large amounts of organic carbon due to the considerable influence of plant root exudate. These exudates contain a mixture of sugars, sugar alcohols, and organic acids. Additionally, root cap cells that slough off growing plant roots contribute organic carbon to the rhizosphere. As a result of this extra organic carbon, the rhizosphere typically contains higher numbers of microbes than bulk soil **(Table 15.3)**. This rhizosphere effect provides evidence for the profound influence of plant roots on soil microbial communities.

In addition to supporting higher microbial biomass, rich nutrients associated with the rhizosphere support the activity and proliferation of diverse microbial communities. Because microorganisms vary in their ability to use different carbon sources, the mixture of available carbon compounds largely determines the microbial community composition within a given rhizosphere. Obviously, microorganisms that proliferate in this region receive a clear nutritional benefit. Let's look at the rhizosphere from a different perspective. Do plants benefit by providing nutrients to soil microorganisms?

Complex rhizosphere microbial communities can influence plant growth both positively and negatively. Although some microbes are pathogenic for plants, the majority are not. Many microbes have beneficial effects on the growth of plants. Moreover, an extensive and sophisticated two-way communication

TABLE 15.3 Rhizosphere influence on soil microbial communities

Bacterial group	Rhizosphere soil (number/per gram)	Bulk soil (number/per gram)	Relative abundance of microorganisms
Ammonifiers	5×10^8	4×10^6	125:1
Gas-producing anaerobes	3.9×10^5	3×10^4	13:1
Anaerobes	1.2×10^7	6×10^6	2:1
Denitrifiers	1.26×10^8	1×10^5	1,260:1
Aerobic cellulose degraders	7×10^5	1×10^5	7:1
Anaerobic cellulose degraders	9×10^3	3×10^3	3:1
Endospore formers	9.3×10^5	5.75×10^5	1:1

exists between the partners. Some of the mechanisms used by soil bacteria to promote plant growth include:

- Production of phytohormones or compounds that interact with phytohormones, which directly stimulate plant growth.
- Production of antibiotics that prevent the growth of pathogenic microorganisms.
- Fixation of atmospheric nitrogen (N_2) to a form that the plants can use.
- Solubilization of phosphate that can be taken up by the plant roots.

CONNECTIONS In **Section 17.2**, we will consider several examples of symbiotic microorganisms specialized for growth in the rhizosphere. These include microorganisms that promote the growth of plants by converting atmospheric nitrogen into compounds plants can use directly.

Microbial communities in soils

Soils are fascinatingly complex and heterogeneous, in both the abiotic and the biotic sense. The immense microbial diversity within soils and the distribution of these microbes reflects this complexity. The use of high-throughput DNA sequence analysis has allowed the microbial communities of different soils to be compared **(Figure 15.26)**. We now know that soils that appear to be very similar in the physical sense can sometimes share very few, if any, of the same microorganisms. This is because the complex and heterogeneous soil matrix is associated with chemical gradients that influence microbial community composition and diversity. For example, sequencing of soil DNA has demonstrated how the diversity of soil microorganisms is highly dependent on soil pH **(Figure 15.27)**. Soils with high or low pH tend to have decreased diversity relative to neutral pH soils. Furthermore, soils of similar pH sampled far apart from each other on the globe can have microbial communities more similar to one another than to adjacent soils with very

Figure 15.26. Overlap of microbial operational taxonomic units (OTUs) from different soils This Venn diagram demonstrates that very few microorganisms are common to all soils. The data for this comparison are small subunit ribosomal RNA (SSU rRNA) gene sequences obtained from different soils. Note that the numbers add up to 100 and represent the overall OTU distribution.

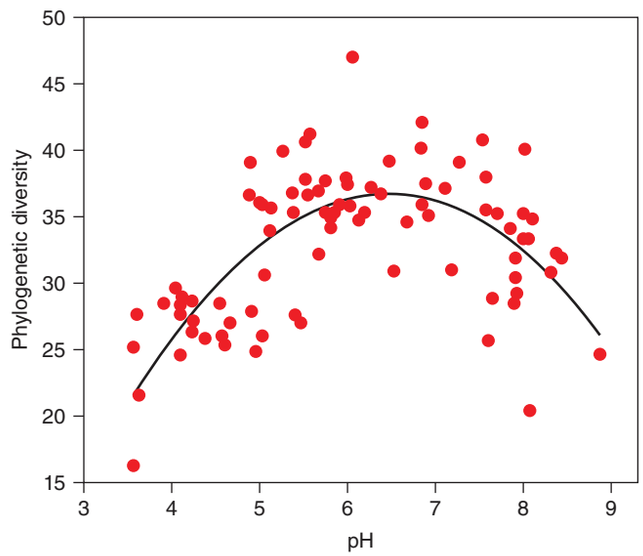

Figure 15.27. Bacterial diversity in soil and its relationship to pH Soil pH is an important determinant of bacterial diversity and composition. The soils shown here distribute primarily by pH despite originating from disparate habitats including tropical forest, coniferous and deciduous forests, prairie, grassland, tundra, and desert. *Source*: http://aem.asm.org/content/75/15/5111.long

different pH values. Ongoing research continues to identify additional influences on soil microbial community composition, including soil texture, moisture, nutrient concentration, temperature, and depth. These discoveries were made possible through the use of high-throughput DNA sequence analysis of small subunit ribosomal RNA (SSU rRNA) genes (see Section 5.2), and these findings challenge fundamental ideas about the distribution of microbes within and between ecosystems. Let's take a look at some key microbial groups that play important functional roles in the soil environment.

In general, soil microbial communities respond directly to their environments. Think about the last time you took a walk in the woods and came upon an old stump or fallen tree. Microorganisms cannot easily degrade this plant biomass, like the lignocellulose that we introduced earlier. Lignocellulose eventually decomposes but much of it does not mineralize, or break down, completely to CO_2 and water. Such incomplete mineralization contributes to soil organic matter. Although most microorganisms cannot degrade complex lignocellulose, certain basidiomycetes fungi specialize in its degradation. The fruiting bodies of these fungi are often visible on rotting trees **(Figure 15.28)**. Some of these fungal species carry out "brown rot," where cellulose and hemicellulose, but not lignin, are degraded. Other species carry out "white rot," where cellulose and hemicellulose are degraded and lignin is completely mineralized. This is accomplished by production of cellulase and hemicellulase enzymes that convert the polymers to their component sugars and lignin-degrading enzymes, such as peroxidases and oxidases. Along with a small number of bacteria, these fungi are the only known microorganisms that can depolymerize lignin. Fungi therefore play an essential role in the decomposition of plant matter.

The actinomycete bacteria are well known for their high abundance in soils and the specialized roles they play in soil ecosystems. In Chapter 12, we looked at the prominence of actinomycetes in the pharmaceutical industry and their role in the production of antibiotics and other types of drugs. The production by these organisms of so many secondary metabolites that happen to be of pharmaceutical interest must have some link to their natural habitat. Recall that secondary metabolites are small organic molecules produced by cells but not essential for the normal growth of the organism. The actinomycetes, such as members of the genus *Streptomyces*, produce and secrete a number of enzymes like hydrolases that break down a number of different compounds, proteases that degrade protein, chitinases that break down chitin, cellulases that break down cellulose, and amylases that break down starch. Together, these enzymes effectively break down much of the plant organic matter, providing the actinomycetes with ample nutrients. The production of antibiotic secondary metabolites by actinomycetes inhibits the growth of potential competitors for these nutrients.

The incomplete breakdown of plant biomass, especially lignin, results in the accumulation in soil of recalcitrant organic molecules. These molecules, humic substances, contribute to the important aggregation properties of soils, resulting in the formation of clumps and a complex spatial heterogeneity. The diversity of microenvironments provides opportunities for many different types of specialist microorganisms, resulting in high diversity. Typically, microbial growth is limited in bulk soils, away from the influence of the plant root rhizosphere, as the organisms are in a state of famine in which all available nutrients are quickly used. Such conditions select populations that can survive for long periods under these conditions, including microorganisms like *Bacillus* spp. bacteria, from the *Firmicutes* phylum, that form heat- and desiccation-resistant endospores. Input of nutrients from plant exudates and decomposing plant matter supports the proliferation of those organisms that can take advantage of these nutrients with high growth rates.

Bioremediation

As we have seen in the previous section, different soil conditions support distinct microbial communities. In every location, microorganisms proliferate that are adapted to these conditions, especially soil chemistry and available nutrients. Although we have focused on naturally occurring nutrients, human-made materials can proliferate in soils. Microbiologists are exploring how to use microorganisms to clean up soil contamination through a process known as **bioremediation (Figure 15.29)**.

Human activities generate considerable waste, much of it ending up in soils. Diverse communities of soil microorganisms degrade some of this waste quite easily. As we saw in Chapter 14, microbes recycle this waste through the biogeochemical cycles. Since industrialization and the development of chemical industries, more and more human-generated waste compounds cannot be degraded easily by typical soil inhabitants. Tens of thousands of synthetic organic chemicals are in commercial use. These **xenobiotics**, chemicals not naturally found in or produced by organisms, are often detrimental to human and animal health by being toxic, carcinogenic, mutagenic, or

B. Contaminated site following treatment with hydrocarbon-degrading microbes

Figure 15.29. Bioremediation Microorganisms can be used to help clean up sites contaminated with harmful contaminants, such as petroleum hydrocarbons. **A.** Petroleum contamination caused barren conditions and poor growth of native plants. **B.** Following bioremediation treatment including application of hydrocarbon-degrading bacteria, this site is safe for cultivation of food crops.

teratogenic. Moreover, because these chemicals do not occur as part of natural processes, microorganisms have not evolved the ability to degrade them efficiently.

Major types of xenobiotics of concern include the petroleum-derived polycyclic aromatic hydrocarbons (PAHs), chlorinated solvents such as polychlorinated biphenyls (PCBs) and trichloroethylene (TCE), and nitroaromatics such as 2,4,6-trinitrotoluene (TNT), which are used as explosives (Figure 15.30). Generally, laws regulate the disposal of such chemical wastes. Nevertheless, many sites throughout the world are contaminated extensively. As we have seen, soil microorganisms can degrade most organic compounds. Natural microbial communities probably will degrade even the most resistant of these pollutants over time. Unfortunately, time may not be available. The land may be slated for development or the contaminants may be causing health problems in nearby human populations. So, how can we clean up these areas? One way is for the contaminated soil to be removed physically and transferred to another location where it can degrade naturally. Alternatively, it can be incinerated, which can release toxins to the environment. Both of these options are expensive and problematic. The third option of bioremediation may be a less expensive and more feasible alternative.

What are the strategies used for bioremediation? As we noted earlier, we can simply let nature take its course. However, such natural biodegradation is slow and often limited by the lack of available O_2; the best degrading enzymes typically require oxygen. **Biostimulation** involves providing missing O_2 and limiting nutrients, such as nitrogen and phosphorus, to increase the activity of the resident microorganisms. Sometimes degradation pathways for a given xenobiotic have not yet evolved, but natural substrates can be added to the environment to induce degradation pathways with broad substrate range. For example, the methane or toluene pathways can stimulate trichloroethylene (TCE) degradation. In an example of **cometabolism**, methane can be added to a TCE-contaminated area. Naturally occurring microorganisms that use methane as a carbon source are stimulated, and these microorganisms produce metabolic enzymes that degrade TCE. In **bioaugmentation**, bacteria known to degrade the contaminant can be added to a contaminated environment. Many scientists apply molecular methods to study these processes with the hope of better understanding them so that bioremediation can be used more consistently. A constant challenge will be keeping ahead of the continual development of new xenobiotics.

Although we have focused on microbial contributions to bioremediation in soils, it is worth mentioning that bioremediation plays an important role in the degradation of pollutants

Figure 15.30. Important targets of bioremediation This figure shows the structures of some of the major contaminants that are subject to bioremediation efforts.

in aquatic ecosystems as well. For example, the majority of oil released to the marine environment by the *Exxon Valdez* (1989) and BP *Deepwater Horizon* (2010) spills was dispersed and degraded by marine bacteria, many of which existed at low relative abundance prior to the spills. Both natural and enhanced microbial biodegradation, enhanced by supplementing with nitrogen primarily, eliminated some of the most toxic compounds associated with these spills, such as PAHs (Figure 15.30).

15.4 Fact Check

1. Distinguish between A, B, and C soil horizons.
2. Differentiate between the rhizosphere and bulk soil.
3. What factors influence microbial communities in soils?
4. Explain how lignocellulose is degraded in the environment.
5. Why are most microorganisms unable to degrade xenobiotics easily?

15.5 Deep subsurface and geothermal ecosystems

Can life exist in the absence of photosynthesis-driven primary production?

We tend to think of the sun as the source of all energy supporting life on Earth. Indeed, photosynthesis accounts for a significant amount of the energy harvesting that occurs on our planet. We also know that a substantial amount of biomass exists in Earth's deep subsurface (see Table 15.1). What supports life in these ecosystems well below the reach of sunlight? Photosynthetic-derived organic carbon, O_2, and NO_3^- can be carried down into subsurface habitats by groundwater flow and sedimentation, thereby supporting heterotrophic metabolism. However, many deep subsurface systems have minimal input from these photosynthetic-derived nutrients. Instead, these ecosystems rely on bacterial and archaeal chemolithoautotrophic primary producers that harvest chemical energy. In this section, we will explore a few of these unusual environments. First, we will investigate deep subsurface microbiology. Then, we will explore the microbial communities found around deep sea hydrothermal vents. Finally, we will look at the communities associated with terrestrial hot springs. Throughout our investigation of these ecosystems, we will see how communities can thrive in the absence of photosynthesis-driven primary producers. Understanding these systems is critical to understanding life on Earth given that the evolution of life may, ultimately, be linked intimately with these enigmatic microbial ecosystems.

CONNECTIONS Recall from **Sections 6.1** and **13.2** that microorganisms are categorized metabolically on their source of energy, their source of electrons for redox reactions to produce ATP, and their source of carbon for forming organic material for growth. A chemolithoautotroph acquires energy through oxidation of preformed chemicals in the environment (chemotroph), obtains electrons by oxidizing (removing electrons from) inorganic reduced molecules, such as H_2S or Fe^{2+} (lithotroph), and gets its carbon from inorganic carbon compounds, like carbon dioxide (CO_2).

Deep subsurface microbiology

The field of geomicrobiology combines geology and microbiology by investigating the role of microbes in geological and geochemical processes. The field began in the mid-1970s with the discovery of deep sea vent communities and expanded in the mid-1980s to include a range of extreme habitats including deep aquifers, hot springs, hypersaline environments, oil wells, and even subterranean rock. Microbiological surveys performed during oil and gold drilling operations made it clear that the deep subsurface, rather than being a sterile environment, often contained substantial biological material **(Figure 15.31)**. We now realize that the biosphere extends to great depths, in some cases several kilometers below the surface of Earth. At these depths, negligible input from surface nutrients derived from photosynthesis occurs. Additionally, many of these environments are very hot as they approach or breach Earth's mantle. In one study, hyperthermophiles recovered from hot oil wells lived at temperatures up to 115°C. In a study published in 2003, researchers reported the identification of an iron-reducing archaeon isolated from a vent in the Juan de Fuca Ridge of the Pacific Ocean that grew well at 100°C and could continue to replicate

at 121°C, the temperature of an autoclave. Originally named "Strain 121" in honor of this remarkable ability, *Geogemma barossii* could survive for an impressive 2 hours at 130°C but did not replicate at this higher temperature.

CONNECTIONS Extremophilic archaea exhibit numerous adaptations to prevent membrane disruption and the denaturation of proteins and nucleic acids. Some of these adaptations include the presence of tetraether lipids or lipid monolayers in their membranes and abundant α-helical regions, salt bridges, and side chain interactions in their proteins to maintain three-dimensional structure in the face of high temperature. In **Section 4.3**, we learned more about these heat-proofing characteristics of hyperthermophiles.

Over the past decade, samples taken from depths as great as 3 km below Earth's surface in various sites around the world have uncovered novel and diverse species of bacteria and archaea through SSU rRNA gene sequence analysis. The microorganisms living here depend on chemolithoautotrophy for primary production of organic compounds, which respiring microorganisms then use. Because of the chemical processes these microorganisms carry out, they influence the composition of these habitats by altering water chemistry and the mineral and physical properties of rock strata. Compared to respiring organisms, chemolithotrophs generate less energy, pumping fewer protons per electron, resulting in less ATP generation. This characteristic, along with the scant nutrients available, explains the slow growth rates observed for these microbial populations.

To quantify various metabolic processes and growth in core samples (Figure 15.32), researchers often use radiolabeled nutrients. For example, researchers can study basic metabolic processes by measuring the rates of incorporation of radiolabeled acetate into lipids or radioactive thymidine into DNA. Although we still know relatively little about the communities that make up subsurface systems, the basis of life probably begins with chemical and physical interactions between rock and water that release soluble and insoluble minerals, as well as H_2 that can fuel microbial energy metabolism. Metals in the rock, such as iron, react with water to form hydrogen gas (H_2) gas:

$$FeO + 2\ H_2O \rightarrow 2\ H_2 + FeO_3$$

Although this reaction is completely abiotic, it results in the liberation of H_2 that can be used by archaeal methanogens to produce methane (CH_4):

$$4\ H_2 + CO_2 \rightarrow CH_4 + 2\ H_2O$$

The detection of DNA from methanogens in subsurface samples supports this idea. Some chemolithotrophs can oxidize metal ions, such as ferrous iron (Fe^{2+}), and sulfur compounds, such as sulfide (H_2S) or elemental sulfur (S^0), to fuel their energy needs, producing ferric iron (Fe^{3+}) or sulfate (SO_4^{2-}) as end products, respectively. These end products can then serve as terminal electron acceptors for the energy pathways of other microorganisms. The output of metallic metabolism is the release of metal by-products. Although life in the depths exists at a slow pace, the deposition of these metals by biofilm microorganisms concentrates them in ores. The majority of the world's iron, uranium, and gold may have been formed this way over millions of years. Similarly, commercial sulfur deposits result from bacterial sulfate reduction, as is the production of magnetite (Fe_3O_4) and pyrite (FeS_2) by reduction of Fe^{3+} by sulfate-reducing bacteria. The activity of the microorganisms in these deep subsystems means we can view them as important catalysts in rock weathering, a process previously thought to be a largely abiotic process of erosion by water and pressure. The

Microbial communities from deep below the ocean floor

Figure 15.32. Core from marine subsurface Sediment cores from deep below the ocean floor have been found to harbor active microbial communities.

metabolic activities of subsurface microorganisms also mean they contribute to the formation of fossils as they can replace organic materials with minerals. Another important facet of their activity is the technological application of lithotrophic microorganisms to extract metals from mine wastes.

In some parts of the world, mineral-oxidizing bacteria may be responsible for the release of heavy metals into deep groundwater reservoirs, the source of many people's drinking water. The conversion of arsenate (AsO_4^{3-}) to the more soluble and therefore more mobile arsenite (AsO_3^{3-}) has tainted the waters in Bangladesh that run through arsenic-containing rock. Millions of people rely on these aquifer systems so these microbial activities have enormous potential consequences for human health.

Hydrothermal vents

Recall from our Chapter 13 opening story that, in the late 1970s, scientists made a remarkable discovery in the deep waters off the Galapagos Islands. In the darkness of the ocean floor, 2.5 kilometers below the surface, a massive collection of never before seen animals existed around volcanic hot vents. These animals included giant tube worms as well as giant clams and mussels. They all thrived in an ecosystem devoid of light and photosynthetically derived nutrients. The existence of such a huge ecosystem without any contribution from the sun surprised most biologists. What energy source drove this ecosystem and what organisms served as the primary producers? To answer these questions, first we need to look at the geology and chemistry of these vent regions.

Most hydrothermal vents exist on mid-ocean ridges where volcanic activity and plate movement cause the often-violent release of minerals and gases from the interaction of molten rock with seawater (Figure 15.33). These released compounds include CO_2, CH_4, and sulfides such as H_2S. Additionally, large amounts of metals including iron, manganese, lithium, and cesium exist near these vents. Because photons are not available as an energy source, you may have deduced correctly that one or more of these minerals must serve as the primary energy and electron sources to drive carbon fixation, leading to the production of organic carbon compounds needed to support this ecosystem. Bacteria are the primary producers here and they use these compounds, most importantly H_2S, as major electron donors, performing chemosynthesis (Figure 15.34). Sulfide oxidizers, such as the betaproteobacterial *Thiobacillus* sp. and the gammaproteobacterial *Beggiatoa* sp., are examples of free-living, biofilm-forming primary producers. When new vents are formed, ecosystems quickly develop. The biofilms, which can grow into mats several inches thick, first attract small grazing crustaceans such as amphipods and copepods, then larger snails, shrimp, crabs, anemones, clams, mussels, tube worms, fish, octopi, and jellyfish.

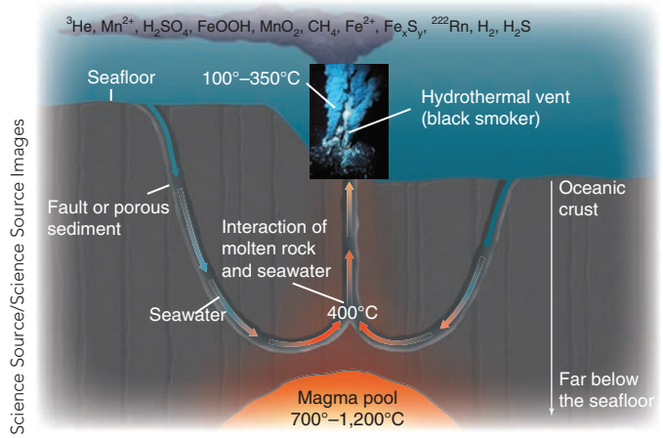

Figure 15.33. Deep sea hydrothermal vent chemistry Vent fluids contain rich mixtures of chemicals. Seawater is drawn beneath the seafloor and is superheated as it encounters molten rock. Chemicals precipitate as the fluids are cooled.

Many invertebrate-associated H_2S oxidizers also exist in these environments. The bacterial symbiont of the giant tube worm also relies on H_2S as a source of energy and electrons. Through its CO_2 fixation, this bacterium supports the growth of the giant tube worms. Whereas the H_2S oxidizers, both free-living and animal-associated, are the main primary producers, a variety of free-living thiosulfate-, methane-, hydrogen-, iron-, and manganese-oxidizing bacteria also have been identified (Table 15.4). With all the organic material resulting from this primary production, many chemolithoheterotrophs also live here. They oxidize the abundant inorganic compounds of the vent for energy and electrons, but they derive their carbon

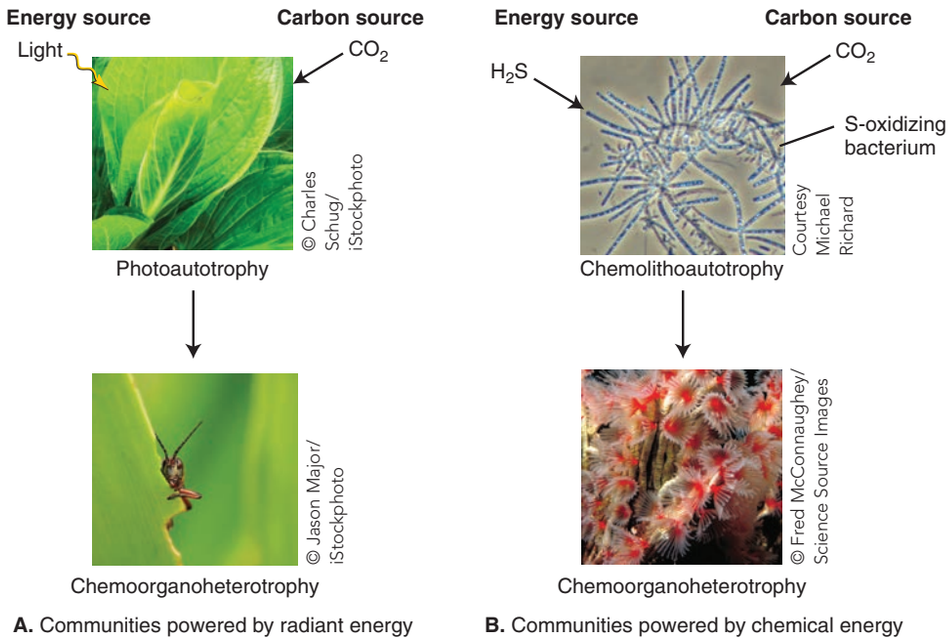

Figure 15.34. Chemosynthesis primary production at hydrothermal vents The generation of energy by S-oxidizing bacteria at deep sea hydrothermal vents can be contrasted with the generation of energy in light-driven habitats. **A.** Photoautotrophs use light to generate energy by photosynthesis. **B.** In deep sea hydrothermal vents, the carbon and energy produced by the S-oxidizing bacteria are used to support the growth of animals such as tube worms.

from organic sources supplied by the primary producers and the various animal species of the ecosystem.

A variety of vents have been discovered worldwide (Figure 15.35) and all of them support dense communities of microbes. The vent fluids are highly reduced and acidic, with a pH range of 2.8–5. Although fluids spewing out of the vent are very hot usually, ranging from 60°C to as high as 464°C, the water temperature at the ocean floor is about 2°C. Rapid cooling results in the precipitation of some of the dissolved chemicals, causing a smoke-like effect, and the formation of chimney-like vents (see Figure 15.33). Each vent system is unique, with different temperatures and combinations of elements dissolved in the vent fluid. "Black smokers," like the Galapagos vents, are very hot and emit high concentrations of sulfides, which hit the cold seawater and immediately precipitate, producing dark plumes (see Figure 4.1). "White smokers" are at lower temperatures, and although they spew a similar chemical brew, the barium, calcium, and silicon precipitate out at these lower temperatures, producing white plumes and pale chimney stacks. The quick cooling results in a temperature gradient that supports organisms of varying temperature optima. The vents thus provide several unique niches for specialized organisms. Microbial growth chambers can be deployed in the flow around the vents to study the colonizing populations of bacteria generated by the microbial mats. After three to eight days, the chambers can be recovered and the DNA extracted for analysis.

Sequence analysis of SSU rRNA genes reveal various free-living and invertebrate-associated H_2S oxidizers. Some studies have shown that gammaproteobacteria represent the dominant primary producers, while other studies have shown that the dominant primary producers are H_2S-oxidizing members of the *Epsilonproteobacteria*. Most studies show that the vent biofilm mats, with substantial biomass, are usually composed of only a few OTUs. Different mats can be composed of different types of microbes at different locations around the vent. Because primary producers may vary from site to site, it follows that the animals they support also vary. Various species of tube worms are common invertebrates of the Pacific thermal vents. A small white shrimp inhabits Atlantic vents, and it too harbors symbiotic bacteria. Whereas tube worms house their symbionts internally, the shrimp appear to farm the bacteria on their surface. They even battle for the best positions near the vent in order to maximize the growth of their bacteria, which they harvest as their main source of food. They and other invertebrates also graze the free-living epsilonproteobacteria that cover the surface of the vents. Such symbiotic relationships are a fundamental necessity for animals to exist in these dark and isolated environments.

Before leaving this topic, we should note that not all vents are hot. Cold seeps, first discovered in the Gulf of Mexico in 1983, release various sulfides like H_2S, CH_4, and other hydrocarbons, but these compounds seep slowly from Earth's crust at about the same temperature as the surrounding seawater.

TABLE 15.4 Metabolic reactions in hydrothermal vent ecosystems

Metabolism	Reaction	Examples in vent environments
Anaerobic		
Methanogenesis	$4\,H_2 + CO_2 \rightarrow CH_4 + 2\,H_2O$	*Methanococcus* spp. common in magma-hosted vents; *Methanosarcinales* at the Lost City field of vents
	$CH_3CO_2^- + H_2O \rightarrow CH_4 + HCO_3^-$ $CO_3^- + 4\,HCOO^- + H^+ \rightarrow 3\,HCO_3^- + CH_4$	
S^0 reduction	$S^0 + H_2 \rightarrow H_2S$	Lithotrophic and heterotrophic; hyperthermophilic archaea
Anaerobic CH_4 oxidation	$CH_4 + SO_4^{2-} \rightarrow HS^- + HCO_3^- + H_2O$	*Methanosarcina* spp. and epsilonproteobacteria at mud volcanoes and methane seeps
Sulfate reduction	$SO_4^{2-} + H^+ + 4\,H_2 \rightarrow HS^- + 4\,H_2O$	*Deltaproteobacteria*
Fe reduction	$8\,Fe^{3+} + CH_3CO_2^- + 4\,H_2O \rightarrow 2\,HCO_3^- + 8\,Fe^{2+} + 9\,H^+$	*Epsilonproteobacteria*, thermophilic bacteria, and hyperthermophilic crenarchaeota
Fermentation	$C_6H_{12}O_6 \rightarrow 2\,C_2H_6O + 2\,CO_2$	Many genera of bacteria and archaea
Aerobic		
Sulfide oxidation[a]	$HS^- + 2\,O_2 \rightarrow SO_4^{2-} + H^+$	Many genera of bacteria; common vent animal symbionts
CH_4 oxidation	$CH_4 + 2\,O_2 \rightarrow HCO_3^- + H^+ + H_2O$	Common in hydrothermal systems; vent animal symbionts
H_2 oxidation	$H_2 + 0.5\,O_2 \rightarrow H_2O$	Common in hydrothermal systems; vent animal symbionts
Fe oxidation	$Fe^{2+} + 0.5\,O_2 + H^+ \rightarrow Fe^{3+} + 0.5\,H_2O$	Common in low-temperature vent fluids; rock-hosted microbial mats
Mn oxidation	$Mn^{2+} + 0.5\,O_2 + H_2O \rightarrow MnO_2 + 2\,H^+$	Common in low-temperature vent fluids; rock-hosted microbial mats; hydrothermal plumes
Respiration	$C_6H_{12}O_6 + 6\,O_2 \rightarrow 6\,CO_2 + 6\,H_2O$	Many genera of bacteria

Figure 15.36. Microbial mats at geothermal springs Geothermal springs often harbor heat-tolerant microbial communities. **A.** The Octopus Spring, an alkaline spring at Yellowstone National Park. **B.** Cyanobacterial mat from Octopus Spring. **C.** Dominant cyanobacteria from mat.

These ecosystems are much slower growing and longer lived because the geological formations that form at these low temperatures are more stable than those of the volatile hydrothermal vents. The methane and seawater react slowly to form carbonate rock instead of vents. Cold seeps have a similar community makeup as hydrothermal vents. *Beggiatoa* mats form and tube worms exist, and like their Pacific vent cousins, they also harbor dense populations of chemolithoautotrophic bacterial symbionts. Thus, the biology and ecology of deep sea seep and vent habitats are intricately linked to the geology and chemistry of the surrounding ocean.

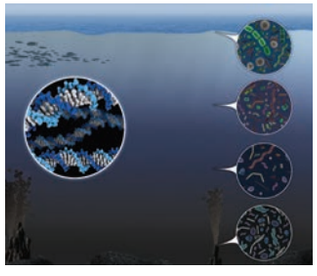
Terrestrial hot springs

Geothermal springs are the terrestrial equivalent of the deep sea hydrothermal vents. Unlike their marine counterparts, however, at temperatures below mid-70°C and at neutral pH, they can have substantial primary production from cyanobacterial oxygenic photoautotrophs and green non-sulfur anoxygenic phototrophs. These organisms are key components of thick microbial biofilm mats with photosynthetic organisms in the upper layers **(Figure 15.36)**. The photosynthetic cells provide organic carbon and energy for the underlying layers, supporting diverse communities that include mostly aerobic chemoorganoheterotrophs in the lower layers.

In hotter acidic springs, often associated with volcanic activity, conditions are not hospitable to photosynthetic organisms. These types of environments, typically rich in inorganic energy sources such as H_2, H_2S, elemental sulfur, and Fe^{2+}, can be dominated by hyperthermophilic archaea such as the crenarchaeote *Sulfolobus*. These chemolithoautotrophs can oxidize elemental sulfur to sulfuric acid (H_2SO_4), and their metabolism thus contributes directly to the acidity of the water. This low pH means that only acidophilic microorganisms are able to survive in these environments, and the community diversity is quite low compared to other less challenging habitats.

Image in Action

WileyPLUS Learning Space



A cross-sectional view of the ocean shows that microbial life can be found at all depths. On the sunny ocean surface, photosynthetic microorganisms exist, whereas heterotrophic microorganisms thrive in the dark and colder lower waters. Deep sea vents provide yet another habitat for many other forms of microbial life. DNA sequencing and analysis allow scientists to study these microbial communities even when individual microorganisms cannot be grown in culture.

1. Imagine you are asked to provide additional detail to this image. Where would you expect to find the following types of microbes: piezophiles, archaea, bacterial cells, and viruses? Explain your answer.
2. Imagine you have been asked to examine the impact of the 2010 Gulf of Mexico oil spill on microbial biodiversity. Outline your design for using a cultivation-independent method to conduct this research.
3. What results might you expect from your study in Question 2 if the disaster had a major impact on the total number of organisms in surface waters? Explain.

15.5 Fact Check

1. What environmental conditions are present in hydrothermal vents? How are these vents thought to form?
2. How does the community around a cold seep differ from that around a hydrothermal vent?
3. Describe geothermal springs as an ecosystem, including the physical conditions and microbes present.

The Rest of the Story

The detection of large numbers of non-thermophilic archaea in marine samples in the early 1990s was unexpected but not an isolated incident. As additional mesophilic and psychrophilic environmental samples were examined in the ensuing years, many more non-thermophilic archaeal organisms have been found. They are widespread in soils, oceans, sediments, deep subsurface, freshwater lakes, and as symbionts of sponges and other animals. To learn more about these non-thermophilic archaea, you can refer to the discussion of the new phylum *Thaumarchaeota*, in Chapter 4. Although widespread, cultivation of these archaea has been extremely difficult. Given their numbers, they must be making substantial contributions to ecosystem function, but to truly understand their function in the ecosystem we must determine how to study these microbes and their corresponding communities.

Alongside ongoing cultivation efforts, other answers lie in the continued application of non-cultivation-based sequencing technologies, as described in Chapter 10. In that chapter's Rest of the Story section, the ongoing research at The J. Craig Venter Institute (JCVI) was highlighted. The Institute's Global Ocean Sampling Expedition, for example, has involved research teams circumnavigating the globe and collecting samples over several years. Microbiologists on the research vessel *Sorcerer II* collected 400-liter water samples every 200 miles while also documenting the environmental conditions at each site. The water collected was passed through smaller and smaller filters to capture and separate different size organisms. These samples are frozen and sent back to land-based research labs for metagenomic analysis. Such a systematic and molecular approach is the new frontier in determining the true biodiversity of microbial ecosystems and a first step in understanding the functions of the countless uncharacterized microbes on this planet.

Summary

Section 15.1: What factors affect microbial communities?

The physiology of individual microorganisms within microbial communities helps to define their roles in those communities.

- Although the foundation of microbiology is the study of microbes in pure culture, microbes exist in complex communities in the environment.
- The total combined biomass of bacteria and archaea on Earth is approximately equivalent to the biomass represented by plants.
- Cultured microbes do not accurately represent microbial communities.
- An **ecosystem** is a community of organisms, including primary producers, **consumers**, and **decomposers**, interacting with each other and their environment.
- Members of communities can be grouped into functional groups called **guilds**.
- **Microbial ecology** involves the study of biodiversity of microbes and their activities within ecosystems, including specialized communities such as the ones that rely on **chemosynthesis**.
- Microbes, being small, exist within microenvironments in which conditions change over short distances.
- The success of microbes and their ability to occupy particular **niches** depends on their ability to obtain different nutrients to produce energy and biomass.
- To access nutrients and protection from antimicrobials in aquatic habitats, biofilm communities form on solid surfaces, held together by exopolysaccharide and engaging in intercellular communication through mechanisms such as quorum sensing.

Section 15.2: How can microbial communities be studied?

Many tools are now available for the dissection of microbial communities in ecosystems.

- The SSU rRNA gene has become the standard marker for cultivation-independent detection of the presence of microorganisms in the environment, and many molecular tools such as high-throughput sequencing, **denaturing gradient gel electrophoresis (DGGE)**, **terminal restriction fragment length polymorphism (T-RFLP)**, **fluorescent *in situ* hybridication (FISH)**, and **flow cytometry** have been developed based on the detection of SSU and other sequences. **Fluorescence-activated cell sorting (FACS)** uses flow cytometry in order to analyze and collect cells that are labelled with a fluorescent dye.
- **Stable-isotope probing (SIP)** is a method that can provide information about the metabolic activities of different organisms in the environment.
- The **operational taxonomic unit (OTU)** concept, based on SSU rRNA gene sequence identity, is becoming the standard for measuring microbial diversity. Use of this tool has made it possible to compare the levels of diversity of different environments.

Section 15.3: What is the nature of life in water?

Most of the life in aquatic ecosystems is microbial in form and living in a state of **oligotrophy**.

- Primary production in marine ecosystems predominantly takes place through photosynthesis by phytoplankton in surface waters.
- Carbon and energy are distributed through the ecosystem through grazing of the phytoplankton by **zooplankton** and viral-mediated lysis.
- Approximately 1 percent of the primary production reaches the seafloor where anoxic, cold conditions render it fairly resistant to biodegradation, resulting in its accumulation over hundreds of millions of years to form rich sediment on the seafloor.
- The atmospheric pressure is extremely high at great depths, where **piezophiles**, microorganisms that are able to survive such high pressures, are found.
- Characterization of marine communities using metagenomic methods has revealed the existence of new organisms with novel proteins and metabolic activities, and some of these organisms have been successfully cultivated using **dilution to extinction** methods.
- Freshwater ecosystems that are part of terrestrial environments typically are less oligotrophic than marine environments.
- Many lakes stratify into upper warmer zones, called the **epilimnion**, and lower and colder zones, called the **hypolimnion**, separated by a layer called the **thermocline**.

Section 15.4: What is the nature of life on land?

Microbes are important components of terrestrial environments with especially rich and diverse soil microbial communities.

- Terrestrial ecosystems can be divided into several **biome** types, and collectively they represent the most diverse habitats on Earth.
- The dominant primary producers in terrestrial environments are plants.
- Soils typically harbor very active microbial communities that, through their decomposition of plant and animal matter, direct the formation of new soil.
- Soils have been categorized into specific types based on physical characteristics, and they are typically divided into horizontal layers called **horizons**.
- The **rhizosphere** directly surrounding plant roots is very rich in carbon due to the excretion of plant root exudates. This results in much higher numbers of microbial cells compared to what is found in the bulk soil.
- The brown rot and white rot fungi are specialized in lignocellulose degradation, whereas the actinomycetes are able to break down a number of other forms of plant biomass through the production of extracellular enzymes.
- Recalcitrant organic molecules, such as **humic material**, do not completely mineralize, accumulating in soils and contributing to the aggregation properties of the soils.
- **Bioremediation** involves the use of microorganisms to clean up environmental contamination.
- Degradation of **xenobiotics**, chemicals that are not normally found in nature, often does not occur easily.
- Commonly used bioremediation strategies include **biostimulation**, **cometabolism**, and **bioaugmentation**.

Section 15.5: Can life exist in the absence of photosynthesis-driven primary production?

Much of Earth's biomass is not subject to sunlight and yet is still metabolically active. Primary production can occur in the absence of sunlight, fueled by inorganic chemical energy.

- Estimates suggest that total subsurface microbial biomass rivals that in total soil microbial biomass.
- Microbial life has been detected at depths of several kilometers where it is likely that chemolithoautotrophic forms of metabolism are responsible for primary production.
- Chemolithoautotrophic metabolism also supports life at deep sea hydrothermal vents in the ocean floor and in terrestrial hot springs.

Application Questions

1. A group of microbial ecologists is researching the biodiversity of a local habitat. According to this description, explain what this means and discuss what might be the next research steps following the initial biodiversity studies.
2. Oxidation and reduction are considered key chemical reactions in microorganisms. Explain how these processes play a particularly important role in microbial generation of energy and give an example.
3. You are attempting to create an anti-biofilm chemical. Identify a component of a biofilm you might consider targeting and describe the specific effect it would have on the microorganisms and the biofilm overall.
4. A research team is writing a grant and proposing the use of SSU rRNA genes as a phylogenetic tool in the study of several newly discovered marine microorganisms. How would they justify that this is the best tool to use for their purposes?
5. Outline and explain how a researcher could go about using fluorescent *in situ* hybridization (FISH) to examine the expression of a nitrogen fixation gene in several previously unknown soil microorganisms.
6. You are on a research vessel and the sampling data show the area to be an oxic, oligotrophic marine environment. In simple terms, explain what this statement tells you about the characteristics of the environment and the metabolic activities of the microorganisms living there.
7. Explain how the metabolic activities of microorganisms in surface ocean waters are connected to those in dark mid-water zones. Give an example to illustrate your explanation.
8. Imagine that you have taken the same sample of seawater and used standard marine isolation medium and the dilution to extinction method to examine the microbial contents of the sample. How would your results be different using these two methods? Be specific and explain the reasons for the differences.
9. Imagine a new agricultural pesticide is now being shown to negatively impact the metabolic activities of white rot fungi in the soil and is actually decreasing the white rot fungal numbers. Soil ecologists are therefore arguing that this pesticide should not be used. What would be their argument, and what would they specifically say about the importance of these fungi in soils?
10. As a new employee of a company called Actinocorp, you are learning at your orientation that the company focuses on recovering and studying novel marine actinomycetes. Why would a company focus on recovering new actinomycetes, and from this brief overview what would you determine the company is trying to do? Explain.
11. A conservation research team is surveying the microbial populations in a deep freshwater lake in New York that consistently has a thermocline throughout the summer. Describe the types of microbes they might expect to find based on the water conditions that will most likely be present in each location (layer) in the lake.
12. A microbiologist working for an oil-drilling company is attempting to obtain samples deep within the drilling site. A camera view shows what appears to be a microbial mat at the current sample site. Explain what metabolic characteristics would be expected in microorganisms at this site. Once a site sample is obtained, how could she go about characterizing these bacteria back in the laboratory. That is, what tools could be used and how?
13. With the bacteria described in Question 11, imagine that it is your job in the lab to conduct an SSU rRNA analysis to determine phylogeny.
    a. Would you elect to use universal primers or bacterial primers? Explain your reasoning.
    b. Detail each of the steps you would use in your SSU rRNA analysis. Explain the purpose of each step you outline.
    c. Based on the location of the sample, what results might you expect in your phylogenetic analysis?

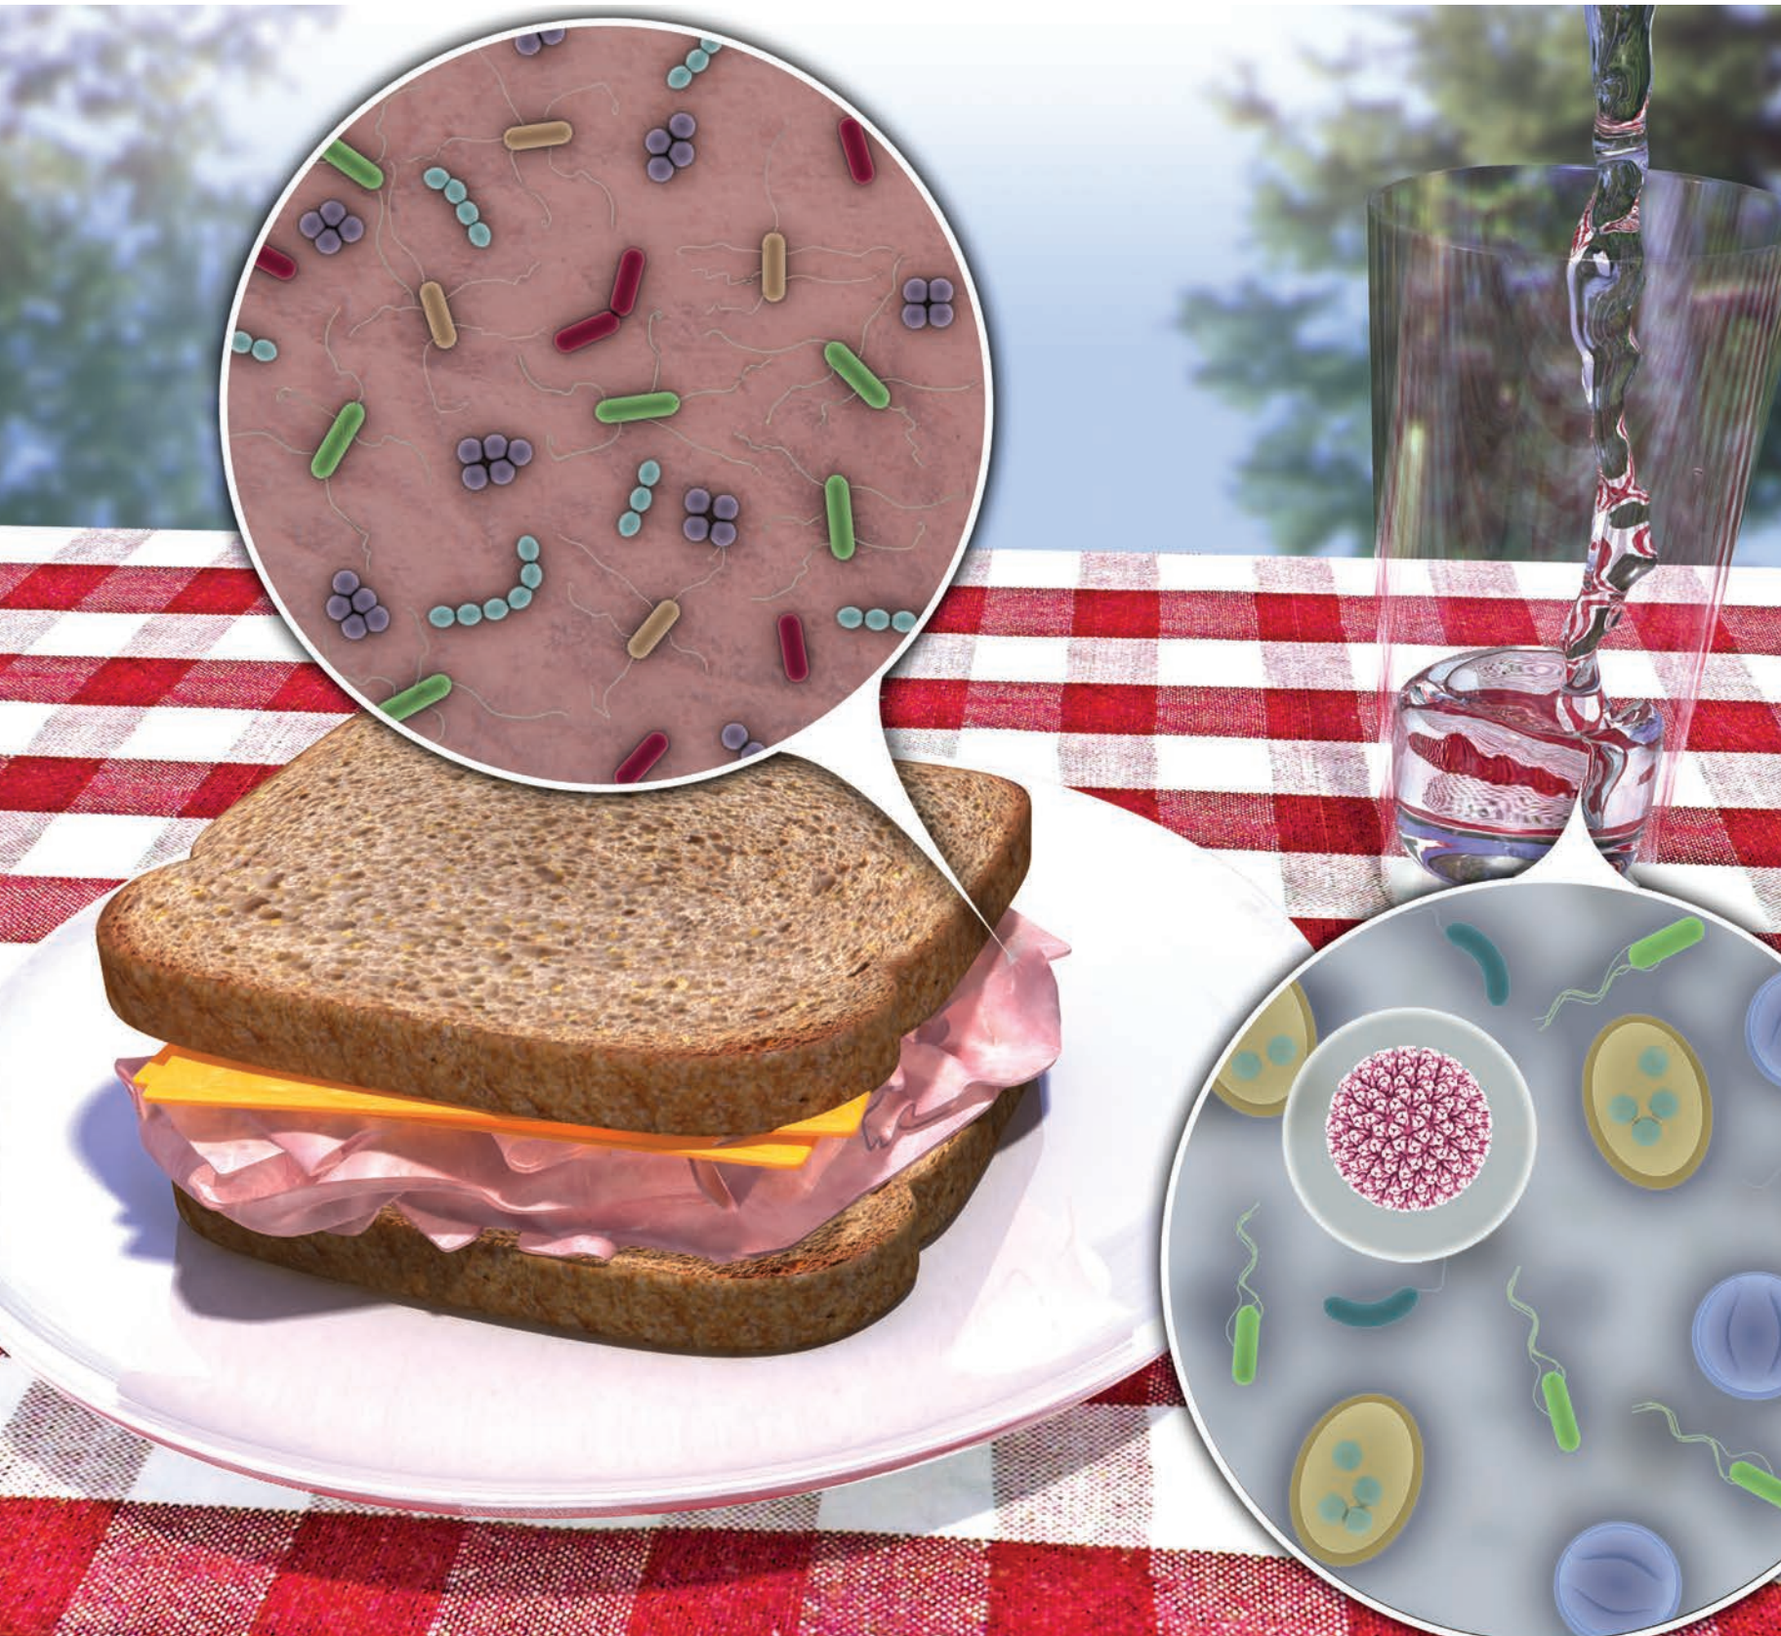
CHAPTER

16 The Microbiology of Food and Water



Sandwiches of packaged luncheon meats are a lunchtime staple for many people. Sitting in their plastic-sealed containers on the supermarket shelf, these meats appear anything but dangerous. If the meat has been contaminated during packaging, however, the microbes that survive and thrive can sicken or kill those who eat it. Such was the case in Canada in August 2008 when meats contaminated by slicing machinery at a Maple Leaf Foods facility in Toronto, Ontario, were distributed to supermarkets nationwide. Fifty-seven people fell ill with listeriosis after eating meat that had been contaminated by a bacterium called *Listeria monocytogenes*. Of these, 22 people died, almost 40 percent of those who became ill. This high percentage of deaths is not unusual because *L. monocytogenes* is one of the more dangerous sources of foodborne disease. In the United States, about 1,600 people get seriously ill with listeriosis annually and 260 of these die.

Listeria monocytogenes has a short history as a pathogen, being first identified as the cause of illness in a 1981 outbreak in Halifax, Nova Scotia. For most of us, the risk posed by *L. monocytogenes* is very low. For the very young, the elderly, pregnant women, and people whose immune system is not working properly, the situation can be disastrously different. Pregnant women may suffer spontaneous abortion. Others can suffer from vomiting, nausea, cramps, diarrhea, severe headache, constipation, and fever. The bacteria can access the bloodstream to reach the brain and spinal cord, eyes, and lungs.

The widespread pattern of the 2008 Canadian outbreak is an unfortunate consequence of our modern method of food preparation. Often food prepared at one or several large facilities is shipped to distant locations. When the system works, it provides an economical method of getting food to many people. When something goes wrong, however, the consequences can be national or even international in scope.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Foods are a source of nutrients and must be protected or altered to inhibit spoilage.

Introduction

Everyone has had the experience of trying to identify a long-forgotten food recovered from the depths of the pantry or refrigerator. Microbial activity can yield unpleasant surprises. Yet, should we be surprised? Because our foods provide us with nutritional resources, we might logically conclude that they may be exploited by microorganisms for the very same reason. When the result of that exploitation is undesirable, we say that our food is spoiled. The spoilage of foods by microorganisms is one component of the field known as food microbiology. Food preservation refers to a group of methods developed to prevent food spoilage and minimize the chance that foods will become contaminated with disease-causing microbes. Food safety is an important aspect of the food industry that deals with minimizing the incidence of foodborne diseases caused by microorganisms. Disease may result from mishandling foods during processing or preparation, either in a commercial setting or in the home.

Not all microbial activity in food is undesirable. Humans have used microbial fermentation for food production to preserve relatively unstable food materials since ancient times. For instance, when converted to cheese, milk remains consumable much longer than it does in its more perishable liquid form. Indeed, fermentation of milk to produce cheese has been described by author Clifton Fadiman as "milk's leap toward immortality." Today, even though we do not need to preserve foods by fermentation when a good refrigerator or freezer will do the job, the practice persists. The taste, texture, and aroma of fermented food products contribute a pleasing variety to our diet. Many enjoy fermented fruits in the form of wine or fermented grains in the form of beer or distilled spirits.

In addition to nutrients from food, living organisms require water, and it too must be free of pathogens and toxic compounds. Like carbon and nitrogen, water is cycled between living and non-living reservoirs. Water removed from natural waters for human use is eventually returned to its source. To protect our drinking water supply and to maintain the natural ecology of water systems, water that is used for everyday living, as well as for agriculture and industry, must be treated before it is released back into the environment. As we will see in this chapter, microorganisms are one of the main tools in removing chemical and biological pollutants from wastewater.

This chapter will specifically focus on several questions:

How can microorganisms spoil food? (16.1)
What techniques are used to minimize food spoilage? (16.2)
How are microorganisms used in food production? (16.3)
How can microorganisms in our food or water cause illness? (16.4)
How can we keep our water supplies safe? (16.5)

16.1 Food spoilage

How can microorganisms spoil food?

Many microorganisms will grow in our food if provided with the opportunity (Figure 16.1). Such growth does not necessarily lead to unsafe food, but most consumers consider such food to be unpalatable or unattractive and refer to it as spoiled. **Perishable foods** can easily support the growth of microorganisms. These include many fresh foods such as green salad ingredients or fresh meat. **Semi-perishable foods**, such as nuts or potatoes are not likely to spoil as quickly. Foods that cannot support microbial growth, often because they lack available water, are called **non-perishable foods**, and they may remain edible for long periods of time, even years. Examples of these foods include flour, sugar, and dried beans.

The likelihood that a food will spoil is related to its qualities as a microbial growth medium, which in turn depends on the characteristics of the food and its surroundings (Table 16.1). **Intrinsic factors** relate to characteristics of the food itself such as its nutrient content or pH. These also include structures that protect the food from microbial invasion, such as rinds or shells. We simulate that protection when we wrap our foods in plastic to protect it from spoilage. **Extrinsic factors** relate to

Figure 16.1. Spoilage of fruit by microorganisms **A.** Fungi produce spores that are easily dispersed and can survive in an inert form for relatively long periods. When they land on a nutrient source, such as food, the spores germinate and the fungus proliferates. **B.** Bacterial soft rot produces discolored and water-distended lesions that develop and expand rapidly. Other microorganisms may invade and a soft, slimy mass of lysed cells and bacteria fills the inside of the fruit.

TABLE 16.1 Factors affecting microbial growth in foods

Intrinsic factors	Extrinsic factors
Water availability	Temperature

Biological structures such as rinds or shells	

the conditions under which a food is stored. For example, cold temperatures in a refrigerator will slow the growth of human pathogens that grow best in warmer temperatures of the body.

Moist foods are more perishable than dry foods. However, water content alone is not the key factor in spoilage. Rather, one must consider the amount of water that is available and accessible to microorganisms. You may recall from Section 6.2 that this is called water activity (a_w). Most fresh foods have an a_w above 0.99, which is sufficient to support the growth of most microorganisms. Most spoilage bacteria require an a_w above about 0.91 (Figure 16.2). Foods that are dry or possess a high-solute content, usually of sugar or salt, have reduced a_w values. Fungal spoilage organisms, such as molds, can grow at lower a_w of approximately 0.8. Foods with lower a_w values are generally quite stable and have long shelf lives. Though spoilage bacteria require an a_w above about 0.91, one notable salt-tolerant bacterium is *Staphylococcus aureus*, which can grow at an a_w around 0.86. This can be significant for foods such as ham with a relatively high-salt content that reduces available water, because some strains of *S. aureus* secrete microbial **enterotoxins** that act on the intestine leading to foodborne illness. This is why your picnic ham should not remain out of the cooler for too long.

CONNECTIONS Enterotoxins act on the gut ("entero" refers to intestine), and those produced by *S. aureus* can induce severe vomiting. Enterotoxigenic strains of *S. aureus* discussed in **Section 21.2** are a leading cause of foodborne illness. They are most commonly found in foods that have been improperly cooked or insufficiently refrigerated.

The nutrient content of a food affects its likelihood to spoil and also determines the types of microorganisms that might contribute to the spoilage (Table 16.2). Fruits and vegetables are rich in carbohydrates, but low in protein. As a consequence, their spoilage patterns reflect metabolic pathways that microorganisms use to degrade carbohydrates resulting in accumulation of acids and gas from fermentation of sugars (see Section 13.3). Foods that contain the structural polysaccharide pectin, which

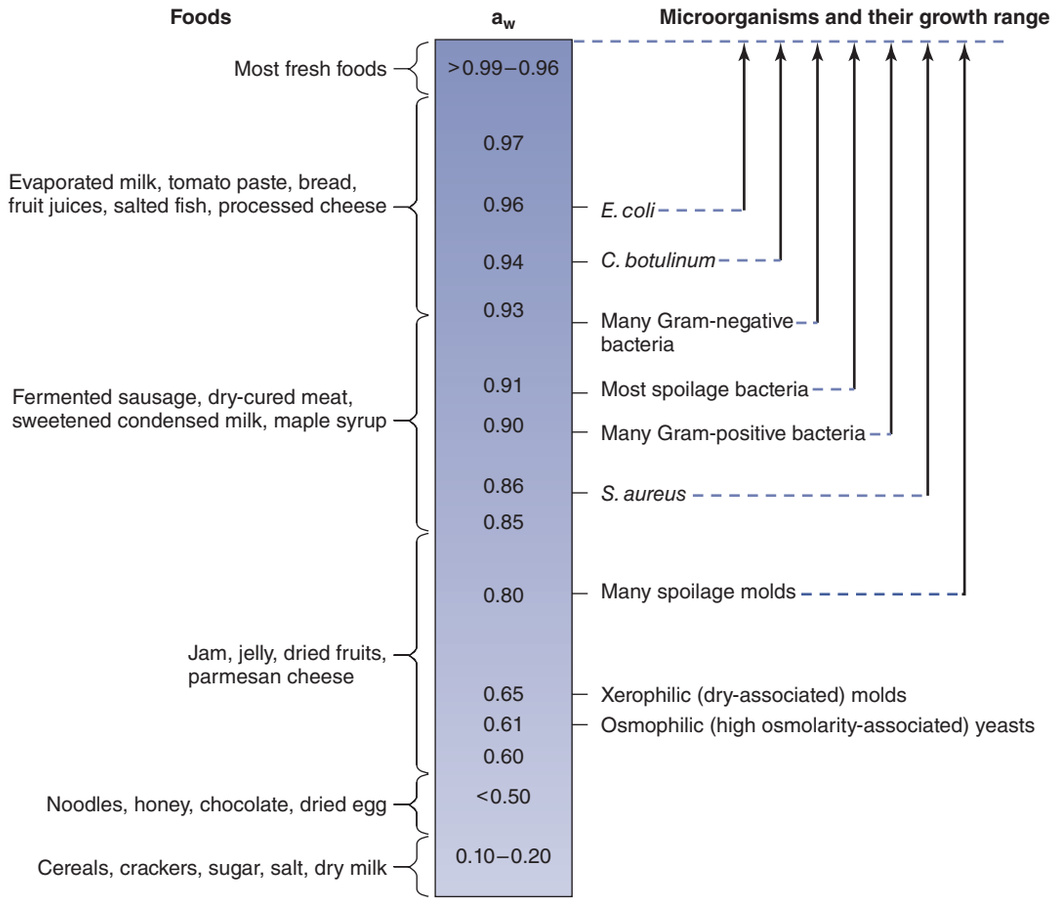

Figure 16.2. Water activity (a_w) Foods with a high a_w value, approaching 1.0, have readily available water and can support microbial growth. Foods with a low a_w value, approaching 0, contain very little available water; these foods are resistant to microbial growth.

TABLE 16.2 Typical spoilage patterns of selected foods

Food	Microbial substrates	Spoilage reactions	Products	Effects of spoilage	Common spoilage organisms
Fruits, vegetables	Pectin	Hydrolysis	Methanol, uronic acids	Soft rot, loss of fruit structure	Bacteria: *Erwinia, Pseudomonas, Corynebacterium*
	Sugars	Fermentations	CO_2, organic acids, alcohols	Souring, acidification	Fungi: *Aspergillus, Botrytis, Rhizopus, Penicillium, Alternaria,* various yeasts
Fresh meat, poultry, seafood	Proteins	Proteolysis, deamination	Amino acids, peptides, amines, H_2S, ammonia, indole	Bitterness, souring, bad odor, sliminess	Bacteria: *Acinetobacter, Aeromonas, Campylobacter, Escherichia, Listeria, Micrococcus, Pseudomonas, Salmonella*
	Carbohydrates	Hydrolysis, fermentations	CO_2, organic acids, alcohols	Souring, acidification	Fungi: *Candida, Cladosporium, Mucor, Penicillium, Rhizopus, Rhodotorula, Sporotrichium*
Milk	Lactose	Hydrolysis, fermentations	Lactic acid, CO_2	Souring, clumping	Bacteria: lactic acid bacteria (including *Streptococcus, Leuconostoc, Lactococcus, Lactobacillus), Pseudomonas, Proteus*
	Proteins (casein)	Proteolysis, deamination	Amino acids, peptides, amines, H_2S, ammonia, indole	Bitterness, souring, foul odor, sliminess	Fungi: *Candida, Geotrichum*

helps hold the cells of plant tissue together, may be attacked by microorganisms capable of pectinolysis. The result is a release of methanol or uronic acid, characteristic of pectin breakdown (see Table 16.2). The fruit or vegetable undergoes "soft rot" and loses its structure, becoming soft and mushy with a distinctly unpleasant taste (see Figure 16.1B).

Fruits are typically more acidic than vegetables. Because of this, mold spoilage is more common on fruit. The slower-growing fungi are generally more tolerant of lower pH and can grow on fruits that are too acidic to support bacterial growth. For example, lemons spoil extremely slowly, but will eventually be covered by mold if abandoned in the refrigerator. Faster-growing bacteria out-compete molds at near neutral pH, as found in many vegetables.

A variety of microorganisms can degrade the carbohydrate, protein, or fat components of milk. Souring caused by *Lactobacillus* sp. and *Streptococcus* sp. can cause formation of curds and a sour taste. Some of these reactions are desirable and produce cheese. Contamination of milk by *Clostridium* sp. or intestinal bacteria like *Escherichia coli* produces gas. Growth of *Alcaligenes* sp. or *Klebsiella* sp. causes the milk to become slimy. This variety of reactions reflects the nutrient-rich nature of milk.

Potential spoiler microorganisms must have access to a food item. Microorganisms that spoil fruits and vegetables are often found in soil; such foods are unlikely to be spoiled by intestinal microorganisms. However, fresh produce can sometimes be contaminated with incorrectly treated manure that has been used as fertilizer in the field or untreated rinse water containing intestinal pathogens from sewage. It is not unusual to find intestinal inhabitants on poultry or fresh meats. Their source is typically the carcass from which the tissue has been derived, or other animals nearby in the feedlot, farm, or slaughterhouse. Workers and airborne dust within food-processing plants are additional sources of microorganisms that can contaminate and spoil foods.

Food spoilage typically becomes evident when the contaminating microorganism(s) reach late exponential growth. In the late exponential phase, the metabolic activities of the increased numbers of microorganisms will consume significant amounts of the food-related nutrients. Accumulation of metabolic end products, along with microbial biomass, result in detectable food defects that include foul odors, sliminess, or visible tissue destruction. Exponential growth may occur early due to the plentiful supply of substrates, but damage to the food will not be evident because the microbial population is relatively small. In general, biologically induced spoilage is not detectable at microbial densities below 1 million (10^6) per milliliter (mL) or gram (g) of product. Above that, some sensory evidence of deterioration may be evident and, at $>10^9$ mL^{-1} or g^{-1}, structural change is apparent.

CONNECTIONS The microbial growth curve described in **Section 6.4** is useful for characterizing the behavior of a microorganism under defined conditions.

The concept of exponential growth is important to food preservation, affecting both the quality and safety of food products. A newly purchased carton of pasteurized milk can remain at room temperature for several hours with little adverse effect. If the initial population is about 10^3 mL^{-1} and doubles every 30 minutes at room temperature, the

population might reach 10^4 mL^{-1} before the carton is discovered and refrigerated. This microbial density is not high enough to produce visible damage. However, the increased number of microorganisms now in the milk could damage the milk quality and lead to quicker spoilage if the milk is left on the counter again.

The lag phase at the beginning of the growth cycle, when organism numbers remain fairly constant, and the exponential phase, during which the number of living organisms doubles in a given time, are most critical to determining microbial spoilage (see Figure 6.18). Often a product is already noticeably spoiled before growth stabilizes in the stationary phase. By extending the lag phase or reducing the rate of microbial growth, a product's shelf life can be extended. For example, microbial growth can be minimized during food handling through the use of chlorinated water to wash soil from harvested plants, the early and efficient removal of damaged or diseased products from the harvest, or use of scrupulously clean utensils during milking. All of these precautions will ensure that the microbial load on a product is small. The lag phase is extended, and more time will pass before the microorganisms reach exponential phase. Certain preservation methods, such as heat processing, can also reduce or even eliminate the microbial load on foods. Other preservation practices aim to produce conditions that are not optimal for microbial growth by manipulating either intrinsic factors, such as pH, or extrinsic parameters, such as storage temperature. This extends the lag phase, delays entry into exponential phase and increases microbial generation time. **Figure 16.3** illustrates how various types of processing and use of refrigeration for preservation can alter the characteristics of raw milk to produce dairy products that are considerably less perishable.

16.1 Fact Check

1. List the intrinsic and extrinsic factors that affect microbial growth in food.
2. What is water activity (a_w), and how is it related to food spoilage?
3. Explain how the microbial growth phases can be manipulated to reduce food spoilage.

Raw milk has a neutral pH, contains the nutrients lactose, fat, protein, minerals, and naturally harbors microbes such as lactic acid bacteria.

© Tanuki Photography/iStockphoto

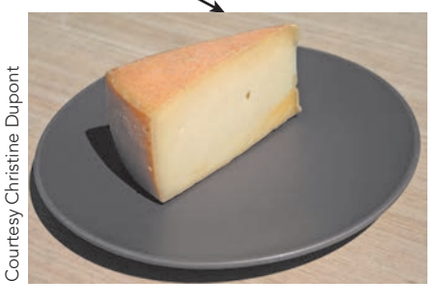
Refrigerated, pasteurized milk begins with a reduced microbial load from heat processing, and storage at cold temperature increases generation time.

Courtesy Christine Dupont

Salted butter has a low a_w, a solid structure to reduce microbial mobility, and low pH.



Courtesy Christine Dupont

Cheese has a low a_w (salt, little water), and its solid structure reduces microbial mobility.

Courtesy Christine Dupont

Yogurt has a pH ≤ 4.4, which is inhibitory to many contaminating microbes.

Figure 16.3. Alteration of milk as a microbial growth medium Raw milk is suitable for the growth of natural microbiota as well as contaminating microorganisms. Processing of milk into various products aims to change the physical and chemical form of milk to make it less favorable for growth of spoilage microorganisms.

16.2 Food preservation

What techniques are used to minimize food spoilage?

We have seen that reducing the growth of contaminating microorganisms in food can be achieved by altering the food product to make it less optimal for growth. Food preservation techniques prevent, or at least discourage, microbial growth and maintain food safety by destroying or restricting the growth of foodborne pathogens. Some techniques of food preservation, such as drying meat and fruit in the sun, have been practiced for most of human history. This ancient method has been repopularized in the sun-dried tomatoes that adorn your pizza or salad. Another old preservation technique is to add high concentrations of salt or sugars to foods. Heating food and refrigeration are other preservation techniques that extend the length of time a product can be stored before becoming unsuitable for consumption.

Reduction of the water activity (a_w) of food

Because microorganisms need available water to flourish, removing water from food can prevent spoilage, sometimes indefinitely. Oven-drying can replace sun-drying for large-scale commercial production (Figure 16.4). Drying is sometimes used in conjunction with wood smoking to impart flavor to certain products. Chemicals in the smoke, including phenolics, also inhibit microbial growth and contribute to preservation.

In **freeze-drying**, which is also known as **lyophilization**, the food is first frozen and then dried under a vacuum, often with subsequent storage in watertight packaging. The process is expensive but efficient and can be useful for special purposes. Freeze-dried foods are compact and lightweight, making them convenient for transport. Campers often carry freeze-dried food in a backpack and add water on site to rehydrate it before consumption.

Drying reduces a_w by removing water. An alternative for decreasing the amount of available water in foods is to bind water molecules by the addition of solute, such as sugar or salt, making water unavailable to microorganisms. For thousands of years, humans have practiced food preservation by the addition of large amounts of sugar or salt (NaCl) to food. Neither option is viewed as particularly healthy today, but this strategy is still used in foods like jams, jellies, and salted meat (Figure 16.5).

C. Freeze-dried (lyophilized) soup

Figure 16.4. Drying reduces water activity (a_w) **A.** Fruits can be dried using low heat in ovens or by the sun. **B.** Smoking used with heat-drying adds additional chemicals inhibitory to microorganisms. **C.** Freeze-dried foods are sealed in watertight evacuated packs. Water can be added, as in the right half of the bowl, before heating.

If you've ever read ingredient labels on prepared food, you may have noticed glycerol, sorbitol, or xylitol are commonly listed. These are sugar alcohols used to bind water, but they are less sweet than sugar and do not contribute to tooth decay. Unfortunately, ingestion of large amounts of products like sorbitol, as found in some sugar-free foods, can also lead to diarrhea because they draw water from cells lining the intestine.

Control of temperature

In industrialized countries, surely the most prominent food preservation method is cold temperature in the form of **refrigeration**. Like sugaring or salting, this practice has deep roots; the ancient Romans reportedly used ice and snow to pack seafood. Modern household refrigerators are usually set at about 4°C, whereas commercial chillers may operate at 1–2°C. However, cold storage is not foolproof. Some bacteria can tolerate refrigerator temperatures; such *psychrotolerant* microorganisms can grow and spoil food even while the food is refrigerated. An example is *Listeria monocytogenes*, introduced in the opening story of this chapter. Fortunately, most human pathogens do not grow well at refrigerator temperatures, instead preferring warmer temperatures of a living body.

Extending storage by freezing is possible for some foods, although not all. Ice crystal formation during the freeze-thaw process can damage food tissue, producing a mushy thawed product that bears little resemblance or taste to the original fresh material. Apples and citrus fruits, for example, undergo this transformation after freezing. A typical home freezer operates at about −20°C, below the temperatures that permit most microbial growth. In addition, a_w is reduced by the conversion of liquid water to ice crystals. It is important to monitor how long frozen food has been stored, because the cold, dry

Figure 16.5. Adding solutes reduces water activity (a_w) High concentrations of solutes bind water molecules, making water unavailable for microbial use. **A.** Many meats are preserved by soaking in NaCl (brine) or covering in dried salt. **B.** Jams and jellies contain high concentrations of sucrose.

atmosphere of the freezer will lead to physical defects such as freezer burn. Moreover, some slow microbial growth may be possible in small pockets of fluid that do not freeze because of their high-solute content. Frozen foods will remain unspoiled for months, but not indefinitely.

High-temperature processes also have a role in food preservation. Most obviously, thorough cooking of a food will kill most or all of its microbial community, although once cooled the food item is subject to recontamination. **Canning** is a high-heat process that involves heating a food to 100°C or above for an extended period of time, usually 20–100 minutes and under pressure of 10–15 psi. Traditional canning processes often use a temperature of 121°C, the temperature of a laboratory autoclave that is used to sterilize equipment and solutions, also known as "retort" temperature in the canning industry. Traditional canning, sometimes called appertization, has its roots in a process devised by Frenchman Nicolas Appert. From about 1795 to 1810, Appert developed a method in which food sealed inside a corked glass jar was heated in boiling water for several hours. Treated products were stable indefinitely, an advantage exploited by Napoleon's armies as their supply routes extended across great distances of European territory. Sealed glass jars became available by the 1880s, and home canning of foods became a common domestic chore **(Figure 16.6)**.

David Pollack/© Corbis

Figure 16.6. Home canning During World War I, Europe could not supply enough food for Allied forces, so the U.S. National War Garden commission was established to encourage Americans to use idle land for growing fruits and vegetables to send to troops. Households were educated on how to preserve food through the distribution of detailed manuals and local canning lessons.

Although improvements were made to commercial appertization processes, the commercial canning industry nearly foundered in the early part of twentieth century because of problems with the disease **botulism**. Botulism is a paralytic and deadly illness caused by botulinum toxin produced by *Clostridium botulinum*, which is normally an innocuous bacterial inhabitant of soils and aquatic sediments (see Microbes in Focus 21.2). *Clostridium botulinum* is a strictly anaerobic, endospore-forming chemoorganoheterotroph, and so the low-oxygen and high-nutrient content of canned foods provides ideal conditions for germination of spores and growth of the organism. Botulinum toxin is the most toxic natural substance known. Early commercial canning procedures sometimes did not eliminate *C. botulinum* endospores from foods entirely. As a result, the industry was plagued with periodic outbreaks of botulism, resulting in severe illness and regular fatalities among those who consumed the contaminated food. Intense consumer reaction to botulism outbreaks led to research by commercial canners in the 1920s to establish protocols designed to vanquish endospore survival in canned products. The concept of decimal reduction time, or D value, arose from this research. Recall from Section 6.5, the D value is the time required to kill 90 percent of the target organisms under specific conditions. Knowing the D value for a target organism, like endospores of *C. botulinum*, under set conditions, such as temperature or pH, allows treatment of that product to render it safe for consumption.

CONNECTIONS Endospores of *C. botulinum* may germinate under anoxic conditions in cans or sealed jars and produce botulinum neurotoxin. The toxin blocks release of acetylcholine at the neuromuscular junction causing flaccid paralysis, which can lead to death because the muscles needed for breathing no longer function. See **Section 21.2** for details.

Today, commercial canners aim for "commercial sterility," but not necessarily absolute sterility as a lab microbiologist would require of bacteriological media. However, canned goods are generally free of danger from pathogenic microorganisms. Either no viable organisms can be detected by the usual culturing methods, or the very low number is inconsequential because other intrinsic or extrinsic factors are not conducive to growth. Botulism is now an extremely rare foodborne illness in industrialized countries and is almost never linked to commercially canned products. Nonetheless, improper home canning of foods still claims lives. Botulinum toxin is inactivated by heat, so home-canned foods should be thoroughly heated before eating. Acidic canned foods are safer because they inhibit the growth of *C. botulinum*.

Heat can affect the flavor or texture of some food products adversely, making them unsuitable for high-heat processing. Heat processing, or **pasteurization**, was developed by Louis Pasteur to avoid such problems. Pasteur's original goal was to develop a process to prevent wine from souring without causing irreparable damage to the wine from heat. He found that mild heating could prevent souring without greatly affecting the flavor of the wine. His success was primarily due to killing the majority of alcohol-metabolizing acetic acid bacteria and other spoilage microorganisms in the wine. Today,

TABLE 16.3 Pasteurization processes for milk

Process	Temperature and time employed
Low-temperature hold (LTH)	63°C (145°F) for 30 min
Flash-heating	
High-temperature, short-time (HTST)	72°C (161°F) for 15 sec
Ultra-high temperature (UHT)	138–150°C (280–304°F) for 2 sec or less

pasteurization uses a variety of techniques to destroy microorganisms, without cooking the food product. Pasteurization processes include heating, irradiation, or applying high pressure. You may know that milk is typically pasteurized, but so are other products such as fruit juices, dried fruit, beer, honey, and liquid eggs. The specific time and temperature used in pasteurization depends on the item being treated, but the typical goal is to kill 99–99.9 percent of pathogens, spoilage bacteria, and fungi.

The original process of milk pasteurization involved heating milk in batches to a temperature of at least 62.8°C and holding it there for 30 minutes. This is termed the **low-temperature hold (LTH)** method (Table 16.3). Modern dairies often use **flash-heating**, which forces a small volume of milk between metal plates or pipes heated to very high temperatures (Figure 16.7). Small volumes reach the required temperatures much more quickly and evenly than large volumes. Exposure for only a very short time to high temperatures will kill the required number of microorganisms. Another advantage of flash-heating is that nutrients, such as vitamins, are not exposed to long periods of heat that may destroy them (as occurs in the LTH method).

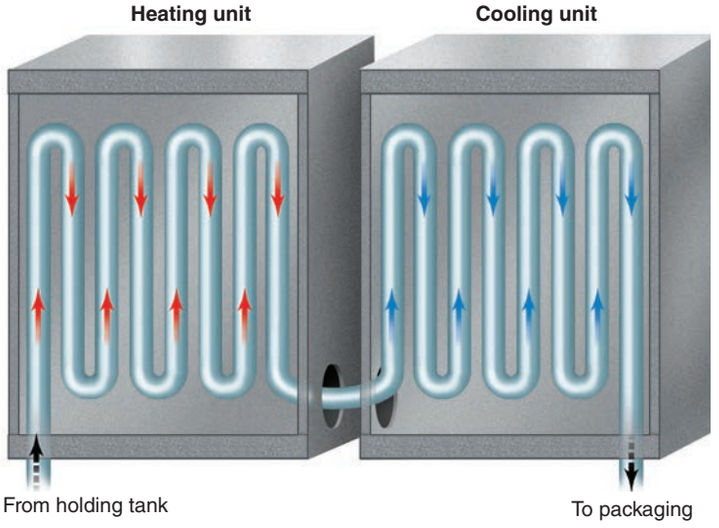

Figure 16.7. Flash-heating pasteurization Flash-heating allows continuous flow-through. In order to kill contaminating microorganisms, a small volume of raw liquid flows for a specified but very short period of time through metal plates or tubing (*left*) heated to a very high temperature. Liquid then passes through a cooling unit (*right*) to quickly lower the temperature to prevent excessive heat denaturation of nutrients. The product is then packaged.

A common flash-heating method uses the "high-temperature, short-time" (HTST) process, where milk flows for at least 15 seconds at a temperature of 72°C. This is the minimum temperature and time required for fluid milk sold for consumption in the United States; however, commercial processors often use variations of this protocol. "Ultra-high temperature" (UHT) processing (138–150°C for a few seconds or less) is commonly used for milk products and juices, and when combined with aseptic packaging, such products can be safely stored at room temperature for several weeks (usually 90 days). Coffee creamers, juice boxes, beer, and heat-and-serve soups are examples of products that may be processed this way.

An early target of milk pasteurization was *Mycobacterium bovis*, the agent of bovine tuberculosis (TB), which can also cause TB in humans (see Section 21.3). Although *M. bovis* is controlled by strict veterinary practices today, outbreaks still occur. Other pathogens potentially carried in raw milk include species of *Brucella, Salmonella, Campylobacter, Coxiella burnetti,* and pathogenic *Escherichia coli* strains. These are all non-spore-forming bacteria that are killed by pasteurization.

Increase in acidity of food

Microbial spoilage occurs most readily in a pH ranging from 6 to 8, where many microorganisms prefer to grow. Food is preserved from spoilage if the pH can be made more acidic or more alkaline without impairing the food's appeal. Humans ingest very few alkaline foods due to their bitter taste; egg white is one such alkaline food. We don't seem to mind acidity, however, and perceive it as tartness. However, too much acid in a food can be perceived as sour. In a process known as **pickling**, the pH of a food can be reduced by storing or marinating it in a chemical such as dilute acetic acid (vinegar), or by allowing lactic or acetic acid production to occur naturally through microbial fermentation. Pickling achieves a pH of less than 4.6, a condition that deters the growth of most microorganisms (Figure 16.8). During pickling of vegetables or meats, spices or sugar may be added to

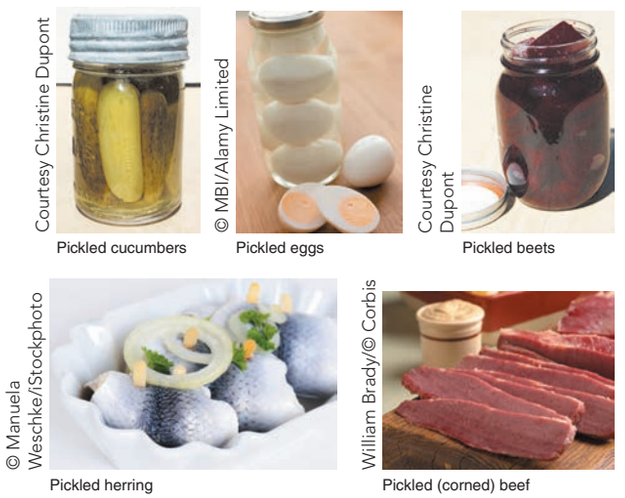

Figure 16.8. Common pickled foods Pickling involves the production or addition of lactic or acetic acid in food to reduce the pH below 4.6, which is inhibitory to microbial growth.

fuel desired microbial metabolism and impart specific flavors. Foods have been preserved through pickling for much of human history.

Addition of chemical preservatives

Acetic acid is one of several weak organic acids used as food preservatives. In 1908, sodium benzoate was the first chemical food preservative permitted by the U.S. Food and Drug Administration (FDA). Propionates and sorbates have also been used in some types of food for decades. All of these acids have "generally recognized as safe" (GRAS) status awarded by the FDA, permitting their widespread use. The preservative effect of these weak acids is restricted to relatively acidic foods because the acid molecule must be in a protonated form to cross the plasma membrane and disrupt microbial activity. For example, sodium benzoate helps preserve products such as fruit juices, pickles, ketchup, salad dressings, and soft drinks. Significantly lowering pH inhibits growth of even yeasts and molds that can generally tolerate relatively low pH.

Another chemical that is widely used in cured meat products is sodium nitrite ($NaNO_2$), which has multiple effects. Nitrite inhibits some spoilage microorganisms, as well as *C. botulinum* and other gas-producing clostridia. Sodium nitrite also stabilizes the red color of cured meats and contributes to flavor development. Nitrite seems to exert its inhibitory effect by interfering with cellular respiration by targeting nonheme iron-sulfur proteins, such as ferredoxin, in susceptible microorganisms (see Section 13.4). Unfortunately, nitrite reacts with secondary amines to form nitrosamines, some of which are known carcinogens. Nitrosamines have been detected at low levels in cured meat products. As a result, nitrite levels are controlled, and often isoascorbate is added concurrently to prevent nitrosamine formation.

A more recent approach to food preservation is biocontrol through the use of microbial products called **bacteriocins**, produced by some bacteria that have been used in food fermentations for millennia. Bacteriocins are small proteins that do not affect the organisms that produce them, but exert a negative effect on other closely related bacteria. This microbial version of chemical warfare provides a means for one type of microorganism to out-compete another for available resources. Nisin and pediosin are the two bacteriocins most investigated. Nisin has GRAS status for certain uses and is commercially available. It is used in products such as milk, cheeses and other dairy products, canned goods, and baby foods. It inhibits *C. botulinum* and other Gram-positive spoilage bacteria. Pediocin synthesized by *Pediococcus* species is effective against *Listeria monocytogenes*. An alternative to adding the bacteriocin is to add bacteriocin-producing bacteria strains to the food, an approach that fits nicely with the production of fermented food products.

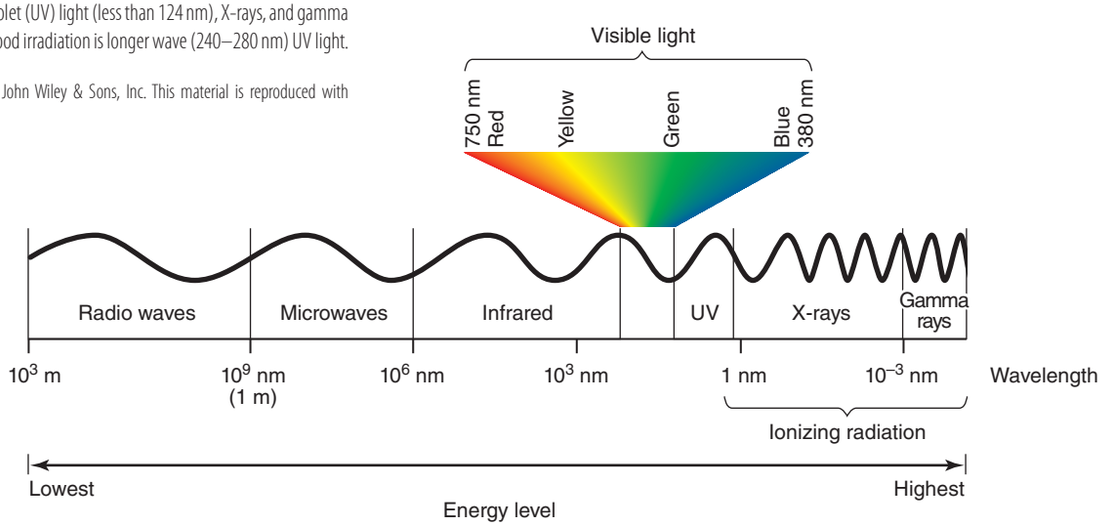
Irradiation of food

Exposing food to radiation, termed **irradiation**, has been recognized for decades as an effective way to reduce the number of microorganisms on the surface of or, to a limited extent, within fresh food products. Most consumers do not understand how radiation works and may associate radiation of food with radioactive food, thinking this technology is dangerous to them. World War II, atomic bomb testing, and nuclear accidents like Chernobyl and Fukushima have likely left consumers wanting little to do with radiation of any description. In reality, food irradiation is extremely safe and effective and is widely used. Radioactive material is not added to food. Instead, the food is simply exposed to the radiant energy of an external radiation source.

Radiation harmful to microbes includes ionizing radiation and non-ionizing radiation (Figure 16.9). **Ionizing radiation** refers to radiation of short wavelength with sufficient energy to remove electrons from molecules in a medium, producing ions. In cells, ionizing radiation produces oxidative damage and toxic free radical generation, all of which directly or indirectly damage nucleic acid. Ionizing radiation in the form of X-rays or gamma rays can be used to pasteurize or even sterilize foods, particularly in regions where refrigeration is not widely available. Sources of ionizing radiation include gamma rays from cobalt-60 or cesium-137, X-rays, or electron beams. Cobalt-60 sources used for medicine are sometimes "recycled" for use

Figure 16.9. The electromagnetic spectrum Ionizing radiation on the short-wavelength end of the spectrum includes some ultraviolet (UV) light (less than 124 nm), X-rays, and gamma rays. The only form of non-ionizing radiation used for food irradiation is longer wave (240–280 nm) UV light.

Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.



in the food industry once they have become too depleted for medical use (cobalt-60 has a half-life of about 5 years).

Ultraviolet (UV) radiation has a wavelength range of 10–380 nm. UV radiation in the wavelength range of 240–280 nm is the most lethal form of **non-ionizing radiation**. It causes the formation of damaging thymine dimers in deoxyribonucleic acid (DNA), which prevents transcription and DNA replication. UV radiation does not penetrate materials very well, and so its use is limited in the food industry to surface sterilization only. UV lights may be installed in rooms where cheeses or sausages are stored for aging or ripening to reduce the microbial load in the air. UV light may also be used to reduce viable microorganisms on surfaces such as warehouse shelving or in equipment such as plastic milk bags used for aseptic filling of liquid foods. Technological advances over the last quarter century have led to more powerful UV lamps with better penetrating power. Consequently, UV is being increasingly used in water disinfection protocols (see Section 16.5).

CONNECTIONS Exposure to natural UV light causes thymine dimers, and as we learned in **Section 7.5**, cells can repair this damage when it happens on a small scale. Extensive formation of thymine dimers, as would occur through exposure to UV disinfecting lights, causes DNA damage that exceeds the cell's repair capabilities, resulting in cell death.

Irradiation is of considerable benefit in the handling of raw meats, especially hamburger and poultry, to eliminate foodborne pathogens such as *Escherichia coli* O157:H7, *Salmonella*, and *Campylobacter*. These have been the cause of several large and infamous outbreaks of illness usually related to undercooking of raw meat (see The Rest of the Story, Chapter 21). Proper handling and thorough cooking eliminates the risk, but there is no guarantee this will occur in restaurants or even at home. Raw products devoid of these microorganisms are impossible to obtain with certainty at the meat processor level because they are frequent inhabitants of the animal gut and can contaminate carcasses during butchering and processing. Radiation treatments to eliminate potential pathogens have been permitted in the United States since 1990 for poultry and 1997 for raw and frozen ground beef. With 48 million cases of foodborne illness causing 3,000 deaths in 2011 in the United States, the Centers for Disease Control and Prevention (CDC) supports the increased use of food irradiation. Food irradiated with ionizing radiation must be labeled as such, using the Radura **(Figure 16.10)**, the international symbol for radiation and appropriate wording.

Courtesy USDA

Figure 16.10. The Radura The Radura is the international symbol for food products irradiated with ionizing radiation. It resembles a plant in a circle, and is usually green. The U.S. Food and Drug Administration version is shown here. Along with the Radura, irradiated foods must have written labeling such as "treated with radiation" or "treated by irradiation."

Use of modified atmosphere packaging (MAP)

Many foods are rapidly spoiled by the activities of aerobic microorganisms. One way to slow such activity is to remove the oxygen (O_2) required by the growing microorganisms. This strategy is employed in **modified atmosphere packaging (MAP)**, or vacuum packaging. MAP is frequently coupled with refrigerated storage. In vacuum-packed foods, microbial respiration and respiratory activity of fresh vegetables and fruits leads to O_2 depletion and carbon dioxide (CO_2) accumulation within the sealed package. One example of MAP, used for products such as cured luncheon meats or wieners, uses relatively impermeable plastic pouches, which are then evacuated and sealed. As a result, growth of aerobic spoilage bacteria and fungi is discouraged, and growth of relatively innocuous fermentative microorganisms, such as lactic acid bacteria (LAB), is favored. When significant microbial growth does eventually occur, usually following the stamped expiration date, the food item may become slimy, sour, and off-smelling so that it is unlikely to be eaten. If the food is eaten, such microorganisms are unlikely to cause illness.

CONNECTIONS In **Section 13.3**, we were introduced to LAB, a loose grouping of Gram-positive bacteria that produce lactic acid as a main product of their metabolism, which is always fermentative. See **Figure 13.18** for a review of the metabolic pathways for microbial production of lactic acid.

In other MAP processes, the atmosphere surrounding the food is altered and maintained by gassing the package or container with an appropriate gas mixture before sealing. For fresh fruits and vegetables, aerobic microorganisms are largely responsible for spoilage. MAP packaging for such produce typically uses high levels of CO_2 (greater than 10 percent), low levels of O_2 (less than 10 percent), with N_2 making up the balance. Coupled with refrigeration, this significantly reduces spoilage **(Figure 16.11)**. High-O_2 MAP is

Courtesy Christine Dupont

Figure 16.11. Modified atmosphere packaging (MAP) for fresh produce The pepper on the left was stored for three weeks at room temperature with no packaging. The pepper on the right was refrigerated for three weeks in its original MAP package. This form of MAP is used extensively for produce that is shipped long distances.

used for packaging raw red meats. A high-O_2 level oxidizes hemoglobin and aids in maintaining the color of the meat while reducing anaerobic growth from contaminating organisms such as *Clostridium*.

Hurdle technology

You may wonder if a sealed pouch made of relatively impermeable plastic, filled with food and depleted in O_2, might prove a suitable habitat for *Clostridium botulinum*, a strict anaerobe. Indeed, if MAP technology is used with foods where the presence of *C. botulinum* is possible, then additional preservative methods must also be applied. This is an example of **hurdle technology**, which employs multiple constraints or "hurdles," each of which the microorganism in question must overcome in order to proliferate (Figure 16.12). The application of combined multiple hurdles works synergistically to control the growth of pathogens and spoilage microorganisms in a food. To control *C. botulinum*, for example, any one of the following hurdles may be employed because each is inhibitory to *C. botulinum*:

- A pH of < 4.6, as for pickling or marinating in acidic solutions
- An a_w of < 0.96, such as in salt-curing (see Figure 16.2)
- A high NO_2 or O_2 gas concentration, as for MAP packaging
- A temperature of < 4.4°C, as for freezing or refrigeration

These individual hurdles are relatively intense, and any of them can significantly alter the food. When these hurdles are applied together, however, their intensities can be much milder. This is the basis of hurdle technology that maintains food freshness over longer periods of time, avoids or reduces food processing, and reduces chemical additives—all of which modern consumers demand. Understanding the physiology of various spoilage microorganisms and knowing pathogens associated with certain foods has allowed such advances in food technology.

Consider some of the products in your own kitchen. Can you determine how they are preserved and whether multiple hurdles are in use? Do you have honey in the cupboard? It is likely pasteurized. What other feature does it possess that enables you to leave it sitting on a shelf at room temperature for a long time without spoiling?

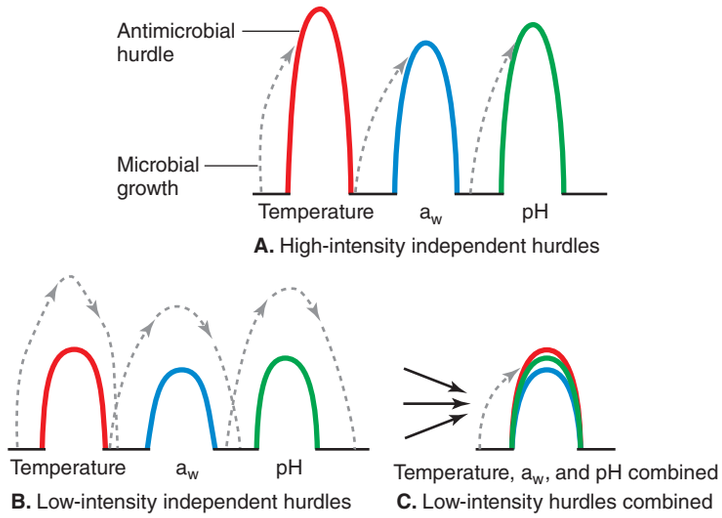


Figure 16.12. The hurdle technology concept Each constraint applied is a hurdle the microorganism must overcome in order to proliferate. **A.** When used independently, each antimicrobial hurdle must be of sufficient intensity to inhibit microbial growth, represented by the dashed line. Thorough cooking, salting or dehydration, or pickling can each prevent microbial growth but significantly alters the food. **B.** Reducing the intensity of the hurdle is desirable to maintain food freshness but does not sufficiently inhibit growth when each is used independently. **C.** When hurdles are used together, they sufficiently inhibit microbial activity enough to allow lowering of the intensity of the preservation treatment and thereby maintain food freshness.

16.2 Fact Check

1. How can a_w be reduced in food products, and why will this prevent spoilage?
2. Describe the various ways temperature is used to control microbial growth in food.
3. Explain how the chemicals acetic acid, sodium benzoate, and sodium nitrite function as food preservatives.
4. How can biocontrol methods such as the use of bacteriocins be used in food preservation?
5. Explain how different radiation methods are used to control or destroy microorganisms in food products.
6. What is modified atmosphere packaging (MAP) and how is it used in the food industry? Give an example.
7. Describe hurdle technology and how it can be used in preventing botulism.

16.3 Food fermentation

How are microorganisms used in food production?

Although microorganisms in food are often associated with spoilage, microorganisms are also used purposefully to preserve and create food and food products with unique qualities. As specific microorganisms metabolize specific foods, their metabolic by-products can impart desirable flavors, aromas, and textures that are not found in natural foods. Examples of this microbial bounty include breads, wines, cheeses, pickled vegetables, olives, and dry sausages, as well as many other popular foods. Indeed, one could survive a lifetime eating only foods that are the products of microbial activity.

Historical writings and other records show that, millennia ago, human societies relied on microbial fermentation to preserve or stabilize foods, including milk as cheese and yogurt, grains as bread and beer, and fruits as wine. These ancient

TABLE 16.4 Fermented foods and beverages and associated microorganisms

Food	Starting material	Fermenting microorganisms
Beer	Barley, hops	*Saccharomyces cerevisiae, Saccharomyces uvarum*
Cheeses	Milk	Lactic acid bacteria and molds
Chocolate	Cacao beans	*Candida rugosa*, lactic acid bacteria, *Acetobacter, Gluconobacter*
Coffee	Coffee beans	*Erwinia dissolvens, Saccharomyces* spp.
Kimchi	Cabbage and other vegetables	Lactic acid bacteria
Miso	Soybeans	*Aspergillus oryzae*
Green olives	Unripened olives	*Leuconostoc mesenteroides, Lactobacillus plantarum*
Sake	Rice	*Aspergillus oryzae*
Sauerkraut	Cabbage	*Leuconostoc mesenteroides, Leuconostoc plantarum, Leuconostoc brevis*
Summer sausage	Meat	*Pediococcus* spp. and other lactic acid bacteria
Soy sauce	Soybeans	*Aspergillus oryzae* or *Aspergillus soyae, Lactobacillus delbrueckii*
Surströmming (pickled herring)	Herring (fish)	*Haloanaerobium* bacteria
Tempeh	Soybeans	*Rhizopus oligosporans, Rhizopus oryzae*
Yogurt	Milk	Lactic acid bacteria
Wine	Grapes	*Saccharomyces cerevisiae, Candida* spp.

practitioners had no concept of "microorganisms" or "fermentative metabolism," yet they did recognize that if certain steps were followed, a predictable sequence of events occurred in a raw food material, converting it to a desired end product. That end product might be valuable because it had superior spoilage resistance compared to the original material, or because it introduced a pleasing sensation on the palate, or, in the case of alcoholic beverages, because it evoked an interesting change of mental state. Table 16.4 lists a variety of fermented foods.

The concept of a **starter culture** or inoculum was established in these early societies. Starter cultures are preparations of microorganisms that are added to food to aid in the production of fermented products. For example, taking leftover dough from a previous bread-making session and adding it to a new dough ensures that bread will rise. In today's industrialized age we have numerous other food preservation strategies from which to choose, yet fermented foods continue to be very popular worldwide because their diverse sensory properties add variety to the diet.

Fermentation of milk products

An amazing array of microorganisms, and variants on metabolic pathways, contribute to food fermentations, and the exact biochemistry that is taking place in each of the thousands of fermented products found globally is still not completely known. However, we are aware of some of the main metabolic pathways and groups of microorganisms involved. One group that is particularly prevalent in food fermentation is the lactic acid bacteria (LAB). Certain LAB, such as *Lactococcus lactis* (Microbes in Focus 16.1), are capable of fermenting the milk sugar lactose, a disaccharide of glucose and galactose, and are used in producing fermented dairy products such as cheese, buttermilk, koumiss, kefir, sour cream, and yogurt.

In commercial production of yogurt, milk is first centrifuged to remove some of the fat (Figure 16.13). Milk solids are increased by evaporation concentration or the addition of powdered milk solids to enhance the rich texture of the final product. The preparation is pasteurized, and a defined

Microbes in Focus 16.1
LACTOCOCCUS LACTIS

Habitat: Naturally found on green vegetation and in raw milk

Description: Gram-positive chain-forming coccus (*top*), 0.5–1.5 μm in diameter; an aerotolerant anaerobe with strictly fermentative metabolism

Key Features: Two subspecies (*L. lactis* subsp. *lactis* and subsp. *cremoris*) are widely used in making buttermilk, yogurt, and cheese. *Lactococcus lactis* grows well between 20 and 30°C, and hydrolyzes lactose and casein, producing lactic acid to a concentration of 1 percent, reducing pH to approximately 4.5 in suitable conditions. Nisin is produced commercially from *L. lactis* subsp. *lactis* cultures for addition to a wide variety of foods. It helps prevent the growth of spoilage organisms and has activity against foodborne pathogens such as *Staphylococcus* and *Clostridium*. Nisin is believed to destabilize the plasma membrane.

1. Begin with whole milk.
2. Adjust fat content, increase concentration of milk solids.
3. Pasteurization
4. Add mixed starter culture: *Lactococcus thermophilus* + *Lactobacillus delbrueckii* subspecies *bulgaricus*.
5. Ferment at 38–46°C for 6–8 hours until desired acidity and pH are reached.
6. Add fruit and sweeteners.

Figure 16.13. Process Diagram: Steps in making yogurt Milk fats are reduced by centrifugation, and milk solids are increased. Pasteurization minimizes populations of microorganisms present in the whole milk, and a defined starter culture of LAB is added to initiate fermentation. Lactic acid production coagulates milk proteins to thicken the milk. Fermentation proceeds until 0.9 percent acidity and pH 4.4 are reached.

starter culture is added. *Lactococcus thermophilus* and *Lactobacillus delbrueckii* subspecies (subsp.) *bulgaricus* are used because they produce volatile aromatic compounds that produce the distinctive aroma and flavor of yogurt. Lactic acid production during fermentation coagulates milk proteins (mostly casein) to thicken the milk. *Lactococcus thermophilus* and *Lactobacillus delbrueckii* subsp. *bulgaricus* are specifically used in yogurt production because they produce volatile aromatic compounds, particularly acetaldehyde, providing the distinctive aroma and flavor of yogurt. Fermentation proceeds at controlled temperatures until at least 0.9 percent acidity and pH 4.4 are reached (minimum standards for yogurt manufacture in the United States).

Other LAB are involved in producing fermented vegetables and meats. *Leuconostoc mesenteroides* is active in sauerkraut and *Lactobacillus brevis* in fermented meats. *Pediococcus acidilacti* is often a component of starter cultures used to produce dry or semidry fermented sausages and salamis. Sugars are added to these meat mixtures to provide a carbohydrate source for fermentation. Molds such as *Penicillium* often grow naturally on the surfaces of these meat products, producing other distinctive flavors. The principal function of LAB in food fermentation is to produce acid, which is responsible for the preservation of food. Of course, these bacteria also impart tangy flavors and pleasing aromas to fermented food products.

Historically, the production of fermented products relied on the activities of microorganisms found in the raw materials, and today this is still sometimes true, especially with ethnic foods produced in relatively small quantities for local use. However, a reliance on the natural microbiota can cause problems. If only a few cells are present, very weak fermentation may result, and if normally less abundant microorganisms dominate a particular batch of starting material, the entire process may go awry. Who wants cheese tasting strongly of acetone, butanol, and ethanol? This could happen if certain clostridia predominate in the fermentation process. To avoid these imbalances, commercial-scale fermentations usually employ specific, defined starter cultures. Large numbers of microorganisms of a desired strain are added to ensure operation of the desired fermentative pathways at predictable rates so that consistent product characteristics result. Starters are often mixed cultures. In dairy fermentations, one or more primary strains may act as a dominant acid producer. Acid production in milk results in coagulation and stabilization of milk proteins and is responsible for preservation. Other secondary strains of microorganisms are added to produce metabolites that contribute flavor or other qualities to the food. These secondary strains usually account for only 10–20 percent of the starter culture.

This use of starter cultures is expensive, but not as expensive as the cost of a ruined product line. Food-processing companies often purchase frozen starters with desirable characteristics from another company whose primary business is starter culture production. The starter is then added directly to the raw materials according to the manufacturer's instructions. This protocol in itself has made the production of fermented foods a more predictable enterprise, though some would argue that it produces a monotonously consistent product. The desire by some for batch-to-batch variety will help maintain the distinctive fermented products on a small, cottage industry scale.

Lactobacilli, depending on the species, may metabolize different sugars via different routes. Some LAB are homofermentative, producing lactic acid as their major (>85 percent) end product of fermentation (see Figure 13.17). For example, LAB in the genera *Lactococcus* and *Pediococcus* produce only lactic acid. Other LAB are heterofermentative, producing smaller amounts (~50 percent) of lactic acid in addition to various other fermentation end products (see Figure 13.18). Milk contains 0.15–0.2 percent citric acid, and metabolism of this substrate may be a key contributor to flavor and aroma, producing CO_2, lactic and acetic acids, and diacetyl, the component responsible for buttery flavor. A particular *Propionibacterium* strain is used as a secondary strain in the manufacture of Swiss cheese because of its ability to produce propionic acid, acetic acid, and CO_2 from lactic acid **(Figure 16.14)**. The acids contribute to the taste we associate with this type of cheese, whereas the gas produced is responsible for the holes in the finished product.

Fungi sometimes contribute to dairy fermentations as well. *Penicillium* molds are secondary strains required for Camembert and blue cheeses. The proteolytic and lipolytic activities of the molds contribute greatly to the sensory qualities of

Swiss cheese

Figure 16.14. Examples of starter cultures for cheese making Starter cultures consist of high numbers of primary lactic acid-producing strains of bacteria (LAB) whose principal role is to lower the pH during fermentation. Primary strains can also play a secondary role in flavor by release of metabolites. Secondary bacteria and/or fungi are present in lower proportions in starter cultures. Their primary role is to provide additional distinctive flavors and aromas.

these products. Mold is allowed to penetrate the blue cheese, whereas Camembert and Brie-type cheeses are surface-ripened. **Figure 16.15** shows the steps used in cheese making, which begins with pasteurized milk to rid the product of undesirable microorganisms. The milk is homogenized to evenly distribute the fat. Starter culture is added to induce acid production. Acid production coagulates the milk, forming solid *curds* made up mostly of the milk protein *casein* and its hydrolysis products, but also containing trapped liquid *whey*. Whey contains soluble nutrients, such as proteins, sugars, and minerals. Milk can also be coagulated using citric acid. Addition of the protease "rennin," otherwise known as "chymosin," facilitates coagulation. Rennin digests casein, producing a precipitated protein product. Rennin was initially harvested from calf stomachs but is now produced by recombinant DNA technology; equivalents are produced from various fungi or plants. Whey is kept with the curd to make loose unripened (unaged) cheeses, such as ricotta or cottage cheese. Processing of these cheeses stops here.

For other cheeses, the curd is cut into small 1-cm cubes to aid in whey release. Heating removes more fluid and causes shrinkage, then the curd is salted in brine. For hard cheeses, such as Cheddar, the curd is pressed to express whey and bind the curds together. For cheeses with a creamy texture, such as blue cheese, the curd is placed into molds to drain whey by gravity. The microbial cultures are not destroyed by these processes, and their activities are allowed to continue during storage or aging to produce ripened cheeses. For blue cheese, the cheese mass is pierced with steel needles to form holes through which air penetrates to allow *Penicillium roquefortii* mold to grow, producing the blue "veins" found in this type of cheese. Some cheeses are unripened and do not go through an aging process.

Koumiss is traditionally prepared from mare's milk, which is fermented by a mixture of lactobacilli and a lactose-fermenting yeast, producing both lactic acid (about 1 percent) and as much as 2 percent ethanol in the product; yeast-derived CO_2 provides effervescence to the product. Ethanol production by yeast is inhibitory to the growth of many microorganisms and is responsible for the preservation of such alcoholic beverages.

Product defects may occur when the wrong microorganisms dominate a fermentation. With starting materials rich in carbohydrates, a bacterial lactic acid fermentation may ensue when a yeast ethanolic fermentation was desired, or vice versa. In other words, LAB often spoil products like wine, and an undesired alcoholic taste and frothiness in lactic acid-based fermented products is frequently due to contaminating yeasts attacking the available substrates. Heterofermentative bacteria, such as *Clostridium* and *Leuconsostoc* species, can be problematic because they tend to cause "blown" or "gassy" cheese because of excessive CO_2 and/or H_2 accumulation during cheese making or after cheese has aged for several weeks. These bacteria can ferment lactose and the end products of desired fermentations, such as lactate and citrate. Occasionally, one may observe a package of late-blown cheese in the grocery store **(Figure 16.16)**. The use of only high-quality pasteurized milk, good starter cultures, and excellent sanitation protocols throughout the cheese-making process help reduce the chances of gas defects.

An infection by lytic bacteriophages can cause a fermentation to halt due to destruction of the populations of fermenting bacteria. Obviously, cheese manufacturers derive no profit from huge vessels of milk and lysed bacteria unable to convert lactose into lactic acid. One cause of late-blown cheese

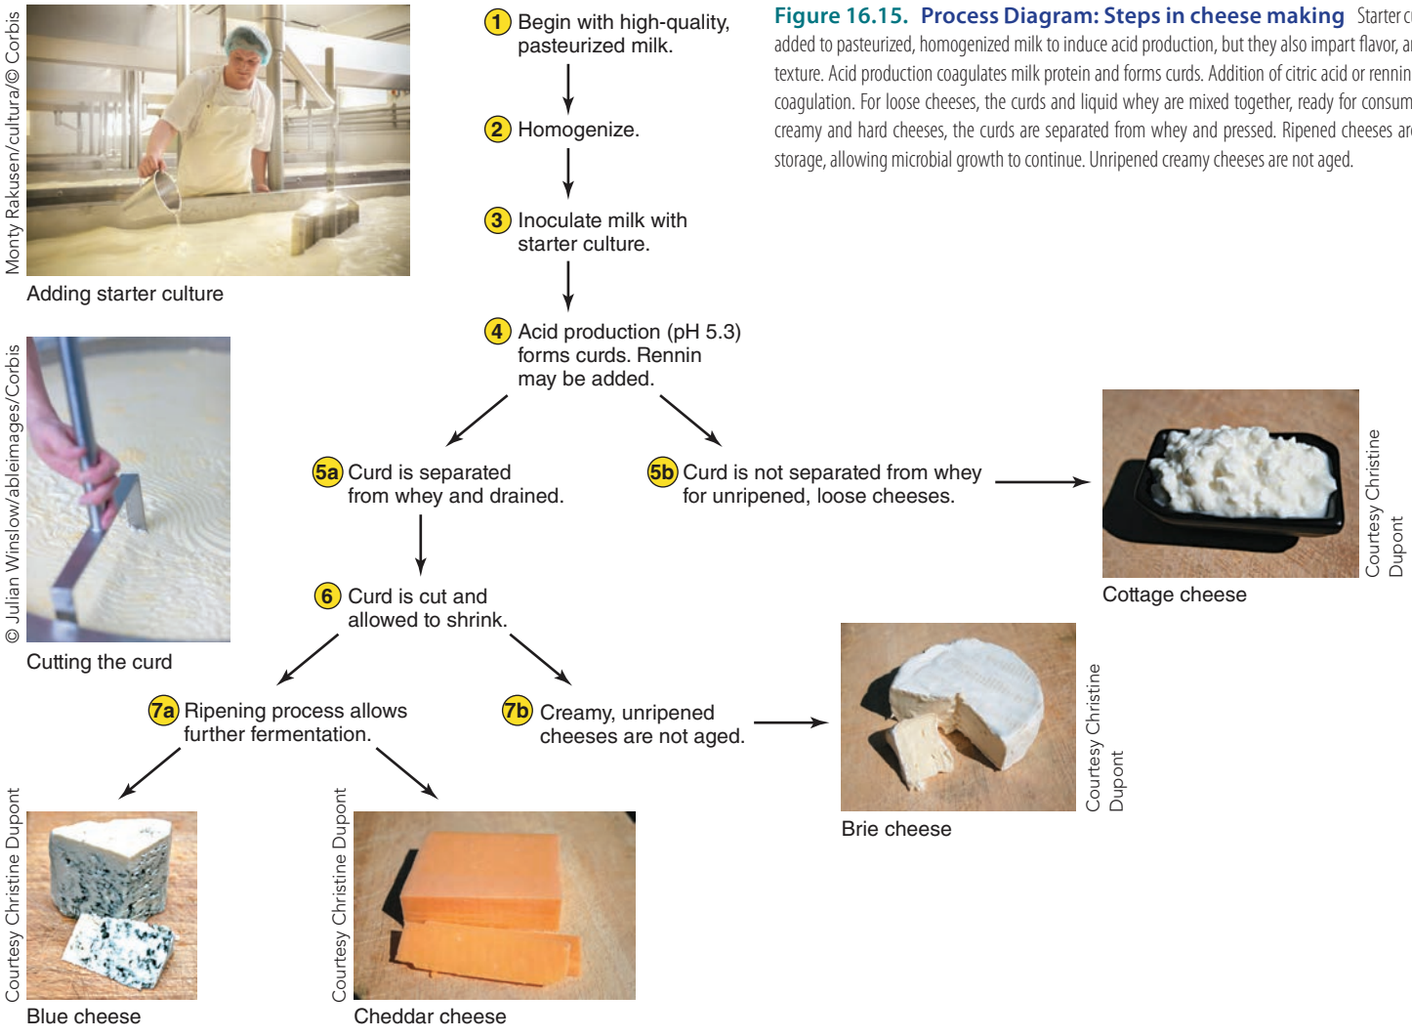

Figure 16.15. Process Diagram: Steps in cheese making Starter cultures are added to pasteurized, homogenized milk to induce acid production, but they also impart flavor, aroma, and texture. Acid production coagulates milk protein and forms curds. Addition of citric acid or rennin facilitates coagulation. For loose cheeses, the curds and liquid whey are mixed together, ready for consumption. For creamy and hard cheeses, the curds are separated from whey and pressed. Ripened cheeses are aged by storage, allowing microbial growth to continue. Unripened creamy cheeses are not aged.

is contamination with LAB bacteriophages that significantly reduce populations of desired LAB strains, allowing for proliferation of contaminating bacteria that would otherwise not present a problem. Bacteriophage infection has plagued the dairy product fermentation industry in the past, but today scientists know how to alleviate the problem.

Figure 16.16. Wheel of late-blown Leicester cheese Note the accumulation of gas (CO_2 in this case) within the package, indicating undesired fermentation was still active after packaging. The causative species was shown to be a salt-tolerant strain of *Leuconostoc mesenteroides*, present as a contaminant in the starter culture.

Several methods are used to avoid phage infection of starter cultures. Good manufacturing practices, such as aseptic technique, are particularly important, especially during starter culture production. Second is the use of media that are not conducive to phage infection. LAB bacteriophages need calcium ions (Ca^{2+}) to adsorb to their hosts; accordingly, low-calcium phage-inhibitory media are used to grow the bacteria. A third method is to employ strain rotation, which takes advantage of the fact that bacteriophages are often strain-specific. Multiple strains of bacteria that can fulfill the same role in starter culture function are rotated into and out of the mix so that an accumulation of phages that can infect a particular bacterial strain does not occur. Microbiologists who develop starter cultures continually create more phage-resistant strains through mutation to add to the pool of rotating strains. In other words, microbiologists strive to keep their starter cultures at least one step ahead of the destructive viruses.

CONNECTIONS Bacteriophages are found in large numbers wherever their bacterial hosts exist. See **Sections 5.1** and **8.2** to review how bacteriophages infect and lyse bacterial cells.

TABLE 16.5 Examples of traits found on mobile genetic elements in starter culture bacteria

Starter	Plasmid/transposon-linked traits

Starter culture inoculum failure is another factor that may lead to a defective food product, or no product at all. Before the genetics of LAB became the subject of research, it was not recognized that many of the critical features of fermenter strains were coded on mobile genetic elements, like plasmids, and not on the chromosome **(Table 16.5)**. This is especially true in the lactococci. Loss of a plasmid from a strain could lead to loss of a critical feature of that bacterium as a fermentation starter. Some commercially important strains have been genetically manipulated by inserting the genes for such critical characteristics into the chromosome, thus preventing their loss.

Fermentation with mold

In Western countries, food products resulting from LAB and yeast fermentations dominate. However, mold fermentation of solid substrates is used extensively in Asia to produce food products, such as miso, a fermented soybean paste used as a base for soups and sauces **(Figure 16.17)**. Other examples are tempeh and soy sauce. Tempeh originated in Indonesia and is prepared from soybeans, although other legumes, cereals, and agricultural by-products may also serve as starting materials.

Traditionally, soy sauce was produced in wooden tanks by a static fermentation process that took 1–2 years. Today, computer-controlled fermentations using large enamel or stainless-steel tanks are the norm, but the process is still lengthy and requires two stages **(Figure 16.18)**. The first stage is called a *koji* fermentation. *Koji* refers to various cultivated molds used in making fermentation products, such as soy sauce, miso, and sake or rice wine. The seed *koji* mold contains a mixture of strains pregrown on a similar substrate to produce enough fungal mass to mix into the soybean-wheat mix. For soy sauce, a mixture of soaked, steamed soybeans and roasted cracked wheat (in a ratio of about 1:1) is inoculated with spores of the aerobic mold *Aspergillus oryzae*, or *Aspergillus sojae,* and spread in layers about 5 cm deep. Over 2–3 days, the mold grows throughout the solid substrate, producing the extracellular proteases and amylases it requires to hydrolyze the macromolecular material in the substrate. The distinctive flavor of soy sauce comes from the amino acids that are released from the hydrolyzed soybean proteins.

The second stage in the production of soy sauce, known as the *moromi* fermentation or mash stage, involves addition of salt water (brine) and depletion of available oxygen by sealing the mash in air-tight vats to prevent further mold growth. The mold-derived enzymes continue to hydrolyze proteins, polysaccharides, and nucleic acids in the mash to produce a liquid rich in soluble nutrients. This now enables associated halophilic LAB and osmophilic yeasts to use the released nutrients to carry out lactic acid and ethanol fermentation. Fermentation continues for several months at 35–40°C in the sealed containers. Thereafter, the *moromi* mash is pressed to collect the liquid phase, which is pasteurized and may be filtered and aged in casks before bottling. The end product contains up to 2 percent ethanol, lactic acid (pH 4.8), and salt (18 percent), all of which inhibit growth of microbial contaminants. Modern processes may use specific bacterial and yeast inocula to better

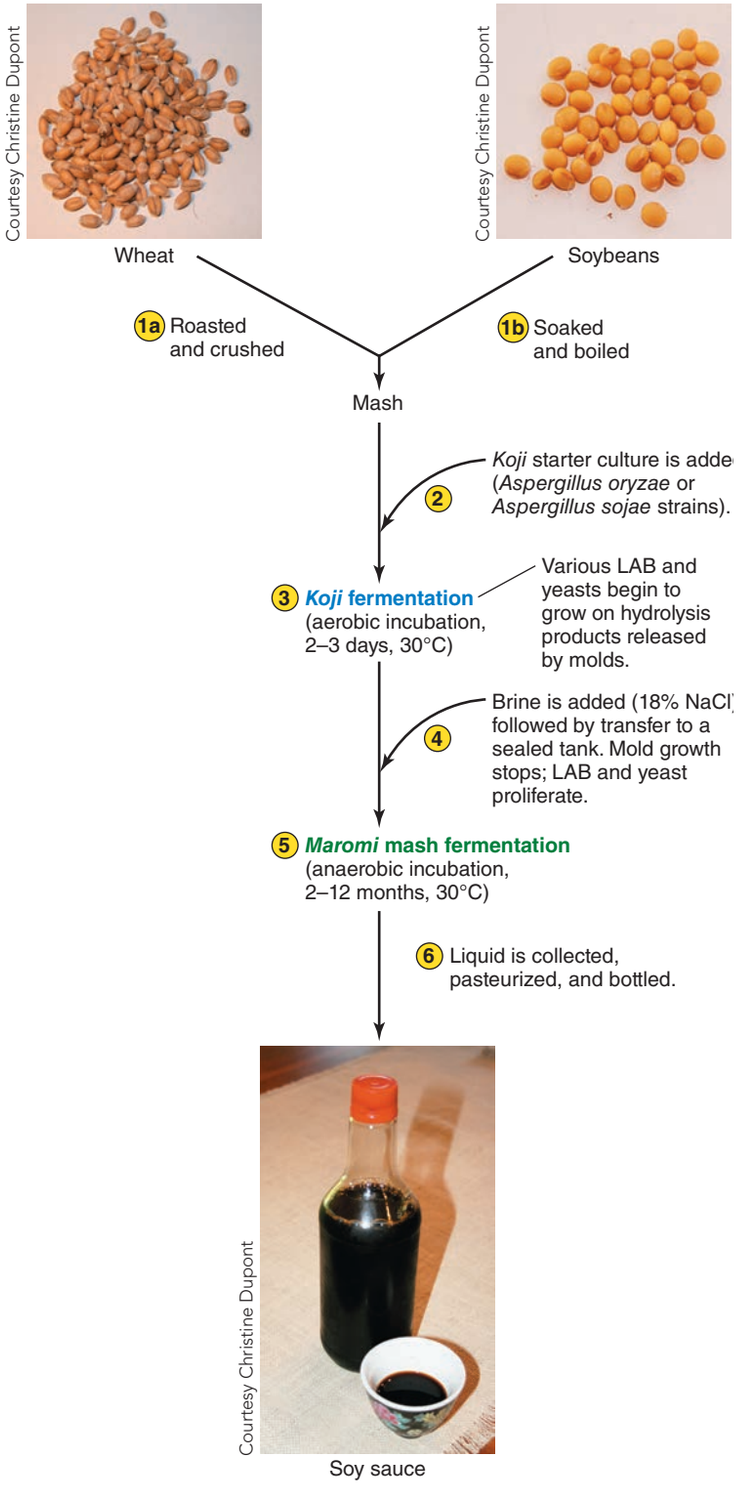

Figure 16.18. Process Diagram: Production of soy sauce Prepared wheat and soybeans are inoculated with *koji*—a mixture of cultivated mold strains. The *koji* fermentation step encourages growth of the aerobic mold throughout the substrate to maximize extracellular enzyme production. The resulting breakdown products from starches and proteins are used by LAB and yeast in the next anaerobic *moromi* mash fermentation stage. The end product contains ethanol, low pH (lactic acid), and salt, all of which are inhibitory to growth of microbial contaminants.

control product characteristics, but traditionally, the microorganisms active in secondary fermentation are derived from the substrate mixture. A similar two-stage process is required for the brewing of sake, or rice wine (Figure 16.19).

Figure 16.19. Cultivating *koji* for sake brewing A *Toji*, or brewing artisan, is cultivating *koji* in a traditional manner. In this case, steamed rice is inoculated with *Aspergillus oryzae* spores (*left*). The inoculated rice is then placed into wooden containers to cultivate the *koji* mold (*right*). Individual manufacturers have their own proprietary versions of *koji*, some of which are centuries old.

Vinegar manufacture

The origin of vinegar is almost certainly rooted in the souring of wine. In the distant past, someone who was initially disappointed to discover that their wine cache had spoiled ultimately recognized that the resultant liquid was not harmful and was not objectionable in taste, at least in small quantities. Further investigation revealed that the liquid was a good flavoring agent, paving the way for the current popularity of vinegar as a condiment. Vinegar is also used in the food industry as a pH control agent, as a preservative, and as a flavoring agent. Ketchup, sauces, salad dressings, pickles, and mayonnaise all contain vinegar.

Vinegar's main component is dilute acetic acid. Yet, simply diluting concentrated (glacial) acetic acid does not yield the same product. True vinegar is produced through microbial activity that adds flavor components in addition to the acetic acid to provide its final characteristics. These arise in part from the alcohol source used. The starting material is some type of alcoholic solution metabolized by bacteria belonging to a group known as the "acetic acid bacteria," to produce acetic acid. Diluted pure ethanol is used for distilled or white vinegar; wines (from grapes in Europe, rice in Asia), fruit ciders, and malt liquors are other starting materials. Normally, a vinegar manufacturer produces these alcoholic starting materials in the same general manner used in the beverage alcohol business. However, the aroma and other aesthetic aspects that are so important to alcoholic beverages, such as wines, are of no consequence in vinegar because, in the second stage of the process, the alcoholic solution is purposely spoiled as it is converted to an acetic acid solution.

The acetic acid bacteria are strict aerobes, and the oxidation of ethanol is one route that they use to obtain energy and carbon:

$$\underset{\text{ethanol}}{CH_3CH_2OH} \rightarrow \underset{\text{acetaldehyde}}{CH_3CHO} \rightarrow \underset{\text{acetic acid}}{CH_3COOH}$$

Acetic acid bacteria can also metabolize sugars and are tolerant of pH values below 5, as might be expected of microorganisms that produce organic acids as the end products of their

metabolism. All known acetic bacteria are α-Proteobacteria and belong to one of two genera, *Acetobacter* and *Gluconobacter*. Species of *Acetobacter* can further oxidize acetic acid to CO_2 and water (H_2O), and are called complete oxidizers. *Gluconobacter* strains are used to make vinegar because they are incomplete oxidizers and accumulate acetic acid.

The earliest and simplest method of vinegar manufacture, known as the Orleans process, is a surface culture technique where the acetic acid bacteria grow as a biofilm, or adherent community, on the surface of the ethanolic solution, gradually converting the alcohol to acid. Once a suitable level of acidity is reached, about two-thirds of the total volume is drawn from the bottom of the vessel to avoid disturbing the biofilm bacteria, and is replaced with fresh ethanolic starting material. The operation is a semicontinuous process, albeit not a very efficient one, requiring about 2 weeks for sufficient acetification to occur. It is still used, though only at small scale. The high-tech method of making vinegar uses a submerged culture technology with a bioreactor called the Frings Acetator, a far more efficient semicontinuous operation that produces product in 24–48 hours under highly controlled conditions. **Figure 16.20** depicts the Quick or Trickle method of vinegar production, a "medium-tech" approach that employs acetic acid bacterial biofilms growing on an inert support material such as beech wood chips or birch twigs.

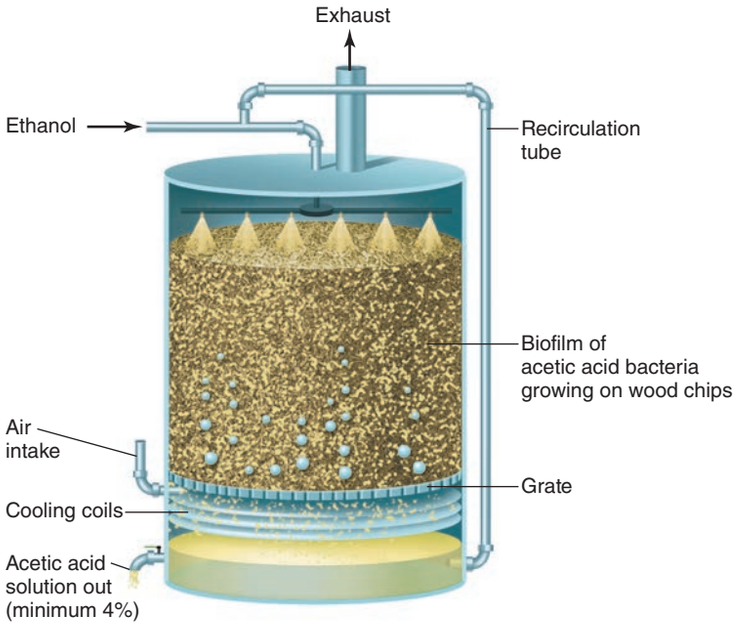

Figure 16.20. Quick or Trickle method of vinegar production The ethanol-containing liquid is introduced onto a bed of inert support material such as wood twigs or shavings. As the fluid passes through the bed by gravity, the adherent biofilm of acetic acid bacteria metabolizes the ethanol to acetic acid. Air is constantly diffusing up through the bed to ensure the bacteria have sufficient oxygen. The acidic liquid drips through the grate at the bottom and is recirculated as necessary to obtain a 4 percent minimum acetic acid concentration. The process requires approximately 4–5 days.

16.3 Fact Check

1. How are lactic acid bacteria (LAB) used in food production? Provide examples.
2. What are starter cultures, and how are they used to prevent undesirable results in microbial food products?
3. Describe examples and causes of the defects that may occur in products such as cheese due to the presence of undesirable microorganisms.
4. Describe the steps that can be taken to prevent destruction of LAB by phages.
5. What is the role of mold (*koji*) in soy sauce production?
6. Explain why the *moromi* mash stage requires removal of oxygen and addition of salt.
7. Explain how bacteria are used to produce vinegar.

16.4 Foodborne and waterborne illness

How can microorganisms in our food or water cause illness?

The provision of food that is safe to eat is a major focus of the food industry and a primary goal of food handling, processing, and preservation technologies. Inevitably, however, foodborne illnesses do occur, and while the occurrence of a lethal illness such as botulism is extremely rare, foodborne illness unfortunately is not. The true number of foodborne illnesses that occur on a yearly basis is unknown because many cases are never reported. As stated in Section 16.2, the CDC estimated 48 million cases of foodborne illness led to 3,000 deaths in 2011. **Table 16.6** shows the top five most common pathogens associated with foodborne illness. Foodborne illness may range from a nuisance to death. The severity of disease depends on the microbial species or strain, host-related characteristics, including genetics and state of health, and other factors such as the type of food involved.

CONNECTIONS **Chapter 21** describes how several pathogens associated with foodborne illness cause disease.

TABLE 16.6 Top five annual foodborne-disease estimates for the United States (2011)

Bacteria	Number of reported illnesses per year	Foods
Salmonella spp.	1,027,561	Poultry, eggs
Clostridium perfringens (enterotoxin)	965,958	Reheated meats
Campylobacter spp.	845,024	Poultry, dairy
Staphylococcus aureus (enterotoxin)	241,148	Gravies, meats, puddings
Viruses		
Norovirus	5,461,731	Many foods

Outbreaks of foodborne or waterborne illness are known as "common source outbreaks" as the incidence pattern typically reflects the fact that many people are exposed to the causative agent and become ill at about the same time from the same source (see Figure 18.19). The common vehicle of transmission that spreads the pathogen could be a contaminated food item ingested by a large number of people at an event such as a party or picnic. After an incubation period, a significant proportion of people who ingested the food will become ill within a fairly short window of time. Consumption from a shared contaminated water source has the same effect. A tragic example occurred in the summer of 2,000, in the town of Walkerton, Ontario, where contamination of one of the town's wells by *E. coli* O157:H7 sickened hundreds of people and killed seven (see Chapter 21 opening story). This bacterium more commonly causes foodborne outbreaks, usually from contaminated ground beef. Once the food has been consumed, or the defective water supply is discovered and replaced by a safe source, the number of cases diminishes rapidly.

A particular pathogen might tend to be transmitted more often through food or more often through water, but in many cases transmission by either route may occur. For example, typhoid fever, a serious disease caused by *Salmonella* Typhi (see Microbes in Focus 18.2), is classically considered a waterborne disease, but it can be spread through contaminated food. On the other hand, salmonellosis, a milder salmonella-caused illness, is most frequently foodborne, although outbreaks of salmonellosis resulting from contaminated water certainly have been reported (Figure 16.21).

CONNECTIONS Common source outbreaks show an epidemiological pattern of cases that is distinctive from those caused by pathogens transmitted from person to person. See **Section 18.3** for further discussion.

Although there are exceptions, agents of foodborne illness most commonly cause sudden or acute symptoms that reflect disruption of the gastrointestinal tract. The stomach and/or intestine may become inflamed. Gastritis, gastroenteritis, and enterocolitis are terms used to describe inflammation of the stomach, intestine, and colon, respectively. Symptoms such as nausea, vomiting, and diarrhea are common results of this trauma.

Enterotoxins, mentioned in Section 16.1, are secreted microbial toxins that cause or contribute to the intestinal symptoms in affected individuals. This frequently occurs because enterotoxin action stimulates water and electrolyte release from the cells lining the gut, resulting in diarrhea and dehydration. "Oral rehydration therapy" (ORT), which increases fluid intake by mouth as opposed to intravenously, may be an effective means of combating these effects. ORT can be particularly important in infants and small children, who do not have a large volume of body fluids, and in individuals suffering from extended bouts of severe diarrheal illness, as occurs with the waterborne disease cholera (Figure 16.22).

CONNECTIONS *Vibrio cholerae,* the bacterial agent of cholera, attaches to intestinal cells following ingestion of contaminated water. Once attached, it secretes a potent enterotoxin that causes ion imbalances in intestinal cells, causing significant water loss across cell membranes, resulting in massive diarrhea and dehydration. ORT replaces lost fluids and restores ion balance. See **Chapter 21** for details.

Colloquially, foodborne illness is often referred to as "food poisoning," a reflection of the fact that the first food illnesses linked to microbes truly were poisonings. Staphylococcal food illness was recognized in 1914 and definitively linked to an enterotoxin produced by *Staphylococcus aureus* in 1930. In reality, food poisoning may be an intoxication or an infection.

A **foodborne intoxication** refers to illness caused by ingestion of microbial exotoxins as is the case with *S. aureus* food poisoning. Toxins produced by microorganisms may be present in food even though the organisms that produced them are no longer present when the contaminated food is eaten. Generally in foodborne intoxication, the microorganisms themselves may be harmless, and ingestion of the cells alone may be safe; it is the toxin that they produce that causes illness. A classic example of food intoxication is illness that follows consumption of ham sandwiches or potato salad that is left out too long and fosters growth of *S. aureus* that produces a potent enterotoxin (see Figure 21.22). Toxins are not necessarily destroyed unless food is thoroughly cooked or reheated properly. Because many foods that come in contact with *S. aureus* are only warmed or served cold, it is important to follow good hygiene practices such as hand washing when preparing foods. Illness from *S. aureus* enterotoxin is usually short-lived, but a more lethal example of food intoxication occurs after consuming foods in which *C. botulinum* has produced the toxin that results in deadly botulism. Anaerobic growth of *C. botulinum* and/or other contaminating bacteria in cans produces gas, which is evidenced by bulging of the can **(Figure 16.23)**. Because the toxin will be present in the food, symptoms may appear relatively quickly after ingestion, sometimes within 30 minutes and usually within six hours.

A **foodborne infection** requires consumption of the organisms themselves. When these living pathogens are ingested, they actively multiply within the body, typically in the small or large intestine. In the body, these organisms may also produce a toxin that initiates symptoms when the level becomes high enough. Symptoms of food infections typically do not appear immediately as the organisms will enter a lag phase of growth before showing the exponential increase causing illness. Foodborne infections may appear the day after ingestion of the offending food. Bacteria that commonly cause foodborne infections include *Salmonella, Shigella, E. coli,* and *Campylobacter.* Thorough cooking of food will usually prevent foodborne infections. It is particularly important to cook ground meat well so that bacteria that originated on the surface of the meat, but are now distributed throughout, will be killed. Ineffective cooking of hamburger patties has led to deadly outbreaks of *E. coli* O157:H7.

16.4 Fact Check

1. Describe the incidence pattern typically observed for a food or waterborne outbreak.
2. How do foodborne or waterborne pathogens cause diarrhea?
3. Differentiate between foodborne infection and foodborne intoxication. Give some examples of pathogens associated with each.

Michael P. Gadomski/Science Source

Figure 16.23. Gas production from microbial growth Bulging cans result from accumulated gas and should be suspected of containing *C. botulinum* toxin.

16.5 Microbiological aspects of water quality

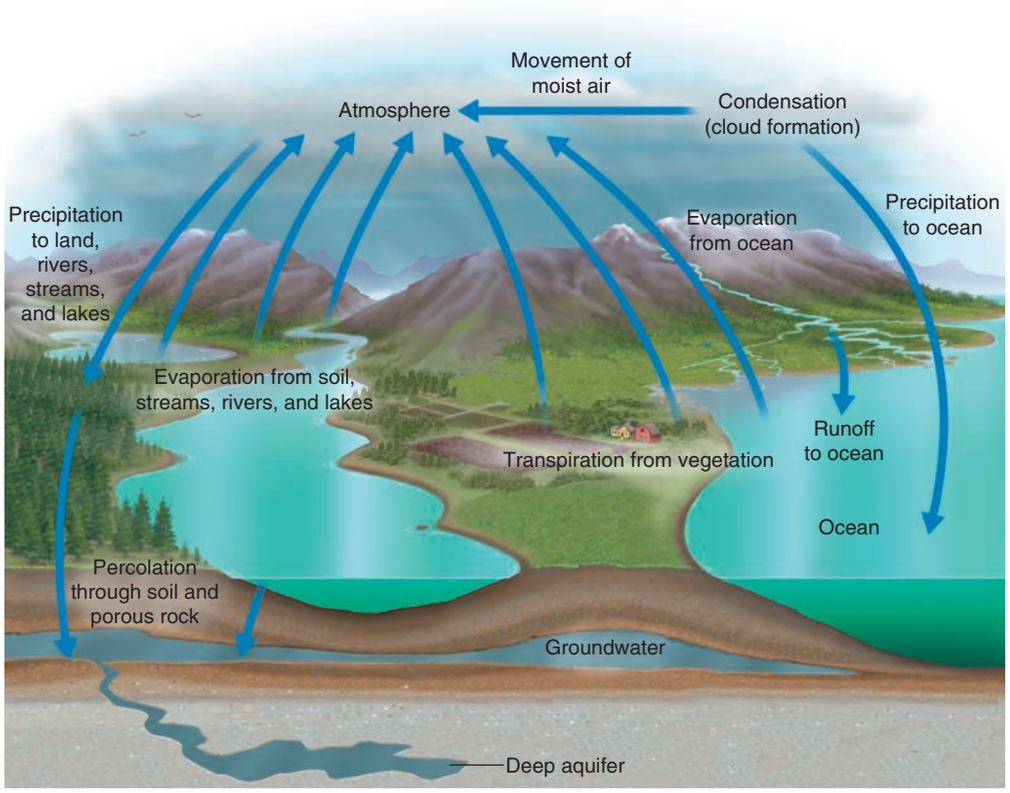
How can we keep our water supplies safe?

Although we may be exposed to pathogens in the food we eat, far more often we face the risk of widespread exposure to pathogenic microbes in the water we drink. Moreover, foodborne pathogens may be transmitted to new human hosts through water contamination because water is involved in food irrigation, processing, and preparation. People who live in areas of the world where waste is treated before it is emptied into natural waters, and where drinking water is monitored for safety, generally have more than an adequate supply of drinkable, or **potable**, water. Potable water is free from intestinal bacteria and pathogens. In many developing areas of the world, potable water is not always available. In these areas, waterborne diseases still kill thousands of people every year. For example more than 60,000 cases of cholera were reported in the African country of Zimbabwe in 2008, and almost 3,000 people lost their lives from drinking unsafe water containing the pathogen *Vibrio cholerae* (see Microbes in Focus 21.7). The 2010 outbreak in Haiti resulted in over 20,000 cases and more than 900 deaths.

About 70 percent of the surface of our planet is covered by water. Of that, about 97 percent is saltwater and 3 percent is the freshwater that sustains us. Water cycles as it evaporates from oceans, rivers, and lakes. Water also evaporates from plants by a process called transpiration. Water vapor condenses in the atmosphere to form clouds and falls as precipitation **(Figure 16.24)**. When precipitation falls on land, usually in the form of rain or snow, water may flow back into oceans, rivers, lakes, or streams, carrying organic materials with it, or it may pool in permeable underground geological formations known as "aquifers." Aquifers are replenished from water percolating slowly through porous soil and rock down from the surface of the earth, but they can be depleted if the amount of water withdrawn exceeds that recharging the aquifer. For example, the Ogalla aquifer that underlies the agricultural heartland of the midwestern United States is being depleted, mostly for irrigation, at a rate predicted to exhaust it within a few decades. Freshwater found in lakes, rivers, streams, and aquifers is useful and accessible to human populations, but about 70 percent of Earth's freshwater is locked away in glaciers, permanent snow, ground ice, and permafrost.

As humans explored and spread across this once sparsely populated planet, new settlements were often established near a body of water. This practice not only provided a ready mode of transport and an escape route from enemies, but it also ensured an adequate supply of potable water. The flow of water also conveniently washed away the various waste materials accumulated by occupants of the settlement. When waste levels were small, surface waters could diminish them naturally over time through microbial activity, oxidation, or photochemical breakdown from exposure to ultraviolet light

Figure 16.24. The water cycle Recycling of Earth's freshwater supply occurs through the water (hydrologic) cycle. Aquifers and surface water are sources of drinking water. Excessive removal from these sources can prevent their renewal.



Alters: Biology: *Understanding Life*, copyright 2006, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

from the sun. Today, many large cities are still located near a water source. However, the time is gone when water could dilute away the wastes of those residing in the settlement on the shore. The natural regenerative powers of lakes and rivers cannot deal with wastes produced by the masses of humans living in modern urban areas.

In heavily populated regions, raw water from a source, such as a river, may be used for some purpose and then released back into the source, only to be taken up and reused for another purpose a short while later or a short distance downstream. This pattern may be repeated many times as the water moves down the length of the river. In essence, the water cycle becomes shortened. There is less and less time and opportunity for the water to be cleansed by the biodegradative activities of its natural microbial inhabitants, for oxygenation, and for natural chemical and photochemical reactions to occur. The reality along a river is that communities downstream inherit and rely on a raw water source comprised partly of water that was released by their upstream neighbors. In some regions, so much water is removed from rivers for industrial use or diverted for agricultural use, especially irrigation, that the river may be reduced to a mere trickle, or end miles upstream of its natural mouth. For example, in theory the Colorado River discharges into the Gulf of California, but in reality its flow often fails to reach that far.

No water body on the planet is guaranteed to be pristine, regardless of how remote from civilization it may seem. Chemical contaminants may disperse through the air as well as through surface and subsurface water flows. Wild animals may deposit feces and urine containing pathogenic microbes directly into a water body or onto the land where subsequent runoff into a nearby stream potentially carries these pathogens. We can never confidently and safely quench our thirst by drinking directly from a lake or stream. Instead, we must protect our raw water sources, treat our wastewater, and purify and monitor our drinking water to ensure its potability and our health.

Protection of our water sources employs strategies to prevent contamination by industrial chemicals or agricultural runoff through severely restricting development in areas where water drains into rivers and lakes. New York City enacted these strategies to protect its water supply in the nineteenth century. The Croton, Catskill, and Delaware reservoir systems in upper New York State provide exceptionally high-quality raw water to New York City residents from the largest unfiltered surface water supply in the world.

Wastewater, or **sewage**, is water carrying soluble or solid wastes originating from human activities, including farming and manufacturing. Household or *domestic wastewater*, consists of toilet waste, bathing water, cooking wastes, laundry wastes, and other waste products originating from everyday living. In addition, surface runoff, or *storm water*, from urban streets is often treated before it is allowed to enter water reservoirs. In urban centers, wastewater treatment plants help to minimize the amounts of contaminating material from urban centers entering the source water. In some locations, water goes through another purification process before being made available for drinking. In rural settings, water is treated on a much smaller scale. The discussion below focuses primarily on the treatment of urban domestic wastewater. However, the same general processes may be used in the on-site treatment of industrial wastes. As we shall see, as in the natural regeneration of freshwater, the treatment of wastewater relies heavily on the talents of microorganisms.

Principles of wastewater treatment

Wastewater contains a literal stew of chemicals and microorganisms, and for health and aesthetic reasons, it must be treated before it is released into environmental water sources. Wastewater from the petrochemical industry, plastics manufacturers, metallurgy and electronics industries, or pharmaceutical manufacturers may, in addition, be laden with toxic substances such as cyanides, heavy metals, or organic solvents. Industrial plants frequently maintain their own treatment or pretreatment systems, designed and optimized to deal with the characteristics of their particular wastes. This is often needed because industry-derived toxic substances may be lethal to the microorganisms of the municipal treatment system, which generally treats mostly domestic wastewater. A large-scale dairy operation would not produce toxic chemicals, but the high organic load of its outflow could exceed the capacity of a local sewage treatment facility, again necessitating pretreatment on site prior to release into the municipal system.

A wastewater treatment plant is designed to achieve several goals before the outflow, or **effluent**, of cleaned wastewater exits the plant and is discharged into the receiving water, such as a lake or stream. These goals include:

- A reduction in the total organic carbon (TOC) of the wastewater.
- The removal or inactivation of any harmful microbes in the wastewater.
- A reduction in the level of inorganic nutrients, which are nitrogen- and phosphorus-containing compounds, such as ammonium (NH_4^+), nitrate (NO_3^-), and phosphates.

Wastewater treatment plants receive a variety of contaminants **(Figure 16.25)**. Some of these chemicals, such as synthetic pesticides and pharmaceutical drugs excreted in urine, are difficult to break down and are referred to by the acronym **POP**, which stands for **persistent organic pollutant**. If present in wastewater, certain of these organics may be found in effluents exiting the plant. They may also be detected in natural waters. The concentrations are typically very low, and the significance of POPs in natural waters is uncertain. Evidence is becoming clear that even vanishingly small quantities of some POPs may affect reproduction and development of fish and mammals because they tend to accumulate in tissues.

The treatment of large-scale wastewater is a multistep process, typically encompassing two or even three levels of treatment at the municipal facility. Ideally, municipal treatment facilities handle only wastewater from designated sanitary sewers—those receiving domestic sewage. However, the storm sewer systems that handle surface runoff in many urban areas are not totally separate from the sanitary sewer system. As a

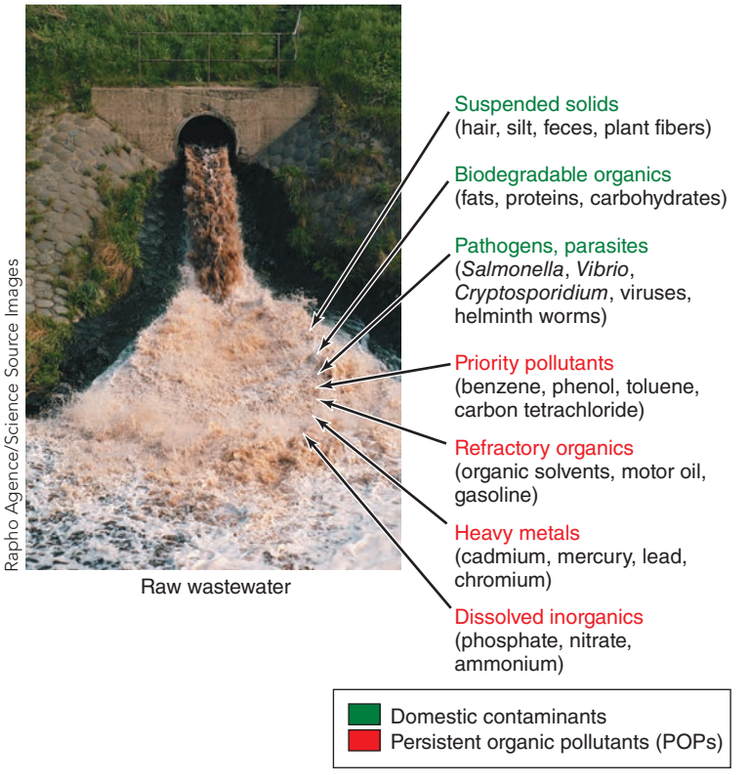


Figure 16.25. Classes of contaminants in wastewater The composition of wastewater varies greatly, depending on the sources of the waste entering the treatment facility. Typical domestic contaminants are handled relatively well by conventional treatment technologies. Persistent organic pollutants (POPs) are not as effectively degraded or neutralized. POPs are generally industry-associated contaminants, but individuals are also responsible for releasing some of these into wastewater by, for example, improperly disposing of drugs, cleaning solutions, solvents, and other chemicals down the sink or toilet.

result, after storms the treatment plant may be inundated with large volumes of water originating from combined sewer lines (partly domestic wastewater and partly storm water). If the incoming volume overwhelms the capacity of the plant, partially treated or untreated sewage may be released directly into the receiving water. Cities with such combined sewers are working toward replacing them with separate sanitary and storm sewer lines, but this is a slow and expensive undertaking. **Figure 16.26** shows an overview of the flow of wastewater through a plant operating a pretreatment step followed by primary and secondary treatments and final disinfection of the effluent.

Pretreatment of Wastewater

The pretreatment step of wastewater treatment sends incoming material through a series of grates and coarse metal screens to ensure that large objects such as branches, stones, or pieces of metal that might damage or clog plant equipment are removed from the incoming wastewater. Screening of the incoming wastewater also removes much of the gravel and grit that may be present, particularly if the plant is treating waste from combined sewers. Solid debris is collected by periodically scraping the grates and screens and is frequently deposited in landfills.

Primary Treatment of Wastewater

Primary treatment of wastewater involves the physical removal of particulate matter by sedimentation, and oils by skimming. Pretreated wastewater flows into large tanks where it is typically retained for several hours to separate these materials. Oil and grease and any material less dense than the water float to the surface and are removed by skimmers. Suspended materials that are denser than the water fall to the bottom of the tank and are removed by a raking apparatus that scrapes the material from the tank bottom into a hopper, forming the **primary sludge**, which is collected and then pumped to the **anaerobic sludge digester**. The digester processes this waste under anoxic conditions and will be described later. About 40–60 percent of the suspended solids are removed during sedimentation, along with the microbes that adhere to the particles. However, not all microbes are removed, nor are dissolved organic and inorganic compounds. The effluent derived from the primary treatment step is further subjected to secondary treatment.

Secondary Treatment of Wastewater

Secondary treatment of wastewater follows primary treatment and makes use of microbial activities to degrade the organic content of the sewage, further improving the quality of the wastewater. The two main strategies for secondary treatment include the "trickling filter" and the "activated sludge" process. A particular plant will likely employ either trickling filters or an activated sludge system, but not both. Trickling filters and activated sludge units contain communities of microorganisms that would be found in natural waters, but these populations are far denser and break down waste much faster under the conditions provided in the treatment plant.

Trickling Filter The advantage of a **trickling filter** is that it is simple and relatively passive in operation, making it inexpensive to run **(Figure 16.27)**. Trickling filters are used for municipal and on-site wastewater treatment, such as for farms and industrial plants. It consists of a bed of solid material, such as crushed rock, or special molded plastic units that are contained in a cement tank. Effluent from primary treatment is pumped to a rotary spray boom that sprays the effluent across the filter bed surface. The fluid percolates through the bed by gravity, then collects beneath. As the fluid trickles downward, it serves as a source of substrates for a complex microbial biofilm community growing on the bed matrix. This community includes a variety of bacteria, fungi, and protozoa that feed on components of the effluent, as well as more complex organisms such as rotifers, nematodes, and worms that graze on the inhabitants of the biofilm. Grazing activity helps to keep the biofilm in a state of constant renewal, which in turn helps to maintain efficient removal of potential organic and inorganic growth substrates in the effluent trickling through the filter.

CONNECTIONS Biofilms can be complex communities of various adherent microbes, in which the majority of the cells are metabolically active. See **Figure 2.34** and **Sections 2.5** and **15.1** for some examples of biofilm communities.

Figure 16.26. Process Diagram: General schematic of a wastewater treatment plant In an effective treatment plant, wastewater moves through a pretreatment screening, followed by physical primary treatment, and biological and physical secondary treatment. Effluent from these treatments is subjected to final disinfection before being released to a natural water system. Treated, collected solids (sludge) can be added to soils.

The top and bottom of the filter bed are exposed to the air, and air may also be piped into the interior of large beds, to ensure that oxygen is available to the organisms making up the biofilm. Recall from Chapter 13 that aerobic metabolism is more efficient than anaerobic metabolism, so biofilm microorganisms exposed to oxygen will be more effective in removing materials from the effluent. Regions in the interior of most biofilms may still be anoxic. Substances are removed from the effluent as they are assimilated by the biofilm. Microbial utilization of the organic portion of matter leaves behind the inorganic mineral components, a process called mineralization (see Section 14.2). Mineralized matter is adsorbed by the slimy biofilm matrix composed of proteins, nucleic acid, and exopolysaccharide (EPS; see Section 15.1), a high-molecular-weight polymer composed of various sugars that is secreted by microorganisms into the surrounding medium. The adsorption of organic and inorganic matter by EPS facilitates their metabolism by the biofilm microorganisms and removes these pollutants from the effluent. The effluent from the trickling filter then moves to the disinfection stage.

One of the drawbacks of trickling filters is seen when the incoming effluent is quite high in organic compounds, leading to excessive growth of the biofilm. The EPS-containing biofilm (see Figure 16.27C) can plug the filter bed, leading to accumulation of water on the surface. The filter then must be dismantled, cleaned, and reassembled. Trickling filters are also sensitive to the surrounding air temperature; they are not very effective in the cold. This limits their use to regions with mild winters.

Activated Sludge Activated sludge systems are used for municipal wastewater treatment plants. An activated sludge process relies on the formation of **flocs**—clumps of biomass consisting of adsorbed material and biofilm microorganisms. **Activated sludge** is comprised of accumulated flocs, the formation of which is critical to efficient function of the activated sludge unit. The word "activated" refers to the effect that the perfusion of oxygen throughout the otherwise thick and oxygen-free mixture has on the resident microorganisms in the sludge. An activated sludge unit is composed of two parts; an *aeration*

Figure 16.27. Trickling filter **A.** Overview of a trickling filter system. Wastewater is sprayed evenly over a filtration bed of rock, shown in **B.,** about 2 m deep, or plastic matrices 12 m deep. The nutrients in the percolating wastewater support a microbial biofilm on the bed matrix, as shown in **C.** Biofilm formed by microbes that have colonized the extensive inner surface area of a small 2.5-cm-diameter plastic matrix (manufactured by Headworks BIO, Inc.) forming the bed of a treatment system. Microbial metabolism removes pollutants from the effluent.

tank, which mechanically mixes the sludge and purges it with air or sometimes pure O_2, and a settling tank or clarifier that collects sludge (see Figure 16.26). Primary treatment effluent enters the aeration tank and is retained there for 5–10 hours **(Figure 16.28)**. The effluent is then moved into the settling tank where the flocs settle as sludge. Some of the activated sludge is used to reseed the aeration tank. Excess sludge is moved to the anaerobic digester. Some mineralization of readily biodegradable organic matter does occur, but, as in the trickling filter, it is assimilation of materials by microorganisms that drives the purification process.

GIPhotostock/Science Source Images

Figure 16.28. Aeration tank of activated sludge system Effluent enters the aeration tank where a constant stream of air oxygenates and mixes the wastewater to promote the aerobic growth of floc-forming microorganisms, responsible for the removal of organic and inorganic matter.

Floc formation occurs because of the presence of EPS-forming microorganisms, such as *Zoogloea*. As in the trickling filter, these organisms are important to biofilm formation. The EPS matrix they form acts as glue to form the floc into a firm, dense particle. As these slime-formers grow, they tend to entrap other microorganisms as well, including pathogens. The flocs serve as substrate to which other microorganisms, including bacteria, fungi, and protozoa, can attach and grow. It is essential that proper floc formation occurs to support the large number of microorganisms responsible for degradation of biological material, removal of fine solids and heavy metals, and to promote settling of floc. Well-formed flocs range in size from $<1\,\mu$m (one-millionth of a meter) to more than $1{,}000\,\mu$m (a millimeter). The floc microorganisms, along with free-floating (planktonic) microorganisms within the roiling liquid of the aeration tank, actively take up the substrates available in the effluent and grow. The microbial community within an activated sludge system is similar to that found in a trickling filter, although fungal populations are smaller.

After being held for a suitable time in the aeration tank, the floc-laden **secondary sludge** is pumped to the settling tank, where a rapid settling of floc is desirable to separate the sludge from clarified effluent. The clarified effluent is next sent to the disinfection process to kill remaining microbes. Part of

Perspective 16.1
IMPLICATIONS OF SLUDGE BULKING

A fundamental goal of sewage treatment involves activated sludge that is formed when air is percolated through the mixture of sewage and sludge in the secondary treatment tank. In the presence of oxygen, the microorganisms in sludge typically can metabolize nutrients faster than they can in the absence of oxygen. The action of the microorganisms in the activated sludge drives sewage treatment. But the process does not always run smoothly. For example, when the level of organics in the wastewater is high and the oxygen level is low, such as in effluent from a brewery, conditions are optimum for growth of filamentous bacteria, which can enter the treatment system in the incoming wastewater. Large strands of bacteria, such as *Sphaerotilus* or *Thiothrix*, provide a large surface area for the sludge to collect in loose associations instead of tight, dense particles. This sludge may not settle, but instead result in sludge bulking **(Figure B16.1)**. Sludge bulking can stall the treatment process.

Sludge bulking is the bane of sewage plant operators worldwide, principally because, even though the problem has been known since the 1920s, science has not yet provided effective ways to avoid it. Solving the problem in a wastewater treatment system, with its huge volume and presence of numerous compounds, is far more complicated than solving a bacterial infection in the body, where the use of an antibiotic may be all that is needed. Moreover, despite the example provided above, the root of sludge bulking is by no means clear. Studies have linked both low-dissolved oxygen and high-dissolved oxygen, and both low and high ratios of nutrient to microorganisms to sludge bulking.

Because no certain solution is known, avoidance requires the experience and ingenuity of the plant operator. Good background data on the environment of the treatment tanks can help to detect changes. Manipulating the conditions of the treatment system to return the altered parameters to their former values may be needed. The list of parameters is long, so the solution to sludge bulking may not be easy.

Figure B16.1. Flocs Well-formed floc particles (*left*) are compact and will settle. Poorly formed floc (*right*) is loose and of low density and will tend to remain in suspension.

the settled floc is used as a starter culture and is recycled to inoculate the next volume of incoming effluent in the aeration tank. Once in the tank, it becomes part of the activated sludge, some of which is sent to the anaerobic sludge digester for degradation. Sludge recycling is quite important to maintain the very high levels of microbial activity in the aeration tank. Similarly, flocs that settle are important to settling tank function. If flocs do not settle well, clumps of solid material and microbes will remain in the fluid effluent and cannot be properly disinfected. Moreover, the material contains bound pollutants, such as heavy metals. This problem, referred to as "sludge bulking," is described in **Perspective 16.1**.

The effluent exiting the activated sludge unit is much reduced in its total organic carbon (TOC) because much of the organic content of the water that entered the aeration tank is now retained in the settled floc that forms the secondary sludge. The reduction in organic carbon in the effluent is reflected in a reduction in the **biochemical oxygen demand (BOD)** or biological oxygen demand. BOD is the amount of dissolved oxygen required by microorganisms to decompose the organic matter in sewage or water. As you might expect, the BOD of raw sewage entering the treatment plant is relatively high. If treatment is effective, the BOD of the effluent should reflect the lower concentration of organic compounds and be relatively low. Incoming effluent from a slaughterhouse or a dairy could exert significant pressure on a treatment plant designed to handle only domestic sewage **(Table 16.7)**.

Because most microorganisms use carbon compounds for their growth and survival, water that is loaded with carbon-containing pollutants is apt to support the growth of microbes, including those that can make us ill. Although BOD measures only the amount of carbon that can be metabolized by microorganisms rather than the total organic carbon of the sample, it is the most common measure of organic pollutants in water. Much research has determined the correlation between BOD and the nature of the water source. In general, a natural water

TABLE 16.7 BOD_5[a] reduction in a wastewater treatment plant

Waste type	BOD_5 (mg L^{-1})
Biologically treated effluent	10–<20
Vegetable processing	200–500
Raw domestic sewage	200–600
Dairy wastewater	900
Slaughterhouse wastes	1,000–4,000
Cattle shed effluent	20,000
Pigsty effluent	25,000

[a] BOD_5 refers to measurement of oxygen demand over a five-day period at 20°C in the dark.

source, such as a lake, river, or stream, has a low BOD, indicating that the organic content of the water, and hence the number of bacteria in the water, are relatively low. A high BOD indicates the water is polluted with organic material and supports high numbers of bacteria. These bacteria may not be a health concern, but, more often than not, high numbers of bacteria are a sign that the water has been recently contaminated with feces, and perhaps by feces-dwelling pathogenic bacteria. BOD is also useful in monitoring how well a sewage treatment plant is operating. The BOD should drop as water progresses through the treatment steps.

BOD relates directly to the dissolved oxygen (DO) in the water. The DO is used by bacteria when organic nutrients are present in the water; the combination of oxygen and carbon-containing nutrients enables the bacterial population to grow and divide. As microorganisms break down the organic nutrients, the oxygen content of the water drops. Clearly, the levels of oxygen and carbon in the water are linked. High levels of carbon-containing compounds support large populations of microorganisms that use oxygen to metabolize them and thereby decrease the level of oxygen in the water. When oxygen levels get too low, the water will not support aquatic species like invertebrates and fish. See **Toolbox 16.1** for a description of how to measure BOD.

In addition to a decrease in the total organic carbon, a significant reduction in the number of intestinal pathogens in the effluent occurs during secondary treatment. Microorganisms that are adapted to conditions in the treatment plant will out-compete intestinal pathogens for resources in this environment. Thus, the pathogens will grow poorly, if at all. Predation by protozoans and other bacteria is also a factor. Microbial populations will face similar predator pressure, but the smaller populations of intestinal pathogens will be decimated more quickly than other microorganisms. Finally, many of the surviving pathogens will settle with the floc. Properly formed activated sludge can remove about 90 percent of enteric bacteria, 90–99 percent of enteric viruses, and about 90 percent of protozoan parasites such as *Giardia* and *Cryptosporidium parvum* **(Microbes in Focus 16.2)** that may be present in wastewater. However, considering only percent reduction can be misleading. Removing 90–99 percent of a microbial population whose density is 10^6 per 100 milliliters still leaves behind an appreciable number of organisms.

The conventional activated sludge process may be modified to increase the removal of nitrogen (N) and/or phosphorus (P) from the clarified effluent. These elements may ultimately reduce the water quality in natural waters where they are often a limiting nutrient for natural plant and microbial populations. If they are released with effluent from a treatment plant, they may result in overgrowth of populations leading to **eutrophication** of the lake or stream. Eutrophication results from

Toolbox 16.1
MEASURING BIOCHEMICAL OXYGEN DEMAND (BOD)

An important task of water quality determination is measuring the amount of organic (carbon-containing) material in the water body. This can be accomplished by measuring the BOD. The BOD test measures the rate at which microorganisms use oxygen. Microorganisms are seeded in a water sample saturated with oxygen and incubated at a specific temperature (20°C) over a specific period of time (five days). By measuring the amount of oxygen used, the test provides a measure of how much organic material is present in the sample. The test is done in the dark to prevent photosynthesis, which generates oxygen. Microorganisms, usually from activated sludge, are added to the sample. Then the test bottles are sealed to prevent entry of more oxygen. Dissolved oxygen (DO) is measured at the beginning and end of the five-day incubation, with the difference representing the BOD.

Like all assays, performance of the BOD test requires precision and care so that the results are an accurate reflection of the reality of the water. Standard methods allow results from one region or one time to be compared with results obtained from other locations or from the same spot at a different time. The use of a control sample to which microorganisms are not added is essential. Today, the BOD test is automated, and the various parameters are programmed into the test software. However, BOD remains a test that is done hands-on by many water inspectors and sewage treatment personnel.

Test Your Understanding

You must often dilute your samples before carrying out the BOD test. The water used for diluting should also be used as a control in a separate bottle. After the five days of incubation, what BOD results would you expect to see with a control water sample and why?

Microbes in Focus 16.2
CRYPTOSPORIDIUM PARVUM

Habitat: Digestive tracts of various birds and mammals, such as cattle. Oocysts may be shed with feces into water sources. Shown are cells of *C. parvum* infecting the human intestine.

Description: *Cryptosporidium* means "hidden spore cyst"; a protozoan with a complex life cycle; oocyst is 4–5 μm long and contains four sporozoites.

Key Features: This protozoan may cause severe diarrhea, especially in those with weakened immune systems. It resists digestion by lysosomes of phagocytes and other cells, and reproduces in vacuoles formed within cells of the intestine. Oocysts formed are resistant to chlorination and UV light and are too small to be filtered by some treatment systems. *Cryptosporidium parvum* caused the largest recognized waterborne outbreak in U.S. history in Milwaukee in 1993. Over 400,000 people fell ill, and more than 100 died.

increasing the availability of limiting nutrients in an aquatic ecosystem, leading to rapid growth in autotroph populations, particularly algae. Microbial decomposition of the increased biomass creates anoxic conditions, resulting in severe reduction of water quality, negatively impacting aquatic animal populations. The strategy for nitrogen removal is to encourage nitrification followed by denitrification. Several protocols have been developed to achieve this, but the overall idea is to replace the single aeration tank with several tanks to permit sequential aerobic (for nitrification) and anaerobic (for denitrification) activities, achieving the following overall reaction sequence:

Nitrification **Denitrification**

[ammonia → nitrite → nitrate] followed by [nitrate → nitrite → NO → N_2O → N_2]

CONNECTIONS Although denitrification is a desired process in wastewater treatment, it is not desirable in agricultural soils because it removes nitrogenous nutrients, such as nitrate and ammonia often supplied by fertilizers that are needed for plant growth. See **Section 14.3** for a description of the denitrification process and how it contributes to the global cycling of nitrogen.

Conventional denitrification processes are relatively expensive, requiring the input of oxygen and organic material to maintain the desired cultures of bacteria. This in turn creates a significant amount of bacterial sludge. A recent approach has been to short-cut the multistep nitrogen removal reactions and use bacteria that can convert ammonium (NH_4^+) and nitrite (NO_2^-) directly to N_2 in an anaerobic process known as anammox (anaerobic ammonium oxidation). The overall process is as follows:

$$NH_4^+ + NO_2^- \rightarrow N_2 + 2H_2O$$

Anammox bacteria bypass the nitrate conversion step. They are chemolithoautotrophs and do not require organic material. They release significantly less of the greenhouse gases CO_2 and NO_2, and, due to their slow growth, reduce sludge production. Anammox bioreactors are designed for the culture of aerobic ammonium oxidizing bacteria and anammox bacteria. First, ammonium-oxidizing bacteria convert about half of the ammonium to nitrite, then the anammox bacteria convert the remaining ammonium and nitrite to N_2. The desired process can be obtained by controlling the oxygen concentration in the bioreactor.

Phosphorus removal can be achieved biologically by using an anoxic/oxic process in place of conventional aeration. Here, a short-term anoxic stage is used prior to the aerobic phase to encourage inorganic phosphate release in the absence of O_2 as a result of polyphosphate hydrolysis from volutin. Volutin is a granular inorganic phosphorus-containing storage substance found in the cytoplasm of various bacterial and fungal cells. During the period in the aeration tank, soluble phosphorus is taken up by vigorously growing microorganisms and thus is removed from the effluent when floc particles settle in the settling tank. Other physicochemical methods can enhance removal of nitrogen and phosphorus. For instance, raising the pH of ammonium-containing effluent will encourage formation of gaseous ammonia (NH_3), which can then be stripped from the water. At an appropriate point in the treatment process, chemicals such as alum ($KAl(SO_4)_2 12H_2O$), calcium sulfate ($CaSO_4$), or ferrous sulfate ($FeSO_4$) can be added to the wastewater, leading to Al/Ca/Fe phosphate formation. These phosphates are insoluble and precipitate out of solution, thereby removing phosphorus from the fluid phase. The **Mini-Paper** describes research aimed at identifying and understanding the microorganisms and conditions important for phosphate removal.

Following the activated sludge process or treatment by a trickling filter, the fluid phase or effluent is typically disinfected and released from the treatment plant. In the next few paragraphs, however, we will follow the trail of the collected primary and secondary sludge that moves into the anaerobic sludge digester.

Anaerobic Sludge Digester Completion of secondary treatment of wastewater involves the anaerobic sludge digester—essentially a large anoxic bioreactor operating in a semicontinuous mode—that allows final anaerobic digestion of remaining organic wastes **(Figure 16.29)**. Sludge is typically held from 2 to 4 weeks in the digester, which can be designed to operate in a mesophilic mode, functioning optimally at 35–37°C, or thermophilic mode, functioning optimally at about 50°C. The latter has the advantage of more rapid reaction rates and a greater degree of pathogen kill.

Mini-Paper: A Focus on the Research
ENHANCED BIOLOGICAL REMOVAL OF PHOSPHORUS

H. G. Martín, N. Ivanova, V. Kunin, F. Warnecke, K. W. Barry, A. C. McHardy, C. Yeates, S. He, A. A. Salamov, E. Szeto, et al. 2006. Metagenomic analysis of two enhanced biological phosphorus removal (EBPR) sludge communities. Nat Biotechnol 24:1263–1269.

Context

A major concern in communities around the world is the large amount of environmentally damaging phosphorus that is found in municipal and industrial wastewater in the form of inorganic phosphate. If this phosphorus is not removed during the water treatment process, it finds its way into the effluent, causing eutrophication in waterways and environmental degradation. A process called "enhanced biological phosphorus removal (EBPR)" has been widely adopted in wastewater treatment plants over the past 30 years to reduce the amount of phosphorus in the wastewater. The EBPR process involves naturally occurring bacteria in activated sludge that, under oxic conditions, accumulate phosphorus as intracellular polyphosphate. The polyphosphate-containing cells are then allowed to settle as floc, resulting in greatly reduced phosphorus levels in the effluent water.

Although the EBPR process is used worldwide, its performance is not always reliable. Incredibly, the assumption that bacteria of the genus *Acinetobacter* (that were easily cultured from wastewater treatment systems) are primarily responsible for EBPR has now been shown to be incorrect. Instead, the EBPR-active organisms turn out to be a newly discovered but dominant uncultured member of the *Betaproteobacteria* that has been termed *Accumulibacter phosphatis*. Even though this organism had not yet been isolated in pure culture, metagenomic-sequencing methods might allow reconstruction of complete genomes of these bacteria. With this information in hand, as well as the knowledge of other organisms present in the EBPR community, it would be possible to examine the metabolic relationships that develop during the EBPR process. The study presented in this paper was a metagenomic analysis of two EBPR sludges set up in laboratory-scale reactors. The results from this lab-scale study provide data that can be meaningfully extended to the real-world scale of the treatment plant.

Experiments

Two lab-scale batch reactors were seeded with water obtained from treatment plants in Wisconsin and Australia and operated under typical EBPR cycling conditions. DNA was isolated from sludge samples and subjected to shotgun sequencing (see Section 10.1), followed by analysis of the sequence reads to find overlaps and to identify 16S rRNA genes. *Accumulibacter phosphatis* was clearly the dominant organism in the EBPR community, and the near-complete assembly of its genome from the sequence data showed it to be approximately 5.6×10^6 bp in size. This genome sequence made it possible to reconstruct the metabolic pathways of *A. phosphatis*. Examination of the proposed pathways raised several questions about the details of their operation; these will have to be addressed through a combination of metabolic modeling and experimentation. Perhaps surprisingly, *A. phosphatis* was found to have genes for N_2 fixation, CO_2 fixation, and high-affinity phosphate transporters that would be very useful under phosphorus-limited conditions. These functions are clearly not required in the EBPR systems, but are perhaps important for survival in nutrient-poor habitats, such as freshwater.

Impact

This metagenomic analysis opens many avenues for the study of EBPR, ultimately leading to a practical understanding and improvement of the process. The availability of the *A. phosphatis* genome sequence will allow examination of the gene expression changes during EBPR cycling, which could result in sequence-based diagnostic tools for following the process in wastewater treatment plants. Such diagnostic tools would be especially useful when based on a thorough understanding of the metabolic processes that are developed through metabolic modeling and testing of hypotheses through experimentation. This study is a terrific example of the use of the sequence-based metagenomic approach to provide valuable information about complex microbial communities.

Questions for Discussion

1. This research was carried out using Sanger sequencing. How do you think the outcome might have differed if some of the more recent high-throughput sequencing methods had been used?
2. What is the rationale of using samples from more than one treatment plant?
3. The sequences of many other microbes were found in the EBPR sludge. What might be some of their functions within the EBPR system?

However, this advantage is offset by the disadvantage of the energy required to maintain high-reactor temperatures. Particularly in temperate regions, the reactor may be partly underground to take advantage of the insulating properties of the surrounding soil. Over the course of the incubation period, organic materials in the sludge are degraded by a large and diverse anaerobic microbial community.

In the anaerobic sludge digester, organic material is broken down to organic acids, alcohols, carbon dioxide (CO_2), and hydrogen gas (H_2) by primary fermenters. Microorganisms cooperatively process acids and alcohols to acetate and H_2. Homoacetogens and methanogens constitute the final groups in the microbial food web. You may recall the discussion of similar anaerobic biodegradation of organic substrates in Chapter 14

Martin Shields/Science Source Images

Figure 16.29. Anaerobic sludge digester Anaerobic microbial digestion of organic material in sludge takes place under anoxic and heated conditions. The majority of the digester is underground to help maintain temperature. The roof is suspended so that it may be vented in response to accumulated CO_2 and CH_4 (methane) within the reactor. Methane can be collected as a fuel source.

(see Figure 14.5). The biogases methane (CH_4) and CO_2 are products of an anaerobic sludge digester. Methane is frequently captured and burned to provide energy to the plant and surrounding community. Processed anaerobic sludge is the other main product, consisting of indigestible materials and microbial biomass. Anaerobes produce far less biomass per unit of substrate metabolized than do aerobes because their metabolism is not as efficient. This is one reason why anaerobic digestion is usually preferable to aerobic processing of this material. Because a treatment plant must handle a considerable volume of sludge, disposal of this leftover material is a significant problem in waste treatment. Aerobic sludge digestion is sometimes practiced, particularly with industrial wastes because it is more rapid than anaerobic digestion. However, it requires an O_2 supply and does not yield combustible biogas.

A considerable number of pathogenic microbes may be killed during the digestion process, but their populations are only reduced, not eliminated. Moreover, if wastewater entering the plant contains recalcitrant organic compounds or considerable amounts of metals, these too may be concentrated in the sludge. Thus, sludge from the anaerobic digester can potentially be considered hazardous material. This is one reason why it is undesirable for industrial wastes to enter plants treating mostly domestic wastewater.

Digested sludge is typically dehydrated before meeting one of several fates. It may be dried and then incinerated, with an associated energy recovery. Or it may be added to a landfill. Sludge added to the land in this way is first stabilized by the addition of materials that transform it so that the hazardous constituents, such as heavy metals, are immobilized or converted to a less toxic form. The sludge can be treated with lime to raise the pH and stabilize the material, or it can be allowed to naturally decompose to stabilize it. If this material meets certain standards imposed by the relevant jurisdictional agency, it can be termed a **biosolid**. Stabilized biosolids may be used as soil conditioners in horticulture and agriculture, supplying nutrients to the soil and improving its texture and water-holding capacity. These materials have also been used in the remediation of severely disturbed landscapes such as abandoned mine sites.

The nutrients found in biosolids include N, P, K, and trace elements such as Ca, Cu, Fe, Mg, Mn, S, and Zn, all of which are needed by crop plants. It is critical that biosolids applied to soils do not add hazardous materials, including pathogenic microbes, to the environment. Class A biosolids are considered safe because they do not have detectable levels of *Salmonella*, enteric viruses, and viable helminth (worm) eggs. This type of biosolid can be applied freely and with minimal restrictions in small amounts to garden soils or in bulk amounts to larger croplands. The use of Class B biosolids is more restricted because these are of lesser quality due to their low but still detectable numbers of pathogens. Other regulated qualities of biosolids include the metal content and the degree of vector attraction. The latter refers to attraction of flies, mosquitoes, rodents, and birds to the biosolids because these vectors could transmit pathogens to humans. The United States recycles about 50 percent of all biosolids to land under regulation and quality standards of the U.S. Environmental Protection Agency (EPA).

Effluent Disinfection

Disinfection is the last step in wastewater treatment. Disinfection of water relies on the addition of chemicals to inactivate infectious agents that may be present. The aim of disinfection is to kill bacteria and viruses that normally reside in the intestinal tract and that can be present in feces-contaminated water, but were not eliminated in previous stages of treatment. A simple method of disinfection is **chlorination**. The water is dosed with a hypochlorite solution, either $Ca(OCl)_2$ or NaOCl (bleach). Adding hypochlorite to water forms hypochlorous acid (HOCl):

$$NaOCl + H_2O \rightarrow HOCl + NaOH^-$$

Hypochlorous acid is a strong oxidant that will oxidize the organic matter in the water, including microorganisms. It will also oxidize any reduced inorganic compounds that may be present, such as NH_4^+ or reduced Fe. Hypochlorous acid may also be produced by percolating chlorine (Cl_2) gas through the water where it will react with H_2O to form HOCl.

A disadvantage of chlorine use is the formation of chlorinated by-products, such as trihalomethanes and haloacetic acids, that result from oxidation of organic matter by reactive chlorine ions. These may harm the environment or act as weak carcinogens. Accordingly, alternative disinfection protocols for waters containing significant levels of dissolved organic carbon are becoming more common. **Ozonation** uses ozone (O_3) to disinfect water and is one alternative that produces fewer by-products than chlorination. Ozone is an inherently unstable molecule that generates a free oxygen radical, which is a powerful oxidizing broad-spectrum disinfectant. It is fairly costly to run an ozone generator, but one advantage over chlorine is that the ozone can be generated as needed. Chlorine gas is highly poisonous but has to be stored on-site, creating a potential hazard in the event of an accidental release. Ozone is generated by passing air over a high-potential electrode.

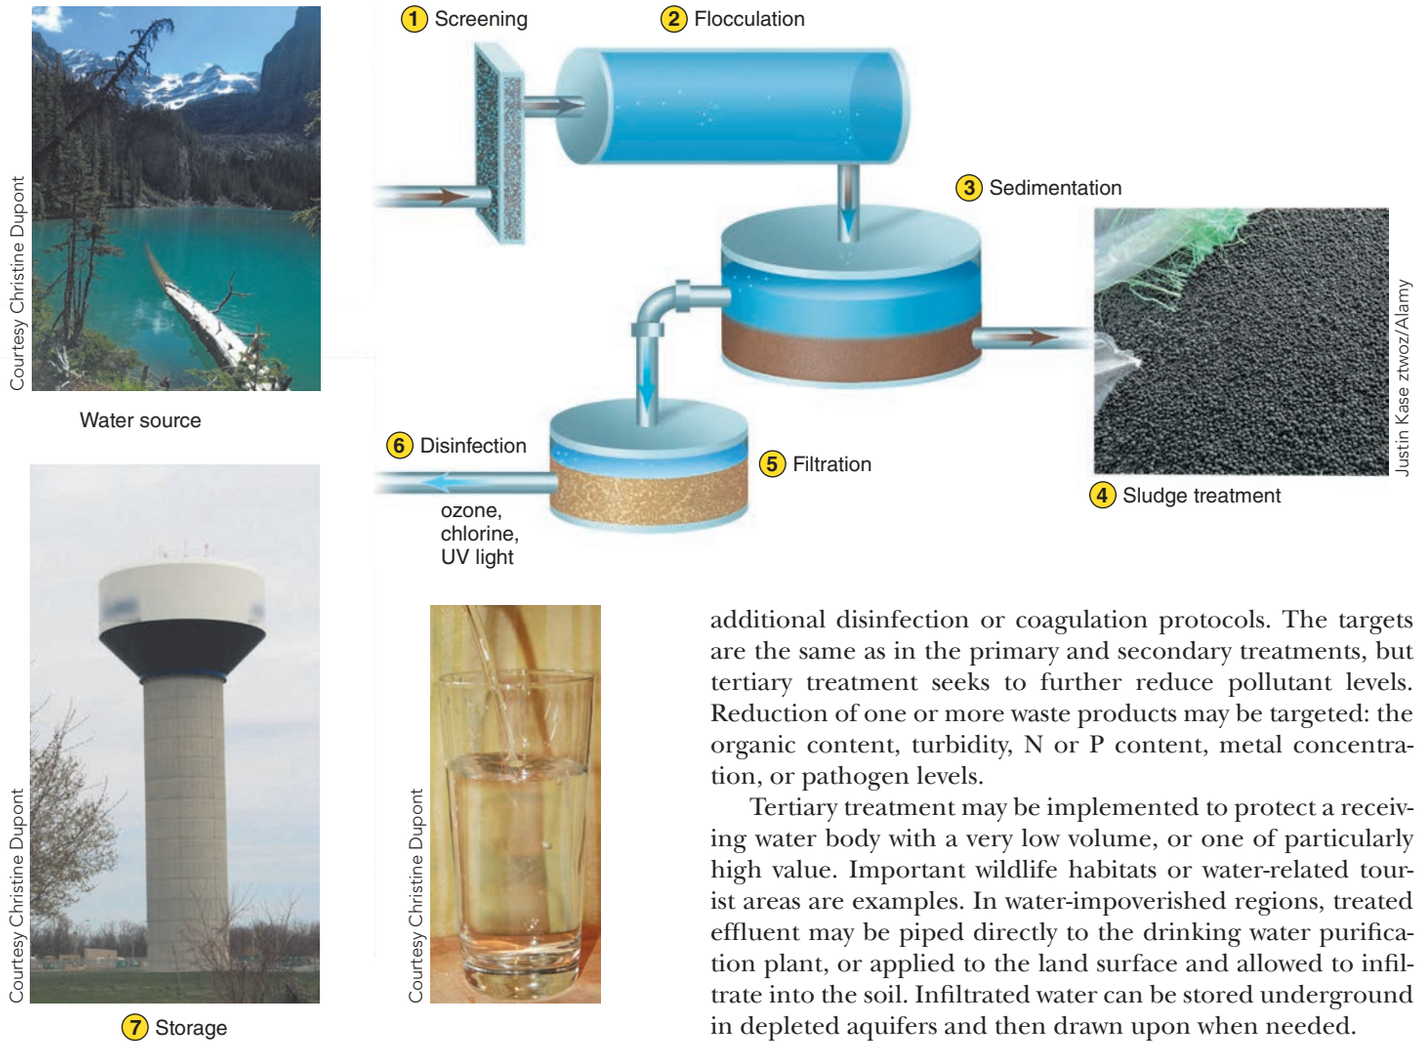

Figure 16.30. Process Diagram: General schematic of drinking water purification Untreated water may be screened to remove large objects before it enters the flocculation tank. A chemical such as alum is added to promote floc formation. The floc-laden water moves to a sedimentation tank where the floc settles as sludge, which is removed and treated, similar to that for a wastewater treatment plant. The clarified water is filtered through thick layers of sand, activated charcoal, or other specific filtration media. Filtered water is disinfected and stored, ready for distribution.

Ultraviolet (UV) radiation is another method of disinfection. The ability of UV to cause damage to important biomolecules, such as nucleic acids and proteins, is well known, and the development of more powerful UV lamps that can send the short-wave UV rays deeper into the water volume has led to increased use of this strategy. Many disinfection procedures use combinations of chlorination or ozonation with UV radiation.

Tertiary Treatment of Wastewater

Tertiary treatment of wastewater, which is rarely used, employs additional biological or physicochemical protocols to effluent water prior to disinfection. Modern technologies exist that will permit the production of very clean effluents, but they are quite costly and not widely implemented. The techniques typically involve some types of physicochemical processes, including filtration, activated carbon adsorption, reverse osmosis or additional disinfection or coagulation protocols. The targets are the same as in the primary and secondary treatments, but tertiary treatment seeks to further reduce pollutant levels. Reduction of one or more waste products may be targeted: the organic content, turbidity, N or P content, metal concentration, or pathogen levels.

Tertiary treatment may be implemented to protect a receiving water body with a very low volume, or one of particularly high value. Important wildlife habitats or water-related tourist areas are examples. In water-impoverished regions, treated effluent may be piped directly to the drinking water purification plant, or applied to the land surface and allowed to infiltrate into the soil. Infiltrated water can be stored underground in depleted aquifers and then drawn upon when needed.

Drinking water purification

Ensuring a supply of clean drinking water includes selecting the best available source, such as a river, lake, or aquifer, and protecting that source from contamination. Although microbial numbers can be reduced significantly in a well-operated water treatment plant using conventional wastewater treatment technologies, microbes still remain in the effluent. These microbes are introduced into the receiving water when the effluent is discharged from the plant. Drinking water sources may also be contaminated by wild or domestic animals that discharge potential pathogens into a river, lake, or stream. For these reasons, water is often purified before it is made available to citizens for drinking.

Purification of drinking water varies significantly depending on the quality of the water source. Compared to surface waters, aquifer water is usually relatively free from sediment, plant, animal, and microbial material, and requires fewer steps to clarify it. Most purification procedures incorporate many of the same steps used in wastewater treatment, with similar but more stringent results **(Figure 16.30)**.

Raw water, especially from surface water sources, may first be screened to remove large particulate matter, such as sticks. It then enters a flocculation basin where a chemical such as aluminum sulfate (alum) is added. Alum forms gel-like floc

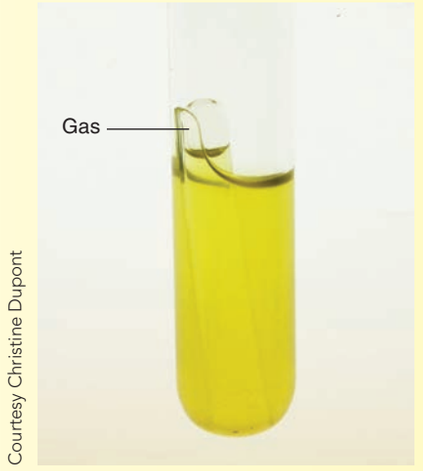
Toolbox 16.2
MOST PROBABLE NUMBER (MPN) METHOD

The most probable number (MPN) method is commonly used to generate a statistical estimate of microbial numbers in water samples, as well as in samples of foods, soils, milk, and juice. Such samples can contain heterogeneous microbial mixtures. As a result, exact cell numbers of a particular organism, like *E. coli*, can be impossible to determine. The MPN method estimates the size of a microbial population based on biochemical attributes of an indicator organism, such as coliform bacteria. It does not directly quantify the exact number of microorganisms in a sample or confirm fecal coliforms are indeed present. It is considered a *presumptive* test, useful for screening purposes only.

The sample to be tested is added to growth medium. An enrichment broth such as lauryl tryptose broth is used to encourage the growth of fecal coliforms. *Escherichia coli*, along with *Enterobacter, Proteus, Citrobacter,* and *Klebsiella,* produce acid and gas from lactose in the broth. Gas production indicating the growth of such coliforms can be visualized in an inverted gas-collection tube called a "Durham tube" **(Figure B16.2)**. In theory, if at least one coliform bacterium was present in a tube of broth, gas should be in that tube.

There are many variations on the MPN method, and the volume and number of replicate tubes tested will vary depending on the type of sample. The pattern of positive and negative test results for gas production is used to derive a statistical estimate of the population.

To better understand the MPN method, let's examine how drinking water is tested. As shown in **Figure B16.3**, 15 tubes containing 10 mL of broth are inoculated with the sample being tested. Five tubes are inoculated with 10 mL of sample, five tubes are inoculated with 1 mL of sample, and five tubes are inoculated with 0.1 mL of sample. Note that the broth in the first set of replicate tubes is prepared at double (2×) concentration to accommodate a 10-mL sample. This will result in a 1× concentration for optimal growth of coliforms. The rest of the tubes contain a 1× concentration of broth. The inoculated tubes are incubated for 48 hr at 35°C and are noted for the presence or absence of gas production. The tubes exhibiting gas production for each set of replicate tubes are counted to generate a score. In our example, a number series of **4 3 1** is produced. Using the MPN reference table, this score gives a value of 33 coliforms per 100 mL of water. The values in the table are generated by probability estimates. Most countries require residential water supplies to contain zero coliforms per 100 mL. The water source in our example is therefore not suitable for drinking. For testing wastewater, a higher dilution series would be used as the number of coliforms would be expected to be greater.



Courtesy Christine Dupont

Figure B16.2. Test for gas production Prior to sterilization, a small inverted Durham tube is placed inside a larger tube containing the growth media. Following sterilization, a sample is added to the tube and incubated. Any gas produced will collect in the tube and can be easily visualized.

The MPN test gives an estimation of numbers of possible fecal coliforms. However, not all coliforms are of fecal origin. *Enterobacter aerogenes* is a common soil bacterium, so its presence in a water sample does not necessarily indicate fecal contamination. For this reason, samples that are positive for gas production are further tested to confirm the presence of fecal coliforms. If confirmed, the species is then identified.

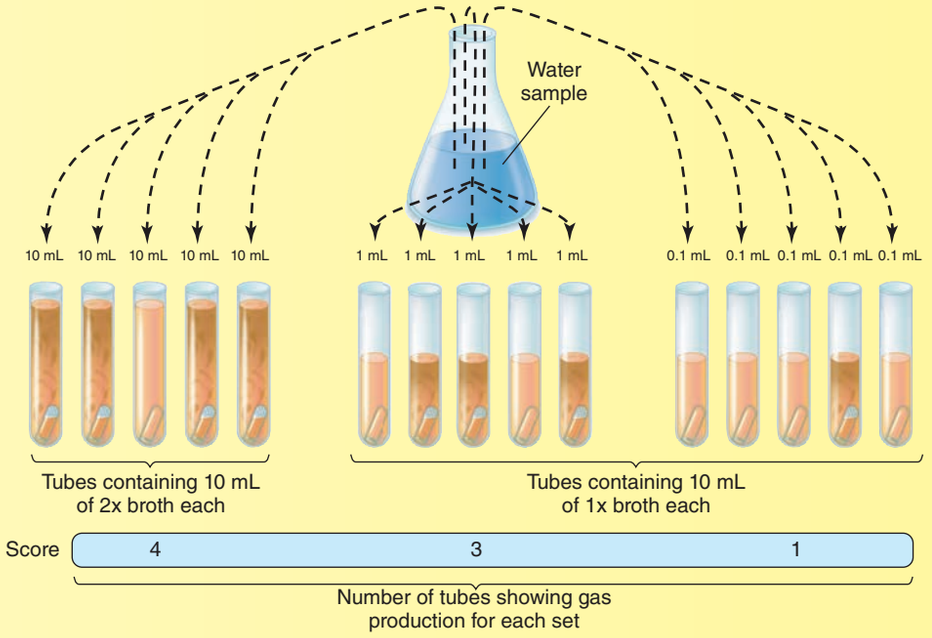
- A *confirmed* test is used to confirm fecal coliform bacteria are present from the MPN test. A confirmed test is only done if the MPN test is positive. All tubes showing gas formation are selected, and a loopful from each is inoculated to a medium more selective for fecal coliform detection, such as brilliant green lactose bile broth or EMB agar. If the tube shows gas production

precipitates that trap suspended particles, including microbes and other organic material. The floc-containing water is then moved to a sedimentation tank, where the flocs are allowed to settle as sludge. The clarified water is then filtered.

The most common type of filter is a sand filter, which uses physical and biological activity to purify water. Water moves vertically down through a deep layer of sand, which often has a layer of activated carbon on the surface to remove dissolved chemical contaminants. The high surface area of the sand supports biofilm formation that adsorbs incoming microbes, including viruses, and a variety of organic and inorganic materials that may contribute to foul taste and odor. The sand also presents a physical barrier to the passage of particulate matter, including spores, cysts, and microbial cells.

Membrane filters are often employed instead of or in combination with sand filtration. Membrane filters can remove particles larger than 0.2 μm. This may be the only sure way to remove *Cryptosporidium* oocysts that are resistant to chlorination and ultraviolet radiation (see Microbes in Focus 16.2).

The final step in water purification is disinfection by chlorination or ozonation, often combined with UV irradiation. The advantage of chlorination is its residual effect—a small amount of chlorine remains in treated water and can protect it from recontamination during storage and as it flows through distribution channels. Ozonation and UV light have no residual effect, but have the advantage that they do not tend to produce by-products, as can occur with chlorination.



From L. S. Clesceri, E. Greenberg, and A. D. Easton (eds). 1998. Standard methods for the examination of water and waste water, 20th ed. American Public Health Association, Washington, DC.

Figure B16.3 Procedure for the most probable number method A series of sample volumes are inoculated in suitable growth media. Each sample volume is repeated five times to produce five replicate tubes. Following incubation, the tubes are recorded for gas production to generate a score, which is applied to a reference table to generate an estimate of the numbers of bacteria.

Most probable number reference table (MPN/100 mL) for five replicate tubes of sample sizes 10 mL, 1 mL, and 0.1 mL

or growth occurs on EMB agar, the confirmed test is considered positive. Other selective media can be used.

- A *completed* test identifies the particular species present from the confirmed test. It uses more specific biochemical tests, such as rapid bacterial identification systems (e.g., API20E; see (Toolbox 13.1).

Other methods can be employed to estimate coliform numbers. The membrane filtration technique filters a water sample through a membrane. The membrane is then transferred to an appropriate growth medium for quantification and identification. A more recent method for coliform testing is an enzymatic assay for β-galactosidase because all bacteria belonging to the coliform group possess this enzyme.

Test Your Understanding

Imagine you are working in a public water-testing lab and your coworker is analyzing the daily MPN test results. She walks in with a concerned look and asks you to confirm her results because she believes she has a positive presumptive test. What does this mean, and if she is correct, what should she do next?

Before water is released for drinking, it is tested to ensure its purity. Public health drinking water standards state that drinking water should be entirely free from pathogenic microorganisms. However, routine examination of water for the presence of all human pathogens would be a time-consuming, difficult, and expensive task. Microbiologists do not test for every potential pathogen that might remain in the water but instead use a presumptive test for **indicator organisms**. These are microorganisms whose presence in a water sample indicates the possible presence of fecal matter, and thereby potential pathogens. Because many pathogens associated with drinking water are of fecal origin, having been introduced by sewage, bacteriological tests are designed to detect the indicator organisms called **fecal coliforms**—a group of bacteria found in the intestinal tract of humans and other animals. Fecal coliforms are a subset of coliforms, which are Gram-negative, non-spore-forming, facultative anaerobic bacilli belonging to family *Enterobacteriaceae*. The most numerous fecal coliform bacterium in intestines is *E. coli*, although it only constitutes about 1 percent of microbes present in the human intestine.

Most fecal coliform bacteria are not pathogenic or are of low virulence, but their presence in water indicates the presence of fecal matter. And, if fecal matter is present, then pathogens, such as *Vibrio cholerae*, *E. coli* O157:H7, *Salmonella* Typhi, and *Cryptosporidium* may also be present. A widely used test to estimate coliform numbers in water is the **most probable number (MPN)** method, as described in **Toolbox 16.2**.

16.5 Fact Check

1. Distinguish between domestic wastewater and storm water.
2. What are the goals of wastewater treatment?
3. Outline and explain each of the steps of wastewater treatment.
4. What is the significance of exopolysaccharide (EPS) as it relates to floc formation and wastewater treatment?
5. What is biochemical oxygen demand (BOD) and how is it involved in sewage treatment?
6. Outline the steps in drinking water purification.
7. How are the terms "indicator organism" and "fecal coliform" related to the process of water treatment?

The Rest of the Story

Listeria monocytogenes is found widely in soils, vegetation, water, sewage, milk, and animal feces. Usually, but not always, common sanitary procedures used in meat-processing plants are effective in killing the organism. How *L. monocytogenes* comes to contaminate meats is not precisely known, but because it is killed by heating during the meat-processing stage, contamination likely occurs afterward in the packaging and slicing process. *Listeria monocytogenes* does not grow in foods having a water activity (a_w) value of less than 0.92 (see Figure 16.2) and/or a pH less than 4.39. Moist, ready-to-eat meats, like cold cuts and wieners therefore present the most risk. Unlike most pathogens, cool temperatures do not prevent the growth of *L. monocytogenes*. Lunchmeats are not commonly cooked in the home before being consumed, and wieners are frequently not sufficiently heated before being consumed.

The listeriosis outbreak that occurred in Canada in the summer of 2008 cost Maple Leaf Foods $27 million, paid to the relatives of those who died after eating the contaminated meats. Moreover, consumer confidence was shaken in this once stalwart Canadian food company. The outbreak spurred a report to the Canadian government that found both Maple Leaf Foods and the Canadian Food Inspection Agency at fault for lapses in inspection policy and cost-cutting measures that enabled *Listeria* problems to persist. The damage suffered spurred this and other companies to implement more stringent equipment inspection and cleaning policies, established in the aftermath of the 2008 outbreak. Nonetheless, pathogen outbreaks linked to tainted meat continue to occur. Indeed, you may remember that the largest meat recall in Canadian history occurred in 2012, following 18 people made sick from pathogenic *Escherichia coli* distributed with meat that was prepared at the XL Foods' Lakeside Packers plant in Brooks, Alberta. These examples reinforce the importance of microbial control and rigorous inspection standards when managing food supplies for human consumption.

Image in Action

WileyPLUS Learning Space The sandwich and water at this picnic all contain several species of microorganisms. On the slice of ham, *Listeria monocytogenes* (maroon), *Salmonella* Typhi (tan), *Escherichia coli* (green), *Staphylococcus aureus* (purple), and *Leuconostoc mesenteroides* (light blue) are present. The water is contaminated with bacteria including *Escherichia coli* (green) and *Vibrio cholerae* (teal), and protozoa, including cysts of *Giardia lamblia* (yellow) and oocytes of *Cryptosporidium parvum* (blue). Additionally, viruses such as rotovirus (pink) can also be carried in drinking water.

1. Imagine a child is spending time playing at the park on this sunny, warm day before finally coming to the table to enjoy this picnic lunch his parent has set out for him. During that extended period of time, the *S. aureus* bacteria on the ham have reproduced significantly. Describe the key features of the foodborne illness that may result due to this organism.
2. What preservation methods should have been employed during the manufacture of the ham to prevent the growth of pathogens and spoilage organisms? Provide an example for each.
3. What disinfection methods could have been used to prevent contamination of the water?

Testing and surveillance for *L. monocytogenes* includes monitoring ready-to-eat food products, as well as packaging and slicing equipment, floors, drains, and storage areas. For many years, surveillance was difficult and time-consuming, with contamination being discovered many days later because of the time it takes for the growth of cultures. Current methods are reliable and more rapid, making use of immunodetection and DNA-based technologies. These *Listeria* surveillance techniques can provide results in 2 or 3 days, rather than a week. Because *Listeria* is ubiquitous, eradicating the organism is probably not possible, but a commitment to maintaining constant surveillance of the entire food production process, using modern and rapid detection systems, can prevent a repeat of the Maple Leaf Foods outbreak in the future.

Summary

Section 16.1: How can microorganisms spoil food?

Food spoilage is related to microbial growth and will vary depending on the number of microbes present, type of food, type of microorganism, chemical/physical parameters of the food, and storage conditions.

- **Perishable foods**, such as some fresh fruit, are rapidly spoiled.
- **Semi-perishable foods**, such as nuts and potatoes, degrade more slowly.
- **Non-perishable foods**, such as flour, sugar, and dried beans, rarely spoil.
- **Intrinsic factors**, such as nutrient content, water activity (a_w), pH, and oxidation-reduction potential, are characteristics of the food.
- **Extrinsic factors**, such as storage temperature and presence of gases, are characteristics of the environment of the food.
- Proper storage of food can inhibit production of microbial **enterotoxins** that can cause foodborne illness.

Section 16.2: What techniques are used to minimize food spoilage?

Reducing a_w, temperature control, and using chemical preservatives are important means of food preservation.

- A_w can be reduced by heat-drying or **freeze-drying (lyophilization)** processes, and/or the addition of high concentrations of solutes, such as sugar or salt.
- **Refrigeration** severely inhibits the growth of many microorganisms, but not all (e.g., *Listeria monocytogenes*).
- Freezing can be efficient, although freeze-thaw cycles can damage food cells due to ice crystal formation.
- Temperature can be useful in killing microbial cells and spores and include **canning**, or appertization, and **pasteurization**.
- **Flash-heating** is more efficient than **low-temperature hold (LTH)** methods.
- A pH of 4.6 or less is inhibitory to spoilage microorganisms. **Pickling** uses acetic acid to reduce the pH to less than 4.6.
- **Botulism** is prevented by applying high temperature and low pH to kill endospores of *Clostridium botulinum*.
- Natural microbial preservatives include **bacteriocins** (e.g., nisin), lactic acid, and acetic acid.
- **Irradiation** of food serves to disrupt genetic material and/or cause oxidative damage to contaminating microbes. This includes the application of **non-ionizing radiation** in the form of **ultraviolet (UV) radiation** or treating with **ionizing radiation** (gamma rays and X-rays).
- **Modified atmosphere packaging (MAP)** uses plastic films to maintain an altered atmosphere inside the food package.
- **Hurdle technology** uses multiple individual constraints, or hurdles, to control microbial growth. This avoids the severity needed to inhibit growth using just one constraint.

Section 16.3: How are microorganisms used in food production?

Microbial fermentation of food produces end products such as lactic acid that inhibit the growth of spoilage microorganisms. Metabolites can also add pleasing flavors and aromas to foods.

- Industrial fermentations often use **starter cultures** or inoculums containing certain microorganisms, such as lactic acid bacteria (LAB), to maintain batch-to-batch consistency.
- The primary purpose of acid production by microorganisms is to retard the growth of unwanted microorganisms while promoting the growth of desired microorganisms.
- Vinegar manufacture is an ancient use of microorganisms, which relies on species of acetic acid bacteria that oxidizes the ethanol in the starting liquid to acetic acid.

Section 16.4: How can microorganisms in our food or water cause illness?

Foodborne illness can be caused by **foodborne intoxication** due to microbial release of toxins or by a **foodborne infection**, which occurs when growth of the ingested pathogen in the body occurs.

- The same principles and causes of foodborne illness also apply to contamination of drinking water.
- Outbreaks of foodborne or waterborne illness are caused by a common source of transmission, such as a supply of hamburger or a contaminated water supply.

Section 16.5: How can we keep our water supplies safe?

Contamination of water can be biological or chemical.

- **Potable** water is usually only attainable following water treatment.
- **Wastewater**, or **sewage**, from domestic and industrial sources needs to be treated before being released to the natural environment to reduce microbial and chemical loads to acceptable levels in order to protect water supplies.
- The goals of wastewater treatment include a reduction of total organic carbon (TOC), a reduction in numbers of microorganisms, and a reduction of inorganic compounds that contain nitrogen and phosphorus to prevent **eutrophication** of natural waters.
- Wastewater treatment processes include the use of **primary treatment** to physically remove sediments and grease that form **primary sludge**, followed by the use of **secondary treatment** that relies on formation of complex microbial biofilm communities capable of mineralization of organic compounds and binding pollutants to improve water quality.
- Secondary treatment uses a **trickling filter** unit or an **activated sludge** unit.
- **Tertiary treatment**, such as filtration, is sometimes used for wastewater treatment prior to release of treated effluent.
- The disinfection occurs by **chlorination**, UV light, or **ozonation** before final release of **effluent** to a natural water supply.
- An activated sludge process relies on **flocs**, which are clumps of biomass consisting of microbes, EPS, and absorbed material.
- **Secondary sludge** consists of settled flocs and is further treated along with primary sludge in an **anaerobic sludge digester**, which completes the digestion of organic material by anaerobic microbial communities.
- When properly done, wastewater treatment reduces **biochemical oxygen demand (BOD)** by reducing organic matter that acts as substrate for microorganisms.

- **Persistent organic pollutants (POPs)** are synthetic chemicals that are resistant to degradation by microorganisms and can bioaccumulate in tissues when released in effluent.
- A by-product of waste treatment is treated **biosolid**, derived from digested sludge, which can sometimes be used as a nutrient for crops.
- Water to be released for drinking is tested for the presence of **fecal coliforms**, a group of **indicator organisms** that suggests intestinal pathogens may be present. The **most probable number (MPN)** method is commonly used to test for fecal coliform bacteria.

Application Questions

1. *Listeria monocytogenes* is a psychrotolerant bacterium. Given this fact, explain why food manufacturers focus their *Listeria* testing efforts on ready-to-eat foods.
2. As both support microbial populations, explain the differences between spoiled milk and yogurt. Be specific.
3. Imagine you are training food handlers at the local restaurant. Identify two or three key points you should teach them regarding safe food handling. Explain the microbiology behind each.
4. Dairy farmers disinfect their milking equipment each day to keep the initial microbial load in the fresh milk very low. Describe how this will help minimize spoilage of the milk for the consumer.
5. Those training to be wine or cheese makers must be educated on the proper sanitation of their equipment. Explain why this is important to them, and describe some specific effects if their sanitation efforts are not thorough.
6. You just bought some fresh sliced ham for your daily lunch sandwich. Imagine you accidently left the unpackaged ham out of the refrigerator overnight. Explain the type and source of illness that may likely arise due to eating ham that has not been refrigerated. Contrast that with the type and source of illness that may likely arise due to eating poorly cooked hamburger.
7. Imagine you are talking with your friend who is against the use of chemical preservatives in foods because of perceived ill health effects from consuming these chemicals. You explain to your friend that although there may be valid reasons for these concerns, there are also valid reasons for adding preservatives to foods. Provide two or three examples of preservatives and explain to your friend how those chemicals act to prevent spoilage or illness.
8. During a tour of a waste treatment plant, the guide explains that aerobic digestion is preferred in the activated sludge process and anaerobic digestion is preferred for processing of sludge in the anaerobic digester. Explain the reasoning.
9. Last summer, an outbreak of *Cryptosporidium parvum* occurred at a water park. The water was recycled and reused in the park, but park officials thought the water was safe because it was chlorinated. Explain how the outbreak could have occurred even though there was chlorination, and what could have been done instead to prevent the outbreak.
10. Early settlers of the American West did not have refrigerators in their covered wagons to keep food fresh along the trail. Many times they would salt their meat to keep it from spoiling. Explain how this would keep their meat safe and prevent microbial growth.
11. Your friend read online that unpasteurized milk is healthier to drink because it contains more vitamins. She wonders if this information can be trusted and doesn't want to risk her own safety until she knows for sure. She asks your advice. Describe to her the reasoning behind the practice of pasteurizing milk and then explain how the different pasteurization processes for milk can address her concern about nutrients and vitamins.
12. Your task is to develop an inexpensive but effective mechanism for treating drinking water in the developing country of Zimbabwe where cholera caused by contaminated water recently killed thousands of people.
    a. What challenges do you face in trying to establish a safe water supply for a village in Zimbabwe?
    b. What would be some of your basic goals for treating their drinking water?
    c. Given the challenges and your overall goals, outline and explain the minimum procedures you would try to establish for a water treatment facility.

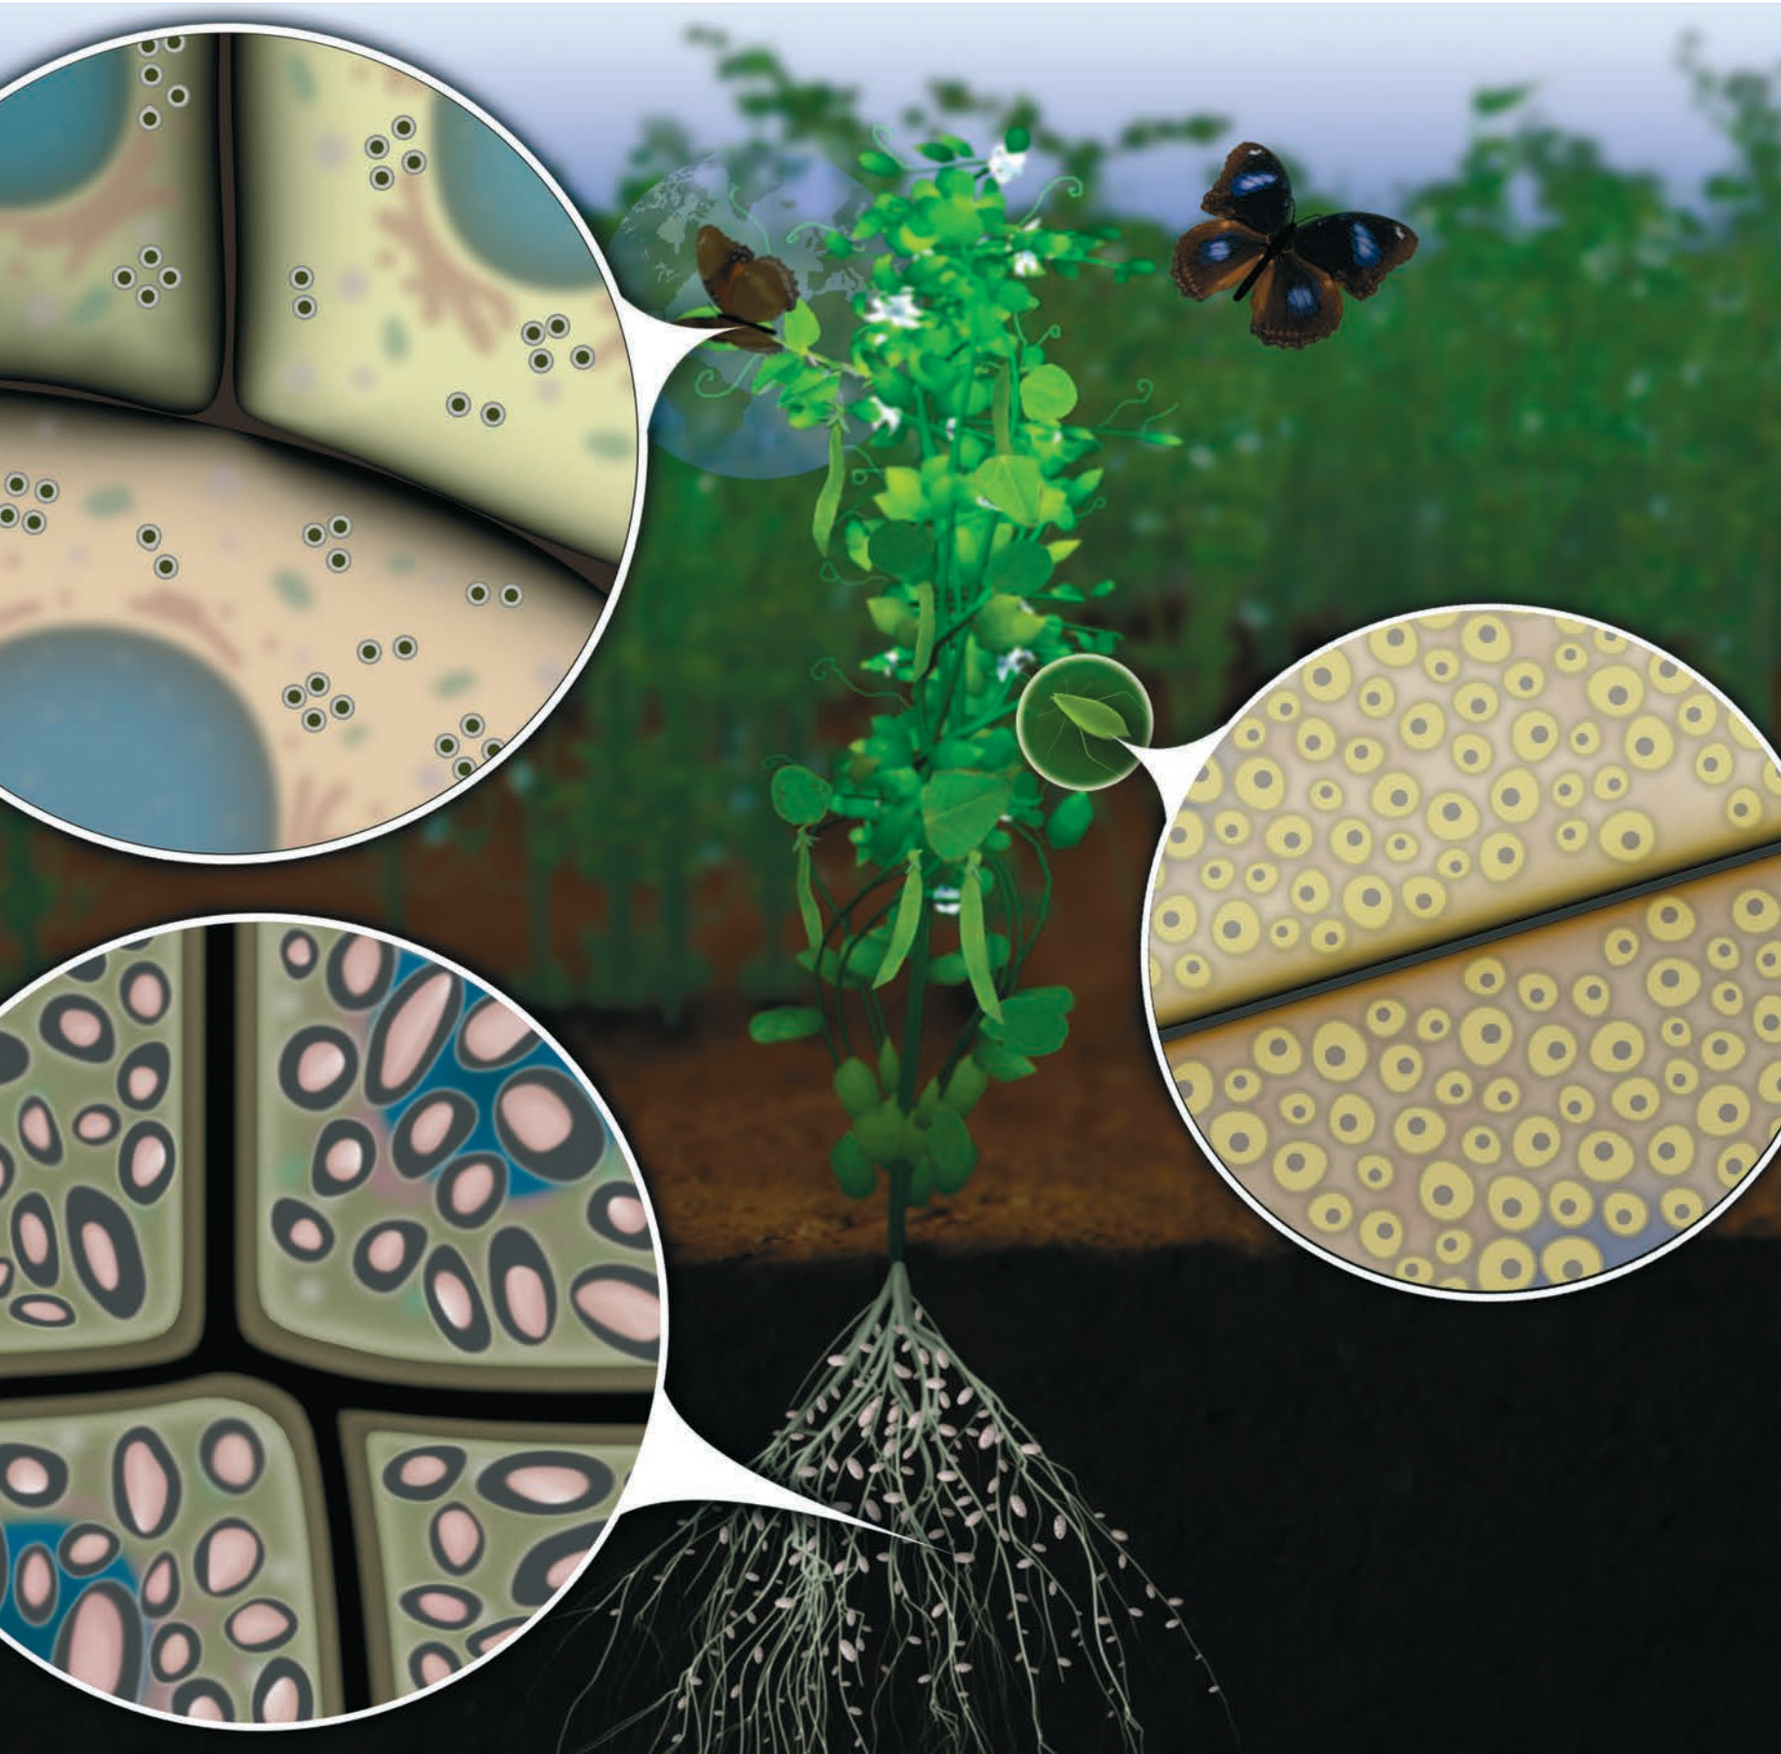
CHAPTER

17 Microbial Symbionts



An infection that makes females? In the early 1920s, researchers studying butterflies found a curious trait in some populations of the blue moon butterfly *Hypolimnas bolina* in the Fiji islands. Many populations were composed almost exclusively of females, like the legendary Greek Amazons. Males were rare. At first, this did not seem so unusual. It was known that females of many insect species, such as aphids, commonly produce only daughters by parthenogenesis, an asexual mode of reproduction not requiring males. However, this was not what was happening in the butterflies. In 1924, a New Zealand researcher named Hubert Simmonds showed that mating with males *did* occur in these populations, and genetically male embryos *were* produced, although they died before hatching. Males died in astounding proportions, resulting in females vastly outnumbering males. Through meticulous breeding experiments over many generations, Simmonds and others reported that the "female-only" trait was passed directly from mother to daughter and was not due to parthenogenesis. What could be causing this?

A few interested scientists tried to determine the mode of the male-killing. They had an idea that population domination by females was due to an infection that affected male embryos but not females. However, without modern molecular technologies and using only simple culture methods, they were unable to isolate any infectious agent. Around the same time, scientists M. Hertig and S. B. Wolbach were studying the mosquito *Culex pipiens*. They observed a tiny microorganism living within the tissues of the mosquito, which they described and formally named *Wolbachia pipientis*. About 50 years later, in 1971, scientists found that in matings between *Wolbachia*-infected male mosquitoes and uninfected females, all the embryos died mysteriously before hatching. They hoped that unlocking the secrets of this killing mechanism, which appeared to be linked to a *Wolbachia* infection, might lead to a control for mosquito populations. Suddenly, interest in this previously obscure bacterium began to increase.

Wolbachia has since been found to infect an astounding number of insect species, in addition to the blue moon butterfly. Sequence analyses estimate that *Wolbachia* is present in up to 76 percent of insect species—but it may be higher. *Wolbachia* is present in a number of other arthropod groups, including crustaceans (shrimp and lobsters), spiders, and centipedes. In this way, *Wolbachia* currently holds the honor of being the most widespread infection on Earth!

With the help of modern molecular tools, we now know that *Wolbachia* infections are inherited through maternal lines, directly from infected females. In some species, all females are infected. To maintain successful inheritance, *Wolbachia* alters the reproductive capabilities of its hosts to favor females and, in some cases, can even convert genetically male embryos to females.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Some microbial symbionts are damaging to the host, while others are beneficial.

- Figure 17.1: Symbiosis: A continuum between damaging and benefiting the host

Microbial symbionts of plants use photosynthetic products from their plant partners.

- Figure 17.8: Process Diagram: Nodule formation by infecting rhizobia
- Figure 17.10: Exchange of carbon and nitrogen compounds between plant host cells and bacteroids

Humans possess beneficial microbial symbionts that colonize outer and inner body surfaces.

- Microbes in Focus 17.2: *Streptococcus mutans*, a sweet tooth and cavities
- Toolbox 17.1: Germ-free and gnotobiotic animal
- Perspective 17.1: Probiotics—Do they work?

- Perspective 17.4: Death of coral reefs

CONNECTIONS for this chapter:

The surfaces of animals and microbial consortia **(Section 6.3)**

Colonizing symbionts and disease **(Chapter 21)**

Microbial symbionts of the digestive tract host energy needs **(Sections 13.3** and **13.4)**

Legume plants, protein, and N_2-fixing bacteria **(Section 17.2)**

Introduction

Disproportionate media and medical attention given to disease-causing microbes often results in a negative bias toward the relationships between microbes and humans. In reality, the majority of host-microbe interactions are non-harmful, and even beneficial. The relationships between these microbes and their hosts are extraordinary in terms of their interdependence and complexity. Yet, compared to many disease-causing microbes, we know little about the fascinating life of these beneficial microbes. Many of these microbes have evolved in association with their host species over thousands or even millions of years in a dynamic interaction where both parties have formed an intimate, and in many cases, obligate relationship, where one species cannot live without the other.

Just how dependent are animals and plants on their microbial partners? Judged against microbes, animals and plants are metabolically challenged in terms of the range of food sources they can use collectively. If you took away the microorganisms that animals harbor and which contribute to their nutrition, there would be little hope of survival for the current diversity of animal species. They simply would not be able to exploit the range of food sources that they do, much of which can only be broken down by the microbes they harbor. For example, the vast majority of animal species are herbivores and are directly dependent on the consumption of plant material, primarily cellulose. However, few of these animals can digest cellulose. They do not possess the genetic information to make the cellulase enzymes that can hydrolyze the bonds linking the glucose units of cellulose. A few invertebrates, like termites and crayfish, produce some endogenous cellulase, but even they require a significant contribution from their microbial inhabitants to hydrolyze enough cellulose to survive. Without the microbes that do this for them, these animals could not obtain their carbon and energy requirements and the vast numbers of herbivores this planet sustains would not exist. Plants also depend upon microbes for their success. Even though they use photosynthesis to meet their energy needs and fix CO_2 to meet their carbon requirements, most depend on the microbes in the surrounding soil, and sometimes in the plant tissues themselves, to provide other nutrients (such as nitrogen and phosphorus compounds) that are required for growth and reproduction.

Although many close relationships exist between free-living macroscopic species, the intimate associations we will examine in this chapter focus on the host-microbe kind. Many involve microbes that are not free-living but are found exclusively associated with a host species that they live in. Incredibly, every type of multicellular organism is likely to harbor at least one microbe whose existence is limited to only that host type. One may think of a plant or animal as an independently functioning unit, but that is rarely ever the case—most do not exist as single species at all but are inextricably united with microbes on and in them; they are an ensemble of species. As the late Carl Sagan once said, "We are each of us a multitude."

This chapter will explore a spectrum of symbiotic relationships involving microbes and their plant and animal hosts by addressing the following questions:

What is a symbiont? (17.1)
What roles do microbial symbionts play in plants? (17.2)
What are the roles of symbionts in humans? (17.3)
What are the roles of symbionts in herbivorous vertebrates? (17.4)
What are the roles of symbionts in invertebrates? (17.5)

17.1 Types of microbe-host interactions

What is a symbiont?

A **symbiont** is an organism that has entered into a *long-standing and intimate* relationship, termed **symbiosis** (Greek for "together living"), with an organism of another species. There are many types of symbiotic relationships. **Mutualism** occurs when there is benefit to both species. **Commensalism** occurs when one species benefits while the other is unaffected. **Parasitism** occurs when one species benefits while the other is harmed. Although these are clear definitions, symbiotic relationships do not always fall neatly into these categories; many symbiotic relationships can show aspects that range on a spectrum from mutualism to parasitism (Figure 17.1). The degree of damage or benefit is not always apparent, as it is frequently relative to the criteria used for study. For example, temperate viruses (see Section 8.3), like bacteriophage lambda, are symbionts that move between a parasitic (lytic phase) and commensal (integrated prophage) relationship with their host. Some temperate phages, like the one that infects pathogenic strains of *Corynebacterium diphtheriae*, may even be mutualists, as they provide toxins or other invasion factors for their host bacteria, making them more successful pathogens (see Section 21.2). Some commensals and even some mutualists can damage their hosts

Figure 17.1. Symbiosis: A continuum between damaging and benefiting the host
Many symbiotic relationships exhibit a spectrum of characteristics, showing aspects of parasitism, commensalism, and mutualism. Organisms may be considered to be mutualists under some conditions, but commensals or even parasites under other conditions. In relationships involving many symbiotic partners it is especially difficult to determine where each symbiont may lie on the continuum.

SPL/Science Source

Figure 17.2. Fungal parasitic ectosymbionts Athlete's foot is caused by several species of parasitic fungi associated with humans.

under certain conditions. For example, many animal species, including humans, harbor benign strains of *Escherichia coli* in the gut. The relationship can be considered mutualistic because the animal provides a protected environment and nutrients, and *E. coli* provides vitamin K_2 in return. However, vitamin K_2 can be acquired from food, so *E. coli* is not a required source. Thus, the relationship can be considered more commensal than mutualistic. Under the right circumstances, even benign strains of *E. coli* can become parasitic and cause disease if they gain access to body tissues, through intestinal injury for example. Indeed, many mutualistic relationships appear to have developed from original parasitic relationships. In this chapter, we will use the term" parasitic," or "pathogenic," to indicate that the symbiotic microbe is obviously or predominantly damaging to its host. Use of the terms commensal or mutualist will infer that it is not obviously or predominantly pathogenic under normal circumstances.

Ectosymbionts (*ecto* meaning "outer") live on the surface of their host. Examples include the normal bacteria and yeast that exist on human skin, but also include parasitic fungal species, such as those that cause athlete's foot and skin infections **(Figure 17.2)**. Parasitic ticks, lice, and fleas are examples of insect ectosymbionts that live in association with many animal species. The term "ectoparasite" better describes the harmful nature of these ectosymbionts. **Endosymbionts** (*endo* meaning "within" or "inside") live within the body of a host, sometimes even within the host cells themselves. We will normally use the term "endosymbiont" for internal microbes that have a mutualistic or commensal relationship with their host. Parasitic endosymbionts, such as the malarial parasites of genus *Plasmodium* (see Section 23.2), are described as endoparasites.

Microbial species can also form symbiotic relationships with other microbes. Lichens are such a case. Take a walk in the forest, and you will certainly notice the mossy and paper-like growths on the bark of trees and on rocks **(Figure 17.3)**. These are not plants, but lichens, which are also the favorite meal of reindeer and caribou in the barren Arctic regions where plant growth is sparse. Although **lichens** have been classified as individual species, each one is actually a composite organism, composed of two or three different microorganisms. One of these organisms is fungal and is called the **mycobiont** (*myco* refers to fungi). The other one, or sometimes two, has photosynthetic capabilities and is called the **photobiont**. The photobiont is usually a green alga, but in about 10 percent of lichen types it is cyanobacterial. Often, the photobionts are arranged in a distinct zone or layer exposed to sunlight within the lichen where their main function is to produce carbon sources for the mycobiont through photosynthesis **(Figure 17.4)**. Cyanobacteria and eukaryotic algae are typically photosynthetic aquatic organisms with limited cellular differentiation. When they associate with fungi in the lichen, the result is a life-form that is quite plant-like, and in fact plays the role of the plant in many ecosystems where plants cannot survive.

Within symbiotic relationships, more than one species of symbiont may be present. It is not uncommon for animals to harbor a consortium of microbes—a stable community in which the growth or survival of members is interdependent (see Section 6.3). The digestive tracts of many animal species harbor such consortia of symbiotic microbes that, in addition to providing nutritional benefits, are necessary for maintaining homeostasis in their host. Disruptions in normal symbiotic microbial populations may result in overpopulation of one particular type of microbe, presenting serious implications for the health of the host.

CONNECTIONS As we learned in **Section 6.3**, microbial consortia are often present in sediments. In this chapter we will see that consortia are also commonly found associated with animals, especially in the digestive tracts of vertebrates.

17.1 Fact Check

1. Differentiate between the types of symbiotic relationships: mutualism, commensalism, and parasitism. Describe an example of each.
2. Differentiate between ectosymbionts and endosymbionts.
3. Define the terms "mycobiont" and "photobiont." How are they related to the term "lichen"?
4. What is meant by the term "consortium of microbes"?

17.2 Symbionts of plants

What roles do microbial symbionts play in plants?

We have defined a symbiont as an organism that has evolved a long-standing and intimate relationship with another species. Not all relationships are symbiotic because many microbes can form transient and loose associations with other species, including plants. Soil bacteria can obtain numerous advantages by living near, on, or in living plants. As we explored in Section 15.4, saprophytic soil microbes can convert dead plant material to organic nutrients and form loose but important relationships with plants. These microbes take advantage of dead plant material, and nearby living plants use the resulting organic nutrients for growth. As a result, the soils that surround plants are some of the most complex communities known. Recall from Chapter 15 that the diversity of microbes in a ton of soil (from 2×10^6 to 4×10^6 species) likely exceeds that of all the oceans on Earth combined (2×10^6 species).

As we know, the vast majority of plants carry out photosynthesis, using energy from the sun to convert CO_2 into useful carbon compounds (see Section 13.6). Plant-associated microbes that can use the products of photosynthesis have an advantage over those that cannot. These microbes exhibit a variety of mechanisms to get and use photosynthetic products from their plant partners. Some are pathogens, damaging plants to obtain plant products. Others form mutualistic relationships in which they provide growth-promoting compounds for the plant in return for carbon-rich nutrients. Mutualistic plant endosymbionts that aid in the uptake or manufacture of nutrients *inside* the plant are some of the most successful plant symbionts (Table 17.1).

As we saw in Section 15.4, the rhizosphere represents soil immediately surrounding plant roots and is the richest soil area in terms of nutrient availability. This is in contrast to the non-plant-associated soil, in which carbon nutrients are generally more scarce. Released root exudates are rich in carbon-containing amino acids and other organic acids that support the activity and proliferation of large and diverse microbial communities in the rhizosphere. However, microbes are not limited to life on the outside of plants. Some actually live within the tissues of plants. These organisms are called **endophytes**, a specific term that refers to plant endosymbionts. Modern molecular tools confirm that a large number of different types of bacteria and fungi live within the tissues of various plant species. Typically, endophytic microorganisms are discovered by sterilizing the surface of the plant, carefully cutting through the plant tissue to avoiding contamination with external microbes, and placing recovered tissue on microbial growth media. Endophytic microbes that have been isolated in this manner represent a hidden world ripe for scientific investigation. Relatively few endophytic relationships have been investigated, but the best-characterized systems are mutualistic. One group has been intensively studied for many years—the bacteria that carry out symbiotic N_2 fixation.

Symbiotic N_2 fixation

Recall that in the nitrogen cycle (see Section 14.3) a critical step is the conversion of atmospheric N_2 to ammonia (NH_3). This is an energy-intensive process called nitrogen fixation

TABLE 17.1 Some microbial endosymbionts of plants

Symbiont	Plant	Description of relationship
Frankia filamentous bacteria	Actinorhizal plants (e.g., alder tree)	Infection of the root. Host provides fixed carbon to support N_2 fixation by the endosymbiont.
Mycorrhizal fungi	Most plant families	Infection of the root. Host provides fixed carbon to the fungus. Fungus aids in uptake of nutrients such as phosphorus from the soil
Nostoc filamentous cyanobacteria	Herbaceous flowering plants, often with very large leaves (e.g., gunnera plant)	Intracellular infection of glands at the base of the leaves. Host provides fixed carbon to support N_2 fixation by the endosymbiont.
Rhizobia (species of *Rhizobium, Bradyrhizobium, Sinorhizobium, Mesorhizobium*)	Members of the *Leguminosae* family (peas, beans, clover, alfalfa)	Infection of the root. Host provides fixed carbon to support N_2 fixation by the endosymbiont.

(shown below), which is carried out by the nitrogenase enzyme (see Section 13.7).

$$N_2 + 8\,e^- + 8\,H^+ + (12 - 24\,ATP) \xrightarrow{\text{nitrogenase}} 2\,NH_3 + H_2 + (12 - 24\,ADP + 12 - 24\,P_i)$$

The nitrogenase enzyme, found only in bacteria and archaea, is irreversibly inactivated by O_2. Nitrogen-fixing organisms can therefore only carry out this process under anoxic conditions, or they require some way to prevent the detrimental effects of oxygen on the nitrogen fixation pathway. Some types of endosymbiotic nitrogen-fixing bacteria differentiate into specialized cell types, called **bacteroids**. These bacteroids use their relationship with the plant to solve the problems of both high-energy requirements and oxygen toxicity by inducing the plant root to produce a protective structure called a **root nodule**, in which the plant provides a continual supply of nutrients to the bacteria and shields them from high concentrations of O_2 (Figure 17.5).

Inside the root nodule, oxygen, even at low concentration, must be prevented from reaching the nitrogenase enzyme. This is managed through the use of a plant-derived hemoprotein called **leghemoglobin** (Figure 17.6A). Leghemoglobin tightly binds O_2, similar to the way that blood hemoglobin binds O_2 and keeps it from reacting with the nitrogenase enzyme. However, the bacterial symbionts must have oxygen for the tricarboxylic

B. Root nodule filled with leghemoglobin

Figure 17.6. Leghemoglobin Leghemoglobin is produced by the plant host and keeps O_2 from binding with the bacterial nitrogenase enzyme, which would destroy it. **A.** Structure of leghemoglobin molecule showing the heme structure (gray and blue atoms) with central Fe atom (orange) and bound oxygen atoms (red). **B.** Sliced root nodule showing red coloration due to leghemoglobin.

acid (TCA) cycle and electron transport system, which they use to generate energy from carbon nutrients that are provided by the plant. In this metabolic process, leghemoglobin serves a dual purpose: delivering a steady supply of O_2 to the membrane-associated electron transport system while keeping it away from nitrogenase. In doing this, leghemoglobin gives the interior of the nodule its characteristic red color (Figure 17.6B).

Legume plants of the family *Leguminosae*, such as beans, peas, alfalfa, clover, and peanuts, are notable for their ability to form root nodules harboring bacteria collectively known as **rhizobia**. The majority of rhizobia are from the *Rhizobiales* order of the α-Proteobacteria, and some are from the β-Proteobacteria. Much effort has been devoted to the study of legume nodules and their bacterial partners because of the agricultural importance of crop and animal forage plants such as soybeans, peas, and alfalfa. Throughout recorded human history, cultivation of legume plants has been used to enrich agricultural soils, and crop rotation involving legumes is a long-standing practice for maintaining soil fertility. Not until the late nineteenth century, however, was it shown that root nodules contributed to soil fertility and that bacteria within the nodule convert atmospheric nitrogen to a biologically available form. Fixed nitrogen provides a nutritional advantage to the plants on marginal soils where available nitrogen sources are limited. The isolation and cultivation of the bacteria from the root nodules quickly developed into an agricultural inoculant industry.

Before planting, roots of seedlings are dipped in the bacterial inoculant suspension, or seeds are coated with a preparation containing the bacteria. Upon growth, the bacteria invade the root to form nodules. Inoculating legume crops with root nodule bacteria can have a dramatic effect on the growth of the host plant (Figure 17.7). The agricultural use of symbiotic nitrogen-fixing bacteria is very appealing considering that nitrogen fertilizer production requires large amounts of costly fossil fuels and that nitrogen fertilizer runoff from fields to aquatic environments has environmentally detrimental consequences (see Perspective 15.2).

Different types of rhizobia have characteristic host ranges, meaning they form nodules only on particular types of legumes. For instance, *Sinorhizobium meliloti* (see Microbes in Focus 13.2) forms nodules on alfalfa, but not on beans, peas, or soybeans. On the other hand, *Bradyrhizobium japonicum* forms nodules on soybeans, but not on beans, peas, or alfalfa. Later in this section, we will examine some of the reasons for this host specificity.

Development of Legume Root Nodules

Root nodule formation is an exquisitely controlled developmental process with well-defined stages. The process begins when a free-living rhizobial cell migrates toward the root hairs of a suitable host plant. The first visible outcome of this association is curling of the root hair around the cell to form a structure called a "shepherd's crook" (Figure 17.8). Interestingly, if culture supernatant from a compatible bacterial symbiont grown *in vivo* is applied to a legume root, the root hairs will start to curl. However, forming the shepherd's crook itself requires direct physical attachment of the bacterial symbionts.

Next, the bacterium must infect the plant tissue. Although "infect" may seem like a strange term to use because it is usually associated with disease, symbiont cell entry has many parallels to infection by intracellular pathogens. Many use type III or type IV secretion systems and endocytosis to gain access to host cells (see Section 21.1). These systems appear to have been selectively maintained during evolution of symbionts and pathogens alike.

CONNECTIONS Type III or type IV secretion systems are used by many Gram-negative pathogens, such as *Bordetella pertussis, Salmonella*, and pathogenic *E. coli* strains, to deliver toxins to host cells. See **Chapter 21**.

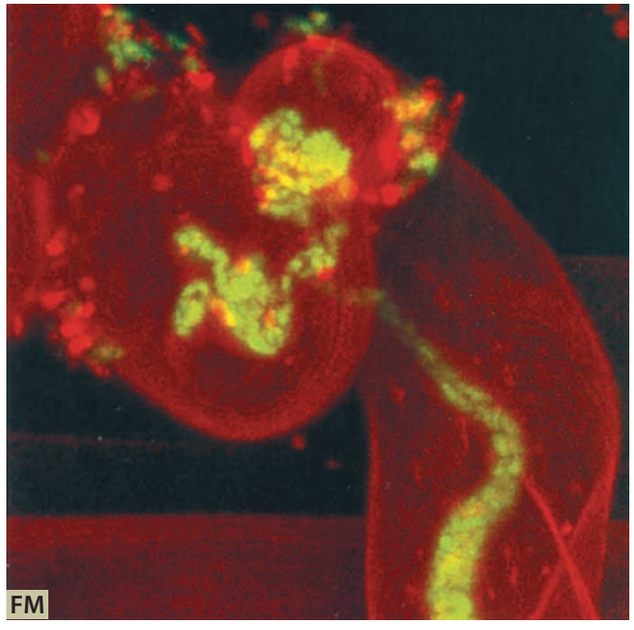
Figure 17.8. Process Diagram: Nodule formation by infecting rhizobia A free-living, potential symbiotic bacterium is attracted to the root hair. Flavonoid secretion by the plant host induces production of Nod factor in rhizobia to induce root curling. Attachment induces a series of changes in the root and the bacterium, producing a shepherd's crook and a plant-wall-bound infection thread from which the replicating bacteria enter the root cells to form an enlarged root nodule. These infecting bacteria remain encased in a host-derived membrane, change their cell walls, and further differentiate into non-replicating bacteroids, capable of fixing N_2.

The infection process begins with an invagination of the plant cell wall that forms a narrow tube called the **infection thread** (Figure 17.9). As the infection thread lengthens, the bacteria divide so that the infection thread becomes filled with dividing cells. As the plant root cells continue to divide, the nodule structure starts to form. The infection thread extends toward the center of the developing nodule and begins to branch. Near the extending tip of the infection thread, bacteria are taken up by the host cells and are surrounded by a host plasma membrane derived from the infection thread. Once inside the cell, the bacteria differentiate, gain the ability to fix N_2, and are now termed bacteroids. Even though the bacteroids are within the plant host cell, they remain separated from the plant cytoplasm by the surrounding plant cell membrane. During the differentiation process, the bacteroids become larger, lose their flagella, modify their cell wall, and sometimes change from rod shaped to multilobed. The fully differentiated N_2-fixing bacteroids are unable to divide; they are terminally differentiated.

Bacteroids can fix N_2 because leghemoglobin protects nitrogenase from the inhibitory effects of free O_2, and the cells are given the necessary metabolic resources from the plant.



From D. Gage, et al., J. Bacteriol., 178:7159-7166, 1996, Fig. 2i. Reproduced with permission of the American Society for Microbiology

Figure 17.9. Infection thread Fluorescent green rhizobia cells can be seen filling the infection thread in a root hair.

The ability to fix N_2 is coupled with an inability to divide further; bacteroids cannot proliferate. This would appear to be a tremendous evolutionary disadvantage for the bacteria. However, this is only a dead end for the individual bacteroids. The reproductively competent bacteria that fill the infection thread are genetically identical to the bacteroids and, having increased their numbers greatly here, release more progeny to the soil to infect another host once the nodule decays. This is an important advantage the bacteria gain from their association with plants.

Genetic Analysis of Nodulation

Understanding of the nodulation processes was elucidated by creating a series of mutant rhizobia that were screened for alterations in symbiotic phenotype, such as the inability to induce root nodules, or the formation of root nodules that lacked nitrogen-fixing ability. This involved painstakingly inoculating single mutant colonies one by one onto legume seedlings that had been germinated from surface-sterilized seeds, raising those seedlings without an added nitrogen source, and observing over time for the production of nodules and nitrogen-fixing ability. The mutant bacterial strains that showed a symbiotic phenotype different from the wild type were then examined to determine which genes were interrupted. These experiments resulted in the identification of several *nod* genes that are required for nodulation, *nif* genes that are directly involved in the synthesis of the nitrogenase enzyme, and *fix* genes that are required for synthesis of other products needed for nitrogen fixation.

Recall that one of the first changes to be detected in the formation of a legume root nodule is curling of the root hairs. This does not require the presence of the bacterial cells; it can be induced by exposure to culture supernatant from a potential bacterial symbiont. This provided strong evidence for the production of a diffusible compound by the bacteria. The *nod* genes were discovered because culture supernatant from the *nod* mutant strains did not induce root hair curling. Interpretation of these experimental results suggested that the *nod* genes were involved in the production of a lipochitin oligosaccharide signaling compound, the Nod factor, that controlled the nodule formation process. Many different Nod factors exist and are structurally unique to different species of rhizobia. Different Nod factors can be recognized by specific types of host plants, and this contributes to the plant host range on which the rhizobia can form nodules.

Although Nod factors are signals directed from the bacteria to the plant, signaling also takes place in the other direction, from the plant to their potential bacterial symbionts. Determination of the type of plant on which the rhizobia can form nodules requires specific plant-secreted compounds called flavonoids that are involved in *nod* gene expression in the bacteria. Specific plant flavonoid compounds are detected by the bacterial NodD transcriptional activator protein, which then induces *nod* gene transcription, resulting in production of the Nod factor, which induces root curling (see Figure 17.8). For example, the alfalfa flavonoid luteolin is recognized by *Sinorhizobium meliloti* NodD, whereas genistein from soybeans is recognized by *Bradyrhizobium japonicum* NodD.

Nodule Metabolism

The nitrogen fixation process requires much energy in the form of ATP (see Section 13.7). The rhizobia receive nutrients from the plant and metabolize them to generate the required ATP. What carbon compound is metabolized by the bacteroids as they fix nitrogen? In the plant, sucrose, a disaccharide product of carbon fixation composed of glucose and fructose, is transported from the photosynthetic leaves to the roots. One might expect that the bacteroids metabolize sucrose directly, but this doesn't seem to be the case. Genetic experiments demonstrated that rhizobial mutants deficient in sucrose, glucose, and fructose metabolism can still fix nitrogen within nodules. It is therefore not likely that immediate products of photosynthesis are fueling nitrogen fixation directly.

Following these experiments, researchers showed that mutant rhizobia incapable of incorporating C_4-dicarboxylic acids, such as succinate, fumarate, and malate, form nodules that could not fix N_2. As a result, the likely carbon nutrients used for N_2 fixation are C_4-dicarboxylic acids, which are used in the TCA cycle (see Figure 13.20), which is an important part of the metabolic relationship between the legume plant and the bacterial symbionts **(Figure 17.10)**. In return for C_4-dicarboxylic acids provided by the plant, the bacteroids provide nitrogen in a form that the plant can use directly for its metabolism. Depending on the host/symbiont species pairing, this supply is in the form of ammonia and/or amino acids.

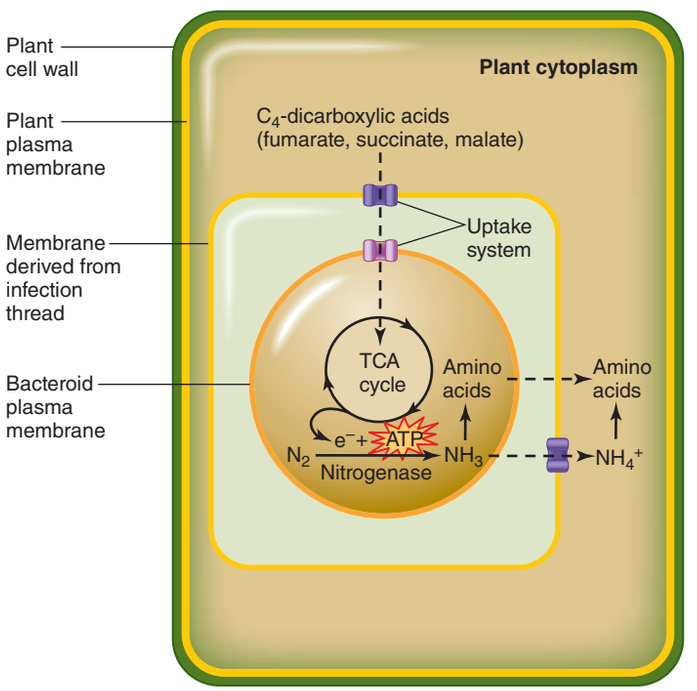


Figure 17.10. Exchange of carbon and nitrogen compounds between plant host cells and bacteroids C_4-dicarboxylic acids, such as malate, succinate, and fumarate, are manufactured by plant cells and are taken up from the plant cytoplasm by bacteroids to enter into the TCA cycle. The electrons and ATP that are generated are used by nitrogenase to convert nitrogen gas to ammonia through nitrogen fixation. Ammonia is used by the bacteroid to manufacture amino acids. Excess ammonia diffuses across the membrane into the plant cytosol, where it is reduced to ammonium, which is then used to manufacture amino acids for protein synthesis in the plant cell.

17.2 Fact Check

1. Explain the role some endophytes play in plants.
2. Why do nitrogen-fixing bacteria induce formation of root nodules?
3. What role does the protein leghemoglobin play inside the nodule?
4. Outline and describe the stages of root nodule formation. Include an explanation of the term "bacteroid" in your outline.
5. What genes are known to be involved in the nodulation process?
6. In the metabolic relationship between plants and bacteroids, what does each provide for the other?

17.3 Symbionts of humans

What are the roles of symbionts in humans?

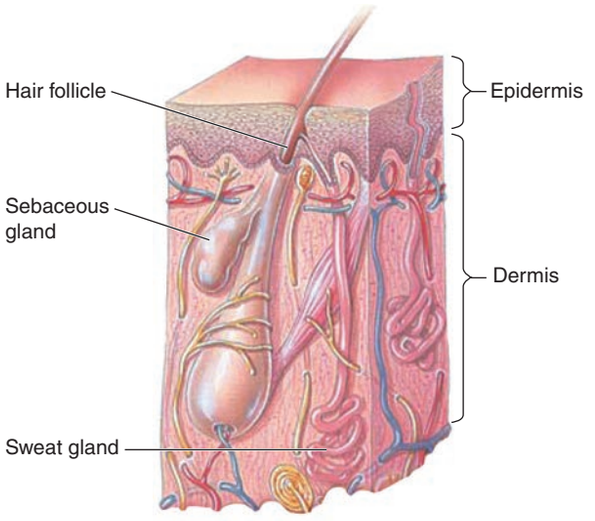
Vertebrates, such as humans, do not appear to harbor intracellular endosymbionts. However, most possess symbionts that colonize outer or inner body surfaces, such as the skin and intestinal tract. The human **microbiome**, the total of all the microbes living on and in the body, is enormous in terms of sheer number and species diversity. In 2007, the U.S. National Institutes of Health launched the Human Microbiome Project with the ambitious goal of defining all microbial species inhabiting the gut, the skin, and the female urogenital tract, as well as the nasal and pharyngeal cavities. It was an immense undertaking because of the huge number of species that are postulated to inhabit humans; the size of their collective genomes dwarfs the human genome by orders of magnitude. On a smaller scale, a European Union initiative is examining human intestinal microbiota. Both these projects will enlighten the relationship between human health and the microbial populations we carry.

Even though only a small number of people have been studied so far, it is apparent that there is no consistently definable microbial community in terms of species within and among humans. We each seem to have our own unique microbiome, which can change with age and diet. Although it is doubtful that there will ever be a defined species profile that represents the typical human, it may be possible to broadly define microbial communities in terms of prevalent phyla, and maybe common genera and species. A useful beginning to determining the relationship between health and our microbial symbionts is to look at the common microbial groups that inhabit the body.

Skin

To us, skin may appear to be a uniform surface, but to microbes it is as varied as the Earth's surface. Sebaceous glands and hair follicles form deep canyons where anaerobes can find a home (Figure 17.11). Areas dense in sebaceous glands are like seas of oil. Simply swabbing the skin, a common sampling method employed in the majority of skin microbiota studies, may not accurately reflect the microbes present in the depths of pores and hair follicles. As you may rightly guess, the microbiota of skin varies locally, depending on oiliness, sweatiness, hairiness, and environmental exposure. Differences in numbers and variety of microbes exist between the toes (moist and warm) where microbes abound, to the inner forearm (dry and cool) where densities are significantly lower.

Although attempts to identify microorganisms of human skin are inconsistent in sampling methods and sites, some generalities seem to be emerging. Skin is dominated by members of the Gram-positive phyla *Actinobacteria* and *Firmicutes* and the Gram-negative phyla *Proteobacteria* and *Bacteroidetes*. Not surprisingly, the proportions of phyla, families, and genera found depend on the sampling site (Figure 17.12). The oily skin of the head is dominated by members of phylum *Actinobacteria*. The major family here is *Propionibacteriaceae*. A dominant member of this family is *Propionibacterium acnes*, and as its name suggests, it can cause acne. Moist areas, such as toe spaces and the sole of the foot, are dominated by members of the families *Staphylococcaceae* and



Kuntzman, Tortora: *Anatomy & Physiology for the Manual Therapies*, copyright 2010, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 17.11. Cross-section of skin Schematic showing the different layers, glands, and a hair follicle. Oil-secreting sebaceous glands and hair follicles form deep pores in the dermis of the skin, providing an environment for the growth of anaerobes.

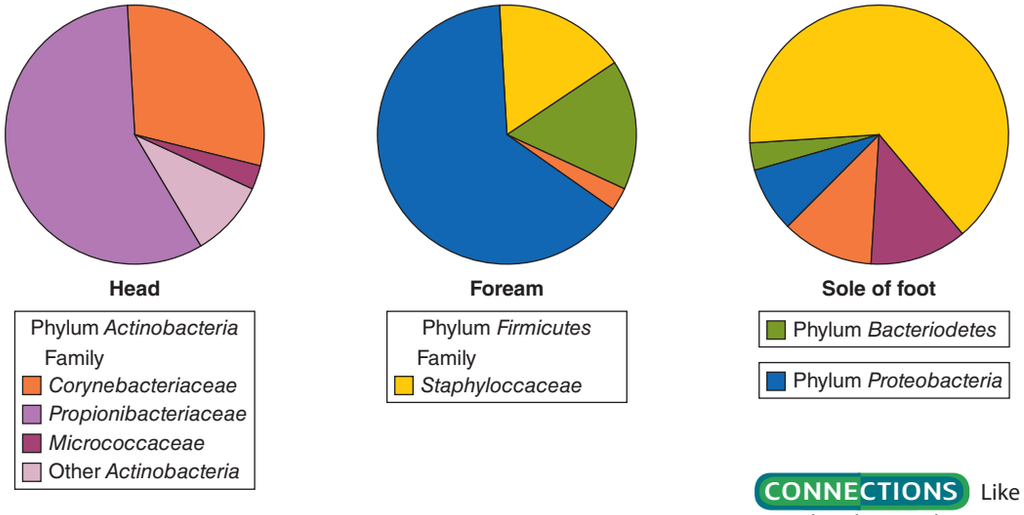


Figure 17.12. Major bacterial phyla and families found on select skin areas Relative proportions are shown, based on 16S rRNA gene analyses.

Corynebacteriaceae, with smaller numbers of the phylum *Proteobacteria*. Dry areas of the skin show the most diversity, with mixed members of the four phyla. For example, the forearm is dominated by members of phylum *Proteobacteria*, particularly of the genus *Pseudomonas*. This is followed by phyla *Firmicutes* and *Bacteroidetes*, with low numbers of *Actinobacteria*. In general, the dry areas that harbor much diversity are less stable over time with regard to community membership and structure. Among the small numbers of individuals studied, skin microbial variation at the level of phyla and family appears to be more dependent on the ecological site than on the individual. For example, the composition of the heel microbiota is more similar among individuals than to other sites on the same person.

Few studies have comprehensively examined single-celled eukarya of the skin. Members of the yeast genus *Malassezia* (Microbes in Focus 17.1) appear to be the most common fungal inhabitants of skin. Examination of 18S rRNA genes show *Malassezia* is not present on the skin of all persons and is only a minor skin component in healthy persons, as well as many other mammalian species. Some *Malassezia* species are a major cause of dandruff in humans and other skin conditions in animals. Members of the genus *Candida* can sometimes also be found on skin. Very recently, Archaea have been found on human skin.

CONNECTIONS Like the yeast *Malassezia*, potential pathogens such as bacterial species *Staphylococcus aureus, Streptococcus pyogenes*, and *Pseudomonas aeruginosa* frequently can be isolated from skin. See **Chapter 21** for more details on these pathogens.

Much more research is required to understand how skin microbial communities relate to human health and disease. That said, it is known that skin microbiota participate in the development of proper immune responses and the prevention of disease from pathogens, many of which can be found as minor inhabitants on skin. We will examine the general relationship between symbionts and immune function and disease prevention later in this section, when we cover the digestive tract.

Microbes in Focus 17.1
MALASSEZIA

Habitat: Sebaceous glands of many animals, including humans

Description: Aerobic eukaryal yeast, 5–7 μm in diameter, producing spherical conidia and filamentous hyphae

Key Features: Members of the genus *Malassezia* produce lipases that break down the oils on the skin into free fatty acids for consumption. Excessive growth of *Malassezia* yeasts causes a buildup of fatty acids on skin, producing irritation, hair loss, and flaking skin. Different species have been associated with dandruff, psoriasis, and other skin conditions in humans and animals.

Lester V. Bergman/© Corbis

Vagina

The vagina is in contact with skin and is situated near the anus. As a result, it is not uncommon to find bacteria present from both surfaces. For example, *Staphylococcus epidermidis*, a common skin bacterium, and yeast species of the genus *Candida* are frequently found in the vagina. Fecal bacteria, such as *Enterococcus faecalis* and *E. coli* are also found here commonly, but not consistently. Many of these microbes are likely to be transient, rather than resident, as they do not appear to replicate here to appreciable numbers under ordinary circumstances. Lactobacilli originating from the intestinal tract are the exception and appear to truly colonize the vagina of healthy women as symbionts. Most women studied are colonized with one or two species of *Lactobacillus*, most commonly *L. acidophilus*.

Many studies examining colonization of the vagina and vulva have focused on *Candida* because some species, such as *C. albicans*, cause vulvo-vaginal yeast infections, estimated to affect 75 percent of women over 40 years of age. *Candida* species are also commonly associated with diaper rash in infants. Favorable conditions for the growth of *Candida* include a moist environment and a near neutral pH. The composition of vaginal microbiota is affected by sexual practices, diabetes, antibiotic treatment, age, and hormone levels that affect pH. Vaginal pH is nearer to neutral in post-menopausal women over the age of approximately 50, favoring the growth of *Candida*; yeast infections caused by *Candida* species increase in this age group. By contrast, women of child-bearing age tend to have acidic

vaginal pH, favoring the growth of lactobacilli that in turn maintain this low pH by releasing acidic metabolic products, such as lactic acid. Maintenance of this homeostasis means yeast infections are relatively uncommon in this age group.

Oral Cavity

The human oral cavity is a heavily colonized area of the body, second only to the colon, or large intestine. Like the colon, it provides a warm, moist, nutrient-rich environment, and its varied landscape (teeth, tongue, mucosal surfaces) provides a variety of surfaces for diverse populations of microbes. Over 700 bacterial species have been detected in the mouth by 16S rRNA gene analysis, over half of which have not been cultivated. A few yeasts, such as *Candida* species, can also be found here. As on skin, community profiles vary by location. For example, the tongue is dominated by lactobacilli, and the exposed tooth surface is dominated by a diversity of Gram-positive streptococci, commonly referred to as "viridans streptococci." Viridans streptococci include species such as *Streptococcus sanguinis* and *Streptococcus mutans*, the agent of dental caries or cavities **(Microbes in Focus 17.2)**. Although most of the species found in the oral cavity of healthy humans are considered to be commensals, or even mutualists, many have pathogenic potential.

Most of the research conducted on oral cavity microbiota has focused on pathogens, particularly those involved in dental diseases. Almost all oral microbiota adhere to surfaces in some way. Many readily adhere to other cells, leading to biofilm formation (see Section 2.5). Most of us are familiar with **plaque** biofilms (see Figure 2.34), the adherent layer of bacteria and their organic compounds, that forms on tooth surfaces. If left unattended by regular brushing and flossing, it can have serious consequences.

Plaque formation and cavities are two negative outcomes of the activities of our oral symbiotic bacteria. Early colonizers of the tooth surface are dominated by viridans streptococci **(Figure 17.13)**. They adhere via pili to the pellicle, an amorphous coating on the tooth surface composed of non-cellular materials, largely proteins from saliva and components shed and secreted by bacteria. Below the gum, or gingiva, anaerobic species of *Fusobacterium* in turn adhere to colonizing streptococci. Their filamentous form provides a large surface area for further adherence of other colonizers. The adherent cells become embedded within a strong, self-produced matrix of exopolysaccharide substance (EPS; see Section 15.1), proteins, and DNA. Plaque will continue to increase if not kept in check by brushing three or four times daily. Unchecked growth results in an increase in biofilm thickness, reduction in oxygen concentration, and a change of the bacterial profile from aerobic Gram-positive species to Gram-negative anaerobes such as *Fusobacterium*.

Plaque buildup is a major cause of periodontal disease that can result in a loss of gum and bone tissue, infection, and eventual tooth loss **(Figure 17.14)**. *Gingivitis*, or inflammation of gingiva, is usually the first sign of trouble. When plaque below the gingiva builds up, bacterial components, such as enzymes and cell wall material, cause inflammation and damage to the epithelial cells surrounding the tooth. This extends the gap between the tooth and tissue, allowing further invasion of plaque bacteria. Some of the anaerobic plaque bacteria, such as *Porphyromonas gingivalis*, produce proteases that further damage epithelial cells, encouraging the invasion of bacteria into tissue and causing further inflammation.

CONNECTIONS Inflammation is a common tissue response to bacterial components in which defensive molecules and cells are brought in to clear infection. When clearance cannot be achieved, chronic inflammation occurs, leading to further damage. See **Sections 19.3** and **21.3** for details.

Digestive Tract

Of all the vertebrate body surfaces available for colonization, the digestive tract is the richest in microbes, both in species diversity and numbers. Why is this? In general, the gut provides a relatively protected and constant environment for microbes, and it is a good place to access nutrients. What gut microbes do for the animal is not as clearly defined. As you can imagine, for humans, it is difficult to do carefully controlled experiments in order to answer this question. Instead, model organisms, such as mice, are frequently used as surrogates. In general, experiments using germ-free and gnotobiotic animals have demonstrated that symbiotic microbes provide nutritional, immunological, and developmental benefits. **Germ-free** animals are born and raised under completely sterile conditions. They have no symbionts or any other microbial inhabitants.

Microbes in Focus 17.2
STREPTOCOCCUS MUTANS, A SWEET TOOTH AND CAVITIES

Habitat: Surface of teeth in humans

Description: Gram-positive facultative anaerobe belonging to viridans streptococci. Diameter 0.5–0.7 μm

Key Features: *Streptococcus mutans* is capable of metabolizing a wider variety of carbohydrates than other Gram-positive organisms. It converts sucrose into extracellular glucans that adhere it to the tooth surface. Consuming sucrose enhances colonization of *S. mutans*. Fermentation of glucose and other sugars into lactic acid results in a drop of the local pH below 5. Large populations of *S. mutans* overcome the neutralizing capacity of saliva, maintaining this acidic condition for extended periods of time, resulting in demineralization of the tooth. Low pH favors the growth of *S. mutans*, while inhibiting most other colonizers, enhancing the potential to cause tooth decay.

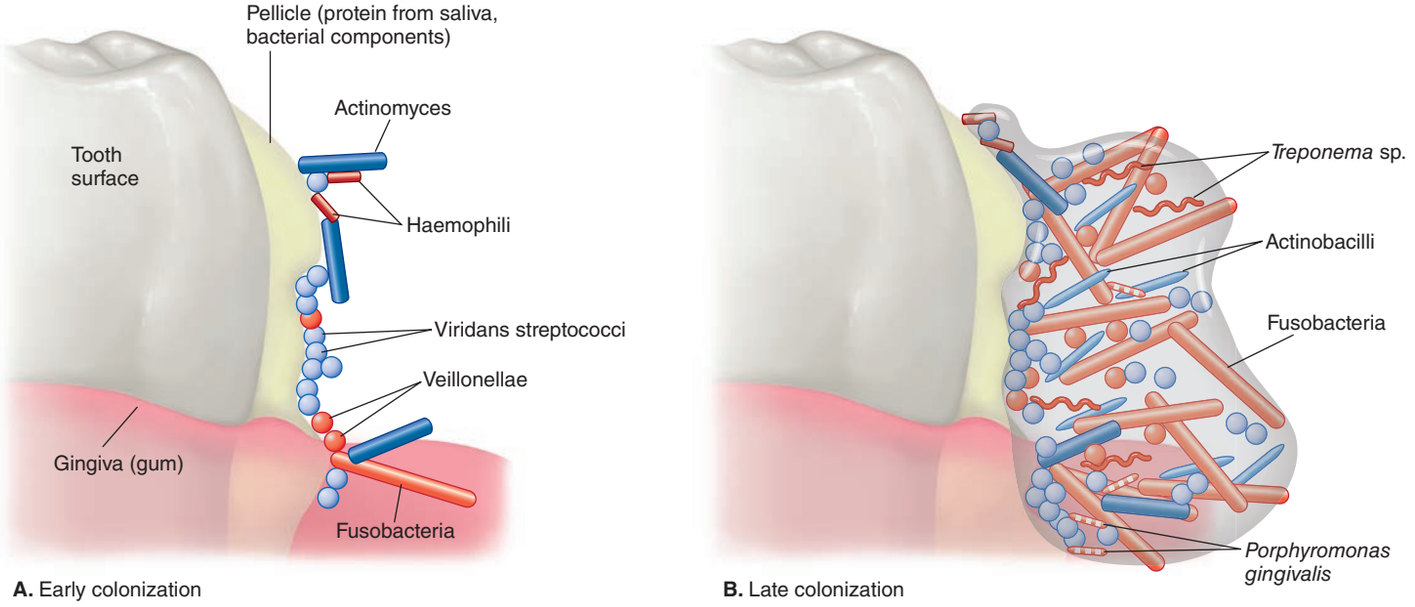

Figure 17.13. Formation of a plaque biofilm Gram-positive bacteria are shown in shades of purple and Gram-negative bacteria are shown in shades of red. **A.** Early colonizers are composed largely of Gram-positive viridans streptococci, which adhere to the pellicle of the tooth above and below the gum (gingiva. Other colonizers include smaller numbers of actinomycetes, *Haemophilus* species, and veillonellae. Fusobacteria are anaerobes normally found in small numbers on the tooth surface below the gingiva. **B.** If left undisturbed, plaque populations increase, becoming dominated by Gram-negative anaerobic groups, in particular fusobacteria, which provide an extended surface for attachment allowing other bacteria to thicken the plaque layer and extend it below the gum line. Invasion of plaque below the gum line leads to inflammation of the gingiva and eventual loss of bone supporting the teeth.

Gnotobiotic animals are initially germ free, but are introduced to a few select or known (*gnotos* is Greek for "known") species for controlled study. **Toolbox 17.1** describes how germ-free and gnotobiotic animals are produced. Comparisons of conventionally raised animals with germ-free or gnotobiotic animals can give insight into possible roles of symbiotic bacteria.

Trying to decipher the roles of the individual symbionts in the gut, as in any complex ecosystem, is a monumental task. Controlled studies designed to determine the contributions from each species in such a diverse population are often difficult, if not impossible. Studying symbionts in isolation, such as in gnotobiotic animals, often does not fully explain

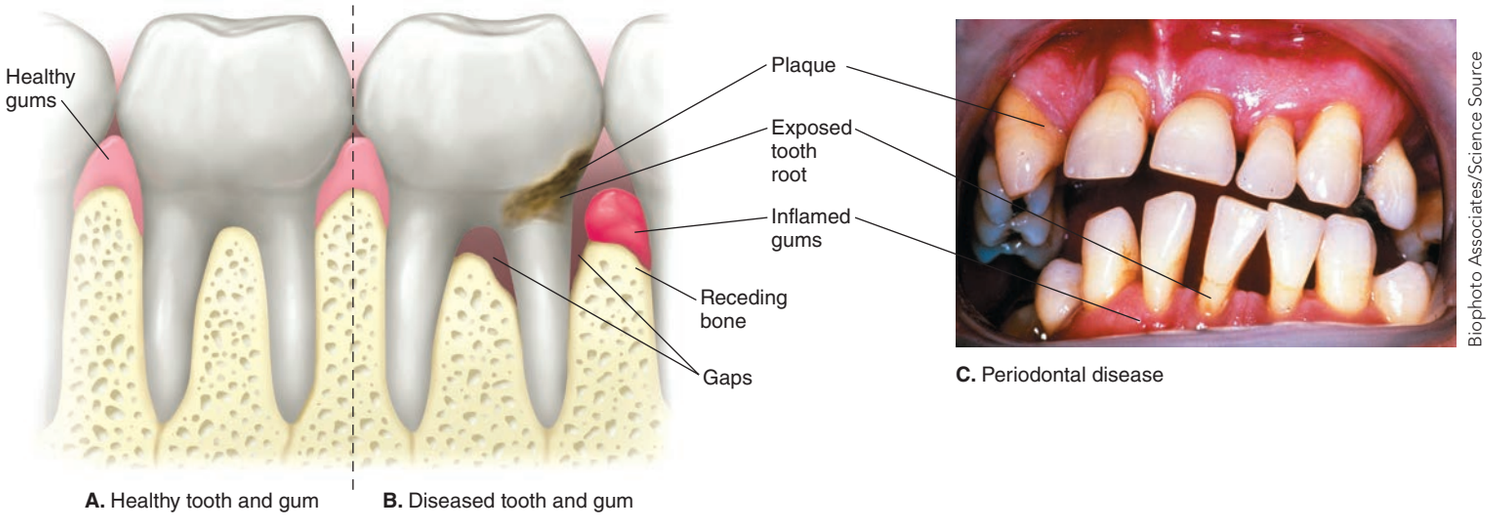

Figure 17.14. Periodontal disease starts with accumulation of plaque below the gum line **A.** Healthy gums are tightly adhered to the tooth and plaque is minimal. **B.** Accumulation of plaque below the gumline produces inflammation and tissue damage, resulting in an extending pocket of separation of tooth and gum. As plaque bacteria continue to move into the pocket, further inflammatory damage occurs and destruction of teeth and bone ensues. **C.** Periodontal disease showing inflamed and receded gums and plaque buildup.

Toolbox 17.1
GERM-FREE AND GNOTOBIOTIC ANIMALS

Controlled comparative studies using germ-free and gnotobiotic animals and their normally colonized counterparts have helped shed some light on the importance of symbiotic microbes. In the case of mammals (usually mice, rats, or pigs), the young are surgically removed aseptically to prevent the contamination that invariably happens from the birthing process. Just passing through the birth canal inoculates the newborn with vaginal and fecal microbiota. The animals are then maintained in isolation chambers on sterile bedding, fed sterile semisynthetic food, and given sterile water. Even the air they breathe is sterile. Animal keepers must enforce this sterility by wearing gowns, gloves, and masks.

Gnotobiotic animals are produced from germ-free animals by purposeful inoculation of just one or a few known species of microbes. Inoculation can be done by supplying the microbe(s) in food or water, or swabbing them onto the skin. The animals are then maintained under sterile conditions to study the effects of the inoculated microbes. Protocols for germ-free fish, birds, and reptiles have also been developed. Sterile eggs are fertilized *in vitro* and raised in sterile conditions.

Test Your Understanding

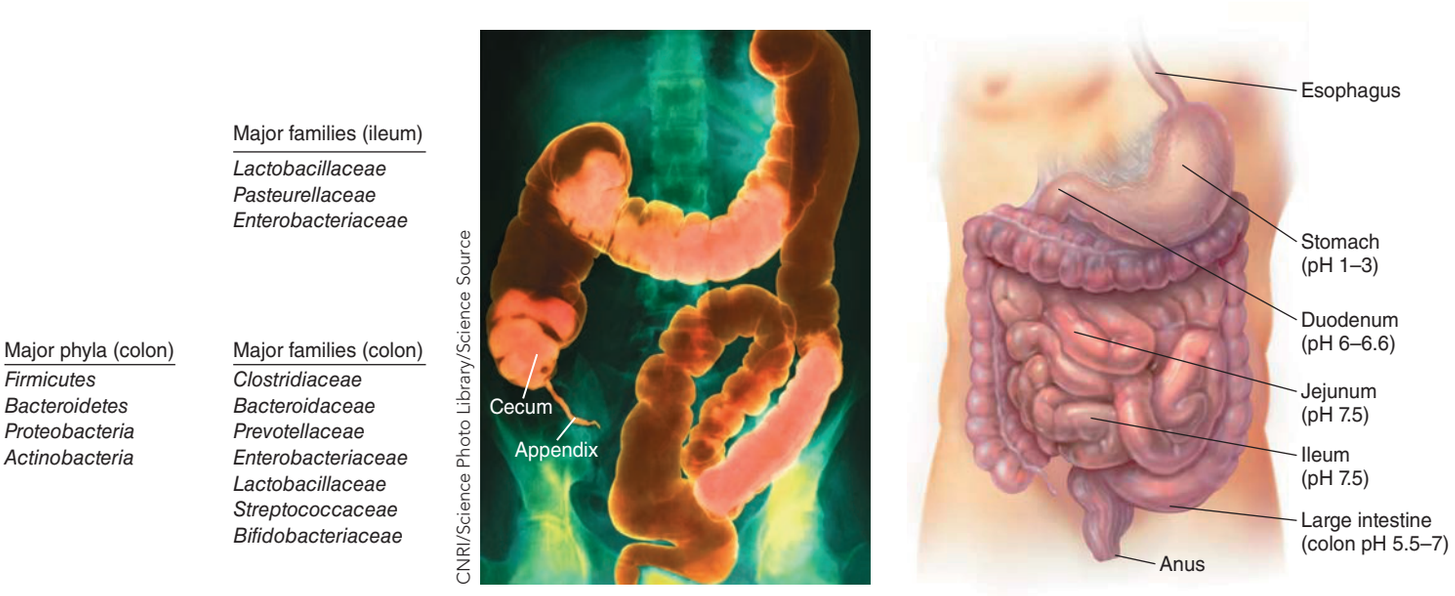
Maintaining germ-free animals leaves little room for error. Imagine you are training someone who will be working in your lab to raise germ-free mice for research on intestinal flora. What aseptic techniques would you highlight in your training, and how would you explain why they are important?

their role within the dynamic structure of the gut ecosystem. Symbionts of the digestive tract can be even more difficult to study because, for the majority of vertebrates, most symbionts have not been characterized let alone cultured. As we learned in Chapter 6, characterization and understanding of the microbial symbionts have been enhanced by new molecular methods, such as 16S small subunit (SSU) rRNA gene sequencing (see Chapter 1 Mini-Paper and Toolbox 1.1) and FISH analyses (see Toolbox 6.2). These techniques allow a glimpse of these inhabitants beyond what culture methods can achieve.

GenBank, the world's largest database of genetic sequences, contains at least 1,100 distinct and mostly uncharacterized 16S rRNA gene sequences from the human intestinal tract. Each unique sequence represents a bacterial species, or operational taxonomic unit (OTU; see Section 15.2). Some researchers believe the true number of gastrointestinal bacterial species may be in excess of 2,500. Viruses, especially phages, are also a large part of this community. In one study, over 1,200 different viral genomes were identified in human feces. Of course, some of these may just be "passing through" rather than associated with the microbes colonizing this environment. The finding of plant-specific viruses in feces indicates the transient nature of some of these viruses, but resident phages are certain to exist as they are known to be major contributors to genetic diversity in resident bacterial populations by facilitating exchanges of genetic information (see Sections 9.4 and 21.4).

The digestive tract is a continuous tube that goes from mouth to anus. Compared to the digestive tract in many other species, like ruminants, the human digestive tract is quite simple. The major organs consist of the stomach, the small intestine (consisting of the duodenum, jejunum, and ileum), and **colon**, or large intestine (Figure 17.15). The stomach is a single large chamber, where food is hydrolyzed by hydrochloric acid. The pH of the stomach is approximately 2, and few microbes can withstand this environment. For many intestinal pathogens like *Salmonella*, *Vibrio*, and most *E. coli* strains, ingestion of 10,000 or more bacterial cells is needed to cause disease. Some pathogens can withstand or temporarily neutralize the acid to increase their survival in the stomach. For these, ingestion of only a few cells can cause disease. Controlled studies have shown as few as ten *Shigella dysenteriae*, an acid-resistant relative of *E. coli*, can survive transit through the stomach to colonize the intestine. *Helicobacter pylori*, a common pathogenic human symbiont, can actually colonize the stomach. It protects itself by neutralizing acid during its transit to the stomach wall (see Microbes in Focus 18.4). Australian researcher Dr. Barry Marshall made medical history when he drank a concentrated culture of *H. pylori* to prove it caused gastric and duodenal ulcers, and indeed he developed ulcers (see Perspective 6.1). He then treated himself with antibiotics and the infection and the ulcers disappeared—a rather risky demonstration of cause and effect (see Koch's postulates, Section 18.4).

As we move from the stomach through to the colon, the digestive system becomes increasingly less acidic and more anaerobic. This environmental change is accompanied by increasing numbers and species of microorganisms. Few studies have been done on isolated areas of the small intestine, and it appears from these that the duodenum and jejunum have only scant colonization. The ileum shows progressively higher numbers of bacteria and is dominated by the families *Lactobacilliaceae, Pasteurellaceae*, and *Enterobacteriacea*, although the proportions of these vary with individuals. Members of the genera *Lactobacillus* and *Bifidobacterium* have received much attention as they are common components of yogurt and have been linked to health benefits—although, as Perspective 17.1 points out, evidence for health benefits is controversial.



Tortora, Derrickson: *Principles of Anatomy and Physiology*, 13e, copyright 2012, John Wiley & Sons, Inc. This material is reproduced with permisson of John Wiley & Sons, Inc.

Figure 17.15. Human digestive tract structure and major bacterial groups The acidic pH of the stomach prevents colonization by most microbes. The less acidic ileum and colon contain substantial numbers of bacteria; the major microbial phyla and most prevalent families found here are shown on the left.

At the junction of the ileum and colon is the **cecum**, a dead-end pocket that extends a short distance from the junction. Humans have a small pouch projecting from the cecum called the *appendix* (see Figure 17.15). Like the colon and cecum, the appendix contains anaerobic bacteria. Individuals who have had their appendix removed do not report a negative impact, so it appears to have little importance in humans. In many animal species, like rabbits, mice, and beavers, the cecum is greatly enlarged and has critical digestive functions, which will be described later.

The human colon contains one of the highest densities of microorganisms known for any microbial habitat—approximately 9×10^{10} bacterial cells per gram of wet fecal matter. That gives an estimate of 4×10^{13} bacteria in the colon. In comparison, the human body is made of approximately 3×10^{13} cells (see Chapter 1, The Rest of the Story). Given that the colon is the only significant contributor to bacterial populations in the human body, this means that you possess approximately equal numbers of bacterial cells and human cells! As we learned in Chapter 6, the colon is an example of a continuous culture system because a portion of the microbes that inhabit it are continuously expelled in feces and are replaced by growth of the remaining inhabitants.

Humans, like other omnivores and carnivores, use **colonic fermentation**. Material that is not absorbed in the small intestine is passed to the colon where the microbes take over. Most of the undigested substrates for microbial breakdown are dietary fiber consisting of complex carbohydrates, such as cellulose, hemicellulose, and pectins found in plant structural materials that are not broken down by host enzymes. Some of these can be degraded and fermented by symbiotic microbes via mixed-acid fermentation (see Section 13.3) producing short-chain fatty acids, predominantly acetic acid, propionic acid, and butyric acid, in order of predominance. In solution, these acids readily lose a proton to produce the ions acetate, propionate, and butyrate, which are absorbed by the colon and transported to the liver where they are used as energy sources. Between 5 and 10 percent of our caloric uptake may be due to absorbance of these microbial fermentation by-products in the colon.

Colonizing microorganisms of the intestinal tract are not generally found attached to the cells lining the intestinal surface. Attachment appears to be a feature largely reserved for pathogens (see Section 21.1). Instead, symbiotic microorganisms form a biofilm on the periphery of the mucous layer that coats the intestinal epithelium. The biofilm extends into the lumen of the intestine **(Figure 17.16)**, where most of the community resides. This is probably why feces contain such a large number of microbial cells. On average, feces contain as much microbial weight as undigested foodstuffs. In healthy people, the deeper areas of the mucous layer in the colon contain very few microorganisms.

CONNECTIONS Coating of the body's internal passageways with mucus is an important defense against invasion from microbes. This is discussed in **Section 19.2**.

The single most problematic aspect of collecting samples representing specific areas of the intestinal tract is that surgical procedures are required. In the few cases studied, samples were obtained from patients who required intestinal surgery

Perspective 17.1
FOOD PROBIOTICS—DO THEY WORK?

Who would believe that people would actually choose to eat or drink concentrated bacteria? This would seem to be, at the least, distasteful to most, but clever marketing has changed attitudes. Descriptions like "good" and "beneficial" bacteria have helped remove previous misconceptions that all bacteria are bad. Even better are descriptions of "live active culture" and "probiotics"; these leave the word "bacteria" out altogether. The truth is that humans have been eating bacterial cultures for centuries. Bacteria have long provided the flavors and textures of fermented products like yogurt and sour cream (see Chapter 16).

Probiotics are defined by the Food and Agriculture Organization (FAO) of the United Nations as "live microorganisms administered in adequate amounts which confer a beneficial health effect on the host." Prebiotics are non-digestible dietary supplements that are preferentially metabolized by those bacteria thought to promote good health. In humans, prebiotics are dietary fiber, which we cannot digest, but many bacteria can. Synbiotics are a marriage of the two—preparations containing probiotics and the prebiotics that supposedly feed them. But do probiotics in our food actually aid our health? The answer is yes, no, and maybe.

Any postulated health effects have to be proven by controlled, clinical studies in humans. The effects of ingested probiotics have been studied for many diseases and conditions, including Crohn's disease, constipation, diarrhea, irritable bowel syndrome, allergies, cancer, lactose intolerance, and obesity. However, the effects have varied considerably between studies, few have been repeated, varying conditions and age groups are used, they are not consistent in the strains or numbers of microorganisms used, and sometimes not enough people are included to make results statistically significant. Some studies use large microbial numbers that are not relevant to the numbers present in our grocery store foods. Despite these shortcomings, ingested probiotics seem to provide fairly consistent benefit in humans suffering from symptoms of lactose intolerance, diarrhea precipitated by antibiotic use, and childhood diarrhea. Because of the inability to compare results, these studies have been unable to definitively establish the magnitude of benefit, as well as the best species and strains for use. They do, however, collectively show that the concept of probiotic therapy is a promising avenue for treatment and possibly for prevention of several disease conditions.

If the effect of probiotics is real, how might they act? Some evidence from animal or *in vitro* studies suggest that probiotic microbes may interfere with the colonization of pathogens in the gut, but few human studies have demonstrate this. Other studies show probiotics stimulate the immune system, but that does not mean there is a health benefit from this. Indeed, many intestinal disorders are related to over-activity of the immune system. Interestingly, none of these studies have shown that the ingested probiotic bacteria actually colonize the gut. They are present in the feces, but this may be due to passive transfer following ingestion. Supporting this, several studies show that when the probiotic consumption stops, the bacteria disappear from feces, indicating colonization does not occur. However, lack of colonization may not be critical in providing benefit. The probiotic effect may be due to ingestion of bacterial products, rather than ingestion of live bacteria. This appears to be the case for improvement of lactose intolerance. The degradation of lactose is due to the ingestion of the acid-resistant β-galactosidase enzyme in fermented milk products produced by probiotic bacteria.

If numbers of live bacteria are important, then what is this number? Many companies advertise the numbers and species of live microorganisms in their products, but this information varies greatly. The minimum number of live probiotic bacteria needed for therapeutic use is considered to be a minimum of 10^8 to 10^9 live cells per day. Members of the bacterial genera *Lactobacillus* and *Bifidobacterium* are most commonly used in these products, but there is substantial variation in the species and strains used. This is important because studies indicate that different strains can show extensive differences in physical sensitivities and metabolic activities. Many of the probiotic bacteria in grocery store yogurts **(Figure B17.1)** are destroyed in the acidic environment of the stomach and by proteases and lipid-destroying bile salts farther on in the digestive tract. In addition, yogurts and prepared capsules of live cultures commonly show drastic drops in the number of live bacteria from the time of manufacture (the number quoted on the product label) to the expiration date. This is not surprising for *Bifidobacterium* because it is an obligate anaerobe and will be killed upon contact with oxygen. Much work still needs to be done in identifying optimum probiotic strains for particular health benefits and adopting enhanced survival methods in consumer products. In the meantime, be wary of the supposed health benefits some companies advertise.

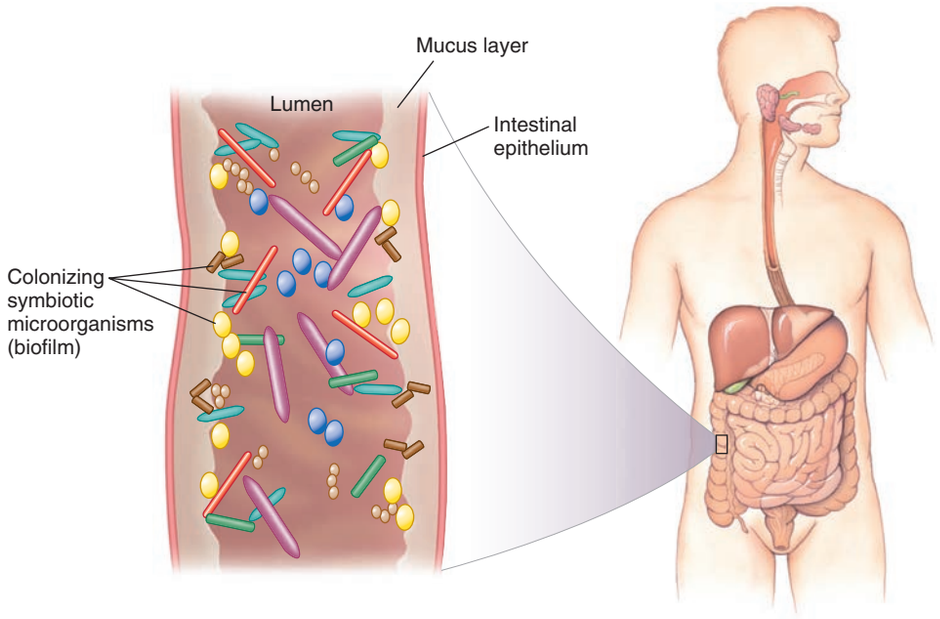

Figure 17.16. Biofilm of the intestinal mucus Most colonizing symbiotic microorganisms are not attached to the epithelial cells lining the lumen of the intestine. Instead, they form a biofilm on the outer edge of the mucous layer that extends into the lumen of the intestine. Colonization of the epithelium would result in infection and subsequent inflammation and damage. The ability to colonize and/or invade the intestinal epithelium is largely a feature of specialized intestinal pathogens.

Allen, Harper: *Laboratory Manual for Anatomy and Physiology*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

for other reasons. For some animal species, like cows, a surgical plug, called a cannula, is inserted directly through the skin and through the digestive tract wall to form a conduit for collecting samples directly from a specific area of the digestive tract **(Figure 17.17)**. In humans and most other vertebrates, the most convenient and therefore most frequently used way to collect intestinal microbiota is from feces. Most of the microorganisms represented in feces are of course from the colon. Fecal microbiota may not, however, be completely representative of the colon. Feces probably contains organisms carried from the small intestine and is likely predominated by lumen species, with species in mucus less represented. Although these studies may not be ideal and are subject to some interpretation, they give some insight into the diversity and variation of the human microbial inhabitants of the gut.

Analyses of rRNA genes show the human gut microbiota is dominated by bacteria. Only three or four species of archaea, all methanogens, have been found along with a small number of eukaryotic species, mostly yeast. Little disagreement is reported among studies on the major groups and their proportions, but the specific genera and their numbers vary widely among individuals. The most abundant bacteria found in the colon and feces of young healthy adults are anaerobes belonging to the phylum *Firmicutes*, class *Clostridia*, followed by the phylum *Bacteroidetes*, predominated by members of the families *Bacteroidaceae* and *Prevotellaceae* (see Figure 17.15). Following this are facultative anaerobes of the phylum *Proteobacteria*, of which the family *Enterobacteriacea* dominate, including *E. coli* and relatives, and the phylum *Actinobacteria*, including members of the genus *Bifidobacterium*. *Lactobacillaceae* and *Streptococcaceae* are other members of the phylum *Firmicutes* but show much lower numbers.

What do symbionts do in the human digestive tract? Obviously a great deal of metabolism is occurring **(Table 17.2)**. The majority of gut microbes are metabolically diverse, using and producing a wide variety of molecules, making it difficult to decipher the exact relationship or dependence. Metabolites produced from some microbes are used by others. For example, members of the genus *Clostridium* produce lactate as an end product of fermentation, and this can be used by *Enterobacteriaceae*. You may recall from the Chapter 4 Mini-Paper that *Methanobrevibacter smithii*, the only dominant archaeon found in the human intestine, uses formate, H_2, and CO_2 (all end products of fermentations from bacteria) to produce methane (CH_4). Methanogens increase fermentation efficiency by removing the inhibiting end product H_2.

Currently, we know very little about the dynamics of the consortium of intestinal microorganisms, how it is controlled, and how it relates to intestinal health. Modern molecular techniques are just beginning to provide some clues. Differences in the microbial communities of healthy individuals versus patients with ulcerative colitis, inflammatory bowel disease, Crohn's disease, and colon cancer have been noted. In general, microbial diversity is changed or diminished in patients with these conditions. However, it remains to be established if

Nancy Hamilton/Science Source

Figure 17.17. Cow with surgically installed permanent cannula A cannula allows samples to be directly collected from the intestinal tract.

TABLE 17.2 Major groups and metabolic activities of intestinal microorganisms of humans

Major group	Characteristics	Metabolic activities
Phylum *Firmicutes,* Class *Clostridia*	Gram-positive anaerobic spore-forming bacilli	Fermentation of starch, glucose to butyrate and acetate
Phylum *Bacteroidetes,* Family *Bacteroidaceae*, Family *Prevotellaceae*	Gram-positive non-spore-forming rods or cocci	Fermentation of plant-derived carbohydrates
Phylum *Proteobacteria,* Family *Enterobacteriaceae*	Gram-negative non-spore-forming bacilli	Fermentation of various sugars
Phylum *Actinobacteria*	Gram-positive non-spore-forming rods or cocci	Fermentation of starch to lactate
Domain *Archaea* *Methanobrevibacter smithii*	Only archaeon consistently present in the gut	Methane production from CO_2 and H_2

these differences are the result or the cause of perturbations in microbial populations. The **Mini-Paper** presents a successful approach to re-establish a healthy, balanced microbiota in patients suffering from colitis caused by *Clostridium difficile* infection.

Besides supplying some vitamins and calories, what other roles do the symbionts of our intestine provide? Not surprisingly, germ-free mice must ingest almost twice as many calories to maintain their body weight and frequently need vitamin K_2 and vitamin B supplements, compared to normal mice. However, this is not just due to a reduction in colonic fermentation products by microbes. Compared to their normal counterparts, germ-free mice show marked impairment of nutrient absorption through the intestinal wall. Other functional and morphological abnormalities of germ-free mice include a thinner intestinal wall and reduced mucous secretion. In addition, repair of intestinal injury is markedly impeded. Reconstitution of germ-free mice with symbiotic bacteria obtained from conventionally raised mice results in profound improvement of digestive function and morphology.

Intestinal microorganisms are also important for preventing intestinal infections. With such a high density of colonizers in the colon, competition for nutrients and space is intense—most newcomers cannot easily become established. This is known as **competitive exclusion** and is based on the principle that different species requiring the same resources cannot coexist. Many intestinal pathogens, like those of genera *Salmonella, Shigella, Vibrio*, and pathogenic strains of *E. coli,* colonize the less crowded small intestine by attaching to epithelial cells. Symbiotic intestinal microbiota also produce a variety of anti-microbial compounds such as bacteriocins, which are small peptides that have toxic activity on related microorganisms (see Section 16.2). For example, some strains of *E. coli* can produce bacteriocins against competing pathogenic *E. coli* strains, reducing their ability to colonize.

You may be surprised to know that microbial symbionts are also important for the correct functioning of the immune response. This is another way that colonizing microbes help protect against infection and disease. Germ-free animals are more prone to infections, immune-mediated diseases, and allergies—all evidence of immune dysfunction. Transplantation of these animals with microbiota from their normal counterparts improves immune function. Such studies have led to the "hygiene hypothesis," which presumes that the lack of exposure to a wide spectrum of microbes including those causing common childhood infections results in an increased risk of allergies and autoimmune diseases, both of which are increasing in incidence, particularly in the developed world.

Why would intestinal microbes be needed for proper immune function? An overview of what many scientists believe happens between the immune system and resident microorganisms may help to answer this question. As mentioned earlier, symbiotic microbes of the intestine tend to colonize only the edge of the mucous layer and lumen. The basal layer of mucus is much too viscous for them to penetrate effectively. However, small numbers of these inhabitants and their components do routinely get through the mucous layer to contact the epithelium. Many of these intestinal inhabitants are closely related to pathogens. For example, there are commensal strains of *E. coli* and pathogenic strains of *E. coli.* Commensal species and strains do not have the genetic capacity to aggressively invade and damage intact intestinal tissues or to overcome host immune defenses of a healthy host, as can intestinal pathogens (see Chapter 21). However, commensal organisms frequently possess surface molecules similar to those of related pathogens, and these can be recognized by the immune system. When these molecules come in contact with immune cells, they can stimulate an immune response that can also protect against related pathogenic strains. This important routine contact stimulates immune responses on a continuous basis, keeping it "primed" and ready for rapid defense against an invading pathogenic microorganism. In this way, commonly benign normal microbiota provide practice for building immune defenses. Chapters 19 and 20 will describe the complex mechanisms of immune stimulation.

Contact with symbionts is also essential for training the immune system to recognize and tolerate these normal microbial inhabitants. Many allergies and autoimmune diseases have been linked to an imbalance or deficit in normal microbiota, preventing the immune system from distinguishing normal ever-present molecules from potentially harmful ones. Subsequently inappropriate and often aggressive immune responses occur to an otherwise insignificant stimulus. This overzealous response to a non-existent threat damages the host.

Mini-Paper: A Focus on the Research

FECAL BACTERIOTHERAPY: "REPOOPULATION" OF THE GUT

E. O. Petroff, G. B. Gloor, S. J. Vanner, S. J. Weese, D. Carter, M. C. Daigneault, E. M. Brown, K. Schroeter, and E. Allen-Vercoe. 2013. Stool substitute transplant therapy for the eradication of *Clostridium difficile* infection: 'RePOOPulating' the gut. Microbiome 1:3–12.

Context

Clostridium difficile is an anaerobic Gram-negative, endospore-forming rod-shaped cell sometimes found in very low numbers in the intestinal tract of many animal species, including humans. In healthy individuals, vegetative growth of *C. difficile* is restricted due to the metabolic environment produced by a diverse gut microbiota. Disruptions to these gut microbial communities can favor germination of endospores and allow proliferation of *C. difficile*. This shift is thought to be due, at least in part, to an increase in cholate metabolites that are required for spore germination. Cholate derivatives would otherwise be quickly metabolized by the normal microbiota.

Infection with *C. difficile* occurs most commonly following the use of broad-spectrum antibiotics for the treatment of diseases such as pneumonia and skin infections. The *C. difficile* cells produce two potent toxins (see Table 21.7) that kill cells of the gut epithelium, producing severe diarrhea and abdominal pain. Infection is acquired by ingestion of spores from fecal contamination, usually in hospital or long-term care facilities. In the United States, it is estimated that 50 percent of elderly patients will acquire this infection after a four-week hospital stay.

Conventional treatment of first-time *C. difficile* infections uses metronidazole or vancomycin after stopping the antibiotic therapy that precipitated the infection. However, up to 35 percent of patients experience recurrence of *C. difficile* infection, and of these, 65 percent develop debilitating and chronic disease despite aggressive antibiotic treatment. In the United States, 14,000 patients die each year of chronic *C. difficile* infection. An effective therapy is needed desperately. Researchers have turned to an old (China, fourth century), but recently revived method of therapy known as fecal transplantation therapy, where stool samples from healthy donors are transplanted into the colon of patients with disease. The donated fecal samples are first screened for bacterial and viral pathogens. The feces is diluted, usually in saline, homogenized in a blender, and filtered to remove particulate matter. The solution is then transplanted into the colon using a variety of methods either rectally or orally (using a tube or packaged pills).

Despite showing very high success rates (approximately 92 percent), fecal transplants are not commonly used for first-time or recurrent *C. difficile* infections. Why not? The treatment is still considered experimental, and at this time is not yet an approved therapy. Regulatory authorities must first ensure the protocols being used are safe and effective in clinical settings. Complicating the ability to establish standardized treatment protocols are the variety of dosages used and the ways researchers prepare and deliver the stool preparations. Of most importance may be the quality and consistency of stool used; there is great variation in microbial composition even from a single individual over time.

In this study, the researchers hypothesized that a cultured stool substitute, called "RePOOPulate," would be an effective treatment for recurrent *C. difficile* infection. They reasoned that removing the need for donor feces would eliminate donor sample variation and the requirement for pathogen screening. Furthermore, an approach using live cultures might help to alleviate some of the hesitation faced by feces-based therapies.

Experiment

The study began by culturing bacterial isolates from the stool of a healthy 41-year-old female, under strict anaerobic conditions, using various agar media. Cultured isolates were screened for resistance to a range of antibiotics, and those isolates showing resistance were removed from the study. This was necessary in case the patients used in the study required further antibiotic treatment. After this screening and taxonomic identification, 33 bacterial isolates were included in the study.

In deciding what amount of each culture to use for the RePOOPulate infusion, the researchers compared their list of bacteria with a database collection of stool samples from healthy donors. The stool sample dataset that best matched the profile of the 33 isolates was chosen as a guide to infer the relative abundance of each isolate in the final RePOOPulate mixture **(Figure B17.2)**. Members of the phylum *Firmicutes* dominated the mixture. Each final 100-mL bacterial suspension was made in sterile saline solution to a concentration of 3.5×10^9 CFU mL^{-1} and placed at 4°C until used within 24 hours. For each treatment, the RePOOPulate suspension was deposited during colonoscopy along the transverse colon.

The two patients used in the study had recurrent infections with a highly virulent strain of *C. difficile*. Following treatment, both patients recovered completely and remained symptom-free six months after treatment. The researchers also monitored the change in the microbial profiles over time. The patients began with very different microbiota profiles from each other before treatment, with sequences matching those in the RePOOPulate formula rarely present. Up to two weeks after treatment, they both had profiles consisting largely of RePOOPulate bacteria, indicating that these species successfully colonized the colon and were not just transient. After this time, the RePOOPulate profile diminished, and the microbiota become more diverse in both patients. One patient stabilized with a gut microbiota composed largely of *Firmicutes*, while the other stabilized to a composition largely of *Firmicutes* and *Verrucomicrobia*.

Impact

This novel approach to the reestablishment of a healthy gut microbiota shows that a defined mixture of cultured bacterial strains can replace actual fecal preparations, at least in the two individuals studied. This is of importance because this approach might help optimize the species, family, and phylum profiles for treatment and determine if the proportion of these are relevant. So far, this is the only existing approach that allows standardization and repeatability of the formula.

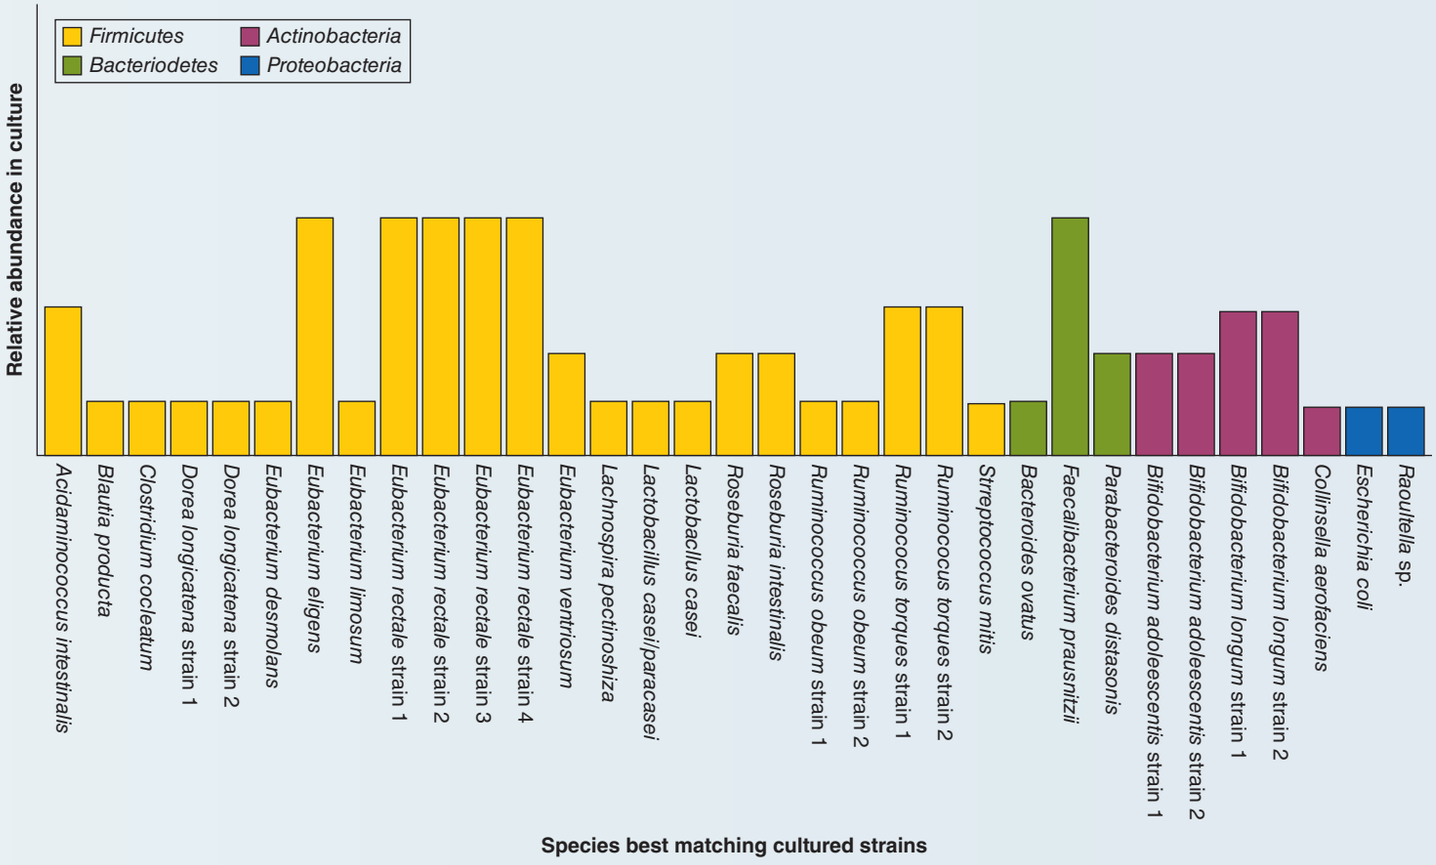

Figure B17.2. Bacterial profile of the RePOOPulate stool substitute To identify the 33 isolates used, 16S rRNA gene sequencing was carried out, and the sequences were aligned to sequences of a large database. The closest genus or species match is shown along with the relative abundance of each used in the formulation.

Understanding the physiology of a defined culture may also assist in uncovering the precise role that transplant organisms play in eliminating *C. difficile* infection. Currently, transplant therapy seems to work, but no one knows precisely why. The fecal substitute also guarantees the absence of pathogens, thus eliminating costly screening.

Preliminary studies have shown that microbial transplant may also be beneficial for other intestinal diseases, such as Crohn's disease. The success of fecal transplants has been much more variable in this regard. Using defined bacterial cultures may allow targeted treatment for different intestinal diseases. Expanding on this, defined culture therapies might be useful for other health conditions, such as psoriasis, allergies, and even mental health disturbances, such as severe anxiety, dementia, and schizophrenia. Research is ongoing in these areas.

Questions for Discussion

1. What are some of the ways that transplant microbiota may interfere with colonization of *C. difficile*? For one of these, develop a hypothesis that can be tested by experimentation.
2. In order to regulate fecal transplants or cultured transplants, authorities must first decide if these therapies are to be regulated like drugs or like tissue transplants. Do you think these therapies are more like drugs or transplant material?

Lastly, investigations on gut-to-brain communication suggest that intestinal microbiota may influence mental health in humans and animal models. It is known that some species of intestinal microbes produce neurotransmitters, such as GABA, in significant amounts. The contribution of these products in regard to physiology, depression, and anxiety are not fully known. However, recent studies have linked improvement of depression and anxiety in humans and animals to oral receipt of various lactobacilli and *Bifidobacterium* species.

17.3 Fact Check

1. What types of microbes are found as symbionts on human skin?
2. Explain the environmental conditions that affect the numbers and types of symbionts presenting in the human vagina.
3. What connects *Streptococcus mutans*, sugar, and cavities?
4. How are germ-free and gnotobiotic animals used to study symbiotic bacteria? Provide an example.
5. Explain how the pH of the human digestive tract affects the number and diversity of microbes.
6. What types of microbes are symbionts in the human digestive tract?
7. Explain several ways intestinal microbiota assist in preventing intestinal infections.

17.4 Symbionts of herbivores

What are the roles of symbionts in herbivorous vertebrates?

Herbivorous vertebrates, like cattle, zebras, geese, and rabbits, depend on the consumption of leafy plants for their energy needs. However, like humans, they do not possess the genes that produce the cellulase enzymes necessary to break down cellulose, the major material of plants. Cellulose, like starch, is composed of long chains of glucose molecules. Starch consists of glucose units joined by α-1,4-glycosidic linkages that are easily hydrolyzed by the enzyme amylase produced by many animals, whereas cellulose is composed of β-1,4-glycosidic linkages that require cellulase for hydrolysis **(Figure 17.18)**. Without cellulase, the glucose in cellulose cannot be released for use. This is not of concern for omnivores (like humans) or carnivores, because our nutrition does not rely solely on the conversion of cellulose into usable material. Herbivores, however, rely almost completely on this conversion, and they depend on their symbiotic microorganisms to do this. Consequently, their

Figure 17.18. Structure of cellulose and starch Both cellulose and starch are carbohydrates made by plants, composed of units of glucose. Starch is an energy storage polymer with glucose units joined by α-1,4-glycosidic linkages, which are easily hydrolyzed by the enzyme amylase produced by animals. Cellulose is an extracellular structural polymer with glucose units linked by β-1,4-glycosidic linkages. The tight packing of linear, not helical, molecules contributes to their strength but impedes their enzymatic digestion. With a few exceptions, animals do not possess the enzyme cellulase to hydrolyze this bond.

Figure 17.19. Idealized cow showing a body dominated by a digestive system "The Durham Ox" by John Boultbee, 1802. Desirable features of livestock were commonly exaggerated in eighteenth- and nineteenth-century paintings. For cattle, a large capacity for digestion was a characteristic of good breeding.

digestive systems have evolved to cultivate symbiotic microorganisms on a grand scale.

Functionally, herbivores are fermentation vats with legs. Their bodies are dominated by a digestive tract containing a large fermentation chamber needed to accommodate their symbiotic microbes and the large amounts of forage they must ingest to thrive (Figure 17.19). The major fermentation chamber of omnivores and carnivores—the colon—is relatively small in comparison. Although colonic fermentation works well for diets that are primarily digestible by the host alone, it is not sufficient for herbivores. To extract nutrients, primarily short-chain fatty acids, microbial fermentation is necessary. The two basic templates for accommodating fermentation in herbivores are **cecal fermentation** and **rumen fermentation**. Recall that the cecum is a dead-end pouch at the junction of the ileum and colon (see Figure 17.15 and part A of Figure 17.20). In cecal fermentation systems, the cecum is the major site of fermentation (see Figure 17.20B). The **rumen** is a major digestive organ found in a group of herbivores, called **ruminants** (see Figure 17.20C). In rumen fermentation, the primary site of fermentation is the rumen. Several examples of vertebrates and the different fermentation systems they use are shown in Table 17.3.

Cecal Fermentation

A cecal fermentation system is really just an elaboration of the colonic fermentation system (see Figure 17.20). To accommodate cecal fermentation, the cecum is greatly enlarged to become a fermentation vessel for extracting nutrition from plant material. Both the cecal and colonic fermentation systems

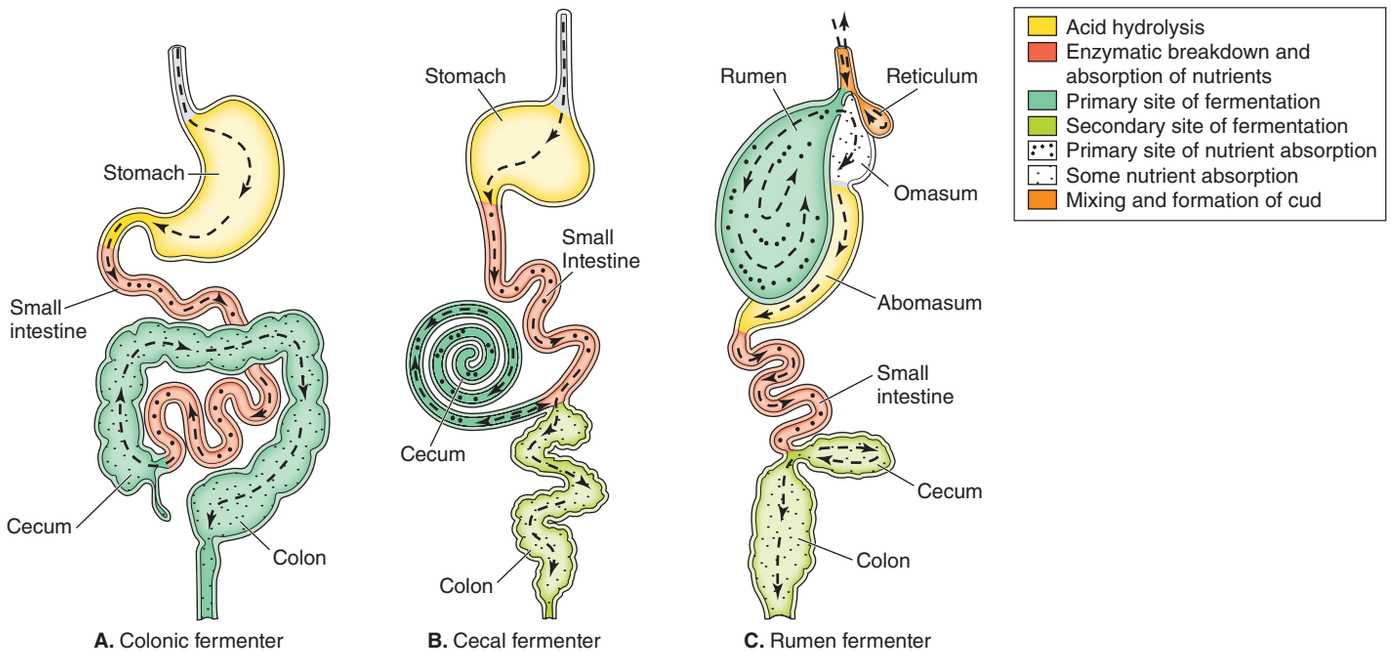

Figure 17.20. Vertebrate digestive systems for digestion of different diets Different digestive systems are designated for colonic fermentation, cecal fermentation, and rumen fermentation. **A.** Colonic fermenters carry out most microbial fermentation in the colon. Food enters the stomach and undergoes hydrolysis by acid, then is passed to the small intestine where it is digested by host enzymes and absorbed. Undigested material is passed to the colon where it is fermented by microbes. In colonic fermenters, the cecum is rudimentary. **B.** Cecal fermenters carry out most fermentation in the cecum. Digested and undigested food is passed to the cecum where it undergoes extensive fermentation. Any remaining undigested material is passed to the colon where further fermentation may take place. **C.** Rumen fermenters (ruminants) carry out most fermentation in the rumen. Before reaching the rumen, large pieces of food sink to the reticulum where they are mixed into cud, regurgitated and chewed, then swallowed to enter the rumen. In the rumen, the pulverized food fragments are fermented. Fermented, liquified material and microbes flow to the omasum and on to the abomasum, an acid stomach. Here, microbes from the rumen are digested along with fermented material. The rest of the ruminant digestive process is similar to that of cecal fermenters. Note that the cecum is shorter and is not a major fermentation chamber in ruminants.

TABLE 17.3 Fermentation systems used by vertebrates

Colonic fermentation	Cecal fermentation	Rumen fermentation
Humans	Rabbits	Deer
Dogs	Koalas	Antelope
Bears	Guinea pigs	Cattle
Cats	Mice	Buffalo
Carnivorous fish (e.g., sharks)	Herbivorous fish (e.g., angel fish)	Camels
Carnivorous birds (e.g., eagles)	Herbivorous birds (e.g., geese)	Sheep

are referred to as hindgut fermentation systems. Hindgut fermentation relies on host digestive processes in the stomach and small intestine first, and microbial fermentation processes last. The fermentation products of the cecum and colon that are not used by the microbes themselves are then available to be absorbed by the host, along with microbial products such as vitamins. The rest is expelled in feces. Approximately 20–30 percent of the caloric requirement of various cecal fermenters may be provided by absorption of short-chain fatty acids, predominantly acetate, propionate, and butyrate, all released through microbial fermentation.

Herbivorous cecal fermenters need to consume large amounts of food to survive because relatively little of the total mass consumed is converted into usable products for the host. Some cecal fermenters, like rabbits and beavers, compensate somewhat for this inefficiency by practicing *coprophagia*, or eating of feces. You may not think of feces as a valuable food source, but feces from hindgut producers is a concentrated package of potential nutrients, being full of dead and live microorganisms in addition to partially digested food particles. As unpalatable as it seems, coprophagia serves several important purposes for these animals:

- Microbes in feces are a source of nutrients, especially nitrogenous compounds like amino acids, which may be lacking in a plant-based diet.
- Ingestion by young herbivores of their mother's or herd mates' feces quickly provides a mature community of intestinal symbiotic microbiota, allowing them to utilize a diet of plants.
- Feces passed the first time is rich in partially digested food and water and consuming it a second time provides more calories and an extra opportunity for water and nutrient extraction. This second feces is then expelled as a hard, dry pellet (Figure 17.21).

B. Rabbit "second" feces

Figure 17.21. Nutrient extraction by coprophagia **A.** Rabbit feces passed through the digestive system the first time is soft and moist and contains incompletely fermented materials, including microbes, which are a source of nitrogen compounds. This feces is re-ingested for complete fermentation and further nutrient and water absorption. **B.** Feces that is passed the second time is hard and dry and contains little usable material.

Rumen Fermentation

Rumen fermentation provides a more efficient way for herbivores to extract nutrients from plant material. Up to 70 percent of the caloric requirements of ruminants is provided by absorption of short-chain fatty acids, which are major products of microbial fermentation. Unlike cecal and colonic fermenters, which use hindgut fermentation, ruminants use foregut fermentation, fermenting their food first using microorganisms. Any undigested, unabsorbed material is then passed through the stomach, the small intestine, cecum, and colon, which function in the conventional manner. This arrangement allows ruminants to benefit nutritionally from their symbionts in two ways:

- They receive fermentation and other products produced by the microbes, such as vitamins.
- They digest rumen microbes as a proportion of them pass into the stomach and intestine along with the fermented slurry. Hindgut fermenters cannot digest their own intestinal microbes and so miss this potential source of nutrition.

Ruminants have a number of other interesting digestive processes to increase fermentation efficiency. They do not chew their food as it is ingested. They tear it off and swallow, which allows them to feed quickly and move on. The large, heavy food first sinks to an open chamber called the reticulum, and the lighter, smaller material goes to the rumen, where major fermentation processes occur (see Figure 17.20C). Particulate material in the rumen forms a heavy slurry that eventually gravitates to the reticulum to mix with the larger food material, forming cud. Cud from the reticulum is regurgitated, then chewed into a paste, then swallowed again (you may think this is another pretty unpalatable way to get calories). Reducing the plant material to small pieces increases the surface area available for microbial attack, and thus maximizes fermentation product yields. Consequently, ruminants spend significant amounts of time (up to 40 percent of their day) chewing their cud.

Next, well-fermented, liquified material and microbes flow to the omasum. Here, water and electrolytes are absorbed. Rumen material that is not thoroughly broken down cannot flow into the omasum, and remains in the rumen where it is further fermented. From the omasum, product moves into the abomasum, which is a true stomach. The abomasum secretes acid and also lysozyme that breaks down bacterial cell walls (see Figure 2.18), facilitating harvest of the nutrition contained in the bacteria. The rest of the digestive process is a similar story to that of cecal fermenters. In the small intestine, enzymes degrade

substrates, including material of microbial cells, and further nutrient absorption occurs. A smaller amount of fermentation happens again in the cecum and colon, but contributes less than 15 percent of the total digestion. Overall, it is a very efficient system for capturing the energy locked in plant material, with up to 80 percent of total plant carbohydrates being converted into usable energy. Approximately 40 percent of the energy comes from cellulose alone. Compare that to humans eating a vegetarian diet, extracting very little energy from cellulose.

What are the symbionts of the ruminant digestive tract? One of the best-studied ruminant systems is that of the cow, although studies in sheep, goats, and deer reveal similar community profiles. Rumen microbial communities, in order of proportion, are bacteria (predominately *Firmicutes* and *Bacteroidetes*), protozoa (mostly ciliates), fungi (mostly yeasts), and archaeons (methanogens). Except for some yeasts, all are anaerobes. Yeasts scavenge O_2 that enters the rumen and maintain the anaerobic conditions needed for efficient fermentation. Although *Firmicutes* and *Bacteroidetes* are the predominant phyla in the rumen, as they are in the human colon, the species profile is not the same. Rumen bacteria are predominated by cellulolytic species and others that degrade structural carbohydrates of plants. Although some of these species have been found in some humans, they are a very small minority of the bacterial population. Some species, such as *E. coli*, are ubiquitous, existing in the digestive tracts of all vertebrates. Methanogenic archaeons, including *Methanobrevibacter smithii* (see Microbes in Focus 4.4), are also found in the rumen. However, *M. smithii* is not a dominant archaeon in ruminants as it is in humans. The different microbial communities reflect, by way of their metabolic capabilities, the vastly different diets of these two host species. Thus, humans and cows have different gastrointestinal ecologies.

What do symbionts do in the ruminant digestive tract? The biochemical reactions that occur in the rumen are complex and involve a wide variety of microorganisms. As we will see later in this section, the community profile can change with diet. Modern farming focuses on rapid growth, which means domestic ruminants are often fed starch-rich grains and protein-rich legumes. The natural diet of ruminants, however, is cellulose-based grasses and leaves. **Figure 17.22** shows an overview of cellulose conversion in the ruminant.

A variety of bacteria and protozoa hydrolyze cellulose to glucose and then ferment this to organic acids. The major organic acids that are the end products of rumen fermentation are the short-chain fatty acids acetate, propionate, and butyrate (see Figure 13.20). These are absorbed directly through the rumen into the bloodstream to become the primary energy source for the ruminant. Bacteria appear to be responsible for the majority of fermentation in ruminants. Many of the protozoa are actually predators of the bacteria, maintaining the ecological balance in the rumen **(Figure 17.23)**.

CONNECTIONS In eukaryal cells, acetate, propionate, and butyrate are converted to acetyl-CoA and oxidized through the TCA cycle in mitochondria, ultimately releasing ATP for the animal's metabolic needs. See **Section 13.3** for a review of the TCA cycle.

Numerous other biochemical pathways form a complex web of reactions that support the ecology of rumen microbial populations. Many rumen microbes produce other compounds as fermentation end products such as lactate, succinate, and ethanol. However, appreciable amounts of these are not normally found in rumen contents. These products are quickly further

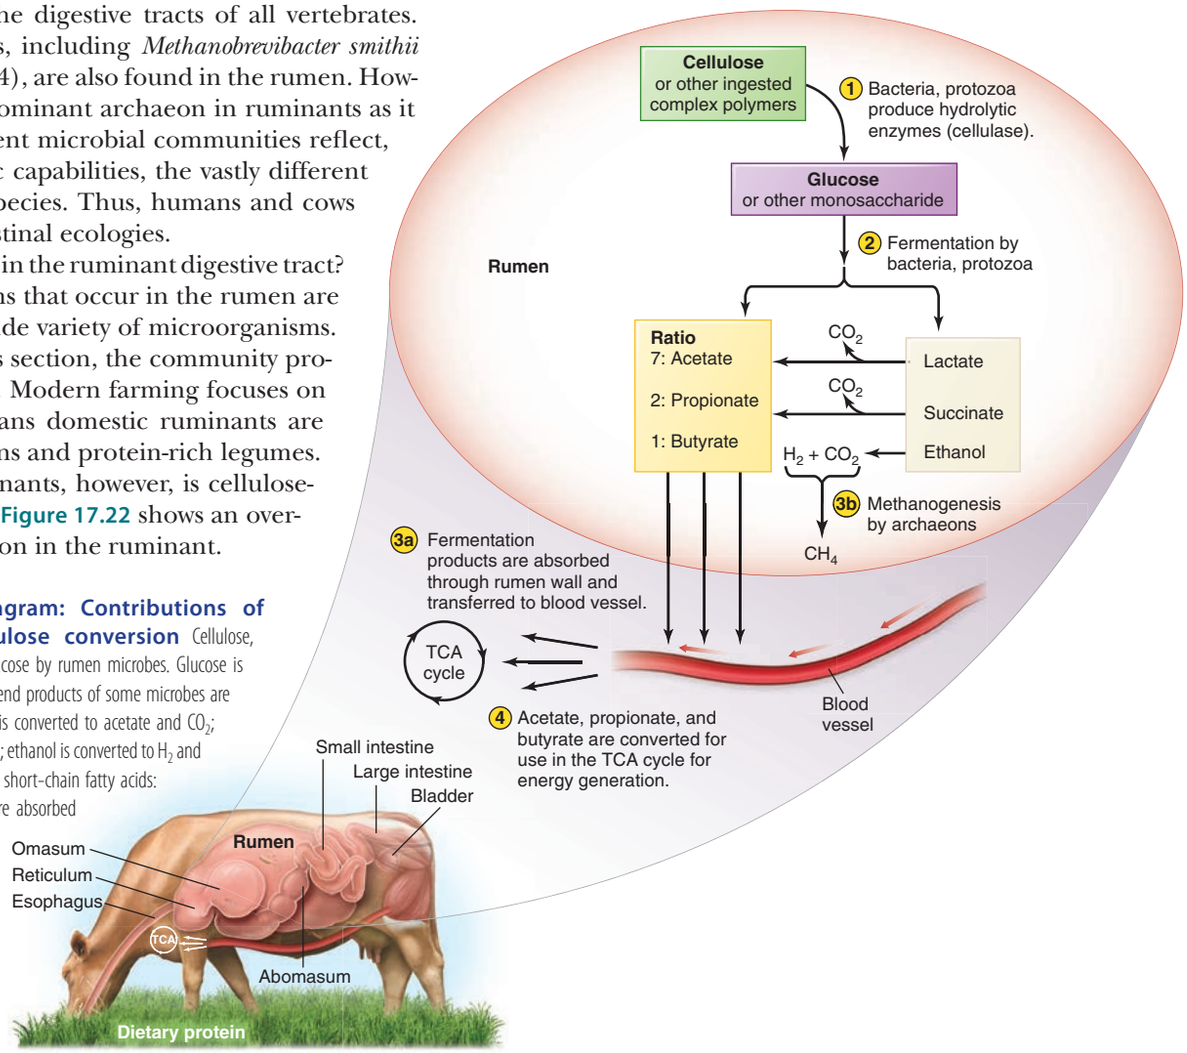

Figure 17.22. Process Diagram: Contributions of rumen symbionts in cellulose conversion Cellulose, or similar polymers, are degraded into glucose by rumen microbes. Glucose is taken up by microbes and fermented. The end products of some microbes are converted by others. For example, lactate is converted to acetate and CO_2; succinate is converted to propionate and CO_2; ethanol is converted to H_2 and CO_2. The major waste products include the short-chain fatty acids: acetate, propionate, and butyrate. These are absorbed through the rumen wall, diffuse into the bloodstream, and are delivered to host cells where they enter the TCA cycle as an energy source for generating ATP. The gases CO_2 and H_2, also fermentation waste products, are converted to CH_4 by methanogenic archaeons, and expelled by the host.

Figure 17.23. Predatory protozoa of the rumen Micrograph of protozoa from a cow rumen. Many protozoa feed on the bacterial inhabitants of the rumen, maintaining homeostasis.

metabolized by other rumen microbes (see Figure 17.22). Methanogens can reduce excess acetic acid to methane (CH_4) and convert CO_2 and H_2 into CH_4. You may recall from our investigation of fermentation in the human colon, the removal of H_2 by methanogens helps fermentation efficiency by keeping this rate-limiting end product in low concentration. This results in the production of more acetate, propionate, and butyrate, and therefore more energy for the herbivore. Some of the anaerobic gut bacteria can convert CO_2 and H_2 into acetic acid, a process known as acetogenesis, further increasing the amount of acetate available for uptake. Acetogenesis occurs according to the following reaction:

$$2\ CO_2 + 4\ H_2 \rightarrow CH_3COOH + 2\ H_2O$$

An equally valuable contribution of the rumen microorganisms is their ability to convert the nitrogen compounds urea and ammonia (NH_3) into amino acids (see Figure 13.42). Dietary sources of urea and ammonia come from protein and other nitrogenous components of digested plant material, but are also produced endogenously by the ruminant as metabolic waste products from the breakdown of amino acids (Figure 17.24). Urea and ammonia diffuse into the bloodstream and are transported into the rumen, where the microbes recycle them into amino acids (see Figure 13.45). Cellulolytic bacteria are extremely efficient at this nitrogen conversion. It is estimated that 50–80 percent of microbial protein in the rumen is produced using urea and ammonia. Ruminants benefit from this microbial activity in several ways, including:

- Supplying cellulolytic microbes with these nitrogen compounds facilitates their growth increasing the digestion of cellulose and enhancing fermentation. This increases the harvest of fermentation products by the host.
- Digesting rumen microbes provides a source of protein for the ruminant. This allows ruminants to exist on poor-quality food, such as grass, which is low in protein and amino acids.

Most of the amino acids harvested by the host from digestion of rumen microbes are incorporated into muscle protein, an important consideration for the commercial production of food animals. Recapturing amino acids from microbes gives ruminants an advantage when feeding on protein-poor diets in comparison to cecal and colonic fermenters, who pass most of their microbes in an undigested form in feces. Consequently, cecal and colonic fermenters must either eat more or be fed higher quality and more expensive food. Pound for pound, it is more expensive to feed a pig (colonic fermenter) or a horse (cecal fermenter) than a cow or sheep (both ruminants), all other conditions being equal.

CONNECTIONS Recall from **Section 17.2**, legumes such as clover and alfalfa have mutualistic relationships with bacteria that can fix N_2 and convert it into amino acids for plant use. Therefore, these plants are highly nutritious, being rich in protein and amino acids.

Non-cellulose carbohydrates, such as starch and pectin (composed of units of galacturonic acid), are also present in plants and fermented by various microbes. Not surprisingly, changing the diet of ruminants can alter the specific proportions of microbes in the rumen. Table 17.4 shows some bacteria known to dominate the rumen contents of cows fed with different diets.

Studying rumen microbiology helps us understand the many serious consequences of diet-related changes to ruminant microbial communities, which have enormous effects on the health and development of the animal. For example, a rapid switch to starch-rich grains from grass can cause a drastic drop in rumen pH, a condition known as acidosis. This is due to the rapid fermentation of readily digested carbohydrates, leading to the overproduction of organic acids. Negative impacts of this process include the following:

- Increased acid is absorbed across the rumen wall into the bloodstream, exceeding the buffering capacity of blood and other body fluids, which can lead to death.
- Released acids exceed the absorption capacity of the rumen wall. The rumen begins to acidify below its normal pH of 6 to 7. This encourages the growth of acid-tolerant lactic acid bacteria such as *Streptococcus bovis*. Under these conditions, *S. bovis* grows quickly and produces large

TABLE 17.4 Diet and changes in bacterial communities in the rumen of cows

Primary diet	Primary catalytic process	Dominating bacteria
Grass	Cellulose degradation to glucose	*Fibrobacter succinogenes* *Prevotella ruminicola* *Ruminococcus albus*
Alfalfa/clover	Pectin degradation to galacturonic acid	*Lachnospira multiparus*
Corn/barley	Starch degradation to glucose	*Ruminobacter amylophilus* *Succinomonas amylolytica* *Streptococcus bovis*

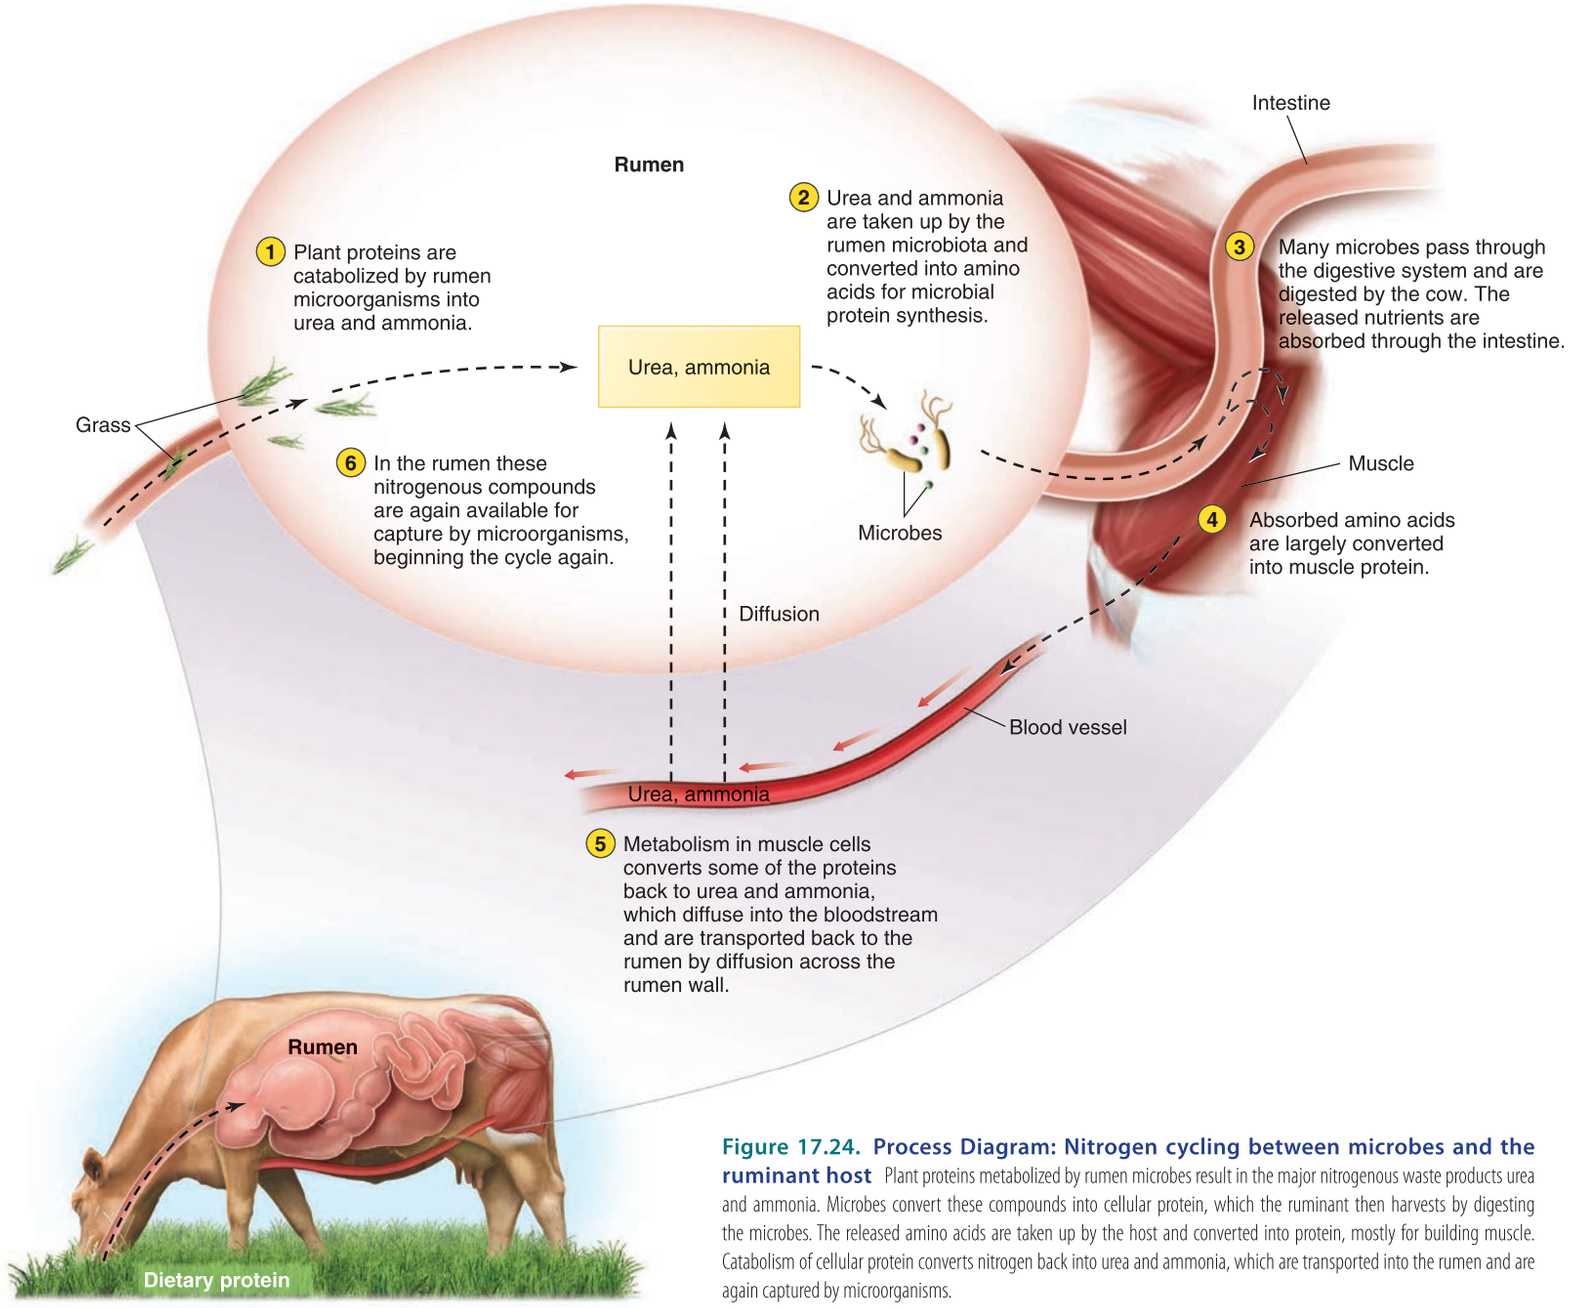

Figure 17.24. Process Diagram: Nitrogen cycling between microbes and the ruminant host Plant proteins metabolized by rumen microbes result in the major nitrogenous waste products urea and ammonia. Microbes convert these compounds into cellular protein, which the ruminant then harvests by digesting the microbes. The released amino acids are taken up by the host and converted into protein, mostly for building muscle. Catabolism of cellular protein converts nitrogen back into urea and ammonia, which are transported into the rumen and are again captured by microorganisms.

quantities of lactic acid, further acidifying the rumen. When the pH drops to 5.5, a large proportion of rumen microbes are killed. Rumen food cannot be further processed and does not move out of the rumen. The animal stops feeding and can weaken and die.

Avoiding acidosis can be accomplished by a gradual change to a grain-rich diet. This allows rumen communities to reach a new and stable equilibrium that maintains normal levels of organic acids.

Microbial fermentation produces gaseous waste products, and ruminants can generate startling quantities, consisting mostly of CO_2 (45–70 percent) and CH_4 (20–30 percent). For cows, gas production is estimated to be between 200 and 400 liters *per day*. This gas must be expelled regularly, through eruction, which is similar to belching (another interesting mannerism of ruminants, imparted by their microbial inhabitants). With such large quantities of gas being generated, anything that interferes with the expulsion of gas can be deadly to the ruminant. A condition called bloat occurs when gas cannot be expelled. The rumen quickly expands to an extreme size, restricting internal organs, resulting in respiratory collapse and death. In most cases, bloat is caused by improper diet and is usually associated with a sudden switch from cellulose-based grass to fresh clover or alfalfa, foods rich in protein. The large quantities of protein that are released rapidly by microbial degradation act as foaming agents that mix with gas to create froth in the rumen slurry. This effectively traps the gas instead of allowing it to rise freely for release by eruction. It was once common practice to relieve the pressure caused from bloat

Perspective 17.2
COWS CONTRIBUTE TO CLIMATE CHANGE

In reading the previous section, you may have recognized that the major gases produced by cows—carbon dioxide and methane—are greenhouse gases. When present in the atmosphere, these gases trap radiant energy, preventing its dissipation to space. Thus, cows pose a concern for climate change because methane is a potent greenhouse gas. Cow populations have increased greatly over the past century as a result of human demand for meat and dairy products. Currently, there are an estimated 1.4 billion cattle on the planet—a source of approximately 15 percent of the total methane released into the atmosphere. When you consider the biochemistry involved in methane production in cows, it is their microbes that present the problem, although the two can hardly be separated. Researchers have been trying to find ways to reduce methane production in cows. They have found that high-quality feeds, like alfalfa pasture, results in significantly less methane than cattle kept on grass pasture **(Figure B17.3)**. However, high-protein diets are more costly to supply and increase the danger of bloat.

Courtesy Christine Dupont

Figure B17.3 Cows grazing on grass Cattle fed grass produce more methane than those fed high-protein fodder, such as alfalfa.

by stabbing the animal in the rumen. Surprisingly, many lived through this! Nowadays, antifoaming agents are commonly administered. **Perspective 17.2** describes another consequence of rumen gas production.

All animals studied so far have microbial symbionts. In most cases, the host and the symbionts are inextricably connected. From a molecular and ecological perspective, animals, as well as many plants, must be viewed as a conglomerate of species. Adopting this holistic view is certainly a step forward in understanding the checks and balances that affect host health and how disruptions in the host/microbe ecology contribute to disease.

17.4 Fact Check

1. Explain the advantage of foregut fermentation versus hindgut fermentation for herbivores.
2. What are the major end products of fermentation in the digestive system of animals? What is their importance?
3. Explain why ruminants can exist on poorer quality food than cecal fermenters.

17.5 Symbionts of invertebrates

What are the roles of symbionts in invertebrates?

Symbiotic microbial relationships occur widely within invertebrates. Housing for these symbionts ranges from colonization in the gut lumen to the formation of specialized cells, and even organs, whose exclusive function is cultivating endosymbionts in the host. You may recall that this was the case for deep sea giant tube worms, introduced in Chapter 13. For many of these invertebrates, the symbioses are obligate relationships that have developed through evolution.

Commonly, the symbionts of invertebrates, like those of vertebrates, are not readily cultured in the lab. Therefore, much of what is known about their existence and ecology is often based largely on DNA sequencing. Such molecular technologies have given new insights into the world of microbes by allowing us to glimpse some of their genes, and through this, some of their biochemical activities. Estimates based on such molecular analyses show that 15–20 percent of all insect species have nutritional bacterial symbionts and often harbor multiple symbionts. Fewer species carry yeast or protozoa. Common to almost all of these insects is an incomplete diet that lacks essential nutritional components such as amino acids, sterols, or vitamins. As you might guess, the symbiotic microbes produce these required or supplementary nutrients, which are needed for proper development and reproduction. For example, aphids extract plant phloem or xylem fluid (known as sap), which is rich in sugars but low in amino acids and other nitrogenous compounds required by the aphids. Tsetse flies feed exclusively on vertebrate blood, which lacks several vitamins needed for fly fertility. Termites consume cellulose from wood and other dead plant material, which they cannot digest efficiently themselves. In most of these partnerships, the symbiont and the host cannot survive without each other. It is an obligate mutualistic relationship. These are some of the most complex and fascinating relationships known to exist between microbes and multicellular organisms. Studying specific ways that symbionts contribute

to the health of insect pests and disease vectors also sets a foundation for the development of more effective control strategies.

How do scientists determine what nutrients are supplied by symbionts? Most studies use insects, such as aphids, that have been rendered symbiont-free, or aposymbiotic, by treatment with antibiotics. These aposymbiotic insects are then maintained on chemically defined diets that mimic their natural diet, but with additional supplemented components that support insect growth and reproduction. Researchers then compare these diets to similarly defined diets required by symbiotic aphids. Specific nutritional components needed by the aposymbiotic insects, but not needed by the symbiotic insects, are identified as being supplied by the symbionts. Such dietary comparisons have revealed the essential amino acids required by aphids, that is, those amino acids that the aphids cannot manufacture themselves. Presumably, these are made by their symbionts because plant sap lacks amino acids. Interestingly, aposymbiotic aphids do not fare particularly well compared to symbiotic insects fed similar fully supplemented diets, indicating that the symbiotic benefit may be more than just nutritional.

In most insect studies, there is often little direct evidence to demonstrate that the symbionts make essential nutrients because most symbionts cannot be cultured *in vitro* for confirmatory metabolic studies. Genome sequences, when available, can be useful in confirming that the symbionts are at least capable of synthesizing the nutrient. Whether or not the nutrient is made available to insect tissues is another question. In the pea aphid, which is the best-studied insect symbiosis, this has been confirmed for the essential sulfur-containing amino acid, methionine. Supplying symbiotic aphids with ^{35}S allows tracking of molecules into which sulfur is incorporated, and has shown the endosymbiont *Buchnera aphidicola* incorporates it into methionine, and releases this to aphid tissues **(Figure 17.25)**. Further studies show that aphids harboring *Buchnera* produce methionine whereas aposymbiotic aphids do not. Together, these results provide strong evidence that methionine is made by *B. aphidicola* and passed to the insect. Tryptophan, leucine, and the vitamin riboflavin are other compounds provided by *B. aphidicola*. Up to 50 percent of these compounds are released to the host.

Studies that compare structure, biochemistry, and genetic information of related modern insect species and their symbionts can be used to trace the evolutionary origins of the symbiosis events. Based on these comparisons, scientists group endosymbionts into two major types. **Primary endosymbionts** have evolved along with their hosts over millennia; **secondary endosymbionts** are more recently acquired. As we will see, the nature of the relationship between a host and its primary endosymbionts is quite different from the relationship between a host and its secondary endosymbionts.

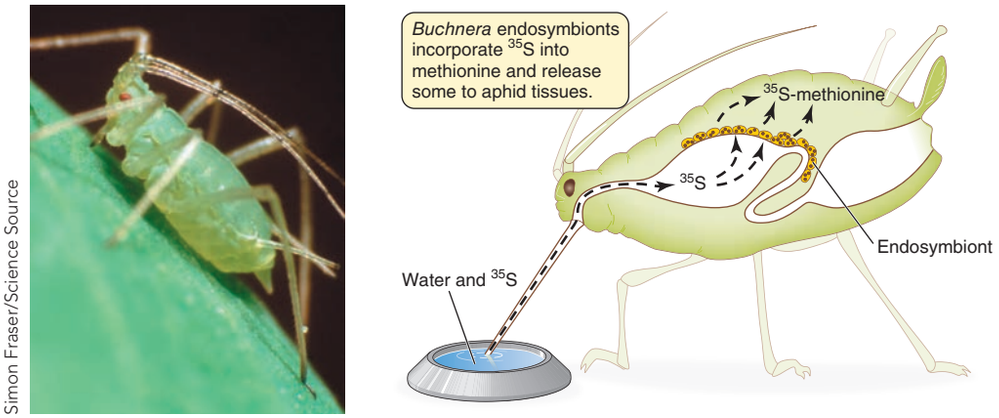
Aphids

Aphids are one of the best-studied insect/microbe symbiotic systems, and we will use them as an example to understand endosymbionts.

Primary Endosymbionts

Primary endosymbionts show evidence of **co-speciation** with their hosts, whereby an ancestral host/microbe association subsequently diversified into a number of different but related host-symbiont species. Almost all species of modern-day aphids are associated with primary endosymbionts belonging to the genus *Buchnera*. The few aphid species that lack a *Buchnera* species have a yeast primary endosymbiont instead. The aphid-*Buchnera* symbioses that we see today appear to have arisen from a single event approximately 200 million years ago. Development of symbiosis and diversification of both host and bacteria is thought to have evolved by the following scenario.

A free-living bacterium infected an aphid-like insect, and both managed to survive and propagate. The bacterial species was perhaps somewhat more successful inside the host than outside. Those bacteria that were less damaging and more beneficial to the host were more likely to be passed along from host to host. Hosts that were able to better maintain the bacteria in their cells were also more successful. The association increased the fitness of both species. To secure propagation of the intracellular microbe, the host cells became specialized to better host the bacteria. Compared to the outside world, the intracellular environment was relatively nutrient-rich and protected. Any bacterial genes used to make molecules that the bacteria could readily acquire from the host became redundant. Mutational events that inactivated these genes were of little consequence. Over time, the bacteria lost many of the genes needed for independent living, becoming more and more dependent on the host. The host became dependent on the bacterium for



A. Aphids feed on plant sap.

B. ^{35}S is converted to methionine by endosymbionts.

Figure 17.25. Evidence for methionine production by the aphid endosymbiont *Buchnera* **A.** Aphids feed on plant sap, which is lacking in several amino acids. Aphids cannot synthesize any of their essential amino acids, such as methionine. **B.** Supplying aphids with the radioactive element ^{35}S shows that ^{35}S appears first in the amino acid methionine only within the bacterial endosymbionts. Later, ^{35}S-methionine is found in the surrounding aphid tissues, indicating that it is released from the bacteria to the aphid cells.

essential nutrients, allowing the insect to feed on plants that it could not otherwise exploit as a food source. This evolution did not happen along a single path. Many different successful adaptations occurred at the genetic level in both the host and the symbiont, and these branched off to become unique pairings of species of aphids and species of *Buchnera*, which are all phylogenetically related to one another. This co-speciation is common to the development of all primary endosymbionts of insects.

All primary endosymbionts of insects have a number of common characteristics that are evidence of evolutionary events that occur during co-speciation. These characteristics include the following:

- They have highly reduced genomes.
- They are found exclusively in specialized host cells, called **bacteriocytes**.
- They are maternally transmitted through generations from mother to offspring.
- They are required by the host for survival and/or fertility.

We can examine some of these characteristics in more detail.

All insect primary endosymbionts that have been sequenced have highly reduced genomes. For example, the average genome size for *Buchnera* species is 660,000 base pairs, about seven times smaller than its relative *E. coli* K12 at 4.6 million base pairs. *Buchnera* lacks the genes required for DNA repair and recombination, and genes for making the cell wall constituent LPS (see Chapter 2). The genes for biosyntheses of amino acids essential for the aphid hosts are present, but most others are missing. Only some of the genes for the TCA cycle are present. *Buchnera* obtains TCA cycle intermediates from the host instead of generating them by the TCA cycle, which commits it to being an obligate intracellular endosymbiont.

Both gene loss and dependence on the host for biosynthetic compounds is also a common feature of obligate intracellular bacterial pathogens. Examples include *Rickettsia*, the causative agent of arthropod-borne diseases such as typhus and spotted fevers; *Chlamydia trachomatis* and *Mycoplasma genitalium*, both sexually transmitted pathogens that can cause pelvic inflammatory disease and sterility; *Mycobacterium leprae*, the causative agent of leprosy; *Treponema pallidum*, causing syphilis; and *Borrelia burgdorferi*, the causative agent of Lyme disease (see Microbes in Focus 18.5). All of these organisms have highly reduced genomes and depend on host cells to provide them with certain molecules they can no longer manufacture themselves.

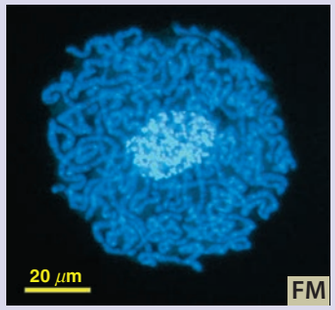
The bacterium *Candidatus* Carsonella ruddii (see Appendix C), the primary endosymbiont of a psyllid insect, has the smallest genome of any cell known to date **(Microbes in Focus 17.3)**. Astoundingly, DNA sequence analysis has shown that it has lost the ability to carry out independent DNA replication, transcription, and translation. These are three of the most fundamental requirements for life. How can this microbe possibly exist? Researchers postulate that this microorganism likely relies on using the missing gene products from the host cell, in the same way that mitochondria rely on the products encoded in the cell chromosome for carrying out processes they similarly lack (see Section 1.2). If this is true, it means *Candidatus* Carsonella ruddii may be a transition form in the road to a new cellular organelle. It is not yet known what this endosymbiont does for the host cell.

Microbes in Focus 17.3
CANDIDATUS CARSONELLA RUDDII: IS IT A CELL OR AN ORGANELLE?

Habitat: Found exclusively in bacteriocytes of the sap-sucking psyllid insect *Pachpsylla venusta*

Description: Gram-negative rod, shown here as blue-stained strands packing the host bacteriocyte cell. The nucleus of the host cell is bright blue.

Key Features: The genome consists of just 159,662 base pairs, comprising a mere 182 genes, about half the number found in *Buchnera aphidicola*. *Candidatus* Carsonella ruddii appears to have achieved an organelle-like existence, depending on the host cell to supply it with missing DNA replication, transcription, and translation factors, similar to the dependence of mitochondria and chloroplasts.



Courtesy Atsushi Nakabachi, Toyohashi University of Technology

CONNECTIONS Recall from **Perspective 15.1** (and Appendix C) that *Candidatus* designation is used for proposing species names for uncultured microorganisms for which DNA sequence information exists along with some information regarding the microbe's structure, metabolism, reproduction, and the environment in which the organism is naturally found.

Primary endosymbionts are never found in a free-living form, being present only inside host bacteriocytes. Bacteriocytes appear to have no other function but to house the endosymbiont **(Figure 17.26)**. In some aphid species, *Buchnera* in

Figure 17.26. Specialized aphid bacteriocyte cells harboring *Buchnera* endosymbionts A section of a bacteriocyte cell showing *Buchnera* cells, each approximately 35 μm in diameter, packing the cytoplasm.

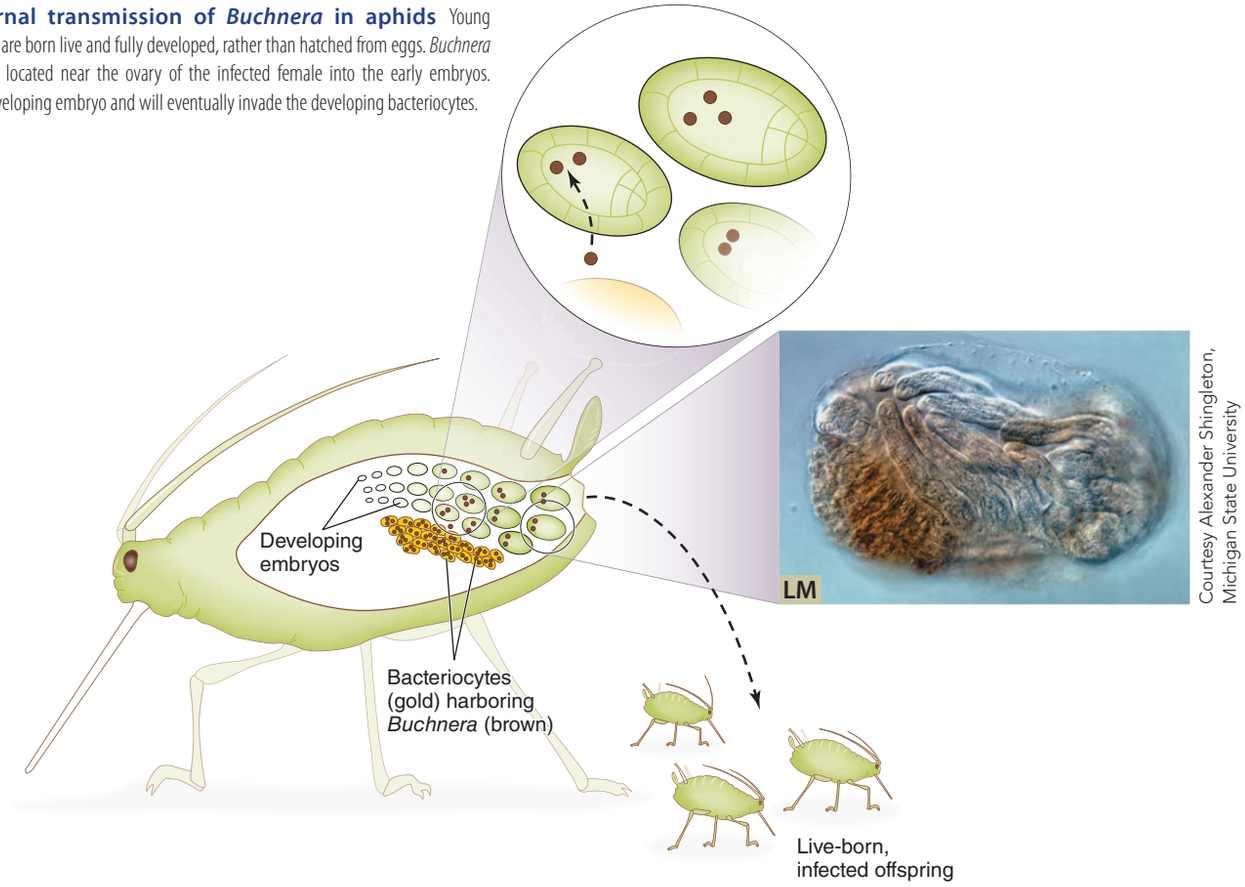

Figure 17.27. Maternal transmission of *Buchnera* in aphids Young aphids develop in the ovary and are born live and fully developed, rather than hatched from eggs. *Buchnera* migrate from the bacteriocytes located near the ovary of the infected female into the early embryos. *Buchnera* replicate inside the developing embryo and will eventually invade the developing bacteriocytes.

bacteriocytes constitute up to 10 percent of the aphid's mass. In aphids, the formation of bacteriocytes is genetically preprogrammed, and they are formed even in aposymbiotically maintained lines of aphids, indicating the profound influence this ancient relationship has had on shaping the genome, and consequently the development of the host.

If primary endosymbionts are not found free-living in the environment, how do insects acquire them? This cannot be left to chance occurrence since survival of the insect species requires possession of the primary endosymbionts. In most cases, the insects inherit them from their mother, a process termed **maternal transmission**. For aphids, which can give birth to live offspring, *Buchnera* migrate from bacteriocytes and infect the embryo as it develops inside the ovary **(Figure 17.27)**. Other modes of maternal transmission involve the deposition of the microbial symbionts or infected bacteriocytes directly on or in eggs, causing the hatchlings to become infected as they develop. In comparison, males do not efficiently transmit the symbionts and so become a dead end for symbiont propagation. As primary endosymbionts are required for their hosts, they are found in both males and females. This is the case for aphids, tsetse flies, and ticks. Maternal transmission also occurs for some secondary endosymbionts.

Secondary Endosymbionts

Many insect species harbor one or sometimes two primary endosymbionts, plus one or several other secondary endosymbionts. It is possible that some secondary endosymbionts may eventually become primary endosymbionts. Secondary endosymbionts show much more diversity in terms of their association with the host. Their characteristics include the following:

- They are more recently acquired and do not show evidence of co-speciation with their host.
- They can sometimes be found in the environment as free-living forms.
- They are not restricted to bacteriocytes and can sometimes be found in a variety of cells.
- They may live extracellularly in the insect gut or the body cavity.
- They are not always present or essential.
- They are not always maternally transmitted.

Some secondary endosymbionts that rely on maternal transmission are found only in females, as they are not always required by their hosts. You may recall from the chapter opening story that *Wolbachia*, a secondary endosymbiont of many insect species, is capable of skewing sexual ratios to favor females in order to perpetuate its own transmission. Depending on the host species, *Wolbachia* selects for females by one of the following:

- "Male-killing": death of infected male embryos (as is the case for the blue moon butterfly).
- Cytoplasmic incompatibility: infected males are unable to produce viable embryos when mated with uninfected females or even females infected with a different strain of *Wolbachia* (as is the case for the mosquito *Culex pipiens*).

- Parthenogenesis (no males required): unfertilized eggs develop into embryos (as happens with some mite and wasp species).
- Feminization: converts genetic males to fertile females or sterile pseudo-females (as happens in the Asian corn borer moth).

How *Wolbachia* actually carries out any of the reproductive manipulations is not yet known.

For some endosymbionts, being a mutualist or a parasite may be a matter of degrees. Where the *Wolbachia* symbiosis falls on the symbiosis continuum is a matter of speculation. In *Drosophila, Wolbachia* infection appears to diminish a fly's lifespan by 50 percent, suggesting that it is parasitic. On the other hand, *Wolbachia* kills males. Reducing male populations may offer a competitive advantage to the females for food and habitat, in turn increasing the success of *Wolbachia* and *Drosophila* as a species in a mutualistic manner. The European tick *Ixodes ricinus* is an ectoparasitic symbiont of several animal species and is an important vector species of human Lyme disease, caused by *Borrelia* species in western Europe. The tick harbors a bacterial endosymbiont, of proposed name *Candidatus* Midichloria mitochondrii, which lives not only inside the tick, but *inside* the mitochondria themselves **(Perspective 17.3)**. The endosymbionts enter cells of the ovary and appear to take over many of the mitochondria in a parasitic manner, using the membrane-bound organelle as a nutrient source and brood chamber within which to multiply. Despite this takeover, they are not obviously damaging to ticks and may even be mutualistic. *Candidatus* Midichloria mitochondrii are present in all female ticks and, to ensure their transmission, they invade the eggs in the ovary and establish themselves in mitochondria of the developing ovarian tissue of new female offspring.

Termites

Termites fall into two evolutionary groups. "Higher" termites primarily feed on plant materials found in soil or on fungus. "Lower" termites feed primarily on wood. Both groups of termites have a metabolic dependence on the microbes they harbor in their digestive tracts. Despite being first observed in 1856, little is known about these microbes, largely because their populations are hugely diverse and the majority resist cultivation attempts. The symbionts found in lower termite guts consist of a consortium of protozoa, bacteria, and archaea that live freely in the lumen of the termite gut, but most surprising

Perspective 17.3
MIDICHLORIANS—NOT JUST FOR JEDI

Even George Lucas, the creator of *Star Wars*, was impressed with the endosymbiotic relationships of microbes. His fictional midichlorians—those endosymbiotic entities that exist in all life-forms and communicate with "The Force"—played a prominent role in the *Star Wars* universe. Jedi knights possessed the highest concentrations of midichlorian symbionts in their cells. Mr. Lucas based the concept of midichlorians on the endosymbiotic theory that gave rise to mitochondria and chloroplasts of eukaryal cells (see Section 3.4). To honor the concept of midichlorians, a bacterial endosymbiont of the tick species *Ixodes ricinus* has been given the proposed name of *Candidatus* Midichloria mitochondrii (see Appendix C). This is the first bacterium discovered to reside *within* animal cell mitochondria **(Figure B17.4)**, which was once an endosymbiont itself.

Figure B17.4. *Candidatus* Midichloria mitochondrii Endosymbionts can be seen within mitochondria. Intact mitochondria are also present in the host cell.

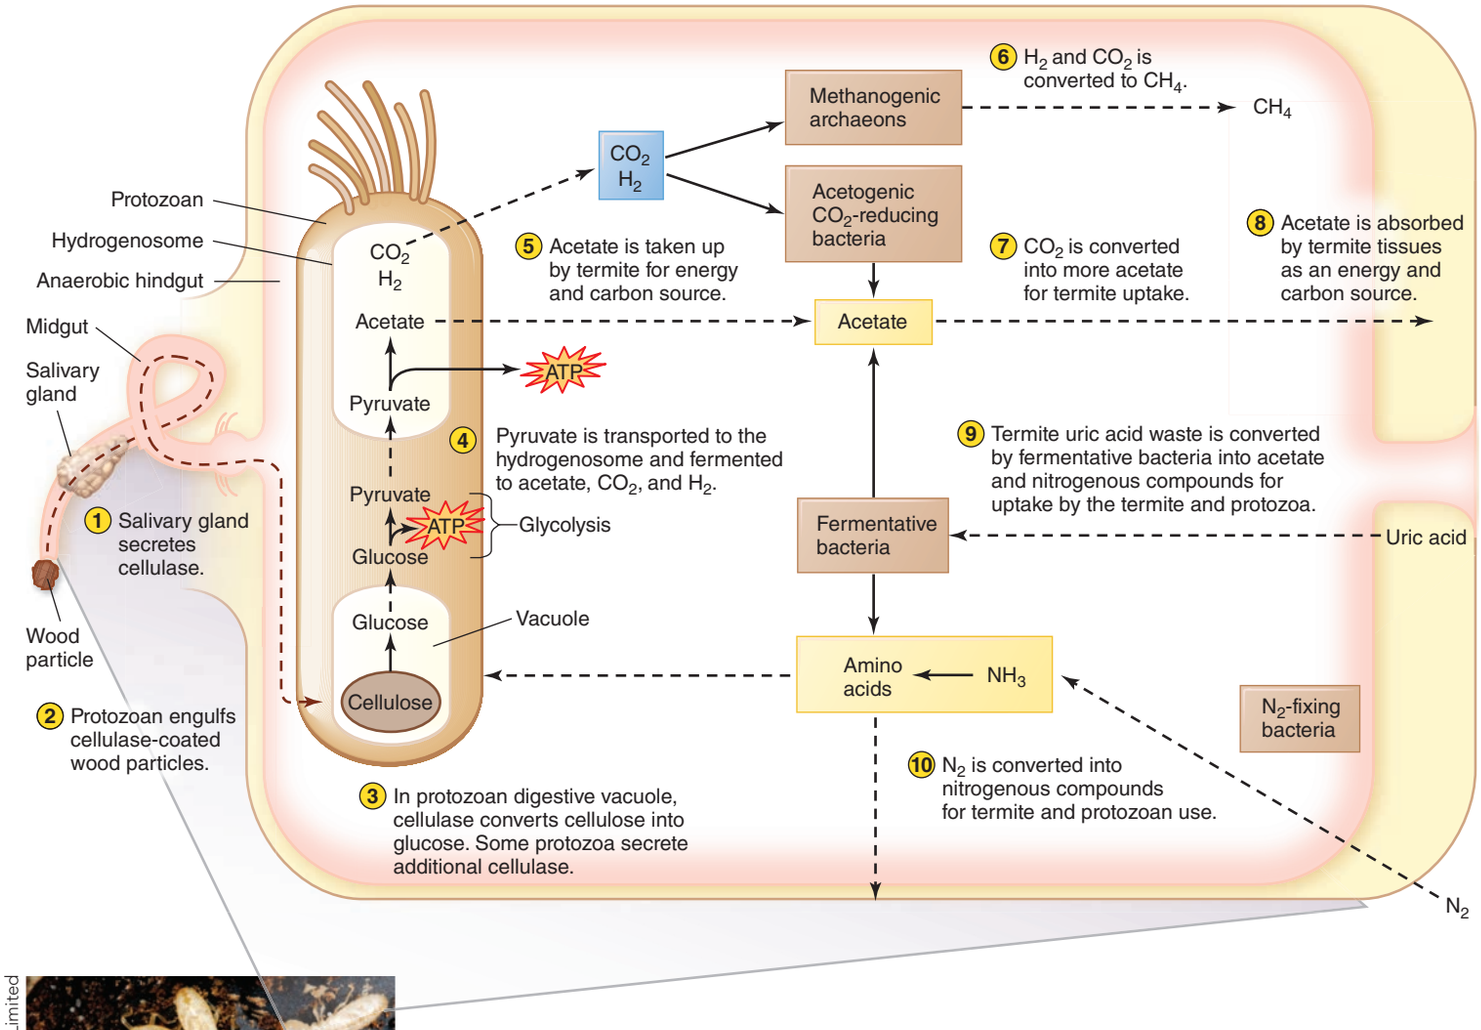
is the finding that some bacteria reside *inside* many of the symbiotic protozoa—endosymbionts of endosymbionts! Higher termites do not possess protozoa or archaea, but only bacteria. In this section, we will look specifically at the lower termites.

Lower termite species are major insect pests, most notorious for eating houses. They selectively eat dead plant material and lumber makes an attractive meal. Termite diets consist primarily of cellulose; the nutrient-rich contents of the cells are long gone. An exclusive diet of cellulose lacks nitrogen, which is needed for the biosynthesis of compounds, such as amino acids, vitamins, and nucleotides. How then do termites survive on such a poor diet?

Over 400 different species of protozoa have been documented from various lower termite species and are estimated to make up an incredible 30–50 percent of the weight of the termite (see Figure 3.25).

Symbiotic relationships between termites, their protozoa, and bacteria are quite different from those found in herbivores. The major fermenting microbes in the termite gut are protozoa, not bacteria. Wood particles are first chewed into small pieces by the termite. Termites are one of a very few animals capable of producing their own cellulase. Cellulase is secreted by the termite salivary glands and attaches to the ingested cellulose particles. These move through the midgut and into the anaerobic hindgut where most of the microbial metabolic action occurs. **Figure 17.28** shows a summary of the major contributions of symbionts thought to occur in the termite.

As mentioned earlier, termites need nitrogen compounds for biosynthesis, and these are not found in their cellulose-rich diet. Nitrogen-fixing bacteria can convert N_2 into nitrogenous compounds, such as ammonia, for termite use. These bacteria utilize the acetate released from protozoan fermentation as an



Scott Camazine/Alamy Limited

Figure 17.28. Process Diagram: Metabolic activities of symbiotic microbes of lower termites Termite salivary glands produce cellulase that coats chewed cellulose particles. The particles move into the anaerobic hindgut (size exaggerated) and are engulfed by protozoa. This begins the protozoan conversion of cellulose to acetate, CO_2, and H_2. Acetate is an energy and carbon source for the termite. H_2 and CO_2 are converted by bacterial symbionts to more acetate, and to CH_4 by archaeons. Nitrogen compounds are synthesized by bacteria for termite and protozoan use.

energy source for this process. Nitrogen compounds are also contributed by fermentative bacteria that break down the termite waste product uric acid and convert it to ammonia, which can be released to the termite. Whereas released ammonia can be directly assimilated by the termite, the symbionts can convert the ammonia into other nitrogenous compounds, such as amino acids for their own growth. To access this microbial nitrogen, termites routinely regurgitate and share their hindgut contents, upon request from their fellow termites, who then digest it in their foregut and midgut.

The hydrogen and CO_2 that are waste products of the protozoa are captured by methanogenic archaea. They use hydrogen as an electron donor to convert CO_2 into methane gas (CH_4). Recall that methanogens increase fermentation efficiency by removing the inhibiting end product H_2. This results in the production of more acetate, and therefore more energy for the termite. As in the rumen, some termite gut bacteria carry out anaerobic acetogenesis by converting CO_2 and H_2 into acetate. This further increases the amount of acetate available for uptake. Interestingly, the mix of methane, acetate, and other metabolic products of the termite digestive system can be detected by sniffer dogs. Well-trained dogs have a very high rate of success in locating termite infestations.

CONNECTIONS Acetate is a common end product of mixed-acid fermentation reactions, and can be further utilized by organisms capable of carrying out the TCA cycle and aerobic respiration. See **Sections 13.3** and **13.4** for a review of these metabolic pathways.

The role of the intracellular bacterial inhabitants of the protozoa remains a matter of speculation. They do not appear to contribute to the cellulolytic activity in their protozoan hosts. Protozoa that have had their bacterial endosymbionts eliminated by antibiotic treatment can still degrade cellulose. The intracellular location of the bacteria is also not a result of phagocytosis or infection. Analysis of 16S rRNA genes show that these endosymbiotic bacteria are related to each other, but are not related to bacteria residing free in the gut. The nature of the protozoa and their bacterial symbionts remains enigmatic.

Shipworms

Shipworms are termites of the sea. There are about 65 different marine species, and many are known for eating the timber hulls of ships and wood pilings of wharves. Shipworms are actually bivalve mollusks, related to clams. Their soft bodies look like worms, but they have a shell that they use to scrape shavings from wood for food, making burrowing holes that soon riddle the wood, much like that seen in houses with termites (**Figure 17.29**). Like termites, their diet consists of cellulose. Whereas termites rely on a multitude of microbes in their digestive tracts for their nutritional needs, shipworms have only a few species of bacteria, and surprisingly, they are not in the digestive tract. Instead, the bacteria are housed in the gills inside bacteriocytes that form a specialized gland-like organ from which the endosymbionts secrete cellulases. The duct of the gland runs into the digestive tract, where the cellulose is degraded into glucose for use by the shipworm. Shipworms also need nitrogenous compounds, and as you have likely guessed, they get these from N_2-fixing endosymbionts. Again, this is similar to termites. Surprisingly, *Teredinibacter turnerae* can both secrete cellulase and fix nitrogen in association with shipworms, which is a dual metabolic accomplishment rarely found in the bacteria.

The shipworm endosymbiont *T. turnerae* has some commercial interest. First, cellulases produced by symbionts of wood-eating species, like termites and shipworms, may be valuable for the production of ethanol from cellulose crop wastes, a renewable alternative to fossil fuels, discussed in Section 12.4. Second, the rare combination of cellulose degradation and N_2 fixation in a single, culturable bacterium makes it a candidate for producing protein from waste cellulose without the need for nitrogen fertilizers. It may therefore be useful for producing a cheap protein-rich animal feed supplement. Third, *T. turnerae* produces a very stable protease that remains active at high temperatures (50°C for at least 60 minutes), tolerates a wide range of pH (4–12), is functional in high-salt concentrations up to 3M NaCl, and is stimulated by oxidizing agents, such as hydrogen peroxide. These characteristics would make this protease a useful addition to laundry detergents and other cleaning agents.

B. Shipworm tunnels

Figure 17.29. Shipworms: "Termites of the sea" **A.** *Bankia setacea* shipworms on a submerged timber. The main body of the shipworm mollusk is hidden inside the timber. Their siphons, through which they take water in and expel waste material (the pinkish pellets), are all that can be seen. **B.** Damage is caused by consumption of wood particles as the shipworms tunnel through the wood. Shipworms harbor bacteria in a specialized organ from which the endosymbionts secrete cellulases. One of these endosymbionts, *Teredinibacter turnerae,* can fix nitrogen as well as digest cellulose.

Corals

All corals possess photosynthetic algal endosymbionts, called **zooxanthellae**, which are mutualistic partners of the coral polyps. The majority of zooxanthellae are dinoflagellates of a single genus *Symbiodunium*. In the coral, they are contained within specialized intracellular vacuoles, called "symbiosomes" found in the cells surrounding the gut **(Figure 17.30)**. In many cases, the zooxanthellae make up the majority of the cellular mass of the coral, indicating it has a major role in coral biology. What is this role?

The lifeblood of the coral is the photosynthetic activity of the zooxanthellae. The zooxanthellae supply the coral polyps with carbon compounds, primarily in the form of glycerol, through the fixation of CO_2 (see Section 13.6). Up to 95 percent of the glycerol is transferred to the coral tissues. Without the zooxanthellae, corals starve because most species cannot acquire enough carbon from their captured diet to meet their needs **(Perspective 17.4)**. The coral, in turn, supplies the zooxanthellae with concentrated CO_2 from cellular respiration, which is needed to maximize the photosynthetic biosynthesis

Perspective 17.4
DEATH OF CORAL REEFS

Zooxanthellae are the pigment producers of corals, with different species giving distinctive colors to various types of coral. Death or expulsion of the zooxanthellae results in loss of color, termed "bleaching" **(Figure B17.5)**. Prolonged bleaching results in death by starvation of the coral, leaving only the skeleton. Corals can regain their symbionts from the environment and recover, as long as bleaching has not been prolonged.

The events that mediate bleaching are not precisely known. Laboratory studies indicate changes in pH, UV radiation, salinity, and temperature can cause the coral to expel and often digest their zooxanthellae, but this has not been definitively demonstrated in the complex environment of nature. Pathogen outbreaks have sometimes been the cause of bleaching events. Although these factors fluctuate with natural events, such as hurricanes and deep water upwellings, most scientists agree that the rate and extent of recent bleaching events is not completely normal.

Prior to the 1980s, coral bleaching was a rare and isolated event. Since then, massive mortalities of corals and their reef communities have expanded to many areas. Most analyses point to climate change, largely due to human activities, as the main cause of these bleaching events. Climate change is considered the primary threat to the world's remaining reefs. In 1998, the increased ocean temperatures brought by el Niño caused significant bleaching of 60 percent of the world's reefs. Changes in the average reef water temperatures of just 1° or 2°C for several consecutive weeks is not tolerated, and the corals die.

© Michael Patrick O'Neill/Science Source

© Mark Conlin/Alamy Limited

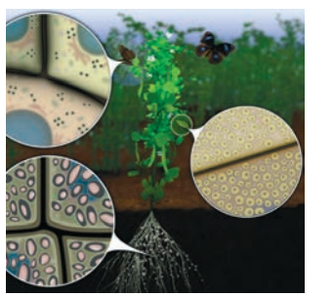
Figure B17.5. Effects of coral bleaching The coral on the *left* has intact endosymbiotic zooxanthellae, and consequently the reef community is diverse with numerous animals. The coral on the *right* has undergone bleaching—the result of the death of the zooxanthellae. The coral dies, resulting in loss of productivity, fewer animals, and less diversity overall.

of carbon compounds by the zooxanthellae. The coral, of course, also supplies the algae with a protected environment. The carbonate skeleton produced by most coral species is a formidable fortress, protecting the zooxanthellae from currents and predators. The mutualistic resource coupling between the coral and zooxanthellae is the foundation for the spectacular diversity of vertebrate and invertebrate species found in coral reefs. Fish, invertebrates, and algal species feed off the coral, and these serve as prey for other inhabitants of the reef.

17.5 Fact Check

1. Differentiate between the terms "primary" and "secondary" endosymbionts of insects.
2. Outline and explain how the aphid-*Buchnera* symbiotic relationship is believed to have developed.
3. Why do endosymbionts evolve to have highly reduced genomes?
4. What is maternal transmission? Explain why this process is necessary for primary endosymbionts.
5. Describe the role of symbiotic protozoa in lower termites. What metabolic products are provided by the protozoa?
6. Describe the location and role of symbiotic bacteria in shipworms.
7. What are zooxanthellae, and what role do they play as symbionts?

Image in Action



WileyPLUS Learning Space This illustration shows three different instances of microbial symbiosis. The pea plant acts as a host to N_2-fixing bacteria known as rhizobia, which infect the plant root and eventually form elongated nodules. The pea plant is also host to a pea aphid (*right*). *Buchnera aphidicola* are bacterial endosymbionts typically found in specialized cells known as bacteriocytes in aphids. A male and female blue moon butterfly are shown at the top with the ovary of the female butterfly infected with bacteria of the *Wolbachia* genus.

1. If you were to analyze the mature root nodules in this image genetically, what bacterial genes related to nodule formation would be expressed? What genes are expressed to initiate nodule formation? Explain.
2. While examining the genome of *Buchnera aphidicola*, the aphid symbionts in this image, you determine that several genes for production of certain amino acids and many needed for the TCA cycle are missing. What does this genetic finding tell you about the symbiotic relationship between the aphid and *Buchnera*?
3. Like many endosymbionts of insects, *Wolbachia* relies on maternal transmission. What is meant by this term, and do you think this is a successful infection strategy? Defend your answer.

The Rest of the Story

The *Wolbachia* story has yet another interesting twist. Filarial diseases in humans, such as river blindness (onchocerciasis), elephantiasis (lymphatic filariasis), and heartworm disease in dogs, are caused by species of filarial nematodes that are transmitted by biting flies and mosquitoes. River blindness alone is estimated to affect over 18 million people in Africa, the Arabian peninsula, and Latin America. In 1994, the Filarial Genome Project was established, funded by the World Heath Organization. Researchers hoped that sequencing the genomes of these nematodes would give new insights into disease mechanisms and lead to new controls and therapies to combat these devastating diseases. To their surprise, some of the cloned cDNA isolated from nematode cells contained gene sequences identical to those of *Wolbachia*.

Wolbachia symbionts have now been found in almost every species of filarial nematode where they appear to be obligate mutualists. As in arthropods, *Wolbachia* is maternally transmitted through the reproductive tract of female nematodes. Because it is found in 100 percent of worms in affected species, *Wolbachia* is a potential target for filariasis control. Even more amazing is that recent studies indicate that much of the damage from filarial diseases is not caused by the worm but by *Wolbachia*. Components of the bacterium are released by dead worms and initiate damaging inflammatory immune responses (see Section 19.4). Treating patients with antibacterial drugs that can be taken up by the worm could be an effective treatment for these diseases because the worms require *Wolbachia*. Indeed, recent clinical trials using antibiotics have shown great success in preventing disease and halting reproduction of the worms in the host. Researchers are hopeful that antibiotic treatment of patients will also prevent transmission of filarial nematodes from humans to mosquitoes, breaking the cycle.

Summary

Section 17.1: What is a symbiont?

A **symbiont** is an organism that has, through evolution, developed an intimate association with another species. The relationship is referred to as **symbiosis**.

- There are three general types of symbiosis; **Parasitism**, where one species benefits by harming the other, **commensalism**, where one species benefits and the other is neither harmed nor benefited, and **mutualism**, where both species benefit.
- Many symbioses do not fall neatly into the above three categories at all times.
- **Lichens** are a mutualistic partnership between a **mycobiont** and a **photobiont**.
- Many symbioses involve multiple species of interdependent symbionts existing together as a consortium.
- Symbionts can be described according to their placement on or in the host. **Ectosymbionts** live on the surface of their host and **endosymbionts** live within the tissues or even within the cells of their host.

Section 17.2: What roles do microbial symbionts play in plants?

Most plants have symbiotic relationships with soil microorganisms.

- **Endophytes** are plant endosymbionts.
- **Rhizobia** are endophytes that can infect plant root cells to become N_2-fixing endosymbionts known as **bacteroids**.
- The formation of a **root nodule** requires cooperation between the rhizobium and the plant.
- The expression of bacterial *nod* genes needed to initiate nodule formation occurs only in the presence of a compatible host plant.
- Invasion of the plant root begins with formation of an **infection thread**.
- The root nodule provides a protected and low-oxygen environment required by the nitrogenase enzyme of bacteroids.
- Production of **leghemoglobin** by the root cells further protects the nitrogenase enzyme.
- Bacteroids in the root nodule are dependent on the plant cell for carbon compounds, which are used in the TCA cycle to generate ATP needed to drive nitrogen fixation.
- Bacteroids provide the plant with nitrogen, in the form of ammonia and/or amino acids.

Section 17.3: What are the roles of symbionts in humans?

Vertebrates, such as humans, do not harbor endosymbionts, but they commonly cultivate large numbers of ectosymbionts on their body surfaces, especially in their digestive tracts.

- Ribosomal RNA gene-sequencing projects have given insight into symbiont populations. The human **microbiome** is not completely defined, but it is enormous in terms of sheer number and species diversity.
- Symbionts are intrinsic to the good health of vertebrates. They prohibit pathogen colonization by **competitive exclusion** and production of bacteriocins. They facilitate the normal development of the intestinal mucosa. They promote normal development of immune response and assist in priming of the immune system. They participate in digestion of foodstuffs, synthesis of vitamins and essential amino acids, and nutrient conversion (synthesis of amino acids from urea and ammonia).
- Moist, warm locations generally harbor the densest and most diverse microbial populations.
- The skin is dominated by the bacterial phyla *Actinobacteria* and *Proteobacteria*, but the profile of microbiota varies locally.
- The vagina and vulva are largely colonized by species of *Lactobacillus*, which maintain an acid environment. Small numbers of transients from skin and the colon can commonly be found.
- The oral cavity is the second most populated microbial habitat in humans.
- **Plaque** is a biofilm of bacteria that forms on the tooth surface. An overgrowth of plaque leads to anaerobic conditions and a change in the population from predominantly Gram-positive streptococci to Gram-negative anaerobic bacteria. This leads to periodontal disease.
- *Streptococcus mutans* causes dental carries as it is a potent producer of lactic acid. Sucrose increases the ability of *S. mutans* to colonize the tooth.
- The **colon** is the most heavily colonized site of the human body. It is one of the largest and most diverse microbial populations known.
- **Germ-free** and **gnotobiotic** animal models are useful for studying the roles of symbionts in host metabolism and health.
- The symbiotic populations found within the lumen of the intestine form a biofilm on the outer mucous layer. They generally lack the ability to colonize the epithelium lining the digestive tract—this is an ability possessed by pathogens.
- The major products of microbial fermentation are butyrate, propionate, and acetate. These are absorbed and used as energy sources by the body.
- Methanogenic archaea convert CO_2 and H_2 to CH_4. This increases the efficiency of fermentation by keeping H_2 concentrations low.
- Human intestinal microbiota consist primarily of anaerobic bacteria from the phyla *Firmicutes* and *Bacteroidetes*, although individuals have their own unique species profile.
- Humans use **colonic fermentation** to extract some of the nutrients from otherwise undigested foodstuffs.

Section 17.4: What are the roles of symbionts in herbivorous vertebrates?

Herbivores depend on their intestinal symbionts to hydrolyze cellulose to glucose.

- **Cecal fermentation**, like colonic fermentation, relies first on the host digestive enzymes to break down and absorb food compounds. Microbial breakdown and fermentation of any remaining compounds happens afterwards, in the **cecum**.
- Some cecal fermenters, like rabbits, practice coprophagia to increase their nutrient uptake.
- **Rumen fermentation** relies first on food digestion and fermentation by the microbes in the **rumen** of **ruminants**. Fermentation products are then absorbed through the rumen. Any remaining compounds, including rumen microbes, are then digested in a manner similar to that of cecal fermenters.

- An important function of the rumen microbiota is the conversion of urea and ammonia into amino acids for microbial protein.
- Rumen fermentation is advantageous because the rumen microbes can be digested. This allows ruminants to compete more successfully than cecal fermenters on poorer quality food, low in nitrogen compounds.

Section 17.5: What are the roles of symbionts in invertebrates?

Microbial endosymbionts are of widespread occurrence in insects, particularly those whose diet lacks required nutritional components.

- Insects raised in a sterile environment or having been cleared of their symbionts by antibiotic treatment fail to thrive and eventually die of nutrient starvation.
- **Primary endosymbionts** are intracellular endosymbionts. They have highly reduced genomes, are found in specialized host cells called **bacteriocytes**, are passed through the generations by **maternal transmission**, are required by the host for survival and/or fertility, and show evidence of **co-speciation** whereby both host and symbiont have evolved into new species together.
- **Secondary endosymbionts** are sometimes found in insects harboring primary endosymbionts. They are recently acquired and do not show evidence of co-speciation with their host. They can sometimes be found free-living in the environment, are not always found in bacteriocytes, and can sometimes be found in other cells or be found extracellularly in the host body cavity. They are not always maternally transmitted, and are not always present or essential.
- Lower termites harbor large numbers of symbiotic anaerobic protozoa, bacteria, and archaea in their hindgut.
- Protozoa assist in the degradation of cellulose, converting it to CO_2, H_2, and acetate.
- Acetate is used as an energy source by the termite and is used by N_2-fixing bacteria that supply ammonia to the termite for its nitrogen needs.
- Other bacteria convert the nitrogenous compound uric acid into amino acids, vitamins, and nucleotides.
- Methanogenic archaea keep H_2 concentrations low, increasing the efficiency of fermentation.
- Some bacteria convert CO_2 into acetate, increasing the amount available for uptake.
- Shipworms possess an obligate bacterial endosymbiont that secretes cellulase, releasing free glucose for host uptake. The symbiont also fixes N_2 to produce nitrogenous compounds for the host.
- **Zooxanthellae** are photosynthetic obligate intracellular algal endosymbionts of coral polyps that supply the coral with carbon compounds, primarily glycerol, through the fixation of CO_2.

Application Questions

1. Legumes are often planted by farmers to enrich soil. Imagine you are teaching agriculture students the microbiological rationale behind this practice. Explain how this works to enrich the soil as opposed to using nitrogen-rich fertilizers.
2. Describe how mutagenesis was used to determine the role of *nod* genes in nodulation.
3. In the United States, about 75 percent of liquid soaps are labeled as "antibacterial soaps." Most of these contain triclosan or triclocarbon, which inhibit bacterial and fungal enzymes involved in fatty acid synthesis. Although these soaps do not appear to greatly reduce the spread of infections, what might they do to normal skin microbiota? Is this a concern?
4. Some patients are prescribed proton pump inhibitors for controlling gastric acid levels. Explain why long-term use of acid inhibitors can be associated with stomach and intestinal infections.
5. Coral bleaching is considered an indicator of coral reef stress. Explain the events that lead to coral bleaching and the role of the endosymbionts in this process.
6. Some endosymbionts are known for possessing highly reduced genomes. What types of genes are often missing? Explain how these organisms survive in their absence.
7. We learned that archaea are found in the digestive tracts of many animal species. What is their role in maintaining the ecology of the digestive system? What would happen if the archaea were removed?
8. Imagine you are advising a farmer who is raising grass-fed beef. He would like to change to corn feed. Advise the farmer of the microbiology implications of this change.
9. Although herbivore ruminants may consume protein-poor diets, they still obtain necessary amino acids. Explain the role of microbial symbionts in this process.
10. An Associated Press report in 2008 revealed the presence of many different antibiotics in waterways. Although the report focused on the human health implications, identify and explain some of the effects these drugs may have on other vertebrates and invertebrates, based on your understanding of microbial symbionts from this chapter.
11. In this chapter, you learned how the role of bacterial symbionts is often studied by killing them with an antibiotic such as tetracycline and observing the effects in the host. You might know of someone who requests antibiotics from the doctor even when told that antibiotics will not help. Explain to your friend what will happen to the bacterial symbionts when such drugs are taken and the health benefits that may be lost.
12. A new species of aphid has been discovered, and your lab project focuses on examining the microbial symbionts present in this species.
    a. Initially you attempt standard culturing methods but they do not yield much data. Why might this be?
    b. How might you go about pursuing your project goals without using culture methods? What lab methods are available to you and what method would you choose?
    c. Describe how the method you chose above will actually work to reach your project goal. Be specific.
13. Your assigned lab project is to determine the precise contributions of an individual bacterial species to the overall ecology in the mouse digestive tract.
    a. Explain why this might be a difficult task to undertake.
    b. Based on your reading in this chapter, what approach can you take in the lab to accomplish this goal?

CHAPTER

18 Introduction to Infectious Diseases

The summer of 1952 was especially unsettling for many Americans. The Cold War was escalating, the United States was embroiled in the Korean War, and another enemy lurked at home—poliovirus. Outbreaks of poliovirus infection had occurred in the United States since the late 1800s. By the middle of the twentieth century, these outbreaks became more common and affected more people. In 1952 alone, over 21,000 cases of paralytic polio occurred. No treatment existed then, or now.

Most often, poliovirus infection results in no overt disease or a mild disease characterized by fever, headache, and nausea. In less than 1 percent of infected people, however, the viral infection leads to paralysis and, in some cases, death. During the first half of the twentieth century, survivors of paralytic poliovirus often required the use of crutches or wheelchairs. For many people, the poliovirus-associated paralysis resulted in severe breathing problems. These individuals were placed in iron lungs, which were metal cylinders that generated negative pressure to artificially draw air into the person's lungs. In the 1940s and early 1950s, these iron lungs filled entire hospital wards.

Even though no treatment existed, people understood that poliovirus was transmitted easily and that transmission often occurred through contaminated water or direct contact. Swimming pools were closed in many communities during July and August of 1952 to help prevent the spread of the virus. In some cases, parents did not allow their children to play with the neighbors or attend summer camp. Fear of polio was rampant.

Fear was not the only response to polio. Scientists and physicians responded as well, and their work eventually led to the development of effective vaccines. Perhaps more interestingly, the poliovirus epidemics spurred other responses. Franklin D. Roosevelt, for instance, founded the National Foundation for Infantile Paralysis, the fund-raising organization now known as the March of Dimes. Through this group, millions of Americans contributed money to combat the disease, helping support important research. Additionally, individuals affected by paralytic poliovirus, individuals often reliant on crutches or wheelchairs, led efforts to decrease discrimination against people with disabilities. For instance, they fought to increase access to public buildings. These efforts eventually resulted in the passage of the Americans with Disabilities Act in 1990. The poliovirus epidemics of the early twentieth century have had long-lasting effects on areas as diverse as the public funding of research and the basic civil rights of all Americans.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Certain microbes cause infectious diseases.

- Table 18.1: Signs and symptoms of specific infectious diseases
- Microbes in Focus 18.1: Measles: A highly contagious disease
- Toolbox 18.1: Measuring the virulence of pathogens
- Figure 18.3: Genetics of a pathogen and its virulence

Although mechanisms of pathogenesis differ, some common features exist.

- Table 18.2: Virulence actions of various pathogens
- Figure 18.5: Evading host defenses through antigenic variation
- Table 18.3: Selected strategies for evading host defenses
- Perspective 18.1: Genome editing: A powerful and controversial new technique

Microbial pathogens can be transmitted in various ways.

- Table 18.4: Selected zoonotic diseases
- Figure 18.11: Prevalence and incidence: Epidemiological measures of infectious diseases in a population
- Microbes in Focus 18.3: Chikungunya virus: An emerging pathogen
- Figure 18.18: Epidemic curve and temporal pattern of an outbreak

We can determine how specific microbes cause disease.

- Figure 18.23: Genetic variations among individual hosts and susceptibility to pathogens
- Perspective 18.2: The armadillo: An ideal animal model?
- Figure 18.24: Acquisition of virulence factor genes

Pathogens evolve via various mechanisms.

CONNECTIONS for this chapter:

Pathogens can evade host defenses in various ways **(Section 7.1)**

Host genetic differences and viral pathogenesis **(Section 8.1)**

Operons and the regulation of gene expression **(Section 11.2)**

Life cycle of *Plasmodium falciparum* **(Section 23.2)**

Introduction

The human story has been closely linked with infectious disease. Bubonic plague. Smallpox. Influenza. These infectious diseases and many others—diseases all caused by microbes—have shaped our history in profound ways.

In the 1340s, the bubonic plague, a disease caused by the bacterium *Yersinia pestis*, ravaged human populations worldwide. Historians estimate that 75 million people may have died from this disease, also known as the Black Death, in just a few years. The population of Europe plummeted, decreasing by approximately one-third. The impact of the disease extended beyond the deaths of millions. With the extreme loss of life in Europe, inexpensive land became available, ultimately impacting the feudal system that was predominant before the plague; in the aftermath of the plague, many serfs had the opportunity to become landowners.

When Europeans first visited the Americas in the fifteenth and sixteenth centuries, they brought with them more than just muskets, axes, and clothes. They also brought with them a host of disease-causing microbes. Because the people of the New World had never been exposed to these infectious agents, they were especially susceptible to them. Historians now speculate that 95 percent of indigenous Americans died from these infectious diseases at the time. The ravages of smallpox, perhaps more than the guns of the Spaniards, may have led to the end of the Inca Empire, considered by some historians to have been one of the greatest civilizations ever.

In the span of less than two years, from 1918 to 1919, an H1N1 strain of influenza virus, known as the Spanish flu, traversed the globe, killing an estimated 50 million people **(Figure 18.1)**. During this time, more people died from influenza than had been killed in World War I, which had been the most destructive war in the history of humankind. In the United States alone, an estimated 675,000 people died from the flu.

Despite the enormous impact of infectious disease, we made great strides against infectious diseases throughout the twentieth century. People in developed countries experienced fewer infectious diseases because of advances in health care and sanitation. We also developed effective means of diagnosing and preventing infections and/or treating the associated diseases. With the development and mass production of penicillin, deaths in the United States due to bacterial infections dropped dramatically. The poliovirus vaccine, approved for use just a few years after the frightening summer of 1952 mentioned in this chapter's opening story, ended a major viral scourge. As deaths due to infectious diseases decreased, the average life expectancy in developed countries increased significantly (see Figure 18.1). The changes were so remarkable that, in 1968, the Surgeon General of the United States, William H. Stewart, announced, "The war against infectious diseases has been won."

Of course, we now realize that his statement of victory was premature; we clearly have not vanquished infectious diseases **(Figure 18.2)**. According to the World Health Organization (WHO), infectious diseases caused over ten million deaths worldwide in 2004. In 2013, approximately 1.5 million people worldwide died from tuberculosis and 584,000 people died from malaria. Roughly 35.3 million people are living with HIV.

As we have seen with SARS and the H1N1 strain of influenza virus, the ease of travel today means that an infectious agent can spread around the globe in a matter of days, if not hours. While our population increases, our exposure to new environments and new animals increases, leading to more frequent transfers of infectious agents from animals to humans. Because of global climate change, the ranges of certain disease vectors, such as the mosquitoes that spread malaria, West Nile virus, and Zika virus, may change. How potential changes in mosquito distribution would affect disease spread remains unclear. Finally, and perhaps most discomfortingly, our use of the very drugs lauded by Surgeon General Stewart and others has led to the evolution of drug-resistant strains of many bacteria. Today, because of the evolution in bacteria of antibiotic resistance, we may be less able to combat diseases caused by *Staphylococcus aureus* than we were 30 years ago. The battle against infectious diseases has not been won.

Throughout our exploration of microbiology, we have seen that the microbial world exhibits a dizzying array of diversity. Bacteria, archaea, viruses, and eukaryal microorganisms come in a multitude of shapes and sizes. All of these microbes, though, share at least one fundamental feature—they need

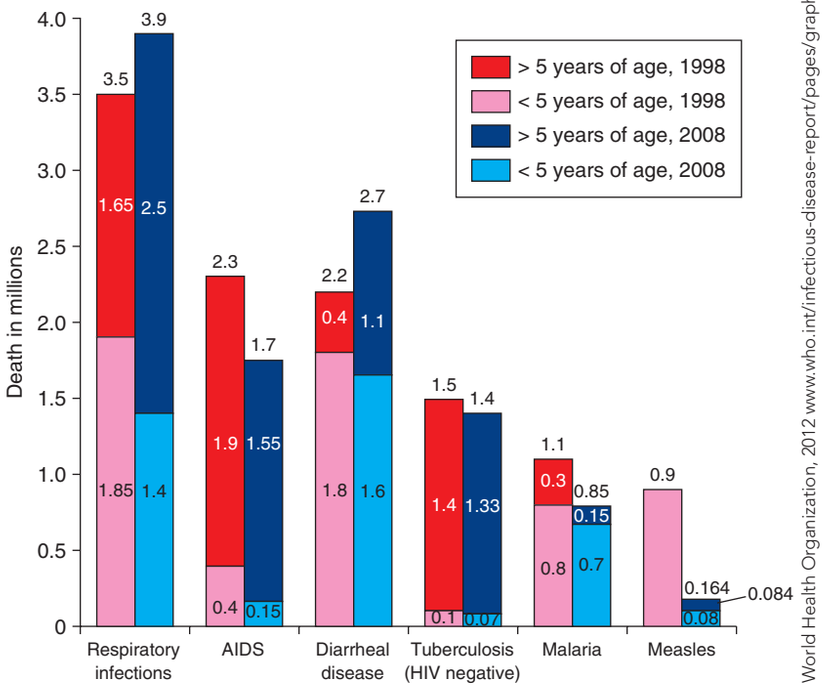
Figure 18.1. Mortality associated with the 1918–1919 influenza pandemic Throughout the twentieth century, improvements in public health, sanitation, and medical treatments caused a steady decrease in the rate of death due to infectious diseases in the United States. In association with this decrease, the average life expectancy rose significantly. The dramatic increase in infectious disease deaths in 1918 and 1919 resulted from the 1918 influenza pandemic, which resulted in the deaths of between 500,000 and 675,000 Americans.



World Health Organization, 2012 www.who.int/infectious-disease-report/pages/graph5.html

Figure 18.2. The continuing toll of infectious diseases Despite the progress made in our ability to prevent and treat infectious diseases, infectious disease burden remains high, especially in developing countries. As shown here, deaths from some infectious diseases, like measles, decreased significantly from 1998 to 2008. Deaths from other infectious diseases, like respiratory diseases and tuberculosis, remained fairly constant over this time period.

basic resources in order to replicate. This need for resources generally determines the environment in which a given microbe exists. Phototrophic organisms, as we learned in Chapter 13, obtain the energy needed to synthesize organic molecules from sunlight and, as a result, need to reside in environments where sunlight is accessible. As we saw in Chapter 17, some microbes exist in partnerships with other organisms. In these partnerships, the interaction between the organisms allows the microbe to obtain needed resources and dictates its preferred environment.

Microbes that cause disease typically obtain resources through a partnership with another organism, the host organism. The host organism can be thought of as their environment. In many respects, an infectious disease merely represents the consequence of a relationship between a host and a parasite that lives at the expense of the host. Unlike most of the microbes that we discussed in Chapter 17, these microbes damage the host in their quest for resources. This association between a host and a disease-causing agent is likely as ancient as life itself and certainly is not restricted to humans. Despite a focus of this chapter on diseases of humans, we should remember that specific microbes cause disease in respective hosts from all forms of life, including other microorganisms, plants, animals, and humans.

Let's consider the idea of infectious disease in humans a little further, using poliovirus as an example. As we noted in the opening story of this chapter, poliovirus infection can lead to neuronal damage and paralysis. More typically, viral replication is limited to cells of the gastrointestinal tract. When replicating within these cells, the virus needs an extraordinary amount of the cell's resources. To acquire these resources, poliovirus has evolved mechanisms to inhibit host cell translation, thereby maximizing the translation of viral mRNAs. As a result of the host cell translation inhibition, the infected cells die. In other words, disease occurs because of the microbe's quest for resources.

In subsequent chapters, we will focus on how hosts protect themselves from infectious diseases, how various types of microbes cause disease, and what strategies we have developed to protect ourselves from these disease-causing microbes. In this chapter, we will focus on more general topics related to infectious diseases. Specifically, we will address these questions:

What is an infectious disease? (18.1)
How do microbes cause disease? (18.2)
How are infectious diseases transmitted? (18.3)
How can we determine the cause of an infectious disease? (18.4)
How do new infectious diseases arise? (18.5)

18.1 Pathogenic microbes

What is an infectious disease?

To start our exploration of infectious diseases, let's first clarify the meanings of several commonly used terms. **Disease** generally refers to a disturbance in the normal functioning of an organism. An **infectious disease** is any disease caused by a microbe. **Communicable diseases** are infectious diseases that can be transmitted between individuals. Non-communicable infectious diseases, in contrast, generally cannot be transmitted between individuals. A **contagious disease** is a communicable disease that can be transmitted easily, often by contact or being in close proximity to another individual. With these definitions, then, we can classify tetanus, AIDS, and measles as infectious diseases. Microbes cause all three of these diseases. Tetanus is non-communicable; it occurs when the bacterium *Clostridium tetani* enters a wound and produces a toxin, but is not transmitted from person to person. AIDS is communicable. The causative agent, HIV, certainly can be transmitted from person to person. However, transmission requires the transfer of certain bodily fluids from an infected individual to a non-infected individual. Finally, measles is a contagious disease. The causative agent, measles virus, can be transmitted easily between individuals who have minimal contact with each other or are in close proximity to each other. **Zoonotic**

TABLE 18.1 Signs and symptoms of specific infectious diseases

Disease	Cause	Signs	Symptoms
Acquired immunodeficiency syndrome (AIDS)	Human immunodeficiency virus (HIV)	Opportunistic infections, decreased $CD4^+$ T-cell count	Fatigue, muscle aches
Malaria	*Plasmodium falciparum*	Fever, anemia	Muscle pain, headaches
Flu	Influenza virus	Fever	Muscle aches, malaise
Salmonellosis	*Salmonella* Typhimurium	Diarrhea, fever	Abdominal cramps

diseases are caused by microbes that naturally reside in animals and can cause disease when transmitted to humans. For example, rabies is a zoonotic viral disease that is occasionally transmitted to humans through the bite (saliva carries the virus) of an infected animal, such as a raccoon or a bat.

Microbes that frequently cause diseases are referred to as **pathogens**; the term **pathogenesis** refers to the process by which a pathogen causes disease. **Infection** refers to the replication of a pathogen in or on a host. We generally refer to subjective disease states—muscle aches, for instance—as **symptoms** of a disease. Symptoms are difficult to quantify. More objectively defined disease states that can be readily observed or measured—like a rash or fever—are referred to as **signs** of a disease. From a medical perspective, specific disturbances typically characterize specific diseases. A sore throat and muscle aches are symptoms that characterize influenza. Vomiting and diarrhea may be signs of food poisoning (Table 18.1).

Not all pathogens have the same intrinsic ability to cause disease. **Primary pathogens** tend to produce disease readily in healthy hosts. Examples include *Bacillus anthracis*, the bacterium that causes anthrax, and *Yersinia pestis*, the bacterium that causes plague. Typically, infection with these pathogens will result in disease. Conversely, **opportunistic pathogens** cause disease only under certain circumstances. As an example, let's look at the fungus *Candida albicans*. This eukaryal microorganism frequently resides in or on the human body without causing any disease. However, an overgrowth of *C. albicans* can occur among people with a weakened immune system, resulting in oropharyngeal candidiasis if the overgrowth occurs in the mouth and throat or vulvovaginal candidiasis if the overgrowth occurs in the vagina. Today, people with HIV disease represent the single largest group of people with weakened immune systems and, as a result, are the people most susceptible to opportunistic pathogens.

CONNECTIONS HIV weakens the immune system by infecting and ultimately destroying $CD4^+$ cells, a key component of the human immune system. In **Section 20.2**, the functions of T cells, including $CD4^+$ cells, will be explored.

The distinction between primary and opportunistic pathogens seems relatively clear, but the relationship between infection and disease is quite complex. Poliovirus, the pathogen that we introduced in the opening story, can be considered a primary pathogen; it causes disease in otherwise healthy, immunocompetent individuals. Every single person exposed to poliovirus does not become infected, and, as we noted, paralytic poliomyelitis only occurs in a fraction of the people who become infected. The rate of infection depends on the proportion of hosts that are susceptible to the pathogen. For instance, factors influencing a host's susceptibility to a pathogen may include prior exposure to the microbe through disease or vaccination. Genetic factors also may affect a host's susceptibility to a pathogen. Hosts that are not susceptible to a pathogen do not become infected even after they are exposed to the pathogen.

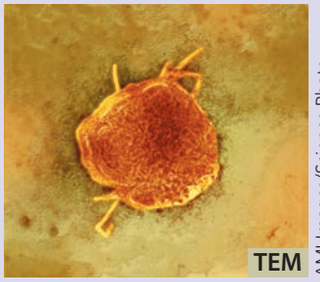
CONNECTIONS In **Section 8.1**, we examined the susceptibility of two mouse strains to mouse hepatitis virus (MHV). Because of genetic differences between the mouse strains, this virus can bind to and infect cells of one mouse strain but not the other.

The rate of disease among infected individuals also depends on the **case-to-infection (CI) ratio**, or the proportion of infected people who develop the disease. The CI ratio of different microbes can differ dramatically. Measles virus (Microbes in Focus 18.1), for instance, has a CI ratio of approximately

Microbes in Focus 18.1
MEASLES: A HIGHLY CONTAGIOUS DISEASE

Habitat: Humans; infects many cell types including respiratory epithelial cells and leukocytes

Description: Enveloped ssRNA virus in the *Paramyxoviridae* family. Approximately 150–300 nm in diameter, with helical nucleocapsid symmetry



AMI Images/Science Photo Library/Photo Researchers, Inc.

Key Features: Measles virus can be transmitted by respiratory secretions, and aerosolized viral particles can remain infectious for several hours. Although an effective measles virus vaccine has been available since the 1960s, 189 cases of measles in the U. S. were reported to the CDC in 2015. Many of these cases were linked to an outbreak that began at the Disneyland resort in California. Most affected people were unvaccinated.

Toolbox 18.1
MEASURING THE VIRULENCE OF PATHOGENS

How can the virulence of a particular strain of a pathogenic microbe be determined? One could simply infect a susceptible animal and record the severity of disease that ensues. It should be obvious that this approach poses problems. Most notably, it is very subjective. Conditions that one person considers severe may be considered mild by someone else. To avoid this reliance on judgment, one could measure specific disease states. For instance, a body temperature between 99°F and 101°F (37.2°C and 38.3°C) might constitute mild disease, whereas a temperature over 101°F (38.3°C) might constitute severe disease. This approach may provide a more objective measurement of disease, but it also is more time-consuming because the temperature of each infected animal must be measured.

To more easily provide accurate and objective measures of virulence, researchers may determine the LD_{50}, or lethal dose 50. This measurement shows the amount of a pathogen or toxin that kills an average of 50 percent of the test subjects. To determine the LD_{50} of a bacterial toxin, groups of test animals would be inoculated with different concentrations of the toxin. At very low doses of toxin, few or none of the animals would die. At very high doses, 100 percent of the animals would die. By analyzing the data, researchers can determine the amount of toxin predicted to kill an average of 50 percent of the animals (see Figure 5.24). Alternatively, researchers can use this type of assay to determine the ID_{50}, or infectious dose 50, of a microbe. With this test, researchers can determine the amount of microbes needed to cause an infection in 50 percent of the inoculated hosts.

Why use 50 percent rather than the 100 percent to characterize the lethal dose? With the scatter of values for each measurement, it is laborious and often unclear exactly what represents a given dose value giving 100 percent response. However, it is possible to identify asymptotically the value to which high doses are forming a plateau. This value is taken as the 100 percent response, and the 50 percent value can be calculated that is both accurate and consistent for defined conditions.

Both LD_{50} and ID_{50} measurements convey information about the virulence of a microbe or the toxicity of a toxin. Tetanus toxin, a potent neurotoxin produced by the bacterium *Clostridium tetani*, has an LD_{50} of approximately 0.001 $\mu g\,kg^{-1}$. Cholera toxin, produced by the bacterium *Vibrio cholerae*, conversely, has an LD_{50} of approximately 250 $\mu g\,kg^{-1}$. Tetanus toxin, in other words, is roughly 250,000 times more potent than cholera toxin.

Because LD_{50} and ID_{50} measurements require the use of many animals, researchers have been using these tests much less frequently. Instead, researchers studying the virulence of viruses may determine a somewhat related value, the $TCID_{50}$, or tissue culture infectious dose 50 (see Section 5.3). By using this assay, researchers can determine the amount of virus that leads to a productive infection in tissue culture 50 percent of the time.

Test Your Understanding

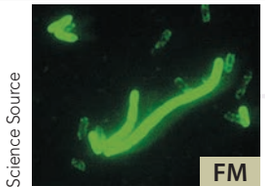
Researchers examined the LD_{50} of three different strains of *Staphylococcus epidermidis* that caused sepsis in hospital patients. Using a mouse LD_{50} assay, they found the LD_{50} of strain A to be 2.54×10^9, strain B to be 2.35×10^9, and strain C to be 4.71×10^9. What do each of these results mean, and what conclusions can you draw about each of the three strains? Explain.

0.95 in previously unexposed people. In other words, about 95 percent of all people who become infected with measles virus will develop the disease. In contrast, less than 1 percent of people infected with poliovirus develop paralytic poliomyelitis.

By determining the case-to-infection ratio of a pathogen, researchers can begin to quantify the **pathogenicity** of that microbe. Pathogenicity is a relative measurement of the ability of a microbe to cause disease. Species in the *Shigella* genus exhibit high pathogenicity; the ingestion of only a few cells can cause disease. Species in the *Salmonella* genus, however, exhibit low pathogenicity; disease usually only occurs after the ingestion of thousands of cells. **Virulence**, in contrast to pathogenicity, refers to the intensity of the disease produced by a microbe. Without a doubt, the 1918 strain of influenza virus, often referred to as the "Spanish flu," caused severe disease. Even though modern influenza infections may be severe and cause a significant number of deaths annually, they usually do not cause widespread deaths in the majority of the population. The virulence of the 1918 influenza virus strain was much greater than the virulence of most other strains of influenza virus. We should note that comparing the virulence of one pathogenic species to the virulence of another species is problematic. For instance, one cannot determine if the diarrheal disease caused by *Salmonella* is more or less severe than the respiratory disease caused by influenza virus. Researchers can compare the virulence of different strains or isolates of a specific pathogen **(Toolbox 18.1)**. These types of studies provide quantitative data about the ability of pathogens to cause disease in a host organism.

Genetic differences between two strains of a pathogen may account for differences in virulence. For example, the bacterium *Yersinia pestis*, the causative agent of plague, produces a series of nucleoside monophosphate kinases (NMPKs), enzymes involved in the synthesis of nucleotides. One of these enzymes, adenylate kinase (AK), is involved specifically in the biosynthesis of AMP and dAMP, precursors of the nucleotide adenosine. To investigate the importance of this enzyme to *Y. pestis* virulence, researchers at the Pasteur Institute mutated certain bases within the *Y. pestis* gene encoding AK. A specific mutation, which resulted in a change in amino acid 87 from a

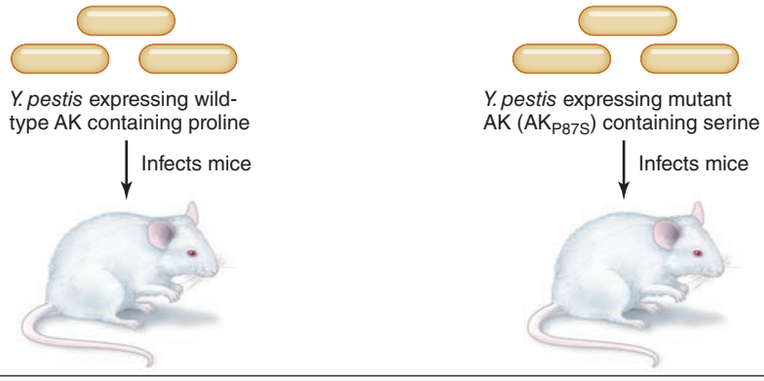
Observation: The *Yersinia pestis* adenylate kinase (AK) enzyme is involved in the biosynthesis of adenosine.



ATP + AMP $\overset{AK}{\rightleftharpoons}$ ADP + ADP

Hypothesis: Thermosensitive mutants of AK will lead to decreased growth at the non-permissive temperature 37°C.

Experiment: Mutate codon 87 of AK gene, changing the amino acid from proline to serine. Compare pathogenesis of wild-type and mutant strains.



Results: AK_{P87S} mutant exhibited greatly decreased pathogenesis.

Conclusion: Adenylate kinase contributes to the pathogenesis of *Y. pestis*.

Y. pestis strain	CFU injected (iv)	% Lethality
Wild type	0	0
	3.6	20
	36	100
AK_{P87S}	0	0
	150	0
	15,000	0

Figure 18.3. Genetics of a pathogen and its virulence To investigate the role of adenylate kinase in the replication of *Yersinia pestis*, researchers constructed a mutant strain of *Y. pestis* in which amino acid 87 of adenylate kinase was changed from a proline to a serine (AKP87S). When injected into mice, less than 50 colony-forming units (CFU) of the wild-type strain resulted in the deaths of all the mice. In contrast, the mutant strain was avirulent. Even when injected with 1.5×10^4 CFU of bacteria, none of the mice died.

proline to a serine, caused the adenylate kinase enzyme to be more sensitive to elevated temperatures and proteolytic digestion than the wild-type enzyme. To determine the effects of this mutation on the ability of the bacterium to cause disease in an animal host, the investigators determined the number of colony-forming units (CFU) required to kill mice. Following intravenous injection with fewer than 50 CFU of wild-type *Y. pestis*, all mice died. When the researchers inoculated mice with the mutant *Y. pestis*, no mice died, even when they were inoculated with 1.5×10^4 CFU of the bacteria (Figure 18.3). This mutation resulted in the extreme **attenuation**, or decrease in virulence, of this pathogen. In this particular case, the virulence of the microbe decreased so markedly that it no longer caused disease with any noticeable frequency. It became avirulent.

When an attenuated strain of a pathogen infects a host, the microbe still replicates. As a result, the host still mounts an immune response to the infectious agent. This immune response to a weakened form of the pathogen allows the host to better combat future infections with more virulent forms of the pathogen. Attenuated strains of pathogens often are effective **vaccines**, agents that can stimulate the immune system's response to a particular microbe and provide some immunity to that microbe. In fact, this ability to measure virulence and identify less virulent strains of pathogens has been instrumental in the development of vaccines.

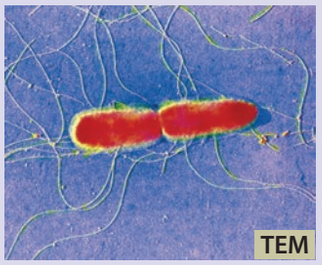
The oral poliovirus vaccine represents a classic example of an attenuated vaccine. To create this vaccine, Dr. Albert Sabin allowed strains of the three existing wild-type serotypes of poliovirus to replicate repeatedly in a monkey epithelial cell culture line (see Toolbox 5.1 for a review of cell culture techniques). Sabin then measured the virulence of the viral strains and observed that they had become greatly attenuated. When used as a vaccine, these attenuated forms of poliovirus rarely cause disease, but instead provide the recipient with strong, long-lasting protection against wild-type poliovirus.

Finally, some people may become infected with a pathogenic microbe but never exhibit any overt signs or symptoms of disease. In these cases, the person is said to be asymptomatic, even though the microbe may still be replicating within these hosts. The host, as a result, often acts as a **carrier** that can transmit the infectious agent to others. Probably the most famous carrier of a pathogenic microbe was a cook named Mary Mallon, also known as Typhoid Mary. Ms. Mallon was a carrier of *Salmonella* Typhi (Microbes in Focus 18.2), the bacterium that causes typhoid fever. During the early part of the twentieth century, at least 53 people developed typhoid fever

Microbes in Focus 18.2
SALMONELLA TYPHI: THE CAUSE OF TYPHOID FEVER

Habitat: Infects humans. No other known hosts. Transmitted by fecal contamination of food and water

Description: Gram-negative, motile bacterium, approximately 2 μm in length, within the family *Enterobacteriaceae* of the *Gammaproteobacteria* phylum. Commonly referred to as *Salmonella* Typhi, a subspecies of *Salmonella enterica* (see Appendix C).



CNRI/Science Source

Key Features: Typhoid fever affects roughly 20 million people annually. Increasingly, antibiotic-resistant isolates of this pathogen are being identified. A 2015 report, for example, documented the explosive increase in infections by a specific multidrug resistant strain in *S.* Typhi in Malawi.

after coming in contact with food prepared by Ms. Mallon, even though she did not show any signs or symptoms of the disease. Because she refused to adequately prevent transmission of the pathogen from herself to others, the New York City Health Department twice placed her in quarantine. The second time, she remained in quarantine until her death over 20 years later.

In this section, we have examined some common features of infectious diseases and reviewed some important terminology. However, an obvious question remains: How do microbes cause disease? We will address this important question in the next section.

18.1 Fact Check

1. Explain the following terms: "infectious disease," "zoonotic disease," and "pathogenesis".
2. Differentiate between primary pathogens and opportunistic pathogens and provide examples of each.
3. What is a carrier?

18.2 Microbial virulence strategies

How do microbes cause disease?

As we will see in subsequent chapters, bacteria, viruses, and eukaryal microorganisms often cause disease via dramatically different mechanisms. Indeed, even among members of any one of these groups, the mechanisms of pathogenesis may differ greatly. Despite this great variation, we still can identify some commonalities. Most notably, pathogens (1) gain entry to the host, (2) attach to and invade specific cells and/or tissues within the host, (3) evade host defenses, (4) obtain nutrients from the host, and (5) exit the host. Frequently, cellular damage to the host occurs as a result of these processes. Moreover, pathogenic microbes typically produce products that facilitate several of these events (Table 18.2).

Often referred to as **virulence factors**, these products enhance the pathogen's ability to cause disease and may distinguish a pathogenic microbe from a closely related non-pathogenic relative. In Section 23.1, we will examine *Ophiostoma novo-ulmi*, the fungus that causes Dutch elm disease. This pathogen produces xylanase, an enzyme that allows that fungus to degrade plant cell walls, thereby allowing the pathogen to obtain nutrients. In Section 21.1, we will examine *Neisseria gonorrhoeae*, the causative agent of gonorrhea. This pathogenic bacterium produces IgA protease, an enzyme that destroys host IgA antibodies, thereby helping the pathogen evade the host defenses.

CONNECTIONS In bacteria, genes encoding various virulence factors often are clustered together, forming a pathogenicity island, or PAI. As we will see in **Section 21.3**, these PAIs may be transferred between bacteria through horizontal gene transfer, thereby allowing bacteria to acquire several virulence factors as a single genetic unit.

As we begin our examination of pathogenesis, we will discuss events that occur within the host, saving a discussion of entry and exit for the next section. We will focus in this section on the molecular bases of invasion, evasion of host defenses, and cellular damage. Drawing from the viral, bacterial, and eukaryal worlds, we will look at a few examples of how pathogens achieve these goals. The following chapters will provide a more thorough understanding of these topics.

Attachment, invasion, and replication

For many pathogens, attachment to and invasion of specific cells and/or tissues precedes pathogen replication and the onset of disease. Bacteria use various features, including fimbriae, pili involved specifically in attachment, and lipoteichoic acid, a cell wall component of Gram-positive bacteria, for attachment. Viruses generally attach to cells via a very specific interaction between a viral attachment protein and a cellular receptor (see Figures 8.1 and 8.3). This attachment often triggers entry of the virus or its genome into the cell, a necessary event for all viruses. Some pathogens attach in a less specific manner. For instance, spores of the rice blast fungus adhere to most hydrophobic surfaces, including cells. For other

TABLE 18.2 Virulence actions of various pathogens

Virulence action	Viruses	Bacteria	Eukaryal microorganisms
Attachment and invasion	HIV: Envelope gp120 attaches to CD4 molecule on certain immune system cells.	*Escherichia coli*: Enteropathogenic and enterohemorrhagic strains produce intimin, an adhesion molecule.	*Giardia lamblia*: Ventral disk allows adherence to epithelial cells of small intestine.
Evade host defenses	Herpes simplex virus: Following acute replication, only the viral genome remains in the cell nucleus, and is not detected by immune cells.	*Neisseria gonorrhoeae*: The organism produces IgA protease, an enzyme that destroys the host IgA antibodies.	*Trypanosoma brucei*: The organism undergoes antigenic variation to periodically change its surface proteins.
Obtain nutrients from the host	Human papillomavirus: Viral E6 and E7 proteins inhibit cellular p53 and Rb tumor suppressor proteins, thereby driving the cell to replicate and produce DNA synthesis molecules needed by the virus.	*Mycobacterium tuberculosis*: Mycobactins, iron-binding proteins, allow the pathogen to acquire iron from the host.	*Plasmodium falciparum*: Nucleoside transporter proteins allow the pathogen to obtain purines from the host.
Cause cellular damage	Poliovirus: Replication induces apoptosis in infected neurons.	*Clostridium botulinum*: Produces botulinum toxin, a powerful neurotoxin that results in flaccid paralysis.	*Cochliobolus carbonum*: Produces HC-toxin that inhibits host cell histone deacetylases.

fungal pathogens of plants, a more specific interaction occurs between glycoproteins on the spore surface and molecules on the plant cell surface. Following attachment, some pathogenic fungi of plants develop specialized invasion structures that allow the fungus to penetrate the plant cuticle, a waxy protective covering present in most plants (see Figure 23.9).

The ability to attach to, invade, and replicate within the host often determines the **host range** of a pathogen—the group of organisms that the pathogen can infect (see Figure 8.1). Molecular changes in the pathogen can alter which cells a pathogen can attach to or invade. In turn, these changes can alter the host range of a pathogen. To explore this concept, let's examine the emergence of canine parvovirus, a small, single-stranded DNA virus that causes severe vomiting and diarrhea in puppies. Canine parvovirus type 2, or CPV-2, first appeared in dog populations in the late 1970s and quickly spread throughout the world. Sequence analysis studies have shown that CPV-2 is very closely related to feline panleukopenia virus (FPV), a parvovirus that infects cats, and mink enteritis virus (MEV), a parvovirus that infects minks, raccoons, and cats. Initially, CPV-2 could infect dogs, but not other species. Within a few years of its appearance, however, CPV-2 evolved into two related strains, CPV-2a and CPV-2b. These strains exhibit an expanded host range and are able to replicate in various wild and domestic canine and feline species **(Figure 18.4)**. The host range differences exhibited by these viruses can be attributed to specific mutations within the VP2 capsid protein. A few specific mutations within VP2 of either FPV or MEV altered the host range of the virus, allowing it to infect dogs. A few additional mutations in this capsid protein resulted in the expanded host ranges exhibited by CPV-2a and CPV-2b.

Evading host defenses

As we have seen previously, pathogenic microbes can infect all living organisms. In response to these threats, all living organisms have evolved defense mechanisms against pathogens. Unsurprisingly, the microbial pathogens, in turn, have evolved myriad ways of evading these host defenses **(Table 18.3)**. In this section, we will begin to explore these defense mechanisms. Rather than providing a comprehensive overview, we will focus on just a few specific examples. First, we will explore mechanisms whereby human pathogens evade particular defenses that we possess. Next, we will examine how bacteriophages evade two specific defenses that exist in bacteria.

Human Defenses

As we will see in more detail in Chapters 19 and 20, the immune system present in many organisms provides a remarkable defense against various pathogens. To a large extent, the ability to prevent diseases caused by pathogens relies on the ability of the immune system to recognize the pathogens and inhibit their replication. To investigate how microbes evade this host defense, we will examine two specific pathogens of humans, the protozoan *Trypanosoma brucei* and herpes simplex virus.

TABLE 18.3 Selected strategies for evading host defenses

Evasion strategy	Example	Function
Antigenic variation	Influenza virus, *Trypanosoma brucei*	Avoid antibody-mediated immunity of host
Latency	Herpes simplex virus, Epstein Barr virus	Avoid detection by host immune system
Capsule formation	*Streptococcus pneumoniae*	Inhibit phagocytosis
Biofilm formation	*Pseudomonas aeruginosa*	Prevent access of host defense molecules to bacterial cells
Direct cell-to-cell spread	*Listeria monocytogenes*	Avoid exposure to host immune system

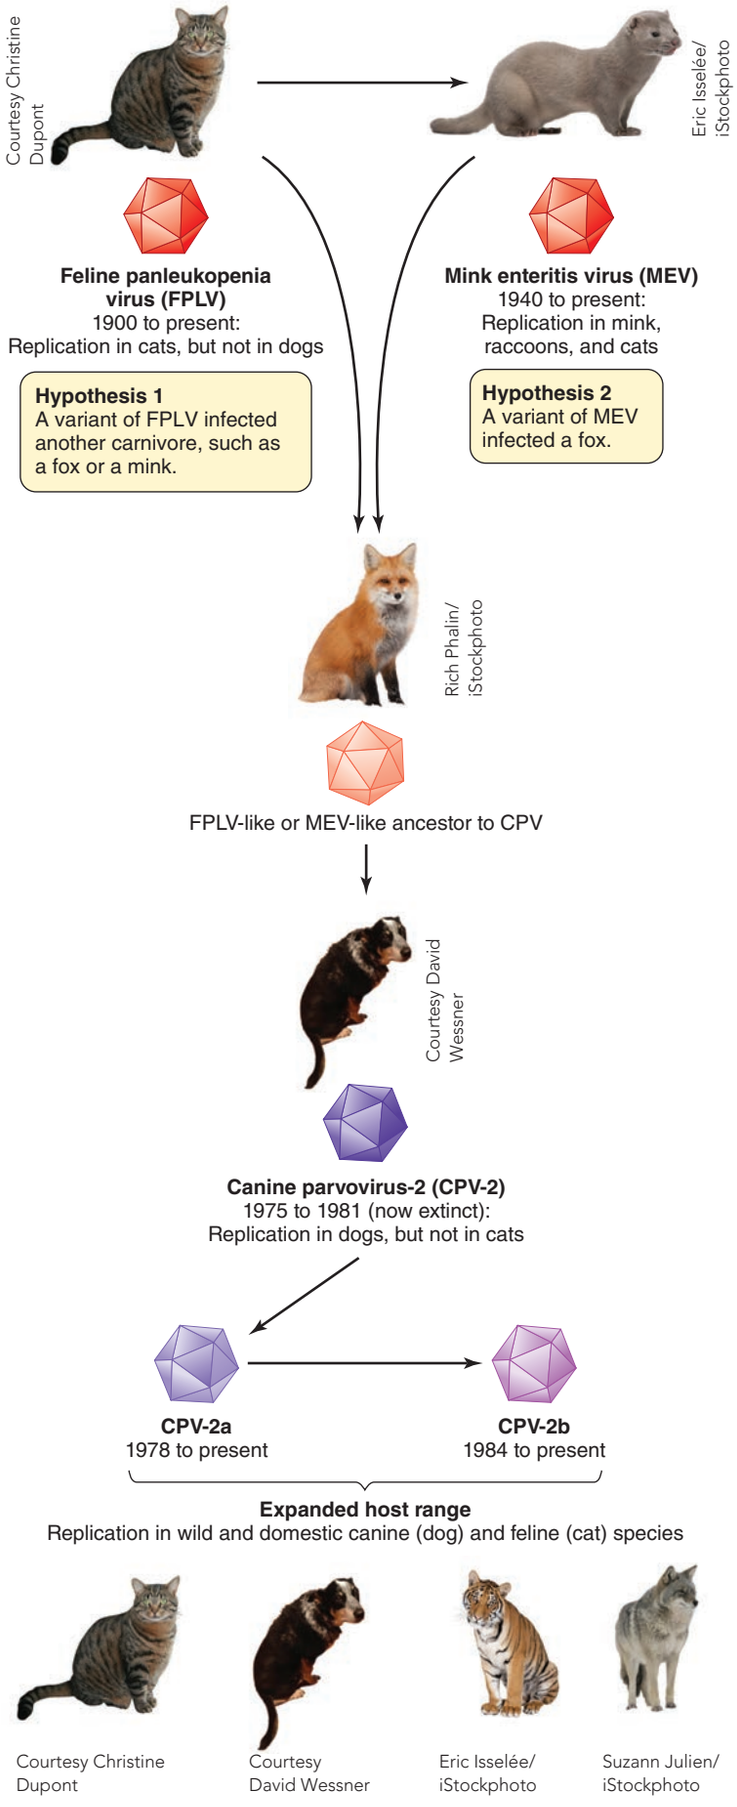


Figure 18.4. The emergence of canine parvovirus Modern canine parvoviruses (CPV-2a and CPV-2b) exhibit an expanded host range, capable of replicating in wild and domestic canine and feline species. Based on DNA and protein sequence analyses, researchers hypothesize that these viruses evolved from either feline panleukopenia virus (FPV) or mink enteritis virus (MEV), possibly via an intermediate virus that could infect foxes. In a short period of time, a mutation in an ancestral strain of virus changed the capsid protein permitting it to replicate in canine cells, thereby altering and enlarging its host range to include dogs. Two hypotheses exist to explain the apparent evolution of feline-like parvoviruses to canine parvoviruses.

As we will see, these two pathogens evade the human immune system in two very different ways.

Trypanosoma brucei, which causes sleeping sickness, evades the immune system by altering the composition of its surface antigens—proteins on the surface of the pathogen to which the host immune system typically responds—by making antibody to bind these surface proteins (see Section 20.1). Termed **antigenic variation**, this process allows the pathogen to avoid being eliminated by the host (Figure 18.5). When the host immune system begins eliminating pathogens displaying one particular surface antigen, the surface antigens on the pathogens change, thereby providing the pathogen with a mechanism for evading the immune response.

To further understand this process, let's examine *T. brucei* in more detail. During an infection, the surface of this extracellular pathogen is coated with over 1×10^7 molecules of variable surface glycoprotein, or VSG. The *T. brucei* genome contains genes for over a thousand different VSG molecules. However, only one of these molecules is produced at a given time. This thick coating shields other cell surface molecules

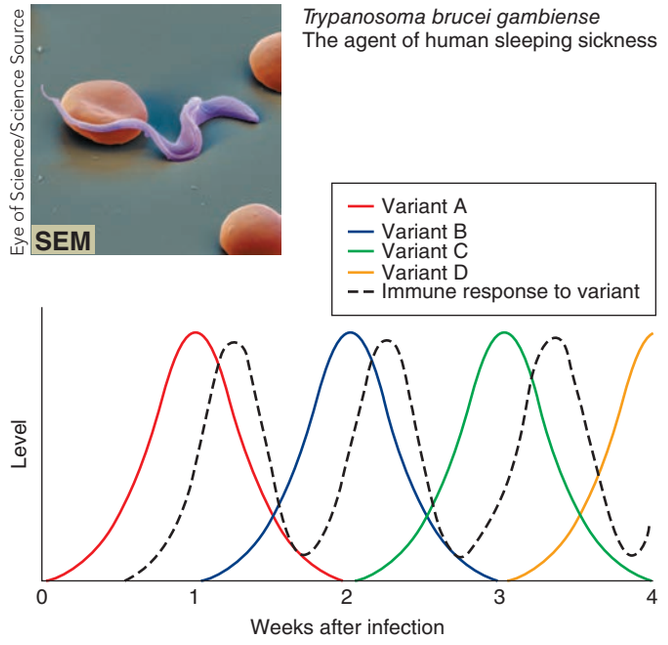

Figure 18.5. Evading host defenses through antigenic variation During a trypanosome infection, the immune system mounts a response, primarily targeting the major surface antigen. During the infection, the trypanosomes alter their surface antigen (indicated by the color changes between variants A, B, C, and D). When the surface antigen shifts, the host immune system is less effective and must play catch-up, giving the pathogen a chance to resume replicating.

from the host immune response. However, a strong immune response to the VSG molecules themselves is generated. To evade this response, *T. brucei* cells change the VSG expression pattern periodically. When a new VSG is produced, the host's existing immune response becomes much less effective. For a period of time, the pathogen can replicate relatively unencumbered by the host until the host's immune system responds to this new VSG and the numbers of *T. brucei* cells within the host again begin to decline until a new VSG is produced.

CONNECTIONS The bacterial pathogen *Salmonella* Typhimurium alters one of its major surface antigens—the flagellin subunit of its flagellum—by turning off the expression of one flagellin gene and turning on the expression of another flagellin gene. This switch occurs through the inversion of the regulatory region of an operon. A detailed description of operons can be found in **Section 11.2**.

Herpes simplex viruses avoid detection by the host immune system in a very different way. Following a period of replication in epithelial cells, some virus particles enter sensory neurons. The viral capsid travels to the cell nucleus and establishes **latent infection**, during which the viral genome remains present within the cells but transcription is limited to only a few non-structural genes and new virions are not produced. Few, if any, viral proteins are made that would be targeted by the host immune system response. Periodically, though, **reactivation** occurs (Figure 18.6). This reactivation process often occurs when the host experiences some type of cellular stress. Full transcription, translation, and virion production ensues. Newly produced virions travel down the neuron, leave the cell, and infect epithelial cells. As viral replication then resumes, cellular damage also resumes, resulting in an outbreak of cold sores or genital lesions.

Of course, antigenic recognition is not the only defense against pathogens. The host can attempt to limit replication and spread of intracellular pathogens, such as viruses, by inducing cell death. **Autophagy**, a term first used in 1963, refers to a specific type of intracellular degradation in which cytoplasmic material destined for destruction is encased in a lipid membrane and sent to the lysosome. It appears to be a degradation process present in most, if not all, eukaryal organisms. In the late 1990s and early 2000s, several researchers showed that autophagy also plays a role in tumor suppression. In 2004, the role of autophagy in limiting the spread of an infectious agent within a host was demonstrated.

We now have good evidence that certain pathogens can evade or, in some cases, use the host defense system for their own benefit. For an example, let's consider poliovirus. *In vitro* studies have demonstrated that experimental activation of the autophagy pathway leads to increased viral replication. Moreover, experimental inhibition of autophagy leads to decreased viral replication. Researchers hypothesize that the intracellular membrane structures formed during autophagy serve as additional scaffolds needed for poliovirus replication. In this particular case, the pathogen not only evades a host defense system, but also uses the defense system to augment its own replication.

CONNECTIONS Pathogens display a wide range of strategies to evade host defenses. As we saw in **Perspective 7.1**, the Vif protein of HIV allows this virus to evade a specific retrovirus-directed defense mechanism of human cells.

Another type of host-induced cell death is **apoptosis**. During apoptosis, a highly ordered cascade of chemical signaling events occur that result in cellular suicide (Figure 18.7). The

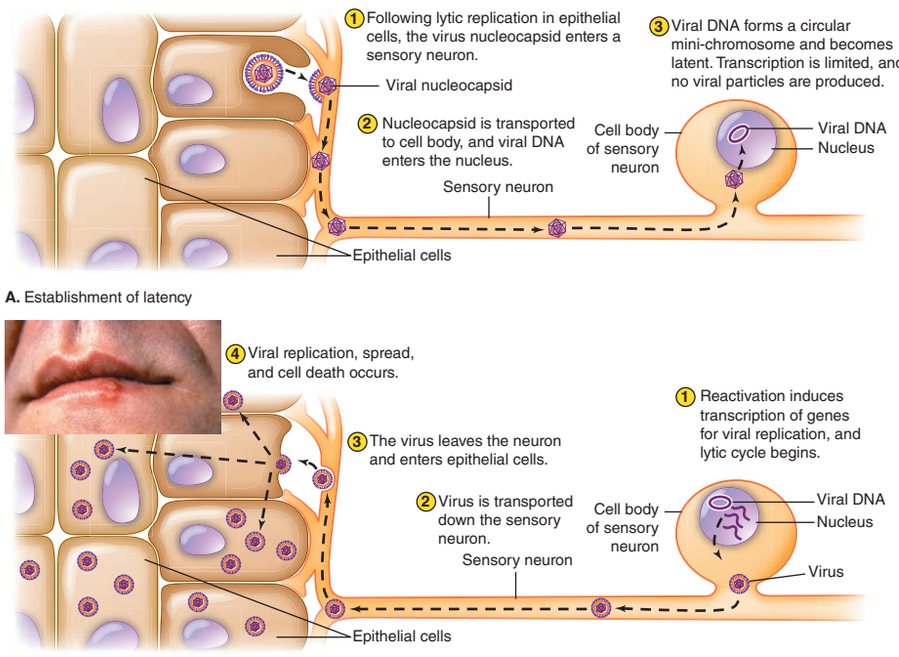

Figure 18.6. Process Diagram: Herpes simplex virus latency and reactivation **A.** Following an initial period of replication and acute disease, the virus enters a sensory neuron. It travels to the cell nucleus and the viral genome exists in a latent state. **B.** In response to some stress encountered by the host, the virus can undergo reactivation. The virus leaves the sensory neuron, infects an epithelial cell, and resumes replication. Transcription and translation of viral genes lead to the production of more virus particles and a recurrent outbreak of cold sores or genital lesions.

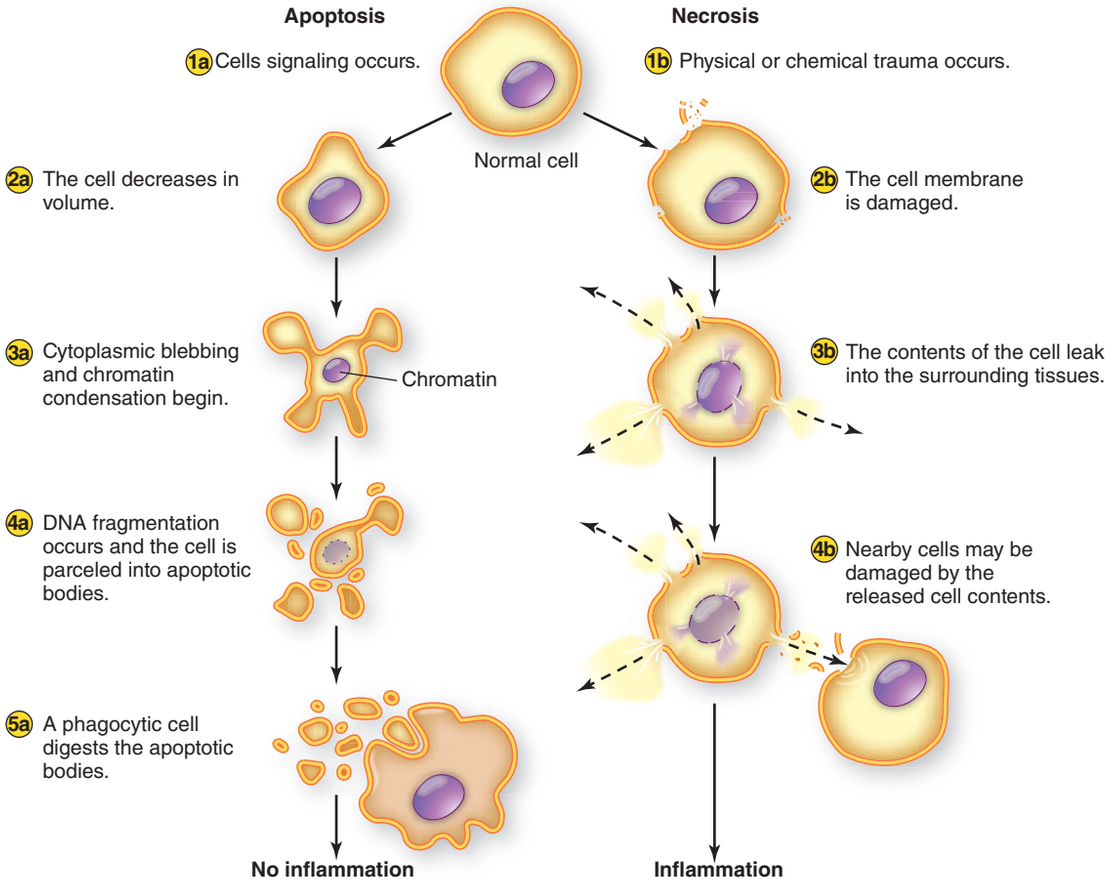

Figure 18.7. Process Diagram: Apoptosis and necrosis Apoptosis (*left*) is programmed cell death and results from the induction of specific chemical signaling pathways. Apoptosis results in the systematic deconstruction of the cell into small, membrane-bound apoptotic bodies, which then are taken up by phagocytes and digested. As cellular contents are not released to the surrounding tissues, apoptosis does not induce inflammation or cause damage to surrounding cells. Necrosis (*right*) occurs when the cell has sustained significant physical or chemical damage, such as happens during infection. Uncontrolled death of the cell results in the release of cellular contents, many of which can damage other cells and induce inflammation.

process is characterized by the fragmentation of DNA by endonucleases that selectively cleave the DNA between nucleosomes, resulting in fragments of DNA that are multiples of 180 base pairs in length (i.e., 180, 360, 540, etc.). Additionally, the cell itself fragments into small membrane-bound apoptotic bodies to be disposed of by phagocytic cells. Apoptosis, like autophagy, is a tightly controlled process that results in a "quiet death" without the release of cell-signaling molecules that induce inflammation, which can cause further damage to other cells. Presumably, destruction of infected cells by autophagy or apoptosis reduces the spread of the pathogen to other cells. In the case of poliovirus, however, disease results from the host's attempts to limit the infection through apoptosis of infected neurons.

Necrosis, in contrast, is a different type of cell death that occurs when cells are injured by structural damage or loss of oxygen supply due to trauma or infection. It results in cell rupture and the release of toxic cell contents and cytokines to the surrounding tissues, resulting in further damage and inflammation. Unlike apoptosis, necrosis is the equivalent of a cellular train wreck, resulting in collateral damage to many healthy neighboring cells.

CONNECTIONS Other microbial pathogens also cause disease by inducing apoptosis in their host. As we will see in **Section 21.1**, several bacterial pathogens produce cytolysins, toxins that damage the plasma membrane. For example, α-toxin, a cytolysin produced by some strains of *Staphylococcus aureus*, creates pores in the plasma membrane of host cells, which then leads to apoptosis.

As we will see in more detail in Section 22.2, a common strategy among viruses that infect eukaryal cells is to prevent apoptosis early in the infection cycle and then induce apoptosis late in the infection cycle. Preventing cell suicide during viral infection and replication ensures progeny virions are successfully produced. Subsequent induction of apoptosis facilitates release of virions in the form of apoptotic bodies to be taken up by neighboring cells to start the infection cycle again. Infection via apoptotic body formation also avoids provoking host defenses, such as inflammation and detection by antibody.

Bacterial Defenses

When considering infectious diseases, it is important to remember that infectious agents threaten all forms of life,

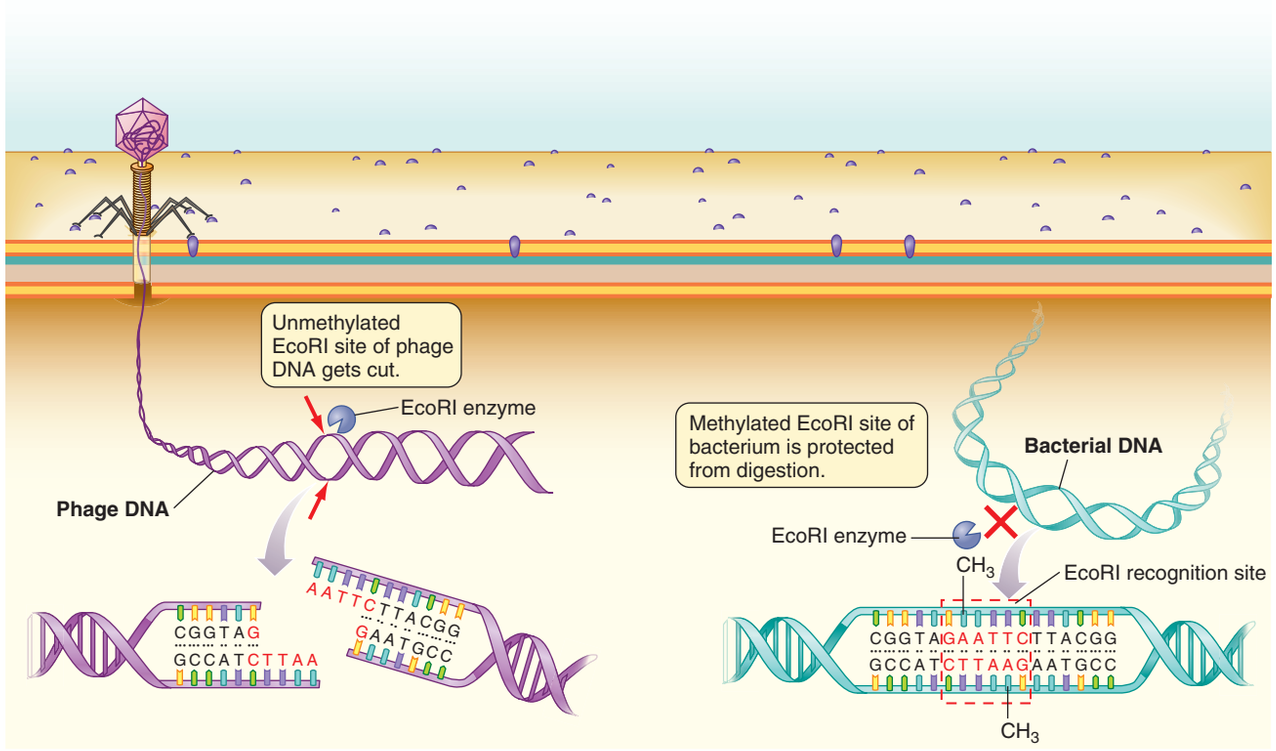

Figure 18.8. Process Diagram: Restriction enzymes—bacterial defenses against viruses Following their attachment to a host cell, bacteriophages inject their genome into the cell. To prevent infection, host cell restriction enzymes can cleave the invading phage genome, thereby preventing the generation of new phage particles and protecting the cell. To protect their own DNA from cleavage by endogenous restriction enzymes, bacteria modify their DNA, usually by adding a methyl group (—CH_3) to bases within the restriction enzyme recognition sites. The restriction enzymes do not cleave this modified DNA. Invading bacteriophage DNA may not possess these DNA modifications and, as a result, is subject to cleavage.

even bacteria and archaea. As we will see in this section, both bacteria and archaea possess several mechanisms of defending themselves against bacteriophages. Not surprisingly, phages possess mechanisms for evading these host defenses. Here, we will explore two specific systems used by bacteria and archaea to protect themselves from viral infections – the restriction-modification system and the CRISPR-Cas system. In both cases, we will focus on the bacterial systems and then examine how viruses can circumvent these defenses.

Restriction-modification

As we saw in Section 9.3, restriction enzymes have played a major role in the development of molecular biology techniques. Of course, restriction enzymes do not exist simply to benefit our research endeavors. Rather, they represent an effective host defense for bacteria and archaea against viruses.

Because restriction enzymes cleave double-stranded DNA at specific nucleotide sequences, they destroy any unprotected DNA molecules that contain these particular recognition sites. For example, when the DNA of a bacteriophage enters a bacterial cell, host restriction enzymes cleave it and the infection is blocked. Although this strategy seems straightforward, an obvious question arises. How does the bacterial cell protect its own DNA from degradation by the restriction enzymes? The answer may seem familiar. As we learned in Section 7.5, DNA repair mechanisms often depend on the methylation of DNA. Similarly, bacteria protect their DNA from degradation by adding methyl groups (—CH_3) to specific bases within their DNA. The restriction enzymes do not cleave this methylated DNA, thereby preventing them from cleaving host DNA containing restriction enzyme recognition sequences. This process is referred to as the **restriction-modification system** (Figure 18.8). Invading bacteriophage DNA, conversely, may not be methylated and, as a result, may be subject to restriction enzyme cleavage and degradation.

Of course, the story does not end here. Bacteriophages possess mechanisms for evading this host defense system. Certain bacteriophages encode proteins that can inhibit host cell restriction enzymes. Other phage stimulate the host cell's methylases in an effort to methylate their own DNA before it is cleaved. The genomes of still other phage contain few or no sequences recognized by the host cell restriction enzymes. All of these evolutionary adaptations allow the phage to subvert bacterial restriction-modification systems.

CRISPR-Cas

Microbiologists have understood the basic aspects of the bacterial restriction-modification system since the 1960s. Another anti-viral defense system in bacteria has a much shorter history. The **CRISPR-Cas system** (clustered regularly interspaced short palindromic repeats and CRISPR-associated) was first observed in *Escherichia coli* in 1987. The role of this system as a type of

adaptive immunity in bacteria and archaea, however, was not realized until 2007-2008. The CRISPR-Cas system consists of two major components. A series of short repeated sequences within the genome, typically between 20 and 50 nucleotides in length, each separated by a unique spacer region of a similar length, makes up one part of the system. *Cas* genes make up the other part of the system. Many of these genes code for polypeptides involved in the CRISPR-Cas process, like nucleases and helicases.

Between 2000 to 2010, several research groups made an interesting observation. The spacer regions in the CRISPR region were not random DNA sequences. Rather, many of these spacer regions appeared to be derived from bacteriophage or plasmid DNA. Moreover, researchers showed that bacteria could add new spacers to the CRISPR locus following exposure to a particular bacteriophage and that the addition of a new spacer conferred that bacterium with subsequent resistance to infection by that phage. In other words, the system appears to represent an adaptable immune mechanism. Moreover, researchers have since used this system to develop a powerful, and controversial, genome-editing technique **(Perspective 18.1)**

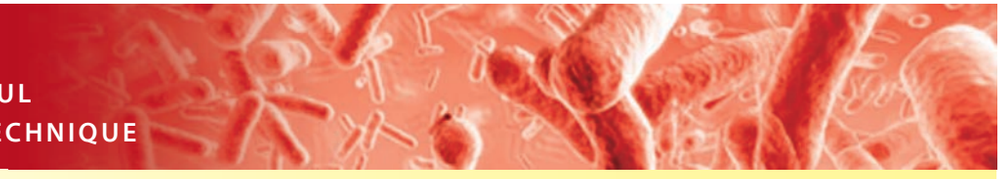
Let's look a little more closely at how this host defense works. When a bacterium is exposed to phage DNA, proteins such as Cas1 and Cas2, encoded by specific *cas* genes, recognize the foreign DNA and cleave it into smaller segments. One of these segments is then inserted between two repeats in the CRISPR region, thereby gaining a new spacer sequence in the bacterial genome. Subsequently, the entire CRISPR region is transcribed, consisting of the repeats and acquired spacers, producing a precursor CRISPR RNA (pre-crRNA) molecule. Other Cas proteins cleave this precursor RNA into a series of mature crRNAs, each of which contains a repeat region and a spacer region. These crRNAs then circulate within the cell until they encounter complementary DNA, which they then target for destruction through an RNA interference-like process **(Figure 18.9)**. Through the initial action of inserting the new phage DNA segment, the bacterium and its descendants have acquired resistance to this particular phage.

As we can see from this brief overview, the CRISPR-Cas system provides bacteria and archaea with an adaptable and powerful resistance to bacteriophage infections. Perhaps we should not be surprised, then, that bacteriophages possess mechanisms to evade this host defense. In one particular set of experiments, researchers at the University of California at Berkeley and Umeå University in Sweden showed that phage accumulated mutations in regions of their DNA targeted by the CRISPR-Cas system and underwent recombination within these regions. It appears as though the host defense system drives the evolution of the pathogen.

Pathogenesis

Pathogens usually exhibit several properties that, in concert, lead to pathogenesis. Often, pathogenic bacteria cause disease through the production of **toxins**, poisonous substances produced by an organism that damage the host. Some bacteria, like *Clostridium botulinum*, produce exotoxins, toxins produced inside the cell that are released or transported to the outside. These toxins can have various effects on their target cells (see Table 21.5 and Table 21.7). The lipopolysaccharide component of the cell wall of Gram-negative bacteria (also referred

Perspective 18.1
GENOME EDITING: A POWERFUL AND CONTROVERSIAL NEW TECHNIQUE



The CRISPR-Cas system provides bacteria and archaea with an effective means of protecting themselves from bacteriophage infections. It also has been adapted by molecular biologists to specifically alter the genomes of eukaryal organisms. This ability to alter DNA sequences in a very specific manner could have enormous biomedical benefits. It also raises important ethical questions.

In 2012, Dr. Jennifer Doudna, a researcher at the University of California at Berkeley, Dr. Emmanuelle Charpentier, a researcher at Umeå University in Sweden, and their colleagues showed that Cas9, one of the Cas proteins identified as part of the CRISPR-Cas system, induces double-stranded breaks in DNA. Moreover, the location of these breaks is site-specific, determined by an associated crRNA. Additionally, the DNA sequence at this break site can be altered in a very specific manner.

By early 2013, several research groups, including the groups led by Doudna and Charpentier, showed that this CRISPR/Cas9 system could be used to specifically alter, or edit, the genomes of cells from many organisms, including humans. The implications of this breakthrough are staggering. Potentially, CRISPR/Cas9 could be used to correct genetic diseases of humans by replacing the mutant sequence itself, instead of the current, and not very successful, method of relying on the random insertion of a wild-type allele. Indeed, several companies exploring this potential have been created.

The technique also could be used to alter the DNA in embryos, thereby creating heritable changes. Indeed, in early 2015, Chinese researchers reportedly created genetically modified human embryos. Although these embryos were intentionally rendered non-viable, their very creation raises serious ethical questions. Should we use this, or any other technology, to alter human embryos in a heritable way? If so, what kinds of alterations are acceptable? Should we allow modifications for eye color or only for mutations leading to detrimental conditions? Who decides what conditions are detrimental? Dr. Doudna and other leading researchers have urged caution and recommend that attempts to create altered humans be delayed until the ethical issues can be fully explored.

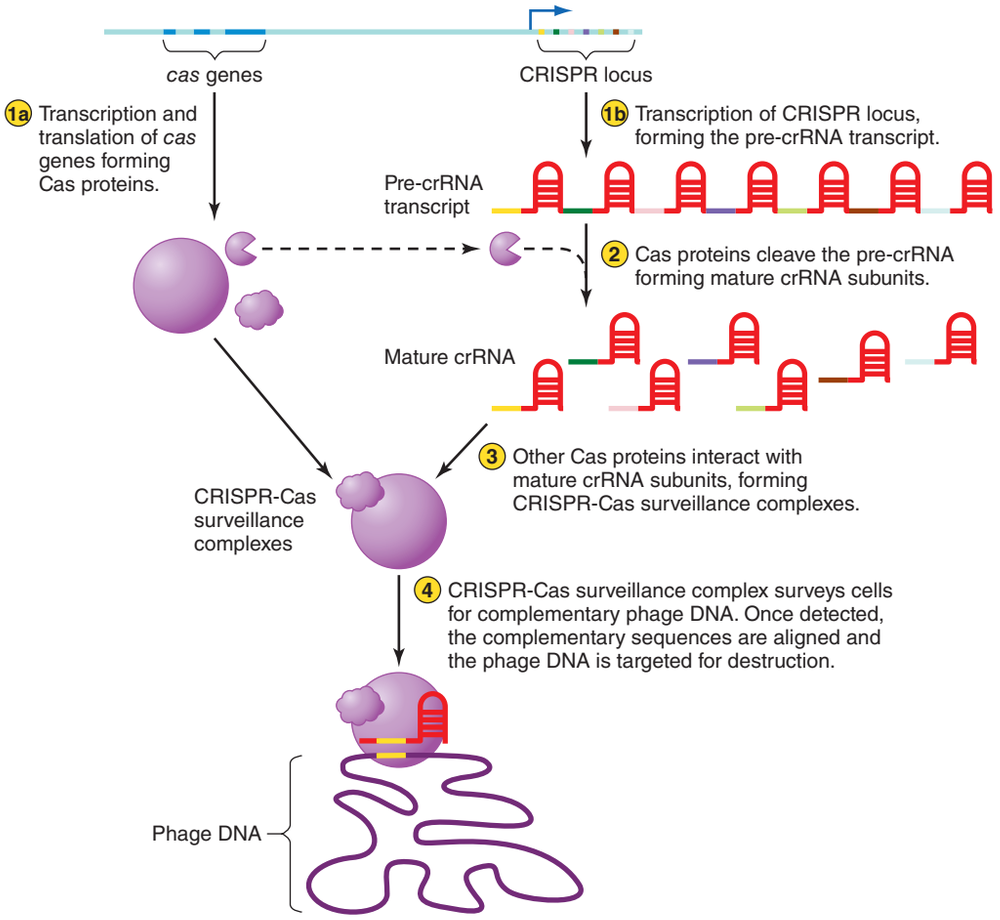


Figure 18.9 Process Diagram: CRISPR-Cas immunity in bacteria The CRISPR-Cas system consists of *cas* genes (*left*) and the CRISPR locus (*right*). The CRISPR locus, in turn, consists of short repeated segments that are separated by unique spacer segments (shown as colored regions). The spacer sequences are derived from phage genomes to which the bacterium previously had been exposed. Following transcription of the CRISPR locus, the pre-crRNA transcript is processed by a specific Cas protein, resulting in a series of mature crRNA molecules. Other Cas proteins combine with each mature crRNA molecule, forming a series of CRISPR-Cas surveillance complexes. For simplicity, only one such complex is illustrated here. If a complex recognizes bacteriophage DNA in the cell complementary to its unique spacer sequence, then that phage DNA will be targeted for destruction.

to as endotoxin) and the lipoteichoic acid component of Gram-positive bacteria also can act as toxins. We will explore the specific actions of various bacterial toxins more thoroughly in Section 21.1.

Viruses generally do not produce toxins. Rather, diseases caused by viruses often result from the intracellular replication of these microbial pathogens. Let's examine this concept in more detail. As we noted in the opening story of this chapter, poliovirus can cause paralysis. The disease occurs because infected motor neurons, the neurons that interact with muscle cells, die. One could assume that infected motor neurons die because the replicating virus lyses the host cell. However, it appears that the cause of cell death is apoptosis.

In this section, we have seen examples of how pathogens—bacterial, viral, and eukaryal—invade hosts, evade the host defenses, and cause cellular damage. We also must consider how pathogens enter and exit hosts and spread within a population. We will investigate these issues in the next section.

18.2 Fact Check

1. Describe some microbial features that facilitate attachment or entry.
2. Explain how attachment and host range of a pathogen are related. Provide an example.
3. Identify and describe microbial strategies for evading host defenses.
4. How can autophagy or apoptosis induce disease?

18.3 The transmission of infectious diseases

How are infectious diseases transmitted?

For a pathogen, simply replicating within a host is not sufficient for continued survival. An individual host organism eventually will die. The microbe, then, must be transmitted successfully between susceptible hosts. Some pathogens, like HIV, are transmitted directly from one host to another. Other microbes, like influenza virus, must remain stable in the outside environment during transmission, remaining capable of initiating an infection when they encounter new susceptible hosts. Still

other pathogens, like *Vibrio cholerae*, may replicate in a specific host, causing disease, and also replicate in the external environment. As we will discover in this section, the transmission of pathogens from one individual to another depends on where the pathogen replicates, how stable it is in the environment, and how it exits its host. In turn, transmission between individuals affects how pathogens spread within populations.

Routes of transmission

How a pathogen moves from one host to another represents an interesting and important aspect of studying infectious diseases. **Transmission**, the spread of an infectious agent from its source to a new host can occur in many ways. **Direct transmission** refers to spread that occurs via physical contact between an infected individual and a susceptible individual. **Indirect transmission** refers to spread that occurs from one individual to another via another object, such as a contaminated inanimate object, called a **fomite**, water, food, or an insect. Other, more specific categories of transmission also can be described.

Generally, routes of pathogen transmission are related to how the pathogens enter and exit their hosts. The site of replication in the host, in turn, often determines entry and exit. Pathogens that can replicate within the intestinal tract, like the bacterium *Vibrio cholerae* and the virus rotavirus, are eliminated through feces. The pathogens then may contaminate water supplies, be transferred to hands, or be transferred to fomites, like doorknobs. Another susceptible host may ingest the pathogens, either by drinking contaminated water or transferring the pathogens from a fomite to his or her mouth. This type of transmission, in which a pathogen is excreted in the feces of one individual and then ingested by another individual, is referred to as **fecal-oral transmission**. Pathogens that replicate in the respiratory tract usually exhibit **airborne transmission**, also referred to as aerosol transmission. In these instances, infectious pathogens leave an infected host when the host coughs or sneezes. The pathogens also may leave a host when he or she laughs, burps, or simply talks. The pathogens then can be inhaled directly by a second host or become deposited on a fomite and transferred to the nose or mouth of a second host.

Vector-borne transmission involves an intermediate arthropod vector that delivers the pathogen from one host to another. In some cases, the vector is simply acting as a cargo ship, passively transferring the infectious agent as it carries out its activities. The pathogen does not replicate on or in this vector. This type of vector-borne transmission is a form of **mechanical transmission**. An example of mechanical vector-borne transmission is the movement of *Ophiostoma novo-ulmi*, the fungus that causes Dutch elm disease, from host to host by a beetle. Mechanical transmission can also happen, for example, when plant viruses get transmitted from plant to plant by pruning shears An insect vector also transmits *Plasmodium falciparum*, the protozoan that causes malaria. In this case of vector-borne transmission, however, the pathogen replicates and develops within a mosquito vector. When an infected mosquito then bites a susceptible human, the pathogen enters the new host and continues its replication cycle. In contrast to mechanical transmission, this type of vector-borne transmission is referred to as biological transmission.

CONNECTIONS *Plasmodium falciparum* undergoes a complex life cycle that requires replication on both mosquitoes and humans. The details of this life cycle, and how the replication of *P. falciparum* leads to disease, will be addressed in **Section 23.2**.

Sexual transmission refers to transmission that occurs during vaginal, anal, or oral sex. Infectious diseases that are spread sexually are referred to as **sexually transmitted infections**, or **STIs**. Some sexually transmitted pathogens reside on the surface of the penis or within the vaginal or anal canals and are transmitted through direct contact during sex. Other sexually transmitted pathogens, like HIV, are present in semen and vaginal fluids and can be transferred from these fluids through small abrasions in the vagina, anus, or penis to the bloodstream of another person.

HIV also can undergo **vertical transmission**, passing from parent to child. Most commonly, vertical transmission of pathogens occurs from mother to child *in utero*, during birth, or shortly after birth. Because HIV can exist in the breast milk of an HIV-positive woman, breastfeeding can lead to the vertical transmission of this pathogen. In the absence of preventive measures, approximately one-third of infants born to an HIV-positive woman will acquire the virus. In contrast, **horizontal transmission** refers to transmission of a pathogen between members of a species, other than parent to offspring **(Figure 18.10)**.

Finally, humans may become infected by pathogens through **zoonotic transfers**. In these cases, the pathogen is transmitted

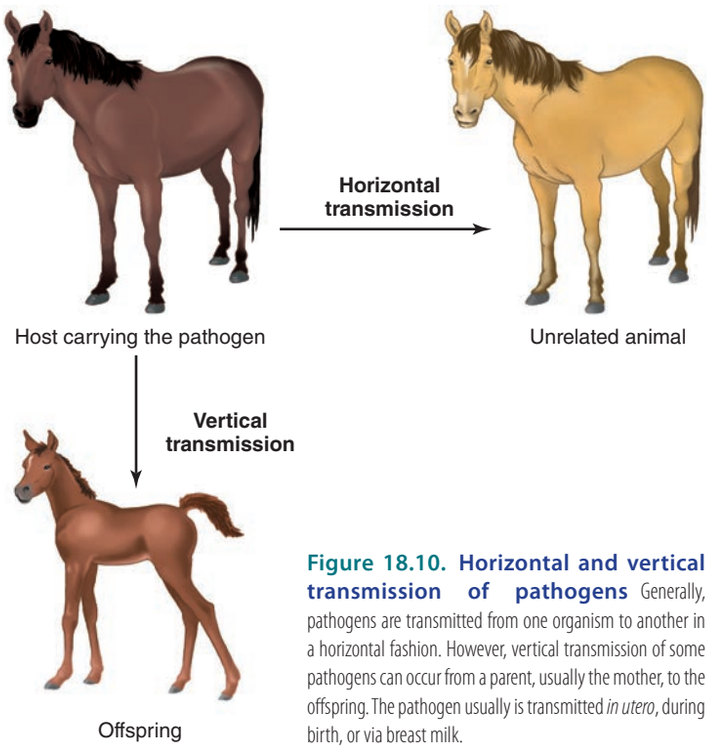

Figure 18.10. Horizontal and vertical transmission of pathogens Generally, pathogens are transmitted from one organism to another in a horizontal fashion. However, vertical transmission of some pathogens can occur from a parent, usually the mother, to the offspring. The pathogen usually is transmitted *in utero*, during birth, or via breast milk.

TABLE 18.4 Selected zoonotic diseases

Disease	Pathogen	Animal reservoir
Rabies	Rabies virus	Raccoons, bats, skunks, foxes
Hantavirus pulmonary syndrome	Hantavirus	Various species of rats and mice
Ebola virus disease	Ebola virus	Unknown (fruit bats?)
Anthrax	*Bacillus anthracis*	Cattle, sheep, goats
Tularemia	*Francisella tularensis*	Various species of rodents, rabbits
Psittacosis	*Chlamydia psittaci*	Many bird species

from its animal **reservoir host** to a human (Table 18.4). The reservoir host represents the species that the pathogen normally infects. Often, but not always, the reservoir host species shows low disease prevalence, whereas infection of humans results in acute disease. For example, increasing evidence indicates that fruit bats are the reservoir host for ebolaviruses. A very severe disease occurs when these viruses are transmitted to humans. Often, humans serve as **dead-end hosts**, or incidental hosts, for zoonotic transfers; the pathogen may replicate within an infected person and cause severe disease, but is not efficiently transferred from one person to another. In other words, human-to-human spread of the pathogen does not occur or occurs inefficiently.

The highly pathogenic H5N1 avian influenza virus presents a good case with which to illustrate the concepts of zoonotic transfers and dead-end hosts. Between 2003 and 2011, approximately 580 confirmed human cases of H5N1 influenza were reported. Of these infections, 340 resulted in death, making the virus quite virulent in humans. In almost all of the cases, the virus was transmitted to humans from poultry. Very few cases of human-to-human transmission have been reported. However, researchers and public health officials remain very concerned about this virus. It could mutate in such a way that transmission between humans becomes more likely. Indeed, in the fall of 2011, researchers reported that they had identified specific mutations within the H5N1 influenza virus genome that makes it much more transmissible between ferrets. These same mutations could make it more transmissible between humans (see Perspective 22.4).

Epidemiology

To more fully understand how pathogens are transmitted, we need to examine not just the interactions between a pathogen and a single individual. Rather, we need to examine the interactions between pathogens and populations. **Epidemiology** is the study of patterns of disease in populations. Epidemiologists investigate all diseases—cancers, chemical poisoning, obesity, genetic diseases, and, of course, infectious diseases. Epidemiologists concern themselves with determining the source of diseases, identifying disease risk factors, designing and evaluating infection control policies, and predicting the future spread of disease. They also investigate the **morbidity rate**, or rate of disease, and **mortality rate**, or rate of death, associated with diseases. Statistics and mathematical modeling of disease patterns form a large part of epidemiology and provide valuable predictions of disease spread and identification of the major parameters involved in the transmission and control of disease. The ultimate goal of these studies is quite simple. The more we know about how infectious diseases spread, the better equipped we are to prevent them.

Organizations throughout the world, such as the Centers for Disease Control and Prevention (CDC) in the United States and the Institute for Public Health Surveillance in France, rely on communication with local health officials to collect and report relevant data from populations to assist them in identifying the frequency of disease and death and in evaluating treatment and prevention practices. As you can imagine, information cannot be gathered from every single member of a large population because of practical and monetary restrictions. Frequently, only a subset of the population can be observed. For example, to get information on HIV infection rates in South Africa, researchers from various organizations commonly monitor women by visiting maternity wards. Researchers then use these data to predict levels of infection in the wider population.

Epidemiologists report the status of an infectious disease in a population using specific quantitative and qualitative terms. To understand how a pathogen may affect a population, we must first understand these terms.

Case

In the context of infectious disease, a case must be specifically defined in order to unambiguously diagnose and count affected individuals. A case may be defined as an individual who exhibits the disease. Alternatively, a case may be defined as an individual who is infected, but may or may not be showing signs or symptoms of disease. These asymptomatic individuals may be identified through diagnostic testing, such as PCR, culture, or ELISA (enzyme-linked immunosorbent assays; see Toolbox 20.2).

Among people, asymptomatic, subclinical infections usually do not come to the attention of health care workers and therefore do not get recorded as cases. However, routine diagnostic testing is carried out in farmed animals to determine the infection status of animals for certain agents such as the foot-and-mouth disease virus, which causes foot-and-mouth disease (see Section 24.5), and *Mycobacterium bovis*, which causes tuberculosis in cattle. With these tests, researchers can detect subclinical infections, which are infections that have not yet progressed to a noticeable disease state.

Incidence and Prevalence

Incidence refers to the number of new cases appearing in a population during a specific time period. Incidence may be reported as a proportion and is then referred to as the incidence rate. For example, the incidence rate of tuberculosis in Africa during 2006 was 363 per 100,000 people (or roughly 0.36 percent), according to the World Health Organization (WHO). For 1990, the incidence rate was 162 per 100,000 people.

Figure 18.11. Prevalence and incidence: Epidemiological measures of infectious diseases in a population Prevalence is an estimate of how common or widespread a disease is within a population over a defined period of time. Incidence gives information about the risk of contracting the disease within a population over a defined period of time. Prevalence will always be higher than incidence because it includes all existing cases, not just new cases.

Prevalence refers to the total number of cases in a population at a particular point in time or during a particular time period. Again, prevalence often is reported as a proportion and is then referred to as the prevalence rate. For example, the prevalence rate of tuberculosis in Africa during 2005 was 547 per 100,000 people, according to the WHO. In 1990, the prevalence rate was 333 per 100,000. The prevalence of disease is always higher than the incidence because it includes both new and preexisting cases **(Figure 18.11).**

Incidence and prevalence reporting represent the most common epidemiological measures of infectious disease in populations. These measurements not only tell us the level of infectious disease in a population, but also allow us to make comparisons within and between populations over time. Incidence rate is one of the best indicators of disease risk in a susceptible population, and it also tells us how fast a disease is spreading in a population. For example, China and India had the largest overall number of new tuberculosis cases in 2007. Does that mean China and India were hotspots for tuberculosis? Not necessarily. The number of new cases does not reflect the total population size. To compare the risk of tuberculosis between populations, we need to compare the incidence rates—how many new cases occurred within a given population size.

China and India are the two most populated countries in the world, and even a large number of new cases may correspond to a low incidence rate. Even though China and India have the largest number of new tuberculosis cases, these countries did not have the highest incidence rate. The incidence rate of tuberculosis was much higher in several African countries and Cambodia, indicating a higher density of disease and therefore a greater risk of infection in these countries.

To better understand how an infectious disease is spreading in a population, we need to compare the incidence and incidence rate over time. **Table 18.5** shows the incidence and incidence rate of tuberculosis in China, South Africa, and the Netherlands for the years 1990 and 2010. In 1990, over 15 times more people in China than in South Africa became infected with tuberculosis. However, the incidence rate was only about two times higher in South Africa. From these numbers, we could speculate that the risk of acquiring tuberculosis was fairly similar in both countries. The situation changed drastically by 2010. China's incidence rate dropped slightly and South Africa's rate skyrocketed. In 2010, the incidence rate of tuberculosis was 13 times higher in South Africa than in China. During this same period, the incidence and incidence rate of tuberculosis remained very low in the Netherlands. What caused the dramatic increase in the tuberculosis incidence rate in South Africa? Between 1990 and 2010, the number of people with HIV/AIDS increased dramatically in South Africa. The incidence of tuberculosis showed a positive correlation with HIV infection rates. This correlation is explained by the destruction of immune cells by HIV. Specifically, HIV leads to the destruction of T helper (T_H) cells, which are central to the adaptive immune response (see Chapter 20). A diminished T_H cell population means that immunity to tuberculosis is severely compromised. In other words, people with HIV/AIDS are more susceptible to tuberculosis. In 2013, over 50 percent of all new tuberculosis cases in South Africa occurred in HIV-positive people **(Figure 18.12)**.

Incidence also can be used to identify **emerging diseases** that previously are unknown, or known diseases with a recent significant increase in incidence. The pathogens associated with these diseases likewise are referred to as emerging pathogens. Examples of pathogens that cause emerging diseases include HIV, Ebola virus, Zika virus, *Helicobacter pylori*, *Escherichia coli* O157:H7, SARS-CoV, *Borrelia burgdorferi*, *Clostridium difficile*, and Chikungunya virus **(Microbes in Focus 18.3)**. By analyzing incidence patterns, we also can uncover re-emerging diseases, those known diseases that have recently increased in incidence after a previous significant decline. Examples of re-emerging diseases include tuberculosis, necrotizing diseases caused by *Streptococcus pyogenes*, and invasive diseases caused by *Staphylococcus aureus*.

Incidence tells us how fast a disease is spreading within a population, whereas prevalence gives us an indication of the disease burden within a population. Prevalence describes how many individuals are living with the disease at a given time. These pieces of information are particularly useful for health care systems that need to plan for the care of patients. Incidence and prevalence rates are also useful for monitoring the

TABLE 18.5 Comparison of incidence and incidence rates for tuberculosis

Country	Population[a]		Incidence		Incidence rate[b]	
	1990	2010	1990	2010	1990	2010
South Africa	37	50	110,000	490,000	300	980
China	1,145	1,341	1,700,000	1,000,000	150	75
Netherlands	15	17	1,500	1,200	10	7

[a] In millions.
[b] Per 100,000.

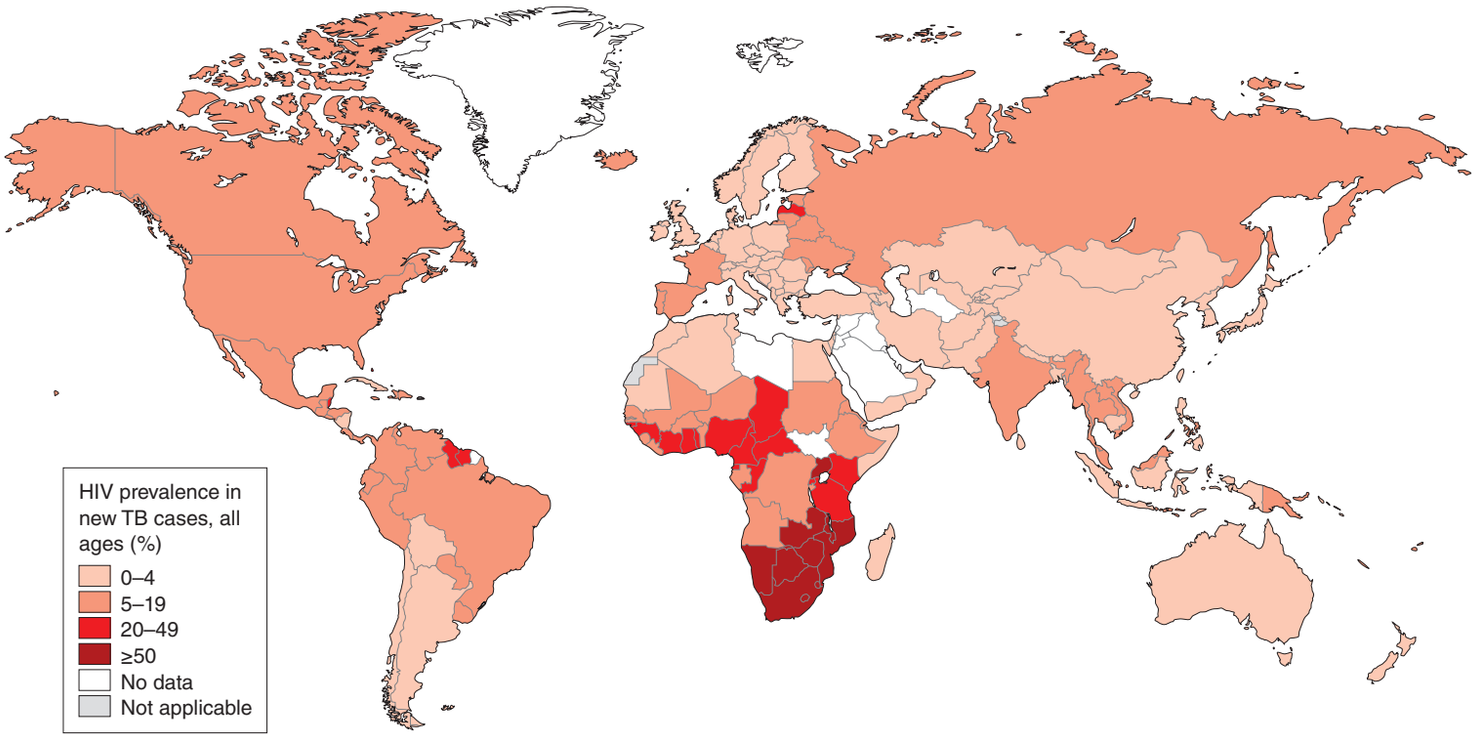

Figure 18.12. HIV prevalence among people with TB, 2013 In sub-Saharan Africa, many of the people newly diagnosed with tuberculosis also are HIV-positive.

Microbes in Focus 18.3
CHIKUNGUNYA VIRUS: AN EMERGING PATHOGEN

Habitat: Infects a variety of mammals, including humans. Also infects mosquitoes

Description: Enveloped ssRNA virus, about 65–70 nm in diameter, with an icosahedral capsid; member of the *Togaviridae family of viruses*.

Key Features: Chikungunya disease, characterized most commonly by joint pain and fever, first was described in the early 1950s. The name is derived from a word in the Kimakonde language spoken by the Makonde people of southeast Tanzania and northern Mozambique that means contorted or bent. The virus is transmitted to humans by mosquitoes and has caused periodic outbreaks throughout parts of Africa, Asia, and the Indian subcontinent since then. In 2013, the first cases of chikungunya in the Western Hemisphere were reported. The virus spread rapidly in this region. Between late 2013 and early 2015, nearly 1.4 million suspected cases of chikungunya disease were reported.

effectiveness of infection control and treatment programs. For an example, let's look at HIV/AIDS.

As shown in **Figure 18.13**, the incidence of HIV-related deaths in the United States increased greatly throughout the 1980s and early 1990s. As more people became infected with HIV, more people developed and died from AIDS. However, the rate of HIV-related deaths per year began to decline rapidly around 1995. Why did this happen? Around this time, highly active antiretroviral therapy (HAART) became available. This effective HIV treatment option decreased HIV-related mortality. Even though people continued to become infected with HIV, deaths declined. The data, then, present a clear indication that the treatment strategies are working.

Patterns of infectious disease

When do health officials become concerned about the incidence of an infectious disease? For some diseases, like extremely drug-resistant tuberculosis, a single case can be alarming because it cannot be effectively treated and is contagious. For other diseases, like measles, it takes an unusually large number of cases to raise the alarm. In this section we will define terms used by epidemiologists to describe the presence of infectious disease in populations.

Endemic Disease

An **endemic disease** or agent is one that is habitually present in a population. For example, rabies is endemic to North American foxes, raccoons, skunks, and bats. For many endemic diseases, cyclical patterns of increased and decreased incidence occur.

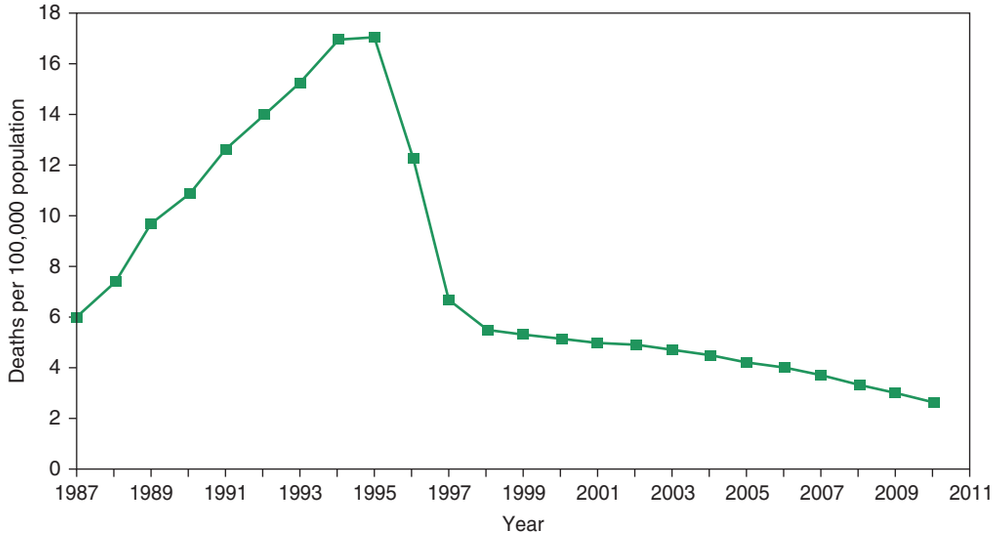

Figure 18.13. Incidence of HIV-related deaths in the United States The incidence of HIV-related deaths in the United States increased rapidly through the 1980s and early 1990s. However, the incidence began to decline around 1995, when effective antiretroviral therapies became more readily available.

This periodicity is usually a function of seasonal changes or variations in population immune status. For example, in the United States and Canada, the incidence of human encephalitis from West Nile virus infection peaks in late summer and fall following the height of local mosquito (the vector) populations **(Figure 18.14)**. Immune status also can cause fluctuations in incidence. In a non-immune population, a previously high incidence of an infectious disease results in a population composed largely of immune survivors. Any susceptible individuals in this population will be widely dispersed so the agent is no longer frequently transmitted. Consequently, incidence drops to a low level **(Figure 18.15)**. As non-immune offspring join the population, the population shifts again to a high level of susceptible individuals and another peak in incidence occurs. Such periodicity is found in several endemic diseases, such as chickenpox, influenza, pertussis, and measles.

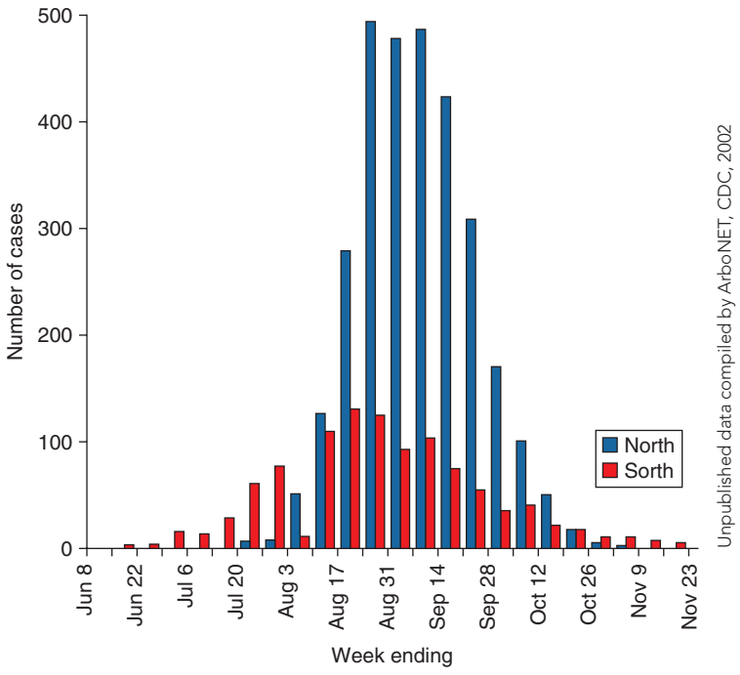

Figure 18.14. Seasonal incidence of West Nile encephalitis In the northern United States, incidence of disease rises sharply in August and declines through the fall months, closely paralleling vector populations of mosquitoes. In southern states, cases appear over a wider range of months because there is less variation in mosquito populations.

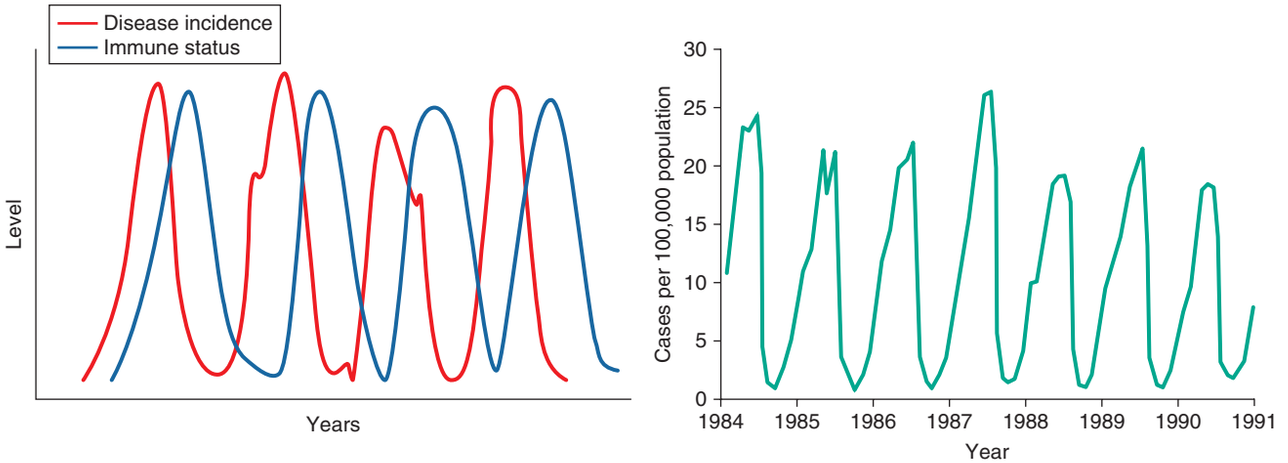
Epidemic

An **epidemic** occurs when the incidence of a disease significantly rises above that normally expected for a population. The term **outbreak** refers to an unexpected cluster of cases appearing within a short period of time in a localized population. There is no absolute dividing line between an outbreak and an epidemic. In general terms, an epidemic involves a larger proportion of the population than an outbreak. Sometimes epidemics are defined by a certain cut-off value. For example, in 1990, the U.S. Centers for Disease Control and Prevention (CDC) officially declared an influenza epidemic in the United States when the mortality rate from influenza rose above the expected 6.7 percent set in previous years. Endemic diseases can reach epidemic levels if enough susceptible individuals are present **(Figure 18.16)**.

Pandemic

A **pandemic** is an epidemic concurrently affecting populations globally, usually on more than one continent. Some pandemics have covered the world, such as the H1N1 Spanish flu of 1918 **(Table 18.6)**. The progression of an outbreak to a pandemic occurs in stages that can be monitored, and this information can be very valuable in preventing spread. The H1N1 swine flu was declared a pandemic by the WHO in June 2009, based on reaching influenza pandemic alert Phase 6. What does this mean? The WHO uses a six-phased approach, based on defined phases that past influenza pandemics have been observed to follow, for influenza preparedness and response plans. Criteria for the six phases of influenza pandemic alert are presented in **Figure 18.17**.



A. Disease incidence and immune status

B. Periodicity of chickenpox incidence

Figure 18.15. Periodicity of disease incidence When a pathogen enters a susceptible, non-immune population, there will be an initial high incidence of disease. Survivors of infection will be immune and incidence will drop to a low level. **A.** The incidence of disease may exhibit a cyclical pattern. As young are born into the population, the proportion of immune individuals decreases and the incidence increases. This periodicity commonly is seen for many endemic diseases. **B.** Varicella-zoster virus, the cause of chickenpox, is endemic to the United States and shows cyclical occurrence in incidence.

Types of epidemics

Cases of infectious diseases within populations do not occur randomly; they occur in patterns. These patterns describe how an outbreak or epidemic moves temporally (with time) and spatially (with location) in populations. The temporal pattern of an outbreak or epidemic is presented in the form of an epidemic curve **(Figure 18.18)**. The frequency of cases is plotted against an appropriate time interval. The shape of the curve can help to reveal the nature of the epidemic. Spatial patterns can be tracked on a map to help visualize the pattern of cases.

Common-Source Epidemics

A **common-source epidemic** or outbreak occurs when there is a single source of infection to which the population is exposed **(Mini-Paper)**. For example, outbreaks of *E. coli* O157:H7 frequently can be traced to contaminated food or sometimes water (read about the Walkerton outbreak in the opening story of Chapter 21). Similarly, *Cryptosporidium* outbreaks often can be traced to contaminated freshwater supplies. Because a large number of susceptible individuals are exposed to the source of infection in a short period of time, common-source epidemics typically show a sharp increase in disease incidence. A slower but marked decline then occurs; fewer individuals in the exposed population remain susceptible **(Figure 18.19)**. The time over which cases are reported tends to reveal the disease **incubation period**, the period between pathogen entry and the appearance of illness. Cases in common-source epidemics tend to remain spatially isolated near the local source of infection, which facilitates its identification **(Figure 18.20)**.

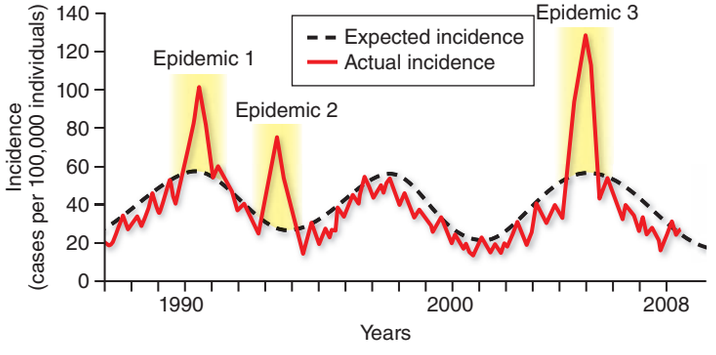

Figure 18.16. Endemic diseases may become epidemic The dashed line shows the expected cyclical incidence, resulting from historical patterns of endemic disease. Epidemics, shown as peaks 1, 2, and 3, arise when the incidence of endemic disease rises above that expected.

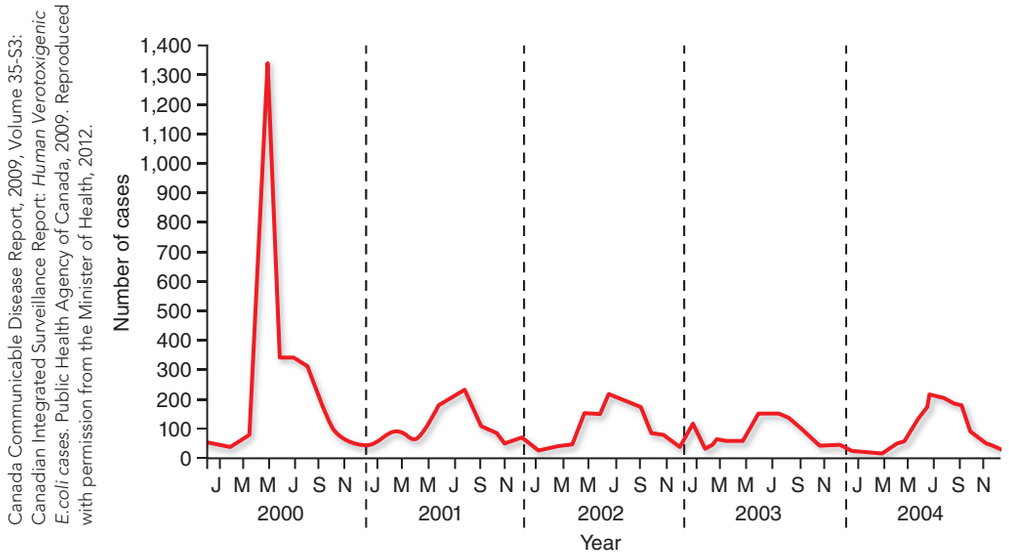
TABLE 18.6 Notable pandemics of humans

Disease	Causative agent	Years
Plague	*Yersinia pestis*	541–747 1346–1451 1665–1666 1855–1859
Smallpox	Variola virus	1493–1591 1665–1666 1870–1875
Flu	Influenza virus H1N1 Influenza virus H2N2 Influenza virus H3N2 Influenza virus H1N1	1918–1920 1957–1958 1968–1969 2009–2010
Cholera	*Vibrio cholerae*	1816–1826 1829–1851 1961–current
Typhus	*Rickettsia prowazekii*	1528–1566
AIDS	Human immunodeficiency virus (HIV)	1981–current

Phase 1	No reports of humans infected with new influenza viruses. The risk of human infection with circulating animal influenza viruses is considered to be low.
Phase 2	No reports of humans being infected with new influenza viruses. However, the risk of human infection with a circulating animal virus is considered to be high.
Phase 3	**Pandemic alert phase.** Human cases of infection with a new virus exist, but no general human-to-human transmission is reported.
Phase 4	Verified human-to-human transmission in small clusters, showing limited spread, indicating the virus is not yet adapted to humans.
Phase 5	Larger clusters of human-to-human transmission spread, but cases remain localized. This indicates the virus is adapting to humans and is a strong indication that a pandemic is imminent.
Phase 6	**Pandemic phase.** Sustained human-to-human transmission with increased outbreaks in the general population.

Figure 18.17. Six phases of influenza pandemic alert The World Health Organization (WHO) established a six-phased approach for influenza preparedness and response plans. Phases 1 and 2 are the inter-pandemic period involving surveillance and monitoring of predominantly animal viruses. Phases 3 through 5 indicate a new virus is infecting humans and the level to which the virus can be spread in populations. These are response phases that call for planning and measures to control spread, such as implementation of vaccination, triage recognition in health care settings, and suspension of elective activities such as traveling. Phase 6 declares a pandemic where infections with the new virus have reached the global communities.



Canada Communicable Disease Report, 2009, Volume 35-S3: Canadian Integrated Surveillance Report: *Human Verotoxigenic E.coli cases*. Public Health Agency of Canada, 2009. Reproduced with permission from the Minister of Health, 2012.

Figure 18.18. Epidemic curve and temporal pattern of an outbreak Cases of Shiga toxin-producing strains of *Escherichia coli* in Canada show a seasonal pattern, peaking in summer months. The *E. coli* O157:H7 outbreak in Walkerton, Ontario, significantly increased the number of cases in Canada over a very short period of time in 2000.

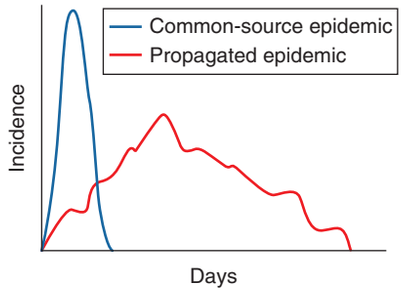


Figure 18.19. Propagated and common-source epidemics Common-source epidemics (blue line) commonly display a single peak in incidence because the majority of cases will have encountered the source of infection within a short period of time. The time over which cases appear corresponds to the incubation period. In propagated epidemics (red line), each case becomes a source, causing several other cases, which results in numerous cases over several incubation periods and multiple small peaks.

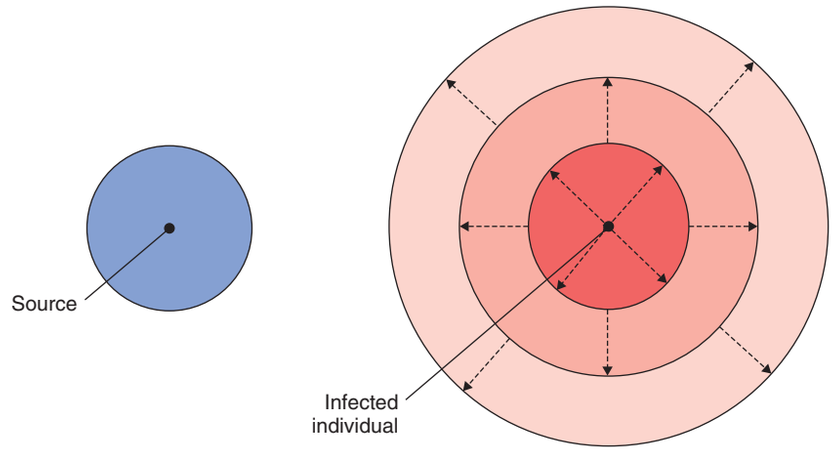

Figure 18.20. Movement of common-source and propagated epidemics **A.** In a common-source epidemic, cases will tend to cluster near the source of infection, which remains relatively static. **B.** In a propagated epidemic, the source is moved with each new infection. Cases first will appear near the source, usually an infected individual, but will begin to radiate away from this source as transmission moves the infection from individual to individual.

Mini-Paper: A Focus on the Research
EPIDEMIOLOGY OF AN INFECTIOUS DISEASE

R. J. Montali, C. A. Scanga, D. Pernikoff, D. R. Wessner, R. Ward, and K. V. Holmes. 1993. A common-source outbreak of callitrichid hepatitis in captive tamarins and marmosets. J Inf Dis 167:946–950.

Context

As we mentioned in the opening story of Chapter 5, outbreaks of an often fatal hepatitis affecting golden lion tamarins (GLTs) had been reported by veterinarians at several zoos in the United States and the United Kingdom during the early 1980s. Because these primates are endangered, the zoo officials were especially eager to determine the cause of this disease.

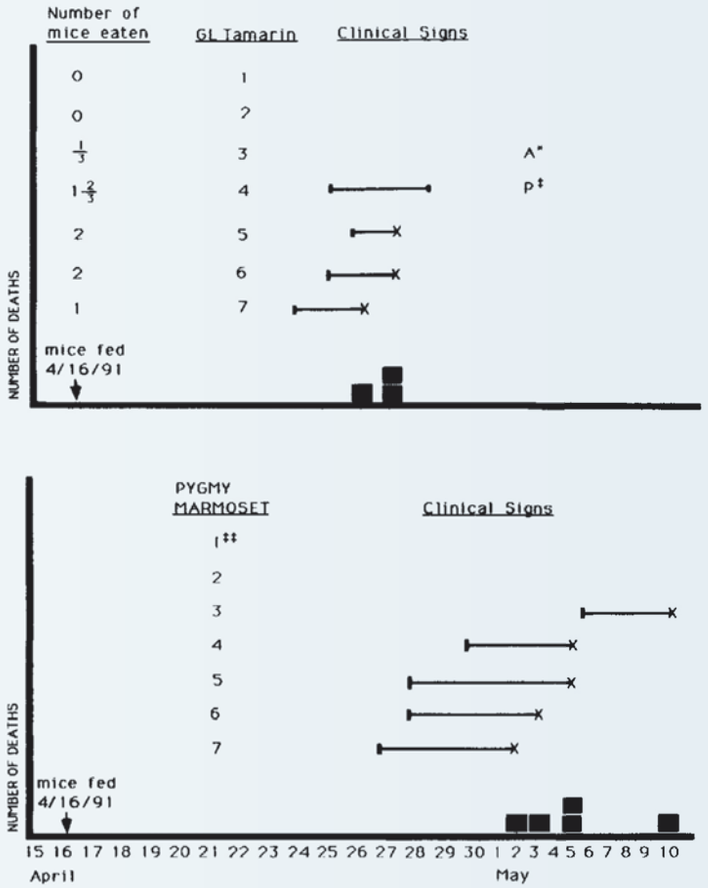
Initial studies showed that a virus caused the disease in these primates. Researchers demonstrated this point most conclusively by inoculating common marmosets, non-endangered primates related to GLTs, with a bacteria-free liver homogenate obtained from a GLT that had died from the disease. The marmosets developed a similar disease, leading the researchers to conclude that a virus caused the disease. Subsequently, the researchers determined that the virus was an arenavirus (see Section 5.4 for information about different groups of viruses). This determination was made through a series of immunological and genetic studies. However, a major question still remained. How were the GLTs becoming infected? In other words, the virologists and veterinarians wanted to know the source of the virus and how it was transmitted.

A subsequent outbreak of this disease at the Fort Worth Zoo in Texas allowed researchers to address this very important question. The answer allowed zoos to better protect their GLTs from future outbreaks.

Experiments

In April of 1991, an outbreak of hepatitis among marmosets and tamarins, referred to as callitrichid hepatitis (CH), occurred at the Fort Worth Zoo. Four of seven GLTs became sick and three of them died. Five of seven pygmy marmosets also became sick. All five of them died. The animal handlers observed that all of the animals initially showed signs of disease about two weeks after having been fed neonatal mice **(Figure B18.1)**. The outbreak, then, appeared to be a common-source outbreak, and the source of the infection appeared to be the neonatal mice.

Because the mice appeared to be the source of the infection in the tamarins and marmosets, the researchers next wanted to demonstrate that the mice actually contained the infectious agent—a strain of lymphocytic choriomeningitis virus (LCMV). To accomplish this goal, the researchers used a solid-phase immunoassay. Briefly, liver homogenates from the mice, affected primates, and uninfected primates were spotted onto a nylon membrane. The membrane then was probed with serum from an animal that had been experimentally inoculated with the virus (CHV), LCMV antibodies (LCMV), serum from an uninfected GLT (Tamarin control), and serum from an uninfected guinea pig (G. pig control). As seen in **Figure B18.2**, CHV and



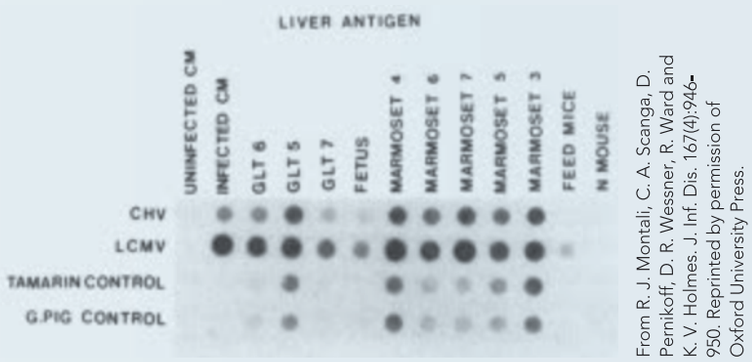
From R. J. Montali et al. 1993. J Inf Dis 167(4):946–950. Reprinted by permission of Oxford University Press.

Figure B18.1. Time course of disease among tamarins and marmosets at Fort Worth Zoo Mice were fed to the animals on April 16, 1991. Animals began showing clinical signs of disease about two weeks later. Blocks represent fatalities.

LCMV antibodies reacted strongly with all of the affected GLTs and marmosets, the fetus of one of the tamarins, and the feed mice. In contrast, these antibodies did not react with liver homogenates from an uninfected marmoset or an uninfected mouse. Additionally, the control sera reacted only weakly with all of the samples. Based on these results, the researchers concluded that LCMV antigens were present in all of the affected animals and the potential vector—the feed mice.

Impact

These findings had profound implications for zoos. If the virus were being transmitted to GLTs from mice used as food supplements, then the outbreaks should end if mice were no longer fed to the primates. This information was conveyed to zoos throughout the country and outbreaks of callitrichid hepatitis stopped.



From R. J. Montali, C. A. Scanga, D. Pernikoff, D. R. Wessner, R. Ward and K. V. Holmes. J. Inf. Dis. 167(4):946-950. Reprinted by permission of Oxford University Press.

Figure B18.2. Solid-phase immunoassay detection of viral antigens Liver homogenates were spotted onto a nylon membrane and probed with serum from an animal previously infected with CHV, LCMV-specific serum, tamarin control serum, and guinea pig control serum. Liver samples from all of the affected animals reacted strongly with CHV-specific and LCMV-specific serum.

The findings of this paper raised additional questions. Could wild mice harbor this virus? Could these wild mice, which are quite common in zoos, transmit the virus to GLTs? Could infected mice transmit the virus to humans? Could the virus be transmitted from infected GLTs to zoo personnel or visitors to the zoo?

Outbreaks of callitrichid hepatitis have occurred in several zoos that did not use mice as a food source. Presumably, these outbreaks occurred when primates came in contact with infected wild mice. Therefore, wild mice may be a source of infections. In none of the outbreaks, however, has there been any evidence of primate-to-primate transmission. The potential role of this virus in human diseases still needs to be determined.

Questions for Discussion

1. The aborted fetus of an infected GLT contained viral antigens, as shown in Figure B18.4. What does this finding tell you about the transmission of the virus?
2. The onset of disease, as shown in Figure B18.3, is typical of a common-source outbreak. What would this graph look like if the virus were propagated?

Successful location of the source usually allows the outbreak to be rapidly controlled. For example, removal of contaminated food or chlorinating the drinking water can stop outbreaks of *E. coli*.

The cholera outbreak of 1854 in the Soho area of London represents one of the most famous examples of a common-source epidemic. English physician John Snow, widely regarded as the first epidemiologist, showed that cholera resulted from contaminated drinking water. By tracking the location of cholera cases on a map **(Figure 18.21)**, Snow linked the cases to a single source of contaminated water obtained from the Broad Street pump. People living near another neighborhood pump, from which they obtained their water, did not become ill. Snow convinced the Board of Guardians to remove the handle from the pump to prevent access to the contaminated water supply. Although new cases of the disease probably already were declining, Snow's observation often receives credit for ending the outbreak.

Propagated Epidemics

A **propagated epidemic** or outbreak results from infection passing from one host to another, either directly or indirectly. Propagated epidemics usually stem from the introduction of an infected individual into a susceptible population. Diseases easily transmitted between individuals produce propagated epidemics. Examples of such propagated epidemics include measles, influenza, chickenpox, and tuberculosis. Propagated epidemics also occur for some vector-transmitted diseases, such as yellow fever and malaria. Both agents are delivered by mosquitoes and replicate very efficiently in humans, resulting in a pattern of spread similar to diseases in which the pathogen is transmitted directly from person to person.

Propagated epidemics typically show a gradual increase in incidence as the infection is spread to more and more individuals, eventually reaching a peak. At this point, a significant proportion of the population is infected, has recovered and is immune, or has died. Fewer members of the population remain susceptible to infection. As opposed to common-source epidemics, cases in a propagated epidemic will continue to appear over more than one incubation period. For example, measles has an incubation period of approximately 10 days. During this time, newly infected individuals do not show clinical signs of disease and are not yet cases. After this time, they become cases, and a new batch of individuals will be infected, resulting in a resurgence of cases approximately every 10 days. Propagated epidemics will show spread away from the initial site of introduction, and can cover large geographical areas.

Many infectious diseases do not show classic common-source or propagated epidemic curves. For example, cholera usually begins as a common-source epidemic but, in crowded and unhygienic conditions, it spreads from person to person, resulting in a mixed epidemic of propagated and common-source transmission. As a result, investigating the epidemiology of an infectious disease is not a simple task. Determining what causes an infectious disease and how the microbe is transmitted, however, is quite important. Effective treatment and prevention strategies depend on accurate information about these topics. In the following analysis of a specific investigation, we will begin to see how these issues can be addressed.

Figure 18.21. Cholera and the Broad Street pump: Mapping cases of cholera to a source In London in 1854, John Snow linked cholera with contaminated drinking water by carefully plotting known deaths on a map. He noticed cases were tightly clustered around the Broad Street pump. His systematic investigation confirmed all cases had obtained their water from this particular pump, which under microscopic examination was shown to contain organic matter. Snow suspected the contamination came from a sewer that was located above and just a few feet away from the shallow well that supplied the Broad Street pump. For his innovative thinking and actions, John Snow is considered to be the father of epidemiology.

18.3 Fact Check

1. Describe the concepts of fecal-oral transmission, respiratory transmission, vector-borne transmission, and sexual transmission. Provide examples of each.
2. Differentiate between vertical and horizontal transmission.
3. Explain how zoonotic transfer, reservoir host, and dead-end host are related.
4. Distinguish between morbidity and mortality.
5. Describe how the terms "case," "incidence," and "prevalence" are used in epidemiology.
6. What are emerging and re-emerging pathogens? Give examples.
7. Differentiate between outbreak, epidemic, and pandemic.

18.4 Proving cause and effect in microbial infections

How can we determine the cause of an infectious disease?

The study of epidemiology, as we just saw, allows us to determine how infectious diseases spread through a population. From these studies, we may be able to determine the mode of transmission, infectivity, and natural vector of a pathogen. However, such studies do not allow us to determine whether a specific microbe causes a specific disease. This piece of information is absolutely necessary because prevention and treatment options depend on our ability to conclusively determine which microbe causes a given infectious disease. In this section, we will investigate this important topic. Additionally, we will look at a molecular corollary of this topic. More specifically, we will begin to address how we can determine which genes within a pathogenic microbe contribute to its pathogenicity.

Koch's postulates

Today, we know that microbes cause various diseases, and we may take for granted the evidence supporting this fundamental knowledge. A nineteenth-century physician and microbiologist, Robert Koch, generally is credited with providing evidence for this causality. Koch investigated the link between bacteria and disease. He identified *Bacillus anthracis* as the causative agent of anthrax, *Mycobacterium tuberculosis* as the causative agent of tuberculosis, and *Vibrio cholerae* as the causative agent of cholera. Koch's most famous contribution to microbiology and medicine was his development of **Koch's postulates**, a guideline for demonstrating that a specific microbe causes a specific disease. Although we now recognize that these postulates have limitations, they still represent important guides to determining the causes of infectious diseases.

Based on translations of Koch's initial lectures about these postulates, Koch argued that three criteria should be met to clearly prove that a microbe causes a disease.

1. The suspected microbe should exist in every individual with the disease and account for the signs and symptoms of the disease.
2. The microbe should not be fortuitously associated with other diseases as a non-pathogen.
3. After being isolated and grown in a pure culture, the microbe should cause the same disease following inoculation of a healthy host.

A fourth postulate, stating that the suspected microbe then should be re-isolated from an experimentally inoculated host, often has been added to this original list.

To some extent, you may have seen Koch's postulates in action when visiting your physician. Strep throat is caused by *Streptococcus pyogenes* and is characterized by a severe sore throat, enlarged tonsils, and a fever. To determine if a person has strep throat, a physician often will conduct one of two tests. First, a throat swab may be used for a rapid strep test. In this test, the throat swab is analyzed for the presence of specific molecular determinants found in Group A streptococci, the group to which *S. pyogenes* belongs. The results of this test are available within minutes. Second, the throat swab may be streaked on agar plates. Following a period of incubation, the plates can be observed for the presence of *S. pyogenes* colonies. With these tests, then, the physician is applying Koch's first postulate—the causative microbe must be identified in every person with the disease, and its presence should account for the signs and symptoms of the disease.

This very example, however, also illustrates some of the limitations of Koch's postulates. First, *S. pyogenes* can be found in many people without strep throat. In other words, this microorganism is not always associated with disease. Second, other bacteria and viruses cause diseases with signs and symptoms similar to strep throat. *S. pyogenes* is not the only microbe that can cause this type of disease.

CONNECTIONS Today, clinicians have at their disposal relatively rapid tests for numerous human pathogens. Often, these tests rely on enzyme-linked immunosorbent assays (ELISAs). In **Toolbox 20.2**, we will investigate these assays more thoroughly.

Our current understanding of ulcers presents a fascinating example of the importance and modern relevance of Koch's postulates. Until quite recently, physicians assumed that gastric ulcers, lesions in the mucosal lining of the stomach, resulted from too much acid **(Figure 18.22)**. Additionally, some physicians also thought that the overproduction of acid resulted from stress. Treatment typically involved attempts to decrease stress and neutralize the excess acid. Usually, antacids were recommended. For many years, though, microbiologists had noticed curved bacteria in tissue samples taken from the stomachs of people with ulcers. However, the significance of these bacteria was not adequately explored; no one isolated or characterized these organisms.

Two researchers at the University of Western Australia, Drs. Robin Warren and Barry Marshall, changed our understanding of stomach ulcers in the 1980s. Warren observed that he always saw these curved bacteria associated with gastric tissue that showed signs of inflammation, or gastritis. Furthermore, the number of bacteria seemed to correlate with the severity of the inflammation. These observations, they reasoned, fulfilled Koch's first postulate. To further explore the possible role of these bacteria, Warren and Marshall isolated the bacterium, now known as *Helicobacter pylori* **(Microbes in Focus 18.4)**, and grew it in the laboratory.

To fully address Koch's third postulate (inoculation of a healthy host with the microbe causes the disease), the researchers took a very bold approach, an approach that almost seems more likely to occur in a Hollywood movie than in a real

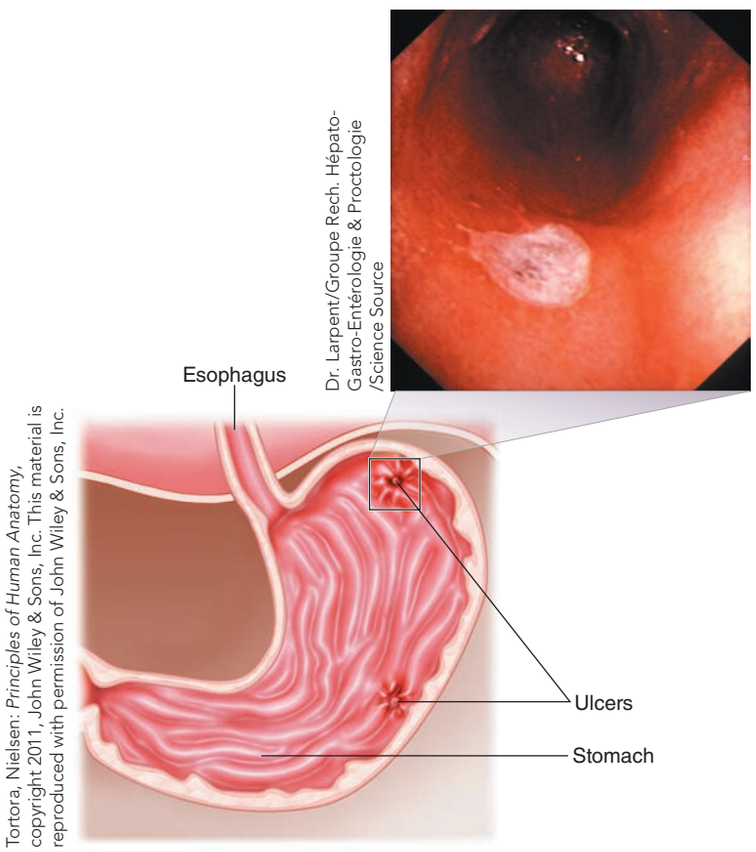

Figure 18.22. Gastric ulcers Physicians used to assume that the ulcers formed from too much acid. Now, most physicians agree that the bacterium *Helicobacter pylori* plays a significant role in the development of ulcers.

Microbes in Focus 18.4

LIFE IN THE STOMACH: *HELICOBACTER PYLORI*

Habitat: Stomach and small intestine of several types of animals, including humans, cheetahs, dogs, and cats

Description: Slow-growing, spiral-shaped, Gram-negative bacterium about 3 μm long with flagella

Key Features: Roughly 50 percent of all humans are colonized by *H. pylori*, although rates are higher in developing countries and lower in developed countries. The bacterium produces urease, an enzyme that converts urea to bicarbonate and ammonia. These molecules can neutralize acid, thereby creating an acid-free zone around the bacillus, which protects it during transit from the lumen of the stomach into the more neutral layers of mucus, where it begins its colonization of the stomach wall. The bacterium is equipped with several highly active flagella to help it drill through the thick mucous layer lining the stomach.

© NIBSC/Photo Researchers, Inc.

microbiology laboratory. They grew a pure liquid culture of *H. pylori*. Then Marshall and another volunteer drank it. Both of them developed an inflammation of the stomach lining, or gastritis. Furthermore, *H. pylori* could be isolated from biopsies of their stomachs. This experiment showed a strong link between *H. pylori* infection and gastritis. More thorough studies involving large numbers of people showed a link between infection and both gastritis and ulcers.

In this particular case, researchers used Koch's postulates to do more than just identify the microbe responsible for a disease. Warren and Marshall also changed dramatically the standard treatment regimen for ulcers. As we stated earlier, ulcers had been treated most commonly with antacids. After all, if excess acid causes ulcers, then decreasing the amount of acid should be the best treatment. Once physicians realized that a bacterium causes ulcers, antibiotics became the preferred treatment regimen. Today, people with ulcers typically are treated with a series of antibiotics. Warren and Marshall, in fact, showed that 80 percent of people with ulcers could be cured if *H. pylori* were eradicated. Because of these discoveries, Warren and Marshall received the Nobel Prize in Physiology or Medicine in 2005.

Despite the obvious value of Koch's postulates, there are some legitimate drawbacks and criticisms of them. For example, although *H. pylori* is indeed identified in many individuals with stomach ulcers, the regular use of certain medications also can result in the development of ulcers. Moreover, *H. pylori* can be found in many individuals without ulcers, existing as a member of the human microbiome. As a result, Koch's first postulate is not satisfied completely for stomach ulcers and *H. pylori*. Furthermore, Koch himself admitted the potential limitations of his third postulate—if a healthy host is inoculated with the suspected microbe, then the host will develop the disease. On its surface, this postulate states that every host experimentally inoculated with a suspected pathogen should develop the disease. Koch observed that not all individuals respond equally to pathogens. Some individuals may exhibit resistance to a pathogen. To put it another way, not every individual inoculated with a potential pathogen will develop the associated disease. Genetic variations among the host organisms influence their susceptibility to various microbes. We encountered an excellent example of this concept in Chapter 5 when we discussed mouse hepatitis virus. The A59 strain of mouse hepatitis virus (MHV-A59) readily infects BALB/c mice. Conversely, SJL/J mice are largely resistant to this virus **(Figure 18.23)**. Why? The SJL/J mice possess an allele of the MHV receptor gene that codes for a protein not readily recognized by the virus.

The third postulate also necessitates that a suitable experimental host for the disease exists. If we are studying a dangerous human pathogen for which no suitable treatment exists, then obviously we cannot experimentally inoculate humans to demonstrate that the potential pathogen causes the disease (the example of Warren and Marshall notwithstanding!). Rather, we need to identify a suitable animal **(Perspective 18.2)** that (1) can be infected by the microbe and (2) consistently develops a disease as a result of the infection. We should note, though, that the disease state in an animal model does not always perfectly mirror the disease state in humans. Some people also may argue that we technically cannot grow obligate intracellular pathogens in pure culture. These microbes only can replicate in the presence of host cells. This argument, though, seems to be an issue of semantics rather than a legitimate criticism of Koch's postulates. Nonetheless, these examples highlight some of the difficulties associated with applying Koch's postulates to the letter. Indeed, Koch's postulates are sometimes modified to suit individual diseases as best possible, reflecting the wide-ranging diversity of pathogens, culturability, and pathogenicity.

Molecular Koch's postulates

Despite being developed over a century ago, Koch's postulates continue to influence our ability to demonstrate the causal relationship between microbes and diseases. Today advances in molecular biology allow us to examine the influence of specific microbial genes and gene products on pathogenesis. In other words, we can not only identify the culprit microbe, but also the specific molecules that contribute to it virulence. Stanley Falkow, a noted microbiologist at Stanford University, proposed a list of **molecular Koch's postulates**, modeled after the original postulates of Koch. According to Falkow:

- The virulence factor gene should be present and expressed in pathogenic strains of the microbe.
- Experimental inactivation of the virulence factor gene should lead to a decrease in virulence.
- Experimental reversion of this inactivating change should result in a restoration of virulence.

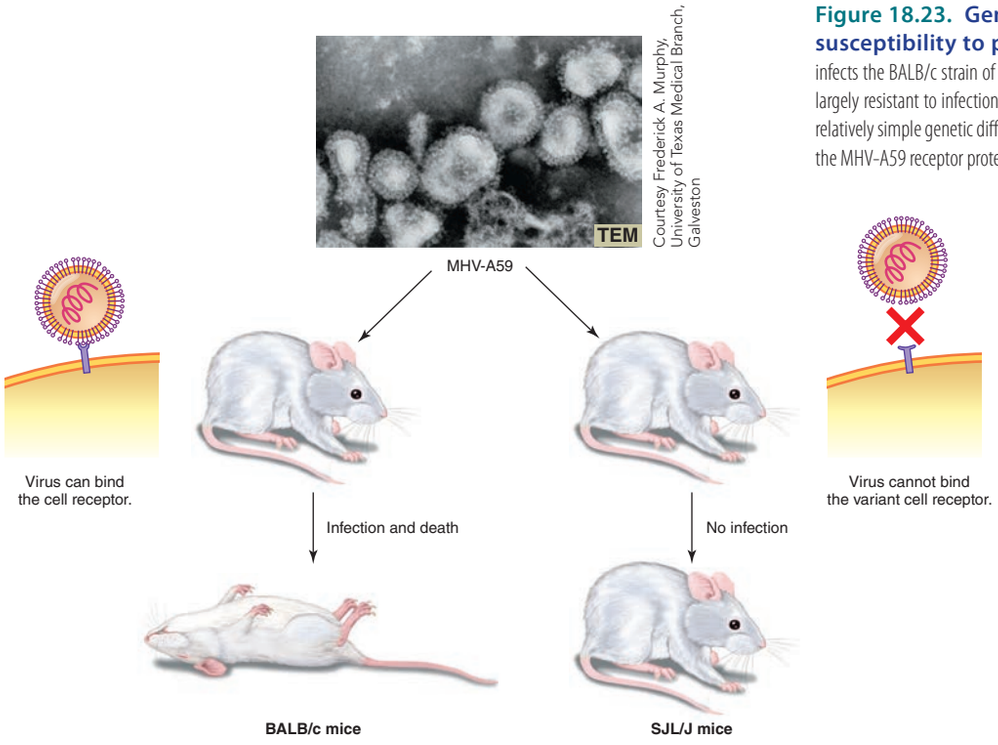

Figure 18.23. Genetic variations among individual hosts and susceptibility to pathogens Mouse hepatitis virus strain A59 (MHV-A59) readily infects the BALB/c strain of mice. Conversely, another common laboratory strain of mice, SJL/J, is largely resistant to infection by MHV-A59. This dramatic difference in susceptibility results from a relatively simple genetic difference between the two mouse strains. SJL/J mice produce a variant of the MHV-A59 receptor protein to which the virus cannot bind.

- The virulence factor gene should be expressed during an infection.
- Resistance to the virulence factor must provide protection.

Put simply, Falkow postulated that we should be able to demonstrate the contribution of specific genes, and their products, to the pathogenesis process. Through molecular techniques, we should be able to inactivate or remove suspected virulence factor genes from a pathogenic organism. In the absence of essential virulence factors, the microbe should exhibit decreased virulence. A microbe, in other words, is not inherently pathogenic. Specific molecular attributes contribute to the pathogenic phenotype. These virulence factors may affect some of the processes that we discussed earlier and include adhesion factors, invasion factors, toxins, and secretion systems.

In many cases, these virulence factors allow the microbe to better obtain nutrients. Invasion factors, for instance, allow microbes to enter cells, thereby providing them with access to needed resources. In other cases, these virulence factors may allow the microbe to better exit an infected host. Exiting a host is a necessary prerequisite to infecting another host and allowing the microbes to continue replicating. By obtaining the genes for some or all of these factors, the bacterium becomes, in a manner of speaking, more aggressive. It becomes more virulent.

The genes for these virulence factors can be transferred from one cell to another via several different mechanisms, including conjugation, transduction, and transformation **(Figure 18.24)**. Interestingly, the chromosomes of many pathogenic strains of bacteria contain **pathogenicity islands**, or **PAIs**, regions of the chromosome that contain multiple virulence factor genes (see Section 10.3). These pathogenicity islands contain various genetic elements that have been obtained from various sources.

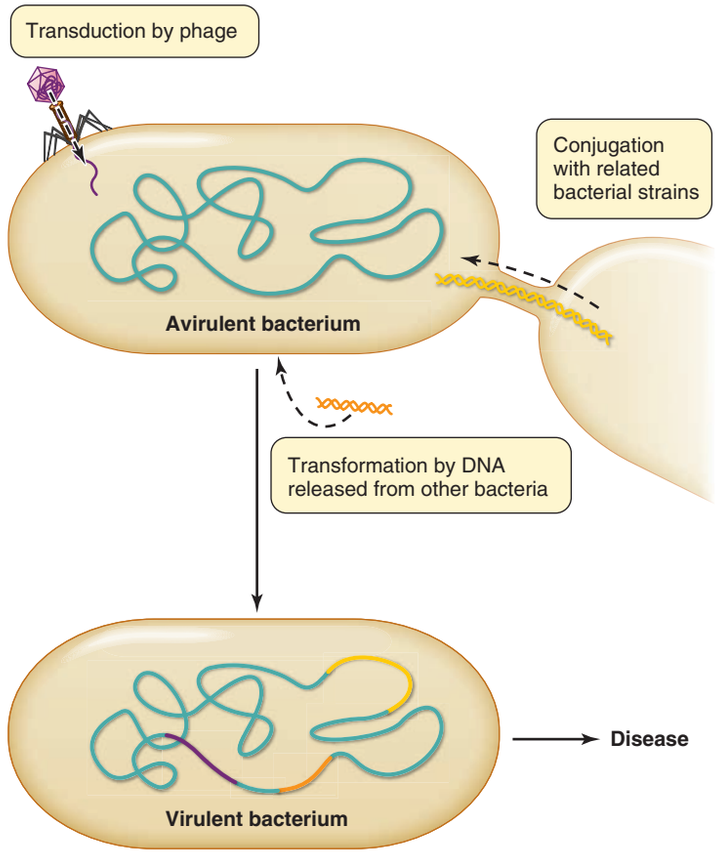

Figure 18.24. Acquisition of virulence factor genes An avirulent bacterium may obtain genes for virulence factors, such as adhesion factors, invasion factors, or toxins, through a variety of mechanisms, including conjugation, transduction, and transformation. After acquiring these genes, the previously avirulent bacterium may become virulent and produce disease.

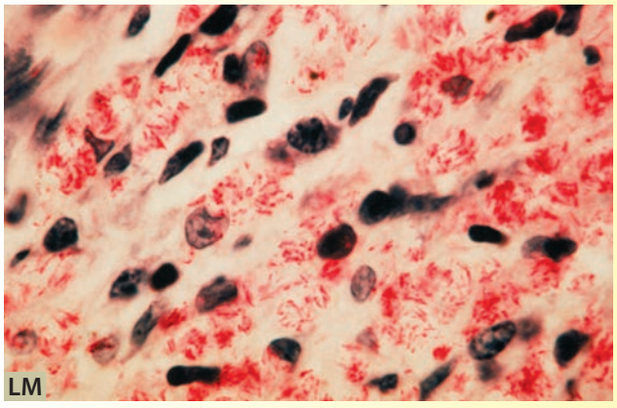
Perspective 18.2
THE ARMADILLO—AN IDEAL ANIMAL MODEL?

Studies with animals have provided us with invaluable information about human diseases. As we mentioned in the previous section, animals can be instrumental in proving Koch's postulates. We also depend on animals for basic studies on the transmission, prevention, and treatment of infectious diseases. Indeed, much of what we know about human pathogens depends on studies conducted in various model organisms. Quite often, these studies are conducted in mice. In fact, if there were a biomedical hall of fame, then mice probably would be among the inaugural inductees. Armadillos, on the other hand, probably are not high on many people's lists of important model organisms. That said, much of what we know about leprosy, or Hansen disease, we owe to the nine-banded armadillo.

The causative agent of leprosy, *Mycobacterium leprae*, has proven to be especially difficult for researchers to study. We know that the bacterium, discovered in 1873 by Gerhard Armauer Hansen, is rod shaped, and is an obligate intracellular pathogen **(Figure B18.3)**. In other words, it only replicates within cells. Genetic studies have shown that *M. leprae* lacks a number of genes needed for, among other activities, metabolism and DNA replication. Presumably, these genes have been lost as *M. leprae* evolved from a free-living organism to an intracellular pathogen. This dependence on a host cell also makes it difficult to study *M. leprae*. In fact, researchers have not been able to develop any kind of medium or identify any cell line that supports *M. leprae* replication.

Luckily, the bacterium does replicate in armadillos due to their cool body temperature of 32°C to 35°C, which is ideal for *M. leprae* **(Figure B18.4)**. Researchers can inject bacteria into an armadillo, and over a period of time, the bacteria replicate and can be recovered from the animal. Additionally, *M. leprae* causes a disease in the armadillos, so the effectiveness of potential drugs can be tested in them. Finally, there is ample evidence that wild armadillos have naturally occurring *M. leprae* infections and have harbored the pathogen long before they were used for research. Furthermore, a study published in April 2011 provides evidence that transmission of *M. leprae* from armadillos to humans can occur.



Science Photo Library/Science Source

Figure B18.3. *Mycobacterium leprae* This rod-shaped bacterium is extremely slow growing, with a doubling time of approximately 13 days. Although the bacterium was discovered over 125 years ago, researchers still have not developed a means of cultivating this microorganism in the laboratory on prepared media and under controlled conditions.

Steve Bower/iStockphoto

Figure B18.4. Using armadillos to grow the leprosy bacterium The bacterium that causes leprosy, *Mycobacterium leprae,* still cannot be cultivated in the laboratory. To circumvent this problem, researchers have used a rather unusual research animal—the armadillo. *M. leprae* can be injected into the footpad of armadillos. It replicates in, and later can be isolated from, this host organism.

Evolutionary pressure, it appears, has selected for the linkage of these individual virulence factor genes into a cohesive genetic structure. We will explore the origins and evolution of pathogenicity islands more thoroughly in Chapter 21. In the next section of this chapter, we will look more generally at the evolution of pathogens.

CONNECTIONS We now know that horizontal, or lateral, gene transfer commonly occurs among various organisms and can affect greatly the genomes of these organisms. Experimental evidence demonstrating this process was discussed in **Section 10.3**.

18.4 Fact Check

1. What are the key postulates put forth by Robert Koch?
2. How were Koch's postulates specifically used in determining that *H. pylori* was the cause of ulcers?
3. What are some of the limitations of Koch's postulates?
4. Describe Falkow's molecular Koch's postulates.

18.5 The evolution of pathogens

How do new infectious diseases arise?

In the preceding sections, we explored the concept of an infectious disease, how microbes cause diseases, what factors affect the spread of infectious diseases within a population, and how we determine that a specific microbe causes a specific disease. To complete our introduction to infectious diseases, another major puzzle needs to be addressed. We need to investigate how new infectious diseases arise.

Some infectious diseases, like toxic shock syndrome, Legionnaire's disease, Ebola virus disease, Lyme disease, SARS, and AIDS, are classified as emerging or re-emerging. As we will see in this section, several events can lead to the emergence of a new disease or re-emergence of a previously recognized disease. Here we focus on two particular scenarios. First, a host population may come in contact with a pathogen it has not encountered previously, much as we saw with the golden lion tamarins. Second, a microbe that is not a strong pathogen can become more virulent. We will end this section by briefly examining what we can do to remain vigilant of these emerging infectious diseases.

Encountering a new population

A new or emerging disease may arise when an existing pathogen encounters a new population, perhaps through a zoonotic transfer. Following such a transfer, referred to as a "spillover," the microbe may cause only limited disease. During the hepatitis outbreak among golden lion tamarins that we discuss in this chapter's Mini-Paper, researchers were concerned about the possible zoonotic transfer of lymphocytic choriomeningitis virus (LCMV) from these primates to humans. They did not know how the virus would interact with a human host. Apparently, the concerns were unwarranted; even veterinary pathologists who worked very closely with the dying animals did not become infected. In other cases, the transfer of a pathogen to a new host species may result in significant disease. Outbreaks of Ebola virus disease represent a very dramatic example of this outcome.

To explore more fully the emergence of new human infectious diseases, we will briefly examine the emergence of HIV/AIDS and Lyme disease. In the case of HIV, as we will see, a virus was transferred from non-human primates to humans. In the case of Lyme disease, a change in human activities caused humans to come in contact with a pathogen more frequently.

HIV/AIDS

HIV/AIDS represents a horrific example in which a zoonotic transfer has led to a worldwide emerging disease. Through extensive sequence analysis studies, researchers have concluded that HIV has evolved from **simian immunodeficiency virus (SIV)**, a virus found in various non-human primates throughout Africa. Possibly, the virus was transferred from a non-human primate to a human during a hunting trip. Initially, the virus may have replicated poorly within infected humans, or been transmitted poorly from human to human. Over time, though, the virus mutated to become the human-adapted HIV. Again, based on sequence comparisons of SIV and HIV strains, researchers estimate that the initial transfer of the virus to humans probably occurred in the early 1900s.

The zoonotic transfer of SIV to humans, and eventual evolution of HIV, appears to have occurred more than once. We know that two main types of HIV, HIV-1 and HIV-2, currently infect humans. HIV-1 is by far the more prevalent of these viruses and is the virus most typically referred to when we discuss AIDS. Conversely, HIV-2 tends to be found primarily in western Africa and is associated with a less severe form of disease. Four genetically discernible groups of HIV-1, the M, N, O, and P groups, have been identified. Group M viruses, the group associated with the HIV/AIDS pandemic, can be subdivided further into nine discernible subtypes, or **clades** (A–D, F–H, J, and K). Additionally, recombinant forms of these clades, referred to as circulating recombinant forms (CRFs), have been identified **(Figure 18.25)**. Although the distribution of these clades is worldwide, certain clades are more common in certain geographic areas. For instance, clade B HIV-1 predominates in the United States, whereas clade C predominates in southern Africa.

The identification of these HIV variants raises an interesting and important question: What is the origin of HIV? Genetic analyses show that HIV-2 most closely resembles SIV isolated from sooty mangabeys (SIV_{smm}), whereas HIV-1 group M isolates most closely resemble SIV isolated from chimpanzees (SIV_{cpz}). HIV-1 group N isolates also most closely resemble SIV isolated from chimpanzees, whereas HIV-1 group O and group P isolates appear to be related to viruses found in gorillas. This genetic information indicates that there have been multiple separate spillover events, of SIV or SIV-like viruses into humans. This evidence raises a very compelling question: could a new form of HIV arise through yet another zoonotic transfer?

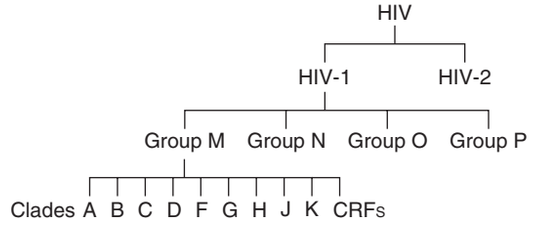


Figure 18.25. Genetically distinct groups of HIV with different geographic distributions Two distinct viruses, HIV-1 and HIV-2, have been identified. HIV-1 can be further subdivided into four groups: M, N, O, and P. Ninety percent of HIV infections are due to HIV-1 group M. Nine distinct subgroups, or clades, of group M have been identified. Recombinant forms of these clades (CRFs) also have been identified.

Microbes in Focus 18.5
BORRELIA BURGDORFERI AND LYME DISEASE

Habitat: Ticks, deer, rodents, humans, and other mammals

Description: Spirochete, Gram-negative bacterium; may be over 20 μm long, but less than 1.0 μm wide

Key Features: Lyme disease is the most common tick-borne illness in America. Unlike most other bacterial pathogens, *B. burgdorferi* does not need iron. Typically, the relative absence of free iron within humans presents a major limitation for bacterial growth. Many bacterial pathogens, as a result, have evolved specific mechanisms to acquire this essential element from the host. *B. burgdorferi* has addressed this problem in another way. It does not contain iron-associated proteins normally found in other organisms and can grow in the absence of this metal.

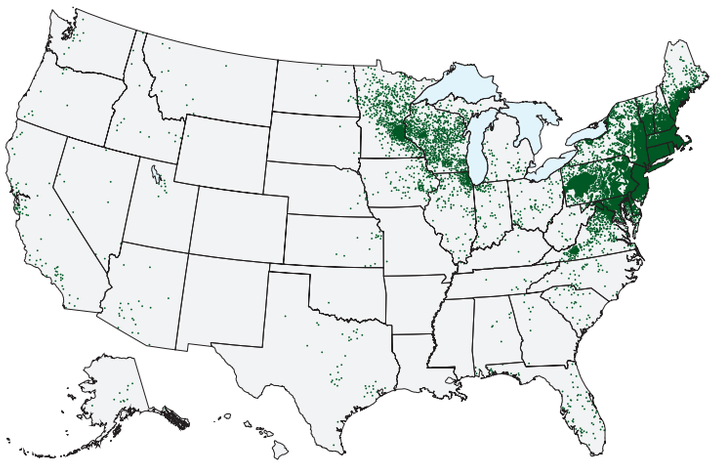
A. Incidence of Lyme disease in the United States



B. Locations of confirmed Lyme disease cases in 2013

Figure 18.26. Increasing incidence of Lyme disease in the United States The increase in Lyme disease has resulted primarily from the expansion of human habitation. As housing developments have spread into previously wooded areas, contact with Lyme disease vectors has become more common. **A.** The annual number of cases of Lyme disease has increased since 1995. In 2013, over 25,000 cases were confirmed. **B.** Although cases of Lyme disease occur throughout the United States, the majority of the cases occur in the northeast and upper Midwest. Each dot indicates a county in which at least one confirmed case of Lyme disease occurred.

Lyme Disease

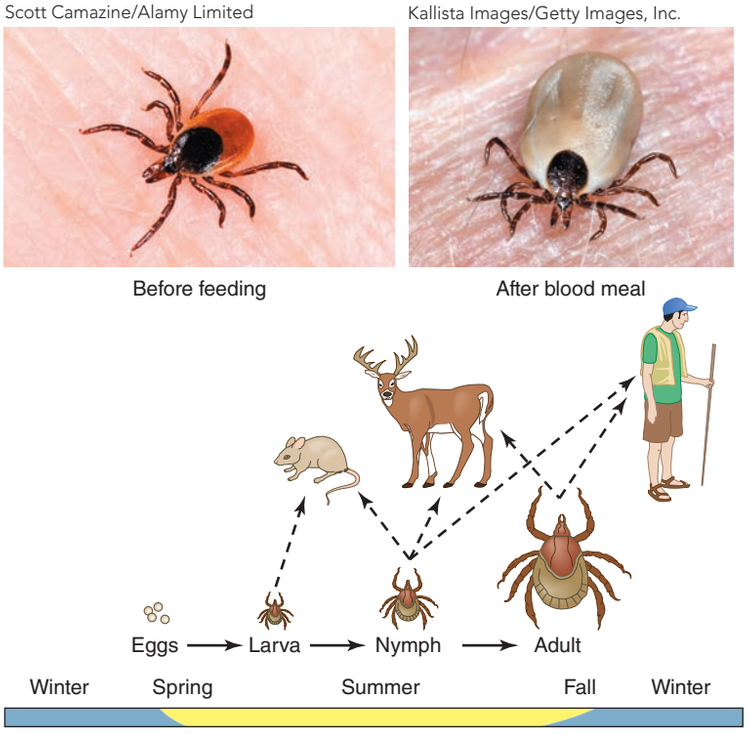
The emergence of Lyme disease in the United States presents a very different situation. This disease, caused by the bacterium *Borrelia burgdorferi* **(Microbes in Focus 18.5)**, first caught the widespread attention of the medical community and American population in 1975. At that time, physicians reported a cluster of cases of an arthritis-like disease in young people in Old Lyme, Connecticut. In 2013, over 25,000 confirmed cases of Lyme disease occurred in the United States, mostly in the northeastern part of the country **(Figure 18.26)**.

What led to the emergence of this disease? To address that question, we need to know a little more about the infectious agent—*B. burgdorferi*. In the northeastern United States, this bacterium normally resides within white-footed mice and to a lesser extent in other rodent species, its natural reservoirs. It spreads from one individual to another via species of the blacklegged tick, *Ixodes*. The tick ingests blood containing the bacterium from one animal and then transfers the bacterium to the next animal that it bites. If the tick bites a human, then it can transmit the bacterium to the human. Disease occurs in this new host **(Figure 18.27)**. Humans are only incidental hosts; the pathogen is not transmitted from person to person.

In all likelihood, *B. burgdorferi* has been infecting deer, rodents, and other animals for many, many years. Transmission of the bacterium from ticks to humans also has been occurring for this time. Indeed, a historical review of medical literature reveals several cases of what was probably Lyme disease throughout the 1900s. What changed over the last 40 years? The emergence of Lyme disease can be directly tied to changing human activities. Changing patterns of development and farming practices, for example, have affected deer and rodent populations. As a result, contact between people and deer, rodents, and other potential reservoirs of *B. burgdorferi* is increasing **(Figure 18.28)**. This disease has emerged, not because the infectious agent has changed in any way, but because our exposure to it has changed.

Microbes becoming more virulent

As we have just seen, some emerging diseases, like HIV/AIDS and Lyme disease, arise primarily when an existing microbe comes in contact with a new host. Other emerging diseases arise when a microbe becomes more virulent, and yet others



A. Life cycle of the deer tick; humans are incidental hosts

B. Bull's-eye rash typical of Lyme disease

Figure 18.27. Lyme disease Caused by a bacterium transmitted by ticks, Lyme disease is a serious human disease. **A.** The pathogenic bacterium associated with Lyme disease is *Borrelia burgdorferi*, which can be spread from ticks to mice, deer, or humans. Although nymphs and adults occasionally bite humans, the nymphs probably are more likely to transmit the bacterium. **B.** In humans, the infection commonly causes a bull's-eye rash around the site of the tick bite.

arise when a pathogen gains resistance to antimicrobial drugs. The microbe, in other words, genetically changes in various ways. A microbe may, for instance, acquire a gene that codes for a virulence factor. Alternatively, a microbe that we can control through the use of drugs may develop a means of evading our control measures. In this case, the virulence of the microbe does not change, but it becomes more of a threat because of its ability to avoid control. To illustrate both of these scenarios, we will look at two specific examples, pathogenic *Escherichia coli* and methicillin-resistant *Staphylococcus aureus*.

Pathogenic *Escherichia coli*

Escherichia coli normally inhabits our intestinal tract. Usually, this bacterium is non-pathogenic, causing us no harm. In fact, it benefits us in many ways, helping us digest food and providing us with some important nutrients and vitamins. We know, though, that *E. coli* also is associated with severe intestinal diseases, or enteritis. How can one microorganism be both a common commensal species and a major pathogenic threat? The pathogenic strains of *E. coli* have obtained various virulence factors. As a result, these strains of *E. coli* no longer reside within our intestinal tract as harmless commensals. Rather, they cause disease.

Let's look at *E. coli* strain O157:H7 as an example. This strain of *E. coli* is found most commonly in cattle, where it generally does not cause any disease. When humans ingest beef contaminated with this bacterium, however, a life-threatening intestinal infection can occur. To a large extent, the increased virulence of this strain results from its production of Shiga-like toxins, toxins derived from *Shigella* species. The toxin genes probably were transferred from *Shigella* to *E. coli* via a transducing bacteriophage. The Shiga toxins are secreted by the bacteria, bind to a specific receptor found on various human cells and are internalized. Within the human cell, the toxin interacts with ribosomes, halting translation; destruction of the host cells ensues.

CONNECTIONS Recall from **Section 16.2** that although cattle are a primary reservoir of *E. coli* strain O157:H7, the cells of cattle lack the Shiga toxin receptor. As a result, this strain of *E. coli* is not pathogenic in these animals.

Of what benefit to the bacteria are these toxins? In a paper published in 2006, microbiologist Dr. Alison O'Brien and colleagues provided some insight into this

Courtesy David Wessner

Figure 18.28. Emerging diseases and increased exposure to reservoir species As human populations and their habitats (suburban living spaces) have expanded, our contact with other species has increased. The increased incidence of Lyme disease is related to our increased contact with deer, mice, and other potential reservoirs of *Borrelia burgdorferi*.

important evolutionary question. They demonstrated that a mutant strain of *E. coli* O157:H7, in which the Shiga toxin gene had been inactivated, adhered less well to epithelial cells *in vitro* than a strain with a functional Shiga toxin gene. Furthermore, the mutant strain was less able to colonize mice than the strain expressing Shiga toxin. It appears as though the toxin helps the bacteria remain in a hospitable environment. You can read more about *E. coli* O157:H7 in Chapter 21.

CONNECTIONS Along with diphtheria toxin, cholera toxin, tetanus toxin, and others, Shiga toxin is classified as an A-B toxin. These exotoxins share a common structure, containing an enzymatically active A subunit and a membrane-binding B subunit **(Section 21.1)**.

Methicillin-Resistant *Staphylococcus aureus*

Like *Escherichia coli*, *Staphylococcus aureus* is a very common microorganism. Quite frequently, it resides as a commensal on the skin or in the nasal passages. It can cause superficial skin infections, such as abscesses, when the protective layer of the skin is breached. As we saw with *E. coli*, certain strains of *S. aureus* have obtained various virulence factors, and these strains can cause a variety of human diseases. For example, *S. aureus* strains that produce toxic shock syndrome toxin (TSST) can cause the rare but potentially fatal disease known as toxic shock syndrome (see Section 21.2). Strains expressing enterotoxins often cause food poisoning. An even bigger medical concern has been the development of **methicillin-resistant *Staphylococcus aureus* (MRSA)**. This strain of *S. aureus* is resistant to a wide range of antibiotics and, as a result, is very difficult to treat. The first reports of MRSA came out in 1961, just two years after methicillin was first used to treat *S. aureus*. Since the 1990s, the number of MRSA infections has exploded. Treatment with standard antibiotics no longer works. Rather, physicians must treat MRSA infections with less common antibiotics, like vancomycin, to which most strains of MRSA are still sensitive. Unfortunately, vancomycin-resistant *S. aureus* strains, or VRSA, have been observed.

CONNECTIONS Pathogenic *Staphyloccoccus aureus* strains are notorious for producing diverse toxins that can cause a variety of diseases in humans and animals. You can read about these toxins and the diseases they cause in **Section 21.1**.

Addressing the problem

In the face of this threat of emerging diseases, what can we do to protect ourselves? Surveillance may be our most effective weapon. If we become aware of an epidemic quickly, then we may be able to curtail its spread. Internationally, the World Health Organization (WHO) organizes many surveillance programs. Organizations such as the Pan American Health Organization (PAHO) coordinate some regional programs. In the United States, the Centers for Disease Control and Prevention (CDC) coordinate or participate in several infectious disease-monitoring programs (Table 18.7). The Border Infectious Disease Surveillance (BIDS) Project, for instance, represents a program jointly run by the United States and Mexico. As part of this program, facilities on both sides of the U.S. and Mexican border track and report several different infectious diseases in an attempt to better understand the spread of diseases across the border. The prevalence of antibiotic-resistant strains of various bacteria is documented by the National Antimicrobial Resistance Monitoring System (NARMS), a program that includes, among others, members of the CDC, the Food and Drug Administration (FDA), and the U.S. Department of Agriculture (USDA).

In addition to these specific programs, the United States also monitors the incidence of a series of infectious diseases through the National Notifiable Diseases Surveillance System. Originally designed as a means of monitoring the occurrence of smallpox, plague, cholera, and yellow fever among American officials serving in other countries, the program now involves the reporting of a lengthy list of infectious diseases (Table 18.8) in all 50 states, the District of Columbia, and Puerto Rico. This information is published regularly in *Morbidity and Mortality Weekly Report* (*MMWR*), a weekly publication of the CDC (Figure 18.29). Additionally, the

Figure 18.29. *Morbidity and Mortality Weekly Report (MMWR)* Published weekly by the Centers for Disease Control and Prevention (CDC), the *MMWR* provides health professionals with up-to-date information about various infectious diseases. It also includes information about other diseases and health-related issues.

CDC presents an annual account of this information. The World Organization for Animal Health (OIE) monitors and reports on notifiable diseases in animals.

Through these surveillance programs, we can quickly become aware of an outbreak of an infectious disease. With today's communication capabilities, information about the disease can be distributed rapidly to physicians and local or regional government officials. Hopefully, a rapid response can lead to an equally rapid curtailment of the outbreak.

18.5 Fact Check

1. Describe conditions that may cause an emerging or re-emerging disease to arise and provide examples.
2. Describe how *E. coli* O157:H7 is thought to have emerged and persisted.
3. Identify some of the infectious disease surveillance systems in place and describe their objectives.

Image in Action

WileyPLUS Learning Space This illustration depicts the desk of a medical researcher studying different microbial diseases. The top folder describes polio and contains an image of the poliovirus (lower right picture) and an image of motor neurons undergoing apoptosis during an active poliovirus infection (lower left picture). The graph shows the rapid fall of new polio cases per year shortly following the introduction of the polio vaccine. The folder beneath describes malaria and holds an image of *Plasmodium falciparum* gliding between red blood cells. Nearby, a bottle of the antimalaria drug artemisinin is present. The folder on the right describes tuberculosis, including an image of *Mycobacterium tuberculosis*, and bottles of the antibiotic rifampicin and the tuberculosis vaccine BCG (Bacillus Calmette-Guérin).

1. Imagine you open the poliomyelitis folder and begin reading about the disease and pathogen. You encounter the virulence section and see that the organism has a CI ratio of less than 1. Explain the meaning of this information and how this number is related to the virulence of the poliovirus.
2. As you examine the tuberculosis folder, you encounter an epidemiology report on the incidence and prevalence of tuberculosis in New York City. What do these two terms mean, and how may the epidemiologists use this information to understand and study the disease in New York City?

The Rest of the Story

The poliovirus scare of the early 1950s in the United States quickly dissipated, thanks to the development of two effective vaccines. In 1955, an inactivated poliovirus vaccine, developed by Dr. Jonas Salk, was approved for use. Other researchers, including Drs. Albert Sabin and Hilary Koprowski, developed attenuated vaccines, which were approved for use in the early 1960s. With the development of these vaccines, the number of poliomyelitis cases in the United States dropped dramatically. In 1952, 58,000 cases were reported. In 1957, following a nationwide immunization program, there were only about 5,600 cases. In 1964, 121 cases were reported. The last case of wild poliomyelitis in the United States occurred in 1979. Since then, only sporadic cases, caused by the vaccine itself or imported to the United States from other countries, have been reported. The development of an effective vaccine against poliovirus has eliminated the threat of this infectious disease.

Given the unbridled success of the U.S. vaccination program, the World Health Organization (WHO) launched of the Global Polio Eradication Initiative in 1988. Their goal? The worldwide eradication of polio. The results have been impressive. With support from the WHO, the U.S. Centers for Disease Control and Prevention (CDC), Rotary International, and UNICEF, massive vaccination campaigns have occurred in countries throughout the world. In 1994, the entire Western Hemisphere was declared polio-free. By 1999, only about 7,000

Figure 18.30. Cases of poliovirus today Since the development of the poliovirus vaccines, the number of poliovirus infections has decreased dramatically. In fact, many parts of the world are considered polio-free. Despite the efforts of many governmental and non-governmental agencies, however, this pathogen has not been completely eliminated. Infections continue to occur in several countries, most notably in Pakistan and Afghanistan.

cases of polio were reported worldwide. In 2006, roughly 2,000 cases were reported, and most of them occurred in only four countries—Nigeria, India, Pakistan, and Afghanistan. The lofty goals of the Global Polio Eradication Initiative seemed within reach.

Since 2006, even greater progress has been made. On February 25, 2012, the World Health Organization removed India from the list of polio endemic countries. Not a single case of polio occurring from wild-type virus had been documented in this country in over a year. In July 2015, Nigeria celebrated a full year without any new cases of wild poliovirus disease and, in September of 2015, it was removed from the list of polio endemic countries. Indeed, in August 2015, not a single case of polio occurring from wild-type virus had been reported anywhere in Africa for over a year. At the end 2015, poliovirus remained endemic only in Pakistan and Afghanistan **(Figure 18.30)**. We will learn more about poliovirus and the poliovirus vaccines in Section 24.5.

Summary

Section 18.1: What is an infectious disease?

- A **disease** reflects any disturbances in the normal functioning of an organism, whereas an **infectious disease** is caused by a microbe that can be transmitted from host to host.
- A **communicable disease** is an infectious disease that can be transmitted between individuals, whereas a non-communicable disease generally cannot be transmitted. A **contagious disease** can be transmitted quite easily. A **zoonotic disease** is caused by a microbe that normally resides in an animal and causes disease when transmitted to humans.
- Microbes that frequently cause disease production are **pathogens**. The process by which pathogens cause disease is **pathogenesis**. **Infection** refers to the replication of a pathogen in or on its host. Specific **symptoms** and **signs** generally are associated with specific diseases.
- **Primary pathogens** have an intrinsic ability to produce disease in a proportion of uncompromised hosts, whereas **opportunistic pathogens** only cause disease under certain circumstances.
- The **virulence** of a pathogen is a measure of the intensity of disease that it causes. **Pathogenicity** refers to the ability of a microbe to cause disease. Often, the **case-to-infection (CI) ratio** of a microbe reflects its pathogenicity.
- Strains of a pathogen that have experienced **attenuation** exhibit decreased virulence. Attenuated strains of a pathogen may be effective **vaccines** that stimulate the immune system to respond to that pathogen. A **carrier** is infected by an infectious agent and may transmit it to others even though the carrier may be asymptomatic.

Section 18.2: How do microbes cause disease?

- To cause an infection, most pathogens must attach to or invade specific host cells or tissues and replicate. Additionally, they must evade host defenses. Various **virulence factors** promote these activities and enhance a pathogen's ability to cause disease
- Attachment generally occurs through specific protein:protein interactions and often determines the **host range** of a pathogen.
- Some pathogens, like *Trypanosoma brucei*, evade the host immune response by continually altering their surface molecules, a process known as **antigenic variation**. In contrast, herpes viruses avoid the host immune response by establishing a **latent infection**; new viral particles are not produced until **reactivation** occurs.
- Polioviruses utilize the host cell process of **autophagy**, which limits the cell-to-cell spread of some infectious agents, to augment its own replication.
- Even bacteria possess host defenses to protect themselves from pathogens. The **restriction-modification system** and **CRISPR-Cas system** both probably evolved to help bacteria protect themselves from bacteriophages.
- Pathogens cause disease in a variety of ways. Some bacteria produce **toxins** that lead to death of target cells. Some virus-infected cells experience programmed cell death, or **apoptosis**. **Necrosis**, in contrast, refers to a less ordered form of cell death that often results from structural damage of a loss of oxygen.

Section 18.3: How are infectious diseases transmitted?

In addition to causing disease within an individual host, many pathogens also are transmitted between hosts. Understanding patterns of transmission furthers our ability to prevent transmission.

- **Transmission** of an infectious agent may occur in several ways. **Direct transmission** requires physical contact between an infected individual and a susceptible host. **Indirect transmission** may occur through a contaminated inanimate object, or **fomite**, water, food, or an insect.
- Pathogens that are excreted in the feces of one individual and then ingested by another individual exhibit **fecal-oral transmission**. Pathogens that leave an infected host through coughs and sneezes and are inhaled by another individual exhibit **airborne transmission**. **Mechanical transmission** refers to pathogens that are transmitted by a vector, but do not replicate in or on the vector.
- Several pathogens undergo **sexual transmission** and cause **sexually transmitted infections (STIs)**.
- **Vertical transmission** occurs from parent to child. **Horizontal transmission** occurs between other members of a species.
- **Zoonotic transfer** involves transmission of a pathogen from its natural animal host, or **reservoir host**, to a human. Often, the human is a **dead-end host** for that pathogen.
- **Epidemiology** is the study of patterns of disease in populations. Epidemiologists study the rate of disease in a population, or **morbidity rate**, as well as the rate of deaths due to diseases, or **mortality rate**.
- Two important measures of diseases in population are **incidence**, which is the number of new cases in a population within a specific period of time, and **prevalence**, which is the total number of cases at a particular point in time.
- By monitoring infectious disease rates within populations, epidemiologists can identify **emerging diseases** and re-emerging diseases.
- Diseases habitually present in a population are referred to as **endemic diseases**. An **epidemic** occurs when the incidence of a disease increases significantly above the normally expected levels **Pandemic** refers to an epidemic that spans a large global region. An **outbreak** refers to a cluster of diseases appearing within a short period of time in a localized population.
- **Common-source epidemics** occur when there is a single source of infection, such as a contaminated water supply, to which a large number of people are exposed in a relatively short period of time. The time over which cases are reported is related to the **incubation period**, the period between pathogen entry and appearance of illness.
- **Propagated epidemics** occur when the infection is transmitted from one host to another.

Section 18.4: How can we determine the cause of an infectious disease?

Prevention and treatment options necessitate that the specific cause of an infectious disease is determined.

- Historically, **Koch's postulates** have be used to demonstrate that a specific microorganism causes a specific disease. **Molecular Koch's postulates** list ways in which the role(s) of specific virulence factors in the pathogenesis process can be demonstrated.
- Virulence factors may include adhesion factors, invasion factors, toxins, and secretion factors. Many pathogenic strains of bacteria contain multiple virulence factor genes on regions of the chromosome called **pathogenicity islands (PAIs)**.

Section 18.5: How do new infectious diseases arise?

Emerging or re-emerging infectious diseases may arise in different ways. For example, a pathogen may encounter a new population or a microbe may become more virulent.

- A new population may be encountered through a zoonotic transfer, as we have seen with HIV. This human virus arose from **simian immunodeficiency virus (SIV)**, a virus found in non-human primates in Africa. HIV-1 subsequently evolved within humans into several **clades**, or genetically distinct subtypes.
- A new population may be encountered when the range of the microbe or the range of the host change, as we have seen with Lyme disease.
- The virulence of a microbe may increase when it acquires specific virulence factors, for example, a toxin gene.
- The virulence of a microbe also may increase when the microbe develops resistance to available treatments. This has led to the development of **methicillin-resistant *Staphylococcus aureus* (MRSA)**.
- Extensive surveillance networks are employed to alert physicians and state and local authorities to the emergence or re-emergence of infectious diseases.

Application Questions

1. Consider whether each of the following bacteria would be a primary pathogen or an opportunistic pathogen. Give reasons for your answers.
   a. Enterotoxigenic *Staphylococcus aureus*
   b. *Escherichia coli*
   c. *Vibrio cholerae*
   d. *Clostridium botulinum*
2. Explain the statement that disease is an unintended consequence of obtaining nutrients.
3. Explain how a microbe might result in a disease that is not infectious. Give an example.
4. What factors can affect the virulence of a pathogenic microbe?
5. In simple terms, explain why the zoonotic transfer of a pathogen may cause severe disease within the recipient host. Why is the recipient often a dead-end host?
6. Are emerging diseases *new* diseases? Defend your answer.
7. Emerging and re-emerging diseases often are seen in areas afflicted by war. Why?
8. Several virulence factor genes often are grouped together in the pathogen genome, forming a pathogenicity island. Explain how this genetic unit might form. What are the evolutionary benefits of linking together several virulence factor genes?

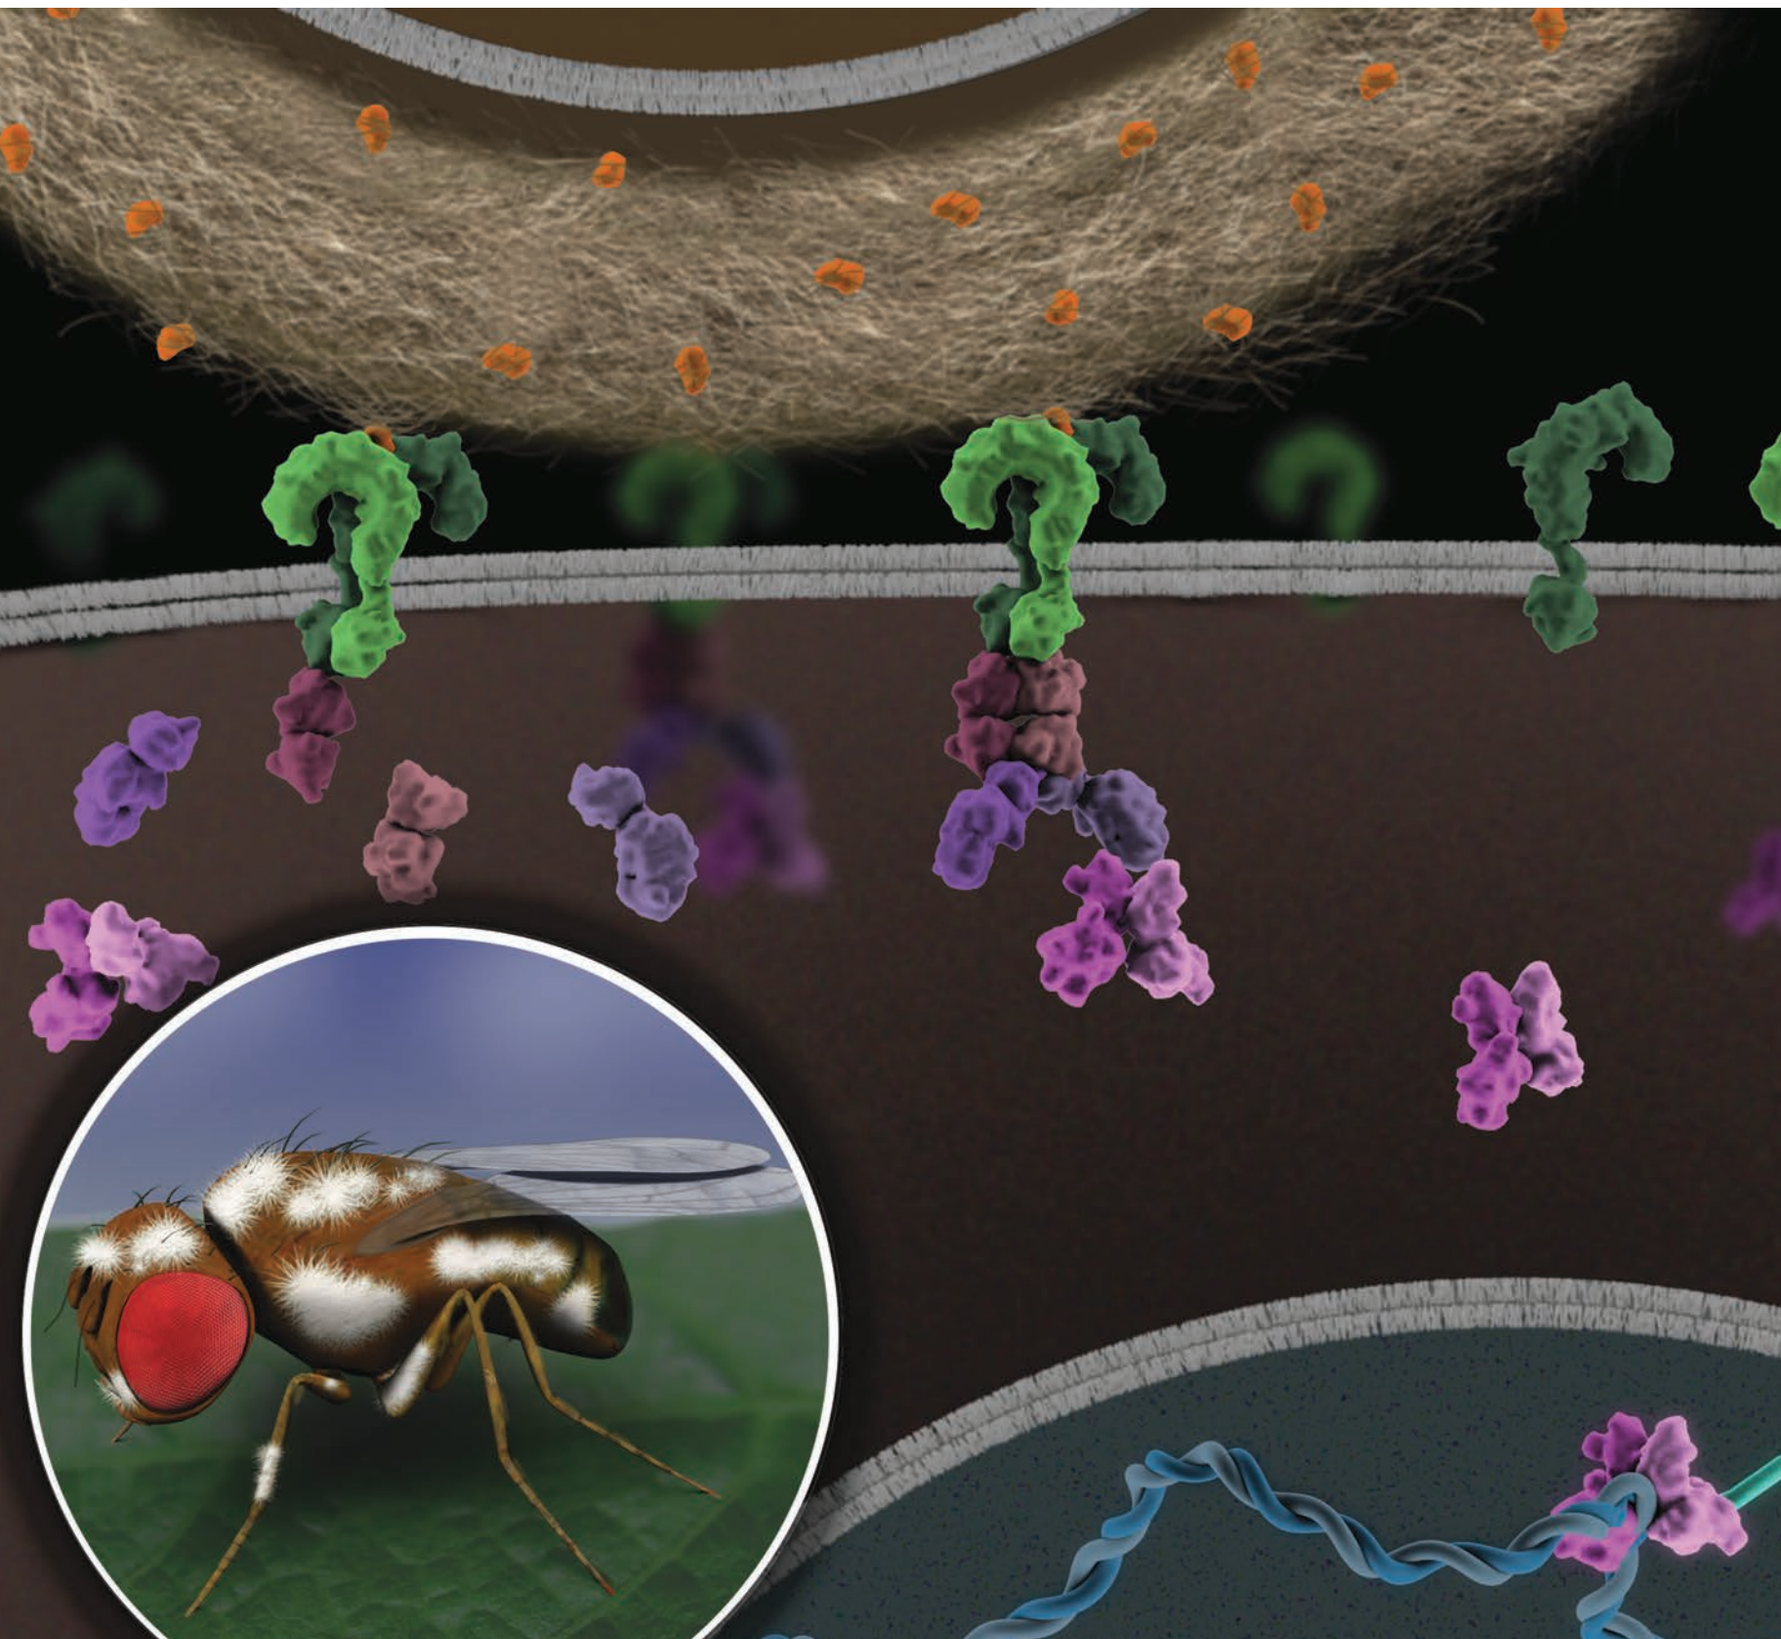
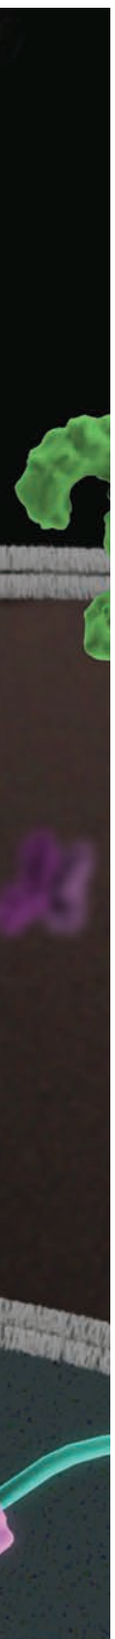
CHAPTER

19 Innate Host Defenses Against Microbial Invasion





In 1991, a group of researchers was studying differentiation in the developing embryo of *Drosophila melanogaster*, the common fruit fly. They discovered a cellular molecule that was involved in the determination of the dorsal and ventral orientation in the embryo. Although they did not know it at the time, this molecule, which they named Toll (after the German slang word for "fantastic"), had another astounding function. It was part of an evolutionarily ancient system capable of recognizing a range of microbial components and initiating immune defenses in many multicellular species. In *Drosophila,* Toll turned out to be important in adult flies for resistance to fungal infections and some bacterial infections.

Since 1996, a panel of proteins structurally similar to Toll was found in vertebrates, and these were named Toll-like receptors (TLRs). Like the protein found in *Drosophila*, they too were transmembrane proteins shown to have important immune functions. The first characterized mammalian TLR was TLR4. It was found to recognize the bacterial endotoxin LPS. Portions of this detection and signaling system have also been found in plants and nematodes. In all multicellular species examined, these proteins appear to be at the root of pathogen sensing. As you will see, in mammals TLRs detect pathogens by taking advantage of the biochemical signatures that are found in microbes, but not in host cells. In mammals, only a very small number of different kinds of these sensors exist, but they are found in almost all cells. They function as an early warning system but also carry out the monumental task of activating appropriate innate and adaptive immune defenses. After decades of hunting for the molecular mechanism of how cells first detect a microbial invasion, it appeared that the missing puzzle pieces of how pathogens are first detected were found.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

The cornerstone of the functioning of the immune system is the recognition of self versus non-self components.

The body has many innate physical and chemical barriers to prevent infection.

Use of adjuvants in vaccines **(Sections 20.4** and **24.5)**

Introduction

We live in a world teeming with microbes. Every second of every day, we breathe, touch, and ingest them. We are immersed in microbes, and microbes are opportunists. If our bodies provide a suitable environment for their growth, they will exploit this opportunity to prosper and spread, often at our own expense. We begin Chapter 19 with an introduction to the subject of immunology, followed by an overview of the physical and chemical barriers that help to prevent infections. The main focus will be on the innate immune system, which includes the cells and molecules that first recognize and respond to microbial components. Chapter 20 will focus on adaptive immunity and will provide an underpinning of knowledge needed to understand the host/pathogen interactions discussed in Chapters 21, 22, and 23.

In all multicellular organisms, the first line of immune defense against microbial invasion is conducted by innate mechanisms that are preprogrammed from birth and through evolution to sense and even identify the nature of microbial invaders. Innate immune defense mechanisms appear in plants, invertebrates, and vertebrates. Innate immune defenses are of primitive origin, appearing long before adaptive immunity of vertebrates. As we will see, being of ancient roots does not mean innate immunity is a rudimentary or simple system. During our exploration of innate defenses, we will answer the following questions:

Are there different types of immunity? (19.1)
What are the built-in barriers to infection? (19.2)
What is an early response of the body to infection? (19.3)
How do we sense or detect the presence of pathogens? (19.4)
What cells first defend us against infectious agents? (19.5)
What kinds of immune defenses do invertebrates have? (19.6)

19.1 Immunity

Are there different types of immunity?

An organism's defense mechanisms are composed of various cell types and molecules that are responsible for clearing the body of foreign invaders and abnormal cells, such as cancer cells. The **immune system**, composed of cells, molecules, and associated tissues involved in identifying foreign agents, fighting infection, and ridding the body of abnormal cells, is one of the most complex systems known in terms of its interactions with and effects on other cells in the body. **Immunology** is the study of the components and processes of the immune system. The cornerstone of the functioning of the immune system is the recognition of *self* versus *non-self* components.

The outcome of an infection is often the result of a tug-of-war between the microbe, which is trying to reproduce, and the host, which is trying to clear the body of the invader and prevent disease. A healthy host has many effective strategies for passively and actively preventing, clearing, or reducing most infections. Because of this, many pathogens, microbes that routinely cause disease, have developed strategies for evading, destroying, or overwhelming host immune defenses. Therefore, it is of utmost importance to gain an understanding of the normal operation of the immune system if we are to comprehend how pathogens cause disease.

The term **immune** can be broadly defined as the state of being resistant to infection and subsequent disease. An immune individual may be *passively* resistant by nature. For example, recall from Chapter 5, the first requirement in animal viral infections is attachment of a virus to the correct receptors on the cell surface. Dogs are immune to infection with human immunodeficiency virus (HIV) because, as a species, they lack the correct cell surface receptors. From an immunological perspective, being immune means one can *actively* mount a defensive **immune response** to an invading microbe and prevent it from causing disease. An immune response defends the body against foreign agents, such as bacteria, fungi, parasitic worms, protozoa, viruses, and toxins. New information on immune defense is constantly generated by research, and it shapes our approach in combating infectious as well as non-infectious diseases, such as cancer and asthma. These insights have given rise to new advances in the fields of vaccine design and genetic improvement of livestock and crops, as the example in **Figure 19.1** demonstrates.

A. Diseased potato seedling **B.** Disease-resistant seedling

Figure 19.1. Engineering disease-resistant transgenic potatoes Researchers produced disease-resistant potatoes by integrating a synthetic gene that codes for a small antimicrobial peptide. The structure of the peptide was based on two potent antimicrobial peptides found naturally in some insects. **A.** The control potato with no genetic modification succumbs to infection from the fungus *Fusarium solani* on the lower stem, which has caused it to fall over. **B.** The potato possessing the new antimicrobial peptide gene shows resistance to the pathogen as evidenced by its erect growth. In the future, crops like these may combat the rising use of pesticides and improve crop yields.

Although most of us may commonly think of a successful immune response as leading to destruction of the microbial agent, this is not always the case, even in a healthy individual. The term "sterile immunity" describes a response that results in clearance of the agent. For example, when a person becomes infected with influenza virus, the body mounts an immune response and, assuming the person survives the disease, the virus is then completely cleared from the body. In other instances a person may be infected, but the infection is kept in check by the immune system so that disease does not occur. This can be described as "non-sterile immunity." An example of non-sterile immunity is infection with the bacterium *Mycobacterium tuberculosis*, the causative agent of tuberculosis. There is a high level of natural immunity to this microorganism in humans. Approximately 90 percent of people who become exposed to *M. tuberculosis* (about one-third of the world's population is infected) mount an immune response that is capable of preventing active disease. However, some individuals can continue to harbor non-replicating *M. tuberculosis* in lung tissue for many years. Thus, the immune response that is mounted results in non-sterile immunity that protects from disease but does not necessarily clear the bacterium. In Chapter 21, we will look more closely at the pathogenesis of *M. tuberculosis*. Sterile immunity is always a desirable goal for vaccine development for infectious diseases because such vaccines prevent the carrier states that serve as reservoirs of infection for unvaccinated or immune-compromised individuals (see Section 18.1). Regardless of the final result of an infection, an immune response will occur. The outcome depends on how effective the immune response is in protecting from disease.

Innate and adaptive immunity

In vertebrates, immunity can occur at two levels: **innate (non-specific) immunity** and **adaptive (specific) immunity**. As the term implies, innate immunity involves immune mechanisms that are present at birth and do not require previous exposure to the microbe. Thus, the innate immune response is a first line of immune defense, being mobilized within minutes of detection of a foreign invader. At the genetic level, innate immunity is hard-wired, involving germline genes that encode various proteins that can distinguish self from non-self components. Detection of foreign material by the innate immune system is non-specific, accomplished by recognition of common, broad-based foreign features. In contrast, adaptive immunity is acquired only *after* exposure to a particular microbial agent or other foreign substance. It involves rearrangements of genes within specific cells of the adaptive immune system. These cells are called T cells and B cells, which we will learn about in Chapter 20. These rearrangements allow the manufacture of selected immune proteins that are tailored to bind to specific components of the particular infectious agent, as opposed to only common foreign molecules. An amazing result of an adaptive immune response is immunological memory. If the invader is encountered again, those tailor-made molecules can be quickly produced to prevent infection. In humans, immunity to the chickenpox virus is acquired this way. As we will see, innate and adaptive immune mechanisms are not mutually exclusive in vertebrates. They work together in response to infection to provide a one-two punch to destroy the invader and to mobilize immune forces quickly the next time the invader is encountered.

CONNECTIONS Most people know that you can get chickenpox once but you usually do not get it again. Immunity to the virus has been acquired through the adaptive immune system, which prevents successful reinfection. However, sterile immunity to the chickenpox virus is not always achieved. The virus finds its way into peripheral nerves and can remain dormant for many years. If the individual's immune system becomes compromised, as often occurs in the elderly, the virus can use this opportunity to reactivate infection and cause a different disease called shingles. This disease is discussed in **Section 22.1**.

19.1 Fact Check

1. What is meant by the term "immune"?
2. Define sterile and non-sterile immunity.
3. Describe the key features of innate and adaptive immunity.

19.2 Barriers to infection

What are the built-in barriers to infection?

To cause an infection, a microbe must first establish itself in the body. This is not always an easy task because the body has many built-in barriers to microbial invasion. If a microbe manages to overcome these barriers, host immune responses will begin. It is important to keep in mind that these barriers, although innately produced, are not part of the immune system. They do not identify or actively fight infection, but their significance in protection from infection is not to be underestimated.

Skin

Intact human skin, and indeed the skin of most animals, is not an inviting environment for colonization by most microorganisms (**Figure 19.2**). The skin of most mammals is generally cool, dry, and acidic (pH 5.0). It is covered in an armor of keratinized cells called the "stratum corneum." Above this outer layer is a layer of oil (sebum) secreted by sebaceous glands. The oils are composed of fatty acids that are inhibitory to

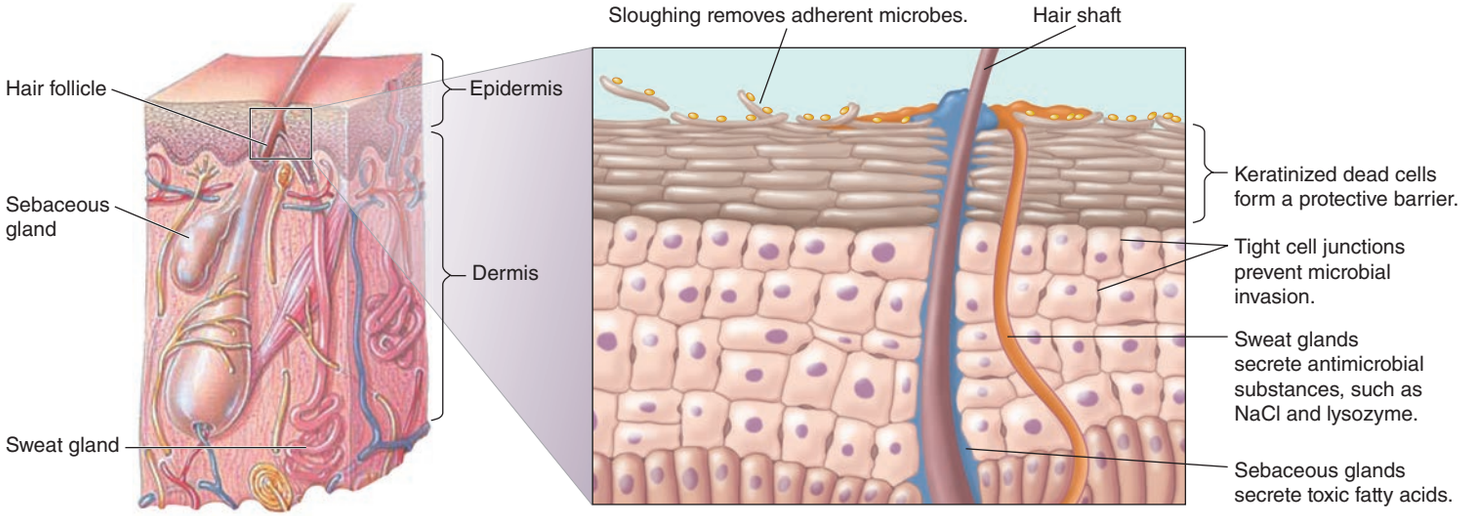

Figure 19.2. Chemical and physical defenses of skin The outer epidermis consists of interwoven dead, flattened, keratinized cells that are constantly sloughed. Underlying cells are connected by tight cell junctions. Sweat glands secrete antimicrobial substances, and sebaceous glands release oils containing fatty acids on the surface of the skin.

many microorganisms. In addition, sweat glands, when present, deposit other antimicrobial substances, such as NaCl and lysozyme, an enzyme that degrades the peptidoglycan of bacterial cell walls (see Section 2.4). Underneath this outer layer are layers of epithelial cells with tight cell junctions that hold adjacent cells firmly together, effectively sealing any gaps to prevent microbes from penetrating. The constant sloughing of the outer epithelial cells, called "desquamation," helps to rid the skin of pathogenic microorganisms. Constant cell division in the basal layer of the epidermis replaces the sloughed cells. The entire epidermis is replaced in about 48 days. Few microorganisms can actually breach the barriers presented by skin, and usually some form of trauma, such as a cut, is required for entry.

Skin is also home to large numbers of symbiotic yeast and bacteria that form the normal microbiota of skin. These are well adapted to living in this cool, dry, acidic environment and colonize much of the available surface. In this respect, skin is really a miniature ecosystem, with all niches being filled by resident skin microbiota. The resident microbiota compete with each other for space and nutrients, making it difficult for new microorganisms, including pathogens, to establish themselves in this habitat. Therefore, we should view the microbes living on our skin as integral to our good health.

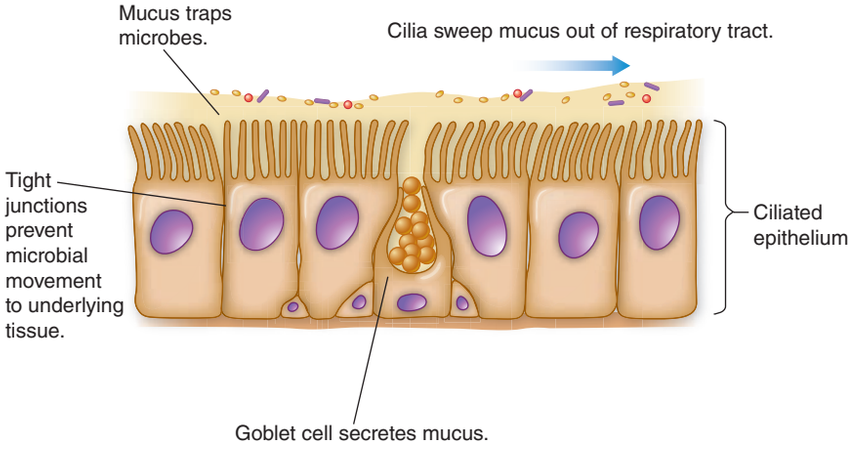
CONNECTIONS Competitive exclusion is an important function of skin microbiota. The normal microbiota of the body is important, not only for preventing pathogens from causing disease, but it is also key to normal immune system functioning. See **Section 17.3** for a review.

Mucosal membranes

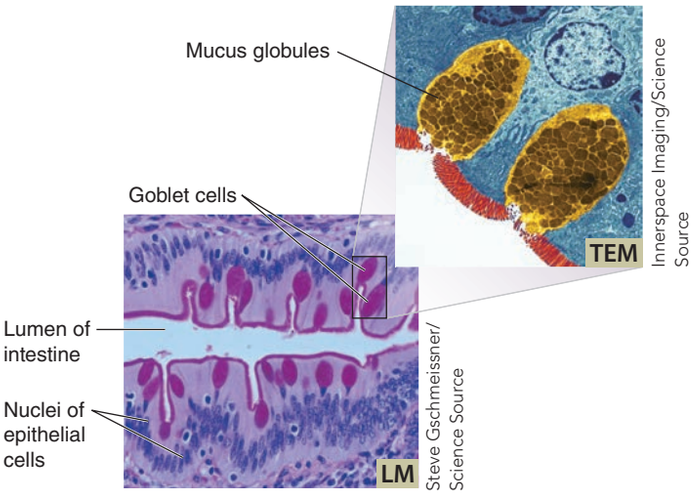
The inner surfaces of the body, such as the respiratory tract, digestive tract, urogenital tract, and conjunctiva of the eye socket, are warm and moist and are not shielded by a casing of keratinized cells. These are much more inviting living conditions for microbes. To help protect these surfaces from infection, various particle removal systems are present that incorporate diverse intrinsic physical, mechanical, and chemical barriers (Figure 19.3). These surfaces, sometimes called "mucosal surfaces" or "mucous membranes," are lined with **mucosal membranes** composed of tightly packed epithelial cells with tight junctions. Mucosal membranes are kept constantly moist by fluids, such as saliva, tears, and/or **mucus**. Mucus is a viscous and adherent mixture of hydrated glycoproteins called "mucins," secreted by specialized goblet cells found scattered in mucosal membranes of the upper respiratory tract, the stomach, intestine, and genital tract. Mucus coats the membrane surface, forming a gelatinous layer to reduce contact of microbes with the epithelium. Its thick, sticky texture traps microbes, reducing their ability to move. Constant removal of mucus controls microbial colonization of these surfaces.

Special ciliated epithelial cells line the upper respiratory tract and vagina and rhythmically beat their cilia to mechanically move mucus and entrapped particles out of these passages. This mechanism is referred to as **mucociliary clearance** and serves a very important function, as discussed in Perspective 19.1. The intestine is not lined with ciliary epithelium. Instead, it uses the mechanical motion of **peristalsis**, wave-like contractions of smooth muscle to keep intestinal contents, including mucus, moving along. This action reduces the ability of ingested microbes to attach to the mucosal surface. The flushing action of tears, urine, and saliva also helps to dislodge and remove mucus and microbes from respective mucosal surfaces.

Mucus may also contain antimicrobial substances, such as lysozyme, defensins, and lactoferrin, which are secreted by epithelial cells. Defensins are one family of proteins belonging to a larger group of **antimicrobial peptides**. Antimicrobial



A. Ciliated mucosal surface of upper respiratory tract



B. Mucosal surface of small intestine

Figure 19.3. Defenses of mucosal membranes lining inner body surfaces **A.** The mucosal membrane of the human upper respiratory tract consists of a thin outer layer of epithelial cells with tight junctions. Goblet cells, not associated with all mucosal membranes, secrete mucus that traps particulate matter, including microbes, and prevents their contact with the surface. Cilia of the upper respiratory tract continuously remove mucus and trapped particles, further preventing colonization of the surface. **B.** Goblet cells of the small intestine can be seen interspersed among epithelial cells lining the lumen. The color-enhanced micrograph insert shows globules of mucus packing a goblet cell.

peptides have been identified in plants, invertebrates (see Section 19.4), and vertebrates. They are low-molecular-weight proteins secreted by various cell types that appear to disrupt microbial membranes, resulting in gaps or pores. **Lactoferrin** is an iron-sequestering protein secreted by various cells, including epithelial cells of the respiratory tract. Withholding elemental iron from microorganisms inhibits their growth, as bacteria require it for metabolism. We'll discuss the role of iron later on in this section. Examples of physical and chemical defenses of specific mucosal membranes are listed in Table 19.1.

Recall from Section 17.3 that skin and mucosal surfaces, especially the intestine, are colonized with large numbers of

TABLE 19.1 Physical and chemical innate defenses associated with mucosal membranes

Site	Mucosal surface	Defense
Eye	Conjunctiva	Filtering by eyelashes
		Lysozyme
		NaCl
		Flushing by tears
Digestive tract	Mouth	Lysozyme

Perspective 19.1
MESSY MUCUS

The importance of mucociliary clearance is evident in patients with cystic fibrosis, which is a genetic disease. An aspect of the disease is poorly hydrated mucus, which is abnormally thick and sticky. Mucus, even the normal kind, is very good at trapping microbes that enter the respiratory tract. In cystic fibrosis patients, the extreme viscosity of the mucus overwhelms the ability of the cilia to transport it out of the upper respiratory tract, and so it becomes a sink for inhaled microbes and descends to the lower areas of the lungs. Consequently, cystic fibrosis patients suffer almost continual respiratory infections. Lung infections with *Pseudomonas aeruginosa* are common and are notoriously difficult to treat because the bacteria can establish an impervious layer called a biofilm (see Section 2.5), which is resistant to penetration with antimicrobial drugs. Such infections are a major cause of death in cystic fibrosis patients. Their inability to clear mucus from the upper respiratory tract becomes a detrimental condition and illustrates the importance of mucociliary clearance as a barrier to infection.

microbes that form the normal microbiota. Competitive exclusion by these populations serves to deter colonization by new microbes, including pathogens, and keeps any one population from dominating this environment. Many species inhabiting the intestine produce essential vitamins needed for good health in humans and some animal species. As we saw in herbivores (see Section 17.4), these microorganisms are essential for breaking down fibrous substances, such as cellulose, which cannot otherwise be used by the host.

Disturbances in normal microbiota, such as can occur with oral antibiotic use, may reduce some microbial species and increase others. This may result in short-term digestive disturbances, such as diarrhea. Other surfaces such as the lung and the uterus are only scantly colonized, if at all. The effective barriers in the upper respiratory tract and the vagina prevent most microbes from entering these regions. Transient microbes that do enter are removed by mucociliary clearance or are destroyed by various antimicrobial substances (see Table 19.1).

Natural barriers of the body prevent most microbes from establishing infection. However, if a breach in one of the protected surfaces occurs, then immune responses begin. An injury, such as a cut or a burn, allows entry of opportunistic pathogens that could not otherwise gain access to tissues. As we will see in Chapters 21 to 23, some pathogenic microbes have evolved strategies to colonize or invade intact barriers.

TABLE 19.2 Iron-binding molecules of the body

Iron-binding protein	Location	Function
Hemoglobin	Red blood cells	Binds oxygen
Myoglobin	Muscle and heart cells	Binds oxygen
Transferrin	Plasma	Transport of iron around the body
Lactoferrin	Milk, tears, saliva	Antimicrobial activity in secretions by binding iron
Ferritin	Cells, small amounts present in plasma	Storage of iron

Iron: The limiting element

We mentioned earlier that limiting the availability of free iron in the body has an important bacteriostatic effect. Although limiting iron does not constitute a structural barrier, like skin or mucosal surfaces, it is nonetheless a noteworthy innate barrier to infection. Indeed, as we will see in Chapter 21, producing virulence factors for stealing iron from the body is a common feature of bacterial pathogens. Most iron in the body is not in free form. It is kept sequestered by specialized iron-binding molecules, including hemoglobin, ferritin, transferrin, and lactoferrin **(Table 19.2)**. Iron is important for the function of a variety of proteins in bacteria, as it is for all cells. It is needed for cytochromes that catalyze redox reactions within cells. In animals, iron is an integral component of oxygen-binding heme proteins such as hemoglobin of red blood cells and myoglobin of muscle cells. In humans, most iron in the body (50–80 percent) is associated with hemoglobin of red blood cells. Lactoferrin binds iron particularly strongly, a feature that is an advantage in fluid secretions, including milk, to prevent iron from being made available to microbes that might otherwise abound in these rich fluids. There is a wealth of convincing evidence that iron deficiency actually protects against many infectious diseases such as malaria, plague, and tuberculosis. Equally, there is substantial evidence that iron supplementation can predispose one to bacterial infection and exacerbate some diseases, such as tuberculosis (see Chapter 21). Free iron can also be dangerous. It is a potent catalyst for the formation of toxic free radicals. This is another reason for cells to keep iron in a chemically bound form.

19.2 Fact Check

1. Explain how skin and mucosal membranes protect the body from microbes.
2. What antimicrobial roles do lysozyme, defensins, and lactoferrin play in the body?
3. How does the body limit iron availability, and how does this protect against microbes?

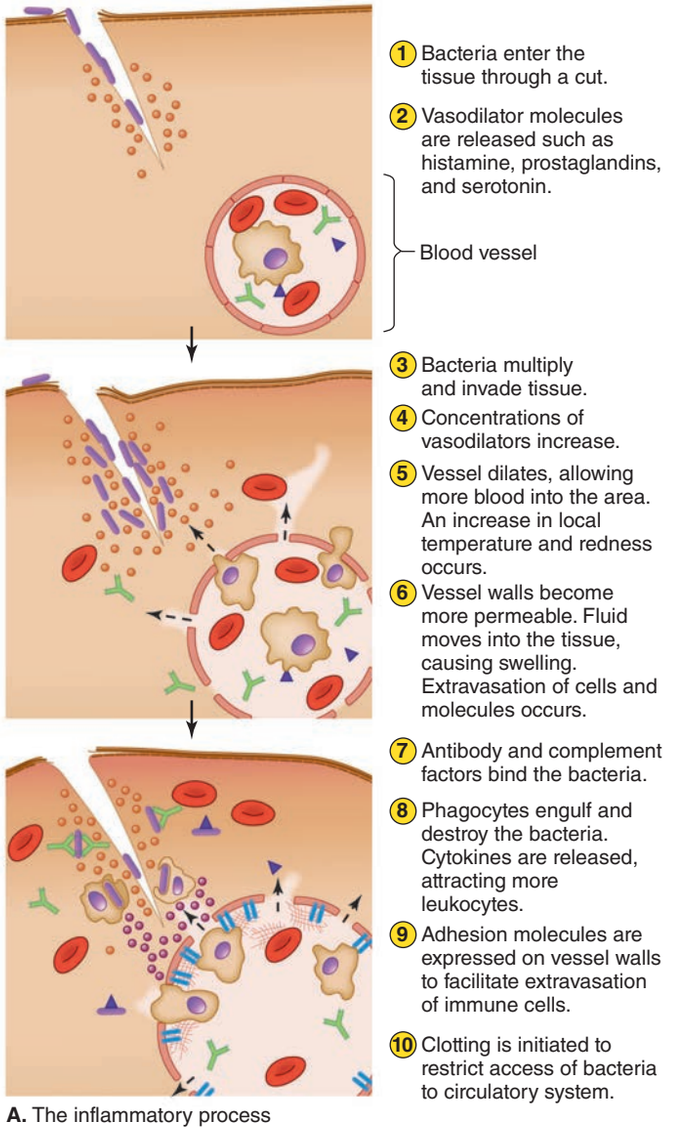
19.3 The inflammatory response

What is an early response of the body to infection?

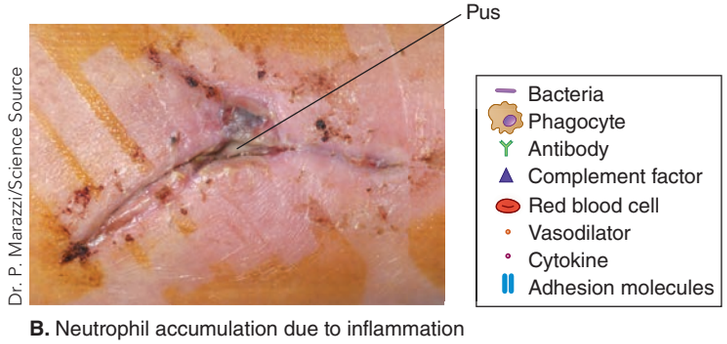
What happens if a microbe manages to get past the barriers and other passive defenses of the body? We can first look at a relatively common occurrence and one with which we are all familiar: an infected cut. Although a few microbes may directly invade intact skin, most access the underlying tissues only through breaks. Once microbes enter tissue, several simultaneous events occur. Tissue injury caused by the external trauma results in release of various cell-signaling molecules, called "effector" molecules, which have direct effects on surrounding cells. Examples produced from local cells include histamine and prostaglandins that are important effectors in initiating **inflammation**. Inflammation is a progression of physiologic events that activate cells to release molecules involved in defense and repair to the damaged or infected site. We can identify the clinical signs of inflammation that accompany an infected cut: swelling, redness, and heat. Inflammation itself is not an immune response. Rather, it is a frequent precursor that facilitates immune responses. Immune responses can occur without inflammation. Indeed, not all pathogens will evoke an inflammatory response. Examples include HIV and *Vibrio cholerae*.

Sometimes the invading microbe can initiate release of effector molecules from the surrounding cells by producing substances such as lipopolysaccharide (LPS, an endotoxin) or various exotoxins. Release of histamine from tissue mast cells (see Section 19.5) also activates the plasma-derived fibrin and kinin clotting pathways that restrict infection and tissue damage by forming a mesh-like barrier to wall off damaged blood vessels and associated tissue. Activation of these pathways triggers release of more **proinflammatory molecules** that stimulate inflammation and attract cells with immune functions to the site. An important group of proinflammatory molecules produced by cells during an infection are **cytokines**. Cytokines are secreted, soluble, low-molecular-weight glycoproteins that are produced by cells involved in immune reactions. Examples of cytokines include interleukins, tumor necrosis factor-alpha (TNF-α), and interferons (IFNs). Cytokines are the chief signaling molecules used by cells to communicate information during an immune response. They initiate cell-signaling pathways that result in the expression of certain cellular genes controlling a variety of immune functions. Some cytokines recruit **leukocytes**, commonly called "white blood cells," to come to the damaged site for cleanup. Leukocytes, such as macrophages, neutrophils, T cells, and B cells (described later) have immune functions. Release of cytokines from the site of inflammation/infection forms a chemical gradient that guides the migration of nearby leukocytes to the site. Imagine the scent of a cooling apple pie left on a windowsill that attracts a distant bear out of the forest. This cytokine gradient functions in a similar way.

The initiation of the inflammatory response is not fully understood but involves three major processes: (1) vasodilation, (2) increased vessel permeability, and (3) **extravasation**, the movement of cells and molecules from blood vessels into tissues (Figure 19.4). **Vasodilation** is an increase in the diameter of the blood vessels. Vasodilation at the site of infection brings



A. The inflammatory process



Dr. P. Marazzi/Science Source

B. Neutrophil accumulation due to inflammation

Figure 19.4. Process Diagram: The local inflammatory process
A. Tissue damage and exposure to microbes begins inflammation by release of vasodilator effector molecules, an increase in vessel permeability, and migration or extravasation of defensive cells and molecules from the circulatory system. Phagocytes, such as neutrophils and macrophages, can engulf and destroy invading bacteria. Clotting factors form a mesh-like barrier to wall off the injured area from the rest of the body to limit the spread of infection. **B.** Neutrophils are the most numerous leukocytes in blood and can accumulate as pus.

more blood, and with it, more defense cells and molecules to the area. The local increased blood volume results in clinical signs of redness and increased temperature in the area. Prostaglandins and histamine are potent vasodilators, released from mast cells upon encountering certain stimulatory molecules associated with damage, such as hydrogen peroxide and activated complement components.

Increased vessel permeability of the dilated vessel walls is another characteristic of the inflammatory response. It is a result of the loosening of the cell junctions that line blood vessels, creating gaps that allow fluid and cells from the blood to move into the tissues where they can combat the infection. Extravasation is facilitated by dilation and increased permeability of the vessels. Fluid carries plasma components, such as antibodies and complement factors, discussed later, into the affected area to aid in the destruction of microbes. Excess fluid in inflamed tissues appears as swelling or edema of the local area.

As the inflammatory response progresses, concentrations of inflammatory effector molecules increase in the local area. This induces cells of the vessels to produce surface molecules that bind passing leukocytes from the blood, allowing them to adhere and pass through the vessel walls, actively facilitating extravasation. As more blood enters the area, the adherent cells, mostly phagocytes such as neutrophils and macrophages, accumulate in the affected tissue. **Phagocytes** are specialized leukocytes that engulf and destroy microbes. Once phagocytes have entered the tissue, they begin to take up foreign particles and damaged cells. Active phagocytes release chemoattractants, such as interleukin 8 (IL-8), that attract more cells with immune function to the area. Phagocytes, especially neutrophils, can increase to large numbers as they are recruited to the site, and appear as pus in infected lesions.

Some local inflammatory responses are large enough to induce further responses from the body. For example, the cytokines IL-1, IL-6, and TNF-α can signal cells of the liver to produce other secreted molecules, such as C-reactive protein (discussed later) that take part in fighting the early phase of infection/damage. These three cytokines work on the hypothalamus to produce **fever**, a prolonged increase in the core body temperature of endothermic animals. This temperature increase can restrict the growth of many pathogens, allowing the immune system time to clear them. Fever benefits the immune system directly by increasing production and activity of leukocytes as well as speeding up tissue repair. Too high a fever can have detrimental effects due to denaturation of critical enzymes needed for cellular metabolism.

Inflammation is a process that works in favor of the body, at least when it is contained locally to the infected site. However, if the infecting microbe escapes the initial site and distributes to other locations (including the bloodstream) in large enough numbers, a **systemic inflammatory response** can occur. This takes place when the chemical signals that cause inflammation are released on a grand scale producing widespread inflammation in the body. This type of inflammation often leads to physiological shock, characterized by a drastic drop in blood pressure as large quantities of fluid leak from the circulatory system. In turn, vital organs, such as the brain, heart, kidney, and liver, no longer receive full supplies of blood, resulting in organ damage and, in many cases, death. **Septic shock** is a systemic inflammatory response induced by systemic or widespread presence of bacteria in the body. Septic shock is a common outcome to untreated infections that are not contained by the immune system. **Toxic shock** is due to the systemic presence of microbial exotoxins that stimulate the immune system. Once septic shock or toxic shock begins, it is very difficult to prevent its progression. High death rates (30 to 50 percent) result even with intensive care. Identifying the microbial products that evoke the inflammatory response and mapping the body's chemical signals that amplify the inflammatory response are intense areas of research toward developing effective therapies for the treatment and prevention of septic and toxic shock.

Two potent proinflammatory cytokines are IL-1 and TNF-α, produced from phagocytes and T cells. Injection of large amounts of either of these cytokines in animal models has shown they can induce clinical signs of septic shock in the absence of infection. LPS, commonly known as endotoxin, produced by Gram-negative bacteria such as *Escherichia coli* and *Pseudomonas*, and exotoxins such as the so-called superantigens, produced by some strains of *Streptococcus pyogenes* and *Staphylococcus aureus* (see Chapter 21), stimulate immune cells to overproduce these and other proinflammatory cytokines to very high levels. Consequently, serious infection with these organisms often leads to a systemic inflammatory response.

19.3 Fact Check

1. What is inflammation, and what are the results of the inflammatory response?
2. Describe the role of cytokines in response to infection, and provide examples.
3. Define systemic inflammatory response, septic shock, and toxic shock, and explain how these terms are related

19.4 The molecules of the innate system

How do we sense or detect the presence of pathogens?

Inflammation is a common early response to damage and infection that can facilitate immune responses by transporting a variety of immune cells and secreted defense molecules to the site of infection. Now we will examine molecules of innate immunity to see how they actually detect the presence of pathogens and signal this information to initiate immune responses. Because innate immunity is the first line of immune defense, it must act quickly and be able to readily recognize foreign substances in

the body, without having encountered them before. Multicellular organisms have evolved relatively simple but very effective means to accomplish this, as we will see next.

Pathogen-associated molecular patterns

Humans can recognize foreign objects and organisms visually. We assign "foreignness" to things that are notably very different from other things we encounter on a frequent basis. For example, a moose grazing on the roadside in Australia would be recognized as being foreign to Australians even if they didn't know it was a moose. The innate immune system is also based on the recognition of foreign material. The body does not perceive foreignness visually but does so biochemically. Microbes contain a variety of unusual molecules that are easily recognized by the host as being foreign. These **pathogen-associated molecular patterns (PAMPs)** are broad-based molecular signatures or motifs commonly found in many pathogens but not normally found in the host. Examples include the lipid A component of Gram-negative LPS, teichoic and lipoteichoic acid from Gram-positive cell walls, and mannose of bacterial and yeast cell walls. These and other molecules are recognized by **pattern recognition receptors (PRRs)** produced by host cells. PRRs are encoded by the host and can be secreted or membrane-bound proteins. Most are present all the time and act as sensors for microbes in the host. Although only a small variety of PRRs are produced by the host, they recognize a diverse array of microbes including bacteria, fungi, viruses, and protozoa. This makes them non-specific in terms of identification of a particular microbe but gives them the broad spectrum necessary for surveillance of infection. In evolutionary terms, innately produced PRRs appear to be ancient. They exist in various forms in invertebrates, vertebrates, and plants and are a fundamental aspect of all foreign-organism recognition systems.

Toll-Like Receptors

Important PRRs involved in the initiation of immune responses in invertebrates and vertebrates are the **Toll-like receptors (TLRs)** (see the chapter opening story). TLRs have evolved as an early warning system for the detection of pathogens. Toll receptors were originally described in *Drosophila melanogaster* embryos. Since then, genomic sequencing of various organisms from plants to humans has uncovered many similar genes, all coding for Toll-like proteins with important immune functions. TLRs are transmembrane proteins with exterior domains that recognize different PAMPs, and cytoplasmic domains that activate distinct components of signaling pathways. Each type of receptor has a specific binding target or **ligand** to which it binds. Over ten different TLRs have been reported in humans and mice but not all have had their ligands identified.

In vertebrates, TLRs are expressed in diverse cell types such as epithelial cells, cells of the brain, and the front-line cells of the immune system, such as neutrophils and macrophages. The amount and profile of TLRs expressed is characteristic of the cell type and even the stage of development of the cell. As shown in **Figure 19.5**, individual TLRs recognize and bind to

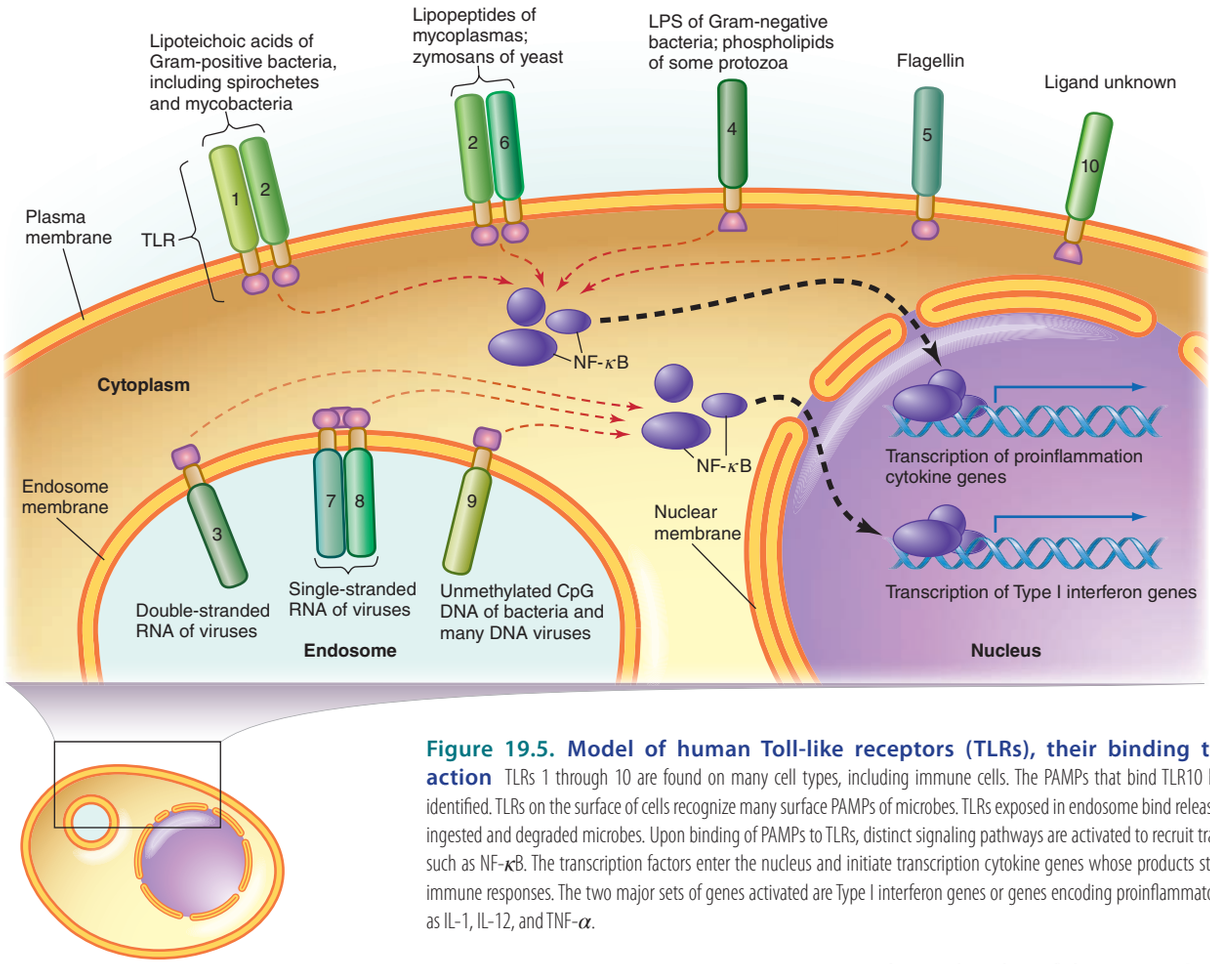


Figure 19.5. Model of human Toll-like receptors (TLRs), their binding targets, and action TLRs 1 through 10 are found on many cell types, including immune cells. The PAMPs that bind TLR10 have not yet been identified. TLRs on the surface of cells recognize many surface PAMPs of microbes. TLRs exposed in endosome bind released nucleic acids of ingested and degraded microbes. Upon binding of PAMPs to TLRs, distinct signaling pathways are activated to recruit transcription factors, such as NF-κB. The transcription factors enter the nucleus and initiate transcription cytokine genes whose products stimulate and direct immune responses. The two major sets of genes activated are Type I interferon genes or genes encoding proinflammatory cytokines, such as IL-1, IL-12, and TNF-α.

specific PAMPs. For example, TLR4 binds LPS of Gram-negative bacteria and TLR5 binds flagellin, the structural protein of bacterial flagella (see Section 2.5). TLR9 recognizes unmethylated pairs of adjacent cytidine and guanosine nucleotides. These are referred to as **CpG dinucleotides**, commonly found in bacterial and some viral DNA. The discovery that host cells could recognize biochemical differences between microbial and host DNA was astounding, and is described in the **Mini-Paper** of this chapter. Many of the PAMPs that bind TLRs have been identified through *in vitro* assays. As such, it is unclear if all of these recognitions are relevant *in vivo*.

TLRs not only recognize a panel of PAMPs but also signal the general nature of the pathogen to the immune system. In so doing, binding of a TLR to its particular PAMP target initiates cellular signaling pathways that allow the immune system to deal with the invader more effectively. A transcription factor called "nuclear factor-kappa B" (NF-κB) is recruited through this pathway to enter the nucleus, along with other customized sets of transcription factors. These induce transcription of a customized set of genes whose products protect the host against the category of pathogen identified. There appear to be two general categories of cytokines induced: one group called **Type I interferons (IFNs)** that have numerous antiviral activities and proinflammatory cytokines. We'll learn about Type I IFNs near the end of this section. To see how proinflammatory cytokines facilitate clearance of the pathogen, let's look at what happens when a phagocyte contacts a Gram-negative bacterium. TLR4 binding of LPS signals expression of genes encoding the cytokines IL-1, IL-12, and TNF-α. Recall that IL-1 and TNF-α induce beneficial fever in the host. TNF-α also activates genes that increase phagocytic abilities and stimulate the phagocyte to divide to produce an army of phagocytes. TNF-α also induces the phagocytes to secrete more proinflammatory cytokines to call in other cells of the immune system. IL-12 secretion by phagocytes activates T cells to initiate adaptive immune responses that selectively target the particular Gram-negative pathogen.

You may recall from Chapter 17 that filarial diseases associated with infection of nematode worms is largely due not to the worms but to the worm endosymbiont *Wolbachia*. The inflammatory response that produces damage is initiated through TLR4 recognition of *Wolbachia* LPS released from dead worms. In river blindness, this TLR4 activation occurs in cells of the eye, resulting in chronic infiltration of immune cells into the cornea, causing opacity and eventually blindness. In elephantiasis, treatment with antinematodal drugs releases *Wolbachia* into the circulatory system and severe systemic inflammation occurs. Similarly, in Section 19.3, we learned that injection of purified LPS can cause the same symptoms as septic shock. Again, this is through direct stimulation of TLR4 and the resultant production of the proinflammatory cytokines IL-1 and TNF-α. **Table 19.3** shows some of the additional effects of these two cytokines on innate functions and the adaptive immune system, which we will explore in more detail in Chapter 20.

Another example of how TLR binding begins immune responses is through TLR3 detection of double-stranded RNA, a common intermediate produced during viral replication. Double-stranded RNA in the cell signals the presence of a virus and induces expression of Type I IFNs in the cell. These IFNs have antiviral activities that help cells resist viral infection, and they will be discussed at the end of this section.

TABLE 19.3 **Effects of cytokines TNF-α and IL-1 produced by macrophages and neutrophils**

Effect	TNF-α	IL-1
Production of fever	+	+
Proliferation of phagocytes	+	−
Production of molecules for extravasation of leukocytes	+	+
Increases vascular permeability	+	+
Stimulates production of C-reactive protein (binds microbes)	+	+
T-cell activation (for adaptive immunity)	+	+
Induction of IL-8 and IL-6 (stimulates adaptive immunity)	+	+

TLR signaling is also crucial for the activation of adaptive immunity and appears to be a major process linking the innate and adaptive systems. For example, an innate function of macrophages is to engulf and destroy microbes. Activation of TLR-signaling pathways induces macrophages to become more efficient killers, but also stimulates production of the surface molecules needed for their interaction with T cells, the main controllers of the adaptive immune system. We will explore the specific functions of T cells in Chapter 20.

You may wonder how scientists determined the binding targets and other immune functions of individual TLRs. Understanding the function of individual parts of the immune system is akin to trying to assign roles to all of the parts of a modern jet engine when you don't know how the system was designed. One way to tell the function of the parts is to remove specific pieces one at a time and then observe the effect. To confirm the function and provide insight into how the different parts are interrelated, you can remove the piece that you think it interacts with and see if you get a similar effect. This approach is called "reverse genetics" and is widely used in immunology and disease research, just as it is used throughout biology. The availability of complete genome sequences and associated molecular tools makes this type of research feasible. For example, to determine the function of TLR2, researchers produced TLR2 knockout mice engineered to lack the gene for TLR2. Then they examined the immune response of these mice to various injected microbial compounds and compared them to the immune response of control non-knockout mice. Although the mutant mice produced normal immune responses to most compounds, they did not respond to peptidoglycan. The control mice did. Based on these results, TLR2 was assigned the function of peptidoglycan recognition.

Identification of the molecules that bind TLRs and the resulting type of immune response that is stimulated by this binding has been instrumental in the design of new vaccine formulations. One of the components often included in

vaccine preparations is an **adjuvant**. An adjuvant enhances the immune response to the microbial components in the vaccine formulation by stimulating the innate immune system. For example, the adjuvant Ribi.259 has been shown to specifically activate TLR4 in a manner similar to bacterial LPS. Unlike LPS, it does not evoke inflammation and is safe for use in veterinary applications. Synthetic unmethylated CpG dinucleotides that mimic bacterial DNA exhibit adjuvant activity and can stimulate innate cellular responses by binding to TLR9. The **Mini-Paper** describes the initial characterization of immunogenic DNA sequences. CpG dinucleotides are the basis for the newly developed DNA vaccines, many of which have shown a high level of protection from experimental infections in animal models.

CONNECTIONS Adjuvants greatly enhance the effectiveness of vaccines in a variety of other ways described in **Section 20.4**. Modern vaccine formulations routinely use adjuvants to boost immune stimulation. See also **Section 24.5** for the history of vaccination and details of vaccines, including DNA vaccines.

Other research on TLR-signaling pathways promises new therapies for human chronic inflammatory diseases, such as inflammatory bowel syndrome and Crohn's disease. By interfering with binding of the molecules identified in induction of inflammation to their TLRs, or disruption of the signaling pathways, chronic inflammation may be reduced or eliminated. Prevention of LPS-induced septic shock by similar blocking techniques also holds great promise.

Mannose-Binding Lectin and C-Reactive Protein

TLRs are just one type of pattern recognition receptor (PRR). Some PRRs are secreted instead of being membrane-bound. **Table 19.4** lists an example of a secreted PRR: **mannose-binding lectin (MBL)**. **Lectins** are proteins that bind carbohydrates. *N*-acetylglucosamine of peptidoglycan and the carbohydrate mannose can be bound by MBL. Mannose is found in the cell walls of a variety of microorganisms such as the yeast *Candida albicans* and bacteria of the genus *Salmonella*. Molecules composed of repeating units of *N*-acetylglucosamine and mannose are not a constituent of eukaryal cells; they are recognized by the immune system as a pathogen-associated molecular pattern (PAMP). When these molecules are encountered, MBL binds at the microbial surface **(Figure 19.6)**. This coating of the microbial surface is called **opsonization**, and it leads to two important events: activation of complement (described shortly), leading to leakage and death of the microbial cell, and **phagocytosis** by macrophages. Phagocytosis involves the formation of large cytoplasmic extensions that surround the particle and then fuse to engulf the microbial cell. Phagocytosis is facilitated by opsonization as macrophages possess receptors for bound MBL that allow them to adhere to the opsonized microbial cell. The processes of opsonization and phagocytosis are discussed in more detail later (Section 19.5).

The importance of secreted PRRs in immunity is evident in patients or animal models where mutations exist in genes coding for secreted PRRs. MBL deficiency is considered to be the most common cause of non-HIV human immunodeficiency. Because it is an innately produced protein, MBL is thought to be particularly important for protection in very young children

TABLE 19.4 **Some secreted pattern recognition receptors (PRRs) of vertebrates**

Receptor	Molecule bound
Mannose-binding lectin (MBL)	Mannose of bacterial and fungal cell walls and *N*-acetylglucosamine of bacterial peptidoglycan
C-reactive protein	Phosphatidylcholine/phosphocholine of bacterial and fungal membranes
LPS-binding protein	Lipopolysaccharide (endotoxin) of Gram-negative cell walls
Complement factor C3b	Variety of cell wall components, including lipoteichoic acid of Gram-positive cell walls, and LPS of Gram-negative bacteria

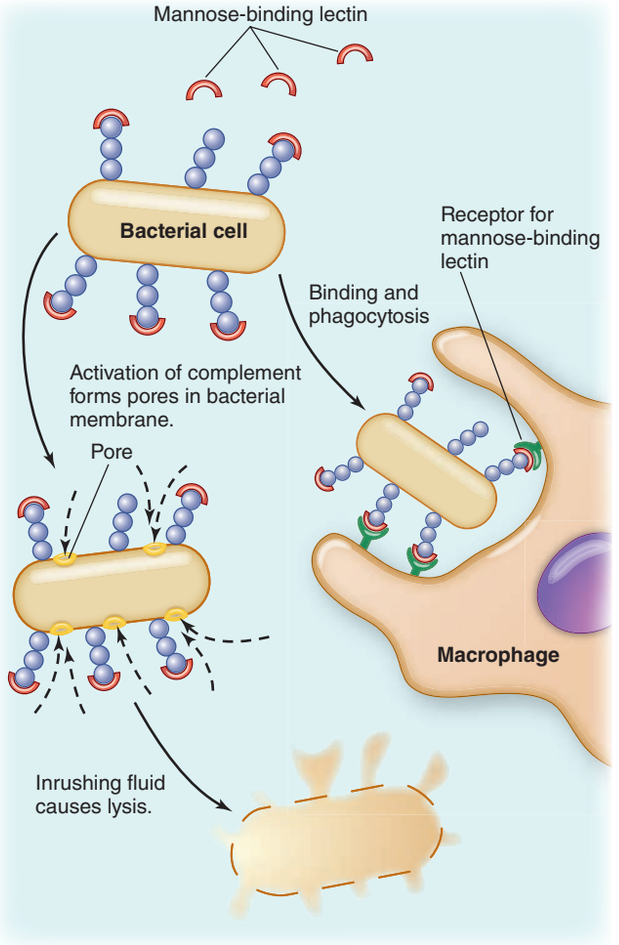

Figure 19.6. Opsonization of a bacterial cell by mannose-binding lectin Coating of a microbial cell with mannose-binding lectin can facilitate phagocytosis by macrophages, which possess receptors for the bound lectin. Opsonization with mannose-binding lectin also activates complement, leading to destruction of the microbe by lysis.

Mini-Paper: A Focus on the Research
MAMMALIAN CELLS CAN RECOGNIZE BACTERIAL DNA

A. M. Kreig, A.-K. Yi, S. Matsin, T. J. Waldschmidt, G. A. Bishop, R. Teasdale, G. G. Koretzky, and D. M. Klinman. 1995. CpG motifs in bacterial DNA trigger direct B-cell activation. Nature 374:546–549.

Context

The 1998 finding that the first mammalian Toll-like receptors (TLRs) appeared to initiate immune responses in cells by recognition of specific bacterial components began a number of intensive searches for other TLRs and their binding targets. It had been known for some time that bacterial DNA could induce immune responses in mammals. The first accounts of this phenomenon began in 1984 with the recognition of apparent antitumor activity of DNA extracted from *Mycobacterium bovis* BCG, widely used in humans as a live vaccine against tuberculosis. Subsequent studies showed DNA extracted from eukaryotic cells did not evoke immune responses; it was not immunogenic. The immunogenicity of bacterial DNA came as a surprise to researchers. After all, how could a molecule as ubiquitous as DNA evoke immune responses? Yet, there definitely appeared to be some way for cells to distinguish between bacterial DNA and eukaryal DNA. These initial reports prompted researchers to investigate the biochemical differences between bacterial DNA and DNA from a variety of eukaryal organisms, including plants.

As early as 1943, scientific literature reported an interesting finding: extensive methylation existed in mammalian DNA. We now know that eukaryotes commonly methylate their DNA in order to package it into the nucleus and as a mechanism for transcriptional silencing. This became an early clue into a possible discriminatory feature between bacterial DNA and that of eukaryotes. In the early 1990s, researchers began to test a variety of synthetic oligonucleotides composed of particular methylated and unmethylated base sequences for their ability to evoke immune responses. Not all unmethylated sequences tested were found to be immunogenic. The common denominator deduced from immunogenic oligonucleotides appeared to be adjacent C and G nucleotides, referred to as "CpG dinucleotides" ("p" refers to the phosphodiester bond between the nucleotides).

These early findings prompted Arthur Kreig and Dennis Klinman and their colleagues to determine the basis for the immunogenic activity of bacterial DNA. In 1995, they published their results in the scientific journal *Nature*. They write:

> In considering explanations for the mitogenicity (activation of lymphocytes) of bacterial DNA, we noted that CpG dinucleotides are generally present at the expected frequency of 1 per 16 dinucleotides in microbial DNA, but they are only about one-quarter as prevalent in vertebrates. In addition to this "CpG suppression," the cytosines in CpG dinucleotides are highly methylated in vertebrates, but not microorganisms.

Could prokaryotic unmethylated CpG motifs be a pathogen-associated molecular pattern recognized by cells of vertebrates?

Experiments

Kreig and Klinman's group conducted a series of experiments designed to progressively define the immunogenic activity of DNA. In their first experiment, they established that unmethylated *Escherichia coli* DNA, but not methylated *E. coli* DNA, was immunogenic. They extracted *E. coli* genomic DNA and chemically methylated an aliquot *in vitro*. The extent of methylation was determined by exposing the DNA to HpaII, a restriction enzyme that can only cleave at unmethylated recognition sequences. As a control, the DNA was also subjected to MspI, which can cut both methylated and unmethylated sites, to show that DNA could be cleaved. The DNA was completely protected from digestion with HpaII, but not MspI, establishing the *E. coli* DNA was fully methylated.

Methylated and unmethylated *E. coli* DNA molecules were then added separately to cultured B cells of the immune system, and the cells were examined for immune stimulation. A hallmark of B-cell immune stimulation is rapid cell division and this was assessed by measuring the incorporation of radiolabeled thymidine (^{3}H-thymidine) in newly replicated B-cell DNA. The striking results, shown in **Figure B19.1**, showed only that unmethylated DNA (open boxes) stimulated the B cells in a dose-dependent manner. Methylated DNA (filled circles) did not stimulate at any of the concentrations used.

The researchers then established that unmethylated CpG motifs were responsible for the observed B-cell activity. They began by constructing more than 300 different synthetic oligonucleotides, some containing one or more CpG dinucleotides with and without methylation. Some of these are shown in (**Table B19.1**). These were individually tested for B-cell stimulation by comparing levels of gene expression, measured by ^{3}H-uridine incorporation into newly synthesized RNA and antibody production (IgM) from the B cells.

The researchers found oligonucleotides lost their ability to stimulate B cells when the CpG dinucleotide was specifically eliminated. For example, compare oligonucleotide 2 to 2a, 3D to 3Dc, and 3M to 3Ma in Table B19.1. They also found loss of immune stimulation if the cytosine of the CpG pair was methylated, as would be expected in eukaryal DNA. For example, compare oligonucleotide 3D to 3Dd, and 3M to 3Mb. They further determined whether the position of the dinucleotide pair and the surrounding sequences had any influence on immune stimulation. The best immunostimulatory effects were found in oligonucleotides with centrally located unmethylated CpG dinucleotides surrounded by two upstream purines and two downstream pyrimidines. For example, compare oligonucleotide 2,

having no methylation and strong immune activity, to 2d and 2d. Comparison of oligonucleotide 1 and 1c revealed that methylation of the last CpG did not significantly affect immune activity of the oligonucleotide. In contrast, methylation of the central CpG in 1b greatly reduced its immune activity. Bacterial DNA appeared to be specifically recognized as foreign by virtue of its unmethylated CpG motifs, a feature not found in eukaryotic cells.

Impact

The importance of the immune stimulatory effects of CpG motifs has not been lost on researchers. Development of a whole new generation of DNA-based therapeutics and vaccines is progressing rapidly. In 2000, TLR9 was identified and confirmed to initiate immune responses to CpG dinucleotides. Identification of the cells expressing TLR9 has allowed researchers to better understand the immune responses to bacterial DNA. CpG motifs can directly activate macrophages, B cells, and dendritic cells, which in turn produce cytokines to activate other cells of the immune system. It has even been demonstrated that administration of DNA containing CpG dinucleotides can redirect inappropriate host immune responses, such as occurs with autoimmune diseases. When used in conjunction with components derived from the infectious agent, CpG motifs demonstrate strong adjuvant activity, stimulating the immune response against the target pathogen components. Addition of CpG-containing DNA to some of our conventional vaccines has been shown to boost their effectiveness in animal models. These exciting findings have led to the design of plasmid-based DNA vaccines with built-in CpG motifs that carry genes for the expression of specific microbial components or tumor antigens. The continuous production of microbial product from the plasmid within cells enhances immune responses and requires delivery of very little vaccine.

Extensive studies using various DNA vaccines have been carried out in animals including humans, establishing the general safety of CpG-based vaccines. Although several DNA vaccines have advanced to human clinical trials including those against West Nile virus, HIV, and some cancers, they have yet to show enough potency to be considered useful. However, several highly effective DNA vaccines are licensed for use in animals, including a melanoma vaccine for treating aggressive cancers of the mouth and feet in dogs and a vaccine for salmon infectious hematopoietic necrosis virus. Once again, DNA has turned out to be a surprising molecule.

Questions for Discussion

1. The following oligonucleotides have been designed for incorporation into a DNA vaccine. Which one would you expect to be the most immunogenic? Defend your answer by contrasting it to the others.

2. Adenoviruses are large DNA viruses that replicate their DNA in the host cell nucleus. Would you expect this viral DNA to be immunogenic? What about DNA from poxviruses that replicate in the cytoplasm?

3. A safety concern that is often raised regarding DNA vaccines is the potential for recombination with host DNA. What other concerns would you have regarding DNA vaccines?

whose adaptive immune system is not yet fully developed. Recent investigations have indeed shown that MBL deficiency is correlated with increased susceptibility and frequency of respiratory infections in children from 5 to 18 months of age, the age of weaning from mother's antibody-containing milk. Clinical evidence also indicates that adults with low-serum levels of MBL suffer from more frequent and severe bacterial and fungal infections than do individuals with normal MBL levels. Consequently, trials using recombinant and serum-derived MBL as therapeutic treatments for individuals who suffer from these frequent infections are underway.

C-reactive protein is another secreted lectin present in serum. It recognizes and binds to phosphatidylcholine of microbial membranes and phosphocholine, a component in the capsules of some bacteria and some fungal cell walls. C-reactive protein is manufactured by the liver in response to inflammation. Like MBL, bound C-reactive protein opsonizes the microbial cell, leading to uptake by phagocytosis, and activates the complement cascade (see below), which results in lysis of the microbial cell. As C-reactive protein concentrations increase with inflammation, this protein is commonly used as a non-specific biomarker of inflammation. A C-reactive protein test is most often done to monitor certain inflammatory diseases such as rheumatoid arthritis. More recently, C-reactive protein is used as an indicator of a person's risk for coronary disease and hypertension, both of which are characterized by inflammation.

Complement

Complement is a collective term that refers to a group of more than 30 serum proteins involved in binding microbial surfaces and lysing membranes. Complement components exist as inactive precursor proteins in the blood. Enzymatic cleavage and conformational changes of the precursors occur through a cascade, whereby one activated complement factor acts on another precursor in a sequential manner. An end result of the complement cascade is formation of the pore-forming **membrane attack complex (MAC)**, which leads to microbial death by lysis (see Figure 19.6).

The complement cascade is an innate mechanism designed to occur early in infection to kill microbes before they get a chance to proliferate. In the presence of microbes, it can be activated by several simultaneous mechanisms, which helps to ensure a wide variety of pathogens will trigger the cascade and lysis by MAC will occur. As we will see, the complement system can be activated by harnessing both innate and adaptive immune responses, and so occurs whether the host can or cannot specifically recognize the particular infecting microbe. As well as directing lytic activity, complement factors also allow for more efficient uptake of microbes by phagocytes, and induce inflammatory and immune responses. Activation of the complement cascade is accomplished through any one of three different activation pathways: the **classical pathway**, the **alternative pathway**, and the **lectin pathway**.

The Classical Pathway

The classical pathway, so called because it was the first complement activation pathway described, leads to the use of all of the complement factors, named complement factor 1 (C1) through complement factor 9 (C9) **(Figure 19.7)**. The other two activation pathways funnel into this same cascade at various points, so examination of the classical pathway provides a good overview of how this system works. Initiation of the classical pathway involves the binding of C1 to microbial membranes.

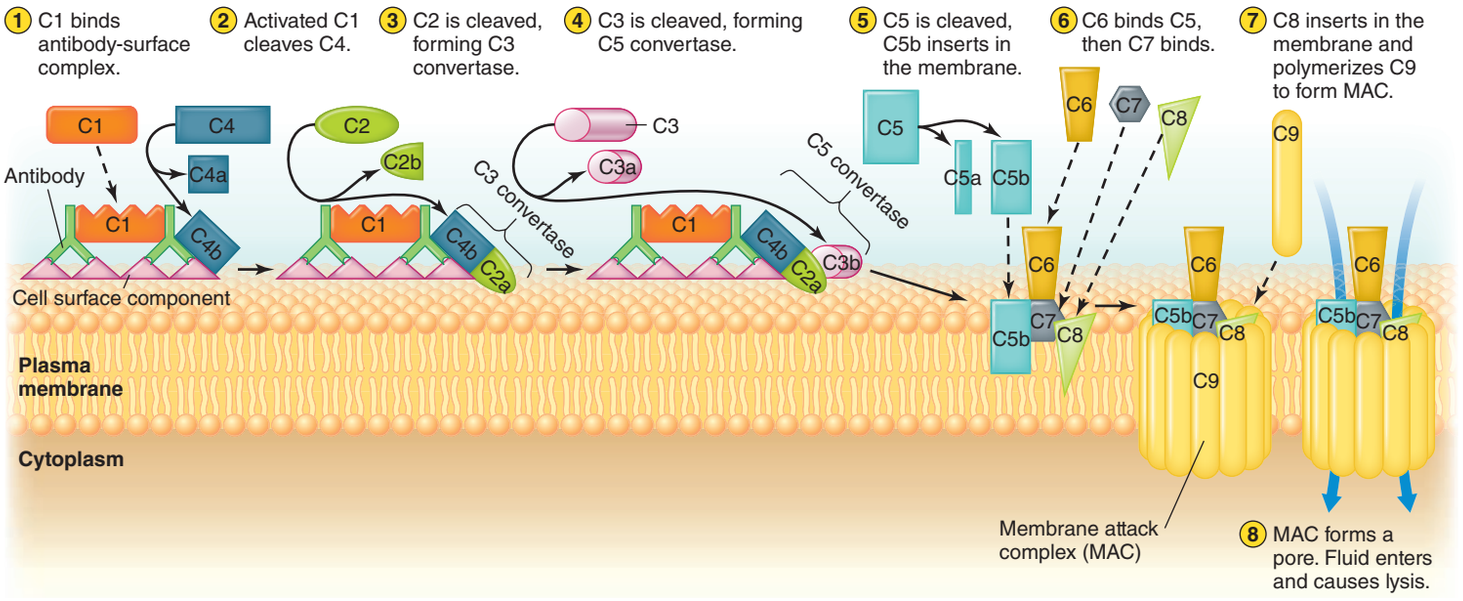

Figure 19.7. Process Diagram: The classical complement activation pathway and the formation of the membrane attack complex (MAC) The classical pathway is initiated by antibody binding to the microbial surface. Complement factor C1 binds the terminus of bound antibody and forms an active complex that initiates a series of cleavages, beginning with C4 to form MAC. MAC forms an open pore in the membranes of bacteria (shown here), or of enveloped viruses, permitting the free diffusion of water into the microbe. The result is disruption of the membrane and lysis.

C1 C1 is a complex composed of several peptides. C1 binds to the surface of some pathogens by directly recognizing certain surface components, such as lipoteichoic acid of Gram-positive cell walls and LPS of Gram-negative walls. As such, it acts as a PRR, but it can also bind surfaces that have been coated with C-reactive protein or **antibody**. Antibodies are secreted glycoproteins that bind to microbes and their components and are produced by B cells of the adaptive immune system. Antibodies and B cells will be described in more detail in Chapter 20. A common diagnostic test that takes advantage of the ability of C1 to recognize any antibody bound to a microbial surface is called the complement fixation test (CFT), described in **Toolbox 19.1**. This test is used to indirectly detect the presence of antibodies specifically produced as a result of infection with a pathogen. The ability of the adaptive immune response to initiate the innate complement cascade is just one example of the synergy between these two systems. Once sufficiently bound at a microbial surface, C1 undergoes auto-catalysis, cleaving itself to produce an active protease that cleaves the next complement component in the cascade, C4.

C4 Cleavage of C4 by activated C1 results in the products C4a, which is released, and C4b. The product C4b can bind to the surface of the target cell where it remains associated with C1.

C2 In its bound and active form C4b binds C2, bringing it into position for active C1 to cleave into C2a and C2b. The smaller C2b fragment is released while C2a remains surface-bound to form the complex C4b2a, also known as the "C3 convertase complex."

C3 The C3 convertase complex acts upon C3, converting it into C3a and C3b. Because the C3 convertase complex has enzymatic activity, it can cleave *many* molecules of C3 upon contact. Some of the produced C3b diffuses away, and the rest remains associated with C4b2a at the cell surface. The resultant complex formed is C4b2a3b, also known as the "C5 convertase complex."

C5 The enzymatic C5 convertase complex cleaves molecules of C5 into C5a and C5b. The larger C5b fragment associates with the next several components to form the membrane attack complex (MAC).

C6, C7, C8, C9, and MAC MAC is formed by the sequential interaction of C5b, C6, C7, C8, and C9 with the microbial membrane. The complex C5bC6C7 forms an anchor to the membrane via insertion of the hydrophobic site of C7 into the lipid bilayer. C8 next associates with this complex, similarly inserting into the membrane and now able to initiate polymerization of up to 15 C9 molecules in the membrane. This large complex of C9 polypeptides forms pores in microbial membranes **(Figure 19.8)**. In Gram-negative bacteria, disruption of the outer membrane allows lysozyme present in serum to destroy the peptidoglycan layer. Water can enter the resulting protoplast and the cell lyses (see Section 2.4). A summary of the complement components of the classical pathway is shown in **Table 19.5**. Most

TABLE 19.5 Activation and functions of complement components

Component	Result/Function
C1	Binds at microbial surface; self-activates to form C1 protease to cleave C4
C4a[a]	Degranulation of mast cells and basophils
C4b	Binds to microbial surface with C1 protease, then binds C2 to form a complex
C4b + C2 + C1 protease complex	C1 protease cleaves C4b-bound C2
C2a	Binds to C4b
C2b	Increases vascular permeability
C4b2a (C3 convertase)	Cleaves C3
C3a	Leukocyte chemoattractant; degranulation of mast cells and basophils
C3b	Binds to C4b2a, opsonin
C4b2a3b (C5 convertase)	Cleaves C5
C5a	Degranulation of mast cells and basophils; phagocyte chemoattractant; stimulates antibacterial activities of phagocytes
C5b	Associates with membranes; binds C6 to begin MAC formation; neutrophil chemoattractant
Bound C6	Binds C7
Bound C7	Inserts in membrane; binds C8
Bound C8	Inserts in membrane; polymerizes C9
C9	In presence of C8, several C9 units polymerize to form a pore in the microbial membrane; completes formation of MAC
MBL-surface complex (C1-like activity)	Cleaves C4
Factors B, D	Combines with C3b to form C3bBb (C3-like convertase)
C3bBb (C3-like convertase)	Cleaves C3 to form C3bBbC3b (C5-like convertase)
C3bBbC3b (C5-like convertase)	Cleaves C5 to begin MAC formation

Red = components unique to classical pathway
Blue = components unique to alternative pathway
Purple = components shared by classical and lectin pathways only
Green = components unique to lectin pathway
Black = components shared by all pathways
[a] Note that the various complement factors were named according to their order of discovery, so their numerical designations do not necessarily relate to their position in the cascade.

Figure 19.8. Membrane attack complex (MAC) Molecular model of the assembled complex, showing the large central pore that leads to membrane disruption and lysis.

Gram-positive bacteria appear somewhat resistant to lysis by complement due to their thick peptidoglycan layer, which retards access of MAC components to the underlying plasma membrane. Gram-positive bacteria can still effectively initiate the complement cascade to produce accessory complement molecules with important immune functions, as seen later.

Direct destruction of enveloped viruses via complement-fixing antibody and MAC formation is an important antiviral defense. Lysis of virus-infected cells can also occur because prior to exit from the host cell, many enveloped viruses first insert viral transmembrane proteins into the host cell membrane in preparation for envelope formation (see Section 8.5). When these cells are recognized by complement-fixing antibody, they can be lysed by MAC formation, preventing the formation of infectious viral particles.

The Lectin Pathway

We were earlier introduced to mannose-binding lectin (MBL). It binds the PAMPs, mannan, and *N*-acetylglucosamine, found on the surface of many microbes. Once bound, MBL further complexes with other serum proteins to impart a C1-like activity on the complex, which then activates the complement cascade (see Table 19.5). The mannose-binding pathway is not activated by antibodies, and therefore its initiation can occur in the absence of an adaptive immune response. **Figure 19.9** shows an overview of each of the pathways.

The Alternative Pathway

The alternative pathway is also activated in an antibody-independent manner. This pathway begins with an alternative form of C3b, which is generated in small amounts in the serum as a result of spontaneous hydrolysis of C3. This free altered C3b binds to a variety of cell wall PAMPs, such as zymosan of yeast, LPS of Gram-negative bacteria, and lipoteichoic acid of Gram-positive bacteria. Bound C3b binds another serum protein, factor B. Bound factor B is acted upon by serum factor D to form the cell surface complex C3bBb. This forms a C3 convertase-like complex that actively hydrolyzes C3 to form C3b at the microbial surface. This C3b then associates with

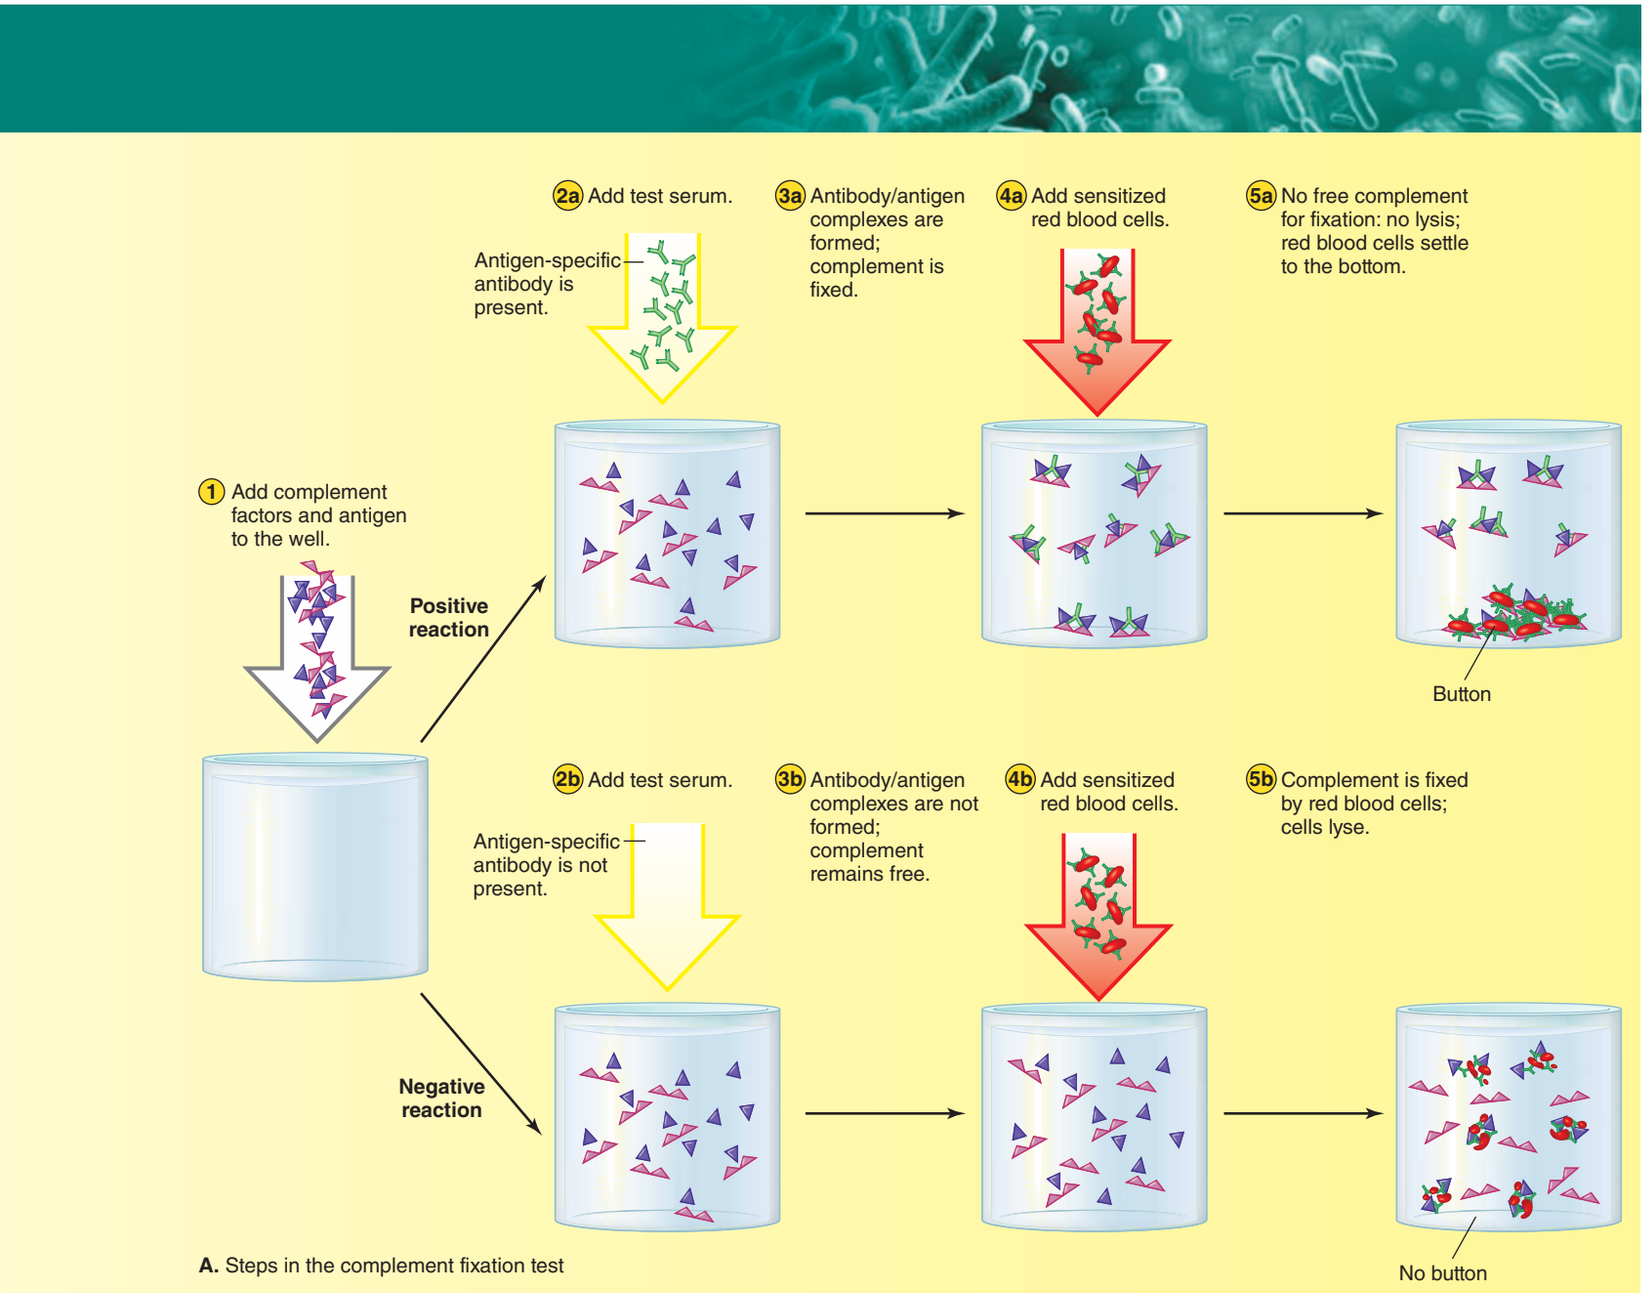
Toolbox 19.1
THE COMPLEMENT FIXATION TEST

The complement fixation test (CFT) is an important serological test used to determine the presence of antibodies specific to a particular microbe from a sample of serum. This in turn *indirectly* indicates infection or recent past infection. The test takes advantage of the ability of C1 to react with almost any antibody-bound surface. So, while the antibody is specific in its recognition of the particular pathogen, complement binding to antibody is non-specific in terms of pathogen recognition.

By adding a preparation of a specific microbial component, or the microbe itself, antibodies are detected in serum because antibody-bound complexes "fix" or bind a specific amount of complement added in the test well. **Figure B19.2** shows the steps in a CFT. To detect whether complement has been fixed, "sensitized" sheep red blood cells are used as indicators for lysis. These cells are prepared by coating them with specific antibody that binds sheep red blood cells (anti-sheep red blood cell antibody) to make them sensitive to lysis if complement is present. If specific antibodies to the microbe in question are present in the test serum, then complement is fixed and is no longer available to take part in lysis of the antibody-coated red blood cells. These cells will settle out of the suspension and form a "button" in the well, giving a positive test that indicates specific antibodies *are* present for the microbe being tested. If specific antibodies are *not* present, then complement is not fixed and is available to lyse the indicator red blood cells. Consequently, no button forms in the well, resulting in a negative test. A CFT requires two days to complete and requires highly standardized and specific microbial preparations. Despite these limitations, it is the gold standard of diagnosis for several infectious agents.

Test Your Understanding

The CFT was used to test a patient for the zoonotic disease known as Q fever, caused by the bacterium *Coxiella burnetii*. The patient was told that the test came back positive but that it did not indicate whether he had a current or past Q fever infection. What was observed to call the results for this patient positive? In view of these results, why are the doctors unclear whether the infection is current or occurred in the past?



Leon J. Le Beau/Biological Photo Service

Figure B19.2. Process Diagram: Complement fixation test **A.** Infection with a particular pathogen results in production of antigen-specific antibody in a serum sample. In the presence of specific antigen derived from the pathogen, complement is fixed and not available to lyse antibody-coated red blood cells (sensitized). The cells settle out and form a "button" at the bottom of the well. This indicates a positive test. If infection did not occur, antigen-specific antibody will not be present in the test serum, leaving free complement, which can lyse sensitized red blood cells. A negative test shows no button. **B.** Standard dilutions of serum samples are done to quantify the amount of specific antibody present. Samples 1 to 6 show positive test results, indicated by buttons formed at high serum concentrations. Sample 7 shows a negative test result, with no buttons formed.

Figure 19.9. Complement activation pathways and actions of released complement factors The pathways differ in mode of initiation but share several common steps leading to the formation of MAC in microbial membranes. Initiation of the classical pathway involves binding of C1, often in the presence of antibodies, to the microbial surface. The lectin pathway begins with serum mannose-binding lectin (MBL) attaching to mannose or *N*-acetylglucosamine of LPS (not shown) units on the surface of the microbe. In the alternative pathway, initiation begins when spontaneously produced C3b binds certain microbial components, such as LPS. As well as forming the MAC, several of the complement products have important activities in inflammation, and opsonization.

C3bBb to form C3bBbC3b, a complex analogous in function to C5 convertase, which generates the MAC. The unique components of the alternative pathway are shown in Table 19.5.

Accessory Functions of Complement

Although it is apparent that only some of the components produced by complement activation actually participate in the cascade, one must wonder what becomes of the other products that are released. As you might guess, some of these soluble products have important biological functions that contribute indirectly, but significantly, to immune defense. The effectiveness of this built-in conservation of purpose is due to several amplification steps within the system. Once initiated, the process quickly generates many thousands of activated complement factors. Amplification occurs because complexes, such as the C3 and C5 convertases, have enzymatic activity, and so a single complex can convert hundreds of complement substrate molecules into their active forms. This not only results in acceleration of MAC formation and rapid lysis, but also generates critical concentrations of complement products that serve as chemoattractants and proinflammatory molecules. These concentrations are generated within a few minutes of complement activation in a manner similar to an avalanche, where just a few falling objects trigger a much larger slide at a local site.

Let us now examine some of the other functions of the generated complement components (see Figure 19.9 and Table 19.5). As well as participating in the complement cascade, some C3b is released into the surrounding area where it serves as a pattern recognition receptor (PRR), binding a variety of microbial cell wall components. Millions of molecules of C3b can be deposited on the microbial surface in a matter of minutes as a result of complement activation. This resulting opsonization facilitates phagocytosis of the microbial cell by phagocytes of the immune system **(Figure 19.10)**. The processes of opsonization and phagocytosis will be discussed in more detail later.

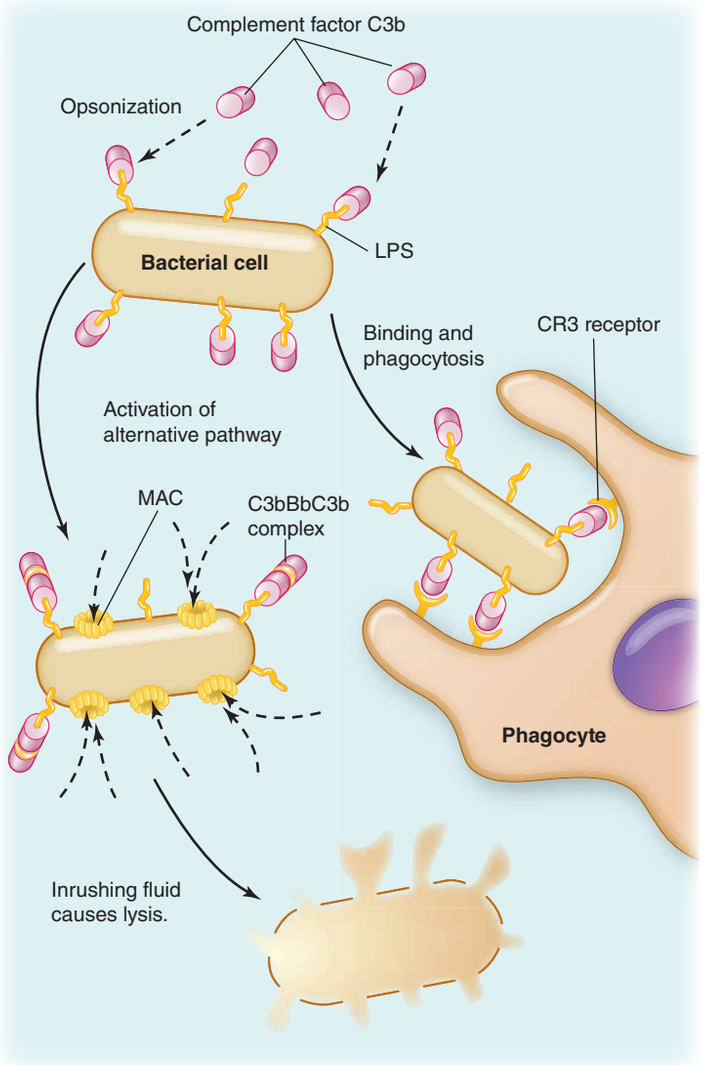

Figure 19.10. Opsonization of a bacterial cell by complement factor C3b Coating of a microbial cell with C3b molecules facilitates phagocytosis by neutrophils and macrophages. These phagocytes possess CR3 receptors (CR complement receptor) on their surface that specifically bind to the C3b molecules coating the bacterial cell. Opsonization with C3b also activates the complement cascade, leading to the membrane attack complex (MAC) and destruction of the microbe by lysis.

C3a serves as a chemoattractant for leukocytes. Large amounts of C3a, produced from complement activation, create a chemical gradient from the site of infection toward which leukocytes will migrate, conveniently bringing them in to assist in clearance of the infection. C3a, along with released C4a and C5a, stimulate inflammation at the site by causing the release (degranulation) of histamine-containing vesicles from tissue mast cells (see Section 19.5). Lastly, released C5b is a powerful chemoattractant for neutrophils. As we can see, complement activation produces a variety of molecules with important immune actions, all contributing to clearance of infection.

Type I interferons

Type I IFNs are a class of cytokines, of which interferon-alpha (IFN-α) and interferon-beta (IFN-β) are the major members. These two cytokines have the ability to produce a generalized antiviral state in infected cells and uninfected neighboring cells, which protects them from viral infection **(Figure 19.11)**. More than 300 genes show increased levels of expression when cells are exposed to Type I IFN. Some of the outcomes of this gene induction are as follows:

- **Inhibition of ribosome binding:** As we saw in Chapters 5 and 8, all viruses rely on host cell ribosomes for translation of their proteins, so progeny virus particles are not produced if ribosomes do not bind mRNA efficiently.
- **Changes in membrane components:** Cell surface changes discourage viral attachment and entry into cells.
- **Degradation of RNA:** This impedes cellular replication, limiting the availability of available host cells and restricts metabolic functions of infected cells making them unsuitable hosts. As you can imagine, this can kill the infected cell as well, but is of overall benefit for the host.
- **Proliferation of cytotoxic natural killer cells** (see Section 19.5): These cells can destroy infected host cells, preventing the manufacture and spread of virus.

IFN-α is produced mostly by leukocytes, and IFN-β is produced by numerous cell types. A third type of IFN (classified as Type II IFN) is interferon-gamma (IFN-γ), which is an important cytokine produced by T cells of the adaptive immune system. It has very different activity from the Type I IFNs, as we will see in Chapter 20.

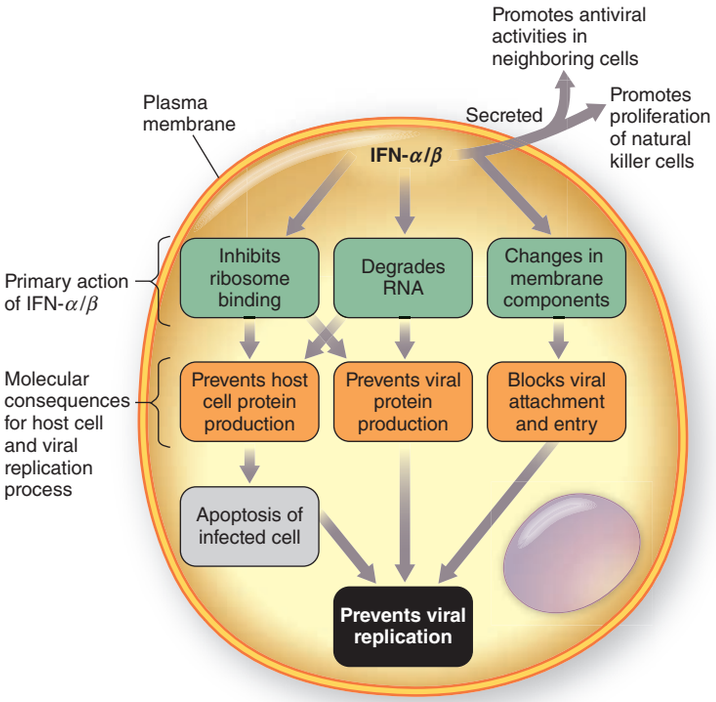

Figure 19.11. Type I interferons Type I interferons IFN-α and IFN-β activate a variety of defenses against viruses in infected and neighboring cells. Secretion of Type I IFNs promotes production of natural killer cells, which are able to destroy virus-infected cells.

19.4 Fact Check

1. Explain how pathogen-associated molecular patterns (PAMPs) and pattern recognition receptors (PRRs) interact in the body.
2. What are the functions of Toll-like receptors (TLRs), and how do they link innate and adaptive immune responses?
3. What is complement, and how does it protect against microbial pathogens?
4. Compare and contrast the following complement activation pathways: classical pathway, alternative pathway, and lectin pathway.
5. Describe the effect of Type I interferons (IFNs) on host cells.

19.5 The cells of innate immunity

What cells first defend us against infectious agents?

The molecules involved in innate immunity have the ability to recognize pathogen-associated molecular patterns (PAMPs) and work in synergy with each other and with cells of the immune system. We have already seen that binding of C-reactive protein and MBL to their target PAMPs initiates the complement cascade and results in opsonization, which facilitates phagocytosis by neutrophils and macrophages of the immune system. Cell-associated TLR recognition of PAMPs results in the expression of genes that are needed for cellular immune responses, such as the production of Type I IFNs that provide immunity to viral infections. Chemoattractants produced through the complement cascade, like C3a, attract neutrophils

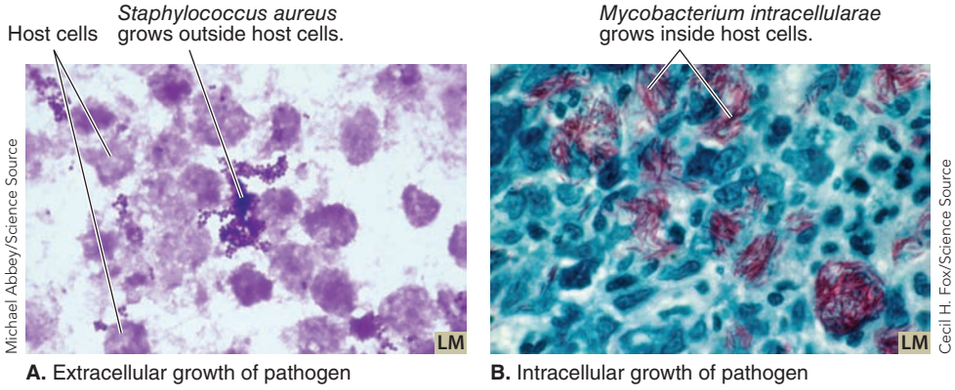

Figure 19.12. Extracellular or intracellular growth of pathogens **A.** Extracellular growth: *Staphylococcus aureus* cells, stained purple, can be seen in clusters outside host cells, and are susceptible to phagocytosis and killing by phagocytes. **B.** Intracellular growth: *Mycobacterium intracellularae*, shown stained red, filling host cells. Intracellular bacteria are not accessible for uptake and killing by phagocytes.

to the site of infection, and the inflammatory mediators C4a and C5a stimulate inflammation. All work together in the defense against pathogens. In this section, we will focus on the functions of the cells involved in innate immunity.

Cellular defense is initially carried out by phagocytes and natural killer (NK) cells. These cells can respond quickly to an invasion before the cells of the adaptive immune system can act. Invading microbes have two basic strategies for existence and replication once inside the body. They can be extracellular, which means existing outside the cell, or they can be intracellular, existing inside cells (Figure 19.12). To be effective, innate immune defenses need to combat both. Some microorganisms such as *Salmonella* species can adopt both lifestyles (see Figure 21.6), making them especially successful at eluding the immune system. Of course, the success with which microbes establish themselves in the environment of the body depends on how well they are equipped with the physiological and structural tools for a pathogenic existence. For example, pathogenic strains of *Streptococcus pneumoniae* have an outer capsule that inhibits phagocytosis, allowing them to proliferate extracellularly (see Section 21.1). Recall in Chapter 7, Griffith described the phenotype of pathogenic, encapsulated strains as smooth or S strain, and they readily killed mice. Griffith's R strain, without the capsule, were readily phagocytosed and did not cause disease. Another example is the intracellular pathogen *Mycobacterium tuberculosis*. This pathogen produces various neutralizing compounds that reduce intracellular killing by phagocytic cells, allowing it to exist *inside* macrophages. Such strategies will be discussed in Chapter 21.

Phagocytes

A phagocyte or phagocytic cell is a functionally descriptive term used to describe wandering cells of the immune system that engulf large extracellular particles, such as bacterial cells and dead host cells that they come across in their travels. Neutrophils, along with monocytes and macrophages are phagocytes. Once activated by Toll-like receptor (TLR) binding and cytokine signaling, these phagocytes become adept killing machines.

Neutrophils

Neutrophils are present in large numbers in the blood of vertebrates and are the most abundant cell of the immune system found in normal human blood. Their large numbers allow them to efficiently patrol the body to find invading microbes. Consequently, they are often the first to arrive *en masse* at the site of a bacterial infection. Neutrophils (Figure 19.13) are characterized by a multilobed ("poly") nucleus of different shapes ("morph"), giving them an alternative name "polymorphonuclear leukocytes" (PMNs). They also contain numerous membrane-bound, chemical-containing vesicles called **granules** in their cytoplasm. Granules are easily seen when specifically stained. Neutrophils get their name from the fact that their granules do not readily stain with the acidic dye eosin or the basic dye methylene blue. This is due to the neutral nature of the substances contained in their granules, such as lactoferrin and lysozyme. Granules containing the enzyme lysozyme are specifically referred to as **lysosomes**.

Monocytes and Macrophages

Monocytes and **macrophages** are collectively referred to as "mononuclear cells" because of their large, single, round or horseshoe-shaped nucleus (Figure 19.14). Mononuclear cells are produced in the bone marrow and are released to the blood as monocytes. Monocytes circulate in the blood for one to two days, after which time they move into tissues and further differentiate into mature macrophages (see Appendix D Origin of Blood Cells). Macrophages are "beefed up" versions of monocytes. They are larger, contain more organelles, especially lysosomes, have numerous projections, and are more efficient in the processes of phagocytosis and intracellular killing.

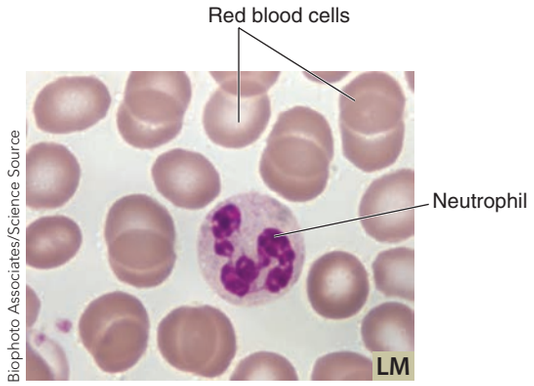

Figure 19.13. Neutrophil The darkly stained multilobed nucleus, from which these cells derive their alternative name of polymorphonuclear leukocyte (PMN), is clearly visible. Neutrophils are the most plentiful immune cell in human blood.

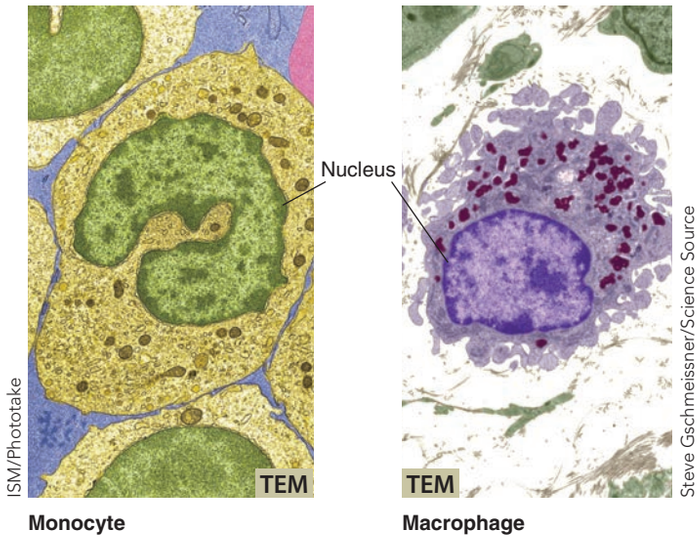

Figure 19.14. Monocytes differentiate into macrophages Monocytes (*left*) circulate in the blood before migrating to the tissues where they differentiate into macrophages (*right*). The large nucleus can be seen in both cells. The macrophage is larger than the monocyte, has more surface extensions and organelles, including lysosomes, and is more active in phagocytosis and intracellular killing.

Macrophages can be found wandering throughout the body or as permanent residents in certain tissues. Some of these resident macrophages have specialized functions and are given names specific to their place of residency. Examples include alveolar macrophages of the lungs, mesengial cells of the kidney, Kupffer cells of the liver, and histiocytes of connective tissue.

Microbial Capture and Killing by Phagocytes

For a phagocytic cell to kill an extracellular microbe, it must first identify the microbe as being foreign and then capture and internalize it to begin its destruction. Although some extracellular microbes can be directly bound by specific receptors present on the phagocyte surface, most are first opsonized. As previously mentioned, opsonization is the covering of the microbial surface with molecules called **opsonins** that bind foreign substances. Examples of opsonins are C-reactive protein, antibodies, MBL (see Figure 19.6), and complement component C3b (see Figure 19.10). Some of these are recognized by receptors on the surface of various phagocytes. C3b opsonin is recognized by complement receptors CR1, CR2, and CR3, found on the surface of neutrophils and macrophages. The exposed portion of opsonizing antibody, the F_C portion, is recognized by a specific receptor, the F_C receptor (F_CR) of macrophages and neutrophils (see Figures 20.32 for antibody structure). Opsonization by lectins, such as MBL and C-reactive protein, activates the complement cascade, and the resulting C3b molecules further coat the target for opsonization. These and other common methods of opsonization used by vertebrates are shown in **Figure 19.15**. Opsonization allows the phagocyte to indirectly bind to the microorganism for effective phagocytosis. The effect is analogous to the addition of the small bumps on the surface of a basketball that allow your fingertips to get a better grip on its otherwise slippery surface.

To investigate the importance of opsonization, researchers have used strains of mice deficient for C3 from which C3b is derived. Experimental infection of these mice with *Pseudomonas aeruginosa* resulted in the accumulation of significantly higher numbers of bacteria in the blood compared to that of normal control mice. These deficient mice showed decreased ability of neutrophils to bind and ingest *P. aeruginosa*, compared to their normal counterparts. Not surprisingly, documented cases of human C3-deficient patients show recurrent and severe infections with a variety of organisms, indicating an important role for opsonization by C3b for phagocytosis and killing.

The starting point for intracellular killing is phagocytosis. When a phagocyte encounters a microorganism, it begins the process of phagocytosis. Phagocytosis is specifically used to ingest large particulate matter such as bacterial cells. Phagocytosis is a specialized form of **endocytosis**, a generalized process for the uptake of external materials by cell membrane extension or invagination and fusion to form a vesicle inside the cytoplasm of the cell. This vesicle is an **endosome**. Endocytosis of matter is carried out by most cells of the body and can be accomplished by other mechanisms, detailed in Chapter 20 and Figure 20.12. The endosome formed by phagocytosis is called a **phagosome**. Phagocytes secrete lactoferrin into the phagosome to keep iron away from bacteria they may have engulfed (see Section 21.1). Destruction of the particle begins within the phagosome. The resulting phagosome enters into

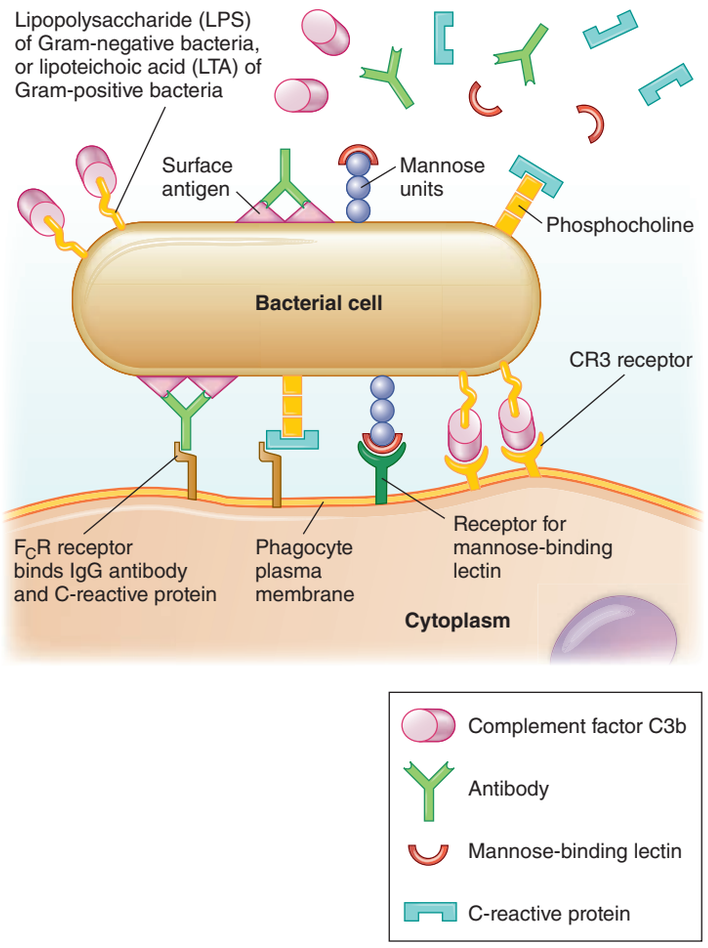

Figure 19.15. Opsonization of bacterial cells Phagocytes possess a variety of specific receptors on their surface for binding to various defense opsonins that coat microbial cells.

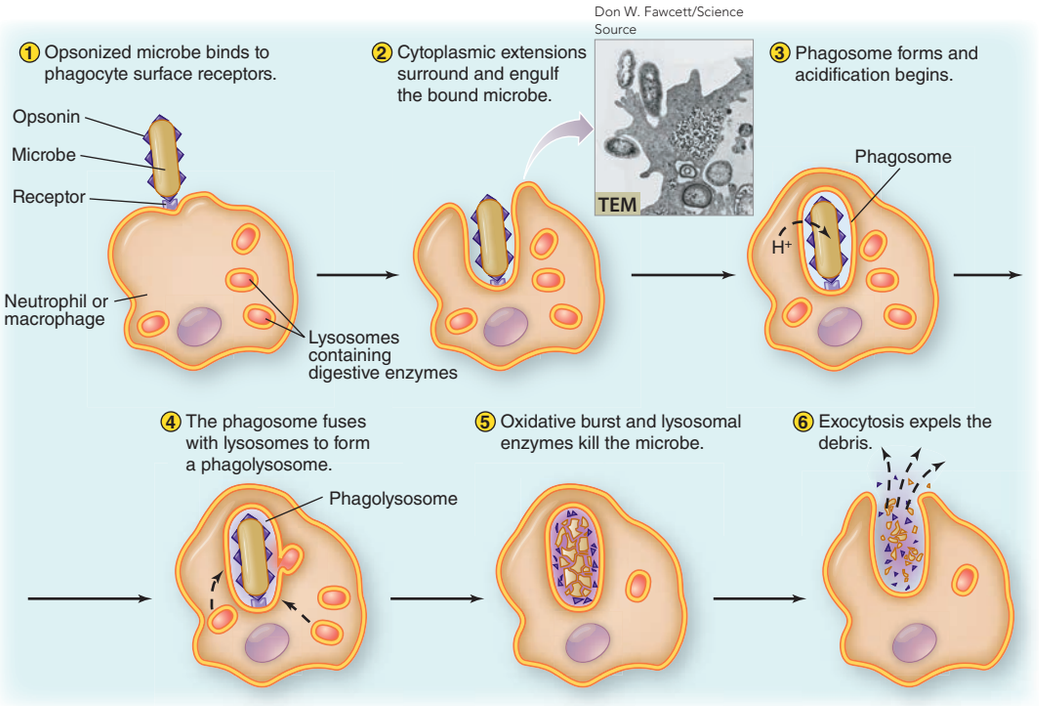

Figure 19.16. Process Diagram: Phagosome formation and intracellular killing A foreign object, the bacterial cell in this case, is often first opsonized. A phagosome forms and enters the endocytic pathway. Degradative enzymes in combination with toxic compounds from the respiratory burst kill and degrade the microbe.

the **endocytic pathway** where a sequence of fusions with other cytoplasmic vesicles and acidification occurs to digest the endocytosed material. After a series of biochemical changes, the digested material is expelled by membrane fusion with the plasma membrane. This process is referred to as "exocytosis" (Figure 19.16).

Endocytosis and exocytosis
ANIMATION

Within the endocytic pathway, phagocytes employ several strategies to kill phagocytosed microorganisms:

- Enzymatic degradation.
- Inactivation by acidification.
- Formation of pores in bacterial membranes causing lysis.
- Destruction by toxic oxygen compounds.

The first step following formation of the phagosome is acidification to pH 4.0–5.0. At this pH, most microbes are inactivated but not necessarily destroyed. To effectively kill microbes, the phagocyte engages two more strategies. The phagosome fuses with lysosomes to form a **phagolysosome**. As mentioned previously, lysosomes contain lysozyme and a variety of other antimicrobial agents, including proteases and antimicrobial peptides, such as defensins (Table 19.6). Recall that defensins are antimicrobial peptides that are thought to form pores in microbial membranes to cause leakage and lysis. These antimicrobial substances empty into the phagosome upon fusion with lysosomes, and the low pH activates these compounds to begin digestion of the microbe. The phagolysosome can be thought of as the "stomach" of the cell, because the end result is destruction and degradation of the ingested material.

In addition to acidification, macrophages and neutrophils carry out a unique process called the **respiratory (oxidative) burst**, named because of its large requirement for cellular oxygen. The respiratory burst produces many highly toxic oxygen compounds inside the phagolysosome, some of which are listed in Table 19.7.

The combined action of these toxic oxygen compounds is usually sufficient to quickly kill and degrade most endocytosed microbes. In many cases, the infection is rapidly cleared by neutrophils without the need for adaptive immune responses. If the infection persists, the concentrations of cytokines increases, such as IL-8 and IL-1 from activated phagocytes and damaged cells. This causes migration of more neutrophils to the site and

TABLE 19.6 Antimicrobial compounds of lysosomes and their effects

Molecule	Killing action
Lysozyme	Hydrolysis of peptidoglycan of the bacterial cell wall
Proteases	Degradation of proteins
Defensins	Form pores in bacterial membranes

O_2^-	Superoxide anion
NO	Nitric oxide

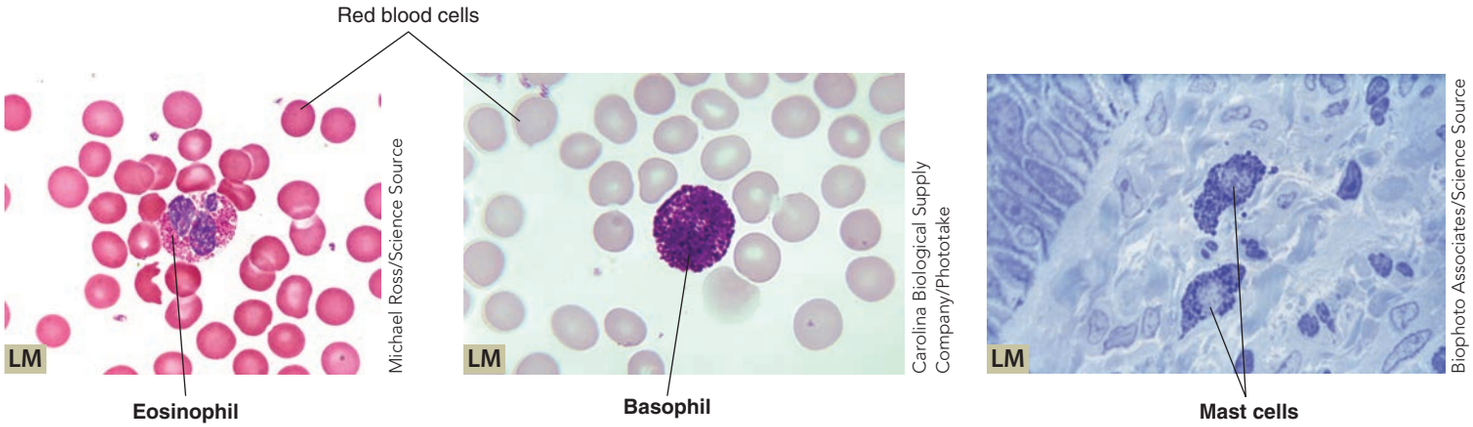

Figure 19.17. Eosinophils, basophils, and mast cells Stained blood smear of a central eosinophil surrounded by red blood cells (*left*). The many granules in the cytoplasm are stained with the dye eosin and appear red. The multilobed nucleus is blue. Stained blood smear of a central basophil surrounded by red blood cells (*middle*). The many basic-staining granules (blue) pack the cytoplasm and obscure the nucleus. Stained smear of mast cells in tissue (*right*). The numerous granules in the cytoplasm are stained dark blue. Nuclei are stained pale blue.

begins the recruitment of monocytes from the blood for assistance. In the tissues, the monocytes mature into macrophages. Once stimulated by the activities of binding and phagocytosis, the macrophage exhibits enhanced phagocytosis, increased respiratory burst, and production of antimicrobial compounds such as defensins and lysozymes. In addition to destroying microorganisms, macrophages and neutrophils also interact directly with cells of the adaptive immune system by presenting peptides from the degraded microbe (see Section 20.2).

The end result of phagocytosis is the degradation of the microbe into small molecular components. For full activation, that is, maximally enhanced phagocytosis and killing, neutrophils and macrophages require the help of cytokines, such as tumor necrosis factor-beta (TNF-β) and interferon-gamma (IFN-γ), produced from T cells of the adaptive system. Again, this illustrates the interdependence of the innate and adaptive immune systems. It is hard to imagine any microbe capable of surviving such an arsenal of killing mechanisms, but some pathogens have devised ways of preventing intracellular killing.

CONNECTIONS Many pathogenic bacteria, such as *Salmonella* Typhimurium, *Mycobacterium tuberculosis*, and *Mycobacterium leprae*, actually live inside the phagosome of macrophages. They avoid destruction by producing microbial products that interfere with the fusion of the phagosome with lysosomes and other endocytic vesicles. See **Figure 21.6** and **Section 21.3** (Pathogen Study 2: *Mycobacterium tuberculosis*) for details.

Eosinophils, basophils, and mast cells

Eosinophils, basophils, and mast cells generally act against extracellular parasitic worms, many of which are far too large for phagocytosis (Figure 19.17). **Eosinophils** are found in tissues and contain numerous granules that stain red with the dye eosin. **Basophils** are also found in the blood and carry granules that stain with basic dyes. The differential staining of the granules of these two cell types indicates they are of different chemical properties. **Mast cells** are found widely in tissues.

Eosinophils, basophils, and mast cells are **cytotoxic cells**. This means that they kill their target, such as a parasite, by releasing their toxic granular contents directly onto the target cell in a process called **degranulation**. To do this, mast cells and basophils usually require the presence of IgE antibodies produced by B cells of the adaptive immune system (see Section 20.6). IgE is specifically made in response to allergens and parasites to recruit the killing action of basophils and mast cells. These cells can bind free, unbound IgE using surface receptors for the IgE antibody. When the IgE that is bound to mast cells or basophils contacts its specific target—the parasite or an allergen—the cell is triggered into releasing its granular components. Basophils and mast cells are also stimulated to degranulate in the presence of the complement components C3a and C5a even before the adaptive immune response has had a chance to produce IgE (Figure 19.19).

Eosinophils have receptors for another type of antibody, IgG, and will bind to IgG-coated parasites. This causes degranulation in a manner similar to mast cells and basophils (Figure 19.18).

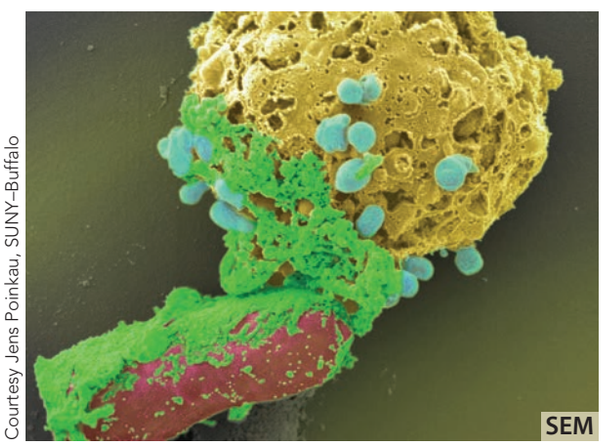

Figure 19.18. Eosinophils degranulating to attack a parasitic fungus The eosinophil, shown in yellow, has released toxic protein (called "major basic protein") onto the surface of a germinating fungal spore, shown in red. Concentrated toxic protein is shown in blue as it leaves the eosinophil, changing to green as it disperses. The numerous dark indents on the surface of the eosinophil are due to the fusion of granules with the plasma membrane during degranulation.

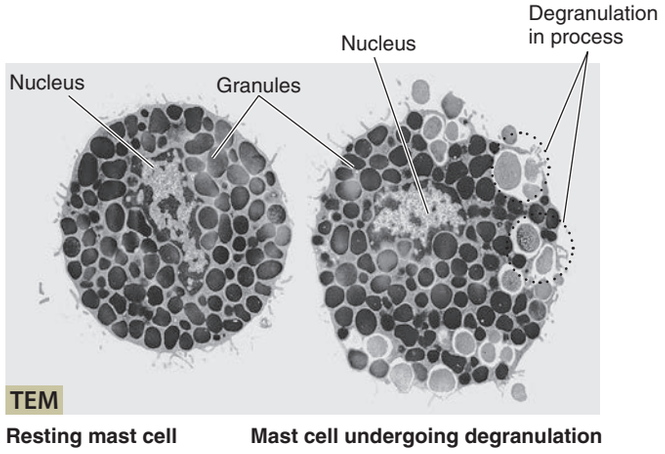

Courtesy Theoharis Theoharides, Tufts University Sackler School of Graduate Biomedical Sciences

Figure 19.19. Mast cell undergoing degranulation Intact granules are electron-dense and appear as dark spheres filling the cytoplasm. A resting mast cell is shown on the left. A mast cell degranulating is shown on the right. Fusion of granule and plasma membranes results in the release of granular components. Degranulation results in release of the electron-dense contents; these vesicles appear paler.

Despite being able to interact with specific antibodies, these cell functions are strictly innate as they do not recognize the specific infectious agent but rather only recognize the antibodies produced because of the infection. This is yet another example of how the innate and adaptive arms of the immune system work together.

Many of the released chemical components of the granules are not only cytotoxic, but also are potent stimulators of inflammation. An example is histamine, introduced in Section 19.3. Induction of a strong inflammatory response at the site of infection irritates the parasites, making it difficult for them to become established in the host. Other released chemicals have the ability to cause muscle contractions and excess mucus secretion, both of which help to dislodge the parasite from host tissues. Mast cells, eosinophils, and basophils are also involved in allergy responses in vertebrates.

Natural killer (NK) cells

So far we have examined the immune response to extracellular microorganisms, but how does innate immunity deal with intracellular pathogens? Obviously, there is no easy way to get at a microbe once it is inside a host cell. It would be analogous to you trying to retrieve your keys locked inside your car without actually entering the vehicle. In an emergency you may have to damage your car to get them out. This is what **natural killer (NK) cells** do. Their targets are the infected cells themselves. NK cells are cytotoxic cells; they are *not* phagocytic and they cannot internalize their target. Rather, they attach to infected cells and release their toxic granular contents, resulting in death of the infected host cell and maybe the microbe along with it. Any released intact microbes can then be effectively killed by neutrophils and macrophages.

Two of the granular components of the NK cell's cytotoxic arsenal are **perforin** and **granzymes**. Perforin is a peptide that is thought to produce pores in the target cell membranes. In this model, it is proposed that perforin forms channels in the target cell that assist in the uptake of the released granular components, such as granzymes. Perforin is found in many cells with cytotoxic activities, including cytotoxic T cells of the adaptive immune system (see Section 20.2). Granzymes induce apoptosis, a type of cell-directed programmed cell death, in target host cells. Recall from Section 18.2, apoptosis is a highly ordered cascade of chemical-signaling events that results in cellular suicide (see Figure 18.7).

In order for NK cells to be effective in fighting infection and limiting damage to the host, they must distinguish normal cells from infected cells. But how? NK cells would not have access to PAMPs because they are inside infected cells and so could not use this to determine if the cell was infected. Furthermore, NK possession of PRRs for PAMPs would not explain the ability of NK cells to recognize tumor cells, which do not express microbial products. Studies have confirmed that NK cells lack any receptors for PAMPs or specific microbial or tumor-expressed molecules present on an abnormal cell's surface. So, what do they recognize?

It is known that normal cell-to-cell communication in the body often involves physical contact between specific cell surface molecules. A common method of determining cellular recognition patterns is to investigate the cell's repertoire of surface receptors. Surface receptors are a subset of the collection of various molecules that decorate the surface of cells in the body. Each type of receptor has a specific ligand to which it binds. For example, the cell surface receptor CR3 of neutrophils and macrophages binds the ligand complement factor C3b (**Figure 19.20**; see also Figures 19.10 and 19.16).

Often, the ligand to which a receptor binds is located on the surface of other cell types, as this is critical for cell-to-cell recognition and communication. The number and kind of surface molecules on a cell are specific to the cell type and even the developmental stage of the cell. As such, these surface molecules are used as markers to identify and classify cells. Characterization of cell surface molecules can give important

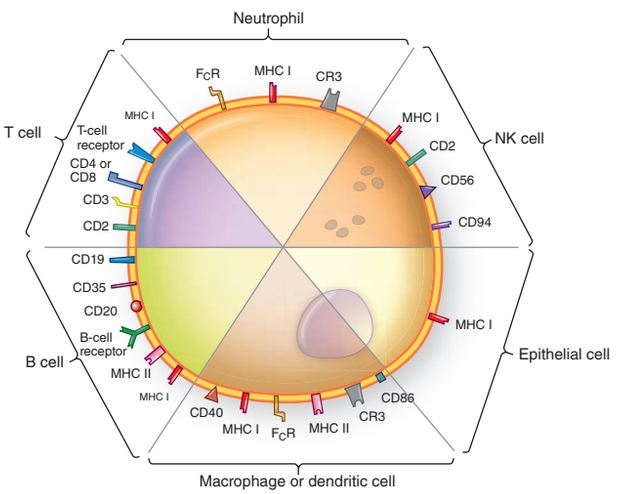

Figure 19.20. Cell surface molecules The number and pattern of surface molecules is characteristic of cell types. Thus, these molecules serve as markers to identify and classify individual cells in a mixture of cells. Some of the most important markers used for cell identification of immune system cells are the CD (cluster determinant) molecules, some examples of which are shown here.

information as to what the cell is capable of binding to and so gives clues as to its function.

Early studies of the types of tumor cells that are killed by NK cells revealed that these tumor cells had little or no expression of surface markers called **class I major histocompatibility complex (MHC I)** molecules. MHC I molecules are expressed on the surface of all normal nucleated vertebrate cells. Individuals have their own unique form of MHC I, and this allows the immune system to detect non-self cells, such as transplanted cells and cells such as cancerous cells that may have abnormal MHC I molecules. From studies on tumors, it appeared that the *lack* of MHC I on the tumor cells triggered degranulation of NK cells. Other studies using human MHC I-deficient cell lines showed that NK cells readily killed these. However, when genes for expression of MHC I molecules were added back to the cells, they were no longer targets for NK killing. This led to a hypothesis for NK targeting whereby NK cells are able to bind to MHC I molecules on the surface of normal cells. In this event, an inhibitory signal is sent and killing is not initiated. Yet, when an NK cell comes in contact with a cell without MHC I molecules, killing is initiated. Of course for this to be true, NK cells must possess a receptor for MHC I. This was indeed confirmed as receptor CD94.

Because the default setting in NK cells is to undergo degranulation in the absence of an inhibitory signal following contact with another cell, then they must also have an activating receptor that registers contact before degranulation proceeds. NK cells recognize several different cell surface ligands that signal they are in cell contact **(Figure 19.21)**.

From accumulated evidence, the current model, diagrammed in parts A and B of Figure 19.21, is as follows:

- When an NK cell contacts another cell, binding between an activating receptor on the NK cell and an activating ligand on the surface of the contacted cell occurs.
- When an NK cell simultaneously also binds to MHC I of the contacted cell, inhibitory signals are produced.
- This *prevents* initiation of killing.
- When no MHC I is encountered upon cell contact, an inhibitory signal is not produced and killing is initiated; degranulation and the release of perforin and granzymes occurs to cause apoptosis of the bound cell.

NK cells can therefore discriminate normal cells from abnormal cells by the presence or absence of the surface molecule MHC I. One of the characteristics of infected cells is often the loss or reduction of MHC I surface molecules. This has been widely reported in studies examining cells infected with various viruses and intracellular bacterial pathogens. Controlled studies of cellular MHC I expression in phagocytes show that phagocytosis of inert foreign substances, such as latex beads or individual microbial components, do not result in the repression of MHC I expression. However, cells that harbor pathogenic microbes commonly display reduced MHC I expression. Detailed studies show that these pathogens produce molecules that actively interfere with host cell MHC I production and/or transport to the cell surface. Why would pathogens do this? After all, this would seem to be a disadvantage because it allows their infected host cell to be vulnerable to attack by NK cells.

We can hypothesize that reducing MHC I expression in a host cell is somehow advantageous to the pathogen, and indeed this is the case. Normally, an infected cell couples peptide components released from the infecting pathogen during growth to MHC I molecules. The MHC I:peptide complexes are then presented on the surface of the infected host cell. The presentation of MHC I:peptide signals cells of the adaptive immune system, specifically cytotoxic T cells (see Section 20.2), to destroy the presenting infected cell. By interfering with normal MHC I expression, pathogens are thus able to avoid killing of their host cell by the adaptive immune system. However, as we have learned, reducing MHC I expression signals innate killing by NK cells. As a result, there is a functional synergy between NK cells of the innate system and cytotoxic T cells of the adaptive system that provides for the destruction of any infected cells missed by the other. The pathogen cannot win, or so it would seem. Some viruses have, through natural selection and evolution, developed tactics to circumvent killing by NK cells while at the same time reducing the expression of host cell MHC I molecules to avoid detection by cytotoxic T cells (see Figure 19.21C). An example is human cytomegalovirus, presented in **Microbes in Focus 19.1**.

CONNECTIONS MHC I molecules are involved in adaptive immune responses and are used to specifically tag infected cells for destruction by cytotoxic T cells. **Section 20.2** describes this activity.

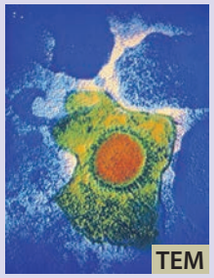
What about infected cells that still display normal MHC I markers? It would seem they would escape NK cell detection.

Microbes in Focus 19.1
COVERT OPERATIONS OF HUMAN CYTOMEGALOVIRUS

Habitat: Human cytomegalovirus infects 60–90 percent of adult humans, but disease is rare. Various tissues can be infected, and the virus can remain latent for many years, not causing active infection.

Description: Enveloped, icosahedral, double-stranded DNA virus of 150-nm diameter belonging to family *Herpesviridae*

Key Features: Human cytomegalovirus (CMV) produces a mimic MHC I molecule. This copycat protein is expressed on the surface of infected cells and binds to the NK CD94 receptor (recall this binds to MHC I) and "fools" the NK cell by making the infected cell appear to have normal MHC I distribution. As a result, cytotoxic killing of infected host cells is reduced, and the virus can continue to commandeer cells, making it a highly successful pathogen, but thankfully, one of low virulence in healthy adults. CMV infection in the developing fetus can cause death or neurological damage in 5–10 percent of infants of infected mothers.



CNRI/Science Source

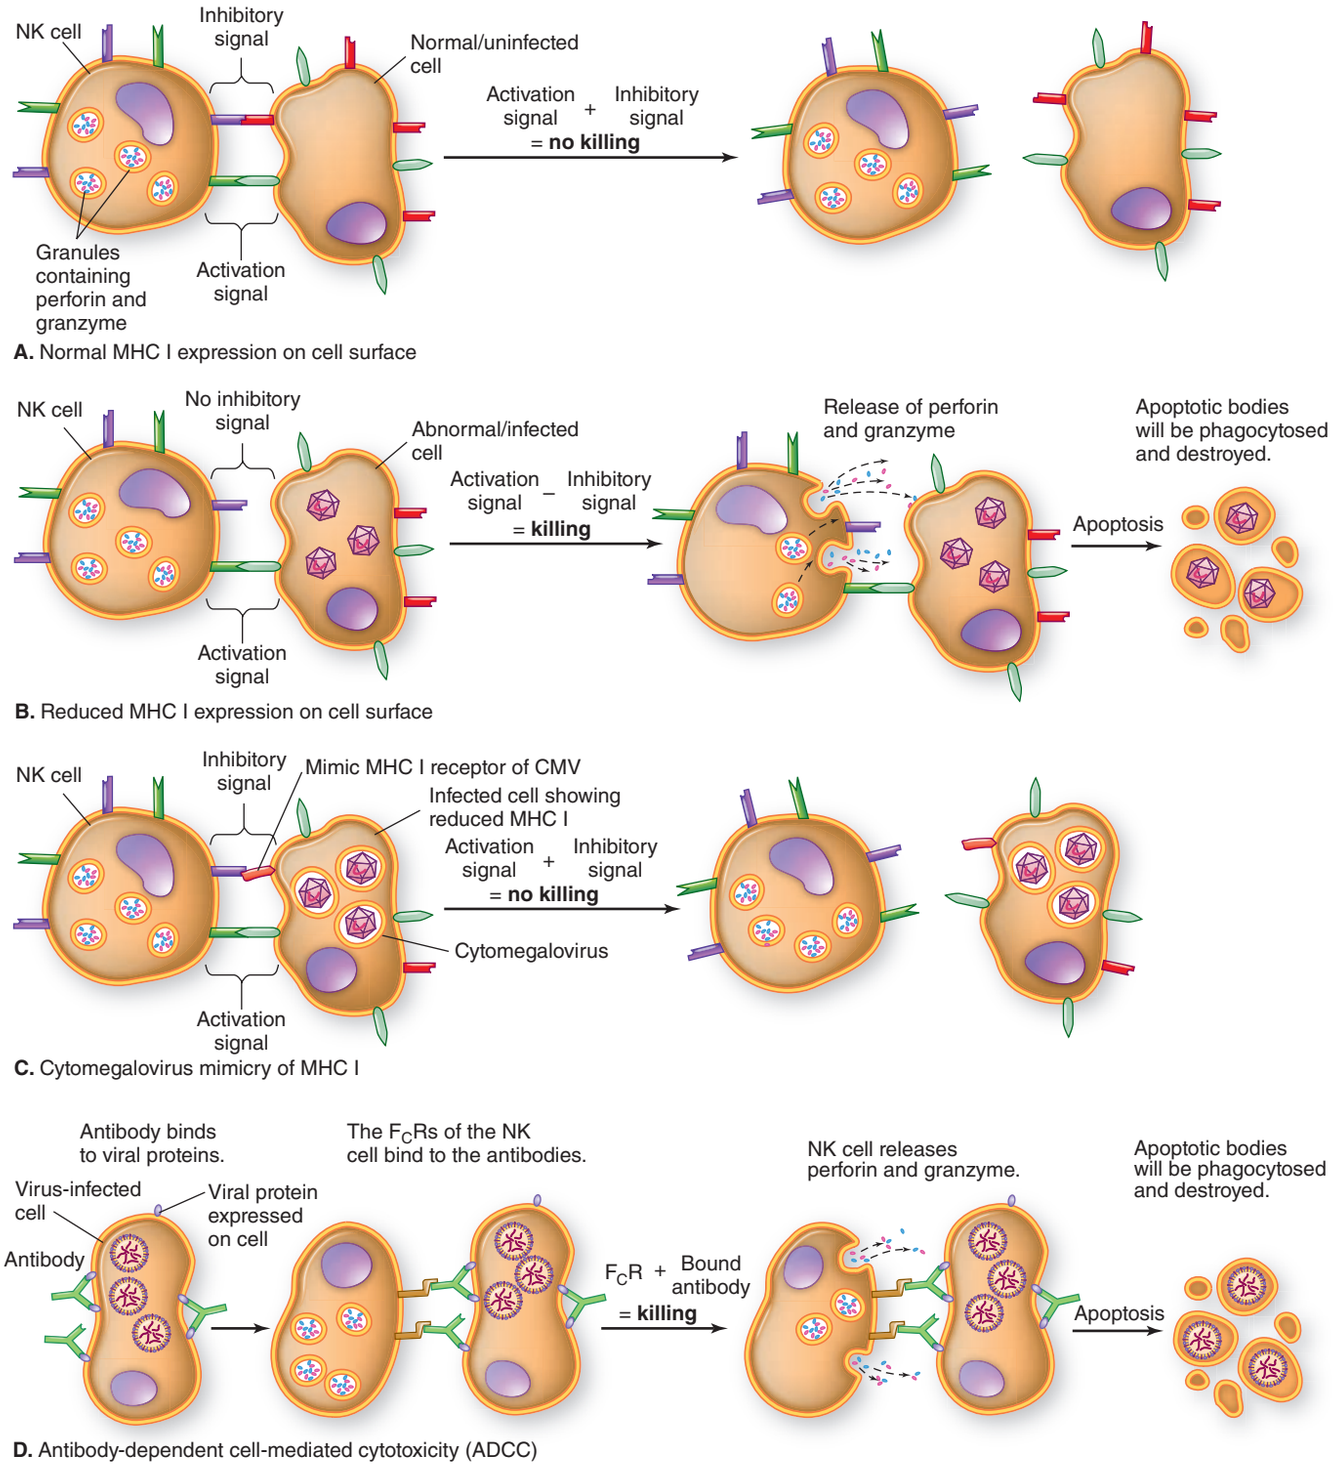


Figure 19.21. Activities of NK cells **A.** NK cells recognize normal cells through binding of the NK cell CD94 surface molecule to MHC I molecules on the surface of other body cells. This produces an inhibitory signal that counteracts the bound NK cell activation signal, preventing degranulation and killing of the cell. **B.** Infected or abnormal cells typically show reduced MHC I expression, consequently inhibitory MHC I binding does not happen. The activation signal triggers degranulation, resulting in apoptosis of the infected/abnormal cell. **C.** Molecular mimicry is carried out by human cytomegalovirus (CMV). Infection with the virus causes reduced MHC I expression on the surface of the host cell. Within the infected cell, CMV produces a peptide that mimics MHC I that binds CD94 receptors on the NK cell. This produces an inhibitory signal in the NK cell, allowing the infected cell to escape detection. **D.** Antibody-dependent cell-mediated cytotoxicity (ADCC) by NK cells requires the binding of antibody to an infected cell. ADCC by NK cells can kill virus-infected cells.

However, NK cells use a second mechanism that works in conjunction with the adaptive immune system to target these MHC I-presenting infected cells. This process is called **antibody-dependent cell-mediated cytotoxicity (ADCC)**. NK cells, like macrophages, possess F_C receptors on their surface that can bind to antibody (see Figure 19.15). Binding of NK cell F_C receptors to an antibody-coated infected cell leads to NK cell degranulation, causing apoptosis of the target cell (see Figure 19.21D). The combined mechanisms of ADCC and recognition of abnormal MHC I allows NK cells to detect and kill a broad spectrum of infected cells without having to specifically recognize the pathogen.

CONNECTIONS Recall in **Section 8.4, Figure 8.23**, that enveloped viruses of eukaryotic cells frequently insert their viral envelope proteins into the host plasma membrane as part of their packaging and egress processes. These viral proteins are thus exposed on the surface of infected cells and can be recognized by antibodies produced by the adaptive immune system.

We have covered many important aspects of innate immunity and immunity in general. Before we leave the subject of vertebrate innate immune responses, let's consolidate some of the information we have learned and begin to link it to our next chapter on adaptive immunity. We are exposed to microbes every day, and therefore it is inevitable that some of these microbes will gain access to our body tissues, mostly by breaches in our protective coverings—skin and mucosal membranes. When this happens, innate immune responses are the first line of defense to prevent spread of the infection and the ensuing damage caused. The degree to which innate immune responses occur depends on a number of parameters, including how many and what type of microbes are present. In many cases, innate immune defenses are sufficiently effective in clearing a microbial invasion so that adaptive immune responses do not occur to any large extent.

Microbes that produce molecules such as LPS, that efficiently stimulate inflammation, produce a sizable inflammatory response. The result is that very large numbers of immune cells can be brought into the affected area. The large concentrations of cytokines that are subsequently released by cells with immune activities attract and activate cells of the adaptive immune system (Chapter 20). The adaptive immune system is capable of producing a wide variety of molecules that are tailor-made to components of the particular infectious agent. Thus, molecules that are outside the repertoire of the innate system can be targeted, leading to a greater ability to destroy these microbes. In this way, the adaptive immune system works together with the body's innate responses to clear infections. Of course, pathogenic microbes have found ways to circumvent the immune system and can go on to cause disease. We will introduce some of these in Chapters 21, 22, and 23. We've largely been referring to innate immunity in vertebrates, so before we leave this chapter, we'll look briefly at the immune defenses of invertebrates.

19.5 Fact Check

1. What is the role of phagocytes in innate immunity?
2. Describe the steps involved in the process of phagocytosis.
3. Describe the respiratory burst and its effect on microbes.
4. What are the roles of eosinophils, basophils, and mast cells?
5. What are MHC I molecules, and how do they influence NK cells?

19.6 Invertebrate defenses

What kinds of immune defenses do invertebrates have?

Invertebrates are far more numerous than vertebrates in terms of species, diversity, and populations, yet little is known regarding the spectrum of defense mechanisms used by these creatures. Defense mechanisms in invertebrates appear to be strictly innate, involving both cells and molecules. Interestingly, investigations in sponges and copepod crustaceans have revealed a memory response, which is the hallmark of vertebrate adaptive immune responses. The nature of this invertebrate memory response is not yet known. Cells homologous to T and B cells, involved in the adaptive response in vertebrates, have not been identified in invertebrates. Similarly, no genes have been found that show any homology to those used in adaptive response, such as genes encoding antibodies or MHC molecules. Despite the lack of adaptive immunity, innate defense mechanisms in invertebrates are surprisingly varied, adaptable, and efficient in combating infection.

Most of what is known about invertebrate immune functions has been derived from just a few model organisms, such as *Drosophila melanogaster*, and *Limulus polyphemus*, the American horseshoe crab **(Figure 19.22)**. The horseshoe crab is a large aquatic invertebrate related to scorpions, native to the Atlantic Ocean from Maine to the Mexican Yucatan. As different to us as crabs and flies may seem, they show many parallels to vertebrates, possessing intricate signaling processes and numerous functional homologies. Valuable

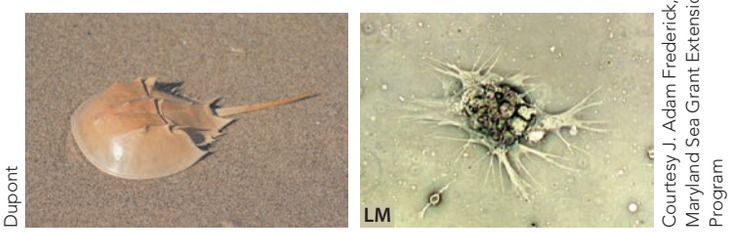

Figure 19.22. The hemocyte: A phagocytic cell of invertebrates Much of the research on hemocyte function and invertebrate immune defenses has been performed on *Limulus polyphemus,* the horseshoe crab (*left*). The large size of horseshoe crabs makes it convenient to collect hemolymph (invertebrate blood) and return the crab to the water. A hemocyte (*right*) is found in hemolymph and body tissues where it recognizes, engulfs, and destroys foreign cells using lysozyme, cytotoxic peptides, and toxic forms of oxygen.

genome-sequencing projects have also uncovered many molecular homologies with genes involved in the innate immune responses of vertebrates. For many of these genes, and others involved during infection, functions have not yet been precisely assigned.

In vertebrates we have seen that the processes of inflammation, complement activation, production of antimicrobial peptides, opsonization, and killing by phagocytes and cytotoxic NK cells are important in innate immunity. We have also seen that the initial detection of the presence and nature of a pathogen in vertebrates is done through TLR signaling. A brief tour of some key features of invertebrate defenses will illustrate some of the functional parallels with vertebrate innate defenses. What is striking is how little information has been gathered about these invertebrate systems compared to what is known about those of vertebrates. Perhaps this is not surprising as the vast amount of research in immunology and infectious disease continues to focus on humans.

Invertebrate molecules of defense

Just as we have seen for vertebrates, specific molecules are produced by the cells of invertebrates that act in synergy with other cells to stimulate immune responses. We'll begin our comparison with inflammation, which you'll recall is a common physiological response in vertebrates to damage and infection.

Inflammation-Like Responses

Invertebrates do not possess blood vessels, so there is no close parallel to all of the inflammatory responses. However, there are a number of cytokines released by cells upon damage and infection that have the ability to attract phagocytic cells called **hemocytes** (see Figure 19.22) to the infected area. There is also a clotting system similar in function to our own fibrin clotting system. Melanin encapsulation and the coagulogen system in *Limulus* are examples of clotting systems that will be discussed later.

Complement-Like Molecules

A major purpose of complement activation is lysis of microorganisms. However, invertebrates have not been found to produce complement. Investigation of genetic databases of some invertebrates has uncovered some C1-like genes and some C6-like genes, but a role for these has not been deduced. Invertebrates synthesize a large number of antimicrobial peptides that lyse microbial cells in a manner similar to complement. As described at the end of this chapter (see The Rest of the Story), some of these antimicrobial peptides are induced by activation of Toll receptors. Unlike the TLRs of vertebrates, Toll receptors of invertebrates do not function as PRRs. Instead, they are activated *after* detection of a microorganism.

Antimicrobial Peptides

A large number of antimicrobial peptides have been identified in insects, crustaceans, and nematodes. Experimental infection of *Drosophila* with various microorganisms has shown that the innate system can recognize and discriminately respond to various groups of microorganisms with a selection of antimicrobial peptides produced in response to such infections. The known targets of some of the antimicrobial peptides of *Drosophila* are listed in **Table 19.8**. Unlike most vertebrate antimicrobial peptides, these peptides are induced and are not normally present at all times. For example, fungal infections result in increased expression of the antifungal peptide drosomycin. In infections with Gram-negative bacteria, the anti-Gram-negative peptides diptericin and drosocin are induced.

Opsonization

A number of secreted molecules, including lectins and peptidoglycan-recognition proteins, have been found in various invertebrate species that can opsonize microbes for phagocytosis. Genetic sequencing of several invertebrate species has found up to nine genes encoding MBL-like lectins. How these proteins are used in these species is not yet known.

Invertebrate cellular immune responses

Unlike vertebrates, invertebrates do not have a wide variety of specialized immune cells. Again, comparatively little is known

TABLE 19.8 ***Drosophila*** **antimicrobial peptides and their targets**

Peptide	Target
Attacin	Gram-negative bacteria
Diptericin	Gram-negative bacteria
Drosocin	Gram-negative bacteria
Defensin	Gram-positive bacteria
Metchinikowin	Fungi
Drosomycin	Fungi

about the roles of these cells, and few species have been intensively studied.

Cytotoxic Cells

Earthworms have cytotoxic cells called "coelomocytes" that may be similar to NK cells, at least in function. However, little is known about these cells or how invertebrates in general combat intracellular pathogens.

Phagocytes

The invertebrate main line of cellular immune defense is the hemocyte (see Figure 19.22). Hemocytes form a collection of wandering cell sets that migrate from hemolymph, the invertebrate equivalent of blood, into the tissues. Hemocytes can recognize and bind foreign particles and engulf them. Like vertebrate phagocytes, these cells also produce a repertoire of toxic oxygen intermediates, antimicrobial peptides, and enzymes, such as lysozyme, that can destroy many microorganisms.

Cellular defense has been most intensely investigated in the horseshoe crab, *Limulus polyphemus* (see Figure 19.22). Its relatively large size makes it a convenient source of hemolymph for study. When hemocytes are stimulated by contact with bacteria, or even just LPS, they undergo dramatic physiological and morphological changes. They assume an irregular, amoeba-like shape with numerous cytoplasmic projections. This phenotypic change gives these activated cells the name **amoebocytes**. The various granules produced in amoebocytes contain numerous clotting factors and antimicrobial peptides.

In addition to their phagocytic functions, amoebocytes have two very important innate functions that differentiate them from phagocytes of vertebrates. First, upon the recognition of a foreign substance, microorganisms included, a chemical-signaling pathway is induced that results in the secretion of **melanin**. As well as having direct toxic effects, melanin polymerizes to coat or encapsulate microorganisms. This is a primary defense against microbial invasion in invertebrates. The second non-phagocytic function of amoebocytes involves the formation of a clot to wall off the invader and prevent its spread. This sequestering of the microbes also facilitates destruction by antimicrobial peptides released from the amoebocyte. One of the PAMPs that triggers clotting is LPS. This characteristic is used in the *Limulus* amoebocyte lysate assay, as described in **Toolbox 19.2**. The assay ensures substances such as injectable drugs, fluids, and surgical tubing are free of LPS.

The importance of innate mechanisms is evidenced throughout the animal kingdom and can even be found in plants. We observe many parallels in innate defense between vertebrates and invertebrates. The fact that invertebrates are one of the most successful groups of organisms on Earth speaks to the effectiveness of innate mechanisms.

19.6 Fact Check

1. What organisms have been used the most to study immunity in invertebrates?
2. What role do antimicrobial peptides, opsonization, hemocytes, amoebocytes, and melanin play in the invertebrate immune response?

Toolbox 19.2
THE *LIMULUS* AMOEBOCYTE ASSAY FOR LPS

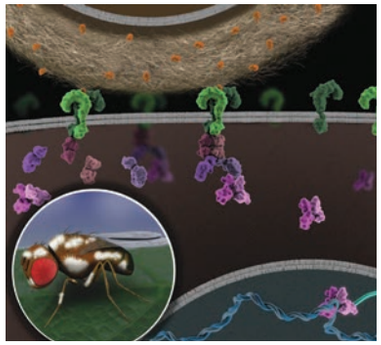
Amoebocytes are very sensitive to bacterial LPS. When an amoebocyte encounters a Gram-negative organism, LPS is detected by surface receptors. This causes migration of the amoebocyte granules to the plasma membrane. Degranulation occurs in a manner similar to NK or mast cells. Clotting factors are released from the granules and become activated upon contact with LPS. The end result of the clotting cascade is conversion of the protein coagulogen into a polymerized, insoluble gel designed to trap microorganisms, prevent their spread, and reduce their access to nutrients. The ability of coagulogen to form clots is the basis of a simple *in vitro* commercial assay to detect residual amounts of bacterial LPS on medical equipment or fluids used *in vivo*. In this simple assay, the sample from the equipment or solution is mixed with lysate containing clotting factors and coagulogen prepared from horseshoe crab amoebocytes. If the mixture coagulates after 45 minutes, then the test is positive for LPS, indicating the product being tested is contaminated.

Test Your Understanding

You are the owner of a medical supply company and when training new lab technicians you emphasize the importance of running the *Limulus* amoebocyte lysate assay on your company's products. Explain what would happen in a patient if a lab mistake resulted in a positive *Limulus* amoebocyte lysate assay outcome being falsely interpreted as negative.

Image in Action

WileyPLUS Learning Space Toll receptors are found in *Drosophila* and help provide protection from fungal infections, such as the one shown in the fly in this image. Numerous related Toll-like receptors are found in vertebrates. Toll-like receptors are important pattern recognition receptors involved in the innate immune response and signal the adaptive immune response to begin. In this image of a mouse cell, Toll-like receptors (green proteins) have bound to zymosan (orange protein) on a yeast cell. Binding sets off a signaling cascade of cellular proteins (shades of purple), ultimately resulting in the activation of the transcription factor NF-κB (pink dimer). NF-κB is shown binding to DNA in the nucleus at the bottom, where it is initiating transcription of the genes involved in immune defense against fungal pathogens.



1. What TLRs are expected to bind to zymosan? What is the outcome of this binding?
2. What is another pathogen-associated molecular pattern that would be present in yeast? What innate pattern recognition receptors would bind to it?
3. What kind of innate immune cells would you expect to be activated during an extracellular fungal infection in mice?
4. Explain how you might design an experiment to investigate the role of the different TLRs in responding to fungal infections in mice.

The Rest of the Story

Since their discovery, Toll-like receptors (TLRs) of vertebrates have been on center stage in immune research. Not only can these molecules sense the presence of pathogens, they can also determine the nature of the microbe and chemically communicate this to the host. Based on this information, the host is then able to utilize the best defense mechanisms to deal with the pathogen. Research into the functioning of TLRs has revealed their roles in mammalian immune dysfunctions, such as autoimmune diseases and allergies, as well as new insights for the design of improved vaccines and therapies for infectious diseases.

What about invertebrates? How do Toll receptors function in immunity? Investigation of the originally discovered *Drosophila* Toll receptor has shown that its role in the immune response is somewhat different from the TLRs in vertebrates. It is not directly involved in the initial binding of pathogen-associated molecular patterns, but rather is activated at the *end* of a signaling cascade that is presumably initiated by other largely unidentified cell surface receptors. The result of Toll activation is the transcription of various antimicrobial peptides against fungi and Gram-positive organisms. Toll activation is also required for defensive melanization.

Toll-independent signaling pathways for immune responses also exist in *Drosophila*. This was discovered by studying a strain of flies that was shown to be highly susceptible to experimental infections with Gram-negative bacteria, but not with Gram-positive bacteria. It was found that these flies had a recessive homozygous mutation in a gene named *imd* for immune deficiency gene. Activation of this *imd* pathway results in transcription of the anti-Gram-negative antimicrobial peptides diptericin, drosocin, and attacin. So it appears that the pattern-recognition receptors of invertebrates, like those of vertebrates, are able to effectively communicate to the cell the nature of the pathogen and, with this information, signal production of the most appropriate antimicrobial products.

Summary

Section 19.1: Are there different types of immunity?

Immunology is the study of the components and processes of the immune system.

- An individual who is protected from infection is said to be **immune**. Immunity is provided by intrinsic barriers of the body and specialized molecules and cells of the **immune system**.
- The immune system distinguishes non-self molecules from normal self components.
- Vertebrates have both **innate (non-specific) immunity** and **adaptive (specific) immunity**. Both work together to prevent or minimize disease caused by pathogens.

An **immune response** actively defends the body against foreign agents and cancerous cells.

- Innate immune defenses exist in all multicellular eukaryotes and can recognize biochemical differences between microbes and host cells.
- Components of the innate immune system recognize common components of microbial groups but cannot precisely identify a particular pathogen.
- The adaptive immune system is found only in vertebrates and requires exposure to the pathogen. The molecules it produces are specific to the pathogen.

- The adaptive system is designed to work with the innate immune system to provide an increased level of protection against infection.

Section 19.2: What are the built-in barriers to infection?

Skin and **mucosal membranes** are body surfaces exposed to microbes.

- Skin is constructed of epithelial cells with tight cell junctions that prevent passage of most microbes.
- Skin prevents colonization by most pathogens because it is cool and acidic, produces antimicrobial toxic fatty acids, salts, and lysozyme, is heavily colonized by resident microbiota, and the outer layer of cells is constantly sloughed.
- Mucosal membranes line the moist inner surfaces of the body. These surfaces inhibit colonization by pathogens because they secrete antimicrobial substances, such as **lactoferrin** and **antimicrobial peptides**, are covered with viscous **mucus**, which is removed by **peristalsis** (intestine), flushing by fluid (conjunctiva, urinary, and intestinal tracts), and **mucociliary clearance** (urogenital and respiratory tracts).

Section 19.3: What is an early response of the body to infection?

Inflammation is a physiological response to microbial invasion and damage. It is triggered by release of **proinflammatory molecules**, such as histamine and **cytokines**, from local cells.

- Three immediate consequences of inflammation are **vasodilation**, **extravasation**, and an increase in vessel permeability. These effects facilitate immune responses by bringing in cells, such as **phagocytes**, and molecules with immune functions to the damaged site where microbes have likely entered.
- Release of cytokines, primarily by **leukocytes**, is the primary mode of communication used to signal information regarding an infection.
- Cytokines can produce **fever**, enhance inflammation, and stimulate further immune responses.
- Excessive inflammation can be damaging to the host, and can produce a **systemic inflammatory response**, leading to **septic shock** or **toxic shock**.

Section 19.4: How do we sense or detect the presence of pathogens?

- The molecules involved in innate immunity have the ability to recognize **pathogen-associated molecular patterns (PAMPs)**. These are broad-based molecular motifs associated with microbes but not normally found in the host.
- Molecules that recognize and bind PAMPs are called **pattern recognition receptors (PRRs)**.
- An important group of membrane-bound PRRs are **Toll-like receptors (TLRs)**. TLRs are molecular sensors that can detect microbial presence, identify the nature of the pathogen, and signal appropriate immune responses, including induction of adaptive immune responses.
- There are a number of TLRs, each of which can bind to a particular **ligand** of microbial origin.
- TLR9 detects unmethylated **CpG dinucleotides** in DNA of bacterial and viral origin.
- **Adjuvants** used in vaccines often contain molecules recognized by TLRs.
- The result of TLR binding is the expression of a number of genes that are needed for cellular immune responses.
- Two important secreted PRRs are the **lectins**, **C-reactive protein**, and **mannose-binding lectin (MBL)**.
- Binding of C-reactive protein and MBL to microbes results in **opsonization**, which facilitates **phagocytosis** and activation of **complement**.
- Inactive complement components in serum are enzymatically cleaved and activated upon detection of microbes. The end result is formation of the **membrane attack complex (MAC)** on microbial surfaces, which leads to lysis of microbial membranes, enhancement of inflammation, opsonization of microbes, and attraction of leukocytes.
- Complement can be activated through the **classical pathway**, which utilizes **antibody**, or the **lectin pathway**, or the **alternative pathway**.
- **Type I interferons (IFNs)** are produced by cells when a viral infection has been detected. They confer a generalized antiviral state in nearby infected and uninfected cells.

Section 19.5: What cells first defend us against infectious agents?

Phagocytes (**neutrophils**, **monocytes**, and **macrophages**) and **cytotoxic cells** (**eosinophils**, **basophils**, **mast cell**, and **natural killer cells**) are the first line of innate defensive cells.

- Phagocytes are the first line of defensive cells involved in clearance of extracellular pathogens.
- Phagocytosis, is a specialized type of **endocytosis**, used to engulf large particles, such as bacterial cells, and is carried out by phagocytes.
- Phagocytosis is facilitated by opsonization. **Opsonins**, such as antibody or C3b, coat the microbe.
- Phagocytosis forms an **endosome** called the **phagosome** that enters the degradative **endocytic pathway**.
- The phagosome fuses with **lysosomes** to form a **phagolysosome**, where killing of microorganisms is accomplished by the production and action of acidic pH, lysozyme, proteases, antimicrobial peptides, and toxic oxygen species formed by the **respiratory (oxidative) burst**.
- **Eosinophils**, **basophils**, and **mast cells** contain numerous granules that provide immunity against large extracellular parasites, such as worms. When activated by IgE, their combined effect is designed to irritate, dislodge, and damage the parasite.
- **Natural killer (NK) cells** are the first line of defensive cells involved in clearance of intracellular infections.
- NK cells possess **granules** containing **perforin** and **granzymes**.
- Release of the contents of the granules by **degranulation** causes apoptosis of the contacted abnormal/infected cell. Any surviving microorganism is then ingested and destroyed by phagocytes.
- Abnormal cells are recognized by NK cells through the lack of **class I major histocompatibility complex (MHC I)** molecules on their surface.
- Cells infected with enveloped viruses can be also be targeted for destruction by the **antibody-dependent cell-mediated cytotoxicity (ADCC)** action of NK cells, which uses F_C receptors (F_CR) to bind antibody-coated cells.

Section 19.6: What kinds of immune defenses do invertebrates have?

Immune defense in invertebrates is strictly innate.

- **Hemocytes** are phagocytic cells induced by inflammation-like responses.
- **Amoebocytes** are activated hemocytes that respond to bacterial cell wall molecules, such as LPS. They produce coagulogen and signal **melanin** release to encapsulate microbes.
- PRRs, such as lectins and peptidoglycan-binding proteins, opsonize microbes.
- Although invertebrates do not possess complement, lysis of invading microorganisms is induced by antimicrobial peptides.
- Cytotoxic cells are produced in some species.
- Toll receptors, at least in *Drosophila*, are used only after the pathogen has already been detected to conduct information regarding the nature of the pathogen to cells involved in immune responses. They are not PRRs because TLRs are in vertebrates.

Application Questions

1. Smokers have been shown to have cilia damage and reduced cilia beat frequency. Explain how this may result in increased vulnerability to lung infections in smokers.
2. People who are taking oral antibiotics often experience intestinal upsets, such as mild cramping and diarrhea. Using your knowledge of the role of normal microbiota, explain why this may occur.
3. Postoperative patients are told to look for warning signs of infection at their surgical incision site such as redness, swelling, and heat. What activities are involved in causing these clinical signs and why might these indicate an infection?
4. Based on your understanding of the role of TLR4, describe how a TLR4 knockout mouse's immune system would react differently to LPS injection than the immune system of a normal mouse.
5. A young researcher is attempting to identify an adjuvant that can be safely added to a new vaccine. The researcher is considering LPS. Provide an analysis of whether LPS would serve as a desirable vaccine adjuvant.
6. Your mother had a blood test to check her levels of C-reactive protein, and the results show her levels are above the normal average. What would this result reveal, and how would you explain this to her?
7. Hepatitis A and hepatitis B can be treated by administering interferon-alpha (IFN-α) and antiviral drugs. Explain to a hepatitis patient what the interferon is doing for them as part of their treatment.
8. An experimental cancer treatment involves removal of MHC I molecules on tumor cells and is being tested in a mouse model. What effects would you expect this treatment to have on the NK cells in the mouse model? Explain.
9. Imagine a patient's innate immune system suffers from an inability to produce mannose-binding lectin. What effects would be observed and why?
10. Some strains of the opportunistic pathogen *Streptococcus pyogenes* cause necrotizing fasciitis, a serious and sometimes fatal skin infection that will be examined in Chapter 21. Common anti-inflammatory medications, such as ibuprofen, have been implicated in the precipitation of this disease. Explain this link.
11. Imagine you are in a lab studying the specific effects of cytokines. How might you go about designing an experiment to study the chemoattractant activity of IL-8? Explain what results you would expect.
12. You are asked to design a hypothetical pathogenic bacterium that is able to effectively overcome or avoid three innate immune defenses or detection mechanisms.
    a. What three innate defenses will your pathogen be able to overcome?
    b. What do those defenses normally do?
    c. How will your pathogen overcome each of those defenses?

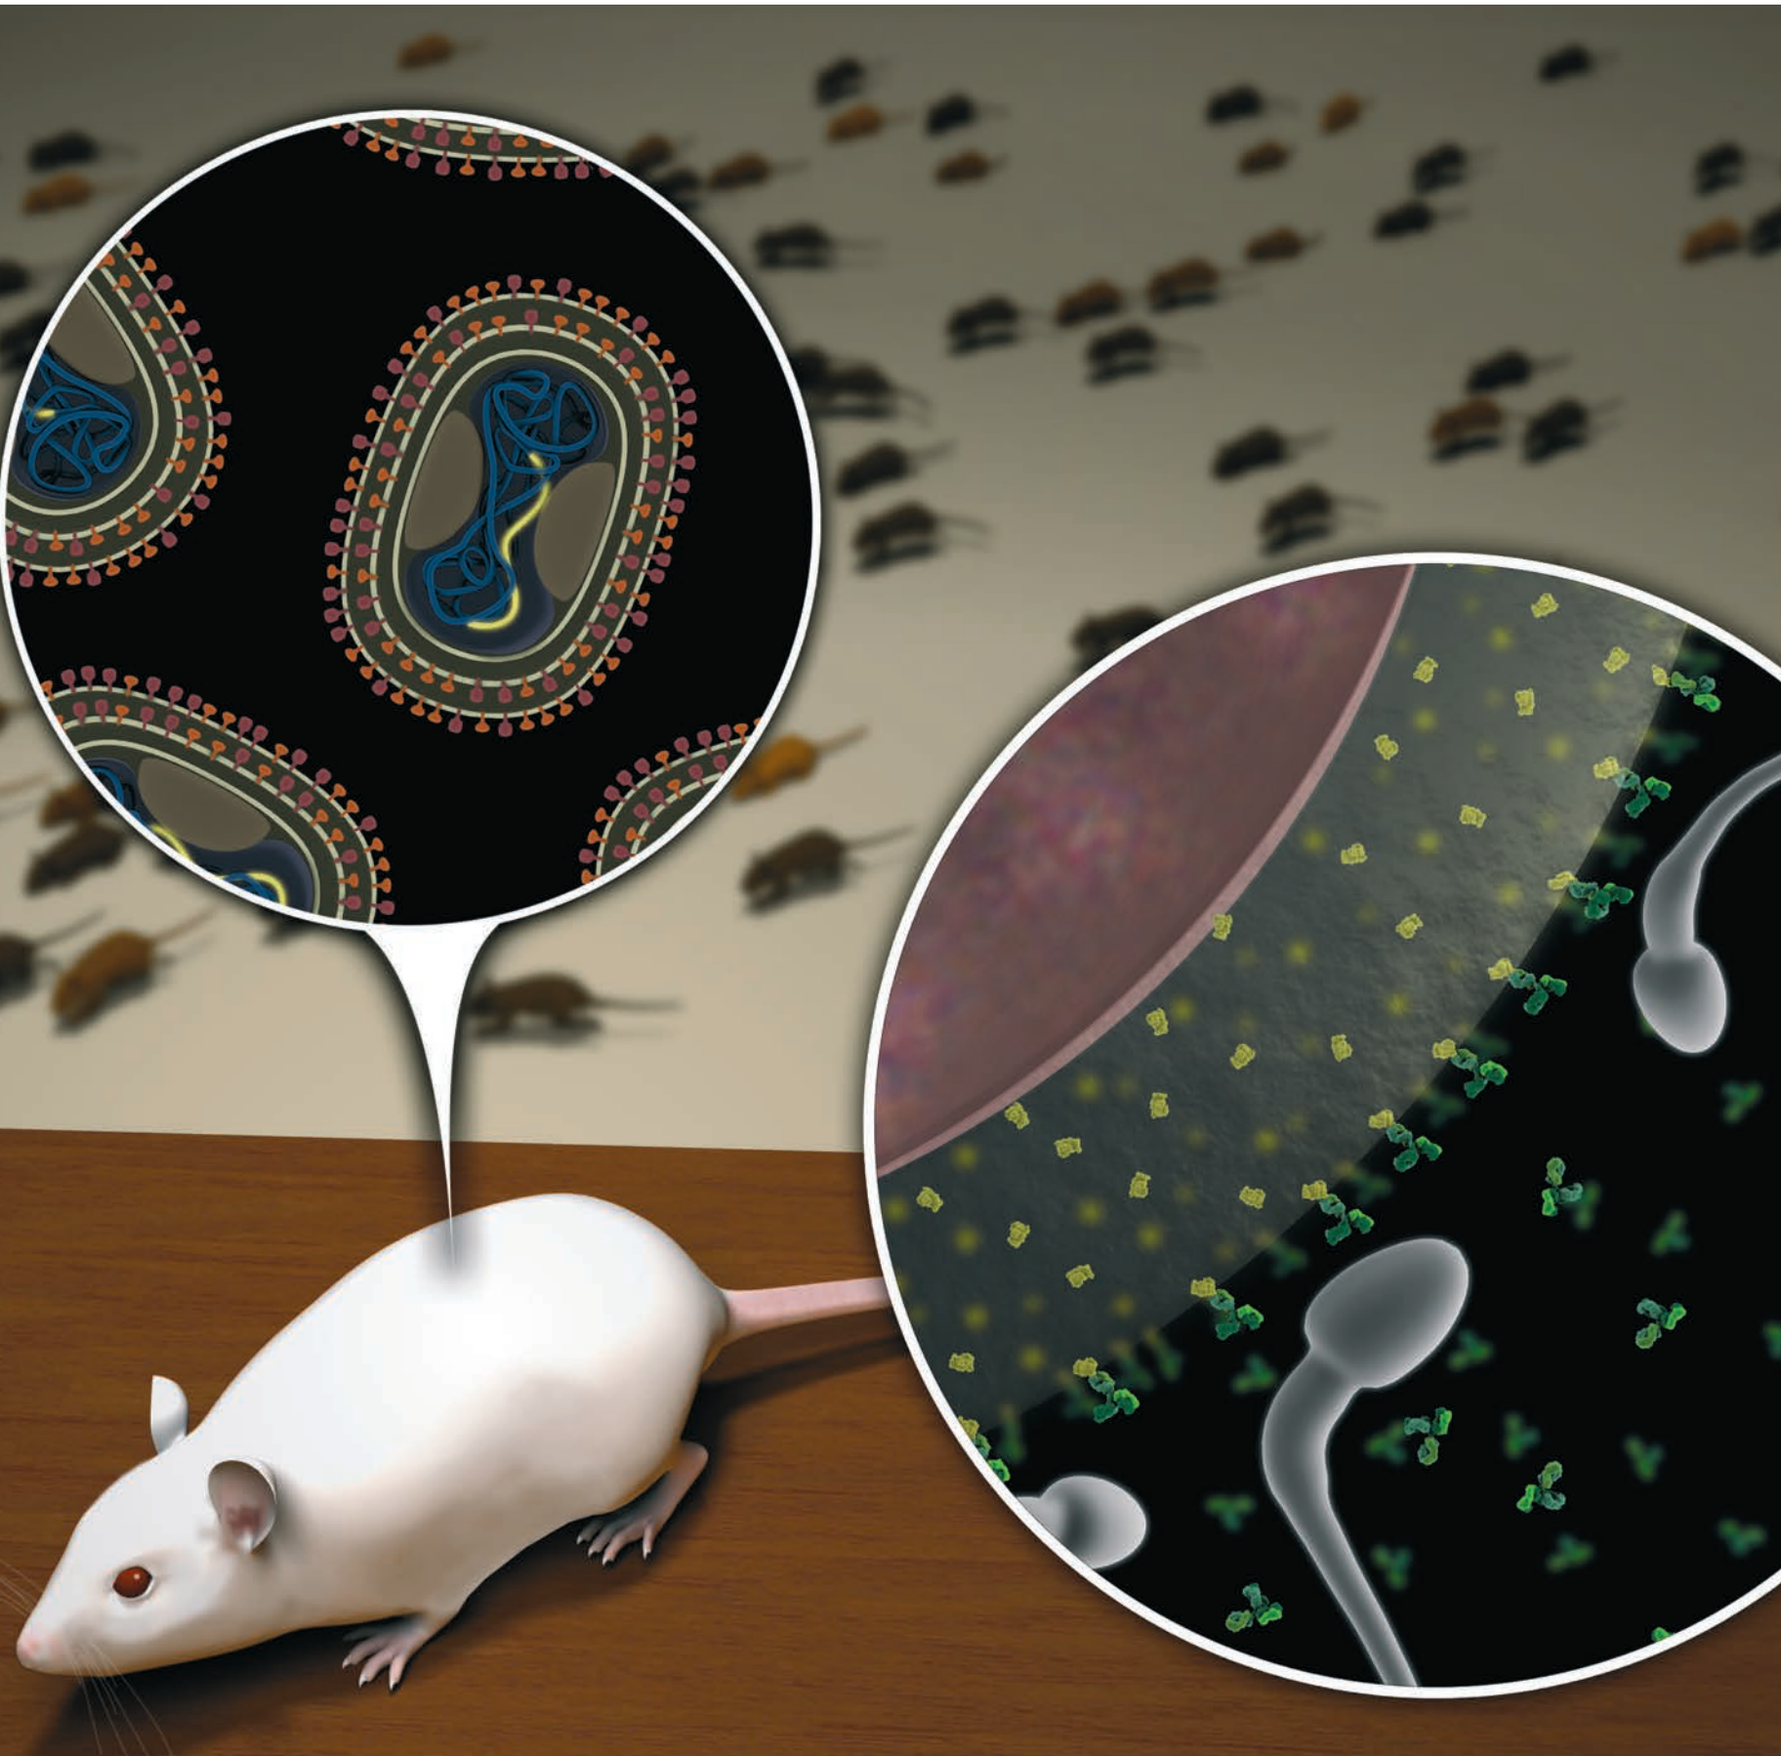
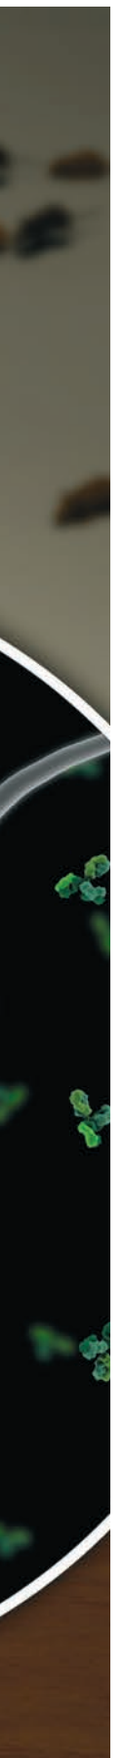
CHAPTER

20 Adaptive Immunity





In 1998, a research project in Australia became the focus of scientific and political discussion The scientists were working on a method of contraception to help control plagues of rodents in grain barns in Australia. Their research focused on developing a method to use the mouse's own immune system to produce infertility—a concept known as "immunocontraception." To do this, they re-engineered ectromelia virus, a relatively benign mouse virus that causes the disease mousepox. Into the genome of the virus, they inserted the gene for a mouse egg surface protein called mZP3, a receptor for sperm. The hope was that the virus would now produce the sperm receptor mZP3 protein and infected female mice would produce antibody against it. Antibody would block the sperm receptor, rendering the female mice infertile. To achieve high rates of infertility, researchers needed to produce high levels of antibody against mZP3. They used their knowledge of adaptive immune responses, supplying the virus with a second gene that codes for a small protein called interleukin-4 (IL-4). IL-4 is known to boost the production of antibody in mammals—a response desired by the researchers to maximize the contraceptive effect.

However, things didn't go as planned. When the engineered virus was experimentally used to infect mice, it unexpectedly killed them. The researchers had turned a relatively harmless virus into a lethal pathogen. Even more surprising, the engineered virus killed a large proportion of mice that had been previously exposed to normal ectromelia mouse virus. These mice should have been resistant to the engineered virus.

This case immediately raised red flags. Should this research be published and released to the public arena where it could be used for the intentional engineering of viruses with increased lethality? Parallels were drawn to apocalyptic video games such as *Resident Evil*, where engineered viruses are released upon the human race with disastrous results. Concerns were further fueled because ectromelia virus is related to variola virus, the human smallpox virus. This virus is already naturally virulent and is on the short list of potential agents for biological warfare. In the wrong hands, could this information be used to make the smallpox virus even more deadly? As you read this chapter, you will gain insight into the workings of the adaptive immune response and decide for yourself whether or not these are legitimate concerns. We will return to our story "of mice and men" near the end of the chapter.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Adaptive immunity is based on the production of specialized immune receptors that bind foreign antigen.

- Figure 20.1: Immune receptors of T cells and B cells
- Figure 20.5: Primary and memory immune responses

T cells are the central control cells in adaptive immunity.

Capsules and immune evasion by pathogens **(Section 21.1)**

Introduction

Despite the best efforts of our innate defenses, myriad microbes are still capable of invading our bodies. Mostly, these are pathogens that have evolved strategies to elude innate immune defenses. This is where the adaptive immune system of the jawed vertebrates steps in. This arm of immunity is designed to specifically recognize almost any foreign molecule, including those possessed by pathogens. It is a very effective, highly coordinated system, capable of producing a spectacular diversity of immune recognition molecules far beyond that of innate immunity. Best of all, this system can genetically "remember" these molecules and, in many cases, provide lifelong protection, making vaccination a feasible strategy for control of many infectious diseases (see Chapter 24).

Successful pathogens must evolve specific strategies to overcome, outlast, or circumvent adaptive immune responses. Many of these mechanisms will be covered in Chapters 21, 22, and 23. We need to understand the workings of the adaptive immune system first, and we will structure our exploration of adaptive immunity around the following questions:

What is the advantage of adaptive immunity? (20.1)
What are the central cells in adaptive immunity? (20.2)
How are adaptive immune responses initiated? (20.3)
What cells can launch adaptive immune responses? (20.4)
Are there different responses to extracellular and intracellular pathogens? (20.5)
How are antibodies produced (20.6)?

20.1 Features of adaptive immunity

What is the advantage of adaptive immunity?

In Chapter 19, we defined immunological immunity as the defensive response to microbial invasion that occurs at a molecular and cellular level. We further defined innate or non-specific immunity as involving immune mechanisms that are already present at birth and do not require previous exposure to the microbe. It is based on molecules that are genetically hardwired in each cell to distinguish self from non-self components. As you will recall, many of these molecules are pattern recognition receptors (PRRs) that recognize pathogen-associated molecular patterns (PAMPs), which are broad-based molecular motifs commonly found in microbes (see Section 19.4). Innate systems cannot recognize the precise identity of the microbe, only its general nature and that it is foreign. Adaptive or specific immunity can precisely recognize and remember a particular type of invading microbe. This immune response is found only in jawed vertebrates, and involves the production of specialized immune receptor molecules through genetic rearrangements in response to an infecting agent. Although this may seem like an incredible feat, we will see that the effectiveness of the adaptive immune response is based on relatively simple principles.

Immune receptors and antigen

The innate and adaptive immune responses are functionally intertwined, and thus the separation of the two categories is really based on the genes that are employed by the two systems. We can make this definition even more precise. The adaptive immune response is immunity based on the production of specialized **immune receptors** that bind foreign antigens. An **antigen** is any component that can be specifically bound by an immune receptor. Immune receptors include **T-cell receptors (TCRs)** and **immunoglobulin (Ig) molecules**. TCRs are on the surface of **T cells**, which are also called **T lymphocytes**. T cells are produced in the thymus and, as we will see in Section 20.2, are the orchestrators of adaptive immune responses. Immunoglobulins are produced by **B cells** or **B lymphocytes**, circulating lymphocytes that give rise to antibody. Immunoglobulins include surface **B-cell receptors (BCRs)** and the secreted version of a BCR, antibody (Figure 20.1). Immune receptors arise from random rearrangements in the genes that code

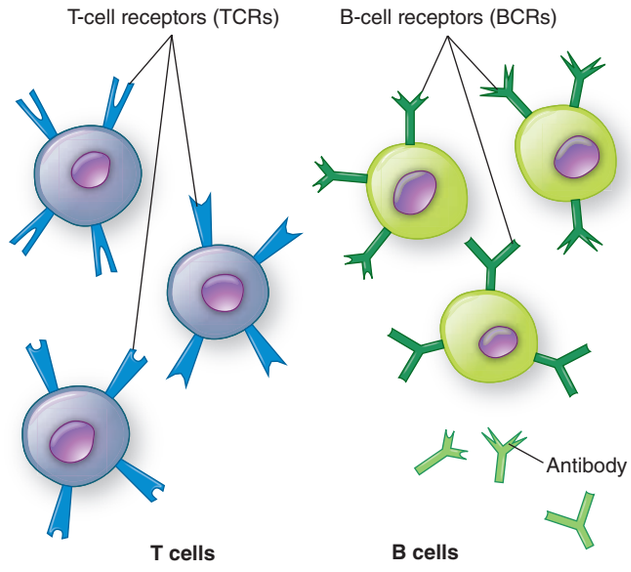

Figure 20.1. Immune receptors of T cells and B cells Membrane-bound T-cell receptors (TCRs) and B-cell receptors (BCRs) recognize and bind to foreign antigens. Antibodies, produced by specialized B cells, are a secreted form of BCRs, and similarly bind to antigens. Individual T cells and B cells produce only one antigen-binding type (shape) of immune receptor that binds to a particular antigen.

for the peptides making up these immune receptors (see Section 20.6). T cells and B cells are leukocytes that are central to adaptive immunity. This chapter will present the process by which these cells and their immune receptors can recognize foreign antigen and generate adaptive immune responses.

CONNECTIONS Recall from **Section 19.4** that antibodies are secreted glycoproteins that bind to microbes and their components and are produced by B cells of the adaptive immune system.

Before moving on, we need to clarify some related terms: "antigen," "ligand," "epitope," and "immunogen." An antigen is any component that can be bound by a TCR or an immunoglobulin. In Chapter 19, the general term "ligand" was used to describe molecules that bind to receptors. Antigens are ligands that are bound by immune receptors. Innate immunity does not involve the production of immune receptors (TCRs or immunoglobulins), and therefore targets bound by molecules and cells of the innate immune system are correctly defined as ligands, but not as antigens. The distinction between these terms is important. For example, you would not use the term "people" when you are only referring to adult males. "Antigen" is a much more precise term than "ligand." The specific interaction between antigen and immune receptors is the cornerstone of adaptive immunity.

The term "antigen" is often incorrectly used to broadly describe any component that induces an immune response. The correct term for a substance that induces an immune response is immunogen. Immunogen is a general term just as ligand is a general term. Immunogens are immunogenic—they induce innate or adaptive immune responses, or both.

Individual T cells and B cells of the adaptive immune system produce only one antigen-binding species of immune receptor. The unique shape of that receptor makes it specific to a single **epitope** of the antigen (Figure 20.2). An epitope is a single site on a larger antigen molecule that is recognized by an immune receptor. It is the smallest unit that can be bound. Different T and B cells can produce different immune receptors that recognize different epitopes. Binding between the TCR or BCR and the antigen depends on the specificity of the receptor for the epitope. The correct fit provided by chemical and conformational configuration must be present for binding to occur.

The production of immune receptors by the adaptive immune system involves rearrangements of genes that code for the TCR in T cells and immunoglobulin molecules in B cells (see Section 20.6). These rearrangements are limited to T cells and B cells and do not occur in germline cells, that is, eggs and sperm. Consequently, adaptive immunity is not passed along to offspring. Infants must build their own T- and B-cell profiles as they move through life with many inevitable exposures to a multitude of infectious agents.

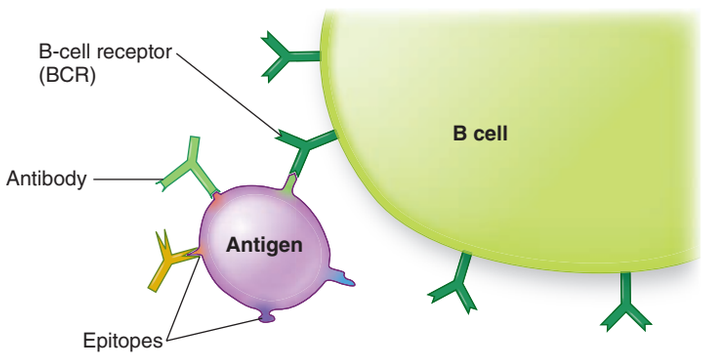

Figure 20.2. Epitopes bound by specific immune receptors Different epitopes of an antigen can be recognized by different immune receptors. Shown here is binding of a B-cell receptor (BCR) and antibodies to different epitopes.

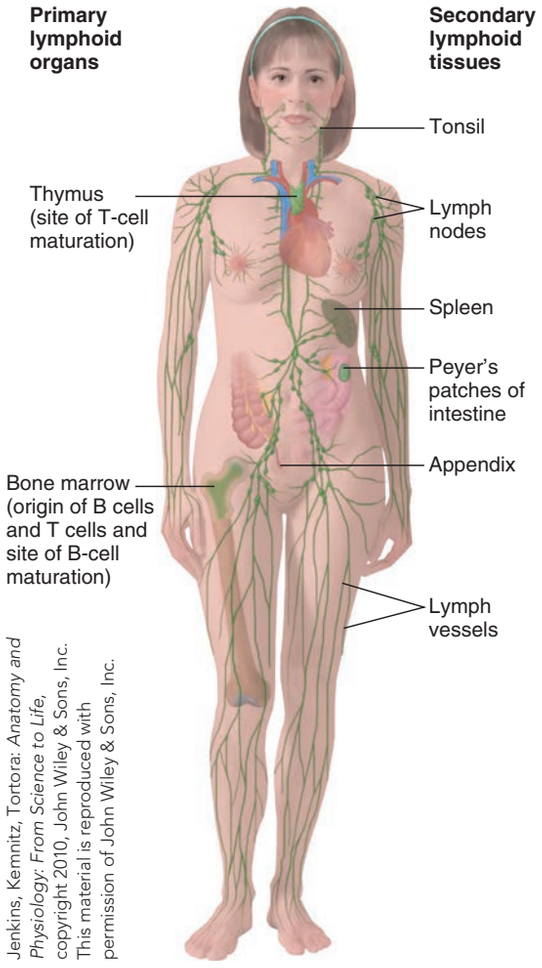
Lymphocytes and lymphoid tissues

T cells, along with B cells and natural killer (NK) cells (see Section 19.5), are classified as **lymphocytes**, which are small round leukocytes that bear specialized receptors that bind other cells to direct immune responses (Figure 20.3). Lymphocytes are generated from stem cells in the bone marrow and mature in the primary lymphoid organs, the bone marrow and thymus (see Appendix D). T cells mature in the thymus, for which they are named, the "T" standing for thymus (Figure 20.4). Mature T cells with unique TCRs are released into the circulatory system. B cells mature in the bone marrow; their name is derived from an antibody-producing organ in young birds, called the bursa of Fabricius. From the circulatory system, T cells and B cells access secondary lymphoid tissues distributed around the body. Examples are the spleen, lymph nodes, tonsils, appendix, and Peyer's patches of the small intestine. These specialized tissues house dense populations of recirculating T and B cells and detain antigen to allow exposure required for the activation of these lymphocytes. Organ surfaces in contact with microbes, such as the skin, pharynx, and intestine have collections of associated lymphoid tissues, including peripheral lymph nodes, secondary lymphoid organs, and diffuse collections of dendritic cells and macrophages. Examples include SALT (skin-associated lymphoid tissue), MALT (mucosal-associated lymphoid tissue), and GALT (gut-associated lymphoid tissue).

Primary and memory immune responses

When cells of the adaptive immune system encounter an infectious agent for the first time, only a few cells can recognize the antigens carried by the pathogen. Again, this is because only

Figure 20.3. Lymphocyte Stained cells from blood showing a central lymphocyte surrounded by red blood cells.



Jenkins, Kemnitz, Tortora: *Anatomy and Physiology: From Science to Life*, copyright 2010, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 20.4. Lymphoid tissues of the human body Lymphocytes originate in bone marrow and mature in the primary lymphoid organs where they produce their unique immune receptors. B cells mature in bone marrow, whereas T cells mature in the thymus. Both cell types circulate through the lymph vessels and secondary lymphoid tissues as well as the blood vessels (not shown).

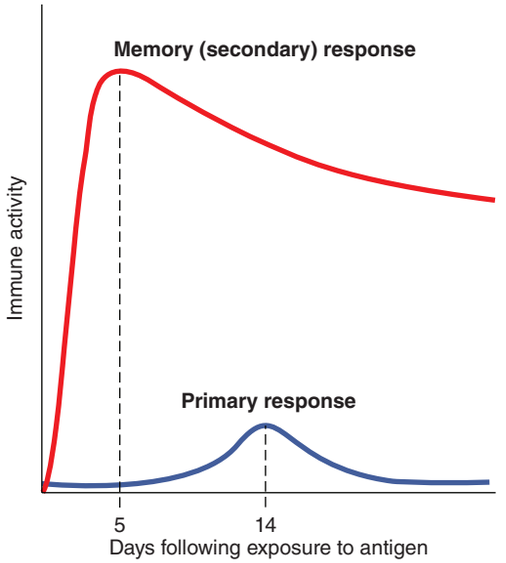


Figure 20.5. Primary and memory immune responses A primary immune response (blue line) occurs following a first-time exposure to an antigen. It produces a relatively low level of immune activity that peaks at 10 to 17 days and is of short duration. From this primary response, long-lived memory cells are generated. When memory cells are subsequently exposed to that same antigen, a memory response (red line) occurs. The memory response is characterized by a high level of immune activity that peaks quickly at two to seven days and lasts for a much longer time. By the second day, the activity has already surpassed the peak level of a primary response.

a few cells will carry immune receptors capable of recognizing the particular epitopes of the pathogen molecules. These cells respond by greatly increasing their activity and numbers over several days in a process called a **primary immune response**. During this response, vast numbers of cells specific to the antigen are generated through **clonal expansion**, which refers to the many rounds of cell division that follow activation of a T cell or B cell. The end result is a tailored population of immune cells all capable of recognizing the *same* foreign molecule. Unlike many innate immune responses that are already present and can act immediately, a primary immune response requires time to generate these specific cell populations, producing a peak in activity approximately two weeks following first exposure to the antigen (Figure 20.5). Most of the cells generated by clonal expansion are short-lived, but some survive for years following antigen exposure. These **memory cells** confer an immunological **memory** or **anamnestic response** ("anamnestic" meaning "recall to memory" from Greek) originating from the stimulation of memory cells. The memory response is characterized by a faster and more vigorous adaptive immune response upon a repeated exposure to antigen. When the same agent is encountered a second time, memory cells give rise to a secondary immune response in a larger and more accelerated fashion. Of course, many pathogens are encountered more frequently than this, and the terms "memory" or "secondary immune response" are often used interchangeably to refer to all subsequent memory responses to that antigen. Each time the antigen is encountered, the memory response gains in strength. The details of immunological memory will be covered in Section 20.2. Often, immunological memory gives rise to such a fast and strong response that the pathogen is stopped in its tracks upon another encounter, even years later. In many cases, we are unaware that we have even been exposed again. This is a principal advantage of the adaptive immune system.

Evolution of adaptive immunity

Let's consider how adaptive immunity appears to have arisen in vertebrates. All aspects of adaptive immunity are rooted in the formation of immune receptors—TCRs and immunoglobulins. As you will recall from Section 19.1, adaptive immunity is not present in invertebrates. Adaptive immunity is exclusive to vertebrates, but not all vertebrates. In the evolutionary tree of life, it appears abruptly in jawed or cartilaginous fish. Jawless fish, like lamprey, have no adaptive immunity. They lack the genes used to make immune receptors. As a consequence, jawless fish and invertebrates cannot produce antibody or TCRs, and they lack the associated T and B cells. Of course, they do not have immunological memory.

Most researchers who study the genetic evolution of adaptive immunity agree that a transposable element, probably

a retrotransposon (see Section 5.2), led to the ability to perform gene rearrangements that characterizes modern immune receptors. Transposable elements, as you may recall from Section 9.4, are noted for their ability to move genes around, cause genetic rearrangements, and even duplicate genes. The transposable element is thought to have invaded a germline cell in an ancestor of the cartilaginous fish and inserted itself randomly into an immunoglobulin-like precursor gene. Insertion into this particular gene meant that the gene could undergo rearrangements and diversify through the descendents of the evolutionary line, leading to the formation of genes for TCRs and immunoglobulins. Remnant DNA sequence from this original transposable element is still present in the genes for immune receptors and confers the ability of these genes to rearrange their DNA segments in different ways to produce an astounding number of different receptor combinations to generate matches to antigens. Immunologist Charles Janeway of Yale University likened this transposable element invasion to an immunological Big Bang. The ability to generate an incredible collection of immune receptors to suit a multitude of foreign antigens has allowed the jawed vertebrates the ability to recognize and defend themselves against a larger spectrum of potential antigens compared to their innate-restricted jawless kin and invertebrates.

20.1 Fact Check

1. What is adaptive immunity and how is it different from innate immunity?
2. How are the terms "antigen," "ligand," "epitope," and "immunogen" involved in an immune response?
3. Differentiate between primary immune response and memory immune response.
4. Describe how the adaptive immune response is thought to have evolved in vertebrates.

20.2 T cells

What are the central cells in adaptive immunity?

Initiation of adaptive immunity is a complex process requiring antigen presentation, cell signaling, and production of stimulatory molecules. To understand the adaptive immune response, we will need to take a closer look at the cells involved and their functions. A central theme in the initiation of an adaptive immune response is the activation of T cells. T cells are the orchestrators of adaptive immune responses.

Cells involved in adaptive immune responses, including T cells, need to be activated before they can participate in adaptive immune responses. Cells that have never encountered antigen are referred to as "naïve" cells. This means they have not been activated through antigen binding. When a T cell is activated, it undergoes clonal expansion and differentiation, resulting in a population of long-lived memory T cells and short-lived effector T cells. Memory cells are responsible for the previously mentioned immunological memory that generates the much faster and more aggressive memory immune response. **Effector cells** are fully armed cells that directly carry out immune functions. In the case of T cells, the effector activity varies with different T cells and will be described next.

Effector T cells and their functions

Effector cells are action cells. They are short-lived and armed with direct immune functions. For T cells, the effector activity depends on whether they carry the CD4 or CD8 surface marker glycoprotein, or co-receptor, on their surface. The T-cell subsets carrying these co-receptors are called **$CD4^+$ T cells** and **$CD8^+$ T cells**. The co-receptors are needed for activation of T cells by interacting with molecules on the surface of other cells. The effector function of activated $CD4^+$ T cells is primarily the secretion of large concentrations of cytokines. The profile of cytokines secreted by effector $CD4^+$ T cells enhances and directs the immune functions of various other cells, including $CD8^+$ T cells. For this reason, effector $CD4^+$ T cells are commonly referred to as **T helper cells (T_H cells)**. Cytokine help from T_H cells is an absolute requirement for full function of adaptive immune responses.

The effector function of activated $CD8^+$ T cells is primarily cytotoxic killing of infected cells. For this reason, effector $CD8^+$ T cells are referred to as **cytotoxic T cells (T_C cells)**. T_C cells can directly kill contacted infected cells by releasing granzymes and perforin that cause apoptosis. This is similar to the action of natural killer (NK) cells (see Section 19.5). T_C-cell killing and T_H-cell functions will be described in more detail later. For now, let's look at how these cells are activated.

CONNECTIONS Cytokines are small, secreted glycoproteins that are produced by various cells during an immune reaction (see **Section 19.3**). They are the major communication molecules used to direct immune responses. Examples include interleukins, interferons, and tumor necrosis factor-alpha (TNF-α).

T-cell activation

Activation of a T cell first requires binding of the T-cell receptor (TCR) with an antigen in the form of a peptide. However, T cells cannot bind free peptide; it must be "presented" to them by other cells known as **antigen-presenting cells (APCs)**. The APCs are macrophages, dendritic cells, and B cells that can take up and degrade foreign material. The resulting peptide antigens are then presented to T cells. Recall from

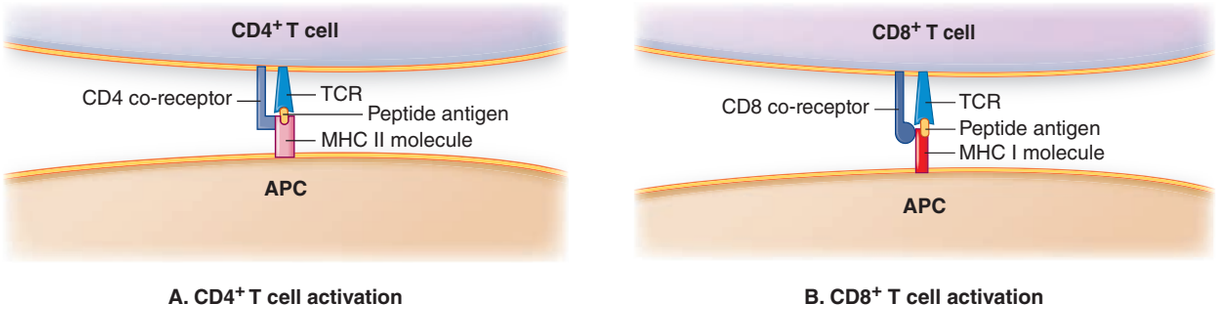

Figure 20.6. Antigen presentation to T cells by an antigen-presenting cell (APC) The membrane-bound T-cell receptor (TCR) on the surface of mature T cells binds foreign peptides presented by MHC molecules. Antigen binding by the T cell is governed by the specificity of the TCR and the peptide bound by the MHC molecule of the APC. **A.** Activation of a $CD4^+$ T cell requires specific binding of MHC II–presented peptide with the TCR and simultaneous binding of the T-cell CD4 co-receptor with the MHC II molecule of the APC. **B.** Activation of a $CD8^+$ T cell requires specific binding of MHC I-presented peptide with the TCR and simultaneous binding of the T-cell CD8 co-receptor with the MHC I molecule.

Section 19.5 that macrophages are phagocytic leukocytes of the innate immune system, but because they can also present antigens, they can activate the adaptive immune system. **Dendritic cells** are wandering leukocytes that specialize in sampling and degrading smaller extracellular material to similarly present it to the adaptive immune system. Recall that B cells are circulating lymphocytes that give rise to antibody, but they also bind and degrade antigen for presentation to T_H cells. The different roles macrophages, dendritic cells and B cells play in stimulation of immune responses will be discussed in Section 20.4.

The peptide antigens presented to T cells are bound to special surface molecules on APCs called major histocompatibility complex (MHC) molecules. MHC molecules are proteins that are generated intracellularly and bind peptides produced from the breakdown of microbial proteins inside cells. Once an MHC molecule binds to a peptide, the MHC:peptide complex is transported to the APC surface where it can contact nearby T cells. It is important to note that only peptides can be presented on MHC molecules. Non-proteins, such as lipids and carbohydrates, cannot be bound. As well as requiring binding between the TCR and the MHC-presented peptide, activation also requires binding of the T-cell co-receptors (CD4 or CD8) to the MHC portion of the MHC:peptide complex. MHC molecules are categorized as either **class I major histocompatibility complex (MHC I)** molecules (see Section 19.5) or **class II major histocompatibility complex (MHC II)** molecules. The two classes are structurally different, originate in different compartments of the cell (see Section 20.3), and have different abilities to stimulate immune responses. The CD4 co-receptor binds only the MHC II molecule, and the CD8 co-receptor binds only MHC I. This restriction means that $CD4^+$ T cells can only be activated by binding peptides associated with MHC II molecules; they are MHC II-restricted. Conversely, $CD8^+$ T cells are MHC I-restricted and can only be activated by binding peptides associated with MHC I molecules (Figure 20.6). Table 20.1 summarizes the characteristics of effector T-cell types.

As you can imagine, an innumerable number of different peptides are generated when cells degrade microbial proteins. With innate immunity, foreign molecules are recognized by their possession of intact common PAMPs. However, degraded protein peptides would not be expected to possess common chemical features. How then can T cells possibly recognize these if each peptide is different? To accomplish this, a collection of T cells is generated, each with its own unique TCR (Figure 20.7). The custom TCRs are generated during maturation in the thymus by random rearrangements of the genes encoding the TCR peptide chains in each individual T cell. Each T cell released from the thymus has a unique TCR that does not change its structure for the life of the cell. It

TABLE 20.1 Characteristics of effector T cells

T-cell type	Effector function	Co-receptor	MHC class restriction
T helper cell (T_H)	Cytokine secretion	$CD4^+$	MHC II
Cytotoxic T cell (T_C)	Cytotoxic killing	$CD8^+$	MHC I

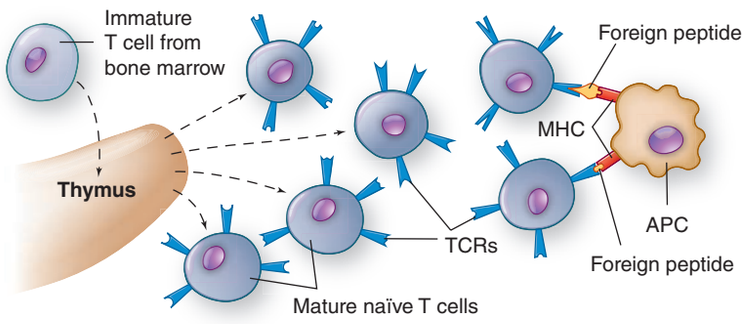

Figure 20.7. Maturation of T cells in the thymus Each unique TCR of the naïve T-cell population is generated during maturation in the thymus. Thus, each mature T cell has TCRs that are capable of recognizing a particular antigen; the cells are said to be antigenically committed. The enormous variety of TCR conformations ensures that some of the TCR conformations will specifically bind to a particular peptide presented by APCs.

is considered to be "antigenically committed," able to bind to only a specific epitope of an antigen. If a presented peptide from an APC can bind to the TCR, then activation can proceed. If binding does not occur, then initiation of a T-cell response will depend on the arrival of another T cell with the correct receptor conformation. This may seem like a lottery, but the number of different TCRs generated in the body is vast—estimated to be 2.5×10^7—so there is a strong possibility that some of the available TCRs will be able to bind to the presented peptide and begin a response.

Because of the antigen commitment of the original activated T cell, the resulting memory and effector cells all carry identical antigen-specific TCRs; they are all genetically identical clones of one another (Figure 20.8). Each is therefore capable of recognizing the same epitope of an antigen. The seemingly incredible feat of producing specialized molecules designed and manufactured in response to an infecting agent is based on the relatively simple principle of antigen commitment and clonal expansion. The specificity of the TCR is therefore the cornerstone of the customized adaptive immune response that follows.

CONNECTIONS Defense cells, such APCs and T cells, can infiltrate a damaged or infected site during inflammation. See **Section 19.3** for details.

Activation of CD4⁺ T Cells Once binding between the CD4⁺ T-cell TCR and the presented peptide has taken place, the CD4 co-receptor binds to the MHC II portion of the MHC II:peptide complex of the APC (see Figure 20.6). Recognition of the MHC II molecule by CD4 is a pivotal step in activating a bound CD4⁺ T cell. Without this binding, activation of the CD4⁺ T cell will not proceed even though the TCR has bound the peptide antigen presented by the MHC II molecule.

When all criteria for T-cell activation have been met, several T-cell genes are expressed, including those encoding certain cytokines. An important cytokine produced as a result of activation of CD4⁺ T cells is **interleukin-2 (IL-2)**. IL-2 functions as a growth factor for T cells, inducing resting cells to enter into cell division for clonal expansion and differentiation into a population of effector T_H cells and memory CD4⁺ T cells. Memory cells carry all necessary co-stimulatory surface molecules needed for quick action upon a subsequent exposure to the same epitope. Activation also results in the expression of the IL-2 receptor (IL-2R) on the T-cell surface, which binds IL-2 (Figure 20.9). When the armed T_H cells next bind MHC II-presented peptide, they deploy their effector functions, secreting large concentrations of cytokines that enhance and direct the immune functions of various other cells including CD8⁺ T cells, B cells (see Section 20.6), and macrophages (see Section 19.5). Without this cytokine help from T_H cells, adaptive immune responses will not progress.

Cell-mediated immunity
ANIMATION

Activation of CD8⁺ T Cells Recall that nearly all somatic cells, including cells with immune functions, produce MHC I molecules and can present endogenous antigen on their surface. However, only dendritic cells and macrophages, both of which are APCs, are proficient at producing enough stimulatory molecules, including MHC I:peptide complexes, to activate naïve CD8⁺ T cells. Successful interaction between the TCR of the CD8⁺ T cell and MHC I:peptide on a dendritic cell or macrophage is the first step in initiation of clonal expansion of the CD8⁺ T cell into a population of memory CD8⁺ T cells and

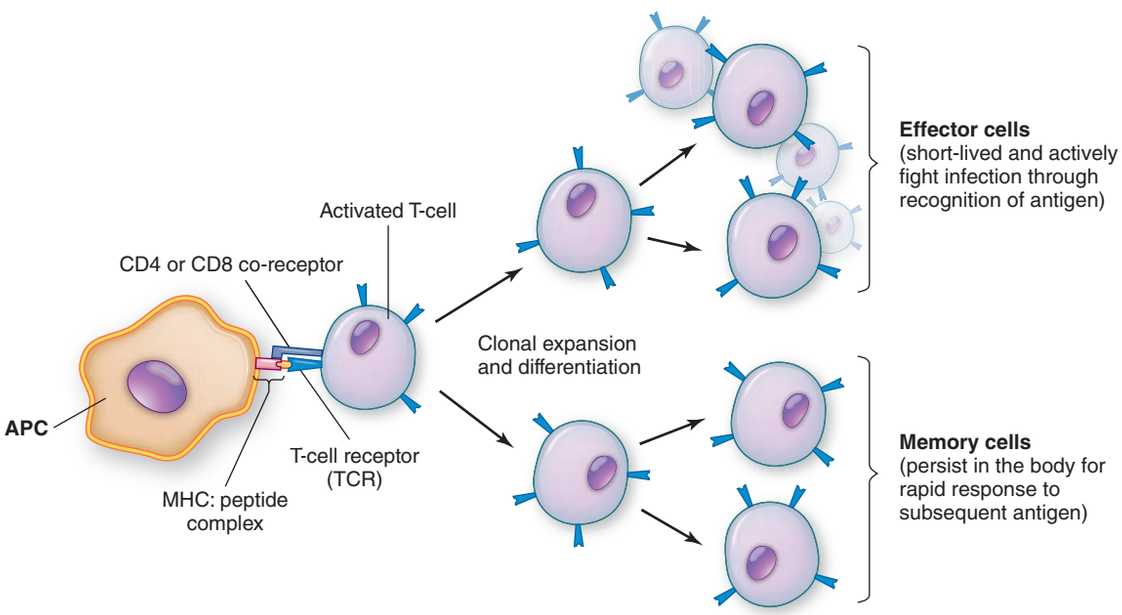

Figure 20.8. Clonal expansion of an activated T cell Encounter of a T cell with peptide presented on an MHC molecule by an APC results in activation, which in turn results in rounds of cell division and differentiation into a population of long-lived memory T cells and short-lived effector T cells. As all the resulting T cells have identical TCRs specific for the activating antigen, this proliferation is known as clonal expansion.

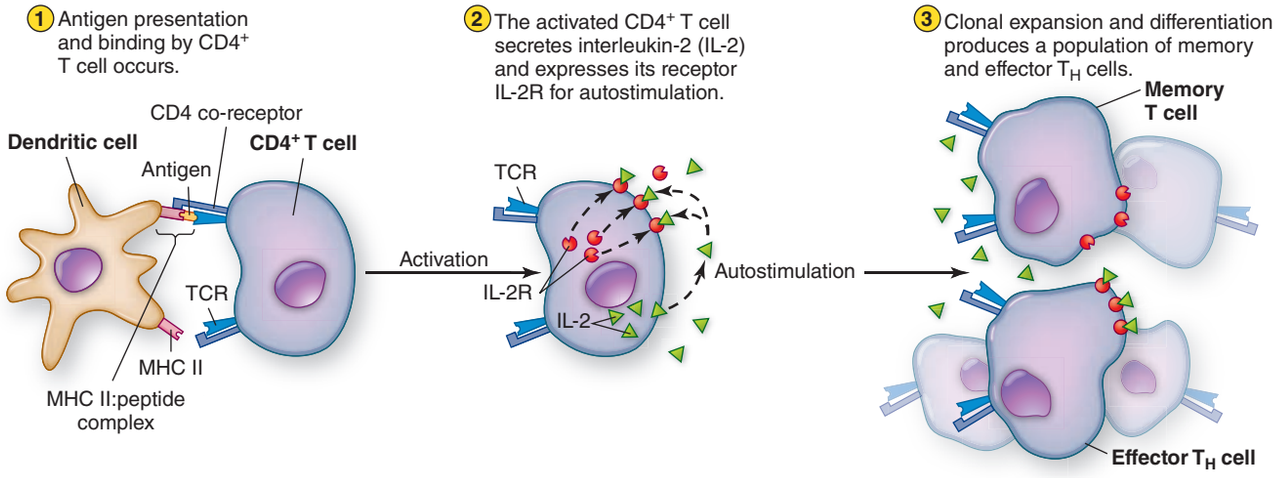

Figure 20.9. Process Diagram: CD4+ T-cell activation and clonal expansion Binding of the antigen-specific TCR to peptide presented by MHC II molecules on a macrophage or dendritic cell begins a signaling process that results in expression of the T-cell growth factor IL-2 and its surface receptor IL-2R by the CD4+ T cell. Binding of IL-2 on the CD4+ T cell begins cell stimulation, resulting in rounds of cell division (clonal expansion) and the production of a population of antigen-specific effector T_H cells and memory cells.

effector CD8+ T cells. Recall that effector CD8+ T cells have cytotoxic activity and are called T_C cells. The clonal expansion of CD8+ T cells, like that of CD4+ T cells, requires the cytokine IL-2. A major source of this cytokine is from activated CD4+ T_H cells. The requirement for IL-2 for T_C-cell production has been demonstrated using mice engineered to lack the IL-2 gene. These mice, called IL-2 knockout mice, are unable to efficiently produce T_C cells. Although there appears to be more than one way to activate CD8+ T cells, the general scheme of activation, shown in **Figure 20.10**, is as follows:

- Binding of a CD8+ T cell TCR with MHC I:peptide presented by a dendritic cell or a macrophage, leads to expression of the receptor IL-2R on the CD8+ T-cell surface.
- In the presence of a sufficient number of IL-2-secreting T_H cells, IL-2 is bound by the CD8+ T cell.

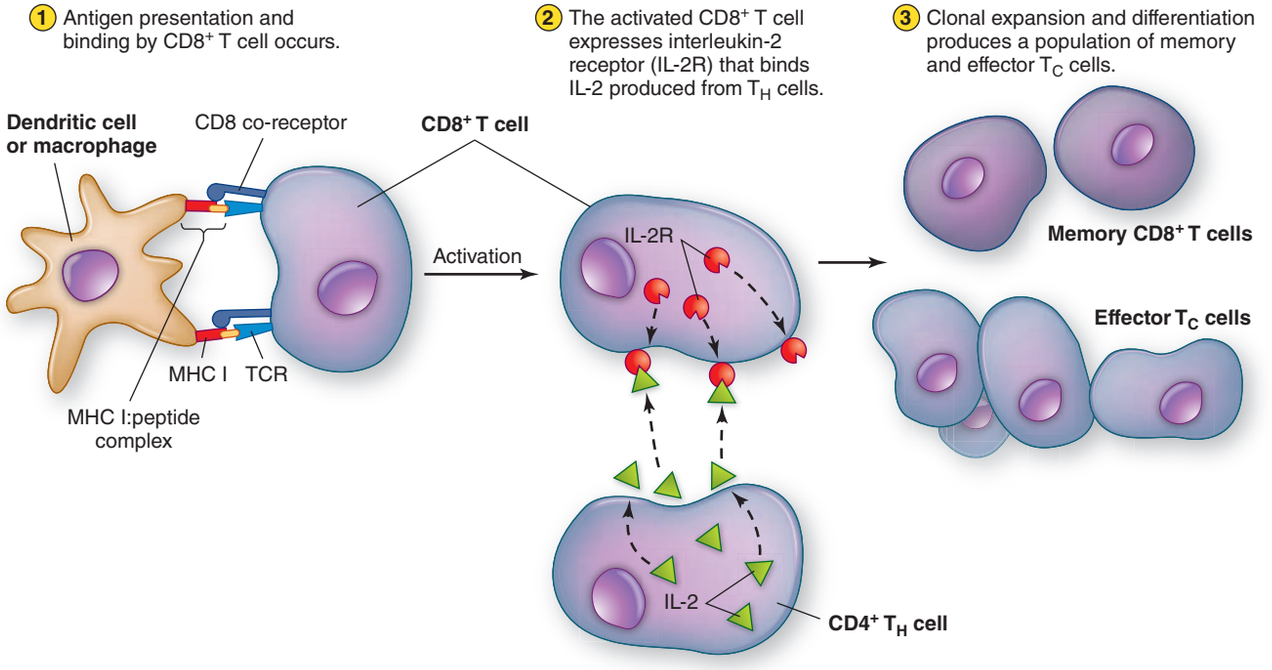

Figure 20.10. Process Diagram: CD8+ T-cell activation and clonal expansion Binding of the antigen-specific TCR to peptide presented by MHC I molecules on a macrophage or dendritic cell begins activation, resulting in expression of IL-2R by the CD8+ T cell. Assistance is generally required from activated T_H cells, which provide the cell growth factor IL-2. The result is a population of effector T_C cells with cytotoxic capabilities and a population of memory CD8+ T cells.

- This induces clonal expansion of the activated CD8+ T cell into a population of effector T_C cells and memory CD8+ T cells, all carrying the identical antigen-specific TCR.
- When T_C cells contact other infected cells displaying the same MHC I:peptide complex, they can bind by their TCR in an MHC I-restricted manner.
- This binding signals the T_C cell to release its toxic components, resulting in apoptosis of the target cell.

T_c cells migrate to sites of infection and can directly kill any infected cell they find that presents the *same* peptide in association with MHC I on its surface **(Figure 20.11)**. Presentation of MHC I:peptide by infected cells therefore targets them for destruction. Cells presenting MHC I:peptide are conventionally referred to as "target cells." Killing of a target cell is accomplished by binding of the TCR of the T_C to the target cell's MHC I:peptide complex. This is followed by the release of toxic molecules contained in the granules of the T_C, including perforin and granzymes, which results in apoptosis of the target cell.

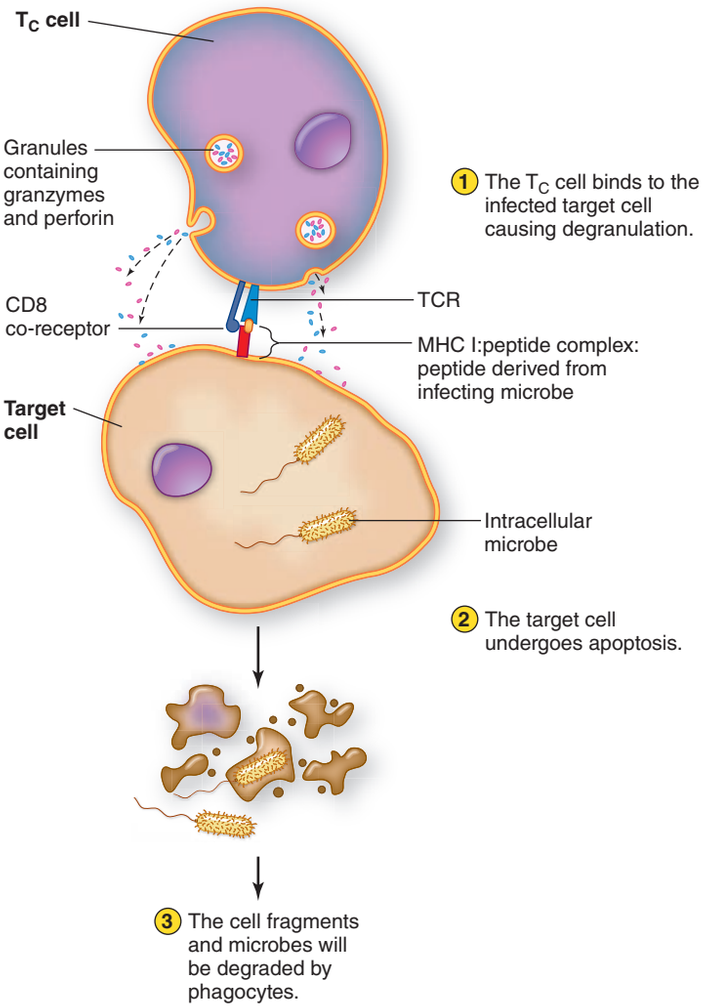

Figure 20.11. Process Diagram: Killing of an infected cell by a cytotoxic T cell A cytotoxic T cell (T_C cell) binds to its target cell in an antigen-specific and MHC I-restricted manner. This binding signals the release of perforin and granzymes at its bound surface, resulting in apoptosis of the target cell.

CONNECTIONS Perforin is thought to produce pores in the target cell membrane that allow the uptake of granzymes that induce apoptosis. See **Section 19.5**.

Killing by T_C cells is a very important response to infections involving intracellular pathogens such as viruses. Destroying this infected cell restricts the proliferation of the pathogen because it no longer has a host cell. Any viable pathogens released from the dead cell can then be taken up by local neutrophils and macrophages for destruction.

As dendritic cells and macrophages can express MHC I:peptide on their surface, logically, they can be targets for T_C cells as well as activators for naïve CD8+ T cells. This may serve a self-policing function. As the numbers of T_C cells accumulate, clearance of infected cells takes place, so the further activation of CD8+ T cells by an APC is no longer required. In fact, excessive activation of these cytotoxic cells can be detrimental to the host (see Section 20.5). As the number of infected cells decreases, the APCs become targets for destruction, further cytotoxic stimulation does not occur, and the response diminishes.

Memory cells and the memory response

The establishment of immunological memory is an important and usually desired result of the activation of adaptive immune responses. It is dependent on the production of memory cells as a result of clonal expansion. The production of memory T cells and memory B cells (see Section 20.4) often results from strong stimulation of adaptive immune responses. As we have seen, the presence of these cells produces a faster and more vigorous adaptive immune response when the same antigen is encountered again. Memory cells generally have fewer requirements for activation than do their naïve counterparts. They are primed for action so that when they encounter the antigen again, they can rapidly undergo clonal expansion and differentiate into effector cells and more memory cells (see Figure 20.8). This clonal expansion contributes to a faster and larger adaptive response (see Figure 20.5) and, in many cases, prevents the pathogen from establishing a repeated infection.

20.2 Fact Check

1. Explain how a foreign peptide the body has never encountered would be expected to be recognized by T cells.
2. Explain the process of T-cell activation, including how co-receptors, TCRs, antigen-presenting cells, and MHC molecules are involved.
3. Distinguish between CD8+ and CD4+ effector T cells.
4. Describe the effects of IL-2 production from CD4+ T cells.
5. Distinguish memory T cells from their naïve counterparts. How are memory cells formed?

20.3 Antigen processing

How are adaptive immune responses initiated?

Let's continue to further trace some of the specific events that lead to a T-cell immune response. As we know, the initiation of T-cell activation requires the presentation of antigen by an APC. The pathway used to process antigen within the APC generally depends on the source of the antigen, whether it is from a microbe that is extracellular or intracellular. These factors will impact the immune response that is generated.

Exogenous antigens and the endocytic pathway—Activation of CD4+ T cells by MHC II:peptide

Exogenous antigens, or extracellular antigens, are antigens that have entered the cell from the extracelluar environment. As we saw in Section 19.5, endocytosis is the process of uptake of exogenous particles. Endocytosis occurs in three general ways **(Figure 20.12)**:

- Phagocytosis, a form of endocytosis, is used to take in a large object such as a bacterial cell. Of the APCs, only macrophages and certain types of dendritic cells carry out phagocytosis.
- Receptor-mediated endocytosis is carried out by many cell types and occurs when uptake is initiated through the binding of particles such as viruses or bacterial components to specific cell surface receptors (see Section 8.2).
- Pinocytosis is used by all cells to take in macromolecules such as nutrients. This can be thought of as "drinking" by the cell.

Recall from Section 19.5 (see Figure 19.16) that the vesicles formed through phagocytosis (phagosomes) and receptor-mediated endocytosis (endosomes) enter the endocytic pathway for digestion of their contents. Although many microbial components are degraded in the endocytic pathway, proteins are of primary importance for triggering adaptive immune responses. Only they can activate T cells.

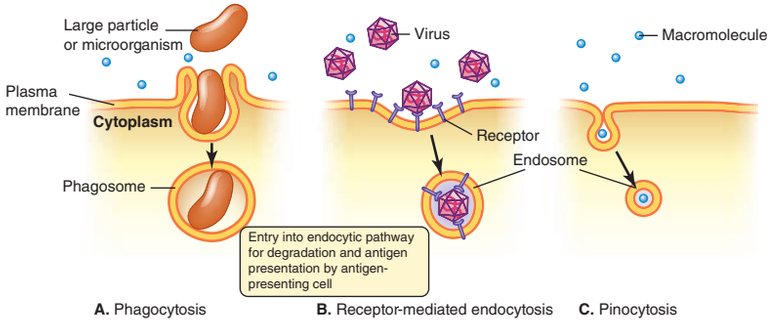

Figure 20.12. Endocytosis **A.** Phagocytosis is used to engulf large particles such as bacterial cells. The plasma membrane surrounds the particle to produce an endocytic vesicle, called a phagosome. **B.** Receptor-mediated endocytosis occurs when smaller particles such as bacterial components or virus particles bind to specific cell surface receptors. This initiates invagination in the plasma membrane leading to formation of an endosome. **C.** Pinocytosis uses tiny invaginations of the plasma membrane to bring small amounts of extracellular fluid-containing nutrients and other small macromolecules into the cell. Small endosome vesicles are formed.

The proteins are digested in the endosome into small peptides of 13–18 amino acids in length. The peptides are then bound by specialized MHC II molecules, supplied by vesicles of the Golgi apparatus participating in the endocytic pathway **(Figure 20.13)**. The production of MHC II molecules is restricted to APCs; they are not produced efficiently by other

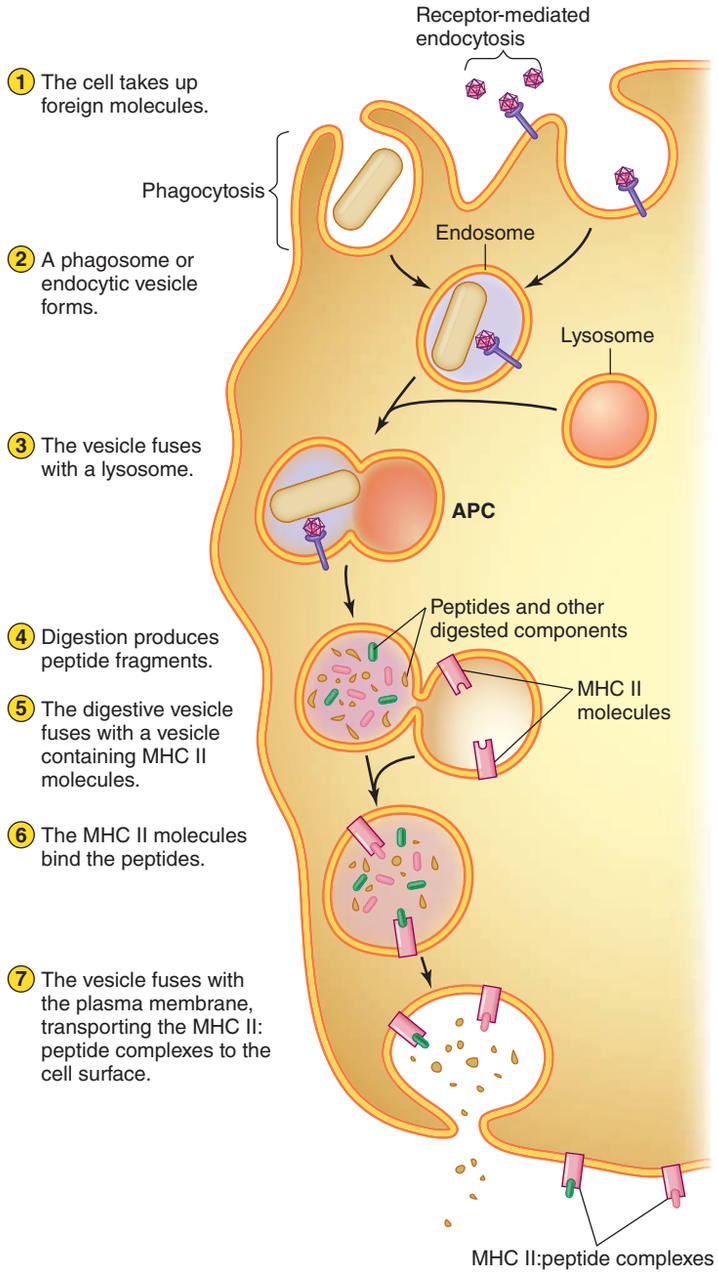

Figure 20.13. Process Diagram: The endocytic pathway for presentation of exogenous peptides on MHC II Exogenous antigens such as extracellular microbes are taken up by the cell. The vesicle formed enters a series of processes resulting in digestion of the microbial components and presentation of the peptide fragments on MHC II molecules at the surface of the APC.

cells of the body. This is an important distinction from MHC I molecules, which you will recall are produced by most cells of the body. Peptide-bound MHC II molecules are brought to the surface of the APC to await binding with a compatible T-cell receptor (TCR) of a $CD4^+$ T cell. Remember, only $CD4^+$ T cells can bind peptides associated with MHC II.

Intracellular antigens and the endogenous pathway—Activation of $CD8^+$ T cells by MHC I:peptide

Endogenous antigens are those that originate *within* the cell from intracellular pathogens. Viral proteins of virus-infected cells are commonly processed by the endogenous pathway as these proteins are produced by the cell's own translational machinery in the cytoplasm. When other intracellular microbes infect a cell, their molecular components enter the cytoplasm as they replicate or die.

Endogenous proteins are not processed inside endosomes, but in the cytoplasm by a specialized complex of proteolytic enzymes, the **proteasome** (Figure 20.14). Proteasomes degrade cellular proteins as well, such as those that are misfolded or no longer needed. The cell tags these proteins with another small protein called "ubiquitin," which targets them for proteasome degradation. This is crucial for cellular housekeeping in the same way that we must dispose of leftover consumable items in our own homes. Proteasomes degrade proteins into smaller peptides, six to nine amino acids in length. The peptides are then transported from the cytoplasm to the endoplasmic reticulum, where they associate with MHC I molecules produced by the cell (see Section 19.5). From here, the MHC I:peptide complex is presented on the cell surface (Figure 20.15).

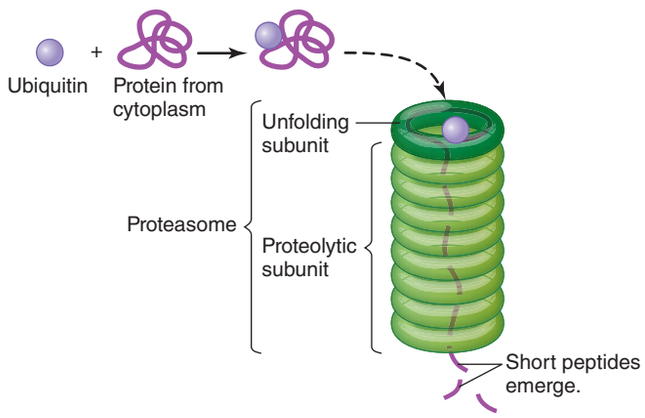

Figure 20.14. Degradation of proteins by the proteasome Cytoplasmic protein is designated for degradation by association with ubiquitins, which are small proteins that attach to targeted proteins. Ubiquitin-associated protein is transported to the unfolding subunit of the proteasome. Here, the protein is linearized for insertion into the central channel of the proteolytic subunit. Several specific proteases contained within this subunit break various peptide bonds of the chain, producing peptides six to nine amino acids in length. The peptides will bind to MHC I molecules and be transported to the cell surface.

Antigen cross-presentation—Activation of both $CD4^+$ and $CD8^+$ T cells

So far we have learned that macrophages and dendritic cells endocytose foreign substances that they find in their environment. They next degrade the proteins of these larger substances into small peptides. The peptides are bound by MHC II molecules and transported to the surface of the cell (see Figure 20.12). From here, they await recognition by a TCR on a $CD4^+$ T cell (recall that $CD4^+$ T cells are MHC II-restricted). If this happens, the $CD4^+$ T cell becomes activated. However, activation of $CD8^+$ T cells requires antigen to be presented by MHC I molecules. This happens when foreign protein from within the cell cytoplasm is degraded and presented through the endogenous pathway (see Figure 20.16). It would follow then that activation of $CD8^+$ T cells only occurs when a macrophage or a dendritic cell is infected by an intracellular pathogen. That said, exogenous antigens have been shown to stimulate $CD8^+$ T cells in some cases. Even though this would seem to violate everything we have just covered, pathogens can infect cells other than APCs, such as epithelial cells or muscle cells. How then is an adaptive immune response mounted to such an intracellular pathogen?

Part of the answer lies in the innate ability of macrophages and dendritic cells to endocytose dead or dying infected host cells or their parts. One might expect these proteins to be processed through the exogenous pathway and presented as MHC II:peptide. As these infected cells contain parts of the pathogen, or even the pathogen itself, proteins from the pathogen

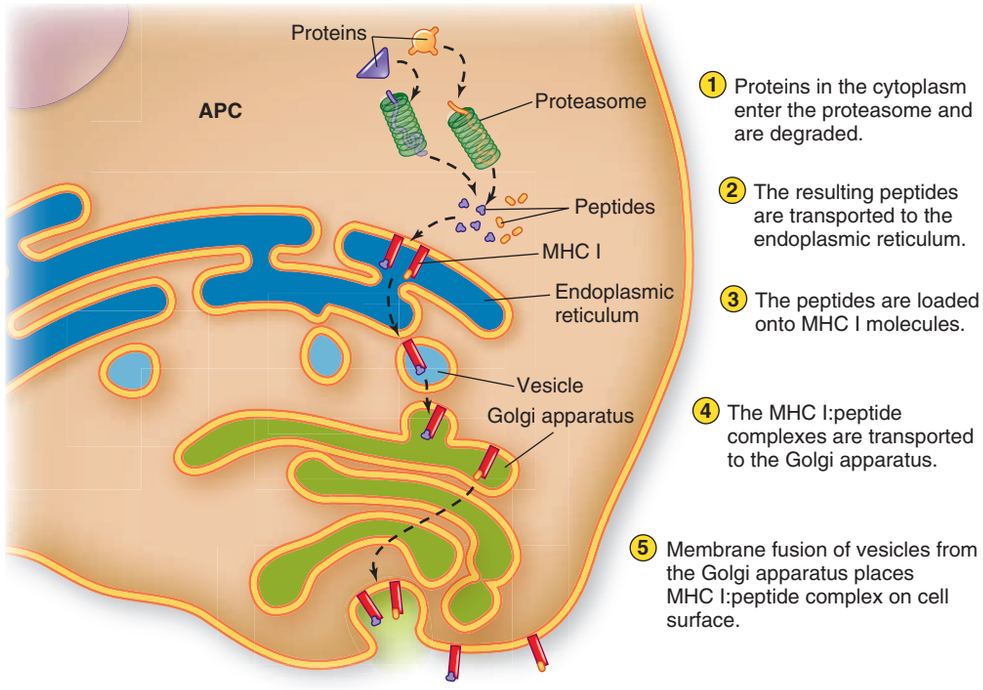

Figure 20.15. Process Diagram: The endogenous pathway for presentation of cytoplasmic peptides on MHC I Endogenous antigens such as those from intracellular pathogens originate in the cytoplasm. The proteins are degraded and eventually bound by MHC I molecules. These MHC I:peptide complexes are transported to the surface of the APC, resulting in presentation of the peptide antigen.

will also get processed and presented by MHC II. This can activate $CD4^+$ T cells. So far in this scenario, $CD8^+$ T cells have not been activated and no T_C cells have been generated. The intracellular pathogen is still on the loose.

As we know, activation of $CD8^+$ T cells requires antigen to be presented by MHC I. There must then be a mechanism to bind exogenously acquired antigen to MHC I molecules in APCs. This is accomplished through a process known as antigen **cross-presentation** that shuttles proteins from the endocytic pathway into the endogenous pathway. It is not yet known exactly how the shunt functions, and there appears to be more than one pathway involved. The importance of cross-presentation is that it allows both $CD4^+$ and $CD8^+$ T-cell activation for an effective adaptive response to intracellular pathogens. Now a population of antigen-specific T_C cells can be generated to seek out any host cell that is infected. Antigen cross-presentation is especially important for generating a protective immune response to viruses that do not infect APCs.

20.3 Fact Check

1. What are exogenous antigens and how are they processed?
2. Explain how an APC interacts with a $CD4^+$ T cell. What is the result on the T cell?
3. What are endogenous antigens, and how are they processed?
4. Explain how an APC interacts with a $CD8^+$ T cell. What is the result on the T cell?
5. Explain how a $CD8^+$ T cell recognizes and kills infected target cells.
6. What is the purpose of antigen cross-presentation?

20.4 Antigen-presenting cells

What cells can launch adaptive immune responses?

As we have seen, most cells in the body are capable of presenting endogenous antigens on MHC I molecules. However, only APCs can launch adaptive responses. Recall that APCs are dendritic cells, macrophages, and B cells. Why can only these specific cells activate T cells? Imagine what would happen if all cells of the body could induce adaptive immune responses by presenting antigen to T cells. It could easily cause immune overreaction. Specialized APCs ensure that activation of T cells occurs in a controlled manner and only when there is sufficient need. Only these cells possess the required characteristics for efficiently activating T cells. These include the following:

- The expression of high numbers of MHC molecules on their surface
- Proficiency in the processing and presentation of peptides to T cells
- The display of the surface stimulatory molecules required for T-cell activation.

As shown in **Table 20.2**, different APC types have different capabilities for T-cell activation. Dendritic cells can initiate primary immune responses by activating naïve T cells, and memory responses by activating memory T cells. Dendritic cell interaction with circulating effector $CD4^+$ T_H cells induces these cells to secrete cytokines for further immune functions. Interaction of any target cell presenting MHC I:peptide with circulating effector $CD8^+$ T_C cells will cause the T_C to deploy its cytotoxic killing action. Macrophages and B cells are generally not adept at activating naïve T cells and, consequently, are not proficient at initiating primary immune responses. However, macrophages are potent activators of memory $CD4^+$ and $CD8^+$ T cells, and thus can initiate memory responses. B cells, as we will see in this section, are limited to interactions with T_H cells. We will now examine the different APCs in more detail.

Dendritic cells

Dendritic cells are a collection of multifunctional cells whose predominant role is to present peptides to the adaptive immune system for activation. They take in substances from their environment in a non-specific manner and present them to T cells in the form of peptide fragments associated with MHC II molecules on their cell surface. Dendritic cells can bind ligands for endocytosis through a variety of pattern recognition receptors (PRRs) that are found on their surface. They can also take in extracellular macromolecules from their environment by engulfing extracellular fluid in a process called "pinocytosis" (see Figure 20.12). They are not armed to be efficient killers of microbes compared to the "professional" phagocytes: macrophages and neutrophils. They lack the ability to generate the respiratory (oxidative) burst, but they do possess lysosomes with a supply of hydrolytic enzymes that degrade proteins. Like other cells of the body, if a dendritic cell becomes infected, it can also present peptides through the endogenous route on MHC I molecules.

Dendritic cells derive their name from the many long cytoplasmic extensions possessed by mature cells that resemble the dendrites of nerve cells **(Figure 20.16)**. The majority of dendritic cells are derived from monocytes (see Appendix D). Dendritic cells are produced in the bone marrow and mature in diverse locations. Eventually, the cells move into various tissues and take up residency. Here, they further differentiate into a number of distinct subsets, characterized by variation in cell surface markers and cytokine secretion. The subsets are given names such as Langerhans cells of the skin, interstitial dendritic cells

TABLE 20.2 Activities of antigen-presenting cells

Antigen-presenting cell	Activated cell types	MHC restriction	Outcome
Dendritic cell	Naïve $CD4^+$ T cells	MHC II	Primary response; generation of memory and effector $CD4^+$ T cells (T_H cells)
	Naïve $CD8^+$ T cells	MHC I	Primary response; generation of memory and effector $CD8^+$ T cells (T_C cells)
	Memory $CD4^+$ T cells	MHC II	Memory response; generation of T_H cells
	Memory $CD8^+$ T cells	MHC I	Memory response; generation of T_C cells
	T_H cells	MHC II	Cytokine secretion
	T_C cells	MHC I	Cytotoxic killing
Macrophage	Naïve $CD8^+$ T cells[a]	MHC I	Primary response; generation of memory and T_C cells
	T_H cells	MHC II	Cytokine secretion
	T_C cells	MHC I	Cytotoxic killing
	Memory $CD4^+$ T cells	MHC II	Memory response; generation of T_H cells
	Memory $CD8^+$ T cells	MHC I	Memory response; generation of T_C cells
B cell	T_H cells	MHC II	T_H2 cytokine secretion and B cell proliferation

[a] Only in certain instances.

of mucosal membranes and internal organs, and interdigitating dendritic cells of the thymus and spleen. These strategic placements provide ample opportunity for dendritic cells to encounter foreign substances as they enter the body.

Dendritic cells are particularly competent in their abilities to express MHC molecules, present antigen, and produce various co-stimulatory molecules needed to stimulate T cells. Studies have shown that dendritic cells are the most efficient at activating naïve $CD4^+$ T cells. Recall that naïve cells are resting cells that have not yet come into contact with antigen. The ability of dendritic cells to initiate this appears to be due to the stringent requirements of naïve T cells for several accessory molecules found only on the surface of dendritic cells. Earlier, we discussed the need for controlling initiation of adaptive immune responses. If the correct signals are not produced, then initiation of T-cell responses will not be initiated. Macrophages and B cells have been demonstrated *in vitro* to activate naïve $CD4^+$ T cells, but only when present in very large numbers. In contrast, activation can be accomplished with very few dendritic cells.

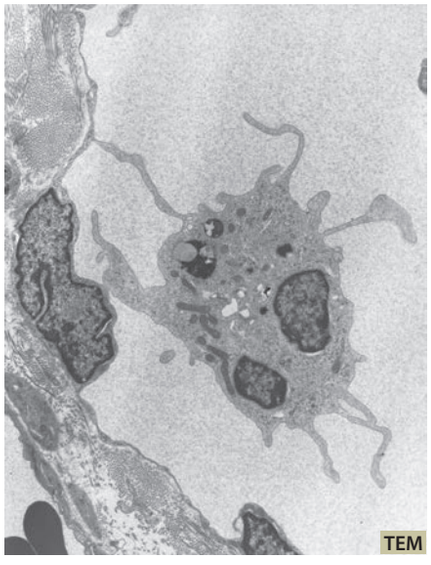

Figure 20.16. Dendritic cell Long cytoplasmic extensions are characteristic of dendritic cells and are used for capturing foreign substances.

The general process of dendritic cell activation and presentation to $CD4^+$ T cells is shown in **Figure 20.17**. In their place of residence, dendritic cells are thought to be at rest. Once a dendritic cell encounters and ingests a particle, it becomes activated through Toll-like receptor (TLR) signaling (see Section 19.4). The activated dendritic cell migrates to a regional lymph node and presents antigen to T cells to initiate adaptive immune responses.

Dendritic cells typically express a large number of many different TLRs. Activation results in:

- A dramatic increase in the ability to present foreign peptides,
- An increased expression of a wide variety of cytokines and stimulatory cell surface molecules such as MHC II, for interaction with T cells,
- Migration to the regional lymph nodes where T cells are concentrated.

Macrophages

As we have already learned, macrophages are cells important in both innate and adaptive immunity. Their innate functions include phagocytosis and intracellular killing (see Section 19.5). As professional APCs, they also have the ability to initiate memory immune responses through presentation of processed peptides to memory $CD4^+$ and $CD8^+$ T cells. Along with dendritic cells, macrophages also play a key role in determining the course of $CD4^+$ T-cell differentiation into subsets that support either cell-mediated immune functions or B-cell humoral functions. This topic is discussed in Section 20.6.

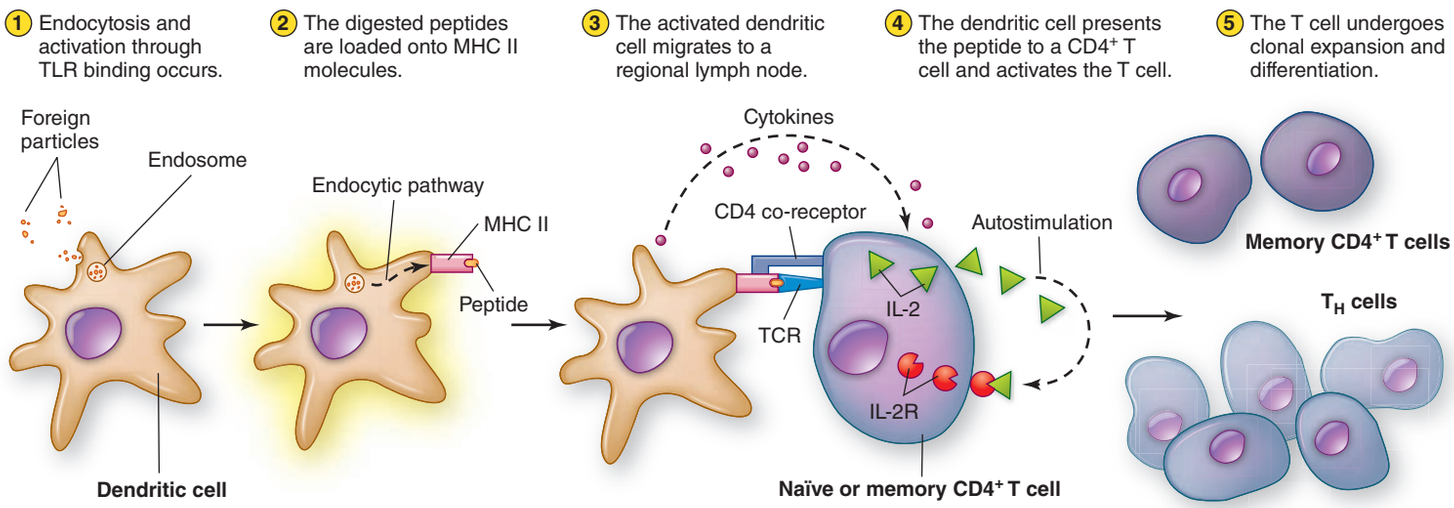

Figure 20.17. Process Diagram: Dendritic cell presentation of antigen to a CD4+ T cell Dendritic cell activation by exogenous antigen begins with binding and endocytosis of the particle. Toll-like receptors (TLRs) are activated, causing increased MHC II and cytokine production. Digestion occurs through the endocytic pathway and peptide is bound to MHC II. The dendritic cell begins its migration from tissue to a regional lymph node where it will contact T cells. Successful binding of presented peptide with a CD4+ T cell results in T-cell activation, clonal expansion, and differentiation into CD4+ memory cells and effector T_H cells.

B cells

B cells mature and migrate from the bone marrow to circulate in secondary lymphoid tissues such as the spleen and lymph nodes where they await encounters with antigen. Because B cells commonly reside in secondary lymphoid tissues, they frequently bind unprocessed antigens carried to these tissues on the surface of dendritic cells. They can also bind free antigen, an especially important function of B cells in the spleen, which screens large volumes of blood for antigen. B cells have two very important roles in adaptive immunity:

- B cells present MHC II:peptide to T_H cells.
- B cells produce antibody.

In this section, we will limit our examination of B cells to their antigen-presenting functions. Antibody production will be examined in Section 20.6. B cells express unique BCRs on their surface, much as T cells express TCRs. BCRs and antibody belong to a large family of proteins known as immunoglobulins (Ig), all of which can bind antigen in a specific manner. Antibody is a secreted version of the BCR. Like TCRs, the BCRs found on mature B cells are randomly generated. B cells have two mechanisms of generating diversity in their immunoglobulin chains:

- The genes that encode the immunoglobulin polypeptide chains undergo random rearrangements.
- The sequence of the immunoglobulin antigen-binding domain undergoes point mutations and deletions.

Thus, a wide variety of BCRs is generated constantly in the bone marrow, and mature B cells are antigenically committed. The large variety of BCRs at hand helps ensure that when a foreign substance is present, like a microbe or toxin, some of the B cells will be able to bind it.

BCRs can bind antigens directly from the surrounding environment. The antigens they bind are also not restricted to proteins, as we will see later in Section 20.6. In this, B cells are unique. Their BCRs do not require peptides to be presented in an MHC format as T cells do. The general process of B-cell antigen presentation is shown in **Figure 20.18**. Binding of free antigen to a BCR begins the process of endocytosis. More specifically, this process is receptor-mediated endocytosis as the BCR is a specific receptor for the antigen (see Figure 20.12). Once internalized, the antigen is broken down in the endocytic pathway and the peptides the antigen contained are presented by the B cell on MHC II molecules, just as we have seen with other APCs (see Figure 20.13). Unlike other APCs, B cells do not activate naïve T cells. Instead, they activate T_H cells that have been produced through activation of a naïve or memory CD4+ T cell by a dendritc cell or macrophage. When a B cell presenting MHC II:peptide binds a T_H cell, it stimulates the T cell to secrete cytokines. The cytokines secreted by the T_H cell (see Section 20.5) in turn stimulate the B cell to undergo clonal expansion and differentiation into antibody-secreting **plasma cells** and memory B cells. This proliferation and differentiation is absolutely dependent on interaction with T_H cells as it requires cytokines supplied by the T_H cell. In this way, the T_H cell "helps" the B cell.

Characteristics of antigens presented by antigen-presenting cells

Generally speaking, to evoke a primary adaptive immune response, it is crucial that antigen be taken up, processed, and presented by dendritic cells. Certain characteristics of microbial components can dictate the efficiency with which these activities proceed. Microbial components that are very small

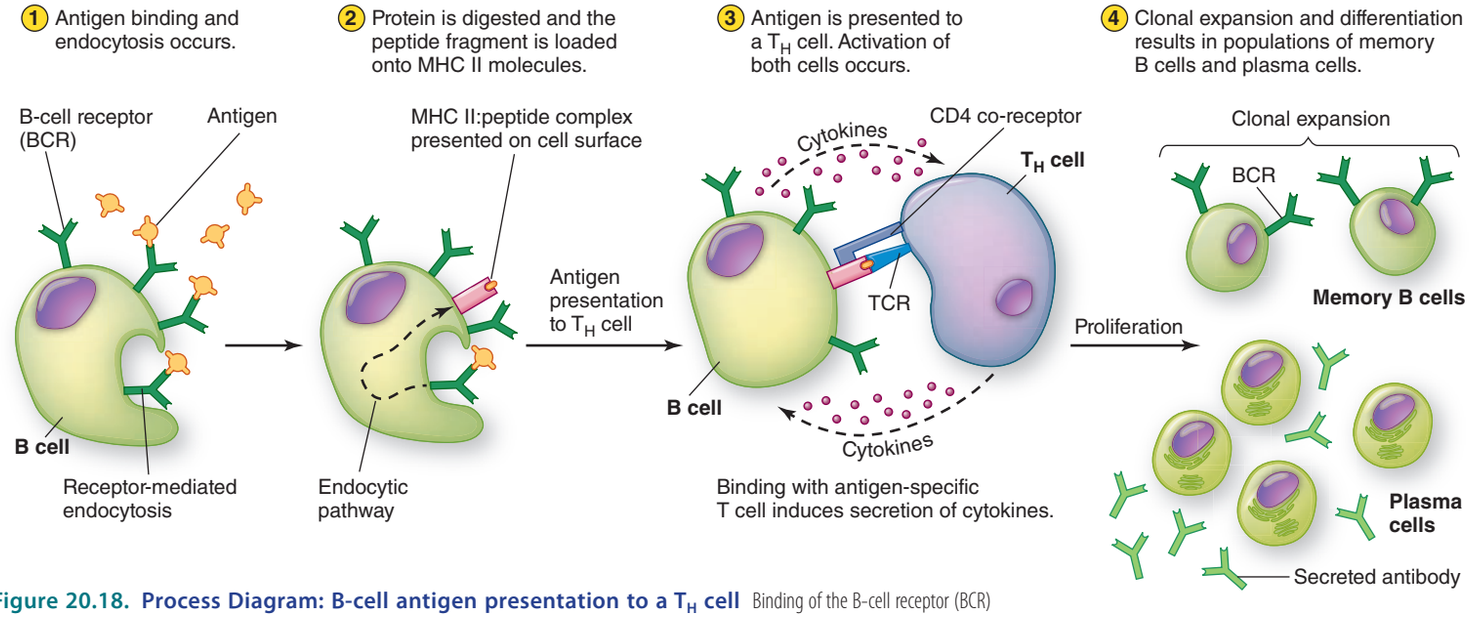

Figure 20.18. Process Diagram: B-cell antigen presentation to a T_H cell Binding of the B-cell receptor (BCR) with antigen begins the process of receptor-mediated endocytosis. Digestion of the antigen occurs through the endocytic pathway, and the resulting peptides are bound to MHC II molecules and presented to T_H cells. Binding of the B-cell MHC II:peptide with a T_H cell induces secretion of cytokines causing the B cell to undergo clonal expansion and differentiation into antibody-secreting plasma cells and memory B cells.

and soluble, such as small peptides, are not typically good substrates for cell uptake and thus are poor stimulators of adaptive immune responses. Components that are resistant to the degradative effects of the endocytic pathway or the proteasome are also poor stimulators as they cannot be broken down into the required peptide lengths for binding to MHC molecules. These factors need to be considered in designing a vaccine.

Many vaccines are composed of specific molecules purified from the pathogens for which they are designed. However, the immunogenicity of these molecules is often reduced when they are isolated away from the more complex structure of the pathogen. Frequently, administration of these purified components does not produce memory cells in sufficient numbers to provide the long-term immunological memory that is required of effective vaccines. Small molecules such as peptides, can be made more immunogenic—a term we have used earlier to describe the relative ability to stimulate an immune response—by mixing them with adjuvants. Recall from Section 19.4, adjuvants are commonly added to vaccine formulations to enhance the immune response to an antigen. Adjuvants are composed of inorganic salts or organic compounds, such as oils or microbial components. When adjuvants are mixed with the target antigen, a substantial number of long-lived memory cells are generated. This means that we require fewer injections of vaccine "boosters" to provide us with long-term immunity. Adjuvants act in the following ways:

- Precipitating the substance to make it a physically larger particle. This appears to facilitate uptake by dendritic cells and macrophages. An example of this type of adjuvant is aluminum potassium sulfate, commonly referred to as alum. Alum is the most common adjuvant that is universally licensed for use in humans. Organic compounds such as squalene, a large omega-2 oil, are also sometimes used.
- Releasing the complexed antigen over time. This appears to give the immune system more opportunity to interact with it. Longer antigen exposure is generally required for production of immunological memory. Mixing antigen with mineral oil (incomplete Freund's adjuvant), commonly used in animals, results in release of antigen over time and produces the immunological memory required for an effective vaccine.
- Binding Toll-like receptors (TLRs; Section 19.4) of dendritic cells and macrophages. This promotes uptake of antigen and provides for more efficient MHC presentation. TLR stimulation also enhances the production of proinflammatory cytokines to stimulate inflammation.

In addition to mineral oil, Freund's complete adjuvant contains mycobacterial cell wall components that can directly activate TLR2 (see Section 20.5). This adjuvant is not commonly used as its potency often results in severe and chronic inflammation at the injection site. DNA vaccines owe their adjuvant effects to the DNA molecule itself through TLR9 signaling (see Mini-Paper, Chapter 19). The DNA is of bacterial origin and is recognized as foreign by the innate immune system. In most cases, the particular pathogen gene that has been inserted into the DNA vaccine for expression in host cells simply provides an antigen to direct the specificity of the adaptive immune response.

CONNECTIONS Vaccines are preparations of microbes or their components used to immunize against microbial diseases by conferring immunological memory through the production of memory cells. For more details on vaccines and formulations, see **Section 24.5**.

20.4 Fact Check

1. What are the key features of dendritic cells, and how do they function?
2. Describe the roles of B cells in adaptive immunity.
3. How do BCRs play a role in antigen presentation?
4. What are adjuvants, and what are they capable of doing in the body?

20.5 Humoral and cell-mediated immune responses

Are there different responses to extracellular and intracellular pathogens?

We have so far surmised that cytokine secretion by T_H cells is required to help in the activation of both B cells for antibody production *and* T_C cells for cytotoxic killing. Recall from Section 19.4 that opsonization of extracellular microbes by antibody activates the classical complement pathway and results in lysis of the pathogen. Opsonization by antibody also facilitates phagocytosis of microbes by neutrophils and antigen-presenting macrophages. There is often little use for antibody production in the elimination of intracellular pathogens, such as viruses or *Mycobacterium tuberculosis*. Antibodies usually enter host cells only if they attach to the pathogen while it is extracellular and are brought into the cell. Cytotoxic killing of infected host cells by T_C cells is often a requirement for clearance of intracellular infections. As we have learned, destroying infected host cells restricts the replication of the pathogen, and any released pathogens from the dead host cells can then be taken up by local neutrophils and macrophages for destruction. Activating T_C cells would not help in clearing extracellular microorganisms such as *Streptococcus pyogenes*, as T_C cells can only recognize and kill infected host cells. It is therefore wasteful to have both these cell types activated at the same time.

Examinations of the relative levels of antibody and the cell populations that are produced in immune responses to specific pathogens are, in fact, known to be generally polarized to either a **humoral immune response** for enhanced antibody production or a **cell-mediated immune response** involving little antibody, killing of infected cells by T_C cells, and increased intracellular killing by macrophages. What decides which type of response is produced? That clearance of extracellular pathogens requires antibody production whereas clearance of intracellular pathogens requires a cell-mediated response may be obvious, but how does the immune system "decide" this?

T_H1 and T_H2 T-cell subsets

Studies in mice have shown that activated T_H cells secrete distinct patterns of cytokines that are correlated with either a humoral or a cell-mediated immune response. In mice, the different profiles have been investigated extensively and have led to the functional classification (no differential cell markers have yet been identified) of T_H cells as being of different subsets. Of the several subsets of T_H cells recently classified, we will focus on **T_H1 cells**, correlating with a cell-mediated response, and subset **T_H2 cells**, correlating with a humoral response. The pattern of cytokine secretion from mouse T_H1 cells is dominated by the proinflammatory cytokines IL-2, tumor necrosis factor-alpha (TNF-α), and interferon-gamma (IFN-γ). That of T_H2 cells is predominantly IL-4, IL-5, IL-6, IL-10, and IL-13. The pattern of cytokine production differs in other species such as cattle and humans **(Table 20.3)**. However, most experts agree these species do show *overall* differential cytokine patterns related to the type of immune response. The designation of T_H1 and T_H2 has therefore become the paradigm for describing activated T_H-cell functions. The influences of some of the T_H1 and T_H2 cytokines on the immune response are summarized in **Figure 20.19**.

Generally, *in vitro* studies have shown that the T_H1 phenotype in most mammals develops when $CD4^+$ T cells undergo activation in the presence of IL-12 and IL-18 **(Figure 20.20)**. These two cytokines are produced by dendritic cells and macrophages as a result of innate TLR signaling. T_H1 cells secrete the cytokine IFN-γ, which enhances macrophage intracellular killing functions and MHC II:peptide presentation to $CD4^+$ T cells. The T_H2 phenotype is produced by exposure of $CD4^+$ T cells to IL-10 and IL-4. IL-10 is produced by macrophages and dendritic cells that have undergone activation through a different pattern of TLR stimulation. The source of IL-4 remains unclear; B cells, mast cells, and activated T_H2 T cells have all been implicated. It is also unclear if memory $CD4^+$ T cells are irreversibly committed to either the T_H1 or T_H2 subset upon subsequent

TABLE 20.3 Cytokines produced by human T_H1 and T_H2 subsets

Cytokine	T_H1[a]	T_H2[a]
IL-2	+	−
IFN-γ	+	−
TNF-α	+	−
IL-3	+	+
IL-4	−	+
IL-5	−	+
IL-6[b]	+	++
IL-10[b]	+	++
IL-13[b]	+	++

[a] Relative amounts produced are indicated by number of + symbols, or −, not produced.

[b] T_H1 cells of mice do not produce IL-6, IL-10, or IL-13.

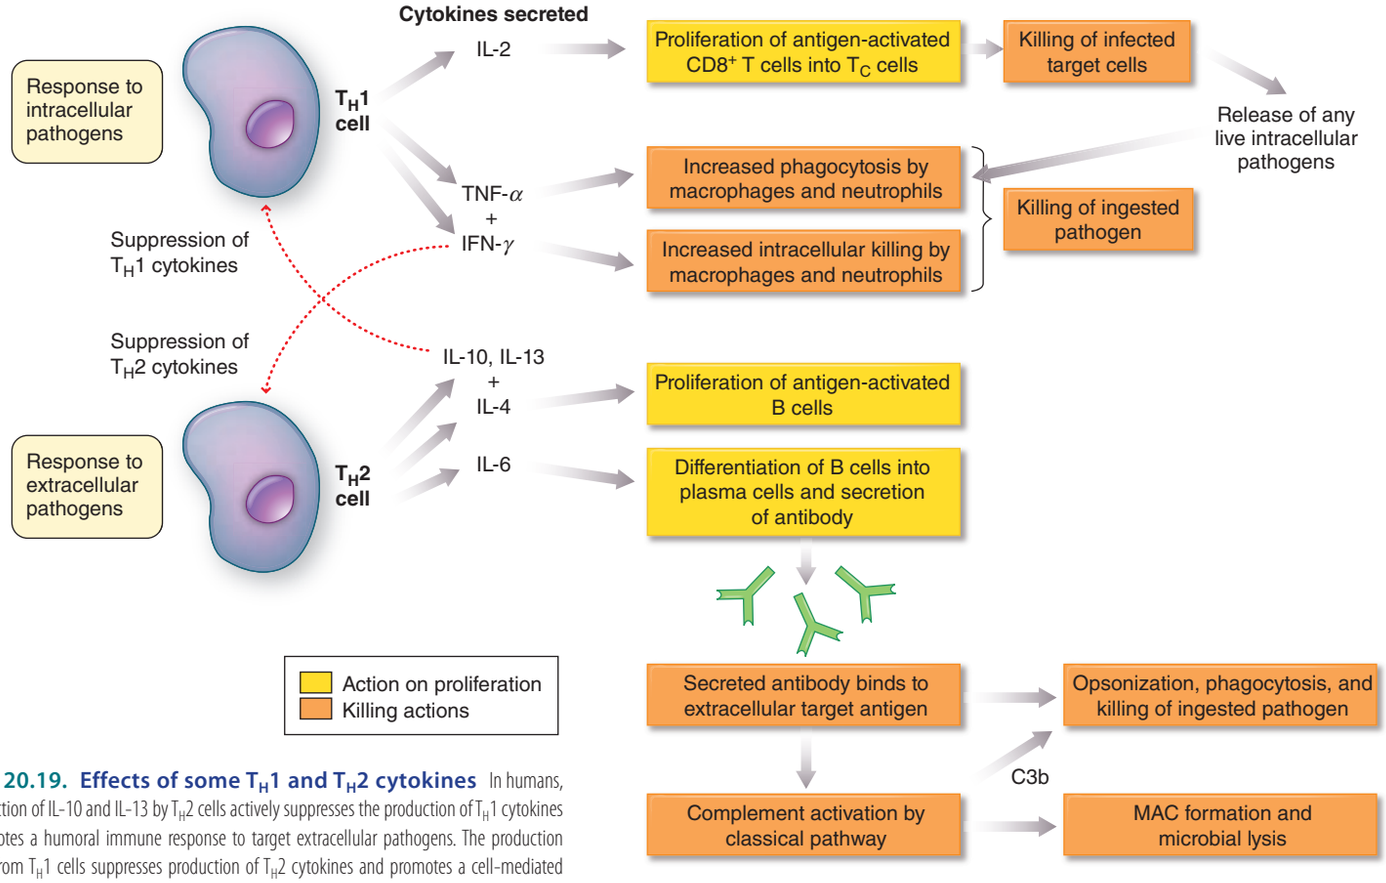

Figure 20.19. Effects of some T_H1 and T_H2 cytokines In humans, the production of IL-10 and IL-13 by T_H2 cells actively suppresses the production of T_H1 cytokines and promotes a humoral immune response to target extracellular pathogens. The production of IFN-γ from T_H1 cells suppresses production of T_H2 cytokines and promotes a cell-mediated immune response to target intracellular pathogens. Other cytokines induce expression of specific genes associated with various humoral or cell-mediated immune responses as depicted.

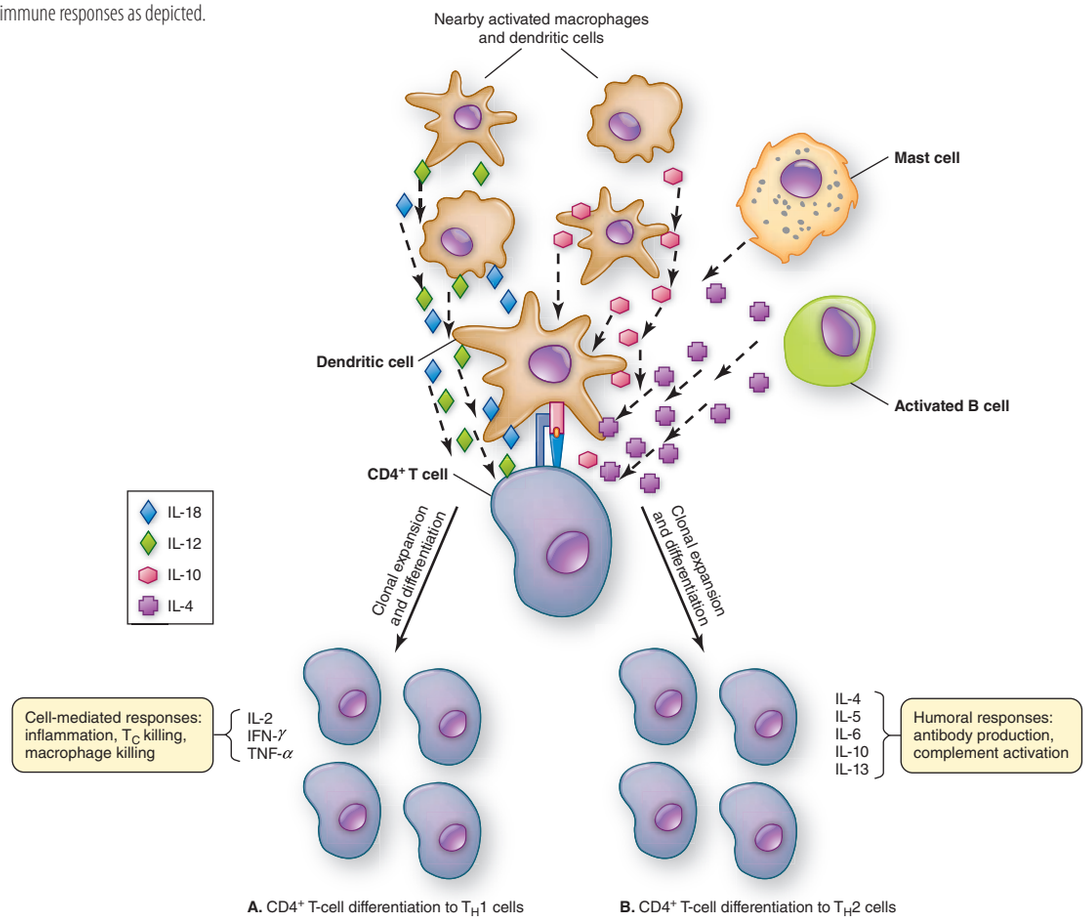

Figure 20.20. Development of a naïve $CD4^+$ T cell into T_H1 or T_H2 cells Activation of a naïve $CD4^+$ T cell begins with interaction with an antigen-presenting dendritic cell (*center*). **A.** Clonal expansion and differentiation of $CD4^+$ T cells into T_H1 cells is decided by the relative concentration of IL-12 and IL-18 produced by neighboring activated macrophages and dendritic cells. T_H1 cells secrete the cytokines IFN-γ, IL-2, and TNF-α involved in cell-mediated responses. **B.** Clonal expansion and differentiation into T_H2 cells occurs in the presence of IL-4, produced by activated mast cells and B cells, and IL-10, produced by nearby activated macrophages and dendritic cells. T_H2 cells secrete cytokines that serve to enhance humoral responses.

antigen challenge. In any case, the innate system has a strong influence on the direction of the adaptive response.

It is logical that cells of the innate system, which first contact foreign substances, should inform the adaptive system on how to destroy those substances. As we have seen in Chapter 19, pathogen-associated molecular patterns (PAMPs) stimulate TLRs at the innate level. As you will recall, TLRs sense the presence of various classes of pathogens and signal directions for adaptive immune responses by triggering signaling pathways that lead to the expression of select groups of cytokine genes that in turn chemically communicate to the $CD4^+$ T cells of the adaptive immune system to differentiate into either T_H1 or T_H2. This appears to be the basis of the humoral versus the cell-mediated decision.

CONNECTIONS TLR stimulation by pathogen-associated molecular patterns (PAMPs) is central in the development of immune responses. See **Section 19.4**.

Once a T_H1 or T_H2 profile has been established, it appears to be self-perpetuating, ensuring other $CD4^+$ T cells undergoing activation are similarly polarized. This is accomplished by the mutually antagonistic effect of some of the cytokines that are involved in polarization. For example, *in vitro* studies have shown IL-4 and IL-10 from T_H2 cells inhibit the production of IL-12 from activated macrophages. In turn, the loss of IL-12 slows production of the cytokines TNF-α, IL-2, and IFN-γ in T_H1 cells. Conversely, IFN-γ from stimulated T_H1 cells inhibits the T_H2 cytokine IL-4 (see Figure 20.19). Thus, the perpetuation of the profile of the cytokine environment guarantees the specific immune response is maintained until the clearance of the pathogen. This "locking in" of a humoral or a cell-mediated immune response may sometimes have negative repercussions, as illustrated in **Perspective 20.1**. The **Mini-Paper** describes the potent ability of IL-4 to maintain suppression of the protective cell-mediated immune response in mice infected with mousepox virus.

Mini-Paper: A Focus on the Research
ATTEMPTING TO ENGINEER A VIRUS TO IMPROVE IMMUNOCONTRACEPTION

R. J. Jackson, A. J. Ramsay, C. D. Christensen, S. Beaton, D. F. Hall, and I. A. Ramshaw. 2001. Expression of mouse interleukin-4 by a recombinant ectromelia virus suppresses cytolytic lymphocyte responses and overcomes genetic resistance to mousepox. J Virol 75:1205–1210.

Context

As we have seen in the opening story of this chapter, mouse plagues in Australia severely impact agriculture, causing extensive losses to grain crops and grain stores. There has been much interest in developing methods to control these rodents, and one idea has been to use the mouses's own immune system to render them infertile. This process, called "immunocontraception," has been used to control populations of other animals in the wild such as deer. One of the most popular cellular targets used in immunocontraception is the zona pellucida protein, which forms a membrane surrounding the oocyte and is involved in binding spermatozoa. This protein has been developed as a drug that causes antibodies to be produced against the animal's own oocytes. Wild animals can be remotely injected using darts. This paper describes experiments performed by Australian scientists that were designed to increase the immunogenicity of a mousepox virus that had been engineered to express the mouse zona pellucida protein.

Experiment

The mousepox virus was engineered with a copy of the mouse cytokine interleukin-4 (IL-4), which is known to boost the production of antibody, and this is the response that was desired by the researchers to maximize the contraceptive effect. Let's take a look at how this recombinant virus was engineered. The mousepox virus has a large genome of 208 kb, and because it is a virus, the genome is packaged into virus particles in the cell and is not found as an extrachromosomal replicon in cells, as plasmids would be. Once extracted from the viral particles, the naked genome cannot be placed back into cells to begin viral replication. Instead, insertion of DNA sequences into the viral genome are first constructed by *in vitro* molecular methods and introduced into these viral genomes by homologous recombination events within the eukaryotic host cell, resulting in recombinant viruses.

Mammalian cells growing in culture are able to produce the essential nucleotide thymidine monophosphate using two alternative pathways: one involving thymidylate synthetase enzyme and the other involving thymidine kinase (TK) enzyme. TK has been developed as a selectable marker, and is commonly used in the construction of recombinant viruses. This gene is naturally present in poxviruses and herpesviruses, and although it is required for reproduction of the virus in animals, it is dispensable for growth in mammalian cell culture. The host TK enzyme is also not required for mammalian cell growth, as long as the thymidine monophosphate pathway is still functional. Conveniently, the thymidylate synthetase pathway, but not the TK pathway, can be inhibited by drugs such as methotrexate or aminopterin, and this provides a method to select for infection of TK^- cells by TK^+ viruses. TK^- viruses can still replicate in TK^- cells in the absence of the inhibitor drugs.

The recombinant virus construction for this study started with a mousepox vector, ECTV-602, which was TK– due to an insertion of the *Escherichia coli lacZ* gene within the TK gene. Mouse TK– cells were infected with this virus, and were subsequently transfected with a previously constructed plasmid pFB-TK-IL4, which contained the IL-4 gene expressed under the control of a viral promoter as well as a TK^+ marker from the herpesvirus HSV. Recombination between

Perspective 20.1
TOO MUCH OF A GOOD THING?

Persons living in tropical areas who are routinely exposed to parasitic helminths, such as threadworms, maintain a humoral response to clear these infections. Recall from Section 19.5 that immunity to large parasites requires production of IgE antibody, which is a humoral response. When exposed to intracellular pathogens, such as *Mycobacterium tuberculosis*, these people appear to have a limited ability to mount a cell-mediated immune response, required for protection from tuberculosis. This may explain the low success rate of the tuberculosis BCG vaccine when used in children living in the tropics, areas prone to nematode infections. The vaccine does not appear to evoke a strong cell-mediated immune response in these children and consequently memory is not produced. Conversely, BCG vaccination programs conducted throughout many European countries since the mid-1900s resulted in very good protection from childhood tuberculosis. It is hypothesized that the protective cell-mediated immunity that is mounted in the majority of BCG-vaccinated persons in European nations is made possible because of the scarcity of parasitic worm infections.

TABLE B20.1 **Virus titers in spleens of C57BL/6 mice seven days after infection with recombinant control ECTV or ECTV expressing IL-4**

Virus	Titer (PFU*g^{-1}) in spleen		
	10^2 PFU	10^3 PFU	10^4 PFU
Control ECTV [ECTV-602(TK^+)]	3.0×10^4	2.8×10^4	1.5×10^2
ECTV-IL4(TK^+)	2.5×10^5	3.5×10^5	6.6×10^7

* Plaque-forming units (see Section 5.3).

the ECTV-602 vector and the plasmid resulted in a recombinant virus designated ECTV-IL4(TK^+) that expressed IL-4 and had a TK^+ phenotype, allowing selection for growth in TK^- cells in the presence of aminopterin.

When this engineered virus was tested on mice by footpad inoculation, it unexpectedly killed them. As shown in **Table B20.1**, the numbers of virions in the spleens of infected animals were much higher after infection with the IL-4-expressing virus ECTV-IL4(TK^+) compared to the control virus ECTV-602(TK^+) that did not express IL-4. Even more surprising, the IL-4 expressing virus killed a large proportion of mice that were immunized with the normal mouse virus and should have been resistant to infection. As we have learned, IL-4 drives the antibody response at the expense of the other arm of the immune system known as the cell-mediated response. This cellular response is involved in the production of cytotoxic T cells that are necessary for killing infected cells to contain the spread of the virus. Without an effective cellular response, the virus was not controlled and high mortality resulted.

Impact

The results from this study were very interesting from a scientific point of view because they directly demonstrated the suppression of cell-mediated immune responses by IL-4 as well as inhibition of memory T-cell development. This study also showed that a single gene could convert a relatively harmless virus to a deadly virus that even killed animals that had been vaccinated. In other words, the pathogenicity of the virus was increased dramatically. Some have called for caution with respect to the development of immune-regulating vaccines. Could immunization with certain vaccines lock in a pattern of immune response when exposed to other microbes? Further research in these areas continues to be very valuable to our understanding of the immune response and disease. This study is surely not the last one to yield surprising and unexpected results. Make sure to read The Rest of the Story to find out more about the controversy that followed the publication of this study.

Questions for Discussion

1. Why was it necessary to carry out the recombinant virus construction using a bacterial plasmid?
2. What aspects of immunology and infectious disease do you think this line of research will help us to understand more completely?

Immune-mediated damage

Whereas the immune response has protective functions against infectious agents, it can also cause damage. For example, *Neisseria meningitidis*, a cause of meningitis, produces severe inflammation of the meninges, the lining that surrounds the brain and spinal cord. The influx of fluid and cells creates excessive pressure that damages the nerves, leading to paralysis and often death. Similarly, the inflammatory damage that occurs with *Neisseria gonorrhoeae* infection can cause sterility (see Section 21.1). Some strains of *Staphylococcus aureus* and *Streptococcus pyogenes* produce toxins called superantigens, which activate large numbers of $CD4^+$ T cells by bypassing the need for specific peptide recognition. The proliferation of activated $CD4^+$ T cells results in excessive production of potent proinflammatory cytokines such as interleukin-1 (IL-1), IFN-γ, and tumor necrosis factor-TNF-α. This produces a systemic inflammatory response (see Section 21.2). Unfortunately, the robust inflammatory response to these infections affords little protection against these pathogens.

Another type of immune damage occurs as a result of the generation of cross-reactive antibodies. These are antibodies produced against a specific microbial component that can also bind to host components with similar epitopes. Infection with certain strains of *S. pyogenes* can lead to rheumatic heart disease after the infection is cleared due to the continued binding of the cross-reactive antibody to heart valves. This is thought to lead to complement fixation and lysis of the tissue, and more inflammatory damage (see Section 21.3). Infection with *Mycobacterium tuberculosis* often causes a chronic cell-mediated response because of the continued release of TNF-α produced by infected macrophages that are unsuccessfully attempting to destroy the bacterial cells The continued inflammatory recruitment of immune cells to the focus of infection results in a pathological lesion, which damages the lung tissue (see Section 21.3).

Viruses can also cause immune-mediated damage to host tissues. Infection by hepatitis B virus itself does not appear to result in any significant cell damage, but liver disease results from the cytotoxic T-cell destruction of infected hepatocytes. Infection with this virus can also cause kidney damage produced by the accumulation of antigen:antibody complexes in the kidney, resulting in capillary blockages and complement activation (see Section 22.2).

In the future, the redirection of an inflammatory cell-mediated immune response to a humoral response may be therapeutic for treating septic shock and chronic inflammatory diseases such as Crohn's disease and ulcerative colitis of the intestine. Similarly, redirection from a T_H2 to a T_H1 response in antibody-mediated autoimmune diseases such as lupus and type 1 diabetes mellitus or allergic diseases such as asthma has the potential to offer valuable treatments for individuals suffering from these ailments. Stimulation of specific sets of TLRs with their ligands has shown promising results in shifting T_H1/T_H2 immune responses.

20.5 Fact Check

1. Compare and contrast humoral responses and cell-mediated responses.
2. Distinguish between T_H1 and T_H2 cells.
3. Describe how the following would work in conjunction to respond to a pathogen: PAMPs, TLRs, cytokines, and $CD4^+$ T cells.

20.6 B cells and the production of antibody

How are antibodies produced?

In Section 20.4 we learned that binding of specific antigen to the BCR is the first step in initiation of B-cell activation. Antigen binding induces the B cell to express MHC II molecules and cytokine receptors on its surface. A striking ability of B cells is that they can recognize protein antigens as well as non-protein antigens such as polysaccharides and lipids. They can also bind *free* antigen; it does not have to be presented to them on MHC molecules. Recall that T cells do not generally have this ability—they are MHC-restricted and so require antigen to be in the form of MHC-bound peptides for recognition. Non-protein components, although they may be taken in and degraded by APCs, are not bound to MHC molecules for presentation.

B-cell response to protein antigens

As we saw in Figure 20.18, BCR-bound antigen is internalized in the B cell by receptor-mediated endocytosis. The next critical step in B-cell activation is antigen-specific binding between the B-cell-presented MHC II:peptide and the TCR of a T_H cell. As we learned in the previous section, bound T_H2 cells are much more effective at stimulating B cells than are T_H1 cells. Binding to a B cell begins a cytokine dialogue that stimulates the T_H2 cell to secrete cytokines such as IL-4 and IL-6, necessary for B-cell clonal expansion and differentiation into antibody-secreting plasma cells (see Figure 20.18). This proliferation and differentiation is absolutely dependent on interaction with T_H2 cells. In presenting antigen to the T_H2 cell, the B cell uses the T_H2 cell for its own proliferation and differentiation for the ultimate purpose of producing antibodies. The interaction between the antigen-specific T_H2 cell and the B cell can be seen as a request for permission to proceed with antibody production. True to the theme of the adaptive immune response, this two-way activation produces a tightly regulated antigen-specific response to invasion. A summary of T-cell and B-cell activation by antigen is given in **Figure 20.21**.

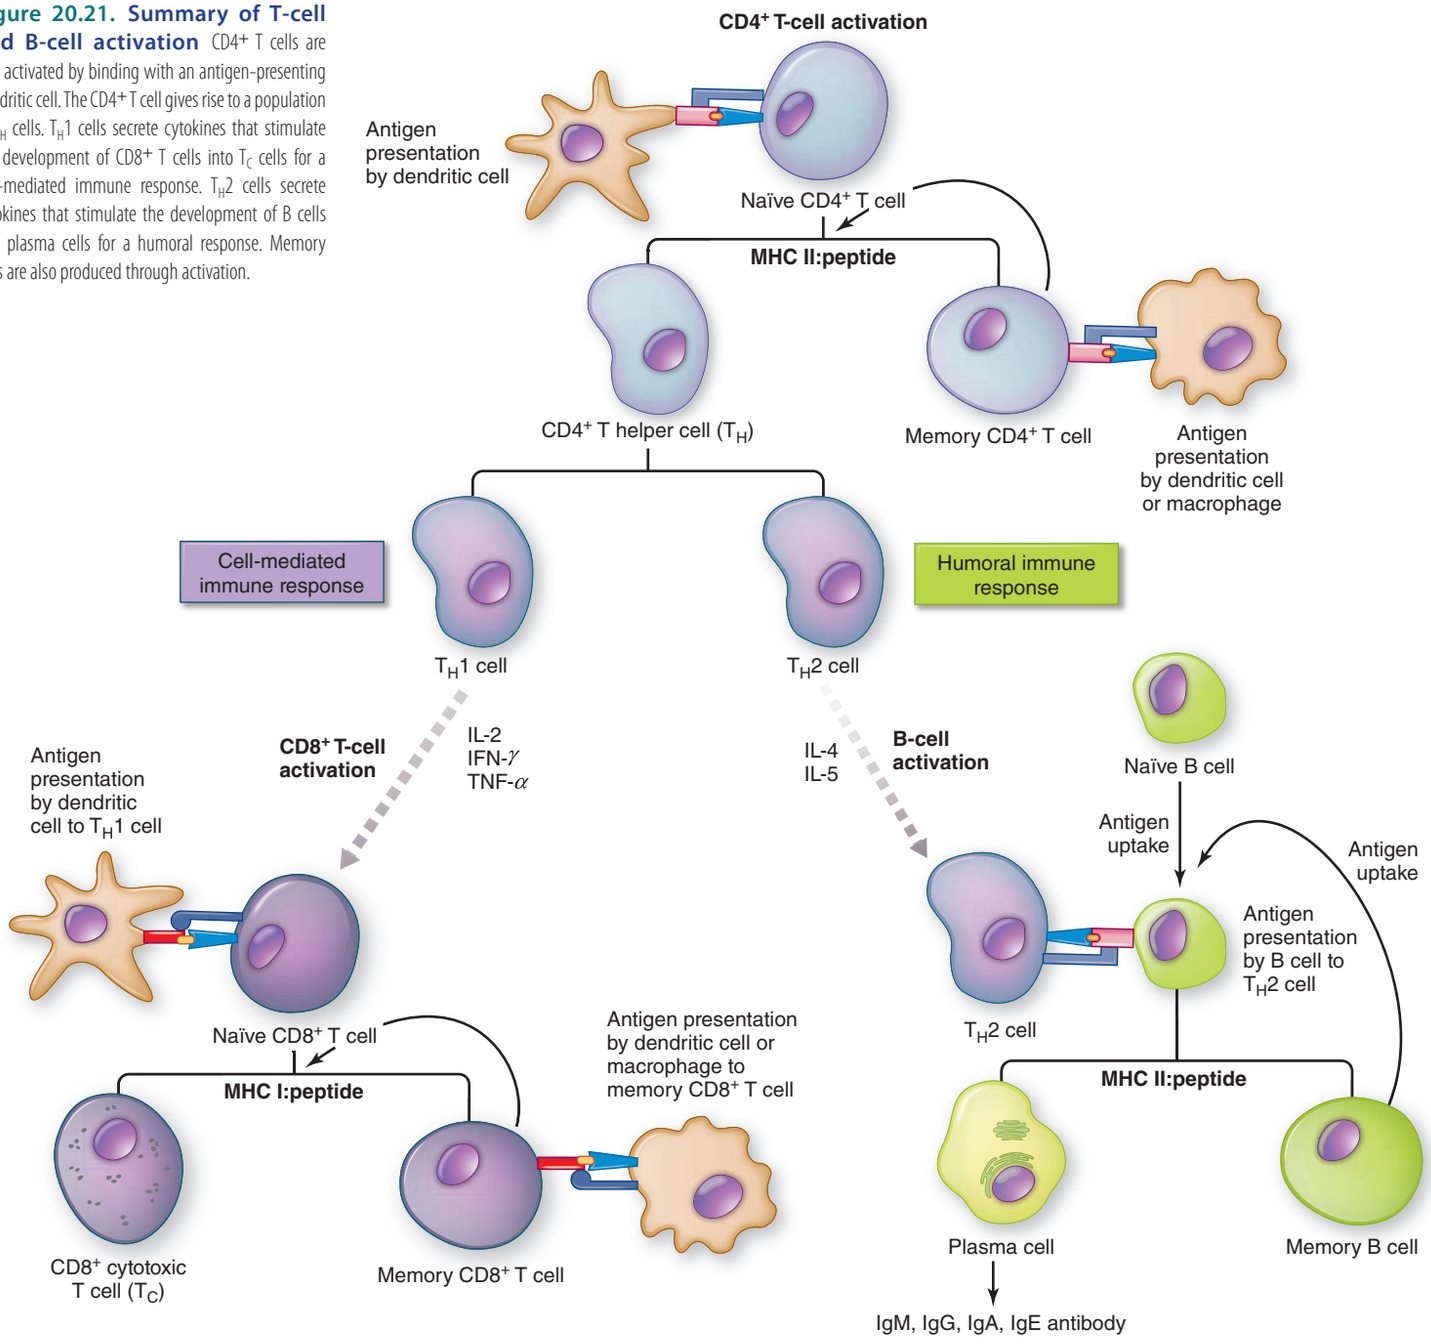

Figure 20.21. Summary of T-cell and B-cell activation CD4+ T cells are first activated by binding with an antigen-presenting dendritic cell. The CD4+ T cell gives rise to a population of T_H cells. T_H1 cells secrete cytokines that stimulate the development of CD8+ T cells into T_C cells for a cell-mediated immune response. T_H2 cells secrete cytokines that stimulate the development of B cells into plasma cells for a humoral response. Memory cells are also produced through activation.

Antibody is a secreted form of the immunoglobulin BCR and therefore has the same epitope specificity. Memory B cells are also produced as a result of activation of B cells with T_H2 cells. They give rise to a memory response when the same antigen is encountered again. **Figure 20.22** shows a humoral primary and memory response. The second encounter with the same antigen results in higher levels of antibody production within a shorter time and of greater duration than the first encounter. Subsequent exposures to antigen often elicit responses that are even faster and of greater magnitude.

The specificity of the immune response means that during a memory response to a particular antigen, exposure to a second, new antigen will generate a primary immune response. The two different antigens are treated as independent events. This means that one may mount a primary immune response at the same time that memory responses are mounted to other antigens.

B-cell responses to non-protein antigens

We have learned that B cells have the unique ability to recognize non-protein antigens such as polysaccharide components of bacteria. Recognition and production of antibody to these non-protein antigens is critical for immunity against many encapsulated pathogens such as *Haemophilus influenzae* **(Microbes in Focus 20.1)** and *Streptococcus pneumoniae* (see

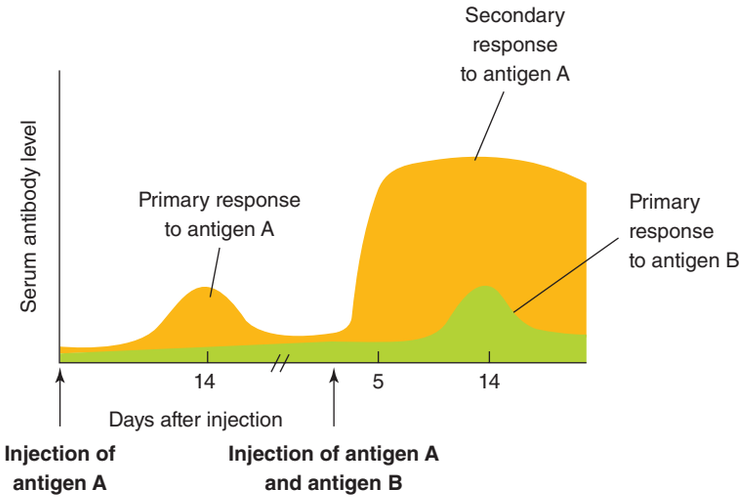

Figure 20.22. The humoral primary and memory response to specific antigen Injection of antigen A into a naïve animal produces a primary humoral immune response of short duration, producing a low amount of antibody that peaks at 10 to 17 days following injection. When injected later with this same antigen, a secondary immune response is induced. This is evidenced by the shortened time it takes to reach peak levels of antibody production (approximately two to seven days) and the much greater amount of antibody produced. The response also lasts longer (months to years). The introduction of antigen B at the same time as the second injection with antigen A illustrates the immune system treats antigen B independently of A, and a primary immune response for B is induced.

Microbes in Focus 7.1), both of which cause meningitis and pneumonia. We have also learned that B cells present peptide antigens, not carbohydrate antigens, to T_H2 cells for antibody production. How then do B cells make antibody to substances such as carbohydrates?

The BCR itself is not restricted to binding peptides. It can bind to non-protein antigens too, as long as the BCR-antigen conformation is compatible. Figure 20.23 shows the process of antibody production to a carbohydrate antigen. When a BCR binds a non-protein antigen, receptor-mediated endocytosis begins. In the process, other molecules—including proteins attached to the carbohydrate or in close proximity—will also be endocytosed. This is a pivotal step for the production of antibody against non-protein components because the peptides can be presented on MHC II molecules to T_H2 cells. Following this, T_H2 cells are stimulated to produce the cytokines needed for clonal expansion and differentiation of the B cells into plasma cells and memory B cells. The role of the protein is to activate the T_H2 cell so that the B cell can proliferate. Because of clonal expansion, the plasma cells produced will secrete antibody specific to the non-protein antigen—the same antigen that was first bound by the BCR of the original B cell. Thus B cells can produce antibody to *any* type of antigen and are not restricted to binding just proteins.

Mice or humans without a thymus cannot produce functional T cells but can sometimes still produce antibody. At first, this seems to pose a dilemma. If antibody production requires T_H2 cells and athymic individuals cannot make mature T cells, how does antibody production occur? Certain types of antigens with highly repetitive structures such as flagellin protein and polysaccharides commonly found in bacterial capsules have the ability to crosslink several BCRs on a single cell at once (Figure 20.24). When a critical number (10–21) of BCRs become linked, the B cell is stimulated to undergo proliferation into antibody-secreting plasma cells without interacting with T_H2 cells. Antigens that can stimulate antibody production without engaging T_H2 cells are called **T-independent antigens**, for thymus-independent antigens.

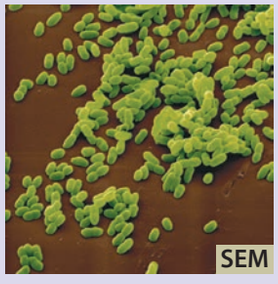
As we have seen in Chapter 2, many capsules are made of carbohydrates. Capsules commonly have the property of preventing phagocytosis, and pathogens possessing capsules are not readily cleared by phagocytes. A critical protective response against such pathogens is production of opsonizing antibodies against the capsule. These coat the capsule to facilitate ingestion by phagocytes. However, waiting for significant antibody levels to be produced by conventional T_H2 interaction can take many days in a primary immune response (see Figure 20.24). Pathogens can quickly reach lethal numbers during this immunological interval. The ability of B cells to begin producing antibody immediately upon contacting these antigens can reduce this time and is often critical for protection from encapsulated pathogens. As described in Perspective 20.2, some pathogens that cause meningitis in children can evade clearing by the adaptive immune system by coating themselves with T-independent antigens. To develop effective vaccines against these pathogens, the capsular polysaccharides are chemically bound, or conjugated, to a peptide antigen to form **conjugate vaccines**. Section 24.5 describes some commonly used conjugate vaccines.

Microbes in Focus 20.1
SLIPPERY *HAEMOPHILUS INFLUENZAE*

Habitat: Strictly human inhabitant carried asymptomatically in the nasopharynx by approximately 40 percent of adults

Description: Gram-negative coccobacillus, 0.3–0.8 μm in length

Key Features: Pathogenic strains all possess one of six different types of capsule carbohydrate. Strains carrying type b capsule cause 95 percent of *H. influenzae* disease in children, predominantly meningitis and pneumonia. The capsule interferes with phagocytosis by preventing C3b opsonization of the bacterial cells (see Sections 19.4, 19.5, and 21.1). Antibody produced against the polysaccharide capsule successfully opsonizes the bacteria and provides protection.



Eye of Science/Science Source

CONNECTIONS Possession of a capsule is a common feature of extracellular pathogens such as *Streptococcus pneumoniae* and *Haemophilus influenzae*. Capsules help pathogens to escape immune detection and avoid phagocytosis. See **Section 21.1** for details.

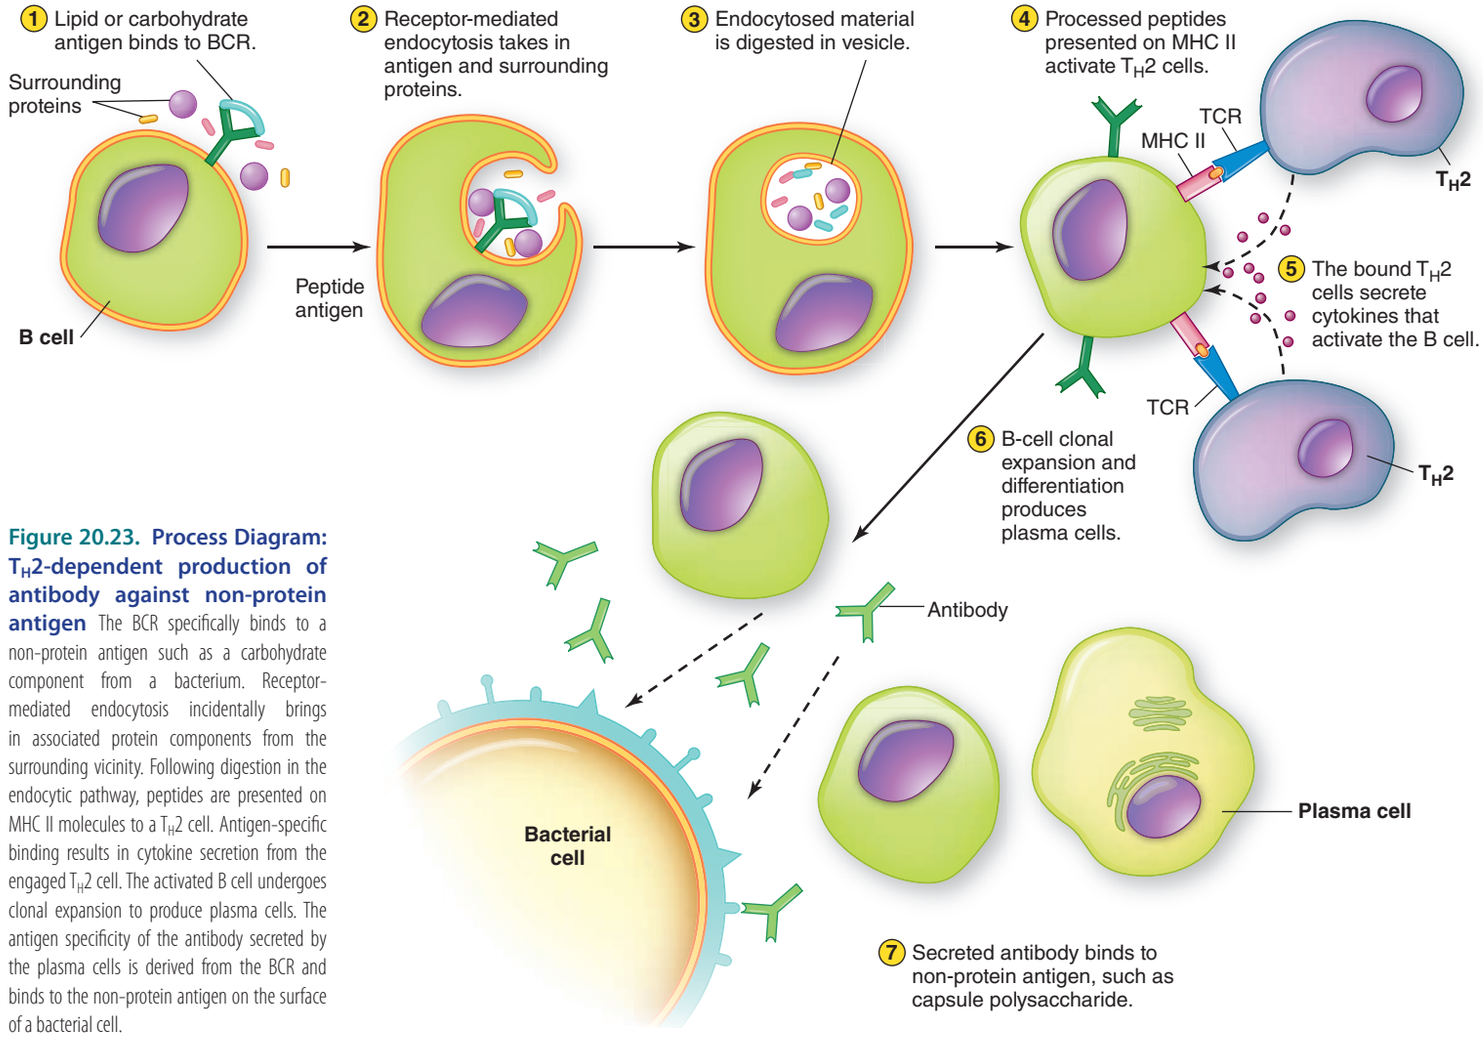


Figure 20.23. Process Diagram: T_H2-dependent production of antibody against non-protein antigen The BCR specifically binds to a non-protein antigen such as a carbohydrate component from a bacterium. Receptor-mediated endocytosis incidentally brings in associated protein components from the surrounding vicinity. Following digestion in the endocytic pathway, peptides are presented on MHC II molecules to a T_H2 cell. Antigen-specific binding results in cytokine secretion from the engaged T_H2 cell. The activated B cell undergoes clonal expansion to produce plasma cells. The antigen specificity of the antibody secreted by the plasma cells is derived from the BCR and binds to the non-protein antigen on the surface of a bacterial cell.

Activation of B cells with T-independent antigens is generally weaker than activation by T_H2 cells. As a result, memory B cells are not formed and fewer antibodies are produced. Also, the type of antibody that is first produced, called IgM (immunoglobulin M), is of relatively low affinity and does not bind antigen strongly. Large amounts of high-affinity antibody, called IgG (immunoglobulin G), and memory B-cell production requires T_H2-dependent interaction. Examination of the different types of antibody produced by B cells will be our next topic.

Antibody production by plasma cells

Plasma cells are antibody factories, possessing large amounts of cytoplasm to accommodate the high levels of translation and secretion needed to turn out great numbers of antibody molecules, estimated at up to 2,100 molecules per second per cell (Figure 20.25). Plasma cells become terminally differentiated

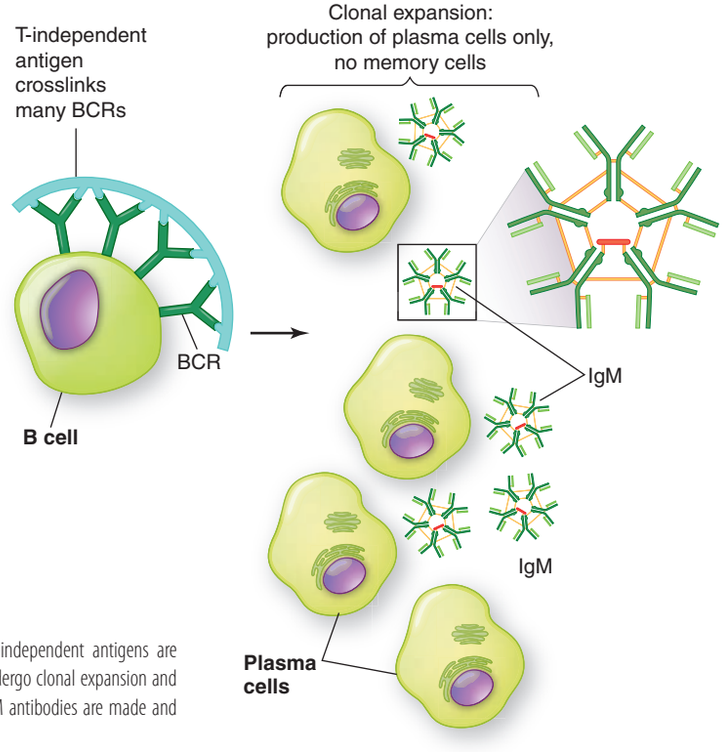

Figure 20.24. Activation of a B cell by a T-independent antigen T-independent antigens are highly repetitive in structure, allowing crosslinking of many BCRs on a B cell. Linking activates the B cell to undergo clonal expansion and differentiation into antibody-secreting plasma cells without the help of T_H2 cells. Low-affinity pentameric IgM antibodies are made and memory B cells are not formed.

Perspective 20.2
VACCINES AGAINST T-INDEPENDENT ANTIGENS

Pathogenic strains of *Streptococcus pneumoniae, Haemophilus influenzae*, and *Neisseria meningitidis* all possess capsules and are major culprits in meningitis. There are approximately 90 different serotypes of *S. pneumoniae*, six major strains of *H. influenzae*, and six major strains of *N. meningitidis*, based on differences in the polysaccharides that make up the capsules. The capsule interferes with phagocytosis by preventing C3b opsonization of the bacterial cells (see Sections 19.4 and 19.5). Protection against these strains is totally dependent on host production of antibody specific to the capsular polysaccharide. Capsular polysaccharides with their repetitive structure are T-independent antigens. The T_H2-independent response is of major importance in disease protection from these pathogens. Those who can mount this response have substantially less risk of developing serious disease and permanent disabilities such as deafness, which often results if they recover. The group at greatest risk is young children. Why? It seems that young children under five years of age do not have the full complement of all the subpopulations of B cells found in mature immune systems. Before this age, B cells do not respond well to T-independent antigens. However, young children can mount conventional T_H2-dependent antibody responses.

Vaccinating infants involves using conjugate vaccines, capsular polysaccharides that are conjugated to foreign protein molecules such as inactivated diphtheria toxin (see Section 21.2). The addition of a protein to the target antigen essentially converts the polysaccharides from T-independent antigens to T-dependent antigens. The peptide addition is now displayed by the B cell on MHC II molecules, resulting in antibody production to the capsular polysaccharide in a T_H2-dependent manner. This provides protection for young children by producing immunological memory to the capsular polysaccharide. Immunized children can quickly mount a protective antibody response when they encounter *S. pneumoniae*, *H. influenzae*, or *N. meningitidis*. Currently, the conjugated vaccines used in children for protection against *S. pnuemoniae* include only thirteen of the nearly 90 different polysaccharide types (see Figure 24.17). For *H. influenzae*, the vaccine contains a single species of conjugated type B capsular polysaccharide. These are the most prevalent polysaccharides found in pathogenic strains of these bacteria. The conjugated vaccines are routinely given a few weeks after birth; their widespread use has extensively reduced the incidence of serious disease in very young children. The most recent *N. meningitidis* vaccine, currently used in children, contains a mixture of four conjugated capsular polysaccharides.

and cannot undergo cell division. All plasma cells are produced from the proliferation and differentiation of activated naïve or memory B cells. Plasma cells undergo apoptosis after about two days, but the antibodies they secrete are often quite stable and can remain in circulation for many weeks.

All the antibodies produced from a single plasma cell are identical to each other. They can bind to only a particular epitope on an antigen. Recall that antibody is a secreted form of the immunoglobulin BCR, so it has the same specificity for epitope as the original BCR. Again, this specificity is genetically predetermined from the original maturation events involving gene rearrangements in individual B cells. Different epitopes are bound by different antibodies, produced from different plasma cell populations **(Figure 20.26)**.

The ability of individual antibody molecules to bind to a specific epitope makes antibodies useful tools for isolating and detecting a specific antigen from a complex mixture. To produce a single species of antibody in large amounts, a single

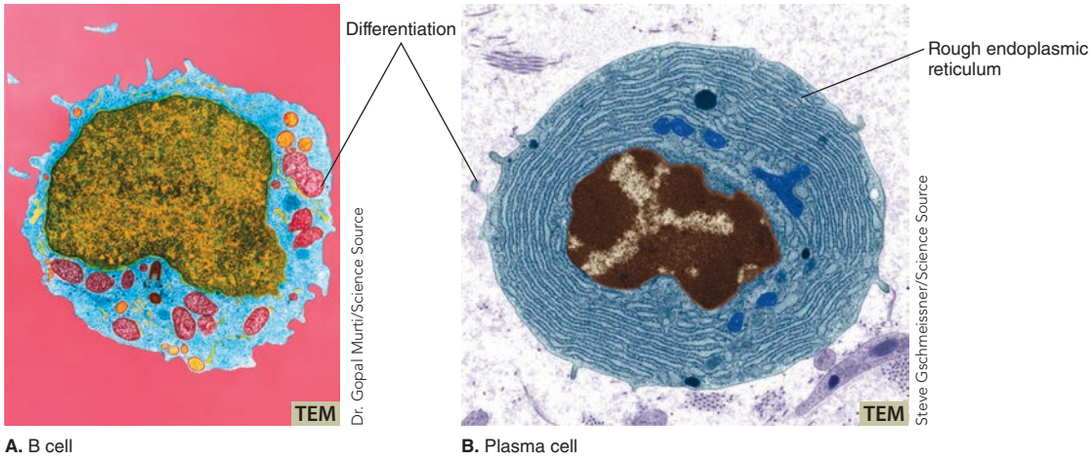

Figure 20.25. B cell and plasma cell **A.** The B cell shows a small amount of cytoplasm surrounding the large, dark nucleus. **B.** The plasma cell shows elaborate rough endoplasmic reticulum and extensive cytoplasm to accommodate large amounts of antibody production.

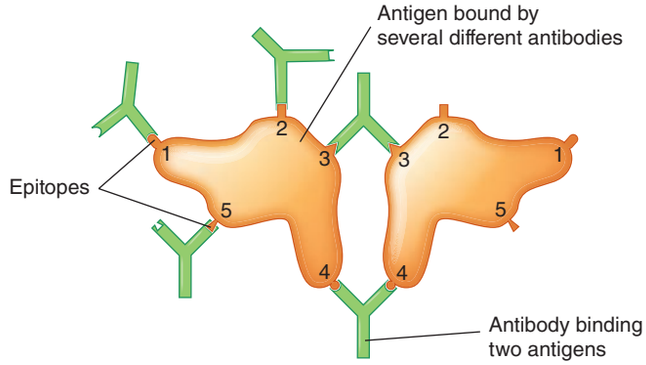

Figure 20.26. Many epitopes exist on a single antigen. Epitopes 1 to 5 are regions of the antigen that are actually bound by immunoglobulin (antibody is shown here). Different epitopes are bound by different antibodies as dictated by the specificity of the antigen-binding site. A single antigen can be bound by five different antibodies, recognizing five different epitopes, and a single antibody can bind two antigens possessing the same epitope.

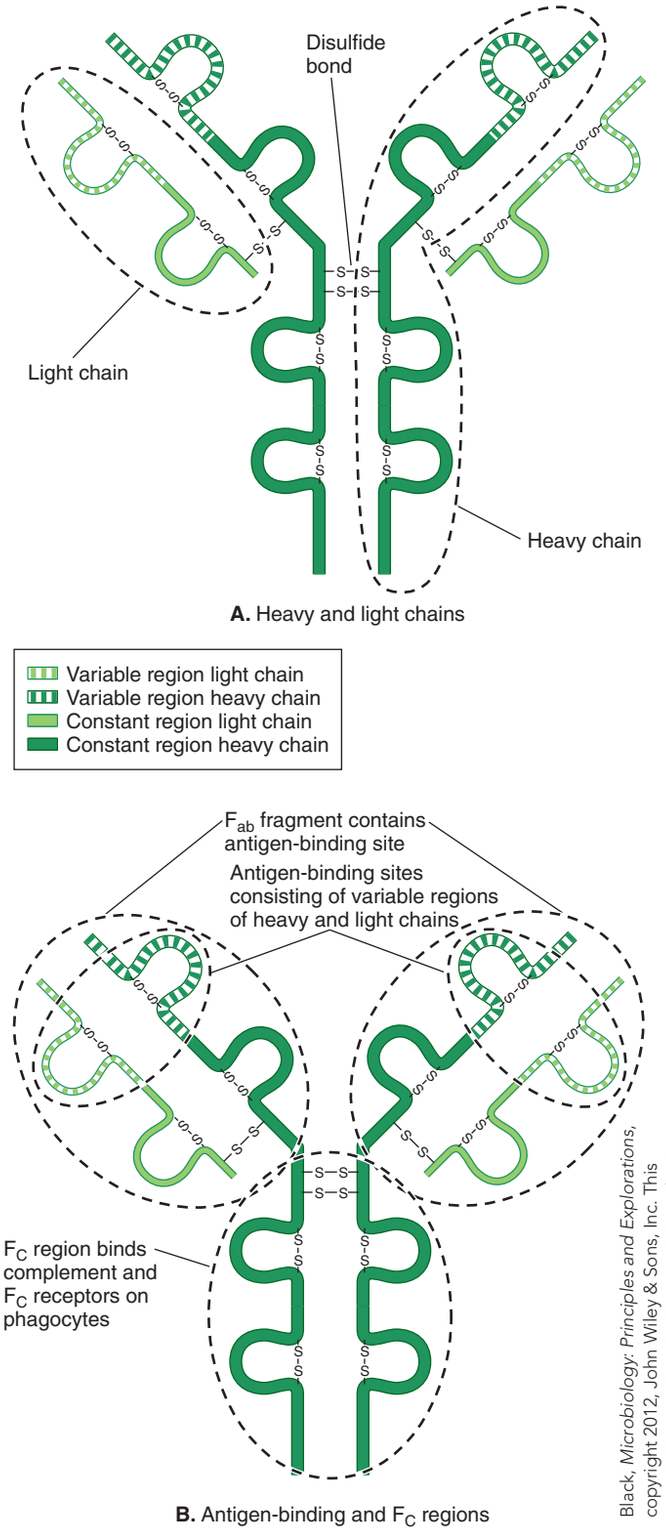
antibody-secreting plasma cell could be isolated and cloned in the lab to provide a ready source of specific, homogeneous antibody termed **monoclonal antibody (mAb)**. This may sound simple enough but a complication arises because antibody-producing B cells are short-lived, dying in seven to ten days, and so cannot be sustained in culture. In 1975, Cesar Milstein and Georges Kohler, working at the University of Cambridge, figured out how to make hybrid B cells called "hybridomas," which could be cultured to provide mAb. For this milestone discovery, they won the Nobel Prize in Physiology or Medicine in 1984. **Toolbox 20.1** describes the method for producing hybridomas and mAb, and discusses some of the applications of mAb technology.

Immunoglobulin structure and diversity

A molecule of IgG antibody is made up of four polypeptide chains: two identical "light" or short chains and two identical "heavy" or large chains **(Figure 20.27)**. The chains each possess several internal disulfide bonds, and disulfide bonds also exist between the chains, holding them together. The numerous disulfide bonds stabilize the molecule, making it resistant to denaturation and proteolysis. Antibody can therefore remain functional for long periods of time in the body. In fact, the half-life for IgG is approximately 20 days in serum.

Each IgG molecule is roughly Y-shaped, consisting of two F_{ab} (fragment, antigen-binding) portions that contain an antigen-binding site each, allowing for a single antibody to simultaneously bind two identical epitopes of one or two antigens. The actual site involved in antigen binding consists of the variable (V) regions of a heavy and a light chain. Sequence variation in just this small area of the genes encoding the heavy and light chains takes place in B cells to produce a variety of antibody specificities. This results in different amino acids in the variable regions that determine the specificity of epitope binding. The remainder of the light and heavy chains consists of constant (C) regions, so named because the amino acid sequence in these regions is always the same among IgG molecules. The base of the Y comprises the F_C site. This site also has important biological properties, as we will see.



Black, *Microbiology: Principles and Explorations*, copyright 2012, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 20.27. Immunoglobulin G (IgG) **A.** The IgG molecule is made up of two identical light chains and two identical heavy chains, held together by disulfide bonds. The heavy and light chains also have internal disulfide bonds. Each light chain consists of a variable (V) region and a constant (C) region. Each heavy chain consists of a V region and three C regions. **B.** The antigen-binding site consists of the V regions of a heavy and light chain. IgG fragmented by treatment with the protease papain yields three fragments; two of these fragments are called the F_{ab} portions, forming the branches of the Y, and are associated with antigen binding. The F_{ab} fragments are composed of one C region and one V region of a heavy and a light chain held together by disulfide bonds. Each antibody has two F_{ab} portions and can simultaneously bind two identical epitopes. The third fragment is the F_C (fragment crystallizable) portion of the antibody. It possesses biological functions such as complement binding and interacting with F_C receptors of phagocytes.

Toolbox 20.1
MONOCLONAL ANTIBODY (mAb) PRODUCTION

The general procedure for production of monoclonal antibody is outlined in **Figure B20.1**. First, a mouse is inoculated with antigen against which the mAb is to be directed. Next, the mouse is tested for production of antibody to the antigen. This can be done with a simple blood test using an indirect ELISA test, described in Toolbox 20.2. The mouse is next euthanized and B cells are collected from the spleen. Antibody-producing B cells are short-lived and cannot be cultured indefinitely. To prevent death and to allow the B cells to continue

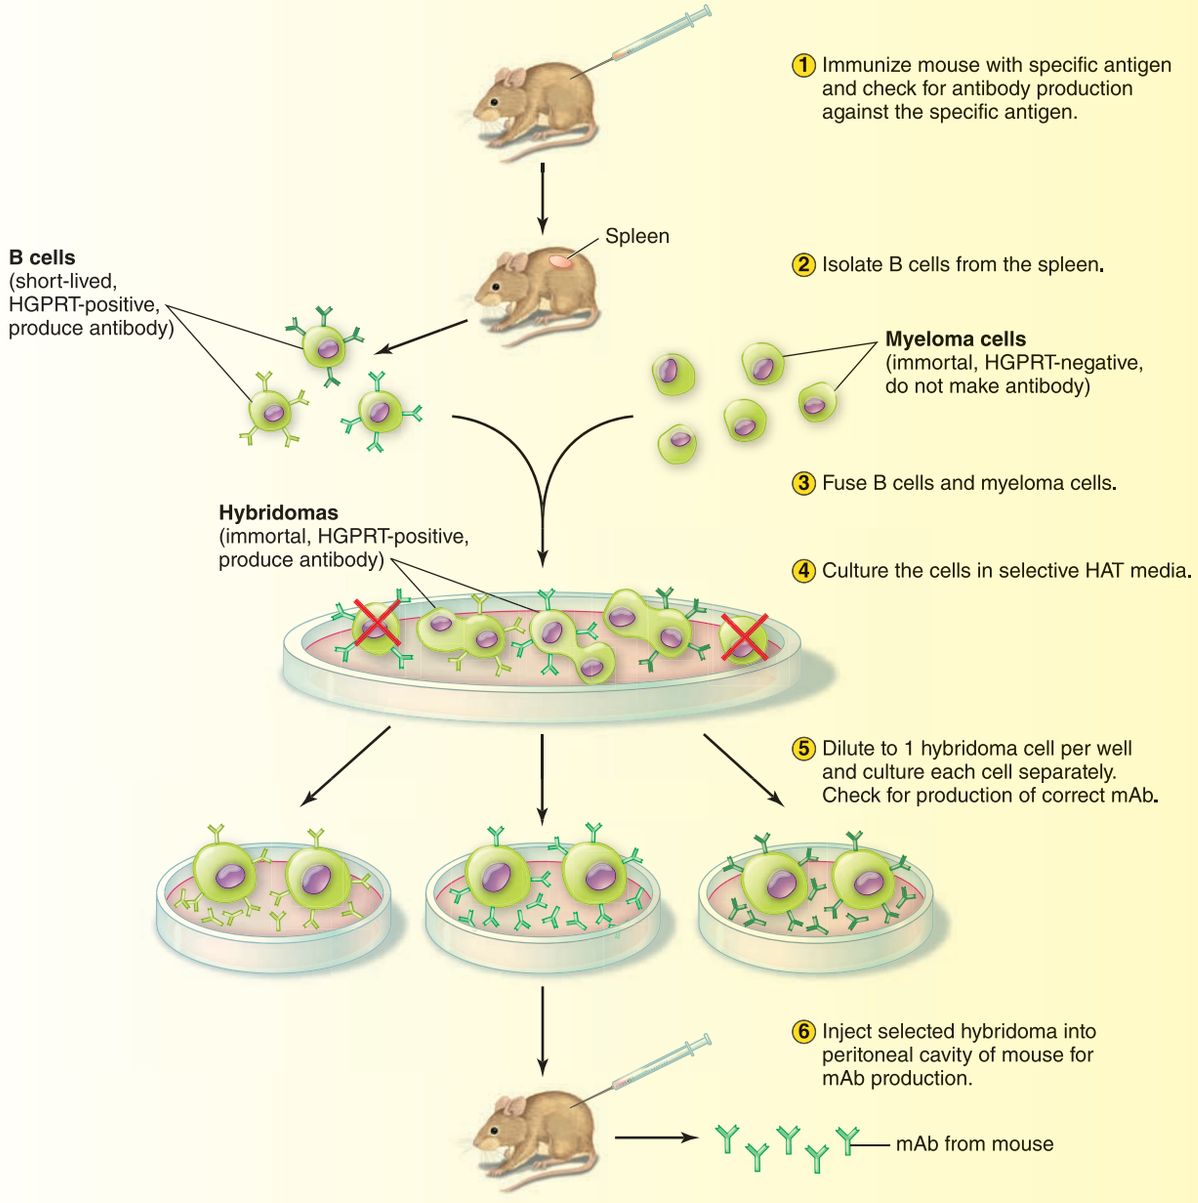


Figure B20.1. Process Diagram: Procedure for monoclonal antibody (mAb) production Mice are inoculated with the antigen to which the mAb is to be formed. B cells, which produce antibody but are short-lived, are harvested and fused to myeloma cells to impart immortality. The hybridomas are selected on special medium containing hypoxanthine, aminopterin, and thymidine (HAT). Only the hybridomas will survive as they possess the enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT) from the B cells and are long-lived. Hybridoma clones producing mAbs that bind the antigen are isolated. Selected hybridomas are individually seeded in the peritoneal cavity of another mouse where they will grow into a population of identical cells producing a single type of mAb.

replicating to produce antibody, the B cells are fused to myeloma cells. These are transformed B cells that do not produce their own antibody but are immortal—they have undergone mutations that allow them to continue to replicate indefinitely. Fusion of the two cell types produces a hybridoma that has the antibody-secreting characteristics of the original B cell and the ability to continue to replicate, conferred by the myeloma cell. Union of the cells is accomplished by adding polyethylene glycol (PEG), which facilitates membrane fusion.

Of course, the mix of B cells, myeloma cells, and hybridomas means there must be a way to select only the hybridoma cells. Elimination of the myeloma cells is accomplished by using a line of myeloma cells that are defective for the enzyme hypoxanthine-guanine phosphoribosyltransferase (HGPRT). When grown in the presence of culture media containing the compounds hypoxanthine, aminopterin, and thymidine (known as HAT medium), cells lacking the HGPRT gene cannot survive and thus die upon incubation. As shown in **Figure B20.2**, aminopterin blocks synthesis of GTP and TTP needed for DNA synthesis. Thymidine allows for TTP production. Cells producing HGPRT can use hypoxanthine to make GTP.

B cells produce HGPRT but are short-lived and will die in all growth media. Myeloma cells lack the HGPRT enzyme and cannot use hypoxanthine; thus they cannot synthesize GTP and will die in HAT medium. The hybridomas contain a functional HGPRT gene from the B-cell genome and are conferred with the ability to replicate indefinitely from the myeloma genome, and so they will be the only cell type to survive prolonged incubation in HAT media.

A collection of different hybridomas will result after selection and must be screened to see which are producing an antibody to the original antigen. The hybridomas collected from the HAT media are diluted to an appropriate concentration such that each well into which they will be placed contains a single hybridoma cell. The diluted cells are transferred to individual wells of a multiwell culture plate and are allowed to grow. The culture supernatant is collected and tested for the presence of antibody to the antigen. Again, this can be done using an ELISA test (see Toolbox 20.2). As all the cells in a single well are clones, they produce only one species of mAb capable of recognizing a single epitope. The individual mAbs are screened for specificity and binding strength to the target antigen before large-scale culture.

Hybridomas have been notoriously difficult to culture in large amounts *in vitro*, and consequently mAb production in cell culture is often suboptimal. Because of this it is usually more cost-effective to use a live mouse or a rabbit as a culture vessel. The chosen hybridoma line is injected into the peritoneal cavity of the mouse and grows as a tumor, pumping mAb into the peritoneal fluid, which can be harvested after killing the mouse. Improved techniques for *in vitro* culture of mAb and recombinant technologies using cloned antibody gene fragments expressed using phage or yeast are soon to replace this method.

Monoclonal antibodies are useful because they ensure maximum specificity for the target antigen, which eliminates or reduces binding with related antigens that may be present. Monoclonal antibody technology is being used in medicine for therapy against chronic inflammatory diseases such as intestinal Crohn's disease. In this case, delivery of a mAb against the proinflammatory cytokine tumor necrosis factor-alpha (TNF-α; see Chapter 19) can greatly improve the patient's condition. For research and commercial purposes, mAbs are frequently used for detection and purification of proteins and virtually any other substance to which an antibody can be made. As Toolbox 20.2 shows (see direct ELISA), the specificity of mAbs makes them invaluable reagents for testing samples for the presence of enzymes, hormones, infectious agents such as HIV, and toxins such as pesticides.

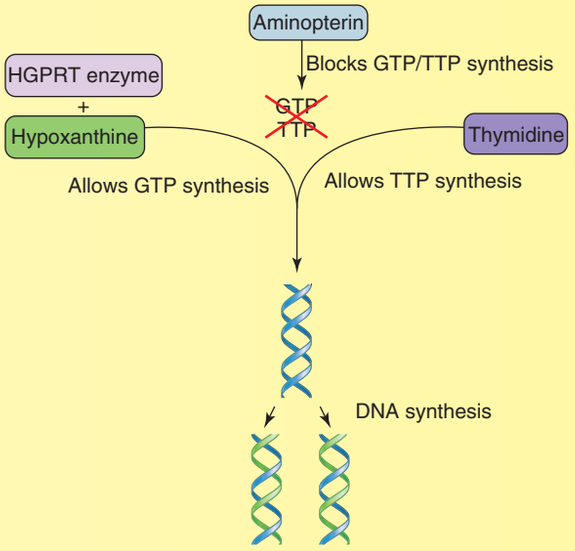

Figure B20.2. Selection for hybridomas In the presence of medium containing hypoxanthine, aminopterin, and thymidine (HAT medium), only hybridomas are able to replicate. They possess the gene encoding HGPRT from the fused B cell, which allows them to synthesize GTP for DNA synthesis. They also possess the ability to replicate from the fused myeloma cell.

Test Your Understanding

Imagine the HAT medium being used in your lab was mistakenly prepared without hypoxanthine. What effects would this have during the preparation of your hybridomas? Explain.

Generation of Immunoglobulin Diversity

In a human, it is estimated that between 10^6 and 10^8 different antibodies can be produced. Given that there are only about 15,000–20,000 genes in the human genome, what accounts for such diversity? Generating this astounding repertoire is accomplished through a series of recombination events involving just a few gene regions. Humans, like most mammals, have two different copies of the light-chain coding region, or locus, in DNA. As shown in **Figure 20.28**, one copy exists on chromosome 2 and is called the kappa (κ) locus. The other is on chromosome 22 and is called the lambda (λ) locus. Each mature B cell expresses either κ or λ light chains, producing a ratio of approximately 60 to 40, respectively, in humans. Each light-chain locus contains numerous V (variable) gene regions, about 40 for each κ and λ region, and multiple J (joining) segments for joining V and constant (C) regions together by recombination. There is one C region for the κ locus and four C regions for the λ locus. The single heavy-chain locus is on chromosome 14. The heavy-chain locus has five C regions, each of which determines the class of antibody produced, that is, IgA, IgD, IgE, IgG, or IgM. The heavy locus also contains about 65 V regions, 6 J regions, and 65 D (diversity) regions. The V, J, and D regions all form the variable region of the heavy-chain polypeptide. The D regions are not found in light chains.

To understand how the recombination events produce different immunoglobulin outcomes, we can briefly examine the assembly of just one chain in a developing B cell: the κ light chain. In the assembly of the variable region, one randomly selected V gene segment is joined to one of the five J (joining) segments adjacent to the light-chain constant (C) gene segment. Several successive recombination events produce a single continuous DNA region for expression of the κ light chain **(Figure 20.29)**. Following transcription, the pre-mRNA is spliced and the exons of the V, J, and C regions are joined to form a continuous coding region for translation into the final κ light chain polypeptide. Lambda light chains and heavy chains undergo recombination events in a similar manner. The final immunoglobulin is constructed of two identical heavy chains and two identical light chains held together by disulfide bonds. The specificity of antigen binding is determined by the combination of the light-chain V region and the heavy-chain V region of the immunoglobulin. Gene rearrangement occurs in a similar manner for generating diversity in TCRs of T cells. Mature B cells leave the bone marrow, each with their unique

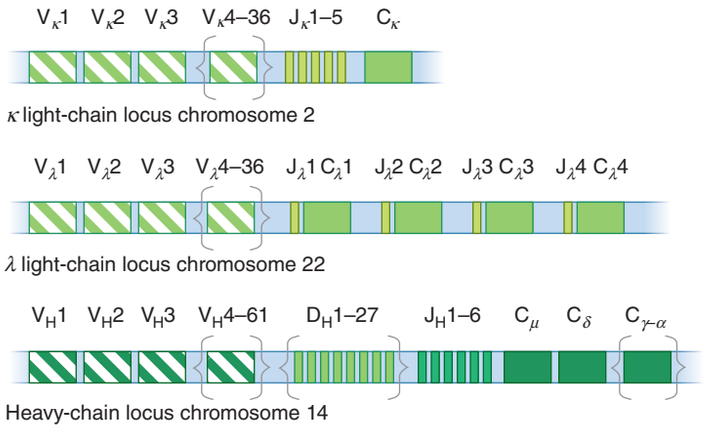

Figure 20.28. Arrangement of immunoglobulin light- and heavy-chain loci in germline DNA The two light-chain loci are located on different chromosomes and vary from each other in V, J, and C regions. The heavy-chain locus is located on a third chromosome and has an additional region, the D (diversity) region, that forms part of the V region of the heavy chain. Heavy-chain C regions determine the class of antibody that will be produced; IgM uses $C\mu$, IgD uses C_δ, IgG uses $C\gamma$, IgE uses $C\varepsilon$, and IgA uses $C\alpha$. These loci undergo recombination only in maturing B cells to produce a diverse population of immunoglobulins.

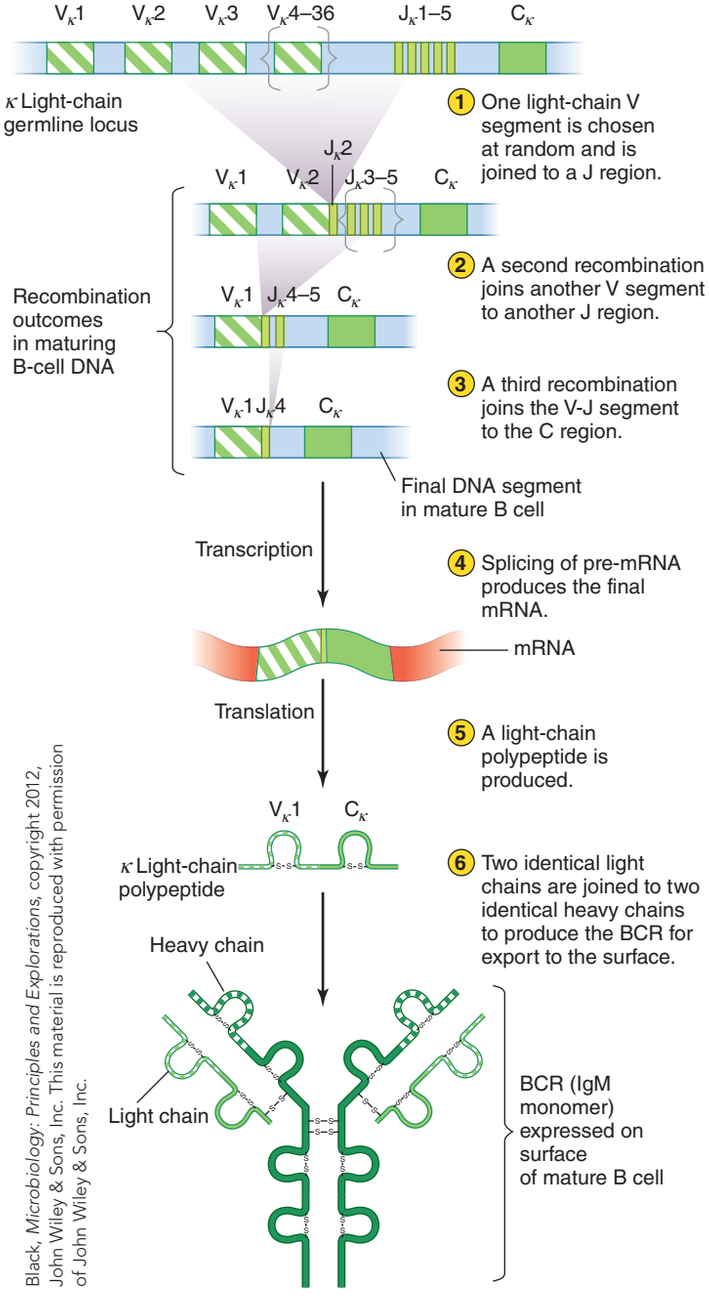

Figure 20.29. Process Diagram: Immunoglobulin κ light-chain formation Recombination events join one of several light-chain V gene segments to one of several J regions that are located adjacent to the κ chain C gene. Lambda light chains and heavy chains are built in a similar manner from different DNA locations, similarly encoding a variety of gene segments. Together, the light-chain V region and the heavy-chain V region determine the specificity of antigen binding.

BCRs. Presentation of peptide antigens and binding to a T_H cell leads to B-cell activation and further changes in the immunoglobulin molecule. These include antibody class-switching and affinity maturation.

Antibody Class-Switching

B cells, unlike T cells, do not proliferate in a perfectly clonal manner. The first class of antibody to be secreted in a primary immune response is immunoglobulin M (IgM) (Table 20.4). As the antibody that is produced is a reflection of the membrane-bound BCR, it follows that the BCR of naïve B cells is therefore a membrane-bound version of IgM monomer. As B-cell clonal expansion and differentiation progresses, a new type or class of antibody, such as IgG, IgA, or IgE, is synthesized. This is referred to as **class-switching**. As shown in Table 20.4, each antibody class has different characteristics and somewhat different functions so the humoral response can be tailored to the specific type of pathogen. The class of antibody produced is determined by the structure of the heavy-chain constant region and appears to be influenced by the cytokine environment of the B cell at the time of activation. A new antibody class is generated by joining the existing variable region with a new heavy-chain constant region.

TABLE 20.4 Classes of secreted antibody and their main functions

Class	Structure	Features	Primary functions
IgA	 Dimer	Secretory antibody of mucosal membranes, tears, milk, saliva	Agglutination of antigen; binding to phagocyte F_C receptors for phagocytosis
IgE	 Monomer	Binds surface receptors of mast cells and basophils	Crosslinking with antigen induces degranulation in mast cells, eosinophils, basophils; involved in parasitic infections and allergic reactions
IgG	 Monomer	Major antibody in serum; crosses placenta	Complement activation; opsonization for phagocytosis; toxin neutralization; ADCC killing by NK cells
IgM	 Pentamer	First antibody made in primary immune response; present in serum	Complement activation; agglutination of antigen for phagocytosis

Black: *Microbiology: Principles and Explorations*, copyright 2012, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

IgM

Secreted IgM is a very large molecule composed of five monomer units joined together by disulfide bonds and a small polypeptide. This multimeric structure provides exceptional capacity to simultaneously bind several identical epitopes at once, resulting in maximum agglutination of particles to help prevent dissemination of the pathogen and assist in phagocytosis. IgM also fixes complement very efficiently. These characteristics make it well suited for collecting and lysing pathogens present in an infected area. Low amounts of IgM in the serum can bind and fix complement more effectively than similar amounts of IgG. This is especially important early in infection, when serum antibody levels are low.

IgG

IgG is the major antibody present in serum. It is a monomer, and because of its relatively small size, it readily enters tissues and diffuses quickly to move out to contact antigen. Its small size also allows it to cross the placenta to provide protection against infections in newborns. As the antibody is not of the newborn's own making, this immunity is referred to as passive immunity.

IgA

The majority of IgA is produced as a dimer, made of two units held together by a small polypeptide chain. Dimerized IgA is secreted from mucosal surfaces and into body fluids such as tears, saliva, and milk. IgA in milk provides passive immunity for the newborn. It is the most abundant class of antibody produced by the body. It is estimated that the average adult human secretes between 5 and 15 g of secretory IgA a day! Lesser amounts of monomer IgA can be found in serum. As we learned in Chapter 19, mucosal surfaces are a main contact and entry surface for pathogens. Because of its dimeric form, secretory IgA can effectively agglutinate pathogens at these surfaces, preventing their binding to host cells and collecting them within the mucus for elimination.

IgE

IgE is a monomer normally produced in very small amounts. It is a potent initiator of degranulation of mast cells and basophils of the innate system. Although release of the granular contents of these cells has beneficial effects for protecting against parasitic worms that are too big to be phagocytosed, this can also induce allergic reactions. This is principally due to the effects of vasodilation and smooth muscle contraction produced by histamine and other potent effectors of inflammation. Allergens such as pollen stimulate the production of IgE rather than IgG from B cells. The cause of this is not precisely known but appears to involve a defect in cell regulation of antibody production. Just like parasites, allergens crosslink the IgE molecules on the surface of basophils and mast cells, signaling the cell to degranulate.

IgD

IgD is a monomer that is co-expressed along with IgM on the surface of mature B cells prior to class-switching. It is not normally secreted and its functions have not been characterized.

Affinity Maturation

Another amazing consequence of the activation of B cells by T_H2 cells is **affinity maturation**, which progressively increases the binding strength of the immunoglobulin for its epitope. As B-cell proliferation and class-switching occurs, random mutations in the variable region of the genes encoding the heavy and light chains take place. This limited mutation, referred to as "somatic hypermutation," generates a population of B cells that produce BCRs that differ in just one or a few amino acids in the variable portion of the chain. The result is a collection of B cells that have slightly different affinities for the same epitope. The specificity is maintained, but the binding strength varies. Those cells with very-high-affinity BCRs bind epitope more tightly when it is encountered. This produces a stronger and more prolonged B-cell stimulation, resulting in more expansion of this particular population. Consequently, they out-compete B cells with weaker-affinity BCRs. Affinity maturation results in a population of B cells that have "learned" to better recognize the pathogen. The antibody that is produced during a humoral response therefore progressively increases in binding strength; it adapts to the antigen. This selection is akin to Darwin's process of natural selection, resulting in adaptation and increased replication fitness. The memory B cells produced also increase in fitness, expressing BCRs with very high affinity. Upon second encounter with the same antigen, this stronger binding of the BCRs stimulates more B-cell proliferation, producing more memory B cells, more plasma cells, and therefore more antibody. The antibodies that result bind much stronger than those that are first produced in a primary response. Even at low concentrations, they are very effective in binding antigen. They come out of the gate running, which contributes to the overall efficiency of the humoral response in clearing infections.

Detection of specific antibody, commonly from a blood sample, is a valuable diagnostic indicator of recent exposure to pathogens. Quantitation of antibody levels and detection of the different classes of antibody can give further information as to the immune status of an individual. For example, detection of IgM indicates a very recent infection, resulting from a primary exposure. A simple test that detects antibody in a serum sample is the indirect **enzyme-linked immunosorbent assay (ELISA)**. Another use of antibody is for the direct ELISA. A direct ELISA takes advantage of the ability of antibody to specifically bind to its target antigen and can be used for the identification of almost any substance such as an illegal drug or an environmental contaminant to which an antibody can be made. These two ELISA tests are described in **Toolbox 20.2**.

Protection by antibodies

How does antibody binding protect the host from infection? Protection is achieved in several ways, depending on the type of antibody. Binding of an antigen by antibody can result in:

- Prevention of binding of pathogens or action of toxins on host cells.
- The fixation of complement causing lysis of microbial membranes.

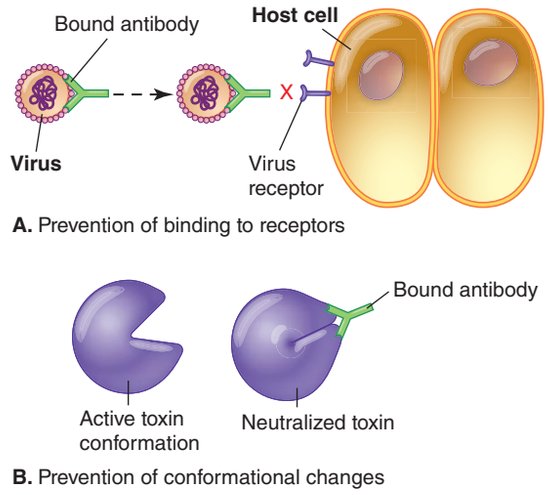

Figure 20.30. Antibody neutralization of pathogens and toxins **A.** Binding of antibody can physically block agents (virus shown here) from binding to receptors on host cells. **B.** Antibody binding to foreign agents such as viruses and toxins can neutralize their activity by preventing them from undergoing conformational changes needed for their activities.

- The opsonization of pathogens to facilitation of phagocytosis.
- Agglutination (clumping of antigen) for prevention of dissemination and facilitation of phagocytosis.
- Activation of eosinophils, basophils, and mast cells.
- Destruction of infected cells by NK cells using ADCC-mediated killing (see Figure 19.21D).

Many pathogens and toxins require specific receptors to attach to host cells for colonization or uptake. Binding of antibody to their surface can physically block their ability to bind to these receptors and can also constrain the ability of toxins and viruses to undergo necessary conformational changes needed for their activity, thus neutralizing them **(Figure 20.30)**. This is similar to attaching a padlock to a door to prevent it from opening. Bound antibodies can also activate the complement cascade by the classical pathway, resulting in disruption of the viral or bacterial membrane by formation of the membrane attack complex (MAC) as shown in **Figure 20.31**.

CONNECTIONS Complement is an important innate first line of defense against many pathogens, and antibody binding to pathogen surfaces is an important activator of the complement cascade. See **Section 19.4** for details.

Coating of antibody on a bacterial cell surface (opsonization) facilitates phagocytosis through binding of the exposed F_C portion of the bound antibody with the F_C receptor (F_CR) on the phagocyte **(Figure 20.32)**. Some pathogens produce their own surface molecules that mimic the action of F_CRs **(Perspective 20.3)**. These antibody receptors render antibody ineffective by binding them upside down by their F_C portions

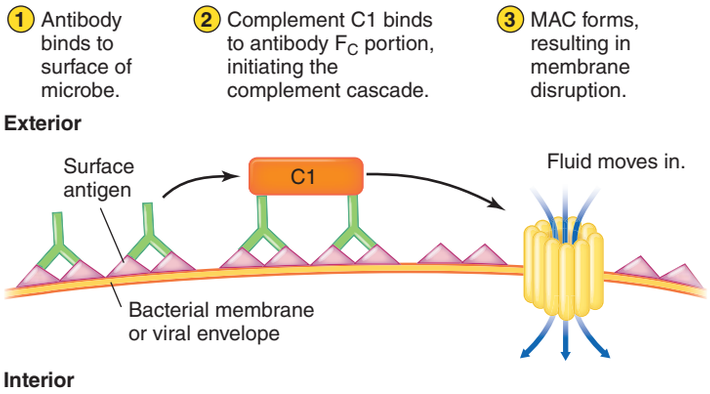

Figure 20.31. Process Diagram: Antibody initiation of complement and lysis Binding of antibody to the surface of a bacterial cell permits serum complement factor C1 to bind to the F_C portion of the antibody. Binding begins the complement cascade, resulting in formation of the membrane attack complex (MAC) and lysis of the bacterium or disruption of the viral envelope. Lysis kills the bacterium and damage to the viral envelope prevents viral attachment.

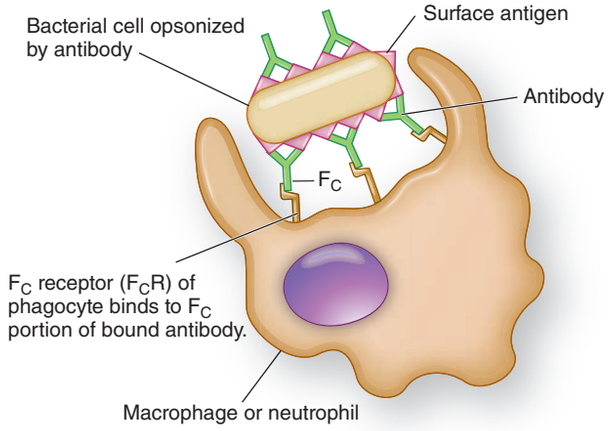

Figure 20.32. Antibody opsonization and phagocytosis Coating of antibody on a bacterial cell surface (opsonization) facilitates phagocytosis through binding of the F_C portion of the antibody molecule with the F_C receptor (F_CR) of the phagocyte.

and thus preventing opsonization, phagocytosis, and complement fixation. Agglutination or clumping of antigen is accomplished by the ability of a single antibody to bind to more than one antigen **(Figure 20.33)**. Agglutination produces a much larger particle, which not only impedes dissemination and facilitates uptake by phagocytes and dendritic cells, but also provides stronger immune stimulation through TLR signaling.

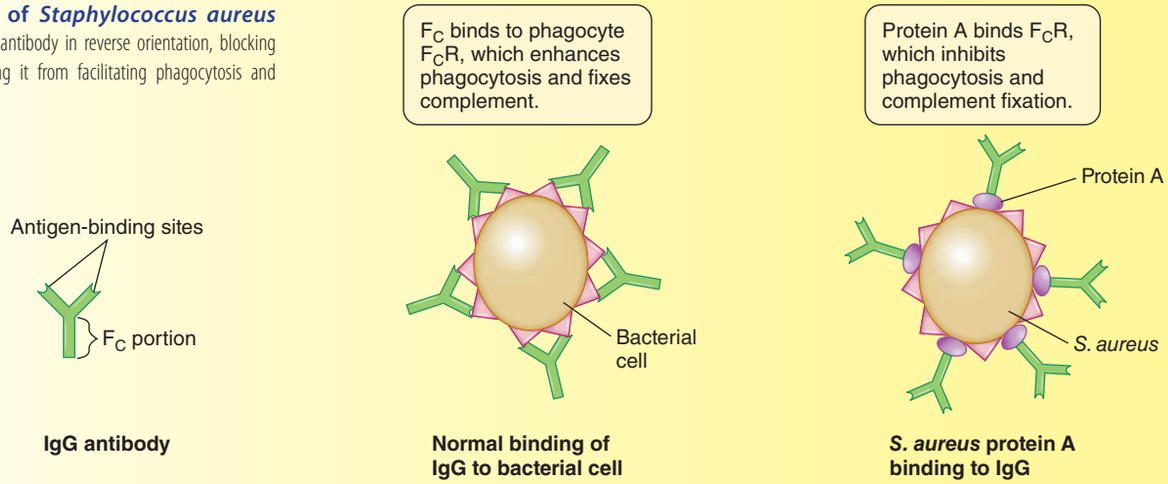
Antibody, specifically of the IgE class, helps to prevent parasitic worm infections and is also involved in allergic

Perspective 20.3
TURNING ANTIBODY UPSIDE DOWN

The extracellular pathogens *Staphylococcus aureus* and *Streptococcus pyogenes* produce surface molecules—protein A and M protein, respectively—that mimic the action of F_CRs. Both of these pathogens are associated with a number of diseases, many of which involve abscess formation. Avoiding phagocytosis and lysis by complement gives them time to establish an abscess, which helps to wall them off from the defenses of the host, including the diffusion of antibody into the abscess. Protein A and M protein are mounted onto the surface of the pathogens, where they bind the F_C portion of antibody, rendering it ineffective **(Figure B20.3)**. This prevents opsonization, phagocytosis, and complement fixation.

Antibody such as IgG possesses two antigen-binding sites at the ends of the branched structure that bind to pathogens. When bound this way, the F_C portion of the antibody remains free to bind to F_C receptors (F_CR) of phagocytes, and to bind complement for lysis. *S. aureus* coats its surface with protein A, which binds to the F_C region of antibody, holding the antibody in reverse orientation. The F_C region is no longer available for complement fixation or to bind with phagocytes.

Figure B20.3. Action of *Staphylococcus aureus* protein A Protein A binds antibody in reverse orientation, blocking access to the F_CR and preventing it from facilitating phagocytosis and complement fixation.



Toolbox 20.2
ENZYME-LINKED IMMUNOSORBENT ASSAY (ELISA)

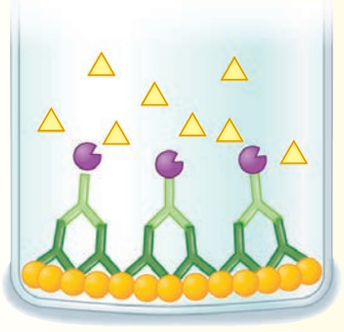
Indirect ELISA Test

Indirect ELISA tests are used to detect infectious agents indirectly by directly detecting specific antibody that is produced as a result of the infection. Depending on the infectious agent, urine, saliva, or blood serum can be tested.

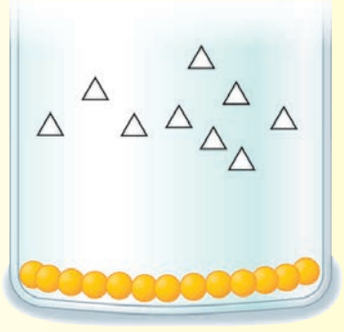
A schematic of the indirect ELISA test is shown in **Figure B20.4**. This test uses antigen prepared from the infectious agent (often the entire disrupted microbe) to coat the surface of a test well. Into this coated well, the serum sample is added and the antibody it may contain is allowed to attach to the antigen on the surface of the well. Any unattached antibody not specific to the test agent is then removed by washing with buffer. To detect the specific bound or primary antibody, a secondary antibody is used. This antibody is conjugated to an enzyme for detection and is added and allowed to attach to the primary antibody. Any unbound secondary antibody is then washed away. As the secondary antibody is directed against the primary antibody, it must be made in an animal species different from the species being tested. For example, Figure B20.3 shows the detection of human IgG, the primary antibody, from a serum sample. The secondary antibody is goat anti-human IgG antibody produced by injecting pooled human IgG into a goat. Because human IgG is a foreign protein to a goat, it will produce antibodies against it. Goat serum will then contain antibodies directed against *any* human IgG molecule. The goat antibodies are collected and an enzyme is covalently bound to them. Production of conjugated secondary antibody is usually done commercially and purchased ready to use for ELISA tests. Detection of the goat secondary antibody in the well is then done with addition of substrate to detect the bound enzyme. Conversion of the substrate by the attached enzyme results in a colored product that can be readily measured by spectroscopy.

Direct ELISA Test

A direct ELISA, or sandwich ELISA, as it is sometimes called, is used for the detection and/or quantitation of almost any substance to which

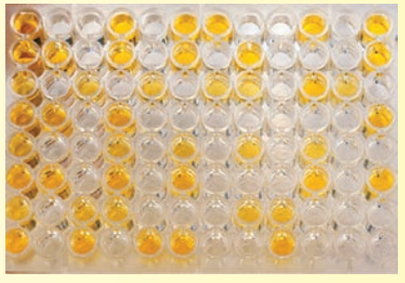


Positive test



Negative test

Hank Morgan/Science Source



Yellow wells are positive for serum antibody to the antigen.

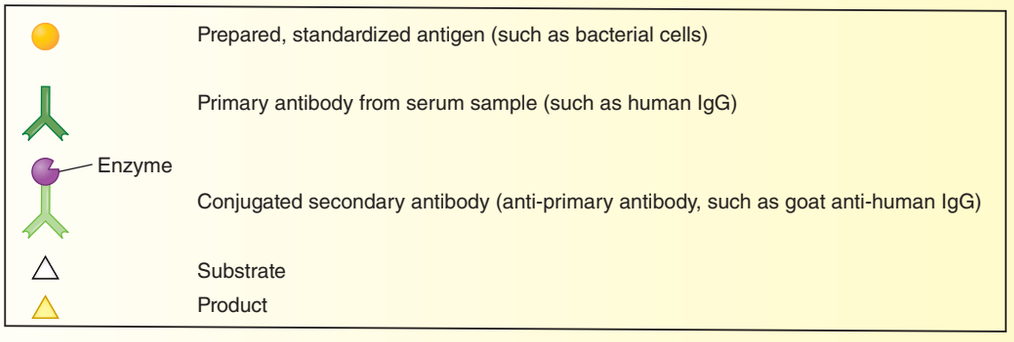


Figure B20.4. Indirect ELISA Antigen is first coated on the surface of the well. The test serum that may contain antibody (the primary antibody) to the antigen is next added. After washing, a secondary antibody conjugated to an enzyme is added, then washed again. If antibody against the antigen is present in the sample, it will be bound by the secondary antibody, and a colored product results after addition of substrate. Shown is the schematic for a positive test (*left*), a negative test (*center*), and an actual ELISA test showing positive and negative wells (*right*).

an antibody can be made. The sample is usually of industrial or toxicological importance. For example, in beer brewing, a direct ELISA is often used to check concentrations of microbial by-products and enzymes to monitor quality. Specific herbicides in water samples or illegal drugs in serum or urine samples are other examples applicable to direct ELISA testing. Direct ELISAs are not commonly used to test for infectious agents, as these agents are usually concentrated in tissues and not found free in high enough numbers in fluid samples to be detected this way.

The direct ELISA test begins with coating the surface of a test well with antibody prepared against the target substance **(Figure B20.5)**. Often, the antibody used in this first step is a monoclonal antibody (see Toolbox 20.1). It is specially selected to bind to only one particular epitope of the antigen. This ensures maximum specificity for the target in order to eliminate or reduce binding with related substances that may be in the sample. Into this coated well the sample suspected of containing the target substance is added and incubated to allow the target to attach to the antibody. Any unattached substances are then removed by washing with buffer. To detect the bound target, another layer of antibody that is also specific to the target is then added. This can be a second monoclonal antibody directed to a different epitope of the same antigen, but often serum collected from an animal immunized with the target substance is used. This antiserum contains polyclonal antibody, a collection of antibodies directed against different epitopes of the target antigen. To detect the sandwiched target substance, a secondary antibody conjugated to an enzyme is added and allowed to attach to the primary antibody. Any unbound secondary antibody is then washed away. Substrate to the conjugated enzyme of the secondary antibody is added, and the colored product is measured by spectroscopy.

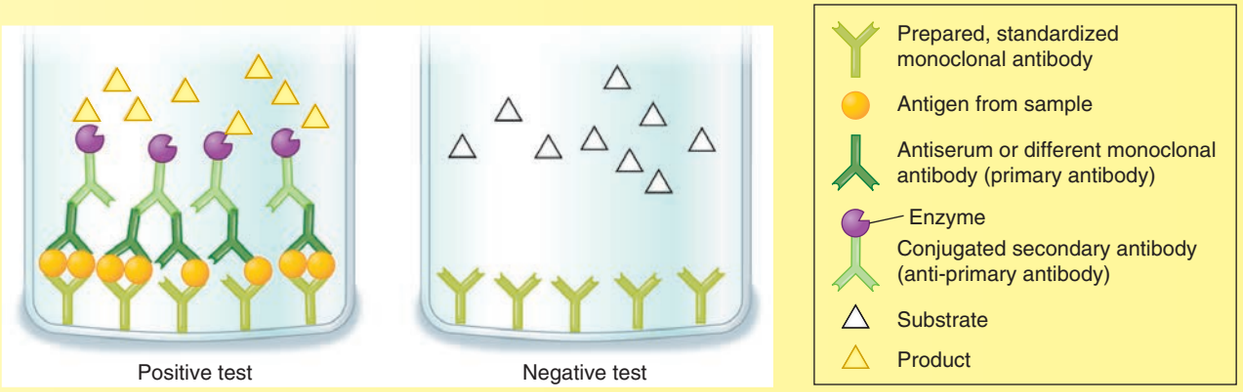

Figure B20.5. Direct ELISA An antigen-specific monoclonal antibody is first coated on the surface of the well. The test sample that may contain target antigen is next added. After washing, standardized antiserum or another monoclonal antibody is added (primary antibody), then washed. Secondary antibody conjugated to an enzyme is added and washed. If antigen is present in the sample, it will be recognized by the primary antibody, and this in turn is bound by the secondary antibody. A colored product results after addition of substrate. The schematic shows a positive and a negative test.

Test Your Understanding

You believe that a newly discovered plant from South America contains a medically important protein that could be used in cancer treatment. How would you use a direct ELISA to demonstrate that the protein is present in the plant extracts? Be sure to explain the specific "tools" you need to do this.

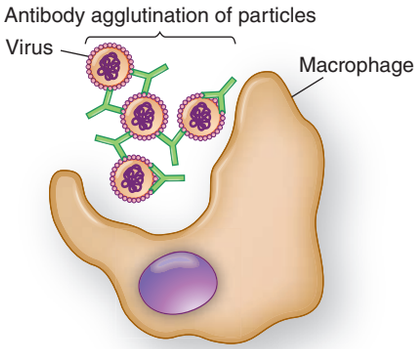

Figure 20.33. Agglutination by antibody and phagocytosis Antibody binding that links together several antigens (virus shown here) creates a physically larger target for more efficient phagocytosis.

reactions. When produced, IgE attaches to receptors for the F_C portion of the IgE molecule on the surface of basophils and mast cells (see Section 19.5). When several of these IgE antibodies are bound, the cell degranulates, releasing chemical irritants such as histamine and toxic proteins (Figure 20.34). These can kill the parasite, or at least encourage it to move to another host. Eosinophils have F_C receptors for IgG. Attachment of tissue eosinophils to IgG-coated parasites causes degranulation in a manner similar to mast cells and basophils.

20.6 Fact Check

1. What are T-independent antigens, and how do they stimulate antibody production?
2. What are monoclonal antibodies?
3. Describe the general structure of IgG antibody.
4. Distinguish between the structures and functions of the different classes of antibodies.
5. How are class-switching and affinity maturation involved in primary and memory responses?
6. Explain the various protective effects of antigen-antibody binding.

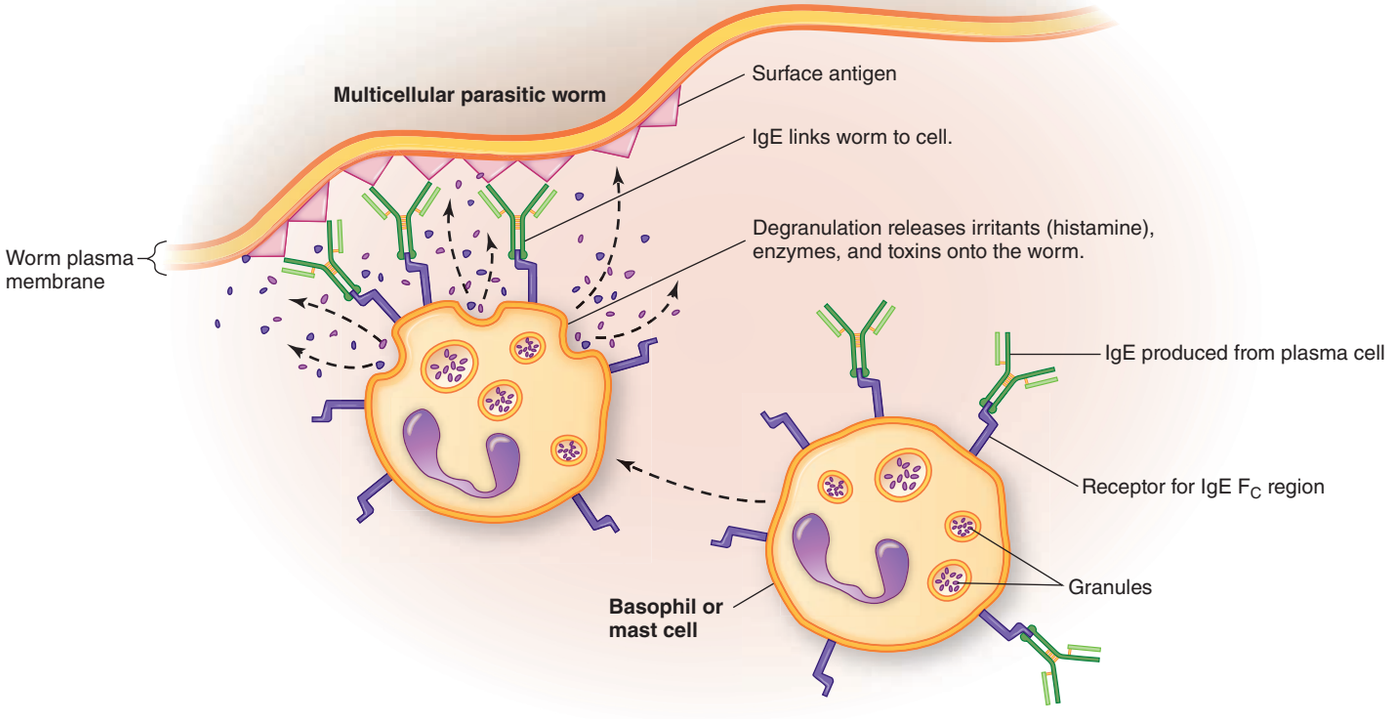

Figure 20.34. Immunoglobulin E (IgE) action against a parasitic worm Antibody of the IgE class coats the surface of basophils and mast cells. When these antibody-coated cells contact antigen several antibodies on the surface are crosslinked, signaling degranulation of the cell. Degranulation releases chemical irritants such as histamine and toxic proteins onto the parasite.

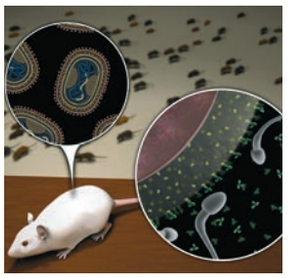
Image in Action



WileyPLUS Learning Space A white lab mouse has been inoculated with an engineered mousepox virus containing the mouse egg-sperm receptor *mZp3* gene (yellow) and IL-4 gene (aqua). The inset on the right shows how this immunocontraception method was designed to work. Following the inoculation of the female mouse with the virus, antibodies (green) produced against the mZp3 sperm receptor attach to this receptor on the surface of the egg. Sperm are blocked from binding and entering the egg, preventing fertilization.

1. Imagine you were asked to develop an animation to accompany this image and provide additional detail. The animation would feature how the antibodies involved in the immunocontraception process were produced in the mouse following the viral inoculation.
2. The virus in the image also contains the IL-4 gene to boost anti-mZp3 antibody production. Describe the normal role of IL-4 in the mouse immune response and how it contributed to lethality in the inoculated mice.

The Rest of the Story

In hindsight, the lethal effect of the IL-4 engineered ectromelia virus shouldn't have been so surprising. We've seen that IL-4 drives production of antibody and suppresses the cell-mediated response. What kind of adaptive immune response do you think is needed to control viral replication? You are correct if you answered a cell-mediated response. This cellular response is involved in the production of the cytotoxic T cells (T_C cells) that are necessary for killing infected cells to contain the spread of virus. Without an effective cellular response, the ectromelia virus was not controlled and high mortality in the mice resulted.

Anyone, microbiology students included, who understands basic immunology could have predicted lethality may occur. In fact, the researchers themselves did not overlook this possibility. The mousepox lethality experiments were quickly and sharply scrutinized because of the fear of bioweapons development. Some public groups began calling for general censorship of scientific research to prevent the dissemination of "sensitive" scientific information to the public domain, including to other scientists. This left many scientists outraged. It has since been deemed that the research did not violate the United Nations Biological and Toxin Weapons Convention, which forbids "the development, production, stockpiling, or acquirement of biological agents or toxins that have no justification for peaceful or defensive purposes." In fact, prior to the publication of the engineered mousepox virus, several papers had been published by other researchers describing the ability of IL-4 to enhance lethality of viruses. As you can see, it is difficult or impossible to draw a definitive line in the sand as to whether scientific information poses more of a security risk or more of a benefit. In the future, this new knowledge may be used to help design better vaccines and immune-regulating therapies for allergies and autoimmune diseases.

Summary

Section 20.1: What is the advantage of adaptive immunity?

Innate immunity involves genes that are genetically hardwired, being identically coded in each cell. Adaptive (specific) immunity relies on rearrangements within genes encoding the **immune receptors** of T cells and B cells.

- Immune receptors are the **T-cell receptors (TCRs)** of **T cells** and **immunoglobulin (Ig) molecules** of **B cells** that include the **B-cell receptors (BCRs)** and antibody.
- Only immune receptors can bind **antigen**. The smallest part of an antigen that can be recognized by an immune receptor is called an **epitope**.
- The specificity of immune receptors for antigen is the cornerstone of customized adaptive immune response. The variety of immune receptors generated ensures that almost any foreign invader will be recognized.
- B cells and T cells are **lymphocytes** produced in the bone marrow.
- T cells mature in the thymus, and B cells mature in the bone marrow.
- Genetic rearrangements produce unique TCRs and BCRs that are antigenically committed.
- Lymphocytes are housed in secondary lymphoid tissues distributed around the body.
- Exposure to a new infectious agent produces a **primary immune response** involving **clonal expansion** of activated cells.
- The immunity produced can take several days to peak and produces long-lived **memory cells** that convey immunological memory.
- Exposure to the same agent a subsequent time results in a **memory** or **anamnestic response**, sometimes called a secondary immune response, which will be faster and more potent.
- Adaptive immunity is unique to vertebrates, with the exception of the jawless fish.

Section 20.2: What are the central cells in adaptive immunity?

Adaptive immune responses begin with the activation of T cells.

- Only **antigen-presenting cells (APCs)** can activate T cells. These include macrophages, **dendritic cells**, and B cells.
- T-cell activation requires correct binding of the TCR with specific peptide presented on **class I major histocompatibility complex (MHC I) molecules** or **class II major histocompatibility complex (MHC II) of APCs**.
- CD4 or CD8 co-receptors of **$CD4^+$ T cells** and **$CD8^+$ T cells**, respectively, must also correctly interact with the MHC molecules of the APC to activate the T cell.
- Activation of a T cell results in production of **interleukin-2 (IL-2)**, which induces clonal expansion to produce a population of genetically identical memory T cells and **effector cells**, all possessing the same antigen-specific TCR.
- Effector T cells include **T helper cells (T_H cells)** and **cytotoxic T cells (T_C cells)**. Each has different immune activities. They migrate to the site of infection and exert their particular effector activity when they encounter the same antigen that was used to stimulate them originally.

Section 20.3: How are adaptive immune responses initiated?

Exogenous antigens are derived from extracellular microbes that are ingested and degraded in the endocytic pathway by APCs. **Endogenous antigens** are present in the cytoplasm and are derived from intracellular pathogens.

- Peptides derived from exogenous proteins are presented to $CD4^+$ T cells by MHC II molecules on the surface of the APCs.
- $CD4^+$ T cells are MHC II-restricted due to required binding of the CD4 co-receptor with MHC II.
- Activated $CD4^+$ T cells undergo clonal expansion to give rise to memory $CD4^+$ T cells and effector T helper cells (T_H cells).
- T_H cells secrete large amounts of cytokines that serve to direct further immune responses.
- The **proteasome** degrades endogenous proteins into small peptides. These are presented to $CD8^+$ T cells by MHC I molecules.
- $CD8^+$ T cells are MHC I-restricted due to required binding of the CD8 co-receptor with MHC I.
- Activated $CD8^+$ T cells undergo clonal expansion to give rise to memory $CD8^+$ T cells and cytotoxic T cells (T_C cells).
- T_C cells recognize MHC I:peptide presented on the surface of infected cells. They then release perforin and granzyme to cause apoptosis of the infected cell.
- **Cross-presentation** of antigen allows exogenous antigen, derived from phagocytosis of dead or dying cells carrying intracellular pathogens, to be presented on MHC I molecules for the activation of T_C cells that will kill other infected cells.

Section 20.4: What cells can launch adaptive immune responses?

APCs—dendritic cells, macrophages, and B cells—can express a high number of MHC:peptide complexes to activate T cells.

- The most important APC in primary immune responses is the dendritic cell, which possesses all the co-stimulatory signals necessary to efficiently stimulate naïve T cells.
- Macrophages and dendritic cells can stimulate memory T cells to produce the memory response.
- B cells possess antigen-specific BCRs on their surface that bind free antigen, including non-protein substances.
- BCRs are immune receptors that arise from random genetic rearrangements in the genes that code for the peptides making up the BCR. Each B cell carries a unique BCR that can bind to a specific antigen. Like T cells, they are antigenically committed.
- Binding of antigen to the BCR begins endocytosis and processing of protein antigens for MHC II presentation to T_H cells.
- B-cell interaction with T_H cells results in T_H-cell cytokine production that in turn causes B-cell clonal expansion and differentiation into antibody-secreting **plasma cells** and memory B cells.
- Antibodies are immune receptors. They are secreted versions of the membrane-bound BCR.
- The addition of adjuvant to components, especially small soluble peptides, significantly increases their immunogenicity.

Section 20.5: Are there different responses to extracellular and intracellular pathogens?

T_H cells are the main cytokine-secreting cells of the adaptive immune system. A **humoral immune response** is generally evoked by extracellular pathogens and is governed by **T_H2 cells**. A **cell-mediated immune response** is generally evoked by intracellular pathogens and is governed by **T_H1 cells**.

- The humoral response is characterized by clonal expansion of B cells and differentiation into plasma cells, production of large amounts of antibody from plasma cells, and suppression of cell-mediated immune responses.
- Antibodies are needed for opsonization and complement fixation of extracellular pathogens.
- A cell-mediated response is characterized by the production of T_C cells, increased macrophage functions, and suppression of humoral immune responses.
- T_C cells are needed to kill infected cells, and macrophages are needed to engulf and destroy the resulting cell fragments that may carry the pathogen.

Section 20.6: How are antibodies produced?

Antibody production begins by a BCR of a B cell binding an antigen by recognition of an eptitope.

- Binding of antigen by BCRs initiates endocytosis and degradation of the antigen by the B cell, followed by presentation of the peptides on MHC II molecules.
- Binding of the MHC II:peptide complexes to compatible T_H2 cells, stimulates the T_H2 cells to secrete cytokines, causing B-cell clonal expansion and differentiation into memory cells and plasma cells for production of antibodies with the same specificity as the original BCRs.
- Antibody can be made to many different substances, including polysaccharides, lipids, and proteins.
- Antibody production to non-protein substances begins when the BCR binds the substance and endocytosis begins.
- Any other substance that is associated with the bound substance will also be taken in. Some of these will be proteins.
- The endocytosed substances are degraded, and any protein will be digested into peptides that can be bound to MHC II molecules.
- Next, compatible T_H2 cells are bound to the presented peptide, and clonal expansion of the B cell results in plasma cell and antibody production.

- The antibody that is produced is of the same specificity as the original BCR and will bind to the non-protein substance.
- In a primary humoral response, the first immunoglobulin class produced is IgM because the BCRs of naïve B cells are single units of membrane-bound IgM.
- As the humoral response progresses, B cells undergo **class-switching** and **affinity maturation**.
- Class-switching results in immunoglobulin of classes IgG, IgA, or IgE.
- Affinity maturation increases the affinity of the BCR for the epitope, resulting in a larger stimulation signal for B-cell proliferation, a larger population of plasma cells and memory cells, and more antibody and of higher affinity.
- A humoral memory response begins with production of IgG, IgA, or IgE.
- B cells can produce antibody to **T-independent antigens**; highly repetitive molecules such as capsule polysaccharides that crosslink many BCRs.
- T-independent B-cell activation does not involve T_H2 cells, does not induce class-switching or affinity maturation, does not produce memory B cells, and produces only IgM.
- Capsule polysaccharides of pathogens are chemically bound to a peptide antigen to form **conjugate vaccines**, allowing interaction with T_H2 cells to produce memory B cells to the T-independent antigen.
- The specificity of antibodies is the basis for **enzyme-linked immunosorbent assay (ELISA)** diagnostic tests.
- **Monoclonal antibodies (mAbs)** are commonly used in the direct ELISA.

Application Questions

1. An organ transplant recipient is being given Tacrolimus, an important immunosuppressant drug that reduces IL-2 production. Describe the specific effect this would have in the body, and why this effect would be necessary in a transplant patient.
2. A knockout mouse has been engineered to lack the IL-12 gene. Explain the ways in which this mouse's immune system would behave differently from one with an intact IL-12 gene.
3. In order to determine the effects of various T_H1 cytokines on T_H2 cells, a researcher is culturing a subset of T_H2 cells *in vitro*. She adds IFN-γ to the culture flask. What effect might this have on T_H2 cells? Explain why this effect might have evolved in these types of cells.
4. *Mycobacterium tuberculosis* is an intracellular bacterial pathogen that multiplies inside the phagosome of macrophages. What type of adaptive immune response would be important in clearing this pathogen? Explain your answer.
5. *Streptococcus pneumoniae* is an encapsulated extracellular bacterial pathogen that can cause pneumonia and meningitis. What type of adaptive immune response would be important in clearing this pathogen? Explain your answer.
6. Imagine you are trying to design a new vaccine. How could you generate memory B cells from a bacterial polysaccharide? Describe the immune mechanisms you must target to do this.
7. Imagine someone else in your lab is trying to design a different vaccine. However, his challenge is to generate memory B cells from a small bacterial peptide. How might he do this? What immune mechanisms must he target in his approach compared to what you suggested in Question 6?
8. Babies born with DiGeorge syndrome often lack thymus function. Given this diagnosis, what type of antigens would their immune systems respond to and in what ways would they be immunodeficient? Explain your answer.
9. IgA deficiency is a common immunodeficiency in humans. Describe the typical role of IgA antibodies. Explain what effects this deficiency may have on a person's immunity.
10. HIV is initially diagnosed using an indirect ELISA. Using a diagram and a written description, explain how an indirect ELISA for HIV testing would be carried out. Be sure to describe the specific components used in testing, including their source.
11. Crohn's disease involves significant intestinal inflammation that appears to be caused by an immune response shift that causes excessive amounts of proinflammatory cytokines such as tumor necrosis factor-alpha (TNF-α). What subset of T cells most likely plays a major role in this disease? Explain.
12. If you needed to design a treatment for Crohn's disease to inhibit the excess TNF-α, how could you use your knowledge of cytokines from this chapter to shift the profile of the cytokine environment in these patients? Explain the rationale and the specifics of your approach.

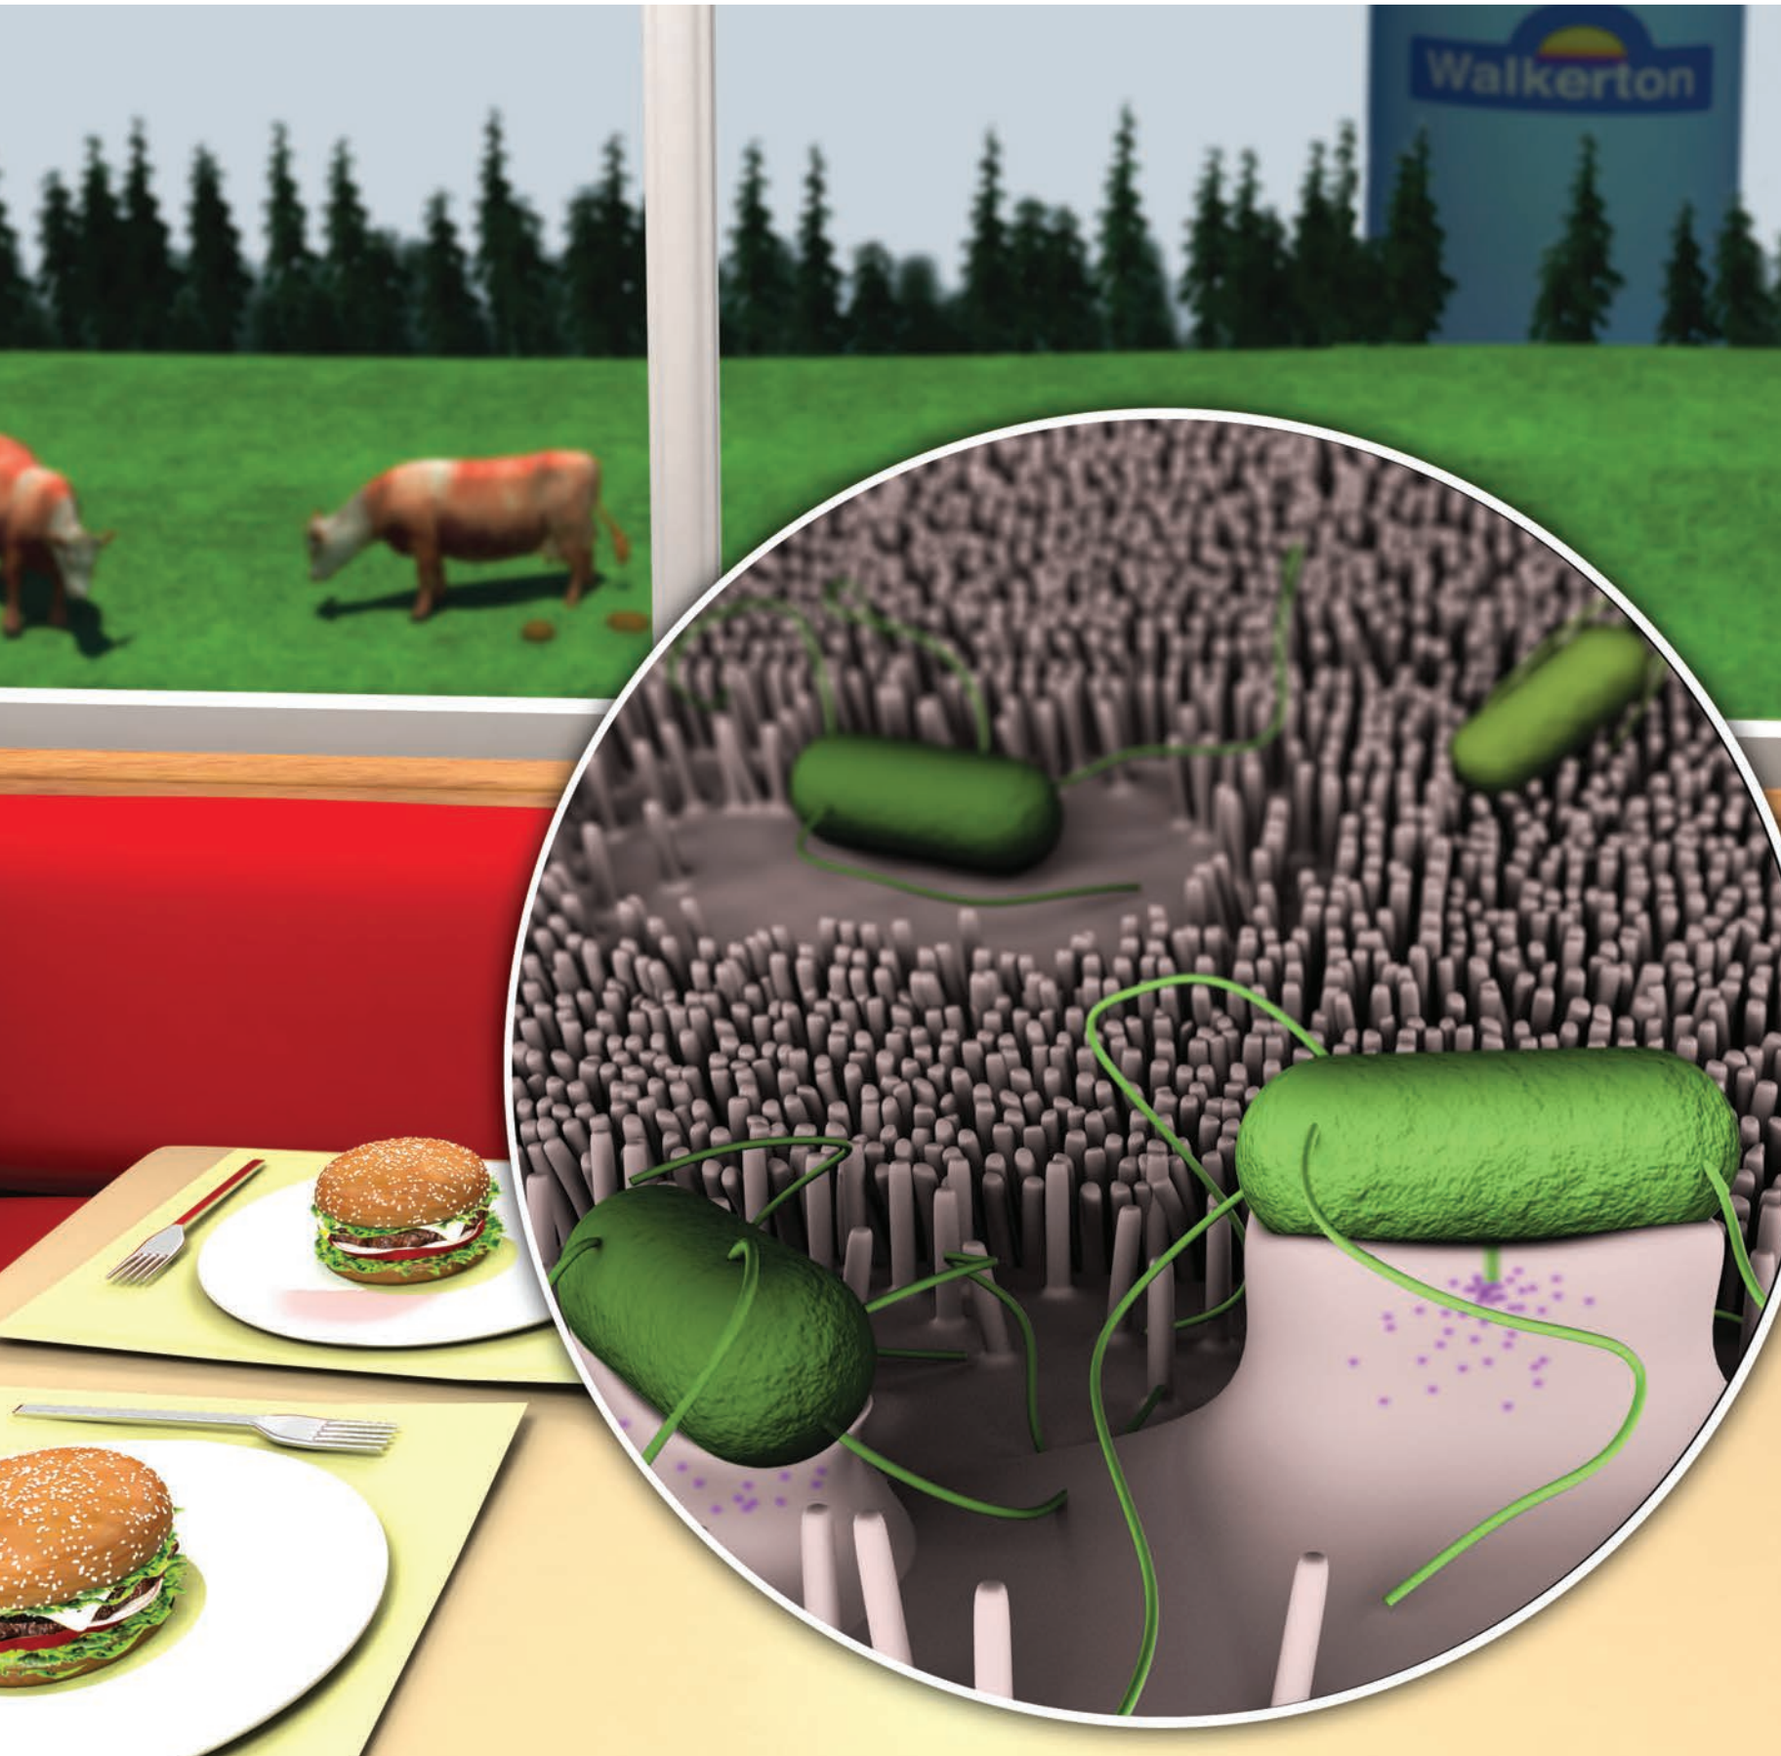
CHAPTER

21 Bacterial Pathogenesis



In May 2000, a torrential downpour soaked the small town of Walkerton, Ontario, Canada. A few days later, many of the townspeople began to complain of bloody diarrhea, vomiting, cramps, and fever. By the end of two weeks, hundreds were sick. Seven people died. The cause of the illness was shown to be *Escherichia coli* serotype O157:H7. Most *E. coli* strains are harmless commensals of the large intestine of healthy individuals, but not this strain. This strain of *E. coli* acquired genetic elements that allowed it to attach to the microvilli projections of the human intestine where it produced deadly toxins called Shiga toxins—a recent addition for *E. coli*. As their name suggests, these toxins are closely related to toxins produced by the pathogen *Shigella dysenteriae*, which also causes severe intestinal disease.

Clinical signs of infection with *E. coli* O157:H7 in humans include bloody diarrhea, severe cramping, and dehydration. Even with treatment, between 2 and 7 percent of infected individuals will go on to develop further life-threatening complications approximately one week after onset of gastrointestinal symptoms. These include widespread destruction of red blood cells, diabetes, renal failure, seizures, stroke, and coma.

Cattle are a major reservoir for *E. coli* O157:H7. Interestingly, infection in cattle is subclinical—they are not affected by the Shiga toxins and do not show any signs of disease. In Walkerton, the downpour washed the pathogen from manure on a nearby cattle farm into the town's shallow well. Tests of water sampled just before the illnesses began revealed *E. coli* contamination, but the town's two water system managers failed to notify the public health authorities or the townspeople. During the investigations that followed, the two men admitted to faking microbiological tests and chlorination records. They were formally charged and sentenced.

This was not the first or last time O157:H7 has tragically reared its ugly head. Another highly publicized outbreak took place in the United States in 1993 and involved undercooked hamburgers from a supplier for fast-food restaurants in four western states. Over 600 people fell ill, and four died. This case made clear the necessity for thoroughly cooking ground beef. Since then, other outbreaks have been traced to a variety of sources including salami, apple juice, lettuce, onions, and potatoes. How is it that *E. coli*, a normally harmless resident of the intestine, suddenly became a deadly pathogen?

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Virulence factors are used to attach to host cells, avoid immune clearance, and damage host cells to obtain nutrients.

- Table 21.1: Some major virulence factors of selected pathogens
- Mini-Paper: *Escherichia coli* injects its own receptor
- Perspective 21.1: Iron, vampires, fashion, and the white plague

Toxins are major virulence factors used by many bacterial pathogens.

- Toolbox 21.1: Serotyping

CONNECTIONS for this chapter:

Systemic microbial components can cause deadly inflammation **(Sections 19.3** and **19.4)**.

$CD4^+$ T cells are the central lymphocytes involved in the adaptive immune response **(Sections 20.2, 20.3,** and **20.5)**.

Role of capsules in avoidance of host immune responses **(Perspective 20.2)**

Temperate phages can transfer virulence factors **(Section 8.3)**.

Introduction

In this chapter, we will examine bacterial pathogens. The diseases produced in various species of host organisms by bacterial pathogens are as diverse as the pathogens themselves, and we will not attempt to cover all of them. Rather, we will cover common aspects of bacterial pathogenesis—the processes used by pathogens to produce disease. In doing this, some common bacterial pathogens and the diseases they cause will be used to illustrate some shared aspects of pathogenesis.

Like any organism, pathogenic microorganisms have, through evolution, developed strategies to secure nutrients from their surroundings. Bacterial pathogens can survive in a living host by obtaining nutrients through *damaging tissue*. This distinguishes them from non-pathogenic bacteria that may also be living on or within the body, but do not damage tissue to obtain nutrients. Pathogens are not evil entities that set out to purposefully kill their host, although that may sometimes be the outcome; the host is simply a nutrient source and a place to live, and pathogens have adapted to exploit this habitat. It is really no different from the way humans exploit the resources of the planet. This also results in damage, and although we do not do this for the purpose of destroying the environment, harm may be an outcome.

Bacterial pathogens can produce a spectrum of diseases that range from damage due to production of a single toxin, to diseases produced largely because of a robust but relatively ineffective host immune response. In many cases, the damage is caused by both the pathogen and the host response to the pathogen. Most bacterial pathogens follow a common scheme that leads to the establishment of infection. The pathogen must gain access and often attach to host tissue, avoid host defenses, and get nutrients needed to multiply. These requirements are some of the key aspects of bacterial pathogenesis that we will investigate. As we shall see, many of the products produced by pathogens that allow them to carry out these processes are encoded on specific genetic elements that can be transferred between strains and even other species. This genetic mobility is a principal feature in pathogen evolution.

Our investigation of bacterial pathogenesis will focus on answering the following questions:

What are some common features of bacterial pathogens? (21.1)
How do bacterial toxins act on host cells? (21.2)
How do bacterial pathogens cause disease? (21.3)
How do some bacteria become pathogens? (21.4)

21.1 Bacterial virulence factors

What are some common features of bacterial pathogens?

We previously came across the term "virulence factor" (see Section 18.2). A virulence factor is a product made by a pathogen that enhances its ability to cause disease. As you might imagine, the range of virulence factors that pathogenic bacteria produce is vast **(Table 21.1)**, but surprisingly, many of these virulence factors act in common ways. Any bacterial pathogen must perform a few basic tasks to establish itself in the host.

- It must gain access to tissues.
- It must evade, or overcome, host defenses.
- It must obtain nutrients, usually by damaging cells and/or stealing nutrients away from the host.

For example, the sexually transmitted primary pathogen *Neisseria gonorrhoeae* first attaches to cervical or urethral epithelial cells using fimbriae, then invades the underlying tissues. Here, production of the cell wall component, endotoxin, evokes an intense inflammatory response in the host (see Section 19.3). The inflammation damages tissue, such as the fallopian tubes, and produces most of the symptoms of gonorrhea. *Neisseria gonorrhoeae* also produces various enzymes that damage cells directly **(Figure 21.1)**. Tissue damaged by inflammation and enzymes facilitates invasion and provides nutrients. To successfully do all this, the bacterium must evade host immune responses. One of its key strategies is to change its surface antigens continually, particularly the pilin proteins of fimbriae, which renders antibodies ineffective. In addition, the bacterium produces an IgA protease for degrading host IgA antibodies. Fimbriae, endotoxin, and IgA protease are major virulence factors of this pathogen. In this section and the next section, we will survey the most common virulence factors of bacteria. We begin with examining attachment factors, capsules, secretion systems, and iron-binding proteins. The multitude of bacterial toxins, a prominent feature of many pathogens, will be examined in Section 21.2.

CONNECTIONS How are virulence factors of pathogens identified? Recall from **Section 18.4** that a useful experimental approach is based on molecular Koch's postulates. A systematic series of tests are carried out involving mutations that either inactivate or remove suspected virulence factor genes or produces from a pathogenic organism. Such a mutant should exhibit decreased ability to cause disease.

Attachment factors

Attachment to host tissues is a critical step for most pathogens. Without attachment, most bacteria would be routinely removed by friction and fluids, or even be displaced by other microbes. Many pathogens possess mechanisms that allow them to attach to host cells directly. Non-pathogenic bacteria tend to colonize extracellular surfaces of the body, such as

TABLE 21.1 Some major virulence factors of selected pathogens

Organism	Disease	Virulence factor	Action
Bordetella pertussis	Whooping cough	Fimbriae	Attachment
		Pertussis toxin	Disrupts cell ion balance
		Invasive adenylate cyclase	Disrupts cell ion balance
Escherichia coli O157:H7	Hemorrhagic colitis and kidney failure	Tir	Receptor for attachment
		Intimin	Attachment to Tir
		Type III secretion system	Injects Tir for attachment
		Shiga-like toxins	Stops translation in host cells
Helicobacter pylori	Gastritis, ulcers	Urease	Neutralizes gastric acid (HCl)
		Vacuolating cytotoxin A (VacA)	Host cell death, inflammation
		Flagella	Transport through mucus
		Cytotoxin-associated antigen (CagA)	Disrupts host cell cytoskeleton
		CagA type IV secretion system	Injects CagA
Neisseria gonorrhoeae	Gonorrhea	Fimbriae	Attachment and immune evasion
		IgA protease	Destruction of IgA antibody
		Lipooligosaccharide (LOS; a form of endotoxin)	Evokes inflammatory damage
Streptococcus pneumoniae	Pneumonia, meningitis	Capsule	Anti-phagocytic
		Pneumolysin	Forms pores in host cells
		Autolysin	Lysis of bacterial cell to release peptidoglycan (produces inflammation)
Streptococcus pyogenes	Various skin, throat, and systemic infections	Capsule	Anti-phagocytic
		M protein	Prevents binding by antibody
		Hyaluronidase	Degrades connective tissue
		Streptokinase	Degrades fibrin clots

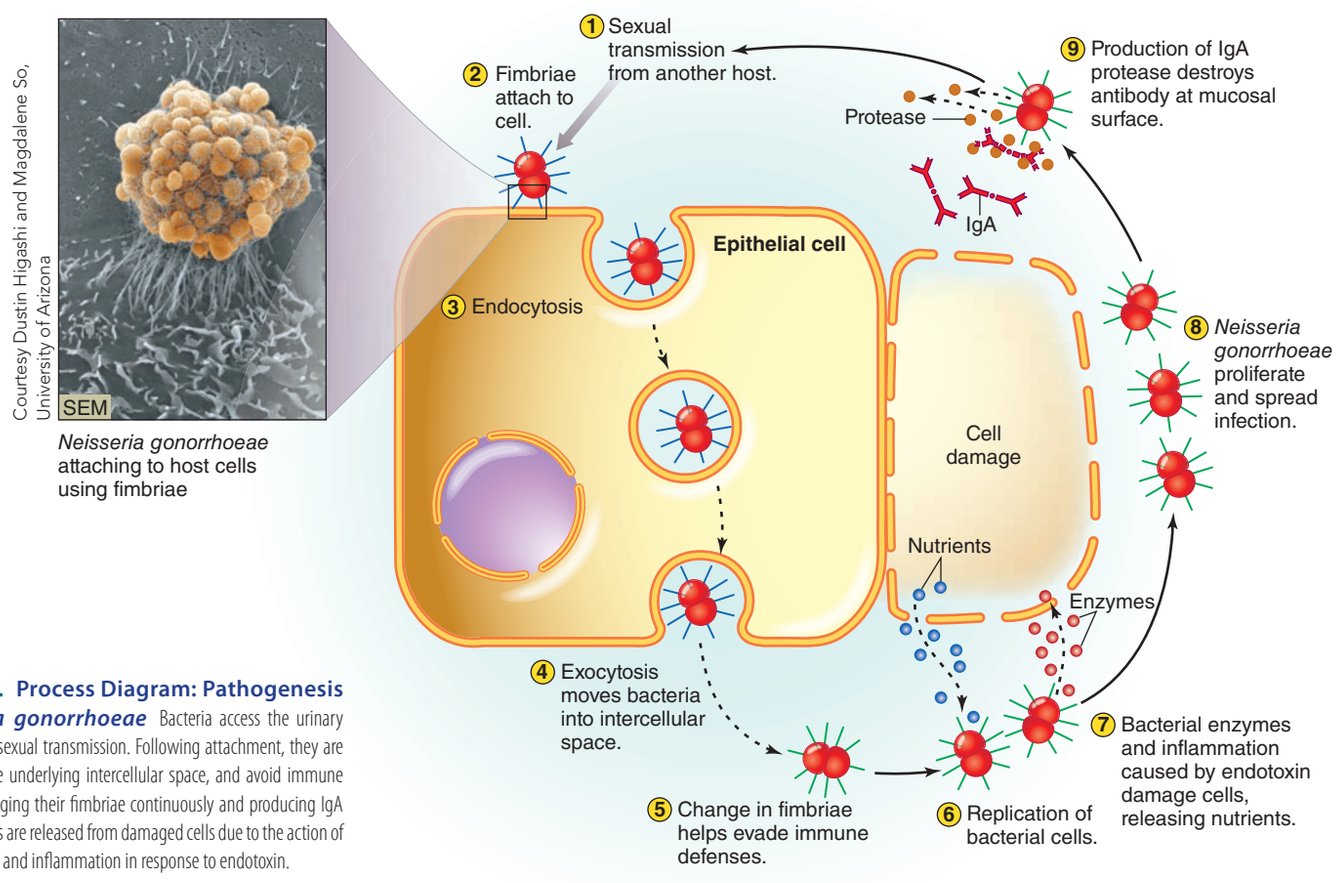

Figure 21.1. Process Diagram: Pathogenesis of *Neisseria gonorrhoeae* Bacteria access the urinary tract or cervix by sexual transmission. Following attachment, they are transported to the underlying intercellular space, and avoid immune clearance by changing their fimbriae continuously and producing IgA protease. Nutrients are released from damaged cells due to the action of bacterial enzymes and inflammation in response to endotoxin.

TABLE 21.2 Pathogens that bind host fibronectin

	Pathogen	Disease
Gram-positive	*Corynebacterium diphtheriae*	Diphtheria
	Clostridium difficile	Colitis
	Clostridium perfringens	Gas gangrene
	Mycobacterium tuberculosis	Tuberculosis
	Staphylococcus aureus	Various skin and invasive diseases
	Streptococcus pyogenes	Various invasive and toxic diseases
Gram-negative	*Escherichia coli*	Urinary and gastrointestinal diseases
	Treponema pallidum	Syphilis
	Borrelia burgdorferi	Lyme disease
	Porphyromonas gingivalis	Gum disease

mucus or the dead outer layers of skin. You may recall from Section 17.3 that non-pathogenic commensal strains of gut bacteria colonize the lumen of the intestine and do not routinely attach directly to intestinal cells. Pathogenic strains, such as *Escherichia coli* O157:H7 and *Helicobacter pylori* (see Microbes in Focus 18.4) have specific mechanisms to attach directly to cells of the gastrointestinal tract.

Attachment factors that are used commonly by bacteria include fimbriae, fibronectin-binding proteins, and various membrane-associated molecules, such as lipoteichoic acid of Gram-positive bacteria (see Section 2.4) and outer membrane proteins of Gram-negative bacteria. In addition to these common molecules for adherence, some bacteria produce specialized proteins for attachment. Molecules produced by bacteria that allow them to bind to and colonize host tissues are generally referred to as **adhesins**. Extracellular bacterial pathogens can adhere directly to cells or to the host *extracellular matrix*, a mesh-like support material composed of fibrous molecules, such as collagen and fibronectin proteins that anchor cells to the matrix, and gel-like substances that fill intercellular spaces, such as hyaluronic acid and sulfate proteoglycans.

Fibronectin-Binding Proteins

Fibronectin is a large glycoprotein found circulating in plasma and as fibers of extracellular matrix material where it anchors cells to support surfaces, such as basement membranes and collagen. The ability to bind host fibronectin is important in establishing colonization for many bacterial species, but is probably best studied for *Streptococcus pyogenes* and *Staphylococcus aureus*. *Staphylococcus aureus* produces several **fibronectin-binding proteins** that are predominant adherence factors for skin, nasal mucosa, and endothelial cells lining blood vessels. Once *S. aureus* gains access to the bloodstream, usually from a skin infection, fibronectin-binding proteins allow it to attach to and invade the vessel walls, moving into surrounding tissues from there. This activity is responsible for the ability of *S. aureus* to colonize heart valves, producing endocarditis. The pathological importance of fibronectin-binding proteins has been demonstrated by expressing the *S. aureus* fibronectin-binding protein on the surface of *Lactococcus lactis*, a normally non-pathogenic Gram-positive organism. Recombinant *L. lactis* expressing *S. aureus* fibronectin-binding protein can readily infect heart valves in animal models. Other pathogens that use fibronectin-binding proteins as part of their pathogenesis are listed in Table 21.2.

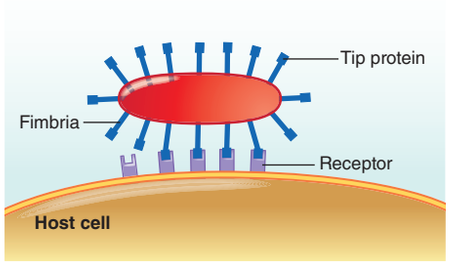
Fimbriae

Many bacteria adhere to host surfaces using fimbriae, pili that are primarily used for attachment (Table 21.3). They adhere

TABLE 21.3 Pathogens that use fimbriae for adherence

Bacterium	Attachment surface	Disease
Bordetella pertussis	Ciliated epithelial cells of upper respiratory tract	Pertussis (whooping cough)
Corynebacterium diphtheriae	Upper respiratory tract and skin epithelial cells	Diphtheria
Escherichia coli intestinal pathogenic strains	Intestinal cells	Diarrhea and enteritis
Escherichia coli uropathogenic strains	Urinary epithelial cells	Cystitis (bladder infection), urethritis
Haemophilus influenzae	Sialic acid	Meningitis, pneumonia
Klebsiella pneumoniae	Collagen	Meningitis, pneumonia
Neisseria gonorrhoeae	Cervical and urethral epithelial cells	Gonorrhea
Pseudomonas aeruginosa	G_{M1} gangliosides found on a variety of cell types	Pneumonia and skin disease in compromised persons
Salmonella Typhimurium[a]	Various intestinal cells	Gastroenteritis
Streptococcus agalactiae	Mucosal epithelial cells	Neonatal meningitis
Streptococcus pneumoniae	Pharyngeal epithelial cells	Pneumonia
Streptococcus pyogenes	Fibronectin, collagen	Pharyngitis, tonsillitis, invasive skin diseases
Vibrio cholerae	Intestinal microvilli (receptor unknown)	Cholera (severe diarrhea)

[a] *Salmonella enterica* serovar Typhimurium (see Appendix C for nomenclature).



A. Attachment by fimbriae

© Kwangshin Kim/Science Source

B. Fimbriae of *E. coli*

Figure 21.2. Attachment by fimbriae **A.** Fimbriae attach to receptors on cell surfaces using an adhesive tip protein. **B.** Fimbriae of enterotoxin-producing *Escherichia coli* appear orange in this color-enhanced micrograph.

to host tissues and non-biological surfaces, including medical implants. The end of each fimbria strand has a specific adhesive tip composed of a tip protein used for attachment (Figure 21.2). Fimbriae are assembled sequentially, beginning with the tip protein to which pilin subunits are added from the bottom up. Finding fimbrial binding targets is often done *in vitro* by selective addition of various oligosaccharides to cultures of bacteria. If subsequent attachment to target host cells is blocked, this indicates the oligosaccharide has been bound, and is a binding target for the adhesin.

Why are fimbriae commonly used for bacterial adhesion? A major barrier to bacterial attachment is electrical charge. Host cell and bacterial cell surfaces are covered with molecules that confer an overall net negative charge, causing electrostatic repulsion between the two. Fimbriae may assist in attachment by spanning the distance of the repulsion, overcoming the need for the bacterium to get close to the cell.

Most Gram-negative bacteria and some Gram-positive bacteria produce fimbriae under certain conditions. Commonly, several different types of fimbriae can be produced by a single bacterium, and the type of fimbriae expressed is frequently modified in response to environmental conditions. A well-studied example of this occurs in *Neisseria gonorrhoeae* (Microbes in Focus 21.1). As noted in the introduction, fimbriae are a major virulence factor of this sexually transmitted bacterium, being needed for adherence to epithelial cells of the urethra and cervix. Once infection has been established, expression of fimbriae can be turned on and off. This is known as "phase variation." Expressed fimbriae can also undergo amino acid changes via genetic recombination. This is known as "antigenic variation." The appearance and disappearance of fimbriae and the constant change in protein sequence presents a moving target to the adaptive immune system. By the time specific antibody is made to one type of fimbriae, another is produced, or the fimbriae disappear altogether for a time, rendering present antifimbrial antibody ineffective.

Uropathogenic *E. coli* strains, which cause the majority of urinary tract infections in women, also exhibit phase variation. These strains typically express numerous types of fimbriae, with some sets being expressed under some conditions, and other sets expressed under other conditions. Certain fimbria sets are needed to establish infection, and others are needed to maintain infection during the ensuing changes in the urinary tract. Regulation of fimbria expression patterns is accomplished by recombination between different fimbria genes and between genes and signaling molecules in the environment.

Special Adherence Proteins Tir and Intimin: Home Renovations by *E. coli*

Intestinal enteropathogenic and enterohemorrhagic strains of *E. coli* share a particularly interesting way of anchoring themselves to the microvilli of enterocytes, the epithelial cells lining the intestinal mucosal surface. Attachment of these strains happens on two levels. One level is by attachment using various fimbriae that bind to cell surface glycoproteins, and a second level is mediated by interaction with a specific *E. coli* surface protein named intimin and its specific receptor, Tir, on enterocytes.

Enteropathogenic *E. coli* strains are a significant cause of non-bloody diarrhea in young children in developing countries. Enterohemorrhagic strains, such as O157:H7, cause disease worldwide ranging from non-bloody diarrhea to severe hemorrhagic colitis, often complicated with development of hemolytic uremic syndrome (HUS). This syndrome is caused by Shiga-like toxins, sometimes called "verotoxins," to distinguish them from those produced by *Shigella dysenteriae.* Enteropathogenic and enterohemorrhagic serotypes use type III secretion systems (see Section 2.4) to inject proteins that disrupt host cell signaling and induce cytoskeletal changes that produce the formation of unusual pedestal-like structures under the attached *E. coli* cells (Figure 21.3). It is thought that remodeling of intestinal cells affords *E. coli* space away from competing microbes and projects them farther into the lumen of the intestine, allowing better access to nutrients. The lesions that are related to formation of pedestals are called "attachment and effacing" (AE) lesions. These AE lesions seriously

Microbes in Focus 21.1
NEISSERIA GONORRHOEAE

Habitat: Human urinary and reproductive tracts

Description: Gram-negative, facultative intracellular coccus 1 μm in diameter

Key Features: *Neisseria gonorrhoeae* (shown here inside neutrophils) is the causative agent of gonorrhea, a sexually transmitted disease characterized by purulent (pus) discharge from the reproductive tract. Attachment to mucosal epithelium is mediated by fimbriae. The bacterium produces an endotoxin that evokes an intense local inflammatory response, which contributes to tissue damage, facilitating invasion of the pathogen.

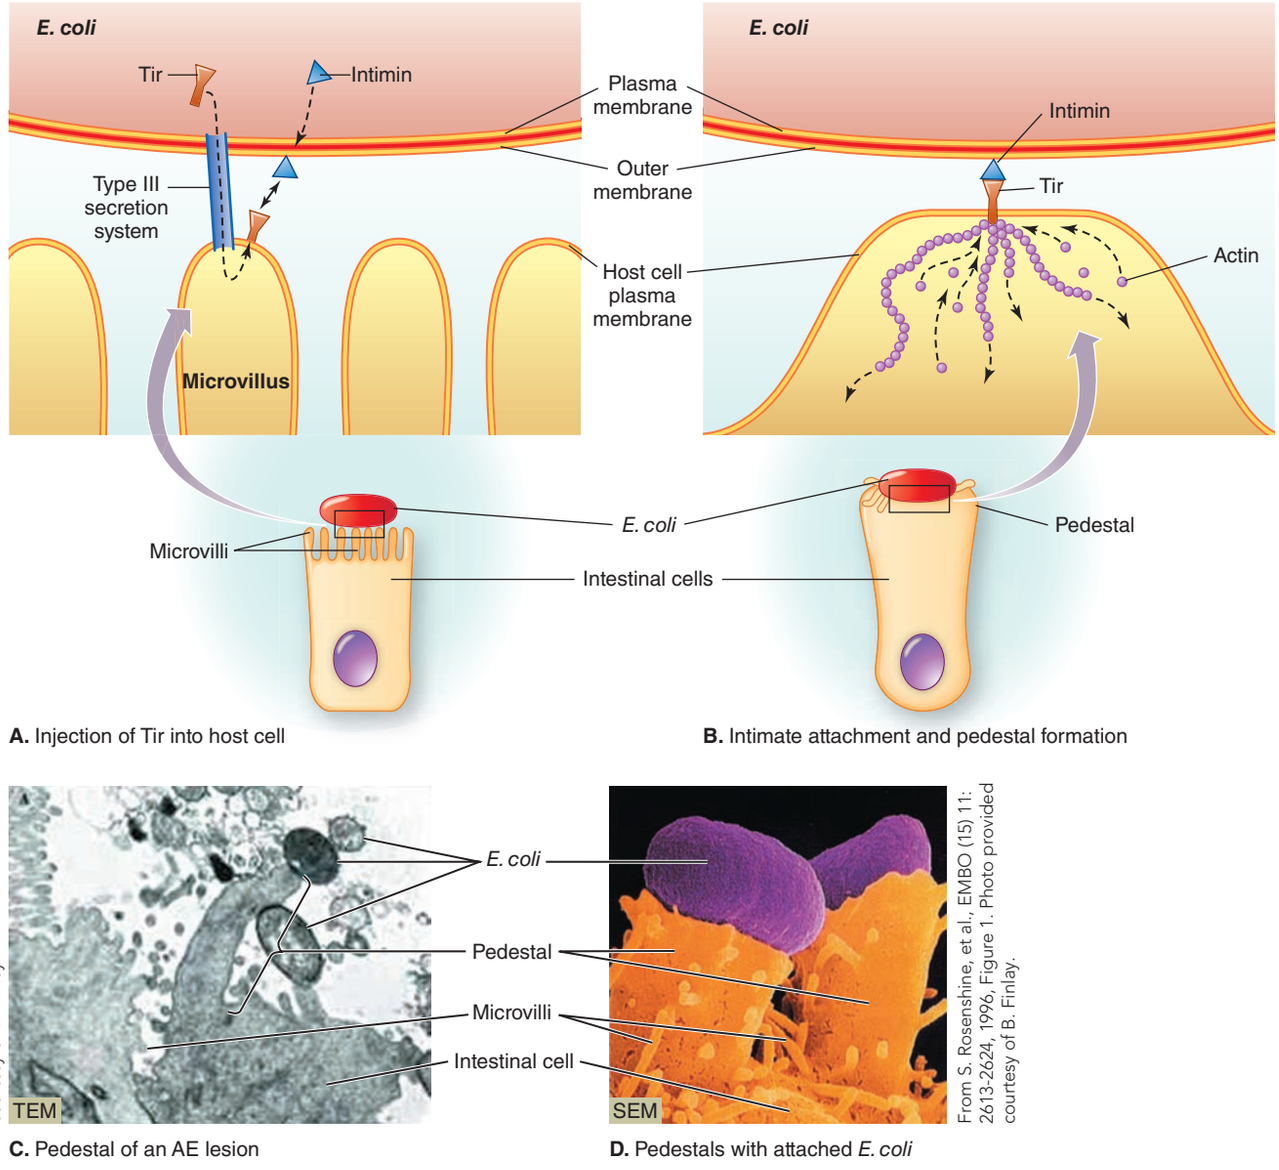

Figure 21.3. Formation of attachment and effacing (AE) lesion by enteropathogenic and enterohemorrhagic *Escherichia coli* **A.** Contact with the host microvillus induces *E. coli* expression of the surface adhesin protein intimin and the receptor protein Tir. Tir is translocated into the host cell using a type III secretion system. **B.** Intimin binds Tir and Tir initiates polymerization of actin in the host cell, deforming the microvilli and forming a large pedestal-like structure characteristic of AE lesions. **C.** Pedestal formation on an AE lesion on rabbit intestinal cells. **D.** Pedestal formation by *E. coli*, shown purple in this color-enhanced micrograph on cultured human HeLa cells.

impact the functions of the gut, resulting in tissue degeneration and loss of nutrient absorption that are characteristic of the diseases caused by these strains. This may be advantageous to the bacteria by making more nutrients available for them.

The receptor, Tir, which is needed for pedestal formation, was first identified on the surface of infected cells and therefore was naturally thought to be host cell-encoded. Interestingly, Tir was only found on cells with *E. coli* attached and was never found on uninfected control cells. It was thought that the attachment of *E. coli* somehow induced the host cell to express Tir. Researchers began to investigate the nature of this unusual interaction. To their surprise, they found that Tir was not a host cell product at all, but instead was injected by *E. coli* (see Figure 21.3A and **Mini-Paper**). The bacterium makes its own host cell receptor!

Capsules

Recall from Section 2.5, a capsule is an extracellular, loosely organized matrix of polymers that surrounds some bacterial cells. Capsules are most often composed of polysaccharides, but sometimes can be polypeptides or a mixture of both. Their role in pathogenicity is primarily to protect the bacterium from phagocytosis and lysis from complement, both of which are important early immune defenses (see Sections 19.4 and 19.5). Many pathogens owe their success to possession of a capsule **(Table 21.4)**, and it serves as their primary virulence factor. Mutants of these strains that do not produce capsules are non-pathogenic as they are easily phagocytosed and destroyed by host phagocytes. You may recall from Section 7.1 Griffith's demonstration of this in mice with *Streptococcus pneumoniae*.

TABLE 21.4 Bacterial pathogens possessing capsules as a major virulence factor

Pathogen	Capsule composition	Disease
Bacillus anthracis	Poly-D-glutamic acid	Anthrax
Campylobacter jejuni	Various polysaccharides	Invasive intestinal disease
Enterococcus faecalis	Various polysaccharides	Urinary tract infections, various hospital-acquired invasive diseases
Escherichia coli K1	Sialic acid	Neonatal meningitis
Haemophilus influenzae	Six different capsule types; one is polyribitol phosphate	Pneumonia, meningitis
Klebsiella pneumoniae	>77 different capsule polysaccharide types	Pneumonia, meningitis
Neisseria meningitidis	Sialic acid	Meningitis
Pseudomonas aeruginosa	Alginate (biofilm formation)	Pneumonia
Salmonella Typhi[a]	*N*-acetylglucosamine uronic acid	Typhoid fever
Staphylococcus aureus	Various amino sugars	Invasive skin diseases, pneumonia
Streptococcus agalactiae	Sialic acid	Neonatal meningitis
Streptococcus pneumoniae	>90 different capsule oligosaccharide types	Meningitis, pneumonia
Streptococcus pyogenes	Hyaluronic acid	Variety of invasive and toxic infections

[a] *Salmonella enterica* serovar Typhi (see Appendix C for nomenclature)

CONNECTIONS The major virulence factor of *Streptococcus pneumoniae, Haemophilus influenzae*, and *Neisseria meningitidis* is their capsule, which allows these pathogens to avoid provoking a T-cell immune response. See **Perspective 20.2** for details.

Capsules can aid in adherence and interfere with phagocytosis and complement activation in several ways. Host opsonization molecules, such as complement C3b and antibody made to cell wall antigens, can diffuse through the capsule and bind to the cell surface. However, their opsonization role is rendered ineffective as they remain buried in the capsule and cannot be contacted by phagocyte receptors needed for efficient phagocytosis and killing (**Figure 21.4**; see Figures 19.16 and 20.32). Anti-capsule antibody provides protection from encapsulated pathogens because opsonization of the capsule allows effective uptake and killing by phagocytes.

Successful avoidance of phagocytosis by extracellular pathogens means that few bacterial components enter the endocytic pathway of macrophages and therefore few are presented to T cells. Without strong T-cell stimulation, B-cell clonal expansion does not occur and consequently, less antibody directed against the pathogen will be made. Without sufficient antibody to bind to the cell, complement factor C1 of the classical pathway is not efficiently fixed and formation of MAC (membrane attack complex) does not occur (see Figures 19.7 and 19.9). In this way, the capsule also protects the pathogen from lysis by complement.

The alternative pathway of complement activation does not depend on antibody binding, so presumably MAC formation can still occur to lyse the bacterial cells. Even though this appears to be the case with many capsule-forming strains of bacterial pathogens, some of the most virulent pathogens prevent this activation pathway as well. They do this by constructing capsules made of molecules commonly found in their host,

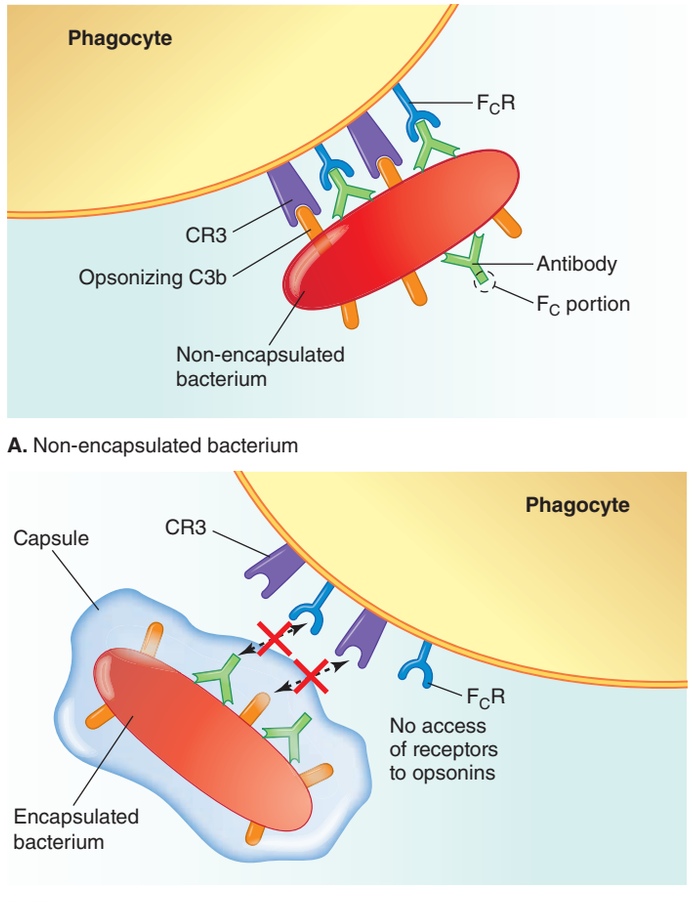

Figure 21.4. Capsules inhibit opsonization and phagocytosis
A. Non-encapsulated bacteria are opsonized with C3b and are readily phagocytosed by binding with C3b receptors (CR3) of phagocytes. Similarly, antibody-coated bacteria are bound by phagocyte receptors (F_CR) that bind the exposed antibody F_C portions to facilitate phagocytosis. **B.** In encapsulated bacteria, any C3b or antibody that moves through the capsule to attach to the cell surface will not be available for phagocyte binding.

Mini-Paper: A Focus on the Research
ESCHERICHIA COLI INJECTS ITS OWN RECEPTOR

B. Kenny, R. DeVinney, M. Stein, D. J. Reinscheid, E. A. Frey, and B. B. Finlay. 1997. Enteropathogenic *E. coli* (EPEC) transfers its receptor for intimate adherence into mammalian cells. Cell 91:511–517.

Context

Enteropathogenic and enterohemorrhagic strains of *E. coli* deliver several virulence factors by their type III secretion systems. These virulence factors are involved in the development of degenerative AE lesions, which are characteristic of infection with these strains. The virulence factors needed for AE lesion development, including all the genes for production of the type III secretion system, are encoded adjacent to one another on a block of sequence known as the locus of enterocyte effacement (LEE). The LEE locus is a pathogenicity island (see Sections 18.4 and 21.4). Included in the LEE locus is the gene encoding the bacterial adhesin intimin, needed for strong, "intimate" attachment to host cells. Mutants defective for intimin do not form pedestals nor fully developed AE lesions.

Researchers knew that the initiation of this disease process occurred when intimin was bound to a membrane receptor protein that was originally named Hp90 and later Tir. However, there were some strange aspects of this receptor. Hp90 was only present in cells with attached *E. coli* and was absent in uninfected cells. The research team, led by Brett Finlay at the University of British Columbia in Canada, set out to investigate the nature of the receptor Hp90. What they found was unprecedented.

Experiment

The first clues that something strange was occurring between host cells and *E. coli* came from earlier investigations done by Finlay's group. They produced polyclonal antibody to an enteropathogenic (EPEC) strain of *E. coli* by injecting the bacteria into a rabbit and later collecting the serum. They used this antibody mix on EPEC-infected and uninfected HeLa cells, a human epithelial cell line. Unexpectedly, the anti-EPEC antibody recognized a protein from infected cells that was the same size (90 kDa) as Hp90. Why would antibody raised to bacterial antigens bind to a host cell protein? At first, they thought this was due to antibody cross-reaction, where antibody made to an EPEC protein was recognizing a similar region on Hp90. However, they did not find the cross-reactive band in uninfected HeLa cells, or those infected with EPEC mutants lacking the type III secretion apparatus.

To investigate further, they made antibody that could recognize a specific region of Hp90. Hp90 has a phosphorylated tyrosine residue and antibody (anti-phosphotyrosine) was made to this. They then labeled EPEC proteins with the isotope ^{35}S by growing cells in the presence of ^{35}S-methionine. When they infected HeLa cells with labeled *E. coli*, they found the anti-phosphotyrosine antibody bound to a labeled EPEC protein that was identical in size to Hp90. These results made the researchers think that maybe Hp90 was of bacterial origin and was delivered via type III secretion from EPEC.

Assuming Hp90 was actually of bacterial origin and that it was secreted, they then tried to locate it in EPEC culture supernatants. They could not find a secreted 90-kDa protein, but did find one that was slightly smaller in size (78 kDa) that had not been previously identified. They managed to find this protein by culturing EPEC under specific conditions to maximize secretion of proteins. They next purified the 78-kDa protein and made antibody to it. Using this anti-78-kDa antibody they located a 90-kDa EPEC cytoplasmic protein. Anti-phosphotyrosine antibody also recognized this EPEC 90-kDa protein, but it did not recognize the 78-kDa protein, indicating the 90-kDa protein was a phosphorylated cytoplasmic version of the 78-kDa secreted protein. The anti-78-kDa antibody and anti-phosphotyrosine antibody recognized Hp90 in the membranes of infected cells, indicating Hsp90 and the 90-kDa EPEC protein were one and the same **(Table B21.1)**. Hp90 was not a mammalian protein after all, and was renamed "Tir" for translocated intimin receptor.

such as sialic acid or hyaluronic acid. Sialic acid and hyaluronic acid capsules, being made of "self" molecules, discourage the binding of C3b, which is the first step in the alternative complement activation pathway. Prevention of the deposition of complement factors on the bacterial surface is termed **serum resistance**. Such bacterial cells, when placed in complement-containing serum, continue to replicate instead of being lysed.

Pathogens that construct their capsules of host "self" molecules are afforded a further degree of protection. Immune responses, including antibody production and complement activation, are not normally elicited by the host's own components, making the pathogen a wolf in sheep's clothing. Thus, possession of a molecular "self" capsule prevents production of opsonizing capsule antibody, which would otherwise allow efficient phagocytosis. The various ways capsules protect pathogens from host immune responses are summarized in **Figure 21.5**.

Avoiding some or all of the host's early defenses, such as complement activation and phagocytosis, buys an opportunity for the pathogen to replicate to numbers that can outpace host immune defenses. By the time a protective adaptive immune response is mounted to the capsule, the pathogen is often already well established. As we learned in Section 20.6, T-independent immune responses to capsule components are essential in bridging the time between first infection and the production of protective anti-capsule antibodies. This response allows rapid production of anti-capsule antibodies before a routine T-cell-dependent primary adaptive response can be made. The memory response is similarly important in protecting the host from these pathogens. The faster and larger memory immune response shortens the time to production of protective antibody (see Figure 20.5).

TABLE B21.1 Results of Western blot analysis using anti-phosphotyrosine antibody and anti-78-kDa antibody

	Membrane fraction		Insoluble fraction[a]	
	EPEC-infected HeLa cells	Uninfected HeLa cells	EPEC-infected HeLa cells	Uninfected HeLa cells
Anti-phosphotyrosine antibody	+	–	+	–
Anti-78-kDa-antibody	+	–	++	–

[a] Insoluble fraction contains HeLa cell cytoskeleton proteins and EPEC proteins from attached bacteria of infected cells.
+ 90-kDa band observed
++ 78- and 90-kDa bands observed
– no bands observed

Next, the researchers set out to find the gene for Tir. They designed a DNA probe based on the N-terminal amino acid sequence of the 78-kDa unphosphorylated version of Tir. The gene *tir* was found to reside in the chromosome within the LEE locus along with all the other genes responsible for pedestal formation in infected cells, including the type III secretion system.

To confirm that Tir was of bacterial origin, they constructed a *tir* mutant by deleting a segment of the coding region. When cells were infected with the EPEC *tir* mutant, Tir could not be detected in infected cells, whereas it could be located in cells infected with wild-type EPEC. Furthermore, no pedestals were produced with the *tir* mutants, indicating Tir was required for this process. To confirm that Tir was injected by the LEE type III secretion system, they mutated one of the genes needed for assembly of the secretion system. Tir was not found in cells infected with this EPEC mutant, confirming it was injected into host cells.

Impact

This was the first time a bacterial receptor was reported to be translocated into the host cell. With so few bacterial receptors having been characterized, it is not known if this may be a more widespread phenomenon. Another pathogen for which injection of a receptor has been reported is *Citrobacter rodentium*, an intestinal pathogen of mice. *Citrobacter rodentium* is closely related to *E. coli* and also contains the LEE locus. It makes similar AE lesions, and as you might have guessed, also translocates its Tir receptor into host cells.

Questions for Discussion

1. Propose reasons why *E. coli* mutants defective for intimin do not form pedestals or fully developed AE lesions.
2. Hemolytic uremic syndrome (HUS) is produced by Shiga-like toxins, which are not delivered by type III secretion. Instead, they are released by bacterial lysis. Do you think that ingestion of an intimin mutant strain of O157:H7 might still cause HUS? Give reasons why or why not.

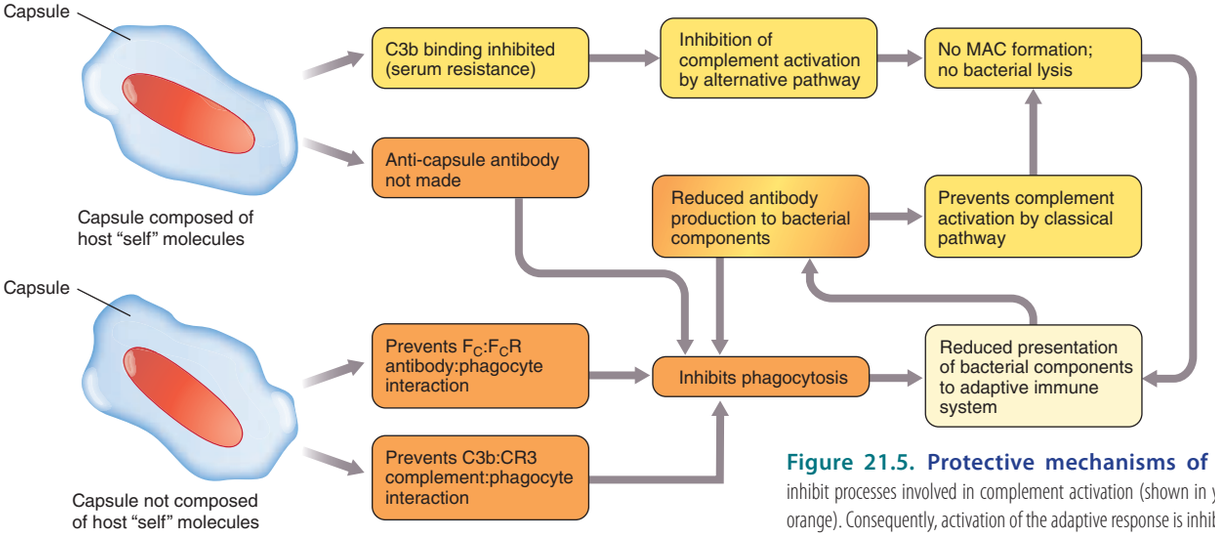

Figure 21.5. Protective mechanisms of capsules Capsules commonly inhibit processes involved in complement activation (shown in yellow) and phagocytosis (shown in orange). Consequently, activation of the adaptive response is inhibited and clearance is reduced.

CONNECTIONS As described in **Perspective 19.1**, capsules participate in biofilm formation for the pathogen *Pseudomonas aeruginosa*, and **Section 15.1** describes the importance of capsule production for biofilm formation for some *Escherichia coli* strains. Biofilm production is also part of the virulence program of *Staphylococcus aureus*, allowing it to reach high cell density early in infection.

Type III and type IV secretion systems

Although some toxins and other virulence factors are released by lysis of the bacterial cell, or secreted to the extracellular environment, others are actually injected directly into the host cell **(Table 21.5)**. Type III and type IV secretion systems are major virulence factors that are often hallmarks of Gram-negative pathogens (see Table 21.1). Gram-positive pathogens often use pore-forming cytolysins to transfer virulence factors into host cells (see Section 21.2). We were introduced to secretion systems in Section 2.5 (see Figure 2.25). Type III secretion systems are injection assemblies that deliver virulence factors directly into the target cell by forming a channel that passes through the plasma membrane and outer membrane of the pathogen and the host cell plasma membrane. Type III secretion systems are the more common of the two injection systems and are often found encoded together with the gene products they will inject. Later, in Section 21.3, we will see that these blocks of sequence are found on pathogenicity islands (PAIs), which we were introduced to in Sections 10.3 and 18.4. It is not unusual for some strains of pathogens to possess more than one type III secretion system. For example, *Salmonella* Typhimurium, a foodborne pathogen that causes enteric infection (salmonellosis) carries two different type III secretion systems. One is used for injecting the proteins SipA and SopE, involved in remodeling of the intestinal cells to which it attaches to induce uptake of the cells by intestinal enterocytes **(Figure 21.6)**. The other is used inside the phagosome for injecting proteins needed to prevent phagosome fusion with lysosomes. The bacilli survive and replicate in the phagosome of macrophages and enterocytes, where they can avoid host immune defenses.

Equivalent in function are **type IV secretion systems**, which have evolved from conjugation systems and can transport a variety of substances, including toxins directly across both bacterial membranes. Some type IV secretion systems deposit these into the immediate environment. For example, *Bordetella pertussis* secretes pertussis toxin at the host cell surface this way. Others have type IV systems that, like type III systems, can traverse the host plasma membrane. For example, *Helicobacter pylori* uses a type IV secretion system to inject

TABLE 21.5 Methods for releasing virulence factors

Method of release	Pathogen	Virulence factor
Cell lysis	*Streptococcus pneumonia*	Pneumolysin
	Clostridium tetani	Tetanus toxin
	Clostridium botulinum	Botulinum toxin
	Gram-negative species	Lipopolysaccharide
	Shigella dysenteriae and *Escherichia coli* enterohemorrhagic strains (e.g., O157:H7)	Shiga toxins
	Several invasive *Escherichia coli* strains, including O157:H7	Enterohemolysin
Secretion to environment	*Streptococcus pyogenes*	Streptolysin O; superantigens
	Staphylococcus aureus	α-Toxin; superantigens
	Clostridium perfringens	α-Toxin, perfringolysin
	Vibrio cholerae	Cholera toxin
	Bordetella pertussis	Pertussis toxin
	Helicobacter pylori	VacA
	Listeria monocytogenes	Listeriolysin
Injection into host cell	*Escherichia coli* enterohemorrhagic and enteropathogenic strains	Tir
	Salmonella Typhimurium[a]	SipA, SopE; various proteins preventing phagolysosome fusion
	Pseudomonas aeruginosa	Exoenzyme S, exoenzyme U
	Helicobacter pylori	CagA
	Agrobacterium tumefaciens	Ti plasmid, VirE2, VirD2

[a] *Salmonella enterica* serovar Typhimurium (see Appendix C for nomenclature)

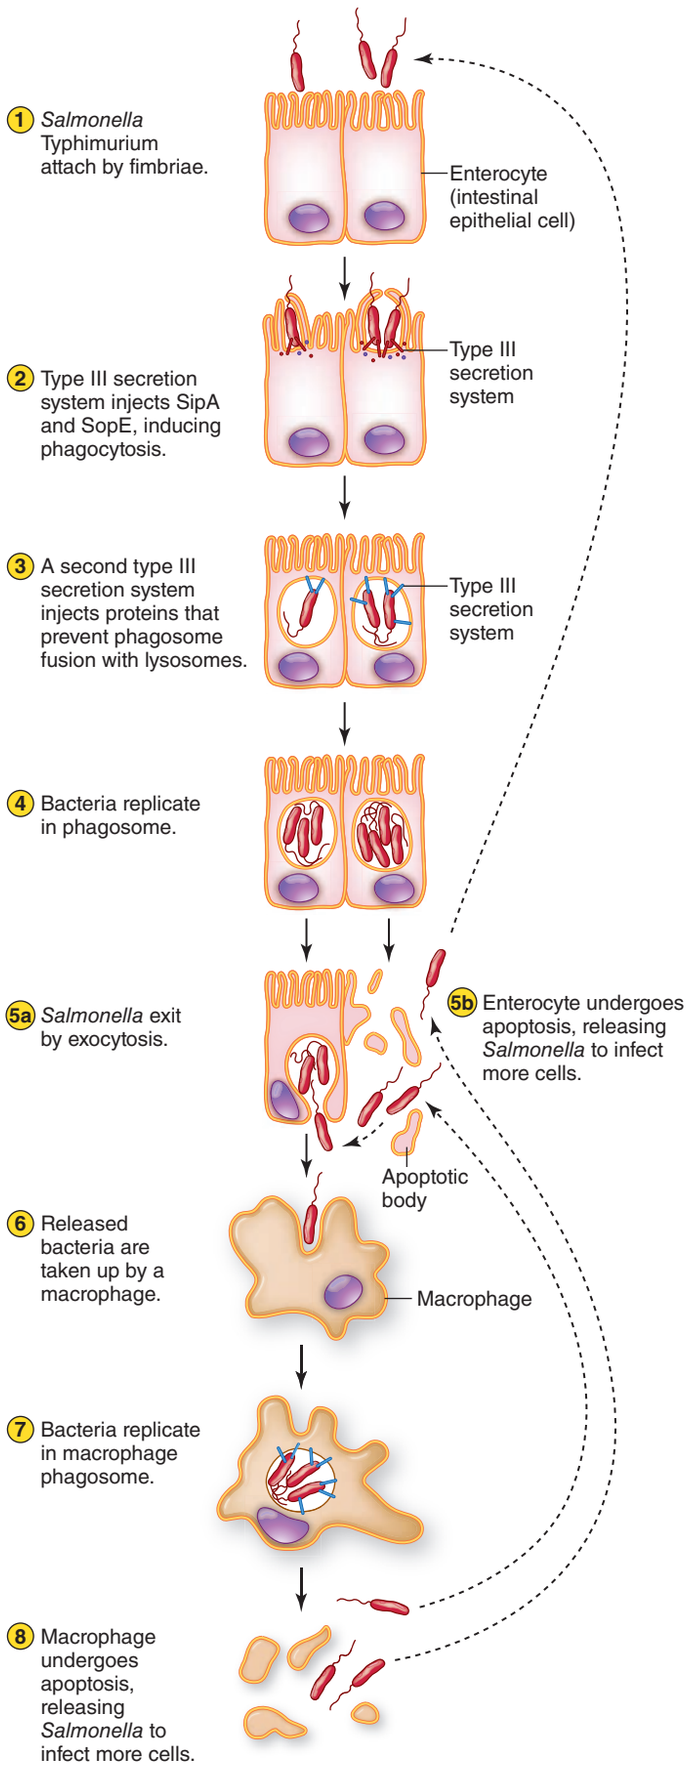

Figure 21.6. Process Diagram: Pathogenesis of *Salmonella* Typhimurium Attachment to enterocytes of the intestinal mucosa is by fimbriae. Two different type III secretion systems are used for injection of virulence factors that induce the formation of pseudopodia for uptake of the bacilli and prevent phagosome fusion with lysosomes. Death of intestinal cells and macrophages is due to apoptosis, which releases *S.* Typhimurium and spreads infection.

CagA toxin into gastric mucosal cells. The plant pathogen *Agrobacterium tumefaciens* uses a type IV secretion system to inject Ti plasmid DNA and protein virulence. Both factors are needed for transformation of plant cells to produce crown gall disease.

CONNECTIONS The natural transforming ability of *Agrobacterium tumefaciens* has been harnessed for the genetic engineering of plants. See **Section 12.5** for more information.

Iron-binding proteins

In Section 19.2, we mentioned that iron is a limiting nutrient for pathogens in the body since it is kept tightly bound by host iron-binding proteins. How then do bacterial pathogens obtain iron? Pathogens have evolved a variety of general strategies to get the iron they need **(Figure 21.7)**.

- They produce their own iron-binding molecules, called **siderophores**, that can scavenge iron from the host by competing with host iron-binding proteins, such as lactoferrin. Some siderophores bind iron very strongly and can steal it away from host iron-binding proteins.
- They produce proteins that can bind host iron-binding proteins and then transport the iron into the cell, letting the host do the iron binding for them.
- They produce metabolites that lower the pH at the site of infection, which reduces the ability of host iron-binding proteins to bind iron, making more available.
- They produce cytolysins that lyse host cells to release their iron stores. For example, producing hemolysins to lyse red blood cells is an effective way to obtain iron as well as other nutrients.

Comparative studies have shown that although many bacterial species have iron-binding proteins for binding free iron, pathogens commonly have specialized proteins for the task of wresting iron away from the host. These iron-binding proteins are virulence factors as they are not produced by non-pathogenic species, and gene knockouts are impeded in their ability to establish disease.

A well-studied mechanism of iron acquisition is that of *Mycobacterium tuberculosis*. Inside the host phagosome, the bacterium produces citric and salicylic acid, which cause the release of iron in the phagosomes. The iron then binds to siderophores called "mycobactins," for transport into the bacterium. Mycobactins can also directly steal iron from host lactoferrin, present in the phagolysosome. As described in **Perspective 21.1**, supplementing iron in tuberculosis patients can actually facilitate disease.

Perspective 21.1
IRON, VAMPIRES, FASHION, AND THE WHITE PLAGUE

Tuberculosis was once considered to be a disease of the nineteenth and mid-twentieth centuries, before the advent of the antibiotic streptomycin. Back then (in fact, up until around the 1960s) tuberculosis patients were sent to treatment facilities called sanatoriums where they received fresh air, nursing care, and rest. Those who could afford it often ate iron-rich meat. This habit served to essentially feed iron to *Mycobacterium tuberculosis*, causing these patients to often fare worse than their fellow patients who remained on iron-poor diets. As early as 1872, frequent relapses were documented in patients given a diet rich in iron while recovering from clinical tuberculosis.

Tuberculosis was commonly called "the white plague" due to the pallor that patients frequently developed. "Consumption" was another popular name, as those suffering from tuberculosis appeared as if they were being consumed, or wasting away—a biological effect of the overproduction of the cytokine tumor necrosis factor-alpha (TNF-α). Physical wasting, weakness, pale skin, and coughing up blood were thought to be the hallmarks of vampires, and many believed tuberculosis patients were actually being visited and slowly consumed by these mythical creatures **(Figure B21.1)**.

Tuberculosis was a disease that did not discriminate between rich or poor, famous or nameless. From 1930 to 1950, the look of tuberculosis actually became fashionable as it reached the most elite of society. Pale, thin, frail, and vulnerable in appearance became the new standards of beauty. Many popular film stars of the time adopted the look **(Figure B21.2)**.

Today, tuberculosis is back and it has a new look. It is a disease associated with poverty, drug abuse, overcrowding, and HIV. Many strains are resistant to multiple drugs commonly used to treat tuberculosis, including streptomycin, and these strains are spreading fast. The white plague has returned. Indeed, approximately one-third of the human population is infected with *M. tuberculosis*.

Figure B21.2. The fashionable appearance of tuberculosis Many movie stars of the mid-1900s adopted the look of tuberculosis, as shown here by Marlene Dietrich.

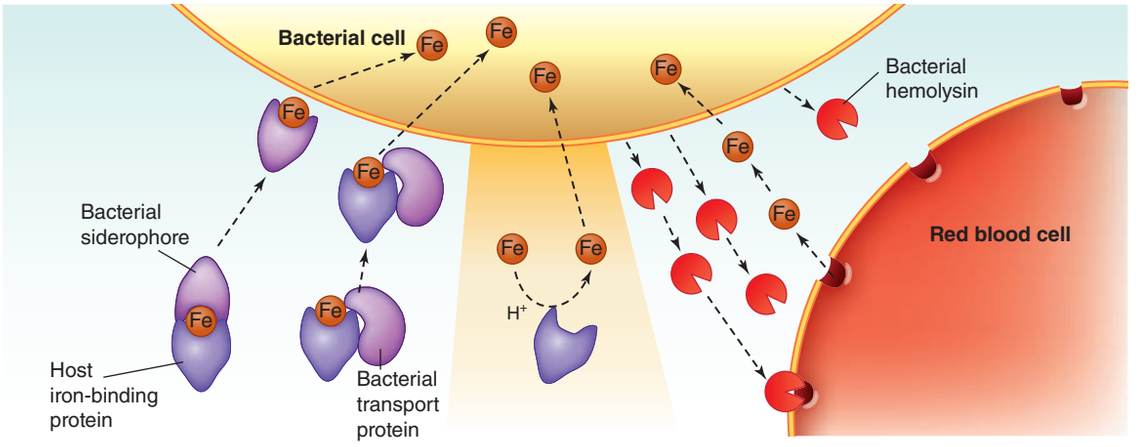

Figure 21.7. Bacterial mechanisms for obtaining iron **A.** Siderophores compete with host iron-binding proteins for iron. **B.** Bacterial transport proteins bind host iron-binding proteins and transport the iron complex to the cell. **C.** Bacterial metabolic products lower the pH, inhibiting the iron-binding ability of host proteins, making it available for bacterial use. **D.** Hemolysins destroy host cells, such as red blood cells, to release intracellular iron.

21.1 Fact Check

1. What are the main virulence factors used by bacterial pathogens?
2. Describe examples of attachment virulence factors.
3. In what ways do capsules protect pathogens?
4. How do secretion systems of Gram-negative bacteria contribute pathogenesis?
5. Describe how bacterial pathogens obtain iron.

21.2 Bacterial virulence factors—toxins

How do bacterial toxins act on host cells?

Continuing from what we have learned in the previous section, toxins are common virulence factors used by bacteria to gain nutrients from the host. A toxin is a poisonous substance that is produced by an organism. Bacterial toxins have diverse origins, structures, and activities, but they can be classified into a few general types based on mode of action or structure. These include endotoxins, A-B toxins, cytolysins, and superantigens. We will look at examples of each in this section but, before we do this, some toxin terminology will be clarified.

***Exo*toxins** are soluble proteins originating in the bacterial cytoplasm that are actively secreted to the external environment or are passively released upon bacterial lysis. Exotoxins have diverse origins, structures, and activities. They are commonly grouped by their structure, such as A-B toxins, for their molecular activity, such as superantigens, or for their cellular activity, such as cytotoxins.

If the toxin is part of the cell wall structure, it is called an ***endo*toxin**. Historically, the term "endotoxin" is reserved only for Gram-negative bacteria because it specifically refers to lipopolysaccharide (LPS). Lipoteichoic acid (LTA) is a Gram-positive cell wall-associated toxin, yet it is not referred to as endotoxin, although it has biological activity similar to LPS. Both these cell wall components can trigger an inflammatory response in the body that is responsible for many of the symptoms of disease. These toxins will be investigated in the next section. Toxins that act directly on host cells are called **cytotoxins**. Cell wall toxins are not cytotoxins because they do not exert their toxic activity directly on cells. Rather, they induce inflammation in the host.

CONNECTIONS The lipid A component of LPS is responsible for the inflammatory activity of endotoxin. It is inserted in the outer membrane of Gram-negative bacteria. Lipoteichoic acid (LTA) of Gram-positive bacteria consists of teichoic acid molecules linked to the plasma membrane by lipid tails. Like lipid A of LPS, LTA is a potent inducer of inflammation. See **Section 2.4** for details of the structure of these two molecules.

Many pathogens cause disease strictly by virtue of the toxins they produce. Diseases due to toxin production are seen with pathogens such as *Clostridium botulinum*, *Clostridium tetani*, *Corynebacterium diphtheriae*, and *Bacillus anthracis*, the causative agents of botulism, tetanus, diphtheria, and anthrax, respectively. Without the toxins, these bacteria are non-pathogenic or are of very low pathogenicity. Other pathogens produce toxins that exacerbate (make worse) disease. Some cytotoxins, commonly called "leukocidins," kill host immune cells (leukocytes) facilitating the replication and spread of the pathogen. Other cytotoxins, commonly called "hemolysins," destroy red blood cells, releasing nutrients such as iron, needed for metabolism and growth of the pathogen.

Endotoxin and lipoteichoic acid

As early as the 1890s, scientists recognized a common heat-stable extract that was responsible for many of the toxic effects of systemic diseases caused by Gram-negative bacteria. They called this toxin "endotoxin," thinking it originated from inside bacteria and was released upon lysis. This endotoxin was later shown to be lipopolysaccharide (LPS). Toxicity of the various forms of endotoxin produced by different Gram-negative pathogens varies with species and strain and also the location of the toxin in the body. The structure of LPS, the most common form of Gram-negative endotoxin, is presented in Figure 2.23. Each section is associated with specific biological properties, as shown in **Figure 21.8**. Analysis of purified endotoxins from various species has shown that the lipid A component is responsible for the toxic properties. The core polysaccharide is usually conserved between genera or species. The O-antigen is a major antigenic target in the body, and antibodies are produced against it. Because the polysaccharide structure of the O-antigen is frequently unique to a particular strain, it can be used for identification by **serotyping (Toolbox 21.1)**. Serotyping is a diagnostic method that uses antibodies made to these substances for identifying closely related strains that differ in their surface antigens. A strain identified by serotyping is called a **serotype**.

During an infection, endotoxin is released through bacterial replication and death. Released endotoxin is highly toxic to mammals, especially when it is present systemically. It is innately recognized as a pathogen-associated molecular pattern (PAMP) by the host. Recognition of endotoxin by cellular Toll-like receptors (TLRs) triggers the release of various

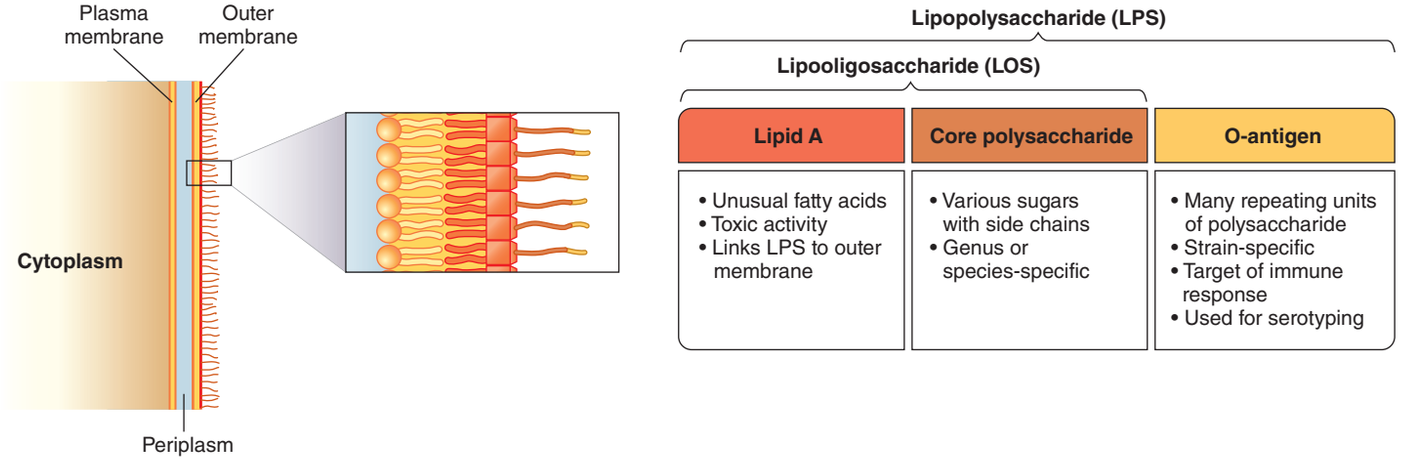

Figure 21.8. Functional structure of endotoxins of Gram-negative bacteria The lipid A portion anchors the molecule to the outer membrane and contains most of the toxic activity associated with endotoxin. The core polysaccharide is usually conserved in polysaccharide composition between genera or species. Lipooligosaccharide (LOS) of *Neisseria* and *Bordetella* species consists only of lipid A and core polysaccharide. Lipopolysaccharide (LPS), found in most Gram-negative species, contains an additional outer strain-specific O-antigen.

Toolbox 21.1
SEROTYPING

Serotyping uses antibodies to differentiate closely related strains by virtue of differences in surface antigens. Such serotypes, or serovars (see Appendix C), are often associated with particular diseases. Serotyping is frequently used to identify pathogens, link cases in a disease outbreak, and trace the origin and movements of a pathogen in populations. Conventional serotyping is done on a glass slide by mixing a sample of the bacterial culture with specific antiserum—serum containing specific antibodies obtained by injecting a rabbit with a particular surface antigen or microbe carrying that antigen. If the unknown strain possesses the particular antigen, then antibody from the antiserum will bind to it and cross-link the bacterial cells, producing a visible agglutination reaction **(Figure B21.3)**. More recently, PCR typing techniques are being developed as an alternative to antibody-typing methods. PCR primers are designed to amplify serotype-specific genes that are responsible for production of the surface molecules.

Serotyping for Gram-negative bacteria is commonly based on the LPS O-antigen, the capsule antigen (if one is present), and the flagella antigen. For *Escherichia coli* and *Salmonella* species, this corresponds to the designation of O:K:H, respectively, for the naming of different serotypes. For example, *E. coli* O157:H7 identifies the O-antigen as reacting with antibody specific for type 157, and the flagella it possesses reacts with antibody raised to type 7 flagella protein. At least 160 different O variations exist for *E. coli*, and more than 60 exist for *Salmonella*. The combinations of K and O antigens are unique enough that they can be used to identify specific strains of bacteria. In many cases, there is a relationship between the particular serotype designation and disease that is caused. For example, *E. coli* O157:H7 is an enterohemorrhagic strain that causes severe intestinal disease, whereas O15:K52:H1 is a uropathogenic strain, causing urinary tract infections (notice the K indicates this strain is also identified by its specific capsule components).

Serotyping is really an indirect way of identifying genetic constitution, as the surface antigens that the antibodies recognize are a reflection of the different genes possessed by these strains.

Figure B21.3. Serotyping A positive agglutination reaction is shown on the *right*, and a negative agglutination reaction is shown on the *left*.

Test Your Understanding

In 2010, an outbreak caused by *E. coli*-contaminated lettuce caused a nationwide recall in the United States. The Centers for Disease Control and Prevention reported the cause to be a Shiga toxin-producing *E. coli* O145 strain. What does the O145 designation mean? How would serotyping be used to characterize this strain?

cytokines that induce inflammation. Large-scale release of endotoxin during severe infections can trigger a systemic inflammatory response, producing septic shock and death. This is a common outcome when Gram-negative pathogens gain access to the circulatory system.

CONNECTIONS Inflammation is a common, early response to infection and is induced when microbial components are recognized by host TLRs. While localized inflammation is often beneficial, systemic inflammation can be deadly. For a review of septic shock, PAMPs, and TLRs, see **Sections 19.3** and **19.4**.

Severe inflammation in some tissues can cause organ damage. For example, *Neisseria meningitidis* is a cause of meningitis or inflammation of the meninges, the lining that surrounds the brain and spinal cord. When *N. meningitidis* gains access to the central nervous system from the bloodstream, it colonizes the meninges. Inflammation is produced primarily by the release of endotoxin. As cells and fluids move into the closed environment of the central nervous system, they rapidly increase the pressure on sensitive neurons, which become permanently damaged. If damage is extensive, death will occur. Inflammatory damage due to endotoxin release also occurs for its close relative, *Neisseria gonorrhoeae* (see Microbes in Focus 21.1). When this pathogen reaches the fallopian tubes, released endotoxin evokes inflammation, which damages cells and leads to sterility. Unfortunately, this robust inflammatory response affords little protection against these pathogens.

LPS is found in enteric Gram-negative bacteria, such as *E. coli* and *Salmonella*. However, some Gram-negative genera, such as *Neisseria* and *Bordetella*, do not have the outer O-antigen component. These shortened non-LPS endotoxins—called **lipooligosaccharides (LOS)**—maintain toxic activity equivalent to that of LPS because they still contain the lipid A component (see Figure 21.8). Endotoxins have several biological activities, listed in **Table 21.6**. Many of the effects produced by low concentrations of endotoxin are important for stimulation of immune responses in the host that in turn can prevent disease. One of endotoxin's most important properties is its ability to evoke inflammation. As we saw in Section 19.3, inflammation in a local area recruits defense cells and molecules needed to combat the pathogen, but systemic production of endotoxin can turn this protective response deadly.

Lipoteichoic acid (LTA) is a cell wall molecule found anchored to the plasma membrane in most Gram-positive pathogens. Similar to endotoxin, it is recognized by TLRs and can induce inflammation. If substantial numbers of bacteria are present systemically, the release of lipoteichoic acid can, like endotoxin, induce septic shock. In this regard, it is the functional equivalent of Gram-negative endotoxin.

Some of the most potent bacterial toxins are those that enter host cells and act selectively on cellular pathways. One of the most powerful toxins known is botulinum toxin or botulin **(Microbes in Focus 21.2)**. Based on toxicity studies in mice, it has been estimated that a single gram of crystalline toxin, if evenly dispersed and inhaled, can kill more than one million people. Other potent bacterial toxins include tetanus toxin, or tetanospasmin of *Clostridium tetani*, and diphtheria toxin of *Corynebacterium diphtheriae*. These bacterial toxins have common structural features and are known as A-B toxins.

TABLE 21.6 Biological effects of endotoxin and lipoteichoic acid

Effect	Protective activity
Fever	Inhibition of pathogen replication Increase in immune cell activities
Complement activation	Lysis by MAC formation[a] Induction of inflammation
Inflammation	Transport of immune cells and molecules to site of infection
B-cell proliferation	Antibody production
IFN-γ expression from T cells	Activation of macrophages and NK cells[a]
Stimulation of clotting cascade	Prevention of pathogen spread

[a] See Chapter 19 for review.

A-B toxins

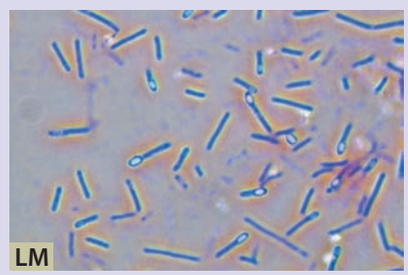
A-B toxins are exotoxins that derive their name from their structure. They are generally composed of two structural parts, an enzymatically active A peptide and a membrane-binding B portion. A-B toxins are produced as inactive precursor proteins

Microbes in Focus 21.2
CLOSTRIDIUM BOTULINUM

Habitat: Aquatic sediments and soils

Description: Anaerobic, Gram-positive rod, approximately 2–5 μm in length, forming terminal endospores

Key Features: Incidental ingestion of botulinum toxin or endospores (shown here as pale ovals within the bacilli) can cause deadly paralysis. Various strains produce biochemically distinct A-B type neurotoxins (types A to G) that affect various vertebrate species. The toxins are produced under anaerobic conditions in metabolically active vegetative cells. Near-identical non-toxigenic *Clostridium* counterparts are taxonomically classed as different species, although the only major genetically distinguishing feature is the lack of the toxin gene. The genes encoding the toxins are acquired by horizontal gene transfer.



© Michael Abbey/Science Source

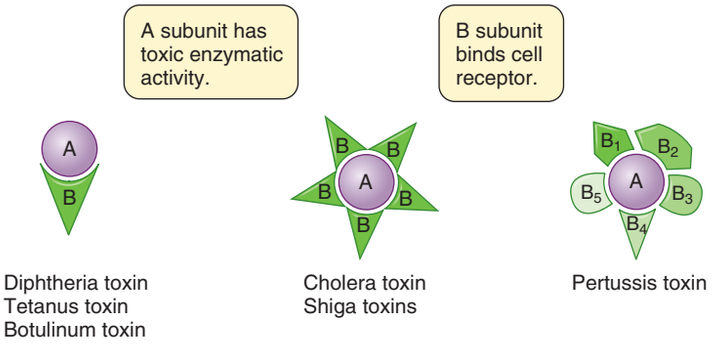


Figure 21.9. Structural variation of some A-B exotoxins Diphtheria toxin from *Corynebacterium diphtheriae,* tetanus toxin from *Clostridium tetani,* and botulinum toxin from *Clostridium botulinum* are composed of single A and B subunits. Cholera toxin from *Vibrio cholerae*, Shiga toxins from *Shigella dysenteriae,* and enterohemorrhagic *E. coli* O157:H7 are composed of a single A subunit with five identical B subunits. Pertussis toxin from *Bordetella pertussis* is composed of a single A subunit with five non-identical B subunits.

that must be cleaved by specific proteases to produce the A and B subunits that make up the active toxin. The location of toxin cleavage depends on the toxin. For example, cleavage can be done by proteases secreted by the host cell or cleavage can occur inside the bacterium, with the subunits held together by a disulfide bond. Some A-B toxins are composed of a single A and B subunit whereas others have multiple B subunits associated with a single A subunit peptide. Many variations exist, as shown in **Figure 21.9**.

The assembled A-B toxin must cross the plasma membrane of the host target cell to carry out its activity. However, the host cell plasma membrane is an effective barrier to the passage of most large molecules. Those that do enter the cell rely on specific transport mechanisms of the cell, such as endocytosis. Receptor-mediated endocytosis is induced by binding of the B portion of the toxin to specific cell surface receptors. These receptors are usually cell-specific and therefore dictate the tissue preference and species specificity of the toxin. For example, *E. coli* O157:H7 produces Shiga-like toxins, which are A-B toxins nearly identical to the Shiga toxins produced by *Shigella dysenteriae.* These *E. coli* Shiga-like toxins cause HUS. The Shiga toxin receptor, called globotriaosylceramide (Gb3), is found on various cell types, including epithelial cells of the kidney and endothelial cells lining the blood vessels and organs. Once taken up, Shiga toxins disrupt protein synthesis by cleaving RNA of the ribosome. Preventing protein production kills cells, but it also causes activation of blood clotting in affected platelets. The clots that form obstruct the small capillaries in organs such as the kidney. As red blood cells attempt to flow through the narrowed passages, they rupture. Renal failure occurs when blood can no longer access kidney tissues. By this same pathology, other organs with rich microvasculature, such as the brain, can also become damaged temporarily or permanently.

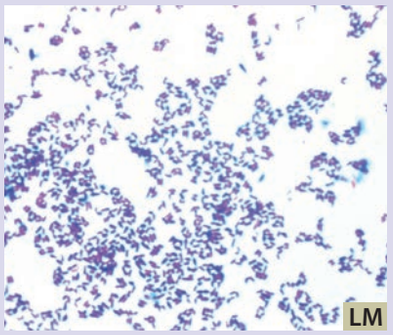
The Shiga toxin receptor is enriched in the kidneys of humans but is lacking in cattle, deer, sheep, and pigs. These species serve as reservoirs of infection as they can carry these O157:H7 strains without becoming ill themselves. The amount and distribution of Shiga toxin receptors in humans varies and may explain why only 10 to 15 percent of persons infected with *E. coli* O157:H7 develop the complications of HUS.

Microbes in Focus 21.3
CORYNEBACTERIUM DIPHTHERIAE

Habitat: Exclusively found in humans and is carried in the pharynx of some adults, less commonly on the skin

Description: Gram-positive, non-motile, irregular non-endospore-forming rod 2–6 μm in length. Rods are often seen positioned at right angles to each other, giving them the appearance of lettering similar to cuneiform or Chinese script.

Key Features: Some strains of *C. diphtheriae* are toxigenic, producing the disease diphtheria. The A-B toxin that is responsible for the disease is actually encoded by a temperate phage that delivers the toxin gene to *C. diphtheriae*. The diphtheria toxin is secreted by *C. diphtheriae* cells colonizing the pharynx, nose, or sometimes skin. Before immunization became widespread in the 1940s, the death rate from diphtheria was approximately 10 percent, mostly in young children.



Dr. Rosalind King/Science

Once the A-B toxin is incorporated inside a membrane-bound endosome, the active A subunit must escape to the cytoplasm to exert its toxic activity within the cell. Different toxins have different ways of doing this. One of the best-understood pathways is that of diphtheria toxin produced by *Corynebacterium diphtheriae*, the causative agent of diphtheria **(Microbes in Focus 21.3)**. In the pharynx, local cell death due to the toxin results in a distinctive fibrous, walled-off lesion called a pseudomembrane **(Figure 21.10)**. The secreted toxin is absorbed into the circulatory system where it is distributed to other tissues possessing diphtheria toxin receptors, such as the heart, kidneys, liver, and spleen. It exerts its lethal effects by preventing protein translation in these cells. The degree of damage

Figure 21.10. Diphtheria pseudomembrane Infection with toxigenic strains of *Corynebacterium diphtheriae* frequently produces characteristic fibrin-encased, adherent lesions in the pharynx.

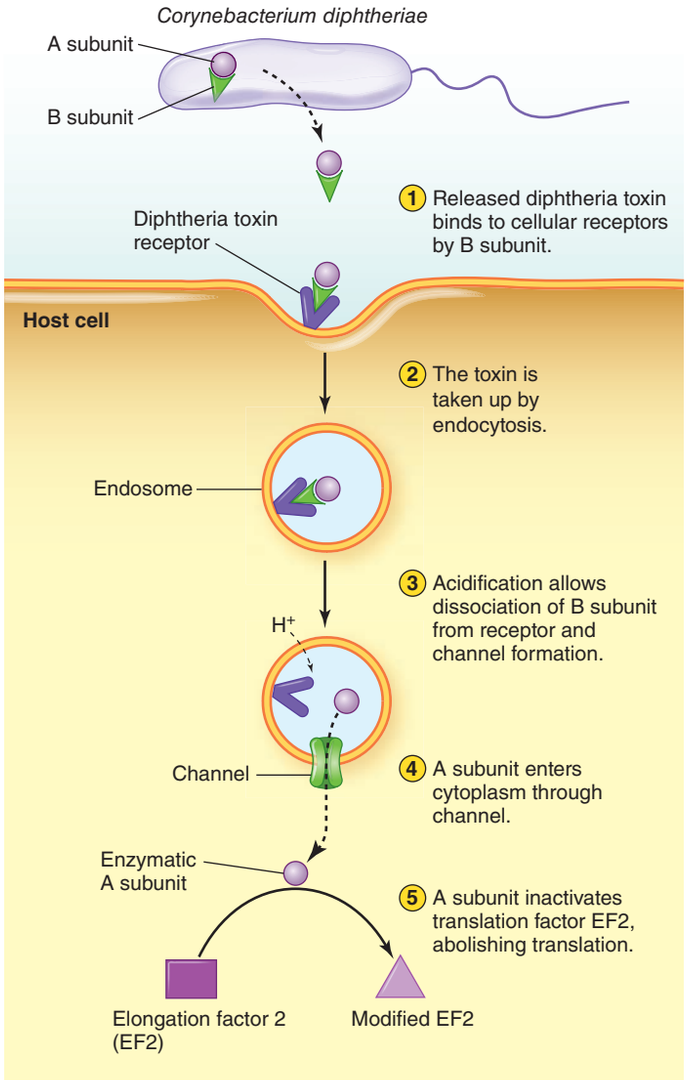

Figure 21.11. Process Diagram: Entry and action of diphtheria toxin Diphtheria toxin is taken up by host cells possessing the diphtheria toxin receptor. Acidification in the endosome causes a conformational change in B subunit, and a channel is formed to allow the A subunit to reach its molecular target EF2 in the host cytoplasm.

incurred by individuals is related to the number and distribution of the receptor.

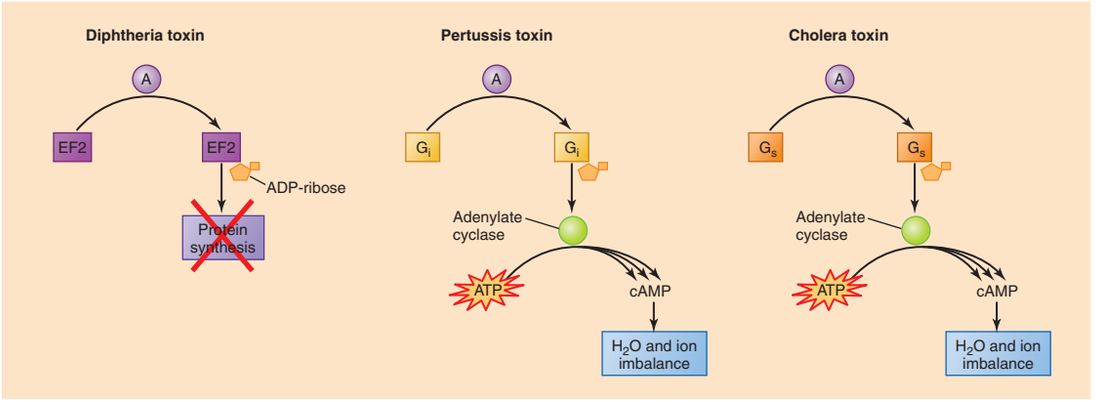
Figure 21.11 illustrates the translocation and action of diphtheria toxin. Inside the endosome, acidification causes conformational changes in the diphtheria toxin, allowing an exposed hydrophobic portion of the B subunit to insert into the endosomal membrane. This forms a channel through which the now dissociated A peptide travels. The molecular target for the A peptide of diphtheria toxin is elongation factor 2 (EF2). As shown in **Figure 21.12**, the A peptide adds an adenosine diphosphate-ribose group to EF2, a process referred to as ADP-ribosylation. EF2 is essential for ribosome movement along messenger RNA molecules in eukaryotes. In its ADP-ribosylated form, EF2 cannot function and protein production is halted. As the A subunit is an enzyme, a single molecule can catalyze the ADP-ribosylation of many EF2 proteins, resulting in inhibition of protein production and death of the cell. Many other A-B toxins carry out ADP-ribosylation or glycosylation of their target molecules **(Table 21.7)**. Others, as in Figure 21.12, directly cleave proteins or ribosomal RNA molecules.

Two examples of A-B toxins that cleave host proteins are botulinum toxin and tetanus toxin, causing botulism and tetanus, respectively. Both are neurotoxins that are closely related in structure and function and act on members of a group of proteins, called SNARE proteins, which are needed for the release of neurotransmitters. To release the neurotransmitters that are contained in vesicles in a neuron, the vesicles must fuse with the plasma membrane of the neuron. The SNARE proteins synaptobrevin, SNAP25, and syntaxin facilitate this membrane fusion. Synaptobrevin is found inserted in the vesicle membrane, and syntaxin is found inserted in the neuron plasma membrane. SNAP25 binds to both, forming a complex that allows the membranes to fuse. Cleaving any of the SNARE proteins **(Table 21.8)** prevents the release of neurotransmitters that mediate muscle movement. Although botulinum and tetanus toxins act on the same cellular process, they produce clinically different diseases. Botulinum toxin prevents muscle contractions, resulting in "flaccid" paralysis, while tetanus toxin produces continuous muscle contraction, resulting in "spastic" paralysis. Several types of botulinum toxins are produced by different strains of *C. botulinum*, with certain types preferentially affecting different animal species and acting on a different set of SNARE proteins. Although botulinum toxin and tetanus toxin both bind to stimulatory nerve terminals of motor neurons, which release the stimulatory neurotransmitter acetylcholine, they use different receptors and are transported to different target neurons. Botulinum toxin acts within the motor neuron, whereas tetanus toxin is transported from the motor neuron to the central nervous system to inhibitory nerve terminals that release the inhibitory neurotransmitters glycine and gamma aminobutyric acid (GABA).

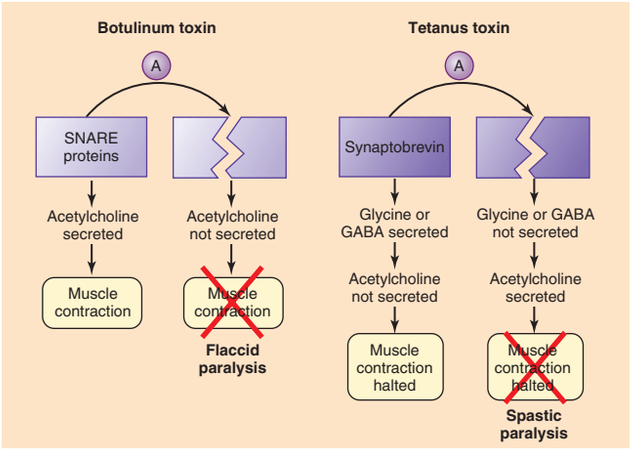
Once the A peptides of the toxins are released to the cytoplasm, they cleave their SNARE protein target, preventing the fusion of neurotransmitter-filled vesicles with the neuron plasma membrane. For botulinum toxin, this prevents the acetylcholine from being released at the neuromuscular junction, and muscle contraction does not occur **(Figure 21.13)**.

For tetanus toxin, once the A subunit enters inhibitory neurons, it prevents the release of glycine or gamma-amino butyric acid (GABA). Glycine and GABA act on motor neurons to block acetylcholine release, ending contraction. Thus, tetanus toxin allows acetylcholine to be continually released from stimulated neurons, causing the associated muscles to persistently contract **(Figure 21.14)**. Anyone who has suffered a severe leg-cramp might be able to imagine how painful this would be. Any small stimulus can trigger a massive contraction so powerful that tendons and even bones can snap **(Figure 21.15)**.

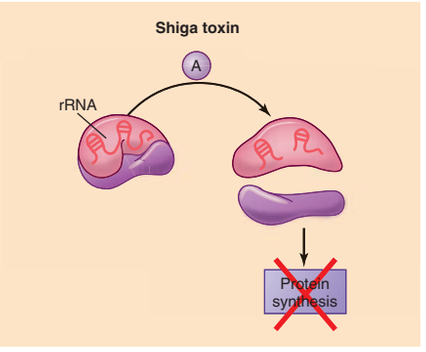
Tetanus is also known as "lockjaw" because the large masseter muscle is often the first to be affected noticeably. In both botulism and tetanus, death is usually due to respiratory failure as the muscles involved in breathing no longer function. Both toxins can act on a variety of animal species. Botulinum toxins are responsible for periodic massive die-offs of fish and aquatic birds, as described in **Perspective 21.2**.



A. ADP-ribosylation of target



B. SNARE protein cleavage



C. Ribosomal RNA cleavage

Figure 21.12. Action of some A-B toxins **A.** Diphtheria toxin (*left*) adds an ADP-ribose unit to translation factor EF2, halting protein synthesis. Pertussis toxin (*middle*) adds an ADP-ribose to the signaling protein G_i, locking it into an activated form, keeping host cell enzyme adenylate cyclase active, and converting ATP into cyclic AMP (cAMP). Excess cAMP disrupts the regulation of water and ion flow in cells, severely impairing cell functions. Cholera toxin (*right*) adds an ADP-ribose to G_s protein, an enzyme with function similar to G_i, resulting in increased cAMP levels in intestinal cells. **B.** Botulinum toxin cleaves SNARE proteins in stimulatory nerve terminals, preventing muscular contraction. Tetanus toxin cleaves the SNARE protein synaptobrevin in inhibitory nerve terminals, causing muscular contraction to be continuous. **C.** Shiga toxins cleave ribosomal RNA (rRNA), preventing protein synthesis.

TABLE 21.7 A-B toxins, source, activity, target cells, and disease

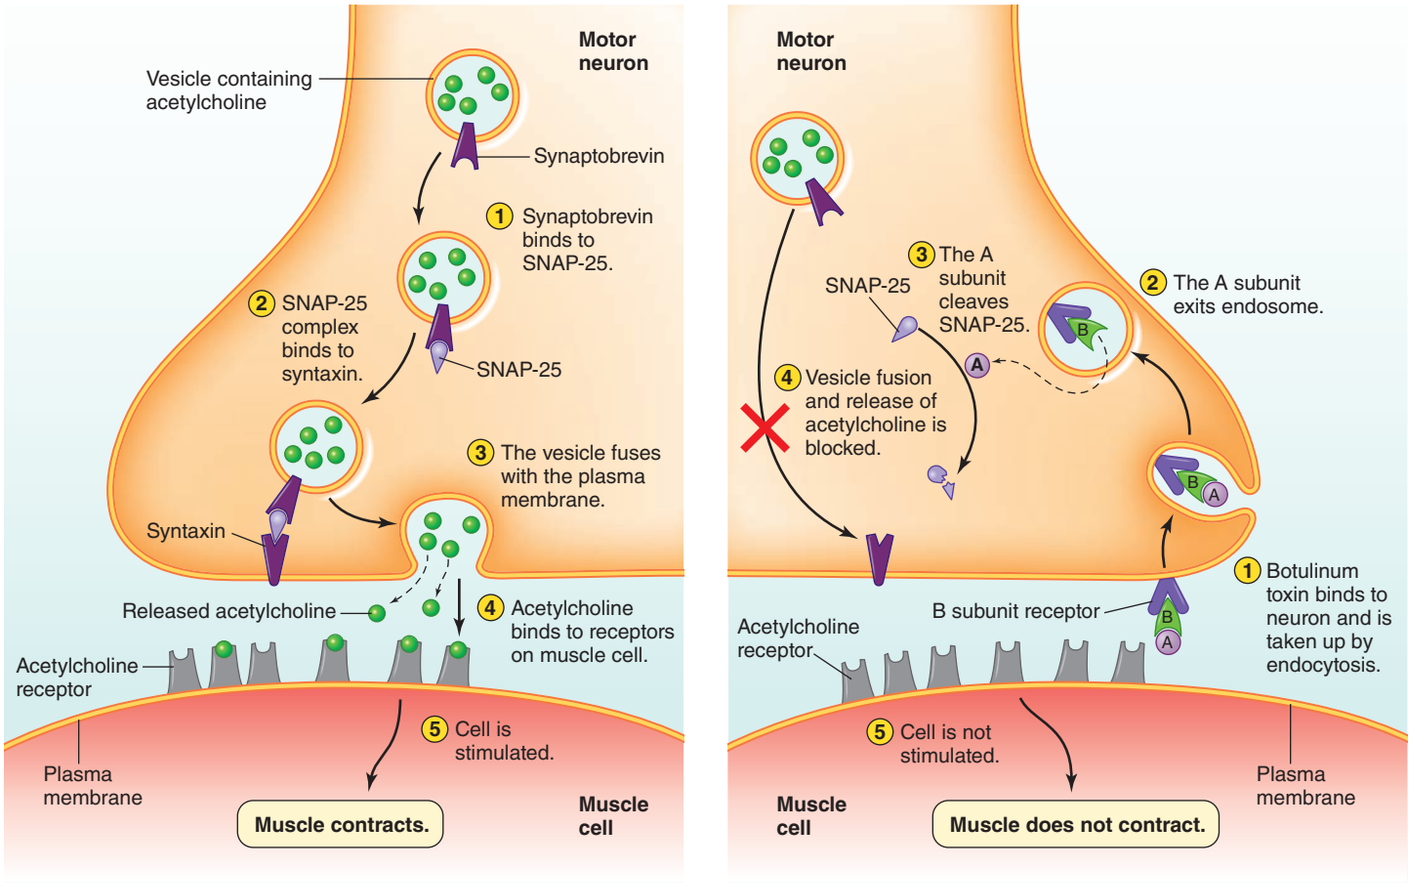
Toxin	Bacterium	Activity	Target cells (receptor-restricted)	Disease
Diphtheria toxin	*Corynebacterium diphtheriae*	ADP-ribosylation of EF2; inhibition of protein synthesis	Upper respiratory tract, heart, nerves, kidney	Diphtheria
Botulinum toxin	*Clostridium botulinum*	Cleaves SNARE proteins needed for release of the neurotransmitter acetylcholine	Motor neurons	Botulism
Cholera toxin	*Vibrio cholerae*	ADP-ribosylation of G_s protein; increases cAMP levels; cellular ion disruption	Cells of the intestinal tract where the bacterium colonizes	Cholera
Invasive adenylate cyclase	*Bordetella pertussis*	Increases cAMP levels; cellular ion disruption	Ciliated cells of the respiratory tract where the bacterium colonizes	Whooping cough (pertussis)
LT (heat labile toxin)	Enterotoxigenic *Escherichia coli* strains	ADP-ribosylation of G_s protein; increases cAMP levels; cellular ion disruption	Cells of the intestinal tract where the bacterium colonizes	Diarrhea
Pertussis toxin	*Bordetella pertussis*	ADP-ribosylation of G_i protein; increases cAMP levels; cellular ion disruption	Ciliated cells of the respiratory tract where the bacterium colonizes	Whooping cough (pertussis)
Shiga toxins	*Shigella dysenteriae* and enterohemorrhagic *Escherichia coli*	Cleaves host ribosomal RNA; inhibition of cell protein synthesis	Kidney, liver, neurons	Hemolytic uremic syndrome (HUS)
Tetanus toxin	*Clostridium tetani*	Cleaves SNARE protein synaptobrevin needed for release of neuroinhibitors	Inhibitory neurons	Tetanus (lockjaw)
Toxin A, toxin B	*Clostridium difficile*	Glycosylation of GTPase enzymes	Many cell types, including enterocytes	Colitis

TABLE 21.8 Specific SNARE protein targets of botulinum and tetanus toxins

SNARE target	Toxin
Synaptobrevin	Tetanus toxin, botulinum toxin type B, D, F, G
SNAP-25	Botulinum toxin type A, C, E
Syntaxin	Botulinum toxin type C

Humans are probably inadvertent victims of botulism. Endopores of *C. botulinum*, like those of *C. tetani*, sometimes contaminate deep wounds and can germinate under anoxic conditions to produce the toxin. More commonly, however, botulism is a result of the ingestion of contaminated food (see Section 16.2). In adults, ingestion of the toxin causes disease whereas ingestion of *C. botulinum* itself, or its endospores, usually does not. The human intestinal microbiota provides a sufficiently competitive environment to prevent germination and growth. Because infants lack protective adult microbiota, germination of endospores can occur in the infant colon, and the toxin is produced. Infant botulism is the most common form of the disease worldwide and is suspected to be one possible cause of sudden infant death syndrome.

A-B toxins are often targeted for use as vaccines because they are principally responsible for the diseases that result from exposure to or infection by the bacteria that produce the toxins. For example, vaccines for diphtheria, tetanus, and pertussis contain denatured A-B toxins called **toxoids**. Toxoids lack the structure required for toxin activity but retain the ability to generate protective antibody against the active toxins. Denaturing the toxin either prevents binding and translocation of the B subunit into the cell and/or destroys enzymatic activity of the A subunit. Diphtheria and tetanus vaccines (the D/d and T in the DTaP/Tdap vaccine blends) are two of the safest and most effective vaccines in use today. They are highly immunogenic, producing a long-lasting protective humoral response. Pertussis vaccine was developed against *Bordetella pertussis*, the agent of contagious whooping cough (see Microbes in Focus 6.2). The vaccine is an acellular pertussis (the aP in DTaP) formulation composed of denatured pertussis toxin (an A-B toxin), in combination with two or more purified proteins used by the pathogen for adherence to ciliated epithelial cells of the upper respiratory tract. These proteins are filamentous hemagglutinin, pertactin, or fimbriae. Why are these added? Production of protective antibody to the pertussis toxoid will prevent disease but will do nothing to prevent infection by the pathogen. These proteins are added to reduce the ability of



A. Normal function of motor neuron

B. Action of botulinum toxin type A on motor neuron

Figure 21.13. Process Diagram: Action of botulinum toxin **A.** Normal muscular contraction involves release of the neurotransmitter acetylcholine from vesicles in terminals of motor neurons. **B.** Botulinum toxin type A cleaves the SNARE protein SNAP-25 needed for release of acetylcholine. Consequently, muscular contraction does not occur.

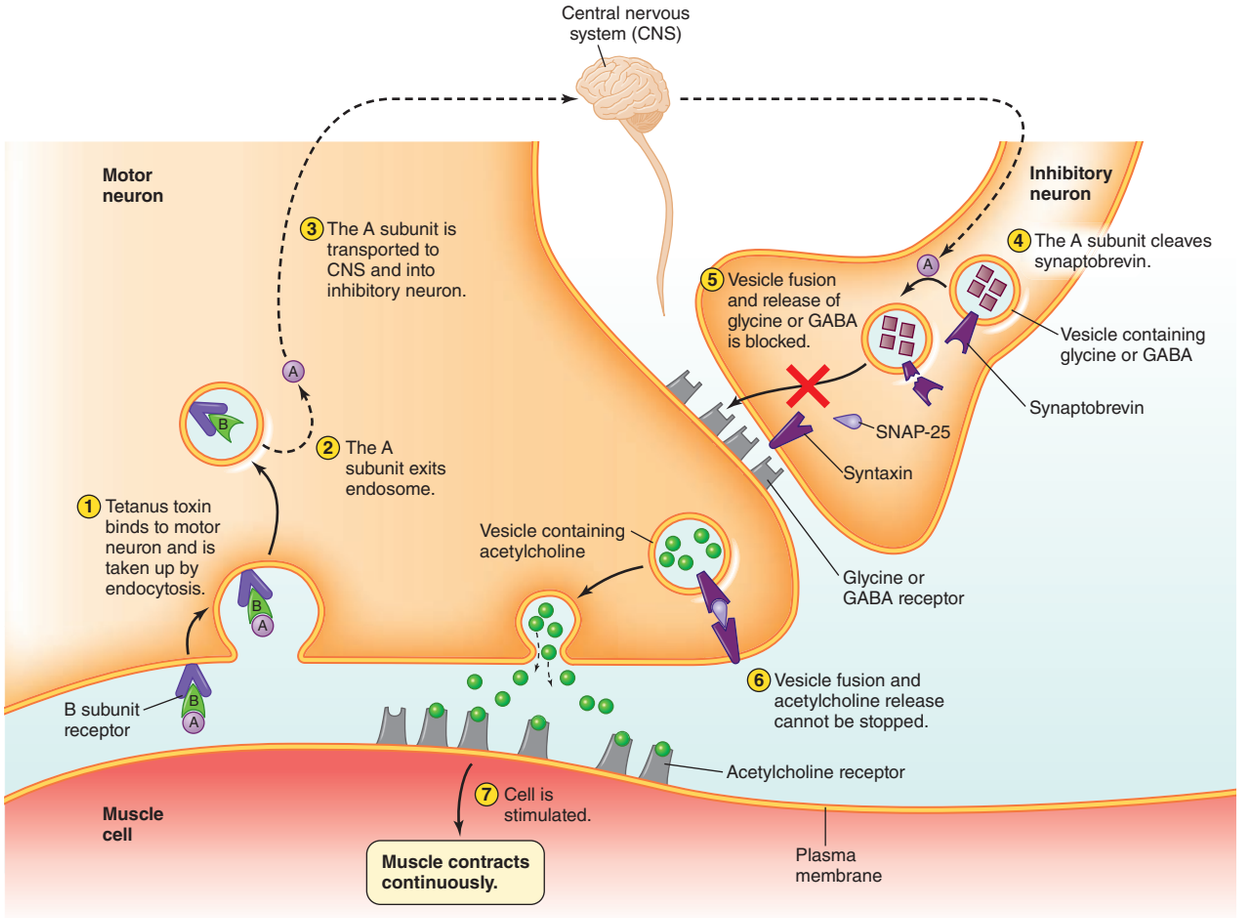


Figure 21.14. Process Diagram: Action of tetanus toxin Once stimulated, normal muscular contractions can be halted by the release of the neuroinhibitory neurotransmitters glycine or gamma-amino butryric acid (GABA) from associated inhibitory neurons. Tetanus toxin is taken up by motor neurons and is transported to the central nervous system, then to inhibitory nerve terminals that release inhibitory neurotransmitters. The A subunit cleaves the SNARE protein synaptobrevin in inhibitory neurons needed for release of glycine and GABA. Consequently, muscular contraction is continuous.

Figure 21.15. Effect of tetanus toxin Muscular contractions can be powerful enough to damage the spine and sever tendons. In this early nineteenth-century painting, Scottish anatomist Sir Charles Bell portrays a soldier with tetanus.

B. pertussis to colonize the respiratory tract, thus preventing its spread in populations.

CONNECTIONS The immunization schedule for diphtheria and tetanus using combined vaccine formulations as well as other currently recommended vaccines is presented in **Figure 24.17**. Vaccines are discussed in **Section 24.5**.

Cytolysins

Cytotoxins that act on plasma membranes are called **cytolysins**. They are commonly, and rather arbitrarily, named. For example, streptolysin is from *Streptococcus pyogenes*, so is named according to its origin. They may also be named according to their order of discovery, as in α-toxin, or the cells they can destroy. For example, hemolysins lyse red blood cells. The ability of many cytolysins to lyse a variety of eukaryal cell types is readily visualized by culture on agar containing red blood cells,

commonly called blood agar. Usually, sheep red blood cells are used for this media. Lysis of blood cells, called **hemolysis**, produces a zone of clearing. Hence, many cytolysins have been named hemolysins because of this *in vitro* reaction.

Hemolysis patterns are characteristic of some species and are often used as a diagnostic tool by clinical bacteriologists. This is the case for identification of *Streptococcus* species, which can produce three patterns of hemolysis on blood agar. Lysis that results in a zone of complete, colorless clearing is called "β hemolysis" (Figure 21.16). Beta hemolysis is produced by pathogenic strains of *Streptococcus pyogenes*. Production of a zone with a dark greenish tinge is called "α hemolysis." Alpha hemolysis is produced by *Streptococcus pneumoniae* as well as many species of *Streptococcus*, such as *S. mutans*, normally found in the oral cavity (see Microbes in Focus 17.2). Interestingly, α hemolysis is not due to complete cell lysis. The greenish cast seen in α hemolysis is due to peroxide-mediated chemical changes that cause discoloration of partially decomposed hemoglobin. The absence of hemolysis is called "γ hemolysis"; a misnomer if ever there was one. Gamma hemolysis is characteristic of the bacterium *Enterococcus faecalis*, a close relative of the genus *Streptococcus*, and can be used to help distinguish it from pathogenic streptococci.

The molecular activities of cytolysins fall into two general categories: pore-forming toxins and membrane-degrading toxins (lecithinases). Table 21.9 lists some examples of membrane-damaging cytolysins and their activities. Pore-forming cytolysins are produced as monomers that polymerize in the membrane to form a circular pore. They anchor to molecules that are specifically found concentrated in eukaryal membranes and not in bacterial membranes. Alpha-toxin from *Staphylococcus aureus* is secreted as monomers that bind to unspecified lipid receptors. The monomers oligomerize, joining together and refolding to form a transmembrane segment that directly inserts into the lipid bilayer (Figure 21.17).

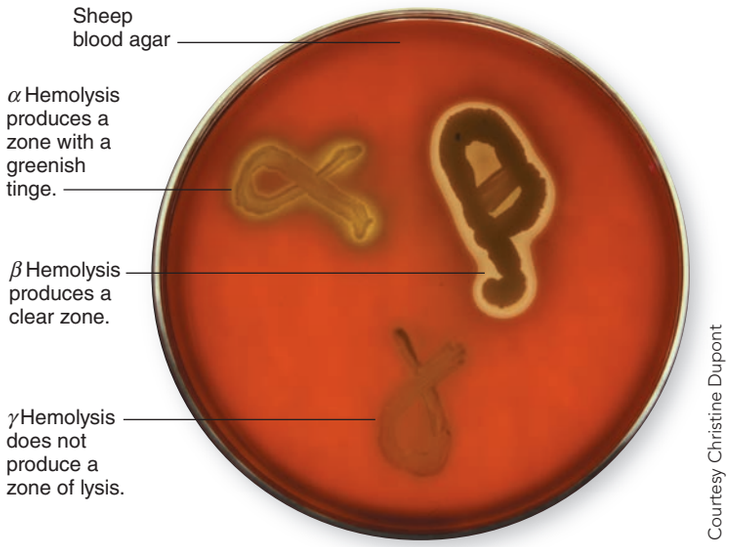

Figure 21.16. Hemolysis patterns of *Streptococcus* species *Streptococcus pyogenes* produces β hemolysis, a zone of colorless, complete clearing. Most other streptococci produce α hemolysis, a zone with a distinct greenish tinge. The absence of hemolysis, produced by *Enterococcus faecalis*, is called γ hemolysis.

TABLE 21.9 Source, action, targets, and diseases produced by cytolysins

Pathogen	Toxin	Activity	Target cell	Disease
Clostridium perfringens	α-toxin[a] (lecithinase)	Degrades membrane lipids	Many cell types	Gas gangrene
	Perfringolysin	Forms pores		
Escherichia coli uropathogenic strains	Hemolysin A	Forms pores	Erythrocytes and nucleated cells	Urinary tract infections
Helicobacter pylori	VacA	Forms pores	Gastric mucosa	Gastritis and ulcers
Listeria monocytogenes	Listeriolysin	Forms pores in endosome	Macrophages	Meningitis and septicemia
	Lecithinase	Degrades membrane lipids	Many cell types	
Pseudomonas aeruginosa	*Pseudomonas aeruginosa*	Forms pores	Many cell types	Skin infections and pneumonia
	Cytotoxin			
Staphylococcus aureus	α-toxin[a]	Forms pores	Many cell types	Skin infections
	Panton-Valentine (PV) leukocidin	Forms pores	Phagocytes	Necrotizing skin and lung infections
Streptococcus pneumoniae	Pneumolysin	Forms pores	Lung and blood vessel cells	Pneumonia
Streptococcus pyogenes	Streptolysin O	Forms pores	Variety of cells	Pharyngitis/tonsillitis, rheumatic fever, rheumatic heart disease

[a] Although both of these toxins are named α-toxin, they are unrelated in structure, function, and origin. To avoid confusion, it is necessary to state the microbial origin of the toxin.

Perspective 21.2
THE GOOD, THE BAD, AND THE UGLY SIDE OF BOTULINUM TOXIN

Botulinum toxin isn't all bad. Since the 1980s, it has been used to treat muscle spasms, tension headaches, and various other neuromuscular conditions. It is perhaps now more popularly known as Botox used for the cosmetic diminishing of "frown" wrinkles caused by contraction of small muscles of the face **(Figure B21.4)**. Local injection of small amounts of the toxin blocks neuroactivation of muscle contraction in the area for several months. Botox is composed of type A botulinum toxin, as are some of its commercial equivalents. Other cosmetically used formulations are composed of type B toxin. Recent studies have shown that equivalent cosmetic application of type A botulinum toxin in rats is transported to the brain. It remains to be seen if there are any long-term adverse effects in humans who use Botox.

Type A botulinum toxin is responsible for most human deaths related to botulism. However, major outbreaks caused by type E botulinum toxin have occurred in fish and aquatic birds. The fish likely feed on toxin-contaminated invertebrates, which are naturally resistant to the toxin, or decaying plant material found in sediments. Dabbling ducks, such as mallards and redheads also feed in these shallows. Domestic animals such as horses and cattle that have access to shorelines may also inadvertently contract the disease this way. Botulinum toxin-affected fish make easy prey but contain the deadly botulism cargo. Fish-eating birds such as red-breasted mergansers **(Figure B21.5)**, horned grebes, loons, and seagulls are often victims of type E fish kills. In 1997, a botulism outbreak caused by type C1 botulinum toxin occurred in a shallow lake in Saskatchewan, Canada. An estimated one million ducks died there during their spring return migration. In the fall of 1999, several thousand such migrating aquatic birds died of botulism in Lakes Erie, Huron, and Ontario. Their bodies littered the shorelines. A classic sign of avian botulism is a flaccid neck, and the disease is often referred to as "limberneck" **(Figure B21.6)**. The inability of affected fowl to hold their heads above water results in drowning. The role of *C. botulinum* and its non-toxigenic relatives appears to be that of an environmental decomposer. The deadly toxin presumably ensures production of a carcass that will supply both the anoxic conditions and nutrients needed for the proliferation of *C. botulinum* **(Figure B21.7)**.

CONNECTIONS The virulence factors of many pathogens are produced through quorum sensing, described in **Section 11.5**. Quorum sensing allows pathogens to produce virulence factors only when cell density is sufficient for these products to be most effective. *Staphylococcus aureus* α-toxin expression is controlled this way. Many Gram-negative pathogens use LuxI/LuxR-type sensing systems similar to that described in **Figure 11.20**. Other examples of pathogens that produce quorum-sensing-dependent virulence factors include *Pseudomonas aeruginosa*, *Vibrio cholerae, Streptococcus pneumoniae,* and pathogenic strains of *Escherichia coli.*

Pore-forming cytolysins can damage cells in a variety of ways. At high concentrations, they form many large holes in plasma membranes, causing cell lysis. The release of cellular contents, especially the vesicle contents of phagocytes, causes damage and necrosis to neighboring cells and induces inflammation. Direct lysis may not be the only mechanism of cell death. Low concentrations of pore-forming toxins often produce fewer and smaller pores that can cause ion fluxes that admit calcium ions, which signal cellular production of vasoreactive substances that induce inflammation. The severe inflammation in

Figure B21.6. "Limberneck" Flaccid paralysis of the neck is characteristic of waterfowl botulism.

Botulinum toxin is considered to be one of the top three biological weapon threats, behind anthrax and smallpox. Terrorists have already attempted to use the toxin as a bioweapon. In 1990, the Aum Shinrikyo cult planned to disperse aerosolized toxin at multiple sites in Japan. They built a *C. botulinum* culture facility and even stables for horses from which they planned to produce antisera (antibody) to the toxin. Thankfully, they did not properly culture the bacterium and the toxin was not produced. However, the Aum group turned its attention to other agents. In 1995, they released sarin, a chemical nerve gas, in the Tokyo subway. Twelve people died, and many more were severely injured.

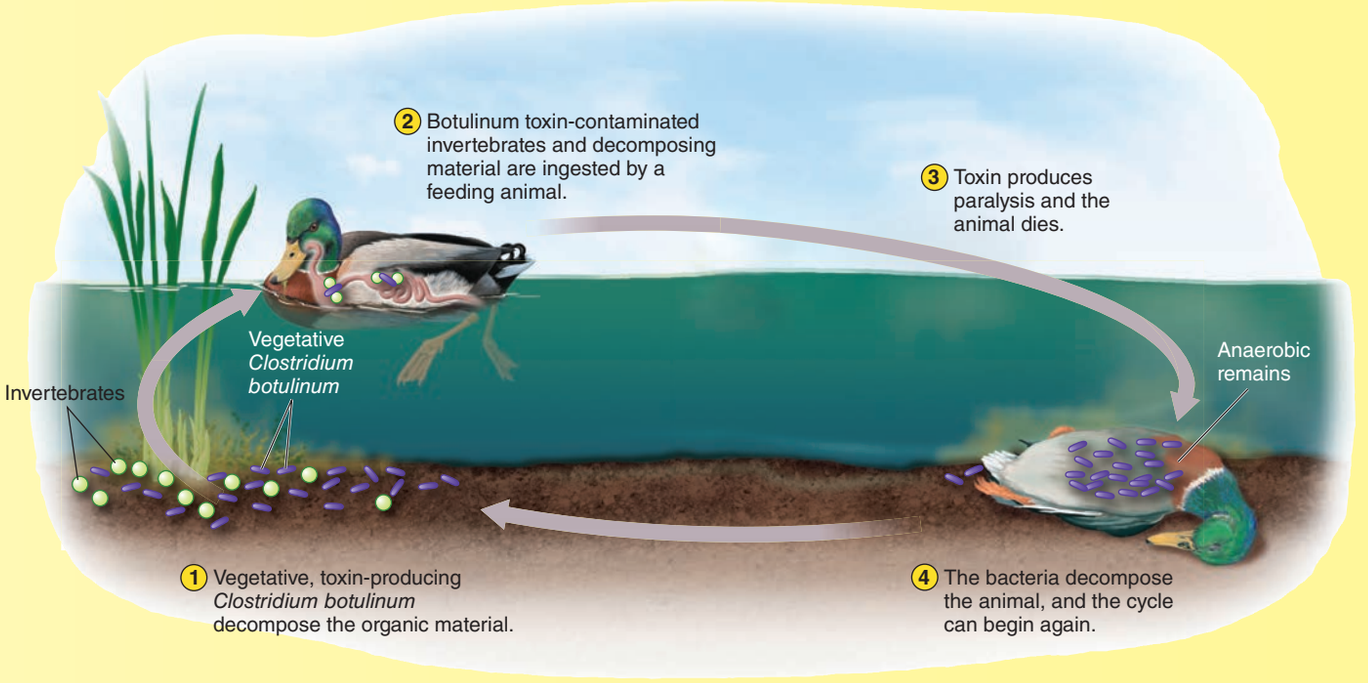

Figure B21.7. Process Diagram: Ecological role of botulinum toxin Vegetative toxin-producing *C. botulinum* cells decompose organic plant and animal matter in warm, anoxic aquatic soils. The toxin-laden decomposing material is ingested by invertebrates. Ducks, feeding in shallow waters, incidentally ingest the contaminated invertebrates and organic material. The toxin kills the host, and the body becomes a new habitat for decomposition, beginning the cycle again.

the lung that characterizes pneumonia produced by *Streptococcus pneumoniae* is due to production of pneumolysin, which acts in this manner.

Another pore-forming cytolysin is perfringolysin of *Clostridium perfringens* **(Microbes in Focus 21.4)**. Perfringolysin binds to membrane cholesterol, found concentrated in rafts within the plasma membrane. Perfringolysin contributes to the tissue destruction in gas gangrene, a disease characterized by muscle necrosis, fever, pain, swelling, and intense gas production resulting from vigorous carbohydrate fermentation under anoxic conditions. Gaseous pockets form within tissues, causing pressure and further necrosis of tissues, facilitating invasion and proliferation in tissue. If left untreated, infection leads to shock and death **(Figure 21.18)**. *Streptococcus pyogenes* produces a similarly acting toxin named streptolysin O, which shares extensive amino acid homology with perfringolysin (60 percent identity), and pneumolysin (48 percent identity) of *S. pneumoniae*.

Sustained calcium influx produced by membrane damage induces cell death by apoptosis. Damaging cells allows

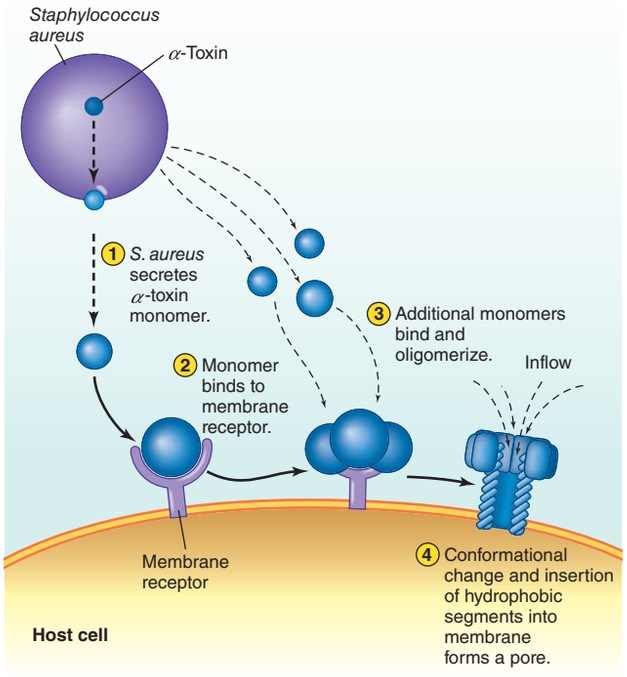

Figure 21.17. Process Diagram: Pore formation by cytolysins *Staphylococcus aureus* α-toxin, like many pore-forming cytolysins, binds to host cells as monomers that oligomerize, causing a conformational change in the peptide units that insert to form a pore in the membrane.

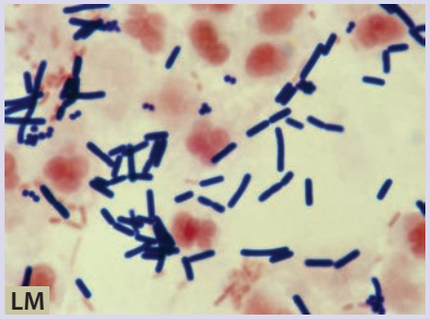
Microbes in Focus 21.4
CLOSTRIDIUM PERFRINGENS AND GAS GANGRENE

Habitat: Intestinal tract of many animal species, including humans

Description: Anaerobic Gram-positive, endospore-forming rod 4–8 μm in length

Key Features: *Clostridium perfringens* is the causative agent of anaerobic soft-tissue infections, including gas gangrene. The toxins perfringolysin and α-toxin (lecithinase) are major virulence factors that can directly kill host cells and induce inflammation. Anoxic conditions severely hamper the ability of phagocytes to carry out phagocytosis and intracellular killing, both of which are oxygen-demanding processes. Destruction of blood vessels and anaerobic conditions prevent penetration of immune cells into the tissues. Similarly, antibiotics do not penetrate the necrotic tissues, and surgical removal of dead tissue, including amputation, is often required.



© John Durham/Science Source

pathogens to invade tissues. An example is *Staphylococcus aureus* (Figure 21.19). Most strains produce α-toxin, sometimes called α-hemolysin, which is a major virulence factor of this pathogen. Mutant strains lacking α-toxin are less pathogenic. In serious infections with *S. aureus*, cell damage by α-toxin generates inflammation that can lead to septic shock, especially if the toxin is present in the circulatory system. Many pathogens use cytolysins to damage tissues, allowing them to infiltrate, spread, and obtain nutrients.

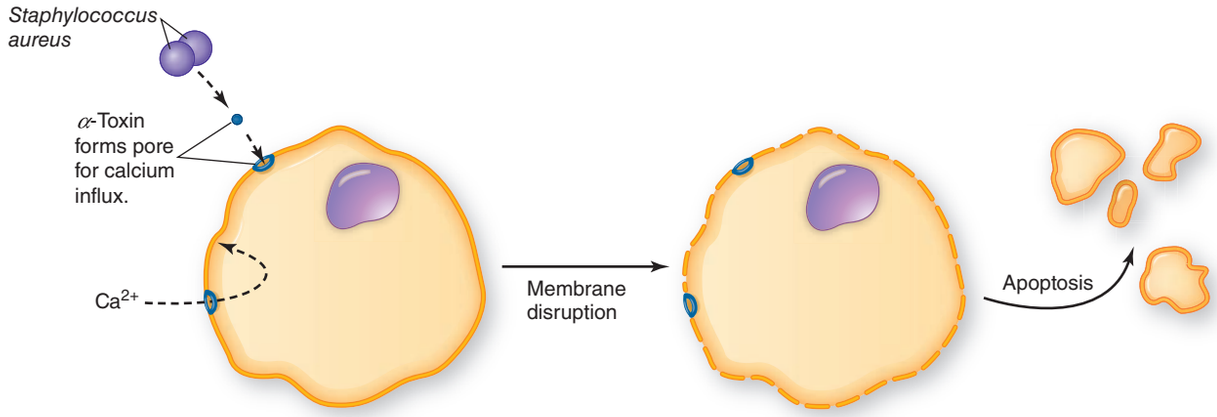
Some cytolysins can efficiently form pores only under acidic conditions, as is found in the endosome. An example is listeriolysin, produced by *Listeria monocytogenes*, a foodborne pathogen we were introduced to in the opening story of Chapter 16.

Scott Camazine/Science Source

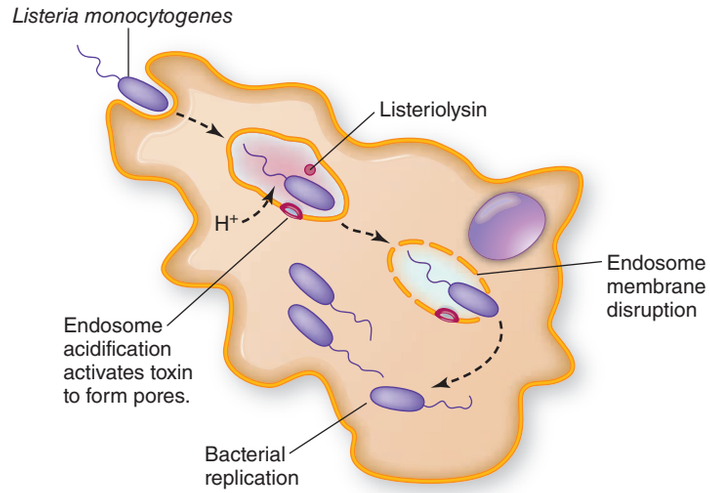
Figure 21.18. Gas gangrene Tissue necrosis, as evidenced by blackening of the toes and swelling on the top of the foot, results from perfringolysin and gas production by *Clostridium perfringens*.

Following ingestion, *L. monocytogenes* is taken up by intestinal macrophages. Production of listeriolysin by phagocytosed bacteria allows disruption of the endosome membrane, preventing intracellular killing and allowing escape of the bacterium into the cytoplasm of the macrophage, where it can replicate (see Figure 21.19B).

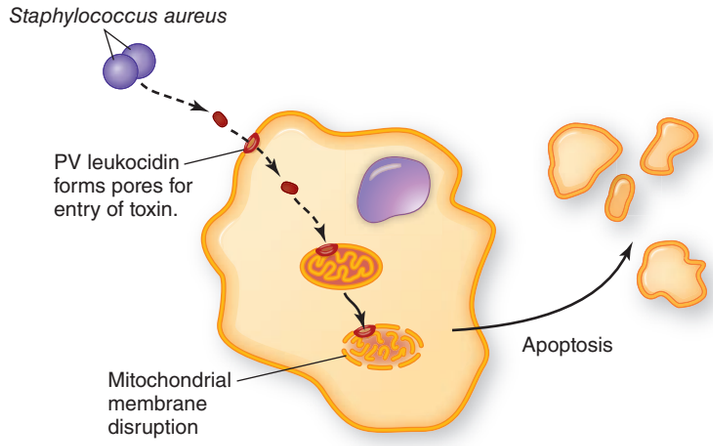
Other cytolysins, such as VacA of *Helicobacter pylori* and Panton-Valentine (PV) leukocidin of *S. aureus*, can enter through the pores they make in the plasma membrane and damage the membranes of mitochondria, inducing apoptosis of the cell (see Figure 21.19C). PV leukocidin is produced as two different polypeptides that combine to form pores in susceptible cells. The toxin primarily attacks phagocytes and epithelial cells, causing extensive damage by apoptosis and necrosis, resulting in necrotizing skin and lung infections. Approximately 2–5 percent of *S. aureus* strains produce the PV leukocidin, which is encoded by a temperate phage (see Section 21.4). An estimated 90 percent of severe *S. aureus* necrotizing skin and lung infections are due to these lysogenized PV leukocidin-producing strains. Fortunately, most people can mount protective immune responses to these strains, preventing spread of the infection. Immunocompromised persons, however, are placed at serious risk when infected with these strains. More recently, PV leukocidin-producing strains have acquired resistance to multiple antibiotics, including methicillin, making them especially difficult to treat and control spread in hospitals and the community.



A. Action of *Staphylococcus aureus* α-toxin



B. Action of *Listeria monocytogenes* listeriolysin



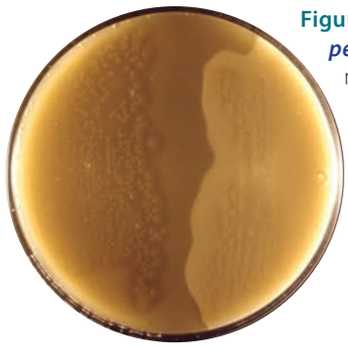
C. Action of *Staphylococcus aureus* PV leukocidin

Figure 21.19. Actions of pore-forming cytolysins **A.** *Staphylococcus aureus* α-toxin can create large pores or small pores (shown here). Small pores allow the influx of calcium ions, which causes membrane damage and induces apoptosis. **B.** *Listeria monocytogenes* enters macrophages by phagocytosis. Listeriolysin is secreted and forms pores in the acidic conditions of the phagosome of macrophages, disrupting the endosome membrane, which allows escape of the pathogen to the cytoplasm where replication occurs. **C.** *Staphylococcus aureus* PV leukocidin produces small pores in plasma membranes, which allow transit of the cytolysin into the cytoplasm to damage mitochondrial membranes, inducing apoptosis.

CONNECTIONS Methicillin-resistant *Staphylococcus aureus* (MRSA) is a serious pathogen because it is often not diagnosed until conventional antibiotic treatment fails. For more information on methicillin resistance, see Section 24.3.

In some cases, it appears that pore formation has an auxiliary function for translocation of other bacterial molecules into the cell. The best-understood case is streptolysin O, produced by *Streptococcus pyogenes*, which translocates the bacterial enzyme NAD-glycohydrolase into the host cell. Here, the enzyme disrupts various cell-signaling pathways, contributing to cell death. Pore formation by Gram-positive pathogens may thus be the functional equivalent of the type III secretion system used by many Gram-negative pathogens to deliver their virulence factors to host cells (see type III secretion systems in this section; also Figure 2.25).

Another group of cytolysins are the **lecithinases**, also called "phospholipases," which degrade eukaryal plasma membranes. Lecithins are a group of various phospholipids, such as phosphatidylcholine, found in eukaryal membranes. Lecithins are enriched in egg yolk, and egg yolk-containing agar provides a simple test for identification of bacteria capable of producing lecithinases **(Figure 21.20)**. Lecithinases cause disruption of membranes, damaging cells and stimulating the production of various



© CDC/Dr. Stuart E. Starr

Figure 21.20. Detection of *Clostridium perfringens* lecithinase (α-toxin) The right side of the egg yolk agar plate shows a zone of precipitated insoluble diglycerides around *C. perfringens* colonies and is the result of hydrolysis of phospholipids (lecithins) by α-toxin. Antitoxin antibody has been added to the left side of the plate prior to inoculation as a control.

proinflammatory cytokines. *Listeria monocytogenes* produces a lecithinase homologous to that of *Bacillus cereus* and *C. perfringens* α-toxin (note that this is one of those cases where a toxin has been named rather arbitrarily; it is not at all related to *S. aureus* α-toxin).

Superantigens

Superantigens are exotoxins with the ability to activate CD4+ T cells. As we learned in Section 20.2, activated CD4+ T cells are potent producers of cytokines. Cytokines are secreted cell-signaling molecules that stimulate immune responses and inflammation. Normally, CD4+ T cells are activated through the binding of their T-cell receptors (TCRs) with specific peptide presented on MHC II molecules of antigen-presenting cells, such as macrophages, dendritic cells, or B cells. Activation also requires secondary interaction between the MHC II molecule of the antigen-presenting cell and the CD4 of the bound T cell (Figure 21.21; also Figure 20.9). The proportion of T cells expected to have TCRs that can recognize a particular peptide is very low, estimated to be less than 0.001 percent of the body's T cells. Thus, normal T-cell activation results in limited T-cell proliferation and localized cytokine production needed for appropriate stimulation and direction of immune response at the site of infection.

CONNECTIONS CD4+ T cells are the central lymphocytes involved in the adaptive immune response. For a review of normal activation of CD4+ T cells, see **Sections 20.2, 20.3**, and **20.5**.

Superantigens activate CD4+ T cells by avoiding the need for specific peptide recognition as well as the requirement for CD4:MHC II binding. They directly cross-link TCRs with MHC II molecules of antigen-presenting cells, such as macrophages (see Figure 21.21B). When superantigens enter the circulatory system, they can activate up to 20 percent of the body's T cells, causing them to secrete the T-cell growth factor IL-2, which in turn causes T cells to replicate to huge numbers. Such large-scale stimulation of T cells results in excessive production of potent proinflammatory cytokines, such as interleukin-1 (IL-1), interferon-gamma (IFN-γ), and tumor necrosis factor-alpha (TNF-α). This produces a systemic inflammatory response that can quickly progress to toxic shock syndrome (TSS), a superantigen-induced systemic shock that can lead to multiple organ failure and death. An epidemic of toxic shock syndrome occurred in 1980 and was associated with tampon use and superantigen-producing strains of *S. aureus* (Perspective 21.3).

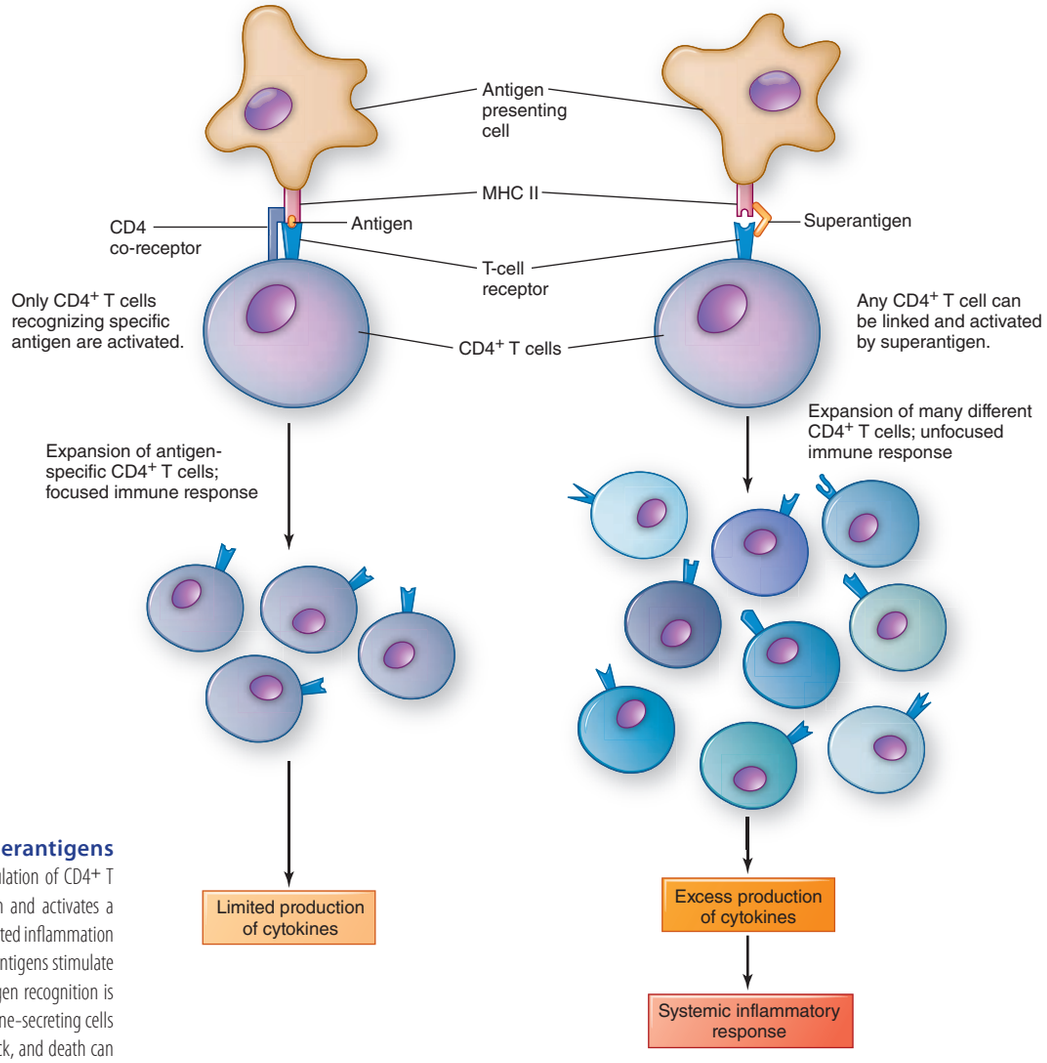


Figure 21.21. Action of superantigens on CD4+ T cells **A.** Normal stimulation of CD4+ T cells requires recognition of specific antigen and activates a small selection of CD4+ T cells, producing limited inflammation and a localized immune response. **B.** Superantigens stimulate many different CD4+ T cells as specific antigen recognition is not needed. A very large population of cytokine-secreting cells results, and system-wide inflammation, shock, and death can occur.

Perspective 21.3
SUPERABSORBENT TAMPONS AND SUPERANTIGENS

Toxic shock syndrome (TSS) was first recognized in 1978. It is a rare but potentially fatal disease that results from bacterial production of superantigen toxins known as TSS-toxins (TSST). In 1980, there were several hundred cases of TSS in the United States. The vast majority of these were associated with *Staphylococcus aureus* and the use of a brand of high-absorbency tampons called Rely that were introduced to the market at this time **(Figure B21.8)**. Synthetic polyacrylate fibers used in the Rely brand tampons were shown to increase the risk of TSS. These materials are no longer used, and Rely tampons were withdrawn from sale by 1981. The incidence of menstrual-related TSS fell dramatically. Tampon manufacturers are now required to provide product labeling and recommended usage information to help women avoid the disease **(Figure B21.9)**.

How do these toxigenic strains end up in tampons? *Staphylococcus aureus* routinely colonizes skin and nasal mucosa. It is thought that tampon-associated TSS occurs when TSST-producing *S. aureus* strains happen to colonize the vagina, probably having been transferred from the skin. The nutrient-rich environment provided by the tampon and the neutral conditions of the vagina during menstruation support the growth of *S. aureus*, allowing it to multiply and produce the toxin, which enters the bloodstream. High-absorbency tampons tend to be changed less frequently, therefore increasing the risk of TSS. Today, approximately 50 percent of TSS cases are still associated with tampon use. Other cases of TSS are associated with wound infections in men, women, and children. *Staphylococcus aureus* is not the only pathogen that can produce TSS. Superantigen-producing strains of *Streptococcus pyogenes* are frequently the cause of wound-associated TSS. Like *S. aureus, S. pyogenes* can also be found on skin, as well as in the pharynx (see Section 21.2).

Figure B21.9. Warning: Tampons are associated with toxic shock syndrome. The U.S. Food and Drug Administration requires specific user labeling of tampons. Labeling includes the warning signs of TSS, what to do if TSS signs appear, the risks associated with tampon usage, including incidence and risk of death, and proper tampon usage.

Not all superantigen-producing bacteria are associated with TSS. Different superantigens vary greatly in their potency and level of expression. The superantigens that cause common food poisoning are produced by strains of *S. aureus* that encode enterotoxins, secreted toxins that act principally on the gut ("entero" refers to intestine; see Section 16.1). These enterotoxins have weak superantigen activity, but have powerful emetic activity, that is, they induce vomiting. Enterotoxigenic strains of *S. aureus* are commonly found contaminating foods that have been improperly cooked or insufficiently refrigerated. Mayonnaise, custards, puddings, cream fillings, gravies, and lunch meats are common culprits in staphylococcal food poisoning, especially because they are often found in self-serve salad bars and buffets where there is often extensive contact with humans—the source of the contamination **(Figure 21.22)**. Between 20 and 50 percent of humans are colonized with *S. aureus* in the nasal cavity and on skin, and between 20 and 50 percent of these strains are enterotoxigenic.

Enterotoxins are not easily denatured by heat but *S. aureus* can be destroyed by heating food thoroughly (60°C, 140°F or above), and proper refrigeration (7.2°C, 45°F or below) will inhibit its growth, preventing production of the toxin. The amount of enterotoxin ingested is rarely enough to cause toxic shock and symptoms usually disappear within 48 hours.

CONNECTIONS *Staphylococcus aureus* is salt tolerant and can survive in salt-preserved foods, like lunch meats and soups. See **Section 16.1** for a review of factors affecting microbial growth in foods.

You may wonder what advantage superantigen production affords the pathogen. It is thought that the unfocused immune response provoked by superantigens does not efficiently target the pathogen, allowing it to continue to reproduce and spread. In addition, stimulated T cells are short-lived, and such extensive proliferation means a large proportion of $CD4^+$ T cells will undergo apoptosis. The result is temporary immunosuppression, which may also afford advantages to the pathogen.

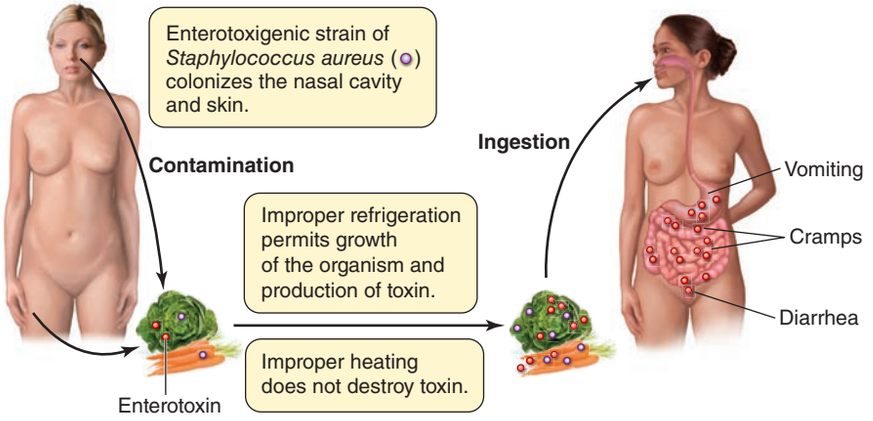
A. *Staphylococcus aureus* enterotoxin can be found in foods.



B. Enterotoxigenic *Staphylococcus aureus* is transferred from humans to food and causes illness.

Figure 21.22. *Staphylococcus aureus* enterotoxin commonly causes food poisoning. A. Many of the rich sauces and dressings present in self-serve buffets are ideal for growth of enterotoxigenic strains of *S. aureus*, particularly if the food is not adequately refrigerated or cooked. **B.** *Staphylococcus aureus* commonly colonizes the nasal cavity and skin and can be transferred from here to foods. Improper refrigeration allows replication of *S. aureus*. If the strain is enterotoxigenic, then the toxin will be produced. Underheating the food may kill *S. aureus*, but may not destroy the toxin. Ingestion of the food results in absorption of the toxin, which causes vomiting, diarrhea, and cramps.

21.2 Fact Check

1. How do endotoxin and lipoteichoic acid enhance the ability of pathogens to cause disease?
2. Describe the structure and action of A-B toxins. Provide an example.
3. What are the two main modes of action of cytolysins? Provide examples.
4. Explain the effects of superantigens on the immune system and the body.

21.3 Survival in the host: Strategies and consequences

How do bacterial pathogens cause disease?

We have learned that pathogens must carry out three basic processes in order to establish themselves in the host. They must (1) gain access to host tissues, (2) overcome host defenses, and (3) get nutrients. We have examined several virulence factors, more or less in isolation, that help pathogens do this. Let's now look at two comprehensive examples that illustrate how bacterial pathogens can cause disease. The first pathogen we will examine is *Streptococcus pyogenes*, an extracellular opportunistic pathogen that many of us harbor unwittingly. The second, *Mycobacterium tuberculosis*, is an intracellular primary pathogen. Both of these pathogens cause significant human disease worldwide, but use very different means to do so.

Pathogen study 1: *Streptococcus pyogenes*

Streptococcus pyogenes **(Microbes in Focus 21.5)** is a particularly resourceful opportunistic pathogen, thanks to the remarkable variety of virulence factors it can produce, many of which have multiple functions. Think of it as a microscopic Swiss army knife of virulence factors. *Streptococcus pyogenes* is commonly found colonizing the pharynx in 10 to 15 percent of people. It can also be found on the skin, and sometimes in the vagina. Most of those colonized have no clinical signs of *S. pyogenes* disease, but the pathogen can be said to be biding its time, waiting for an opportunity. Stated another way, it's often a disease waiting to happen. *Streptococcus pyogenes* is one of the most common bacterial pathogens isolated from infections and is probably best known as a dominant cause of pharyngitis and tonsillitis in children.

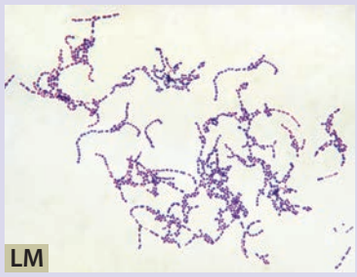
The variety of diseases this bacterium causes **(Table 21.10)** is attributable to (1) the large degree of genetic variation that exists in different strains, providing not only numerous combinations of virulence factors, but also variation in expression of these factors, and (2) various host conditions that allow these strains to produce disease. Predisposing conditions to *S. pyogenes* infection generally involve wounds, weakened immune functions, and poor circulation. Matching the many streptococcal diseases with particular strains or virulence factors has proven to be elusive. For example, cases of streptococcal necrotizing fasciitis, commonly called "the flesh-eating disease" **(Figure 21.23)** often tend to occur in clusters, which

Microbes in Focus 21.5
STREPTOCOCCUS PYOGENES

Habitat: Pharynx, skin, and vagina of humans

Description: Gram-positive, chain-forming coccus 0.5–1.2 μm in diameter. Formerly named Group A streptococci, based on antibody serotyping, it commonly still goes by this name in clinical settings. It produces β hemolysis on blood agar by production of the pore-forming cytolysins, streptolysin O and S.

Key Features: Disease caused by *S. pyogenes* is associated with opportunistic infections and ranges from uncomplicated pharyngitis to life-threatening necrotizing fasciitis, systemic disease due to toxin production, and chronic post-infection heart disease. Significant genetic variability among strains accounts for the range of virulence factors produced.



© Eye of Science/Science Source

would suggest association with particular strains, but there is little evidence for this globally, and molecular analysis of the isolates causing necrotizing fasciitis so far has not led to any consensus on the virulence factors that are primarily responsible for this disease. Examination of the host conditions leading to necrotizing fasciitis similarly shows great diversity, but can be linked to immune status. These include preexisting diabetes mellitus, HIV infection, genetic immune deficiencies, and immunodeficiency produced by medications. Even common anti-inflammatory medications, such as ibuprofen, have been implicated in the precipitation of this disease. A singular commonality seems to be that it often begins at an otherwise innocuous wound site. Treatment with antibiotics may be ineffective as the death of blood vessels makes penetration into the tissues difficult. The anoxic conditions in the damaged tissue prevent migration of phagocytes and impede intracellular killing mechanisms. Often surgical removal of dead tissue, including amputation, is the only effective treatment.

© Biomedical Communications/CMSP/Newscom

Figure 21.23. Necrotizing fasciitis Necrotizing fasciitis is an invasive skin disease that results in severe, rapid tissue necrosis.

Some virulence factors of *S. pyogenes* are associated with particular diseases. For example, strains possessing genes encoding superantigens can cause wound-related TSS (see Perspective 21.3). Some of these superantigens are named SPE toxins, for streptococcal pyrogenic erythrogenic toxin ("pyro," meaning fire, refers to fever, and "erythro," meaning red, refers to rash). They are frequently associated with invasive infections, including scarlet fever. Several variations of SPE toxin genes exist, most being carried by temperate phages, but only types A, B, and C are associated with scarlet fever (see Table 21.10).

Access to Host Tissues

The primary residence of *S. pyogenes* is the pharynx, where it exists either transiently or permanently with the same or different strains present over time. *Streptococcus pyogenes* is probably seeded from the pharynx to skin and occasionally the vagina. Major attachment factors of *S. pyogenes* include fimbriae and a variety of other surface components, most of which have not been well characterized, that allow attachment to host fibronectin and collagen. M protein, a component of fimbriae, allows aggregation of cells and contributes to the formation of microcolonies on the skin and pharynx.

Multiple factors, having as much to do with strain variation as host conditions, likely keep the pathogen at bay. Normal microbiota probably have a significant impact on colonization. If changes in microbiota populations occur, *S. pyogenes* may expand its population, or change expression of genes, initiating inflammation at the site. This development can lead to damage and initiation of infection. Physical damage to skin or mucosa allows *S. pyogenes* to directly access tissue and is often how infections begin.

A recent finding has shown that *S. pyogenes* can induce its own uptake in epithelial cells of the pharyngeal mucosa, a significant reservoir of the pathogen. Here, it escapes microbial competition as well as host immune defenses—particularly antibody—and even antibiotics. Recall that *Salmonella* species also induce their own uptake in epithelial cells to avoid immune defenses, although the mechanism used to induce uptake is different (see Figure 21.6).

Disease Consequences

Pharyngitis and tonsillitis are usually painful but self-limiting infections characterized by inflammation and accumulation of neutrophils that form pus-filled nodules on the tonsils or throat (see Table 21.10). Normally, protective IgA and IgG antibodies against M protein are eventually produced, and the infection is cleared. If you've ever had streptococcal pharyngitis ("strep" throat), it usually takes about ten days to start feeling better without antibiotics. This coincides with peak antibody production from a primary adaptive immune response (see Figure 20.5). However, *S. pyogenes* may still remain in small numbers, either inside epithelial cells or extracellularly colonizing the site. There are over 150 distinct types of M proteins, and antibody protection against one type does not necessarily afford protection against other M types, making reinfection with *S. pyogenes* of

a different M type a common occurrence. Many of us know this well, having suffered multiple bouts of streptococcal pharyngitis.

Occasionally, pharyngitis or tonsillitis can become serious. This can happen in two ways. First, systemic infection can occur when inflammation is severe enough to allow *S. pyogenes* entry into local blood vessels, and from here, into the circulatory system. This can lead to septic shock. Second, post-infection **sequelae** occur. Sequelae (from "sequel," meaning an after-the-fact consequence) happen *after* the *S. pyogenes* infection is cleared and is thought to be immune-mediated. The most common sequelae associated with *S. pyogenes* are glomerulonephritis, acute rheumatic fever, and its more serious chronic manifestation, rheumatic heart disease (see Table 21.10). How *S. pyogenes* precipitates these diseases is poorly understood although various theories exist. Damage to heart tissue is thought to be due to antibody cross-reaction arising from regions of amino acid homologies between some types of M protein and membrane proteins of myocardium and myosin protein **(Figure 21.24)**. It is also proposed that SPE toxins may directly damage heart tissue, initiating inflammation in the heart. Immune complexes involving bundles of *S. pyogenes* antigens, antibody, and complement are also thought to accumulate in these tissues and evoke inflammatory damage. This is thought to contribute to glomerulonephritis, an inflammatory disease of the kidney-filtering units, the glomeruli.

Skin infections are another common consequence of *S. pyogenes* infection. Cuts and scratches on skin allow seeding into tissue. This can lead to impetigo, a superficial disease characterized by oozing lesions that can quickly spread across skin (see Table 21.10). Production of enzymes contributes to spread and cell damage that releases nutrients. Impetigo is also frequently caused by *Staphylococcus aureus* and sometimes by both species together.

Sometimes infection goes deeper, especially if bruising and compromised blood circulation is present. This allows *S. pyogenes* to move through the damaged tissue faster, creating inflammation and further destruction of tissue and vessels. Production of streptokinase and hyaluronidase contributes to spread in tissues. Streptokinase breaks down fibrin clots, which would otherwise help to wall off the spread of infection. Hyaluronidase degrades hyaluronic acid, a common gel-like substance that fills intercellular spaces. Erysipelas, a superficial inflammation of the dermis, and cellulitis, a more extensive inflammation involving the connective tissue, are often associated with bruising, obesity, diabetes, and aging. In some cases, large amounts of tissue are destroyed, producing necrotizing diseases. Strains producing potent superantigens can induce shock even before getting to this stage, as the superantigens are secreted and can readily gain access to the circulatory system.

Necrosis that occurs on the outer layers of skin is termed "necrotizing cellulitis." If necrosis involves all the layers of skin, down to the muscle, it is termed "necrotizing fasciitis" because it spreads along the fascia lining the surface of muscles. Production of pore-forming streptolysin O and streptolysin S results in lysis of a variety of cells, including cells of the immune system. This action contributes to spread and necrosis. The amount expressed of both these toxins varies greatly with strains, and their contribution to disease is not easy to determine in isolation. The toxins are just another facet of the total virulence that is elaborated by particular strains in certain conditions. **Table 21.11** summarizes some of the known virulence factors of *S. pyogenes*.

How do these necrotizing infections occur? There's no concise answer, other than it involves a significant level of invasive tissue destruction. Destruction of blood vessels in the area diminishes oxygen levels and provides ideal conditions for growth of *S. pyogenes*, a facultative anaerobe. Anoxic conditions precipitated by *S. pyogenes* frequently allow other opportunistic pathogens, such as the anaerobe *Clostridium perfringens*, to establish concurrent infection. Reduced blood supply means fewer immune cells can access the infected site, and loss of oxygen diminishes the ability of phagocytes to mount the oxidative burst—an oxygen-demanding process. Tissue destruction also restricts antibiotics from reaching the site and, like gas gangrene (see Microbes in Focus 21.4), often surgical removal of dead, anaerobic tissue is required to stop the spread.

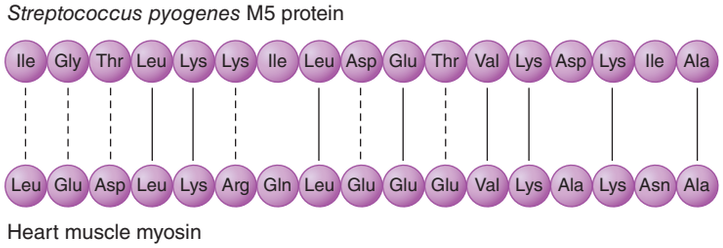

Figure 21.24. Comparison of streptococcal M5 protein and myosin amino acid sequences M5 and myosin proteins each contain a segment with extensive amino acid homology that can be seen when the sequences are aligned. Functionally similar amino acids are indicated with dashed lines. Identical amino acids are shown with solid lines. Dissimilar amino acids have no lines between them. Antibodies generated to the bacterial M5 protein may cross-react with similar sequences in myosin of heart muscle, resulting in autoimmune damage to the heart.

CONNECTIONS Recall from **Section 19.5** that the oxidative or respiratory burst in phagocytes produces many highly toxic oxygen compounds inside the phagolysosome, which destroys endocytosed microbes.

Overcoming Host Defenses

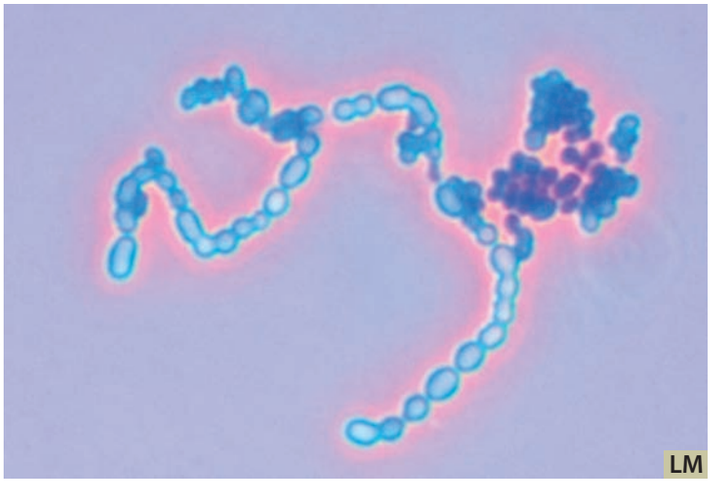
Clearance of extracellular pathogens largely involves opsonization, which leads to phagocytosis and subsequent killing in the phagolysosome. Complement, an innate immunity defense product (see Section 19.4), and antibody, an adaptive immunity defense product (see Section 20.6), are major opsonins. As we have seen, for encapsulated pathogens the capsule is the major target for efficient opsonization as it provides the outermost contact. However, the capsule of *S. pyogenes* is not opsonized by either of these methods because it is made of the "self" molecule hyaluronic acid **(Figure 21.25)**. Capsules that mimic host molecules are serum resistant as C3b does not bind to them, and, of course, antibody is not made to components that are also part of the host. Consequently, complement lysis and phagocytosis is hindered, reducing both intracellular killing and antigen presentation by macrophages and/or dendritic cells to $CD4^+$ T cells of the immune system (see Sections 20.2 and 20.5). This in

TABLE 21.11 Virulence factors of *Streptococcus pyogenes*

Activity	Virulence factor	Function
Adherence	Fimbriae	Attachment to epithelial cells
	M protein	Contributes to the establishment of microcolonies on the skin and pharynx
Anti-phagocytosis	Hyaluronic acid capsule	"Self" capsule prevents antibody formation; capsule prevents contact between antibody bound to wall components and F_CR of phagocytes
	M protein	Binds antibody in inverted orientation, discourages opsonization; some forms implicated in rheumatic heart disease
Serum resistance	Hyaluronic acid capsule	"Self" capsule discourages complement fixation
	M protein	Binds serum factor H, which discourages complement activation
Complement degradation	C5a peptidase	Degrades complement factor C5a (Table 19.5), preventing migration of phagocytes
	Streptococcal inhibitor of complement (SIC)	Prevents and may disassemble MAC[a]
Enzymes	DNase	May contribute to liquefaction and spread through pus; hydrolyzes connective tissue; may contribute to spread
	Hyaluronidase	Degrades hyaluronic acid in host tissues; may contribute to spread
	IdeS	Degrades all IgG antibody
	Streptokinase	Converts serum plasminogen to plasmin, which dissolves fibrin clots, contributing to spread
Toxins	Streptolysin O	Pore-forming oxygen-labile cytolysin acting on a variety of cells; contributes to spread and necrosis; death of leukocytes
	Streptolysin S	Similar to streptolysin O but is oxygen-stable
	Erythrogenic (SPE) toxins	Family of superantigen proteins inducing fever and inflammation

[a] See Chapter 19 for review.

turn reduces the adaptive response, and subsequent antibody production against other antigens of *S. pyogenes*, including M protein, is diminished. Deterring phagocytosis allows a window of opportunity for *S. pyogenes* to expand its population. Naturally, some bacterial cells do get phagocytosed eventually, and protective antibody is made.



© Michael Abbey/Science Source

Figure 21.25. Capsule and fimbriae of *Streptococcus pyogenes* The surrounding hyaluronic acid capsule on this color-enhanced image is pink and the fimbriae layer is white (1,600×).

The capsule is not the only defense against phagocytosis. M protein is a major virulence factor of *S. pyogenes*. It functions in a manner similar to *S. aureus* protein A by binding host antibodies upside down by the F_C portion (see Perspective 20.3), reducing opsonization by antibodies. M protein also binds serum factor H, the presence of which discourages complement binding and contributes further to serum resistance. Avoidance of clearance by phagocytes is further afforded by production of a C5a peptidase, which diminishes the migration of phagocytes into the area. *Streptococcus pyogenes* also produces a unique protein called "SIC" (streptococcal inhibitor of complement), which can prevent the late stages of MAC formation. In addition, *S. pyogenes* produces numerous enzymes that degrade IgG and IgA (see Table 21.11). Recall *Neisseria gonorrhoeae* also possesses an IgA protease, as does *Haemophilus influenzae*.

Although *S. pyogenes* is capable of producing numerous virulence factors, they are not all of equal importance in pathogenesis. Studies using cultured cells or *in vivo* studies show that knocking out any single virulence gene often does not greatly impact the pathogenicity of *S. pyogenes*. This indicates that it is likely the collection of virulence factors that are significant, and different strains appear to mix and match these. The fact that most people who become infected with *S. pyogenes* will suffer only self-limited, mild disease is a testament to the immune defenses of the host in light of such an onslaught of bacterial tactics to undermine these defenses.

Pathogen study 2: *Mycobacterium tuberculosis*

Mycobacterium tuberculosis is the causative agent of tuberculosis, a disease characterized by destruction of lung tissue, where it usually manifests, but it can also occur in other parts of the body, including bone, lymph nodes, and brain. Relatives of *M. tuberculosis* include *M. bovis*, which causes tuberculosis more commonly in animals, and *M. leprae*, the causative agent of leprosy, or Hansen disease, which is in many ways similar to tuberculosis but manifests in the skin and associated nerves. All three of these closely related microorganisms use similar tactics to produce disease.

All members of the genus *Mycobacterium* have unusual cell walls that contain a waxy layer of mycolic acids (from which their genus name has been derived) that resist penetration by most dyes and cannot be Gram-stained. Instead, these cells are stained with carbol fuchsin, a red dye that can permeate the mycolic acid-rich cell wall and is not decolorized by acid-alcohol rinse (hence the name "acid-fast"). The cells stain red, as can be seen in **Microbes in Focus 21.6**.

Access to Host Tissues

Mycobacterium tuberculosis is spread by inhalation of aerosols from individuals with active tuberculosis. The bacterium replicates inside the phagosome of lung macrophages. This intracellular existence affords protection from complement and antibody. We've seen this sort of strategy used by *Salmonella*, *Neisseria*, and even for *S. pyogenes*, which does this on a more limited basis. Like these pathogens, *M. tuberculosis* also facilitates its own uptake into target cells. *Mycobacterium tuberculosis* does this by encouraging opsonization with host complement component C3b and mannose-binding lectin, which in turn bind to CR3 and mannose receptors, respectively, on the macrophage (see Figure 19.10).

Overcoming Host Defenses

As we saw in Chapter 19, the fate of bacteria in the phagosome is usually death by way of acidification, the oxidative burst, and fusion with lysosomes. *Mycobacterium tuberculosis*, like many intracellular pathogens, can obstruct many of these activities in imprecisely defined ways. Phagocytosed *M. tuberculosis* cells interfere with two very important immune functions: (1) they prevent fusion between phagosomes and lysosomes and (2) reduce MHC II presentation of antigen to $CD4^+$ T cells. These two pivotal events can otherwise protect against *M. tuberculosis* infection and indeed against *Mycobacterium* species in general.

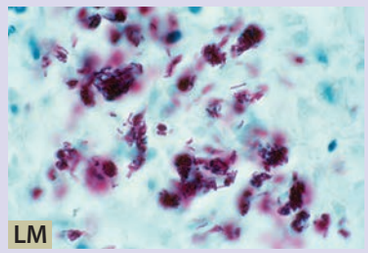
Studies show that the protective immune response to mycobacterial infections is a cell-mediated response, involving (1) activation of T_H1 $CD4^+$ T cells and (2) upregulation of macrophage killing functions. As we learned in Section 20.5, these two immune activities are closely tied to one another. Macrophages are important antigen-presenting cells. Engulfed pathogens are normally broken down in the endocytic pathway and the resulting peptides are loaded onto MHC II molecules for presentation to $CD4^+$ T cells. For mycobacterial infections, production of the cytokines IL-12 and TNF-α by the macrophage signals activated $CD4^+$ T cells to secrete IFN-γ. This cytokine directly stimulates macrophages to increase phagocytosis, oxidative burst activities, and MHC II antigen presentation **(Figure 21.26)**. Individuals who can efficiently mount this cell-mediated immune response often

Microbes in Focus 21.6
MYCOBACTERIUM TUBERCULOSIS

Habitat: Humans are the natural reservoir for *M. tuberculosis*. *Mycobacterium bovis* is found in various mammals and is very closely related, occasionally causing tuberculosis in humans, usually from drinking unpasteurized milk.

Description: Gram-positive rod 2–6 μm in length. The bacteria are acid-fast, shown here as red in a lung tissue sample of a tuberculosis patient. Host cells are blue. Growth is slow, with a doubling time of 24 hours in culture and several days *in vivo*.

Key Features: *Mycobacterium tuberculosis* is an intracellular pathogen and is the causative agent of tuberculosis. It is spread through close contact with aerosol droplets from individuals with clinical disease.



© Richard J. Green/Science Source

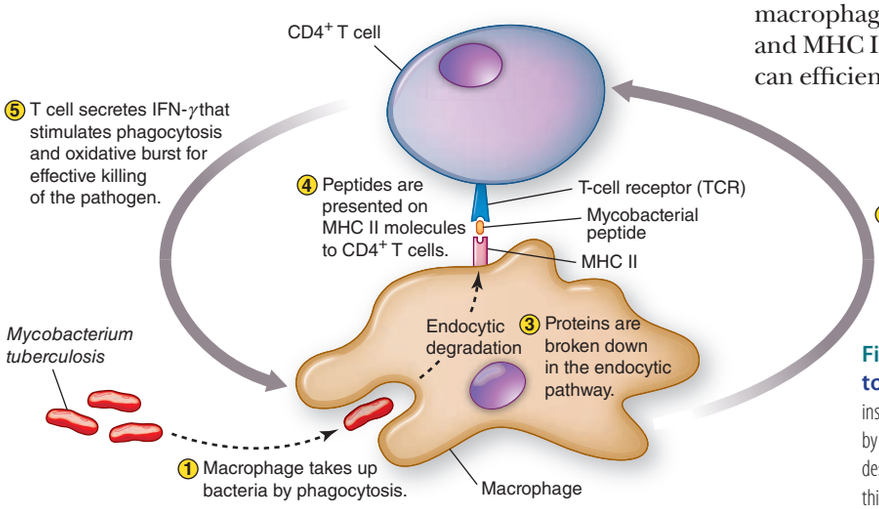


Figure 21.26. Process Diagram: The protective response to *Mycobacterium tuberculosis* *Mycobacterium tuberculosis* can live inside macrophages. The protective immune response requires activation of T_H1 $CD4^+$ T cells by macrophages, which in turn stimulate upregulation of macrophage killing functions to destroy the pathogen. Production of the cytokines IL-12, TNF-α and IFN-γ are crucial to this response.

A. Granuloma lesion

B. X-rays of normal and diseased lungs

Figure 21.27. Granuloma produced by *Mycobacterium tuberculosis* **A.** The center of the lesion contains infected macrophages surrounded by a layer of fibrin and active lymphocytes. The granuloma is produced as a result of a chronic inflammatory response due to the inability of macrophages to kill *M. tuberculosis*. **B.** Calcified granulomas can be detected on X-ray. The normal chest X-ray (*left*) shows clear lungs. The heart can be seen as the dense bulge to the right. The other X-ray (*right*) shows a patient with pulmonary tuberculosis. Dense granulomas appear as diffuse white patches.

achieve protection from clinical tuberculosis disease. It is not clear if *M. tuberculosis* is completely destroyed in this scenario, or if it is just kept inactive by this response. As you might imagine, there is substantial variation in the immune response between individuals.

By preventing phagosome fusion with lysosomes, *M. tuberculosis* avoids the otherwise acidic and degradative environment of the phagolysosome. Arresting further endocytic processing prevents MHC II:peptide presentation so $CD4^+$ T cells are not activated and IFN-γ is not produced. This affords *M. tuberculosis*, a very slow-growing pathogen, the opportunity to grow in the phagosome. However, *M. tuberculosis* must overcome other biocidal effects of the phagosome. Pathogenic mycobacteria produce lipoarabinomannan (LAM), a complex cell wall component that forms a substantial outer layer around the bacterium. LAM downregulates the oxidative burst and neutralizes many of the toxic oxygen species produced by this process (see Table 19.6). LAM is one of the few virulence factors identified for *M. tuberculosis*. Other virulence factors include superoxide dismutase and catalase that also protect it from oxidative damage, contributing to its survival in the phagosome.

Disease Consequences

The damage caused by infection with *M. tuberculosis* is a direct result of the host immune response as it attempts to isolate the infected cells and prevent spread of the bacilli. A cell-mediated chronic inflammatory response ensues because of the cytokine TNF-α produced by activated, infected macrophages that are unable to successfully destroy the bacilli. This recruits immune cells to the area and results in production of a **granuloma**, an encasement composed of fibrin and lymphocytes containing infected and dead macrophages **(Figure 21.27)**. The granuloma is the prime pathological feature of tuberculosis, and in advanced cases the dense, fibrous structure of these lesions can often be detected on an X-ray. Granulomas calcify with age but may still contain live but non-contagious bacilli. Granulomas produce damage in alveoli, the primary gas-exchange surfaces of the lung, resulting in reduced gas exchange.

Although granuloma formation is damaging, it can keep *M. tuberculosis* at bay for many years, primarily by enforcing a siege that keeps *M. tuberculosis* in short supply of nutrients and oxygen. If immune conditions change in the host and the cell-mediated response weakens, the granulomas break down. Breakdown is characterized by caseous necrosis ("caseous" meaning cheese-like), a description for the partial liquefaction of necrotic host tissues inside the granuloma due to the release of the contents of the dead macrophages within **(Figure 21.28)**. This necrotic "soup" provides nutrients for the bacilli, ending the siege, and allowing replication to ensue. The necrotic contents are a concoction of proteolytic enzymes, acids, and toxic oxygen species that cause substantial damage to the integrity of the granuloma and surrounding tissues. As the damaging material leaks out, it destroys lung tissue, producing cavities in

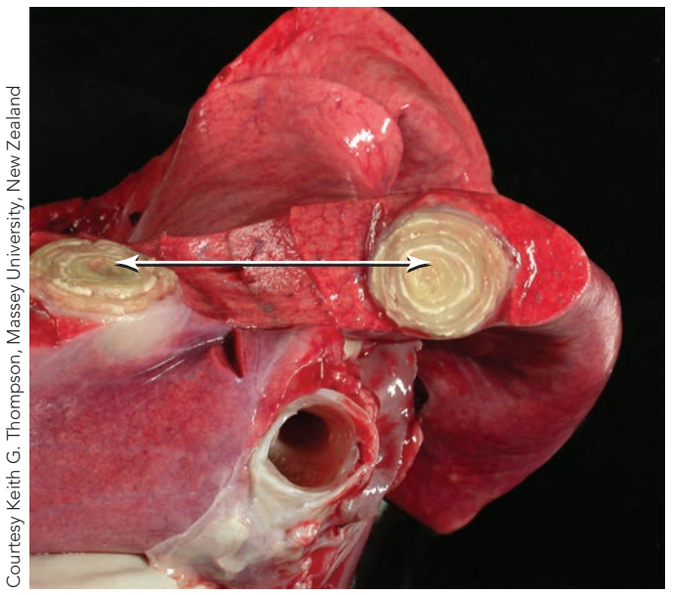

Figure 21.28. Caseous necrosis The area of caseous necrosis in the infected lung, shown cut in two and indicated by the arrow, displays a pale, cheese-like consistency.

the lungs. This is accompanied by full clinical signs of tuberculosis: night sweats and severe coughing with bloody sputum carrying infectious *M. tuberculosis*. This is the most contagious stage of tuberculosis. **Figure 21.29** shows an overview of the disease process for tuberculosis.

Despite the high prevalence of *M. tuberculosis* infection worldwide, there appears to be a substantial level of natural resistance in most individuals to the pathogen. It is estimated that approximately 90 percent of those exposed to *M. tuberculosis* do not develop clinical disease. Close contact and multiple exposures are usually needed to establish infection. Most who are exposed to low levels of *M. tuberculosis* for the first time seem to either clear the bacteria or maintain those remaining in a non-replicative state, the result of an effective cell-mediated immune response. Of those individuals exposed to high levels of *M. tuberculosis*, or who have weaker immunity, the bacilli multiply in the macrophages and granulomas form. This is known as "primary tuberculosis." Most individuals with primary tuberculosis will successfully contain these bacteria for many years without progressing to further disease. This period is known as "latent tuberculosis" and is evidenced by a continuously positive tuberculin skin test **(Toolbox 21.2)** but absence of clinical signs of tuberculosis. Five to 10 percent of those with latent tuberculosis will develop the clinical disease at a later time. This is known as "reactivation tuberculosis." Some people can cycle between latent and reactivation tuberculosis. A small percentage of infected individuals will immediately progress to full clinical tuberculosis. These persons are unable to mount an effective $CD4^+$ T cell response and cannot prevent replication and damage. In these cases, it is not uncommon for *M. tuberculosis* to gain access to the circulatory system and spread to the rest of the lung and other tissues and organs, producing "miliary" (widely seeded) tuberculosis. Miliary tuberculosis is a common form of tuberculosis in young children who lack the mature immune responses needed to keep *M. tuberculosis* sequestered in the lung.

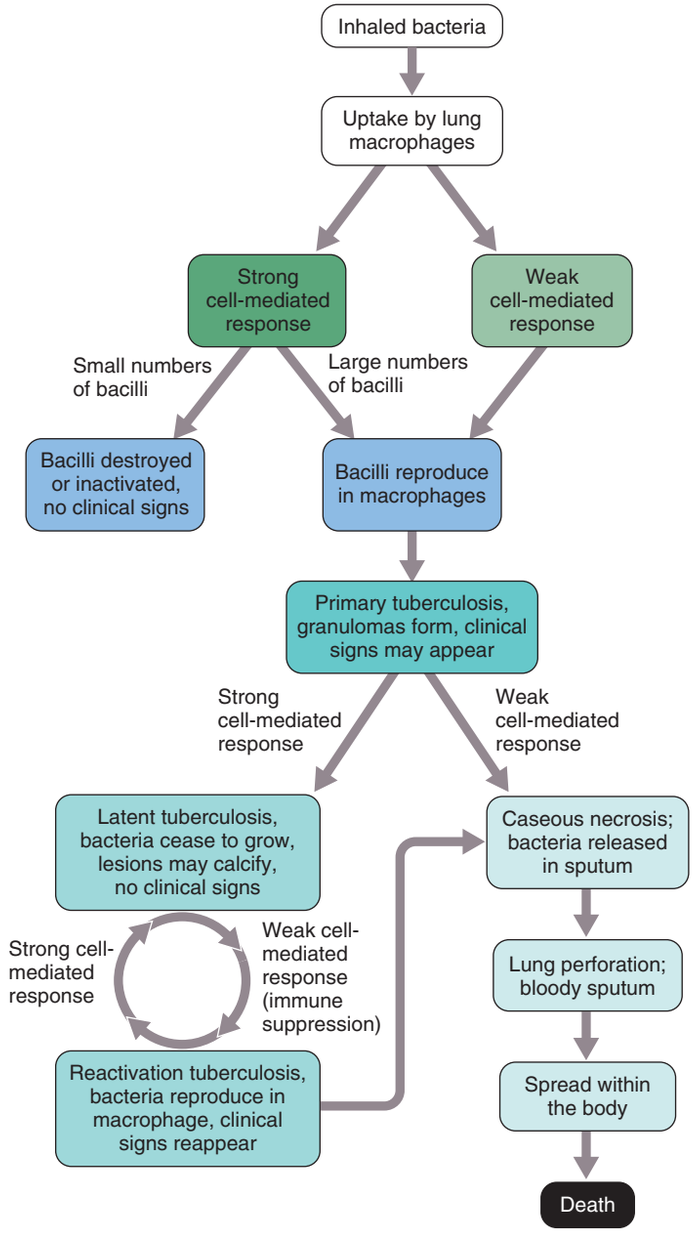

Figure 21.29. *Mycobacterium tuberculosis* pathogenesis in pulmonary tuberculosis The outcome of infection with *M. tuberculosis* is related to the host immune function. Individuals who are able to mount a strong cell-mediated immune response can often contain progression of disease, while those unable to mount this response cannot.

The proportion of each clinical category of tuberculosis can change drastically in areas where other infections, such as HIV, are found. In these areas, primary tuberculosis becomes more prevalent, and the majority of those with latent tuberculosis will develop reactivation tuberculosis with HIV infection. HIV selectively destroys $CD4^+$ T cells, so any hope of defense against *M. tuberculosis* is removed with HIV infection.

Reactivation tuberculosis and clinical disease is accompanied by a drop in IFN-γ levels, waning of the cell-mediated response, and an increase in the humoral response cytokines IL-10 and IL-6, along with an increase in antibody levels for *M. tuberculosis* **(Figure 21.30)**. This spells a poor prognosis against the patient. Antibody has no protective effect against intracellular pathogens, and any extracellular bacilli that are opsonized by antibody are easily phagocytosed by macrophages—an advantage for *M. tuberculosis*.

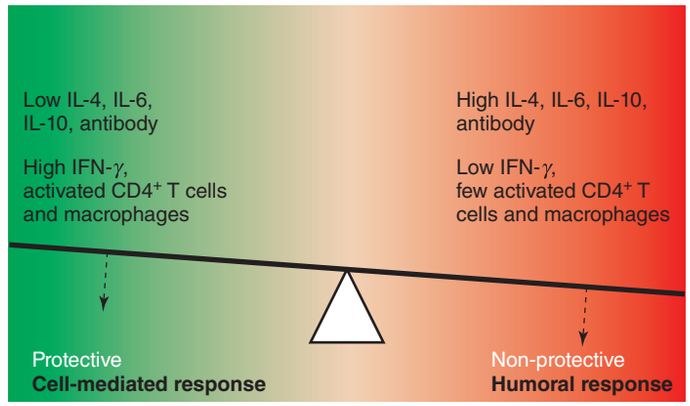

Figure 21.30. Comparison of a cell-mediated response to a humoral response in *Mycobacterium tuberculosis* infection A strong cell-mediated response is protective, limiting the growth and spread of *M. tuberculosis*. As this response changes to a predominant humoral response, protection wanes, indicated here by a tipping of the scale. This is accompanied by changes in cell profiles and levels of key cytokines and antibody directed to *M. tuberculosis*.

Toolbox 21.2
THE TUBERCULIN TEST FOR TUBERCULOSIS

Tuberculin, or PPD (purified protein derivative), is a solubilized mix of cultured *Mycobacterium tuberculosis* proteins that is injected just under the skin, usually on the anterior side (underside) of the forearm. The test measures the immune response to these antigens. Those who have been exposed to *M. tuberculosis* will exhibit a cell-mediated hypersensitivity reaction, an inflammatory response consisting of rapid recruitment of activated immune cells to the area. The test is considered positive if a raised, hardened welt, called an "induration," appears within 72 hours and is 10–15 mm in diameter **(Figure B21.10)**.

The tuberculin skin test is not perfect. It can miss those who may be immunocompromised or are recently infected as they may not yet have activated immune cells. False positive tests can be caused by cross-reaction of tuberculin with similar antigens from other non-tuberculosis mycobacterial species. Often a chest X-ray is used to confirm the presence of granulomas, indicative of active or latent tuberculosis.

© Bart's Medical Library/Phototake

Figure B21.10. Positive tuberculin skin test A hard, raised nodule larger than 10 mm is considered positive for tuberculosis.

Test Your Understanding

Your friend had a tuberculin test as required by his employer. His test came back positive. However, a chest X-ray showed no granulomas and he is not sick. What does his positive tuberculin result mean? Why might his employer ask him to take antibiotics?

21.3 Fact Check

1. Explain why *Streptococcus pyogenes* can cause such a wide variety of diseases.
2. Describe some of the virulence factors of *S. pyogenes* and the specific disease with which each is associated.
3. What are some of the more serious consequences or outcomes of a strep throat infection?
4. What is necrotizing fasciitis, and how does it occur?
5. How does *Mycobacterium tuberculosis* overcome host defenses?
6. What role do LAM, catalase, and superoxide dismutase play in *M. tuberculosis* infection?
7. Distinguish between primary tuberculosis, latent tuberculosis, reactivation tuberculosis, and miliary tuberculosis.

21.4 Evolution of bacterial pathogens

How do some bacteria become pathogens?

In the previous section, we learned that pathogens have distinctive features known as virulence factors, which are needed to cause disease. Virulence factors allow them to attach, invade, and damage host tissue to acquire nutrients. The presence of genes encoding virulence factors is the major distinguishing characteristic between pathogens and their non-pathogenic relatives. In this section we will look at ways bacteria acquire virulence factors, and how pathogens may arise from non-pathogenic prototypes.

The traditional view of evolution holds that random mutations in genomes, those chance mistakes made by DNA polymerase during replication and sequence changes caused by mutagenic agents are acted upon by natural selection. By this, under certain environmental conditions, mutations that have a neutral effect or impart a selective advantage to the organism are kept and passed along to subsequent generations. Those that impart a disadvantage are lost because their possessors are out-competed by those lacking the mutation. Over time, selection forces act on such random gene mutations, molding benign organisms into exploitive pathogens. As you can imagine, this is a painstakingly slow process, even in rapidly multiplying populations. Is this the only evolutionary process that accounts for the rise of pathogens?

Horizontal gene transfer: Evolution by quantum leaps

One of the first clues that another significant process contributed to pathogen evolution was the acquisition of antibiotic resistance. In the 1950s, soon after the widespread use of penicillin, it became apparent that the rapid development of resistance to the same antibiotics in both related and unrelated bacterial species could not be solely explained by random mutational events. Scientists soon showed that antibiotic resistance genes were acquired by transfer of plasmids carrying resistance genes. In 1969, 12,500 people died in Guatemala during an epidemic of *Shigella dysenteriae* when treatment with antibiotics unexpectedly failed. This bacterial strain harbored a plasmid carrying resistance to four different antibiotics! Although resistance to antibiotics does not make a pathogen, the realization that whole genes could suddenly be acquired led scientists to reconsider the evolutionary processes used by microbes.

Horizontal gene transfer, the transfer of DNA by conjugation, transposable elements, plasmids, or temperate phages, is common in bacteria (see Section 9.4). As we have already seen, some pathogens vary from their non-pathogenic or less pathogenic counterparts only because they possess one or a few virulence factors that may be acquired by horizontal gene transfer. In the case of *Corynebacteria diphtheriae,* one gene transfer turns this bacterium from harmless to deadly. The genomics era has since provided much insight into just how prevalent horizontal gene transfer is in bacteria and archaea and how profound its impact has been on pathogen evolution.

CONNECTIONS Comparative genomics of *Bacillus anthracis* and its much less pathogenic relative *B. cereus* exemplify the significance of horizontal gene transfer. The major difference between these two species is just a few genes present in *B. anthracis* that have been delivered by a plasmid (see **Perspective 9.1**).

Pathogenicity Islands: Treasure Troves for Pathogens

From early sequencing projects, it became apparent that large segments of DNA, known as pathogenicity islands (PAIs), were often present in pathogenic strains but not in their non-pathogenic counterparts. Analysis of these segments has revealed some amazing characteristics. The genes contributing to virulence are often found clustered within these segments. The segments themselves have unusual features not found in the rest of the genome; they are conspicuous islands in an otherwise more uniform genomic sea. PAIs commonly encode genes for:

- Adhesion to host cells.
- Invasion of host tissues.
- Toxins that damage host cells.
- Type III or type IV secretion systems for injection of virulence factors.
- Proteins, such as iron-binding proteins, for facilitation of metabolic processes.

An example of a fully sequenced PAI is the locus of enterocyte effacement (LEE) found in some pathogenic strains of *Escherichia coli*, such as O157:H7. The genes encoded on the LEE PAI are directly responsible for the AE intestinal lesions produced by enteropathogenic and enterohemorrhagic strains (see Figure 21.3). LEE encodes genes for intimin production and a type III secretion system for the injection of Tir. Other gene products of the locus are of phage origin and have not yet been characterized.

In addition to the possession of genes related to virulence, **Figure 21.31** shows some other common features of PAIs:

- They contain unusually high or low cytosine and guanosine nucleotide content, as compared to that of the general chromosome (averaging 40–60 percent GC).
- They are flanked by direct repeat regions (used by transposable elements for insertion).
- They contain multiple mobile genetic elements (integrated phage genomes or insertion sequences).
- They have genes that encode enzymes used for movement and integration of DNA segments (integrases or transposases from phages and transposable elements, respectively).
- They are often adjacent to tRNA genes (a common site used by phages for DNA integration).

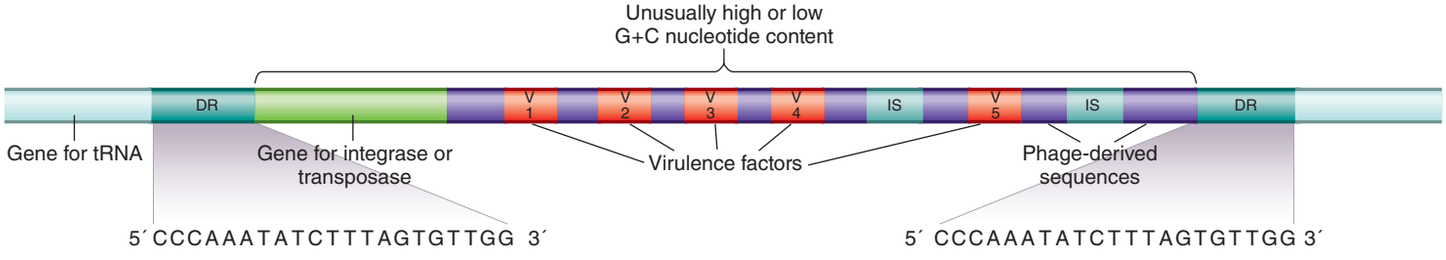

Figure 21.31. General structure of a pathogenicity island (PAI) PAIs are frequently found next to a tRNA gene and are bounded by direct repeat (DR) sequences. Mobile genetic elements, such as phage-derived sequences and insertion sequences (IS) from other bacteria, commonly exist and are thought to carry the various genes coding for virulence factors (V1–5). These sequences are frequently of higher or lower guanosine and cytosine content than the rest of the genome. A gene encoding an integrase or transposase enzyme is present. The enzyme can insert and excise the PAI element or its parts by recognition of the repeat regions within the IS or DR sequences.

The common presence of these unusual genetic features provides clues as to how these islands of sequence are acquired. They are delivered by mobile genetic elements: integrative phages, plasmids, and transposable elements, such as insertion sequences. Comparative genomic studies have revealed that the elements that comprise PAIs, including virulence genes, appear to originate from multiple foreign sources, such as other bacterial species, phages, and even eukaryotes. As we will see in this section, phages in particular have played a prominent role in the acquisition of virulence factors and the evolution of pathogens.

Many of the genetic elements found in PAIs appear to be derived from gene transfer "pools" that are available in ecological habitats such as the gut, skin, and the nasopharynx. The sheer number and concentration of sequences involved in virulence traits makes the habitat of the body a treasure trove of virulence options unlikely to be found outside the body. These transfer pools contain the genetic building blocks that, through time, have undergone rearrangements and further mutations to become the PAIs associated with particular pathogens found in these regions. For example, pathogenic strains of *Vibrio cholerae*, causing severe epidemic diarrhea, possess prophage-encoded cholera toxin **(Microbes in Focus 21.7)**. Cholera toxin, an A-B toxin (see Figures 21.9 and 21.12), is closely related to the *E. coli* heat-labile toxin (LT) encoded on a plasmid-borne PAI found in enterotoxigenic strains of *E. coli*, the common cause of "traveler's diarrhea." Another example of transference of communal sequences is found in the *cag* PAI of the pathogen *Helicobacter pylori*, which causes gastric and duodenal ulcers (see Perspective 6.1). Sequence comparisons show high similarity between several mobile genetic elements found on the *cag* PAI and those found in other gastrointestinal pathogens, including *Clostridium perfringens*, *E. coli*, and *Salmonella* Typhimurium. Also included in this cornucopia of *cag* PAI sequences are homologous genes that code for various virulence factors found in *Bordetella pertussis*, *Salmonella* Typhimurium and *Agrobacterium tumefaciens* (a pathogen of plants).

CONNECTIONS Toxigenic strains of *Clostridium difficile* produce two major virulence factors, toxin A and toxin B that are encoded on a PAI (see Table 21.7). As presented in the **Chapter 17 Mini-Paper**, these strains are responsible for colitis, a serious disruption of the integrity of intestinal cells.

It seems pathogen evolution favors the construction of new virulence factors from existing parts rather than solely relying on the much slower process of random mutation. In many cases, it is not known where the sequences for the parts originated, having changed with time over the course of pathogen evolution. The multitudinous insertions of various mobile genetic elements within many pathogen genomes provide significant genetic plasticity. Their presence facilitates recombination events, resulting in genetic rearrangements and chromosomal segment loss, both of which are commonly found in the genomes of pathogenic bacteria.

Phages: Delivery Vans for Virulence Factors

Bacteriophages have recently been realized to be major players in the evolution of many bacterial pathogens. This is not surprising because phages infect every known and probably unknown bacterial species on the planet. Not only do phages participate in natural selection of their bacterial hosts, but they also facilitate gene transfer between bacteria by transduction (see Section 9.4). As we saw earlier, certain types of DNA phages, such as the *E. coli* phage lambda, can integrate their genome into the bacterial chromosome as part of their life cycle (see Figure 8.21). They are termed temperate phages. Temperate phages are now known to have special significance for many bacterial pathogens.

CONNECTIONS Temperate phages are capable of integrating their genome into the bacterial chromosome, or sometimes into a plasmid. Virus progeny are not produced from the integrated prophage, and few viral genes are expressed. The prophage excises under certain, usually unfavorable conditions to begin the production of progeny virions. See **Section 8.3** for a review.

The relationship among phages, their bacterial hosts, and disease has until recently been overlooked in terms of the ecology and evolution of bacterial pathogens. In the

Microbes in Focus 21.7
VIBRIO CHOLERAE

Habitat: Widely found in aquatic environments, also in many invertebrates. Some strains cause disease in humans periodically.

Description: Gram-negative bacillus 1–3 μm in length, often having a curved rod shape; motile by means of single polar flagellum. Only strains possessing the temperate phage CTX, which encodes cholera toxin, cause significant disease in humans.

Key Features: Cholera toxin is responsible for most of the disease symptoms of cholera. The toxin-induced ion imbalance produces water loss from intestinal cells that results in massive diarrhea that can lead to death. Estimates of cholera deaths are likely greatly underestimated at over 200,000 annually. The *V. cholerae* receptors for the CTX phage are pili, the genes for which are encoded on a PAI. Interestingly, another temperate phage, RSIΦ, produces a product that upregulates cholera toxin expression in the host cell. Recent sequence analysis of the deadliest epidemic strains has shown significant genomic diversity, including the existence of two coexisting circular chromosomes.

TEM

© Dr. Gopal Murti/Science Source

1950s, it was realized that diphtheria was caused only by strains of *Corynebacteria diphtheriae* that carried a certain phage. In the 1980s, it was discovered that the genes for the two versions of Shiga-like toxin found in enterohemorrhagic *E. coli* strains, such as O157:H7, were transferred there by lambda-like phages from *Shigella dysenteriae*, the causative agent of epidemic dysentery. In 1996, the deadliest strains of *Vibrio cholerae* were found to harbor a particular toxin-producing phage (see Microbes in Focus 21.7). While this was a surprising discovery, even more surprising is just how prevalent phage-supplied virulence factors are **(Table 21.12)**. Ever-increasing amounts of genetic information have given microbiologists new insights into the role of phages in the acquisition of virulence factors. It has also become obvious that toxin production can be triggered by excision and entry into the lytic cycle of toxin-encoding prophages and that therapeutic agents that stimulate excision may enhance pathogen evolution by allowing movement of toxin genes and other virulence factors. **Perspective 21.4** describes how antibiotics can actually make some diseases worse by triggering prophage excision and toxin production.

Why would bacteriophages carry virulence genes that cause disease in eukaryal organisms? Phages can only infect and lyse bacteria and archaea, so why cause damage to eukaryal cells? One school of thought regarding phage-derived toxins is that production of the toxin by the phage is directed against some other organism commonly found in the environment. Plants or animals or humans may be inadvertent victims of these toxins.

This theory appears to have some merit. Shiga toxins bind to a lipid receptor found on certain eukaryal cells. As mentioned earlier, the receptor is enriched in kidney and liver tissue in humans. But the same receptor is also found on a predatory protozoan called *Tetrahymena* that is commonly found in aquatic habitats, including sewage treatment facilities and composting animal wastes, where enteric microbes like *E. coli* abound. *Tetrahymena* feed on bacteria and viruses, breaking them down and harvesting their chemical constituents **(Figure 21.32)**. An *E. coli* strain harboring the Shiga-like toxin gene can survive when co-cultured with *Tetrahymena*. These cells appear to be able to kill the predators. Conversely, an *E. coli* strain lacking the toxin gene fared poorly when co-cultured with *Tetrahymena*. Blocking the binding of the Shiga-like toxin to *Tetrahymena* prevents killing. In this case, it would appear that the advantage to the phage is to kill the protozoa that would otherwise consume phage particles and their bacterial host cells. Maybe disease caused by Shiga toxin-producing bacteria really is an inadvertent result of infection with these phage-harboring strains.

Another interesting phage-host relationship involves diphtheria toxin. Within the *Corynebacterium diphtheriae* phage β lies an operon that encodes the toxin gene, and within the bacterium lies another operon encoding an iron-binding siderophore. Expression of both the toxin and the siderophore is negatively controlled by iron **(Figure 21.33)**. High concentrations of iron repress transcription of these genes. As available iron concentrations are always low in the body, the toxin and siderophore are expressed in lysogenized

TABLE 21.12 Genes introduced to bacterial cells by temperate phages

Encoded gene product	Bacterial host	Impact
Botulinum toxin types C1, D	*Clostridium botulinum*	Flaccid paralysis
Cholera toxin	*Vibrio cholerae*	Cholera (massive watery diarrhea)
Diphtheria toxin	*Corynebacterium diphtheriae*	Diphtheria: localized (throat) cell death or systemic damages (heart, kidney)
Enterohemolysin	*Escherichia coli*	Invasion, intestinal cell death (severe diarrhea)
Enterotoxins (superantigens)	*Staphylococcus aureus*	Food poisoning
Exfoliatin toxin	*Staphylococcus aureus*	Scalded skin syndrome
Hyaluronidase	*Streptococcus pyogenes*	Contributes to tissue invasion and spread
O-antigen acetylase	*Shigella flexneri*	Shigellosis (dysentery)
O-antigen synthesis enzymes of LPS	*Salmonella enterica*	Alters O antigens to avoid immune clearance, contributes to enteritis
Outer membrane proteins	*Escherichia coli*	Serum resistance
Pilus	*Vibrio cholerae*	Allows attachment to host cells
Pseudomonas aeruginosa cytotoxin	*Pseudomonas aeruginosa*	Pneumonia and skin infections
PV leukocidin	*Staphylococcus aureus*	Necrotizing infections
Shiga toxins	*Shigella dysenteriae*	Hemolytic uremic syndrome (kidney damage)
Shiga toxins (verotoxins)	*Escherichia coli* O157:H7	Hemolytic uremic syndrome (kidney damage)
Streptococcal pyrogenic toxin (SPE A, C)	*Streptococcus pyogenes*	Scarlet fever
Streptococcal TSSTs (superantigens)	*Streptococcus pyogenes*	Toxic shock
TSST (superantigen)	*Staphylococcus aureus*	Toxic shock syndrome

Perspective 21.4
ANTIBIOTICS TRIGGER TOXINS?

Shiga toxins, produced by some strains of *Shigella* and enterohemorrhagic strains of *Escherichia coli*, are encoded on temperate lambda-like phage genomes. Recall that Shiga toxins attach to certain lipid receptors enriched in human tissues, such as kidney tissue. From here they are taken up and cause cell death resulting in hemolytic uremic syndrome (HUS).

In 2000, a study of the effectiveness of quinolone antibiotic therapy for persons infected with *E. coli* O157:H7 indicated that the risk of developing HUS was greater when antibiotics were given. How can this be? Quinolones are a class of broad-spectrum antibiotics commonly used to treat severe diarrhea. They act on bacterial DNA gyrase or topoisomerase IV, thereby interfering with bacterial DNA replication, resulting in DNA damage. Significant DNA damage induces a ubiquitous bacterial DNA repair system called the "SOS regulon" (see Section 11.3). The SOS response allows bacteria to survive such assaults to their DNA. As you can imagine, damage to the bacterial host cell is a threat to the integrated prophage: if the cell dies, so ends the phage's existence. Many types of prophages are chemically attuned to induction of the SOS response and will excise when it occurs. This begins transcription of phage genes for the replication of progeny virions that then lyse the cell, abandoning ship. Treatment with quinolone antibiotics induces the SOS response, and the Shiga-like toxin-encoding prophage is excised. Transcription of phage genes begins and Shiga-like toxin is produced. Thus, quinolone antibiotic treatment greatly increases the risk of HUS.

A similar case occurs for *Streptococcus canis*, a normally commensal opportunistic pathogen that colonizes the skin of dogs. Many strains harbor a prophage that encodes a protein with superantigen-like effects capable of non-specific activation of T cells. The recent use of DNA-damaging antibiotics has precipitated severe cases of skin disease and toxic shock syndrome in dogs infected with these strains of *S. canis*.

Researchers are concerned that the indiscriminate use of antibiotics may be helping to spread virulence genes by encouraging excision and movement of phages. Indeed, quinolones have widespread veterinary use in production animals, such as cattle, pigs, and poultry. Reports of Shiga toxin-producing strains of several enteric bacterial species have alarmed many scientists. Since 1995, Shiga toxins have been reported in *Citrobacter freundii, Enterobacter cloacae, Aeromonas,* and *Shigella sonnei*, where they were previously not found.

C. diphtheriae. The toxin kills body cells, releasing small amounts of free iron that are in turn bound and transported by the siderophores for the bacterium's own use. Presumably it is to the phage's benefit to supply the bacterium with iron in order to perpetuate its own replication—a phage's way of bacterial farming. The level of codependence between the phage and the bacterium is further evident in that expression of the phage operon is dependent on expression of a bacterial gene, which produces a repressor protein called DtxR (diphtheria toxin repressor). Scientists are just beginning to realize the interdependence between production of disease, the bacterial pathogen, and the phage that infects it. It seems some bacterial pathogens have a mutualistic relationship with their phages. They need their phages as much as the phages need them.

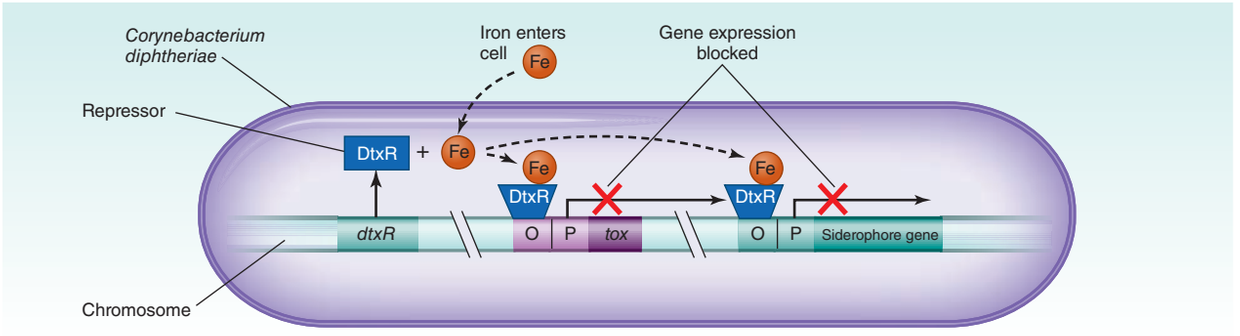
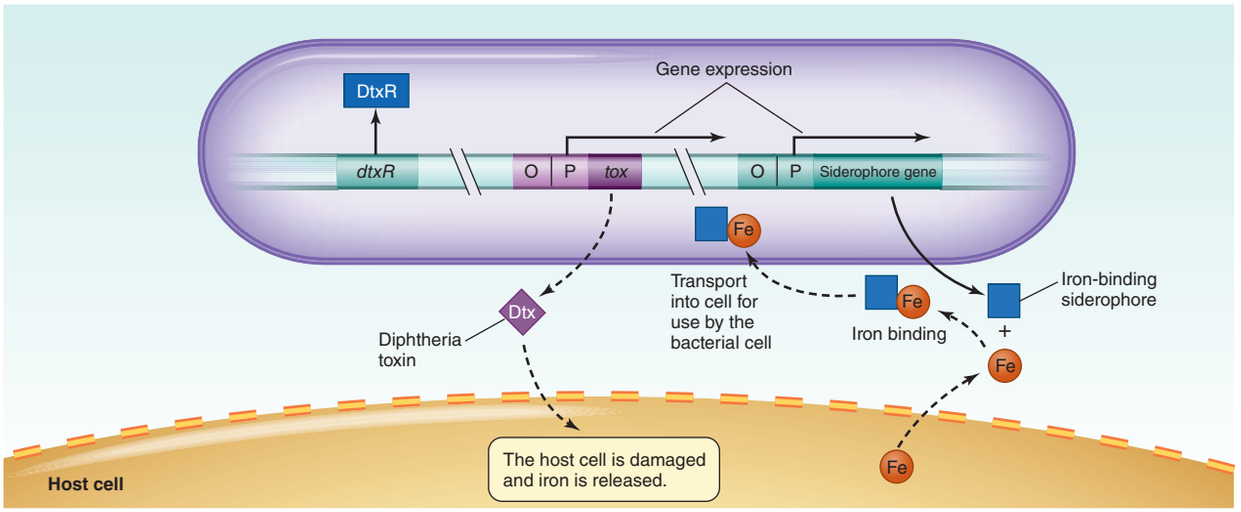
Figure 21.32. Protozoan ingesting a microbe Many protozoa are predators of microbial cells and viruses. The T4 phage particles (fluorescent green) are ingested by *Tetrahymena*. Shiga-like toxin-producing strains of *Escherichia coli* survive when co-cultured with *Tetrahymena*.

Horizontal gene transfer by phages is no doubt an important phenomenon in the acquisition of virulence factors, genetic diversity, and evolution in many pathogens. Studies of the genomes of various bacterial species show that a high prevalence of prophage and phage-derived elements exist in bacterial chromosomes or in the plasmids they carry. For example, genetic analysis of isolates of *E. coli* O157:H7 (see Chapter 10 Mini-Paper) has revealed that the genome contains between 15 and 18 *different* prophages. This adds nearly 1 million extra base pairs to its genome, for a total of 5.4 million base pairs, compared to its non-pathogenic counterpart *E. coli* K12 of 4.6 million base pairs.

Horizontal gene transfer events are known to occur at much higher frequencies *in vivo* than *in vitro*, suggesting that something about the host environment itself facilitates this. One piece of supportive evidence is the observation that prophages in *E. coli* and *Salmonella* are induced to excise and begin a lytic life cycle when exposed to reactive oxygen species, as one would find in the phagolysosome. This results in the production of infectious virus particles that can transport their virulence cargoes to new host cells. Perhaps this is one of the unfavorable conditions exacted upon pathogens by the host that induces the bacterial SOS response and excision of the prophage. The response of the host itself therefore contributes



A. Toxin production in high-iron concentration



B. Toxin production in low-iron concentration

Figure 21.33. Effect of iron on expression of diphtheria toxin gene *Corynebacterium diphtheriae* bacterial genetic elements are shown in blue. Prophage genetic elements are shown in purple. The *dtxR* gene produces a repressor protein DtxR. **A.** DtxR binds free iron, which produces a shape change in DtxR, allowing it to bind the bacterial operators. This prevents binding of RNA polymerase to respective promoters, blocking expression of the prophage-encoded diphtheria toxin and the bacterial iron-binding siderophore. **B.** In the absence of free iron, DtxR cannot bind the operators, and diphtheria toxin (Dtx) and the siderophore are produced as a consequence. The toxin destroys host cells, releasing iron that the siderophore can bind and transport into *C. diphtheriae*.

to evolution of pathogens by accommodating acquisition of new virulence factors.

Protozoa: Prep school for pathogens

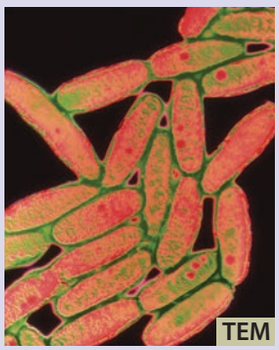
It appears that the intended targets for several animal and human bacterial pathogens are actually protozoa. The best-known example of this is *Legionella pneumophila*, the causative agent of Legionnaires' disease **(Microbes in Focus 21.8)**. The disease was first recognized after an outbreak of severe pneumonia among those attending a convention of the American Legion in Philadelphia in 1976. Over 200 people staying in a hotel became ill, and 34 died. The outbreak was linked to the hotel air-conditioning system, from which the bacterium was isolated. That was not the most surprising finding, however. The bacterium was found to reside inside single-celled amoebae, also commonly found in commercial water systems. The bacterium and its apparent host turned out to be common environmental inhabitants. Studies have shown that the *L. pneumophila* genes that are required for uptake and growth inside their amoebae hosts are also

Microbes in Focus 21.8
LEGIONELLA PNEUMOPHILA: THE ACCIDENTAL PATHOGEN

Habitat: Found in association with various species of free-living amoebae in aquatic habitats. In humans, it can replicate in lung macrophages, but is not contagious.

Description: Gram-negative non-endospore-forming rod 1–3 μm in length

Key Features: *Legionella pneumophila* is the causative agent of Legionnaires' disease, a severe respiratory infection of compromised persons, and "Pontiac fever," a milder, flu-like systemic disease. It is often found in building water systems, such as air-conditioning systems, and hot tubs. The contaminated aerosols are inhaled.



© CAMR/A. Barry Dowsett/Science Source

required for growth inside lung macrophages. *Legionella pneumophila* received its education to be a human pathogen from living in amoebae.

Associations between predatory protozoa, such as amoebae, and intracellular pathogens are not uncommon, having been reported for *Shigella, Listeria, Chlamydia, Francisella tularensis,* and various mycobacterial species. In most cases, the pathogens appear to be endosymbionts; they are able to replicate and establish a stable interaction inside their protozoan hosts. Their intra-protozoal lifestyle, which involves survival inside phagocytic vesicles, may have provided them with the tools needed for intracellular survival in the cells of multicellular eukaryotes. As microbiologists begin to examine the ecological roles of pathogens inside and outside the environment of the body, it is becoming apparent that the evolution of the host-pathogen relationship is much more multidimensional than previously thought.

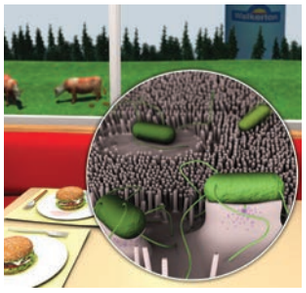
21.4 Fact Check

1. How does horizontal gene transfer play a role in the evolution of bacterial pathogens?
2. What are pathogenicity islands, and what types of genes are contained within these sequences?
3. Explain how phages have played a role in the evolution of bacterial pathogens.
4. Some bacterial pathogens have a mutualistic relationship with phages. Explain what this statement means, and provide an example to illustrate this concept.
5. Explain the role of protozoa in the evolution of some human pathogens.

Image in Action

WileyPLUS Learning Space

Enteropathogenic and enterohemorrhagic strains of *Escherichia coli* attach themselves to the intestine by injecting their own receptor into host cells. An example is *E. coli* O157:H7. This strain is associated with cattle and caused a deadly outbreak in Walkerton, Ontario, Canada.



The enterohemorrhagic *E. coli* in this image are attaching to intestinal microvilli and inducing pedestal formation. This disrupts intestinal structure and function.

1. Identify and describe the potential benefits for the bacteria in the image that are inducing pedestal formation.
2. What proteins are being represented by the green and the pink molecules in the image, and what are their roles in infection and disease?

The Rest of the Story

Escherichia coli O157:H7 was first isolated in 1975 but was not connected conclusively to enteric disease until 1982. At that time, it was determined to be the causative agent of hemorrhagic colitis in four patients in the United States who had all eaten hamburgers at fast-food chain restaurants. Many of the Walkerton, Ontario, residents who fell ill in 2000 are still suffering the effects of *E. coli* O157:H7 as a result of hemolytic uremic syndrome (HUS) produced by the Shiga-like toxins. Their chronic ailments include kidney disease, ongoing diarrhea, arthritis, hypertension, and dysfunctions of the liver, pancreas, heart, and brain.

These outbreaks are some of the worst public health disasters because of the combination of the severity of the disease, its potential for fatality, the frequency of severe complications, and the lack of specific therapeutic interventions. Public health efforts include education in food preparation and the development of rapid tests for the pathogen in cattle, humans, and food and water samples. Research has focused on eliminating the organism in cattle by vaccination. The developed commercial vaccines target *E. coli* O157:H7 type III secreted proteins and/or siderophore receptor and porin proteins. The vaccines reduce numbers of these bacteria shed in feces substantially, thus reducing the risk of water and meat contamination. The publication of the complete genome sequences of two outbreak isolates of *E. coli* O157:H7 may help identify additional virulence genes by comparing these genomes to that of the non-pathogenic strain *E. coli* K12. Such comparisons may lead to the development of better methods of detection and understanding of the evolution of this recently emerged pathogen. Studying the evolution of *E. coli* O157:H7 will allow for a more complete knowledge of the disease process and, it is hoped, better treatment options that may spare future patients the long-term consequences seen in patients from Walkerton.

Summary

Section 21.1: What are common features of bacterial pathogens?

Pathogens use virulence factors to aid in their access and spread in tissues to evade/disrupt host defenses and to obtain nutrients from the body.

- Virulence factors include molecules for attachment, capsules, secretion systems, iron-binding proteins, and toxins.
- Attachment to host cells or tissues is a critical event for colonization/infection. Attachment factors or **adhesins** that are commonly used include fimbriae and **fibronectin-binding proteins**.
- Some pathogens have specialized adhesins. Enteropathogenic and enterohemorrhagic strains of *E. coli* produce the adhesin intimin and the receptor Tir.
- Capsules are major virulence factors of many pathogens. They protect pathogens from immune defenses by blocking contact between cell-bound antibodies and the F_cR of phagocytes, blocking contact between complement C3b and the CR3 of phagocytes, reducing entry to the endocytic pathway, mimicking host "self" molecules, which do not evoke antibody production, and provide **serum resistance** to complement.
- Type III secretion systems are a trademark of Gram-negative pathogens that are used for targeted delivery of virulence factors directly into the host cell. Some Gram-negative pathogens possess **type IV secretion systems** for similar purposes.
- Gram-positive pathogens use pore-forming cytolysins, rather than secretion systems, to transfer virulence factors into host cells.
- Iron is a limiting factor to bacterial metabolism and growth in the body. In the host, it is sequestered by molecules, such as lactoferrin and transferrin and is locked inside cells.
- Pathogens acquire iron from the host by destroying cells, such as red blood cells, and producing **siderophores**, bacterial iron-transporting proteins that can steal iron away from the host iron-binding proteins.

Section 21.2: How do bacterial toxins act on host cells?

- Bacterial toxins are a prominent feature of many pathogens.
- **Cytotoxins** encompass a variety of toxins that act on host cells.
- **Endotoxins** are wall-associated molecules produced by Gram-negative pathogens. Endotoxin is released through growth or death of bacterial cells. The lipid A portion of endotoxin evokes inflammation. The O-antigen is often strain-specific and can be used for identifying **serotypes** using **serotyping** techniques.
- Lipopolysaccharide (LPS) is the most common form of endotoxin, but some Gram-negative pathogens produce **lipo-oligosaccharide (LOS)** that lacks the O-antigen component.
- Lipoteichoic acid (LTA) is the Gram-positive functional equivalent of endotoxin as it also evokes inflammatory responses in the host.
- **Exotoxins** are toxins that are produced inside the cell and are secreted or released upon lysis. They include A-B toxins, cytolysins, and superantigens.
- **A-B toxins** act intracellulary to modify specific molecular targets in host cells. They consist of a B subunit that binds to a host receptor and an enzymatic A subunit that is taken up by the cell. **Toxoids** are denatured toxins that can be used in vaccines.
- **Cytolysins** act on cell membranes, producing damage by forming pores, often detected by **hemolysis** on blood agar media or degrading lecithin of membranes (**lecithinase**).
- **Superantigens** activate T cells in a non-specific manner by linking TCRs with MHC II molecules of antigen-presenting cells. Some superantigens act systemically to produce toxic shock syndrome. Others are enterotoxins, acting on the gut.

Section 21.3: How do bacterial pathogens cause disease?

Streptococcus pyogenes is an opportunistic pathogen that produces a variety of diseases. It possesses a number of virulence factors that are similarly found in other extracellular pathogens.

- Some virulence factors produced by *S. pyogenes* include streptolysins, superantigens, a capsule composed of "self" molecules, and enzymes that degrade host immune molecules and tissues.
- Removing any one virulence factor often has little impact on the ability of *S. pyogenes* to cause disease.
- Some strains of *S. pyogenes* cause post-streptococcal **sequelae**, such as glomerulonephritis and rheumatic heart disease.
- The possession of so many virulence factors contributes to the variety of diseases *S. pyogenes* produces and its success as a human pathogen.

Mycobacterium tuberculosis is a primary, intracellular pathogen that causes tuberculosis. It shares many features characteristic of intracellular pathogens. These include facilitation of its own uptake in host cells, interference with phagosome and lysosome fusion, and obstruction of antigen presentation to $CD4^+$ T cells.

- Some virulence factors produced by *M. tuberculosis* include LAM, catalase, and superoxide dismutase. These help to downregulate and neutralize the toxic oxygen species produced by the oxidative burst.
- The pathogenesis of *M. tuberculosis* is largely determined by the host immune response.

- A strong cell-mediated immune response is protective against this intracellular pathogen and can eliminate it or keep it inactive for life. A humoral response is not protective against intracellular bacterial pathogenesis.
- The hallmark of tuberculosis is **granuloma** formation, which can keep *M. tuberculosis* from spreading, but causes damage to host tissue.
- If the cell-mediated response changes, growth occurs and the granuloma disintegrates. This is characterized by caseous necrosis, which destroys the integrity of the lung and results in distribution of *M. tuberculosis* to other tissues and other people.

Section 21.4: How do some bacteria become pathogens?

Evolution of pathogens involves horizontal gene transfer by conjugation, transposable elements, temperate phages, and plasmids that can very suddenly introduce new virulence factors. Random mutational events, including recombination, also result in the modification of genes over time.

- Genes that contribute to virulence are frequently found grouped together in pathogenicity islands (PAIs). PAIs are usually absent in non-pathogenic or less pathogenic strains or related species.
- Many of the genes found in PAIs are shared among bacteria living in similar niches in the body.
- Temperate phages are major players in the development of many bacterial pathogens.
- DNA-damaging compounds, including some antibiotics that activate the SOS response, can encourage excision of prophages, which can result in toxin production, disease, and movement of phages.
- There is increasing evidence that phages provide toxins to pathogens in order to increase the successful replication of the pathogen.
- Some pathogens have gained the capacity for intracellular survival in multicellular hosts from living in single-celled protozoa, such as amoebae, in the environment. Hosts, such as humans, may be inadvertent victims.

Application Questions

1. Actions of some virulence factors, such as hemolysins, cause host tissue damage. If it is accepted that a pathogen is not necessarily trying to destroy the host, then what is considered the reason or selective advantage for having this type of effect on the host? Explain.
2. A new strain of *E. coli* with increased levels of Shiga-like toxins is found to be the cause of an outbreak. Describe the effects these microbes would have on an infected patient. How could this strain be serotyped?
3. A strain of *Staphylococcus aureus* isolated from a skin infection is resistant to penicillin because it possesses a gene that encodes the enzyme penicillinase that destroys penicillin. Would you consider penicillinase to be a virulence factor? Explain your answer. How might you use an *S. aureus* knockout mutant to prove this?
4. Parents rush to the emergency room with their sick baby. The doctor's diagnosis is infant botulism after he runs tests and learns the baby has ingested honey. The honey, he explains, may contain *C. botulinum* endospores. The parents are shaken and confused because they also ate the same honey, but they are fine. As the doctor, how would you explain to the parents why their baby is ill and they are not?
5. The actor Christopher Reeve (best known for playing Superman) became a paraplegic after a bad fall from his horse during an equestrian competition. He died years later in 2004 of complications due to an infected bedsore. The culprit was a methicillin-resistant strain of *S. aureus*. The actual cause of death was heart failure. Explain the link between his skin infection with *S. aureus* and his resulting heart failure.
6. During infection, there is often a "battle for iron" between the host and the infecting pathogen. Explain how the human body restricts the amount of free iron available to a pathogen. Then explain how some bacteria still manage to get iron from the body.
7. In the lab, a researcher generated a knockout strain of *S. aureus* lacking the α-toxin gene. Describe the effects this mutagenesis would most likely have on these bacteria.
8. A young child is at the pediatrician's office to receive his DTaP vaccination. His parents read the information sheet provided and become concerned when they see that the vaccine contains bacterial toxins. As the child's doctor, explain more fully what the vaccine actually contains and why their child isn't going to receive dangerous toxins.
9. Production of antibody has not been found to be protective against *Mycobacterium tuberculosis* infection. Explain why this would be.
10. You encounter what appears to be a newly emerged strain of bacteria. As you examine its DNA sequence, you determine it has genes for a type III secretion system. What would this sequence analysis tell you about the pathogenesis of these bacteria?
11. Enterotoxigenic strains of *E. coli* can cause diarrhea in travelers to regions where these strains exist as common gut inhabitants in local populations, yet they do not usually cause disease in local populations. Suggest why these strains are a problem for travelers, but not for the locals.
12. If you could design your vision of the ideal pathogenic bacterium that was able to gain access to a host, avoid immune destruction, and obtain nutrients, what virulence factor genes would you insert in its genome? Explain your reasoning for each.

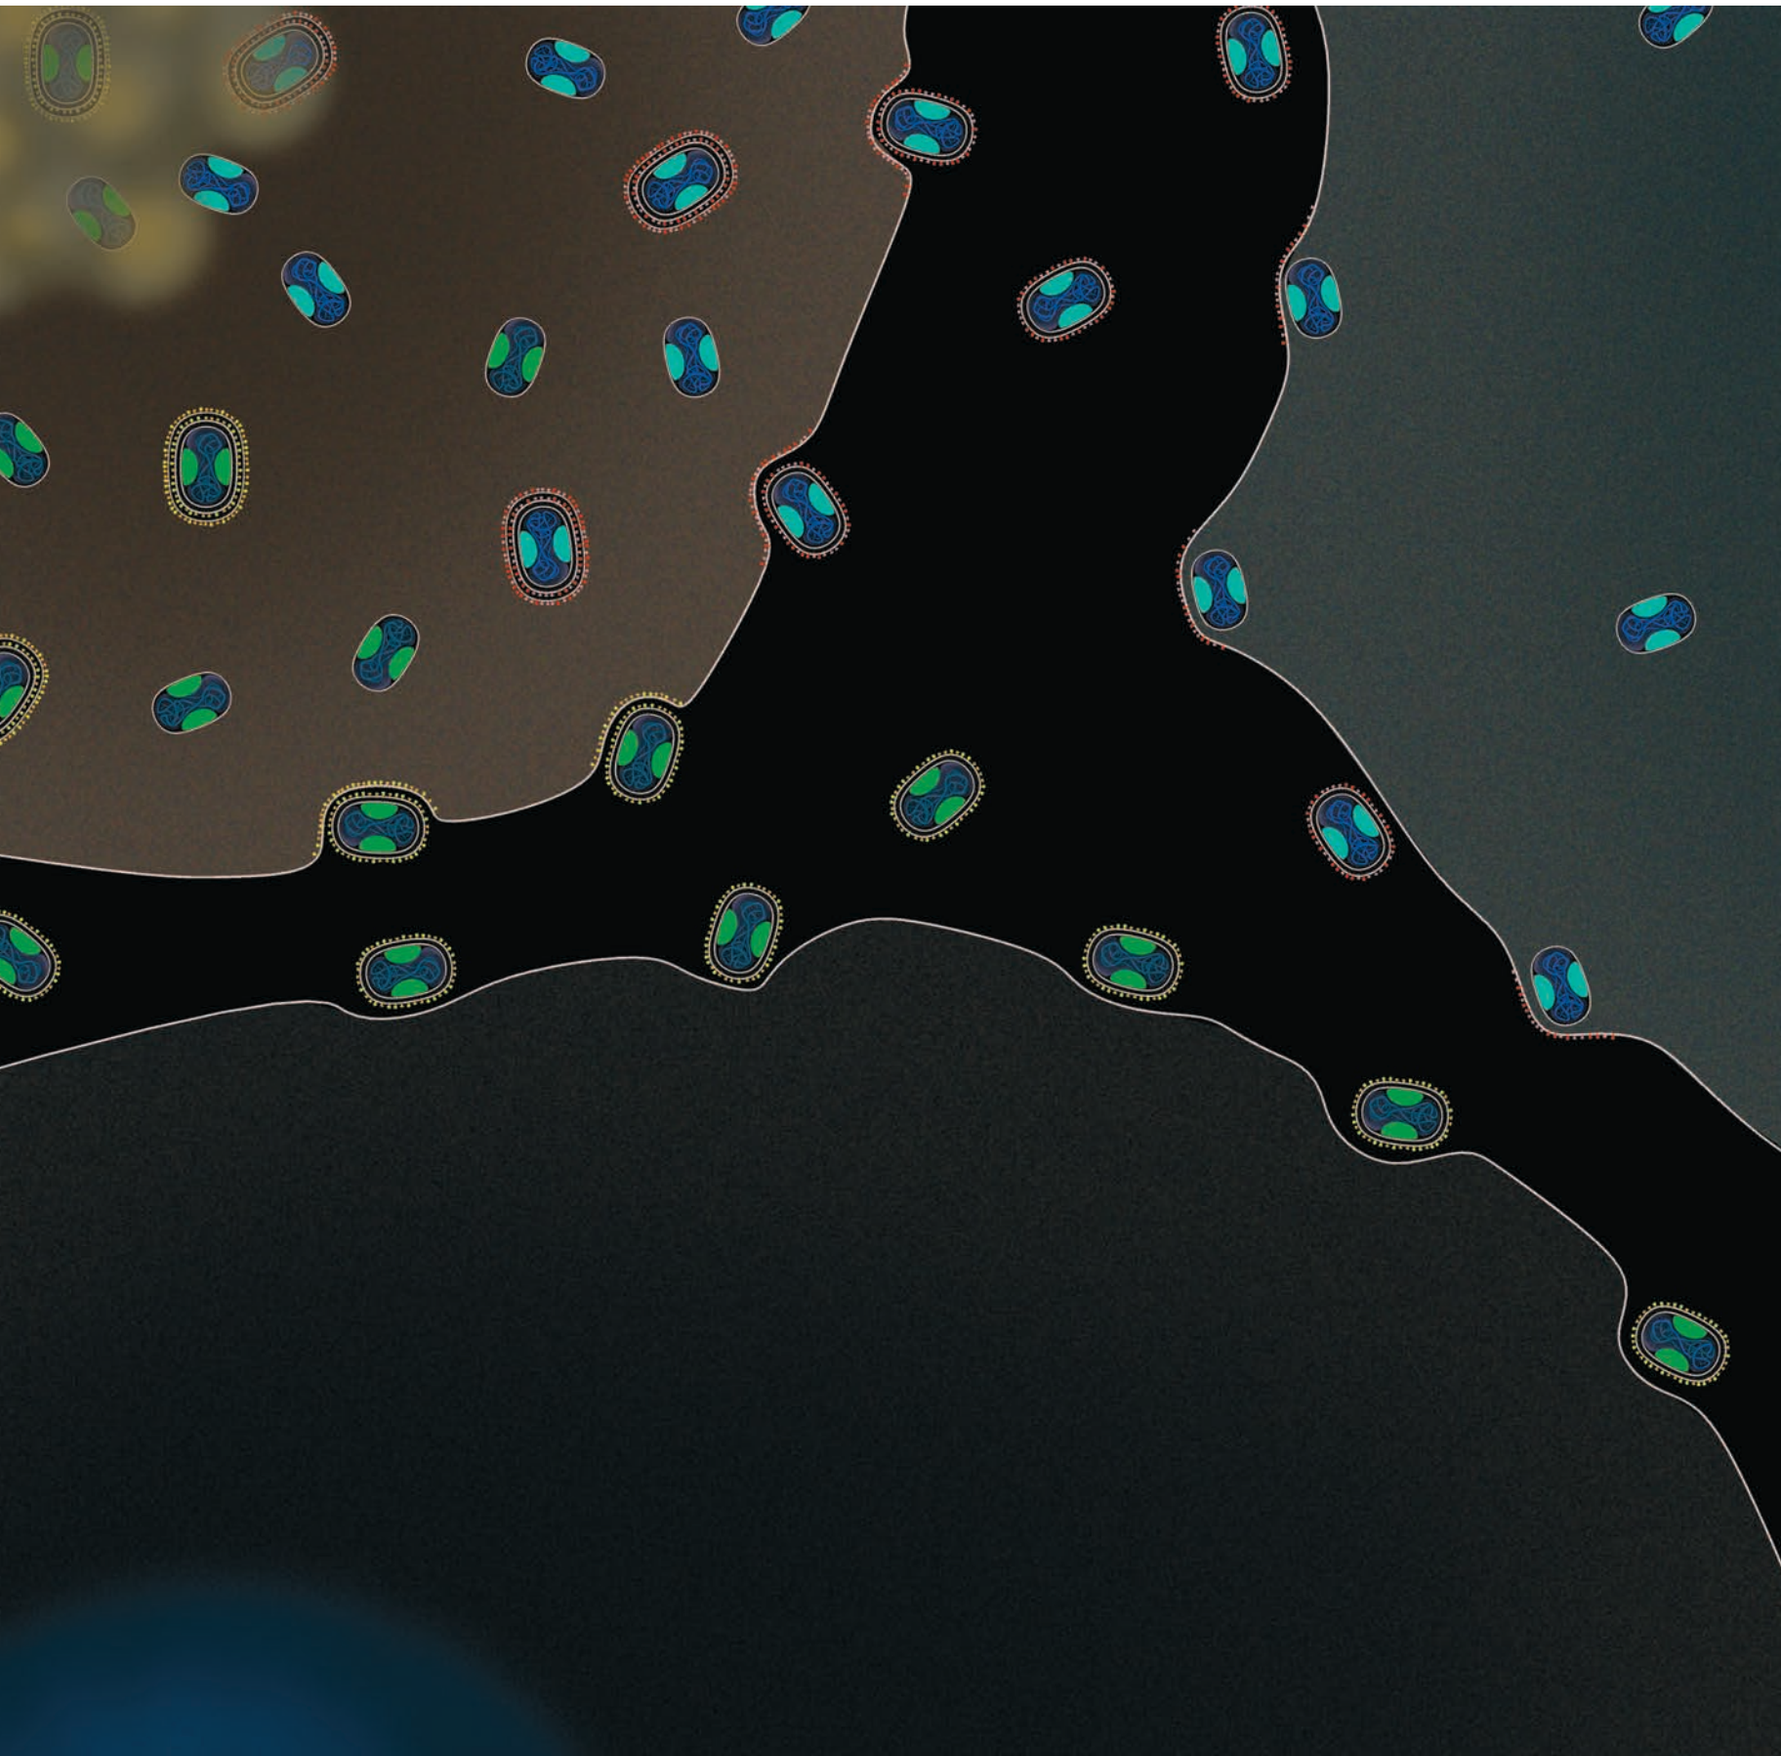
CHAPTER

22 Viral Pathogenesis



We probably have all heard about "introduced species." The term refers to species that are released into a non-native environment. Often, these introduced species become invasive, spreading extensively in the new habitat and causing economic, ecological, and/or human health problems. Sometimes, the introduction of these species occurs accidentally. In other cases, the species are introduced intentionally, without much forethought into their ultimate role in the new location. The introduction of rabbits into Australia falls into the latter category.

It is thought that Europeans introduced rabbits into Australia several times in the 1700s and 1800s. The current problem with rabbits, though, probably results from the 1859 release of a few rabbits by residents of Western Australia. They hoped to generate a population of wild rabbits for hunting. Within a decade, however, the rabbits had spread and multiplied so extensively that hunters could not possibly control their numbers. In the following years, the rabbits caused extensive crop loss and probably led to the extinction of several native plant species. The Australian government tried to contain the rabbits in several ways, including building a 2,000-mile-long fence in 1907, the so-called "rabbit-proof fence." None of their approaches worked.

Then, in 1950, the government decided to employ a type of biological warfare. They intentionally released myxoma virus, a member of the *Poxviridae* family. This virus caused a relatively mild disease in its natural host, the cottontail rabbits of South America, but was highly virulent in the European rabbit that was plaguing Australia. Initially, the strategy seemed to be a success. Over 99 percent of infected rabbits died within two weeks of being infected, and the total rabbit population in Australia plummeted from 600 million to 100 million in just a couple of years. To understand more thoroughly how this virus affected the rabbit populations, we need to explore general properties of viral pathogenesis. Also, we will begin to understand why this control measure turned out to be a very temporary solution.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Viruses can cause many types of infections and can be transmitted from one host to another in a variety of ways.

Proinflammatory molecules and the immune response **(Section 19.3)**

DNA repair mechanisms **(Section 7.5)**

Introduction

In this chapter, we will examine viral pathogens. Like the bacterial pathogens that we examined in Chapter 21, viral pathogens, and the diseases associated with them, exhibit remarkable diversity. Of course, the diseases caused by viruses can be quite devastating. Initially, the myxoma virus that we introduced in the opening story certainly had a devastating effect on its host, the European rabbit. The outbreak of Ebola virus disease that began in 2014 provides another example. By the end of March 2016, when the World Health Organization (WHO) declared that the outbreak no longer was a public health emergency of global concern, there were 28,646 suspected or confirmed cases of Ebola virus infection reported, which resulted in 11,323 deaths. Most of the infections occurred in three countries: Liberia, Sierra Leone, and Guinea. Often, death occurred within days of the infected person experiencing symptoms of disease.

Other viruses affect their hosts in less dramatic ways. Some viruses cause chronic or persistent infections in which the virus may never be completely eliminated from the host and disease occurs long after the initial infection. Still other viruses may cause latent infections, in which viral replication ceases after an initial acute infection, only to resume replicating later, perhaps years after the initial period of replication. In still other cases, the infection does not result in any overt clinical symptoms in the host.

Despite the different types of infections that viruses can cause, all viruses must solve certain key problems. They must get into a permissive host. They must acquire the resources needed for replication. They must evade host defenses. They must spread to a new host. The resulting diseases may arise, for example, from tissue damage caused directly by the replicating virus or from the immune response of the host to the replicating virus. In some cases, viruses cause their host cells to become transformed, or immortalized, resulting in the formation of tumors.

In this chapter, we will investigate these various aspects of viral pathogenesis. We will focus not on specific viral diseases, but rather on general paradigms. A few selected viruses and their associated diseases will be examined in depth to illustrate our main points. Although we will focus primarily on viruses that infect mammals, we also will note the pathogenesis of viruses that infect plants and viruses that infect bacteria. We will conclude by investigating the evolution of viral pathogenesis. As we explore these topics, we will address the following questions:

How do viruses cause disease? (22.1)
How do viruses interact with host cells? (22.2)
How do some viruses cause cancer? (22.3)
How do some viruses become highly virulent? (22.4)

22.1 Recurring themes in viral pathogenesis

How do viruses cause disease?

As we mentioned previously, all viruses must replicate within host cells. This viral replication leads to some damage of the host. The type and extent of damage, however, can differ dramatically. So, what exactly do we mean by viral pathogenesis and disease? To answer this question, we need to define a few terms. To the virologist, infection generally refers to the entry of a virus into a cell. Often, we are exposed to viruses but not infected by them. To understand this distinction, simply think about the number of viruses—viruses that naturally infect other animals, plants, bacteria, or archaea—present in the ocean. When you go swimming, you will be exposed to many of these viruses. Very few, if any, will infect you.

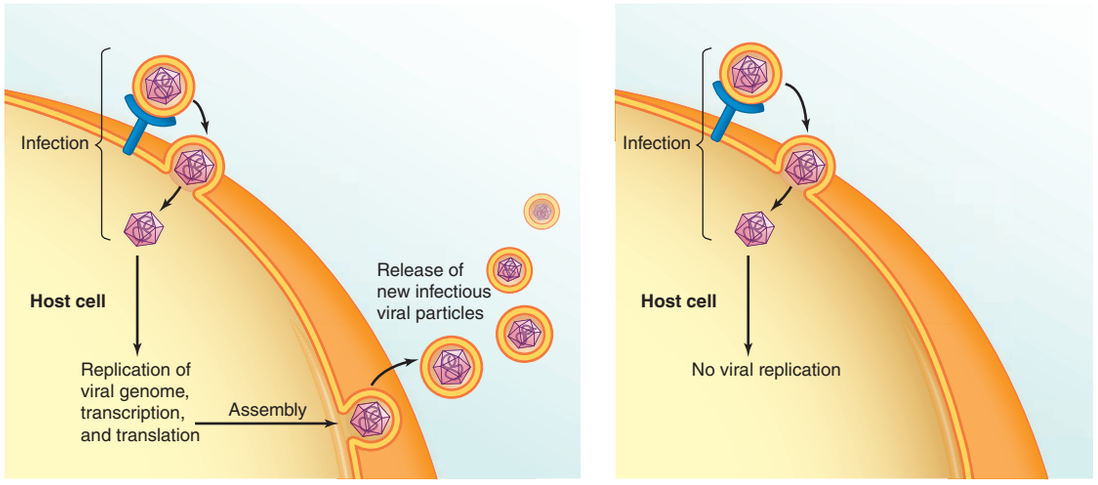
If a virus does enter a cell, one of two outcomes can occur. In a **productive infection**, new infectious viral particles will be produced. In contrast, in an **abortive infection**, few if any new infectious viral particles will be produced (Figure 22.1). Generally, infectious disease occurs during a productive infection. As we will see in Section 22.3, a specific disease state—cancer—may result from an abortive infection. In this section, we will look at different types of productive infections. We also will examine how viruses spread from one organism to another.

Types of infections

As we noted in previous chapters, viruses replicate within host cells using host cell materials. In this way, viral replication damages the infected cell. As we saw in Chapters 19 and 20, the host immune system is designed to eliminate these pathogens, thereby preventing or minimizing the amount of damage done by the virus. The overall outcome of a viral infection, then, depends on two interrelated activities: the replication of the virus and the immune response of the host. We will begin by exploring three different types of infections: acute, latent, and persistent. In each case, we will see how the interplay between viral replication and the host immune response affects the process. In each case, we also will consider how the virus benefits from the particular infection strategy.

Acute Infections

When people typically think about viral infections, they probably think about **acute infections**, which are infections that have a short duration. Indeed, acute infections represent the majority of viral infections that we experience. We



A. Productive infection: Permissive cell

B. Abortive infection: Non-permissive cell

Figure 22.1. Productive versus abortive infections *Infection* refers to the entry of a viral genome into a cell. **A.** If new viral particles are produced, then the infection is productive and the infected cell is referred to as permissive. **B.** If no new viral particles are produced, then the infection is abortive and the infected cell is referred to as non-permissive.

become infected and show signs of disease. After a short duration, we clear the viral infection or, in some cases, the viral infection results in death. Some researchers have described this process as a state of disequilibrium. The virus replicates quickly, producing many new viral particles. After a short delay, the immune system produces a strong response to the infection. The severity of disease may be affected both by the replicative ability of the virus and the strength of the immune response.

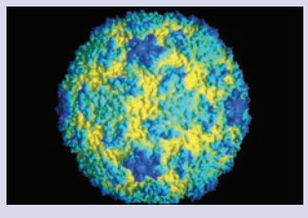
As an example of an acute infection, let's examine a typical rhinovirus infection. Rhinoviruses **(Microbes in Focus 22.1)**, members of the *Picornaviridae* family, are the major causes of the so-called common cold. Viral replication occurs in cells of the upper respiratory tract, and the typical signs of disease include coughing, sneezing, and increased nasal secretions. These signs, however, are quickly resolved. Experimental studies, in which volunteers were intentionally infected with rhinovirus, showed that the amount of virus present in nasal washes, as determined by a tissue culture infectious dose 50, or $TCID_{50}$ assay (see Section 5.3), peaked two to three days after inoculation **(Figure 22.2)**. The amount of virus and the clinical signs of disease decreased significantly by 10 days after inoculation.

Microbes in Focus 22.1
HUMAN RHINOVIRUSES AND THE COMMON COLD

Habitat: Humans

Description: Non-enveloped, icosahedral viruses in the *Picornaviridae* family. About 30 nm in diameter with a single-stranded positive-sense RNA genome of approximately 8,000 nucleotides.

Key Features: Roughly 100 serotypes of human rhinoviruses have been characterized. These viruses probably cause between a third and a half of all cases of the common cold. Although the common cold generally is not a major health threat, the Centers for Disease Control and Prevention (CDC) estimates that children in the United States miss 22 million days of school annually due to colds.



© Jean-Yves Sgro/Science Source

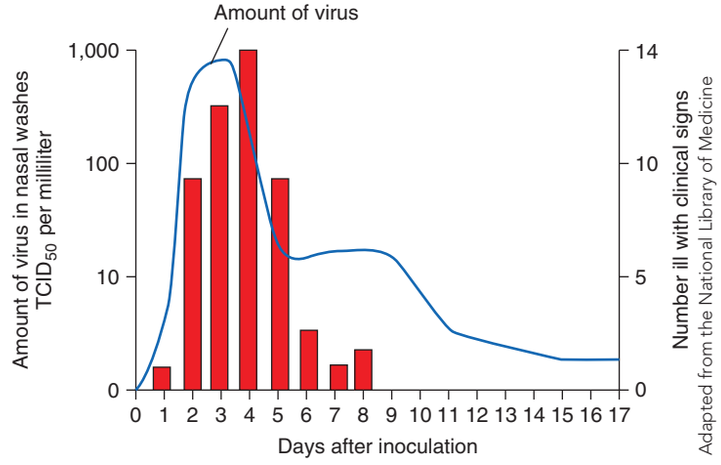


Figure 22.2. Time course of rhinovirus infection Rhinovirus typically results in an acute infection. In this experiment, 17 volunteers were inoculated with rhinovirus. The amount of virus present in nasal secretions, as determined by a tissue culture infectious dose 50 (or $TCID_{50}$) assay, peaked two to three days after infection and decreased markedly within one to two weeks. Clinical signs of a cold (red bars) showed a similar time course.

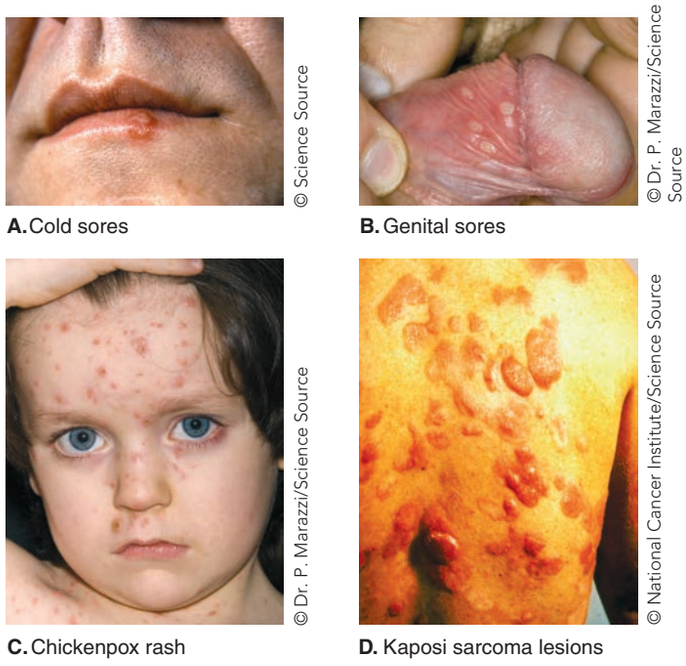
Latent Infections

Not all viruses exhibit the hit-and-run replicative strategy indicative of acute infections. Other viruses have evolved such that they remain present in the host and capable of replicating for extended periods of time. As we noted in Section 18.2, some viruses produce latent infections in which the viral genome remains present in infected cells, but viral replication occurs only sporadically. These viruses typically undergo a period of acute replication immediately after infecting a host. Subsequently, the production of new viral particles stops. Some event then may cause the production of new viral particles to resume, a process referred to as reactivation.

Probably the best-studied mammalian viruses that exhibit latency are the herpesviruses. Members of the *Herpesviridae* family **(Table 22.1)** cause a variety of diseases in humans **(Figure 22.3)**. Human herpesviruses 1 and 2, also known as herpes simplex virus types 1 and 2 (HSV-1 and HSV-2), primarily cause cold sores and genital sores, respectively **(Microbes in Focus 22.2)**. Human herpesvirus 3, also known as varicella zoster virus (VZV), causes chickenpox and shingles. Human herpesvirus type 8 (HHV-8) causes Kaposi sarcoma (KS), a defining cancer of people with HIV/AIDS. Even though the diseases caused by these viruses differ, their replication strategies are similar. All of these viruses display the classic pattern of acute infection, followed by latency, and periodic reactivation.

How is this latent infection and subsequent reactivation achieved? Let's address this question by examining HSV-1. Typically, the virus spreads via direct intimate contact between an infected person and a susceptible person. Primary replication occurs in mucosal cells at the site of infection. This primary infection is often asymptomatic. In other cases, blisters, also known as cold sores, form on the lips or inside the mouth or nose. Newly produced viral particles then enter local neurons and move to the nuclei of these cells (see Figure 18.6). Within the nucleus, the viral DNA exists as an **episome**, a circular genome separate from the host chromosomes. At this stage, expression of most viral genes stops and no new virus particles are made. During latency, one class of genes is transcribed, giving rise to the **latency-associated transcripts (LATs)**. It remains unclear exactly how the LATs affect latency, although some researchers speculate that they may repress the expression of other viral genes. At some point, reactivation occurs and viral replication resumes. The expression of the LAT genes decreases and expression of other viral genes increases. The virus particles travel back down the neuron to the periphery, causing characteristic cold sores. This switch away from latency may be triggered by many different stress events, including exposure to UV light, studying for exams and, in women, menstruation. Reactivation in some way seems tied to the health of the host.



A. Cold sores **B.** Genital sores **C.** Chickenpox rash **D.** Kaposi sarcoma lesions

Figure 22.3. Diseases caused by human herpesviruses The human herpes viruses cause a variety of disease, including: **A.** Cold sores caused by HHV-1 (HSV-1). **B.** Genital sores caused by HHV-2 (HSV-2). **C.** Chickenpox caused by HHV-3 (varicella zoster virus). **D.** Kaposi sarcoma caused by HHV-8.

TABLE 22.1 Human herpesviruses

Designation	Common name	Disease
HHV-1	Herpes simplex virus 1 (HSV-1)	Cold sores, genital ulcers
HHV-2	Herpes simplex virus 2 (HSV-2)	Genital ulcers, cold sores
HHV-3	Varicella zoster virus (VZV)	Chickenpox, shingles
HHV-4	Epstein–Barr virus (EBV)	Mononucleosis, Burkitt lymphoma
HHV-5	Cytomegalovirus (CMV)	Various, mainly immunocompromised hosts
HHV-6	N/A	Roseola
HHV-7	N/A	Not known
HHV-8	Kaposi sarcoma-associated herpesvirus (KSHV)	Kaposi sarcoma

CONNECTIONS As we saw in **Section 8.3**, temperate bacteriophages can exist within their host cell without lysing it. Induction of lytic replication involves the complex regulation of several genes. The activation of this lytic pathway is tied to the overall health of the host cell.

Persistent Infections

In contrast to latent infections, **persistent infections** (also referred to as chronic infections) result in the continuous production of new viral particles. The host does not clear the virus in a reasonable amount of time. Of course, "reasonable" is a subjective term. For most classic persistent infections in humans, the production of viral particles continues for years after the initial infection. This continuous replication requires

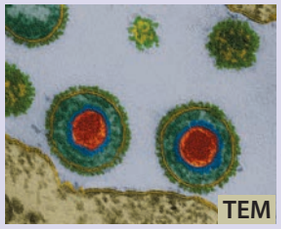
Microbes in Focus 22.2

LIFELONG INFECTIONS: HERPES SIMPLEX VIRUSES 1 AND 2

Habitat: Human

Description: Large enveloped virus about 120 to 200 nm in diameter with a double-stranded DNA genome of approximately 150,000 bp

Key Features: HSV-1, or HHV-1, often is referred to as oral herpes and usually is spread by kissing. HSV-2, or HHV-2, often is referred to as genital herpes and usually is spread sexually. Both types can cause oral and genital infections. Several drugs are available to reduce viral shedding and decrease outbreak severity. Generally, though, the infection is lifelong.



© Eye of Science/Science Source

a balance between the host and the virus; the virus must replicate in the presence of the host's innate and adaptive immune responses.

Several different mechanisms for the maintenance of a persistent infection have been postulated. In some cases, the virus may dampen the immune response, thereby limiting the host's ability to clear the virus. In other cases, the virus may repress programmed cell death, thereby keeping infected cells alive. In still other cases, persistence may result from infection by a viral mutant that exhibits altered replication. Studies with mammalian reoviruses have shown that the establishment of a persistent infection in cell culture may involve genetic changes in either the virus or the host cell, thereby emphasizing the interplay between the two members of this relationship. Mutations in the virus that affect its ability to undergo proteolytic uncoating within a host cell have been associated with persistence. Similarly, mutations in the host cell affecting cathepsin B, a cellular protease involved in reovirus uncoating, also have been associated with persistent reovirus infections. Thus, perturbations of the normal reovirus uncoating pathway, whether caused by a mutation in the virus or the cell, may lead to a persistent infection.

CONNECTIONS For many viruses, disassembly of the viral capsid during the uncoating process must occur prior to replication. For poliovirus, specific conformational changes in the capsid occur after binding of the virus to its receptor. These conformational changes facilitate the exit of the viral genome from the virion **(Section 8.2)**.

Types of transmission

An essential part of any viral disease is transmission from one host to another. For the virus, this process of transmission presents several problems. First, the virus particles must be expelled from the initial host. Second, the virus particles must remain infectious until they encounter a new host. Third, they must gain access to the appropriate cells within the new host. We addressed this issue briefly in Chapter 5. Here, we will explore more fully the horizontal transmission, vertical transmission, zoonotic transmission, and mechanical transmission of viruses. As we will see, some viruses rely primarily on a single mode of transmission. Other viruses, like Ebola virus, can be transmitted in various ways.

TABLE 22.2 Common horizontal transmission strategies

Transmission route	Examples
Respiratory	Rhinoviruses, influenza viruses
Fecal-oral	Polioviruses, hepatitis A virus
Sexual	HIV, human papillomaviruses

Horizontal Transmission

Several different strategies of horizontal transmission exist **(Table 22.2)**. In each case, the processes of exit and entry are closely linked and depend on the types of cells that the virus infects. Human rhinoviruses, the most frequent cause of the common cold, represent a typical example of viruses transmitted horizontally via the respiratory route. Replication occurs in cells of the upper respiratory tract. The disease signs associated with a rhinovirus infection—coughing and sneezing—allow newly produced viral particles to exit the infected host **(Figure 22.4)**. New hosts then become infected by

© Yoav Levy/Phototake

Figure 22.4. Transmission of viruses via the respiratory route Rhinovirus replicates in cells of the upper respiratory tract. Sneezing, a common sign of rhinovirus infection, allows newly formed viral particles to exit the host and enter a new host.

Microbes in Focus 22.3
EBOLA VIRUS: THE CAUSE OF A ZOONOTIC DISEASE

Habitat: Causes zoonotic disease in humans. Natural reservoir unknown, but may be species of fruit bats.

Description: Member of the *Filoviridae* family, approximately 80 nm in diameter and 800 nm in length. Enveloped, with a pleomorphic shape and a linear genome of negative sense single-stranded RNA.

© Scott Camazine/Science Source

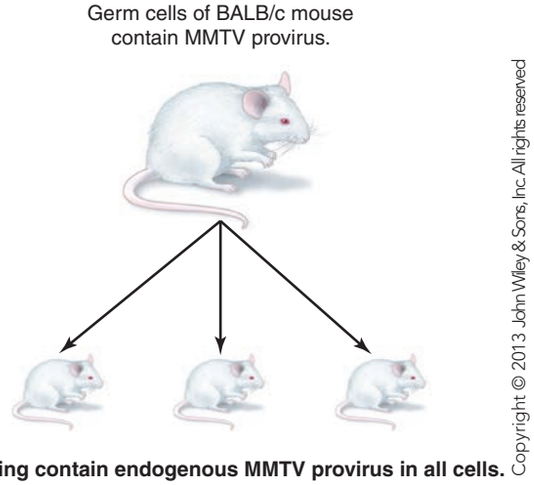
Key Features: The first recorded outbreak of Ebola virus disease occurred in 1976 in Zaire (now the Democratic Republic of the Congo). The disease is characterized by fever, headache, diarrhea, and vomiting. In many cases, extensive hemorrhaging, or bleeding, also occurs. The fatality rate is extremely high. Because of its extreme virulence, several popular books and movies about Ebola virus have been produced.

directly inhaling aerosolized droplets containing infectious virions or by transferring virions deposited on hands or inanimate surfaces to the nose. When the virus particles come in contact with permissive cells in the new host, the infection cycle begins again.

Ebola virus **(Microbes in Focus 22.3)** can be transmitted horizontally by direct contact. In an infected individual, the virus can be found in blood and various bodily fluids, like saliva, urine, sweat, semen, and vomit. Exposure to any of these contaminated fluids, either through mucous membranes or a cut in the skin, can lead to transmission of the virus. Additionally, in May 2015, researchers reported in *Morbidity and Mortality Weekly Report* the possible sexual transmission of Ebola virus. In this particular case, a woman was diagnosed with Ebola virus disease shortly after having unprotected vaginal intercourse with a survivor. The woman reported no other obvious risk factors, and subsequent studies revealed the presence of viral RNA in the semen of the survivor a few months after he first reported signs of the disease. Studies of this mode of Ebola virus transmission are ongoing.

Vertical Transmission

For a few viruses, vertical transmission may occur. This type of transmission can occur in one of several ways. Virus in the blood may be transferred from the mother to the developing fetus through the placenta or during birth. This type of transmission occurs with several important viral pathogens,



Copyright © 2013 John Wiley & Sons, Inc. All rights reserved

Figure 22.5. Vertical transmission of endogenous retroviruses If an integrated retrovirus is present in the germ cells, then the virus is transmitted to offspring. Every cell within the offspring will contain a copy of the retrovirus. BALB/c mice contain an endogenous copy of mouse mammary tumor virus (MMTV). Expression of viral genes and production of virus is stimulated by hormones in the mammary gland. In some mice, MMTV is transmitted by breast milk in a vertical fashion.

including rubella (German measles), hepatitis B virus, hepatitis C virus, and HIV. Some viruses, most notably HIV, also can be transmitted from mother to infant via breast milk. Although the vertical transmission of HIV has been greatly reduced in developed countries, it remains a major issue in developing nations **(Perspective 22.1)**.

Some retroviruses, like mouse mammary tumor virus (MMTV), also exhibit a different form of vertical transmission—transmission via the germ cells. As we noted in Chapters 5 and 8, retroviruses integrate a DNA copy of their RNA genome—the provirus—into the chromosomal DNA of an infected cell. If a retrovirus infects a germ cell, the cells that give rise to sperm and eggs, then the proviral DNA will integrate into the DNA of these gametes and is referred to as an **endogenous retrovirus**. If a sperm or egg containing proviral DNA becomes part of a zygote, then every cell within the developing embryo will contain the endogenous retrovirus **(Figure 22.5)**. In this way, integrated viral genomes are inherited through generations.

The inheritance of endogenous retroviruses does not represent a major means of retrovirus transmission. However, genetic studies have clearly demonstrated that many retroviruses have become integrated into our chromosomes over our evolutionary history. Through sequence analyses, researchers estimate that as many as 98,000 human endogenous retroviruses (HERVs) or HERV fragments exist within our genome, comprising about 8 percent of our DNA! Most of these HERVs contain major deletions or gene rearrangements and are not replication competent. Rather, they are leftover remnants of proviral DNA that integrated into our ancestral DNA millions of years ago. So what function does this DNA serve, if any? Possibly, it is simply junk. Alternatively, these viral sequences may be a source of new DNA sequences that have shaped, and continue to shape, the evolutionary

Perspective 22.1
VERTICAL TRANSMISSION OF HIV

The HIV/AIDS pandemic has wrought untold suffering on populations throughout the world. Sadly, children have not escaped the horrors. According to statistics compiled by the World Health Organization (WHO), roughly 2.6 million children under the age of 15 were living with HIV at the end of 2014 and 220,000 children became newly infected during that year. About 90 percent of these children live in sub-Saharan Africa, and most of them probably became infected through mother-to-child transmission (MTCT), or transmission of the virus from an infected woman to her child. MTCT can occur through several mechanisms. The virus may pass through the placenta, resulting in *in utero* infection. More commonly, the virus is transmitted from mother to child during the birthing process or after delivery, through breast-feeding **(Figure B22.1)**. In the absence of any interventions, the rate of MTCT ranges from 15 percent to 45 percent.

With effective interventions, however, this rate can be greatly reduced. In the United States, the rate of MTCT has decreased dramatically over the past 20 years. In 1992, nearly 1,000 children in the United States were diagnosed with AIDS. Most of these children were born to HIV-positive women and became infected by MTCT. In 2014, 104 children were diagnosed with AIDS **(Figure B22.2)**. Three simple interventions resulted in this dramatic change. First, pregnant women who are HIV-positive receive antiretroviral drugs prior to delivery. Second, C-sections, rather than vaginal deliveries, may be used. Third, HIV-positive mothers are encouraged to feed their infants formula and avoid breast-feeding. As a result of these three interventions, MTCT in most developed countries has decreased significantly.

Because of these great successes, several international programs, including the President's Emergency Plan For AIDS Relief (PEPFAR) and the Global Fund to Fight AIDS, Tuberculosis, and Malaria, have identified the elimination of MTCT as a major goal. Indeed, in June of 2015, the World Health Organization announced that Cuba had effectively eliminated mother-to-child transmission of HIV; fewer than 50 cases per 100,000 live births occurred over the past year. It is hoped that we soon will see this same level of success in other countries throughout the world.

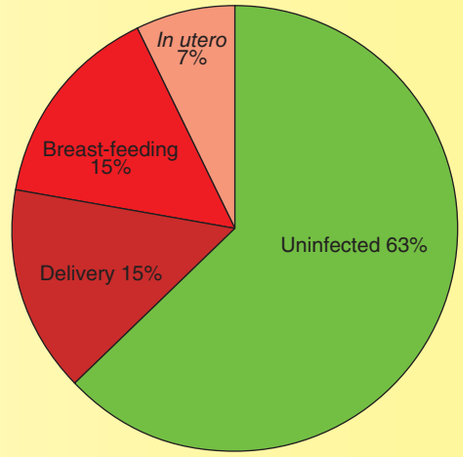


Figure B22.1. Mother-to-child transmission (MTCT) of HIV In the absence of interventions, roughly a third of HIV-positive pregnant women will transmit the virus to the infant. Transmission generally occurs during delivery or through breast-feeding. More rarely, the virus may be transmitted *in utero*.

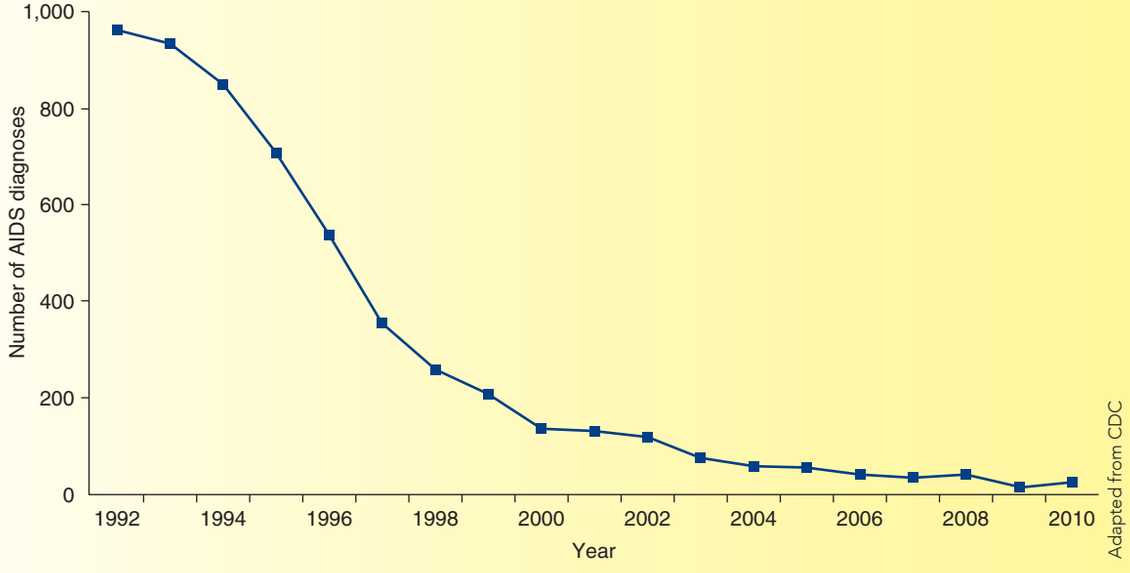

Figure B22.2. Reduction in mother-to-child transmission (MTCT) of HIV in the United States According to the Centers for Disease Control and Prevention, the number of children in the United States with AIDS from MTCT of HIV dropped dramatically since 1992. This decrease resulted from increased testing and the use of various preventive strategies. In August of 1994, the United States Public Health Service recommended use of the antiviral drug zidovudine to prevent MTCT. Bottle-feeding infants and C-section deliveries can further reduce the incidence of MTCT.

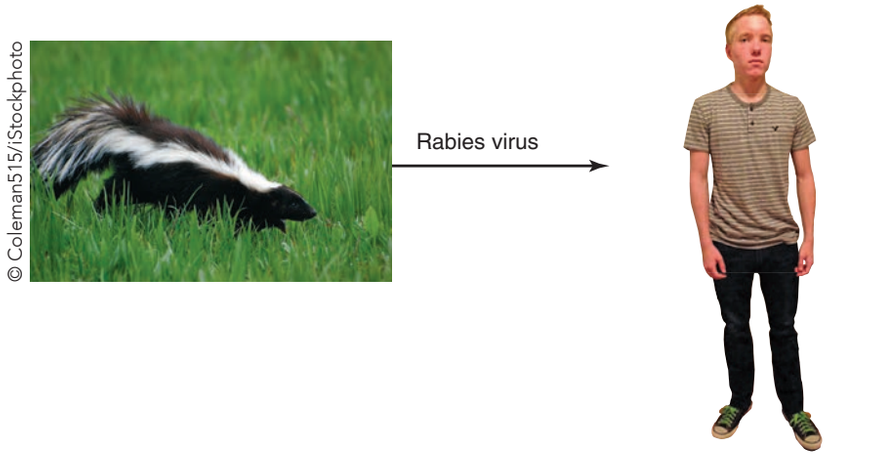
Figure 22.6. Zoonotic transmission of rabies virus
Rabies virus infects many mammals and can be transmitted from an infected animal to a person through the saliva. If untreated, the virus causes a severe, almost always, fatal disease in humans. Transmission between people, however, is very rare. Humans can be considered a dead-end host.



history of many animal species. Indeed, several lines of research indicate endogenous retroviruses have significantly affected the evolution of placentas in mammals.

Zoonotic Transmission

The zoonotic transmission of viruses also may occur, resulting in a disease often referred to as a zoonosis. The natural reservoir hosts for zoonotic viruses typically are vertebrates. Usually, humans are dead-end hosts. Although the virus may cause disease in an infected person, transmission from one person to another occurs infrequently **(Figure 22.6)**. As an example, let's consider rabies virus. This virus infects many species of mammals and can be transmitted to humans through the saliva of an infected animal. In the absence of treatment, the resulting disease in humans almost always is fatal. Spread from human to human, however, rarely occurs. Ebolaviruses also are transmitted from animals to humans. Increasing evidence suggests that the reservoir host for these viruses may be bats. Although infectious viral particles have not yet been isolated from bats, antibodies to ebolaviruses have been identified in bats and viral replication can occur in bats when they are experimentally inoculated with virus. The virus might be spread directly from bats to humans or the virus might be spread from bats to a non-human primate and then from this intermediate organism to humans **(Figure 22.7)**. As the 2014–2016 outbreak has demonstrated, transmission between people can occur. However, the virus is not maintained within the human population, and each outbreak that we have recognized began from a separate zoonotic transfer.

Before leaving this topic, we should note that zoonotic viruses may evolve into more typical human viruses. HIV is a perfect example. HIV evolved from a strain of SIV, simian immunodeficiency virus, which infected a human. Over time, this simian virus became an efficient human virus, very capable of replicating in human cells and being transmitted from one human to another. Moreover, we now know that the transfer of SIV variants to humans has occurred multiple times, giving

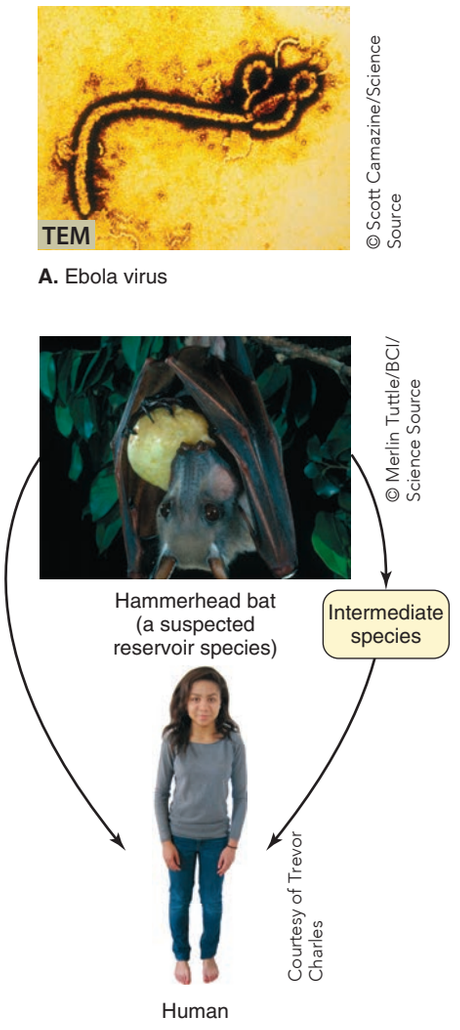


Figure 22.7. Spread of Ebola virus to humans Although the natural reservoir of Ebola virus has not been determined conclusively, increasing evidence indicates that the virus may reside in various bat species, including *Hypsignathus monstrosus*, the hammerhead bat. **A.** Electron micrograph of Ebola virus. **B.** The virus may be transmitted directly from bats to humans or indirectly from bats to a non-human primate and then to humans.

rise the genetically distinct forms of HIV infecting people today (see Figure 18.24).

Mechanical Transmission

In this type of transmission, the virus does not move directly from one susceptible host to another. Rather, some vector facilitates the transfer. For example, medical devices contaminated with the blood of an infected person can transmit Ebola virus. The myxoma virus that we discussed in the beginning of this chapter presents another example. The virus spreads from rabbit to rabbit via mosquitoes or, possibly, fleas. When a mosquito bites an infected animal, the mouth of the biting insect may become contaminated with viral particles. When this insect subsequently bites another animal, the infectious virions can be transferred. It should be noted that the myxoma virus does not replicate in the mosquito or flea. The insect merely serves as a passive vector. Other viruses transmitted by insects, like yellow fever virus, do replicate within the insect vector **(Figure 22.8)**.

CONNECTIONS As we discussed in **Section 5.1**, many plant viruses are transmitted by mechanical means, either employing insect vectors or farm machinery to aid in their spread. Physical disruption of the plant cell cuticle allows for the entry of the viral particles into the cytoplasm of a new cell.

22.1 Fact Check

1. Compare and contrast acute and latent viral infections.
2. What is meant by "endogenous retrovirus"?
3. Provide examples of zoonotic transmission.

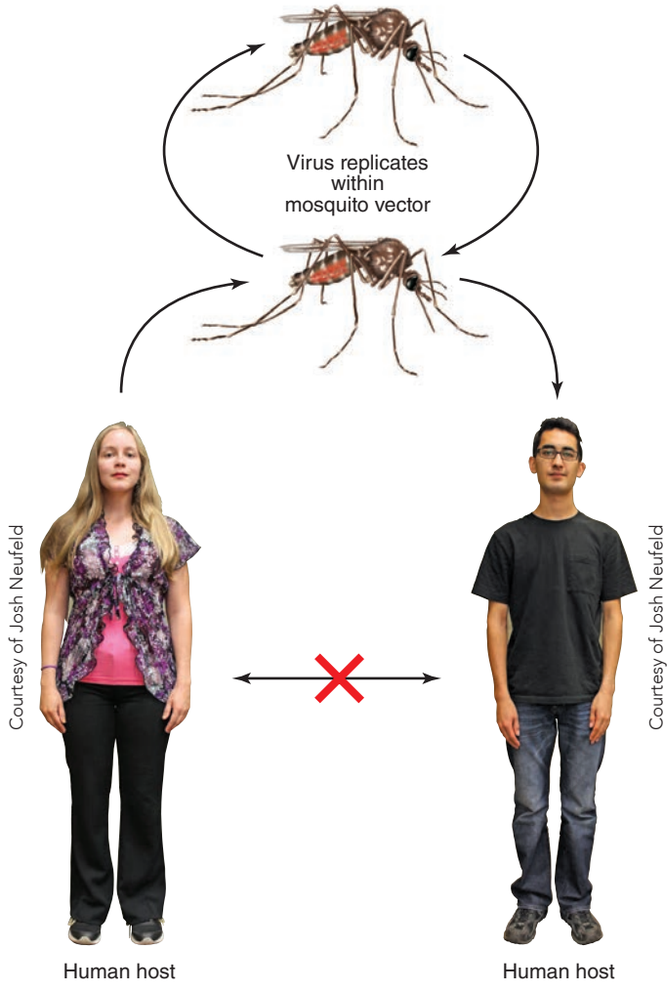

Figure 22.8. Transmission of yellow fever virus in humans Like myxoma virus, yellow fever virus is transmitted by mosquitoes. Unlike myxoma virus, yellow fever virus replicates within the insect vector. Transmission is the same in monkeys, the natural mammalian host for the virus.

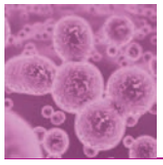
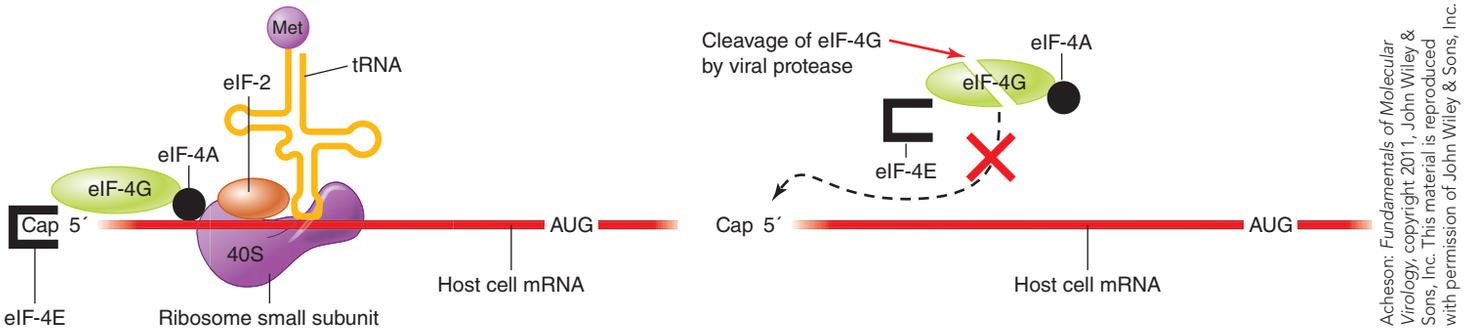


22.2 Interactions with the host: Strategies and consequences

3D ANIMATION

How do viruses interact with host cells?

In the preceding section, we examined the types of infections that viruses can cause and how viruses can spread from one individual to another. In this section, we will examine the effects that viruses have on infected cells and how these effects result in disease. It might be easy to imagine that disease occurs simply because infected cells burst following the accumulation of new viral particles. However, the exact causes of viral-induced cytopathology, both in cell culture and *in vivo*, are complex. For example, phage lambda (λ) encodes at least two polypeptides that coordinate cell lysis. The S protein renders the cell membrane more permeable, permitting the movement of the R protein out of the cytoplasm. The R protein specifically weakens the peptidoglycan layer. In concert, these two proteins facilitate the lysis of the cell. Likewise, the role that cytopathology plays in disease also is complex. In this section, we will examine how some viruses cause cytopathology by inhibiting host cell transcription and translation processes, whereas other viruses cause disease by avoiding host immune responses. In the next section, we will investigate how certain viruses cause disease by modulating the cell cycle.



A. Normal initiation of translation

C. Ribosome loading at IRES of poliovirus: translation of poliovirus RNA

Figure 22.9. Inhibition of host cell translation by poliovirus **A.** Normal eukaryal initiation of translation. **B.** Several picornaviruses, including poliovirus and foot-and-mouth disease virus, inhibit host cell translation by causing the cleavage of eIF-4G, an essential translation initiation factor. Cleavage of this elongation factor results in a greatly decreased level of host cell protein synthesis. **C.** The cleavage product of eIF-4G is recruited to the IRES of the poliovirus RNA molecule by various host factors. This is sufficient for initiation of translation of viral RNA, but not host mRNA.

Inhibiting host cell transcription and translation

Several viruses inhibit host cell transcription or translation mechanisms, thereby freeing up resources needed for their own replication. Poliovirus cytopathology, for example, occurs primarily because the virus effectively inhibits the translation of host cell mRNAs. Indeed, several investigators have shown that poliovirus infection results in a rapid inhibition of host cell translation. The translation of viral mRNAs, however, continues. The viral protease 2A leads to the degradation of the host eIF-4G polypeptide. This host polypeptide, in concert with other host elongation initiation factors (eIFs), forms the cap-binding complex that recognizes the 5′ cap present on mRNA molecules and aids in the initiation of translation. Once host eIF-4G is cleaved, translation of host mRNA decreases dramatically (Figure 22.9). The poliovirus RNA can be recognized by host cell ribosomes in a cap-independent manner, which uses a fragment of the cleaved eIF-4G (see Figure 22.9C). Thus, the virus subverts the translational machinery, allowing for the rapid production of viral proteins. Most likely, this poliovirus-induced inhibition of cellular protein production leads to the death of the cell.

Bunyaviruses, like the tomato spotted wilt virus (TSWV) (Microbes in Focus 22.4), do not directly shut down the translation of host cell mRNAs. Rather, these viruses cause the

Microbes in Focus 22.4
TOMATO SPOTTED WILT VIRUS: A MAJOR AGRICULTURAL PEST

Habitat: Infects species in 35 plant families

Description: Enveloped, single-stranded RNA virus approximately 80 nm in diameter in the *Bunyaviridae* family

Key Features: Tomato spotted wilt virus (TSWV) is common in temperate, subtropical, and tropical regions throughout the world. It causes major crop losses, primarily among tomatoes and lettuce. It also affects ornamental plants.

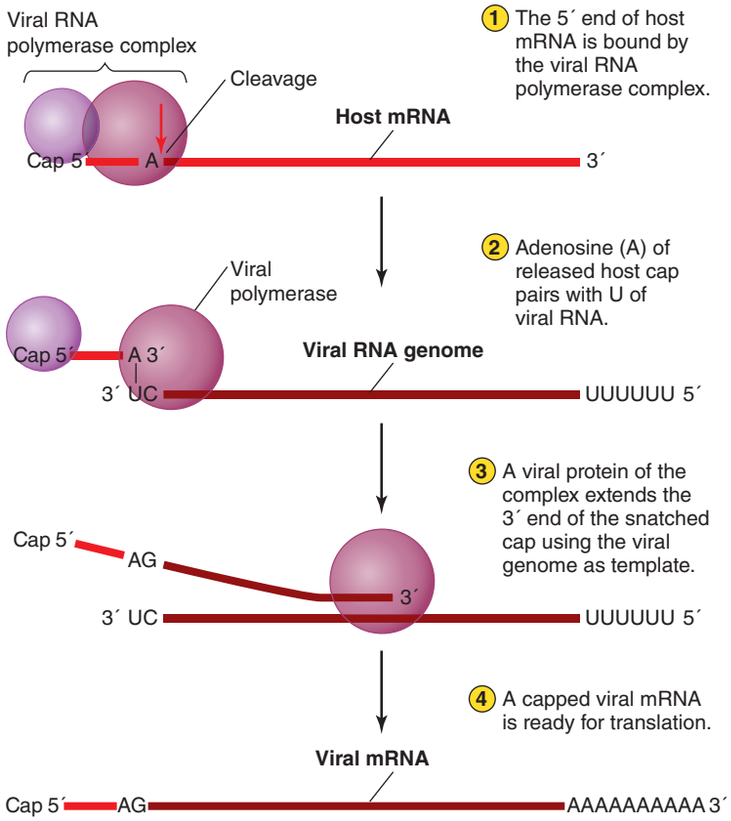

Figure 22.10. Process Diagram: Inhibition of host cell mRNA translation by bunyaviruses and orthomyxoviruses In a process referred to as "cap-snatching," viral proteins cleave ten to twenty 5′ nucleotides from the host mRNA. This sequence then is used to prime synthesis of viral RNA, providing the virus with stable, 5′-capped mRNA. For bunyaviruses, this activity occurs in the cytoplasm. For orthomyxoviruses, such as influenza virus, it occurs in the nucleus.

degradation of host cell mRNA molecules. Viruses of animals and plants in this family cleave the 5′ capped end of host cell mRNA molecules and then use this short piece of the host cell mRNA as a primer for the synthesis of viral mRNA, a process referred to as cap-snatching (Figure 22.10). Influenza viruses of the *Orthomyxoviridae* family also use this cap-snatching strategy. As a result, the virus produces mRNA that will be recognized by the host cell's ribosomes. Additionally, host cell mRNA, now devoid of a 5′ cap, will not be translated and will be degraded. For the virus, additional resources are available for it to use during its replication. For the cell, the destruction of necessary mRNA molecules generally leads to cell death

Poxviruses, like the myxoma virus we discussed in the opening story, also inhibit the translation of host cell mRNA. In this case, an essential viral protein binds to the 40S ribosomal subunit and, in the process, interferes with the initiation of translation. Additionally, another poxvirus protein degrades single-stranded DNA, thereby interfering with host cell DNA replication. Both of these viral activities make more needed materials (amino acids and deoxynucleotides) available for viral replication.

The inhibition of host cell transcription or translation provides the virus with increased access to necessary resources and often leads to death of the host cell. This cell death may result from necrosis of apoptosis. For the host, induction of the apoptotic pathway may be useful in limiting the severity of an infection. Even if the induced cell death results in some localized tissue damage, destruction of an infected cell may prevent the production of more virus particles by that cell and, ultimately, limit the spread of the virus within the host. Conversely, inhibiting apoptosis may be desirable for the virus. If the host cannot destroy infected cells early in the infection, then the virus can continue its replication cycle and produce more virions. Indeed, some herpesviruses and adenoviruses produce proteins that mimic antiapoptotic proteins normally produced by their host cells. In this way, these viruses inhibit the host's attempts to destroy infected cells. Finally, and perhaps surprisingly, some viruses actually induce apoptosis (Perspective 22.2).

Although necrosis and apoptosis may be the most obvious examples of viral-induced cellular damage, some viruses cause cellular damage through other means. Several viruses, including HIV, measles virus, and respiratory syncytial virus, form syncytia (syncytium is singular). Syncytia form when infected cells fuse with adjoining infected or uninfected cells, resulting in

Perspective 22.2
VIRAL INDUCTION OF APOPTOSIS

It may seem logical that apoptosis of infected cells would benefit a host. If infected cells are destroyed early in the infectious process, then fewer new viral particles will be produced. It also may be logical that viruses would benefit from preventing apoptosis. If infected host cells are kept alive, then more new viral particles can be produced. Let's look at another scenario. Could apoptosis be beneficial to a virus?

For ascoviruses, the answer to this question appears to be "yes." These large enveloped viruses of the *Ascoviridae* family contain a double-stranded DNA genome of 120,000 to 180,000 base pairs, exhibit a complex shape, and infect various moth and butterfly species. Ascoviruses appear not to be transmitted directly from host to host. Instead, parasitic wasps transmit the viruses. Female wasps normally deposit eggs in the larvae of appropriate moths or butterflies, an activity referred to as "oviposition." When the eggs hatch, the wasp larvae then feed on the host larvae. If a wasp deposits eggs in an ascovirus-infected host, then the wasp's ovipositor may become contaminated with virus. When the wasp then deposits eggs into another larvae, the virus can be transmitted.

For infected larval cells, a viral protein induces apoptosis, resulting in nuclear membrane fragmentation and DNA cleavage. Additionally, the cell breaks down, forming subcellular vesicles. These vesicles contain viral particles and adhere to the wasp ovipositor, thereby facilitating the spread of the virus. For these viruses, induction of apoptosis represents an essential part of their replication cycle.

B. Inclusion body detection using fluorescent antibody specific to reovirus proteins

Figure 22.11. Formation of inclusion bodies in cells infected by reovirus Some viruses lead to disruptions in cellular morphology and, as a result, cellular function. **A.** In mouse fibroblast cells inoculated with reovirus, inclusion bodies can be seen as dark cytoplasmic spots using differential interference contrast microscopy. **B.** Cells stained with fluorescent-tagged antibodies against reovirus proteins reveal inclusion bodies in the cytoplasm of the same cells. Scale bar: 25 μm.

the formation of a multinucleated giant cell (see Figure 5.16). Typically, cells in each syncytium ultimately die. Other viruses, such as rabies virus, adenovirus, and reovirus, may result in the formation of nuclear or cytoplasmic **inclusion bodies**, which are microscopically visible structures within the cell made of viral or cellular components (Figure 22.11). Again, these structures often impair the normal functioning of the cell and lead to cell death.

Avoiding host immune responses

As we just saw, the disease associated with some viral infections results directly from virus-induced cell death. In many cases, though, the clinical signs of disease associated with a viral infection result more from the host's immune response than from the virus itself. As we discussed in Chapters 19 and 20, the innate and adaptive arms of the immune system can target infected cells for destruction. This activity is a double-edged sword in some respects. On one hand, destruction of infected cells limits the production of new viral particles and limits the spread of the virus. On the other hand, destruction of cells could cause damage to the tissue. As a result, the immune system plays a delicate balancing act by balancing the amount of cells it destroys to limit the infection versus the amount of damage this cellular destruction causes to the body. As we will see in this section, the clinical signs of viral infections often result from actions of the immune system.

To better understand how clinical signs of infection arise from the immune system, we can use Ebola virus as an example. The virus replicates quickly upon infection, producing viral proteins that stimulate macrophages to secrete large amounts of proinflammatory cytokines. These cytokines cause blood vessels to become leaky, ostensibly to allow immune cells to leave the blood and reach the area of the infection. However, the immune response to an Ebola virus infection is extensive and the vasodilation resulting from this systemic inflammatory response leads to hemorrhaging. In many infected individuals, the loss of blood leads to shock and, ultimately, death.

Proinflammatory molecules also contribute to the pathogenesis of a typically less worrisome viral disease, the common cold. We all know what it's like to get a common cold. Sneezing becomes a way of life—at least for a few days. Rhinoviruses typically infect cells of the upper respiratory tract. Perhaps surprisingly, the viral infection itself does not seem to result in much, if any, cytopathology. So what causes us to sneeze? Studies have shown that people with colds have elevated levels of several proinflammatory cytokines, including interleukins-6 and -8 (IL-6 and IL-8). This inflammatory response leads to vasodilation and a buildup of fluids in the upper respiratory tract, inducing a red nose, congestion, and sneezing (Figure 22.12).

Antimicrobial Agents and Chemotherapy, May 1, 2000, vol. 44, reproduced/amended with permission from American Society for Microbiology.

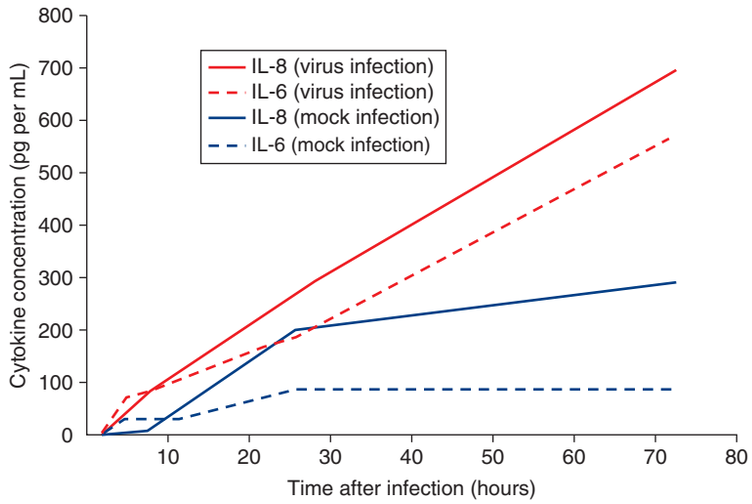

Figure 22.12. Effects of rhinovirus infection on levels of the inflammatory cytokines IL-6 and IL-8 In this experiment, cells were inoculated with rhinovirus (red lines) or mock infected (blue lines). At specified times postinoculation, the concentrations of IL-6 and IL-8 in the cell culture supernatant were determined. Rhinovirus infection leads to a marked increase in both of these cytokines.

CONNECTIONS In humans, invading microbes often trigger the release of various cytokines. These cytokines facilitate communication between cells of the immune system and initiate the inflammatory response **(Section 19.3)**.

The immune response also represents the major cause of disease associated with hepatitis B virus. Again, the virus itself does not appear to result in any significant cytopathology. In most cases, HBV infections are effectively controlled by the immune system, with no obvious disease occurring. Hepatitis, or liver disease, results from the cytotoxic T-cell-mediated destruction of infected hepatocytes (see Chapter 20 to review the action of T_c cells). In some cases, HBV infection also leads to kidney damage because disease results not from the T-cell response, but rather from the antibody response. HBV antigen:antibody complexes form and are deposited in the kidney, resulting in tissue damage. The clinical outcomes of HBV infection can be varied, depending to a large extent on the immune response **(Figure 22.13)**.

Finally, viruses may cause disease indirectly through a process known as **autoimmunity**. Autoimmune diseases occur when the immune system incorrectly targets normal cellular components. In effect, the body attacks itself. Examples of autoimmune diseases include multiple sclerosis (MS), systemic lupus erythematosus (SLE), and rheumatoid arthritis.

How can viruses be involved in this process? In some cases, a viral infection may lead to the release and subsequent recognition by the host immune system of self-antigens. For example, infection with human parvovirus B19 has been associated with the development of SLE and rheumatoid arthritis. Researchers hypothesize that normally sequestered self-antigens may be present in apoptotic bodies formed during a parvovirus infection. These apoptotic bodies then may be engulfed by antigen-presenting cells, and the self-antigens trigger an immune response.

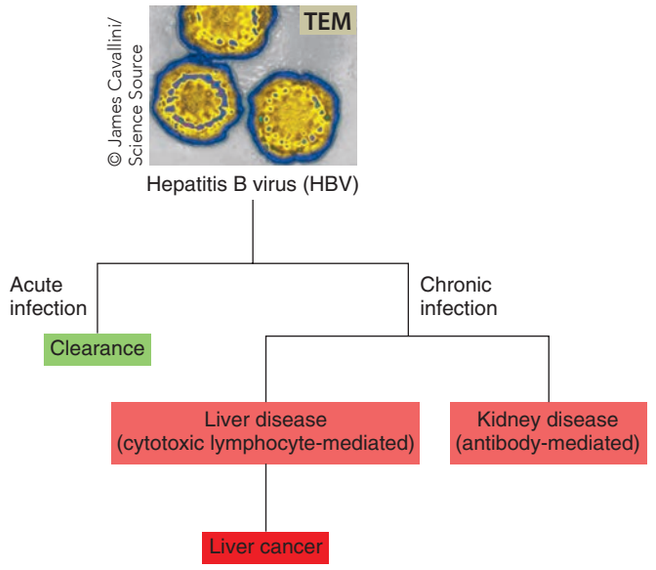

Figure 22.13. Potential outcomes of hepatitis B virus infection In some cases, the immune system clears the virus. In other cases, the infection becomes chronic. During a chronic infection, CTL-mediated attacks of infected hepatocytes can cause liver damage. Additionally, antigen:antibody complexes may cause kidney damage. Chronic infections of the liver may lead to hepatocellular carcinoma, which also is known as liver cancer.

Alternatively, autoimmune diseases may be triggered by viral infections through a process known as **molecular mimicry**. Basically, viral antigens activate immune cells that then cross-react with similar host antigens **(Figure 22.14)**. In other words, the immune response directed against the virus also attacks the host. Although direct evidence for this process is limited, molecular mimicry has been hypothesized as a cause of several human autoimmune diseases.

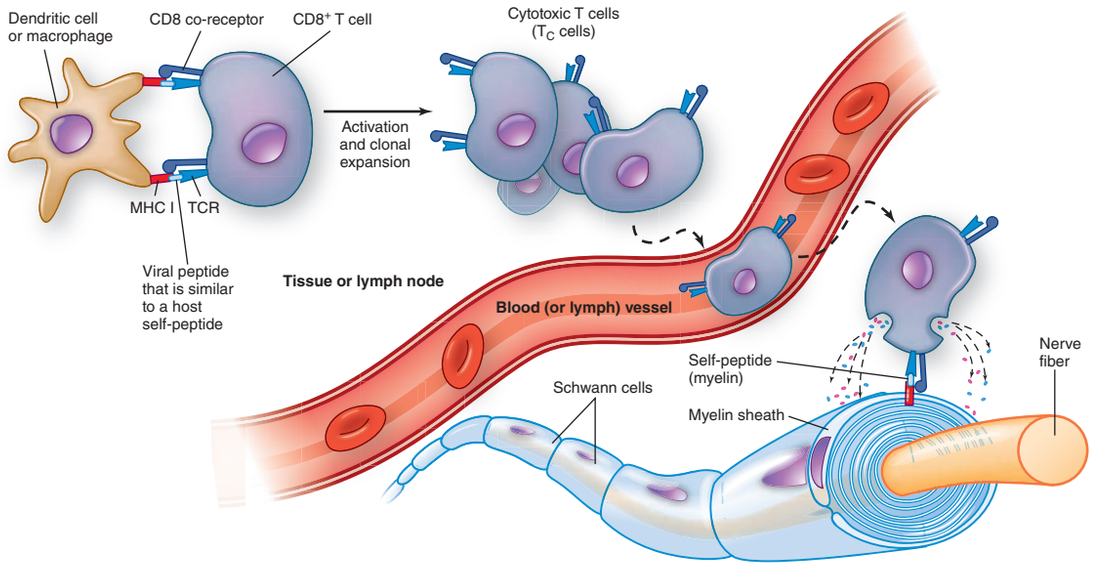

Figure 22.14. Autoimmune diseases and molecular mimicry Viral infections may trigger some forms of autoimmunity. If viral peptides are structurally similar to host cell proteins, then reactive T cells may cross-react with self-peptides, leading to host tissue destruction. In this example, the viral peptide resembles myelin that is produced by Schwann cells surrounding nerve cells, resulting in symptoms of multiple sclerosis.

22.2 Fact Check

1. How do bunyaviruses and influenza viruses inhibit host cell translation?
2. For the host cell, what are the advantages and disadvantages of viral-induced apoptosis?
3. For the virus, what are the advantages and disadvantages of viral-induced apoptosis?
4. In what ways can the immune response to a viral infection lead to disease?

22.3 Viral infections and cancer

How do some viruses cause cancer?

The association between viruses and cancer may seem odd. Many people might think that viruses cause the flu or the common cold; viruses do not cause cancer. As we discussed in Chapter 8, though, Peyton Rous identified a tumor-causing retrovirus in chickens in 1911, the Rous sarcoma virus. Since then, many viruses have been associated with cancer. Indeed, viruses from many different virus families cause the transformation of cells in culture and/or tumorigenesis in humans or animals (Table 22.3).

Transformation refers to phenotypic changes within a cell that cause the cell to no longer be controlled by normal processes. These changes often include changes in cellular morphology, loss of differentiation, immortalization, and loss of contact inhibition (growth is no longer inhibited by contact with surrounding cells). Additionally, transformed cells may exhibit a loss of anchorage dependence; they no longer need to be anchored to a solid surface, such as a Petri plate or, in the body, other biological material. Finally, cells may exhibit increased sugar transport, reduced growth factor requirements, and chromosomal aberrations. **Tumorigenesis** refers to the formation of a tumor, an abnormal growth of tissue. In this section, we will examine mechanisms by which different viruses cause tumor formation. We will focus primarily on two families of DNA viruses—the *Papillomaviridae* and *Adenoviridae*—and one family of RNA viruses—the *Retroviridae*.

DNA tumor-causing viruses

Members of virtually every mammalian DNA-containing virus family have been shown to cause tumor formation in animals or transformation of cells in culture. As we have seen previously, viruses in these families are quite diverse, differing significantly in size, shape, and replication strategies. Despite these differences, the mechanisms by which they transform cells are surprisingly similar. In most cases, the genomes of these viruses contain genes that can be considered **oncogenes**, genes capable of transforming animal cells. As we will see in this section, these viral oncogenes are essential for viral replication.

Papillomaviruses

The association between papillomaviruses and abnormal cellular growth is long-standing. The name itself derives from the observation in the early part of the twentieth century that an infectious agent could transmit skin tumors, commonly called

TABLE 22.3 Mammalian viruses associated with transformation or tumorigenesis

Virus family	Type	Associated cancer	Notes
Papillomaviridae	Human papillomavirus types 16 and 18[a]	Cervical, anal, penile cancer	Oncogenic HPV strains may cause up to 10 percent of all human cancers
Polyomaviridae	SV40	Sarcomas in rodents	Can transform some human cell lines
Adenoviridae	Adenovirus	Transformation of cells in culture	Both E1A and E1B proteins are needed for transformation
Herpesviridae	HHV-8	Kaposi sarcoma	Transforms endothelial cells; defining cancer of people with HIV/AIDS
Herpesviridae	Epstein–Barr virus (HHV-4)	Burkitt lymphoma	Also causes infectious mononucleosis
Hepadnaviridae	Hepatitis B virus	Hepatocellular carcinoma	An effective vaccine is available
Flaviviridae	Hepatitis C virus	Hepatocellular carcinoma	60–85 percent of people infected with HCV develop a chronic infection
Retroviridae	Rous sarcoma virus	Sarcomas in chickens	Led to the identification of proto-oncogenes

[a]Although approximately 70 percent of cervical cancers are caused by either HPV 16 or HPV 18, other HPV types also have been associated with this disease.

Biophoto Associates/Science Source

Figure 22.15. Genital warts. Genital warts are solid benign tumors caused by certain human papilloma viruses (HPVs) and appear as raised nodules on the skin. Some types of HPV also can cause cervical and other cancers.

warts, or **papillomas**. Peyton Rous—yes, the same Peyton Rous who identified the oncogenic retrovirus Rous sarcoma virus (see Section 8.3)—showed in 1935 that papillomaviruses could cause skin cancer in rabbits. We now know that certain human papillomaviruses (HPVs) cause genital warts **(Figure 22.15)**. Other HPVs cause cervical cancer. According to the National Cancer Institute, an estimated 12,900 women were diagnosed with cervical cancer in the United States in 2015, and 4,100 women died from it. About 250,000 women worldwide die from cervical cancer annually.

To understand how papillomaviruses cause cancer, we need to think about their basic replication cycle **(Figure 22.16)**. Papillomaviruses typically infect keratinocytes, which are cells that form the outer layer of skin and certain mucosal surfaces. Keratinocytes are **quiescent cells**; they are not actively dividing. Within quiescent cells, only small amounts of deoxyribonucleotides and enzymes needed for DNA replication may be present. If the cell is not actively replicating, then there is no need to manufacture these materials. For the virus, though, this lack of host cell DNA replication ability presents a problem. The virus cannot replicate its genome without a supply of these molecules. To circumvent this problem, the virus employs a remarkable strategy: it stimulates the cell to enter the S phase of the cell cycle **(Figure 22.17)**. The cell then prepares itself for DNA synthesis by making the deoxyribonucleotides and replication enzymes needed by the virus.

More specifically, papillomavirus proteins interfere with normal functioning of two cellular proteins: retinoblastoma, or Rb, and p53. Both Rb and p53 function as **tumor suppressors**, normal cellular proteins that inhibit cellular replication. Rb binds to specific transcription factors, called E2fs, ultimately blocking the synthesis of other cellular factors needed for entry into the S phase of the cell cycle. Phosphorylated p53 promotes the synthesis of p21, which prevents cell replication. Accumulated phosphorylated p53 also induces apoptosis in damaged cells **(Figure 22.18)**.

In the presence of HPV E6 and E7 proteins, Rb and p53 do not inhibit cellular replication **(Figure 22.19)**. The E7 gene product binds to and inactivates Rb. The E6 gene product

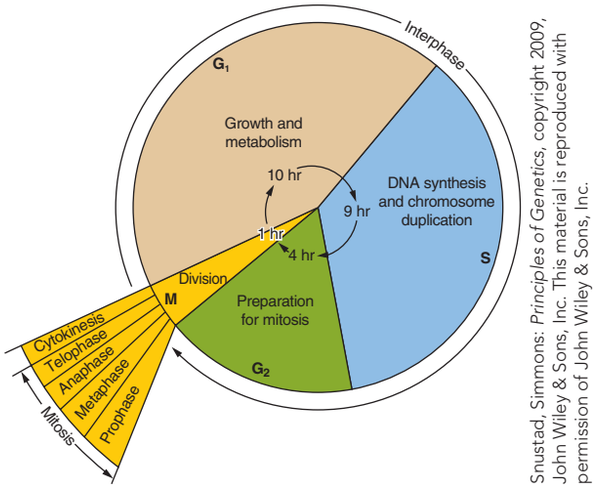
Figure 22.16. Papillomavirus infection of differentiating epithelial cells **A.** Epithelial cells produced by the basal layer normally differentiate and stop replicating as they approach the surface, becoming keratinocytes. **B.** Papillomaviruses infect basal layer cells. The viral DNA is replicated and distributed to daughter cells. Gene products of the viral DNAs interfere with cell cycle control and the transformed daughter cells continue to replicate rather than differentiating. The continued cell replication forms a wart and virions are released from cells of the epithelium surface.



Snustad, Simmons: *Principles of Genetics*, copyright 2009, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 22.17. The cell cycle Dividing cells progress through the cell cycle, undergoing a growth phase (G_1), DNA replication (S), a second growth phase (G_2), and mitosis (M). Quiescent cells typically are arrested in G_1. Because they are not actively dividing, deoxyribonucleotides and proteins needed for DNA replication are usually in short supply.

binds to p53, targeting it for destruction, thereby preventing the transcription of p21. As we will see in **Toolbox 22.1**, researchers can detect these molecular interactions using a form of **immunoprecipitation (IP)**, a technique that uses an antibody to precipitate an antigen. The interactions between the HPV proteins and Rb and p53 cause the infected cell to exit the quiescent state and begin replicating. To prepare for replication, the cell produces deoxyribonucleotides, DNA polymerase, and other products that the virus then uses to replicate its genome. In other words, the virus alters the cell state to obtain necessary molecules. Normally, viral replication then occurs, leading to the production of new viral particles and eventual death by viral-induced apoptosis of the infected cell. The wart may disappear, only to reappear in a nearby location or on another host if transmission occurred. In some cases, though, a productive infection does not occur. The viral genome, or portions of it, accidentally integrates in the host genome. Viral replication aborts when this integration happens. If intact E6 and E7 genes become integrated, then the E6 and E7 proteins continue to inhibit the actions of Rb and p53. The transformed cell continues to divide, unable to undergo apoptosis. Cancer develops over time as these continuously and rapidly dividing cells accumulate genetic mutations **(Mini-Paper)**.

If oncogenesis results from random viral DNA integration, then why is cancer associated only with certain strains of HPV? First, the E7 proteins of oncogenic HPV strains bind Rb with a greater affinity than the E7 proteins of non-oncogenic HPV strains. Thus, cells expressing E7 from an oncogenic HPV strain are driven to mitosis more strongly. Second, only the E6 proteins of oncogenic HPV strains effectively target p53 to the proteasome for degradation. Cells carrying integrated versions of this gene cannot undergo p53-induced apoptosis. Conversely, cells carrying the integrated E6 gene, originating from non-oncogenic

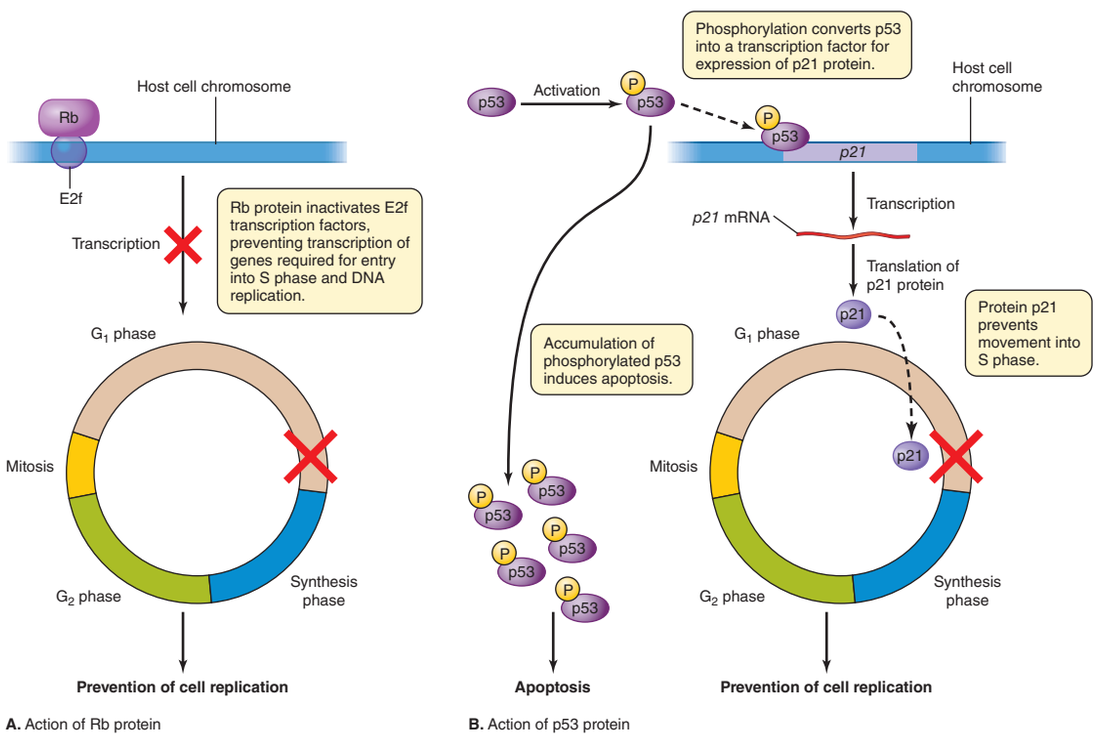


Figure 22.18. Normal action of tumor suppressor proteins Rb and p53 **A.** Rb blocks entry into S phase by binding to and inhibiting E2f transcription factors. To enter S phase, Rb is phosphorylated, allowing E2fs to facilitate the transcription of genes required for entry into the cell cycle. **B.** Upon DNA damage and cell stress, p53 is activated by phosphorylation. Activated p53 is a transcription factor needed for expression of p21. Protein p21 prevents movement into S phase. Phosphorylated p53 also induces apoptosis.

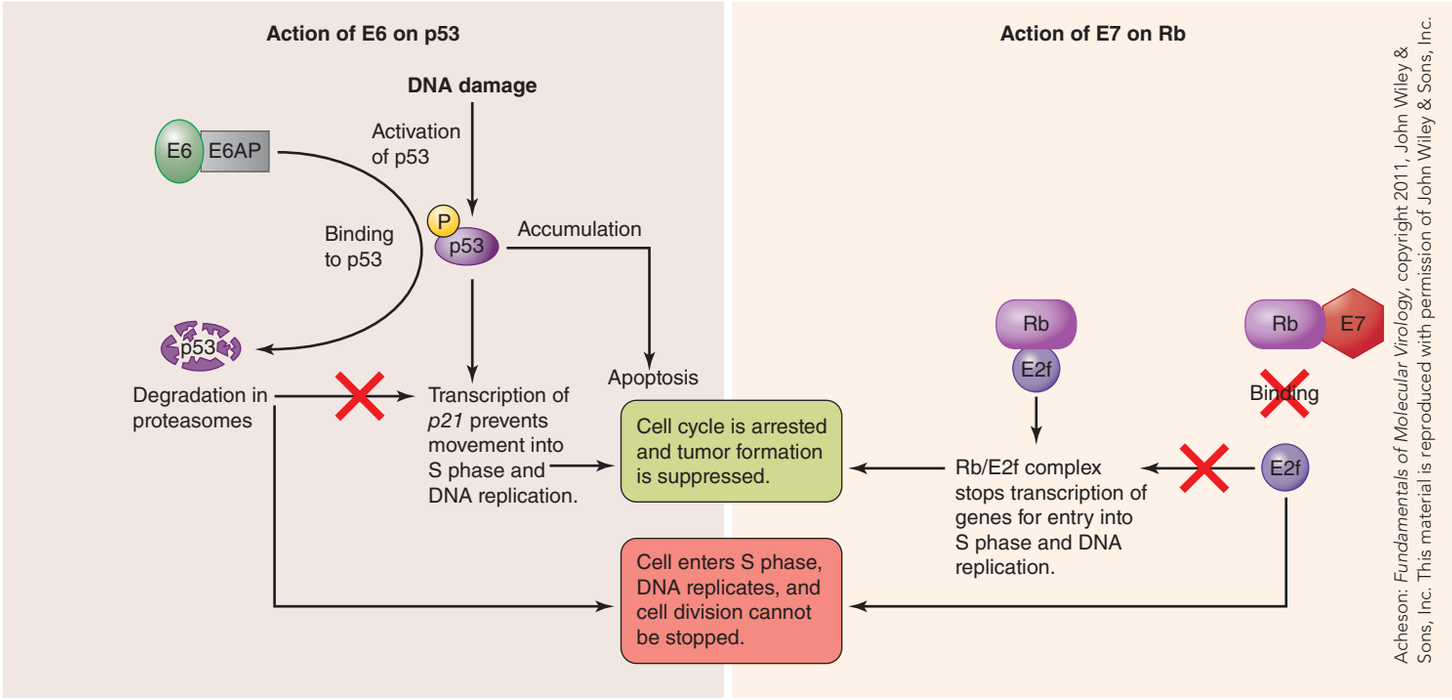


Acheson: *Fundamentals of Molecular Virology*, copyright 2011, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 22.19. Inhibition of tumor suppressors by HPV E6 and E7 proteins Strains of HPV can lead to the development of cancer by inhibiting tumor suppressors. Assisted by the cellular protein E6AP, the HPV E6 protein (*left*) binds to the cellular tumor suppressor protein p53 and targets it for destruction. Destruction of p53 prevents the transcription of p21. The HPV E7 protein (*right*) binds to another cellular tumor suppressor protein, Rb, rendering it inactive. Normally, both p53 and Rb inhibit cell growth. Once these proteins are inactivated by HPV, cellular replication proceeds. When the viral genome integrates, virus particles are not formed and the host cells are not killed, allowing transformation.

Toolbox 22.1
IMMUNOPRECIPITATION

Antibody:antigen interactions can help identify proteins of interest using techniques like the Western blot (see Toolbox 8.1). These same molecular interactions also can be used to isolate a specific protein from a mixture and to identify proteins that bind to each other. Using immunoprecipitation (IP) techniques, researchers determined that the human papillomavirus (HPV) E6 and E7 proteins interact with the p53 and Rb human tumor suppressor proteins, respectively.

To better understand this process, let's first examine the basics of immunoprecipitation. With a relatively simple form of IP, researchers can isolate a specific protein from a mixture of proteins, such as a cell lysate. First, antibodies to the protein of interest are chemically attached to small beads. These beads then are incubated with the mixture of proteins. Because of the specificity of antibody:antigen binding, only proteins in the mixture that interact with the antibodies will attach to the immobilized antibodies. By centrifuging the mixture, investigators can precipitate the antibody/antigen/bead complex; all other proteins remain in the supernatant. In other words, the protein of interest has been separated from all other proteins in the original lysate.

Co-immunoprecipitation can help identify protein:protein-binding interactions. In this technique, often referred to as a pull-down assay, investigators begin by attaching antibodies specific to one member of a suspected protein:protein-binding pair to beads. The beads are incubated with a mixture of proteins, often from a cell lysate. As just discussed, the protein of interest will bind to the antibody and can be immunoprecipitated. Other proteins that bind to this protein also may be precipitated. In other words, binding partners of the antigen will be co-immunoprecipitated. The pelleted beads can be physically or chemically treated to disrupt all weak protein-binding interactions. The released proteins, the ones bound to the immunoprecipitated protein, then can be identified.

Using this technique, researchers showed that p53-specific antibodies pulled down HPV E6 proteins. From this observation, we can hypothesize that the HPV E6 protein interacts with p53. This initial finding contributed to our current understanding of the how human papillomaviruses cause cancer.

Test Your Understanding

Although HPV strains 16 and 18 have been shown to cause cancer, the majority of HPV strains are not associated with cancer. To explain this observation, one could hypothesize that the E6 and E7 proteins of these non-oncogenic HPV strains do not interact with p53 and Rb. Explain how you could use an immunoprecipitation assay to test this hypothesis.

M. Scheffner, B. A. Werness, J. M. Hulbregtse, A. J. Levine, and P. M. Howley. 1990. The E6 oncoprotein encoded by human papillomavirus types 16 and 18 promotes the degradation of p53. Cell 63:1129–1136.

Context

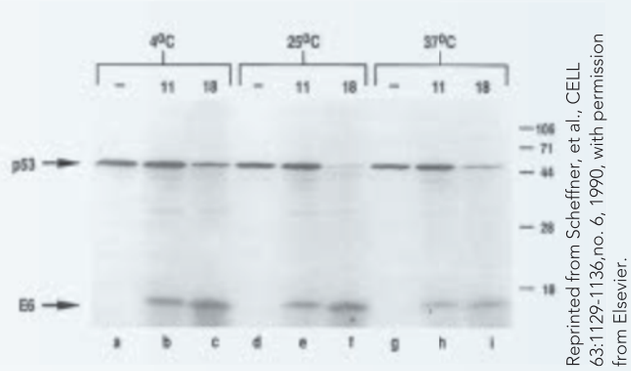
HPV infections cause approximately half of all human cancers caused by viruses. Chief among these cancers is cervical cancer. Understandably, once the association between HPV and cervical cancer was demonstrated in the 1980s, it became critical to determine the reason for this association. Investigators found that HPV E6 and E7 proteins are expressed in cervical cancers. In addition, these proteins can cause the transformation of cell lines. The transformation-inducing ability of these proteins qualifies them as oncoproteins. Because p53 is a well-known tumor suppressor that has a central role in controlling cell growth, researchers investigated the interaction between E6 and p53. Through *in vitro* studies, they confirmed that E6 from cancer-promoting HPV strains associates with p53. In the paper that we are looking at here, researchers investigated the outcome of this association. They examined whether the E6:p53 interaction had any effect on p53 levels or activity. This understanding could be fundamental to developing therapeutics to control or prevent HPV-associated tumors.

Experiment

This study focused on HPV-16 and HPV-18, two strains of HPV associated with cancer and whose E6 protein binds p53, in contrast to HPV-6 and HPV-11, which are relatively benign strains of HPV whose E6 does not bind p53. Both E6 and p53 proteins were expressed from an expression vector in an *in vitro* transcription system, followed by translation of the resulting transcript using a rabbit reticulocyte extract. Such transcription and translation systems are available commercially, and allow production of protein that can be radioactively labeled during translation. In this study, radioactive [L-^{35}S]cysteine was added in order to produce labeled protein. This labeling allowed easy detection of the protein on SDS-PAGE.

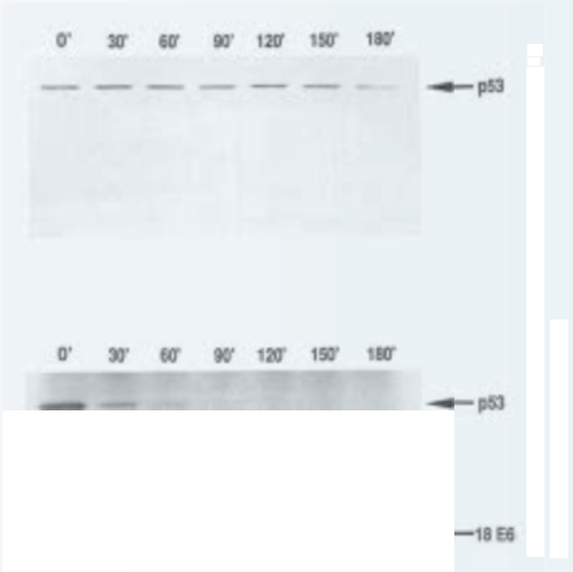
To investigate the interaction between the two proteins, the scientists simply incubated them together for three hours, and then examined the mixture by SDS-PAGE. The levels of the p53 protein decreased after incubation with E6 from HPV-18 **(Figure B22.3)**. Conversely, the incubation of p53 with the E6 protein from HPV-11 did not cause a reduction in p53 levels. A time course experiment **(Figure B22.4)** showed that the HPV-18 E6-dependent degradation of p53 was continuous with time.

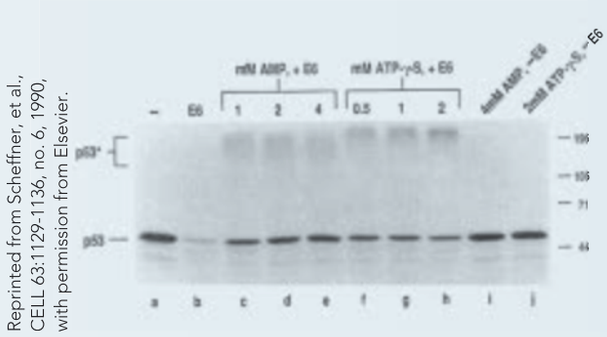
Because protein degradation usually requires ATP as a source of energy, the investigators next examined the role of ATP in E6-induced p53 degradation. Because the *in vitro* translation system used to produce the proteins contained ATP, it was not possible to exclude ATP from the reaction mixtures. Instead, the researchers added AMP, the product of ATP hydrolysis, or ATPγS, an analogue of ATP that cannot



Reprinted from Scheffner, et al., CELL 63:1129-1136,no. 6, 1990, with permission from Elsevier.

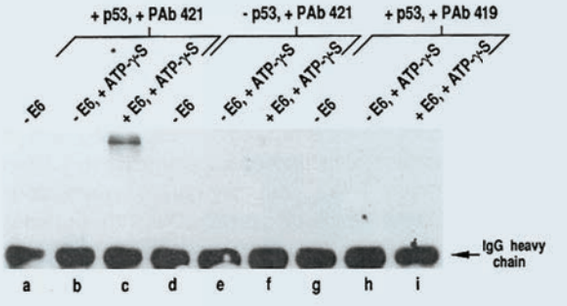
Figure B22.3. HPV-18 E6-induced degradation of p53 Radiolabeled p53 protein was incubated at various temperatures for three hours in the absence of any other proteins (–) or with radiolabeled E6 protein from HPV-11 (11) or HPV-18 (18). Following the incubation, the proteins were separated by SDS-PAGE and then detected. When incubated with E6 from HPV-18, but not HPV-11, the amount of p53 decreased.





Reprinted from Scheffner, et al., CELL 63:1129-1136, no. 6, 1990, with permission from Elsevier.

Figure B22.5. Role of ATP in p53 degradation Radiolabeled p53 was incubated with HPV-18 E6 and increasing amounts of AMP or ATPγS. In the presence of these molecules, p53 degradation was not observed, indicating that ATP hydrolysis is involved in the degradation. Some higher molecular weight versions of p53 (p53*) were observed.



Reprinted from Scheffner, et al., CELL 63:1129-1136, no. 6, 1990, with permission from Elsevier.

Figure B22.6. HPV-18 E6-associated ubiquitination of p53 The tumor suppressor protein p53 was incubated with or without HPV-18 E6 in the presence of ATPγS. The p53-specific antibody PAb 421 or a control antibody (PAb 419) was used to isolate p53 from the reaction. The isolated p53 then was detected with a ubiquitin-specific antibody. When incubated with HPV-18 E6, p53 became ubiquitinated (lane C).

Interestingly, the presence of AMP and ATPγS also caused some of the p53 to run higher in the gel **(Figure B22.5)**, indicating that it had a higher molecular weight. This result only occurred in the presence of E6. The researchers hypothesized that the higher molecular weight forms of p53 might be intermediates of p53 degradation. A common proteolytic degradation pathway in eukarya involves the ubiquitination of the protein to be degraded, followed by movement of that protein to the proteasome (see Section 20.3). To determine whether the higher molecular weight forms of p53 are ubiquitinated, a p53 was pulled out of a reaction mixture containing HPV-18 E6 and ATPγS using a p53-specific antibody, run on SDS-PAGE, and then examined in a Western blot (see Toolbox 8.1) using antibodies specific to ubiquitin **(Figure B22.6)**. The results clearly show that the higher molecular weight form of p53 is ubiquitinated, and ubiquitin therefore is likely involved in the E6-dependent degradation of p53.

Impact

The story of p53 is an interesting one. It was initially thought to be an oncogene itself because early studies were done with a mutant form that was involved in cell transformation. Subsequent work with the wild-type p53 gene revealed that it is a major tumor suppressor protein, and its mutation often is associated with different types of cancers. The finding put forward by this study, that E6 protein from cancer-causing HPV (called "high risk" HPV strains) interacts with p53, leading to its degradation, is consistent with the lower levels of p53 in HPV-associated tumor cells. It was the first study clearly demonstrating E6-associated degradation of p53, suggesting a mechanism for the formation of HPV-associated tumors. Even though HPV vaccines are now available, there still is a need for the development of therapeutics such as antiviral compounds active against existing HPV-induced cancers.

Subsequent work demonstrated that E6 does not work on its own to bind p53 and cause its ubiquitination. A cellular protein, the E6-associated protein (E6AP), catalyzes the covalent linkage of ubiquitin to p53, but does so only in the presence of E6. E6 apparently directs E6AP to p53. E6AP has been shown to be involved in ubiquitination of a number of different proteins, targeting them for proteolytic degradation. The absence of E6AP activity due to mutation now has been linked to another human disease, Angelman syndrome, a severe neurological genetic disorder. So, the study of virus-induced cancer indirectly has led to some understanding of the basis of another human disease.

Questions for Discussion

1. The experiments described in this paper used proteins that were produced in a rabbit reticulocyte system. Another strategy would have been to use proteins produced by overexpression in *Escherichia coli* and then purified using affinity tags. What differences would you expect to see in experiments using such purified proteins?
2. Protein E6AP may be a potential target for the development of therapeutics against cervical cancer. What would be a major concern for using such an approach?

Perspective 22.3
SV40 AND HUMAN CANCERS

SV40, or simian virus 40, is a member of the *Polyomaviridae* family and naturally infects certain non-human primates. The polyomaviruses closely resemble the papillomaviruses. Until recently, these viruses frequently were classified together in a single family. Much like we saw for papillomaviruses and will see for adenoviruses, polyomaviruses infect quiescent cells and cause the infected cells to proceed to the S phase, or DNA replication phase, of the cell cycle. As a result of this shift to the S phase, the cell produces the substrates and machinery needed for DNA replication, which the virus then uses for the replication of its genome. For SV40, a single viral protein appears to be largely responsible for this shift. The SV40 large T antigen binds to and inactivates both Rb and p53, the same two cellular tumor suppressors affected by papillomaviruses and adenoviruses. SV40 does not cause tumors in macaques. However, it is tumorigenic in rodents and can infect and transform some human cells in culture.

Between 1955 and 1963, both the Sabin (oral) and Salk (injectable) poliovirus vaccines, produced in SV40-infected monkey kidney cells, became contaminated with SV40. As a result, nearly 100 million people in the United States became exposed to SV40. Because SV40 causes tumor formation in rodents, there has been much debate about its potential to cause cancer in humans.

Recent studies have shown that SV40 DNA sequences can be detected in cells from several types of human tumors, including ependymomas (tumors of the ependyma, a central nervous system tissue) and osteosarcomas (tumors of the bone). Although SV40 DNA is present in these tumors, epidemiological studies have not shown an increased prevalence of these tumors among people who received the SV40-contaminated poliovirus vaccine. Based on these results, most scientists contend that there is no relationship between the accidental exposure to SV40 and the development of cancer. However, some scientists and advocacy groups continue to argue that a link does exist.

strains, maintain the ability to self-destruct via apoptosis, thus preventing the continuous cell division that leads to cancer.

As we mentioned in Chapter 8, vaccines against HPV now exist. Cervarix, manufactured by GlaxoSmithKline, provides protection against HPV strains 16 and 18. These two strains cause approximately 70 percent of all cervical cancer cases, representing the second leading cause of cancer deaths in women worldwide. Gardasil, manufactured by Merck and Co., provides protection against four types of HPV: HPV 6, 11, 16, and 18. HPV 6 and 11 cause about 90 percent of all genital warts cases. Gardasil 9, approved for use by the FDA in December of 2014, provides protection against these four and five additional HPV types. According to an American Cancer Society news release about Gardasil, this HPV vaccine represents "one of the most important advances in women's health in recent years." In late 2009, the FDA approved the use of Gardasil in boys and men between the ages of 9 and 26. The vaccine has been shown to prevent genital warts in males. It also may reduce the incidence in males of anal and penile cancer, two cancers associated with HPV. More importantly, though, the vaccination of males may reduce the sexual transmission of the virus from males to unvaccinated females.

Adenoviruses

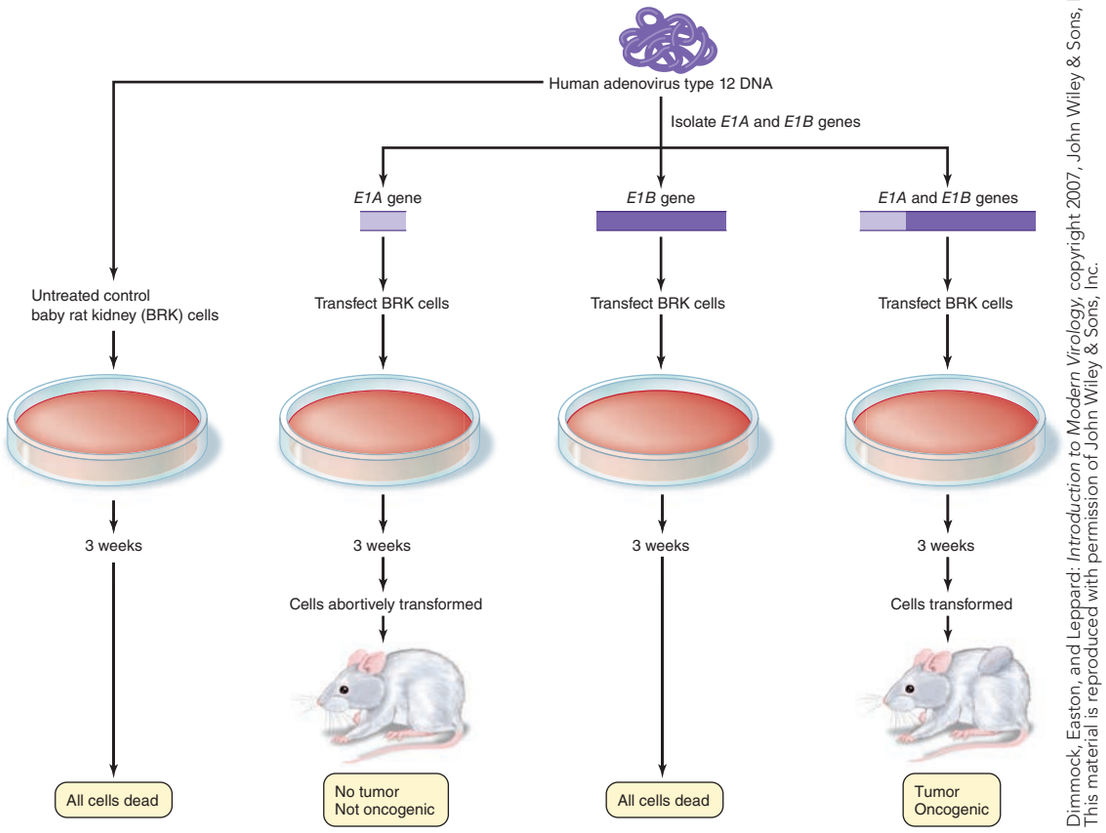
Like the papillomaviruses, the adenoviruses are icosahedral, non-enveloped viruses with a double-stranded DNA genome. Unlike the papillomavirus genome, the adenovirus genome is larger and linear, between 25,000 and 45,000 base pairs in length. These viruses infect a wide range of animals. Depending on the infecting strain, adenovirus infections can have a variety of effects in humans, ranging from cold-like symptoms to diarrhea.

Adenoviruses generally infect quiescent epithelial cells. Although these viruses encode some of their own DNA replication machinery, they still encounter some of the same problems faced by polyomaviruses and papillomaviruses: necessary resources, most notably deoxynucleotides needed for DNA replication, are in short supply. Like HPV and SV40 **(Perspective 22.3)**, the adenoviruses circumvent this problem by causing infected cells to enter the S phase of the cell cycle. They achieve this goal by inactivating the same two tumor suppressors, Rb and p53. The adenovirus E1A protein, like the HPV E7 protein, inactivates the cellular Rb. The adenovirus E1B protein, like the HPV E6 protein, binds to the cellular p53 protein.

No human cancers have been associated with adenovirus infections. Infection of a permissive human cell with a human adenovirus leads to a productive infection and, eventually, cell death by apoptosis. When the viral E1A and E1B genes are transfected into rodent cells in culture, however, the cells become transformed. When these transformed cells then are injected into animals, tumors form. Interestingly, complete transformation and tumor formation only occur when the cells receive both E1A and E1B. When E1A alone is introduced into baby rat kidney (BRK) cells, an abortive transformation occurs; the cells temporarily show signs of undergoing transformation, but then die. In this experimental system, it appears that both the Rb and p53 proteins need to be inactivated for tumorigenesis to occur **(Figure 22.20)**.

RNA tumor-causing viruses

Unlike the DNA-containing viruses, very few viruses with RNA genomes appear to cause cancer. In fact, the only non-retrovirus RNA-containing virus associated with the development of



Dimmock, Easton, and Leppard: *Introduction to Modern Virology*, copyright 2007, John Wiley & Sons, Inc. This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 22.20. Transformation of cells by adenovirus The adenovirus type 12 E1A and E1B proteins are needed to transform cells. When E1A alone is added to baby rat kidney (BRK) cells, an abortive transformation occurs. When both E1A and E1B are added to BRK cells, the cells become fully transformed and cause tumor formation when injected into animals.

cancer is hepatitis C virus, a member of the *Flaviviridae* family. Although infection with hepatitis C virus increases the risk of developing liver cancer, it seems unlikely that the virus transforms the cells itself. Rather, cancer probably results as a by-product of the chronic inflammation produced by the infection. Because of the long-term damage caused to the liver and the liver's constant attempts to replace damaged cells, the genetic material of some hepatocytes eventually becomes compromised and cancer results.

As we will see in this section, many different retroviruses have been associated with tumorigenesis. For these viruses, though, normally occurring viral gene products generally are not responsible for the formation of tumors. Rather, tumorigenic retroviruses lead to tumor formation by altering the host genome. Because retroviruses integrate their proviral DNA into host chromosomes (see Figure 8.20), they can alter cellular **proto-oncogenes**, which are genes that code for proteins involved in cell growth. When the expression or sequence of these genes is altered, the resulting proteins may be overexpressed or function incorrectly, thereby altering the replicative behavior of the cell. In other words, the proto-oncogenes may become oncogenes. This proto-oncogene-to-oncogene conversion can occur in at least two different ways. First, the proviral DNA may integrate near a proto-oncogene and alter the expression of that proto-oncogene, causing the infected cell to become transformed. Second, the retrovirus genome may inadvertently acquire a cellular oncogene and cause transformation by then introducing this oncogene into another cell. Studies of both these ***cis*-acting retroviruses**, retroviruses that activate a cellular proto-oncogene after integrating, and **transducing retroviruses**, retroviruses that have acquired a cellular gene and, as a result, can transfer it to a new cell, have been instrumental in our understanding of the normal cell cycle and have led to the identification of numerous cell cycle control genes. Thus, even though retroviruses themselves may not be tumorigenic, the study of these tumor-causing retroviruses has greatly increased our knowledge of cancer and cell biology.

Cis-acting Retroviruses

As we saw in Section 8.3, the retroviral replication cycle involves conversion of the viral RNA genome into DNA and then integration of this proviral DNA into the host chromosome. This integration event disrupts the host chromosome and therefore is a mutational event. The effect of this mutational insertion depends, of course, on the location of the integration. If the proviral DNA integrates near a cellular proto-oncogene, then the insertion could alter the expression of the proto-oncogene. Altered expression of a gene involved in regulating the cell

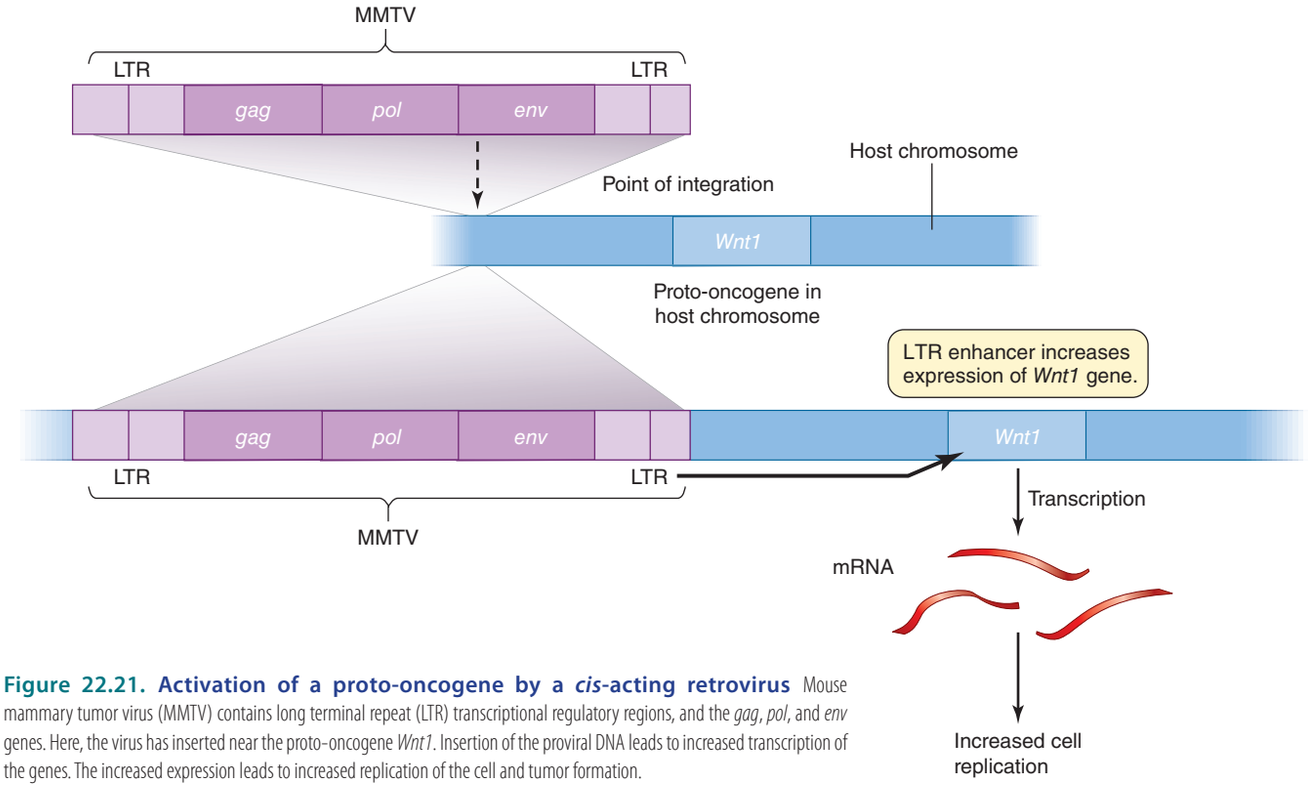


Figure 22.21. Activation of a proto-oncogene by a *cis*-acting retrovirus Mouse mammary tumor virus (MMTV) contains long terminal repeat (LTR) transcriptional regulatory regions, and the *gag*, *pol*, and *env* genes. Here, the virus has inserted near the proto-oncogene *Wnt1*. Insertion of the proviral DNA leads to increased transcription of the genes. The increased expression leads to increased replication of the cell and tumor formation.

cycle could lead to aberrant cellular replication, or tumor formation. The retrovirus is referred to as "*cis*-acting" in this scenario because it affects only an adjoining piece of host DNA.

Probably the best-studied *cis*-acting retrovirus is the mouse mammary tumor virus (MMTV). This virus infects mice and can be spread vertically from a mother to her pups via milk or, endogenously, through the germline. In infected animals, it causes tumors of the breast tissue. However, the MMTV genome does not contain an oncogene. Instead, MMTV causes tumor formation when it randomly integrates near a cellular proto-oncogene. The virus commonly integrates near the cellular gene *Wnt1* or another member of the *Wnt* gene family and increases their expression **(Figure 22.21)**. The products of these genes are involved in cell-signaling processes, and their increased expression leads to altered cell growth. The *cis*-acting enhancer element that drives increased expression of the downstream cellular proto-oncogene is contained in the proviral long terminal repeat (LTR) region. Also contained in the proviral LTR are accessory elements that direct high-level estrogen-regulated expression of the viral genes in mammary cells.

The identification of a virus that causes mammary tumors in mice presents a very interesting question. Could some cases of breast cancer in women have a viral etiology? Researchers have actively investigated this possibility. Although a human equivalent of MMTV has not been identified, researchers have demonstrated that MMTV can infect and replicate in cultured human breast cells. Additionally, some researchers have reported MMTV-like sequences in DNA isolated from human breast cancer samples. These intriguing results present us with additional research questions. Can MMTV infect primary human breast cells? Could MMTV be transmitted from mice to humans? Does a human mammary tumor virus exist? Answers to these questions may provide important insight into tumorigenesis and the basic biology of viruses.

Transducing Retroviruses

Unlike the *cis*-acting retroviruses, the transducing retroviruses contain an oncogene obtained from a cell. When these retroviruses infect a cell, they transfer this genetic material into the new cell through a process known as transduction. Studies of Rous sarcoma virus (RSV) and other transducing retroviruses have led to our current understanding of the genetic basis of cancer and our basic understanding of cell growth. Note that transducing retroviruses are very rare, and as a result, these viruses are not major causes of cancer. Nonetheless, their contributions to the fields of cancer and cell biology are immeasurable. Many of the proto-oncogenes identified thus far, like the *src* proto-oncogene ultimately discovered in RSV, have been identified through studies of transducing retroviruses.

To obtain an oncogene, a retrovirus first must integrate near a cellular proto-oncogene. During the production of new viral particles, transcription of the proviral DNA occurs, resulting in the production of new viral genomes (see Figure 8.20). If this process occurs incorrectly, then an RNA copy of the adjacent cellular proto-oncogene may become incorporated into the

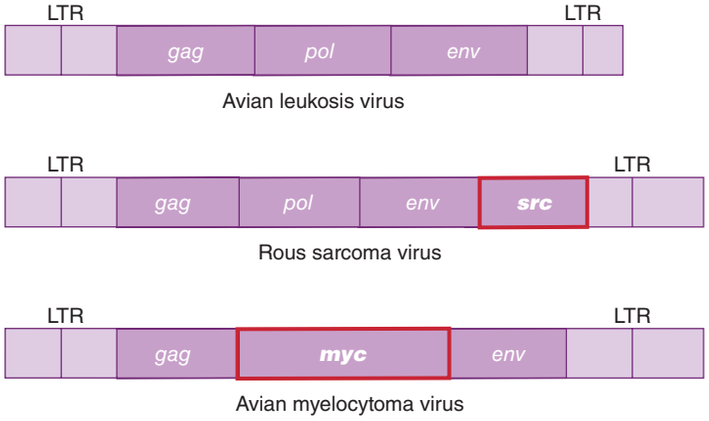

Figure 22.22. Acquisition of cellular proto-oncogenes by transducing retroviruses Avian leukosis virus is a normal (non-transducing) retrovirus, containing the long terminal repeat (LTR) transcriptional regulatory regions, and the *gag, pol*, and *env* genes. The transducing retrovirus Rous sarcoma virus contains the src proto-oncogene, added to an otherwise normal retrovirus genome. The transducing retrovirus avian myelocytoma virus contains the proto-oncogene *myc*, but is missing the entire *pol* and parts of the *gag* and *env* genes.

newly formed viral RNA. In some cases, the cellular sequences become added onto an otherwise normal viral genome. In other cases, the cellular sequences replace parts of the viral genome **(Figure 22.22)**. When these altered retroviruses then infect another cell, the newly acquired cellular sequences will be transduced into the infected cell.

This brief description demonstrates how a retrovirus can acquire a cellular gene. Another question remains. How can this process lead to the conversion of a previously normal proto-oncogene into an oncogene? We can imagine two answers to this question. First, the transduced gene simply may be overexpressed. Strong viral promoters or enhancers may lead to increased transcription of the gene, and this increased expression may lead to transformation of the cell. Second, the cellular gene may become altered in some way. Often, the transduced gene is truncated. In other words, it is missing some 5′ or 3′ sequences. These alterations result in the production of altered proteins that may function aberrantly. The *erbB* gene provides us with an excellent example. This proto-oncogene produces epidermal growth factor receptor (EGFR), a transmembrane protein that binds to epidermal growth factor (EGF). In the presence of this ligand, EGFR undergoes a conformational change and autophosphorylation results. In turn, this phosphorylation of EFGR activates several cell-signaling pathways that ultimately lead to cell proliferation. However, a mutated form of *erbB* carried by avian erythroblastosis virus-H produces an altered form of EGFR that lacks part of the extracellular ligand-binding domain. As a result of this deletion, the protein continuously undergoes autophosphorylation and continuously signals the cell to divide **(Figure 22.23)**.

22.3 Fact Check

1. How do some human papillomaviruses cause cancer?
2. How can retroviruses cause cancer?
3. Compare and contrast proto-oncogenes and tumor suppressor genes.

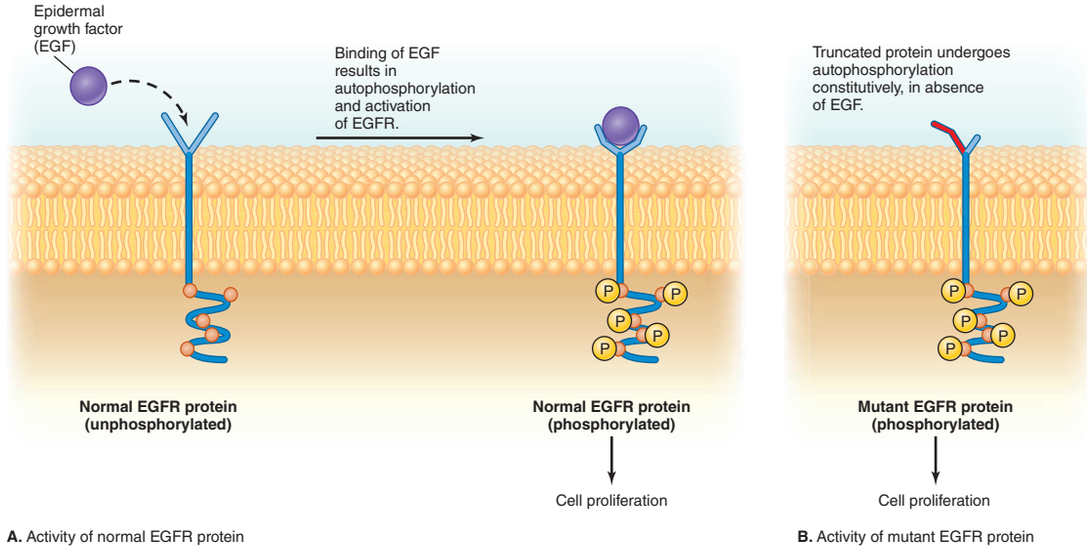

Figure 22.23. Effects of mutating a proto-oncogene Mutations in the cellular *erbB* (*c-erbB*) gene, a proto-oncogene, alter the functioning of the gene's product: epidermal growth factor receptor (EGFR). **A.** When the wild-type protein interacts with its ligand—epidermal growth factor (EGF)—it undergoes autophosphorylation and activates cell-signaling pathways that result in cell proliferation. **B.** The transducing retrovirus avian erythroblastosis virus-H contains a truncated form of this gene that produces an altered form of EGFR. The mutant EGFR lacks most of the ligand-binding domain and, as a result, continuously undergoes autophosphorylation and continuously signals the cell to proliferate.

22.4 Evolution of viral pathogens

How do some viruses become highly virulent?

As we noted in the introduction to this chapter, all viruses infect cells and all viruses, to some degree, damage these cells. The degree of damage, though, may differ. In some cases, the amount of damage that a virus causes may be dependent on host factors. The HIV co-receptor CCR5 provides an interesting example. To infect a cell, the gp120 protein on the surface of HIV initially binds to CD4, a signaling molecule found on the surface of certain immune system cells. After this initial binding event, the virus then interacts with a second molecule, a co-receptor. CCR5, another signaling molecule present on the surface of certain immune system cells, serves as the co-receptor for certain strains of HIV. By studying individuals who were exposed to HIV repeatedly, but did not become infected, researchers made an interesting observation. Some of these exposed but not infected individuals were homozygous for a 32-base-pair deletion in the CCR5 gene. In other words, both copies of their CCR5 gene were mutated. The mutant allele, referred to as CCR5-Δ32, results in the production of a mutant protein that is not expressed on the surface of the cells. As a result, the virus cannot infect host cells. People possessing this mutation, then, exhibit a high degree of resistance to HIV. Perhaps surprisingly, people with this deletion exhibit no discernible defects in their immune systems.

Population studies revealed that this mutant allele is more prevalent in some ethnic groups. Among Caucasians of European ancestry, roughly one percent of the population is homozygous for this CCR5 deletion and 10 percent of the population is heterozygous. Conversely, the mutation is very rare among people of African and Asian descent. We also should note that being homozygous for this mutation does not provide a person with absolute protection from HIV. Different strains of HIV utilize different CCR5-related co-receptors. Importantly, the genetic makeup of a person may affect his or her susceptibility to HIV.

CONNECTIONS As we have seen in **Section 8.1**, genetic studies of viral and host cell proteins identify specific regions of these molecules that are necessary for an infection to occur.

Before leaving our discussion of CCR5-Δ32, let's address another interesting question: Why does this mutation exist? Because the CCR5-Δ32 allele exists in relatively high amounts in certain populations, researchers have speculated that this allele provided protection to some horrific previous infectious disease. If a few people possessing the CCR5-Δ32 allele survived a highly lethal plague, then the allele would have been passed on to their descendants, leading to its high frequency today. Initially, microbiologists and historians speculated that CCR5-Δ32 may have offered some protection against the bubonic plague, which swept through northern Europe during the fourteenth century. Currently, researchers hypothesize that individuals possessing CCR5-Δ32 alleles may have exhibited some protection from smallpox infections.

As we have just seen, host genetics play a part in determining the virulence of viruses. Of course, viral genetics also play a part. In this section, we will see how viral genomes can change via several different mechanisms. To some extent, these mechanisms of change are dependent on the type of genome possessed by a virus and/or viral replication strategy. In the remainder of this section, we will examine three different ways in which viral genomes can change: mutations, recombination, and reassortment. We will conclude this section by asking another question: What factors affect the evolution of viruses?

Mutations

As we noted in Chapter 6, mutations—changes in the genome of an organism—are absolutely necessary for evolution. Minor changes in the genome of an individual may alter the phenotype, or characteristics, of that individual. These phenotypic changes, in turn, may alter the individual's fitness. Finally, an individual with greater fitness may be more likely to reproduce or replicate. These basic processes occur in eukarya, bacteria, archaea, *and viruses.*

Among eukarya, bacteria, and archaea, numerous mechanisms exist to minimize the mutation rate. Although mutations are necessary in the long term, a stable genome certainly is desired in the short term. Among many viruses, especially RNA viruses, these same mechanisms to reduce the mutation rate do not exist. As a result, the mutation rate in many RNA viruses is extraordinarily high.

To understand this high mutation rate, let's begin by examining the replication enzymes used by RNA viruses. As you may remember from our discussion of viral replication in Chapter 8, viruses with an RNA genome cannot rely on the host cell DNA polymerase to replicate their genomes. Rather, they rely on virus-specific RNA-dependent RNA polymerases or, in the case of retroviruses, reverse transcriptases. These enzymes lack a proofreading function, unlike the DNA polymerases used by eukarya, bacteria, and archaea. In other words, viral RNA-dependent RNA polymerases and reverse transcriptases cannot remove bases that were incorrectly added to a nucleic acid strand. What's the significance of this? RNA viruses typically have a mutation rate of 10^{-3} to 10^{-5} per base per genome replication. To put it another way, every time one of these viruses replicates its genome, one out of every 1,000 to 100,000 bases is altered. In contrast, *Escherichia coli* has a mutation rate of approximately 10^{-8} per base per genome replication.

CONNECTIONS As we saw in **Section 7.5**, the DNA polymerases used for DNA replication in bacteria, archaea, and eukarya possess an effective proofreading activity. Other processes, like the bacterial mismatch repair system, further decrease the numbers of mutations that occur.

What are the implications of this high mutation rate? Most importantly, whenever a virus replicates in a cell, the newly formed viruses will be genetically heterogeneous. Each time these viruses replicate, a viral swarm forms. Each divergent virus in the swarm is referred to as a quasispecies. Presumably, some of the mutants will be better able to infect other cells. Other mutants may be more environmentally stable and better able to be transmitted from one individual to another. Still other mutants may be completely non-infectious; the mutation(s) will result in particles unable to enter host cells or replicate within these host cells. This high mutation rate also means that viruses are evolving at a fast rate.

This rapid viral evolution has implications for our ability to prevent viral infections. To understand this point, let's examine influenza virus. Various studies have shown that human influenza has a mutation rate of approximately 10^{-5}. As the virus replicates, mutations accumulate throughout the influenza genome, including within the genes encoding hemagglutinin (HA) and neuraminidase (NA). These membrane-bound proteins are the major targets for our immune system. The structural changes within these proteins usually are so significant that after a few years of genetic changes within the virus, our immune response no longer is effective. This process of mutational changes within the surface proteins is referred to as **antigenic drift**. This process also necessitates the development of a new influenza virus vaccine every year.

Rapid viral evolution also has implications for the treatment of viral infections, particularly for viruses that cause chronic or persistent infections. To understand this point, let's examine HIV. Even though a rather homogeneous population of HIV particles may infect a person initially, a viral swarm quickly develops within the infected person. The virus actually evolves within each host. This evolution has several important implications. First, the virus may evolve to infect different cells over time. The virions most commonly found in seminal fluid, and transmitted sexually, typically use the cell surface protein CCR5 (a chemokine receptor found on macrophages) as a co-receptor to infect cells and are referred to as macrophage-tropic viruses. Over time though, viral mutants often evolve that utilize a related protein, CXCR4, as a co-receptor **(Figure 22.24)**. These viruses preferentially infect T cells and are referred to as T-cell-tropic viruses. Second, the virus may develop resistance to various antiretroviral therapies. As the virus replicates within a person on antiretroviral therapy, mutants that exhibit some resistance to the drugs will possess a selective advantage. These resistant viruses eventually will become the predominant strains present within the individual. As a result, the original drug therapy will begin to fail over time. Because of this common problem, clinicians typically monitor the viral load in a person infected with HIV (see Perspective 5.2). When they detect a rise in the viral load, they usually prescribe a new set of drugs.

CONNECTIONS To more effectively inhibit HIV replication and decrease the likelihood of drug therapy failure, clinicians typically prescribe people living with HIV a combination of three different antiretroviral drugs, often referred to as the triple-drug cocktail. In **Section 24.2**, we will learn more about some of these drugs and how they inhibit HIV replication.

Recombination

Although point mutations provide the basic variation needed for evolution, more dramatic changes in viral genomes can occur. Unsurprisingly, these larger changes can affect the virulence of these viruses. Recombination, or the process of combining two different pieces of nucleic acid, may occur more frequently among viruses than once thought. Most of us probably are most familiar with recombination within the context of meiosis. Among diploid organisms, homologous chromosomes recombine during meiosis, a process often referred to as crossing over. Among viruses, recombination can occur when a cell simultaneously becomes infected by two genetically distinct strains of the same virus. During replication of these two different viruses within the same cell, a type of recombination event may occur. Progeny viruses that have recombinant genomes then form—part of the genome arises from the genome of one input virus and part of the genome arises from the genome of the other input virus.

Coronaviruses, enveloped viruses with a single-stranded positive-sense RNA genome, provide an interesting case study. Studies with mouse hepatitis virus (MHV), a well-studied coronavirus, have shown that recombination occurs at a high rate in cell culture and in animals. If cells or mice are experimentally

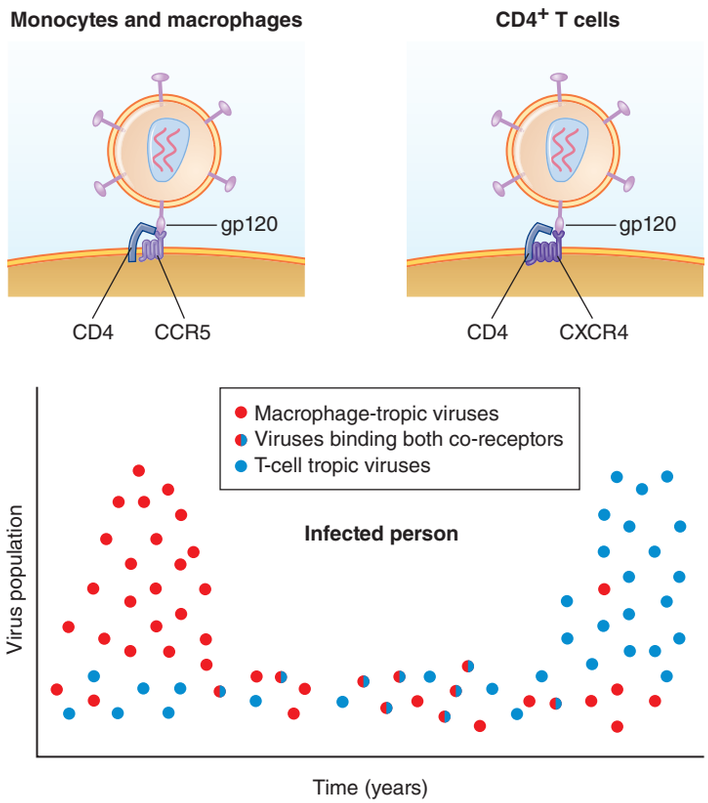

Figure 22.24. Evolution of HIV within an infected person Because of the high mutation rate exhibited by HIV, a person infected with the virus quickly contains a viral swarm, or population of viral mutants. During the course of an infection, the predominant variant of the virus may change from one that preferentially infects monocytes or macrophages (monocyte or macrophage-tropic) to one that preferentially infects T cells (T-cell tropic). This switch occurs because of mutations in the viral gp120 protein that determine whether the virus can utilize the CCR5 or CXCR4 co-receptor. This switch also correlates with the depletion of $CD4^+$ cells and the onset of AIDS.

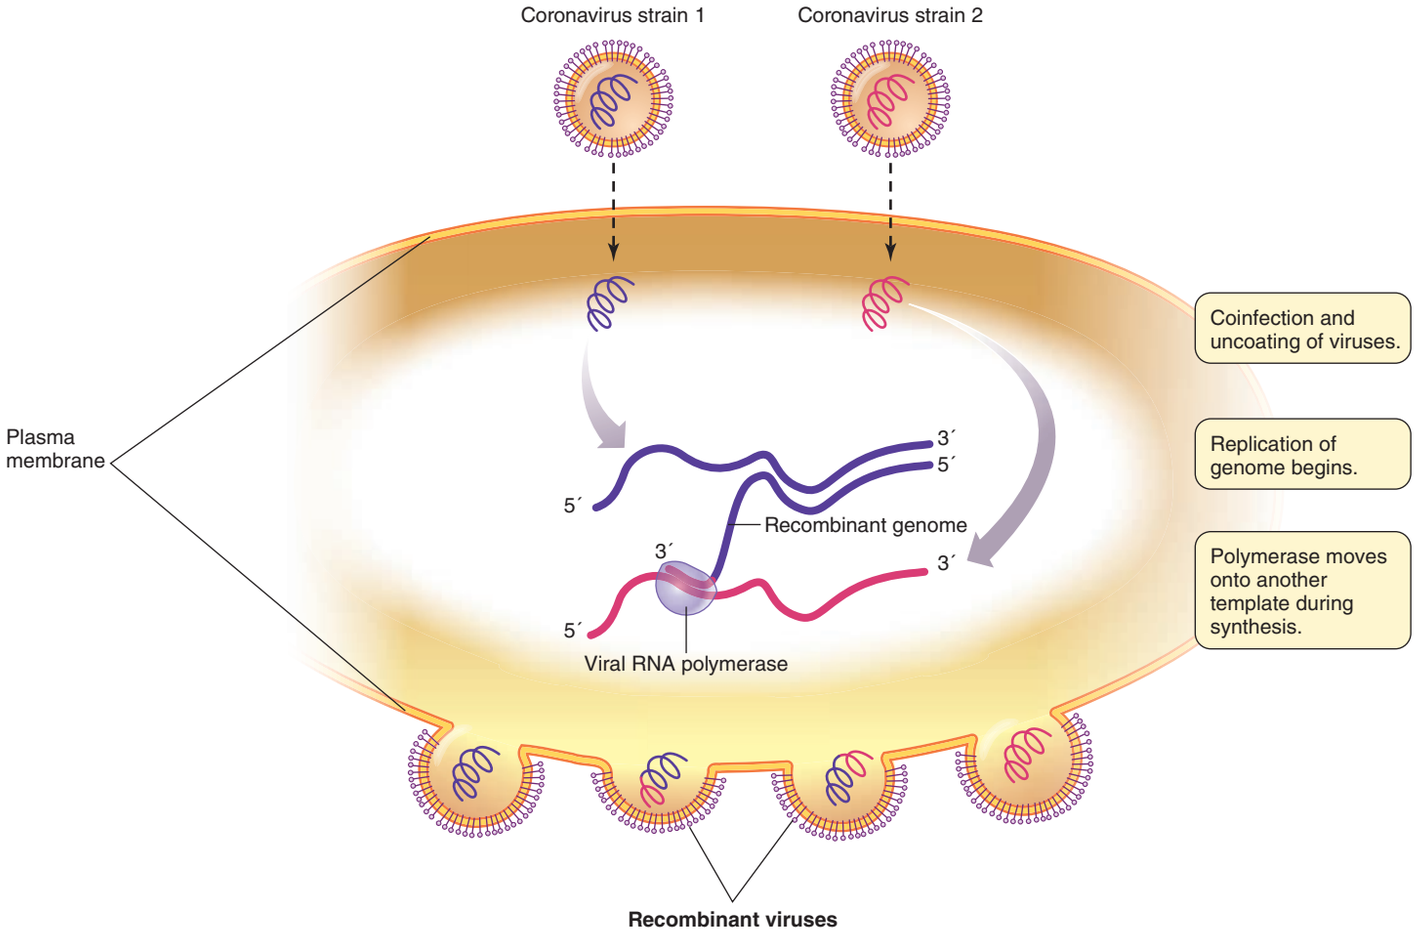

Figure 22.25. Recombination in coronaviruses Following coinfection of a cell with two strains of coronavirus, genome replication begins. Occasionally, the viral polymerase, along with its nascent RNA molecule, will dissociate from the template RNA and bind to another template molecule. Genome replication then resumes. The resulting genome is a recombinant, possessing some sequences from one parental genome and some sequences from the other parental genome.

coinfected with two strains of MHV, as much as 25 percent of the progeny viruses may contain recombinant genomes. This high rate of recombination probably results from the method of genome replication and mRNA production utilized by these viruses. RNA synthesis in coronaviruses appears to be discontinuous; the RNA polymerase begins RNA synthesis from an RNA template and then dissociates from that template RNA strand. The polymerase and nascent RNA molecule then attach to a new location on the same, or another, template strand and RNA synthesis resumes in a process known as "template switching" **(Figure 22.25)**. Let's examine the implications of this replication mechanism. If the polymerase begins using one template strand and switches to a genetically different template strand, then part of the resulting molecule will be complementary to the first template and part of the molecule will be complementary to the second template. In other words, the newly formed piece of RNA will be recombinant.

Now that we understand how recombination can occur in coronaviruses, let's ask a more fundamental question: Does it ever occur naturally? We noted in the preceding paragraph that recombination occurs when cells or animals are coinfected by two strains of MHV. It may seem unlikely that coinfection would occur in nature, that MHV recombination is a laboratory curiosity and not a real-world concern. However, recent studies with the coronavirus associated with severe acute respiratory syndrome (SARS) indicate that recombination among coronaviruses does occur in nature and may affect the evolution and pathogenesis of these viruses.

As we mentioned in Section 5.4, a coronavirus causes SARS. This virus has been named human SARS-CoV. Initial studies isolated a genetically identical virus from civet cats, leading to the hypothesis that the virus was transmitted from these cats to humans. However, surveys of civet cat populations identified SARS-CoV in very few individual cats, leading to the conclusion that civet cats are not the natural host of this virus. Subsequent studies isolated several SARS-like coronaviruses (SLCoV) from different bat species, indicating that bats may be the natural reservoir for these viruses. Indeed, several viruses isolated from horseshoe bats (bat SARS-like coronaviruses, or Bt-SLCoV) closely resemble SARS-CoV, but none appear to be its direct ancestor. Recently, researchers obtained evidence demonstrating that a Bt-SLCoV genome arose via recombination. Part of

the genome very closely resembles the genome of SARS-CoV. These researchers postulated that the virus they discovered arose via recombination between two coronaviruses that infect bats, one of which may be the direct ancestor of the SARS virus. This analysis of viral genome recombination has provided important insight into the natural reservoir of this potentially dangerous pathogen.

Reassortment

As we noted previously, some viruses have segmented genomes. Rather than possessing a single genomic molecule, the genomes of these viruses consist of several discrete nucleic acid pieces, or segments. For most viruses with segmented genomes, each genome segment encodes for one or two polypeptides. A different means of generating genetic variation exists for these viruses. This distinct mechanism is **reassortment**, which involves combining of gene segments from two or more parental viruses. Like recombination, reassortment only occurs if a cell becomes coinfected with two or more genetically distinct strains of a virus. Unlike recombination, individual genome molecules do not undergo recombination to form a hybrid molecule. Instead, progeny virus particles form that contain some genome segments from one parental virus and some genome segments from another parental virus **(Figure 22.26)**. If we think of recombination as analogous to crossing over in meiosis, then we can think of reassortment as analogous to independent assortment in meiosis. Just as every gamete receives one copy of each chromosome during meiosis, each infectious progeny viral particle receives one copy of each gene segment. They may contain all the gene segments from one parental virus, all the gene segments from the other parental virus, or some segments from one parental virus and some segments from the other parental segment.

Reassortment can result in viruses that differ substantially from either of the parental strains. As we noted earlier, influenza viruses have a high mutation rate. The accumulation of point mutations can cause major changes in the surface glycoproteins, resulting in antigenic drift. Influenza viruses also can undergo reassortment. Influenza viruses contain eight genome segments. The HA and NA gene segments encode the hemagglutinin (HA) and neuraminidase

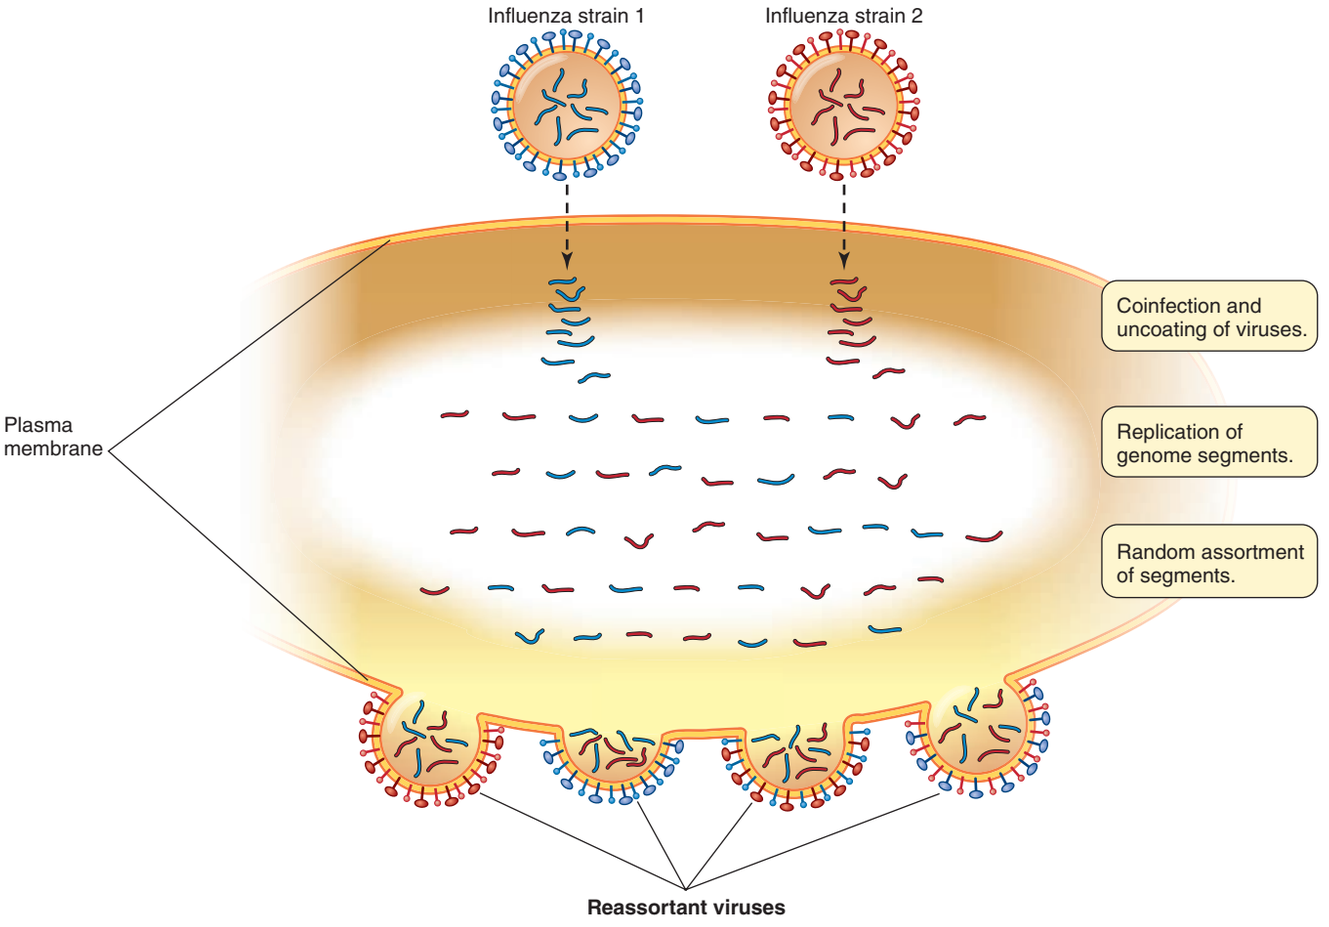

Figure 22.26. Reassortment of viral gene segments For viruses with segmented genomes, such as influenza viruses, reassortment can occur. The process starts with coinfection of a cell with two strains of the virus. Replication of the genome segments then occurs. When new viral particles assemble, progeny viruses may form that contain some genome segments from one parental virus (indicated in red) and some genome segments from the other parental virus (indicated in blue).

(NA) proteins, respectively, the two major antigenic determinants on the surface of influenza particles. Within influenza virus type A, the type of influenza responsible for most human influenza virus infections, 16 genetically distinct subtypes of the HA gene segment (H1–16) and 9 subtypes of the NA gene segment (N1–9) have been identified. If an individual becomes coinfected with viruses of two different subtypes (H1N1 and H2N2, for instance), then reassortment could occur, leading to the formation of a new subtype (H1N2 or H2N1, for instance). Theoretically, 144 different combinations of these two gene segments could exist. The dramatic change in viral antigens caused by reassortment is referred to as **antigenic shift**.

Although 144 influenza A virus subtypes can exist theoretically, a single subtype of influenza A virus typically causes most of the infections throughout the world during any given flu season. From 1968 until 2009, the H3N2 subtype had been the predominant strain. In March and April of 2009, that situation changed dramatically. Officials in Mexico and the United States reported people infected with a different influenza A subtype: H1N1. Because the antigens of this H1N1 virus differed from the antigens associated with the H3N2 virus, very few people had immunity to the new subtype. Consequently, the virus spread with amazing rapidity. By June 11, 2009, over 30,000 cases throughout the world had been reported. The World Health Organization declared an influenza pandemic, the first since the H3N2 strain appeared in 1968. However, the H1N1 virus did not replace the H3N2 virus in human populations. Both influenza subtypes were detected during the 2014–2015 influenza season.

How do these antigenic shifts occur? It's important to realize that influenza A viruses do not infect only humans. These viruses also infect a wide range of animals, including wild birds, domestic poultry, pigs, and horses. Many different influenza A virus subtypes certainly exist in these various species. Reassortment could occur in any of these species, leading to the formation of additional subtypes. One of these viruses could be transmitted to humans, leading to the introduction of a new subtype into the human population—an antigenic shift. This possibility has fueled current concerns about avian flu. Most notably, health care workers have been monitoring two specific avian influenza subtypes, H5N1 and H7N9. Although bird-to-human transmission of both viruses has been documented, human-to-human transmission is rare. However, mutations in these viruses could lead to more efficient human-to-human transmission.

In 2011, two separate research groups investigated the possibility of human-to-human transmission of avian influenza. Both groups conducted gain-of-function experiments, identifying changes in the avian H5N1 virus that led to more efficient transmission of the virus among ferrets, which is assumed to be a good model for transmission among humans. From these experiments, both research groups concluded that human-to-human transmission of the H5N1 subtype of influenza virus is possible. Although this research provides us with valuable scientific insight, it also has raised important ethical implications **(Perspective 22.4)**.

Perspective 22.4
ETHICAL CONCERNS ABOUT AVIAN FLU RESEARCH

Could the H5N1 subtype of avian influenza become better suited to human-to-human transmission? During the latter half of 2011, researchers from two different institutions reported that the answer to this question is "yes." Dr. Yoshihiro Kawaoka and colleagues at the University of Wisconsin, Madison, and the University of Tokyo mutated the H5N1 hemagglutinin (HA) gene and then generated a reassortant virus that contained this gene segment and gene segments from the 2009 H1N1 pandemic virus. This reassortant virus could be transmitted easily between ferrets, which are assumed to be a good model for human transmission of influenza virus. They submitted a manuscript detailing their experiments to the journal *Nature*. Dr. Ron Fouchier and colleagues at Erasmus Medical Center in the Netherlands also generated a H5N1 variant that could be transmitted easily between ferrets. They achieved this result by serially passing the virus from ferret to ferret. In the end, they reported five mutations in the H5N1 virus that made it transmissible between ferrets. They submitted a manuscript detailing their experiments to the journal *Science*.

These results are fascinating. They also are somewhat unsettling. Had these researchers created a supervirus that could kill millions of people? Should this research have been conducted? Should the results be made public? Can we prevent a bioterrorist from replicating their experiments? The advancement of science depends on open sharing of ideas. However, these experiments have started a complex discussion about the limits of scientific research and its communication. Is some research too dangerous to conduct or report?

In December of 2011, the National Science Advisory Board for Biosecurity (NSABB) in the United States recommended that the papers be published only if details about the methods and results were withheld. Complete and open sharing of this research should not occur. However, the Board reversed this decision in March of 2012. Noting that the information in the articles might help public health officials track the natural evolution of more dangerous influenza strains, the NSABB recommended the research be published. The work by Dr. Kawaoka and colleagues was published in *Nature* in May of 2012 and the work by Dr. Fouchier and colleagues was published in *Science* in June of 2012.

That, however, is not the end of the story. In October 2014, the U.S. government announced a temporary moratorium on gain-of-function experiments, such as the ones conducted by Drs. Kawaoka and Fouchier, involving human pathogens like influenza virus, SARS-CoV, and MERS-CoV. During this moratorium, the NSABB and other groups will evaluate the risks and benefits of these types of experiments.

Researchers also have exploited the process of reassortment to investigate aspects of viral pathogenesis. Mammalian reoviruses have been used extensively in this capacity. Because reoviruses have segmented genomes, it is possible to coinfect cells with two different strains of reovirus and isolate reassortant progeny viruses, which are viruses that contain some genome segments from each of the parental viruses. If the two parental viruses exhibit a phenotypic difference, then it would be possible to screen a panel of reassortants and classify them as being like one or the other of the parental viruses. By analyzing the phenotypes of the reassortants and the origins of their genome segments, it may be possible to associate a phenotype with a specific genome segment. Through the use of this approach, researchers have demonstrated that specific reovirus genome segments and, by extension, specific reovirus proteins affect various aspects of reovirus replication. These basic studies have contributed substantially to our understanding of viral pathogenesis.

Evolution

In this section, we have investigated methods by which genetic variation can occur in viruses. As with all organisms, genetic diversity in viruses originates from point mutations. Additionally, certain families of viruses exhibit recombination or reassortment. Both of these processes increase the degree of genetic diversity present in viruses. As we conclude this section, let's think about a more esoteric question: What selective forces drive evolution in viruses?

Within an infected organism, the immune response almost undoubtedly represents the major selective pressure. Viral mutants that have altered antigenic determinants will be recognized less well by the adaptive immune response launched against the original infecting virus. These mutants may be better able to evade the immune response and infect another cell. If an individual is taking drugs to combat a viral infection, the antiviral therapy also represents a major selective pressure. Viral mutants that exhibit increased resistance to a particular drug will be better able to replicate. This type of pressure is a major problem for viruses that cause chronic or persistent infections, where drug use may be long-term.

We could hypothesize that mutations that increase the rate of production of new viral particles would be beneficial. If a viral mutant arises that can replicate faster than the other viruses, then it should become the predominant virus within an infected individual and, from there, in a population. Alternatively, we could hypothesize that mutations that limit replication in a host and, as a result, limit the severity of disease, would be beneficial. After all, it is in the virus's best interest for the host to stay alive so that the virus can continue to replicate. Of course, viruses also must be transmitted from one host to another. We could hypothesize that mutations affecting the transmission of a virus between hosts would benefit the virus. It should be clear then that many different factors affect the evolution of viruses. Likewise, various mutations could affect the virulence of a virus.

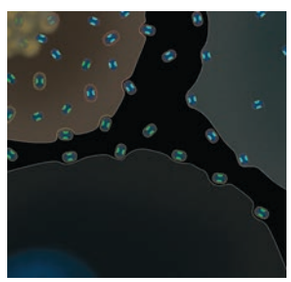
Recent studies with poliovirus have shed some light on this complex issue of virus evolution. Raul Andino, a virologist at the University of California, San Francisco, hypothesized that the high mutation rate exhibited by many RNA viruses may be necessary for the overall success of a virus. To test this hypothesis, they analyzed a mutant poliovirus strain possessing a less error-prone polymerase. This poliovirus strain exhibited decreased neurotropism and decreased virulence. In other words, the high mutation rate of the wild-type virus seems to be necessary for the pathogenicity of the virus. Error-prone polymerases may provide viruses with the genetic plasticity needed to adapt to ever-changing environments.

22.4 Fact Check

1. What is antigenic drift?
2. How does recombination in coronaviruses occur?
3. What is viral reassortment? How does this lead to antigenic shift?
4. Why might a high mutation rate be advantageous to viruses?

Image in Action

WileyPLUS Learning Space As viruses replicate within infected cells, mutant viral particles form that may exhibit very different properties. The cell in the upper left is infected with myxoma virus. From the viral factory (yellow, cloud-like haze in upper-left corner), intracellular mature virions form, with some wrapped in a double-membrane envelope. Among these newly formed virions, genetic differences are indicated by different surface protein and lateral body colors. Some viruses, indicated by yellow surface proteins and green lateral bodies, interact with the cell on the bottom but cannot enter it. Other viruses, indicated by pink surface proteins and aqua lateral bodies, enter the cell on the right but do not replicate. Still other viral mutants could form that infect host cells and replicate very well.



1. Explain how the viral diversity shown in this image could be used to explain why the biological control of the invasive rabbit species ultimately failed.
2. The myxoma virus shown here causes myxomatosis in rabbits. Imagine that you learn it is spread via mechanical transmission. Explain what this means.

The Rest of the Story

Initially, the use of myxoma virus to combat the rabbits in Australia seemed to work. As we noted in the chapter's opening story, the virus was highly virulent in these rabbits, killing a stunning 99 percent of the infected animals. However, the situation soon changed. A year after the myxoma virus was released, its virulence decreased considerably. Studies over the next 30 years showed that fewer and fewer isolates of the virus were virulent in laboratory strains of European rabbits. In 1950, 100 percent of isolated myxoma virus killed 99 percent of infected rabbits. By 1959, less than 2 percent of myxoma virus isolates exhibited this degree of virulence. A less pathogenic form of the virus evolved.

The rabbit population also evolved. In 1950, nearly all wild European rabbits exposed to a virulent strain of myxoma virus died. Today, less than 30 percent of wild rabbits in Australia die when exposed to the same strain of the virus. What do the results of these studies tell us? Most notably, viral pathogenesis is a complex topic, dependent on both the virus and the host.

Summary

Section 22.1: How do viruses cause disease?

The type of infection that develops when a viral genome enters a host cell depends upon two interrelated activities: the replication of the virus and the immune response of the host.

- An **infection** occurs when a viral genome enters a host cell. **Productive infections** produce new infectious viral particles whereas **abortive infections** do not.
- **Acute infections**, such as a typical rhinovirus infection, have a short duration.
- In latent infections, a period of acute infection is followed by a period of latency. Reactivation occurs in response to an environmental or biochemical trigger. During latency, the herpesvirus genome exists within the host cell as an **episome**. **Latency-associated transcripts (LATs)** may help maintain this latent state.
- In **persistent infections**, the virus is not eliminated within a reasonable amount of time. Rather, the continuous production of new viral particles occurs.
- Horizontal transmission refers to the transmission of a virus between individuals; vertical transmission refers to the transmission of a virus from a mother to infant, including the transmission of **endogenous retroviruses**.
- Some viruses, like rabies virus, undergo zoonotic transmission, whereas other viruses, like the myxoma viruses, undergo mechanical transmission.

Section 22.2: How do viruses interact with host cells?

Viruses use host cell machinery to replicate and, in the process, damage host cells.

- Some viruses, like poliovirus, inhibit host cell transcription or translation processes.
- Cellular death may occur in one of several ways, including virus-induced syncytium formation or the formation of **inclusion bodies** that impair cell function.
- Viral pathogenesis also may result from the host immune response. **Autoimmunity** may be caused by the release of self-antigens or **molecular mimicry**.

Section 22.3: How do some viruses cause cancer?

Virus replication may lead to aberrant cellular replication, resulting in cancer.

- Many DNA viruses can cause **transformation** of cells in culture, producing changes within a cell that cause it to become cancer-like. Some viruses cause **tumorigenesis**, the formation of a tumor.
- The genomes of transforming viruses typically contain **oncogenes**, genes capable of transforming cells.
- Tumorigenesis may result from an essential viral protein that causes a **quiescent cell** to enter the cell cycle.
- Viral proteins may inhibit p53 and/or Rb, two **tumor suppressors** that normally inhibit cellular replication in host cells. Certain human papillomavirus (HPV) strains inhibit these proteins, causing **papillomas** and cancer. **Immunoprecipitation (IP)** assays can be used to identify these types of protein interactions.
- Retroviruses also can cause tumorigenesis. ***Cis*-acting retroviruses** integrate near a cellular **protooncogene**, altering that gene's expression. **Transducing retroviruses** acquire a cellular proto-oncogene and then introduce that gene into a new cell.

Section 22.4: How do some viruses become highly virulent?

Mutations, recombination, and reassortment can alter a virus's virulence.

- Random mutations provide the basis for the evolution of all viruses. RNA viruses have an especially high mutation rate, leading to **antigenic drift**.
- Many viruses also undergo recombination. This process may result in progeny viruses containing genomes derived from each parental virus.
- For viruses with segmented genomes, **reassortment** can occur, leading to **antigenic shift** in viruses like influenza virus.

Application Questions

1. From a virus's perspective, explain the potential advantages of acute and persistent infections.
2. Why might stress cause the reactivation of a latent human virus?
3. Explain why apoptosis of infected cells may be beneficial to an organism.
4. We mentioned that cancer may be an unintended outcome of certain virus replication strategies. Explain.
5. Define antigenic drift and antigenic shift. How are these two events similar? How are they different?
6. Explain how bacteriophage lysogeny occurs.
7. What is an endogenous retrovirus?
8. An HIV-infected cell can fuse with adjoining, non-infected cells, forming a syncytium. Explain how this process might occur.
9. Some researchers are concerned that the current H1N1 human influenza virus and the H5N1 avian influenza virus may give rise to a more deadly human virus. How could this occur?
10. For a virus, which is more advantageous: evolving to become highly virulent or evolving to become less virulent? Explain your answer and provide examples.
11. For a respiratory virus like rhinovirus, transmission often occurs through the air. Viral particles exit an infected individual when the host coughs or sneezes and then are inhaled by another susceptible host. The viral particles must remain infectious during this exposure to the outside environment. Devise an experiment that would allow you to measure infectivity of a virus after exposure to various environmental conditions.

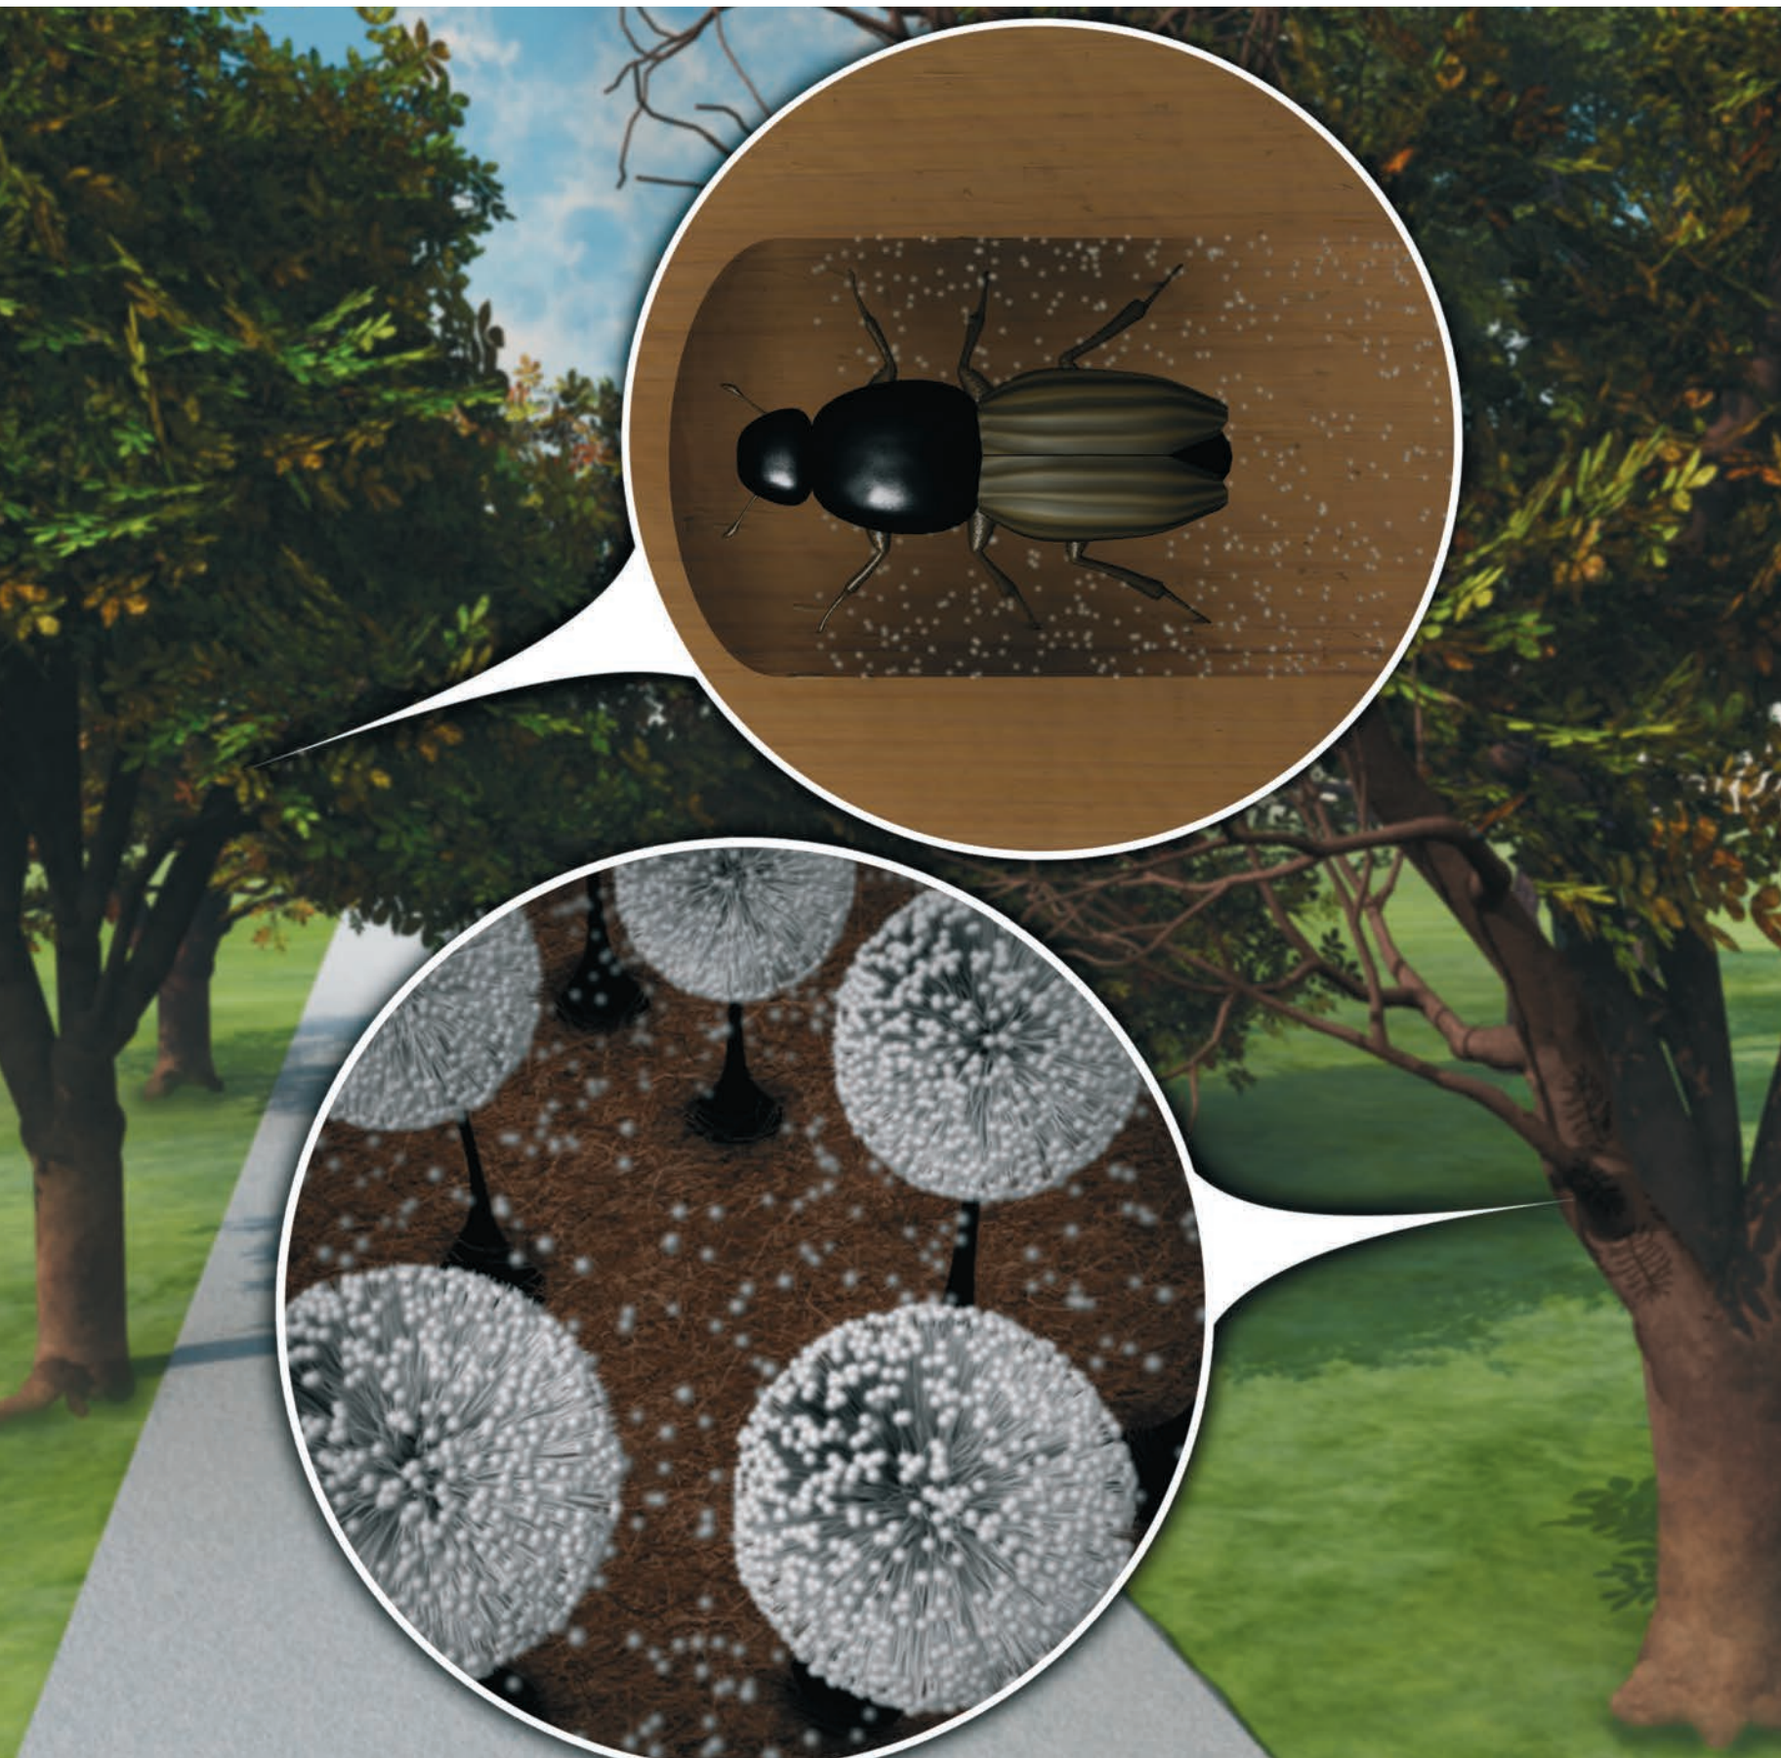
CHAPTER

23 Eukaryal Pathogenesis



In North America, majestic elm trees are—or used to be—one of the most important urban landscape shade trees. They are perfectly suited to this role. Elms display a large and thick canopy, attain heights of almost 100 feet (30 m), grow in a variety of climates and soil conditions, and are relatively fast growing, with lifespans of some 300 years. Unfortunately, mature elm trees are uncommon in North America today. A fungus has killed most of the trees.

The causative agent of Dutch elm disease was first identified in 1921 in the Netherlands, hence the name of the disease. The fungus originally was designated *Ophiostoma ulmi*. It is proposed to be native to Asia because Asian species of elm are somewhat resistant to the fungus, suggesting that they have coexisted with it for a long period of time. Conversely, European and American elm species are highly susceptible to the disease; a mature elm tree can die in as little as two weeks after infection. For this reason, scientists believe the fungus is a recent introduction to these continents. Genetic and physiological analyses of the fungus involved in the most recent European outbreak (mid-1960s) have shown it to be very different from previous strains, and so it is described as a new species: *Ophiostoma novo-ulmi*. For European and American elm trees, this new species is much more virulent than its predecessors.

In North America, Dutch elm disease was first reported in Ohio in 1930. Its origins have been traced to a shipment of infected logs from Europe. Within two years, the disease had reached the Atlantic seaboard. Spread from tree to tree by the elm bark beetle, the fungus reached the Pacific Coast by 1970. Today, it is estimated that over 70 percent of American elm trees have died of the disease. In many areas, once plentiful elms no longer can be found.

Interestingly, this ongoing outbreak of Dutch elm disease may not be the elm's first encounter with this disease. By analyzing levels of fossilized pollen found in peat deposits, researchers have concluded that elm populations in Europe decreased dramatically about 6,000 years ago. Possibly, this decline was caused by climate change or the activities of humans. Alternatively, it may have been caused by a pathogen. Over the past few decades, at least two pieces of evidence have emerged that support this last hypothesis. First, the existence of elm bark beetles from this period has been documented. Second, researchers have identified pieces of elm wood from this period that exhibit elm bark beetle markings. Perhaps these beetles transferred a fungus similar to *O. novo-ulmi* from tree to tree, just as they do today. Perhaps a historical analysis of elm trees and elm bark beetles can shed light on our current elm tree decline.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

Like viral and bacterial pathogens, eukaryal pathogens must gain access to a host, evade host defenses, and obtain nutrients.

- Microbes in Focus 23.1: An AIDS-defining opportunistic infection: *Toxoplasma gondii*
- Mini-Paper: An experimental system for the genomic study of Dutch elm disease
- Figure 23.9: Fungal invasion of plants
- Figure 23.14: Role of toxin production by dinoflagellates

The eukaryal microorganism *Plasmodium falciparum* causes malaria, one of the most devastating infectious diseases of humans.

- Figure 23.15: Global presence of malaria
- Figure 23.16: Process Diagram: *Plasmodium falciparum* life cycle
- Figure 23.17: Merozoite surface proteins (MSPs) and *Plasmodium falciparum* invasion of erythrocytes

Macroscopic eukarya, especially helminths, cause significant human disease.

- Table 23.4: Representative parasitic worms of humans
- Microbes in Focus 23.5: *Ascaris lumbricoides*: A roundworm parasite of humans

Eukaryal pathogens, like their bacterial and viral counterparts, exhibit specific properties associated with virulence.

CONNECTIONS for this chapter:

Endospore formation in bacteria **(Section 2.4)**

Fermentation and lactic acid production **(Section 13.3)**

Mechanism of action of botulinum toxin **(Section 21.1)**

Viral reassortment and changes in virulence **(Section 22.4)**

Introduction

In this chapter, we will investigate eukaryal pathogens. As we noted in Chapter 3, eukaryal microorganisms share a number of fundamental properties with eukaryal cells of multicellular species. However, a great deal of diversity also exists within members of this group. Fungi, algae, and slime molds, for example, all differ significantly from each other. So, what can we predict about eukaryal pathogens? Do eukaryal pathogens exhibit a great deal of diversity? Do eukaryal pathogens share any attributes? Do eukaryal pathogens share any attributes with bacterial or viral pathogens?

We should begin our investigation of these microorganisms by reminding ourselves that disease really can be thought of as an unintended outcome of pathogen replication. Eukaryal microbes, as we discussed for bacteria and viruses, do not want to cause disease (of course, microbes actually do not *want* to do anything!). Rather, microbes need to obtain nutrients in order to replicate. Many eukaryal microbes obtain nutrients without interacting with a host. For instance, algae obtain most of their required nutrients via photosynthesis. A host organism is not required, and as a result, these algae are not pathogens. Many fungi are saprophytes, obtaining nutrients from dead and decaying organic matter. Again, the fungi do not interact with a living host and, consequently, are not pathogens. Other eukaryal microorganisms may interact with a host in a symbiotic, but not parasitic, fashion. As we discussed in Section 17.3, for instance, lichens represent a mutualistic relationship between fungi and certain algal or cyanobacterial species. Other eukaryal microorganisms, most notably various protozoa and yeast, reside within the digestive tract of cows and other ruminants, aiding in their digestive processes. Again, the eukaryal organisms are not pathogens in these cases.

As we saw with bacteria and viruses, several eukaryal microorganisms do cause harm to host organisms and, as a result, are classified as pathogens. In fact, a specific eukaryal microorganism, *Plasmodium falciparum*, is one of the deadliest of all human pathogens. It causes 300–500 million cases of malaria, resulting in one to two million deaths, annually. In this chapter, we will investigate *P. falciparum* and other eukaryal pathogens. In the process, we will note the basic similarities between these pathogens and the pathogenic bacteria and viruses that we examined in the two preceding chapters. Although we will not provide a comprehensive listing of eukaryal pathogens, we will highlight a few key organisms that illustrate our main points. To organize our discussion, we will focus on these fundamental questions:

How do pathogenic eukarya cause disease? (23.1)
How does *Plasmodium falciparum* cause malaria? (23.2)
What do we know about macroscopic eukaryal pathogens? (23.3)
How do some eukaryal organisms become pathogens? (23.4)

23.1 Mechanisms of eukaryal pathogenesis

How do pathogenic eukarya cause disease?

Perhaps it should not be surprising that there are general patterns in how bacteria, viruses, and eukarya cause disease. Like pathogenic bacteria and viruses, pathogenic eukarya must be transmitted from host to host. Many of these pathogens possess specific mechanisms for getting into a host, and certain eukaryal pathogens also possess specific adherence factors that allow them to attach to or enter specific cell types. Once eukaryal pathogens are attached to or are within a host cell, they need to evade host defense mechanisms. Some eukaryal microorganisms cause disease only when the immune system of the host becomes compromised. Other eukaryal microorganisms more actively evade host defense mechanisms by continually altering molecules on their cell surface that elicit a host immune response. Like viruses and bacterial pathogens, eukaryal pathogens also obtain nutrients from their hosts in very specific ways. Some, as we will see in this chapter, produce specific enzymes that digest structural components of the host cell. Others simply penetrate the host cell through brute force. Finally, eukaryal pathogens often produce toxins, factors that damage the host. However, the role of toxins produced by eukaryal pathogens is less well understood than the role of their bacterial counterparts.

Transmission, entry, and adhesion

To initiate an infection, a pathogen must be transmitted between appropriate hosts, gain entry into these hosts, and then, in many cases, attach to specific cells within that host. As we saw in Chapters 21 and 22, bacteria and viruses enter hosts through a variety of mechanisms. Specific protein:protein interactions between an attachment protein on the pathogen and a cellular receptor generally facilitate attachment to specific cells within the host. Pathogenic eukaryal microorganisms use these same basic methods.

In the opening story of this chapter, we introduced *Ophiostoma novo-ulmi*, the causative agent of Dutch elm disease, This pathogenic eukaryal microorganism relies on the help of an insect to be transmitted from tree to tree. The fungus has an interesting relationship with certain bark-burrowing beetle species of which the European elm bark beetle is the most common. Typically, the fungus spreads throughout the tree in xylem tissue, clogging the water-conducting vessels as it grows, eventually killing the tree. The beetles burrow into the bark of the dead branches to lay their eggs. The egg-filled brood chambers provide open spaces for the fungus to grow and form spores, while the beetles hatch and develop. Adult beetles

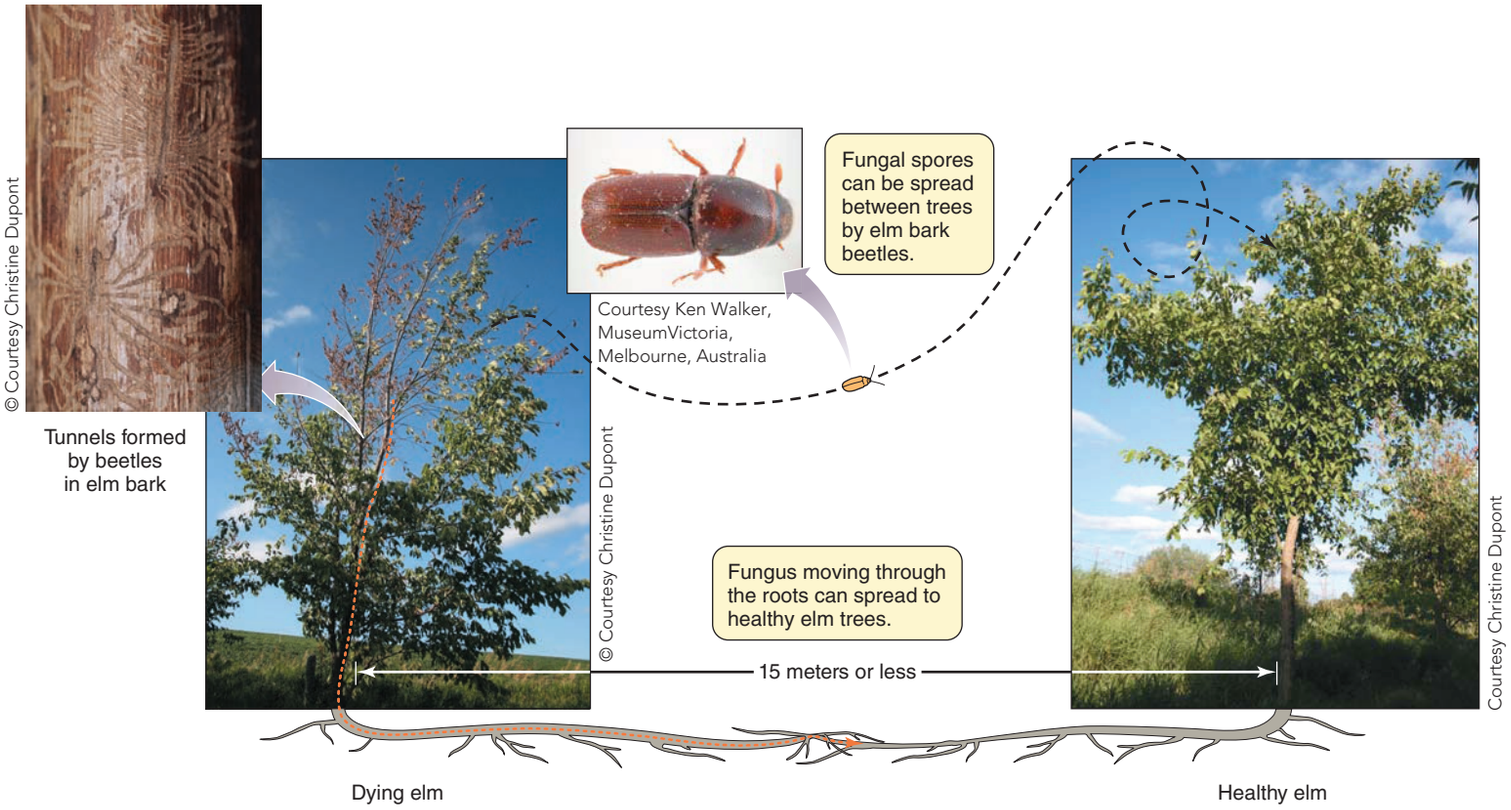

Figure 23.1. Transmission of Dutch elm disease Elm bark beetles transmit the fungus that causes Dutch elm disease quite effectively. The beetles burrow in the bark of diseased trees, forming tunnels, and lay their eggs. Sticky fungal spores become deposited in these tunnels. When beetles hatch and emerge from the tree, they carry spores with them that can infect healthy trees. If trees are close together, the fungus can move between trees via the roots.

emerge from the tree covered in fungal spores, and fly off to feed on new, young bark. The spores gain entry to a new tree in this way, using the beetles to transmit them. As a result, the fungus spreads rapidly (Figure 23.1).

CONNECTIONS We discussed bacterial endospore formation in **Section 2.4**. Both fungal spores and bacterial endospores are environmentally stable structures. However, endospores of bacteria and spores of fungi differ substantially. Fungal spores are reproductive bodies. Bacterial endospores are non-reproductive, dormant structures. Also, bacterial endospores typically are much more stable than fungal spores.

In contrast to *Ophiostoma novo-ulmi*, the protozoan *Plasmodium falciparum* exhibits a more complex life cycle. It needs to infect two or more species to complete its life cycle. This pathogen, the major cause of malaria, spends part of its life cycle in mosquitoes and part of its life cycle in humans. Female *Anopheles* mosquitoes serve as the **definitive host**, the host in which the pathogen replicates sexually. When taking a blood meal, these mosquitoes then can transfer the parasites to a human, the **intermediate host**. Within the intermediate host, the parasite replicates asexually and differentiates (Figure 23.2). We will explore the details of *Plasmodium falciparum* replication in Section 23.2.

Unlike *Plasmodium falciparum*, *Giardia lamblia*, a protozoan we first encountered in Section 3.2, completes its life cycle entirely within a single species. This parasite causes diarrhea in many species of mammals and typically is transmitted through the ingestion of water or contaminated foods that contain giardial cysts. Mature cysts contain four nuclei. Following ingestion, excystation occurs, releasing from each cyst two binucleated **trophozoites**, which are the active feeding forms of protozoan parasites. The trophozoites replicate within the small intestine. As trophozoites progress through the small intestine and enter the large intestine, they undergo encystation, forming cysts, which then are eliminated in the host's feces (Figure 23.3).

Once pathogens enter a host, they often attach to and enter specific cells within the host. In many cases, this interaction with host cells plays a very direct role in disease. For example, the trophozoites of *Giardia* attach to the epithelial cells of the small intestine. In some cases, the trophozoites virtually cover the lining of the small intestine (Figure 23.4). The attachment appears to be mediated by a specific giardial structure: the ventral disk. Disruption of the ventral disk decreases the ability of the trophozoites to adhere to cells. More importantly, the adherence of *Giardia* to the intestinal epithelia probably contributes to its pathogenesis. Although researchers do not fully understand how *G. lamblia* causes diarrhea, many investigators postulate that the attachment of the trophozoites to the lining of the small intestine disrupts nutrient adsorption that normally occurs there. Diarrhea results from this disruption. We can see from this example that a better understanding of *Giardia* attachment may lead to the development of new treatments for this pathogen. If we can block the attachment of giardial cells, then we may prevent the signs of giardial disease.

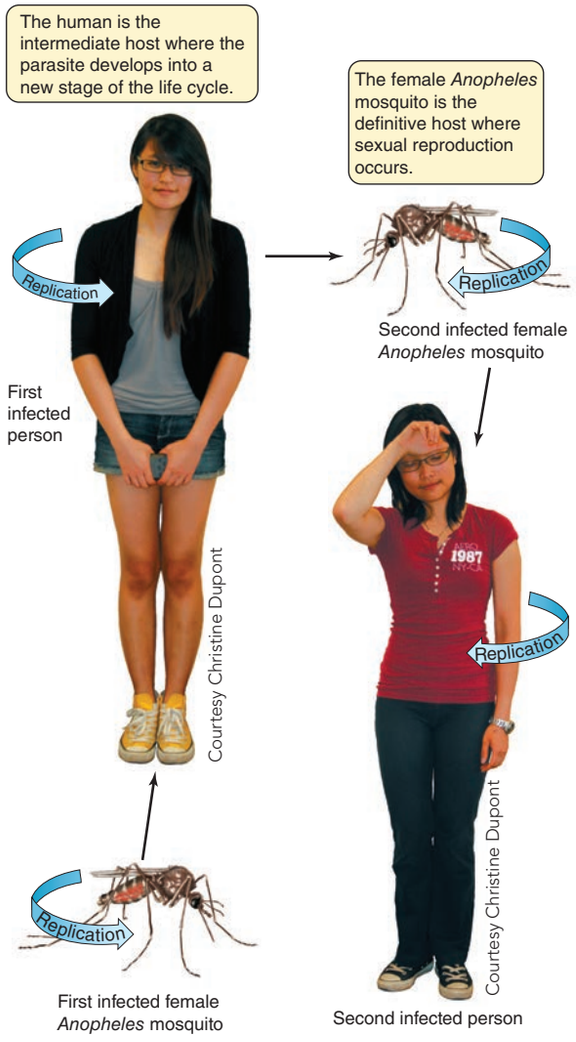

Figure 23.2. Complex life cycle of *Plasmodium falciparum* The protozoan that causes malaria, *Plasmodium falciparum*, requires two hosts to replicate—mosquitoes and humans. When an infected female *Anopheles* mosquito, the definitive host, bites a human, the protozoa enter this new host. Within the human, the intermediate host, the parasites differentiate and replicate asexually. Once released into the bloodstream of the infected human, *P. falciparum* can be ingested by another feeding mosquito, where the pathogen then completes its life cycle and can be transmitted to a second person.

Host organisms have evolved various ways of preventing, or attempting to prevent, the entry and adherence of eukaryal microorganisms. A more detailed understanding of these natural processes may allow us to develop more effective prevention and treatment strategies. To more fully understand the interactions between hosts and pathogens, a good *in vitro* experimental system often is necessary; research on whole organisms often is not feasible. To better understand how elm trees respond naturally to fungal infections, researchers have begun investigating the responses of elm tree cell cultures to *Ophiostoma novo-ulmi* **(Mini-Paper)**. These studies may lead to further improvements in resistance of elm varieties and the return of this majestic tree.

Evading host defenses

For a pathogen, simply entering a host and attaching to appropriate cells within the host is not enough. To cause disease, a pathogen also must evade various host defenses. Bacterial and viral pathogens achieve this goal in many diverse ways. Eukaryal pathogens are no different. Some eukaryal pathogens become pathogenic only when the host's immune system is suppressed. Others cause disease when the ecology of the host changes in

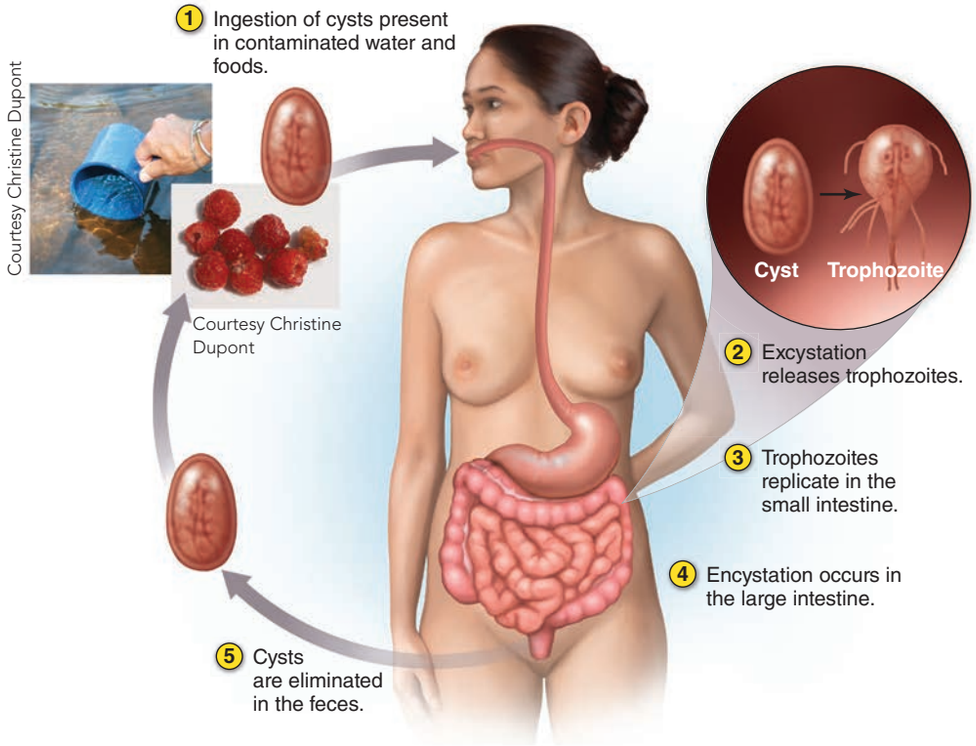

Figure 23.3. Process Diagram: Simple life cycle of *Giardia lamblia* Humans may ingest giardial cysts by drinking contaminated water or eating foods covered with the cysts. Within the body, excystation occurs, releasing trophozoites. This active feeding form of the organism replicates within the small intestine in the host. In the large intestine, encystation occurs and the resulting cysts are eliminated in the feces.

Figure 23.4. Attachment of *Giardia* to the lining of the small intestine During an infection, large numbers of *Giardia* attach to the lining of the small intestine. Some researchers hypothesize that this attachment interferes with normal adsorption of nutrients in the host, leading to disease.

some fundamental way. Still other pathogens actively deceive the host immune system. To investigate these mechanisms of circumventing host defenses, we will focus on three representative eukaryal pathogens of humans—the fungi *Pneumocystis jirovecii* and *Candida albicans* and the protozoan *Trypanosoma brucei*—examining how each of these organisms survives within a host.

The Immunocompromised Host

As we discussed in Section 18.1, some microbes can be classified as opportunistic pathogens; they generally do not cause disease in a healthy host, but can cause disease if the ecology of the host is altered in some way. More specifically, they cause disease when conditions within the host are altered such that replication of the microbe can increase. A decrease in the effectiveness of the host's immune system represents a classic change in the host that facilitates the increased replication of a pathogen.

As we noted in Chapters 19 and 20, eukarya possess complex and highly effective means of controlling microbial infections. However, this barrier to infectious diseases can be compromised under certain circumstances. For example, when people receive an organ transplant, they typically are given immunosuppressive drugs, drugs that inhibit or decrease the activity of certain aspects of the immune system. By intentionally impairing the immune system in this way, physicians can decrease the likelihood that the organ recipient will reject the donated organ. This type of treatment also makes the patient immunocompromised. Immunosuppression also may be caused by a microbial infection. As we discussed in Section 8.2, HIV replicates in, and ultimately destroys $CD4^+$ cells, a critical component of the human immune system. By destroying this key component of the human immune system, HIV leads to the development of acquired immunodeficiency syndrome, or AIDS. A person living with AIDS is immunocompromised and more susceptible to opportunistic infections.

In people living with HIV/AIDS, a number of fungal and protozoal opportunistic infections can occur as a result of the decreased number of $CD4^+$ cells present **(Table 23.1)**. In fact, the presence of opportunistic infections has become a defining characteristic of HIV disease. Indeed, physicians noted the first cases of AIDS, reported in June of 1981, primarily because

TABLE 23.1 Fungal and protozoal opportunistic infections associated with AIDS

	Organism	Disease
Fungi	*Candida albicans*	Thrush
	Histoplasma capsulatum	Pneumonia
	Pneumocystis jirovecii	Pneumonia
Protozoa	*Toxoplasma gondii*	Encephalitis
	Cryptosporidium muris	Gastroenteritis
	Isospora belli	Gastroenteritis

Note: A number of viruses and bacteria also result in opportunistic infections in people with HIV/AIDS. The Centers for Disease Control and Prevention (CDC) maintains a list of all AIDS-defining opportunistic infections.

the patients had one or more opportunistic infections. Most notably, *Pneumocystis jirovecii* (previously referred to as *Pneumocystis carinii*) and *Toxoplasma gondii* **(Microbes in Focus 23.1)** are two eukaryal microorganisms that often infected people with HIV/AIDS.

Pneumocystis jirovecii, a fungus found widely in the environment, appears to reside frequently in the lungs of humans. Antibodies to *P. jirovecii* can be found in most children, indicating typical exposure to this microbe at a young age. *P. jirovecii* also has been identified in 20 percent of healthy immunocompetent adults. This suggests that a portion of the population may be asymptomatic carriers of this microorganism.

Although *P. jirovecii* may be a relatively common inhabitant of our lungs, *P. jirovecii*-associated disease is not common.

Microbes in Focus 23.1
AN AIDS-DEFINING OPPORTUNISTIC INFECTION: *TOXOPLASMA GONDII*

Habitat: Has been found in many species of mammals and birds, although cats are considered the primary host. Oocysts can develop only in members of the family *Felidae*. Roughly 20 percent of humans, a dead-end host, may be harboring *T. gondii* asymptomatically.

Description: Protozoan with infectious oocysts approximately 10 μm in diameter and tachyzoites, which replicate asexually and cause disease, measuring 6 μm × 2 μm

Key Features: In people with HIV disease, *T. gondii* can spread to the brain, causing cerebral toxoplasmosis. Toxoplasmosis can lead to inflammation of the brain, which then can lead to vision problems, severe headaches, and in extreme cases, coma and death. Some reports also have linked *T. gondii* infections to schizophrenia.

Mini-Paper: A Focus on the Research

AN EXPERIMENTAL SYSTEM FOR THE GENOMIC STUDY OF DUTCH ELM DISEASE

M. Aoun, D. Rioux, M. Simard, and L. Bernier. 2009. Fungal colonization and host defense reactions in *Ulmus americana* callus cultures inoculated with *Ophiostoma novo-ulmi*. Phytopathology 99:642–650.

Context

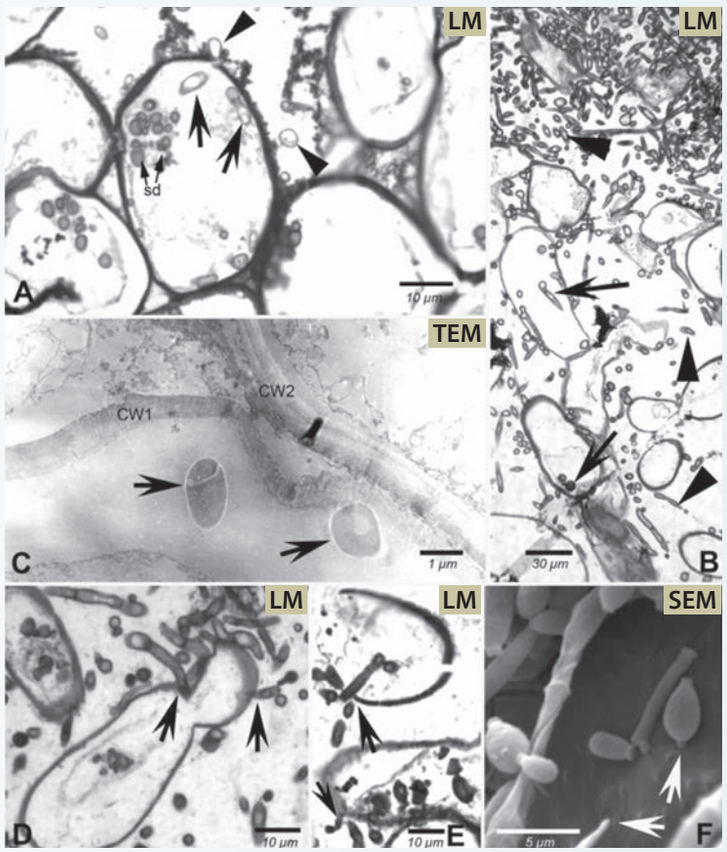
The catastrophic losses of elm trees due to Dutch elm disease, caused by the pathogenic fungus *Ophiostoma novo-ulmi*, have spurred efforts to develop disease-resistant elm varieties. These efforts have resulted in the identification and planting of a number of partially resistant varieties of the American elm, *Ulmus americana*. Traditionally, studies of this host-pathogen interaction have been conducted on young saplings, but this approach limits the extent of the research that can be conducted. The controlled manipulation of saplings and inoculation of these saplings with *O. novo-ulmi* can be difficult. *In vitro* studies provide researchers with the ability to control experimental conditions much more precisely.

Luckily, cells of the American elm, like the cells of many other plants, can be grown in the laboratory. The replication of these cells in culture requires externally supplied plant hormones that promote the growth and division of the plant cells without causing them to differentiate into different cell types. When these cultures grow on solid media, researchers call them "callus cultures." Because the environmental conditions of callus cultures can be controlled very precisely, callus cultures provide researchers with the opportunity to do thorough studies of Dutch elm disease. In this paper, the researchers demonstrate that elm callus cultures can become infected by *O. novo-ulmi*. The investigators also examined the cellular responses to fungal colonization of elm callus cultures. They show that these cultures appear to respond to the fungus in a manner similar to cells of intact elm saplings.

Experiments

To begin these experiments, the researchers first established the callus cultures. The cultures were initiated from tissue cuttings from either buds of mature trees or young leaves that emerged immediately after seed germination. The original plants were not resistant to infection by *O. novo-ulmi*. The formation of callus cultures from these cuttings on solid media was promoted by the addition to the plant growth media of naphthaleneacetic acid and benzyl adenine, which act as plant hormones. In the presence of these hormones, buds gave rise to hard callus cultures. Young leaves, in contrast, gave rise to friable, or less compact, callus cultures. Once a callus culture formed, the researchers could propagate it by inoculating fresh media with small pieces of the callus.

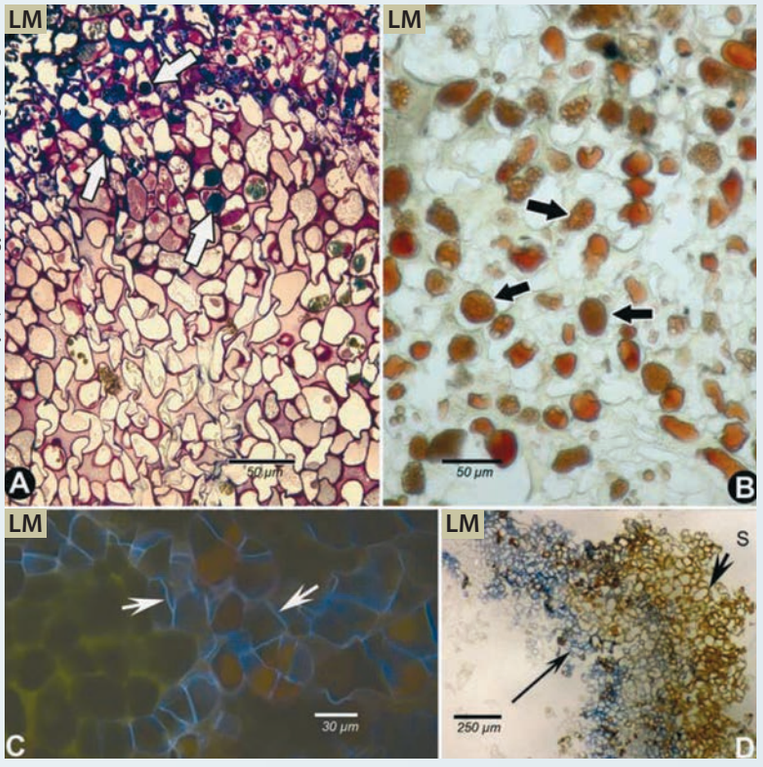
Initially, the investigators determined whether the fungus could infect these *in vitro* cultures. To infect the callus cultures with *O. novo-ulmi*, the investigators simply added a small amount of fungus to a piece of filter paper and then laid it on the elm cells. The fungal cells grew very poorly on the plant growth media in the absence of the elm cells and did not form spore-bearing conidia. In contrast, they grew well on the callus cultures and formed conidia. Microscopic study of the infected callus cultures **(Figure B23.1)** showed the presence of fungal cells, both between cells and within plant cells, indicating that the fungus initiated a genuine infection.



Aoun, M., Rioux, D., Simard, M., Bernier, L. 2009, Phytopathology 99:642-650, Figure 1.

Figure B23.1. Infection of callus cultures by *Ophiostoma novo-ulmi*
Following inoculation of callus cultures with *Ophiostoma novo-ulmi*, fungal cells, indicated by the arrow heads in panels A, B, and C, were observed between and within the plant cells. Additionally, fungal cells appeared to penetrate the cell walls of elm callus cells, as noted by the arrows in panels D, E, and F. sd: starch deposits. CW1 and CW2: callus cell walls.

To analyze the effect of this infection on the callus cells, the researchers investigated the response of the callus cultures to the fungal infection. Previous researchers had shown that elm saplings and leaves respond in very defined ways to fungal infections. Most notably, cells in elm trees infected with *O. novo-ulmi* produce various compounds, including phenolic compounds and tannins. Additionally, infected trees produce increased amounts of suberin, a hydrophobic waxy substance, and lignin, a complex chemical substance that contributes to the strength of wood. All of these compounds function as defense mechanisms for the trees. These same compounds accumulated in the callus cells following infection **(Figure B23.2)**. The callus cultures appear to respond to infection in a manner similar to that of the plant.



Aoun, M., Rioux, D., Simard, M., Bernier, L. 2009, Phytopathology 99:642-650, Figure 3.

Figure B23.2. Callus cell responses to infection After being infected with *O. novo-ulmi*, cells in the callus cultures responded by producing various substances produced by infected trees. **A.** Blue stain (indicated by arrows) indicates deposits of phenolic compounds. **B.** Deposits of tannins, like catechin, in cells are indicated by arrows. **C.** Suberin (purple, indicated by arrows) accumulates around the cell walls. **D.** In a section of a callus culture, lignified cells (indicated by short arrow) appear along the surface of the callus. Suberin (indicated by the long arrow) appears in cells in the internal part of the callus.

In addition to producing compounds typically associated with infections, cells of the callus cultures also exhibited increased expression of the PAL gene. This gene encodes the enzyme phenylalanine ammonia lyase, a central enzyme involved in the pathway leading to the formation of several different phenolic compounds. Elevated PAL expression is commonly associated with host defense response. The levels of PAL transcript in infected callus cultures were evaluated using the RT-PCR technique as described in Toolbox 5.2. Increased expression clearly was associated with infection, as it would be in whole plants.

Impact

In anticipation of the completion of the *O. novo-ulmi* genome sequence, researchers hope to conduct detailed studies on the pathogenicity of Dutch elm disease, using functional genomic methods like transcriptomics and proteomics. These studies would be easier to conduct in callus cultures, rather than in mature plants or seedlings. Most obviously, many more replicates could be tested under many different conditions. With this in mind, investigators first needed to demonstrate that infection studies could in fact be done in callus culture. As Aoun and colleagues have shown, the fungus clearly infects the callus cells, and the infection results in many of the expected responses, including upregulation of PAL, a key infection response-related gene. Based on this study, it should be possible to use the genomics tools along with microscopy to study the molecular mechanisms of infection. Particularly important studies will involve comparing the response to infection of callus cells from pathogen-susceptible and pathogen-resistant lines. These types of studies could result not only in the development of improved resistant lines of American elm, but also in a greater understanding of how fungal plant pathogens operate.

Questions for Discussion

1. The callus cultures that were used in this study were derived from plants that were not resistant to *O. novo-ulmi* infection. Would you expect a callus derived from resistant plants to respond to inoculation with the fungus differently than these callus cultures do?
2. Why do you think it is necessary to provide plant hormones in order for a callus to form?

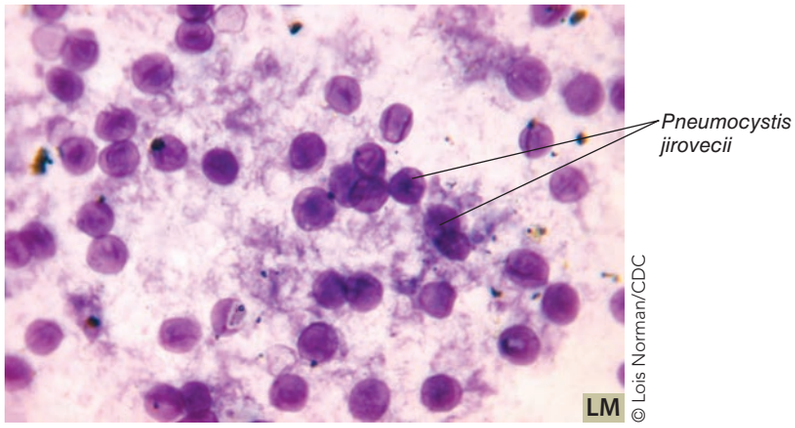


Figure 23.5. *Pneumocystis jirovecii* When *Pneumocystis jirovecii* replicates within the lung, it fills the air spaces, resulting in impaired breathing. Shown here are *P. jirovecii* cells isolated from lung tissue.

However, replication of the fungus is poorly regulated in immunocompromised people. As it replicates, it fills the air spaces within the lungs, resulting in *Pneumocystis* pneumonia, or PCP **(Figure 23.5)**. Patients develop difficulty breathing and, in the absence of treatment, the disease typically is fatal. Despite advances in treatment and prevention, *P. jirovecii* remains a leading opportunistic infection among people with HIV disease **(Perspective 23.1)**.

Altered Microbiota of the Host

The fungus *Candida albicans* is another opportunistic pathogen commonly associated with HIV disease. Like *P. jirovecii*, *C. albicans* replicates more extensively in people with a weakened immune system. Because this yeast often resides within the mouth and throat, a condition known as oral thrush develops when the fungus grows unchecked in these locations. White lesions appear on the tongue and cheeks **(Figure 23.6)**. In severe cases, the fungal growth may clog the esophagus, leading to difficulty swallowing.

Figure 23.6. Oral thrush caused by *Candida albicans* *Candida albicans* is an opportunistic pathogen and frequent resident of the human mouth and throat. Normally, the host controls its growth. However, growth increases in immunocompromised hosts, resulting in thick white lesions such as those seen here.

Candida albicans also causes disease quite frequently in immunocompetent people. In these cases, the host ecology again is altered, but the immune system remains intact. In other words, the normal microbial inhabitants of the host change and, as a result, the environment becomes more hospitable for the growth of this fungus. As we saw in Section 17.3, *C. albicans* normally is a commensal inhabitant of many people, found not only in the mouth and throat, but also in the rectum and vagina. Within the vagina of healthy women, bacteria in the *Lactobacillus* genus create a slightly acidic environment, which limits the growth of *C. albicans*.

CONNECTIONS Why would fermentation result in an acidic environment? Lactic acid bacteria (LAB), which include genera such as *Streptococcus*, *Lactobacillus*, and *Bifidobacterium*, use the enzyme lactate dehydrogenase to convert pyruvate to lactic acid **(Section 13.3)**.

Given this information, we can reason that the elimination of lactobacilli from the vagina would result in an increase in the vaginal pH. In turn, the increased pH would make the environment more hospitable for *C. albicans*. When the population of *C. albicans* in the vagina increases, disease ensues. Itching or burning results from irritation of the vaginal lining caused by the yeast. What would lead to the elimination of lactobacilli in the vagina? Lactobacillus populations decrease when a woman takes antibiotics. Although antibiotics may be taken to eliminate another species of bacteria, lactobacilli also are eliminated. As a result of these microbial community changes, *C. albicans* can flourish.

Antigenic Variation in the Pathogen

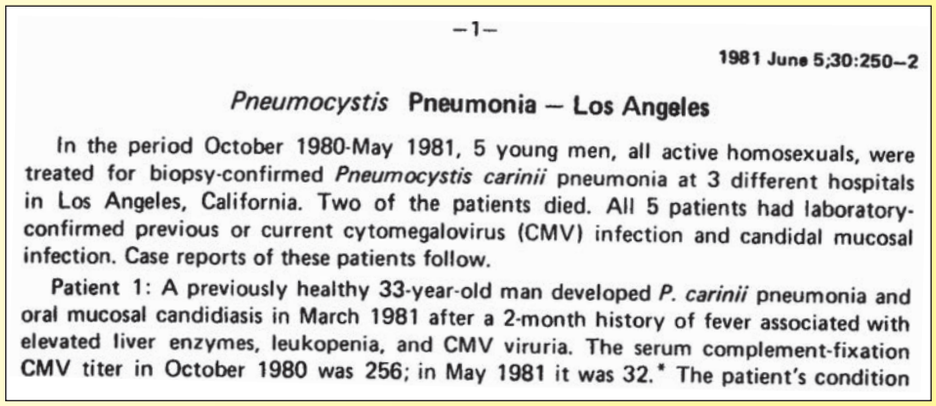
Although some eukaryal microorganisms do not cause disease unless the host's immune system fails, other organisms cause disease even in the presence of a strong immune response. These organisms have evolved a mechanism for evading the immune response: antigenic variation. Trypanosomes present a remarkable example of this strategy (see Figure 18.5). These organisms are characterized by a single flagellum and a **kinetoplast**, a large mass of DNA within their single mitochondrion. Species within the genus *Trypanosoma* and the related genus *Leishmania* cause some of the most devastating human diseases **(Table 23.2)**.

The most medically relevant trypanosomes have complex life cycles that involve replication in both an insect and a mammal. *Trypanosoma brucei* subspecies **(Microbes in Focus 23.2)** present a perfect example. When a tsetse fly ingests these protozoa after biting an infected mammal, the parasites differentiate and replicate within the midgut of the tsetse fly. The parasite then differentiates more and travels from the midgut to the salivary gland of the fly, where additional replication occurs. When an infected fly bites a mammal, the trypanosomes can be transmitted to the bloodstream of the mammal, where they differentiate, replicate, and can be transferred throughout the body. The life cycle can begin again when another tsetse

Perspective 23.1

PNEUMOCYSTIS JIROVECII OR *CARINII*: THE EVOLVING FIELD OF TAXONOMY

The name *Pneumocystis carinii* has permeated the infectious disease literature since 1981, when scientific reports of HIV/AIDS were first published. Indeed, the very first report on what we now know as HIV/AIDS was titled, "*Pneumocystis* Pneumonia–Los Angeles," and focused on five men with "*Pneumocystis carinii* pneumonia," or PCP **(Figure B23.3)**. At the 2001 International Workshop on Opportunistic Protists, though, investigators proposed that the causative agent of this pneumonia be renamed. Today, we refer to it as *Pneumocystis jirovecii*. The name pays homage to the Czech microbiologist Otto Jirovec, the person credited with first documenting *Pneumocystis* infections in humans.



—1—

1981 June 5;30:250–2

Pneumocystis Pneumonia — Los Angeles

In the period October 1980-May 1981, 5 young men, all active homosexuals, were treated for biopsy-confirmed *Pneumocystis carinii* pneumonia at 3 different hospitals in Los Angeles, California. Two of the patients died. All 5 patients had laboratory-confirmed previous or current cytomegalovirus (CMV) infection and candidal mucosal infection. Case reports of these patients follow.

Patient 1: A previously healthy 33-year-old man developed *P. carinii* pneumonia and oral mucosal candidiasis in March 1981 after a 2-month history of fever associated with elevated liver enzymes, leukopenia, and CMV viruria. The serum complement-fixation CMV titer in October 1980 was 256; in May 1981 it was 32.* The patient's condition

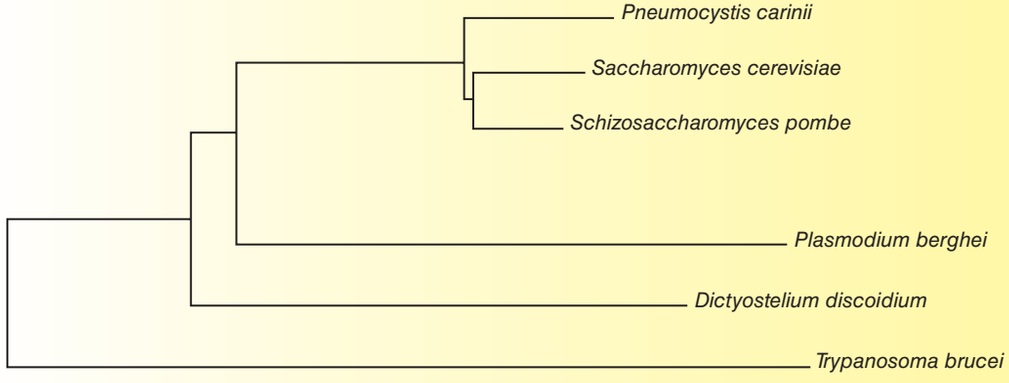
Courtesy CDC

Figure B23.3. *Pneumocystis carinii* pneumonia: The beginning of the AIDS pandemic The first scientific report related to HIV/AIDS was published in June of 1981 in *Morbidity and Mortality Weekly Report* (*MMWR*), a publication of the Centers for Disease Control and Prevention. The article profiled five young men who had *Pneumocystis carinii* (now *P. jirovecii*) pneumonia, a disease normally seen only in immunocompromised people.

One could argue that this name change matters little. After all, as Shakespeare once wrote, "What's in a name? That which we call a rose by any other name would smell as sweet." Although a name may not matter, the taxonomy, or classification, of an organism is very important. Since the 1980s, our understanding of the taxonomy of the causative agent of PCP has changed. Prior to 1988, researchers were unsure if this organism was a fungus or a protozoan. The confusion stemmed from several atypical features of the organism. Most notably, it lacks some features common to fungi and structurally resembles some protozoa. Additionally, it exhibits resistance to several antifungal drugs and exhibits sensitivity to several antiprotozoal drugs. SSU rRNA sequence analysis, however, demonstrates convincingly that *Pneumocystis* species are fungi **(Figure B23.4)**.

More recently, additional DNA sequence analyses have shown that *Pneumocystis* organisms infecting humans are genetically distinct from *Pneumocystis* organisms isolated from other mammalian hosts. Researchers have interpreted this information as evidence that a unique species of *Pneumocystis* infects humans. Because a unique species infects humans, researchers proposed the new name for the *Pneumocystis* variant found in humans: *P. jirovecii*. The initials PCP, however, have become so entrenched in the biological literature that researchers continue to use them. These initials now refer simply to *Pneumocystis* pneumonia.

The story of *Pneumocystis jirovecii* highlights the changing field of biological taxonomy. With newer and more sophisticated molecular tools at our disposal, the taxonomic classification of an organism no longer is based solely on its physical attributes. Increasingly, molecular information helps us better understand the classification of organisms.



From J. C. Edman, J. A. Kovacs, H. Masur, et al. 1988. Ribosomal RNA sequence shows *Pneumocystis carinii* to be a member of the fungi. Nature 334:519–522. Reprinted with permission from Macmillan Publishers Ltd.

Figure B23.4. The causative agent of PCP is a fungus Until 1988, there was disagreement among microbiologists about the classification of *Pneumocystis carinii* (now *P. jirovecii*). Importantly, SSU rRNA sequence analysis showed that *P. carinii* is closely related to *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*, which are fungi, and more distantly related to protozoa such as *Plasmodium berghei, Dictyostelium discoidium,* and *Trypanosoma brucei*. This evidence confirmed that *P. jirovecii* is a fungus.

TABLE 23.2 Selected medically important trypanosomes

Parasite	Geographic distribution	Host species	Vector	Disease
Trypanosoma brucei gambiense	West Africa	Humans	Tsetse fly	Sleeping sickness (chronic)
Trypanosoma brucei rhodesiense	East Africa	Humans	Tsetse fly	Sleeping sickness (acute)
Trypanosoma brucei brucei	Africa	Cattle, antelope, horses	Tsetse fly	Nagana
Trypanosoma cruzi	Central and South America	Humans	Kissing bug	Chagas disease
Leishmania major	Africa, Middle East	Humans	Sandfly	Dermal leishmaniasis

fly feeds on an infected mammal (Figure 23.7). Different subspecies of *T. brucei* cause the diseases African sleeping sickness in humans and nagana in cattle. In humans, the disease is characterized by recurring waves of high fever, along with headaches and joint pain. During the late stages of the disease, the parasites affect the central nervous system, resulting in extreme lethargy. A coma and, eventually, death ensue. For good reason, the geographic distribution of the tsetse fly mirrors the distribution of these trypanosomal diseases. It also is worth noting that nagana has effectively prevented the raising of cattle within large areas of the African continent. Within Africa, cattle generally are raised outside of areas in which the tsetse fly resides (Figure 23.8).

The recurring bouts of fever associated with sleeping sickness correlate with a cyclic variation in **parasitemia**, or the number of parasites present in the blood of an infected person. The fever is a manifestation of the immune system's response to the parasites. The cyclic variation in parasitemia results from the destruction of parasites present in the blood by the host immune system and subsequent emergence of an antigenic variant.

Obtaining nutrients from a host

After a pathogen has entered a host, it must obtain the nutrients necessary for replication. In some cases, as we saw earlier with the fungus *Candida albicans*, nutrients may become available because of a change in the host. Other pathogenic fungi secrete various enzymes that break down host cell barriers and allow access to nutrients. For example, many **phytopathogenic fungi**, or fungi that cause diseases in plants, secrete cellulases, pectinases, and various proteases. These enzymes degrade the plant cell wall, allowing the fungi to invade the host cells. *Ophiostoma novo-ulmi*, the causative agent of Dutch elm disease, produces several such enzymes. For instance, this pathogen produces **xylanase**, an enzyme needed to degrade hemicellulose, a major component of the plant cell wall. Once the fungus breaches the cell wall, it can obtain nutrients from the host.

Although many phytopathogenic fungi secrete various enzymes that degrade the plant cell wall, other phytopathogenic fungi use more of a brute force approach to obtaining nutrients from host cells. Fungi such as *Magnaporthe grisea* (Microbes in Focus 23.3), the causative agent of rice blast, use

Microbes in Focus 23.2
TRYPANOSOMA BRUCEI: THE CAUSE OF AFRICAN SLEEPING SICKNESS

Habitat: Requires two hosts. Subspecies replicate in tsetse flies and one or more mammalian species.

Description: Unicellular, flagellated protozoa. *Trypanosoma brucei gambiense* causes West African sleeping sickness. *Trypanosoma brucei rhodesiense* causes East African sleeping sickness. *Trypanosoma brucei brucei* causes nagana in cattle.

Key Features: The World Health Organization (WHO) estimates that there are 50,000 to 70,000 cases of trypanosomiasis annually. The effects of *T. brucei* infections of people and livestock likely have had an important impact on the history of central Africa.

© Eye of Science/Science Source

Microbes in Focus 23.3
THE RICE BLAST PATHOGEN: *MAGNAPORTHE GRISEA*

Habitat: Infects rice, barley, wheat, rye, and other related plants, causing significant crop loss every year

Description: Fungus that forms hyphae, or long, branching cells. Appressoria develop and infect tissues of the host plants.

Key Features: First seen in the United States in 1996, the fungus has been identified in countries throughout the world. There is some evidence that both the United States and the Soviet Union explored the use of *M. grisea* as a biological weapon during the Cold War. Potentially, it could be used by terrorist groups today. This fungus could devastate worldwide food supplies.

Courtesy Donald Groth, Rice Research Station, Louisiana State University

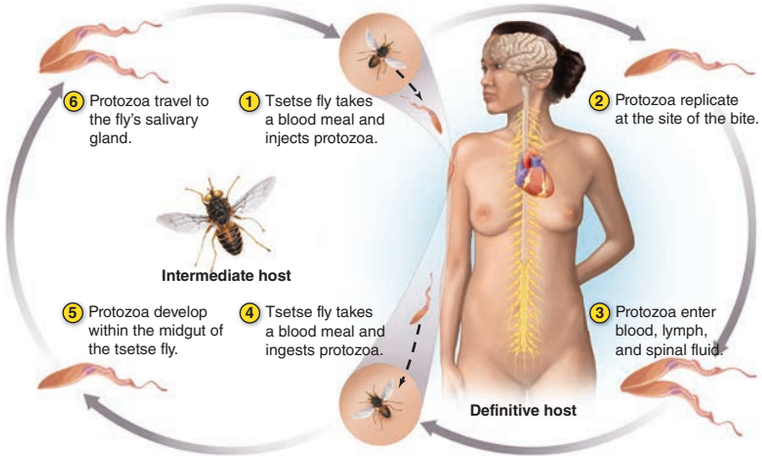


Figure 23.7. Process Diagram: Complex life cycle of *Trypanosoma brucei* subspecies Like *Plasmodium falciparum*, this protozoal pathogen completes part of its life cycle in an insect host and part of its life cycle in a vertebrate host. The pathogen differentiates and replicates within the midgut of the tsetse fly and then travels to the insect's salivary gland. Further differentiation and replication occur at this site. When the fly feeds, the parasite is transmitted to a mammal host. Within the mammal, the parasite differentiates and replicates. It also undergoes antigenic variation to evade the host immune system. The cycle begins again when another fly bites an infected mammal.

specialized cells known as **appressoria** to penetrate the tough plant cuticle. During development, hyphae extend from asexual spores, known as conidia, and develop appressoria. A penetration peg then develops from this structure. Through extreme turgor pressure, outward pressure exerted against the fungal cell wall caused by water within the cell, these extensions simply penetrate the cuticle, thereby allowing the fungus to invade the plant **(Figure 23.9)**.

Specific **mitogens**, chemicals that promote cell division, control the development of appressoria within *M. grisea* in association with a mitogen-activated protein (MAP) kinase pathway. Researchers have demonstrated that strains of *M. grisea* with mutations in the *pmk1* gene, which encodes a MAP kinase, do not produce appressoria and do not invade rice plants. Further research into this pathway may lead to the development of an effective treatment for this pathogen.

Other pathogens possess mechanisms for obtaining specific resources from the host. For instance, species within the genus *Plasmodium* can synthesize pyrimidine rings, the nitrogenous structures in the bases thymine and cytidine, but they lack the ability to synthesize purine rings, the nitrogenous structures in the bases adenine and guanine. All organisms, of course, need these chemicals for the synthesis of DNA and RNA. Rather than make their own purines, *Plasmodium* species obtain them from the host. Within an infected red blood cell, the parasite exists inside a vacuole. Embedded in the parasite's membrane are a series of purine transporter proteins. The *Plasmodium falciparum* transmembrane nucleoside transporter protein, PfNT1, has been well characterized and appears to transport hypoxanthine, a molecule similar to adenosine, from the red blood cell

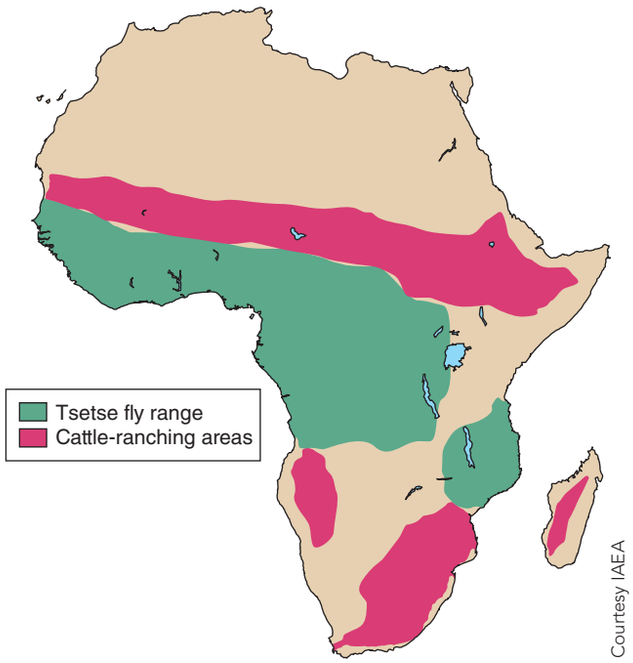

Figure 23.8. Geographic distribution of the tsetse fly in Africa Because *Trypanosoma brucei* must replicate in the tsetse fly, the distribution of trypanosomiasis in Africa mirrors the distribution of the fly. *Trypanosoma brucei* also causes disease in cattle. Areas where the tsetse fly is present, shown here in green, are inhospitable for the raising of cattle. Cattle typically are raised only in areas outside of the tsetse fly range (dark pink areas).

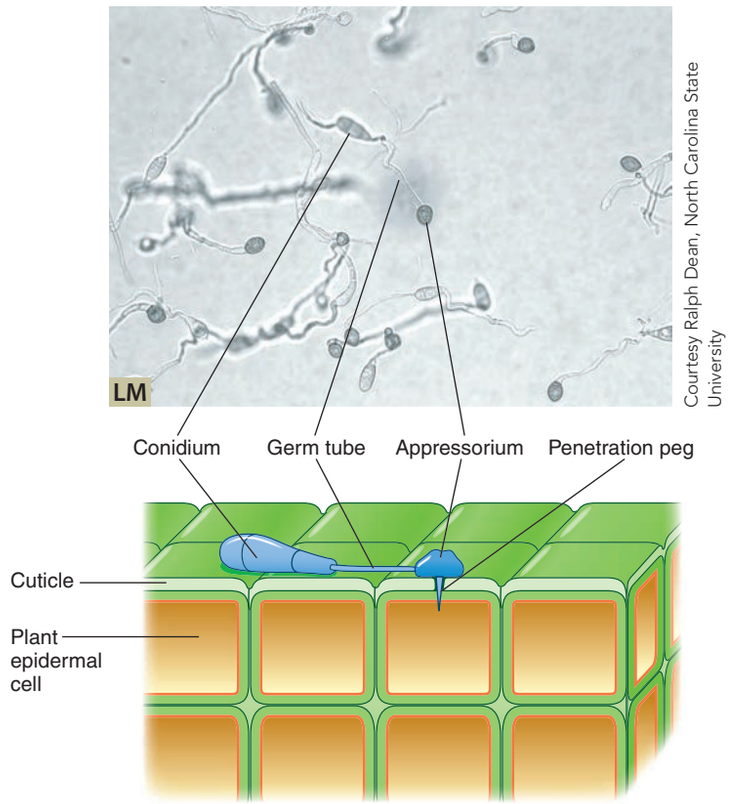

Figure 23.9. Fungal invasion of plants For some phytopathogenic fungi, asexual spores, or conidia, stick to the plant surface. A germ tube, or hypha, then grows and develops an appressorium. This structure develops a penetration peg that can enter the waxy cuticle of the plant, allowing the fungus to invade.

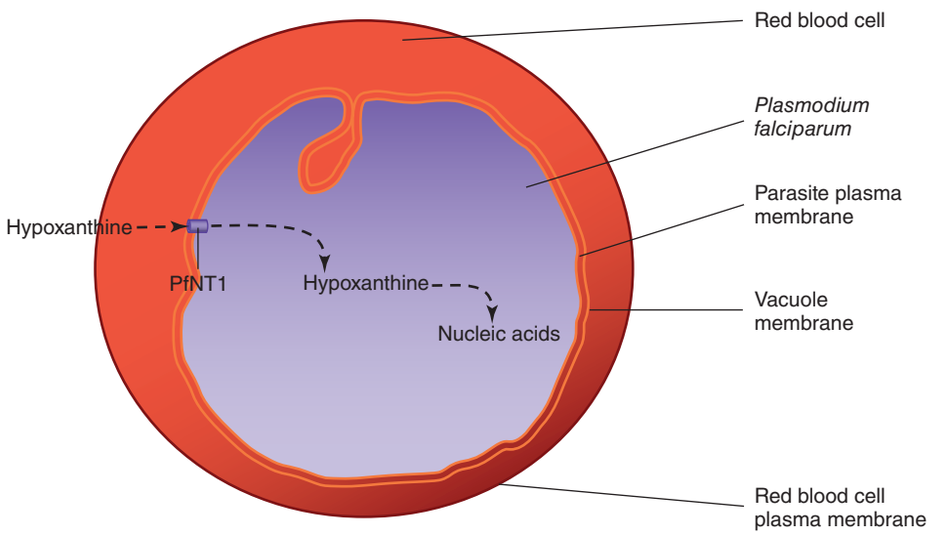

Figure 23.10. Uptake of purine precursors by *Plasmodium falciparum* Within the red blood cell, hypoxanthine enters the *P. falciparum* cytoplasm through a specific transport protein, PfNT1. Related transport proteins may transport other nucleoside-like molecules into the parasite. Within *P. falciparum*, parasite enzymes convert these molecules into nucleic acids.

cytoplasm into the cytoplasm of the parasite. Once hypoxanthine enters the parasite, various enzymes convert it to purine nucleotides (Figure 23.10). Genetic studies suggest that several additional nucleoside transporter proteins, PfNT2, PfNT3, and PfNT4, also exist within this pathogen and may be involved in the transport of other nucleosides and nucleoside-like molecules into the parasite.

Toxins of eukaryal pathogens

As we saw in Chapter 21, a number of bacterial pathogens produce toxins. Often, these toxins facilitate the transmission of the pathogen. Pathogenic strains of the bacterium *Vibrio cholerae*, for instance, express cholera toxin, a potent enterotoxin that causes the watery diarrhea associated with cholera. Most likely, the effects of the toxin allow the bacteria to exit an infected host and, eventually, infect another susceptible individual. Many eukaryal pathogens also express toxins. The effects of these toxins, and their benefits to the eukaryal pathogen, appear to be quite different from the effects and benefits of bacterial toxins.

Several phytopathogenic fungi produce virulence toxins. *Cochliobolus carbonum* (Microbes in Focus 23.4), a fungus that affects maize, produces a toxin referred to as HC-toxin. Studies have demonstrated that this toxin is necessary for the virulence of the fungus. HC-toxin functions as an inhibitor of **histone deacetylases (HDACs)**, which are cellular enzymes that remove acetyl groups (CH_3CO) from histones and, in the process, affect gene expression (Figure 23.11). It is thought that HC-toxin interferes with the expression of genes for host defense molecules, thereby allowing the fungus to colonize the host.

One of the more well-characterized toxins produced by eukaryal pathogens is **α-amanitin**, a toxin produced by mushrooms in the genus *Amanita* (Figure 23.12). Unlike other fungi we have discussed, these mushrooms do not fit our previous definition of a pathogen. They are not infectious. Rather, they can produce disease through intoxication. the ingestion of a substance that leads to a disease. The toxin α-amanitin has an LD_{50} (the dose that is lethal 50 percent of the time) in mammals of approximately 0.1 mg/kg (see Toolbox 18.1 for a review of LD_{50} values). Within a day of ingesting α-amanitin, a person often will develop gastrointestinal problems. More severe effects may occur in the liver and kidneys. The toxin causes the destruction of cells in both organs, eventually leading to liver and renal failure. Death results in about 15 percent of the people who ingest the toxin.

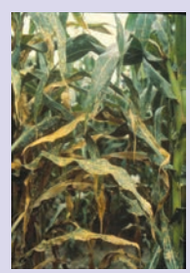
Despite rather horrible effects, the mechanism of action of α-amanitin actually is quite interesting, and researchers have exploited the toxin quite effectively. α-Amanitin binds to RNA polymerase II and inhibits the enzyme. Conversely, RNA polymerases I and III are relatively resistant to the effects of this toxin. During the 1970s, researchers used α-amanitin to investigate the respective roles of the three eukaryal RNA polymerases.

Microbes in Focus 23.4
GETTING THROUGH THE CELL WALL: LESSONS FROM *COCHLIOBOLUS CARBONUM*

Habitat: Mostly affects maize. Widespread distribution.

Description: Phytopathogenic fungus, causing ear and kernel rot and Northern corn leaf spot

Key Features: All phytopathogenic fungi need a mechanism for penetrating the plant cell wall. *Cochliobolus carbonum* produces a host of cell wall-degrading enzymes, including pectinases, xylanases, and cellulases. A single gene, *ccsnf1*, appears to regulate the production of all of these enzymes and, as a result, regulates virulence.



Courtesy Jonathan Walton, DOE Plant Research Lab, Michigan State University

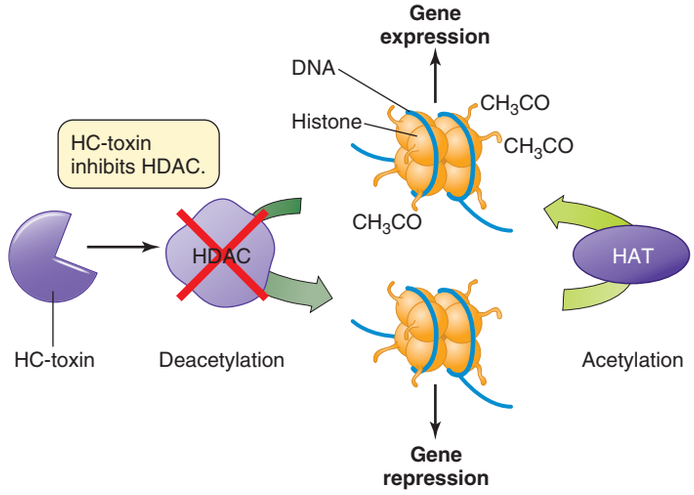


Figure 23.11. Inhibition of histone deacetylases in maize by HC-toxin HC-toxin, produced by the pathogenic fungus *Cochliobolus carbonum*, inhibits host histone deacetylases (HDACs), which remove acetyl groups (CH_3CO) from histones. Histone acetylases (HATs), conversely, acetylate histones. Generally, HDACs lead to gene repression. The exact mechanism of HC-toxin's toxicity is not completely understood.

They observed that α-amanitin reduces the production of mRNA, but not rRNA or tRNA, thereby confirming that RNA polymerase II forms messenger RNA. More recently, X-ray crystallographic studies of α-amanitin complexed with RNA polymerase II have provided insight into how this enzyme functions and have furthered our understanding of transcription.

CONNECTIONS The roles of RNA polymerases I, II, and III are discussed in **Section 7.3**. Bacteria and archaea each contain only a single type of RNA polymerase. However, the archaeal RNA polymerase more closely resembles the eukaryal RNA polymerase II than its bacterial counterpart.

Before leaving this topic, let's ask a somewhat obvious question. If α-amanitin blocks the function of RNA polymerase II and all eukarya possess RNA polymerase II, then how can the *Amanita* mushrooms survive their own toxin? The answer to this question is quite fascinating. The RNA polymerase II enzymes of various organisms, including insects, plants, and mammals, are much more sensitive to the toxin than are the RNA polymerase II enzymes isolated from fungi that produce this toxin **(Table 23.3)**. These fungi, it appears, are resistant to their own toxin; much more of the toxin is needed to reduce by 50 percent the enzymatic activity of their polymerase. Other fungi, like the mushrooms in the *Psilocybe* genus, including the notorious "magic mushrooms," also produce a toxin to which they are resistant **(Perspective 23.2)**. Most likely, these toxins serve to ward off predators.

Saxitoxin represents another well-characterized toxin produced by eukaryal microorganisms. Produced by **dinoflagellates**, a group of algae that possess two flagella, this neurotoxin functions as a sodium channel blocker, preventing the normal flow of sodium ions across the cell membrane. Ingestion of sufficient amounts of saxitoxin results in flaccid paralysis, a condition in which the muscles are limp and cannot contract. In extreme cases, respiratory failure results.

TABLE 23.3 Sensitivity of RNA polymerase II to α-amanitin

Species	*Homo sapiens* (human)	*Caenorhabditis elegans* (worm)	*Saccharomyces cerevisiae* (yeast)	*Agaricus bisporus* (mushroom)

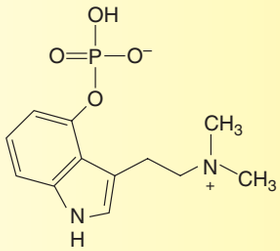
Perspective 23.2
MAGIC MUSHROOMS

We probably all have heard about magic mushrooms. Like the mushrooms we examined earlier in this section, these mushrooms are not infectious, but they do produce a substance that can result in intoxication. Consisting mainly of species in the *Psilocybe* genus, these mushrooms contain psilocybin or psilocyn, which are hallucinogenic compounds **(Figure B23.5)**.

Nathan Griffith/Corbis Images



A. *Psilocybe cyanescens* **B.** Psilocybin

Figure B23.5. Magic mushrooms Certain mushrooms produce psilocybin, a hallucinogenic compound. **A.** *Psilocybe cyanescens* is a potent psychedelic mushroom found throughout the world. **B.** Chemical structure of psilocybin. Once ingested, psilocybin is converted to the metabolically active psilocyn (or psilocin) through dephosphorylation.

These mushrooms have been part of certain Native American rituals for thousands of years. Psychedelic mushrooms have been part of the U.S. counterculture since the 1950s. In 1957, R. Gordon and Valentina Wasson authored an article in *Life* magazine describing their experiences with psychedelic mushrooms in Mexico, thereby introducing them to mainstream America for the first time.

According to people who have ingested these mushrooms, they cause heightened senses of sight, smell, sound, and touch. Many people also claim to have spiritual experiences after ingesting them. Others report dizziness, nausea, anxiety, and paranoia. Because of their effects, the possession of these mushrooms is banned in most countries. In the United States, it is illegal to possess, manufacture, or sell mushrooms containing psilocybin or psilocyn without a license. They are classified as Schedule 1 narcotics, like heroin and LSD.

Within the body, psilocybin and psilocyn function as mimics of serotonin, a neurotransmitter that serves to relay messages within the brain. Serotonin affects many bodily functions, including sexual desire, appetite, and sleep. Additionally, serotonin affects our mood. Low levels of serotonin often are associated with clinical depression. As a result, many antidepressants function by increasing intercellular serotonin concentrations. Although the exact mechanism by which psilocybin and psilocyn produce their hallucinogenic properties is unknown, it most likely acts through the natural serotonin pathway.

As we saw with other toxins produced by mushrooms, psilocybin probably exists within the mushrooms to ward off predation. Ingestion of the compound by predators has deleterious effects. For the mushroom, production of the toxin serves as an effective defense mechanism.

CONNECTIONS Botulinum toxin, an AB exotoxin from the bacterium *Clostridium botulinum*, also causes flaccid paralysis. This potent neurotoxin cleaves SNARE proteins in host cells needed for the release of the neurotransmitter acetylcholine **(Section 21.1)**.

Human exposure to saxitoxin generally occurs indirectly. In many marine environments, periodic blooms of dinoflagellates and algae occur. When the species produce toxins, these blooms often are referred to as **harmful algal blooms (HABs)** or, erroneously, red tides. The increased amount of toxin produced by a larger population can lead to massive fish kills **(Figure 23.13)**. Marine mammals and birds also may be affected. Many filter feeders, especially mollusks and clams, accumulate the toxin within their tissues. If these shellfish are harvested and eaten by humans, then a large dose of toxin can be ingested, resulting in paralytic shellfish poisoning.

As we have seen, both α-amanitin and saxitoxin can severely affect the health of humans if ingested. Of what benefit are these toxins to the organisms that produce them? Unlike the toxins produced by bacteria, which often aid in the transmission of the microorganisms or assist with the bacteria's

Courtesy NOAA

Figure 23.13. Fish kills caused by harmful algal blooms As populations of dinoflagellates or algae increase, the concentrations of toxins produced by these organisms also increase. In extreme cases, these harmful algal blooms can lead to massive fish kills, such as this one in the Chautauqua National Wildlife Refuge in the United States.

C. Effect of copepods on toxin production by dinoflagellates

Figure 23.14. Role of toxin production by dinoflagellates Dinoflagellates may increase toxin production to protect themselves from predatory copepods. **A.** The dinoflagellate *Alexandrium minutum* can produce paralytic shellfish toxin (PST). **B.** *Acartia tonsa*, a copepod, feeds on dinoflagellates. **C.** *A. minutum* produced very little PST in the absence of copepods. The amount of PST produced by *A. minutum* increased significantly when the dinoflagellates were exposed to starving or grazing copepods.

acquisition of nutrients, the toxins produced by most eukaryal pathogens probably function as defense mechanisms. Toxin production likely functions as a deterrent to predation.

To test the hypothesis that toxin production serves as a deterrent to predation, researchers at Goteborg University in Sweden examined the production of paralytic shellfish toxin (PST) by *Alexandrium minutum*, a dinoflagellate, in the presence and absence of *Acartia tonsa*, a copepod that feeds on dinoflagellates. They observed that *A. minutum* produced approximately 2.5 times as much toxin when exposed to the copepod. Based on these results, the researchers concluded that the dinoflagellates could detect the predator and increase their toxin production in response to this potential threat **(Figure 23.14)**.

23.1 Fact Check

1. Compare and contrast the role of insects in the transmission of *Ophiostoma novo-ulmi* and *Plasmodium falciparum*.
2. Explain why certain fungi are opportunistic pathogens.
3. How do some phytopathogenic fungi obtain nutrients from host cells?
4. Should we consider poisonous mushrooms as pathogens?

23.2 Pathogen study: *Plasmodium falciparum*

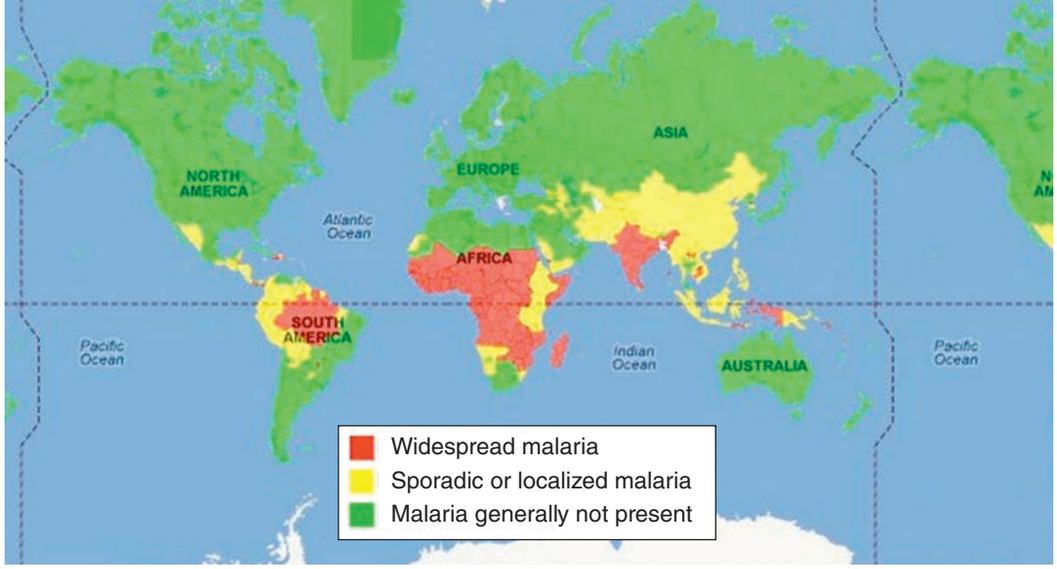
How does *Plasmodium falciparum* cause malaria?

In the preceding section, we examined general mechanisms by which eukaryal pathogens cause disease. In this section, we will examine a single eukaryal pathogen—*Plasmodium falciparum*—in more detail. As part of this case study, we will examine how this pathogen replicates, how it causes disease within a host, and how our knowledge of this microorganism may lead to the development of new drugs to combat it.

Replication of *Plasmodium falciparum*

Malaria represents one of the most devastating infectious diseases of humans. Between 300 and 500 million people become infected every year, and over one million people worldwide die of this disease annually, most of them in sub-Saharan Africa. Several related eukaryal microorganisms cause malaria, including *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, and *Plasmodium malariae*. Of these, *P. falciparum* and *P. vivax* cause most infections and *P. falciparum* is the most virulent malarial parasite.

Malaria probably has affected humans for millennia and, historically, has been present in tropical and subtropical areas throughout the world. Until the middle of the twentieth century, malaria remained a significant problem in the southeastern part of the United States and even in southern



Courtesy CDC

Figure 23.15. Global presence of malaria Despite a worldwide malaria eradication program organized by the World Health Organization (WHO), malaria remains endemic in countries throughout the world. As shown in this map from the United States Centers for Disease Control and Prevention (CDC), malaria remains common in many countries (red) and is sporadically present in many other countries (yellow).

parts of Canada. Through the use of a multifaceted eradication program that included spraying insecticides and draining swamps, the U.S. and Canadian governments eradicated the disease from the United States and Canada by 1951. A subsequent worldwide malaria eradication program, organized by the World Health Organization (WHO), has been less successful. Malaria remains endemic throughout sub-Saharan Africa, India, parts of Southeast Asia, and parts of South and Central America (Figure 23.15).

As we mentioned earlier, *Plasmodium falciparum* causes the most severe cases of malaria. The parasite's life cycle requires two hosts, both mosquitoes and humans. Within the female *Anopheles* mosquito gut, haploid gamete precursors, termed **gametocytes (gamonts)**, are obtained when the mosquito bites an infected person, and the gametocytes mature within the mosquito into gametes. These gametes fuse, producing a zygote, or **ookinete**, which travels to the gut wall and forms an **oocyst**, a cyst-like structure within which the ookinete undergoes meiosis. The oocyst eventually ruptures, releasing haploid **sporozoites**, the infective stage of the pathogen. The sporozoites travel to the salivary gland of the mosquito and can be transmitted to a human when the mosquito feeds.

Within humans, sporozoites travel to the liver. Here they undergo mitosis and are released as **merozoites**, which are diploid forms of the pathogen capable of infecting red blood cells, also known as erythrocytes. The merozoites replicate in erythrocytes, eventually lysing these cells, causing the release of more merozoites, which can infect additional red blood cells. However, some of these merozoites do not invade other erythrocytes. Rather, they form gametocytes, which can be ingested by a feeding mosquito to continue the process (Figure 23.16).

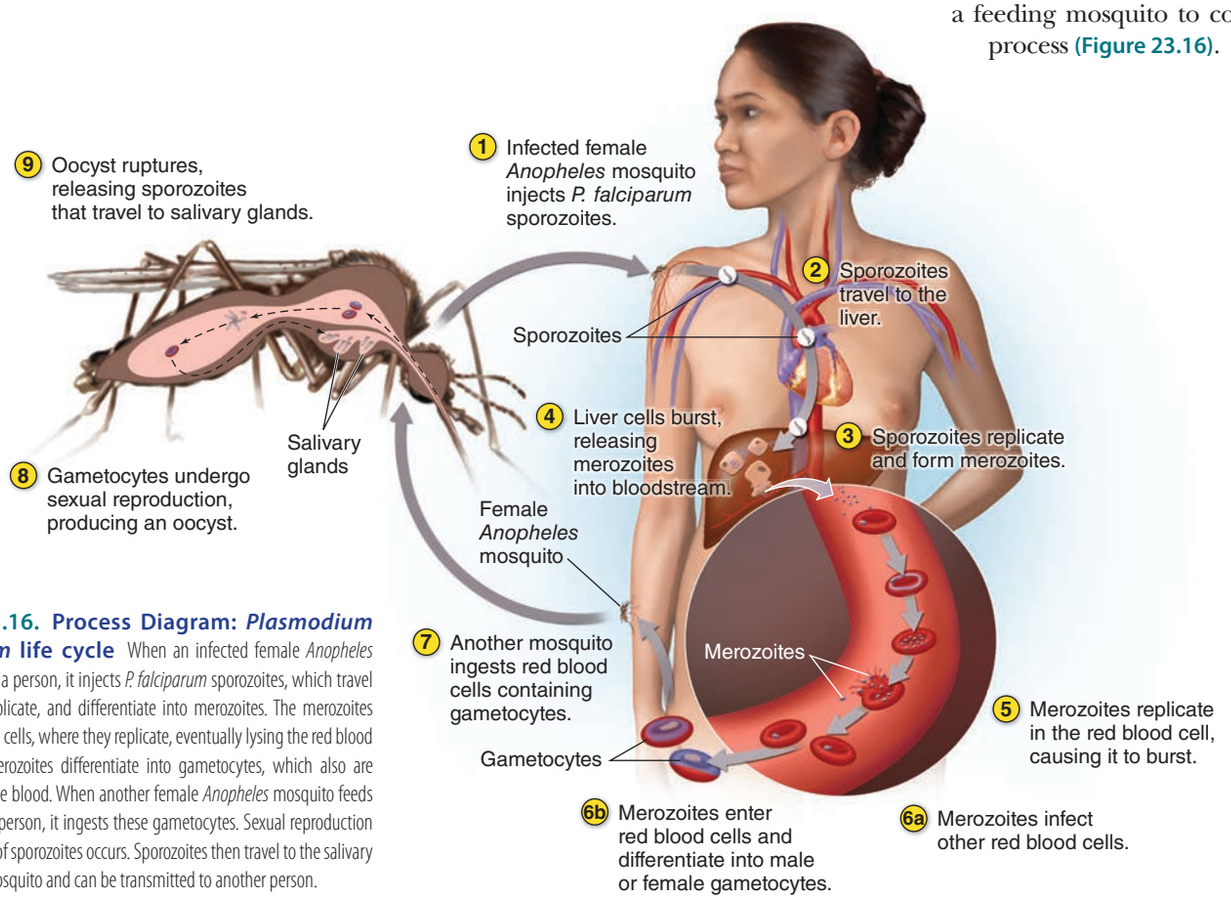


Figure 23.16. Process Diagram: *Plasmodium falciparum* life cycle When an infected female *Anopheles* mosquito bites a person, it injects *P. falciparum* sporozoites, which travel to the liver, replicate, and differentiate into merozoites. The merozoites infect red blood cells, where they replicate, eventually lysing the red blood cells. Some merozoites differentiate into gametocytes, which also are released into the blood. When another female *Anopheles* mosquito feeds on an infected person, it ingests these gametocytes. Sexual reproduction and formation of sporozoites occurs. Sporozoites then travel to the salivary gland of the mosquito and can be transmitted to another person.

Effects of *Plasmodium falciparum* on humans

Most of the clinical manifestations of malaria in humans occur during the erythrocytic stage, where the merozoites replicate asexually. When these infected erythrocytes lyse, the release of merozoites and various toxic materials present within the infected human triggers a strong immune response. The periodic bouts of fever often associated with malaria result from periodic waves of erythrocyte lysis and merozoite release. Eventually, the repeated destruction of erythrocytes also leads to **anemia**, a decrease in the normal number of erythrocytes. As the number of erythrocytes declines, organs no longer receive enough oxygen.

As we have mentioned in this and other chapters, all microbial pathogens—bacterial, viral, and eukaryal—need to enter appropriate hosts and obtain nutrients. *Plasmodium falciparum* is no exception. From its life cycle, it is quite clear how it enters its appropriate hosts. Within each host, the parasite must rely on specific adhesion factors to attach to and invade specific cells. Researchers have begun to understand the mechanism of *Plasmodium* attachment to red blood cells. The surfaces of merozoites, the blood-borne form of the parasite, contain a series of merozoite surface proteins (MSPs), the most abundant of which are MSP1, MSP6, and MSP7. Through *in vitro* studies, researchers have shown that antibodies to MSP7 significantly reduce the ability of merozoites to invade erythrocytes, suggesting that MSP7 is at least partially needed for merozoite invasion. To further these studies, microbiologists examined this issue from a genetic perspective. Using molecular techniques, they disrupted the *msp7* gene in a strain of *P. falciparum*. They demonstrated that this strain invaded erythrocytes less well than the wild-type strain. It appears that MSP7 facilitates invasion of *P. falciparum* to erythrocytes **(Figure 23.17)**.

Following attachment, *P. falciparum* enters the erythrocyte and subsequently resides within a specialized vacuole that is surrounded by the parasitophorous vacuole membrane. Within this vacuole, it ingests and then digests host hemoglobin (Hb). Responsible for carrying oxygen, Hb constitutes up to 95 percent of the total protein within a red blood cell. To access this material, *P. falciparum* takes up host cell cytoplasm through **cytostomes**, which are specialized double-membrane invaginations

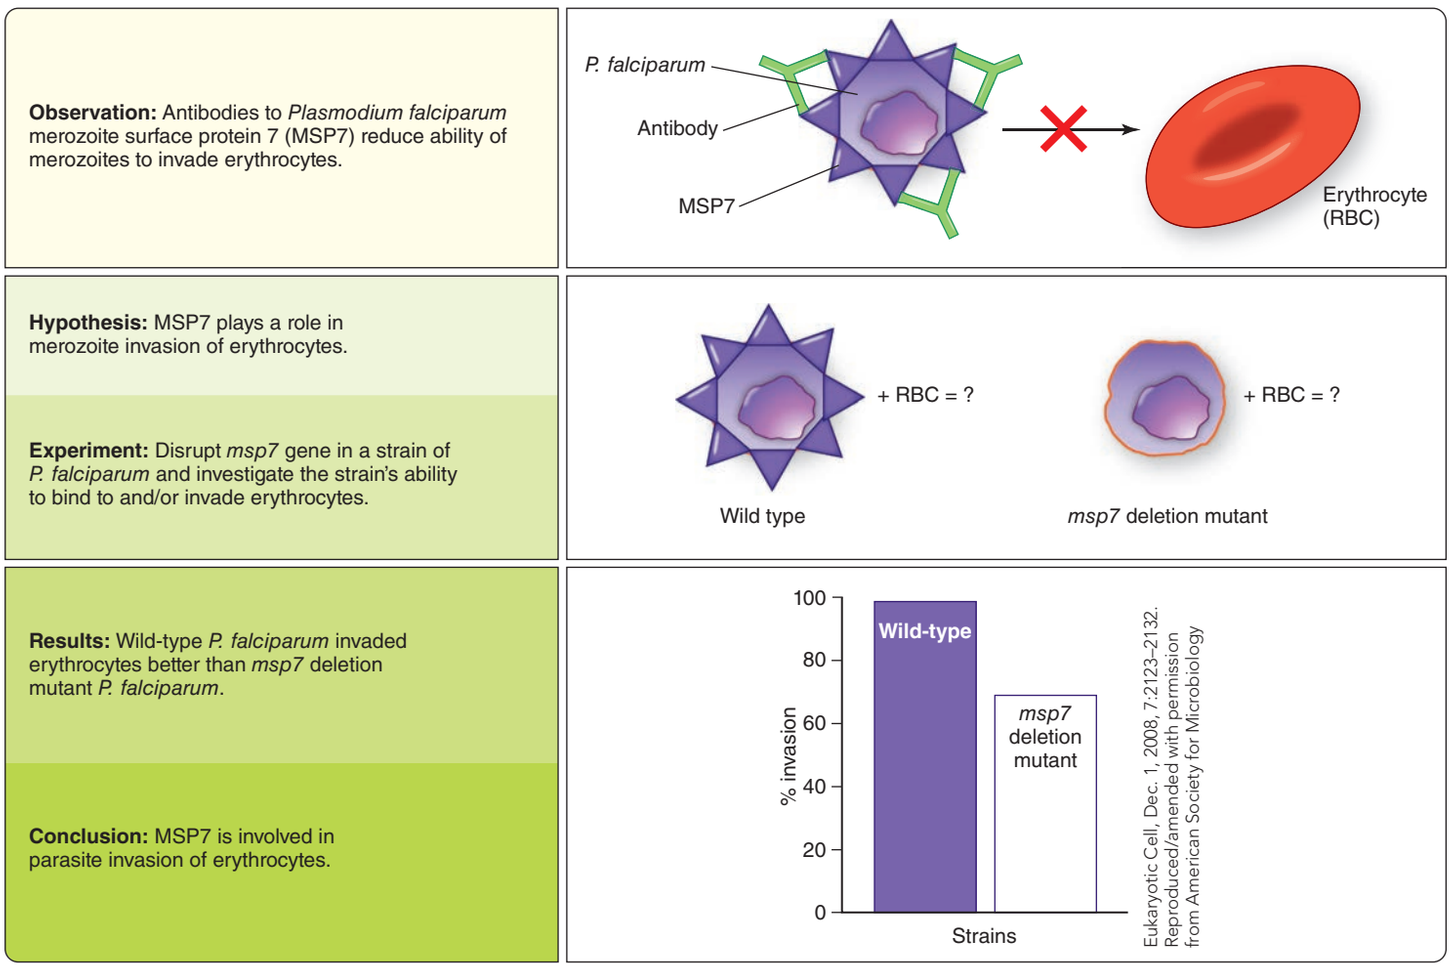

Figure 23.17. Merozoite surface proteins (MSPs) and *Plasmodium falciparum* invasion of erythrocytes Researchers observed that antibodies to MSP7 decreased the ability of *Plasmodium falciparum* to invade erythrocytes. Based on this observation, they hypothesized that MSP7 was involved in invasion. To test this hypothesis, they created a strain of *P. falciparum* that did not express MSP7. This strain invaded erythrocytes less well than the wild-type strain.

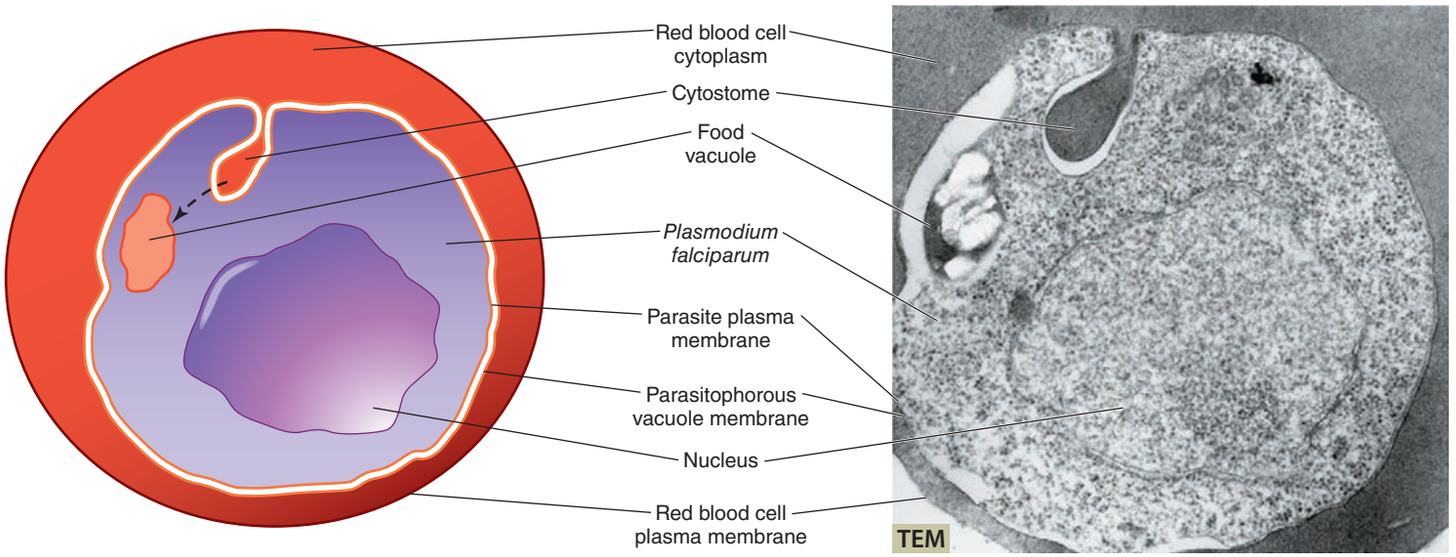


A. Transport of hemoglobin to food vacuole

B. *Plasmodium falciparum* within a red blood cell

Figure 23.18. Acquisition of hemoglobin by *Plasmodium falciparum* The malaria parasite acquires nutrients by ingesting hemoglobin from the host cell. *Plasmodium falciparum* takes up red blood cell cytoplasm and hemoglobin through cytostomes, which are double-membraned invaginations of the parasitophorous vacuole membrane and parasite plasma membrane. Individual vesicles fuse into a larger food vacuole. Proteases within the vacuole digest the hemoglobin. Toxic heme then is polymerized into hemozoin.

of the vacuole and *P. falciparum* membrane, typically referred to as the parasite plasma membrane **(Figure 23.18)**. The material then is transported to a food vacuole. Within this vacuole, a series of proteases digest the hemoglobin first into peptides and then into amino acids. The amino acids leave the vacuole and enter the parasite cytoplasm, where they can be used during translation.

The digestion of hemoglobin results in the release of free **heme**, a cytotoxic component of Hb. Several pathways exist to detoxify this material in mammalian cells. *Plasmodium* possesses its own mechanism for detoxifying heme. Through a poorly understood process, the parasite polymerizes heme monomers, forming a less toxic and insoluble polymer known as **hemozoin**, or malaria pigment. Thus, not only does the parasite possess a mechanism for obtaining nutrients, but also it possesses a mechanism for ridding itself of a toxic by-product.

Strategies for prevention and treatment of *Plasmodium falciparum* infections

Before we leave this discussion of *Plasmodium falciparum* and malaria, let's ask one more important question. How can we prevent human infections? Our detailed understanding of the *P. falciparum* life cycle may help us answer this question. By understanding how a pathogen enters a host, binds to cells within the host, and obtains nutrients, we can better protect ourselves from the pathogen.

Preventing interactions between humans and mosquitoes prevents the spread of malaria. Various methods can help block this interaction. Indeed, the use of insecticides and the elimination of mosquito breeding grounds led to the virtual eradication of malaria from many regions. Increased urbanization and the use of screens in homes decreased contact between people and mosquitoes. Additionally, programs to rid areas of stagnant water—ideal mosquito breeding grounds—and spray insecticides throughout areas with high levels of mosquitoes, further decreased the prevalence of malaria in many regions. In the United States, in fact, the Centers for Disease Control and Prevention (CDC) began as the Communicable Disease Center, an agency devoted largely to the control of malaria in that country. The results in the United States were remarkable. According to the CDC, 15,000 cases of malaria were reported in 1947. That number dropped to 2,000 reported cases in 1950, and the elimination of malaria from the United States by 1951. Now, some cases of malaria still are reported in the United States every year. However, most of these cases occur in people who have traveled to malaria-endemic regions of the world.

Despite the great success of antimalaria campaigns in many regions, the global eradication of malaria has been difficult. In the 1950s, insecticides were used extensively to eliminate the mosquito vector. Resource limitations, political instabilities, and the evolution of mosquitoes resistant to the insecticides all interfered with these efforts. More recently, many groups have advocated the distribution of insecticide-treated mosquito nets to prevent the transmission of *P. falciparum*. The World Health Organization has recommended that long-lasting insecticidal sleeping nets should be distributed freely, or at a low cost, and used by all people in areas where malaria is prevalent. Critics argue that nets will not be used by all people and will not end transmission of the pathogen.

In addition to preventing interactions between mosquitoes and humans, we also can develop more effective antimalarial drugs. For example, a better understanding of the role of merozoite surface proteins (MSPs) in *Plasmodium* attachment to erythrocytes may lead to the development of a drug that interferes with this part of the parasite life cycle. Additionally,

better tests for *P. falciparum* infection are needed so that drugs can be supplied to infected individuals in a timely fashion (Toolbox 23.1). Basic research today in both of these important areas may lead to the end of this scourge tomorrow.

CONNECTIONS Chloroquine, one of the most widely used antimalarial drugs, blocks the formation of hemozoin within *Plasmodium* cells, thereby leading to the accumulation of toxic heme. The mechanism of action of this and other drugs are discussed in **Section 24.2**.

23.2 Fact Check

1. How does *Plasmodium falciparum* enter red blood cells?
2. How does *P. falciparum* acquire nutrients as it replicates in red blood cells?
3. Describe various strategies used to eradicate *P. falciparum*.

23.3 Macroscopic eukaryal pathogens

What do we know about macroscopic eukaryal pathogens?

Parasitic **helminths**, or worms, technically should not be part of our discussion. After all, they are macroscopic. However, these pathogens generally are transmitted via their eggs, or larvae, which are microscopic. As we shall see during this brief overview, these macroscopic parasites also share many of the attributes exhibited by their microscopic counterparts. These macroscopic pathogens need to achieve certain goals: entering a host, attaching to specific cells, and obtaining nutrients. In the process of meeting these goals, they cause disease. For these reasons, we will round out our survey of eukaryal pathogens by investigating this interesting group of disease-causing organisms. Specifically, we will examine two human diseases caused by parasitic worms: ascariasis and schistosomiasis.

Ascariasis

Throughout the world, parasitic worms cause a number of animal and human diseases (Table 23.4). The roundworm *Ascaris lumbricoides* (Microbes in Focus 23.5) and other species in the *Ascaris* genus infect over 1.5 billion people worldwide. These worms exhibit a simple life cycle, replicating in a single host species. Typically, the worms mature within the small intestine of the host, adversely affecting the body's ability to adsorb nutrients. Often, *Ascaris* infections result in no acute signs of disease. Rather, **ascariasis**, or infection with an *Ascaris* species, may result in slower growth and decreased weight gain in children. In more severe cases, the worms may lead to a complete blockage of the small intestine.

When living in the small intestine, mature female worms may grow up to 30 cm in length. The male worms are smaller. The females release eggs that are eliminated from the host in the feces. If another person ingests these eggs, then transmission of the worms occurs. Within the host, the eggs hatch in the small intestine. Immature worms penetrate the blood vessels of the small intestine, travel to the lungs and throat, are

TABLE 23.4 Representative parasitic worms of humans

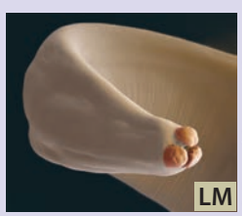
Worm	Location(s)	Disease/ Symptoms	Prevalence (people infected)
Roundworm	Tropical and subtropical regions	Ascariasis, intestine blockage	1.5 billion
Whipworm	Tropical and subtropical regions	Diarrhea, anemia	800 million
Hookworm	Africa, Latin America, Southeast Asia, China	Abdominal pain, anemia	740 million
Pinworm	Temperate regions throughout the world	Itching	200 million
Schistosomes	Africa, China, Caribbean	Schistosomiasis, organ damage	200 million
Lymphatic filariae	Tropical and subtropical regions	Elephantiasis	120 million

Microbes in Focus 23.5
ASCARIS LUMBRICOIDES: A ROUNDWORM PARASITE OF HUMANS

Habitat: Humans. Found in tropical and subtropical regions throughout the world, primarily in areas of poor sanitation

Description: Largest roundworm parasite of human intestines, with females measuring over 30 cm in length. Transmission occurs when eggs are excreted by an infected person and then later ingested by another human.

Key Features: Mature females may release over 200,000 eggs per day. Humans and *A. lumbricoides* have had a long history—fossilized *Ascaris* eggs have been isolated from caves in France inhabited by humans 30,000 years ago.



© Eye of Science/Science Source

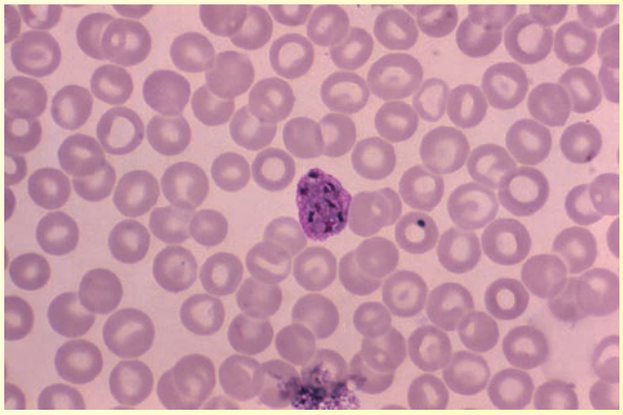
Toolbox 23.1
TESTING FOR MALARIA

The current "gold standard" for malaria diagnosis involves the microscopic examination of finger-prick blood smears. A thick blood smear is done first to examine as many red blood cells as possible on a slide. Typically, a health care worker spreads three drops of blood over a large area of a slide, producing a layer approximately ten cells thick. The smear is allowed to air-dry, stained with Romanowsky or Giemsa stain, and then examined for intracellular malarial parasites. Clinicians view approximately 200 visual fields before concluding that a sample is negative. If a sample appears positive, then a similarly stained thin blood smear consisting of a single layer of cells is examined to determine the number and species of *Plasmodium* parasites **(Figure B23.6)**.

Although microscopic detection for malaria can be very accurate, the microscopist must be skilled in staining and identifying the developmental forms of the malaria parasite. Skill levels may vary greatly among technicians. Because microscopy is time-consuming and requires a precision microscope capable of 1,000 magnification, microscopic diagnosis is restricted to designated facilities. Rapid tests, commonly known as dipstick tests, have been developed as an alternative to microscopy-based tests. Originally developed for personal use by travelers to malaria-endemic areas, these rapid tests can be performed within minutes anywhere and do not require special equipment or training to perform or interpret.

Rapid dipstick tests employ enzyme-linked immunosorbent assay (ELISA) technology (see Toolbox 20.2) and are best known for their use in home pregnancy tests. Dipstick technology has been adapted for the detection of a variety of antigens, including the products of infectious agents, and specific antibodies produced as a result of infection with certain pathogens. Malaria rapid tests use monoclonal antibodies (see Toolbox 20.1) for the detection of *Plasmodium* antigens from a blood sample. Antigen targets include the secreted histidine-rich protein II of *P. falciparum* and the lactate dehydrogenase enzyme of *Plasmodium* species. Monoclonal antibodies developed to lactate dehydrogenase can distinguish amino acid sequence differences in the enzyme of *P. falciparum* from that other, less virulent species of *Plasmodium*. A positive test is indicated by the appearance of a colored band on the supporting strip **(Figure B23.7)**.

Overall, rapid tests are not as sensitive as microscopy. They have a higher rate of false negative results; some individuals actually infected with *P. falciparum* receive a negative test result. Because of this occasional inaccuracy, the rapid tests are not considered



MC Fisher & DM Aanensen, Dept of Infectious Disease Epidemiology, St. Mary's Hospital, Imperial College, London

Figure B23.6. Thin blood smear showing malarial parasite
Plasmodium vivax in red blood cells are stained purple.

TABLE B23.1 Comparison of tests used for malaria diagnosis

Test	Limit of detection (approximate parasite density/μL blood)	Ability to discriminate species	Accessibility
Thick blood smear	50	Fair	Limited
Thin blood smear	>100	Good	Limited
Dipstick test	>100	Limited to certain species	Good
PCR	5	Good	Poor

Source: Adapted from Public Health Agency of Canada (2009).

swallowed, and then return to the small intestine, where they mature and mate **(Figure 23.19)**. The adult worms apparently do not possess any specialized means of attaching to the lining of the small intestine. Within this location, however, they can obtain food sources that pass through the human digestive tract.

Often, individuals with minor ascariasis infections exhibit no symptoms or minor gastrointestinal symptoms. People may first become aware of their infection when they observe a worm in their feces. Clinical diagnosis can be made by a microscopic analysis of one's feces. Treatment typically involves taking an antiparasitic drug for a few days.

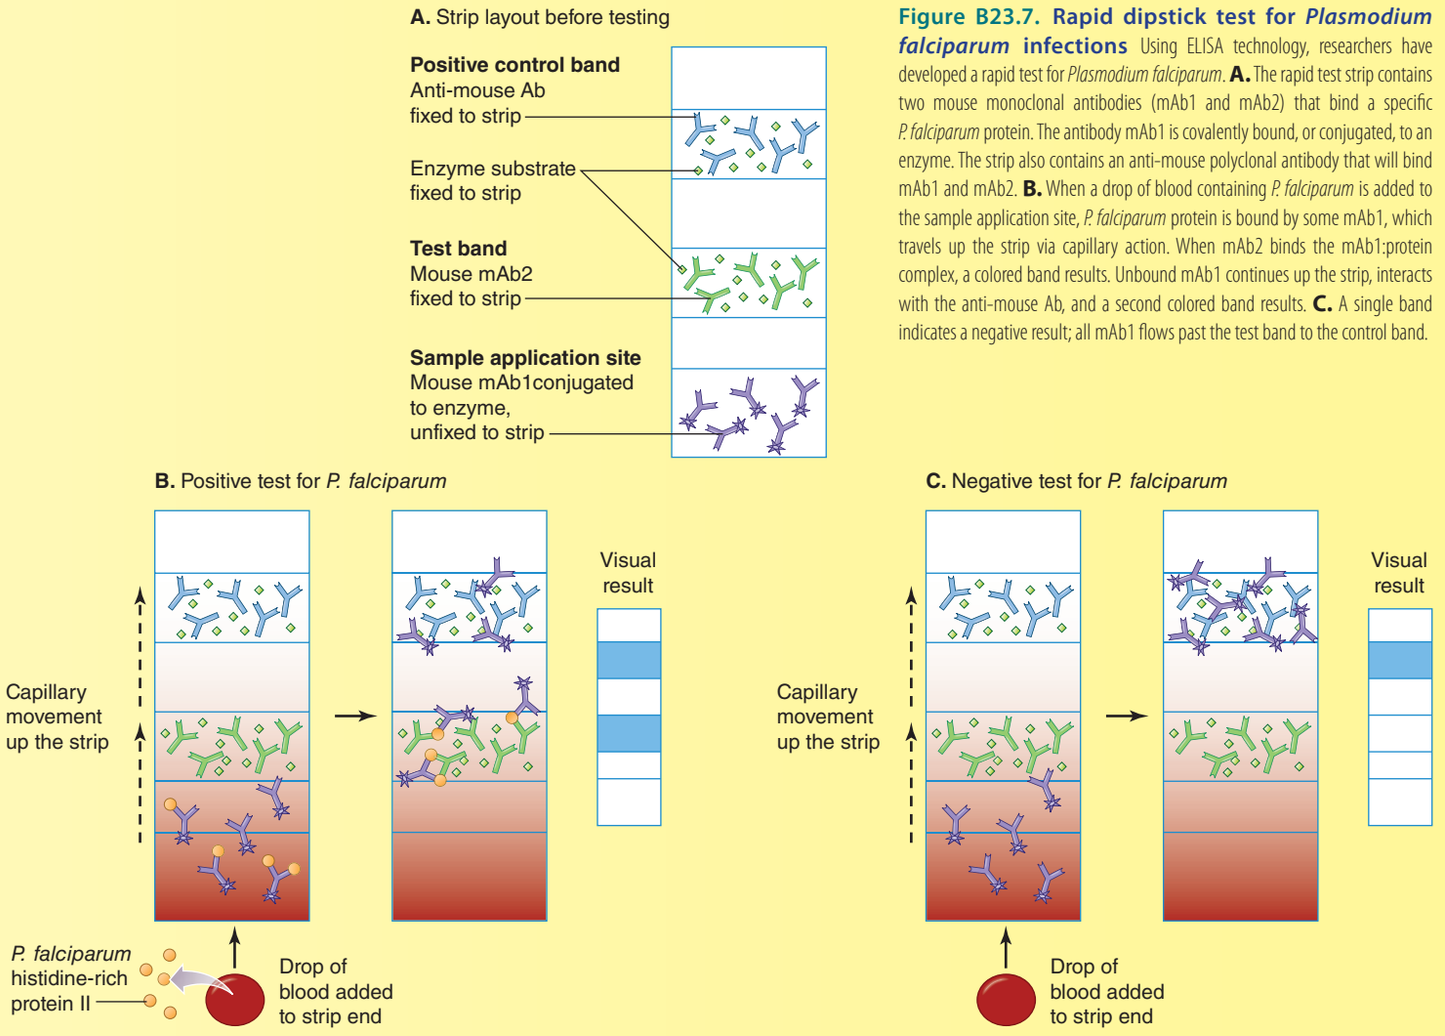


Figure B23.7. Rapid dipstick test for *Plasmodium falciparum* infections Using ELISA technology, researchers have developed a rapid test for *Plasmodium falciparum*. **A.** The rapid test strip contains two mouse monoclonal antibodies (mAb1 and mAb2) that bind a specific *P. falciparum* protein. The antibody mAb1 is covalently bound, or conjugated, to an enzyme. The strip also contains an anti-mouse polyclonal antibody that will bind mAb1 and mAb2. **B.** When a drop of blood containing *P. falciparum* is added to the sample application site, *P. falciparum* protein is bound by some mAb1, which travels up the strip via capillary action. When mAb2 binds the mAb1:protein complex, a colored band results. Unbound mAb1 continues up the strip, interacts with the anti-mouse Ab, and a second colored band results. **C.** A single band indicates a negative result; all mAb1 flows past the test band to the control band.

acceptable replacements for microscopic examination for malaria diagnosis. Nonetheless, testing by the World Health Organization in 2009 showed that the sensitivity of some commercially available rapid tests rivals that of microscopy in patients with relatively high loads of malarial parasites. Alternatively, PCR tests for amplification of genus and species-specific *Plasmodium* genes have been developed. Although PCR-based tests are extremely sensitive, PCR is very expensive and not used routinely for diagnosis. **Table B 23.1** shows a comparison of various tests used.

Test Your Understanding

1. In malaria-endemic areas, why would testing all individuals for the presence of antibodies to *P. falciparum* not be particularly informative?
2. In the rapid test described in Figure B23.7, why is it important to have the positive control band placed last in the sequence?

Schistosomiasis

At least three species of *Schistosoma* infect humans, including *Schistosoma mansoni*, *Schistosoma haematobium*, and *Schistosoma japonicum*. Such **schistosomiasis** infections affect over 200 million people worldwide, from Africa to the Caribbean to China. In children, this disease can result in malnutrition and developmental problems. Long-term infections can result in damage to multiple organs, including the liver, intestines, and bladder.

The complex life cycle of *Schistosoma* species differs substantially from that of *Ascaris* species. Most notably, these organisms spend part of their life cycle in freshwater snails, the intermediate

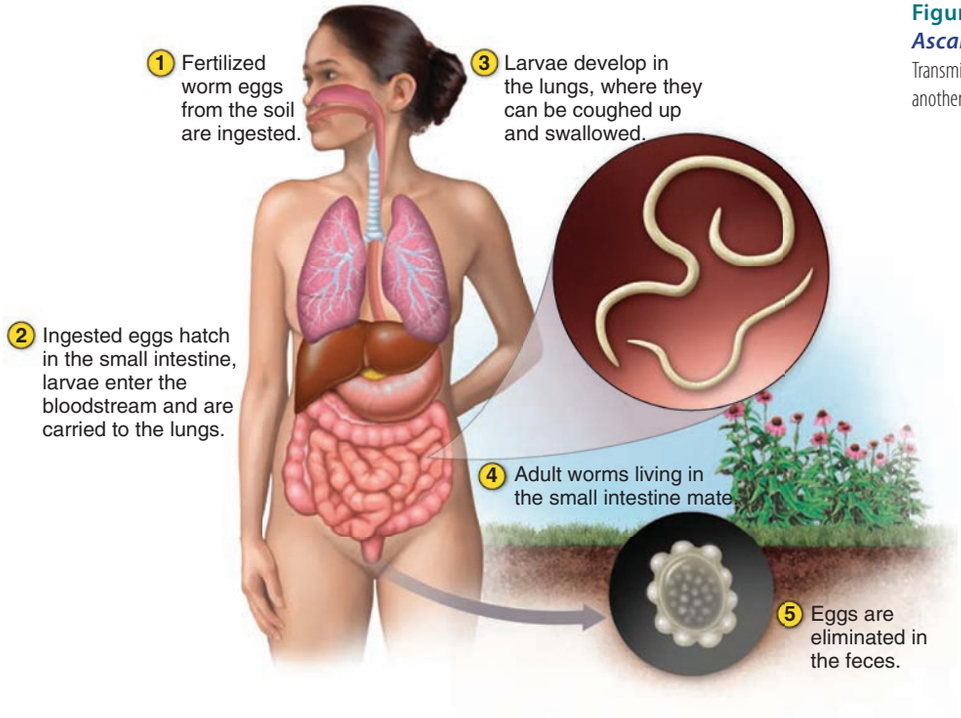

Figure 23.19. Process Diagram: Simple life cycle of *Ascaris lumbricoides* Female worms may reach up to 30 cm in length. Transmission occurs when eggs excreted by an infected person are ingested by another person via contaminated hands or food.

host. Eggs, excreted in the feces or urine of an infected person, the definitive host, hatch in freshwater and the organisms then enter specific snail hosts. Within the snails, the organisms replicate asexually and differentiate, eventually being released again into the water. This form of the organism can penetrate the skin of people who are swimming or bathing in the contaminated water. Once inside a person, the organisms migrate to the blood system, where they mature and mate. Eggs move toward the intestines or bladder, where they are eliminated **(Figure 23.20)**.

23.3 Fact Check

1. List some parasitic worms that cause disease in human.
2. Describe the life cycle of *Ascaris lumbricoides*.
3. Describe the life cycle of *Schistosoma* species.

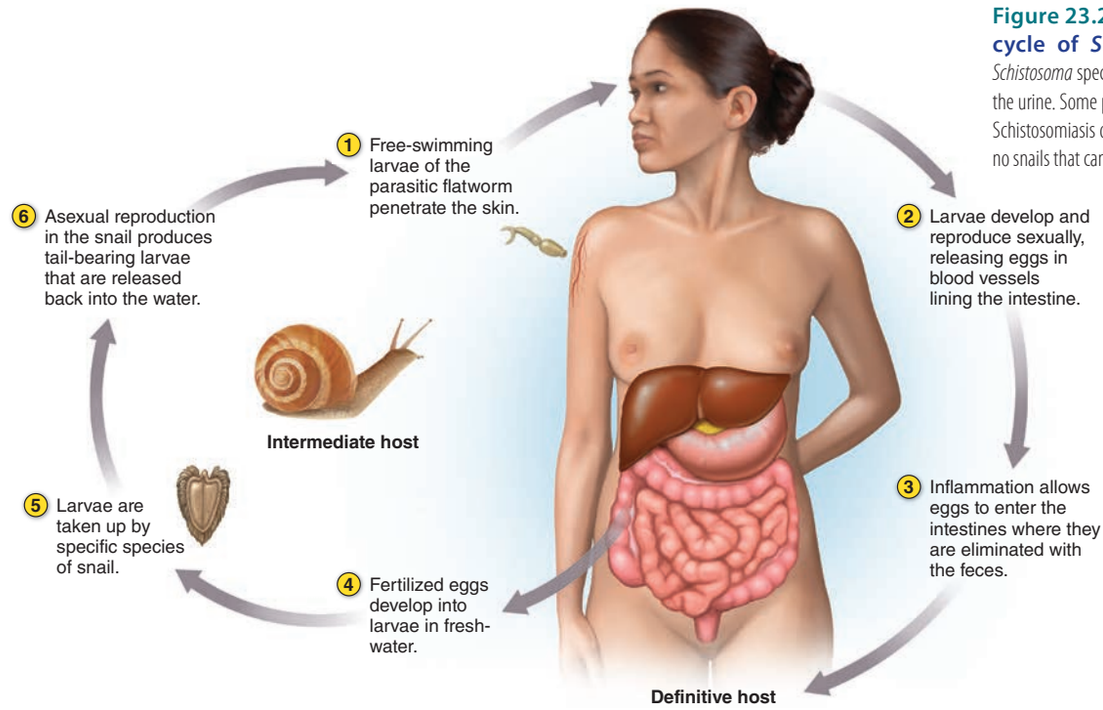

Figure 23.20. Process Diagram: Complex life cycle of *Schistosoma* species The larvae of some *Schistosoma* species travel to the urinary bladder and are released with the urine. Some parasites enter the liver where they damage liver cells. Schistosomiasis does not occur in the United States or Canada because no snails that can serve as intermediate hosts are found there.

23.4 Evolution of eukaryal pathogens

How do some eukaryal organisms become pathogens?

As we have seen throughout this chapter, eukaryal pathogens possess specific mechanisms to infect their hosts. For instance, specific genes encoding adhesion factors, enzymes, or toxins ultimately determine the virulence of these species. Among bacteria and viruses, these virulence genes can be transferred between species through various types of horizontal gene transfer. The acquisition of a virulence factor gene, then, may lead to the emergence of a new pathogen. Although it appears that this same process can lead to the emergence of eukaryal pathogens, the story does not end there. The host organisms also may undergo genetic changes in response to virulent pathogens. In other words, pathogens may affect the evolution of their hosts. In this section, we will examine both of these types of events.

Figure 23.21. Tan (or yellow) spot of wheat Caused by the fungus *Pyrenophora tritici-repentis*, tan (or yellow) spot is characterized by yellow spots on the leaves of wheat. The disease results in significant crop loss.

Acquisition of virulence genes by eukaryal microorganisms

In 2006, researchers presented strong evidence that horizontal gene transfer led to the increased virulence of *Pyrenophora tritici-repentis* **(Microbes in Focus 23.6)**, a fungus that exhibited only moderate virulence prior to 1941. In 1941, a new severe disease of wheat—tan (or yellow) spot—was described, and *P. tritici-repentis* was determined to be the causative agent **(Figure 23.21)**.

How did this fungus quickly evolve into a virulent pathogen? Apparently, the change occurred when *P. tritici-repentis* acquired the gene encoding ToxA, which is a toxin. Researchers showed that strains of *P. tritici-repentis* that lack the *toxA* gene are avirulent. They become virulent if the toxin gene is inserted into their genomes, clearly demonstrating the central role of this toxin in fungal virulence. Another question still remains. How did strains of *P. tritici-repentis* acquire the *toxA* gene in 1941? *Staganospora nodorum*, another fungal pathogen of wheat, also contains the *toxA* gene, but the gene has not been identified in other fungal species. Furthermore, *toxA* genes in *S. nodorum* isolates exhibit more genetic diversity than do *toxA* genes in various *P. tritici-repentis* isolates, suggesting that the gene has entered the latter species more recently. Based on this evidence, researchers predict that *toxA* was acquired by *P. tritici-repentis* from *S. nodorum* sometime around 1940, probably through horizontal gene transfer. The virulence of other emerging fungal pathogens remains less clear **(Perspective 23.3)**.

Microbes in Focus 23.6

***PYRENOPHORA TRITICI-REPENTIS*: THE CAUSE OF TAN SPOT IN WHEAT**

Habitat: Mainly infects wheat, but also may infect rye and other related grasses

Description: Fungus that causes brown or yellow spots to form on wheat leaves as a result of necrosis, or localized cell death

Key Features: A form of the fungus overwinters on wheat stems or other organic matter. Spores are released in the spring and summer. These spores then infect new plants. During a severe outbreak, crop losses may approach 50 percent.

Courtesy Stephen Wegulo, University of Nebraska-Lincoln

CONNECTIONS Most, if not all, living organisms and viruses possess means of sharing genetic material. Viruses with segmented genomes, like influenza viruses, can share genetic material via reassortment **(Section 22.4)**.

Effects of eukaryal pathogens on host evolution

Before leaving this topic of evolution, let's investigate a somewhat different question. How have eukaryal pathogens affected the evolution of their hosts? To explore this question, we will focus on two specific examples: the evolution of humans in response to *Plasmodium falciparum*, the causative agent of malaria, and the evolution of fruit flies in response to α-amanitin, the toxin produced by certain fungi.

The human response to *P. falciparum* and malaria represents a classic case of microbial pathogens affecting host evolution. As we noted previously, *P. falciparum* is transmitted from mosquitoes to humans. In humans, the infection ultimately results in the destruction of red blood cells, causing severe anemia.

Perspective 23.3
CHYTRID FUNGUS: AN EMERGING FUNGAL PATHOGEN

Since the 1980s, scientists have reported major declines in amphibian populations throughout the world. Indeed, the International Union for Conservation of Nature (IUCN) estimates that over 40 percent of amphibian species are threatened. Many factors may contribute to these declines, including habitat destruction, pollution, and global climate change. However, most researchers agree that an emerging microbial pathogen, *Batrachochytrium dendrobatidis (Bd)*, a fungus in the chytrid family, represents the greatest threat to many of these species.

First isolated and characterized in 1998, *B. dendrobatidis* now has been identified in frog populations throughout the world. A 2014 study reported the presence of *Bd* in amphibians from Madagascar. Retrospective studies indicate that it has existed in the United States and Australia since the 1970s. However, it probably originated much earlier in Africa. The fungus has been identified in museum specimens of *Xenopus laevis*, the African clawed frog, from the 1930s. Since the 1930s, *X. laevis* has been exported to pet stores and research centers throughout the world. Most likely, this trade in the African clawed frog has led to the current global distribution of the pathogen **(Figure B23.8)**.

The chytrid fungus spreads through the water and causes lesions on the skin of infected frogs. Most likely, these lesions adversely affect fluid balance and respiration, leading to death. What remains unclear is why the amphibian declines seem to have begun relatively recently. We can formulate at least two reasonable hypotheses. First, the fungus may have obtained a new virulence gene. The fungus, in other words, has evolved new traits. Second, the frogs may be more sensitive to the pathogenic effects of the fungus because of recent increases in pollution or recent changes in the global climate, even if the fungus itself has not changed. More research is needed to answer this important question.

Although the frog declines have been dramatic and, apparently, unrelenting, there are some glimmers of hope. Various species of bacteria produce antifungal compounds. To determine if any bacteria produce compounds toxic to *B. dendrobatidis*, microbiologists have screened bacteria for their ability to limit the growth of the fungus. In 2008, researchers reported that *Janthinobacterium lividum*, a bacterium that normally lives on the skin of certain amphibians, offered some protection to frogs exposed to the chytrid fungus. Perhaps further research into this bacterium will help us stem the loss of frogs.

Figure 23.22. Sickle-cell disease and misshapen red blood cells Wild-type red blood cells exhibit a characteristic biconcave disk shape. Red blood cells from a person with sickle-cell disease have a distorted, sickled shape.

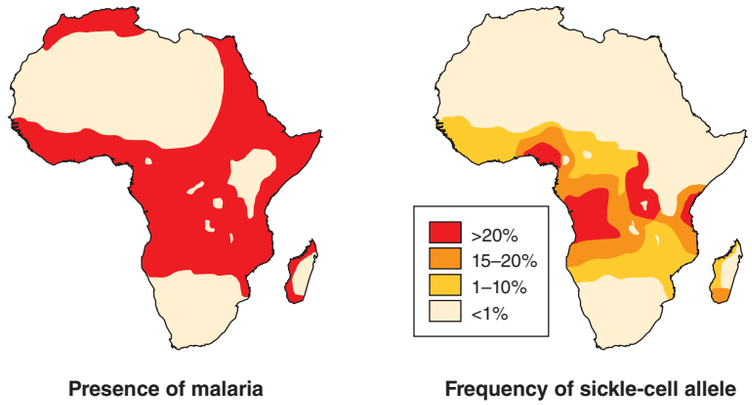
However, some people exhibit a partial resistance to the effects of this microbial pathogen. Their resistance to malaria is tied to another human malady: sickle-cell disease.

Sickle-cell disease results from a mutation in the human gene *HBB* that codes for the β-globin polypeptide, one of the constituents of hemoglobin, the oxygen-carrying protein within red blood cells. In individuals who are homozygous for the mutant allele of this gene, the hemoglobin protein is misshapen. It binds oxygen less well and the red blood cells themselves assume a sickled appearance under certain conditions, rather than remaining spherical (Figure 23.22). In turn, this sickled shape results in the destruction of these cells, causing anemia. The misshapen red blood cells also tend to become clogged in capillaries, resulting in an increased risk of heart problems and stroke.

Because of the severity of this genetic disease, one might assume that the prevalence of the mutant allele within the human population would be quite low. After all, if sickle-cell disease has a significant negative impact on the fitness of people, then it is reasonable to assume that there would be a selective pressure against the allele. Individuals who have sickle-cell disease would be less likely to survive until adulthood and less likely to reproduce. As a result, the mutant allele might be less likely to be passed on to future generations. Nonetheless, the mutant allele and sickle-cell disease are more prevalent among some people of African and Mediterranean descent than one might expect. Among Americans of African ancestry, for example, approximately one in every 500 individuals is homozygous for the mutant allele and has sickle-cell disease. Additionally, roughly one in twelve African Americans carries the mutant allele. These individuals are heterozygous, possessing one wild-type copy and one mutant copy of the *HBB* gene. These individuals do not normally exhibit sickle-cell disease. Under typical conditions, their red blood cells function normally. Their red blood cells may sickle, though, under conditions of oxygen stress, such as during exercise at high altitudes. More importantly, these heterozygous individuals have a 50 percent chance of passing the mutant allele to their offspring. Given the significantly detrimental effects of sickle-cell disease, it is reasonable to wonder why this genetic disease remains somewhat common. It also is reasonable to wonder why it is so much more common among certain populations. Malaria provides the answer to both of these questions. The prevalence of malaria coincides with the prevalence of sickle-cell disease (Figure 23.23). Even though sickle-cell disease is highly detrimental in all circumstances, the sickle-cell trait provides partial protection against malaria. In heterozygous individuals, *P. falciparum*-infected red blood cells tend to sickle much more readily than uninfected cells and infected cells are then destroyed. As a result of this rapid cellular destruction, the pathogen cannot replicate and spread to other cells; the malarial disease is less severe. In other words, heterozygotes possess a selective advantage over homozygous individuals in areas where malaria is common. Clearly, the evolution of humans has been affected by *P. falciparum*.

CONNECTIONS Throughout our evolutionary history, pathogens have shaped our genome in many ways. Biologists postulate that the CCR5 deletion that provides humans with some protection from HIV infection **(Section 22.4)** may have offered protection to humans from smallpox infections hundreds of years ago.

To investigate another example of how eukaryal pathogens can affect host evolution, let's examine fruit flies. The larvae of several species of fruit flies, most notably *Drosophila falleni* and *Drosophila recens*, exhibit a high degree of resistance to α-amanitin, the fungal toxin we first discussed in Section 23.1. One might assume that this increased resistance to the toxin allows the fruit fly larvae to use mushrooms as a food source. However, relatively few species of mushrooms produce α-amanitin. Also, many mycophagous, or fungi-feeding, species of fruit flies have been identified that do not exhibit resistance to this toxin. In general, resistance to the toxin does not correlate



A. C. Allison. 2006. The discovery of resistance to malaria of sickle-cell heterozygotes. Biochemistry and Molecular Biology Education 30(5):279–287. Reprinted with permission of John Wiley & Sons, Inc.

Figure 23.23. Geographic distribution of malaria and sickle-cell disease As shown in these maps, the prevalence of the mutant sickle-cell allele largely overlaps with the prevalence of malaria in Africa. Sickle-cell disease is very detrimental, and there should be a strong selective pressure against the mutant allele. Heterozygotes exhibit resistance to malaria. This resistance provides a selective pressure maintaining the mutant *HBB* allele within populations where the malarial parasite is prevalent.

with mycophagy. So why would some species of fruit flies evolve a toxin resistance? Perhaps the ability to feed on fungi that produce α-amanitin provides the fruit flies with a food source that is underutilized. If the larvae of other species cannot feed on these toxic mushrooms, then *D. falleni* and *D. recens* will face less competition.

John Jaenike, a biologist at the University of Rochester, has proposed another explanation for the evolution of α-amanitin resistance in these species. He proposes that increased α-amanitin resistance protects these species of fruit flies from parasitic worms, like those we discussed in Section 23.3. Nematodes like *Howardula aoronymphium* are common parasites of fruit flies and are sensitive to α-amanitin. Jaenike has shown that fruit flies that breed and feed on mushrooms producing α-amanitin have a greatly reduced parasite burden. The evolution of α-amanitin resistance within *D. falleni* and *D. recens* may provide the fruit flies with an indirect resistance to these parasites. In other words, the toxin production of the fungi has affected the evolution of the invertebrates.

23.4 Fact Check

1. What probably led to the increased virulence of *Pyrenophora tritici-repentis*?
2. Describe the inheritance of sickle-cell disease.
3. Why do the geographic distributions of malaria and sickle-cell disease largely overlap?
4. Provide two possible explanations for the α-amanitin resistance exhibited by some fruit fly species.

Image in Action

WileyPLUS Learning Space This illustration depicts the spread of Dutch elm disease. The tree on the right is infected, with the infection starting on a lower branch, causing the branch to wither and die. The lower zoom-in window reveals fruiting bodies of *Ophiostoma novo-ulmi* on the tree, with spores being released. The tree on the left is a healthy elm tree being attacked by an elm bark beetle (top zoom-in window), the vector that spreads the disease-causing fungus. The beetle burrows through the bark of the elm, leaving behind spores of *Ophiostoma novo-ulmi*.

1. *Ophiostoma novo-ulmi*, like many other phytopathogenic fungi, produces various enzymes to break down host barriers. Imagine a compound produced by a transgenic elm tree that blocked the fungal enzyme, xylanase. What would be the effects, and why?
2. Imagine that a newly introduced species is found to be a natural predator of the elm bark beetle. How might this new change in the environment affect the fungal pathogen *Ophiostoma novo-ulmi*?

The Rest of the Story

Today, new cases of Dutch elm disease still occur worldwide. Replanting of elms in areas previously devastated by the disease in past years show the disease abounds, and newly planted trees still fall victim. In hopes of repopulating lost elm stands, researchers have tried traditional breeding strategies. Susceptible elm tree species have been crossed with more resistant species. Researchers hope that the hybrid offspring will exhibit the increased resistance to Dutch elm disease of the one parent and still maintain all of the desirable traits of the other parental tree.

Scientists also are attacking the problem of Dutch elm disease in a new way. Using some of the molecular biology tools that we discussed in earlier chapters, researchers are attempting to make transgenic elm trees that produce specific antifungal compounds. Genes for these antifungal compounds can be inserted into the genome of an elm tree. As the tree develops, the compounds will be produced, thereby providing the tree with resistance to *Ophiostoma novo-ulmi*. As we learn more about the life cycle and pathogenesis of the fungus, we may identify more genes that produce antifungal compounds. By creating transgenic trees, we may someday again see these majestic trees growing throughout our towns, parks, and forests.

Summary

Section 23.1: How do pathogenic eukarya cause disease?

Eukaryal pathogens can be transmitted between hosts in various ways.

- Insect vectors passively transport spores between hosts for eukaryal pathogens like *Ophiostoma novo-ulmi*.
- Some eukaryal pathogens have a complex life cycle in which they undergo sexual reproduction in the **definitive host** and asexual reproduction and differentiation in the **intermediate host**.
- The eukaryal pathogen *Plasmodium falciparum* must replicate and develop within the mosquito to be transmitted.
- The eukaryal pathogen *Giardia lamblia* undergoes a simple life cycle. It is transmitted via the ingestion of cysts, which then give rise to **trophozoites**.
- Upon entering an appropriate host, eukaryal pathogens must evade the host defenses.
- Some opportunistic pathogens, like *Pneumocystis jirovecii*, only cause disease in immunocompromised individuals, such as people with HIV disease or people on immunosuppressive drugs.
- Other opportunistic pathogens, like *Candida albicans*, cause disease when the normal microbial inhabitants of the host change.
- Some pathogens, like *Trypanosoma brucei* subspecies, actively subvert the host defenses through antigenic variation. These organisms, characterized by a **kinetoplast**, exhibit cyclic variations in **parasitemia**.
- Eukaryal pathogens exhibit various means of obtaining nutrients from their hosts and causing disease.
- Some **phytopathogenic fungi** produce enzymes like **xylanase**. Others use **appressoria** to penetrate host cells physically. In some species, **mitogens** promote appressoria development.
- A number of eukaryal pathogens produce toxins. *Cochliobolus carbonum*, a fungus of maize, produces HC-toxin, which is an inhibitor of **histone deactylases (HDACs)**, disrupting the expression of host defense genes.
- Certain species of fungi produce mushrooms containing toxins such as **α-amanitin**, which can lead to intoxication.
- Certain **dinoflagellates** associated with **harmful algal blooms (HABs)** produce saxitoxin.

Section 23.2: How does *Plasmodium falciparum* cause malaria?

Plasmodium falciparum exhibits a complex life cycle, replicating in mosquitoes and humans, ultimately leading to the destruction of erythrocytes in humans.

- Within humans, the intermediate host, **gametocytes (gamonts)** are released from infected erythrocytes and ingested by feeding mosquitoes.
- Within the female *Anopheles* mosquito, the definitive host, the gametocytes differentiate into gametes, which fuse, forming a diploid **ookinete**. The ookinete forms an **oocyst** and undergoes meiosis, producing haploid **sporozoites**.
- Sporozoites can be transmitted to a human when an infected mosquito bites.
- In the human, these sporozoites initially infect liver cells, where they replicate, releasing diploid **merozoites**, which then infect erythrocytes.
- In an infected human, *P. falciparum* replication leads to malaria.
- To facilitate attachment to red blood cells, the merozoites express a series of merozoite surface proteins (MSPs).
- Once inside an erythrocyte, the merozoites obtain hemoglobin from the host cell through **cytostomes**. Digestion of hemoglobin by the pathogen releases **heme**, which *P. falciparum* then converts to **hemozoin**.
- Replication of merozoites within erythrocytes leads to the destruction of these cells, resulting in **anemia**.
- Although malaria remains a huge global problem, methods of preventing malaria and treating it do exist.
- Insecticide-treated mosquito sleeping nets can prevent the transmission of *P. falciparum*.
- The antimalarial drug chloroquine blocks the formation of hemozoin.

Section 23.3: What do we know about macroscopic eukaryal pathogens?

Macroscopic eukaryal pathogens, like microbial pathogens, obtain resources from their hosts and, in the process, cause disease.

- Parasitic worms, or **helminths**, cause a number of severe human diseases throughout the world.
- The parasitic worm *Ascaris lumbricoides* is transmitted from human to human via contaminated water and causes **ascariasis**.
- Other parasitic worms, like *Schistosoma* spp., are transmitted via an intermediate host—freshwater snails—and cause **schistosomiasis**.

Section 23.4: How do some eukaryal organisms become pathogens?

Some eukaryal organisms become more virulent by acquiring virulence genes.

- Eukaryal pathogens may acquire virulence genes through horizontal gene transfer.
- *Pyrenophora tritici-repentis* became more pathogenic after acquiring the gene for ToxA.
- Eukaryal pathogens may affect the evolution of their hosts.
- The prevalence of **sickle-cell disease** is due, in large part, to the resistance to malaria conferred by the mutant β-globin allele associated with sickle-cell disease.
- Certain mycophagous species of fruit flies have evolved resistance to α-amanitin.

Application Questions

1. Lactobacilli are common inhabitants of the vaginas of women. How does the elimination of these bacteria contribute to disease?
2. Would you describe elm bark beetles as hosts of *Ophiostoma novo-ulmi*? Explain.
3. Would you describe mosquitoes as hosts of *Plasmodium falciparum*? Explain.
4. Compare and contrast the probable role of most fungal toxins with the role of most bacterial toxins.
5. Are mushrooms true pathogens? Explain.
6. Certain phytopathogenic fungi penetrate plant cell walls through the use of appressoria. Describe this process.
7. Some phytopathogenic fungi do not form appressoria. How might these fungi penetrate plant cell walls?
8. Provide descriptions of two different mechanisms utilized by *P. falciparum* to obtain nutrients from host cells.
9. Explain two different ways by which a non-pathogenic fungus could become pathogenic.
10. Describe how *P. falciparum* has affected human evolution.
11. To evade the host immune response, *Trypanosoma brucei* varies its surface glycoprotein, thereby presenting the host with a changing antigenic face. Describe how *T. brucei* could regulate the expression of its surface glycoprotein genes. How could you test your explanation?
12. We mentioned that *P. falciparum* merozoites appear to utilize merozoite surface proteins (MSPs) to attach to human erythrocytes. One could postulate that these MSPs interact with a specific protein present on the surface of the erythrocytes. Describe an experiment that could be used to identify this cellular receptor.

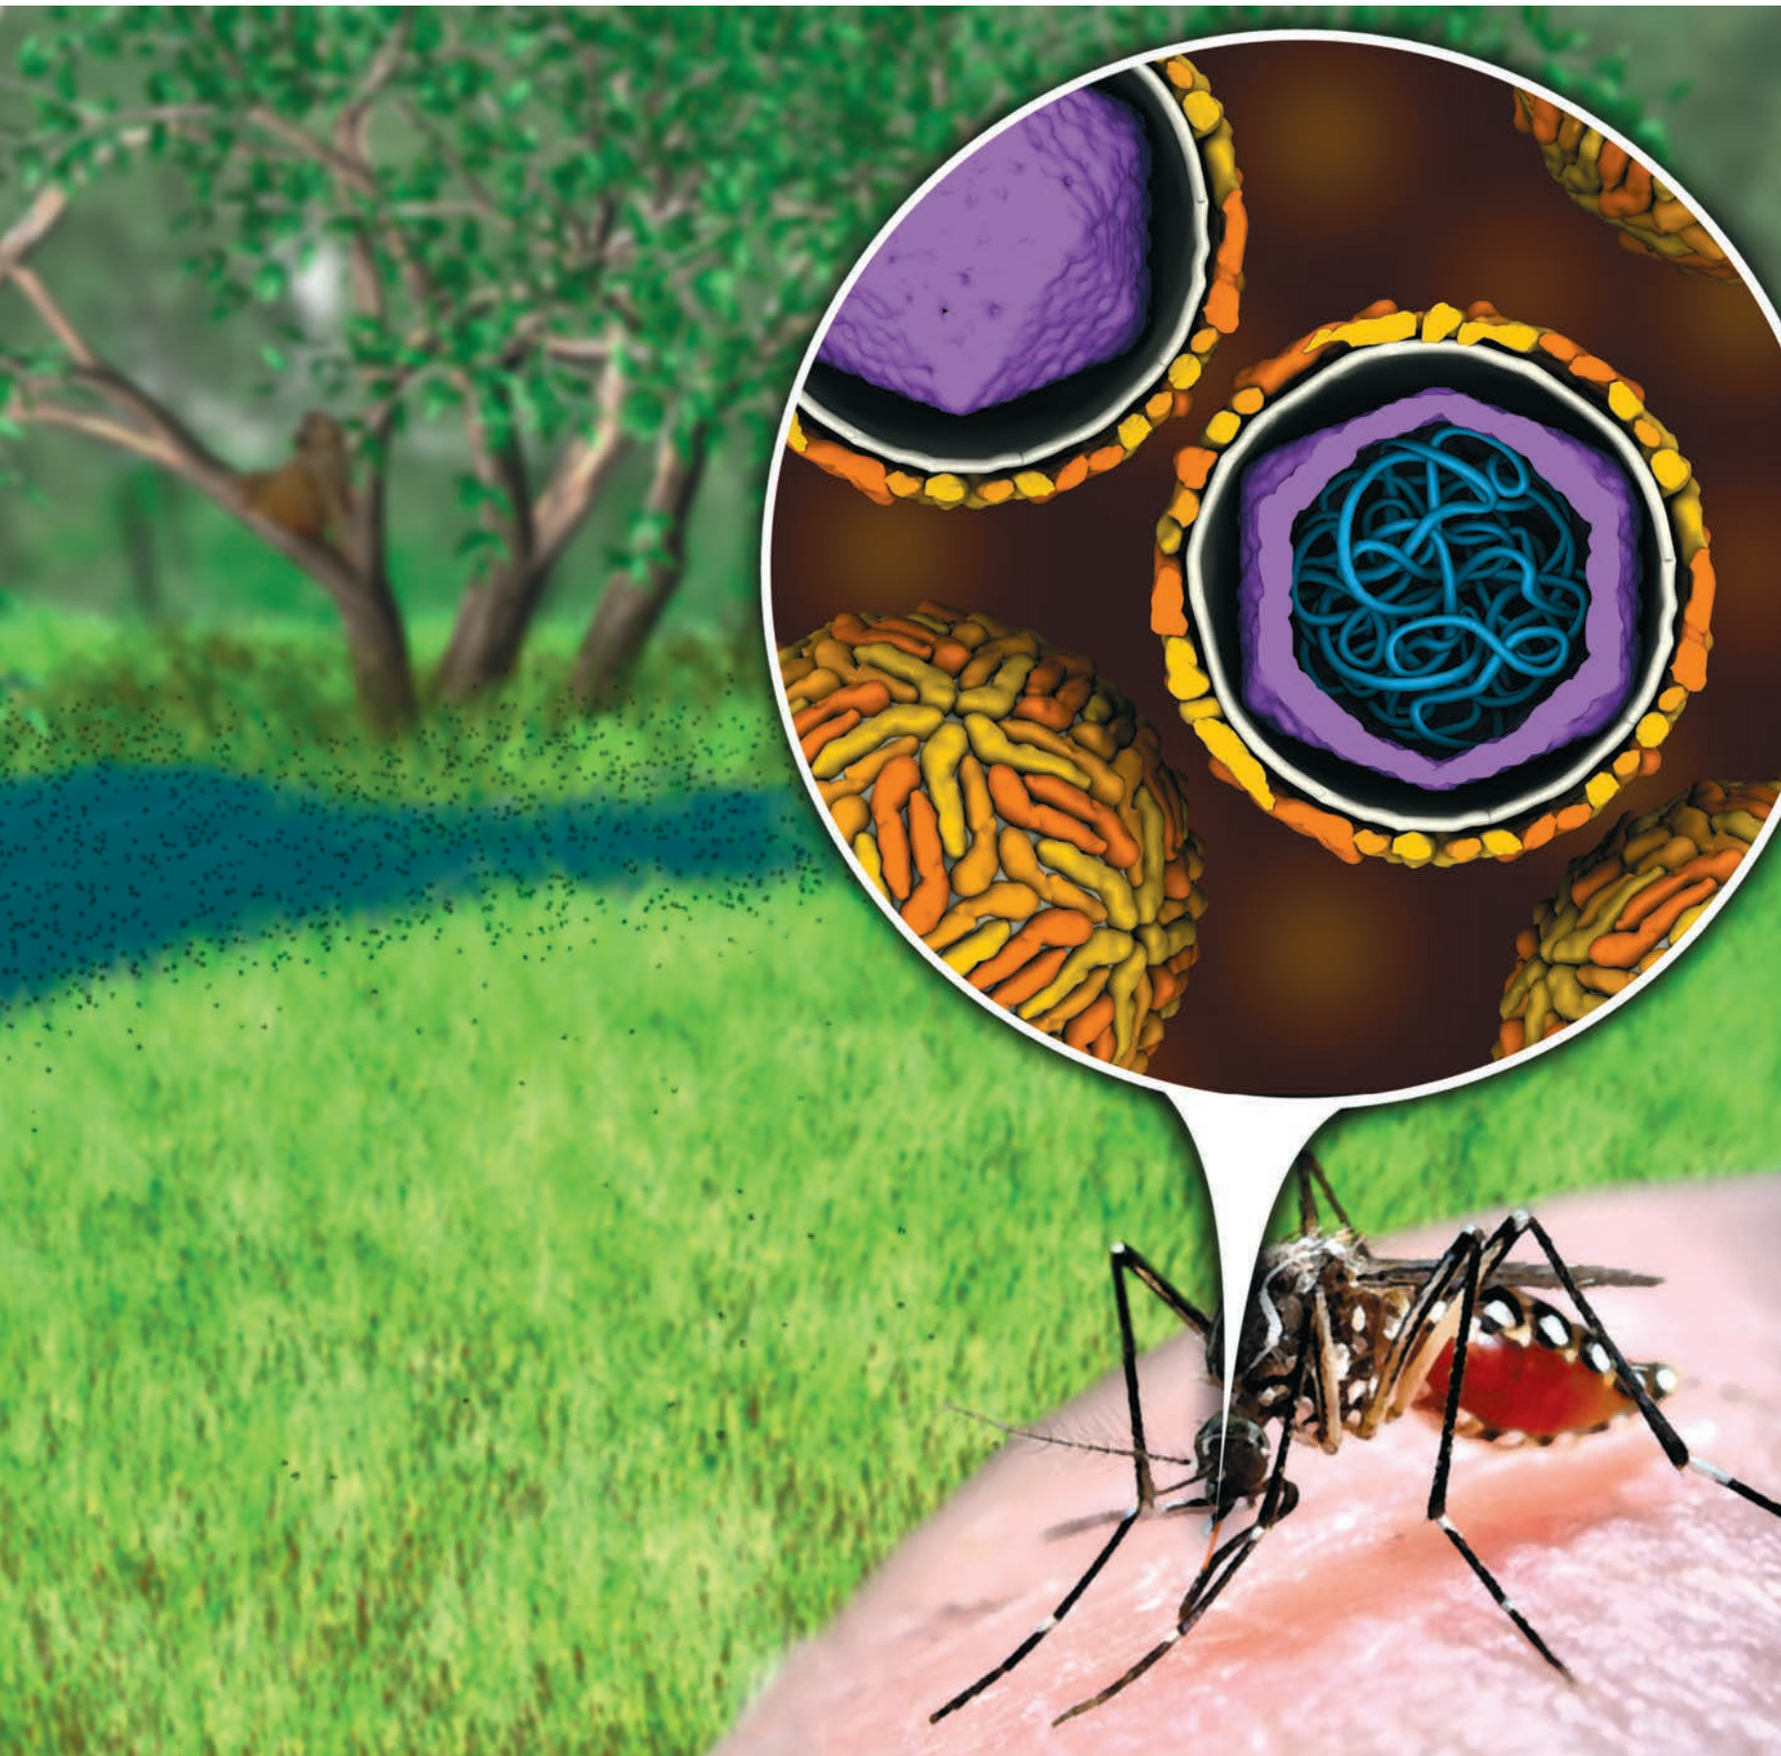
CHAPTER

24 Control of Infectious Disease



Someone in your neighborhood has been diagnosed with yellow fever. Should you be concerned about this infectious disease? What would you need to know to decide this? If you were living in eighteenth- or nineteenth-century Europe or the Americas, you would be gravely concerned. The whisper of yellow fever, or "black vomit" or "yellow jack," as it was sometimes called, would strike fear into your heart. If you were smart, you would move hundreds of miles away to a new city, like so many others did, and then move again as the immigrant wave introduced the disease there also.

In 1793, when yellow fever struck Philadelphia, the capital of the United States at that time, the government vacated the city. No one knew what caused the disease or how it was spread, but it would routinely ravage cities when it came. Usually, it arrived with ships carrying infected people—beginning with the slave ships from Africa, the original home of the virus. Vessels flying the yellow jack flag carried suspected yellow fever victims; they were death ships that were quarantined and prevented from entering port. Sometimes crew members sick with yellow fever were incorrectly diagnosed with malaria and the ship would be cleared. When such a ship entered the Mississippi River in 1878, it unleashed one of the greatest epidemics in American history, striking New Orleans, Memphis, Charleston, and Savannah. In some cities, 85 percent of those infected died.

Yellow fever is a hemorrhagic viral disease, named because the skin and eyes of infected persons commonly turn a striking bright yellow due to the release of the pigment bilirubin from damaged liver cells. Hemorrhaging of blood vessels causes blood to leak into body cavities, including the stomach, and the partially digested clotted blood turns stomach contents black, hence the name "black vomit."

In 1900, an American commission was launched to investigate the disease and find a way to control it. It was to be the first comprehensive scientific study to determine the mode of transmission, the causative agent, and the prevention of yellow fever. The Yellow Fever Commission, as the agency was called, was based in American-occupied Cuba, where yellow fever regularly occurred. Appointed to the study were U.S. Army surgeons Drs. Walter Reed, James Carroll, Jesse Lazear, and Aristides Agramonte. A native Cuban, Dr. Carlos Juan Finlay, also worked with the team and stubbornly held that the disease was transmitted by the common house mosquito, *Aedes aegypti*. This was an unpopular theory in the greater medical community.

Finlay observed that the movement of yellow fever was like that of malaria, a disease known to be transmitted by mosquitoes. Like malaria, yellow fever would attack some households and not others in the same area, and some family members, but not others in the same house. This was not what would be expected for a disease spread by direct person-to-person contact or contaminated water, as was thought by many. Finlay's careful observations and refusal to submit to dogmatic thinking set the yellow fever team down a road that led to the discovery of the yellow fever microbial agent, its transmission, and ultimately, control of this dreadful disease.

CHAPTER NAVIGATOR

As you study the key topics, make sure you review the following elements:

In the past, infectious diseases were not treated effectively because they were not recognized as being caused by microbes.

Antimicrobial drugs target specific microbial processes or structures.

- Table 24.1: Antibiotics and their origins
- Figure 24.4: Spectrum differences of antibacterial agents
- Table 24.2: Action, structure, and targets of antibacterial drug groups
- Figure 24.5: Overview of antibacterial drugs and their targets
- Animation: Antivirals

Resistance to antimicrobial drugs is common in microbes.

- Figure 24.10: Antimicrobial drug resistance mechanisms
- Animation: Premature termination of antibiotic treatment
- Toolbox 24.1: Drug susceptibility testing and MIC
- Mini-Paper: Soil microorganisms possess extensive resistance to antibiotics
- Figure 24.14: Common methods of acquiring resistance genes

Effective public health measures that prevent microbial diseases include immunization, containment of the pathogen, and prediction of future epidemics.

- Figure 24.15: Triangle of epidemiology
- Perspective 24.3: Variolation: Deliberate infection with smallpox virus

Improvements in sanitation, vaccines, and antimicrobial drugs have led to the prevention and control of epidemics.

- Figure 24.17: Current immunization schedule

The cell wall and resistance to antimicrobial agents **(Section 2.4)**

Horizontal gene transfer mechanisms and antimicrobial resistance **(Section 9.4)**

Epidemics, epidemiology, and controlling infectious diseases **(Section 18.3)**

Exposure to pathogenic microbes from untreated water supplies **(Section 16.5)**

Introduction

What would you list as the most significant past or present factors involved in the control of infectious diseases? You are correct if you listed improvements in sanitation, hygiene, nutrition, and the development of vaccines and antimicrobial agents. Increased survival rates in humans and domestic animals are closely correlated to these advancements. Of course, underpinning these improvements has been the attainment of economic wealth and education. Today, in developed nations, relatively few people die prematurely of infectious disease **(Figure 24.1)**. This is not the case in developing nations where, according to the World Health Organization (2008), infectious disease is still a major cause of premature death. Sadly, the majority of these deaths occur in young children from common diseases that can be prevented by vaccination or treatment with therapeutic agents. Diarrhea, malaria, measles, and pneumonia kill approximately four million children under the age of five each year, accounting for about half of all childhood deaths (see Figure 18.2).

Although improved sanitation has significantly reduced infections from foodborne or waterborne agents such as *Vibrio cholerae, Escherichia coli,* and rotaviruses, the added combination of vaccines and antimicrobial drugs has had the greatest impact on reducing overall mortality and illness from infectious diseases. These three measures remain the principal weapons in the treatment and control of infectious disease when employed according to strategies based on sound epidemiological foundations. Of course, disease control resulting from such advancements would not have been possible if it weren't for the nineteenth-century discovery of microbes as agents of many diseases.

Antimicrobial drugs, once hailed as the "magic bullet" to end the battle against infectious diseases, have perhaps been one of the biggest disappointments. Although undoubtedly advancing the treatment of infectious disease, microbes have not surrendered easily to these drugs, making drug resistance a serious threat in the treatment of many infectious diseases. This underscores the need for disease prevention involving surveillance, planning, and implementation of infection control measures, including strategic vaccination programs.

To learn about infectious disease treatment and control, we will focus on answering the following questions:

How did we deal with infectious disease in the past? (24.1)
What kinds of drugs are used to treat infections, and how do they work? (24.2)
How do microbes become drug resistant? (24.3)
How are epidemics predicted and controlled? (24.4)
What are vaccines, and how are they used to control infectious disease? (24.5)

Figure 24.1. Death rates from disease for 1900 and 2013 in the United States Infectious diseases were a major cause of premature death in 1900. In 2013, this has been reduced to a minor cause of death due to improved public and personal health, vaccines, and antimicrobial development.

24.1 Historical aspects of infectious disease treatment and control

How did we deal with infectious disease in the past?

The epidemic "crowd" diseases such as smallpox, plague, cholera, typhus, and influenza began influencing human populations on a large scale only in recent times. These infectious diseases require suitably large populations to be sustained. Prehistoric hunter-gatherer tribes were small and sparsely distributed. They also did not stay long enough in any one spot to contaminate their water supplies or attract disease-transmitting pests like rats and their fleas. They also did not live with domestic animals, which were the original source of many infectious diseases. Human populations began to accumulate about 10,000 years ago with the advent of crops and animal husbandry. Urbanization and travel associated with trade began in earnest around 3000 b.c. in areas around the Tigris and Euphrates rivers Egypt, southern China, and Central America.

Archeological and recorded evidence of the first large-scale plagues appears with the rise of these civilizations.

For most of human history, religious and superstitious beliefs were the only explanations offered as to why these diseases occurred. Diseases and disasters were heralded as punishment by supernatural beings in response to the immoral acts of humans. Afflicted persons were often cast out from society, a control measure that was enacted with moral authority as opposed to public safety. Victims of Hansen disease (leprosy) and other disfiguring diseases were indiscriminately lumped together and banished to live in deplorable camps outside the boundaries of towns. They were considered "unclean" and forbidden to marry or interact with the rest of society. Astonishingly, the last penal leper colony existed in the United States on the Hawaiian island of Molokai and was not transitioned to voluntary residence for treatment until 1969.

The ancient Greeks were the first to separate religious beliefs and disease, although even today superstitions surrounding disease still exist in many cultures. Greek writings document the use of logic and a view of disease as a condition of the physical and not the mystical. Around 400 B.C., Hippocrates, known as the "father of medicine," lectured on disease being a condition of physiological imbalance; he was on the right track. "Disease" is defined today as a disturbance in the normal functioning of an organism, a condition away from health. What Hippocrates didn't know was the cause of the imbalance or how to reestablish this balance to treat disease. While Hippocrates talked largely of maintaining physiologic balance through diet, others took this to the extreme. In an attempt to reestablish balance within the body and "cure" illness, they practiced phlebotomy or venesection, the purposeful lancing of a vein to let "excess" blood drain to cool fever. This may actually have worked temporarily by reducing the level of fever-inducing cytokines such as IL-1 (see Section 19.3). However, it did more overall harm than good as it also diminished immune cells and molecules needed to fight infection. Often, bloodletting reduced blood pressure to the point of unconsciousness. Leeches were similarly used to withdraw blood, and a multitude of imaginative bodily purges were liberally employed. Patients were routinely subjected to such unproven "treatments" at the whim of local health practitioners. These treatments continued well into the nineteenth century until the great microbe hunters of the mid-1800s—Koch, Pasteur, and Lister—provided evidence for the germ theory of disease, which proposed that many diseases were caused by microbes.

Quarantines used to restrict the movement of people exposed to a contagious disease for a period of time to see if they develop the illness began around the fourteenth century in efforts to stop the spread of infectious disease. Ships arriving from areas infected with yellow fever, for example, were required to anchor in a city's harbor for 40 days, or crews were dispatched to nearby islands before being allowed access to port. This was frequently an effective control measure in preventing epidemics. However, epidemics were not limited to humans or even animals. The Great Irish Potato Famine (1845–1851) was due to the airborne water mold *Phytophthora infestans*, which arrived on ships traveling from North America to England. It devastated staple potato crops in Ireland, resulting in the death of one million of the eight million people inhabiting the island. Another million people fled to America, mostly to New York City, to avoid starvation.

One of the most significant weapons in the control of infectious disease has been the development of vaccines. Jenner's development of the smallpox vaccine in 1796 (see Section 24.5) began a rational approach to infectious disease prevention. Robert Koch's development of Koch's postulates (see Section 18.4) were, and still are, instrumental in identifying the infectious agents associated with disease, making it possible to specifically target these agents and apply rational control measures. Lastly, Alexander Fleming's discovery of penicillin in 1928 (see Chapter 12 opening story) started a pharmaceutical revolution that allowed the treatment of a multitude of infectious diseases.

24.1 Fact Check

1. Give several reasons why epidemic diseases, such as smallpox, likely did not impact prehistoric human populations.
2. Why was bloodletting used to control infection? How could this be harmful?
3. What other methods were used to control disease before drugs and vaccines became available?

24.2 Antimicrobial drugs

What kinds of drugs are used to treat infections, and how do they work?

Most of us have been on one type of antimicrobial drug or another at some time in our lives, and many of us would not be alive today if it weren't for these drugs. **Antimicrobial drugs** are compounds used to treat or prevent infections primarily of the body. They are a subset of antimicrobial agents, introduced in Chapter 6, which include any substance that inhibits or kills microbes, including viruses. In this chapter, we will examine the mode of action of some of the more common antimicrobial drugs.

CONNECTIONS In **Section 6.5**, we were introduced to antiseptics, those antimicrobial chemicals that are generally used topically on body surfaces, like skin, and disinfectants, which are typically used on inanimate surfaces to control the growth of microbes.

All antimicrobial drugs used for treatment possess **selective toxicity**; they are more toxic to an infecting microbe than they are to the host when used at recommended dosages.

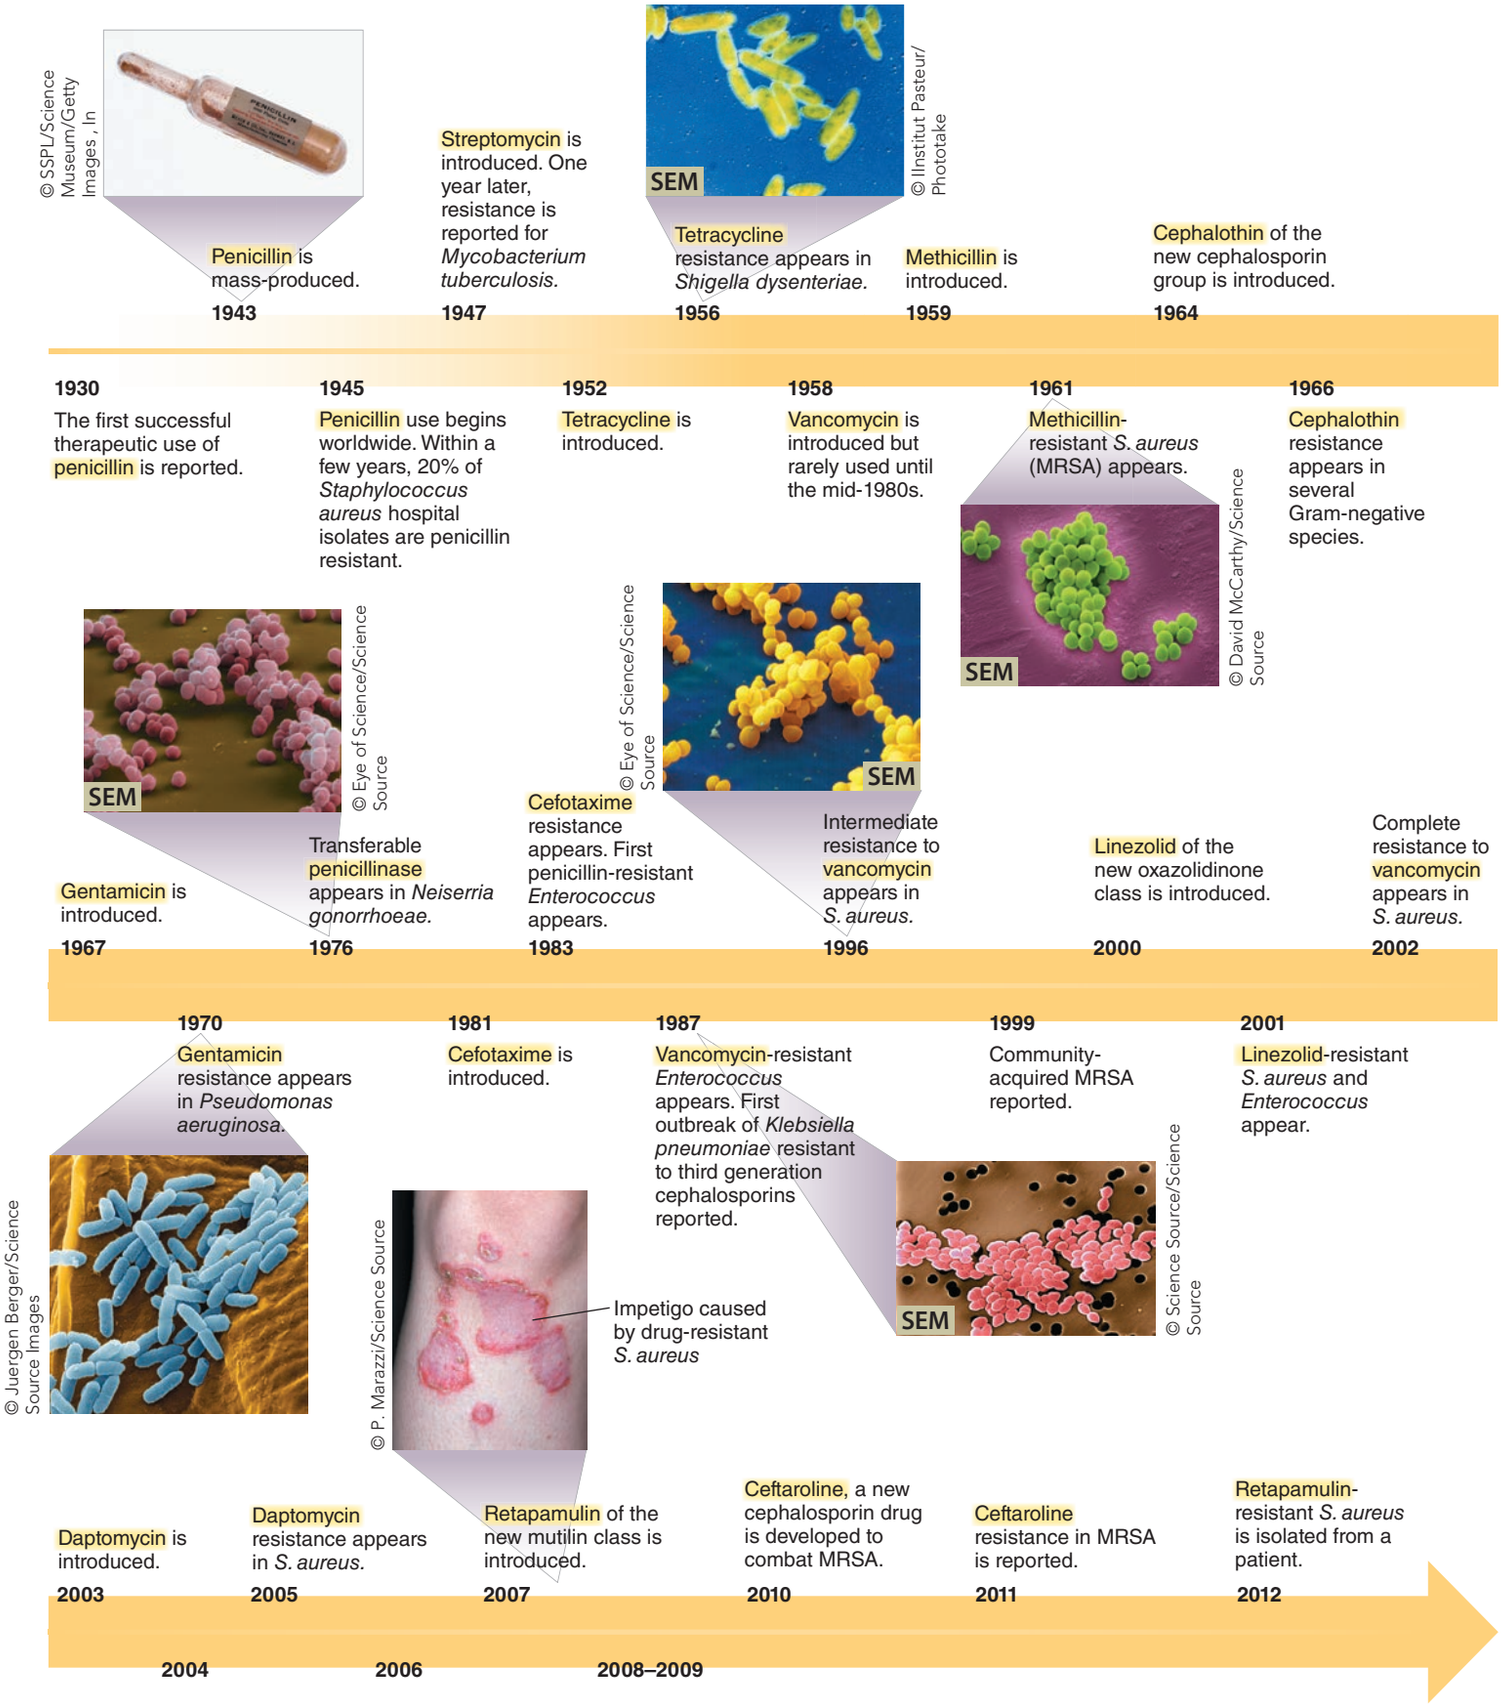

Figure 24.2. Antibacterial drug resistance time line Resistance has been observed for every antibacterial drug ever used for therapy, beginning with penicillin in 1945.

The reason for this lies in their ability to target specific components of microbes. Drugs that do not exhibit sufficient selective toxicity are not used clinically. Despite exhibiting selective toxicity, some antimicrobial agents still have the potential to cause damage to the host, usually because their mode of action has some activity on host cells as well. When correctly used at therapeutic doses, these toxic side effects are minimized while maintaining useful antimicrobial activity. Many antimicrobial drugs are never approved for use because they are too toxic to the body at concentrations needed to combat infection.

Antibiotics are an important group of antimicrobial drugs and are the most widely prescribed therapeutic drugs. The term **antibiotic** was originally used to describe compounds produced naturally by bacteria or fungi that inhibit the growth of other bacteria or fungi. However, many naturally produced antibiotics have been modified into semisynthetic compounds by chemical alteration. Many antibiotics are also now produced through cost-effective chemical processes only and are no longer isolated from their associated microorganisms. Synthetic antibiotics do not originate from microbes; they are designed and produced through technology. Because of the widespread use of synthetic and semisynthetic therapeutic compounds against microbial cells, the term "antibiotic" is often used to include all antimicrobial drugs that act on the cells of microorganisms, but not viruses or subviral particles. This popular definition, which we will use here, reflects the target of the drugs—microbial cells—rather than the origin. We will continue to distinguish natural antibiotics, their semisynthetic derivatives, and synthetic antibiotics to illustrate the important contribution of microorganisms in the development of antibacterial and antifungal drugs.

Recall from the opening story of Chapter 12 that the development of antibiotics began with Alexander Fleming in 1928. He recorded his observations of a particular compound from the common bread mold *Penicillium* that could inhibit cultures of *Staphylococcus aureus*. He isolated this compound, *penicillin*, and others began using it to treat infections in the body. Fleming's "wonder drug" saved countless lives during World War II, when it first came into widespread use. However, it was not long before this curative drug became the driving force in the acquisition and maintenance of resistance genes in the very bacteria it previously killed. This pattern has been repeated with every antimicrobial drug ever used **(Figure 24.2)**.

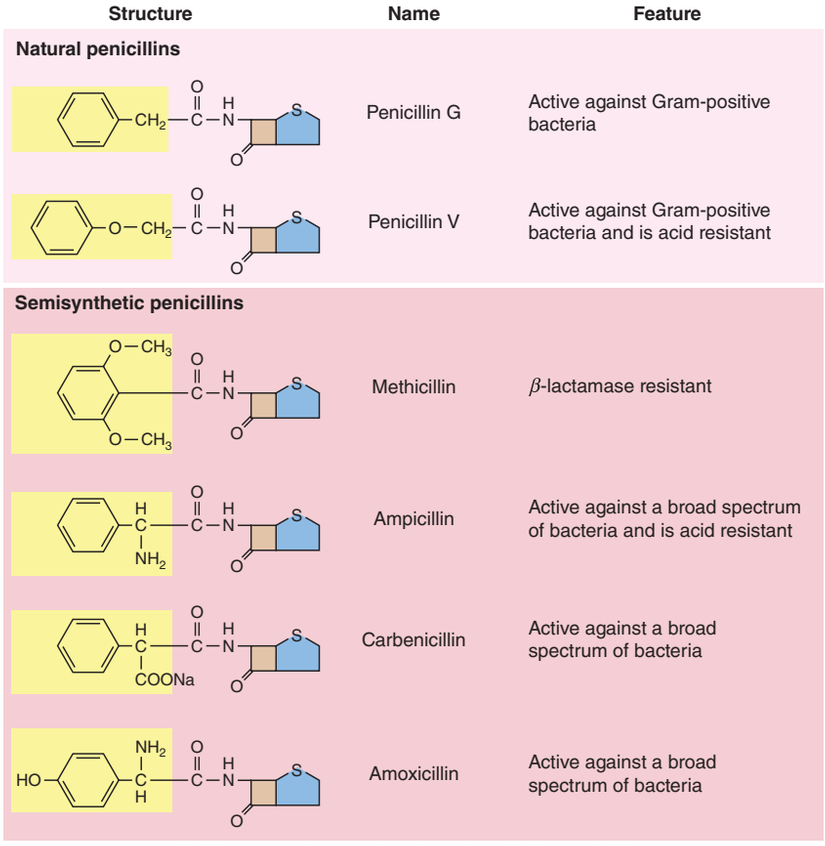
As shown in **Table 24.1**, the bacterial genus *Streptomyces*, common in soils (see Microbes in Focus 12.1), has been particularly valuable for providing antibiotics. Semisynthetic antibiotic derivatives contain modified side chains to improve issues of toxicity, stability, absorption, microbial resistance, or spectrum limitations. For example, as shown in **Figure 24.3**, penicillin G, a naturally occurring antibiotic, is a narrow spectrum drug effective only against Gram-positive bacteria and is destroyed by acid, so is unsuitable for oral ingestion. Ampicillin, a semisynthetic derivative of penicillin G, is a broad spectrum drug, exhibiting activity against Gram-positive and many Gram-negative bacteria **(Figure 24.4)**. It is acid resistant and can be taken orally. Other broad spectrum semisynthetic antibiotics, like methicillin and oxacillin, were developed because they are resistant to attack by penicillin-destroying β-lactamases produced by many strains of *Staphylococcus aureus*, *Enterococcus*, and members of the *Enterobacteriaceae* family.

Antimicrobial drugs can be divided into categories based on the microbial groups they target. These are antibacterial, antifungal, antiprotozoal, and antiviral agents. With few exceptions, antimicrobial drugs do not cross these divisions because they target molecules that are specifically found only in a specific group—a reflection of phylogenetic differences. We will begin with surveying the largest group of antimicrobial drugs, the antibacterial drugs.

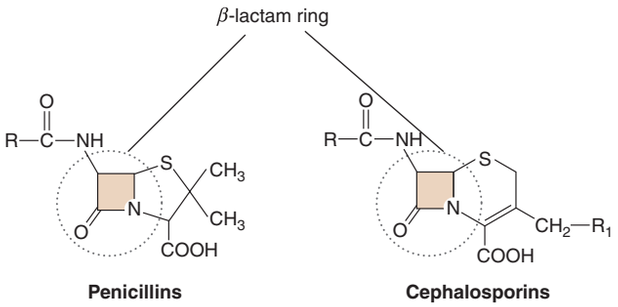
TABLE 24.1 Antibiotics and their origins

Source	Natural antibiotic	Semisynthetic derivatives
Antibacterial antibiotics		
Penicillium chryosgenum (fungi)	Penicillin G, penicillin V	Methicillin, ampicillin, amoxicillin, carbenicillin, oxacillin
Cephalosporium species (fungi)	Cephalosporin	Cephalexin, cephradine, cefradoxil, ceftazidime
Streptomyces griseus	Streptomycin	NA[a]
Streptomyces aureofaciens	Tetracycline	Doxycycline, oxytetracycline
Streptomyces venezuelae	Chloramphenicol	NA[a]
Streptomyces erythreus	Erythromycin	Azithromycin, clarithromycin
Streptomyces kanamyceticus	Kanamycin	Amikacin, arbekacin
Streptomyces tenebrarius	Tobramycin	NA[a]
Streptomyces fradiae	Neomycin	NA[a]
Streptomyces mediterranei	Rifamycin	Rifampin
Amycolatopsis orientalis	Vancomycin	Ramoplanin
Micromonospora species	Gentamicin	NA[a]
Bacillus licheniformis	Bacitracin	NA[a]
Bacillus polymyxa	Polymyxins	NA[a]
Antifungal antibiotics		
Penicillium griseofulvum	Griseofulvin	NA[a]
Streptomyces nodosus	Polyenes	NA[a]

[a]NA: not applicable; not developed or not commonly used.



A. Structure of natural and semisynthetic penicillins



B. Difference between penicillins and cephalosporins

Figure 24.3. Structure of penicillins **A.** Natural penicillins G and V differ only in the structure of the side groups (shown highlighted). Semisynthetic penicillins have modifications of the side groups that can impart resistance to β-lactamases, broaden the spectrum of bacterial groups against which they can be used, and impart acid resistance. Acid resistance permits oral administration. **B.** Penicillins are composed of a 5-member ring structure attached to the β-lactam ring, and a single side group, designated R. Cephalosporins differ by the presence of a 6-member ring that can carry an additional side group, designated R1.

Antibacterial drugs

Before we begin to examine particular drugs, it is important to understand how these drugs work in and out of the body to control bacterial growth. **Bactericidal drugs** are antibacterial drugs that can kill bacteria directly. **Bacteriostatic drugs** prevent replication of bacteria, but do not kill them. These descriptions are based on observations of controlled *in vitro* experiments. A culture treated with a bacteriostatic agent for a short time resumes growth when the agent is removed; the effect is reversible. In a culture treated with a bactericidal agent for a short time, cells are killed; the effect is irreversible. Both bacteriostatic and bactericidal drugs are effective therapies against infection. Inside the complex environment of the body, bacteria are subject to host immune defenses, not just

Figure 24.4. Spectrum differences of antibacterial agents Broad spectrum drug groups, such as tetracyclines and semisynthetic penicillins, are effective against diverse groups of unrelated bacteria. Narrow spectrum drugs, such as penicillin G, polymyxins, and isoniazid affect only small groups of related bacteria.

drugs, so any bacterial cells that are unable to grow will usually be destroyed by the immune system within the course of the antimicrobial treatment.

Antibacterial drugs are frequently subdivided into classes based on their structure, which in turn is related to their mode of action. Most act on bacteria in common ways, interfering with aspects of cell wall synthesis, membrane integrity, ribosome function, polymerase function, or nucleotide synthesis (**Figure 24.5**). **Table 24.2** presents common classes of antibacterial drugs and gives details of the mode of action and structure of some representative antibiotics. We will examine a few of the most commonly used classes of antibacterial drugs in this section.

Inhibitors of Peptidoglycan Synthesis

Members of the **β-lactam class** of antibacterial drugs share the common structural feature of the β-lactam ring (see Figure 24.3B; see also Figure 2.19), required for binding to a group of wall-associated proteins known as **penicillin-binding proteins (PBPs)**. The PBPs have a transpeptidase function, required for joining together the subunits that make up peptidoglycan. Penicillins and cephalosporins are among the most commonly prescribed drugs, accounting for almost 50 percent of antibiotics used.

Beta-lactam antibiotics mimic the terminal alanine amino acids of peptidoglycan precursors, causing the PBPs to bind to them irreversibly. In this state, they can no longer function in the synthesis of peptidoglycan. Different β-lactams have different abilities to interfere with peptidoglycan synthesis. This is related to differences in PBPs and the ability of β-lactams to access them.

CONNECTIONS The PBPs were named because of their ability to bind penicillin before their transpeptidase role in peptidoglycan synthesis was fully revealed. For a review of the action of β-lactams and the PBP transpeptide enzymes, see **Section 2.4**.

Figure 24.5. Overview of antibacterial drugs and their targets Antibacterial drugs act on one of six main cellular targets or processes: (*clockwise from top*) cell membranes, folic acid synthesis (which indirectly inhibits nucleic acid synthesis), transcription, peptidoglycan synthesis (penicillin-binding proteins), DNA synthesis, and protein synthesis (ribosomes).

TABLE 24.2 Action, structure, and targets of antibacterial drug groups

Action	Class/group	Structure	Target	Examples
Antibacterial drugs				
Inhibition of peptidoglycan synthesis	**Natural and semisynthetic antibiotics**			
	β-lactams	 Penicillin G	Peptidoglycan transpeptidases (PBPs)	Penicillins G and V, methicillin, cephalosporins, monobactams, carbenicillin
	Glycopeptides	 Vancomycin	Peptidoglycan peptide subunits	Vancomycin, avoparcin
	Bacitracin (topical use)	 Bacitracin	Isoprenyl pyrophosphate	Bacitracin
Disruption of membranes	Polymyxin B (topical use)	 Polymyxin B	Membranes	Polymyxin B, polymyxin E
Inhibition of ribosome function	Aminoglycosides	 Gentamicin	16S rRNA of 30S ribosome subunit	Gentamicin, neomycin, streptomycin, tobramycin

TABLE 24.2 (Continued)

Action	Class/group	Structure	Target	Examples
	Macrolides	 Erythromycin	Peptidyl transferase site of 50S ribosome subunit	Erythromycin, spectinomycin, carbomycin
	Tetracyclines	 Tetracycline	30S ribosome subunit	Tetracycline, doxycycline, oxytetracycline
	Chloramphenicol	 Chloramphenicol	23S rRNA of 50S ribosome subunit	Chloramphenicol
Inhibition of transcription	Rifamycins	 Rifampin	β-subunit of bacterial RNA polymerase	Rifampin, rifabutin, rifapentine
Inhibition of nucleic acid synthesis	**Synthetic antibiotics**			
	Quinolones	 Ciprofloxacin	Gram-negative DNA gyrase or Gram-positive topoisomerase IV	Nalidixic acid, oxolinic acid, fluoroquinolones (e.g., ciprofloxacin)
	Sulfonamides	 Sulfanilamide	Dihydropteroate synthetase (folic acid pathway)	Sulfisoxazole, sulfanilamide
	Trimethoprim	 Trimethoprim	Dihydrofolate reductase (folic acid pathway)	Trimethoprim

Susceptibility of microorganisms to drugs that act on cytoplasmic or periplasmic targets is a function of the transport of these drugs across membranes. Without transport, they are ineffective. In Gram-negative bacteria, PBPs are found in the membrane-bound periplasm, whereas in Gram-positive bacteria, they are found within the external cell wall (see Figure 24.5). Natural penicillins G and V are not transported across the outer membrane of Gram-negative bacteria, and therefore are only effective against Gram-positive bacteria (see Figure 24.4). However, the addition of amino and carboxyl groups to the penicillin side chain allows these semisynthetic penicillins to be transported through outer membrane porins to act on the periplasmic PBPs. This imparts a much broader range of activity. For example, carbenicillin is often used for treating infections with *Pseudomonas aeruginosa*, a Gram-negative pathogen, whereas penicillin G is used for *Streptococcus pneumoniae*, a Gram-positive pathogen.

Although PBPs are present in all bacteria that manufacture peptidoglycan, in different species they vary in number (most have several different PBPs), amount, and structure. The similarity between PBPs of different species usually follows phylogenetic relatedness, with different β-lactam antibiotics inhibiting some PBPs more so than others. Finally, some bacteria have complex life cycles that prevent β-lactams from being effective. Members of the genus *Chlamydia*, intracellular bacterial pathogens with a two-phase life cycle, are only susceptible to penicillin during differentiation into their infectious, extracellular, spore-like elementary body form. The intracellular reticulate body form, which causes damage, does not possess detectable peptidoglycan. It is presumed that *Chlamydia* express PBPs only during this differentiation process to produce the peptidoglycan associated with the inert elementary body. Treatment with penicillin can therefore result in a noninfectious but persistent intracellular state in the host. For this reason, tetracycline is the preferred treatment (see Figure 24.4).

Inhibitors of Ribosome Function

Inhibiting ribosome function interferes with translation and thus protein synthesis in the bacterial cell. Aminoglycosides, such as kanamycin, neomycin, gentamicin, and their derivatives, act on the ribosome by reversibly binding to 16S rRNA, disrupting interaction of mRNA with tRNA, thus interfering with translation. Aminoglycosides are known for their toxicity in humans and animals, particularly to kidneys and the inner ear apparatus. The mechanism of toxicity remains unknown, but is unrelated to protein synthesis in eukarya. Lower doses are less toxic, but not as effective. For this reason, they are frequently used in combination with other antibacterial drugs.

Macrolides act on the bacterial ribosome by binding near the 50S peptidyl transferase site, blocking elongation of the growing peptide. Like aminoglycosides, tetracyclines, and chloramphenicol, they inhibit protein synthesis. **Figure 24.6** summarizes the action of many ribosome-inhibiting antibiotics. The macrolide erythromycin is effective against Gram-positive bacteria, but is not efficiently taken up by most Gram-negative bacteria.

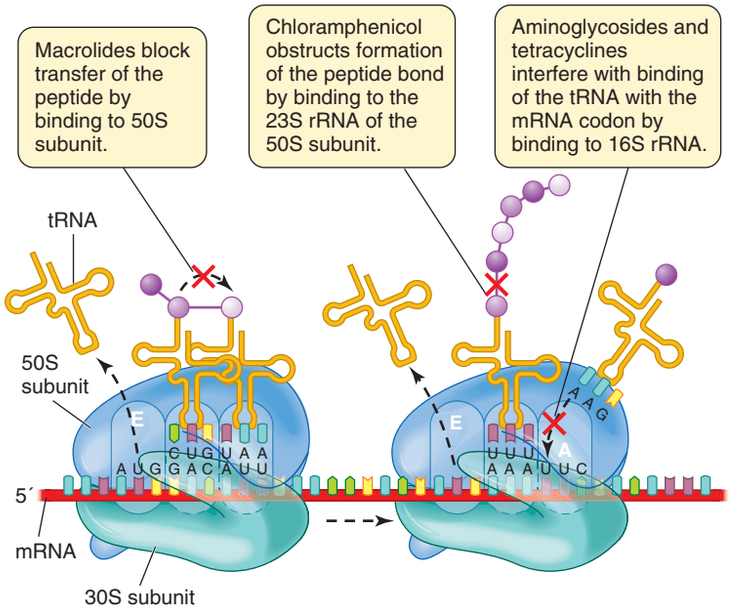

Figure 24.6. Inhibition of protein synthesis by antibiotics Four major groups of antibiotics act on targets of the ribosome to inhibit protein synthesis. These antibiotics are useful in treating bacterial infections because they have a greater affinity for the bacterial ribosome than the eukaryal ribosome.

Tetracyclines and their derivatives act on the 30S ribosome by binding to the 16S rRNA, blocking interaction of the tRNA anticodon to the mRNA codon, thereby inhibiting bacterial protein synthesis. They have an inherent ability to bind RNA secondary structures, making them somewhat active against mRNA of eukaryal cells as well. Fortunately, tetracyclines are not as efficiently taken up by eukaryal cells, but they can cause toxicity in high doses. Tetracyclines can permanently discolor teeth, especially in children, due to formation of localized calcium/tetracycline complexes **(Figure 24.7)**. Tetracycline is effective against many Gram-negatives, most Gram-positives, both of the developmental forms of *Chlamydia*, and the peptidoglycan-deficient bacteria *Rickettsia* giving it one of the broadest spectrums of any antibacterial drug (see Figure 24.4).

Chloramphenicol binds the 23S rRNA of the 50S subunit, interfering with peptidyl transferase activity of the ribosome, which results in the prevention of peptide bond formation. It has a broad spectrum range, but causes a rare and unpredictable form of aplastic anemia, produced from the destruction

Figure 24.7. Tetracycline staining of teeth Staining is due to the ability of tetracycline to bind calcium. Discoloration is permanent and most pronounced when children under five years of age are given tetracycline. Adults given tetracycline frequently report slight darkening of teeth.

of the bone marrow progenitor cells that form erythrocytes and leukocytes. The condition is usually fatal unless a bone marrow transplant is performed, which has long-term complications of its own. Chloramphenicol is a last-chance drug used only in serious infections when other antibacterial drugs are not effective.

Inhibitors of Nucleic Acid Synthesis

Quinolones and sulfonamides are two of the most commonly used synthetic antibacterial drugs. Quinolones are based on the core structure of nalidixic acid, one of the first quinolones to be used. Newer versions are fluorinated to give them better antibacterial activity and less toxicity. Quinolones are broad spectrum drugs that bind to DNA gyrase, particularly of Gram-negative bacteria, and topoisomerase IV of Gram-positive bacteria (see Section 7.2). They can also be used against intracellular pathogens such as *Legionella pneumophila*, *Mycoplasma pneumoniae*, and *Mycobacterium tuberculosis*, because of their ability to enter eukaryal cells.

Sulfonamides (sulfa drugs) are very small antibacterial drugs that are structural analogs of para-aminobenzoic acid (PABA). PABA is used by many bacteria to make folic acid, a necessary precursor for the synthesis of the nitrogenous bases adenine, guanine, and thymidine, needed for DNA synthesis (**Figure 24.8**; see also Figure 13.47). When sulfonamides competitively bind the enzyme dihydropteroate synthetase that incorporates PABA into the folic acid precursor molecule, enzyme function is inhibited and also a non-functional folic acid derivative results. The cells of animals and humans are unaffected by sulfonamide drugs because they take up folic acid, also known as vitamin B_9, from their diet. Similarly, many single-celled eukarya and some bacteria acquire folic acid from their environment and are unaffected by these drugs.

Trimethoprim inhibits another enzyme, dihydrofolate reductase, later in the folic acid pathway. Inhibition of this enzyme prevents synthesis of the folic acid derivative tetrahydrofolic acid, preventing synthesis of thymidine (see Figure 13.47). Sulfonamides and trimethoprim are often used together in a drug combination referred to as "co-trimoxazole."

Antifungal drugs

Fungal pathogens are eukarya and so their metabolic pathways, DNA, RNA, and protein synthesis machineries are very similar to those of their host. Treating fungal infections is notoriously difficult because most effective antifungal agents typically show toxicity to host cells as well. Therefore, finding drugs that exhibit sufficient selective toxicity to fungal cells and not host cells is a challenge. Compared to antibacterial drugs, only a modest selection of antifungal agents is available (**Table 24.3**). Additionally, many fungi have the intrinsic ability to modify agents entering their cytoplasm, rendering the drugs less effective.

Disruption of Plasma Membrane

Desired selective toxicity for an antifungal drug requires a target feature unique to fungi. What would represent such a target? One distinguishing feature of fungi is the presence of ergosterol, instead of cholesterol, in their plasma membranes. Polyene antibiotics bind ergosterol to form pores in the plasma membrane, causing increased membrane permeability, leading to detrimental ion imbalances. Azoles comprise a major group of antifungal drugs and are also widely used for treating and preventing fungal infections in agricultural crops. They disrupt membrane sterol synthesis, including ergosterol synthesis, leading to membrane damage. Some are used systemically, but most are topical. Azoles, such as fluconazole, are commonly used for *Candida* vaginal and skin infections.

Inhibition of Cell Wall Synthesis

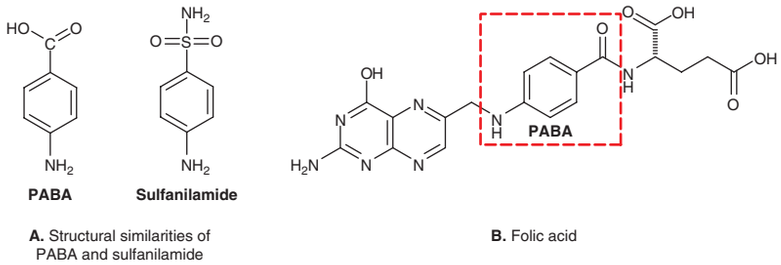
Echinocandins are a group of originally natural antibiotics produced from a variety of fungal isolates that now have many semisynthetic derivatives. They inhibit synthesis of the major cross-linked glucan found exclusively in fungal cell walls by targeting β-1,3-d-glucan synthase. Their action leads to leakage and lysis and thus they have been called the "penicillins of antifungals." Their inhibitory spectrum includes *Candida* spp., *Aspergillus* spp., and *Pneumocystis carinii,* all common culprits in infections of immunocompromised people, such as those living with HIV/AIDS.

Disruption of Mitosis

Griseofulvin is an oral antibiotic used against a few fungal genera causing skin (commonly, ringworm caused by *Microsporum* spp.), hair, and nail infections. The drug binds keratin precursors and becomes incorporated into new keratin, which delivers the drug to infecting fungal cells. The fungal cells transport it in where it binds tubulin, inhibiting the formation of microtubules needed for mitosis.

Antiprotozoal drugs

Like fungal infections, combating protozoal infections is difficult. Not only do protozoa share many structural and metabolic features with the cells of their hosts, but also they share little with each other. Consequently, relatively few broad spectrum and selectively toxic drugs are available, and the toxicity associated with these commonly causes side effects such as vomiting, diarrhea, and nausea (**Table 24.4**). As we saw in Chapter 23, further complicating this is the ability of many protozoa to differentiate into



A. Structural similarities of PABA and sulfanilamide

B. Folic acid

Figure 24.8. Sulfonamides and trimethoprim action **A.** Sulfonamides (sulfanilamide shown here) are structural analogs of para-aminobenzoic acid (PABA), which is a precursor for folic acid synthesis. **B.** Folic acid showing the PABA component.

TABLE 24.3 Action, structure, and targets of antifungal drug groups

Action	Class/group	Structure	Target	Examples
Antifungal drugs				
Inhibition of mitosis	**Natural and semisynthetic antibiotics**			
	Griseofulvin	 Griseofulvin	Tubulin	Griseofulvin
Inhibition of cell wall synthesis	Echinocandins	 Caspofungin	β-1, 3-D-glucan synthase	Caspofungin, papulacandin
Disruption of plasma membrane	Polyenes	 Amphotericin B	Plasma membrane ergosterol	Amphotericin B, nystatin
	Synthetic antibiotics			
	Azoles	 Fuconazole	C14-demethylase	Fluconazole, ketoconazole, clotrimazole, miconazole

distinct forms through their life cycle, and to migrate to different tissues. As a result, many protozoa present a moving target, and treatment of these pathogens can be complicated, requiring a regimen of different drugs. Here, we will look at only a few common drug groups, focusing on antimalarial drugs because they form the largest group of antiprotozoal drugs.

Inhibition of Heme Detoxification

Quinolines, not to be confused with antibacterial quinolones, are antimalarial agents related to quinine, a compound extracted from the cinchona tree of Peru and Bolivia, but can also be made synthetically. Quinine was commonly

TABLE 24.4 Action, structure, and targets of antiprotozoal drug groups

Action	Class/group	Structure	Target	Examples
Antiprotozoal drugs				
Inhibition of heme detoxification	Quinolines	 Chloroquine	Hemozoin (see Section 23.2)	Quinine, chloroquine, primaquine, mefloquine
Free radical formation	Artemisinin	 Artemisinin	Malarial calcium-dependent ATPase	Artemisinin, artemether, artesunate
Destruction of DNA	Metronidazole	 Metronidazole	DNA	Metronidazole

used to treat malaria as long ago as the seventeenth century, but it is highly toxic. In the 1940s, it was replaced by related but less toxic synthetic drugs such as chloroquine. Resistance to quinine is unusual, and it is still used in cases in which the disease-causing agent is resistant to these newer drugs.

Chloroquine diffuses across plasma and lysosomal membranes of host cells and *Plasmodium* parasites, which reside inside erythrocytes during a critical stage in their life cycle. Chloroquine binds to hemozoin, a nontoxic derivative of heme formed by the parasite as it consumes hemoglobin. Binding prevents crystallization of hemozoin and inhibits the ability of the parasite to continue to detoxify heme inside the acidic food vacuole. Free heme accumulates in the parasite food vacuole and destabilizes the vacuole membrane, resulting in the death of the parasite. The crystallization of heme is a process unique to the parasite, thus drugs that interfere with this process do not significantly harm host cells.

CONNECTIONS In **Section 23.2**, we learned that the malaria parasite *Plasmodium falciparum* consumes hemoglobin in infected erythrocytes in order to obtain amino acids. The released heme is a toxic by-product that the parasite must eliminate. Investigating the life cycles and physiology of eukaryal parasites can suggest unique targets for drug development that will minimize host cell damage.

Free Radical Formation

Artemisinin is an antimalarial drug, originally isolated from the plant *Artemisia annua*, but it is also synthesized by genetically engineered yeast (see The Rest of the Story, Chapter 12). Use of artemisinin alone gives rise to artemisinin resistance but, when used in combination with other drugs such as mefloquine, remains an effective treatment against chloroquine-resistant strains of *Plasmodium falciparum*. The mode of action of artemisinin is not completely clear, but is active against the erythrocyte stage of the parasite (see Section 23.2). Artemisinin forms reactive free radicals in the presence of ferrous iron (Fe^{2+}), and it appears that the free radicals irreversibly inhibit a metabolic enzyme, the malarial calcium-dependent ATPase, resulting in parasite death.

Destruction of DNA

Metronidazole, commonly known by its tradename, Flagyl, is a synthetic drug active against some protozoa and anaerobic bacteria that take up the drug and then convert it to its active form. The active form is incorporated into the DNA helix, causing lethal breakages. Flagyl is used to treat intestinal infections of *Giardia, Entamoebae*, and the anaerobic *Clostridium difficile* bacteria (see Chapter 17 Mini-Paper), as well as *Trichomonas vaginalis*, a sexually transmitted protozoan.

Antiviral drugs

As we have seen in Chapter 8, viruses use many host cell systems during the production of new viral particles. Because all viruses utilize the host cell translational machinery to make viral proteins, antiviral drugs cannot target this process. Many viruses also use host cell proteins for DNA replication and transcription. For these viruses, antiviral drugs ideally should not target these processes. So what processes can an antiviral drug target? There are two general approaches to antiviral drug design. One approach has been the development of broad spectrum antiviral drugs that are effective against several viruses. The other approach is to design specific drugs to target specific viruses. For this, detailed knowledge of mechanisms for attachment, entry, uncoating, and egress for individual viruses is used. The majority of antiviral drugs available target HIV, herpes viruses, hepatitis B and C viruses, and influenza viruses. The list of antiviral drugs, although not all covered here, is relatively short compared to those available for bacterial infections.

Inhibition of DNA Synthesis

In the search for broad spectrum antiviral drugs exhibiting selective toxicity, researchers have taken advantage of the fact that, first, many viruses have rapid genome replication rates compared to cellular genome replication rates, and second, many viruses use their own viral DNA or RNA polymerases for replication. Recall from Chapter 8 that single-stranded RNA viruses use a viral RNA-dependent RNA polymerase. Retroviruses use a viral RNA-dependent DNA polymerase. Herpesviruses and poxviruses, which contain double-stranded DNA genomes, use their own DNA-dependent DNA polymerases. This distinction from host cell polymerases has led to the development of a group of antiviral drugs known as **nucleoside analogs** (Table 24.5), which competitively inhibit DNA synthesis by becoming incorporated into the growing chain during viral replication. Nucleoside analogs are structurally similar to nucleosides and, once phosphorylated in the cell, compete with normal nucleotide triphosphates for viral DNA polymerases. Azidothymidine (AZT), also called zidovudine, is a therapeutic drug for HIV infection (Figure 24.9). It is a dideoxythymidine analog that causes DNA chain termination because it lacks the 3´—OH group needed for nucleotide addition. Instead, AZT contains an azide group ($—N_3$) in this position. Because a free 3´—OH group is necessary for DNA elongation (see Section 7.2 for a review of DNA replication and the HIV replication animation in Chapter 8), no additional nucleotides can be added to AZT if it becomes incorporated into a growing DNA chain. Thus, this drug prevents the completion of a DNA copy needed for insertion into the host genome for viral replication (see Figure 8.20). The similar chain terminating drug tenofovir, an analog of adenosine, acts to inhibit the reverse transcriptase of HIV and hepatitis B virus. Retroviruses are not the only viruses to use a reverse transcriptase. Hepatitis B virus belongs to family *Hepadnaviridae* (see Figure 5.26), a family

TABLE 24.5 Action, structure, and targets of antiviral drug groups

Action	Class/group	Structure	Target	Examples
Antiviral drugs				
Inhibition of DNA synthesis	Nucleoside analogs	 Acyclovir (guanine analog)	DNA	Acyclovir, AZT, ribavirin, tenofovir, vidarabine, idoxuridine
Inhibition of influenza virus uncoating	Amantadine	 Amantadine	Influenza virus M2 protein (an ion channel needed for release of nucleocapsids)	Amantadine, rimantadine
Inhibition of influenza virus release	Neuraminidase inhibitor	 Oseltamivir	Neuraminidase (needed to cleave terminal sialic acid to which virus is tethered upon exit from cell)	Oseltamivir (Tamiflu), zanamivir (Relenza)

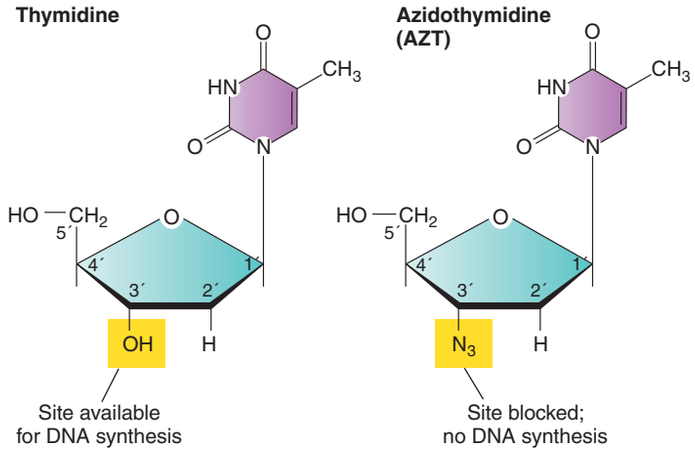


Figure 24.9. Many antiviral drugs are nucleoside analogs. Structurally, azidothymidine (AZT) resembles the nucleoside thymidine. When the triphosphorylated form of AZT is added to a growing DNA strand, it acts as a chain terminator. Additional nucleotides cannot be added to AZT because it lacks an available 3′—OH group.

of DNA viruses that use a reverse transcriptase for replication, as can be seen in Figure 8.13.

The HIV reverse transcriptase has a roughly 100-fold greater affinity for AZT than does our DNA polymerase, or other viral polymerases. In other words, we could say that other DNA polymerases are more selective than HIV's reverse transcriptase; our DNA polymerase usually can distinguish AZT from thymidine. However, the selectivity of our DNA polymerase is not perfect. If a person infected with HIV is taking AZT, then the drug will become incorporated into replicating cellular DNA occasionally, thereby preventing complete replication of the DNA and severely damaging the cell. As a result, serious side effects are associated with AZT. Additionally, resistance to AZT is common in HIV strains due to mutations in the reverse transcriptase gene. Thus, AZT is far from a perfect drug. Today, the ideal treatment regimen for a person infected with HIV involves three different drugs: a triple-drug cocktail. This mixture of drugs more effectively inhibits the replication of the virus. This combination therapy also decreases the frequency with which drug-resistant viral mutants develop. We will investigate why this is in Section 24.3.

Other nucleoside analogs act in a different way. Instead of terminating DNA replication, they produce mutations in subsequent rounds of replication because they cannot be correctly interpreted by polymerase. Acyclovir, a commonly used orally administered antiherpes drug, is a guanosine analog that becomes incorporated into DNA during synthesis. Idoxuridine is a base analog of thymidine and is used in eye drop form for ocular herpes infections. Unfortunately, not all viral polymerases are greatly impacted by these drugs, and many that are often develop resistance.

Drugs Tailored to Specific Viruses

Our understanding of viral replication is directly linked to our ability to develop effective antiviral drugs. The initial binding of the virus to a host cell can be targeted. Penetration of the plasma membrane could be targeted. For viruses that replicate in the host cell nucleus, movement through the cytoplasm to the nucleus could be targeted. Even aspects of assembly and exit from the cell could be targeted. However, the options are somewhat limited because rational design and development of tailor-made drugs is only possible if one has a detailed understanding of how viruses replicate. Examples are the designer drugs oseltamivir (known as Tamiflu) and amantadine compounds (see Table 24.5) that are specifically active against influenza viruses.

CONNECTIONS Tamiflu inhibits viral neuraminidase, an enzyme essential for dissemination of newly budded virions. See **Chapter 8, The Rest of the Story** for more information.

The drugs maraviroc and Fuzeon, mentioned in Sections 8.1 and 8.2, are other tailor-designed drugs that act to block HIV entry. Maraviroc blocks viral attachment by binding to the CCR5 cellular co-receptor (see Section 5.1 and Figure 8.6), and Fuzeon, as its name suggests, blocks fusion between the HIV envelope and the cell plasma membrane (see Figure 8.7). Another approach for tailoring drugs to block viral entry is based on monoclonal antibodies. Recall from Section 20.1, antibodies are products of the adaptive immune system that can specifically and tightly bind select epitopes of molecules. Indeed, the body produces antibodies against invading microbes to protect from disease. It seems logical to harness these powerful molecules to block viral attachment. A recent example is ZMapp, which is an experimental drug therapy against Ebola virus (see Microbes in Focus 22.3). ZMapp consists of a cocktail of three different monoclonal antibodies, each binding to a specific epitope on the virus attachment glycoprotein. We previously described traditional monoclonal antibody technology in Toolbox 20.1. Interestingly, ZMapp monoclonal antibodies are produced through recombinant DNA technology in tobacco plants. The antibodies are designed to inhibit the cell-to-cell spread of the virus, thus reducing viral load, disease progress, and transmission to others. It has been shown to be effective in monkey models, but its very limited use in the 2014 West African Ebola epidemic in a few patients has not yielded conclusive results. In any case, this is just one example of a new avenue of drug development that may pave the way for other effective virus treatments, where none existed before.

24.2 Fact Check

1. What is meant by the term "selective toxicity"?
2. Why is selective toxicity a particular challenge in finding drugs for viruses and eukaryal pathogens?
3. What is the mode of action of β-lactam antibiotics?
4. Which classes of antibiotics are considered ribosome inhibiting, and how do they work?
5. Describe some of the cellular targets and mechanisms of action of antifungal and antiprotozoal drugs.
6. Describe some of the mechanisms of action of antiviral drugs.

24.3 Antimicrobial drug resistance

How do microbes become drug resistant?

Microbes are masters at adapting to adverse conditions because they are experts at genetic change. This genetic adaptability is the reason for their continued success on the planet and their ability to exist in every known habitat ever explored. No other life-form has proven capable of conquering such varied and seemingly adverse conditions (see Section 1.3). Microbes are adept at protecting themselves from various inhibiting compounds found naturally in their environment, and an antimicrobial drug is just another toxic substance, a change to their environment that they must overcome. Today, the development of drug resistance by microbes is a serious challenge to health care, not only for the treatment of common infectious diseases, like strep throat and tuberculosis (see Section 21.3), but also for the prevention of infection following medical procedures. In 2013, the Centers for Disease Control and Prevention (CDC) reported that in the United States alone, more than two million people become ill due to antibiotic-resistant bacterial and fungal infections each year. Of these, about 23,000 patients die. The majority of bacterial pathogens (about 70 percent) causing hospital-acquired infections show resistance to at least one therapeutic antibacterial drug.

As we learned in Section 9.2, the selection for antimicrobial drug resistance genes within a community of bacteria can be demonstrated easily through controlled experiments in the lab. What is the evidence for selection for resistance in clinical settings? The following documented global trends provide compelling evidence that antimicrobial drug use is linked to development of resistance:

- Changes in antimicrobial drug use are positively correlated with changes in prevalence of resistance.
- Increasing the length of antibiotic treatment in patients is associated with increasing rates of colonization of these patients with resistant organisms.
- Microbial resistance is highest in facilities where antimicrobial drugs are used with the highest frequency.
- Patients with resistant strains have received antibiotics more often than patients with non-resistant strains.

This leaves little doubt that resistance is a direct consequence of antimicrobial drug use. However, important questions remain. What are the molecular mechanisms of resistance, where do the genes for resistance originate, how does selection for resistance occur, and how can resistance be prevented?

Molecular mechanisms of resistance

Resistance mechanisms of bacteria have been the most thoroughly studied because bacterial drug resistance is a widespread phenomenon, associated with almost all bacterial pathogens. As shown in **Figure 24.10**, one or more of the

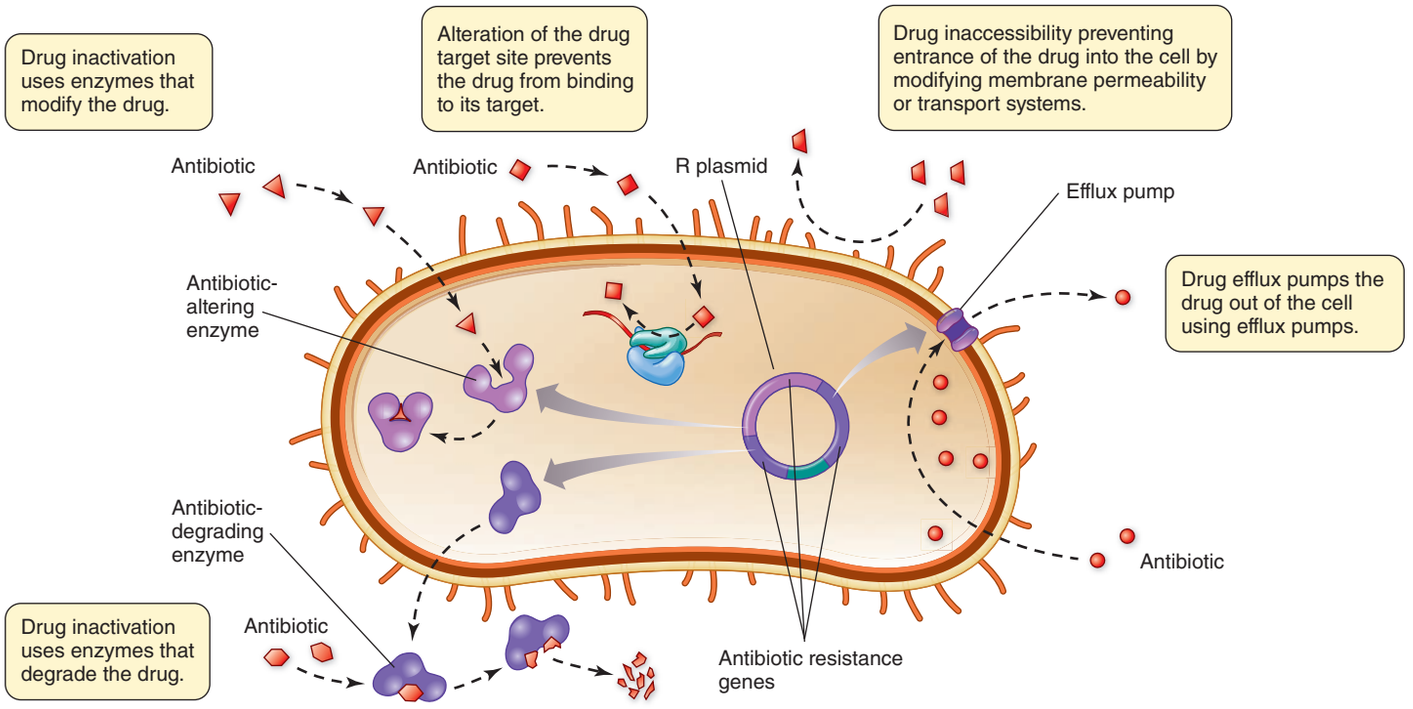

Figure 24.10. Antimicrobial drug resistance mechanisms Microbes resist antibacterial drug action by one or more of the following general mechanisms: drug inactivation, alteration of drug target site, drug inaccessibility, or drug efflux. The genes encoding the products for antibiotic resistance are found on R plasmids (shown here) or on the chromosome.

following four mechanisms is generally used to render drugs ineffective:

- Drug inactivation: Enzymes are produced that destroy or structurally modify the drug.
- Alteration of drug target site: The drug-binding target is modified.
- Drug inaccessibility: The cell prevents the drug from entry.
- Drug efflux: The drug enters, but is quickly exported out of the cell.

Examining just a few examples of drug resistance mechanisms to β-lactams, chloramphenicol, and sulfonamides will provide a model for understanding how resistance to other antimicrobials happens more generally.

Resistance to β-Lactams

Resistance to β-lactams is achieved in four major ways:

- The production of β-lactamase (drug inactivation).
- The alteration of penicillin-binding proteins (PBPs) (alteration of drug target site).
- The reduction of membrane permeability to the drug (drug inaccessibility).
- The removal of the drug from the cell (drug efflux).

β-Lactamase Many different types of β-lactamases exist among bacteria, with some more active against certain β-lactam antibiotics than others. All β-lactamases sever the C–N bond of the β-lactam ring (see Figure 2.19), rendering the drugs unable to bind to their PBP targets. Thus, peptidoglycan synthesis is not disrupted. Beta-lactam-mediated resistance in Gram-negative bacteria is most commonly due to possession of **resistance (R) plasmids** carrying genes for β-lactamases (Figure 24.11). The R plasmids encode genes that confer the ability to resist the antimicrobial activity of one or often several drugs and are usually transferred from cell to cell by conjugation. From Section 2.4, you may recall that one way to combat the activity of β-lactamases is to combine β-lactams with clavulanic acid. Clavulanic acid binds to β-lactamases and inhibits their ability to cleave the β-lactam ring, thus rendering β-lactam treatment effective. R plasmids have become common in populations of *Salmonella* Typhi, *Escherichia coli, Klebsiella pneumoniae,* and *Proteus vulgaris.*

Altered PBPs The most notorious example of PBP-mediated resistance is that of methicillin-resistant *Staphylococcus aureus*, commonly referred to as MRSA (see Section 18.5). *Staphylococcus aureus* normally has genes coding for five different PBPs, all highly susceptible to inactivation by β-lactams. However, MRSA strains have acquired a mobile genetic element from an unknown source, carrying a sixth PBP gene. At least two genes, known as *mecA* and *mecC* have been discovered to code for this newly acquired PBP. These new PBPs are resistant to β-lactams, yet have sufficient peptidyl transferase activity to provide peptidoglycan synthesis in the absence of activity from the other five. It is interesting to note that although methicillin is no longer used clinically, having been replaced by oxacillin and cefoxitin, the label "MRSA" continues to be used as it represents resistance to all β-lactams.

Reduction of Membrane Permeability Recall that one of the reasons for the development of semisynthetic β-lactams was to improve transport across the outer membrane in Gram-negative bacteria. To counter the ability of these newer drugs to reach the periplasmic PBPs, some Gram-negative bacteria produce altered porin proteins to restrict the transport of these drugs.

CONNECTIONS Recall from **Section 2.4** that porin proteins form channels that allow diffusion of small polar molecules across the membrane into the periplasm, where they are then transported by other proteins into the cytoplasm **(Figure 2.24A)**. In many Gram-negative bacteria, the channels are too small for entry of large peptidoglycan-targeting antibiotics like vancomycin, a drug used for the treatment of β-lactam-resistant bacterial infections.

Drug Removal Microorganisms can use **efflux pumps**, as shown in Figure 24.10, to move a drug directly back out of the cell before it can reach its target. Efflux pumps are active transport protein complexes used to move compounds out of the cell. These systems can transport the drug back across the membrane as quickly as it comes in. Multi-efflux pump systems, frequently associated with multidrug resistance, are promiscuous and can transport a variety of structurally unrelated compounds, including antimicrobial agents, out of the cell. Some clinical strains of *Pseudomonas aeruginosa* possess an operon containing genes for multi-efflux pumps, capable of efficiently transporting not just β-lactams, but a variety of drugs out of the cell.

This material is reproduced with permission of John Wiley & Sons, Inc.

Figure 24.11. R plasmids Resistance (R) plasmids contain genes that code for proteins that impart resistance to a range of antibacterial drugs (noted as superscript R). Some examples of these resistance genes are shown. R plasmids also carry genes needed for their transfer to other cells, such as those used for conjugation.

Resistance to Chloramphenicol

Chloramphenicol resistance, which is common in many bacterial strains, occurs in two major ways:

- The production of chloramphenicol acetyltransferase (drug inactivation),
- The reduction of membrane permeability to the drug (drug inaccessibility).

A resistance gene coding for chloramphenicol acetyltransferase (CAT) is often found on R plasmids (see Figure 24.11), especially among members of *Enterobacteriaceae*. The enzyme transfers an acetyl group from acetyl coenzyme A, found in the cell, to chloramphenicol **(Figure 24.12)**. This modified chloramphenicol can no longer bind to its 23S rRNA target. Possession of mutations that increase expression of CAT imparts a high level of resistance to chloramphenicol. Reduced membrane permeability to chloramphenicol is associated with intermediate levels of resistance.

Resistance to Sulfonamides

Recall from Figure 24.8 that sulfonamides interfere with folic acid synthesis, needed for nucleic acid synthesis, by competing with PABA for the enzyme dihydropteroate synthetase. The major mode of resistance to sulfonamides is through alterations of dihydropteroate synthetase (alteration of drug target site). By producing a modified dihydropteroate synthetase enzyme that has reduced affinity for the drug, folic acid can be synthesized in sufficient amounts. Some bacteria can increase their ability to take up preformed folic acid from their environment, rendering the metabolic pathway for folic acid redundant. Similarly, resistance for the drug trimethoprim, which interferes with the same metabolic pathway, occurs by modification of the enzyme dihydrofolate reductase (see Figure 24.11).

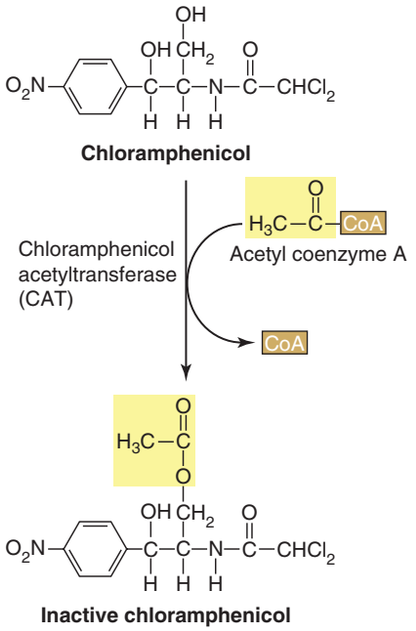

Figure 24.12. Inactivation of chloramphenicol by chloramphenicol acetyltransferase (CAT) Cytoplasmic CAT transfers the acetyl group from acetyl coenzyme A onto chloramphenicol. The presence of the acetyl group prevents chloramphenicol from binding to its ribosome target. Bacterial mutations that increase the expression of CAT produce a high level of resistance to the drug.

Natural selection and drug resistance

The characteristics of microbes, like all beings, are shaped through natural selection, the evolutionary process first described by Charles Darwin that gave rise to the phrase "survival of the fittest." Fitness is measured by an organism's relative ability to reproduce. Through natural selection, the genotypes of organisms possessing favorable traits—those that allow them to reproduce more successfully under the pressures imposed by their environment—will become more prevalent in successive generations. Natural selection forms the cornerstone of evolutionary processes for all genetic beings; microbes are no exception. For a microbial population to survive in the face of a selective pressure, like an antimicrobial drug, it must adapt. Of course, microbes cannot mastermind this adaptation. No organism is able to self-consciously alter its own genes to suit itself. Nor are the genetic changes *caused* by the presence of the selective pressure. Instead, individual microbes acquire changes in their genetic information by chance through spontaneous natural processes such as random mutations, recombination, and horizontal gene transfer (see Section 9.4). These chance genetic changes, which happen all the time in microbial populations, *occur in the absence of the selective agent*, the drug in this case.

CONNECTIONS Recall in **Section 9.2** that two milestone experiments were conducted by Esther Lederberg (replica plating using antibiotics) and Luria and Delbrück (the fluctuation test using phage) that demonstrated resistant mutants were present in cultures *before* the addition of the selective agent.

Although most random genetic changes will have no impact on drug resistance, a few will. In a large population of replicating microbes, it is a biological certainty that a few members will have acquired a genetic change that confers some level of resistance to a given drug, thereby increasing their fitness in the presence of the drug. So, if a few resistant microbes are expected to exist in every population, doesn't that mean some resistant microbes will always remain in a patient after every antimicrobial treatment? Does every patient become a breeding ground for resistant microbes? Of course, the answer is no, or antimicrobial drugs would be relatively useless.

Two important aspects must be considered. First, the effectiveness of antimicrobial drugs comes from their ability to work in synergy with the immune system. Antimicrobial drugs do not need to destroy every single infecting microbe to be effective **(Figure 24.13)**. Indeed, bacteriostatic drugs may not achieve killing in the short time many are used. Antimicrobial drugs only need to reduce or halt the spread of the microbial population enough to let immune defenses clear the infection. Recall that it requires 10 to 14 days to mount a peak adaptive immune response to a new infection, and some microbes can reach high numbers in this time, overwhelming the body (see Figure 20.5). Treatment with antimicrobial drugs can prevent microbes from proliferating to this extent, so when the adaptive response kicks into action, it will not be overcome. Of course, some microbes can evade adaptive immune responses effectively, and will be difficult to eliminate even with antimicrobial agents. HIV is a prime example. Not a single case of absolute clearance of this virus with antimicrobial drug therapy has been recorded. Does

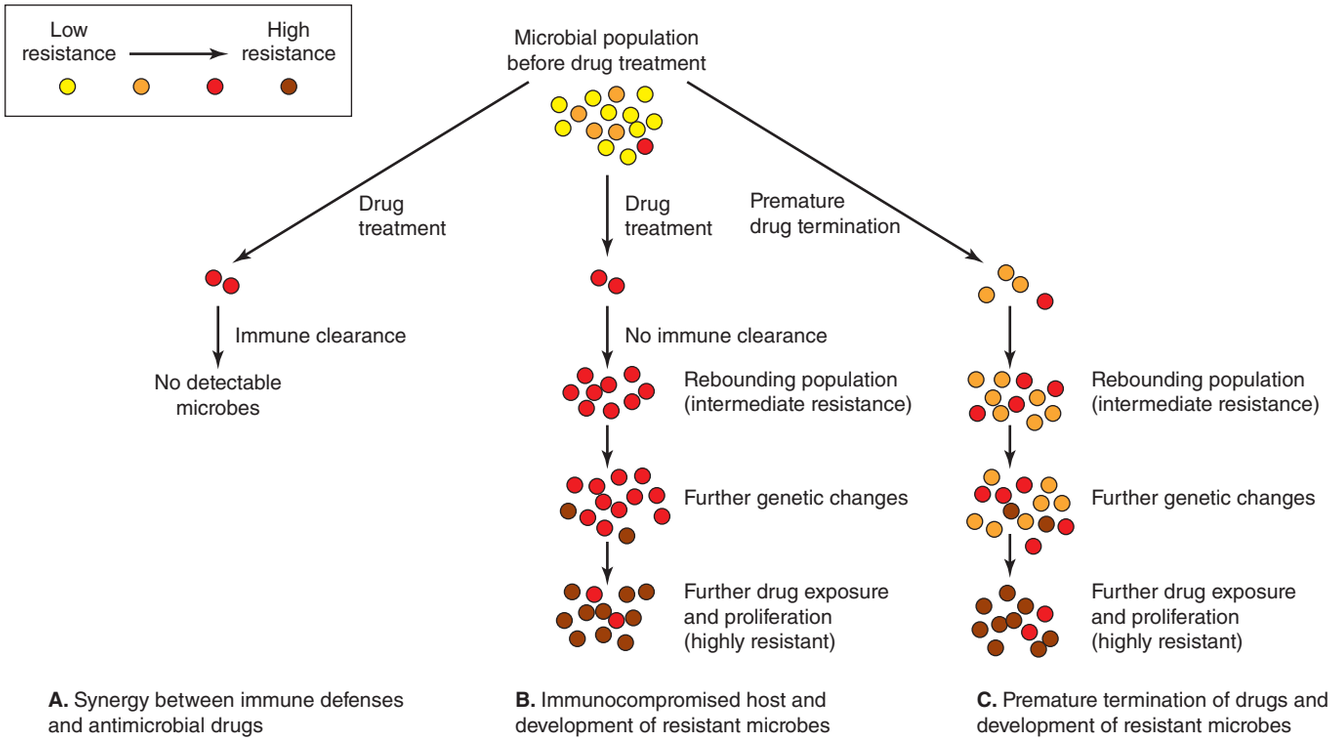

Figure 24.13. Development of resistant microbes In a population of infecting microbes, there may be a variety of resistance levels present. Antimicrobial drug treatment will remove microbes that are susceptible to the drug, leaving microbes with higher resistance levels. (*Left*) In healthy persons with competent immune systems, the few remaining microbes with intermediate drug resistance will often be cleared. Complete clearance is sometimes not achieved with some microbes, such as HIV. (*Middle*) If the host is immunocompromised, drug-resistant microbes not removed by immune defenses may proliferate and acquire other genetic changes that increase resistance. Further exposure to the drug selects for these microbes, giving rise to a highly resistant population. (*Right*) If the drug treatment is stopped prematurely, even microbes with relatively weak resistance may be left to proliferate and go on to acquire further genetic changes. Further exposure to the drug selects for individual microbes that are more resistant, giving rise to a highly resistant population.

this mean that anti-HIV therapy is ineffective? On the contrary, patients live an average of three years without treatment, once clinical AIDS occurs. Patients taking drugs consistently to maintain a low viral load now enjoy a near normal life span. Drug therapy also helps prevent transmission of the virus to others. Anti-HIV drug therapy has tremendous value.

Second, therapeutic concentrations of antimicrobial drugs are sufficiently high to discourage selection for resistance while still being safe for use *in vivo*. How does a physician determine which drug, what concentration, and how long it should be used in treating an infection? *In vitro* **susceptibility testing** is done to establish the sensitivity of a particular microorganism to a panel of select antimicrobial drugs and is used to determine which antimicrobial drug will be most successful in treating a bacterial infection *in vivo*. Susceptibility patterns of various bacteria and fungi are examined by both *in vitro* and *in vivo* tests. Prior to drug approval for clinical use, controlled studies are done *in vivo* to determine how useful a particular antimicrobial drug may be. This includes determining how stable it is inside the body, how quickly it may be metabolized or excreted, and what the effective, therapeutic, nontoxic dose is in patients. This therapeutic dose is related to the **minimal inhibitory concentration (MIC)**. The MIC of a drug is the lowest concentration at which no growth of the microbe being tested occurs *in vitro* after a standardized period of time. The MIC gives a measure of the drug susceptibility of a microbe.

As described in **Toolbox 24.1**, MIC values for various drugs are determined by *in vitro* testing of hundreds of clinical strains of a particular pathogen. The aim of antimicrobial therapy is to maintain a drug concentration above the MIC at the site of infection, as measured in particular tissues or body fluids such as serum, while minimizing toxic side effects. For example, the recommended oral therapeutic dose of penicillin V for treatment of pneumonia caused by *Streptoccocus pneumoniae* is $43\,mg\,kg^{-1}$ body weight per day. This gives an average serum level of $6.0\,\mu g\,mL^{-1}$, which surpasses the established MIC of $0.02\,\mu g\,mL^{-1}$ for penicillin V-sensitive strains of this pathogen. This higher target concentration is used to minimize selection for resistance.

If the immune system can clear most infections with the help of antimicrobial drugs, then how do drug-resistant microbes arise? The immune system is not always effective in clearing resistant microbes, and some patients do not comply with taking their antimicrobial drugs. These are the two most common ways resistant microbial populations develop. Figure 24.13 depicts events in an immunocompromised person. Resistant microbes that remain after the drug course is finished can continue to evade immune defenses and proliferate. The descendants of even partially resistant microbes can acquire more genetic changes, some of which may provide an even higher level of resistance. With further drug exposure and selection, the generational line of microbes goes from susceptible to fully drug resistant. A similar situation occurs when patients are noncompliant and

Toolbox 24.1
DRUG SUSCEPTIBILITY TESTING AND MIC

Minimal inhibitory concentration (MIC) values can be determined by performing a dilution susceptibility test, as shown in **Figure B24.1**. A dilution series, usually twofold dilutions of a particular antimicrobial drug, is inoculated with a standardized culture of the test organism and incubated for a prescribed period of time. The lowest concentration of the drug resulting in no growth is the MIC. The determination of MIC by this method necessitates a separate dilution series for each antimicrobial drug and isolate to be tested. As clinical labs can receive hundreds of samples a day, the tests are commonly formatted for high-throughput automated analysis in plates of 96 wells or more that facilitate multiple tests at a time.

MIC determination using a dilution series is not always a practical way to determine drug susceptibility to a panel of antimicrobial drugs. Many labs will not have the automated equipment required. An alternative and maybe more manageable method for determining MIC is done using antibiotic-impregnated strips, each of which contains a gradient of antibiotic concentrations and allows the MIC value to be read directly off the strip. Etest plastic strips allow a panel of antimicrobial drugs to be tested simultaneously **(Figure B24.2)**.

How does finding the MIC *in vitro* allow one to know if the drug will be effective *in vivo*? Recall that the therapeutic dose needed for effective treatment is not the same as the MIC. The dose is determined by knowing the amount needed to attain a drug concentration higher than the MIC inside the body. A practical way to carry out susceptibility testing and approximating MIC is the Kirby–Bauer disk diffusion test, named after its original developers. The test generates the profile of antimicrobial drugs that a particular isolate is susceptible to, and this in turn determines the drug(s) most useful for effective therapy. A panel of small absorbent disks, impregnated with known concentrations of antimicrobial drugs, is placed aseptically on a Mueller–Hinton agar plate on which a lawn of culture of the microorganism being tested has been seeded at a standardized density **(Figure B24.3)**. The plate is incubated and the zones of inhibition,

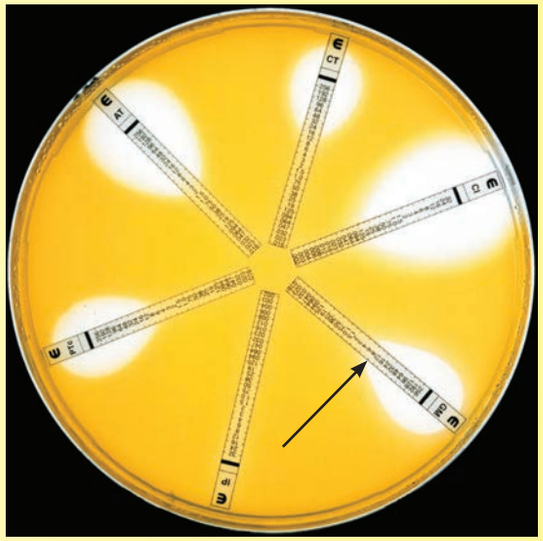

Figure B24.2. Epsilometer test (Etest) Each Etest strip contains a concentration gradient of an antimicrobial drug. The strips are laid on the inoculated plate with the ends containing the lowest concentration in the center. The MIC is read directly off the strip at the point where the zone of inhibition intersects the strip, as indicated by the arrow.

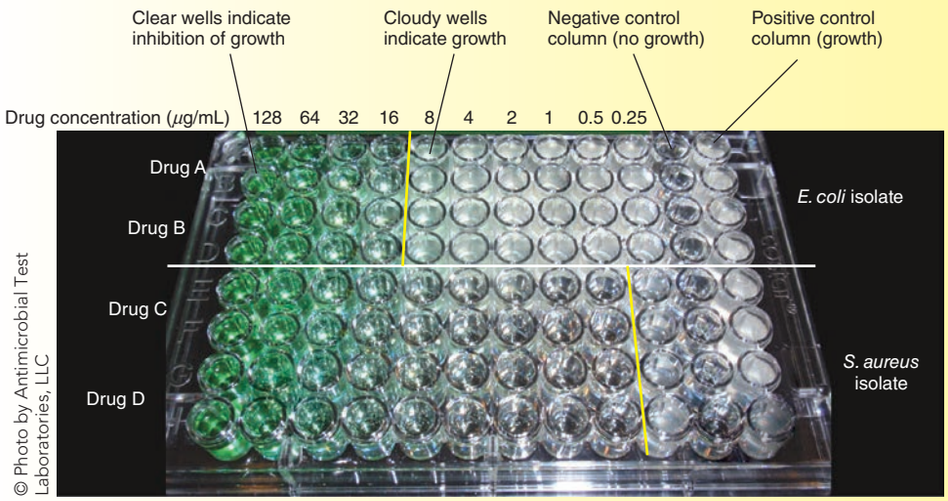

Figure B24.1. Minimal inhibitory concentration (MIC) determination using dilution susceptibility tests Wells contain ten dilutions, shown along the top of the plate, done in duplicate for four different antimicrobial drugs in a green solution. Two clinical isolates, *Escherichia coli (top)* and *Staphylococcus aureus (bottom)*, were inoculated into the wells and incubated for 18 hours. The concentration of the drug in the wells at which no growth first appears is the MIC. As indicated by the yellow lines for the *E. coli* isolate, the MIC is 16 μg mL^{-1} for both drugs A and B. For *S. aureus,* the MIC is 0.5 μg mL^{-1} for drugs C and D.

Figure B24.3. Kirby–Bauer disk diffusion test A lawn of the isolated microorganism is plated on Mueller–Hinton agar and disks impregnated with known concentrations of antimicrobial drugs are added. The diameter of the zone of inhibition for each is measured after a suitable incubation time.

defined as growth-free zones, are measured. The zones are produced because the drug diffuses at a known rate into the agar, resulting in a concentration gradient with the highest concentration near the disk and becoming lower as the distance from the disk increases. For a given drug, the wider the zone, the more susceptible the microbe being tested is. The diameters of the zone of inhibition can therefore be used to determine which drugs the microbe is susceptible to. Each drug diffuses at its own rate so a drug that produces a large zone does not necessarily mean it is more effective at inhibiting growth than a drug showing a smaller zone.

To interpret a Kirby–Bauer test, the zone of inhibition diameter for each antimicrobial drug tested is compared to a table, like that shown in **Table B24.1**, derived from the compilation of hundreds of MIC and zone diameter values for many microbial strains of a particular species. The determination of whether a microbe is resistant, susceptible, or shows intermediate resistance to the various drugs has been determined by correlating these MIC values with the actual therapeutic concentration of the drug found when in the body. For example, if concentrations of ampicillin must reach 9.0 μg mL^{-1} in serum to be effective, then any *S. aureus* isolate with a zone of inhibition diameter less than or equal to 13 mm will have an MIC value greater than 9.0 μg mL^{-1}, and therefore will not be sensitive to therapeutic levels of ampicillin.

TABLE B24.1 **Zone of inhibition diameter and susceptibility for *Staphylococcus aureus***

		Zone of growth inhibition diameter (mm)		
Antimicrobial drug	**Quantity in disk (μg)**	**Resistant**	**Intermediate**	**Susceptible**
Ampicillin	10	<12	12–13	>13
Chloramphenicol	30	<13	13–17	>17
Erythromycin	15	<14	14–17	>17
Tetracycline	30	<15	15–18	>18
Streptomycin	10	<12	12–14	>14

Test Your Understanding

You test a *Staphylococcus aureus* isolate from a patient by using the Kirby–Bauer disk diffusion test and antibiotic-impregnated disks as shown in Table B24.1. The results of your tests are shown below. Which of the following antimicrobial drugs would you recommend to treat this infection and why?

Antibiotic tested	**Diameter of zone of inhibition**
Tetracycline	15 mm
Ampicillin	16 mm
Erythromycin	16 mm

stop taking the drug when they feel better, or miss doses. To treat diseases like malaria and tuberculosis, multiple antimicrobial drugs need to be taken two or three times a day. The average length of treatment for tuberculosis is 6 to 9 months. It is easy to miss a dose or even an entire day during that period and this increases the risk for selection of drug-resistant microbes.

Premature termination of antibiotic treatment
ANIMATION

The origin of drug resistance genes

Where do drug resistance genes originate? Logically, if natural selection is working at the genetic level, then the genes for microbial resistance must have been there in some form before exposure to the drugs. Let's examine where these genes may have originated.

Natural Resistance

Not all microbes become resistant to antimicrobial drugs through the use of these drugs. Indeed, drug resistance is not reserved for pathogens. Many environmental microbes that are not involved in infectious disease also exhibit drug resistance when tested. Although this may seem surprising, this natural resistance has arisen through evolution to accommodate selective pressures *unrelated* to drug use. Let's examine some of the ways natural resistance occurs and relate this to antimicrobial drugs.

Intrinsic Drug Resistance Many microbes are resistant to drugs by virtue of their natural structure or metabolism. They do not possess specific resistance genes to target antimicrobial drugs. We have already seen that Gram-negative bacteria are naturally resistant to some antibacterial agents because the drugs simply cannot pass through the outer membrane. The wall-less bacterial genus *Mycoplasma* is naturally resistant to β-lactams because members do not produce peptidoglycan. The thick layer of hydrophobic mycolic acids that characterizes members of the genus *Mycobacterium* similarly prevents water-soluble drugs from accessing the peptidoglycan or the plasma membrane and prevents transport into the cell. In addition, pathogenic mycobacteria produce intracellular infections, so any drug that is active against them needs to enter both the host cell and the bacterium in order to be effective. Only a few drugs are capable of doing this (see Figure 24.4).

As we have already learned, fungi and bacteria commonly possess naturally evolved membrane multi-efflux pumps (see Figure 24.10), which they use to transport various environmental compounds out of the cell. Due to the rather indiscriminate nature of these multi-efflux pumps, antimicrobial drugs can also be transported out of the cell. This intrinsic drug resistance has not evolved from exposure to antimicrobial drugs.

Resistance Genes in the Environment A second way resistance arises in natural settings is through the development of specific antibiotic resistance genes. Genetic evidence has shown these genes were present long before the use of antibiotics as drugs. How can this be? Consider that most microorganisms live in complex, highly competitive ecosystems. Antibiotic production in these habitats can secure an advantage by limiting the growth of competitors

V. M. D'Costa, K. M. McGrann, D. W. Hughes, and G. D. Wright. 2006. Sampling the antibiotic resistome. Science 311:374–377.

Context

The development of antibiotics as therapeutic compounds has had profound beneficial effects on the treatment of infectious disease. Most antibiotics have their origin in soil microorganisms that produce them to gain a competitive advantage by inhibiting other microorganisms. Soil microorganisms also possess antibiotic resistance genes to counter the effects of the antibiotics they encounter. Could these microorganisms serve as a reservoir for resistance genes that emerge in clinically important pathogens? As a first step in addressing this question, it is necessary to gather some information about the occurrence of antibiotic resistance within environmental communities and then to relate this to the nature of antibiotic resistance that is found in pathogens or potential pathogens.

The study that is described refers to the collective antibiotic resistance that is found in soil microorganisms, known as the "soil resistome." The authors focused on isolating antibiotic-resistant actinomycetes because these Gram-positive bacteria are known as the main antibiotic producers.

Experiment

With the goal of isolating antibiotic-resistant microorganisms from diverse soils, soil samples representing urban, agricultural, and forest locations were air-dried for several days. They were then suspended in sterile water and dilutions spread on solid *Streptomyces* isolation media containing starch and casein, plus cycloheximide to inhibit fungal growth. This media favors the growth of actinomycetes such as *Streptomyces*. During incubation at room temperature, the plates were monitored for the formation of colonies that had the characteristic morphology of sporulating *Streptomyces*. The resulting library had 480 strains, and they were all confirmed by 16S rRNA gene sequence analysis to be members of the *Streptomyces*.

Each of the isolated strains was then screened for the ability to grow in the presence of high levels of each of 21 different antibiotics chosen to be representative of the variety of antibiotics used to treat pathogenic bacteria. These included drugs that have been used for decades and several that have only been available recently. Remember, these strains had been isolated in the absence of these antibiotics. Even so, every strain was found to be resistant to several of the antibiotics, and two strains were resistant to 15 of the 21 antibiotics **(Figure B24.4)**. The 480 strains contained 191 different antibiotic resistance profiles, and the relationships between these profiles are shown in Figure B24.4A, where each black dot represents a profile. A colored line connecting a dot indicates the resistance to the drug. Figure B24.4B shows that several antimicrobial drugs were almost universally ineffective against the collection of microorganisms. These include many *Streptomyces*-produced antibiotics affecting ribosome function (erythromycin, chloramphenicol, tetracycline, and semisynthetic Synercid), and peptidoglycan synthesis

Resistance is indicated by a line connecting a drug and a dot, representing a resistance profile of the isolates tested. **B.** Graph showing proportion of strains resistant to one or more of the 21 drugs tested. **C.** Graph showing proportion of isolates resistant to the drugs tested.

(fosfomycin). Widespread resistance was also present for cephalexin, a natural β-lactam antibiotic produced by a soil fungus, and the ribosome-inhibiting synthetic drug linezolid, which began use only in 2000. Some of the antimicrobial drugs were not effective against any of the 480 isolates (Figure B24.4C), with the most surprising of these being daptomycin, a *Streptomyces*-produced drug permitted for use in 2003, which acts by disruption of the cytoplasmic membrane. Daptomycin is normally thought to be very effective against Gram-positive bacteria, but the soil isolates appeared to readily inactivate it. Resistance to daptomycin had only been observed once before.

Another notable finding was the resistance of five strains to vancomycin, a glycopeptide antibiotic that acts to prevent peptidoglycan synthesis and is usually reserved as an antibiotic of last resort. Most of the resistant microorganisms contained known vancomycin

resistance operons whose expression results in altered peptidoglycan, but one strain did not. This strain appears to owe its vancomycin resistance to an undescribed mechanism. The rise of vancomycin resistance in clinical settings is a major problem, and the demonstration of another possible mechanism of vancomycin resistance is worrying.

Impact

This study demonstrated widespread antimicrobial drug resistance in soil bacteria, despite the limited nature of the screening, which only considered cultivated actinomycetes, estimated to comprise approximately 5 to 6 percent of soil bacteria. Intrinsic antibiotic resistance was found for naturally occurring antibiotics, semisynthetic derivatives and completely synthetic drugs. Although the high incidence of resistance to naturally occurring antibiotics may be expected, resistance to synthetic drugs like linezolid and trimethoprim is surprising, given the apparent absence of selective pressure. Other studies using functional metagenomic techniques have shown that similar patterns of antimicrobial resistance exist in uncultivated microorganisms. Can these mechanisms of antibiotic resistance find their way into pathogens? This is certainly possible because antibiotic resistance genes are commonly found on mobile elements such as plasmids. Indeed, this study may provide a preview of antibiotic resistance that is likely to appear within human pathogens in the future.

Questions for Discussion

1. Why do you think this study focused on the actinomycetes, rather than all cultured soil bacteria or other types of bacteria or archaea?
2. Are all of these genes likely to function solely for antimicrobial resistance, or might some of them have other functions?

for resources. Of course, to compete successfully with these antibiotic producers, microorganisms counter with the development of resistance genes. In fact, some resistant bacteria can even use the antibiotics produced by other microorganisms as a nutrient source as evidenced by the isolation of several antibiotic-consuming species from soil. When grown in the presence of clinically relevant concentrations of antibiotics, these bacteria remained unaffected and indeed were able to grow on media containing the antibiotic as a sole carbon source. Several of these isolates are resistant to multiple antibiotics from different classes. In such natural settings, the pressure of microbial competition leads to antibiotics and antibiotic resistance genes. As we saw in Section 24.1, most antimicrobial drugs used today were developed from such natural antibiotics (see Table 24.1). What about in clinical settings? What is the source of resistance genes in pathogens? As investigated in the **Mini-Paper**, environmental bacteria may indeed be a reservoir for the resistance genes found in pathogens. Let's now look at the several avenues for the acquisition of drug resistance genes.

Resistance Due to Antimicrobial Drug Use

Medically important microbes become drug resistant as a direct consequence of antimicrobial drug use. Even Alexander Fleming noted the appearance of penicillin-resistant *Staphylococcus aureus* in cultures he was working with in the lab. Penicillin-resistant strains of *S. aureus* started appearing in patients receiving the drug shortly after it entered widespread use (see Figure 24.2). Drug resistance genes in clinical strains of microbes come from two sources: preexisting genes and newly acquired genes. The mechanisms of drug resistance are most varied in bacteria, in which they have been most closely investigated. Consequently, we will focus on these.

Modification of Preexisting Genes Random mutations form the basis of all genetic changes and occur because of (1) the imperfect ability of polymerases to precisely copy their template, resulting in spontaneous mutations (see Sections 7.5 and 9.2), and (2) exposure to mutagens, resulting in induced mutations (see Section 7.5). Although these mutational events happen infrequently (for *E. coli* this is between 10^{-6} and 10^{-7} mutations per gene per generation), the rapid replication rate of most microbes means that mutations can accrue in a population over a relatively short period of time. Recall in Section 9.2, the Luria–Delbrück fluctuation test demonstrated that a random mutations that impart resistance to phage in a single *E. coli* cell gave rise to a population of resistant progeny in a test tube (see Figure 9.10). In such a way, key mutations in a preexisting gene, whose major function is not originally to confer antibiotic resistance, can often bestow resistance. For example, bacteria can develop resistance to β-lactam antibiotics through key nucleotide changes in the genes encoding PBPs (penicillin-binding proteins). This results in amino acid changes that allow continued function of the transpeptidase activity, but prevent binding with β-lactam antibiotics. Similarly, exposure to antimicrobial agents frequently selects for mutant genes of natural efflux pump systems that can efficiently move these drugs out, resulting in acquired drug resistance. Each independent random mutation confers a small decrease in affinity to the drug, diminishing bacterial susceptibility to the drug, and making the drug less effective. Resistance to the entire β-lactam family has occurred in this way for strains of *Staphylococcus*

aureus and *Staphylococcus epidermidis, Pseudomonas aeruginosa, Enterococcus faecalis, Enterococcus faecium, Haemophilus influenzae, Neisseria gonorrhoeae*, and *Neisseria meningitidis*, just to name a few.

Is mutational gene modification, leading to resistance, unique to bacteria? No. Resistance of HIV to the antiretroviral drug AZT (see Section 24.2) developed through mutations in the gene encoding the viral reverse transcriptase. Like PBP-mediated resistance, this is not an all-or-nothing event. As HIV accumulates key mutations in the reverse transcriptase gene, its susceptibility to AZT falls markedly. Only four specific mutations at four key sites are needed for complete resistance to AZT. In a virus such as HIV, where there is no polymerase proofreading ability, every generation of new viral genomes contains mutations (see Section 22.4). Studies have shown that it takes as little as 10 months for resistance to appear in people receiving AZT treatment. AZT-resistant HIV strains are now widespread.

Acquisition of New Genes Horizontal gene transfer events involve large-scale sequence changes that are brought about by mobile genetic elements, such as plasmids, transposable elements, and transducing phages, that facilitate horizontal gene transfer. Indeed, these elements can transfer entire resistance genes very quickly from one microbial cell to another. You will recall from Chapter 21 that horizontal gene transfer also moves virulence genes around in a rather promiscuous manner in bacteria, leading to gene transfer in related as well as unrelated species. This happens for resistance genes as well. For example, the transposons Tn5 and Tn10, which encode resistance to aminoglycosides and tetracycline, respectively, are found in many species of Gram-negative bacteria, particularly the *Enterobacteriaceae*. *In vitro* experiments show that the tetracycline resistance transposon Tn5397 can be spontaneously transferred from *Bacillus subtilis*, a common soil bacterium, to an oral *Streptococcus* species. The antibiotic resistance plasmid RP1, which was first found in a clinical strain of *Pseudomonas aeruginosa*, is capable of transfer to just about all Gram-negative bacteria by conjugation. Such R plasmids carrying more than one antimicrobial resistance gene (see Figure 24.11) are themselves produced through the insertion of multiple transposable elements.

CONNECTIONS Recall from **Section 9.4** that microbes, particularly bacteria, can donate, receive, and rearrange DNA to gain new genetic information, including resistance genes, through horizontal gene transfer.

It is no longer uncommon to find multiple-resistant bacteria—the so-called "superbugs"—that are resistant to virtually all antibacterial drugs licensed for use. For example, strains of *Salmonella* Typhi, *E. coli, Klebsiella pneumoniae*, and *Proteus vulgaris* have all been found to carry an R plasmid that is transferable by conjugation that confers resistance to four classes of antibacterial drugs. Maintenance of the entire plasmid is reinforced when exposed to any one of the drugs to which it has resistance. In the same way, resistance cassettes composing a string of multiple transposable element insertions into the chromosome can also be found. These cassettes can also be mobilized for transport to other cells.

Phages tend to be relatively minor contributors in the transfer of resistance genes between unrelated species. Like most viruses, phages tend to be quite host-specific. However, transducing phages can transfer resistance genes onto plasmids, as do many transposable elements. When this happens, the plasmid need only be transferred through conjugation or transformation to confer resistance in other species.

Recombination events play one of the most important roles in gene transfer and gene rearrangements. Previously, we defined recombination as the breaking and rejoining of two different nucleic acid molecules (see Section 9.4). Within cells, recombination can occur between mobile genetic elements and the chromosome, as well as among the mobile genetic elements themselves. All these recombination opportunities mean that it is a relatively easy process to move a gene from one cell to another; microbes have incredible genetic dexterity. **Figure 24.14** summarizes some of the ways resistance genes can be transferred between bacterial cells.

With all this gene movement occurring between species, it is not hard to envision how antibiotic resistance genes from environmental sources, such as the soil bacteria mentioned previously, can inadvertently move into microbes carried by humans and animals, and become selected for by antibiotic use. These environmental strains are suspected of being a hidden reservoir for present and future resistance genes. Another source of resistance genes is normal host microbiota. Any antimicrobial drug that is used systemically (taken orally or by injection), acts not only on the target microbe, but also on a variety of microbes at various sites, such as the intestinal tract, increasing the possibility of selection for resistance genes in a variety of microbes.

The Rapid Rise of Resistance

On average, resistance to a new antibacterial drug occurs in just four to five years after a drug's introduction (see Figure 24.2). How does resistance appear so quickly? This is due to the combined action of (1) transfer of whole resistance genes by mobile genetic elements, (2) high frequency of random mutations, (3) recombination events, and (4) short generation times. Consider that most medically important microorganisms can double their population in less than 24 hours, at least in culture. In comparison, the fastest reproducing multicellular organisms are aphid insects and the nematode Caenorhabditis elegans, whose generation time is a lengthy 2.5 days. Relative to humans with a generation time of about 20 years, microbial acquisition of a new characteristic happens in the blink of an eye. With such short generation times, it is no surprise that resistance has been documented for every antimicrobial drug ever used in clinical settings. The more effective and safe an antimicrobial drug is, the more it is prescribed, and the faster resistance spreads, rendering the drug ineffective. This is a Catch-22 that has not gone unnoticed by the pharmaceutical industry. **Perspective 24.1** discusses this dilemma.

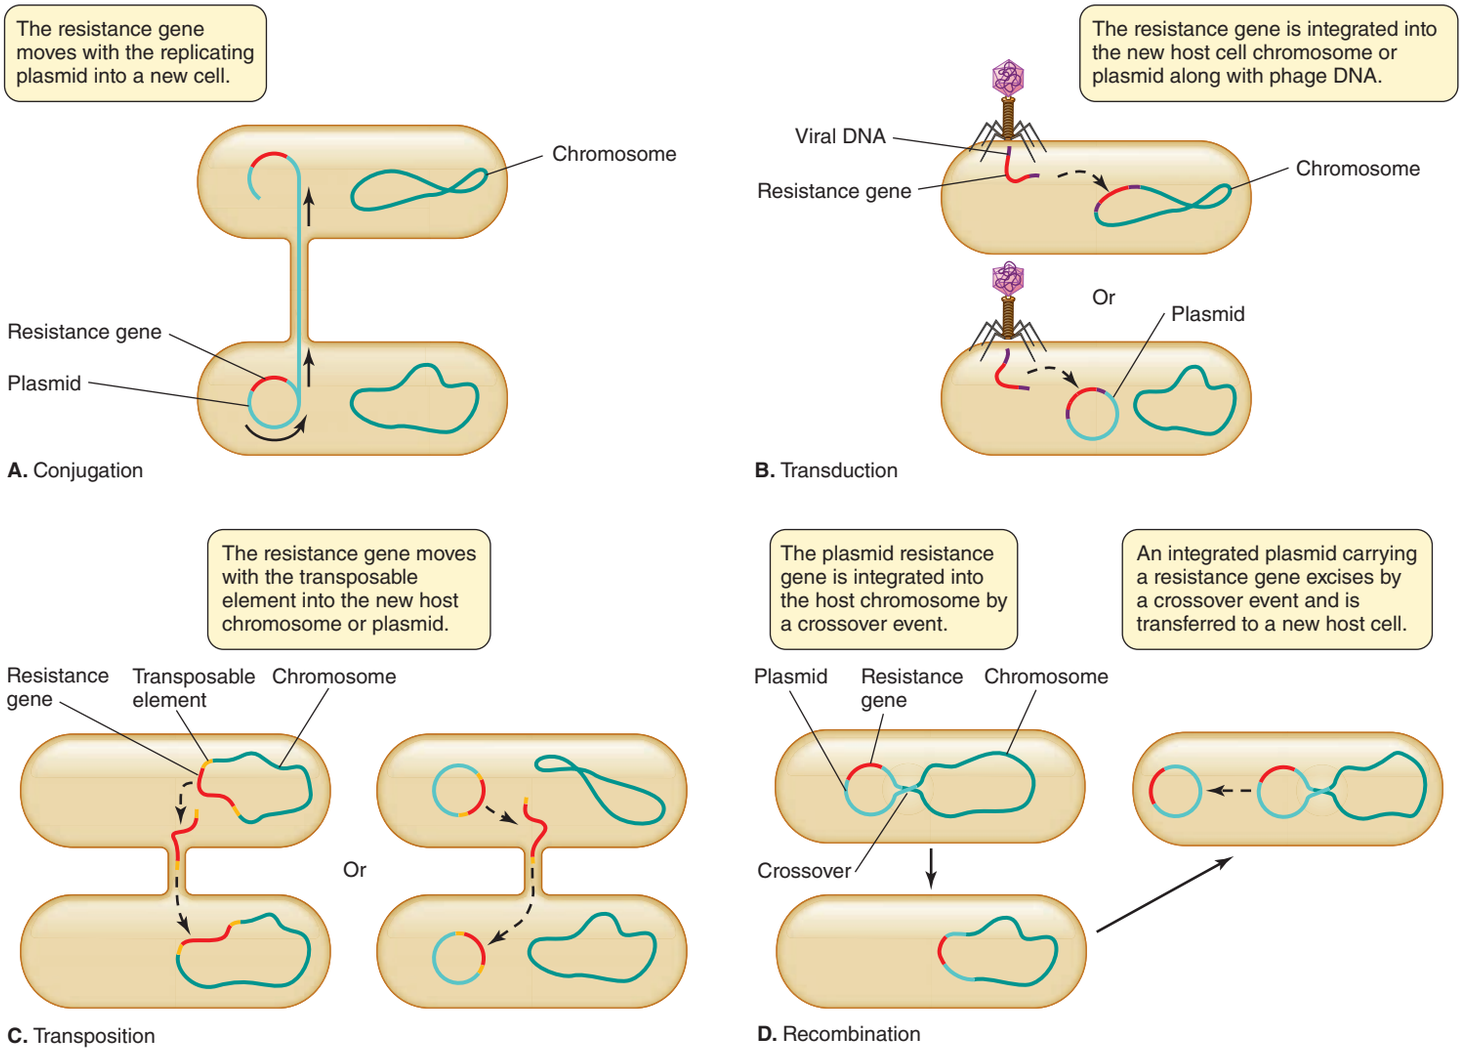

Figure 24.14. Common methods of acquiring resistance genes **A.** Plasmids carrying resistance genes (red) can be transferred to other bacterial cells by conjugation. **B.** Transducing phages can insert resistance genes into chromosomes or plasmids by transduction. **C.** Transposable elements carrying resistance genes on the chromosome or plasmids can be transferred between cells. **D.** Recombination between plasmids and chromosomes can transfer resistance genes within a cell. Once transferred to a plasmid, resistance genes can be easily moved by horizontal gene transfer to other cells.

Rather than continuing to rely solely on the isolation of new compounds by screening products of organisms for antimicrobial activity, the future of antimicrobial drugs includes the rational design of drugs that act on new targets discovered through genomics and structural biology, as will be discussed at the end of this section.

Antimicrobial Resistance in Farmed Animals

The extensive use of antimicrobial drugs over time in human medicine has without doubt led to the rapid rise and spread of resistant microbes. However, agriculture is the largest consumer of antimicrobial drugs. Estimates vary, even within countries: From 40 to 80 percent of all antibiotic use is in farmed animals. What is strikingly different from human applications is how and why these antibiotics are used in animals. The majority of the antimicrobial drugs used in farmed animals are not used to treat infections, but to promote growth of the animals. Massive amounts of data confirm cattle, swine, and poultry fed with subtherapeutic levels of antimicrobial agents show superior weight gain and improved feed efficiencies compared to their antimicrobial-free counterparts. For example, pigs show an increase in weight from 3.3 to 8.8 percent and feed efficiency improves from 2.5 to 7 percent, meaning less food needs to be fed to these animals to achieve an equivalent weight gain to their counterparts not receiving antimicrobial drugs. Similar data exist for cattle and poultry. How low levels of antimicrobial drugs promote growth is not precisely known. Most researchers think that the effects are multifactorial. Studies support evidence for suppression of infectious diseases, such as dysentery, and alteration of normal commensal microbial communities of the gut. It is estimated that as much as 6 percent of the energy in a pig's diet may be harvested by the gut microbiota, instead of by the pig. Reducing

Perspective 24.1
THE PURSUIT OF NEW ANTIBIOTICS: WHY BOTHER?

We use more antibiotics now than ever before in history. We use them more liberally, and we often use them incorrectly. For example, antibiotics are commonly prescribed for undiagnosed infections such as sore throats, which commonly are due to viral infections, against which antibiotics are completely ineffective. This abuse has directly increased the prevalence of antimicrobial resistance, making the drugs less useful. Successful new antimicrobial drugs often become widely used, and this leads to their own uselessness—an endless cycle doomed to repeat itself. One must wonder how the pharmaceutical companies are keeping pace. The reality is, they are not. The number of new antimicrobial drugs approved each year has been decreasing drastically since the 1980s. Although several novel antibiotics have been discovered, few have progressed through clinical trials. Between 1962 and 2000, no new classes of antibiotics were brought to market. In 2000, linezolid, from the class of oxazolidinone synthetic drugs, was approved by the FDA, and in 2003 daptomycin, from the class of lipopeptide antibiotics, followed. The last novel antibacterial drug to make it to market was retapamulin of the mutilin class, introduced in 2007. None of these three classes of antibacterial drugs was actually new, having been discovered in the 1980s. However, for various reasons, usually toxicity issues, they remained undeveloped for human use. They were re-examined largely because of the rise of vancomycin-resistant *Staphylococcus aureus* and *Enterococcus* strains. Is the antibiotic well drying up? Perhaps, but that's not the only reason for the decline in new drugs. Large, international pharmaceutical companies have lost interest in searching. They simply do not make enough profit in the short time a new drug enters the market to the time resistance appears to warrant the expenditure in research and development. The search for just a single useful new antimicrobial drug requires an estimated $1 billion and takes between 10 and 25 years to bring to market.

At the expense of antimicrobial drug discovery, pharmaceutical companies have found that there is more profit to be made with antidepressants and drugs for hypertension, diabetes, cardiac disease. These drugs must be taken for many years, not just a few days, and tend to always remain effective. Antimicrobial drugs have neither advantage. Add to this growing pressures to reduce the use of all antimicrobial drugs and to keep the most effective ones "on reserve," to be used only when others fail, and the antimicrobial market begins to look even less attractive. Who can blame pharmaceutical companies for moving out of the antibiotic business?

microbial population sizes through antimicrobial use may lead to more nutrient uptake for the animal.

Whatever the mechanisms, subtherapeutic antimicrobial drugs do work to promote growth, and the cost benefits are especially rewarding in large-scale intensive farming operations. Does this application of antimicrobial drugs also contribute to the rise of drug-resistant microbes? The answer for animals is "yes," with *Salmonella, Campylobacter, E. coli,* and *Enterococcus* most commonly associated with resistance. However, it is not clear if the use of growth-promoting antimicrobial drugs has contributed significantly to resistance in microbes that are important for human health. Data from various countries lack reproducibility and comparability, making it difficult to link the use of antimicrobial agents in farming to resistance in human pathogens. Despite numerous criticisms, it has been established in several cases that drug-resistant bacteria originating from livestock have been transferred to humans, and bacteria that have developed resistance to one antibiotic used in feed have also developed resistance to related antibiotics used in humans. This is known as "cross-resistance" and may have grave consequences in the battle against multidrug-resistant microbes. An example is the glycopeptide antibiotic avoparcin, which is not used in human medicine but is widely used as an additive in poultry feed (see Table 24.2). In 1998, it was noted that isolates of the genus *Enterococcus* from Denmark and Germany were cross-resistant to vancomycin, which is not used in animal feed but is a critical antimicrobial drug used in control of methicillin-resistant *S. aureus* (MRSA) strains in humans. The transference of this resistance to pathogens like *S. aureus* is a real possibility and will contribute to the dwindling number of options left to combat bacterial pathogens.

For many years, antimicrobial resistance in humans was largely limited to hospital settings, which is a direct result of the frequent use of antimicrobial drugs there. In recent times, resistance has moved into community settings, facilitated by the increasing number of nursing homes, day care centers, and chronic care facilities, use of immunosuppressive drugs, prevalence of HIV infection, and mass transit of people across the globe. In light of this, it can be argued that the contribution of antimicrobial drug use in animals has likely had a minor impact in the rise of resistance in human pathogens. Despite the lack of overwhelming evidence to support the spread of resistance due to farming practices, many countries recognize that antimicrobial agents foster resistance, and microbes frequently do not distinguish between species boundaries. As a result, several countries have banned the routine use of these agents in feed. The European Union banned the routine feeding of all antimicrobial agents to livestock in 2006. Since this, the U.S. Federal Drug and Food Administration (FDA), the U.S. Centers for Disease Control and Prevention (CDC), and the World Health Organization (WHO) have all called for similar bans. The McDonald's Corporation proactively decided in 2003 to purchase chicken only from producers who do not use antimicrobials in feed. This has resulted in the decision of the top ten poultry producers in the United States to voluntarily stop this practice—a significant victory toward the reduction of antimicrobial use.

Combating drug resistance

How do we prevent the development of antimicrobial resistance? Stopping the use of antimicrobials is out of the question, but there are several approaches that, if used collectively, may help to reduce the emergence of resistance.

1. *Reduce Use.* Antibacterial drugs in particular are frequently prescribed, indeed demanded by patients for illnesses that are not of bacterial origin. Rapid, cheap, and more accurate diagnostic tests would aid in the decision-making process for prescribing an antimicrobial agent. Educating physicians, patients, and parents about the risk of antimicrobial drug resistance is needed to change these attitudes and practices.
2. *Use Selective Drugs.* Choosing to use antimicrobial drugs with a narrow target range for a specific pathogen, rather than a broad spectrum drug, will reduce the selection for resistance genes in non-target species of the normal microbiota. In practice, this is difficult because most physicians cannot wait for identification of the microbe to choose a selective drug. Consequently, broad spectrum drugs are often prescribed when the causative agent of the infection has not been identified. Developing rapid tests for diagnosis will be of benefit.
3. *Use Multidrug Cocktails.* Using a combination of antimicrobial drugs that target different aspects of the microbe's structure/physiology means that the microbe must develop simultaneous resistance to all the drugs being given in order to survive. This reduces the likelihood of microbial resistance. We have already seen that sulfonamides and trimethoprim are used in combination because they interfere with two different enzymes in the same synthesis pathway for PABA. Multidrug cocktails that target different pathways are used for HIV infection, tuberculosis, and Hansen disease (leprosy).
4. *Use Effective Infection Control.* Hand washing is one of the most effective ways to prevent the spread of contact diseases. Frequent hand washing among care workers, cleaning staff, visitors, and patients is especially important for infection control in health care facilities where immunocompromised patients abound. The density of compromised patients, workers, and visitors increases the risk for infections with pathogens, many of which are drug resistant (Perspective 24.2). Proper sterilization and quarantine are also important measures.
5. *Develop New Vaccines and Improve Access.* Highly effective vaccines continue to be the cheapest and most effective way to reduce both the spread and impact of disease. Even vaccines that sometimes are not highly protective, such as the yearly formulations of influenza vaccines, still appear to provide enough immunity to reduce severity of disease. This reduces the need to use antimicrobial agents.
6. *Develop Alternatives.* Recombinant DNA technology has recently been used to produce defensins. Defensins are antimicrobial peptides of the innate immune system that have activity against a broad spectrum of Gram-negative and Gram-positive bacteria, fungi, and some enveloped viruses (see Section 19.2). Because they selectively disrupt microbial membranes, as opposed to host membranes, they appear to be excellent candidates for developing novel antimicrobial agents. Furthermore, their membrane-disrupting activity is exerted in several ways, which is expected to make it more difficult for the development of resistance by microorganisms. Such recombinant defensins have shown success in clinical and experimental trials when used as therapeutic agents. Another promising alternative to antimicrobial drugs is phage therapy: the administration of specific phage to destroy bacterial pathogens in the body. As described in Perspective 8.2, phage therapy is an old technology that predates penicillin and has recently been resurrected.

Another approach to find alternatives to the current antimicrobial drugs is to design drugs that will act on new microbial targets. A good place to search for new targets is to start with virulence factors or some other component of microbes needed to

Perspective 24.2
HEALTH CARE-ASSOCIATED INFECTIONS: A RECIPE FOR RESISTANCE

Even though genetic changes occur at low frequency, the large number of microbes present in, on and around humans and animals allows a large number of gene transfer opportunities. These opportunities can reach frightening levels in places like hospitals and long-term-care homes. In the United States alone, these health care-associated infections are estimated to cause two million illnesses per year (5 to 10 percent of hospitalized patients) and cause up to 90,000 deaths per year. As such, health care facilities represent a major public health problem.

The combination of (1) close contact, (2) infectious microbes, (3) contaminated surfaces, (4) immunocompromised patients, and (5) patients with wounds set the scene for maximizing acquisition of health care-associated infections and genetic transfer events. At a molecular level, mobile genetic elements are moving around just as much as the health care workers themselves. In fact, health care workers are often the vectors for the movement of microbes from patient to patient. Now add to these settings the selective nature of antimicrobial drugs, which are always at high use in these places, and you have a recipe for resistance. Several drug-resistant strains of bacteria have arisen in these settings: vancomycin-resistant strains of enterococci (VRE) and *Staphylococcus aureus*, methicillin-resistant *S. aureus* and *Staphylococcus epidermidis*, cephalosporin-resistant *Klebsiella pneumoniae*, and quinolone-resistant *Clostridium difficile*.

interact with host cells. As we learned in Chapter 21, many bacterial pathogens rely on type III or type IV secretion systems for injection of components that allow them to colonize and invade host tissues. Many others need fimbriae to attach to host cells. Using knowledge of the structure and biochemistry of common components like these, scientists can use computer modeling to design chemical prototypes that will interact with these structures.

By screening for conserved genes in groups of pathogens, genomics analysis has uncovered many novel potential drug target sites. Most of these genes code for enzymes in critical metabolic pathways or, in viruses, in assembly or genome replication pathways. Genomics and structural studies can also give insight into how easily a microbe may acquire the mutations needed to resist the action of a particular drug. This is an important consideration in drug design because the ability of microbes to modify their genomes to counter drugs is remarkable. Although few novel designed drugs have made it to clinical trials, these cutting-edge approaches hold much promise in the future of combating infectious disease.

24.3 Fact Check

1. What are four general mechanisms used by microbes for achieving drug resistance? Describe four specific examples of these resistance mechanisms.
2. What is meant by the term minimal inhibitory concentration (MIC), and how is it determined?
3. Some microbes have natural resistance to antimicrobial drugs, while other microbes have become resistant as a consequence of antimicrobial drug use. Describe examples for each mode of resistance.
4. Why are antimicrobial drugs often used in farmed animals, and how is this thought to contribute to the rise of drug-resistant microbes?
5. What approaches can be used to reduce the development of drug-resistant microbes?

24.4 Predicting and controlling epidemics

How are epidemics predicted and controlled?

Although antimicrobial drugs are invaluable for treating individuals with infectious disease, they are not used routinely as a public health measure for prevention of infectious diseases, particularly communicable diseases. As we have just learned, excessive use of antimicrobial drugs leads directly to drug resistance, disrupts normal microbiota balances, and can cause toxicity with prolonged use—not to mention the great expense of such long-term communal use. More practical and effective public health measures are employed to prevent those microbial diseases that present a significant public health risk, that is, communicable diseases capable of causing epidemics. These measures include immunization, the topic of Section 24.5, containment of the pathogen, and predicting epidemics in order to avert their occurrence.

Epidemics involving known infectious agents are rarely completely unpredictable. Even epidemics involving emerging diseases, such as HIV/AIDS, SARS (see Section 5.4), and Ebola, which have only recently entered human populations, did not appear spontaneously (see Sections 18.5 and 22.4). Having studied the viruses responsible for these epidemics, researchers know something about their evolutionary history, how they are transmitted, and who is susceptible. For example, as soon as enough information was gathered in the 1980s regarding HIV, models were developed that predicted HIV would cause significant epidemics in populations practicing unprotected sex with multiple concurrent partners. Unfortunately, this is exactly what happened in many countries. Health care policies and implementation strategies failed to address the aforementioned host and environmental factors needed to stop the epidemic spread of HIV. Where policies have been put into place to address these factors, incidence rates of HIV infection are beginning to stabilize or decrease (see Figure 18.13). For all known communicable diseases, a set of predisposing conditions allows the development of an epidemic in a population. Identifying those parameters can help predict, control, and even prevent epidemics. Let's examine some of these parameters.

CONNECTIONS Recall from our introduction to epidemiology in **Section 18.3** that an epidemic occurs when the incidence of cases significantly rises above that normally expected for a population. You may wish to review the terms in that section.

$R_0 = 1$, the epidemic threshold

Epidemiologists have formulated various mathematical equations to model and predict epidemics. Models for propagated epidemics caused by communicable diseases that are spread directly or indirectly between individuals focus on determining the value R_0, the **basic reproduction number**. R_0 is defined as the average number of new infections caused by an infected individual in a population of susceptible individuals. For example, the R_0 value for measles is 12 to 18, meaning that an infected person will spread the infection to between 12 and 18 other people on average. R_0 values are frequently given as a range because R_0 values for a particular infectious agent differ depending on age, population density, and environmental conditions that may affect the transmission of the agent, such as temperature and humidity. In general terms, R_0 is a function of (1) density of susceptible contacts, (2) transmissibility of the agent, and (3) the length of time an individual is infectious.

Analyses of virtual and real data from past outbreaks generally confirm that if $R_0 < 1$, the disease will not become an epidemic. If $R_0 > 1$, it will become an epidemic assuming that no intervention occurs. $R_0 = 1$ then becomes the epidemic threshold, above which an epidemic occurs, and below which it does not. The reason for this can be shown by a simple example. In a population where $R_0 = 18$, one infected individual will give rise to an average of 18 newly infected contacts, who then each infect 18 others, producing 324 more cases (18×18) who then each infect 18 others, for a total of 5,832 new cases (324×18), leading to an exponential increase in the number of cases over time—an epidemic. When $R_0 < 1$, the disease will not become an epidemic because the number of new infections decreases with each round of transmission—the outbreak ceases. Importantly, $R_0 < 1$ does not necessarily mean the disease disappears completely from the population. It can be perpetuated in an endemic manner as long as susceptible individuals continue to be born or immigrate into the population.

In reality, R_0 can rarely be accurately measured, so the answer to our question about whether epidemics can be predicted has to be "not with precision." Still, it is useful to calculate predicted R_0 values. Estimations of R_0 are valuable in assessing the potential risk for an epidemic and the amount of effort that is needed to prevent an epidemic or possibly eliminate an infection from a population. For example, we can look at H1NI swine flu (see Chapter 8 opening story). The first outbreak was recognized in April of 2009, and subsequent outbreaks occurred quickly (largely through air travel). The following July, the predicted R_0 value for the virus was estimated to be approximately 2. This means that each infected individual was expected to infect two others on average, and with no intervention, up to 80 percent of individuals in an exposed population would become infected. By this estimation, swine flu was expected to continue to spread, and indeed it did, causing a pandemic (see Section 18.3). The CDC estimated for the United States alone that 61 million cases of swine flu occurred from April 2009 to April 2010.

Several communicable diseases have very high estimated R_0 values, indicating they are highly transmissible and therefore likely to produce epidemics in susceptible populations. You can look ahead to Table 24.7, presented in the next section, to see some R_0 value examples. Understanding the factors that influence R_0 is therefore critical to the prevention and control of communicable diseases. Frequently, agents with high R_0 values and that cause serious disease are targets for vaccine development.

Principles of epidemic control

How are epidemics controlled or prevented? To answer this question, we need to know the parameters that influence the development of an epidemic. These same parameters will be involved in stopping it.

The Triangle of Epidemiology

A useful conceptual model for controlling infectious disease is the triangle of epidemiology **(Figure 24.15)**. This framework

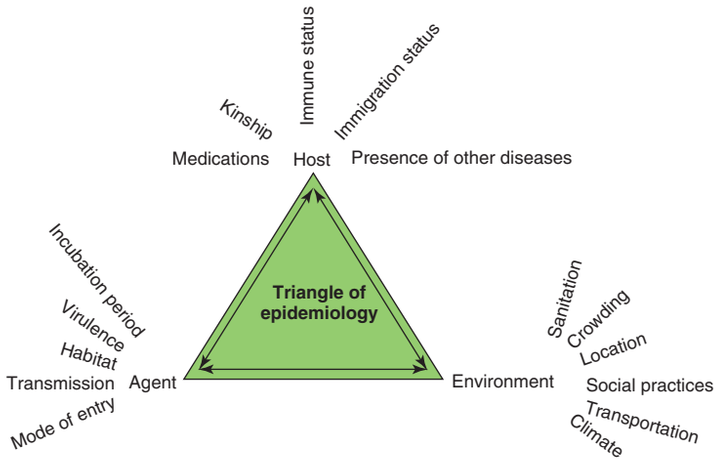

Figure 24.15. Triangle of epidemiology This conceptual model emphasizes the connection between the identified host, agent, and environment in an epidemic. Modifying any one factor or changing a connection, changes the outcome of the disease pattern in a population.

illustrates the connection between the three major factors associated with the development of an epidemic. These are:

1. *Host factors*: age, sex, kinship, immigration status, immune status, presence of other diseases, medications. These factors may identify hosts that are most susceptible to the infectious agent.
2. *Agent factors*: identity of the agent, its habitat, its virulence, incubation period, how it is transmitted or contracted, its mode of entry into the body.
3. *Environmental factors*: physical aspects of the environment such as changes in climate (temperature, rainfall, drought), sanitation, changes in food or water supply, crowding, location (hospitals, schools). Environmental factors also include cultural and social factors, transportation, and hygienic practices—anything that influences exposure of individuals to the agent.

These three factors will be operating in a concerted balance during an epidemic. Therefore, changing the parameters of any one of the three factors can prevent or stop the spread of an epidemic because it severs a connection in the triangle. Control strategies that target these connections generally involve:

- The protection of susceptible populations,
- The containment or elimination of the source of infection,
- The disruption of transmission.

For example, Lyme disease outbreaks are controlled by restricting access to tick-infected environments. Modifying the environment of the host severs the link between the host and the tick-borne pathogen Borrelia burgdorferi (see Microbes in Focus 18.5). Yellow fever can be controlled through vaccination of susceptible populations. Vaccination positively modifies the host immune status, severing the link to the agent without modification of the environment. Modifying the environment by draining standing water and using larvicides contains

or eliminates the mosquito vector source of yellow fever virus. This severs the link between the agent and the environment without changing the host factor. Using both approaches concurrently is even more effective. In the case of a cholera outbreak, containment or elimination of the source of Vibrio cholerae (see Microbes in Focus 21.7) infection can also be achieved by changing the environment by chlorinating the contaminated water source, or locating a new source of uncontaminated water. Both can break the transmission of the agent. Recall that this is the approach John Snow took when he recommended the removal of the pump handle from the Broad Street pump (see Section 18.3). He prevented access to *Vibrio cholerae*-contaminated water and stopped the epidemic.

CONNECTIONS Humans living in developing nations frequently face the risk of exposure to pathogenic microbes in the water they drink. This is especially true for humans living in heavily populated regions where sources of drinking water, such as a river, may be collecting raw sewage. **Section 16.5** describes how wastewater is first treated to protect raw water sources and how drinking water is purified and monitored to ensure public health.

Investigating an Outbreak

A critical public health measure in the prevention of an epidemic is to have accurate surveillance information systems that report the first possible signs of an outbreak. Identifying a localized outbreak can help contain the pathogen and prevent its spread to epidemic proportions. To investigate an outbreak, a systematic procedure is used to identify the agent and the source of infection. These basic "steps" are presented below, and they are often performed simultaneously during outbreak investigations.

1. Define a case.
2. Identify the causative agent. This frequently includes pathological and microbiological examination of tissues, food, water, and other relevant substrates suspected to be involved in the outbreak.
3. Examine the incidence pattern. First, construct an epidemic curve (see Section 18.3, Figure 18.18). The shape of the curve may suggest a common source or propagated epidemic. Second, plot spatial patterns of cases on a map to identify clusters of cases.
4. Determine the magnitude of the problem. Begin by comparing the current incidence with that of past or expected incidence. Then compute the **attack rate**. The attack rate is an incidence rate calculated during an outbreak, and gives the proportion of ill individuals in an exposed population over a short period of time. The attack rate is a measure of the probability of an exposed individual becoming a case, and it is used to estimate how many more individuals are expected to become ill.

$$\text{Attack rate} = \frac{\text{number of new cases during time interval}}{\text{total number of individuals in exposed population}} \times 100$$

5. Examine the data for common host factors, such as similarities in age, gender, immune status, and so on, and common environment factors, such as associations with climate, food, or water supply.
6. From the information collected, develop a working hypothesis, considering the following questions: What is the pattern of the outbreak (common source or propagated; see Section 18.3)? What is the source of the outbreak (water supply, food supply, introduction of an infected individual)? How is the pathogen spread (aerosol, fecal-oral, vector, vehicle)?
7. Test the developed hypothesis by collecting data on all those individuals exposed to the suspected agent or source, and/or perform controlled studies in animal models.

Investigating outbreaks is valuable because it can identify the cause and source of the illness, as well as generate information useful in preventing future outbreaks, improving public health policy, and providing practical training for epidemiologists.

24.4 Fact Check

1. Define R_0, the basic reproduction number. Why is $R_0 = 1$ considered to be the epidemic threshold?
2. R_0 is a function of what factors?
3. What three major factors are associated with the development of an epidemic?
4. What control strategies can be employed to stop the spread of an epidemic?
5. What steps are used to investigate an outbreak?

24.5 Immunization and vaccines

What are vaccines, and how are they used to control infectious disease?

One of the most effective tools in preventing microbial infections and epidemics is to protect susceptible populations through mass immunization using vaccines. **Immunization** is the process of generating immunological memory to prevent infection and/or disease through the introduction of an antigen into the body (see Section 20.1). Although often used as a synonymous term with immunization, **vaccination** is the physical act of injecting or inoculating the immunizing substance into the body. **Vaccines** are preparations of microbes or their components that are used in immunization.

History of vaccination

The term "vaccination" (*vacca* is Latin for "cow") was coined by Edward Jenner in 1798, although he was not the first to practice it. Perspective 24.3 describes the much more ancient vaccination procedure called "variolation," which was commonly used to immunize against smallpox before Jenner's vaccination method replaced it. Smallpox is a highly contagious, systemic viral disease characterized by the formation of numerous vesicles covering the body, including inside the mouth, throat, and inner eyelids (see Figure 1.1A). Before its eradication in 1980, it exhibited a mortality rate of up to 50 percent in infected individuals.

CONNECTIONS In **Section 1.4**, we briefly visited the first recorded vaccination carried out by Jenner. Jenner noticed that the hands of milkmaids, who rarely contracted smallpox, often developed cowpox pustules, and the disease was commonly referred to as "milkmaid's disease." Despite not knowing anything about microbial agents, he correctly reasoned that a purposeful introduction of cowpox material could prevent smallpox **(Figure 1.31)**. Unknown to Jenner, cowpox is caused by the cowpox virus, which is related to variola virus.

By the year 1800, Jenner's vaccination method for smallpox had become widespread in Europe and had reached the shores of America. Following a concerted global vaccination effort that began in 1967, the last naturally occurring case of smallpox was reported in 1977 (Figure 24.16). The disease was declared eradicated in 1980—the first and only infectious disease of humans to have successfully been eliminated from the globe. Vaccination for smallpox became unnecessary after this time and was then stopped. However, the virus is not extinct. A few stocks of wild smallpox virus remain in government labs in the United States and Russia for research purposes.

Interestingly, molecular analysis of the vaccine strain of cowpox virus has shown this virus is not cowpox virus at all, but seems to be a species related to both cowpox virus and variola virus. Vaccinia virus, as it is now known, is postulated to have evolved at some point by recombination between cowpox and variola viruses. It is not hard to imagine recombination happening within persons inoculated with the cowpox virus who were also incubating variola virus. Subsequent mutations resulting in natural attenuation made an effective vaccine

Perspective 24.3

VARIOLATION: DELIBERATE INFECTION WITH SMALLPOX VIRUS

Long before Edward Jenner's first successful vaccination for smallpox, Asian populations practiced a much riskier method of protection against smallpox called "variolation." Variolation was a purposeful inoculation of live smallpox virus (variola virus) into the skin or into a vein, or by inhalation through the nose. The inoculating material consisted of dried material scraped from smallpox vesicles. When it worked, variolation produced a mild case of smallpox, and the recipient recovered to enjoy a life forever protected from smallpox. When it didn't work, recipients died. Though the risk may seem considerable to us, choices were few prior to the 1800s before Jenner's substitution of smallpox virus for immunization with the much more benign cowpox virus. The odds of dying from smallpox by variolation was 1 in 100; the odds of dying from naturally contracted smallpox was 1 in 3, and smallpox was sure to affect almost every generation back then.

Variolation was practiced in China as far back as the tenth century, but it took Lady Mary Wortley Montagu, the wife of Britain's ambassador to Turkey in the early 1700s, to bring this practice to the attention of the Western world **(Figure B24.5)**. She reported how Turkish women would hold gatherings (later referred to as "smallpox parties") to inoculate smallpox preparations into the veins of the unexposed. They selected smallpox material from those who were recovering from the mildest form of smallpox, later called "variola minor." In so doing, the women selected less virulent forms of the virus for variolation. Material from the deadliest and most common form of the disease, variola major, was never used.

Having suffered and survived smallpox herself, Lady Mary had her young son and daughter inoculated. She returned with her family to London where an epidemic of smallpox had begun to take shape. As it reached the households of British royalty, including Lady Mary's own home, several prominent members of the British court, having heard of Lady Mary's successful inoculation of her own children, insisted on having their own children inoculated. News of the success of variolation spread and came to be practiced in other European countries and Russia. Variolation began in Boston in the 1720s. Jenner himself was variolated when he was eight years old. He developed a mild case of smallpox and was subsequently immune to the disease.

Figure 24.16. The world's last case of naturally occurring smallpox Survivor Ali Maow Maalin, who volunteered to help the WHO locate smallpox cases, contracted smallpox in his native Somalia in 1977. Wild variola virus was declared eradicated by the World Health Assembly in 1980.

against smallpox, but no longer caused the mild illness experienced by those infected with cowpox.

Vaccinia virus can be propagated in cell culture and is still maintained in some research labs for studying the biology of poxviruses. When it was in routine use, vaccinia virus was associated with a relatively high rate of serious complications (1 in 1,000 inoculations as compared to 1 in 10,000 or less for most vaccines in use today) and, because it is a live virus, it spread to unvaccinated individuals. Recently, the perceived risk of a concealed bioweapons store of variola virus has instigated a return to smallpox vaccination in the United States. These same undesirable side effects appeared in vaccinia-vaccinated American troops. This includes the spread of sores on parts of the body other than the vaccination site and can lead to blindness if the eyes are affected. In some cases, the sores become widespread, resulting in significant tissue damage and threat to life. Inflammation of the brain (encephalitis) is another life-threatening side effect of vaccinia vaccination. The CDC Advisory Committee on Immunization Practices currently does not recommend routine use of this vaccine.

Vaccine design

Vaccines confer immunological memory through the production of memory cells, which are specialized T cells and B cells that are produced following strong stimulation of the adaptive immune system (see Section 20.2). When the same or closely related agent is encountered again, memory cells will recognize the same antigens on the pathogen that were present in the vaccine, and initiate an immune response.

CONNECTIONS You may recall from **Section 20.1** that the memory response occurs upon re-exposure to an antigen and results in a very rapid and heightened immune response that can prevent a pathogen from causing disease **(Figure 20.5)**.

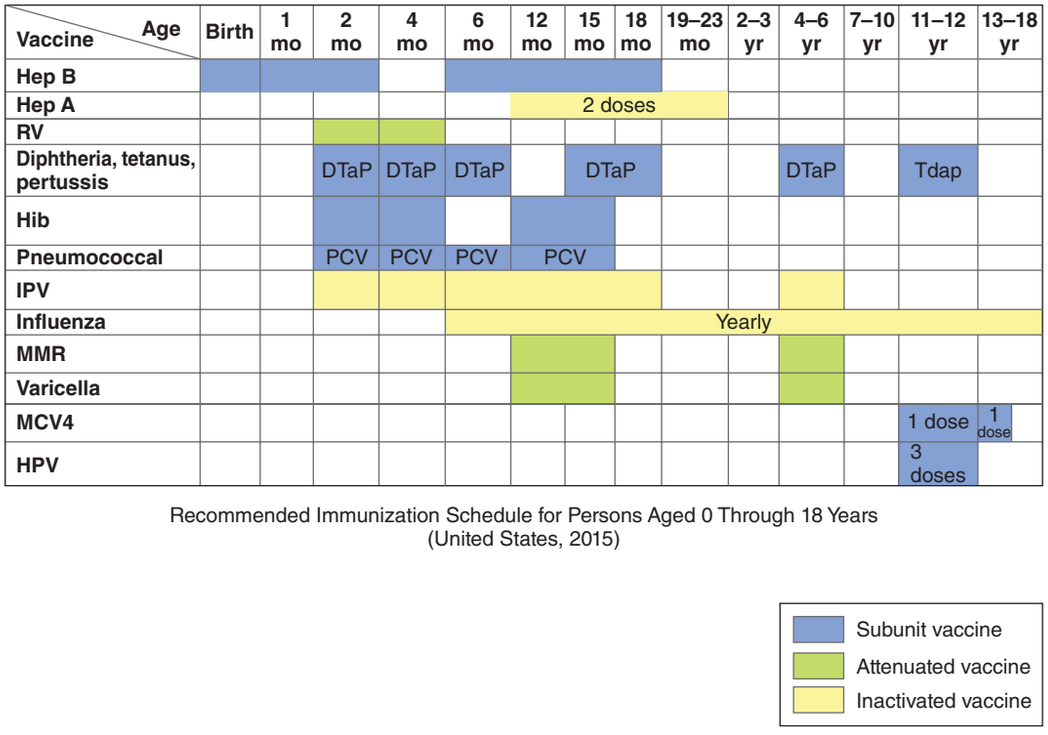
An ideal vaccine is one that generates a high level of immunological memory to protective antigens—those antigens that can elicit an immune response that protects against infection and/or disease. **Figure 24.17** shows the currently recommended vaccines for routine immunizations in the United States. **Table 24.6** provides descriptions of the vaccines. A good vaccine should also not produce serious side effects when used in large populations. There are a number of different ways vaccines are formulated to expose the immune system to protective antigens. Most vaccines follow the four basic designs outlined below.

Attenuated Vaccines

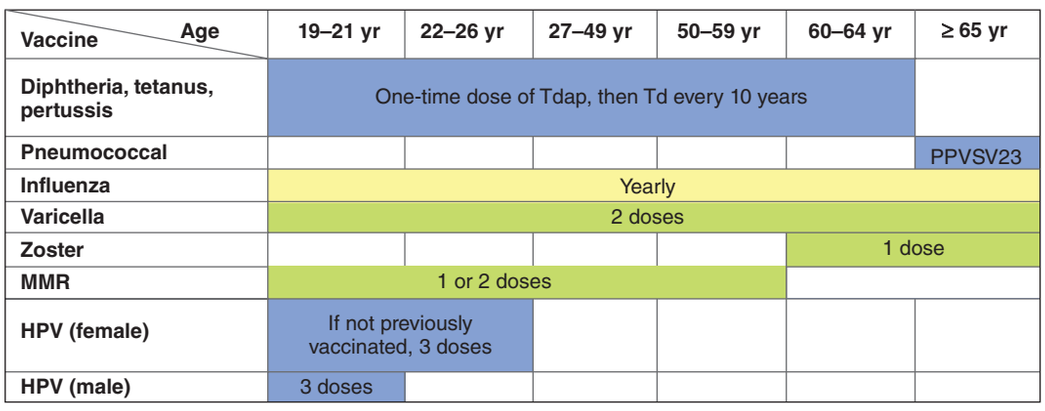
Attenuated vaccines are composed of a live but weakened version of a microbe that is completely or nearly devoid of pathogenicity. These vaccines tend to produce high levels of immunity because the attenuated microbe can replicate to some extent in the body, exposing the immune system to its antigens over a period of time, which results in a strong memory response. Consequently, fewer doses or "boosters" are usually needed. Some attenuated vaccines can be shed from the body and can be passed to other individuals. This contact spread is both a benefit and a disadvantage for attenuated vaccines; it can help protect others but can be transmitted to susceptible individuals in some cases. For example, live vaccinia virus vaccine can be transmitted from vaccinated persons to newborns, where it causes serious disease. Attenuated microbes may also undergo genetic changes, making them more virulent. This has occurred for an attenuated oral polio vaccine formulation, which we will examine near the end of the chapter.

Inactivated Vaccines

Inactivated or **killed vaccines** consist of whole cells or viruses that have been physically inactivated by heat or chemically inactivated by treatment with a denaturing agent such as formalin. The mixture of antigens that are liberated by the inactivation process is then injected into the body. Properly



Recommended Immunization Schedule for Persons Aged 0 Through 18 Years (United States, 2015)



Recommended Adult Immunization Schedule (United States, 2015)

Figure 24.17. Current immunization schedule Recommended immunization schedule for all persons specified by the Centers for Disease Control and Prevention (CDC). Not included are recommendations for those who have not followed this schedule, or special vaccinations for travel to some countries, or vaccines for specialized occupations, such as for rabies vaccination for veterinarians, or vaccines for persons at high risk, such as immunocompromised persons or those with diabetes.

inactivated vaccines cannot replicate in the body, cannot be spread, and cannot regain virulence. Inactivated vaccines typically require several injections to evoke long-term protective immunity because the immune system is exposed to the antigens only for a short period of time. They also tend to produce a higher level of side effects owing to the complex mixture of components that are injected. An example is pertussis vaccine (see *Bordetella pertussis*, Sections 21.1 and 21.2). The first generation of pertussis vaccine consisted of killed whole cell preparations. It was an effective vaccine, but because it was a crude preparation of microbial components, convulsions occurred in 0.1 percent of infants given the vaccine, and a smaller percentage of these suffered brain damage. The new generation of pertussis vaccines consists of acellular subunit preparations, described next.

Subunit Vaccines

Subunit, or **acellular vaccines** consist of one or a select number of isolated protective antigens. They are not composed of whole cells or viruses. In general, these are very safe because they are of defined composition rather than a complex mixture. The currently recommended pertussis vaccines consist of denatured pertussis toxin combined with select purified proteins used for bacterial adherence (see Sections 21.1 and 21.2). The acellular, subunit nature of current pertussis vaccines is represented as aP in the combined DTaP or Tdap vaccines (see Figure 24.17). Like inactivated vaccines, subunit vaccines typically require several injections (an initial injection followed later by "booster" injections) to evoke long-term immunity. Tetanus and diphtheria toxoids, previously covered in Section 21.2, are examples of subunit vaccines. You can see from Figure 24.17 that the DTaP

TABLE 24.6 **Vaccines recommended by the Centers for Disease Control and Prevention for bacterial and viral diseases**

Vaccine	Disease/pathogen target	Description
Vaccines against bacterial diseases		
Hib	*Haemophilus influenzae* type b causing meningitis	Conjugated polysaccharide (polyribitol phosphate) subunit vaccine
DTaP	Against diphtheria (*Corynebacterium diphtheriae*), tetanus (*Clostridium tetani*), and pertussis (*Bordetella pertussis*)	Combination subunit vaccine for children containing inactivated diphtheria, tetanus, and pertussis toxins. Includes other selected antigens of *B. pertussis* to reduce colonization
Tdap	Against diphtheria, tetanus, and pertussis	Combination subunit vaccine for adolescents containing inactivated tetanus and diphtheria toxins. Contains reduced concentrations of inactivated diphtheria and pertussis components
Td	Against diphtheria and tetanus	Combination subunit vaccine for adults containing inactivated tetanus and diphtheria toxins
PCV13	*Streptococcus pneumoniae* causing pneumococcal meningitis in children	Conjugated polysaccharide subunit vaccine containing the 13 most common capsule polysaccharides associated with meningitis in children
PPSV23	*Streptococcus pneumoniae* causing pneumococcal meningitis and invasive disease in adults	Non-conjugated polysaccharide subunit vaccine containing the 23 most common types of capsule polysaccharides associated with adult disease
MCV4	*Neisseria meningitidis* causing meningitis in young adults	Conjugated polysaccharide subunit vaccine containing the four most common types of capsule polysaccharides
Vaccines against viral diseases		
RV	Rotovirus causing gastroenteritis in children	Attenuated oral vaccine containing several strains of type A rotovirus
IPV	Poliovirus causing poliomyelitis	Killed vaccine containing poliovirus types 1, 2, and 3
Influenza	Influenza virus causing seasonal influenza	Polyvalent vaccine containing the dominant circulating strains of influenza A and B types
HepB	Hepatitis B virus causing liver disease	Recombinant subunit vaccine containing the envelope protein HBsAg produced in yeast
MMR	Measles, mumps, and rubella viruses	Killed combination vaccine
Varicella	Herpes varicella-zoster virus causing chickenpox	Live, attenuated vaccine for protection against primary infection
Zoster	Herpes varicella-zoster virus causing shingles	Live, attenuated vaccine for protection against reactivation in adults
HepA	Hepatitis A virus causing liver disease	Killed vaccine
HPV	Human papillomavirus causing cervical, anal, penile, and oropharyngeal cancer	Recombinant subunit vaccine containing capsid proteins of strains associated with the majority of papillomavirus-induced cancers. The vaccine Gardasil 9[a] contains capsids from an additional two of the most common strains causing genital warts (11 and 6).

[a]Gardasil 9 protects against seven oncogenic HPV strains.

or Tdap vaccine for diphtheria, tetanus, and pertussis is given frequently to children to maintain adequate levels of protection. Tetanus and diphtheria toxoids are further recommended every ten years after the age of 18 years.

CONNECTIONS You may recall from **Sections 19.4** and **20.4** that many vaccine formulations use adjuvants to boost their effectiveness. Because small, purified microbial peptides are typically not very immunogenic, they often do not stimulate strong adaptive immune responses. In turn, long-lived memory cells needed for lasting immune memory are not generated in sufficient numbers. Subunit and inactivated formulations therefore frequently include adjuvants.

Conjugate vaccines, introduced in Section 20.6, are modifications of subunit vaccines composed of a polysaccharide

antigen bound to an immunogenic protein. Several conjugate vaccines against pathogens causing meningitis are described in Table 24.6. An example is the Hib vaccine, which consists of the *Haemophilus influenzae* type b capsular polysaccharide (polyribitol phosphate) conjugated to denatured tetanus toxin (tetanus toxoid). The capsular polysaccharide is a protective antigen, but like most carbohydrates, it is not immunogenic in young children Conjugating polysaccharides to an immunogenic protein significantly improves their immunogenicity. Similarly, the *Streptococcus pneumoniae* childhood vaccine (PCV13) consists of 13 different capsular polysaccharides conjugated to diphtheria toxoid (see Perspective 20.2).

CONNECTIONS Recall from **Section 20.6** that capsular polysaccharides are T-independent antigens that do not evoke a B-cell response in young children. Effective immunization against these antigens requires the polysaccharides be bound or conjugated to a foreign protein molecule. This converts the conjugated polysaccharide to a T-dependent antigen, resulting in antibody production and immunological memory.

DNA Vaccines

DNA vaccines (see Chapter 19 Mini-Paper) consist of a cloned gene(s) in a DNA vector, which is then delivered to cells of the body, usually by injection of an engineered virus, or by electroporation of an engineered plasmid using electrical pulses to create pores in cells of muscle or skin. Expression of the cloned gene produces a protective protein antigen that induces an immune response. In this respect, DNA vaccines are similar to recombinant subunit vaccines. However, because the antigen is expressed in cells over a period of time, DNA vaccines evoke a strong memory response, like that of attenuated vaccines. These vaccines do not contain live microbes and are not able to be passed from host to host. DNA vaccines are largely still in experimental stages, but many appear to be very promising. There are only two currently licensed DNA vaccines. One is for farmed salmon to protect against viral infectious hematopoietic necrosis, and the other is for horses to protect against West Nile virus encephalitis. A counterpart of this vaccine is undergoing clinical trials for use in humans.

Vaccine efficacy

Are vaccines really effective? Despite the development of many highly effective vaccines, no vaccine is 100 percent protective for every individual. **Vaccine efficacy**, or the effectiveness of a vaccine, is an average measure of the degree of protection it affords a population. Most routine childhood vaccines have an efficacy range of 85 to 90 percent, meaning between 85 and 90 percent of those given the vaccine will be protected from the associated disease. For largely unknown reasons, a certain proportion of individuals will fail to establish a high enough level of immunological memory to protect them even when they have been vaccinated. This is known as **vaccine failure**, although "immune failure" is likely the underlying reason. Ali Maow Maalin, the survivor of the world's last natural case of smallpox, was himself vaccinated before he contracted the disease (see Figure 24.16).

So, even with a vaccine of high efficacy, we will expect to find a small number of vaccinated individuals who may contract the disease. To illustrate this, we can look at a hypothetical, but realistic, scenario involving a measles outbreak. In a school of 1,000 students, all but 15 of the students have been vaccinated for measles. The measles vaccine has an efficacy of 90 percent. Assuming in this small, dense population that every student becomes exposed after the introduction of an infectious person (and yes, this is completely realistic; measles has an R_0 value of 12 to 18 and is easily transmitted by aerosols), we would expect all 15 unvaccinated students to contract the disease, as well as those who experience vaccine failure. This last group would comprise 10 percent of the vaccinated student population; that is, about 99 of the 985 vaccinated students. The total number of cases expected is then 99 plus 15: 114 cases. Therefore, 99/114, or about 87 percent, of the measles cases in the school are in vaccinated individuals. Unfortunately, when outbreaks of measles do occur, opponents of vaccination often quote these seemingly high percentages as evidence that vaccines are not effective. As you can see, it is a misinformed or maybe purposefully misconstrued interpretation of the data. Imagine what would happen if no one in the school was vaccinated.

Before we leave the topic of vaccine design, you may wonder why there are no vaccines for some seemingly important diseases, like Ebola. Some diseases, as deadly as they may be, may not be of importance from a global health perspective. As devastating as Ebola is to the populations that periodically suffer from outbreaks, Ebola epidemics have, until recently, been confined to small, short-lived outbreaks in some Central African countries. Consequently, there has been little incentive to develop, manufacture, and distribute a vaccine. As well, these are some of the poorest countries in the world, and the infrastructure and monies for distributing and tracking vaccinations is severely lacking. The recent large epidemic in West Africa has brought to realization that this disease can be easily spread by transportation to large populations, can linger for some time, and is very costly to treat and track, even in rich Western nations. Consequently, several vaccines and therapeutic drugs are under development. Other diseases, such as HIV/AIDS and malaria are of global importance because they affect hundreds of thousands of people every year, yet there is no vaccine. Indeed, several vaccines have been formulated but trials in humans have shown poor efficacy. Why? In the case of HIV, this comes down to two reasons. First, as we have learned, the virus mutates rapidly, so any vaccine targeting immune-protective antigens, such as gp120 (see Figure 8.6) will not be effective for long. Second, it can be reasoned that the vaccine target gp120 is absolutely needed for attachment to host cells, so there must be some epitopes of this glycoprotein that cannot be mutated. Although this is indeed the case, vaccines designed to these constant epitopes do not result in antibody that is protective. Recall that vaccines rely on the generation of protective immune responses, and formulating vaccines to simply produce an immune response is often not enough.

Herd immunity

At the level of populations, mass vaccination reduces or prevents epidemics of communicable diseases and can even entirely eliminate some infectious diseases from populations. To accomplish this, does every person need to be vaccinated? Fortunately, the answer is no. Some individuals will be too remote to contact, and others will have underlying health conditions that make vaccination inadvisable. This includes individuals who are immunocompromised, those who have had allergic reactions to previous vaccinations, or those with a history of autoimmune disease. Some people refuse to be vaccinated because of religious choice, or philosophical reasons, as pointed out in **Perspective 24.4**. Lastly, as we have seen, a proportion of vaccinated individuals will experience vaccine

Perspective 24.4
The War Against Vaccines

Vaccines cause autism. Have you heard that one? It's a myth that began with British researcher Andrew Wakefield. In 1998, Wakefield and some colleagues published a paper suggesting a link between the measles vaccine and developmental regression in children. Interestingly, the conclusion stated in the paper was, "We did not prove an association between measles, mumps, and rubella vaccine and the syndrome described." The paper suggested further investigations must be done to relate the dysfunctions reported to the vaccine. This rather innocuous paper started the controversy that continues today in many forms, even though Wakefield was discredited by the British General Medical Council in 2010 and the paper was retracted by the journal *The Lancet*. There have been at least 12 large controlled studies and comprehensive reviews conducted by The CDC, the Institute of Medicine of the National Academy of Sciences, and the UK National Health Service. All have concluded that there is no evidence of a link between the measles, mumps, and rubella (MMR) vaccine and autism. Despite this, the damage from the Wakefield paper was already done. A 2013 Public Policy Polling survey in the United States on conspiracy theories found that 20 percent of Americans believed a link existed between childhood vaccines and autism. A 2015 Pew Research Center report revealed that almost 1 in 10 Americans believe vaccines are not safe for healthy children. Why does this myth not only perpetuate, but evolve?

Having found no scientific basis to link the measles vaccine to autism, anti-vaccine campaigners turned their attention to another vaccine ingredient, the preservative thimerosal, and proposed it to be linked to autism. Again comprehensive scientific studies concluded no link. The goal posts were moved once again, more recently to the "too many vaccines" hypothesis that states the number of vaccines given to young children in such a short time "overloads" the immune system, causing a host of developmental disorders, including allergies. Again, this belief has held sway with a small but vocal group of people despite no scientific evidence to support a negative impact of vaccination on children.

The "anti-vaxxers" movement continues to evolve and gain momentum, with philosophical objections to vaccinations. These include the view that vaccines are foreign material, and a belief that more natural approaches to disease resistance are better. Some opponents of vaccines argue that we should just let children get measles, rubella, chickenpox, whooping cough, and other infectious diseases, as this would be more natural. In the United States, 19 states allow parents to file such "philosophical exemptions" in order to get their unvaccinated children into school. In California, one of the exemption states, the proportion of children entering kindergarten that meet the CDC-recommended federal guidelines for vaccine coverage rate of 95 percent has been declining since 2008. In 2014, the United States saw 644 cases of measles compared to an average of around 60 cases in previous years since 2000.

The worry of course is that under-vaccinated communities undermine herd immunity and this may allow diseases like measles and whooping cough to get a foothold in countries where they are currently eliminated. What would this look like? It might look like the 1950s, in the era before vaccines, when measles infected more than half a million Americans each year and killed roughly 450 of them. Many of the people who survived had serious long-term health effects. Surely parents do not wish this on their children or society. So why do they choose not to vaccinate?

Several studies on the issue conclude that the people who decide not to vaccinate tend to fall into a few characteristic, but not exclusive, camps. Vaccine refusal rates in the United States are highest among young to middle-aged, less educated, low income Americans. However, anti-vaccine sentiments are also found among young, wealthy, well educated communities, including pockets around major universities. Studies with this group show a high level of scientific literacy, so an ability to understand the science presumably exists, but willful use of that knowledge is toward reinforcing beliefs consistent with their worldview. Some suggest that education itself encourages this skepticism, compiled with a distrust of authority and independent thinking. In this, there are parallels to studies on the attitudes of climate change and plant biotechnology skeptics. Instead of reaching rational consensus with scientists and the medical community, who have overwhelmingly shown that vaccines are safe and effective, they are convinced they know what is best for their own children. They filter information for that with which they already agree. This is often referred to as confirmation bias.

Others rely heavily on personal communications and anecdotes, often garnered from the Internet or popular media where there are few pro-vaccine stories to be popularized. This appears to stem from a "herd mentality" and a need to fit in. When the perception is that everyone you know, respect, and care for is anti-vaccine, then the belief is reinforced - community values and opinions outweigh scientific evidence.

Whatever the reasons for choosing not to vaccinate, there often is no personal consequence in ignoring the science. If most people are vaccinated (and it is important to remember that the vast majority of people practice vaccination), then the chance of contracting one of the diseases to which vaccines are designed is very low. It is precisely because vaccines are so successful that many people do not see the need to get them. It will be interesting to see if attitudes change and vaccine rates increase in communities where there have been recent outbreaks.

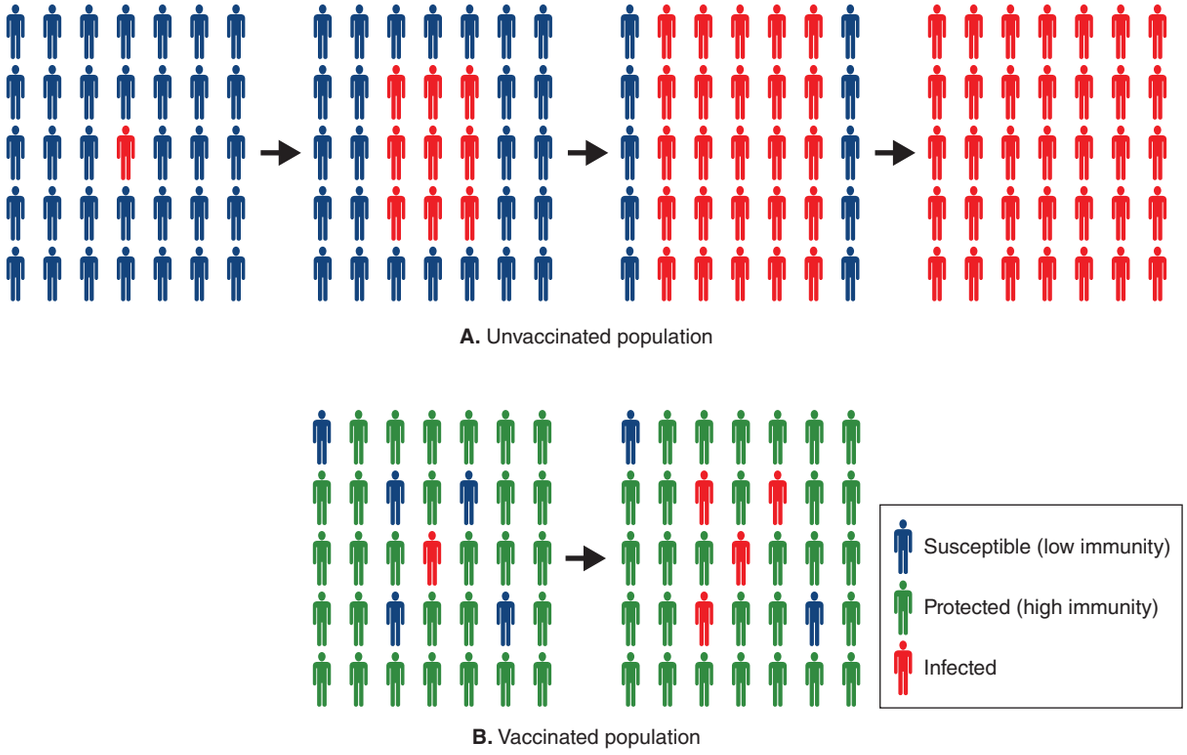


Figure 24.18. Protection by herd immunity **A.** In an unvaccinated population, introduction of an individual infected with a communicable pathogen results in infection of all susceptible contacts, who in turn infect other contacts. Soon the entire population becomes infected. **B.** In the vaccinated population, only unvaccinated, susceptible contacts of the infected individual become infected. Infection does not reach all susceptible individuals because they are at a density too low to allow further contact and spread. Consequently, transmission of the pathogen stops.

failure. Fortunately, a population effect known as "herd immunity" can protect non-immune individuals and stop transmission of a communicable disease.

Herd immunity, sometimes known as "community immunity," occurs when successful immunization of a certain proportion of a population serves to protect the rest of the population from communicable disease. A lack of susceptible individuals in a sufficiently immunized population means that transmission of infection will decline and may cease altogether. Herd immunity effectively establishes a barrier of immune individuals that prevents access of the transmissible agent to susceptible individuals (Figure 24.18). The general aim of public health in guarding against communicable disease is to establish and maintain effective herd immunity through mass immunization.

What number of immunized individuals are needed for herd immunity? The critical proportion of the population required to be immunized to achieve herd immunity is called the **herd immunity threshold**. Table 24.7 shows herd immunity thresholds for some communicable diseases that are controlled through vaccination. Herd immunity thresholds are frequently derived by calculations based on (1) the susceptibility of the population, (2) how communicable the disease agent is (estimated by its R_0 value), (3) the population density (higher densities must have higher herd immunity), and (4) vaccine efficacy.

So far, we have learned that the herd immunity threshold gives an estimate of the proportion of people that must be immunized. That is, the proportion of people that must gain protective immunity. We have also learned that, due to vaccine failure, not everyone who is vaccinated gains immunity. The practical question that must follow this then, is what proportion need to be vaccinated? The herd immunity threshold allows estimation of the **vaccine coverage rate**, the proportion of individuals in the population that must be vaccinated to achieve herd immunity. Usually vaccine coverage target rates are set to slightly exceed herd immunity thresholds, to account for the usually low rates of vaccine failure. For example, the

TABLE 24.7 **R_0 values and herd immunity thresholds for select communicable diseases**

Disease	Transmission	Estimated R_0 value	Herd immunity threshold (%)
Measles	Aerosol	12–18	83–94
Pertussis	Aerosol	12–17	92–94
Diphtheria	Direct contact	6–7	85
Smallpox[a]	Direct contact	6–7	83–85
Polio	Fecal-oral	5–7	80–86
Rubella	Aerosol	5–7	80–85
Mumps	Aerosol	4–7	75–86

[a]Eradicated.

Source: Adapted from History and Epidemiology of Global Smallpox Eradication. From the training course titled "Smallpox: Disease, Prevention, and Intervention." The CDC and the World Health Organization. Slides 16–17.

WHO sets vaccine coverage target rates at 95 percent for measles, which has a maximum herd immunity threshold of 94 percent (see Table 24.7).

For some communicable diseases, global eradication can be achieved through vaccination, as has occurred for smallpox. Why have no other communicable diseases been eradicated? First, candidates for eradication must satisfy the following criteria:

- Long-term immunity can be produced through vaccination.
- Only a few strains exist that need to be considered for vaccine design.
- Only one significant reservoir of the pathogen exists.

Currently, measles, mumps, and rubella (which are conveniently included in the single MMR vaccine), polio, chickenpox, and hepatitis B are on the WHO target list for eradication. In some countries, these diseases have already been eliminated. For example, recall from Chapter 18 that polio was eliminated in the United States in 1979. The last case of wild poliovirus contracted in the United States occurred in a small community where no one was vaccinated for polio. Other cases of polio that have since been detected have been imported by overseas travelers. In many nations, the cost of vaccination remains a major impediment to the successful eradication of these diseases. In the next sections, we will examine the cases of poliovirus and foot-and-mouth disease virus (FMDV) in order to gain some insight into why communicable diseases are so difficult to eradicate, and what control strategies are used to fight these infectious diseases.

Polio—A near success

The development of poliovirus vaccines is hailed as one of the greatest success stories of medicine. Today, the incidence of disease from poliovirus is but a shadow of its former self, and the virus is on the verge of being eradicated entirely. Yet poliovirus is proving to be more difficult to globally eradicate than was first imagined. Skyrocketing populations, civil wars, and political and social unrest have all contributed to lingering reservoirs of infection.

Polio Disease and Transmission

Poliovirus is a very small non-enveloped RNA virus (see Microbes in Focus 5.2) transmitted via the fecal-oral route. Humans ingest the virus from contaminated water and food or through contact with feces-contaminated objects. The virus attaches to a specific immunoglobulin-like receptor known as the poliovirus receptor, which is present on epithelial cells lining the pharynx and small intestine and also on leukocytes and motor neurons. Viral replication in epithelial cells of the digestive tract results in shedding of large numbers of infectious virions. In areas where poliovirus is still endemic (see Figure 18.30), it can be found in lakes, rivers, and streams contaminated by raw human sewage.

When a person ingests poliovirus, a number of outcomes are possible. In most cases, dissemination of poliovirus beyond the epithelial lining of the digestive tract does not reach a significant level. These infections are either asymptomatic or short-lived, producing mild fever, nausea, vomiting, sore throat, constipation, cramps, and stiffness. Recovery is usually complete. However, the virus becomes systemic in some cases, entering the circulatory system and gaining access to the central nervous system. Poliomyelitis then develops as a result of inflammation of the meninges, the layer of tissue surrounding the brain. Most patients recover from this, but in a few, the motor neurons become infected, resulting in nerve damage and paralytic poliomyelitis. Paralytic poliomyelitis results in partial or complete paralysis and is estimated to occur in less than 1 percent of those who develop poliomyelitis. A proportion of paralytic poliomyelitis victims may die due to respiratory failure involving paralysis of the diaphragm. Recall from the opening story of Chapter 18, at the height of the polio epidemic in the 1940s and 1950s, before vaccination, it was common for patients suffering paralysis to be placed in "iron lung" chambers to help them breathe **(Figure 24.19)**.

B. Girl receiving breathing assistance

Figure 24.19. Iron lung machine for polio victims **A.** During polio epidemics in the United States (prior to vaccination in 1955), many patients suffering from poliomyelitis were maintained in iron lungs that used changes in pressure to help them breathe. Although some patients recovered the use of muscles for breathing, others did not and remained in the machines until their death. **B.** Close-up of a young girl positioned in an iron lung.

The Changing Patterns of Polio

You might expect that in an unvaccinated population where high levels of endemic poliovirus exist, the incidence of poliomyelitis, and therefore the incidence of paralytic poliomyelitis, would be high. However, this is not the case. Poliovirus has existed in human populations for thousands of years, yet the incidence of poliomyelitis has risen to become a public health concern only within the past century. Before modern sanitation facilities and vaccination programs, poliovirus commonly infected very young children. Often, these children did not develop poliomyelitis because their naturally immune mothers, who were also exposed to the virus and survived, provided them with transplacental IgG and secreted IgA from breast milk (see Section 20.6). When infected with poliovirus during this time of passive immunity, they were protected from disease by this transferred antibody. Thus, poliovirus was usually only able to cause mild infection, allowing these children to develop their own adaptive immunity to the virus. By the age of five years, most children had acquired adaptive immunity to the virus and were protected from subsequent infections in their later years, greatly lessening the risk of poliomyelitis **(Figure 24.20)**. Under these conditions, the incidence of poliomyelitis among infected individuals is estimated to be 0.05 percent.

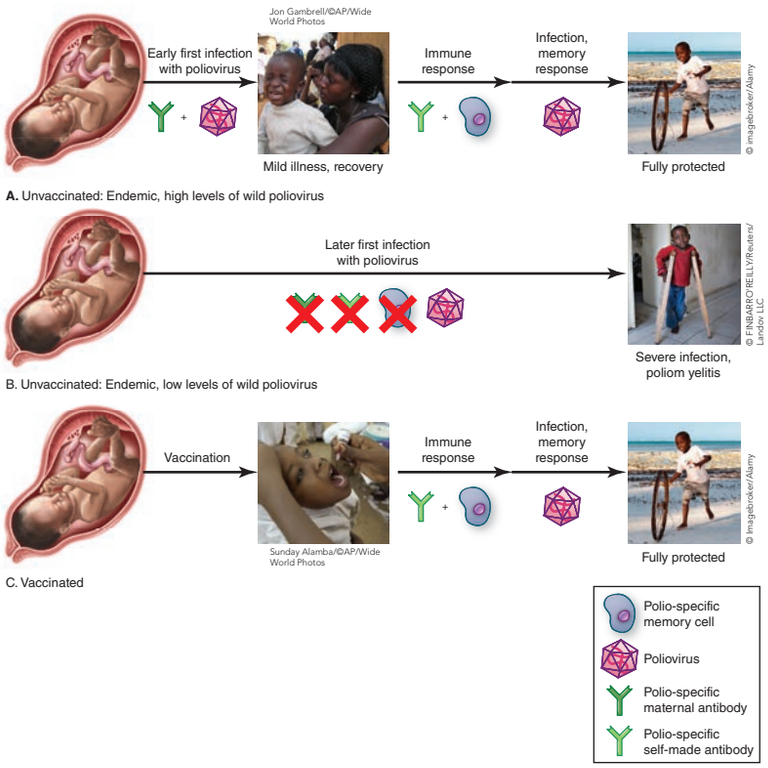

Figure 24.20. Outcome of poliovirus infection and immune status **A.** When high levels of endemic poliovirus are present, first exposure usually occurs in young children who are generally protected from poliomyelitis disease because they carry protective maternal antibody (IgG, IgA) from their exposed mothers. Infection is mild and they produce their own adaptive immunity to poliovirus, which protects them from subsequent infection. By age 5, most children are immune to poliovirus and the incidence of poliomyelitis is very low. **B.** When low levels of endemic poliovirus are present, first exposure usually occurs after the age of five years. Protective maternal antibody is frequently not present. Without protection, infection is more severe and the incidence of associated poliomyelitis increases. **C.** Vaccination, recommended to begin at two months of age, ensures adaptive immunity is present before children are exposed to circulating virus. The immunological memory that is produced protects them from poliomyelitis.

CONNECTIONS Disease incidence, as we learned in **Section 18.3** refers to the number of new cases appearing in a population during a specific time period. Incidence rate reporting is one of the best indicators of disease risk in a susceptible population, and also indicates how quickly a disease is spreading in a population. Incidence reporting, along with prevalence reporting, represent the most common epidemiological measures of infectious disease in populations.

As modern sewage and water treatment facilities became more commonplace in endemic areas, the levels of poliovirus decreased in the environment and exposure was reduced. Although no one will claim that providing clean food and water to populations is an overall disadvantage, it had an undesirable impact on the incidence rate of poliomyelitis. In these low-level endemic areas, there is a longer interval to first exposure to wild poliovirus, typically around five years of age. These older unexposed children have no adaptive immunity to the virus, nor do they have any passive maternal antibody left (see Figure 24.20B). Consequently, they acquire more severe infection upon their first exposure. This increases the chance of travel of the virus to the central nervous system, increasing the risk of poliomyelitis and paralysis. From an epidemiological context, the incidence of poliomyelitis in unvaccinated populations in regions where poliovirus is endemic is related to the age of first exposure to poliovirus. This is because the severity of poliovirus infection depends on the immune status of the individual. The advantage of vaccination is that it ensures young children will have adaptive immunity to poliovirus to protect them from subsequent exposure, regardless of the age at which exposure happens.

Polio Vaccines

In 1952, American Jonas Salk grew the only three serotypes of wild, naturally occurring poliovirus in monkey cell culture, and inactivated the virus particles by treatment with formalin. Formalin treatment denatures viral proteins, preventing attachment and entry into cells. Injection of this inactivated vaccine stimulates a protective immune response, preventing disease upon future exposures (see Figure 24.20C). Widespread use of this "Salk" inactivated polio vaccine (IPV) began in 1955, after the vaccine was proven to be effective and safe in small-scale human trials. Almost immediately, the number of new cases of poliomyelitis dramatically fell in vaccinated groups. **Figure 24.21** shows the drop in incidence of poliomyelitis in the United States, beginning in 1955.

As successful as the original Salk vaccine was, it had a number of drawbacks. Like most inactivated vaccines, it required several injections to produce sufficient protection. This was expensive and made it difficult for many countries to maintain herd immunity. In addition, the vaccine results in a memory response that gives rise primarily to serum anti-poliovirus IgG antibody only (see Table 24.4). Even though circulating IgG prevents the virus from reaching the central nervous system, it reduces but does not prevent wild virus from infecting mucosal cells lining the intestine and pharynx. So, although individuals vaccinated with IPV do not display disease, they are still able to carry and spread wild virus, which is a less than desirable outcome toward eradication.

Figure 24.21. Incidence of poliomyelitis in the United States
Introduction of polio vaccines, beginning in 1955, was followed by a drastic drop in the incidence of poliomyelitis. The last case of poliomyelitis contracted from wild poliovirus originating in the United States was in 1979. Sporadic cases appearing since have been vaccine-derived or imported from other countries.

In 1957, another American, Albert Sabin, decided to improve the vaccine. In order to boost immunity and prevent the spread of wild virus, he developed a live, attenuated oral polio vaccine (OPV). Sabin's first formulation was derived from a single serotype of wild virus and, in 1963, all three serotypes were included. The strains he developed had accumulated various mutations spontaneously in their RNA genomes over a period of culture in monkey cells. The mutations caused decreased viral replication, producing less virulent virus. Sabin correctly reasoned that, if ingested, such weakened strains would replicate in mucosal cells enough to stimulate a protective immune response, but not enough to cause disease. Oral delivery and fewer dosages meant this vaccine was cost-effective for countries that could not afford Salk's inactivated, injectable vaccine.

Perhaps the most significant advantage of the live attenuated virus was that it could prevent replication of wild virulent virus. Wild virus replication is prevented because the attenuated virus replicates in the gut, stimulating production of protective serum IgG and mucosal IgA, which is secreted at the site of infection. The presence of local IgA prevents attachment and infection of wild virus. Individuals vaccinated with the attenuated oral polio vaccine (OPV) are not only protected from disease, but they cannot spread wild virus. Without a reservoir in which to replicate, poliovirus could be completely eradicated. **Table 24.8** compares features of the inactivated and attenuated vaccines.

Beginning in the 1960s, mass vaccination programs switched from using IPV to OPV with the intention of eradicating the wild virus globally (see Chapter 18, *The Rest of the Story*). How successful has this been? Since 1988, when the annual burden of paralytic poliomyelitis was estimated by the Global Polio Eradication Initiative to be more than 350,000 cases, the global incidence of poliomyelitis has dropped by more than 99 percent. In 2013, only 403 cases of poliomyelitis were reported, and the number of countries with endemic poliovirus has fallen from 125 to just 3: Nigeria, Pakistan, and Afghanistan (see Figure 18.30). Nigeria has had no polio cases for a time period that will likely see it declared polio-free. This would not have been possible without OPV use. Unfortunately, unvaccinated individuals infected with wild virus traveling from polio-endemic countries continue to be a source of infection in unvaccinated individuals in other regions. Several countries where wild poliovirus was previously eliminated, including Angola, Chad, the Democratic Republic of the Congo, and parts of the Middle East have re-established pockets of circulating wild poliovirus. In populations consistently practicing childhood polio vaccination, vaccine coverage rates are very high (greater than 90 percent) and risk of infection from importation of wild poliovirus is very low. However, several countries have experienced political and cultural shifts in recent years that have resulted in resistance to vaccination programs. Nigeria's anti-vaccination movement arose in 2003 from a distrust of Western nations, the sponsors of the polio campaigns. As a result, cases in Nigeria rose from less than 200 to over 1,100 in three years. As well, outbreaks in some neighboring previously polio-free countries have resulted (see Figure 18.30), an unfortunate illustration of the importance of maintaining herd immunity. Renewed efforts by the Nigerian government and international health care agencies have since been made to target these regions for vaccination. War, poverty, cultural and religious practices, and lack of government-sponsored vaccination programs are other common barriers that lead to epidemics of diseases that are easily controlled by vaccination.

The Polio Vaccine Compromise

As miraculous as attenuated OPV seems, it has a flaw. Attenuated poliovirus replicates, and any virus that replicates, mutates. Rare cases of poliomyelitis sometimes appear following vaccination with OPV. Analysis of the virus strains from these cases confirm

TABLE 24.8 Comparison of inactivated and attenuated oral polio vaccines

Inactivated polio vaccine (IPV)	Attenuated, oral polio vaccine (OPV)
Developed by Jonas Salk	Developed by Albert Sabin
Injected	Oral
Expensive[a] (needles, trained medical personnel, 3–4 boosters)	Inexpensive[a] (no needles, no special training, 2 boosters)
Serum immunity only (IgG)	Mucosal (IgA) and serum immunity (IgG)
Prevents poliomyelitis but not infection from wild virus (carrier)	Prevents poliomyelitis and infection with wild virus (cannot transmit wild virus)
Does not eliminate wild virus	Eliminates wild virus
No risk of vaccine-associated poliomyelitis	Risk of vaccine-associated poliomyelitis
No transmission of vaccine strains	Transmission of vaccine strains

[a]Both formulations require refrigeration.

they are not wild virus, but genetic deviants of the vaccine strains. The attenuated strains infrequently regain their lost virulence by either recombining their RNA with other related intestinal viruses (type C enteroviruses) of the *Picornaviridae* family or, less often, by accumulating point mutations. It is estimated that less than 1 in every 2.7 million first-time doses of OPV results in vaccine-associated paralytic poliomyelitis. Because of this small but real risk, the WHO no longer recommends OPV-only vaccination. Out of concern for the risk of vaccine-associated paralytic poliomyelitis, the United States banned the routine use of OPV in 2000, and several other polio-free countries have followed suit. This is in accordance with WHO recommendations for countries where (1) wild poliovirus has been eliminated, (2) vaccine coverage rate is high (90 to 95 percent), and (3) the risk of wild poliovirus importation and transmission is very low.

What about countries where poliovirus still circulates? The aim here is poliovirus elimination. In countries where wild poliovirus is prevalent, OPV needs to be used because the risk of wild virus infection and transmission is higher than the risk for vaccine-associated paralytic poliomyelitis. After elimination, the switch to using IPV can be made to prevent outbreaks from imported virus from other regions. This may seem like a simple and logical plan of attack to eradicate polio, but changing epidemiological patterns and cost-effectiveness, demand more complicated vaccination strategies. First, examination of vaccine-associated cases of poliomyelitis has revealed that the vast majority of these viruses derive from attenuated poliovirus type 2. The standard OPV vaccines contain attenuated versions of all three types. However, wild poliovirus type 2 was eradicated in 1999 (and wild type 3 has not been reported since 2012). So, eliminating the unnecessary type 2 strain from the OPV formulations should dramatically reduce the risk of vaccine-associated paralytic poliomyelitis. Indeed, several countries are already using these new two-way OPV formulations. Second, OPV-derived mutant viruses are transmissible. In populations where vaccine coverage rates are low, outbreaks of vaccine-derived poliomyelitis have occurred. A recent example is Nigeria, which saw 155 type 2 vaccine-associated cases of poliomyelitis in the unvaccinated population in 2009 due to a lapse in vaccination. Obviously, these vaccine-derived strains need to be eradicated, but removing the type 2 poliovirus from OPV will not prevent the spread of those in circulation. To pave the way for the switch to the two-way OPV vaccines, the WHO recommends that at least one of the doses in the current OPV vaccination series be IPV. IPV contains inactivated versions of all three poliovirus serotypes and will provide protection against any remaining circulating vaccine-derived type 2 poliovirus. Do we dare to hope that in a few years we will be successful in the endeavor to eradicate poliovirus? If that day comes, polio vaccination, like smallpox vaccination, will disappear like the viruses themselves.

Foot-and-mouth disease: The making of an epidemic

Most of the examples we have been discussing have been human communicable diseases. How are communicable diseases of animals controlled? Let's examine foot-and-mouth disease virus (FMDV), a close relative of poliovirus that has significant impacts on domestic herds **(Microbes in Focus 24.1)**.

In 2001, an outbreak of foot-and-mouth disease (FMD) occurred in the United Kingdom. Media coverage showed gruesome scenes of slaughtered cows, sheep, goats, and pigs unceremoniously dumped into pits, covered with lime, and buried or burned in giant funeral pyres in an effort to stop the spread **(Figure 24.22)**. The epidemic originated from a single pig farm in Britain, the owner of which was later jailed for failure to report this notifiable disease to authorities. In 2007, another smaller outbreak occurred in the United Kingdom.

Foot-and-Mouth Disease Transmission

FMDV can spread by every possible means: aerosol, water, contact, soil, bedding, urine, milk, and saliva. Winds can transmit the virus over many kilometers, and, with an astounding R_0 value between 36 and 73, it spreads explosively in unprotected herds. FMDV causes high mortality in infected young animals and severely cripples adult animals by producing painful lesions on feet and in the mouth **(Figure 24.23)**. The economic losses to agriculture can be enormous, and countries fight hard to keep the virus out—not an easy task. When FMDV entered the highly susceptible population of cloven-hoofed animals in the United Kingdom in 2001, it did what any highly contagious pathogen would do—it created a rapidly spreading epidemic.

To stop the epidemic, between 6.5 million and 10 million animals were slaughtered, trade in animals and their products was halted, and tourism and travel of people were restricted for fear of inadvertent transport of the virus. Even federal elections were delayed. Sadly, there are several high-efficacy vaccines available to combat FMDV. So why aren't they used?

FMD Vaccination and Control Control of infectious diseases in animals frequently follows policies that are very different from those used for humans. The story of FMDV illustrates this. Animals and their products are commodities, traded on international

Microbes in Focus 24.1
FOOT-AND-MOUTH DISEASE VIRUS

Habitat: Infects cloven-hoofed mammals

Description: Small, ssRNA naked virus with icosahedral symmetry belonging to family *Picornaviridae*

Key Features: Foot-and-mouth disease is one of the most highly contagious diseases known. It infects many cell types, particularly epithelial cells of the pharynx, tongue, and clefts of feet where receptors are most prevalent, forming painful vesicles on the mouth, nose, and feet. FMDV rarely infects humans and does not cause serious disease when it does. It causes low mortality in adult animals (3 to 5 percent), but high morbidity that can result in long-term debilitation of animals, which are usually slaughtered. Mortality is highest in very young animals, up to 90 percent.

Figure 24.23. Foot-and-mouth disease lesions Foot-and-mouth disease virus is highly contagious, affecting cloven-hoofed mammals and causing mortality in the young and disabling adults. **A.** Painful vesicles form on the mouth and tongue (shown here, cow tongue). **B.** Vesicles and open sores on the feet of a pig.

markets. To protect domestic herds and flocks from imported disease, strict trade policies are established and maintained. Policies for FMDV prevent the export of animals from areas where FMDV is endemic to FMDV-free areas. This is logical, and you can probably appreciate why FMDV-free countries are so vigilant in screening for the presence of this virus, as it may enter from neighboring endemic areas.

Surveillance for FMDV is done by ELISA to detect the presence of antibodies to the virus (see Toolbox 20.2). If the ELISA is positive, the animal is assumed to be infected and is destroyed along with its herd mates. This type of control program is called "test and slaughter," and is used for several notifiable diseases in livestock, including avian influenza, bovine tuberculosis caused by *Mycobacterium bovis*, and bluetongue, a serious viral disease of sheep and cattle transmitted by midge insects. Vaccination for FMDV confounds detection because the vaccine produces antibody to the virus, making vaccinated and infected animals indistinguishable by ELISA. This results in trade restrictions where vaccination is practiced because authorities cannot guarantee the absence of virus. With this type of economic pressure, it makes sense for countries like the United Kingdom, the United States, and Canada to maintain a FMDV-free, vaccination-free status. For the United Kingdom, maintaining their vaccination-free status cost them an epidemic, loss of their herds, and an estimated $8.5 billion—a cost that many economists consider to have been greater than the economic gains made by not vaccinating. In the wake of the British FMDV disaster, many countries are now reconsidering their vaccination policies and are beginning to vaccinate their herds.

24.5 Fact Check

1. Define the terms "immunization" and "vaccination."
2. Describe the four basic designs of vaccines, and explain the advantages and disadvantages of each.
3. Explain the terms "vaccine efficacy" and "vaccine failure."
4. Define the terms "herd immunity" and "herd immunity threshold," and explain how these terms are related.
5. Describe the differences between the inactivated polio vaccine (IPV) and the attenuated oral polio vaccine (OPV), and briefly explain the reasons for the varying use of these vaccines.
6. Explain why test and slaughter programs are employed for communicable diseases in farmed animals.

Image in Action

WileyPLUS Learning Space The mosquito Aedes aegypti in this image is transmitting the yellow fever virus from a monkey in the forest background to a human. The envelope of the virus is coated with viral protein. In the cut-through, the membrane is visible (white), and the nucleocapsid protein (purple) encases the single-stranded RNA genome.

1. Imagine that a yellow fever outbreak is occurring in this image. Using parameters of the triangle of epidemiology as a guide, what major factors would you aim to control in this epidemic? Explain and give specific examples that could apply to this outbreak.
2. Imagine a new antiviral drug was developed and, because it was so effective, was highly prescribed during this outbreak. Why would this increased use raise concerns about increased likelihood of resistance to the drug? Explain.

The Rest of the Story

In an attempt to demonstrate that yellow fever was transmitted by mosquitoes, Dr. Lazear and Dr. Carroll engaged in self-experimentation with mosquitoes that had fed on the blood of yellow fever victims. They both contracted the disease and Lazear died. Unfortunately, their sacrifice did not confirm mosquitoes were the agent of transmission because they could have contracted the disease from some other source. Mourning the loss of his good friend, Dr. Reed decided to put the question of transmission by mosquitoes to an end once and for all. He carried out controlled infection studies with volunteer American soldiers and newly arrived Spanish immigrants. Reed placed men in each of two specially built cabins. In the "Infected Clothing Building," mosquitoes were completely absent, but for 20 days, the volunteers wore the dirty clothes and slept in the soiled bedding of those who had died of yellow fever. In the "Infected Mosquito Building," the volunteers were given clean clothes and bedding, but were housed with mosquitoes that had previously fed on yellow fever patients. (Can you imagine volunteering for this?) The men in the Infected Mosquito Building contracted yellow fever, whereas those in the Infected Clothing Building did not. Reed had successfully demonstrated mosquitoes were the vectors of yellow fever.

Dr. Carroll was also able to show that the agent could pass through filters normally used to collect bacteria. By injecting the filtrate prepared from infected mosquitoes into human volunteers, he showed that the agent causing yellow fever was not a bacterium or any other sort of microscopic agent known at the time. We now know the causative agent is yellow fever virus, which belongs to the family *Flaviviridae* (flavi means "yellow" in Latin), a group of RNA viruses commonly transmitted by insect vectors.

The repercussions of yellow fever in the New World were, and still are, astounding. During the Spanish-American War (1898) and the American Civil War (1861–1865) more troops died of yellow fever than in combat. In 1803, yellow fever forced the defeat of Napoleon in Haiti after he lost 23,000 soldiers to the disease. This gave him the incentive to sell an expanse of land that stretched from Louisiana into Canada at a bargain price to Thomas Jefferson—the famous Louisiana Purchase. Imagine how differently things may have turned out in the absence of this tiny microbe.

Let's now return to our earlier question posed in the opening story. Should you be worried that your neighbor's case of yellow fever may be the first of many in your area? The answer is no. Yellow fever is not a contagious disease and thanks to the groundwork of the Yellow Fever Commission, simple mosquito control measures such as screening, insect repellents, and removal of standing water has eliminated yellow fever as a public health threat in most countries. Indeed, the last case of urban yellow fever in the United States was in 1942. Your neighbor would likely have quickly been hospitalized upon developing symptoms, effectively isolating the virus from mosquitoes. Furthermore, yellow fever virus is only transmitted by mosquitos of the genus *Aedes*, which do survive cold temperatures. The development of a highly effective attenuated vaccine in 1938 has further reduced the incidence of yellow fever in many African and South American countries, where the virus is still endemic because monkeys remain a reservoir. Vaccination can also protect those who may be traveling to these areas, so they do not bring the yellow fever virus home with them. Unfortunately, it appears your neighbor did not take advantage of this option.

Summary

Section 24.1: How did we deal with infectious disease in the past?

Large-scale epidemics of communicable diseases of humans appeared with the rise of populous civilizations and were spread by trade.

- Domestic animals were the original source of many infectious diseases affecting humans.
- For most of history, religious and superstitious beliefs governed the cause and treatment of infectious disease.
- Before antimicrobial drugs and vaccines, control of infectious disease frequently involved banishment, quarantine, bloodletting, and purging.

Section 24.2: What kinds of drugs are used to treat infections, and how do they work?

Antimicrobial drugs must exhibit sufficient **selective toxicity**. This is especially challenging for treatment of fungal, protozoal, and viral pathogens due to the many features they share with host cells.

- **Antibiotics**, drugs that act on other cells, are the most commonly used antimicrobial drugs.
- The majority of antibacterial drugs act on peptidoglycan synthesis (cell wall synthesis), membrane integrity, DNA synthesis, transcription, folic acid synthesis (nucleic acid synthesis), or ribosome function (protein synthesis).
- Both **bacteriostatic drugs** and **bactericidal drugs** are effective therapies against bacterial infections.
- An important class of antibacterial drugs is the ***β*-lactam class**, which inhibit peptidoglycan synthesis by binding with **penicillin-binding proteins (PBPs)**.
- Semisynthetic antibiotics contain chemical modifications to increase their effectiveness.
- An important class of antiviral drugs are **nucleoside analogs** that interfere with nucleic acid synthesis by viral as opposed to host polymerases.

Section 24.3: How do microbes become drug resistant?

Because of genetic variation, some microbes will always be resistant to the killing effects of an antimicrobial drug. The immune system works in synergy with the drugs to provide clearance.

- **Susceptibility testing** establishes the sensitivity of a particular microorganism to a panel of antimicrobial drugs in order to determine which drug will be most successful in treating an infection.
- The **minimal inhibitory concentration (MIC)** is used to determine if a microorganism will be sensitive or resistant to a particular drug.
- Resistance to antimicrobial drugs is an inevitable consequence of the use of antimicrobial drugs. It is the result of natural selection.
- When a drug is not taken as prescribed, or a patient is immunocompromised, the risk for developing drug resistance increases.
- Drug resistance genes originate from mutation of naturally occurring precursor genes, and horizontal gene transfer by mobile genetic elements.
- Resistance genes are often carried on **resistance (R) plasmids**. Not all of the genes that give rise to resistance have developed because of the use of antimicrobial drugs.
- Microbes may be naturally drug resistant due to intrinsic factors, and genes that have evolved due to the production of antibiotics in natural settings.
- Resistance can develop quickly because of the fast generation times of most microbes.
- Resistance to antimicrobial drugs occurs through drug inactivation by modification of the drug, alteration of the drug target site, drug inaccessibility, preventing entry of the drug, and drug efflux by pumping the drug out of the cell using **efflux pumps**.
- Ways to reduce the development of drug resistance include reducing use of the drugs, using selective drugs, using drug cocktails, using effective infection control, developing new vaccines and increasing access to them, and developing drug alternatives.

Section 24.4: How are epidemics predicted and controlled?

Effective public health measures are used to prevent communicable diseases that threaten populations.

- Calculation of R_0, the **basic reproduction number**, is used to predict the start or spread of a propagated epidemic.
- $R_0 = 1$ is the epidemic threshold. When $R_0 < 1$, an epidemic is unlikely to form. When $R_0 > 1$, an epidemic is likely.
- Major epidemiological factors influencing infectious disease are host factors, infectious agent factors, and environmental factors.
- Changing the parameters of any one of the above factors can prevent and control an epidemic.
- Outbreak investigation is a systematic procedure that involves, defining a case, identifying the causative agent, examining the incidence pattern, determining the magnitude of the problem by computing the **attack rate**, looking for common host and environment factors, formulating a hypothesis, and testing the hypothesis.

Section 24.5: What are vaccines, and how are they used to control infectious disease?

Vaccines are designed to expose the adaptive immune system to protective antigens for the purpose of **immunization**.

- **Vaccination** is carried out to immunize against disease.
- Vaccine designs include **attenuated vaccines**, **inactivated** or **"killed" vaccines**, **subunit** or **acellular vaccines**, and **DNA vaccines**.
- **Vaccine failure** occurs to some degree for all vaccines because some individuals will fail to be fully immunized after vaccination.
- High **vaccine efficacy** does not exist for all diseases; however, where the vaccines do exist, they remain the single most effective way to prevent infectious disease in animals and humans.
- Mass immunization against communicable infectious diseases achieves population-wide protection through **herd immunity**.
- The **herd immunity threshold** is the critical proportion of the population required to be immunized to achieve herd immunity.
- **Vaccine coverage rates** are usually targeted to exceed the herd immunity threshold in order to compensate for vaccine failure.
- Eradication through vaccination can be achieved for those infectious agents where long-term immunity can be achieved, only a few strains exist, and there is a single reservoir host.
- The disease outcome of infection with poliovirus depends on the immune status of the host.
- The strategic use of the inactivated and attenuated polio vaccines can be used to eradicate wild poliovirus.
- Political and social policies, war, poverty, cultural and religious practices, and lack of government-sponsored vaccination programs can be barriers to attaining vaccination targets.
- Testing for the presence of contagious diseases is done to prevent the spread of infectious agents through trade of animals or their products.
- In order to maintain their disease-free status for access to markets, many countries do not practice routine vaccination of domestic herds for communicable diseases because the diagnostic tests used cannot distinguish between vaccinated and infected animals.

Application Questions

1. Imagine you were prescribed a sulfonamide drug to treat a bacterial infection. The doctor explains that the bacterial action of this drug inhibits nucleic acid synthesis. After you leave the office, you start to worry because you realize that your cells also synthesize nucleic acids. Explain why this drug harms the bacteria but isn't going to affect your body cells.
2. You learned that combating fungal and protozoal infections is complicated by the fact that these microbes share many of the same features with the cells of their hosts. Explain how the antifungal drugs known as polyenes and the antiprotozoal drug chloroquine can still show selective toxicity.
3. Your family friend is HIV positive and takes the drug AZT, along with a cocktail of other antiviral medications. You learn that AZT specifically targets retroviruses, but that HIV develops resistance to this drug. Explain the mechanism that this drug uses to combat a retrovirus such as HIV, and how resistance to AZT develops.
4. According to the World Health Organization, drug-resistant strains of *Mycobacterium tuberculosis* are more likely to appear in HIV patients than in tuberculosis patients that are HIV-negative. Provide a hypothesis of why this occurs.
5. You are working in the lab on two different species of bacteria, one of which shows resistance to a particular antibiotic. After mixing

and growing the two species together for a time, you notice that they both exhibit resistance when isolated and cultured on media containing the antibiotic. List and explain the mechanisms that may allow a gene for antibiotic resistance originally found on the chromosome in bacteria species A to now appear on the chromosome of bacteria species B.

6. On the news, you hear a CDC scientist explaining that the widespread overuse of antibiotics will do nothing but select for antibiotic-resistant bacteria. You argue with your friend, who is also watching the segment, that the drugs do not *cause* the resistance. He doesn't believe you. Explain to your friend, then, how excessive use plays a role in resistance.
7. Your child has an ear infection and is given the drug Augmentin, which you read contains amoxicillin and clavulanic acid. Explain why this mixture of drugs helps counter the development of resistance.
8. You are part of a government panel assigned to offer recommendations for reducing antibiotic resistance rates in the United States. One recommendation involves investing research dollars to develop additional rapid diagnostic tests. Explain how the use of such rapid tests could change how antimicrobial drugs are prescribed, and how that change could lead to less resistance.
9. You are part of a research team that has managed to resurrect microbes from the frozen remains of several Ice Age mammals. Out of curiosity, you elect to run a Kirby–Bauer disk diffusion test on one of the bacterial isolates. To your surprise, the Ice Age isolate shows resistance to several antibiotics. Explain why this is possible.
10. In the United States in 1918, the "Spanish flu" resulted in 500,000 deaths, the 1957–1958 "Asian flu" resulted in 70,000 deaths, and the 1968–1969 "Hong Kong flu" produced 34,000 deaths. SARS produced 800 deaths worldwide. All had the same approximate R_0 value. Based on what you learned about the triangle of epidemiology, propose reasons why these diseases produced such different numbers of mortalities.
11. The human papillomavirus (HPV) vaccine is a subunit vaccine that is given in three doses over six months. Imagine that you are a health care provider and that your patient asks you why three doses are necessary to develop immunity to HPV. Use what you've learned in this chapter about subunit vaccines to answer the patient's question.
12. You learned in this chapter that there are varied recommendations for use of the oral and/or inactivated polio vaccines, depending upon the location. Explain the reasoning behind these recommendations in a way that members of the general population could understand and accept.
13. You are assigned the task of determining the minimal inhibitory concentration (MIC) of a newly designed drug that may be effective against a strain of multidrug-resistant *Staphylococcus aureus*.
    a. Explain how you will set up your *in vitro* testing to determine the MIC.
    b. Imagine you test the following five concentrations of the drug: 0.01, 0.02, 0.04, 0.08, and 0.10 μg mL^{-1}. What results would you observe in each of these samples if the MIC was determined to be 0.04 μg mL^{-1}?
    c. Explain how you can now use these *in vitro* results from part b to determine a therapeutic dose for an infected patient.
14. You are involved in investigating an outbreak of a new strain of influenza in New York City that is infecting schoolchildren.
    a. Initial estimates indicate that the R_0 value is between 3.0 and 3.5. Exactly what does this tell your team studying the outbreak?
    b. Would these numbers indicate that an epidemic is possible? Explain.
    c. Your job is to now prevent development of this outbreak into an epidemic in the city schools and beyond. List three or four specific control strategies that you would implement.
    d. Explain how each of your strategies above would impact the spread of the infection in the city schools.

APPENDIX

A Reading and Understanding the Primary Literature

Until recently, the majority of our scientific knowledge was spread by word of mouth, by personal letter, or lectures to other scientists. While the first science journals appeared in Europe toward the end of the seventeenth century, mainstream media showed little interest and many discoveries went unnoticed by the general public. The past hundred years have seen a large expansion in journals dedicated to scientific literature, but also an increase in the public's interest in science. As you prepare your lab reports or science research papers, it is important to know what types of information are relevant, appropriate, and available to you. The goal of this guide is to provide a resource that will assist you in navigating this wealth of information.

Primary objectives

- What types of journal articles are out there?
- How do I know which type of article I need?
- What types of articles should I use for my research?
- Are some journals better than others?
- How do I find an article of interest?
- How can multimedia tools help me understand the journal articles I've chosen?
- How do I organize my references and avoid plagiarism?
- What is the general format of a primary research article?
- What strategy can I use to read and interpret the data in the primary article I've chosen?

Dr. William Osler, the "Father of Modern Medicine," invented the concept of the Journal Club to help doctors stay current on modern research contributions. After all, there are more than 5,000 new biomedical research articles published every day. As future physicians and scientists, students will find it essential to develop skills for locating, analyzing, and understanding scientific research articles. As you begin your research, you may find that there are several types of journal articles, each with a unique purpose and place in your studies.

Scientific literature is classified as primary, secondary, or tertiary references

Primary (1°) literature consists of all scientific literature presenting novel data or ideas. It may also include a revised analysis of previously published data to advance the theories and hypotheses of the authors. Primary literature is most often published in "peer-reviewed" journals, which means that the articles are evaluated by other scientists prior to publication. This process helps ensure that the data published in the journal has undergone a rigorous evaluation and the data have been deemed accurate, unbiased, and scientifically sound by experts in the field. For example, *The Journal of Virology* is a source of primary journal articles, as seen in Figure B8.5 in the text. The authors were testing a new hypothesis, namely that they could study the MHV receptor by adding MHV to the membrane containing cellular proteins from BALB/c mice and cellular proteins from SJL/J mice. In effect, they provided evidence to support their hypothesis that they could use a virus to identify its own receptor protein. If you wanted to cite their data or this specific approach to identifying a receptor protein, you may choose to cite this article like this:

(*Source:* B. D. Zelus et al. 1998. J. Virol. 72:7237–7244.)

Secondary (2°) literature includes summaries of results or ideas previously published in the primary literature and is written for a scientific audience. These review articles, published in journals or edited books, can offer a wealth of information if you have recently begun to research a new topic. Some journals are devoted entirely to review articles, whereas others publish both primary and secondary articles in different sections of the journal. Typically, a review journal can be identified by a name such as "*Trends in…*," "*Advances in…*," or "*Annual Review of…*." Do not be afraid to use the secondary literature in your search, especially because most secondary literature is peer reviewed prior to publication. Often, a paper may include a Comment or Letter, which is written by another scientist and

provides background and insight into the significance of the primary article. These comments often are a great place to identify questions or concerns about the research that you may want to discuss in your own evaluation of the topic.

Tertiary (3°) literature generally is written for an educated member of the general public. It may include articles in mainstream magazines such as *Discover* or *Scientific American*, science sections in *Time* or *Newsweek*, or science textbooks and encyclopedias. Although tertiary literature may offer an evaluation or interpretation of a recent finding, it would not be appropriate to use the tertiary literature in your research in most instances. The main reason for this distinction is that these articles often lack a bibliography, which makes it difficult to verify facts and properly reference your work.

Tertiary literature sources are helpful at the earliest stages of your research. However, much of the information in these sources is classified as "common knowledge" and would not necessarily be cited in your research article. Therefore, although you may certainly draw ideas from the tertiary literature, always refer to the primary or secondary article directly if you intend to include these data in your own analysis of a scientific topic. Table A.1 breaks down the distinctions between the literature.

So, how do you know which types of references are appropriate for your research paper? In general, instructors in an introductory science course may use material from tertiary, secondary, and occasionally, primary literature. They often will use review articles to help clarify a topic from the lecture, because students may not have enough background to understand the primary articles in depth. However, even in your introductory courses, the textbook and encyclopedias are typically not sources you would cite in your references. For advanced science courses, you should plan to rely heavily on the primary and secondary literature. Often, these courses frown upon use of the tertiary literature, particularly if it is used in lieu of the primary articles.

If you are not familiar with a particular research area, it may be difficult to know if the journal is reputable or how rigorous the review process was for publication in that particular journal. What happens if you come across two opposing viewpoints? Is there a way of distinguishing between which journal is better to help you decide which paper is more likely to be correct? This question is a common one, and a difficult one to answer. If you have exhausted other resources, such as review articles, Letters, or Comments, then there is a simple way to compare different journals within a certain field: *impact factor*. The impact factor is a method for calculating the average number of citations per paper published in that journal during the two preceding years. In effect, it tells you how often a particular journal has published articles that are important enough that they have been cited repeatedly by other researchers. This system is not perfect, and there are many criticisms of journal impact factor calculations and interpretations. It is highly discipline-dependent, and many citations to an article may be made by the author(s) of the original article. Thus, more prolific researchers could potentially overinflate the impact factor for a given journal if they routinely publish in that journal. In addition, journals that publish a large proportion of review articles or articles about newly developed methods often have a very high impact factor because they are cited more often.

TABLE A.1 Distinguishing between scientific or peer-reviewed journal articles and popular news articles

	Peer-reviewed articles	Popular/news articles
Authors	Scholars and researchers	Journalists or science writers
Abstract	Included	Rarely included
Bibliography	Included	Rarely included
Format	Standard format, uses language specific to the field of research	No specialized format, contains less technical language
Review process	Peer-reviewed to ensure accuracy	Edited for language/format, not necessarily the content

Locating your article—Beyond Wikipedia

When preparing to write a research paper, it's no secret that many students begin their research with a cursory Wikipedia search. That approach is often very helpful if you want to identify key words to help choose a topic or identify appropriate search terms. A quick search of Wikipedia itself reveals that the web site recommends "you should not cite Wikipedia itself, but the source provided; you should certainly look up the source yourself before citing it. If there is no source cited, consider a different method of obtaining this information." To be clear, it is never appropriate to cite Wikipedia or other encyclopedias in your research paper.

For research into human diseases and medical topics, there are many web sites that may provide more detailed background information if you are not ready to jump right into a primary journal article. In general, these web sites fall into two categories: government-sponsored agencies and private organizations. The web address will help you distinguish between the two groups. Just look for suffixes that indicate a federal government, such as .gov, .eu, or .ca or an international organization, such as .int. These web sites can be cited if you are searching for background information about a disease or if you are looking for recent demographic information. Links to

TABLE A.2 Most commonly consulted government agencies related to health research

National Institutes of Health	http://health.nih.gov/ http://www.clinicaltrials.gov/	Provides links to MEDLINE, clinical trials, and the ability to search for specific health topics
PubMed Health	http://www.ncbi.nlm.nih.gov/pubmedhealth	Based on systematic reviews of clinical trials; provides summaries and full texts of selected recent reviews. Includes general information for consumers and clinicians
Centers for Disease Control and Prevention	http://www.cdc.gov/	Includes information on diseases and epidemiology but also provides links to information about specific topics such as environmental health, emergency preparedness, workplace safety, and travelers' health
World Health Organization	http://www.who.int/en/	WHO is the authority for health within the United Nations system. It is responsible for providing leadership on global health matters and assessing global health trends and up-to-date statistics.
National Cancer Institute	http://www.cancer.gov/	Provides specific information about types of cancer and links to relevant clinical trials

a few of the most commonly consulted health-related government agencies are provided in **Table A.2**.

After you have a basic knowledge of your topic and have identified what search terms will help you refine your search, you can now locate a primary article on your chosen topic. There are several peer-reviewed databases that use slightly different approaches to locate primary articles for your scientific research. Details about each database are summarized in **Table A.3**. You may find different results depending on which database you use, so don't be afraid to try more

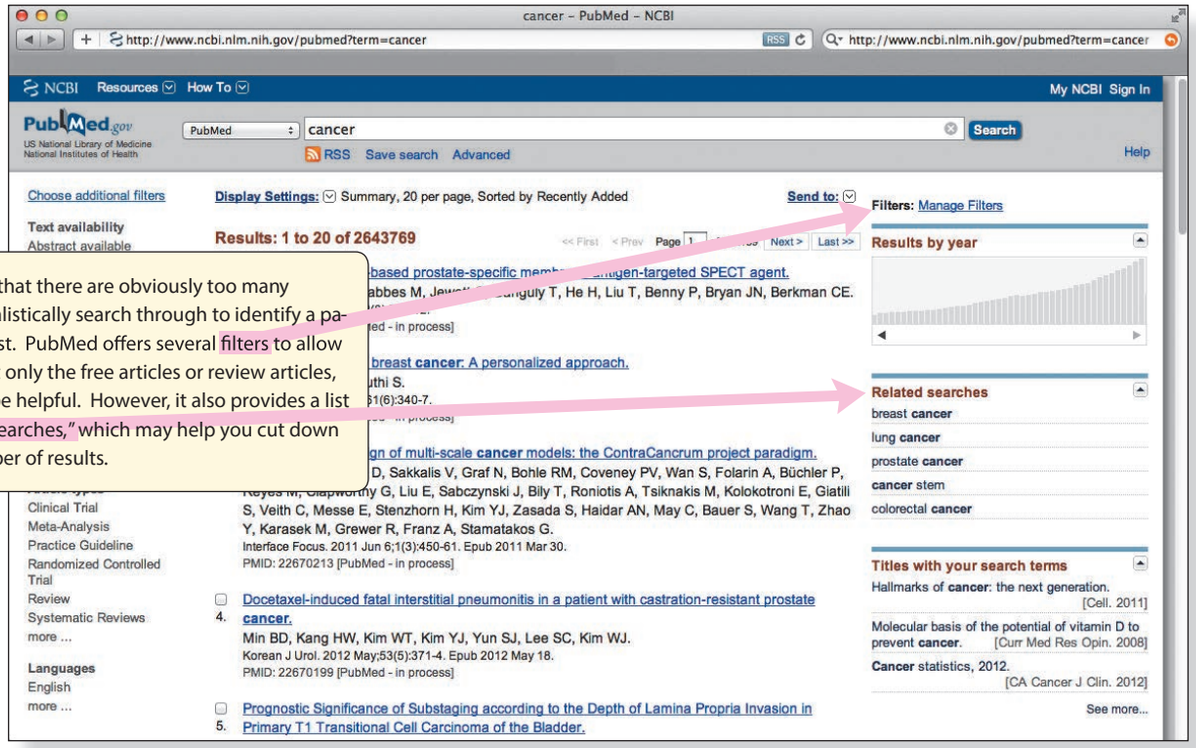
TABLE A.3 Several databases for peer-reviewed articles

Name	Dates	Database	Subscription?	Comments
PubMed (National Library of Medicine)	1946–present	More than 25 million citations for biomedical literature	Free	Uses MeSH[a] vocabulary to index articles Used extensively in North America
EMBASE® (Elsevier)	1947–present	8,400 peer-reviewed biomedical journals and data	Subscription	Finds up to four synonyms for search terms Mostly used by European physicians Lists by publication year or relevance, links to Scopus Biased toward pharmacological usage
Scopus (Elsevier)	1995–present	Patent records, theses, conference abstracts, books, systemic reviews. Science, social science, arts and humanities	Subscription	Lists by relevance Tracks citations backwards and forwards Specialized author search
Agricola (AGRICultural OnLine Access) (National Agricultural Library, USDA)	17th century–present	Extensive collection Catalog and index to the collections of the National Agricultural Library Provides citations (bibliographic references) created by the National Agricultural Library and its cooperators	Free	AGRICOLA is the primary public source for worldwide access to agricultural information. It is a bibliographic database and does not contain the full text. Some citations may include links to full texts available elsewhere from the Internet.
Web of Science (Thomson Reuters)	1900–present	10,000 weekly updates, so it is very current 20–30 journals dropped or changed per month	Subscription	Tracks citations backwards and forwards Specialized author search 77% science; rest social sciences and arts and humanities
Google Scholar (Google)	17th century–present	Scholarly literature, citations/abstracts, peer-reviewed journal articles, dissertations, books, patents, and conference abstracts	Free	Quick and user friendly

[a] MeSH (Medical Subject Headings) is the National Library of Medicine's controlled vocabulary thesaurus.

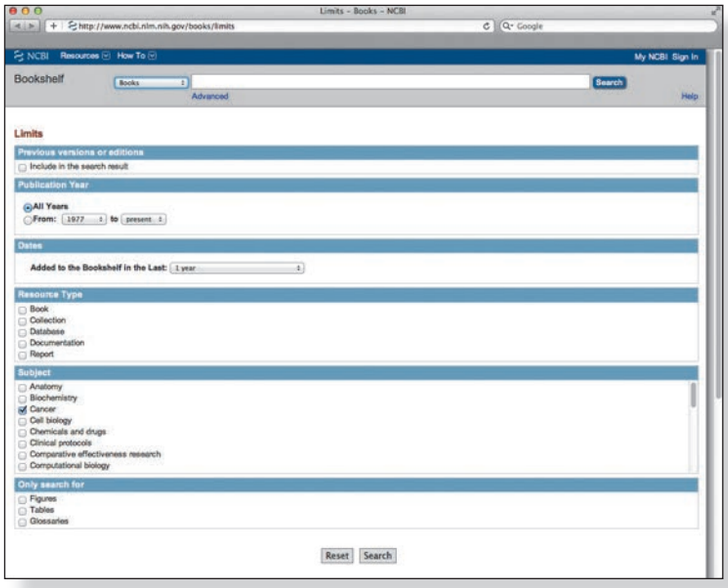
than one if you are having trouble finding an article that interests you.

PubMed is one of the most commonly used resources for locating primary journal articles. It is possible to search by author or topic, and the web site offers a tutorial to assist in refining your search terms to maximize the chances of finding relevant articles and eliminating unwanted ones. For example, if you type in a general search term such as "cancer," PubMed will return over 2.5 million articles. One of the advantages of using PubMed is that the web site offers several helpful hints for narrowing your search and also provides filters for selecting only free full-text articles, review articles, or the most recent articles.



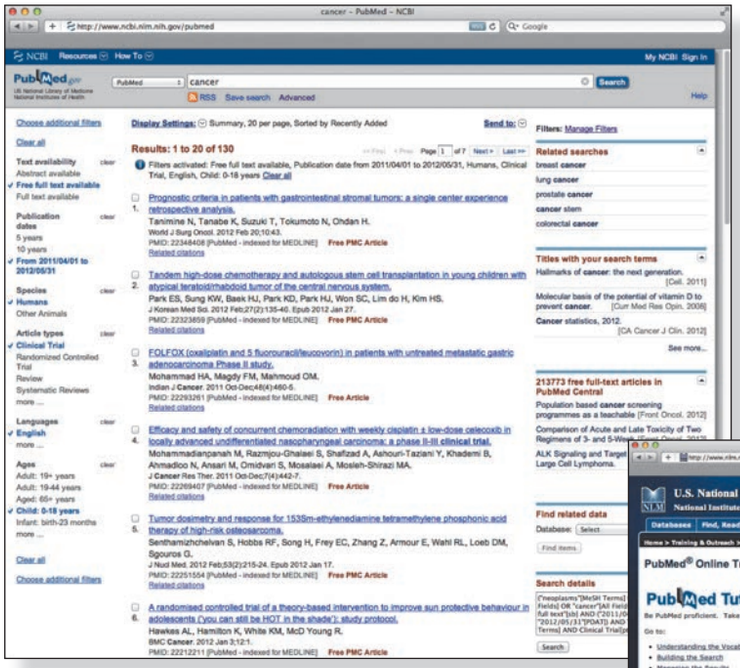
You can see that there are obviously too many results to realistically search through to identify a paper of interest. PubMed offers several filters to allow you to select only the free articles or review articles, which may be helpful. However, it also provides a list of "Related searches," which may help you cut down on the number of results.

You can also set the Limits before your search to help cut down on the irrelevant results. By selecting Limit, you can choose to search for articles based on publication date (most recent), the type of article (review, clinical trial, editorial, etc.), text options (abstract, free full text), and language (published in English or another language). You may also specify articles focusing on a certain species (human vs. animal), gender, or age group.

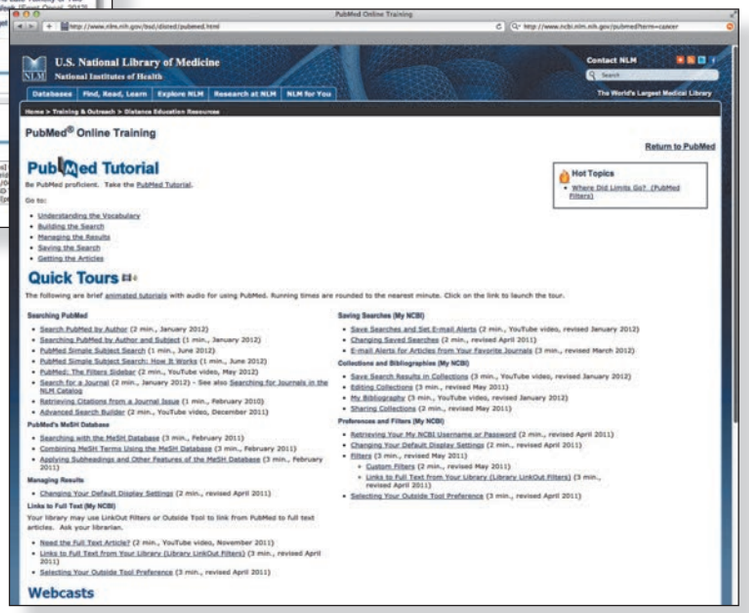


For example, if you actually want to find an article about recent clinical trials involving pediatric cancer, it may be helpful to set the limits for your search. You can select articles published in the past year that are clinical trials in humans, in the subset of cancer, with free full text, in children ages 0–18.

So, don't be afraid to add limits. This will reduce your results dramatically and save you a lot of time sifting through unhelpful articles.



In this case, you went from 2,643,769 articles to 130—much more reasonable!



If you have any difficulties identifying appropriate search terms, PubMed offers several tutorials to assist with your search and also allows you to save your search for a later date.

References or works cited—How to avoid plagiarism and organize your references

After locating your articles, the next step is to begin creating a References or Works Cited section for your paper. It is often much easier to create this section early in the writing process, rather than trying to go back after writing the paper to determine who to cite for each fact. In addition, there are several basic rules for attributions that will help you avoid unintentional plagiarism. First, you do not need to cite information that is common knowledge or part of the basic background you are presenting. For example: Viruses have a lytic or lysogenic cycle. However, you do need to cite an article if you are using specific information, are referring to a specific theory or idea, or if you use any data, figures, images, and tables from an author's work. You should also use direct quotes *very* sparingly and avoid cutting-and-pasting text. Whenever possible, paraphrase and cite the reference, but make sure it is written in your own words. This technique will ensure that your paper flows well and is written in your own style and voice and will also help you avoid accidental plagiarism or taking quotes out of context. Here are several helpful hints for how to cite articles within your text:

Most journals use the name-year system. For example,

> These results are consistent with previous findings (Drosten *et al.*, 2003) or
>
> These results are consistent with the findings of Drosten *et al.* (2003).

If there is more than one article in the same year, use letters. For example,

> (Drosten *et al.*, 2003a)

If there are two authors, include both names. For example,

> (Drosten and Günther, 2003)

If there are several sources, list them chronologically. For example,

> (Drosten *et al.*, 2003; Brandenburg *et al.*, 2007; Leiman *et al.*, 2009)

If it is an interview or personal communication, cite the name and date. For example,

> (D. Wang, personal communication, 2011 Sept 12)

A final word: Always make sure you have read the relevant section of a paper if you are citing it. By reading the section, you can confirm that you are citing the original person or group that made an observation or discovery. The next section will provide some advice about how to approach a paper and read for specific content without being overwhelmed by too many details.

Most primary journal articles follow a similar format, abbreviated as SIMRAD

Summary (or abstract)—concise description of the purpose, results, and conclusions of the paper
Introduction—background information to help the reader understand the purpose of paper
Methods—description of the materials and procedures used in the experiments
Results, And—charts, graphs, and images of the data obtained and experiments performed
Discussion—explanation of the results and their implications to the field of research; corrects misconceptions or previous misinterpretations of the data, and states why the paper is relevant and provides new information relevant to the field.

Tips for how to approach a scientific article

Before you jump into the article:

- Examine the title and keywords to understand the focus of the article.
- Look up definitions of unfamiliar words.
- Read review articles in the field if more background is needed.
- Look at the relevant references for historical perspective.
- Look for Comments or editorials (if available) to see how experts in the field interpret the findings.

Then ask yourself some basic questions:

- Why are they doing this experiment and what is currently known about the topic?
- What is the authors' hypothesis?
- How do the experiments help test the authors' hypothesis?
- What are the basic findings/conclusions? Was the hypothesis correct?
- Why are the authors' data significant? What are the authors' contributions to their field of study?
- What criticisms do you have about the paper? Are experiments missing or unconvincing?

For each of the figures, be able to answer the following questions:

- What question are they asking?
- What was the basic procedure/technique being used to answer the question?
- Are they looking at protein, DNA, RNA, etc.?
- Is the technique appropriate for the questions being asked, and were the experiments properly performed using the correct controls, measurements, and number of repeats (replicates)?
- What are the results and conclusions?
- Are the data convincing, or does it look like the authors are forcing the data to fit a theory?
- If there are criticisms of the data, what might the authors do to improve the paper and convince you that they are really correct in their interpretations?
- Did you notice any trend in the data that was not discussed in the results?
- What questions do you have after reading the paper?
- Do you have any suggestions for follow-up experiments or future directions?

Now for an example taken from Chapter 8 of your textbook

In Perspective 8.1, we explored how researchers at the University of California at San Francisco, Washington University, and the US Centers for Disease Control and Prevention developed a DNA microarray-based technique for identifying viruses. Their original research was published in the journal PLoS Biology (Wang D, Urisman A, Liu Y-T, *et al.* Viral Discovery and Sequence Recovery Using DNA Microarrays. *PLoS Biology.* 2003;1(2):e2.). To read this paper, the first thing you may want to do is to identify key terms and abbreviations to make sure you are familiar with them. By looking them up ahead of time, reading the article will be much easier.

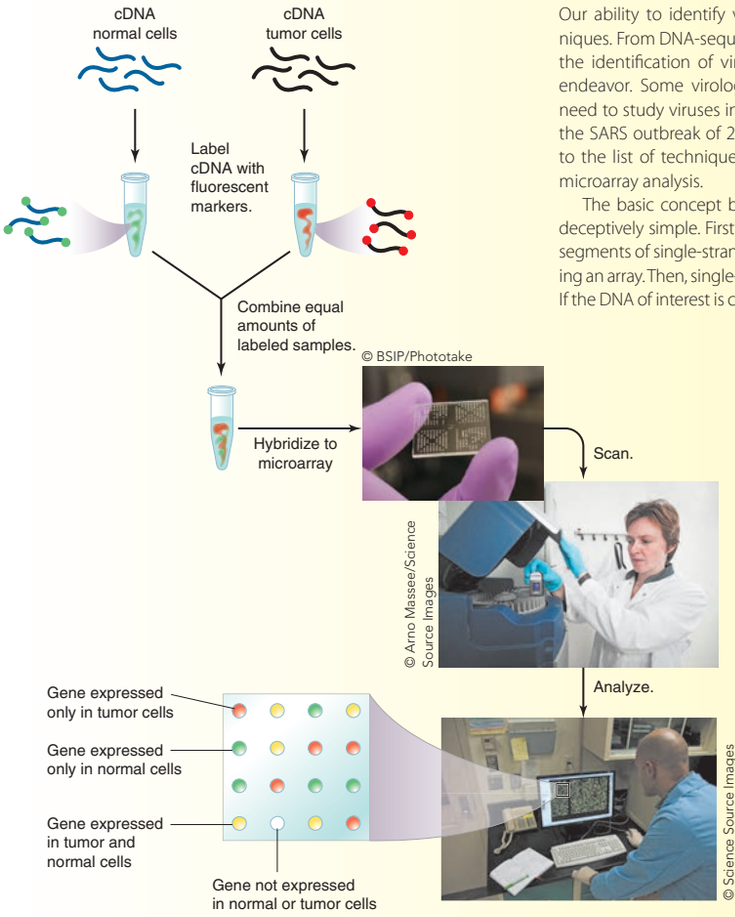
Next, you may want to search for related articles that will help provide the background you need to understand this article or show you how the findings presented in this paper have impacted the field. You may review the section in your textbook related to the subject, although you would not need to cite that directly in the Works Cited for your paper. To locate relevant articles, you can do a PubMed search. In the search window of PubMed, for example, you could type the first author's last name and the first few words of the article's title (Wang viral discovery and sequence recovery).

This initial PubMed search will pull up the article of interest and yield several pieces of information. First, links to similar articles are provided. These articles, which include some review articles, may provide insight into how the technology of DNA microarrays fits into the current research in the field, and also describe its potential significance. Next, PubMed lists over 100 citations of this article. By scanning through this section, you can identify the most current uses of this technology and identify potential follow-up experiments by the same or different researchers. All of this information may be helpful for understanding the original article and would be worth assembling early in your writing process.

Now that you have compiled a list of relevant literature, you can begin answering the basic questions we specified earlier.

- **Why are they doing this experiment and what is currently known about the topic?** You would anticipate finding this information in the introduction section of the paper. The authors describe a previous paper that dealt with the prototype DNA microarray designed for parallel viral detection. Because the paper you are reading builds heavily off of this 2002 work, it will be very helpful to locate this article as well.

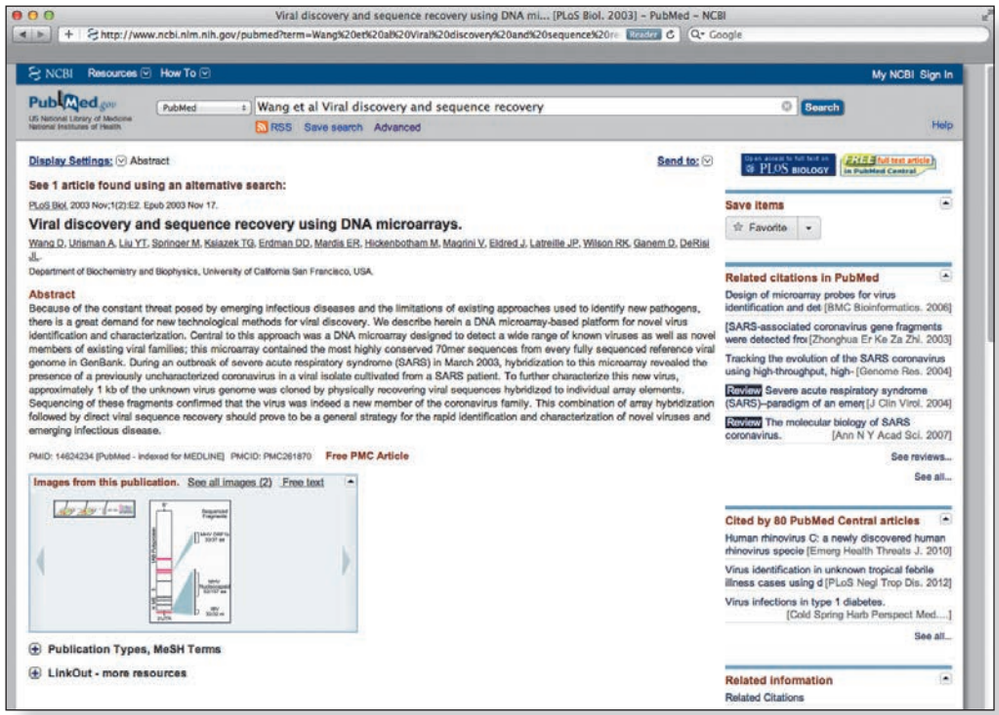
Perspective 8.1
DNA MICROARRAYS AND THE SARS VIRUS



Our ability to identify viruses depends greatly on molecular techniques. From DNA-sequencing studies to PCR to *in situ* hybridization, the identification of viruses increasingly has become a molecular endeavor. Some virologists might even argue that we no longer need to study viruses in animals or cell culture for diagnosis. During the SARS outbreak of 2003, a new molecular technique was added to the list of techniques that can be used to identify viruses: DNA microarray analysis.

The basic concept behind DNA microarray technology is almost deceptively simple. First, a series of specific oligonucleotides, or short segments of single-stranded DNA, is attached to a solid support, forming an array. Then, single-stranded DNA of interest is added to this array. If the DNA of interest is complementary to any of the oligonucleotides,

Figure B8.1. Microarray technology can be used to evaluate large numbers of genes simultaneously. First, oligonucleotides representing the target DNA are attached to a slide. In this example, oligonucleotides corresponding to every human gene are placed on the slide. Next, the nucleic acids of interest are fluorescently labeled. In this example, cDNA (corresponding to expressed genes), derived from normal cells, is labeled with a green fluorescent marker. The cDNA derived from tumor cells is labeled with a red fluorescent marker. These tagged cDNAs then are added to the microarray and the microarray slide is scanned. Using software, researchers can analyze the fluorescence associated with each spot on the slide. If both probes bind (yellow spots), then we know that the gene is expressed in both normal and tumor cells. Red spots indicate genes that are expressed only in tumor cells. Green spots indicate genes expressed only in normal cells.



Utimately, the authors' objective is written explicitly: "…to create a microarray with the capability of detecting the widest possible range of both known and unknown viruses." If you were to paraphrase their objective, you might write something like: "Researchers sought to develop a microarray capable of quickly identifying both known and unknown viruses to aid in the global effort to identify the cause of future global health crises." The hypothesis can also be found early in this paper, stated succinctly within the abstract.

To paraphrase, the authors wanted to test the ability of a new and improved DNA microarray technique to rapidly identify a previously uncharacterized virus.

- **What is the authors' hypothesis?** A microarray that is based on the most highly conserved viral sequences from published viral reference genomes, will be able to identify not only known viruses, but related novel viruses.
- **How do the experiments help test the authors' hypothesis?** Quite simply, they used the 2003 SARS epidemic as a proof-of-principle, showing that the DNA microarray technology successfully identified a new coronavirus within a culture from a SARS patient. They found this by combining an array hybridization with direct viral sequencing recovery.
- **What are the basic findings/conclusions? Was the hypothesis correct?** Within the Discussion section, the authors state that, "In the case of SARS, we were able to ascertain within 24 h that a novel coronavirus was present in the unknown sample, and partial genome sequences of this virus were obtained over the next few days without the need for specific primer design." You may paraphrase this by stating that the authors identified that the unknown virus was a previously unknown coronavirus and quickly identified a partial genomic sequence to aid in identification using this versatile new technique.
- **Why are the authors' data significant? What are the authors' contributions to their field of study?** Again, this information can be found within the Discussion section: "To our knowledge, this is the first demonstration of the feasibility and utility of directly recovering nucleic acid sequences from a hybridized DNA microarray. In light of the continuous threat of emerging infectious diseases, this overall approach will greatly facilitate the rapid identification and characterization of novel viruses." Again, you could restate the significance by saying that this is the first experiment showing that the genomic sequence of an unknown virus can be identified using a hybridized DNA microarray. This is significant, given the need to rapidly identify and characterize novel viral pathogens and prevent the next emerging pandemic before it occurs.
- **What criticisms do you have about the paper? Are experiments missing or unconvincing?** Your criticisms may vary, but it could include concerns about using a retroactive approach and the potential for bias in the results. If the authors knew it was SARS and they found that information within the results, is it possible they were looking at sequences that made it more likely to identify SARS from the data? You may also comment on the fact that the article was very short, which may necessitate some additional research on your part. If you were to present this article for a journal club or research paper, it would definitely be necessary to use additional articles published prior to and subsequent to this article to assure your complete coverage of this topic.

APPENDIX

B Microscopy

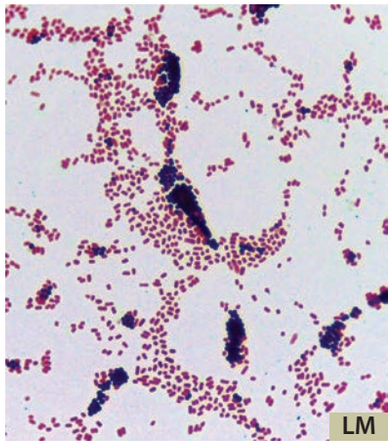
As we noted in Section 1.1, the field of microbiology began with the development of microscopes by Robert Hooke and Anton van Leeuwenhoek. Microscopy has come a long way since van Leeuwenhoek first described microorganisms in vivid detail over three and one-half centuries ago. Let's use this opportunity to explore some of these advances. We'll introduce several important types of microscopy and discuss their uses. As we will see, the microscopy technique used generally depends on the structures being examined and the questions being asked. We'll begin by reviewing some basic principles of microscopy. Then, we will explore more thoroughly two types of microscopy-light, or optical, microscopy and electron microscopy. Throughout this appendix, we will feature images that appear elsewhere in this book. Hopefully, this introduction to microscopy will provide you with a better understanding of how these images were generated and make you think about the advantages and disadvantages of the techniques that were used.

Principles of microscopy

To understand the microbial world revealed by microscopy, we need to be familiar with units of measurement commonly used by scientists. A micrometer (μm), sometimes referred to as a micron, equals one-millionth of a meter, or 10^{-6} m. A nanometer (nm) equals 10^{-9} m. As shown in Figure 2.4, we can see objects larger than about 100 μm with our unaided eyes. Light microscopes allow us to see objects as small as 0.2 μm in diameter, and various forms of electron microscopy allow us to see objects as small as 0.005 μm in diameter.

What factors affect our ability to see objects? The two critical factors are **contrast** and **resolution**. Contrast refers to the difference in light absorbance between two objects or areas. The greater the contrast between an object and its surrounding environment, the easier it is to see that object. Microbiologists can increase the contrast between objects and their surroundings by staining them. Gram staining, which we discuss in Toolbox 2.1, allows us to differentiate Gram-positive and Gram-negative bacteria. The staining procedure also increases the contrast of the bacterial cells. When stained, the light absorbance of the bacteria differs significantly from the light absorbance of the surrounding area (Figure B.1).

Resolution refers to the distance between two objects at which the objects still can be seen as separate (Figure B.2). The closer together two objects are, the higher the resolution necessary to distinguish them will be. Similarly, the smaller an object is, the higher the resolution needed to observe it. The size of most bacterial cells falls below the resolution limit of the human eye. Even if bacterial cells are stained and exhibit significant contrast with their background, they cannot be seen by our unaided- eye.



Courtesy Christine Dupont

Figure B.1. Gram-stained bacteria By staining bacteria, we increase the contrast between the bacterial cells and the surrounding area, thereby improving our ability to see them.

Figure B.2. Resolution The ability to distinguish two objects is referred to as resolution. **A.** Two dots that clearly can be seen as separate are said to be resolved. **B.** If the two dots appear to be fused, then they are not resolved.

To more fully understand resolution, we also need to have some understanding of the properties of light. Light has a number of properties that affect our ability to visualize objects, either with the unaided eye or the light microscope. One of the most important properties of light is its wavelength, or the length of a light ray (Figure B.3). Represented by the Greek letter lambda (λ), wavelength equals the distance between two adjacent crests of a wave. Smaller wavelengths provide greater resolution. In fact, resolution is more important than magnification; the visualization of objects that are magnified but not resolved is not very useful.

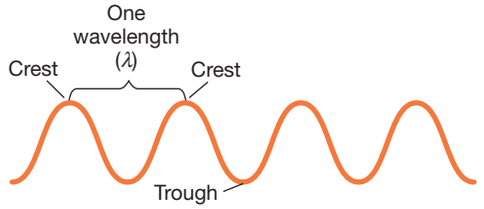


Figure B.3. Wavelength One wavelength is defined as the distance between two crests of a wave. Shorter wavelengths provide greater resolution.

LM Light microscopy

Now that we have explored some of the basics of microscopy, let's look at a specific type of microscopy—light, or optical, microscopy. Robert Hooke and Anton van Leeuwenhoek, microscopists who we first encounter in Chapter 1, developed light microscopes over 350 years ago. With these microscopes, visible light passes through the sample and magnifying lenses. The microscopes crafted by van Leeuwenhoek had a single lens. The quality of these lenses was so high that a magnification of almost 300× was achieved. In other words, the image of the sample was magnified 300 times. This magnification allowed him to view microbial cells. By using more than one lens, even greater levels of magnification can be achieved. A compound light microscope (Figure B.4) basically uses two magnifying lenses, an objective lens and an ocular lens, and the magnification is multiplicative. If the objective lens provides 40× magnification and the ocular lens provides 10× magnification, for instance, then a total magnification of 400× results.

In the simplest form of light microscopy, **bright field microscopy**, light enters the microscope from a source in the base, and often passes through a blue filter, which filters out the long wavelengths of light, leaving the shorter wavelengths and thus improving the resolution. The light then goes through a condenser, which converges the light beams so that they pass through the specimen. The iris diaphragm controls the amount of light that passes through the specimen and into the objective lens. To see specimens clearly at higher magnifications, greater amounts of light are needed.

The ocular lens usually provides 10× magnification, and objective lenses usually provide from 10× to 100× magnification, resulting in a total magnification of 100× to 1000×. At higher magnifications, however, resolution often decreases. The refractive index, a measure of how light passes through a medium, of the air between the lens and the specimen differs from the refractive index of the lens itself. This difference limits the ability to focus, which determines the resolution. To combat this problem, researchers often add a drop of immersion oil to the specimen when using the 100× objective lens. Immersion oil has a refractive index similar to that of the objective lens. When immersion oil fills the gap between the objective lens and the specimen, the ability to focus is improved. At 1000×, the limit of resolution in a compound microscope is approximately 0.2 μm.

The magnification achieved by a compound microscope would be useless if there were no way to increase the contrast between a bacterial cell and the surrounding medium. Most bacterial cells absorb relatively little light. The refractive index of a bacterial cell also differs only slightly from that of water. As we noted earlier, staining can improve the contrast. Differential stains that react differently with various bacteria can be used. These stains are useful in identification. Other stains react specifically with intracellular structures. For example, the lipophilic stains Nile red and Sudan black stain lipids. In negative staining, researchers use stains that are not taken up by the cells. These reagents stain the background surrounding the cell, allowing the unstained cell to stand out against this stained background. Staining cells, however, does have drawbacks. Most notably, staining typically requires fixing cells by heat or chemical treatment before adding dye. The fixing process kills and may distort the cells. The image, therefore, may not accurately reflect the image of a live cell.

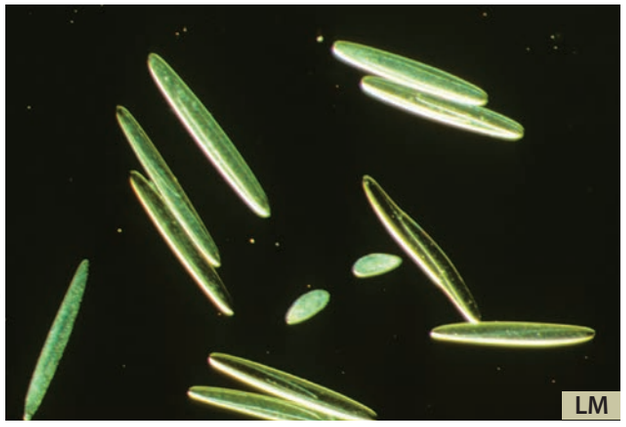
Figure B.4. The compound light microscope In the light microscope, visible light passes through the specimen and magnifying lenses. Often, a filter blocks long wavelength–blue light. The condenser converges the light beams.

Phase contrast microscopy Another approach to increase the contrast is to use **phase contrast microscopy** (Figure B.5), which uses a special condenser (that incorporates an annular ring) and objective lens (that incorporates a phase ring) to amplify the slight differences in refractive index of bacterial cells and the surrounding medium to make cells look much darker. This method has the major advantage that the cells remain alive;



© Esther R. Angert, Ph.D./Phototake

Figure B.5. Phase contrast microscopy By amplifying slight differences in the refractive- index of cells and the surrounding medium, phase contrast microscopy allows cells to be visualized without fixation.

fixation or chemical treatment is not required. Active behaviors such as swimming or gliding can be observed, and cell morphology is not subject to fixation artifacts.

Dark field microscopy In dark field microscopy, light does not pass straight through the specimen to the lens, but instead reflects off the specimen at an angle. The approach results in a dark background with bright objects in it **(Figure B.6)**. While this technique usually does not permit one to see intracellular structures, it can greatly increase the contrast when viewing small transparent cells.

FM Fluorescence microscopy In fluorescence microscopy, the energy of the incoming light, usually in the ultraviolet spectrum, causes electrons in special fluorescent molecules in the sample called *fluorophores* to become excited. This excitation results in light being emitted as the electrons lose energy. The emission light typically is of a different wavelength than the incoming excitation light. Optical filters ensure that only the emission light reaches the eye. Some proteins naturally fluoresce, and these fluorophores have become important tools in microscopy. As we discovered in Toolbox 3.1, green fluorescent protein (GFP) and related molecules like yellow

Figure B.7. Fluorescence microscopy By coupling a fluorophore to a protein of interest, the location of this protein within a cell can be visualized. Here, GFP-tubulin fusion protein allows us to see tubulin within these cells.

fluorescent protein (YFP) and red fluorescent protein (RFP) have been used extensively by microbiologists **(Figure B.7)**. These proteins either can be expressed alone in cells or coupled to a normal cellular protein, in which case the behavior and location of the protein of interest can be observed. Molecules also can be tagged with small chemical structures that have fluorescent properties. Fluorescein, for example, emits a yellow-green light when excited by light of a specific wavelength. Antibodies tagged with these fluorescent molecules can bind to their specific antigens, thus allowing the structures containing those antigens to be detected by the fluorescence.

Confocal laser scanning microscopy We all realize that cells are three dimensional. When using conventional light and fluorescence microscopy, however, we cannot focus on multiple planes simultaneously. We cannot visualize specimens, in other words, in 3D. Confocal laser scanning microscopy (CLSM) offers a solution to this problem. In CLSM, a laser focuses on a single plane within the object and collects images within that plane. The laser then moves through the object, focusing sequentially on adjacent planes, collecting two-dimensional images for each plane. Computer programs then can be used to process these 2D images, producing a three-dimensional reconstruction. As we discovered in Perspective 2.1, 3D reconstructions also can be generated by cryoelectron tomography imaging, providing us with a better understanding of how internal structures like magnetosomes are arranged within cells **(Figure B.8)**.

Figure B.8. Cryoelectron tomography imaging By collecting and processing 2D images obtained from multiple focal planes, 3D images can be developed. Here, the organization of magnetosomes (yellow) within *Magnetospirillum magneticum* cells can be seen.

Electron microscopy

Because light microscopy cannot resolve objects separated by less than about 0.2 μm, this technique cannot provide much information about subcellular components or viruses. With electron microscopy, better resolution occurs and these subcellular objects become visible. Electron microscopy (EM) uses a beam of electrons instead of a beam of light. Because of the very short wavelength of electron beams, the resolution limit of EM is less than 1 nm, a great improvement over light microscopy. Instead of a lens, electromagnets focus the electron beam, and the electrons are detected by their impact with a fluorescent screen, photographic film, or by a charge-coupled device (CCD) camera. Because air molecules interfere with the movement of electrons, the electrons must travel in a vacuum. The first electron microscope was built in 1933 and earned its inventor, Ernst Ruska, the Nobel Prize in Physics in 1986. In this section, we will explore the two most common types of electron microscopy: **transmission electron microscopy (TEM)** and **scanning electron microscopy (SEM)**.

TEM **Transmission electron microscopy** In TEM, the object being observed rests between the electron source and the detector. The differential ability of electrons to pass through the object results in an image. For a specimen to be viewed by TEM, it must first be chemically crosslinked to preserve its structure, dehydrated in ethanol or acetone, stained with electron-dense stains such as uranyl acetate or osmium tetroxide to enhance contrast, and embedded in a block of resin that then is hardened by heat treatment. The embedded sample is then cut with a glass or diamond knife using an ultramicrotome to produce very thin slices called "sections." These sections must be extremely thin (70–90 nm); otherwise, none of the electrons will be able to pass through to the detector.

TEM can be used for visualizing subcellular structures, like a phospholipid bilayer or viruses (Figure B.9). Even single DNA molecules can be seen with TEM. Additionally, TEM images can be colorized, providing more dramatic images. The technique, however, does have some disadvantages. Most notably, the extensive processing requires that living samples must be killed. The processing also can alter some cell structures, resulting in the appearance of artifacts. Alternative methods of sample preparation can provide a better picture of the true structure. For example, the freeze-fracturing technique, which involves freezing the sample and then fracturing it with a knife, often reveals important surface details of intracellular structures (see Figure B2.7).

SEM **Scanning electron microscopy** In SEM, the reflection of a moving electron beam off the surface of a specimen forms a three-dimensional surface view of the specimen. Conceptually, this technique resembles confocal laser scanning microscopy. As with TEM, live samples cannot be visualized by SEM. Specimens must first be fixed and coated with a thin layer of gold or palladium that reflects electrons. Unlike TEM, internal structures are not visible by SEM. Scanning electron microscopy does, however, provide us with a more detailed view of specimen structure (Figure B.10). These images, like TEM images, can be colorized.

In this appendix, we have examined only briefly some of the more commonly used forms of microscopy. In addition to these techniques, microbiologists use other types of microscopy and new developments are continually occurring. The basic principles, though, remain fairly standard. As we have noted here, each microscopy technique has advantages and disadvantages. The type of microscopy used depends on the questions being asked and the information that one wants to obtain. The microscope truly is the microbiologist's best friend.

Figure B.10. Scanning electron microscopy (SEM) Like transmission electron microscopy, SEM provides much better resolution than light microscopy. Additionally, as seen here, SEM provides a three-dimensional view of the specimen, allowing us to see surface details more clearly.

APPENDIX

C Taxonomy and Nomenclature of Microbes

Taxonomy is the practice of classifying organisms, including viruses, into groups based on varying criteria of structure, function, and evolutionary origins as determined by genetic relatedness. As noted in Section 2.6, members of domains *Bacteria, Archaea*, and *Eukarya* can be organized into several hierarchical taxa: phylum, class, order, family, genus, and species. These taxa are sometimes further subdivided into, for example, suborder, subclass, and subspecies.

Nomenclature is the system of naming organisms based on a set of rules. The system of nomenclature and taxonomy of *Bacteria* and *Archaea* is controlled by the International Committee on Systematics of Prokaryotes (ICSP), a committee within the International Union of Microbiological Societies. The general considerations, principles, rules, and notes used in advising nomenclature are published, through the authority of ICSP, in the Bacteriological Code. The Bacteriological Code is a publication that includes all approved names as well as rejected names. The International Journal of Systematic and Evolutionary Microbiology, published by the Society of General Microbiology, is the official journal for the publication and peer review of new taxa and names of bacteria, archaea, and yeasts. Bergey's Manual of Systematics of *Archaea* and *Bacteria* provides current descriptions of taxonomy, ecology, physiology, and other biological properties of all named bacterial and archaeal taxa.

Taxonomic names for species and above are written in italics. Names of genus and groupings above genus are written with an initial uppercase letter. Species names and taxonomic names below species are all lowercase letters. For example, we write *Bacillus cereus* and not *Bacillus Cereus*. Genus names can be shortened after the first full usage in a document to the first upper case letter. For example, *Escherichia coli* can be shortened to *E. coli* after its first appearance in a document. When referring to a member of a genus with unknown species affiliation, the abbreviation sp. can be used. For example, "The fungus *Penicillium* sp. grows well in culture." When referring to multiple species, the abbreviation spp. can be used. For example, "Soil bacteria, such as *Streptomyces* spp., were frequently found in the sample." Note that italics should never be used for writing sp. or spp.; this is a common error.

For the *Bacteria* and *Archaea* domains, members belonging to a species are generally defined as having approximately 70% or greater DNA-DNA relatedness, as determined by a standardized hybridization protocol. This traditional criterion is likely to be reconsidered as genome relatedness assessments are now done by direct DNA sequence comparison. Species can be divided into subspecies to indicate they are phenotypically distinct, yet are genetically very closely related. The name of a subspecies is a combination of three names consisting of the genus name, followed by the species name, then the abbreviation "subsp." (subspecies), and finally the name of the subspecies. For example, we may write *Bacillus cereus* subsp. *mycoides*. Strains within species or subspecies are defined as being independent isolates. Strain names are always written in Roman (non-italics). The term serovar or serotype refers to strains that are differentiated by distinctions in antigenic characteristics as determined by antibody serotyping techniques.

Serovars for many Gram-negative bacteria, particularly those that are associated with disease, are indicated by an antigenic formula, determined by biochemical differences in flagellar antigens (H), outer oligosaccharide components (O) of lipopolysaccharide (LPS), and capsule composition (K). For example, *E. coli* O157:H7 is a serovar named for its biochemical characteristics as identified by specific antibodies to the oligosaccharide of LPS and the flagellar proteins.

For *Salmonella*, the nomenclature is complex and changing. A widely used system has been developed by the Centers for Disease Control and Prevention (CDC) as recommended by the World Health Organization. This system states that the genus *Salmonella* comprises three species: *S. enterica, S. bongori*, and *S. subterranean*. The species *S. enterica* consists of six subspecies of which *S. enterica* subsp. *enterica* has several medically important serovars. To avoid confusion between serovars and subspecies, and to shorten the names after the first full citation in a document, the serovars of *S. enterica* subsp. *enterica* can be written as follows (note only some serovar examples are given): *S.* Typhi, *S.* Choleraesuis, and *S.* Typhimurium. Only the genus name is italicized; the serovar name is written with an uppercase first letter and Roman.

If a microorganism is uncultured, or only partially purified and characterized, then unique taxonomic conventions apply. If some information on cell structure, metabolism, or natural habitat exists, in addition to having SSU rRNA gene sequences or other genomic information, then these partially characterized organisms can be placed in the tentative taxonomic category of *Candidatus*, because they cannot be assigned to a formal taxon. In this case, the proposed genus and species names are Roman and follow the *Candidatus* taxon. For example, an uncultured proteobacterium identified as an endosymbiont of certain insects is referred to as *Candidatus*

Carsonella ruddii. For another example, *Candidatus* Nitrosotalea devanaterra is used as a name for an enriched population of ammonia-oxidizing archaea recovered from an acidic soil. See Perspective 15.1 for further information on designations for microorganisms for which only DNA sequences are known.

Note that in the above paragraphs, the names *Bacteria* and *Archaea* were capitalized and italicized in some cases. Capitalization and italics for *Bacteria* and *Archaea* is appropriate when referring to specific ranks within the context of taxonomy, such as these domain names themselves. In contrast, for most general references to specific bacteria and archaea, lowercase first letters and Roman are appropriate. For example, we would write, "Most bacteria and archaea are difficult to culture from the environment."

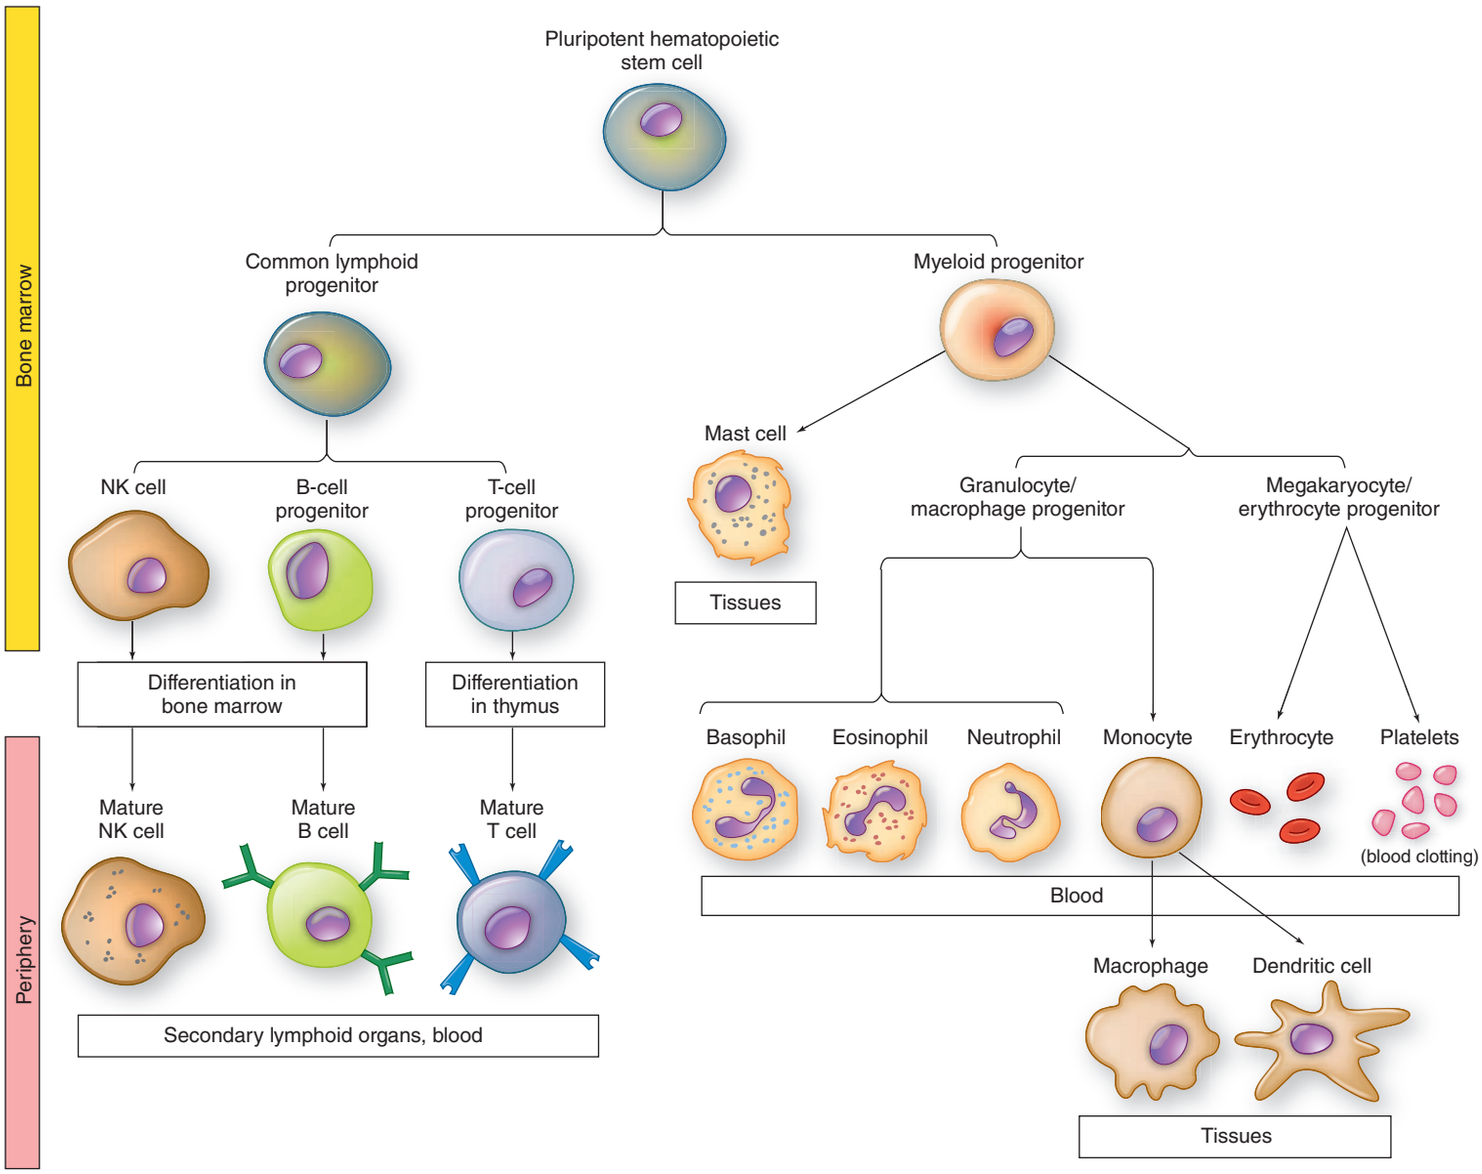
Viruses

The authoritative body on the taxonomy of viruses, virus-like particles, and prions is the International Committee on Taxonomy of Viruses (ICTV), another committee within the International Union of Microbiological Societies. Nomenclature of viruses is unlike other biological naming systems. Names of taxa from species and above are written in italics with an initial uppercase letter. Species names for viruses are not included with the genus name, but are instead stated separately. For example, we would write, "The species *Zaire ebolavirus* of genus *Ebolavirus* was originally isolated from an outbreak in Zaire, 1976." Species names are written in italics but often have several words or identifiers. The first letter of the first word is uppercase. For example, we write *Measles virus*. Other words do not use uppercase unless they are proper nouns, such as *Rift Valley fever virus* (as Rift Valley is a place), or parts of proper nouns, such as *Enterobacteria phage C16* or alphabetical identifiers, such as *Enterobacteria phage H*.

Once a virus has been presented in writing with its formal taxonomic name(s), vernacular names or acronyms (such as HIV-1) may be used. For example, researchers may state that, "All ebolaviruses have a threadlike morphology." When parts of a viral name are used as an adjective, italics and capitals are also not used. For example, it would be appropriate to write, "The ebolavirus polymerase is an RNA-dependent RNA polymerase." The naming of strains, serotypes, and isolates is done by internationally acknowledged specialist groups, such as groups governing the taxonomy of plant viruses or bacteriophages. These names are never italicized. Viroids and retroelements, such as retroposons and retrotransposons, use the same classification and nomenclature rules as is used for viruses. Satellite viruses and prions are not classified as viruses and use more arbitrary classification schema, as deemed useful to researchers who work in these fields.

APPENDIX

D Origin of Blood Cells



Glossary

2D-PAGE Two-dimensional polyacrylamide electrophoresis in which molecules are separated based on both isoelectric point and mass

3′ poly(A) tail String of adenosine monophosphates found on the 3′ end of a growing RNA molecule

454 pyrosequencing High-throughput sequencing method in which incorporation of a pyrophosphate (PP_i) drives a luciferase reaction, producing light that can be detected with a charge-coupled device (CCD) camera

5′ cap A modified nucleotide, 7-methylguanosine, found on the 5′ end of a growing RNA molecule

α-amanitin Toxin produced by mushrooms in the genus *Amanita*; inhibits RNA polymerase II

A-B toxin Two-component toxin possessing a receptor-binding B portion and an enzymatic A portion

ABC transporter System of proteins that binds to a substrate, hydrolyzes ATP to provide energy for transport (ATP-binding cassette), and forms a channel for membrane transport

abortive infection Outcome of a viral infection in which few if any new infectious viral particles are produced

absorbance Measure of the light that is absorbed or scattered as it passes through a solution and does not reach the photodetector in a spectrophotometer

acellular vaccines Vaccine composed of one or of a select number of isolated antigens; not composed of whole cells or viruses; *see also* subunit vaccine

acetotrophic methanogen Organism that produces methane (CH_4) from acetate (CH_3COO^-)

acidophile Organism that grows optimally in low pH environments (pH < 5.5)

activated sludge Secondary wastewater treatment using the perfusion of oxygen through accumulated flocs to maintain aerobic digestion by microorganisms

activation energy (E_A) Energy that must be supplied for a reaction to proceed; determines the rate of a chemical reaction

activator binding site DNA sequence that binds an activator molecule, enhancing binding of RNA polymerase to a promoter

activator molecule Molecule that increases the affinity of RNA polymerase to a promoter

activator protein (cAMP receptor protein, or CRP) A protein that increases gene expression by binding to an activator (transcription factor) which contains a DNA binding domain.

active site Physical location where one or more substrates bind to an enzyme

active transport system Membrane proteins that use energy to move solutes against a concentration gradient

acute infection Infection of short duration

adaptive (specific) immunity Immunity found in jawed vertebrates that occurs only after exposure to a foreign substance, usually following innate stimulation; involves antigen-specific lymphocytes (B cells and T cells) that possess unique receptors generated through random genetic changes in the receptor genes; also called "acquired immunity"

adenine (A) Purine nitrogenous base, along with guanine

adenosine triphosphate (ATP) Cellular biochemical source of energy used to drive coupled biosynthetic reactions

adhesin Any microbial surface structure or extracellular substance that is used to bind to host tissues

adjuvant Any substance that enhances an immune response; commonly used in vaccine formulations

aerobe Organism that grows in the presence of oxygen

aerobic respiration Cellular respiration using O_2 as a terminal electron acceptor; can only be carried out under toxic conditions

aerotolerant anaerobe Organism that does not require oxygen for respiration, but can grow in the presence of oxygen

affinity maturation Progressive increase in the binding strength of antibody for its antigen as the immune response progresses

affinity tag Peptide sequence added to a recombinant protein that will aid in its purification

agar Polysaccharide purified from red algae used as a solidifying agent in microbial growth media

airborne transmission Spread of an infectious agent from a vector or host to another host via an aerosol

alkaliphile Organism that grows optimally in high pH environments (pH > 8.5)

alkyltransferase Enzyme that removes methyl groups from nucleotide bases

allele One of the alternate forms of a gene

allosteric inhibition Inhibition of enzyme action by an effector molecule that binds reversibly to the enzyme allosteric site and is not changed in the reaction

allosteric regulation Regulation of enzyme action by an effector molecule that binds reversibly to the enzyme allosteric site and is not changed in the reaction; regulation can be positive (activation) or negative (inhibition)

alternative pathway Complement cascade activation pathway initiated by the binding of an alternative form of C3b to a variety of cell wall components

amino acid Subunit of a protein molecule

amitochondriate Eukaryal microbe that lacks mitochondria

amoebocyte Invertebrate cell derived from an activated hemocyte, containing antimicrobial peptides and clotting factors to fight infection and reduce tissue damage

anabolism Biosynthesis of macromolecular cell components from smaller molecular units

anaerobic growth Microbial replication in the absence of oxygen

anaerobic methane oxidizers (ANME) Archaea that oxidize methane (CH_4) anaerobically in an important part of the global carbon cycle; known only by DNA sequences and have not yet been cultured

anaerobic oxidation of methane (AOM) Important part of the global carbon cycle carried out by anaerobic methane oxidizers (ANME)

anaerobic respiration Cellular respiration using electron acceptors other than O_2; usually carried out under low oxygen concentrations or anoxic conditions

anaerobic sludge digester Large anoxic bioreactor operating in a semi-continuous mode that allows anaerobic digestion of remaining biowaste sludge following primary and secondary wastewater treatment

anamnestic response Immune response that originates from the stimulation of memory cells and is characterized by a faster and more vigorous adaptive immune response upon repeated exposure to antigen; *see also* memory response

anaplerotic reaction Replenishing reaction that generates a critical metabolic intermediate in order to sustain another metabolic pathway

anemia Decrease in oxygen-carrying capacity of blood, often due to decrease in number of erythrocytes

annotation Use of computer programs to predict the beginning and end of protein-encoding sequences of DNA

anoxic Lacking oxygen

anoxygenic photosynthesis Bacterial phototrophy that does not produce O_2 and uses either PS I or PS II

antibiotic Compound usually but not always, derived from a microorganism that inhibits the growth of other microorganisms; often encompasses synthetic compounds used for the treatment of bacterial, fungal, and protozoal diseases

antibody Secreted immunoglobulin produced by B cells, specifically plasma cells, of the adaptive immune system

antibody-dependent cell-mediated cytotoxicity (ADCC) Killing mechanism used by NK cells; binding of F_CR receptors on the NK cell to antibody that is bound to the surface of an infected cell causes degranulation and apoptosis of the target cell

anticodon Sequence of three nucleotides on tRNA that binds to complementary codon on the mRNA

antigen Any component that can be specifically bound by an immune receptor, namely a T-cell receptor (TCR) or an immunoglobulin (Ig)

antigen-presenting cell (APC) Cell capable of processing and presenting antigen in association with MHC molecules; includes dendritic cells, macrophages, and B cells

antigenic drift Gradual change in viral antigens caused by random mutation

antigenic shift Dramatic change in viral antigens caused by reassortment

antigenic variation Change in molecules on the surface of a pathogen to which the immune system responds; can allow pathogen to avoid immune detection

antimetabolite Chemical analog that is similar in structure to a natural compound but does not participate in the same chemical reactions

Antimicrobial drug Compound used primarily to treat or prevent microbial infections of the body; includes antibacterial, antifungal, antiprotozoal, and antiviral drugs

antimicrobial peptide A member of a group of low molecular weight proteins secreted by various cell types in plants, invertebrates, and vertebrates that appear to destabilize the membrane structure of microbes, resulting in disruptive gaps or pores

antiparallel Arrangement in double-stranded DNA where the 5′ end of one strand is aligned with the 3′ end of the other strand

antiport Mechanism of co-transport that couples the movement of one substance across the plasma membrane with the movement of another in the opposite direction

antiporter Molecule used in co-transport in which the energy-requiring movement of one molecule is driven by the energetically favorable movement of another molecule in the opposite direction

antisense RNA Single-stranded RNA that can interact with specific mRNA molecules through complementary base-pairing

antiseptic Chemical that can be used on living tissue such as skin to kill infectious microbes

apoptosis Cell death accomplished through a highly ordered and tightly controlled cascade of chemical-signaling events within the cell that results in its destruction without the release of damaging cell constituents or triggering of inflammation

appresorium *pl.* **appresoria** Specialized cells of fungi that can penetrate the plant cuticle, enhancing potential for infection

aquaporin Protein channel in the plasma membrane that facilitates passage of water

Archaea Domain in which members are unicellular and lack a membrane-bound nucleus.

ascariasis Infection with a species in the *Ascaris* genus of roundworms

ascus Structure containing haploid ascospores produced by some fungi

assimilation Process by which cells import a molecule and incorporate it into cellular constituents

ATP synthase Membrane enzyme complex that uses the kinetic energy of flowing protons to synthesize ATP from free ADP and P_i

attack rate Special incidence rate calculated during an outbreak and usually covering a short period of time that gives the proportion of ill individuals in an exposed population; used to estimate how many more individuals are expected to become ill

attenuated vaccine Vaccine composed of a live but weakened, or less virulent, version of a microbe that is completely or nearly devoid of pathogenicity yet retains the ability to generate protective immunity in the host

attenuation Regulatory mechanism that occurs after the initiation of transcription but before transcription of the operon is complete; decrease in virulence

autoclave Instrument used to sterilize materials by application of heat and pressure

autoimmunity Immune reactions directed inappropriately against the body's own cells

autoinducer Signal molecule used in quorum sensing that increases in concentration as the density of the population increases

automated sequencing Technique based on Sanger sequencing that yields sequences of up to 1,000 nucleotides; *see also* cycle sequencing

autophagy Intracellular degradation in which materials to be destroyed are encased in a membrane and sent to the lysosome

autotroph Organism that can build complex organic molecules used as nutrients from an inorganic carbon source

auxotroph Organism that requires certain organic precursors from the environment in order to synthesize all necessary cellular constituents

***β*-lactam** Antibiotics containing a *β*-lactam ring that interferes with synthesis of the bacterial cell wall; includes penicillins and cephalosporins

***β*-lactamase** Enzyme that hydrolyzes the *β*-lactam ring of some antibiotics rendering them ineffective

***β*-lactam class** Group of antibiotics, all of which possess a *β*-lactam ring as a common structural feature

***β*-oxidation pathway** Major pathway for the catabolism and oxidation of lipid fatty acid chains into acetyl-CoA, producing significant amounts of NADH and $FADH_2$ for ATP production

B cell Lymphocyte of the adaptive immune system expressing immunoglobulin B-cell receptors (BCRs) on their surface; give rise to antibody-secreting plasma cells; also called B lymphocyte

B-cell receptor (BCR) Membrane-bound immunoglobulin expressed on the surface of B cells that can bind antigen in a specific manner

bacillus *pl.* **bacilli** Bacterial cell that is roughly cylindrical; also called a rod

bacteriochlorophyll Primary photopigment used by anaerobic photosynthetic bacteria

bactericidal drug Antibacterial medication that directly kills bacteria

bacteriocin Antimicrobial peptide produced by one strain of bacteria and that is harmful to another strain within the same family

bacteriocyte Specialized host cell found only in symbiotic insects; houses endosymbionts

bacteriophage Virus that infects bacteria; literally, "bacteria eater"

bacteriorhodopsin Archaeal membrane protein bound to retinal that functions as a light-driven proton pump to generate ATP

bacteriostatic drug Antibacterial medication that prevents the replication of bacteria but does not directly cause bacterial death

bacteroid Endosymbiotic, terminally differentiated bacteria found in symbiotic plants (frequently in root nodules)

barophile Organism that grows optimally under conditions of high pressure

base substitution Type of mutation in which a single base is changed

basic reproduction number (R_0) Average number of new infections caused by an infected individual in a population of susceptible individuals

basophil Cytotoxic cell of the innate immune system found in tissue and blood and named for the distinct staining of its granules with certain basic dyes; generally acts against extracellular parasitic worms in the presence of IgE or C3a or C5a

batch culture A closed system for microbial growth in which nutrients are not replenished and wastes are not removed

bioaugmentation Introduction of microorganisms that increase the rate of degradation of organic wastes or pollutants

biocatalyst Enzyme that facilitates an industrial chemical reaction, often derived from microbes

biochemical oxygen demand (BOD) Measure of the amount of dissolved oxygen required by microorganisms to decompose the organic matter in a sewage or water sample

biofilm Microbial community attached to a surface within a matrix of secreted polymers

biogenic element Elements comprising biomass

biogeochemical cycle Transition of chemicals between organic and inorganic forms that results in cycling through and within parts of the ecosystem

Bioinformatics Field that uses computers to analyze large quantities of biological data, such as DNA or protein sequences

biome Major category of ecosystem characterized by vegetation and climate

bioprospecting Searching for novel organisms, biological materials, or biological processes that can be useful in biotechnology

bioreactor Large culture vessel designed to maximize cell density and product yield during industrial fermentation

biorefinery Facility that converts biomass into industrial products or energy

bioremediation Use of microorganisms to degrade environmental pollutants

biosolid Composted or treated sludge that is suitable for use as soil conditioner in horticulture and agriculture

biosphere Regions on Earth that can support life

biostimulation Addition of O_2 or limiting nutrients to increase the metabolic activity of microorganisms that degrade organic wastes or pollutants

biotechnology Use of biological processes or organisms for the production of goods or services

biphytanyl Isoprene polymer in the plasma membrane of some archaeons; 40-carbon hydrocarbon forming a phospholipid monolayer

botulism Foodborne intoxication resulting in flaccid paralysis that occurs when botulinum toxin produced by *Clostridium botulinum* is ingested

Bt toxin Intracellular protein crystal formed by sporulating *Bacillus thuringiensis* that acts as an insecticide against moths, butterflies, flies, mosquitoes, and beetles

bulk soil Soil that exists away from the influence of plant roots

C-reactive protein Serum pattern recognition receptor (PRR) of the innate immune system produced in early infection

Calvin cycle Common dark reaction pathway used by cyanobacteria and plants for autotrophic carbon fixation

canning High heat process for food preservation where food is heated to 100°C or above for an extended period of time, followed by sealing in a sterilized can or jar

cannulae Hollow glycoprotein tubes that connect individual cells to form a complex network

capsid Protein structure surrounding the genome of a virus

capsomere Subunit of a virus capsid

capsule Polysaccharide layer surrounding some bacterial cells that may shield pathogens from host defense systems

carbon fixation Conversion of inorganic carbon, usually CO_2, from the environment into organic molecules for growth

carboxysome Intracellular compartment that contains key enzymes involved in the conversion of inorganic carbon into organic matter during photosynthesis

carrier Asymptomatic host that can transmit an infectious agent to others

case-to-infection (CI) ratio Proportion of infected individuals who develop disease

catabolism Breakdown of larger molecules into smaller ones for energy production

catabolite repression Process of inhibiting operons that use alternate substrates; glucose inhibits pathways producing enzymes that catabolize other nutrients

$CD4^+$ T cell T lymphocyte expressing the surface molecule CD4. *see also* T helper cell

$CD8^+$ T cell T lymphocyte expressing the surface molecule CD8. *see also* cytotoxic T cell

cecal fermentation Digestive system where the major site of fermentation is the cecum

cecum Dead-end pouch found at the junction of the ileum (distal end of the small intestine) and the colon; vital in many herbivores for microbial-assisted breakdown of partially digested food from the small intestine

cell envelope Structure surrounding the cytoplasm, composed of the plasma membrane, cell wall, and, in Gram-negative cells, an outer membrane

cell Simplest structure capable of carrying out all the processes of life

cell wall Semi-rigid structure at the cell periphery that holds the cell in a certain shape, limits cellular access to chemical compounds, and protects the cell from environmental pressures

cell-mediated immune response Immune response dominated by T_H1 cells, T_C cells, increased activation of macrophages, and inflammation in response to the presence of intracellular pathogens

cellular respiration Metabolic process in which electrons (1) are stripped from a chemical energy source, (2) pass through an electron transport chain to generate a proton gradient that drives the synthesis of ATP, and (3) reduce an electron acceptor

cellulose Polysaccharide in the cell walls of plants and algae with β-1, 4-glycosidic bonds between glucose molecules

chemiosmosis Synthesis of ATP from free ADP and P_i using energy and electrons to create a proton gradient across a membrane; the flow of protons back across the membrane releases energy that is harnessed by ATP synthase to produce ATP

chemoreceptor Receptor that detects chemical signals, such as attractants or repellents

chemostat Continuous culture system in which growth rate and cell density can be manipulated through the nutrient composition of the medium and the flow rate of fresh medium into the culture vessel

chemosynthesis Metabolic process that derives energy from chemicals rather than from light

chemotaxis Process that uses chemical signals from the environment to direct movement

chemotroph Organism that acquires energy through the oxidation of reduced organic or inorganic compounds

chlorination Disinfection process for water treatment that uses the addition of a hypochlorite solution, such as bleach, or percolation of chlorine gas through water to produce hypochlorous acid (HOCl), a strong oxidizing agent

chlorophyll Primary photopigment used by cyanobacteria and chloroplasts

chloroplast Organelle that contains pigments and carries out photosynthesis

cilium *pl.* **cilia** Short filamentous appendage used in locomotion that projects from the surface of a eukaryal cell; shorter and usually more numerous than flagella

***cis*-acting retroviruses** Retrovirus that activates a cellular proto-oncogene after integrating into a host chromosome

clade Genetically distinct subtype of a species

class I major histocompatibility complex (MHC I) molecule Cell surface molecule expressed by many cell types that presents endogenous antigen to $CD8^+$ T cells

class II major histocompatibility complex (MHC II) of APCs Cell surface molecule expressed by antigen-presenting cells that presents exogenous antigen to $CD4^+$ T cells

class-switching Genetic process in activated B cells that results in production of one of the classes of IgA, IgG, or IgE immunoglobulin from the initial production of class IgM

classical pathway Complement cascade activation pathway initiated by C1 binding directly to certain surface components of pathogens, for example, LPS and lipoteichoic acid, or binding to surfaces coated with C-reactive protein or antibody; utilizes complement components C1 through C9

clonal expansion Cell division from a single activated T or B cell resulting in a population of cells with the same specificity for antigen

clone Cell or organism that is genetically identical to another cell or organism

cloning vector DNA molecule to which other DNA fragments can be joined for replication within cells

co-speciation Evolutionary process beginning with an ancestral host/microbe association that subsequently diversified into a number of different but phylogenetically related host–symbiont species

coccus *pl.* **cocci** Bacterial cell that is roughly spherical

codon Sequence of three nucleotides on mRNA that codes for a single amino acid

coenzyme An organic cofactor

coevolution hypothesis Premise that viruses originated prior to or at the same time as primordial cells and continued to coevolve with these hosts

cofactor Small ion or organic molecule essential for enzyme catalytic activity by assisting in the transfer of functional groups

cointegrate Union of plasmid and chromosome as a result of a single recombination event

colon Distal end of the intestinal tract of many vertebrates; frequently harbors large concentrations of symbiotic microorganisms; also called the "large intestine"

colonic fermentation Digestive system where the major site of fermentation is the colon

colony Mound of clonal cells that grows large enough to be seen without a microscope

colony-forming unit (CFU) Viable microorganism that replicates to form a visible colony on a growth medium

comammox Complete ammonia oxidation to nitrate by individual bacteria, such as certain members of the Nitrospira genus

cometabolism Metabolic transformation of a molecule that is not used as a carbon or energy source

commensalism Symbiotic relationship in which one partner benefits, while the other is apparently unaffected

common-source epidemic An outbreak that results from exposure to a single source of infection

communicable disease Infectious disease that can be transmitted between individuals.

community All of the organisms that live and interact in an area at the same time

comparative genomic Field of study that determines evolutionary relationships among organisms based upon DNA sequence data

competent Describes a cell that can take up free DNA from its surroundings

competitive exclusion Concept that different species requiring the same resources cannot co-exist; prevents colonization by competing species

complement Group of serum proteins of the innate immune system that can become activated to undergo a cascade of cleavage reactions in the presence of extracellular pathogens; end result of complement activation is formation of the membrane-attack complex (MAC) and generation of complement factors with supplementary immune functions

complementary DNA (cDNA) Eukaryal DNA strand produced using mRNA transcript as a template for the reverse transcriptase enzyme; it lacks introns and can be inserted into an expression vector

complementary Refers to nucleotide pairing such that adenine (A) always aligns with thymine (T, in DNA) or uracil (U, in RNA) and cytosine (C) always aligns with guanine (G)

complex medium Growth medium for which chemical components are not precisely defined in identity or concentration

conjugate vaccine Vaccine composed of a capsular polysaccharide bound to a peptide; used to immunize against pathogens possessing T-independent antigens

conjugation Transfer of DNA from one cell to another via direct cell-to-cell contact; type of horizontal gene transfer

consensus sequence A recognition sequence that is comprised of the most frequently found base at each position of similar sequences

consortium Microbial community in which growth or survival of members is dependent upon interactions within the community

constitutive expression Constant expression of genes that encode products always needed by the cell such as enzymes for glycolysis or transcription

consumer Organism that consumes other organisms as a source of carbon and energy

contagious disease Communicable disease that can be transmitted easily, often by direct contact or being in close proximity

continuous culture Open growth system to which nutrients are continually added and waste products are continually removed

copy number Number of plasmids within a cell

corepressor Molecule that enhances binding of a repressor protein to an operator

cosmid Hybrid vector composed of plasmid and phage elements

covalent modification Regulation of enzyme action by addition of a chemical entity such as a phosphate group or a methyl group

CpG dinucleotide Adjacent guanine and cytosine nucleotides in a DNA chain; unmethylated CpG dinucleotides are commonly found in the DNA of bacteria and some viruses, but not in eukaryal cells, and can be innately recognized by human Toll-like receptor 9

CRISPR-Cas system Clustered regularly interspersed short palindromic repeats and CRISPR-associated proteins that constitute an anti-viral defense system in bacteria

cross-presentation Pathway in antigen-presenting cells that shuttles proteins from the endocytic pathway into the endogenous pathway to allow for both $CD4^+$ and $CD8^+$ T-cell activation

cultivation-independent method Process of analyzing microbes in an environment that is not dependent upon standard laboratory plating techniques

culture collection Archive of microbial strains for use in microbiology studies and in biotechnology

cycle sequencing Technique based on Sanger sequencing that yields sequence of up to 1,000 nucleotides within hours; *see also* automated sequencing

cytokine Any member of a group of secreted, soluble, low molecular weight glycoproteins used as the primary means of cell-to-cell communication to regulate inflammatory and immune responses; includes interleukins, interferons, and tumor-necrosis factors

cytokinesis Division of the cytoplasm, usually after nuclear division

cytolysin Cytotoxin that causes lysis of host cells by membrane disruption

cytopathic effect (CPE) Visible change in cellular morphology often associated with cell damage or death

cytoplasm Aqueous environment enclosed by the plasma membrane

cytosine (C) Pyrimidine nitrogenous base, along with thymine and uracil

cytoskeleton Network of microfilaments, microtubules, and intermediate filaments within a eukaryal cell that provides structure and directs movement

cytostome Double-membrane structure through which material is taken into a cell

cytotoxic cell Any effector cell of the immune system containing cytotoxic granules, which when released induce apoptosis of target cells; natural killer (NK) cells, mast cells, and cytotoxic $CD8^+$ T (T_C) cells are examples

cytotoxic T cell (T_C cell) Effector $CD8^+$ T cell that induces apoptosis in target cells through MHC I:antigen binding followed by the release of perforin and granzyme

cytotoxin Toxin that acts on host cells

dark reactions Chemical reactions that utilize ATP and NADPH produced by phototrophy to convert CO_2 into organic carbon compounds through carbon fixation

dead-end host Individual in which a pathogen may replicate and cause disease but isn't transferred efficiently to another individual; also called an "incidental host"

death phase Period of growth during which the viable cell population declines

decimal reduction time (D value) Time required to kill 90 percent of target organisms under specific conditions

decomposer Organism that consumes dead organisms as a source of carbon and energy, releasing simple organic products

defined medium Growth medium for which the chemical identity and concentration of all constituents is known

definitive host Host in which a parasite reproduces sexually

degranulation Release of the chemical constituents of the granules of cytotoxic cells by vesicle fusion with the plasma membrane

deletion Mutation in which one or more nucleotide bases are removed from a DNA sequence

denaturing gradient gel electrophoresis (DGGE) Technique that allows electrophoretic separation of DNA fragments based upon DNA sequence differences rather than size

dendritic cell Migrating antigen-presenting cell found in most tissues of the body, characterized by extensive cytoplasmic projections

denitrification Anaerobic conversion of nitrate into N_2

diauxic growth curve Representation of two different rates of cell growth in a medium containing two different nutrient sources that are used sequentially

dideoxy sequencing Technique to determine DNA sequence that relies on incorporation of chain-terminating dideoxy nucleotides and includes cloning of the fragment to be sequenced, DNA synthesis, and gel electrophoresis; *see also* Sanger sequencing

differential centrifugation Process of subjecting a medium containing larger and smaller particles to low-speed centrifugation causing the larger particles (often cells and cell debris) to pellet followed by ultracentrifugation causing the smaller particles (often viruses) to pellet

differential medium Growth medium that allows different types of bacteria to be distinguished visually

dilution to extinction Technique that produces a dilute solution from which samples that contain individual cells can be grown to produce a pure culture

dinoflagellate Type of flagellated unicellular organism; many are photosynthetic; some produce saxitoxin that can block sodium channels, resulting in flaccid paralysis

diploid Possessing two sets of chromosomes

direct transmission Spread of an infectious agent via physical contact between an infected individual and a susceptible individual

directed enzyme evolution Method to improve microbial strains by applying rounds of random mutagenesis followed by selection for desired changes in a particular gene of interest

disease Disturbance in the normal functioning of an organism

disinfectant Chemical applied to non-living objects to kill potentially infectious microorganisms

DNA cloning Replication of recombinant DNA molecules; *see also* molecular cloning

DNA glycosylase Enzymes in this family recognize damaged bases and initiate a base excision repair mechanism.

DNA ligase Enzyme that joins a 5′-phosphate end and a 3′-OH end in a DNA strand; *see also* ligase

DNA polymerase Enzyme that catalyzes production of a new DNA strand from an existing DNA strand

DNA shuffling Method in which DNA fragments are mixed together, denatured, and reassembled into full-length chimeric genes that are products of recombination between the input fragments; can dramatically improve phenotypes by combining multiple beneficial variations into single clones

DNA vaccine Vaccine composed of a cloned gene(s) in a DNA vector, such as a plasmid; delivery into the cells of the body results in expression of the immunizing antigen product of the cloned gene

DnaA DNA-binding protein that acts in strand separation required for DNA replication in bacteria

DnaG Synthesizes short segments of RNA needed to prime DNA replication in bacteria; also called "primase"

ecosystem A community and its physical environment

ectosymbiont Symbiont that lives on the exterior surface of its host

effector Molecule that interacts with a repressor molecule and affects its ability to bind to an operator; often an intermediate of the related metabolic pathway

effector cell Armed, fully differentiated immune cell that directly carries out immune functions; examples include T_C, T_H, and plasma cells

effluent Outflow water that is discharged to another treatment tank or released to a water supply

efflux pump Membrane protein complex used to transport various compounds, such as antimicrobial agents, directly out of the microbial cell; found naturally in many bacteria and fungi

electron transport system Chain of membrane-associated proteins that transfers electrons in a series of steps, yielding energy to move protons across the membrane

electroporation Application of electric current to cells that generates temporary holes in cellular membranes through which DNA can enter

Embden–Meyerhof–Parnas (EMP) pathway Glycolytic pathway where glucose is converted into two molecules of pyruvate, producing a total of two molecules of ATP from each glucose molecule

emerging disease Disease that was previously unknown or that shows a significant increase in incidence

endemic disease Disease that is normally present in a population

endergonic Energy-absorbing chemical reaction having a positive $\Delta G^{o\prime}$ value

endocytic pathway The flow of material internalized by endocytosis and degraded through a number of biochemical processes until its expulsion from the cell; involves a series of vesicle fusion events; only in eukaryal cells

endocytosis Generalized process for the uptake of external materials by cell membrane extension or invagination and fusion to form a vesicle inside the cytoplasm of the cell generally known as an endosome

endogenous antigen Peptide antigen that originates from the cytoplasm of a cell and is presented on MHC I molecules

endogenous retrovirus Proviral DNA integrated into the DNA of host gametes and subsequently found in every cell of a developing embryo

endophyte Endosymbiotic microbe that lives inside plant tissue

endoplasmic reticulum (ER) System of membranes in the cytoplasm of a eukaryal cell

endosome General term for a membrane-bound vesicle produced by endocytosis

endospore Metabolically inert structure with increased resistance to harsh environmental conditions formed by some Gram-positive bacteria

endosymbiont Symbiont that lives within the body tissues or cells of a host; usually refers to internal microbes that have a mutualistic or commensal relationship with their host

endosymbiosis Interaction between cells in which one type of cell is engulfed by another, forming a stable relationship

endotoxin Cell-wall component of Gram-negative bacteria; *see also* lipopolysaccharide (LPS) and lipooligosaccharide (LOS)

enrichment medium Growth medium that contains nutrients or other components designed to favor the growth of particular microbes

enterotoxin Microbial secreted toxin that acts on the gut and causes or contributes to the intestinal symptoms in an affected individual

Entner–Doudoroff pathway Glycolytic pathway interacting with the EMP pathway in which glucose is converted to two molecules of pyruvate, producing one molecule of ATP from each glucose molecule

enzyme Macromolecule that acts as a catalyst to speed up chemical reactions within a cell by lowering the energy of activation

enzyme-linked immunosorbent assay (ELISA) *In vitro* detection system that uses antibodies conjugated to enzymes for the detection of serum antibodies (indirect ELISA) or antigen (direct ELISA)

eosinophil Cytotoxic cell of the innate immune system found in blood and named for the distinct staining of its granules with the dye eosin; generally acts against extracellular parasitic worms in the presence of IgE

epidemic Significant rise in incidence of a disease above that normally expected in a population

epidemiology Study of patterns of disease within populations

epilimnion Surface layer of a stratified lake, which is typically warmer and less dense than the bottom layer

episome Circular piece of viral DNA separate from the host chromosome(s) within the nucleus of a host cell

epitope Single antigenic site on a molecule that is recognized and bound by an immune receptor, such as an immunoglobulin (BCR or antibody) or TCR

error-prone PCR Process in which a gene is PCR amplified under conditions that result in a very high error rate

Eukarya Domain in which members are defined by the presence of a membrane-bound nucleus

eukaryote Organism that is composed of cells that contain a membrane-bound nucleus

eutrophication Increase in the concentration of nutrients, such as nitrogen and phosphate compounds in an aquatic ecosystem, leading to rapid growth in autotroph populations, particularly algae

evolution Inherited change within a population over time

exergonic Energy-yielding chemical reaction having a negative $\Delta G^{o\prime}$ value

exogenous antigen Peptide antigen that enters the endocytic pathway from outside the cell and is presented on MHC II molecules

exon Protein-coding region of a eukaryal gene

exotoxin Microbial toxin that is released into the surroundings or injected into host cells

exponential phase Period of growth during which cells divide to produce two cells at a maximum rate; *see also* log phase

expression vector Agent such as a plasmid that is specifically designed to produce recombinant proteins within a host cell

extravasation Movement of cells and fluid from a blood vessel into the surrounding tissue; occurs during inflammation

extrinsic factor A characteristic of the storage environment of the food, such as temperature and humidity

F plasmid Large, circular dsDNA plasmid required for conjugation; also called the "fertility factor"

F-prime (F′) strain Cells that transfer a limited number of markers at extremely high frequency during conjugation

facultative anaerobe Organism that can use oxygen for respiration when it is present, but also can grow in the absence of oxygen

fecal coliform Group of coliform bacteria indigenous to the intestinal tract of humans and animals

fecal-oral transmission Spread of an infectious agent that is eliminated in the feces of one individual and then ingested by another individual

fed-batch reactor Production system in which a growth-limiting nutrient is added over time to control growth rate resulting in high cell densities

feedback inhibition Allosteric inhibition of an early enzyme in a metabolic pathway by a product produced later in the series

feedstock Biomass serving as raw starting material in industrial processes or biorefineries

fermentation Anaerobic metabolic pathway where electrons generated from glycolytic processing are passed directly to an organic terminal electron acceptor; an industrial culture process for production of microbial products

fever Sustained increase in average core body temperature in endothermic animals

fibronectin-binding protein Adhesin found on many bacterial pathogens, allowing them to bind and colonize the extracellular fibronectin of skin, mucosal surfaces, and blood vessels

fimbria *pl.* **fimbriae** Cell-surface fiber used for adhesion

flagellin Protein that comprises the flagellum in bacteria and archaeons

flagellum *pl.* **flagella** Long filamentous appendage on the surface of cells used for motility

flash-heating Pasteurization method that heats a small volume of liquid to a very high temperature (at least 72°C) for a short period of time (15 s or less); includes high-temperature-short-time (HTST) and ultra-high-temperature (UHT) processes

floc Clumps of biomass consisting of adsorbed material and microorganisms

flow cytometry Method of detecting cells in suspension by measuring scattering of light as the cells pass by a laser beam

fluid mosaic model Model of a membrane composed of a double layer of phospholipids in which proteins are dispersed

fluorescence-activated cell sorting (FACS) Method that uses flow cytometry to sort individual labelled cells based on fluorescence

fluorescent *in situ* hybridication (FISH) Technique that detects specific nucleotide sequences using fluorescently labeled oligonucleotide probes

flux Movement of elements between environmental reservoirs

fomite Inanimate object via which pathogens may be transferred to a susceptible host

foodborne infection Disease caused by the ingestion of live pathogens that actively multiply within the body

foodborne intoxication Illness caused by ingestion of food containing microbial exotoxins

frameshift mutation Addition or deletion of one or more nucleotide bases in a DNA sequence resulting in an altered reading frame

freeze-drying Process for preserving food, whereby food is frozen and then dried under a vacuum, allowing removal of water by sublimation; *see also* lyophilization

functional genomics Field of study to determine biological functions of unknown genes determined from DNA sequence data

fusion peptide A short string of hydrophobic amino acids that mediates merging of membranes between virus and host cell

fusion protein Recombinant protein that contains domains of two or more proteins; typically including a protein of interest fused to a polypeptide that adds a beneficial property such as an affinity tag

gametocyte (gamont) Precursor cell of a haploid gamete, or reproductive cell, in a protozoan

gas vesicle Protein structure in cells that can contain gas and provide buoyancy to cells

gel shift assay Electrophoretic technique that separates molecules based on their size; may be used to identify proteins bound to DNA

gene Segment of DNA that is transcribed into single-stranded RNA, along with the associated DNA elements that direct its transcription

gene therapy Treatment of a genetic disorder by introducing a wild-type allele of a mutant gene that codes for an abnormal or missing protein, thereby eliminating the problem

general secretory pathway Proteins in the plasma membrane that move proteins to the outside of the cell

generation time Average time interval between one cell division and the next

genome All of the hereditary material within a cell

genome editing Precise modification of genome sequence

genomic island DNA sequence transferred from one species to another; result of horizontal gene transfer

genomic library Collection of cloned DNA fragments that comprise the entire genome of an organism

genomics Determination and study of complete genome sequences

genotype Description of the alleles possessed by an organism

germ-free Laboratory animal that is born and maintained in a completely sterile environment free of all microbial contact

Gibbs free energy (*G*) Potential energy that can be released in a chemical reaction

gliding motility Type of locomotion used by some non-flagellated bacteria to move across a surface

glycocalyx polysaccharide-rich layer, including capsule and slime layer, surrounding some bacterial cells

glycolysis Catabolism of glucose to pyruvic acid (pyruvate)

glycosylation Addition of a complex sugar residue to a polypeptide

gnotobiotic Germfree animal that has subsequently been purposefully inoculated with one or a few particular species of microbes

Golgi apparatus Membranous organelle in eukaryal cells in which molecules synthesized within the cell are packaged and distributed

gradient centrifugation Process of subjecting a medium to ultracentrifugation within a tube containing a linear gradient of a salt or sugar solution that will separate particles based upon their relative density within the gradient

Gram stain Technique for staining bacterial cells allowing differentiation into two types of bacteria, Gram-positive bacteria that appear purple and Gram-negative bacteria that appear pink

Gram-negative bacteria Bacterial cells with a thin layer of peptidoglycan in the cell wall surrounded by an outer membrane; lose crystal violet stain in the Gram stain procedure and appear pink

Gram-positive bacteria Bacterial cells with a thick layer of peptidoglycan in the cell wall; retain crystal violet stain in the Gram stain procedure and appear purple

granule Membrane-bound, chemical-containing vesicle found in the cytoplasm of certain cells of the immune system with killing potential

granuloma Pathological lesion resulting from a focus of chronic inflammation and characterized by a nodule-like encasement composed of fibrin and lymphocytes at the periphery and infected and dead macrophages inside

granzyme Peptide produced by cytotoxic cells of the immune system that triggers apoptosis in target cells

green biotechnology Use of advanced biological processes in agricultural applications

greenhouse gas Gas that absorbs infrared radiation in the atmosphere; examples are CO_2 and methane (CH_4)

growth Increase in mass of biological material; an increase in number of microbes

growth curve Pattern observed when cells are grown in a closed system; includes the lag phase, the exponential or log phase, the stationary phase, and the death phase

growth medium Medium that consists of a combination of organic and inorganic materials designed to support the growth of microorganisms.

growth rate Generation time, or average time interval between one cell division and the next

growth yield Number of cells that results from growth over a specific time period

guanine (G) Purine nitrogenous base, along with adenine

guild Group of organisms that carry out similar processes

Haber–Bosch process Process that produces ammonia by a reaction of dinitrogen gas with hydrogen gas; enables production of synthetic nitrogen fertilizer

halophile Organism that requires high salt (NaCl) levels for growth

haploid Possessing a single set of chromosomes

harmful algal bloom (HAB) Population explosion of organisms producing toxins that can lead to death of other aquatic organisms

heat shock protein Molecule produced when cells are exposed to stress such as high temperature; often aid in the correct folding of proteins

helical morphology Structure of a virus in which the capsomeres form a helix and the capsid resembles a hollow tube

helicase Aids in unwinding of DNA during DNA replication in bacteria; also called DnaB

helminth Parasitic worm

hemagglutination Clumping of red blood cells

heme Iron-containing pigment of hemoglobin that is cytotoxic in its free form

hemocyte Wandering phagocytic cell of invertebrates that migrates from hemolymph (blood) into tissue

hemolysis Destruction of red blood cells through production of cytolysins called "hemolysins"

hemozoin Insoluble polymer composed of heme monomers produced by the malaria parasite; sometimes called "malaria pigment"

herd immunity Protection from communicable disease of nonimmunized, susceptible individuals in a population by immunization of a large proportion of the rest of the population

herd immunity threshold Critical proportion of a population required to be immunized to achieve herd immunity

heterotroph Organism that obtains carbon from organic molecules, such as sugars, obtained from the environment

Hfr strain High frequency of recombination cells formed when an entire F plasmid incorporates into the host chromosome during conjugation

high-throughput sequencing Use of post-Sanger-sequencing platforms to sequence many DNA fragments simultaneously and at a fraction of the cost of previous electrophoresis-based approaches; *see also* next-generation sequencing

histidine protein kinase (HPK) Common sensor kinase involved in detecting an environmental stimulus in a two-component regulatory system

histone Protein in eukaryal cells and some archaeons that protects and compacts DNA

histone deacetylase (HDAC) Cellular enzyme that affects gene expression by removing acetyl groups ($CH_3C{=}O$) from histones

homeostasis Active regulation of the internal environment to maintain relative constancy

homolog A gene that has a common evolutionary descent to another gene, either through speciation, gene duplication, or gene transfer.

homologous recombination Process that occurs when two segments of DNA with identical or very similar sequences pair up and exchange or replace some portion of their DNA; also called "crossover"

hopanoid Sterol-like molecule believed to stabilize the plasma membrane of some bacteria

horizon Layer of soil with distinct characteristics

horizontal gene transfer Movement of DNA between microbes; also called "lateral gene transfer"

horizontal transmission Spread of an infectious agent between members of a species that are not parent and offspring

host range The diversity of cells that can be infected by a pathogen or support the replication of a virus or plasmid

humic material Product of incomplete breakdown of plant biomass found in soil

humoral immune response Adaptive immune response dominated by T_H2 cells and characterized by production of large amounts of antibody in response to extracellular pathogens or toxins

hurdle technology The use of multiple constraints or *hurdles* to control the growth of pathogens and spoilage microorganisms in foods; targeted microorganism(s) must overcome each hurdle in order to proliferate

hydrogenotrophic methanogen Organism that produces methane (CH_4) from CO_2 and H_2

hyperthermophile Organism that grows optimally at temperatures greater than 80°C

hypha *pl.* **hyphae** Irregularly branching filaments found in most fungi and some bacteria

hypolimnion Bottom layer of a stratified lake, which is typically cooler and more dense than the upper layer

icosahedral morphology Structure of a virus in which the capsomeres form an icosahedron, or 20-sided polygon, with each capsomere making up a face of the icosahedron

Illumina sequencing High-throughput sequencing approach that uses massively parallel synthesis of DNA fragments on a glass surface, with light emission, in order to sequence large numbers of DNA fragments simultaneously.

immune receptor T-cell receptor (TCR) or B-cell receptor (BCR) capable of binding to antigen

immune response Defensive response mounted by the host involving the immune system

immune system The cells, molecules, and associated tissues and organs involved in identifying foreign agents, fighting infection, and ridding the body of abnormal cells

immune The state of being resistant to infection and subsequent disease

immunization Process of generating immunological memory to prevent infection and/or disease through the introduction of antigen(s), such as microbes or their components, into the body

immunoglobulin (Ig) molecule Secreted (antibody) or membrane-bound (B-cell receptor; BCR) glycoproteins that bind antigen in a specific manner

immunology The study of the components and processes of the immune system

immunoprecipitation (IP) Technique in which an antibody is used to precipitate an antigen

inactivated vaccine Vaccine composed of whole cells or viruses that have been physically inactivated by heat or chemical treatment yet retains the ability to generate protective immunity in the host; *see also* killed vaccine

incidence Number of new cases of a disease appearing in a population during a specific time period

inclusion body Microscopically visible granule within the cell; composed of aggregated cellular or viral materials

incubation period Time between entry of a pathogen into a host and appearance of illness

indicator organism Microbe, particularly fecal coliform bacteria, whose presence in a water sample indicates fecal matter is present and, by association, potential intestinal pathogens

indirect transmission Spread of an infectious agent from one individual to another via an object, like a contaminated inanimate object, water, food, or an insect

inducer Molecule that inhibits binding of a repressor protein to an operator

inducible expression Expression of genes that encode products only when they are needed by the cell

infection Successful colonization and invasion by a pathogen of a host

infection thread Invagination of the plant cell wall that forms a narrow tube produced by a rhizobia-infected root cell; extends into the plant root tissue to deliver the bacteria to root cells

infectious disease Disease caused by a microbe that can be transmitted from host to host

infectious RNA The genome of a positive-sense single-stranded RNA virus that can direct the production of new viral particles after being injected into a host cell

inflammation General term for the tissue accumulation of fluid, proteins, and cells from the blood in response to injury caused by trauma or infection

innate (non-specific) immunity Immunity that occurs as a first response to infection involving cells and proteins that are innately present from birth; found in some form in all multicellular eukaryotes

insertion Mutation in which one or more nucleotide bases are added to a DNA sequence

insertion sequences IS elements Transposable element consisting of the transposase gene flanked by inverted repeats

integrase An enzyme that mediates the integration of viral DNA into a host cell chromosome

interleukin-2 (IL-2) T-cell growth factor cytokine produced by activated $CD4^+$ T cells that induces resting cells to enter into cell division

intermediate filament Protein polymer 9–11 nm in diameter forming a portion of the cytoskeleton in eukaryal cells

intermediate host Host in which a parasite reproduces asexually and differentiates but does not reproduce sexually

intrinsic factor A characteristic inherent quality of the food, such as water and salt content

intron Non-protein coding region of a eukaryal gene; also called an "intervening sequence"

inversion Change in DNA sequence in which a section of DNA is inverted and reinserted into the genome

Ion Torrent A high-throughput sequencing method that measures a pH change with successive nucleotide additions to a growing DNA chain to identify many target DNA molecules simultaneously.

ionizing radiation High-energy, penetrating radiation in the form of short UV light (less than 124 nm), X-rays, or gamma rays; commonly used for pasteurization or sterilization of foods

irradiation Exposure to radiation, commonly used to reduce microbial contamination of food and surfaces

isoelectric point The pH at which a protein contains no charge

isoprenoid Hydrocarbon molecule in the archaeal plasma membrane built from 5-carbon isoprene subunits attached to glycerol 1-phosphate (G1P)

killed vaccine Vaccine composed of whole cells or viruses that have been physically inactivated by heat or chemical treatment yet retains the ability to generate protective immunity in the host; *see also* inactivated vaccine

kinetoplast Large mass of DNA found within the mitochondrion of a trypanosome

knockout mutation Recombination that disrupts a gene

Koch's postulates Guideline for demonstrating that a specific microbe causes a specific disease

lactic acid bacteria (LAB) Grouping of Gram-positive bacteria characterized by production of lactic acid as a main product of their fermentative metabolism; includes various members of *Streptococcus*, *Lactobacillus*, *Lactococcus*, and *Bifidobacterium*

lactoferrin Small iron-transporting protein found in body secretions such as milk, tears, and saliva and found intracellularly in the granules of phagocytes

lag phase Initial period of growth during which cells grow slowly as they adjust to new surroundings

lagging strand Strand of replicating DNA that shows discontinuous elongation from the replication fork

latency-associated transcript (LAT) Herpesvirus transcript made during latency

latent infection Infection characterized by a delay or cessation of disease; in viral disease, characterized by limited transcription of the viral genome; results in reduced immune response; *see also* latency

laws of thermodynamics Set of rules that govern all energy conversions

lecithinase Phospholipase cytolysin that disrupts cell membranes by hydrolyzing various phospholipids, such as phosphatidylcholine, found in eukaryal membranes

lectin Protein produced by plants and animals that binds specific, usually foreign, carbohydrates

lectin pathway Complement cascade activation pathway initiated by the complexing of mannose-binding lectin with other serum proteins to produce C1-like activity, which activates the complement cascade

leghemoglobin An O_2-binding protein produced in root nodules by the plant cells, which protects the nitrogenase enzyme of bacteroids from O_2^- inactivation

lethal dose 50 (LD_{50}) Amount of virus that kills 50 percent of infected hosts

leukocyte Cell with immune functions; includes lymphocytes, neutrophils, monocytes, and macrophages; also known as "white blood cells"

lichen Symbiotic life-form consisting of a fungal species and one or more species of photosynthetic cyanobacteria and/or algae

ligand Molecule that binds to a cell receptor

ligase Enzyme that joins a 5′-phosphate end and a 3′-OH end in a DNA strand; *see also* DNA ligase

light reactions Reactions that convert light energy to chemical energy

lipid Organic macromolecule that does not dissolve in water; important component of cell membranes

lipid raft Pocket of specific lipids within a membrane that often is associated with specific membrane proteins

lipooligosaccharide (LOS) Non-LPS endotoxin produced by some Gram-negative bacteria, which lacks the outer O-antigen component of LPS but maintains the toxic activity of LPS due to the presence of an intact lipid A component

lipopolysaccharide (LPS) Molecule comprising the outer layer of the outer membrane in Gram-negative bacteria; composed of lipid A, a core polysaccharide, and an O side chain

liposome Vesicle made from cell membrane material

lipoteichoic acid (LTA) Cell wall molecule produced by many Gram-positive bacteria and composed of ribose or glycerol polymers and anchored to the cytoplasmic membrane by a lipid tail

liquid chromatography-mass spectrometry (LC-MS) An analytical chemistry approach using liquid chromatography for physical separation alongside mass analysis for measuring the mass of targeted molecules.

lithotroph Organism that removes electrons from inorganic reduced molecules, such as H_2S, H_2, or elemental sulfur (S^0)

lophotrichous Refers to bacterial cells with more than one flagellum at one or both ends

low-temperature hold (LTH) Pasteurization method that heats a large volume of liquid to a low temperature (at least 62.8°C) for a long period of time (30 minutes or more)

lymphocyte Type of leukocyte possessing specific receptors for recognizing antigen or MHC I molecules presented on other cells; includes NK cells, B cells, and T cells

lyophilization Process for preserving food, whereby food is frozen and then dried under a vacuum, allowing removal of water by sublimation; *see also* freeze-drying

lysogen Bacterial cell containing a prophage

lysosome Intracellular granule containing the enzyme lysozyme

lysostaphin Enzyme that cuts the pentaglycine crossbridge of peptidoglycan in *Staphylococcus aureus*

lysozyme Enzyme that degrades peptidoglycan by hydrolyzing the bond between NAG and NAM

macromolecule Large, complex molecule composed of simpler subunits

macrophage Phagocytic leukocyte found in tissue and derived from a blood monocyte; proficient antigen-presenting cells capable of activating T cells of the adaptive immune system

magnetosome Membrane-enclosed structure that contains magnetite

malaria Disease characterized by recurring bouts of chills and fever; caused by the protozoan parasite *Plasmodium* transmitted between humans by the female *Anopheles* mosquito

mannose-binding lectin (MBL) Serum pattern recognition receptor (PRR) of the innate immune system that binds mannose polymers of yeast and bacterial cell walls

mass spectrometry (MS) Technique that involves ionization of target chemicals to characterize ions based on their corresponding mass to charge ratio.

mast cell Cytotoxic cell of the innate immune system found widely in tissues of the body; potent stimulator of inflammation due to the release of the vasodilator histamine from its granules upon stimulation

maternal transmission Direct inheritance of a genetic trait, infection, or symbiont from mother to offspring

mechanical transmission Spread of an infectious agent from one host to another via a vector that physically carries the infectious agent

meiosis Type of nuclear division in eukaryal cells that results in production of haploid cells from a diploid cell

melanin Pigment synthesized by a variety of organisms; in invertebrates, melanin production is a primary innate defense used to encapsidate foreign agents in the body and has direct toxic effects.

membrane attack complex (MAC) Pore-forming structure resulting from complement activation, composed of complement factors C5b, C6, C7, C8, and polymerized C9 that forms in microbial membranes to cause lysis

memory cell Long-lived B or T cell that is produced following strong stimulation of a naïve B or T cell

memory response Immune repsonse that originates from the stimulation of memory cells and is characterized by a faster and more vigorous adaptive immune response upon repeated exposure to antigen; *see also* anamnestic response

merodiploid Partially diploid cell produced by introduction of genome region on a plasmid

merozoite Stage of protozoal parasite; in malaria, released from the liver and can invade human red blood cells

mesocosm Medium- to large-sized contained outdoor enclosure used for experimental study of ecosystems under controlled conditions

mesophile Organism that grows optimally at temperatures between 15°C and 40°C

messenger RNA (mRNA) RNA molecule that is translated to produce a polypeptide

metabolism Chemical reactions within a cell that extract nutrients and energy from the environment and transform them into new biological materials

metagenomics Study of genomes isolated from environmental samples using cultivation-independent methods

methanogen Archaeon that produces methane (CH_4)

methanogenesis Anaerobic metabolic process with methane (CH_4) as a product

methanotroph Organism that can metabolize methane (CH_4)

methicillin-resistant *Staphylococcus aureus* (MRSA) Strain of Staphylococcus aureus that is resistant to a wide variety of antibacterial medications, including methicillin

methyl-accepting chemotaxis protein (MCPs) Transmembrane sensory protein that can sense the presence of attractant or repellent molecules

methylotroph Organism capable of metabolizing 1-carbon compounds such as methane (CH_4) and methanol (CH_3OH)

micro RNA (miRNA) Small RNA molecule that regulates the expression of genes

microaerophile Organism that grows optimally at O_2 concentrations lower than are typically present in the atmosphere

microarray Solid support on which single-stranded DNA molecules within a genome are fixed in position; can be used to

study the transcriptional activity of all genes in the genome simultaneously

microbes Term that includes both microorganisms and viruses

microbial ecology The study of relationships between microbes and their biotic and abiotic environment

microbiology The study of microbes

microbiome The total of all the microbes living in a defined environment, such as soil, the human body, or even part of the body

microcosm Contained laboratory experimental system used for study of ecosystem processes under controlled conditions

microfilament Polymer of actin about 7 nm in diameter forming a portion of the cytoskeleton in eukaryal cells

micronutrient Chemical such as zinc or copper needed in small amounts for growth

microorganism Microscopic form of life

microtubule Polymer of α- and β-tubulin dimers that assemble into fiber about 24 nm in diameter forming a portion of the cytoskeleton in eukaryal cells

minimal inhibitory concentration (MIC) Lowest concentration of a drug at which no growth of the microbe being tested occurs in vitro after a standardized period of time; gives a measure of the drug susceptibility of a microbe

mismatch repair Process that corrects errors in DNA replication by excising several bases around the mismatched base, filling in the resulting gap with the correct bases, and linking together the adjoining fragments

missense mutation Change of a nucleotide base that results in substitution of a different amino acid in a polypeptide

mitochondrion *pl.* **mitochondria** Organelle that contains the electron transport chain and produces the majority of ATP within the cell

mitogen Chemical that promotes cell division

mitosis Type of nuclear division in eukaryal cells that results in production of two genetically identical nuclei

model organism Organism that has been so thoroughly studied that its traits define much of the understanding of other organisms within the group

modified atmosphere packaging (MAP) Packaging technology that substitutes the atmospheric air inside the package with a gas mixture designed to extend the shelf life of a food product

molecular chaperone Protein that helps other proteins to fold or to refold properly

molecular cloning Replication of recombinant DNA molecules; *see also* DNA cloning

molecular Koch's postulates Guideline using molecular tools to demonstrate that a specific microbial product is a virulence factor

molecular mimicry Process in which immune cells react against host antigens that resemble antigens of a pathogen

monocistronic Molecule of mRNA that codes for a single polypeptide

monoclonal antibody (mAb) Antibody that specifically binds a single unique epitope of an antigen; purposefully produced, and usually of IgG class, for diagnostic or research purposes

monocyte Mononuclear leukocyte of the innate immune system found circulating in the blood and maturing into a macrophage upon migration into the tissue

monotrichous Refers to bacterial cells with a single flagellum

morbidity rate Rate of disease

mortality rate Rate of death associated with disease

most probable number (MPN) Presumptive test used to estimate fecal coliform bacteria numbers in a water sample

mucociliary clearance Movement of mucus and entrapped particles out of body passages by the coordinated rhythmic movement of the cilia of special ciliated epithelial cells

mucosal membrane Any of the body's internal surfaces that are lined with mucus-coated epithelium

mucus Viscous secreted fluid containing mucins produced by and covering mucosal surfaces of the body

multiple cloning site Short DNA segment in a cloning vector that contains a cluster of different restriction sites that each appear only once in the plasmid

mutagen Agent that increases the rate of mutation

mutation Heritable change in the base sequence of the genome

mutualism Symbiotic relationship in which both partners benefit

mycelium *pl.* **mycelia** Three-dimensional network of hyphae found in fungi and some bacteria

mycobiont The fungal partner in a lichen

***N*-acyl-homoserine lactone (AHL)** Autoinducer with the ability to induce luminescence

nanotechnology Development and use of devices that are nanometers in size

natural killer (NK) cell Cytotoxic lymphocyte of the innate immune system that recognizes infected and abnormal cells and kills them by releasing toxic granular contents, causing apoptosis of the target cell

necrosis Cell death that occurs through chemical or physical cell injury or loss of oxygen supply; results in cell rupture and the release of toxic cellular contents and cytokines to the surrounding tissues, producing further cell death and triggering inflammation

negative control Regulation of transcription involving a repressor that blocks transcription

negative-sense RNA or ssRNA (-) Viral genomic RNA that is complementary to the viral messenger (positive-sense) RNA

net community productivity Amount of carbon fixed in organic matter minus the amount of carbon lost via respiration

neutrophil Phagocytic cell of the innate immune system containing numerous cytoplasmic granules and characterized by a multilobed nucleus; also known as "polymorphonuclear leukocyte" (PMN)

neutrophile Organism that grows optimally in environments with pH close to neutrality (5.5–8.5)

next-generation sequencing Use of post-Sanger-sequencing platforms to sequence many DNA fragments simultaneously and at a fraction of the cost of previous electrophoresis-based approaches; *see also* high-throughput sequencing

niche Specific functional role of an organism within an ecosystem

nicotinamide adenine dinucleotide (NAD) Cytoplasmic electron carrier molecule serving as a coenzyme

nitrification Conversion of ammonia (NH_3) into nitrite (NO_2^-) and then into nitrate (NO_3^-)

nitrifiers Microorganisms that carry out ammonia (NH_3) and nitrite (NO_2^-) oxidation in the process of nitrification

nitrogen fixation Conversion of atmospheric N_2 into inorganic compounds, such as ammonia, for cell use; *see also* nitrogenase

nitrogenase Large enzyme complex responsible for the conversion of N_2 to inorganic compounds (nitrogen fixation)

nitrogenase complex Multi-enzyme complex that catalyzes the fixation of dinitrogen gas into ammonia

non-homologous recombination Process that occurs when two segments of DNA with little or no sequence similarity exchange or replace some portion of their DNA

non-ionizing radiation Radiation of wavelength longer than 240 nm that does not possess sufficient energy to produce ions in solution; non-ionizing UV radiation of wavelength 240–280 nm can damage DNA

non-perishable food Food that does not support microbial growth due to lack of available water

nonsense mutation Change in a nucleotide base that results in production of a stop codon

Northern blot Use of nucleic acid probes specific to a gene of interest to identify the size of targeted RNA templates of interest.

nuclear magnetic resonance (NMR) Technique to determine protein structure based on measurement of distances between atomic nuclei

nucleic acid Polymer of nucleotides composed of a sugar, a phosphate moiety, and a nitrogen-containing base; includes DNA and RNA

nucleocapsid The capsid and genome of a virus

nucleoid Region in bacterial and archaeal cells that contains the chromosomal DNA

nucleoside analog Antiviral structural analog of nucleosides capable of inhibiting DNA or RNA synthesis by incorporation into growing nucleic acid chains by viral polymerases; prevents the addition of further nucleotides, thus interfering with viral nucleic acid replication

nucleus Membrane-enclosed organelle that contains the chromosomes in a eukaryal cell

nutritional mutant Organism with altered metabolic requirements

obligate aerobe Organism that requires oxygen for growth

obligate anaerobe Organism that cannot grow in the presence of oxygen

obligate intracellular parasite Infectious agent that can replicate only within a living host cell; cannot replicate independently

Okazaki fragment Newly synthesized pieces of DNA and their RNA primers found on the lagging strand

oligotrophy Use of nutrients present in very low concentrations

oncogene Altered form of a proto-oncogene that can lead to uncontrolled cell growth and the development of tumors

oncolytic viruse Virus that infects and kills cancerous cells without harming normal cells

oocyst Structure of protozoal parasites in which meiosis occurs

ookinete Cell formed by fusion of gametes in protozoal parasites like the malaria parasite, forms an oocyst where meiosis occurs

open reading frames (ORFs) Sequence of DNA that can be translated to produce a polypeptide

operational taxonomic unit (OTU) Group of organisms that shares at least 97% SSU rRNA gene sequence identity

operator DNA sequence to which regulatory proteins can bind

operon Transcriptional unit consisting of a series of structural genes that code for polypeptides and the regulatory elements that affect their transcription

opportunistic pathogen Microbe that causes disease only when a host has been compromised

opsonin Any component of the immune system capable of binding and coating a microbial surface to enhance its phagocytic uptake; examples include antibody, C3b, C-reactive protein, and mannose-binding lectin

opsonization Coating of a microbial surface with host components, such as complement or antibody, to aid in phagocytosis

optical density Measure from a spectrophotometer that is roughly proportional to population density within a sample

organelle Intracellular compartment that performs a specific function for a cell

organotroph Organism that removes electrons from organic molecules, such as glucose

oriC Origin of replication; specific site on bacterial chromosome where DNA replication begins

orthologs Gene that evolves from a common ancestral gene and performs the same function in different organisms

outbreak Cluster of cases appearing within a short period of time in a localized population

outer membrane Bilayer found outside the peptidoglycan layer in the cell envelope of Gram-negative bacteria; inner layer is primarily phospholipid, outer layer contains lipopolysaccharide (LPS)

oxidation Removal of an electron(s) from a molecule or atom (the electron donor)

oxidative phosphorylation Chemiosmotic process used by chemotrophs to generate ATP using the energy captured from oxidation of a chemical substrate

oxygenic photosynthesis Phototrophy carried out by cyanobacteria and chloroplasts that produces O_2 and combines PS I with PS II

ozonation The use of ozone (O_3), a powerful oxidizing agent, to disinfect water

PacBio High-throughput sequencing method for sequencing relatively large DNA fragments of interest

packaging sequence A motif on the viral genome that interacts with viral proteins to cause packaging into the capsid

pan-genome Collection of all genes from multiple representatives from a single species or clade within specific bacteria or archaea pf interest.

pandemic Global epidemic, usually on more than one continent

papilloma Wart; caused by a virus

paralog Gene that arises from a duplication event; paralogous genes may develop different functions

parasitemia Presence of parasites in the blood of an infected host

parasitism Symbiotic relationship in which one partner benefits by damaging the other

pasteurization Any technique using mild heating, irradiation, or high pressure to destroy spoilage or pathogenic microorganisms without cooking the food product

pasteurization Any technique using mild heating, irradiation, or high pressure to destroy spoilage or pathogenic microorganisms without cooking the food product

pathogen A microbe that routinely causes disease

pathogen-associated molecular pattern (PAMP) Broad-based molecular signature or motif commonly associated with pathogens but not normally found in the host

pathogenesis Process by which a pathogen causes disease

pathogenicity island (PAI) Region of a chromosome containing multiple virulence factor genes

pathogenicity Relative measurement of the ability of a microbe to cause disease

pattern recognition receptor (PRR) Receptor of the innate immune system capable of recognizing pathogen-associated molecular patterns (PAMPs)

penicillin-binding protein (PBP) Bacterial transpeptidase required for joining together the subunits that make up peptidoglycan of bacterial cell walls

pentose phosphate pathway Glycolytic pathway interacting with the EMP pathway where glucose is converted to a number of 3- to 7-carbon compounds, many of which are used for biosynthesis, and producing NADPH and ATP

peptidoglycan Cross-linked polysaccharide-peptide matrix found in bacterial cell walls

percent G+C Proportion of guanines or cytosines within a genome of interest

perforin Peptide produced by cytotoxic cells of the immune system that is thought to produce pores in target cell membranes

periplasm Space between the inner membrane and outer membrane in Gram-negative bacteria

perishable food Food that readily supports survival and growth of microorganisms, such as fresh lettuce, strawberries, and meat

peristalsis Sequential contraction of smooth muscles that moves material, such as food, along the digestive tract

peritrichous Refers to bacteria with multiple flagella spread over the surface of the cell

persistent infection Viral infection during which new viral particles are continuously produced; also called a "chronic infection"

persistent organic pollutant (POP) Chemicals, such as synthetic drugs and pesticides, that are resistant to degradation and can be present in low concentrations in effluent waters; POPs tend to bioaccumulate in animal tissues

Petroff–Hausser counting chamber Specially constructed microscope slide with a chamber of defined depth and a grid marking off squares of defined area; used for determining cell concentration

phagocyte Leukocyte, such as a macrophage or neutrophil, capable of engulfing particulate matter, such as bacterial cells

phagocytosis Form of endocytosis involving the cellular engulfment of particulate matter, such as bacterial cells, by the formation of cytoplasmic extensions that surround the particle and fuse to form a membrane-bound endosome vesicle called a "phagosome"

phagolysosome Digestive vesicle formed in the endocytic pathway from the fusion of a phagosome with an intracellular lysosome(s)

phagosome Membrane-bound vesicle produced through phagocytosis and containing engulfed particles

phosphorylation Addition of a phosphate group to the —OH group of certain amino acids

photobiont The photosynthetic algal or cyanobacterial partner in a lichen

photolyase Enzyme that repairs thymine dimers by cleaving the covalent bonds linking adjacent thymine bases

photophosphorylation Chemiosmotic process used by phototrophs to generate ATP using light energy

photosynthesis Process by which light energy is captured by organisms to generate chemical energy in the form of ATP to carry out metabolic functions

photosystem Organized structure of photopigments consisting of antennae and a reaction center that absorb energy from photons of light to ultimately generate electrons for production of chemical energy

phototroph Organism that captures light energy, or photons, through the process of photosynthesis to generate chemical energy, such as ATP

phototrophy Acquisition of energy from sunlight

phylogeny Evolutionary history of an organism

phytanyl Isoprene polymer in the plasma membrane of some archaeons; 20-carbon hydrocarbon

phytopathogenic fungus Fungus that causes disease in plants

pickling Acidification of food for storage by adding dilute acetic acid (vinegar) or allowing lactic or acetic acid production to occur naturally through microbial fermentation

piezophile Organism that can withstand high pressure

pilus *pl.* **pili** Proteinaceous fiber that protrudes from the cell surface; often used for attachment

plaque Localized clear area on a lawn of cells caused by cell death; adherent microorganisms and extracellular matrix substances, often produced by both the host and the microbes themselves

plasma cell B-cell-derived, terminally differentiated cell that secretes antibody

plasma membrane Selectively permeable bilayer enclosing the cytoplasm of a cell; composed primarily of phospholipids

plasmid Small, circular extrachromosomal DNA molecule

pleiomorphic Variable in shape

polycistronic Molecule of bacterial mRNA that codes for two or more different polypeptides

polyhydroxyalkanoate (PHA) Natural polyester polymer stored by bacteria when carbon is abundant and used when nutrients are scarce; possible source of biodegradable bioplastic

polyhydroxybutyrate (PHB) Simplest and most common PHA chain produced by microbes

polymerase chain reaction (PCR) Technique that quickly amplifies specific pieces of DNA

polypeptide Macromolecule composed of amino acids joined by peptide bonds; proteins

polysaccharide Macromolecule composed of monosaccharides used in structure or for energy storage

porin Channel in the outer membrane of Gram-negative bacteria that allows movement of essential molecules

positive control Regulation of transcription involving regulatory molecules that increase transcription

positive-sense RNA or ssRNA (+) Viral genomic RNA that can be translated by the host cell (messenger RNA)

post-transcriptional modification Event that occurs after transcription in the production of functional mRNA from the RNA transcript

potable Water suitable for drinking and judged to be free from intestinal bacteria and pathogens

precursor activation Allosteric activation of a late enzyme in a metabolic pathway by a substrate used by an earlier enzyme in the series

prevalence Total number of cases of a disease in a population at a particular time or during a particular time period

primary endosymbiont Obligate endosymbiont that shows evidence of co-speciation with a host and is absolutely required by the host for survival and/or fertility

primary immune response Response of the adaptive system that occurs with first exposure to an antigen, involving activation of naïve T cells and B cells, in the absence of immunological memory

primary metabolite Metabolic product required for growth; produced by microorganisms during the exponential growth phase

primary pathogen Microbe that causes disease in otherwise healthy hosts

primary sludge Sludge that is a product of primary treatment of wastewater; consisting of large particulate matter

primary treatment Physical removal of particulate matter by sedimentation to form sludge and oils by skimming

primase Synthesizes short segments of RNA needed to prime DNA replication in bacteria; also called DnaG

primer Short piece of single-stranded DNA or RNA to which DNA polymerase can add new bases

primer walking Technique in which a DNA sequence obtained from an early sequencing run is used to design a new primer that will anneal farther along the fragment to be sequenced; consecutive runs allow sequencing of the entire DNA segment

prion Infectious agent (proteinaceous infectious particle) composed of protein that can replicate within a host cell and cause transmissible spongiform encephalopathies

productive infection Outcome of a viral infection in which new infectious viral particles are produced

progenote Woese's proposed first living organism containing information stored in genes not yet linked together on chromosomes

progressive hypothesis Premise that viruses originated when genetic material in a cell gained functions that allowed the DNA or RNA to replicate and be transmitted in a semi-autonomous fashion

proinflammatory molecule Any molecule produced by cells, such as certain cytokines, which induces or stimulates the inflammatory response; examples include IL-1, IL-12, TNF-α, and IFN-γ

prokaryote Organism that lacks a membrane-bound nucleus; includes bacteria and archaea

promoter Region of DNA where RNA polymerase binds to begin transcription

proofreading activity Action of DNA polymerase that identifies and removes an incorrect base that has been incorporated into a growing chain

propagated epidemic Pattern of disease characterized by infection passing from one host to another, either directly or indirectly

prophage Phage DNA integrated into host DNA; latent form of a temperate phage

protease inhibitor Drug that blocks the activity of enzymes that degrade proteins; required for the formation of infectious retroviral particles

proteasome Cytoplasmic complexes in eukaryal cells that degrade cellular proteins into peptides that can be presented on MHC I molecules

proteome Collection of proteins within a cell under specific conditions

proto-oncogene Gene involved in normal cell growth

proton motive force Strong potential difference generated by the displacement of protons to one side of the membrane as they are pumped by an electron transport system; drives a flow of H- through ATP synthase to produce ATP

prototroph Organism that can synthesize all necessary cellular constituents from a single organic carbon source and inorganic precursors

provirus Viral DNA that is integrated into the host DNA; latent form of a virus

pseudomurein Polymer similar to peptidoglycan that is found in the cell wall of some archaeons

psychrophile Organism that grows optimally at temperatures less than 15°C

purine Nitrogenous base containing a double-ring structure; includes adenine (A) and guanine (G)

pyrimidine Nitrogenous base containing a single-ring structure; includes cytosine (C), thymine (T), and uracil (U)

pyrosequencing Next generation sequencing method in which incorporation of a pyrophosphate (PP_i) drives a luciferase reaction, producing light that can be detected with a charge-coupled device (CCD) camera; *see also* 454 DNA sequencing

quiescent cell Cell that is not actively dividing

quorum sensing Detection of the presence and number of microbes in the environment that leads to regulation of density-dependent gene expression

random mutagenesis Exposure of genetic material to mutagens such as X-rays, UV light, or chemicals that increase the probability of any mutation

reactivation Resumption of disease after a latent period; can occur due to cellular stress in the host; in viruses, resumption of transcription of a previously latent viral genome

reassortment Packaging of gene segments from two or more parental virus strains into one virus

receptor Membrane protein that binds to a specific molecule in the environment, such as a viral attachment protein

recombinant DNA Linked DNA sequences from two or more organisms forming a DNA molecule that does not otherwise exist in the biological world

red biotechnology Use of advanced biological processes in medical applications

redox reactions Reduction and oxidation reactions involving the transfer of electrons from one molecule to another

reduction Addition of an electron(s) to a molecule or atom (the electron acceptor)

reduction potential Tendency of a molecule to accept electrons; represented by the electrode potential, *E*, which is measured in units of volts (V); also called redox potential

reductive TCA cycle Cycle used by many autotrophic bacteria to produce carbon compounds; essentially runs the TCA cycle in reverse to consume CO_2 to produce carbon compounds at the expense of ATP and electrons, usually in the form of NADH

refrigeration Food preservation done at cold temperature, usually 1–4°C

regressive hypothesis Premise that viruses represent a form of "life" that has lost some of its essential features and has become dependent on a host

regulons Collection of genes and operators globally affected by the same regulatory protein

replica plating Technique to screen colonies for phenotypes that cannot be identified by phenotypic selection; location of mutants on a plate can be determined by location of colonies on a replica plate using selective media or conditions

replication bubble Single-stranded regions where DNA replication proceeds between replication forks

replicon DNA molecule that replicates from a single origin of replication

reporter gene Promoterless gene that is not expressed unless inserted within an actively transcribed gene

repressor Molecule that blocks transcription

reproduction Production of new copies of an organism

reservoir host Natural host that supports replication of a pathogen

reservoir Physical locations of chemical elements that are acted upon through biogeochemical cycles; major global reservoirs include terrestrial (lithosphere), aquatic (hydrosphere), atmospheric (atmosphere), and living (biosphere)

resistance (R) plasmid Plasmid that confers the ability to resist antimicrobial activity of one or usually several drugs

resolvase Enzyme that separates joined DNA molecules in replicative transposition

respiration Metabolic pathway in which electrons generated from glycolytic processing are passed through an electron transport system and on to an inorganic or sometimes an organic terminal electron acceptor; cellular respiration can be aerobic, using oxygen as a terminal electron acceptor, or anaerobic

respiratory (oxidative) burst Generation of highly toxic oxygen compounds, such as nitric oxide and hydrogen peroxide, inside the phagolysosome to kill phagocytosed microbes

response regulator (RR) Protein that regulates transcription in a two-component regulatory system

restriction enzyme Enzyme that cleaves DNA at a specific sequence; may protect host cell from viral infection by cleaving viral DNA

restriction site DNA sequence recognized by a restriction enzyme

restriction-modification system Anti-viral defense system in bacteria involving specific restriction endonucleases and DNA modification enzymes

retrotransposon Piece of DNA that is converted to RNA that can move to a new location within the genome where it is converted back to DNA by a reverse transcriptase enzyme and reinserted into the genome

reverse DNA gyrase Enzyme in hyperthermophiles that increases the supercoiling of DNA

reverse transcriptase PCR (RT-PCR) Process using reverse transcriptase to convert a small amount of RNA into cDNA that can then be amplified using a PCR procedure

reversion Spontaneous recovery of a mutant to perform an action, such as synthesis of an amino acid

rhizobia Refers to various members of the order Rhizobiales, characterized by their ability to form root nodules; the majority of the group are α-proteobacteria, and some are β-proteobacteria

rhizosphere Region of soil immediately surrounding plant roots

ribosomal RNA (rRNA) RNA involved in the structure of ribosomes

ribosome Organelle where protein synthesis, or translation, occurs

riboswitch Sequence of mRNA that binds an effector molecule that regulates transcription of the mRNA molecule

ribozyme RNA molecule that can act as a catalyst within a cell

RNA polymerase Enzyme that transcribes DNA to produce RNA; also called DNA-dependent RNA polymerase

RNA-dependent DNA polymerase or reverse transcriptase (RT) A retroviral polymerase that produces double-stranded DNA using a single-stranded RNA template such as reverse transcriptase

RNA-dependent RNA polymerase A viral polymerase that produces RNA from an RNA template

RNA-seq Methodology involving high-throughput sequencing of cDNA fragments derived from extracted RNA from an organism or sample of interest

root nodule Encasing structure formed on plant roots that houses endosymbiotic nitrogen-fixing bacteria

rumen fermentation Digestive system where the major site of fermentation is the rumen

rumen Major digestive organ that is the primary site of fermentation in a group of herbivores called "ruminants"

ruminant Herbivorous mammal possessing a digestive organ called the "rumen"

S-layer Crystalline-like layer of protein found on the surface of many bacterial cells

Sanger sequencing Technique to determine DNA sequence that relies on incorporation of chain-terminating dideoxy nucleotides and includes cloning of the fragment to be sequenced, DNA synthesis, and gel electrophoresis; *see also* dideoxy sequencing

satellite RNA Infectious agent of plants composed of an RNA genome and a protein coat that is encoded by a helper virus

satellite virus Infectious agent of plants composed of an RNA genome containing a gene that codes for its protein coat

schistosomiasis Infection with a species in the *Schistosoma* genus of flukes

secondary endosymbiont Endosymbiont of insects that can sometimes be found free-living and is not always present or essential and is not maternally transmitted

secondary metabolite Metabolic product not required for growth; often produced by microorganisms during the stationary phase of the growth curve

secondary sludge Sludge that is a product of secondary treatment of wastewater, consisting of accumulated floc material

secondary treatment Wastewater treatment procedure following primary treatment that makes use of microbial activities to degrade the organic content of the sewage; examples include use of a trickling filter or activated sludge treatment

secretory pathway System of membranous organelles involved in protein trafficking within a eukaryal cell

selective medium Growth medium designed to allow growth of only certain target organisms

selective toxicity Characteristic of antimicrobial drugs to exhibit a higher level of toxicity against infecting microbes than against host cells

semi-perishable food Food that is semi-dry, making it low in available water, and that does not easily support microbial growth

semiconservative replication DNA replication in which each strand of the original molecule serves as a template for the construction of a new strand; one strand of the original DNA molecule is found in each of the two new DNA molecules

septic shock Systemic inflammatory response due to bacterial infection, usually due to the presence of bacteria in the circulatory system

sequela *pl.* **sequelae** Damage indirectly resulting from an infection in the host but occurring after the infection has been cleared; thought to be immune-mediated

serotype Strain of a microbe identified by serotyping

serotyping Diagnostic method that uses antibodies for identifying and distinguishing closely related microbial strains or serotypes, based on differences in their surface antigens

serum resistance Characteristic of some bacterial pathogens to prevent lysis in the presence of serum containing complement factors

sewage Water carrying soluble or solid wastes originating from human activities, including farming, industry, and domestic wastes; *see also* wastewater

sex pilus *pl.* **pili** Special type of pilus that connects cells during conjugation, the transfer of DNA

sexual transmission Spread of an infectious agent that occurs during vaginal, anal, or oral sex

sexually transmitted infection (STIs) Infectious disease that is spread sexually through vaginal, anal, or oral sex

Shine–Dalgarno sequence Segment of mRNA that binds to the 16S rRNA of the small ribosomal subunit and properly aligns mRNA on the ribosome

shotgun sequencing Technique for sequencing DNA that shears DNA into short fragments that are sequenced, after which computer programs are used to identify regions of sequence overlap

shuttle vector Plasmid that can replicate in more than one host; typically contains more than one origin of replication

sickle-cell disease Systemic human disease resulting from a specific mutation in the gene that codes for the β-globin polypeptide in hemoglobin

siderophore Bacterial-secreted protein that binds iron from the surrounding medium for bacterial use

sigma (σ) factor Portion of RNA polymerase that recognizes the promoter sequence

sign Objective disease state that can be readily observed or measured, such as a rash or fever

signal peptide Short sequence of amino acids at the amino terminal end of a protein that targets it for the general secretory pathway in the plasma membrane

signal transduction Process producing a cellular response to an external stimulus

silent mutation Change in a nucleotide base that does not alter the amino acid sequence of a polypeptide

simian immunodeficiency virus (SIV) Virus found in non-human primates throughout Africa that may have given rise to HIV

single-stranded DNA-binding protein (SSB) Molecule that attaches to a newly formed single strand of DNA to keep the strands from reannealing

site-directed mutagenesis Method that induces specific mutations within a DNA molecule

site-specific recombination Non-homologous recombination at a particular sequence of DNA

slime layer Structure typically consisting of polysaccharides that surrounds cells of some bacterial species

SOS response Type of DNA repair in response to serious damage

Southern blot Technique for detecting specific DNA sequences by hybridization using labeled probes of complementary sequence

species Basic taxonomic group composed of similar strains that differ significantly from other groups of strains

spirillum *pl.* **spirilla** Bacterial cell shaped like a spiral

sporozoite Haploid infective cell of some protozoan parasites, including the malaria parasite

sRNA Small non-coding RNA molecule that often affects gene expression by interacting with existing mRNA

stable-isotope probing (SIP) Technique that exposes organisms to specific nutrient molecules labeled with ^{13}C or ^{15}N, thus labeling their DNA, which can later be extracted and analyzed

stalk Tubular extension of the cell envelope in some Gram-negative bacteria that increases cell surface area and aids in nutrient acquisition

starter culture Microbial inoculum used in the production of cultured dairy products, fruits, or grains

stationary phase Period of growth in which the rate of cell division equals the rate of cell death and population growth stops

stop codon Sequence of three nucleotides on mRNA that signals the end of translation; UAG, UGA, and UAA typically function as stop codons

strain Distinct subtype of a species that differs genetically, and often phenotypically, from other subtypes

streak plate Petri plate in which microbial cells are spread over a solid medium, separating individual cells that eventually produce isolated colonies

substrate Specific reactant converted by an enzyme into a product

substrate-level phosphorylation Enzymatic production of ATP through the transfer of a phosphate group from a reactive intermediate to ADP

subunit vaccine Vaccine composed of one or a select number of isolated antigens; not composed of whole cells or viruses; *see also* acellular vaccine

suicide plasmid Plasmid vector that cannot replicate in a host cell

sulfur globule Intracellular storage form of elemental sulfur

superantigen Toxin capable of evoking a systemic inflammatory response by directly crosslinking the T-cell receptor (TCR) of $CD4^+$ T cells with MHC II molecules of antigen-presenting cells, such as macrophages

supercoiling Highly twisted form of DNA that produces a more compact chromosome

surface array Crystalline-like layer of protein found on the surface of many bacterial cells; *see also* S-layer

susceptibility testing Controlled *in vitro* testing done to establish the sensitivity of a particular microorganism to various antimicrobial agents

symbiont Organism of one species that has entered into a long-standing and intimate relationship with another species

symbiosis Long-standing, intimate relationship between two different species

symport Mechanism of co-transport that couples the movement of one substance across the plasma membrane with movement of another in the same direction

symptom Subjective disease state, such as muscle aches

syncytium *pl.* **syncytia** Multinuclear mass formed by the fusion of cells

synthetic biology Construction of new biological functions and systems from constituent parts

syntrophic partnership Relationship in which the metabolic activities of the organisms are mutually dependent

systemic inflammatory response Inflammatory response involving a large portion of the body, including the circulatory system, that often leads to physiological shock characterized by a drastic drop in blood pressure because of fluid leaking from the circulatory system

T cell Lymphocyte of the adaptive immune system that matures in the thymus and expresses surface T-cell receptors (TCRs); also called T lymphocyte

T helper cell (T_H cell) Effector $CD4^+$ T cell that secretes cytokines involved in directing immune responses. *see also* $CD4^+$ T cell, T_H1 cell, and T_H2 cell

T-cell receptor (TCR) Membrane-bound immune receptor molecule expressed by T cells that binds specific antigen associated with MHC molecules

T-independent antigen Antigen that can stimulate B cells to proliferate into antibody-secreting plasma cells without requiring B-cell interaction with T cells; possesses highly repetitive structures with the ability to crosslink several BCRs on a B cell

tagged protein See fusion protein

taxon Named grouping in a hierarchical taxonomic system

teichoic acid Polymer of ribitol phosphate or glycerol phosphate attached to peptidoglycan chains in the cell wall of Gram-positive bacteria

telomerase DNA polymerase that replicates DNA at the ends of chromosomes in eukarya

telomere Non-transcribed region at the ends of each eukaryal chromosome

temperate phage Phage that usually integrates its genome into the genome of the host cell, where it is replicated along with the host DNA

terminal restriction fragment length polymorphism (T-RFLP) Technique to profile DNA in a microbial community using position of a restriction site closest to a labeled end of an amplified gene, usually the SSU rRNA gene

tertiary treatment Wastewater treatment protocol sometimes used following secondary treatment, involving additional biological or physicochemical procedures to further remove organic or inorganic material prior to disinfection and release to a natural water source

T_H1 cell Cell belonging to a subset of T helper (T_H) cells that secretes cytokines, such as IL-2, IFN-γ, and TNF-β, to produce a cell-mediated immune response

T_H2 cell Cell belonging to a subset of T_H cells that secretes cytokines, such as IL-4, IL-5, IL-6, IL-10, and IL-13, to produce a humoral immune response

thermocline Layer of water in deep lakes that separates warmer, low-density water from lower, colder, high-density water; characterized by rapid change in temperature and density

thermophile Organism that grows optimally at temperatures greater than 55°C

thermosome Protein complex that functions as a molecular chaperone to refold partially denatured proteins in hyperthermophiles

thylakoids Layered photosynthetic membrane structures

thymine (T) Pyrimidine nitrogenous base, along with adenine and uracil

Ti plasmid Tumor-inducing plasmid in *Agrobacterium tumefaciens* that can transfer genes into a plant cell where they are expressed

tissue culture infectious dose 50 ($TCID_{50}$) Amount of virus that causes cytopathic effects in tissue culture cells 50 percent of the time

titer Concentration of a preparation

Toll-like receptor (TLR) Membrane-associated pattern recognition receptor (PRR) of the innate immune system that recognizes a panel of pathogen-associated molecular patterns (PAMPs) and can induce expression of various cytokines and other products

topoisomerase Enzyme that encourages supercoiling in a chromosome

toxic shock Systemic inflammatory response due to the presence of certain microbial toxins in the circulatory system

toxin Substance of biological origin that damages a host

toxoid Microbial toxin that has been denatured through chemical or physical processes in order to be used in a vaccine

transconjugant Cell that has incorporated DNA from another cell via conjugation

transcription factor One of a series of proteins required for transcription

transcription Process through which segments of DNA serve as templates for the production of complementary strands of single-stranded RNA

transcriptome Set of transcripts encoded by each of the genes within a genome

transducing retrovirus Retrovirus that has acquired a cellular gene and can transfer it to a new cell

transductant Bacterial cell that contains DNA obtained via transduction

transduction Transfer of bacterial DNA from one cell to another by a bacteriophage; a type of horizontal gene transfer

transfer RNA (tRNA) RNA molecule that delivers an amino acid to the ribosome for incorporation into a growing polypeptide during translation

transformation A type of horizontal gene transfer in which a piece of free DNA is taken up by a cell; change within a cell that causes it to become cancer-like

transgenic plant Plant containing DNA that has been transferred from a different type of organism

translation Process of protein synthesis

translocation Change in DNA sequence in which a segment of a chromosome breaks off and reattaches to a different location

transmissible spongiform encephalopathy (TSE) Neurological disease caused by prions

transmission Spread of an infectious agent from one host to another or from its source

transposable element Mobile genetic element

transposase Enzyme that recognizes inverted repeat sequences on a transposon

transposition Movement of DNA via mobile genetic elements or transposable elements

transposon Transposable element that may also contain other genes such as antibiotic resistance genes

tricarboxylic acid (TCA) cycle Series of metabolic reactions used in the oxidation of carbon compounds, producing CO_2, NADH, and ATP; also called the citric acid cycle or Krebs cycle

trichome Smooth unbranched chain of cells seen in associations of cyanobacteria

trickling filter A form of secondary treatment for wastewater effluent that uses a filter bed of solid material, which supports a microbial biofilm community; effluent is distributed across the bed surface by a rotary spray boom

trophozoite Active feeding form of a spore-forming protozoan

tumor suppressor Cellular protein that inhibits cellular replication

tumorigenesis Formation of a tumor

turbidity Cloudiness of a liquid that can indicate density of suspended particles or cells

two-component regulatory system Regulatory system that includes one protein that acts as a sensor and another protein that regulates transcription

Type I interferon (IFN) Includes the cytokines interferon-α and -β produced by many cell types upon viral infection to induce an antiviral state in infected and uninfected neighboring cells

type III secretion system Protein complex found in many Gram-negative pathogens that serves as an injection system to deliver virulence factors, such as toxins, directly into the target cell by forming a tunnel that passes through both bacterial membranes and through the host cell plasma membrane

type IV secretion system Protein complex found in some Gram-negative pathogens that transports toxins or other components directly across both bacterial membranes into the immediate environment or directly into the host cells

ultraviolet (UV) radiation Light with a wavelength range of 100–400 nm

uncoating Disassembly of viral capsids releasing the viral genome

uracil (U) Pyrimidine base found in RNA that interacts with adenine (A)

vaccination Physical act of injecting or inoculating an immunizing substance into the body

vaccine coverage rate Proportion of individuals in the population that must be immunized to achieve herd immunity

vaccine efficacy Effectiveness of a vaccine measured by the average degree of protection it affords a population

vaccine failure Development of disease in individuals despite having received vaccination; usually due to the failure of certain individuals to mount an effective immune response to an immunizing agent

vaccine Preparation containing antigen(s) used to immunize against disease

vasodilation An increase of the diameter of the blood vessel, such as during inflammation

vector-borne transmission Spread of an infectious agent from an infected individual to another organism such as an insect that then transmits the infectious agent to a different susceptible host

vertical transmission Spread of an infectious agent from parent to child

vibrio Bacterial cell shaped like a curved rod

viral attachment protein Protein expressed by a virus used for attachment to the host cell

viral envelope A host cell-derived membrane that surrounds the capsid of certain viruses

virion Complete viral particle

viroid Infectious agent of plants composed of naked RNA

virophage Virus-like particle that replicates in host cell coinfected with helper virus and is detrimental to the helper virus

virulence Degree of severity of disease a pathogen is capable of causing

virulence factor Product made by a pathogen that enhances its ability to cause disease

virulent phage Phage that lyses and kills the host cell when exiting

virus An acellular particle including a DNA or RNA genome surrounded by a protein coat that can replicate only within living host cells

wastewater Water carrying soluble or solid wastes originating from human activities, including farming, industry, and domestic wastes; *see also* sewage

water activity (a_w) Vapor pressure of a liquid relative to the vapor pressure of pure water under identical conditions; measure of water availability in an environment

white biotechnology Use of advanced biological processes in industrial applications

wild-type strain Organisms that usually possess the typical or representative characteristics of a species

X-ray crystallography Crystallization of proteins then subjected to X-ray diffraction to determine protein structure at the level of individual atoms

xenobiotic Chemical not naturally found in or produced by organisms; usually not degraded by microorganisms

xylanase Enzyme that degrades hemicellulose, a component of the plant cell wall

Z-ring Structure composed of FtsZ needed for bacterial cell division

zoonotic disease Infectious disease of animals that can cause disease when transmitted to humans

zoonotic transfer Spread of a infectious agent from its natural animal host to a human

zooplankton Drifting non-photosynthetic microorganisms that act as consumers in the ocean

zooxanthellae Endosymbiotic photosynthetic algal of coral polyps

Index

of the intestinal mucus, 576, 578f
microbes and, 491–493, 491f, 492f
samples, 479, 479f
Biofuels, 382–385
biodiesel and algae, 384, 384f
butanol and acetone, 384–385
ethanol, 382–384, 382f, 383f
Biogenic elements, 459
Biogeochemical cycles
carbon metabolism and, 462–471
major reactions involved in, 458, 458f
metal cycling, 482
microorganisms and, 25, 25f
nitrogen metabolism and, 471–476
nutrient cycling, 459–461
oxygen cycling, 477–478
phosphorous and sulfur and, 478–482
Biogeochemistry, terrestrial context and, 465, 465f
Bioinformatics, 309–312
Bioluminescence, 349, 349f
Biomass feedstock, 381–382
Bioplastics, 385–387, 385f
Bioprospecting, 364
Bioreactors, industrial fermentations and, 365–366, 365f
Biorefinery, 281f, 381–382
Bioremediation, 513–515, 514f
Biosphere, microbes and, 25, 25f
Biostimulation, 514
Biotechnology, 22–23
Biotic nitrogen cycle, 472, 473f
Biotin-labeled telomere probes, 232, 232f
Bishop, J. Michael, 254, 254f
Black Death, 27–28, 28f
Black smokers, 108, 108f, 518
Bloodletting, 821
Blue cheese, 538, 539f
Border Infectious Disease Surveillance (BIDS) Project, 632
Bordetella pertussis
cultivation of, 174, 174f
secretion system and, 720
virulence factors and, 713t
Borrelia burgdorferi, 62, 62f, 590, 630
Botox, 732, 732f
Botulinum toxin
action of, 727, 729f
good, bad, and ugly side of, 732–733, 732f
SNARE protein targets of, 727, 729t
source, activity, target cells and disease, 728t
Botulism
commercial canning and, 531
inadvertant victimization and, 729
red-breasted merganser victims of, 732, 732f
Brie cheese, 538, 539f
Brilliant green agar, 175t
Brown rot, 513
Bt toxins, 395, 395f
Bubonic plague, 602
Buchnera, 589–590, 689f
Buchnera aphidicola, 589
Bunyaviruses, 766–767, 767f
Butanol, 384–385

C

C-reactive protein, 649t, 652
Cable bacteria, 480
Callus cultures
infection of, 794–795, 794f
responses to infection, 795, 795f
Calvin cycle
carbon fixation and, 438–441
process diagram and, 440f
Camembert cheese, 538, 539f
Cancer
adenoviruses and, 776
cellular proliferation and, 774–775, 774f, 775f
cis-acting retroviruses and, 777–778, 778f
DNA tumor-causing viruses and, 770–779
immunoprecipitation and, 773
papilloviruses and, 770–776, 771f
RNA tumor-causing viruses and, 776–779
transducing retroviruses and, 778–779, 779f
viral infections and, 770–779, 770t
Candida albicans
human diseases and, 100, 100f
opportunistic characteristics of, 796, 796f
as opportunistic pathogen, 604
Candida species
oral cavity and, 573
women and, 572
Candidatus carsonella ruddii, 590, 590f
Candidatus Midichloria mitochondrii, 592, 592f
Canine parovirus type 2 (CPV-2), 608, 609f
Canning, food preservation and, 531
Cannula, surgically installed, 578, 578f
Cannulae, cell connectivity and, 116, 116f
Capsids, 132

Capsules
bacterial cell surfaces and, 60t
bacterial virulence factors and, 716–718, 717t
evading host defenses and, 608t
opsonization and phagocytosis and, 717, 717f
pathogens and, 64–65, 64f
protective mechanisms of, 718, 719f
Capylobacter spp., foodborne-disease and, 543t
Carbenicillin, 828
Carbon
Calvin cycle and, 438–441
global carbon budget, 465, 465f
microorganisms and, 166–167
oxidation states for, 459, 459f
Carbon cycle
global carbon cycle, 462–463, 462f
human activity disruption of, 460, 460f
Carbon dioxide, as greenhouse gas, 464–465, 464f, 465f
Carbon metabolism, 462–471
global carbon cycle and, 462–463, 462f
methanogenesis and, 466–468
methanotrophy and, 468–471
photosynthesis, respiration, and decomposition, 463–466
Carbon utilization, 412–421
fermentation and, 415–419, 415f
glycolysis and, 412–415
mutant phenotype, 270, 270f
respiration and, 419
tricarboxylic acid cycle and, 419–421, 420f
Carboxysomes, 40, 41f
Case-to-infection ratio, disease rate and, 604–605
Caseous necrosis, 744–745, 744f
Catabolism, 402, 405f
Catabolite repression, 337–338
Catalyzed reactions, enzymes and, 403, 404f
CD4+ T cells
activation by MHC II:peptide, 682–683
activation of, 679, 680f
adaptive immunity and, 677
antigen cross-presentation and, 683–684
dendritic cell presentation of antigen to, 685, 686f
CD8+ T cells
activation of, 679–681, 680f
adaptive immunity and, 677
antigen cross-presentations and, 683–684
MHC I:peptide activation of, 683
Cecal fermentation, 583–584
Cech, Tom, 141
Cell culture techniques, 144, 144f
Cell cycle, 771, 772f
Cell envelope, 43–59
archaeal cells and, 113–116
bacterial cell wall and, 47–52
gram-negative cells and, 54–57, 55f
gram-positive cells and, 52–54, 52f
plasma membrane and, 43–47, 43f
variation in, 52–58
Cell lysis, 720, 720t
Cell-mediated responses, 688–692, 745, 745f
Cell metabolism, 77–79, 78f
Cell surface, 59–65
adherence and, 63–64, 64f
archaeal cells and, 116–118
capsules and, 64–65, 64f
flagella motility and, 59–63, 61f
molecules, 662–663, 662f
non-flagellar motility and, 63
structures on, 60t
surface arrays (S-layers) and, 65, 65f
Cell walls
antifungal drugs and, 829
archaeal cells and, 114–116, 115f
eukaryal cells and, 80–84, 81t, 82f
Cells, chemical makeup of, 6–8
Cellular immune responses, 666–667
Cellular proliferation, 774–775, 774f, 775f
Cellular receptors, virus and, 240, 240t
Cellular respiration, 415
Cellulase, 511
Cellulitis, 740t
Cellulose
algae and, 80–82
conversion, rumen symbionts in, 585, 585f
eukaryal microorganisms and, 101, 101f
as organic polymer, 382
structure of, 582, 582f
Cenarchaeum symbiosum, 120–121
Centers for Disease Control and Prevention (CDC), 616, 632
Cephalosporin, 370
Cervarix, 776
Cervical cancer, 252, 252f
Chagas disease, 99
Charged-coupled device (CCD) camera, 306
Chase, Martha, 206–207, 207f
Cheddar cheese, 538, 539f
Cheese
late-blown cheese, 538–539, 539f
processing of, 537–539, 539f
starter cultures for, 537, 538f
Chemical preservatives, 533
Chemolithotrophy, 426–427, 427f
Chemoorganotrophs, 426–427, 427f
Chemoreceptors, 62
Chemostat, 190–192, 191f
Chemosynthesis, 517, 517f
Chemotaxis, 354–356, 355f
bacterial cells and, 61–62, 61f
chemotaxis protein function, 354, 354t
mechanism of, 354
methylation and, 356, 356f
mutants and, 354–357, 354f
Chemotrophs, energy acquisition and, 167
Chickenpox rash, 760, 760f
Chikungunya virus, 618, 618f
Chitin, 82
Chlamydia trachomatis, 590
Chlamydomonas, 90, 90f, 93, 93f
Chlamydomonas nivalis, 172, 172f
Chlamydomonas reinhardtii, 90, 90f
Chloramphenicol, 827t, 828–829
Chloramphenicol acetyltransferase (CAT), 835, 835f
Chloramphenicol resistance, 836
Chlorhexidine, 197
Chlorination, 196, 554, 556
Chlorobium, photosystems and, 436, 436f
Chlorobium tepidum, 437, 437f
Chlorophyll, 433–434, 434f
Chloroplasts
eukaryal cells and, 77–79, 78f
origination of, 19, 19f
oxygenic photosynthesis in, 437, 438f
Chloroquine, 831
Cholera
battlefield wounds and, 28
outbreak in London (1854), 623, 624
toxin, 728t
as waterborne disease, 543, 544f
Chytrid fungus, 812, 812f
Cilia, eukaryal cells and, 80
Circular chromosomes, 215, 216f
Circulating recombinant forms (CRFs), 629
Cis-acting retroviruses, 777–778, 778f
Class I major histocompatibility complex (MHCI), 663, 678
Class II major histocompatibility complex (MHC II), 678
Class switching, antibodies and, 701, 701t
Classical pathway, 652–654
Climate change, cows and, 588, 588f
Clockwise (CW) rotation, 354
Clonal expansion, activated T cells and, 679, 679f
Clones, viral, 145, 145f
Cloning vectors, 276–282
cosmid vectors, 281–282, 282f
phage vectors, 281, 282f
plasmid-cloning vectors, 276–281, 277f
Clostridium, 578
Clostridium acetobutylicum, 384–385, 386f
Clostridium botulinum
bacterial defenses and, 613–614
commercial canning process and, 531
key features, 725, 725f
modified atmosphere packaging and, 535
Clostridium difficile, 579, 580
Clostridium perfringens
cytolysins and, 731, 731t
foodborne-disease and, 543t
gas gangrene and, 733–734, 734f
lecithinase (alpha-toxin), 735–736, 735f
Clostridium tetani, 603
Clustered regulatory interspaced short palindromic repeats (CRISPR), 367
Clusters of Orthologous Groups (COG), 311
Co-speciation, 589
Cochliobolus carbonum, 800, 800f
Coding strands, 218
Coenzymes, 403, 405, 405t
Coevolution hypothesis, virus origins and, 140
Cofactors, enzymes and, 403, 404f
Cold seeps, 518–520
Cold sores, 760, 760f
Colistin, 176
Colonic fermentation, 576
Colony, microbial growth and, 173, 174f
Colony-forming units (CFUs), 184, 606
Commensalism, 564
Commercial sterility, 531
Common-source epidemics, 620–623, 621f
Communicable diseases, 603
Comparative genomics, 318–323
genetic variability and, 318–319
horizontal gene transfer and, 319–323, 322f
minimal genome, 318
Competitive exclusion, 579
Complement
accessory functions of, 656–657
activation and functions of, 653, 653t
alternative pathway and, 654–656
antibody initiation of, 703, 704f
classical pathway and, 652–654
complement-like molecules, 666
components of, 652–656

factor C3a, 657
factor C3b, 649t, 656, 656f
fixation test, 654–655, 655f
lectin pathway and, 654
Complementary DNA (cDNA), 153–154, 154f
Complex medium, microbial growth and, 174
Complex structure, bacteriophages and, 136, 136f
Compliment activation pathways, 656, 656f
Compound light microscope, A10
Confluent plates, 184
Confocal laser scanning microscopy, A11
Conjugate vaccines, 694
Conjugation, 286–290
mechanism of, 286–289
uses of, 289–290
Consortium
definition of, 181
methanogenesis and, 467
Constitutive expression, 330
Constitutive operator mutants, 337, 337f
Contagious diseases, defined, 603
Continuous culture, microbial population growth and, 190–192, 191f
Coprophagia, 584, 584f
Coral bleaching, 595, 595f
Coral reefs, 595, 595f
Coral symbionts, 595–596, 595f
Corepressors, effector molecules as, 333
Coronaviruses
appearance of, 150, 150f
recombination and, 781–782, 782f
Corynebacteriaceae, 572
Corynebacterium diphtheriae
diphtheria toxin and, 726, 726f
iron and, 749–750, 751f
Corynebacterium glutamicum, 389
Cosmid vectors, 281–282, 282f
Counterclockwise (CCW) rotation, 354
Covalent modification, enzyme, 331, 331f
Cowpea chlorotic mottle virus (CCMV), 159
Cows
climate change and, 588, 588f
diet and changes in bacterial communities in, 586, 586t
installed cannula and, 578, 578f
CpG dinucleotides, 648
CpG oligonucleotides, 650–651, 651t
Crenarchaeota, 118–120, 476
Creutzfeldt-Jakob disease, 157
Crick, Francis, 207
CRISPR-Cas system, 612–613, 614f
Crohn's disease, 388, 692, 699
Cross-resistance, 844
Crosslinking, peptide chains and, 49–50
Crown gall disease, 390, 391f
Cryopreservation, 193, 194f
Cryptosporidium parvum, 552, 552f
Cultivation
microorganism analysis and, 179–181
viruses and, 143–145, 143f
Culture collections, microbial, 363–364, 363f
Current-conducting pili nanowires, 425, 425f
Curtis, Thomas, 499
Cyanobacteria
bloom, 508f, 509
evolution of, 16
fossils of, 17f
geothermal springs and, 519f
oxygenic photosynthesis in, 437, 438f
PHA deposits and, 387
photosynthesis and, 68
Cycle-sequencing methods, 305
Cysteine, 119t, 449
Cysts, cell walls and, 82–84
Cytokine IL-1, 648, 648t
Cytokine TNF-alpha, 648, 648t
Cytokines, 645
Cytolysins, 730–736
gas gangrene and, 733, 734f
hemolysis patterns and, 731, 731f
lecithinases and, 735–736, 735f
pore-forming, 732–735, 734f
source, action, targets, and diseases and, 731, 731t
Cytopathic effects, virally infected cells and, 143–145, 145f
Cytoplasm
archaeal cells and, 111–112, 112f
bacterial cells and, 38–41, 39t
Cytosine, 208
Cytosine triphosphate (CTP), 451
Cytoskeleton
archaeal cells and, 112–113, 112f
bacterial, 41–42, 42f
eukaryal cells and, 84–86, 85f
hijacking of, 86, 86f
Cytotoxic cells, invertebrate defenses and, 667
Cytotoxic natural killer cell proliferation, 657
Cytotoxic T cells, killing of infected cells by, 677, 681, 681f
Cytotoxins, 723

Effector T cells, 677, 678t
Effectors, repressor proteins and, 332–333
Effluent disinfection, wastewater treatment and, 554–555
Efflux pumps, 835
Ehrlich, Paul, 14
Electricigenic bacteria, 425, 425f
Electromagnetic radiation, microbes and, 193–195, 194f
Electromagnetic spectrum, 533, 533f
Electron microscopy, 151–153, 152f, 153f, A12
Electron sources, microorganisms and, 167
Electron transport system, 422–427
aerobic respiration and, 422–424
anaerobic respiration and, 424–426
ATP synthase and, 428–429, 428f
chemolithotrophy and, 426–427
electron carriers of, 422, 423t
mitochondria and, 422, 423f
proton motive force and, 427–428. 428f
Element cycling, 459–461
Elongation factor 2 (EF2), 727
Embden, Gustav, 412
Embden-Meyerhof-Parnas pathway, 412–414, 413f
Emerging diseases, incidence rates and, 617
Endemic diseases, 618–619
Endo, Akira, 379
Endocytic pathway, 660, 682–683, 682f
Endocytosis, 246, 247f, 659, 682–683. 682f
Endogenous pathway, intracellular antigens and, 683
Endogenous retrovirus, 762, 762f
Endoplasmic reticulum, protein trafficking and, 76, 76t
Endosome formation, phagocytosis and, 659
Endospores, 54, 54f
Endosymbiosis
eukaryal cells and, 94–98, 94f
evidence in support of, 95
lingering questions about, 97–98
mitochondria and chloroplasts and, 19, 19f
modern cells and, 96–97, 96f
secondary, 97, 97f
Endotoxins, 723–725, 724f, 725t
Endpoint assays, 149, 149f
Energy acquisition, microorganisms and, 167
Energy capture, plasma membrane and, 46
Energy metabolism, 402–403
Enrichment media, microbial growth and, 176–177
Entamoeba histolytica, 99, 99f
Enterobacteriacea, 575, 578
Enterococcus faecalis, 572
Enterotoxins, 543, 543t, 737
Entner-Doudoroff pathway, 414, 414f
Entry mechanisms
animal viruses and, 137, 138f
bacteriophages and, 138–139, 139f
plant viruses and, 137–138
Enveloped viruses, 246–247, 246f, 247f
Environmental adaptation, living organisms and, 6
Environmental conditions, microbial growth and, 177
Environmental secretion, virulence factor release and, 720, 720t
Environmental signals, gene expression and, 352f, 351–353
Enzyme-linked immunosorbent assay (ELISA)
antibody detection and, 702, 704–705, 704f, 705f
malaria testing and, 808
Enzymes
activation energy and, 403–404, 403f
catalyzed reactions and, 403, 404f
cofactors and, 403, 404f
DNA replication and, 213, 214t
industrial, 387, 387f
production of, 331–332
regulation of, 330–331
structure and functions of, 6, 7f
Eosin methylene blue agar (EMB), 175t
Eosinophils, 661, 661f
Epidemics, 619–624, 620f
common-source epidemics, 620–623, 621f
epidemic threshold and, 846–847
foot-and-mouth disease, 859. 860f
incubation period and, 620
outbreak investigation and, 848
predicting and controlling, 846–848
propagated epidemics, 623
temporal patterns and, 620, 621f
triangle of epidemiology and, 847–848, 847f
types of, 620–624
Epidermal growth factor receptor (EGFR), 779, 779f
Epidermophton floccosum, 100, 100f
Episome, 760
Epithelial cells, papillomavirus infection and, 771, 771f
Epitopes, 675, 675f, 696, 697f
Epsilometer test (Etest), 838, 838f
Epsilonproteobacteria, 518
Epulopiscium fishelsoni, 37, 38f, 39
Erysipelas, 740t
Escherichia coli
aerobic and anaerobic respiration comparison, 424, 424f, 426
alternative sigma factors and, 344–345
biofilm formation and, 491
cell structure and, 40f
chemotaxis and, 354
circular genetic map of, 281f, 288
commensal and pathogenic strains of, 579
complex and defined media for, 173, 174t
conjugation and, 288
continuous culture and, 191
cytolysins and, 731, 731t
diauxic growth curve of, 335, 336f
digestive tract and, 575
DNA replication and, 211, 211f
enteric disease and, 752
enteropathogenic, 715–716, 716f
experimental evolution of, 272–273, 272f
expression vectors and, 371
fluctuation test and, 275
in focus, 267, 267f
genome sequence of, 320–321, 320f–321f
genome size and, 309
in gut, 565
injecting own receptor and, 718–719, 719t
large scale culture of, 365
mismatch repair in, 230–231, 231f
natural competence and, 285
natural habitats and, 489
pathogenic, 631–632

plasmid vectors and, 281
research and, 13, 14f
ribosomal subunits and, 226
rich medium and, 177
shape of, 36f, 37
SOS regulon and, 343, 343t
virulence factors and, 713t
Escherichia coli O157:H7, 752
Ethanol
as biofuel, 382–384, 382f, 383f
microbe control and, 195
Eukarya
appearance of, 19–20
characteristics of, 9, 9f, 10–11, 14t
DNA replication and, 211–212, 212f
DNA structure in, 208–210, 209f
nuclear membranes and, 228
ribosome components of, 224–225, 224t
spatial separation and, 228, 228f
transcription and, 220–221, 220f
translation and, 225–226
Eukaryal cells
cell wall and, 80–84, 81t, 82f
chloroplasts and, 77–79, 78f
cytoskeleton and, 84–86, 85f
endosymbiotic theory and, 94–98, 94f
flagella and, 60, 85, 85f
mitochondria and, 77–79, 78f
morphology of, 74–86, 75t
nucleus and, 74, 75f
organelles and, 74, 74f
origin of, 94–98
plasma membrane and, 79–80, 79t, 113f
protein trafficking and, 76, 76t
secretory pathway and, 76–77, 77f
Eukaryal DNA viruses, 250–252, 252f
Eukaryal microorganisms
algae, 90–91
beneficial roles of, 101
cellulose breakdown and, 101, 101f
classification of, 88f
diseases caused by, 98–101
fungi, 87–89, 89f
life cycles and, 93–94, 93f
meiosis and, 92, 92f
mitosis and, 91–92, 91f
model organisms, 87–91
phylogeny of, 86–87, 87f
plant diseases and, 99–100
protozoa, 89, 89f
replication of, 91–94
slime molds, 90, 90f
traditional categories of, 88t
Eukaryal pathogenesis
altered microbiota of host and, 796
antigenic variation in pathogen and, 796–798
evading host defenses and, 792–798
evolution and, 811–814
host evolution and, 811–814
immunocompromised host and, 793–796
macroscopic eukaryal pathogens, 807–810
mechanisms of, 790–803
obtaining nutrients from host and, 798–800
Plasmodium falciparum study, 803–807
toxins and, 800–803
transmission, entry, and adhesion, 790–792
virulence gene acquisition and, 811
Eukaryal RNA, 222, 223f
Eukaryotes, 8–9, 9f
Euryarchaeota, 121–125
halophiles, 122–124, 123f
methanogens, 121–122, 121f
ExbB proteins, 56, 56f
ExbD proteins, 56, 56f
Exergonic reactions, 403
Exocytosis, 76
Exogenous antigens, endocytic pathway and, 682–683, 682f
Exons, 222
Exopolysaccharide mutant phenotype, 270, 270f
Exopolysaccharides (EPS), 491–493, 492f
Exotoxins, 723
Exponential phase, microbial growth curve and, 187, 187f
Expression vectors, 371–372, 371f
External stimuli, living organisms and, 6
Extracellular growth, pathogens and, 648, 648f
Extracellular matrix, 714
Extravasation, 645–646
Extremophiles, 120, 120t
Extrinsic factors, microbial growth in foods and, 526–527, 527t

F

F plasmid, 288, 288f, 290f
F-prime strains, 281f, 288–289
Falkow, Stanley, 626
Farmed animals, antimicrobial resistance in, 843–844
Fatty acid synthesis, 451, 451f
Fecal bacteriotherapy, 580–581, 581f
Fecal coliforms, drinking water purification and, 557
Fecal-oral transmission, infectious diseases and, 615
Feedback inhibition, 418, 418f
Feedstock, 381–382
Feline panleukopenia virus (FPV), 608
Fermentation, 415–419, 415f. *See also* Food fermentation
alcoholic fermentation, 417–418
glycolysis and, 24, 24f
industrial, 365
lactic acid fermentation, 416–417, 416f
metabolic regulation of, 418–419
mixed acid fermentation, 418
Ferritin, 644t
Fever, cytokines and, 646
Fibronectin-binding proteins, 714, 714t
Filtration, microbes and, 192
Fimbriae, bacterial adherence and, 714–715, 714t, 715f
Finger-prick blood smears, malaria and, 808, 808f

direct sequencing of ribosomal RNA genes, 495–496
metagenomics and, 497, 499f
nitrogen-fixing bacteria and, 493–494, 494f
small subunit ribosomal RNA and, 495–497, 495f
in soil, 512–513, 512f
stable-isotope probing and, 497, 497f
terminal restriction fragment length polymorphism and, 496–497, 497f
using microarrays to examine, 461, 461f
Microbial dark matter, 500–501, 500f
Microbial ecosystems
aquatic ecosystems, 502–509
deep subsurface and geothermal ecosystems, 515–520
microbes in the environment, 488–493, 488t
microbial community analysis, 493–502
microbial diversity and, 498–499
terrestrial ecosystems, 509–515
Microbial fuel cells, 425, 425f
Microbial genetics, 15–23
biotechnology and industrial microbiology, 22–23
Eukarya appearance and, 19–20
evolutionary time line and, 16f
first microbial life and, 16–18
genetic analysis and, 20–21
genetic molecules and, 20–21
prebiotic evolution and, 15–16
Microbial growth
differential media and, 176, 176f
enrichment media and, 176–177
environmental conditions and, 177
factors affecting, 168–172
measuring population growth, 181–192
media for, 173, 173f
nutrient concentration and, 168–179, 168f
nutrient type and, 168
nutritional factors and, 168–170
osmotic pressure and, 171–172
oxygen effects and, 170–171, 170f, 170t
pH effects on, 171, 171f
phenotype microarrays and, 169, 169f
pure cultures and, 177–179
selective media and, 174–176, 176f
specialized media and, 173–174, 175t
temperature effects and, 172, 172f
uncultured bacteria and, 179–181
water availability and, 171–172
Microbial growth curve, 186–188, 187f
death phase and, 188
exponential phase and, 187, 187f
lag phase, 186
stationary phase and, 187–188
Microbial mats, 519f, 520
Microbial population measurement, 181–192
continuous culture and, 190–192, 191f
direct counts and, 181–185
mathematical growth analysis and, 188–190
microbial growth curve and, 186–188, 187f
turbidity and, 185–186
Microbial symbionts
herbivore symbionts, 582–588
human symbionts, 571–582
invertebrate symbionts, 588–596
microbe-host interactions, 564–566, 564f
plant symbionts, 566–570, 566t
Microbial virulence strategies, 607–614
attachment, invasion, and replication, 607–608
bacterial defenses and, 611–614, 615f
evading host defenses and, 608–611
virulence actions of various pathogens, 607, 608t
Microbiology, defined, 4
Microbiome, 571
Microcolonies, microscopic appearance of, 182–183, 182f
Microcosms, 360
Microcystis aeruginosa, 508f, 509
Microcystis cells, 41f
Microenvironments, 490
Microfilaments, 84–85, 84t
Micronutrients, microbial growth and, 166
Microorganisms
biogeochemical cycling and, 25, 25f
carbon utilization in, 412–421
definition of, 4
electron sources and, 167
energy acquisition and, 167
fermented foods and beverages and, 536, 536t
food spoilage and, 526–529, 526f
laboratory growth of, 173–181
metabolic groups of, 411, 411t
naming uncultured and uncharacterized, 502
nutrient acquisition and, 166–167, 167f
nutritional requirements of, 166–167
Microscopy
cell structure examination and, 82
principles of, A9–A10
Microtubules, 84–85, 84t
Milk and milk products
acid production in, 537
fermentation of, 536–540
pasteurization process and, 532, 532t
Miller-Urey experiment, 16, 18, 18f
Mimivirus, 134, 134t, 135f
Mineral-oxidizing bacteria, 517
Mineralization, 548
Minichromosomal maintenance (MCM) complex, 211–212, 212f
Minimal genome, 318
Minimal inhibitory concentration (MIC), 838–839, 838f, 839t
Mink enteritis virus (MEV), 608
Mismatch repair, mutations and, 230–231, 231f
Miso, 540, 540f
Missense mutations, 229
Mitochondria
electron transport system of, 422, 423f
eukaryal cells and, 77–79, 78f
origination of, 19, 19f
Mitogens, 799
Mitosis
antifungal drugs and, 829
eukaryal microorganisms and, 91–92, 91f
Mixed acid fermentation, 418
Modified atmosphere packaging (MAP), 534–535, 534f
Mold, fermentation with, 540–541
Molecular cloning, 276–282
Molecular genetic modification, 366–379
designer organisms and, 373–379
mutagenesis and, 366–370
recombinant protein production and, 371–373
Molecular Koch's postulates, 626–628
Molecular mechanisms, antimicrobial drug resistance and, 834–839, 834f
Molecular motors, chemical energy conversion and, 85, 85f
Monoclonal antibodies
chronic inflammatory diseases and, 699
plasma cells and, 697
production of, 698–699, 698f
Monocytes, 658, 659f
Monotrichous bacteria, 60
Montagnier, Luc, 254
Morbidity and Mortality Weekly Report, 632, 633f
Morbidity rate, infectious diseases and, 616
Moromi fermentation, 540–541, 541f
Mortality rate, infectious diseases and, 616
Most probable number (MPN) method, 556–557, 556f, 557f
Mother-to-child transmission (MTCT), 763, 763f
Mouse hepatitis virus (MHV), 240f, 241–243, 245, 245f, 781–782
Mouse hepatitis virus strain A59 (MHV-A59), 626, 627f
Mouse mammary tumor virus (MMTV), 762, 762f, 778, 778f
Mousepox lethality experiments, 707
MreB protein, 41–42, 42f
mRNA secondary structure, 346–348
Mucociliary clearance, 642, 644
Mucosal membranes
as infection barriers, 642–644, 643f
physical and chemical defenses and, 643, 643t
Multidrug cocktails, combating drug resistance and, 845
Multiple cloning sites, 280
Mutagenesis, 366–370
Mutagens, 231–233, 231f
Mutations, 229–235
bacterial, 270–275
base substitution, 229
causes and repair of, 230–235
chemotaxis and, 354–357, 354f
DNA glycosylases and, 235
insertions and deletions and, 230, 230f
inversions and translocations and, 230, 230f
mismatch repair and, 230–231, 231f
missense mutations, 229
mutagens and, 231–233, 231f
mutational gene modification, 842
nonsense mutations, 229
photolyase and, 235, 235f

point mutations, 229, 229f
proofreading activity and, 230
silent mutations, 229
types of, 229–230
viral infections and, 234, 234f
viral pathogens and, 780–781
Mutualism, 564
Mycelia, 37
Mycobacterium leprae, 189, 189f, 590
Mycobacterium tuberculosis
access to host tissues and, 743
caseous necrosis and, 744–745, 744f
cell-mediated response and, 745, 745f
determining cause of, 27
disease consequences and, 744–745
diseases and, 743–745, 743f
granuloma produced by, 744, 744f
humoral response and, 745, 745f
immune-mediated damage and, 692
immune response and, 691
iron acquisition and, 721–722, 722f
non-sterile immunity and, 641
overcoming host defenses and, 743–744
protective response to, 743–744, 743f
pulmonary tuberculosis and, 745, 745f
visible colony formation and, 177
Mycoplasma genitalium, 309, 309f, 318, 590
Mycoplasma genome, 376–377
Mycoplasma mycoides, 318
Mycoplasma pulmonis, 293
Mycorrhizal fungi, 567t
Myobacterium bovis, 532
Myobacterium leprae, 628, 628f
Myoglobin, 644t
Myosin amino acid, 741, 741f
Myxoma virus, 765, 765f, 786

N

N-acetylglucosamine (NAG), 47, 48f
N-acetylmuramic acid (NAM), 47, 48f
N-acyl-homoserine lactone (AHL), 349–350, 349f
Nanoarchaeota, 126
Nanoarchaeum equitans, 110, 111f, 126
Nanotechnology, viruses and, 159
National Antimicrobial Resistance Monitoring System (NARMS), 632, 632t
National Notifiable Diseases Surveillance System, 632, 632t
Natural killer cells, 662–665, 664f
Natural resistance, 838–841
intrinsic drug resistance, 839
resistance genes in the environment, 839–841
Natural selection, antimicrobial drug resistance and, 836–839
Necrosis, 611
Necrotizing cellulitis, 741
Necrotizing fasciitis, 740t
Negative-sense single-stranded RNA viruses, 254, 254f
Negative transcription control, 332–334
Neisseria gonorrhoeae
fimbriae and, 715, 715f
pathogenesis of, 712, 713f
proteobacteria and, 66
virulence factors and, 713t
Neisseria meningitidis
immune-mediated damage and, 692
non-flagellar motility and, 63
selective media and, 176
severe inflammation and, 725
Neuraminidase inhibitor, 259, 259f, 832t
Neutrophiles, 171, 658, 658f
New Zealand hot springs, 470, 470f
Next-generation sequencing methods, 305–308
Nicotinamide adenine dinucleotide (NAD), 409, 409f
Nisin, 533
Nitrate utilization, 446–447
Nitrification, 446–447, 472–474
Nitrifiers, 474
Nitrite utilization, 446–447
Nitrites, 533
Nitrobacter winogradskyi, 474, 474f
Nitrogen
AMD biofilm communities and, 479, 479f
fertilizer product, 475, 475f
microorganisms and, 167, 167f
oxidation states of, 472, 472t
termites and, 593–594
Nitrogen cycle
human activity destruction of, 460, 460f
key steps in, 471–472, 472f
microbes influence and, 25, 25f
Nitrogen fixation
characteristics of, 443–445
nitrogen complex and, 472–473
symbiotic, 566–568
Nitrogen-fixing bacteria, 493–494, 494f
Nitrogen metabolism, 471–476
anammox and, 474–475
biotic nitrogen cycle and, 472, 473f
denitrification and, 472–474
human impact and, 475
nitrification and, 472–474
nitrogen cycle and, 471–472, 472f
nitrogen fixation and, 472–473
Nitrogenase, 444, 444f
Nitrogenase complex, 473
Nitrosamines, 533
Nitrosopumilus maritimus, 120, 477, 477f
Nitrous acid, 231, 231f
Noble Prize winners, 254, 254f
Nod factors, 570
Nodulation, genetic analysis of, 570
Nodule metabolism, 570, 570f
Non-cellulose carbohydrates, 586
Non-enveloped viruses, 247–248, 247f
Non-flagellar motility, 63
Non-glucose carbon source metabolism, 429–432
lipids, 430, 432f
polysaccharides, 429–430
proteins and amino acids, 430, 430f
sugars other than glucose, 429
Non-homologous recombination, 284
Non-perishable foods, 526
Non-protein antigens, 693–695
Non-sterile immunity, 641
Nonsense mutations, 229
Norovirus, foodborne-disease and, 543t
Northern blotting, 312–313, 313f
Nostoc filamentous cyanobacteria, 567t
Nuclear magnetic resonance (NMR) spectroscopy, 317
Nucleic acid analysis, 153, 153f
Nucleic acid functions, 6–7, 7t
Nucleic acid synthesis and, 829
Nucleocapsids, 132
Nucleocytoplasmic large DNA viruses (NCLDVs), 140
Nucleoside analogs, 832, 832t, 833f
Nucleotide structure, 449f
Nucleotide synthesis, 449, 450f
Nucleus, eukaryal cells and, 74, 75f
Nutrient acquisition, microorganisms and, 166–167, 167f
Nutrient cycling, 459–461
Nutrient transport
gram-negative cells and, 55f, 56–57
plasma membrane and, 46, 46f
Nutritional factors, microbial growth and, 168–170, 168f
Nutritional mutants, 266–268, 267f, 271, 271f
Nystatin, 176

T-independent antigens, 694, 695f, 696
T lymphocytes, 674
T4 virus, 134t, 135
Tagged proteins, 372, 373f
Talimogene laherparepvec (T-VEC), 158
Tamiflu, 259, 259f, 833
Tampon-associated toxic shock syndrome, 737, 737f
Tan (or yellow) spot of wheat, 811, 811f
Taxonomic identity, metabolic capabilities and, 490
Taxons, 66, 66t
Tdap vaccine, 851–852
Teichoic acid, 54
Telomerase, 215, 216f
Telomerase RNA (TER), 215
Telomere, 215
Telomere-binding proteins, 233–234, 234f
Telomere probes, 232, 232f
Telomers, promoter activity and, 232–233, 232f, 233f
Temin, Howard, 254
Tempeh, 540, 540f
Temperate phages, 748–751, 749t
Temperature
  food preservation and, 530–532
  microbes destruction and, 192–193, 193f
  microbial growth and, 172, 172f
Template switching, 782, 782f
Temporal patterns, epidemics and, 620, 621f
Tenofovir, 832
Teredinibacter turnerae, 594, 594f
Terminal restriction fragment length polymorphism (T-RFLP), 496–497, 497f
Termination, transcription and, 221–222, 222f
Termite symbionts, 592–594, 593f
Terrestrial biomes, 509, 509f
Terrestrial ecosystems, 509–515
  bioremediation and, 513–515, 514f
  microbial communities in soils, 512–513, 512f
  rhizosphere and, 511–512, 512t
  soils, 509–511
  terrestrial biomes map, 509, 509f
Terrestrial hot springs, 519f, 520
Tetanus, 603
Tetanus toxin, 727, 728, 728t, 729t, 730f
Tetanus toxoids, 852
Tetanus vaccine, 729
Tetracyclines, 827t, 828, 828f
Tetrahymena thermophila, 89, 89f, 141, 141f
Textural soil classification, 510, 510f
TH cells, B-cell antigen presentation to, 686, 687f
TH2-dependent antigen production, 694, 695f
TH1 T-cell subsets, 688–690, 688t, 689f
TH2 T-cell subsets, 688–690, 688t, 689f
Thaumarchaeota, 120–121
Thayer Martin medium, 176
Thermococcus kodakarensis, 222
Thermofilum pendens, 110, 111f
Thermophiles, 118–119, 119f, 119t, 172, 172f
Thermophilic habitats, 470
Thermoplasma acidophilum, 112, 112f, 114–116
Thermoproteus tenax, 110, 111f
Thermosomes, 119

Thermostable enzymes, 120, 120t
Thin blood smear, malarial parasite and, 808, 808f
Thiomargarita namibiensis, 37, 38f, 40, 480
Thylakoids, 433, 434f
Thymine, 208
Thymine dimers, 194, 235, 235f
Thymus, T cell maturation in, 678–679, 678f
Ticarcillin, 50
Tir receptor, 715–716
Tissue culture infectious dose 50 (TCID50), 149
TM7 bacteria, 183, 183f
Tobacco mosaic virus, 14f, 134t, 135, 135f, 258
Toll-like receptors
  binding of, 686
  pathogen-associated molecular patterns and, 647–649, 647f
  research into, 668
  signaling and, 685
Tomato spotted wilt virus (TSWV), 766–767, 766f
Ton-B-dependent receptors, 56–57, 56f, 60t
Tonsillitis, 739–741, 740t
Total organic carbon, wastewater treatment and, 550
Toxic shock, microbial exotoxins and, 646
Toxic shock syndrome, 737, 737f, 740t
Toxic shock syndrome toxin (TSST), 632
Toxins
  A-B toxins, 725–730
  antibiotics and, 750
  antibody neutralization of, 702, 702f
  bacterial virulence and, 723–738
  cytolysins, 730–736
  endotoxin and lipoteichoic acid, 723–725
  eukaryal pathogens, 800–803
  serotyping and, 724, 724f
  superantigens, 736–738
Toxoids, 729
Toxoplasma gondii, 99, 99f, 793, 793f, 793t
Transcription, 217–222
  archaea initiation and, 221, 221f
  bacteria initiation and, 218–219, 218f
  eukarya initiation and, 220–221, 220f
  gel shift assays and, 219, 219f
  genes and, 217, 217f
  initiation and elongation and, 217–221
  negative control, 332–334
  positive control, 334–335, 335f
  post-transcriptional modifications and, 222, 223f
  rho-independent, 221, 222f
  termination and, 221–222, 222f
  transcription factors, 220–221, 220f
Transcription activator-like effector nucleases (TALENs), 367
Transcriptomes, 312–314
  microassays and, 313–314, 315f
  Northern blotting and, 312–313, 313f
  RNA-seq technology and, 314
Transducing retroviruses, 777, 778–779, 779f
Transduction, 294–297, 295f
  discovery of, 294, 294t
  mechanism of, 295, 295f
  uses of, 295–297, 296f
Transfer RNA (tRNA)
  amino acid delivery and, 21
  functions of, 217, 218t
  translation and, 223, 224f
Transferrin, 644t
Transformants, 377, 377f
Transformation, bacterial cell, 285–286, 286f
Transgenic plants, 391–394
  bioplastic production and, 387
  herbicide tolerance and, 391–394
  insect resistance and, 394–395
Transgenic tobacco, 394, 395f
Translation, 222–228
  eukaryal nuclear membrane and, 228
  genetic code and, 223, 224f
  initiation and elongation and, 223–227
  of mRNA, 222–223, 224f
  protein folding and, 227
  protein processing and, 227–228
  protein synthesis and, 225, 225f
  protein transport and, 228
  ribosomes and, 224–225, 224t
  Shine-Dalgarno sequence and, 224–225, 225f
  tRNA role and, 223, 224f
Translocations, mutations and, 230, 230f
Transmembrane sensory proteins, 355–356
Transmissible spongiform encephalopathy (TSE), 157, 157f
Transmission electron microscopy, A12
Transmission routes, infectious diseases and, 615–616, 615f
Transmission types, viral infections and, 761–765
Transposable elements, 290
Transposase enzyme, 291
Transposition, 290–295
  mechanisms of, 291–293, 294f
  transposable element uses, 293–295
Transposon insertion mutants, 293, 295f
Treponema pallidium
  shape of, 36f, 37
Treponema pallidum
  antimicrobial drug development and, 14, 15f
  syphilis and, 62, 590
Triangle of epidemiology, 847–848, 847f
Tricarboxylic acid cycle, 419–421, 420f
  anaplerotic reactions and, 420–421
  intermediates used for anabolism, 421t
  mitochondria and, 77–78
  regulation of, 421
Trichloroethylene, 514, 514f
Trichomes, 37, 37f
Trickle method, vinegar production and, 542, 542f
Trickling filter, wastewater treatment and, 547–548, 549f
Triclosan, 195, 196f
Triglyceride synthesis, 451, 452f
Trimethoprim, 176, 827t, 829
Trinitrotoluene, 514, 514f
Triparental conjugation, 289, 292f
Triple sugar-iron agar (TSI), 175t
Trombone model, DNA replication and, 213, 315f
trp operon, 334, 334f, 346, 347f
Trypanosoma brucei
  African sleeping sickness and, 98, 99f
  detection avoidance and, 509–510
  life cycles and, 796, 798, 798f, 799f
Trypanosomatids, 98–99
Trypanosomes, 796–798, 798t
Tryptophan biosynthetic polypeptides, 346–347
Tsetse fly, 798, 799f
Tuberculin test, 746, 746f
Tuberculosis, 617, 617f, 721–722, 722f
Tuberculosis BCG vaccine, 691
Tularemia, 615t
Tumor suppressors, 771–772, 772f, 773f
Turbidity, cultural, 185–186, 187f
Two-component regulatory systems, 351–353, 352t
2D-Page, 315–317, 316f
Twort, Frederick, 133
Type A botulinum toxin, 732, 732f
Type E botulinum toxin, 732, 732f
Type I interferons, 648, 657, 657f
Type II secretion system, 720–721
Type III secretion system, 57, 57f
Type IV secretion system, 720–721
Typhoid Mary, 606–607
Typhus, 28
Tyrosine, 119t

U

Ubiquitin, 683
Ulcerative colitis, 692
Ultra-high temperature (UTH) processing, 532
Ultraviolet light exposure
  DNA and, 233, 233f
  lambda phage particles and, 340, 340f
Ultraviolet radiation
  drinking water purification and, 556
  food preservation and, 534
  microbes and, 193–195, 194f
  wastewater disinfection and, 555
Unculturable microorganisms, 494
Uncultured bacteria, microbial growth and, 179–181
Uridine diphosphate, 49
U.S. infectious disease surveillance programs, 632, 632t

V

Vaccinations
  attenuated vaccines, 850
  combating drug resistance and, 845
  conjugate, 694
  current immunization schedules, 850, 851f
  delivery strategies, 115, 115f
  design, 850–853
  development of, 821
  DNA vaccines, 853
  foot-and-mouth disease, 859–860
  herd immunity and, 854–856, 855f
  history of, 849–850
  impact of, 29–30, 30f
  inactivated vaccines, 850–851
  long-term immunity and, 686
  polio and, 856–859, 857–858, 858t
  recommended, 852t
  subunit vaccines, 851–852
  T-independent antigens and, 696
  vaccine coverage rate, 855, 855t
  vaccine efficacy, 853
  war against vaccines, 854
Vagina, human symbionts and, 572–573
Valine, 119t

Vancomycin, 56, 176
Variola virus, 134t
Variolation, 849
Varmus, Harold, 254, 254f
Vasodilation, 645–646
Venter, Craig, 308, 323
Verotoxins, 715
Vertebrates
  digestive systems and, 583, 583f
  fermentation systems and, 583, 584t
Vertical transmission
  infectious diseases and, 615
  viruses and, 762–764, 762f, 763f
Vibrio, bacterial cell ingestion and, 575
Vibrio cholerae
  pathogenicity islands and, 748, 748f
  proteobacteria and, 66
  shape of, 36f, 37
  toxin production and, 351
  unsafe water and, 545
Vibrio natriegens, 189
Vif protein, 234, 234f
Vinegar manufacture, 541–542, 542f
VirA/VirG signal pathway, 352–353, 353f
Viral antigens, 622–623, 623f
Viral assembly, 258
Viral attachment protein, 240–241
Viral egress, 258–259
Viral envelopes, 132, 136, 137f
Viral gene segment reassortment, 783–785, 783f
Viral infections, mutations and, 234, 234f
Viral particles, in seawater samples, 504, 505f
Viral pathogenesis
  acute infections and, 758–759
  cancer and, 770–779, 770t
  evolution of, 780–785
  horizontal transmission and, 761–762, 761t
  host cell transcription and translation and, 766–768, 766f
  host immune response avoidance, 768–769
  host interactions and, 765–769
  infection types, 758–760
  latent infections, 760
  mechanical transmission and, 765, 765f
  mutations and, 780–781
  persistent infections and, 760–761
  reassortment and, 783–785, 783f
  recombination and, 781–783
  recurring themes in, 758–765
  transmission types and, 761–765
  vertical transmission, 762–764, 762f, 763f
  zoonotic transmission, 764–765, 764f
Viral replication, 249–257
  bacteriophages and, 255–257, 255f
  categorization and, 250
  DNA viruses and, 251–252, 252f
  eukaryal DNA viruses, 250–252, 252f
  one-step virus multiplication curve, 249, 250f
  poxviruses and, 252, 253f
  RNA viruses and, 252–254
  virus classifications and, 251f
Viral shunt, 465
Viral uncoating, 248–249, 249f
Viridans streptococci, 573
Viroid RNA, 155, 155f
Viroids, 155–156, 155f
Virophages, 156
Virulence factor genes, 627–628, 627f
Virulence factors, 607
Virulence genes, 352–353, 353f, 811
Viruses
  animal viruses entry mechanisms, 137, 138f
  assembly and egress, 258–259
  attachment of, 241, 241f
  bacteriophages and, 138–139, 139f
  cell culture techniques and, 144, 144f
  cellular receptors for, 240, 240t
  characteristics of, 9, 13, 14f
  classification of, 150–151, 152f
  clone production and, 145, 145f
  coevolution hypothesis and, 140
  complex symmetry and, 136, 136f
  cultivation of, 143–145, 143f
  cytopathic effects and, 143–145, 145f
  definition of, 132
  differential centrifugation and, 145, 146f
  direct count and, 146–147
  electron microscopy and, 151–153, 152f, 153f
  endpoint assays and, 149, 149f
  entry and uncoating, 246–249
  gene therapy and, 158–159, 159f
  general replication cycle and, 139–149, 139f
  gradient centrifugation and, 145–146, 147f
  helical symmetry and, 135–136, 135f
  hemagglutination assay and, 147–148, 147f
  hepatitis delta virus, 156, 156f
  history of virology, 132–133, 132f
  host cells recognition and, 240–245
  icosahedral symmetry and, 135–136, 136f
  identification of, 151–154
  immune-mediated damage and, 692
  mimivirus, 134, 135f
  names of, 150, 150f, 151t
  nanotechnology and, 159
  nucleic acid analysis and, 153, 153f
  ocean, 505, 505f
  oncolytic viruses, 158
  origins of, 140–142
  plant virus entry mechanisms, 137–138
  plaque assay and, 148–149, 148f
  prions, 156–157, 157f
  progressive hypothesis and, 142
  purification and, 145–146, 147f
  quantification and, 146–149
  regressive hypothesis and, 140–142
  replication cycle and, 136–140
  replication of, 249–257
  retrotransposons and, 142. 142f
  ribozymes and, 141, 141f
  satellite RNAs, 156
  satellite viruses, 156
  structure of, 133–136, 134f, 134t
  symmetry and, 135–136, 135f
  taxonomy of, A–14
  viral envelopes and, 136, 137f
  viroids, 155–156, 155f
  virology today, 158–159
  virophages, 156
  virus-like particles, 155–158
Vitamin B2, 388, 388f
Vitamin B12, 388, 388f
Vitamins
  coenzymes produced from, 405, 405t

  viruses and, 764–765, 764f
Zooplankton, 504

Microbiology has had a rich history, and the impact of the science on society has been far-reaching. This is reflected in the prestigious prizes that have been awarded to microbiologists, many of which are listed here. Most of these prizes are related to medicine, but it is very important to keep in mind that the influence of microbiology is far broader than human health. Microbiology impacts environmental, agricultural, and industrial applications and contributes to knowledge about the fundamental nature of life.

Impact of Microbiology on Society

YEAR AWARDED	SCIENTIST	PRIZE	EVENT OR DISCOVERY
1901	Emil von Behring	Nobel Prize Physiology or Medicine	Serum therapy against diphtheria
1902	Ronald Ross	Nobel Prize Physiology or Medicine	Discovery of malaria parasites in mosquitoes
1905	Robert Koch	Nobel Prize Physiology or Medicine	Discovery of *Mycobacterium tuberculosis*, the bacterium that causes tuberculosis
1905	Martinus Beijerinck	Leeuwenhoek Medal	Discovery of tobacco mosaic virus, nitrogen fixation, and sulfate reduction
1907	Charles Louis Alphonse Laveran	Nobel Prize Physiology or Medicine	Discovery of disease-causing parasites, including malaria
1908	Ilya Ilyich Mechnikov, Paul Ehrlich	Nobel Prize Physiology or Medicine	Discovery of phagocytes and development of the concept of the antibody
1919	Jules Bordet	Nobel Prize Physiology or Medicine	Discovery of complement
1925	Félix d'Herelle	Leeuwenhoek Medal	Discovery of bacteriophages
1928	Charles Jules Henri Nicolle	Nobel Prize Physiology or Medicine	Identification of lice as the transmitters of typhus
1935	Sergei Nikolaevitch Winogradsky	Leeuwenhoek Medal	Discovery of chemolithoautotrophy
1939	Gerhard Domagk	Nobel Prize Physiology or Medicine	Discovery of the first sulfonamide antibiotic
1945	Alexander Fleming, Ernst Boris Chain, Howard Walter Florey	Nobel Prize Physiology or Medicine	Discovery of penicillin
1947	Oswald Avery	Albert Lasker Basic Medical Research Award	Discovery that DNA is the heritable material
1951	Max Theiler	Nobel Prize Physiology or Medicine	Development of vaccine against yellow fever
1952	Selman Abraham Waksman	Nobel Prize Physiology or Medicine	Discovery of streptomycin, effective against tuberculosis
1954	John Franklin Enders, Thomas Huckle Weller, Frederick Chapman Robbins	Nobel Prize Physiology or Medicine	Development of method to cultivate poliomyelitis
1958	George Wells Beadle, Edward Lawrie Tatum, Joshua Lederberg	Nobel Prize Physiology or Medicine	Discovery of the link between genes and enzymes, and bacterial conjugation
1959	Severo Ochoa, Arthur Kornberg	Nobel Prize Physiology or Medicine	Enzymatic synthesis of RNA and DNA
1960	Frank Macfarlane Burnet, Peter Brian Medawar	Nobel Prize Physiology or Medicine	Discovery of acquired immunological tolerance
1962	Francis Harry Compton Crick, James Dewey Watson, Maurice Hugh Frederick Wilkins	Nobel Prize Physiology or Medicine	DNA structure
1965	François Jacob, André Lwoff, Jacques Monod	Nobel Prize Physiology or Medicine	Gene regulation
1966	Peyton Rous	Nobel Prize Physiology or Medicine	Discovery of tumor-inducing viruses
1968	Robert W. Holley, Har Gobind Khorana, Marshall W. Nirenberg	Nobel Prize Physiology or Medicine	Interpretation of genetic code

Impact of Microbiology on Society

YEAR AWARDED	SCIENTIST	PRIZE	EVENT OR DISCOVERY
1969	Max Delbrück, Alfred D. Hershey, Salvador E. Luria	Nobel Prize Physiology or Medicine	DNA replication and bacteriophage genetics
1970	Cornelis Bernardus van Niel	Leeuwenhoek Medal	Demonstration of bacterial photosynthesis as a light-dependent redox reaction
1975	David Baltimore, Renato Dulbecco, Howard Martin Temin	Nobel Prize Physiology or Medicine	Transformation by tumor viruses and discovery of reverse transcriptase
1976	Baruch S. Blumberg, D. Carleton Gajdusek	Nobel Prize Physiology or Medicine	Studies of kuru infection
1978	Peter D. Mitchell	Nobel Prize Chemistry	Formulation of the chemiosmotic theory
1978	Werner Arber, Daniel Nathans, Hamilton O. Smith	Nobel Prize Physiology or Medicine	Discovery of restriction enzymes
1980	Baruj Benacerraf, Jean Dausset, George D. Snell	Nobel Prize Physiology or Medicine	Discovery of the major histocompatibility complex
1980	Paul Berg, Walter Gilbert, Frederick Sanger	Nobel Prize Chemistry	Recombinant DNA and DNA sequencing
1981	Roger Yate Stanier	Leeuwenhoek Medal	Classification of cyanobacteria
1984	Niels K. Jerne, Georges J. F. Köhler, César Milstein	Nobel Prize Physiology or Medicine	Development of technique for production of monoclonal antibodies
1986	Ernst Ruska	Nobel Prize Physics	Design of the first electron microscope
1987	Susumu Tonegawa	Nobel Prize Physiology or Medicine	Discovery of genetic mechanism for generation of antibody diversity
1989	J. Michael Bishop, Harold E. Varmus	Nobel Prize Physiology or Medicine	Discovery of oncogenes
1989	Sidney Altman, Thomas R. Cech	Nobel Prize Chemistry	Discovery of catalytic properties of RNA
1990	Allen Kerr, Eugene Nester, Jeff Schell	Australia Prize	Biological control of crown gall, and use of *Agrobacterium* to engineer plants
1993	Kary B. Mullis, Michael Smith	Nobel Prize Chemistry	Development of PCR and site-directed mutagenesis techniques
1996	Peter C. Doherty, Rolf M. Zinkernagel	Nobel Prize Physiology or Medicine	Discovery of T-cell recognition of target antigens
1997	Stanley B. Prusiner	Nobel Prize Physiology or Medicine	Discovery of prions
2003	Carl R. Woese	Crafoord Prize	Discovery of the third domain of life
2003	Karl Stetter	Leeuwenhoek Medal	Isolation and characterization of archaea
2005	Barry J. Marshall, J. Robin Warren	Nobel Prize Physiology or Medicine	Discovery of the bacterium *Helicobacter pylori* and its role in gastritis and peptic ulcer disease
2008	Harald zur Hausen, Françoise Barré-Sinoussi, Luc Montagnier	Nobel Prize Physiology or Medicine	Discovery of human papillomaviruses and HIV
2008	J. Craig Venter	Kistler Prize	Advances in genomics
2009	Lucy Shapiro, Richard Losick	Gairdner International Award	Discovery of mechanisms defining cell polarity and asymmetry
2009	Elizabeth H. Blackburn, Carol W. Greider, Jack W. Szostak	Nobel Prize Physiology or Medicine	Discovery of telomerase
2010	Leroy Hood	Kistler Prize	Invention of proteomics and genomics instruments
2011	Bruce A. Beutler, Jules A. Hoffman, Ralph M. Steinman	Nobel Prize Physiology or Medicine	Discovery of activation of innate immunity and role of dendritic cell in adaptive immunity
2015	Jennifer Doudna, Emmanuelle Charpentier	Breakthrough Prize	Development of a powerful and general technology for editing genomes

The Three Pillars of Microbiology
