Organization and Characteristics

The genus *Haemophilus* is a member of the family *Pasteurellaceae*. The taxonomy of the genus has evolved rapidly with the availability of sensitive genotyping and protein analysis (Kuhnert and Christensen 2019). Of the current 13 species, nine with host specificity for humans are divided into three phenotypic groups: the *H. influenzae* group (*H. influenzae*, *H. aegyptius*, and *H. haemolyticus*), the *H. parainfluenzae* group (*H. parainfluenzae*, *H. parahaemolyticus*, *H. paraphrohaemolyticus*, *H. pittnamiae*, and *H. sputorum*), and a group comprising the single species *H. ducreyi* (Kuhnert and Christensen 2019; Norskov-Lauritsen 2014). Significant phenotypic and genotypic differences suggest that, while it currently remains a member of the genus, *H. ducreyi* would be more properly recognized as a distinct member of Pasteurella (Sturm 1981; Lagergard et al. 2011). Four species, *H. felis*, *H. haemoglobulinophilus*, *H. paracuniculus*, and *H. parasuis*, colonize and may be responsible for disease in animals. *H. parasuis*, however, will undergo reclassification and validation of as a new genus, *Glaesserella parasuis*, in the near future (Christensen and Bisgaard 2018; Dickerman et al. 2019).

Haemophilus species constitute part of the normal flora of the upper respiratory track of mammalian hosts. All are facultatively anaerobic, nonspore forming, pleomorphic, coccobacilli that are fastidious, requiring rich media supplemented with V factor (nicotinamide adenine dinucleotide [NAD], nicotinamide adenine dinucleotide phosphate [NADP], or nicatinamine mononucleotide) and/or X factor (protoporphyrin IX). *Haemophilus*, from the Greek *blood-loving*, reflects that these growth factors are most commonly provided by erythrocytes–X factor by hemin or hemoglobin and Y factor by NAD. Most *Haemophilus* species grow best when incubated at 35– 37°C in a moist environment supplemented with 5–10% CO_2 and have an optimal pH of 7.6 (Ledeboer and Doern 2015). *H. ducreyi* grows better at 33°C and a pH of 6.5–7.0, and *H. felis*, *H. paracuniculus*, and *H. paraphrohaemolyticus* have a strict requirement for CO_2 enrichment. All species except *H. ducreyi* ferment carbohydrates, producing acid and, in some cases, gas; these characteristics are useful in species identification. Some *H. influenzae* elaborate a polysaccharide capsule.

General Methods for the Identification and Differentiation of *Haemophilus* Species

Collection and Processing

Clinical specimens should be processed promptly since most species are highly susceptible to drying and other environmental changes. The highest recovery rate is obtained if samples

are inoculated directly onto appropriate media for isolation. Automated blood culture systems readily isolate *Haemophilus* species from blood specimens. These should be inoculated into an appropriate blood culture bottle and transported promptly to the laboratory. Cerebrospinal fluid (CSF) specimens should be processed within an hour after collection or, if this is not feasible, inoculated into Trans-Isolate medium and transported at 20–25°C (Castillo et al. 2011). For *H. ducreyi*, swabs from the undermined edge of genital and cutaneous ulcers are the preferred specimen. If immediate inoculation onto culture media is not possible, the use of thioglycollate/hemin-based transport media containing selenium dioxide, L-glutamine and albumin held at 4°C is recommended (Dangor et al. 1993; Lewis and Ison 2006).

Growth of *Haemophilus* requires a source of X and V factors. X factor is immediately available to bacteria from erythrocytes, but V factor must be released from cells by heating (*chocolating*) or peptic digestion (Fildes enrichment). The most common medium used is chocolate agar prepared with 5% horse or sheep blood. Selective media, such as chocolate agar with vancomycin, with or without bacitracin and clindamycin, or cefsulodin is useful in optimizing yields from respiratory specimens. For optimal detection of *H. ducreyi*, the use of more than one culture medium containing vancomycin as a selective agent is recommended, although sensitivity remains low (30–80%) even with these techniques (Lewis and Ison 2006).

Identification

Most *Haemophilus* species grow to 1–2 mm diameter colonies after 24–48 hours of incubation. *H. influenzae* form grayish, semiopaque, smooth, convex colonies. Encapsulated strains may become confluent and demonstrate iridescence, particularly on clear agar. Colonies of *H. parainfluenzae* influenza may be rough and wrinkled. Those of *H. aegypticus* rarely grow larger than 1 mm in diameter and typically require more prolonged incubation than less fastidious species. Colonies of *H. ducreyi* are smooth, cohesive, and grow to a diameter of 0.1–0.5 mm after incubation for three to four days. Indole-producing *Haemophilus* strains have a characteristic pungent smell, like that of *Escherichia coli*. The odor of other strains is described as resembling that of a mouse nest. *Haemophilus* isolates can be stored at ambient temperature after lyophilization in skim milk and by freezing broth cultures or bacterial suspensions in 10% glycerol at –70°C or heavily inoculated cotton swabs at –135°C.

In Gram-stained smears, *Haemophilus* species are small (0.2–0.3 µm × 0.5–1.0 µm) pleomorphic, gram-negative rods. *H. ducreyi* often forms characteristic parallel chains described as *railroad tracks*, *school of fish*, or *fingerprints*, particularly in direct smears of clinical specimens and in broth culture. Identification of *Haemophilus* species is confirmed by the demonstration of X and V factor dependence. X-factor independent species will grow on sheep blood agar, whereas those species requiring both V and X factors cannot. ß-Hemolytic *S. aureus* both secrete NAD and release hemin from erythrocytes, permitting the growth of satellite colonies of *Haemophilus* strains requiring these factors for growth. Some laboratories, therefore, determine X and Y factor dependency by observing satellite colonies of the unknown bacteria around a streak of *S. aureus* (*Staph streak*) on blood agar. The satellite phenomena, however, is not exclusive to *Haemophilus*, and it is sometimes difficult to detect small satellite colonies. The need for X and V factors can also be demonstrated by growth around factor-impregnated filter paper disks or strips. *Quad* and *tri* plates, in which unsupplemented blood agar and media incorporating one or more factors are separated into individual compartments, are also commercially available. Care must be taken to avoid carryover of X factor from the primary isolation media.

The porphyrin test is the most reliable method to detect X-factor dependence and has the additional advantage of being independent of bacterial growth. δ-Aminolevulinic acid hydrochloride is mixed with bacteria from an agar plate culture. X factor-independent strains are able to convert this substrate to porphyrin and porphobilinogen, which are detected after 4–24 hours of incubation by the demonstration of red fluorescence in ultraviolet light or a red color change when the suspension is mixed with Kovac's reagent.

Speciation

Carbohydrate fermentation and the expression of catalase, urease and ß-lactamase are key reactions for further differentiation of *Haemophilus* species (Table 29.1). The observation of hemolysis on blood agar is chiefly useful to distinguish pathogenic *H. influenzae* from the commensal species *H. haemolyticus*, as classical biochemical identification fails to distinguish between these bacteria. Semiautomated and automated biochemical differentiation systems accurately identify clinical strains of *H. influenzae* and H. *parainfluenzae*, but identification failures and misidentifications of other *Haemophilus* species are not uncommon (Rennie et al. 2008; Valenza et al. 2007).

The accuracy of identification of *Haemophilus* species by matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF MS) is comparable to that of phenotypic methods for some species, but that of less commonly encountered species remains challenging (Powell et al. 2013). While increasingly utilized by clinical laboratories, the utility of this method is currently limited by small numbers of reference spectra for some species and the inability to distinguish between some closely related species (Norskov-Lauritsen 2014; Powell et al. 2013).

Nucleic acid amplification tests (NAATs) have been developed for the identification and speciation of cultured bacteria and to directly detect bacteria in blood, other normally sterile body fluids, and respiratory secretions. Methods employing 16S rRNA, housekeeping, or species-specific gene sequencing have been developed. Currently, however, clinical experience with NAATs for *Haemophilus* species other than *H. influenzae* and *H. ducreyi* is limited, and these tests are not generally available.

Genomes and Genetic Diversity

The genetic diversity and population structure of *Haemophilus* have been studied by a variety of techniques, including multilocus enzyme electrophoresis, ribotyping, pulsed-field gel electrophoresis and whole genome, 16S rRNA, and multilocus sequence typing. The first bacterial genome to be completely sequenced was that of *H. influenzae* Rd KW20 (Rd), a nonencapsulated variant of a serotype d strain (Fleischmann et al. 1995). Many complete and draft genomes of encapsulated *H. influenzae*,

TABLE 29.1

Major Differential Characteristics of *Haemophilus* Species

[c] NK, not known.

NTHi, and other *Haemophilus* species have since been reported and have contributed to the understanding of the population structure and pathogenicity. The size of these genomes varies between 1.7 and 2.1 Mb.

Haemophilus influenzae

H. influenzae are divided into encapsulated and nonencapsulated (nontypeable, NTHi) strains. Encapsulated strains express one of six antigenically distinct polysaccharide capsules (types a–f). The capsulation (*cap*) locus consists of two highly conserved regions common to all capsular types and a region containing type-specific genes responsible for capsular biosynthesis. Serotyping of *H. influenzae* is most commonly performed by slide agglutination, counterimmunoelectrophoresis, or enzyme-linked immunoassay using antisera specific for individual capsular polysaccharides. MALDI-TOF MS may also have utility in capsular serotyping of *H. influenzae* (Takeuchi et al. 2018; Mansson et al. 2018). Typing systems based on polymerase chain reaction (PCR) amplification of serotype-specific segments of the capsulation locus and serotype-specific gene probes are more sensitive and specific than serological assays and are available through reference laboratories.

H. influenzae can also be subdivided into eight biotypes on the basis of indole production and the expression of urease and ornithine decarboxylase (Table 29.2) (Kilian 1976). Each of these activities is readily determined by simple colorimetric assets. Biotype I strains include encapsulated serotype a, b and f strains, while serotype a and c strains are frequent in biotype II and serotype d and e strains in biotype IV. Several commercial systems for identification and biotyping are available. These, however, may require additional tests to speciate isolates other than *H. influenzae* and *H. parainfluenzae*.

The population structure of encapsulated serotypes of *H. influenzae* is relatively clonal, whereas NTHi isolates are genetically distinct from encapsulated isolates and more diverse (Meats et al. 2003). It is hypothesized that this genetic heterogeneity results from the acquisition of different members of a complete complement of *contingency genes* available from the population supergenome (Shen et al. 2005). Such genetic exchange is facilitated by the ability of *H. influenzae*, which is naturally transformable, to take up DNA from highly related organisms by recognition of uptake signal sequences that are widely distributed throughout the genome (Danner et al. 1980; Smith et al. 1995). Examples of horizontal gene transfer between NTHi strains and between *H. influenzae* and other respiratory pathogens have been reported (Hiltke et al. 2003; Kroll et al. 1998). The rate of recombination in *H. influenzae* is not known, but it appears to be higher in NTHi than among encapsulated isolates. The simultaneous presence of multiple distinct strains of NTHi in the respiratory tract and the ability to undergo continuous reassortment may be a strategy that allows these bacteria to adapt to changing environmental factors.

H. influenzae has few two-component and global regulatory systems. An alternative strategy for gene regulation is provided by simple contingency loci, which contain di- or tetranucleotide tandem sequence repeats within or 5' to coding regions (Bayliss et al. 2001). These repeats undergo rapid, reversible, recombinase-independent mutation, resulting in alterations in promoter activity or shifts in translational reading frames (*slipped-strand mismatch repair*). *H. influenzae* has multiple such loci, including genes involved in LPS biosynthesis, adhesion, Fe acquisition, and restriction-modification enzyme systems (Bayliss et al. 2001). This phase variation increases fitness by permitting bacteria to very rapidly alter their immunogenic surface structures and nutritional requirements to survive in different ecological niches (Poole et al. 2013).

Infections Caused by *H. influenzae*

Robert Pfeiffer first described the types of species of *H. influenza* during the 1889–1892 influenza pandemic, and until 1918,

TABLE 29.2

Biochemical Classification of *H. influenzae* and *H. parainfluenzae*

Species	Biotype	Indole	Urease	Ornithine Decarboxylase	Associated Capsular Type	Clinical Association
H. influenzae	I	+	+	+	a, b, f	Respiratory and invasive infection
	II	+	+	–	a, c	Respiratory
	III	–	+	–	a	Respiratory
	IV	–	+	+	d, e	Genitourinary, obstetrical, neonatal infection
	V	+	–	+		Invasive
	VI	–	–	+		
	VII	+	–	–		
	VIII	–	–	–		
H. influenzae Biogroup aegypticus		–	+	–		Brazilian purpuric fever
H. parainfluenzae	I	–	–	–		
	II	–	+	+		
	III	–	+	-		
	IV	+	+	+		
	V	–	–	–		
	VI	+	–	–		
	VII	+	+	–		
	VIII	+	–	–		

it was assumed to be the etiologic agent of these infections. It is now recognized as an important cause of respiratory, invasive, and, less commonly, genitourinary and obstetrical infections. *H. influenzae* colonizes the nasopharyngeal tract and, occasionally, the female genital tract. NTHi may be found in the respiratory tract of up to 80% of adults and children, whereas less than 5% of healthy persons are colonized by encapsulated strains, particularly since the introduction of *H. influenzae* serotype b (Hib) vaccines in the 1980s. Bacteria are transmitted by inhalation of airborne droplets or by direct contact with infected respiratory tract secretions. Detailed epidemiologic studies have revealed that *H. influenzae* colonization is a dynamic process. Individual strains are carried for variable periods of time before loss or replacement by new strains, and several distinct strains may simultaneously cocolonize individuals (Murphy et al. 1999; Smith-Vaughan et al. 1996). A single clonal group may predominate during infection, however. The vast majority of colonized persons are asymptomatic.

Infectious Caused by Encapsulated *H. influenzae*

Serotype b *H. influenzae* (Hib) is a cause of invasive disease, including bacteremia, meningitis, epiglottitis, periorbital cellulitis, and soft-tissue and skeletal infections (Wilfert 1990). Serum antibody concentrations of antitype b capsular antibody correlate inversely with the risk of infection. Children between 3 months and 4 years of age are most susceptible to infection because of loss of maternally-acquired immunoglobulin, coupled with an age-dependent impairment in the acquisition of specific antibody against Hib and other T-independent bacterial polysaccharides (Anderson et al. 1977). Hib infection is also more frequent in certain ethnic populations, including Australian and some North American indigenous peoples. Highly immunogenic polysaccharide-protein conjugate vaccines introduced in the 1980s have dramatically reduced the incidence of Hib infection among vaccinated children (MacNeil et al. 2011).

Nonserotype b encapsulated *H. influenzae*, particularly serotypes a and f, are occasional causes of bacteremia and other invasive disease (Soeters et al. 2018). Molecular typing has demonstrated that these invasive strains are clonally related and possess virulence factors that are also found in serotype b strains (Ogilvie et al. 2001; Rodriguez et al. 2003; Ulanova and Tsang 2014; Omikunle et al. 2002; Potts et al. 2019; Singh et al. 2014).

Pathogenesis

The pathogenesis of Hib infections can be divided into four stages: colonization or respiratory epithelium, invasion of epithelial and endothelial cells, persistence in the bloodstream, and central nervous system invasion. Bacterial factors contributing to pharyngeal colonization include hemagglutinating pili, which adhere to mucin, extracellular matrix proteins, and epithelial cells, the major nonpilus adhesin, Hsf, and phosphocholine (Farley et al. 1990; Geme and Cutter 1995; Weiser et al. 1998). The persistence of bacteria at mucosal surfaces is promoted by bacterial products that interfere with the host's physical and immune defenses and damage and impair ciliary function, including protein D and Hsf surface fibril, which are unique to encapsulate strains, and peptidoglycan (Janson et al. 1999; Male 1979; Wilson and Cole 1988; Singh et al. 2014). Adherence of *H. influenzae* to epithelial cells results in the loss of integrity of tight junctions and sloughing of

cells. This epithelial damage, which is attributable in part to the bacterial lipooligosaccharide (LOS), exposes nonluminal epithelial cells and basement membrane, to which bacteria adhere in large numbers. The genome of most *H. influenzae* strains contains *igaA*, a gene that encodes a type I IgA_1 protease (Kilian et al. 1979). This enzyme cleaves the hinge region of both serum and secreted IgA1, eliminating the agglutination activity of free and antigen-bound immunoglobulin.

Endothelial invasion is an active process in which bacteria are taken up within vacuoles and translocated to the basal cell surface and bloodstream. The type b capsule plays a critical role in the persistence of bacteria in the bloodstream (Moxon and Kroll 1988). The hydrophilic capsule may provide a physical barrier to phagocytosis, preventing clearance of Hib from the bloodstream by complement-mediated phagocytosis. Supporting this hypothesis is the observation that the opsonophagocytic killing of Hib is inversely proportional to the amount of capsule expressed by the bacteria. ∝-D-Galactose[1,4]-ß-D-galactose and sialic acid components of lipopolysaccharide (LPS), the major component of the Gram-negative outer membrane, also contribute to resistance to bacterial clearance (Hood et al. 1999; Weiser et al. 1998). After gaining access to the bloodstream, Hib adhere to and damage the blood-brain barrier, allowing bacteria to translocate across intercellular tight junctions to the CSF. LPS increases blood-brain barrier permeability and also contributes to the systemic symptoms of Hib infection.

Diagnosis of Hib Infections

Several growth-independent tools have been developed for the diagnosis of Hib infection. While not intended to replace traditional culture, these are useful in situations where the yield of conventional culture may be low, such as patients who have received antibiotics before diagnostic tests are obtained, and in settings, such as resource-limited countries, where conventional microbiology has limitations. Encapsulated *Haemophilus* species shed capsular polysaccharide during growth, and rapid detection of this antigen by latex agglutination or enzyme-linked immunoassay is possible in up to 90% of cases of Hib meningitis. Antigen may be detectable in CSF for more than a week after bacteria cease to be cultivatable. Antigen detection can be performed on other normally sterile body fluids and concentrated urine; however, the sensitivity and specificity of the assay in these settings is not established. Bacterial nucleic acids also may persistent at sites of infection or in clinical specimens longer than viable bacteria. Single and multiplex NAAT have been developed for the direct detection of Hib and other common meningeal pathogens in cerebrospinal fluid specimens. While results show good agreement with conventional testing and, relative to culture, they are rapid and sensitive, most reported studies have included only small numbers of cases caused by *H. influenzae* (Liesman et al. 2018).

Disease Caused by NTHi

NTHi are common causes of upper respiratory tract infections and conjunctivitis, especially among children, and important causes of lower respiratory tract infections, particularly in young children, adults with chronic obstructive pulmonary disease (COPD) and patients with cystic fibrosis (Van Eldere et al. 2014). Infections result from direct spread from colonized sites in the upper respiratory tract or by contact with infected respiratory secretions. Risk factors for infection include factors that impair normal mucociliary function or result in inflammation, including antecedent viral infection, smoking, alterations in mucous (such as those seen in patients with cystic fibrosis), and anatomic abnormalities. Rare cases of bacteremia and meningitis are also reported, primarily in neonates, the elderly, and immunocompromised persons (Soeters et al. 2018).

The ability of NTHi to adhere to respiratory epithelium and to resist clearance by host immune defenses is critical to their survival. NTHi adhere to and invade bronchial epithelial cells by interactions between phosphocholine and platelet-activating factor receptor (Swords et al. 2000). Multiple and redundant pilus and nonpilus adhesins have evolved to facilitate NTHi persistence in the upper respiratory tract. The P2 and P5 porins and pili mediate binding to mucin (Gilsdorf et al. 1996; Kubiet et al. 2000; Reddy et al. 1996). P5 also binds intracellular adhesion molecule 1 (ICAM1) and carcinoembryonic antigen-related adhesion molecule 1 (Avadhanula et al. 2006; Bookwalter et al. 2008). Other adhesins include P4 (vitronectin, fibronectin), the HMW1 and HMW2 high-molecular-weight surface proteins (extracellular matrix proteoglycans), Hia (a homolog of the Hsf of encapsulated strains that is generally mutually exclusive with HMW1/HMW2), and opacity-associated protein A (Barenkamp and St Geme 1996; Jurcisek et al. 2007; St Geme et al. 1993; Weiser et al. 1995; Su et al. 2016). *Haemophilus* adhesion and penetration protein (Hap) binds fibronectin, laminin, and collagen IV, mediating attachment, bacterial aggregation, and invasion of respiratory epithelial cells (Fink et al. 2002). A second ubiquitous multifunctional adhesin, protein E, binds both vitronectin and, with Hap, laminin (Hallstrom et al. 2011). The ABC transporter protein F binds laminin and human pulmonary epithelial cells (Jalalvand et al. 2013). While considered a nonmotile organism, some *H. influenzae* strains express a homolog of type IV pili (Tfp) and exhibit twitching motility (Bakaletz et al. 2005). Tfp promotes bacterial adherence to respiratory epithelial cells by binding ICAM1 and mucin and plays an important role in the development of biofilm (Jurcisek et al. 2007). Epithelial adherence and other virulence factors of NTHi may be regulated by the DNA methylase gene *mod10A*, with loss of expression caused by polymerase slippage at a long tetrameric repeat tract leading to the upregulation of adhesins (VanWagoner et al. 2016).

Although considered an extracellular pathogen, NTHi, like Hib, may invade and multiply in epithelial cells. Inside cells, these bacterial may be relatively protected from killing by many host immune defenses and antimicrobial agents (Forsgren et al. 1994). Invasion of respiratory epithelial cells by NTHi is mediated by Hap, protein E, HMW1/HMW2, the ABC transporter sensitivity to antimicrobial peptides A (SapA), protein D, IgA1 proteases, and LOS (Kenjale et al. 2009; Ikeda et al. 2015; Mell et al. 2016; Raffel et al. 2013; Ruan et al. 1990; Swords et al. 2001; Clementi et al. 2014). NTHi may also, independent of phagocytosis, be internalized by macrophages.

Lacking a polysaccharide capsule to block host immune factors, NTHi have evolved diverse mechanisms to persist in the respiratory tract. Protein D is a highly conserved surface lipoprotein that both impairs ciliary function and, like LOS, induces

morphological damage to cilia (Forsgren et al. 2008; Janson et al. 1999). While most NTHi express type 1 IgA_1 protease, a clonally related group of strains associated with COPD also possesses a second gene, *igaB*, which encodes a type 2 IgA_1 protease (Murphy et al. 2011). Multiple factors, including phase variation in LOS and the acquisition of human complement inhibitors, such as plasminogen, C4B-binding protein, factor H (P5), factor H-like protein and vitronectin (P4, proteins E and F), contribute to NTHi serum resistance (Barthel et al. 2012; Hallstrom et al. 2006; Hallstrom et al. 2007; Hallstrom et al. 2008; Su et al. 2013). The Sap ABC transporter permits NTHi to evade the bacterial effects of host-derived antimicrobial peptides such as defensins and cathelicidins by transporting these to the bacterial cytoplasm, where they are degraded by peptidase activity (Shelton et al. 2011). Certain modifications to LOS structure may decrease complement deposition and activation and inflammatory responses (Clark et al. 2012). Outer membrane vesicles, blebs separating from the bacterial outer membrane, are able to exploit host immune responses to promote colonization and invasion (Kaparakis-Liaskos and Ferrero 2015).

The formation of biofilm, comprised chiefly of LOS and bacterial and eukaryotic DNA, in a process that requires Hfp and may involve P2, P5, and P6, permits NTHi to persist at mucosal sites (Jurcisek and Bakaletz 2007; Langereis and Hermans 2013; Murphy and Kirkham 2002). In an animal model of middle ear infection, antibody against the DNA-binding protein DNABII, which plays an important role in the structural stability of NTHi biofilm, reduced biofilm mass and resulted in more rapid clearance of bacteria (Goodman et al. 2011).

Antigenic diversity is another strategy by which NTHi avoids immune recognition by the host. Genomic alteration critical virulence factors may occur through slipped-strand misrepair during colonization (Pettigrew et al. 2018). Structural diversity may also arise through point mutations in surface-exposed structures or genetic exchange between NTHi and closely related bacteria (Duim et al. 1994; Shen et al. 2005). Some NTHi strains with defects in components of the methyl-directed mismatch DNA repair system have exceptionally high rates of mutation; this may provide these bacteria with a survival advantage (Watson et al. 2004). The structure of LOS may be modified independently of phase variation in response to environmental cues and growth conditions (Oerlemans et al. 2019). Finally, the structure of some forms of LOS is shared by host glycolipids and glycosphingolipids, and these may fail to be recognized as foreign by the host (Harvey et al. 2001; Ng et al. 2019).

Other NTHi Infections

A recently reported cryptic biotype IV genospecies, *Haemophilus quentini*, is associated with urogenital infections, serious infections of parturient women and neonates (Kus et al. 2019). A distinct NTHi, biogroup *aegyptius*, causes seasonal epidemics of conjunctivitis and a clonal strain of this biogroup caused outbreaks of Brazilian purpuric fever (BPF), a syndrome characterized by purulent conjunctivitis, shock, and hemorrhagic skin lesions, in young children in the 1980s and 1990s (Harrison et al. 2008). BPF-associated strains possessed genes that encode unique adhesins and fimbrial operons that may be responsible for their unusual pathogenicity (Strouts et al. 2012).

Treatment of *H. influenzae* Infections

Serious invasive *H. influenzae* infections are typically treated with parenteral third generation cephalosporins, carbapenems, or ampicillin. Less critical infections may be treated with oral ampicillin or cephalosporins. A quarter to a half of isolates are ampicillin resistant. While beta-lactamase elaboration, predominantly plasmid-encoded class A serine enzymes, is the most prevalent resistance mechanism in NTHi, strains exhibiting beta-lactamase negative ampicillin resistance (BLNAR) and, in some cases, cephalosporin and carbapenem resistance, have emerged rapidly in some countries (Van Eldere et al. 2014). Reduced susceptibility of BLNAR isolates is a consequence of one or more alterations in *fts1*, the gene encoding penicillin binding protein 3 (Ubukata et al. 2001). Most of these strains remain susceptible to quinolone and carbapenem antimicrobials.

Haemophilus parainfluenzae

H. parainfluenzae are the most prevalent *Haemophilus* species in normal flora of the human oropharynx and are a common commensal of the genitourinary tract (Kuklinska and Kilian 1984). Like *H. influenzae*, *H. parainfluenzae* may be subdivided into 8 biotypes (Table 29.2). Interestingly, while *H. parainfluenzae* has a lipid A and inner core LPS very similar to that of *H. influenzae*, it has reduced outer core LPS repertoire and, consistent with the observation that the genome does not contain lengthy tetranucleotide repeat tracts, there is no evidence for phase variation of cell surface components (Young and Hood 2013).

These bacteria occasionally cause respiratory and invasive diseases, most notably endocarditis and biliary tract infections (Darras-Joly et al. 1997). They are frequently isolated from sputum of adults with COPD, but their contribution to exacerbations of pulmonary disease remains controversial (Sethi and Murphy 2001). Antigen and antibody-directed against *H. parainfluenzae* outer membrane antigen preparations have also been detected in the glomeruli of patients with IgA nephropathy, and administration of outer membrane antigens induces glomerular deposition of IgA and mesangial proliferation in an experimental animal model, suggesting *H. parainfluenzae* colonization or infection may trigger immune-complex mediated renal disease (Yamamoto et al. 2002).

Haemophilus ducreyi

First described by Auguste Ducrey in 1889, *H. ducreyi* is the causative agent of the sexually-transmitted genital ulcer disease chancroid (soft chancre) and, more recently, has been recognized as a cause of chronic cutaneous ulcers in children in low-income countries (Lewis and Mitja 2016). Whole genome and multilocus sequencing suggest *H. ducreyi* is composed of two clonal populations that diverged almost 2 million years ago (White et al. 2005; Ricotta et al. 2011; Marks et al. 2018). Strains causing cutaneous ulceration are genetically related to class 1 strains causing genital ulcers and may have evolved through a more recent divergence from these bacteria (Gangaiah et al. 2015; Gaston et al. 2015). The *H. ducreyi* chromosome has no lengthy regions of

synteny with that of Rd or the NTHi 86-028NP (Challacombe et al. 2007; Harrison et al. 2005). Observed differences in genes involved in LOS synthesis, carbohydrate and amino acid utilization, nucleotide biosynthesis, iron acquisition and oxidative stress may account for the phenotypic differences between these *Haemophilus* strains and their adaptation to particular environments.

The pathogenesis of *H. ducreyi* infection has been studied using human and animal models of cutaneous inoculation. The ability of bacteria to cause disease is dependent on the ability to form aggregates, adhere to keratinocytes, extracellular matrix and serum proteins, to damage host cells, and to resist killing by human antimicrobial peptides and phagocytosis by polymorphonuclear leukocytes and macrophages (Alfa and DeGagne 1997; Bauer et al. 2001). The expression of high-molecular-weight LOS may be important for adherence to mucosal surfaces. Three fimbria-like proteins, Flp1, Flp2, and Flp3, contribute to the ability of bacteria to form microcolonies and adhere to fibroblasts—the expression of these adhesins is required for virulence in humans (Nika et al. 2002; Spinola et al. 2003; Janowicz et al. 2011). *H. ducreyi* serum resistance protein A (DrsA), a trimeric autotransporter adhesion involved in serum resistance, is the major fibronectin-binding determinant of the organism and also mediates binding to vitronectin and fibrinogen (Cole et al. 2002; Fusco et al. 2013; Leduc et al. 2009). The *H. ducreyi* homolog of the GroEL heath shock protein binds glycosphingolipids exposed on the surface of epithelial cells, NcaA is a type I collagen-binding outer membrane protein, and fibrinogen binder A (FgbA) contributes to the virulence of *H. ducreyi* in experimental human infection (Alfa and DeGagne 1997; Fulcher et al. 2006; Pantzar et al. 2006).

H. ducreyi expresses two extracellular toxins. Hemolysin (HhdA) is cytotoxic to keratinocytes, fibroblasts, macrophages, and lymphocytes. The cytolethal distending toxin (CTD) causes cell cycle arrest and apoptosis in fibroblasts and lymphocytes; the formation of ulcers is likely attributable to these virulence factors (Cope et al. 1997).

The sensitive to antimicrobial peptides (Sap) influx transporter, proton motive force multiple transferable resistance transporter, and modifications of lipopolysaccharide or LOS mediate resistance to human antimicrobial peptides (Mount et al. 2010; Rinker et al. 2011; Trombley et al. 2015). *H. ducreyi* is highly resistant to complement-mediated killing by human serum. At least four outer membrane proteins contribute to serum resistance, DsrA, DltA (*H. ducreyi* lectin A), LspA1, and LspA2 (Leduc et al. 2004; Mock et al. 2005). LspA1 and LspA2 (large supranuclear proteins A1 and A2) are highly homologous secreted proteins that interfere with protein tyrosine kinase signaling in the early phases of Fc receptor-mediated phagocytosis (Janowicz et al. 2004). Fibrinogen binder A (FgbA) may contribute to virulence by promoting the deposition of fibrin on the bacterial cell surface (Bauer et al. 2009). Lysis of immune cells by HdtA and CTD may also contribute to the ability of *H. ducreyi* to evade host immune responses.

Infectious Caused by *H. ducreyi*

Historically, chancroid has been primarily a disease of resource-limited countries in Africa, Asia, Latin America, and the Caribbean. It is more commonly seen in men, particularly uncircumcised men, and female sex workers, and is a major cofactor for the transmission of HIV (Greenblatt et al. 1988). The global epidemiology of chancroid is difficult to estimate because sensitive and specific laboratory tests are often not available in regions with the highest endemicity. While the precise incidence is unclear, reductions in the proportion of GUD attributable to *H. ducreyi* in many countries have been reported (Gonzalez-Beiras et al. 2016). This has been attributed to a 1991 World Health Organization recommendation for syndromic management of genital ulcer disease (i.e. without microbiological confirmation of etiology), improvements in health care delivery, and with behavioral changes, such as condom use, intended primarily to reduce the risk of HIV prevention.

The inoculum required to cause chancroid is low, 1–100 organisms (Al-Tawfiq and Spinola 2002). In males, cutaneous or mucosal inoculation through minor trauma results in formation of a painful papule following an incubation period of 3–10 days. This becomes pustular and then ulcerates, forming a superficial ulcer with a friable base and ragged undermined edge, characteristically covered by a gray or yellow necrotic exudate. Autoinoculation may cause "kissing ulcers" on opposing skin. Painful unilateral inguinal lymph nodes (buboes) occur in 10–70% of patients and may suppurate and rupture. Most infected women are asymptomatic. Bacteria remain localized to the superficial tissues; invasive infection has not been described.

Recent studies have identified *H. ducreyi* as a previously unrecognized cause of chronic skin ulcers in Africa and the Pacific islands, predominantly in children and sometimes in association with coinfection by *Treponema pallidum* subsp. *pertenue*, the etiologic agent of the cutaneous ulcer disease, yaws (Mitja et al. 2014; Marks et al. 2014). The precise pathogenesis is unclear, but *H. ducreyi* DNA has been detected on the skin of well children, flies, and fomites such as bed sheets, suggesting an environmental reservoir for the bacteria exists (Houinei et al. 2017). No clinical features appear to reliably distinguish ulcerations caused by *H. ducreyi* from yaws.

Diagnosis and Treatment of *H. ducreyi* Infections

Laboratory confirmation of *H. ducreyi* is challenging because of its fastidious growth conditions. Although not routinely available in some countries, NAATs are preferred for the diagnosis of chancroid. Multiplex PCR assays for the simultaneous detection of *H. ducreyi* and other etiologic agents of genital ulcer disease have a sensitivity and specificity of over 95%. While the definitive diagnosis of chancroid requires isolation from genital lesions, the sensitivity of culture, even under ideal conditions, is estimated to be less than 75% when NAATs are considered to be the gold standard (Lewis 2003). Positive serology may persist for months after infection and is useful only for epidemiological investigations.

H. ducreyi is generally susceptible to fluoroquinolones, erythromycin, azithromycin, and ceftriaxone. Ulcers typically improve within a week of initiation of therapy. Treatment failures are more common in persons with HIV infection and may reflect coinfection with other pathogens, particularly herpes simplex virus. Fluctuant buboes may be treated by aspiration or surgical excision.

Other *Haemophilus* Species

H. aegyptius (Koch-Weeks bacillus) is a frequent cause of acute bacterial conjunctivitis in humans and a rare agent of human and veterinary infections (Pittman and Davis 1950). *H. haemolyticus* and *H. paraphrohaemolyticus* are human respiratory commensals and anecdotal causes of invasive infection (Murphy et al. 2007). *H. pittmaniae* and *H. sputorum* colonize the oropharynx of humans and are also rare pathogens (Norskov-Lauritsen et al. 2005; Norskov-Lauritsen et al. 2012).

Introduction

Many observations of spiral bacteria colonizing the gastric mucosa of animals and humans have been noted throughout the 20th century, some of which suggested their role in gastric pathology.[1–3] Despite the presence of these microorganisms, the stomach was still considered a sterile environment. It was the discovery of *Helicobacter pylori* that forever changed our perception of the stomach, and made us view this organ as a habitat for specialized bacteria. Recent evidence supports the theory that humans and *H. pylori* have coevolved for millennia. Genetic studies indicate that humans have been colonized with the organism for at least 58,000 years and that *H. pylori* most likely postdated the evolution of humans.[4–7] Strain types that prevail within certain regions of the world have also been found to correlate with human migration patterns.[5,8]

Isolated from the human stomach in 1982, this organism was first categorized as a spiral-shaped bacterium resembling *Campylobacter*.[9] The organism bore many similarities to the campylobacters, including morphology, growth under microaerophilic conditions, G + C content, among others. As a result, the organism first referred to as a *Campylobacter*-like organism was later named *Campylobacter pylordis* in 1985.[10] The species name was subsequently revised to "*pylori*" in 1987.[11] Electron microscopy and fatty acid analysis of *C. pylori* soon demonstrated that it showed marked differences from the other *Campylobacter* species.[12] *C. pylori* was later reclassified into the new genus *Helicobacter*. This new classification was supported by sequencing studies of 16S rRNA.[13] Early studies described this bacterium as a probable cause of gastritis and peptic ulcer disease, and this etiology would later be validated.[14] Now, there is much evidence to support the role of *H. pylori* in various clinical disorders of the upper gastrointestinal tract, such as chronic gastritis, peptic ulcer disease, mucosa-associated lymphoid tissue (MALT) lymphoma, and gastric adenocarcinoma.[15–17] The clinical significance of *H. pylori* has been emphasized by the World Health Organization, via the classification of this organism as a Class I carcinogen of gastric cancer.[18] This bacterium is currently considered the most common etiologic agent of infection-related cancers and it is believed that up to 5.5% of the global cancer burden is represented by this organism.[19,20] In more recent years, *H. pylori* infection has been implicated in some extradigestive diseases, such as iron-deficiency anemia, idiopathic thrombocytopenic purpura (ITP),

cardiovascular diseases, and diabetes mellitus, among others.[21,22] The isolation, characterization, and recognition of *H. pylori* have generated a renewed interest in the possible association of other spiral mucus-associated bacteria with disease.

Many animals are now known to be colonized by a wide range of highly adapted bacteria that belong to the genus *Helicobacter.*[23] The genus has grown from the initial named two species in 1989 (*H. pylori* and *H. mustelae*) to approximately 46 species.[24,25] The *Helicobacter* species as a group can be broadly categorized according to their site of colonization in the host. Distinct groups of species within the genus have been identified using 16S rRNA gene sequencing. These groups are broadly categorized as gastric (stomach), enterohepatic (intestine, liver or biliary tract) and a subgroup of enterohepatic species which lack a characteristic sheathed flagellum (Table 30.1). Gastric *Helicobacter* species are widely distributed in mammalian hosts and are nearly universally present in the gastric mucosa. This group of organisms can cause an inflammatory response resembling that seen with *H. pylori* in humans.[28] The gastric helicobacters often serve as good models of human disease. Enterohepatic *Helicobacter* species are a diverse group of organisms that have been identified in the intestinal and hepatobiliary tracts of various mammal and bird hosts, with several species associated with human infection (Table 30.2). These organisms have been linked with inflammation in immunocompromised humans where more severe clinical disease is observed.[29] Among the unsheathed subgroup of enterohepatic helicobacters are species associated with gastroenteritis, and possible liver disease in humans.[23,30–32]

This chapter describes the genus *Helicobacter* and characterizes the role of these organisms in the pathogenesis of gastric and enterohepatic disease. Epidemiology, transmission, pathogenesis, virulence factors, along with methods in culture, identification, detection, and treatment, are reviewed. Subsequent discussion of animal models in this chapter illustrates how these models have helped investigators gather pertinent information to further our understanding of this fascinating group of organisms comprising the genus *Helicobacter.*

Genus Description

The genus *Helicobacter* comprises more than 40 species, with additional provisionally named species waiting to be validated. Others have been isolated but await classification. New and more sophisticated techniques, especially in the field of molecular biology, have helped in the further delineation of the genus.[33–36] These Gram-negative, nonspore-forming rods typically have spiral, curved, or fusiform morphology ranging from 0.3 µm to 1.0 µm in width to 1.5–10.0 µm in length. The morphology of the spiral-shaped body varies greatly among the species. For example, *H. acinonychis* is an "S"-shaped organism similar to *H. pylori,* while *H. felis* and *H. heilmannii* have tightly spiraled bodies that resemble a corkscrew. Motility in the genus *Helicobacter* is due to the presence of flagella, which give them a characteristic rapid corkscrew-like or slower wave-like motion[33] Most species have bundles of multiple sheathed flagella, having either a polar or bipolar distribution, while others have a single polar or bipolar flagellum. *H. pylori* isolates, in contrast to other *Helicobacter* species, have multiple monopolar sheathed flagella (Table 30.1). Flagellar distribution can also be peritrichous (*H. mustelae*) or nonsheathed (*H. pullorum*, *H. rodentium,* and *H. mesocricetorum*).[33,34] These basic morphology and motility characteristics are thought to play an important role in the ability of the organism to maneuver successfully in the mucous layer of their host gastrointestinal tracts.

The host range of colonization varies among the gastric *Helicobacter* species, with some being more restrictive than others. For example, *H. pylori* is associated with humans, *H. felis* with cats and dogs, *H. mustelae* with ferrets and minks, *H. salomonis* with dogs, and *H. acinonychis,* which specifically colonizes the cheetah. Other gastric species, for example, *H. bizzozeronii, H. heilmannii,* and related bacteria, exhibit a much broader host specificity, naturally colonizing, cats, dogs, and primates, including humans.[37,38] The presence of gastric *Helicobacter* species is associated with inflammation and/or ulceration, and gastric mucosa-associated lymphoid tissue lymphoma in humans, like *H. heilmannii*, which is known to colonize the gastric mucosa of animals. There is also some evidence to suggest that *H. heilmannii* infection may be an example of a zoonosis.[38–41]The gastric helicobacters are recognized as important pathogens in gastroduodenal disease. In contrast, the enterohepatic helicobacters inhabit the intestinal and hepatobiliary tracts of mammals and birds. In humans, enterohepatic helicobacters, such as *H. canadensis, H. canis, H. cinaedi, H. fennelliae, H. pullorum, H. winghamensis,* and *Helicobacter* sp. *strain flexispira taxon 8,* have been isolated from rectal swabs and feces. Enterohepatic helicobacters have been linked to severe inflammatory lesions in the lower bowel, gall bladders, and livers of infected mammalian hosts including humans.[38–46] Furthermore, *H. mustelae, H. hepaticus,* and *H. bilis,* which are known to have numerous virulence factors, have been found to display carcinogenic potential in animals and have been implicated in causing disease in humans as well.[41]

In the laboratory, most species of *Helicobacter* will grow at 37°C under microaerophilic conditions in an atmosphere of reduced oxygen concentration (5–10% O_2), and increased humidity and carbon dioxide levels (5–12% CO_2). The role of atmospheric hydrogen in the microaerophilic incubation of *Helicobacter* is not fully understood. The requirement appears to be strain dependent, being required by some strains and having a growth stimulating effect in others.[33,34] Routine aerobic atmospheres do not support the growth of most *Helicobacter* species. Some species grow poorly, at best, in these conditions whereas several *Helicobacter* species, such as *H. rodentium*, can grow both in microaerobic and anaerobic conditions.[47] Another rodent enteric species, *H. ganmani* grows best in an anaerobic cabinet, although strict anaerobic conditions can be lethal to the organism.[48] When helicobacters are cultured for a prolonged period of time, or if the growth conditions are suboptimal, cell morphology may become spheroid or coccoid in nature. These unusual forms are not successfully subcultured.[24,49] As shown in Table 30.1, there exists some variation in the key biochemical traits within the genus *Helicobacter* which can therefore aid in species identification. Biochemically, helicobacters display a respiratory type of metabolism. Neither oxidation nor

fermentation is observed when examining standard methods of carbohydrate utilization. However, glucose oxidation appears to occur in *H. pylori,* and oxidase activity is found in all species.[50] Nearly all *H. pylori* strains require arginine, histidine, leucine, methionine, phenylalanine, and valine for growth.[51,52] These amino acid requirement are similar to those required by humans.[53] The principal means of energy production and biosynthesis is believed to occur via glycolysis and gluconeogenesis, respectively. Other catabolic pathways, such as the glyoxylate shunt, is absent in these organisms.[50,54]

Epidemiology and Transmission of *Helicobacter pylori* and Other Helicobacters

Preventing the spread of infectious pathogenic agents has historically relied on public health measures that were based on sound epidemiological data. In the case of *Helicobacter*, and in particular *H. pylori*, the epidemiology and especially the transmission mechanisms are incompletely understood. A thorough understanding of these processes must be first elucidated prior to the possible implementation of control measures for this group of organisms. *H. pylori* in particular, has emerged as one of the most common chronic bacterial infections in the world, affecting half the global population.[55] Although the human stomach is the natural niche for *H. pylori*, there have been reports implicating other sources for the bacterium.[56] Zoonotic transmission routes have been proposed, such as transmission by houseflies, and some domestic animals such as dogs, cats, and sheep, as well as iatrogenic sources.[41,57–59] However, evidence suggests direct person-to-person transmission of the organism, especially from mothers to children and among siblings, is the most probable source. There also appears to be a greater chance of acquiring infection in the early years of life.[6,24,56] This mode of transmission is supported by the clustering of cases within families, and the similarity of genotypes found among isolates of related persons.[60–63] Direct person-to-person transmission is also supported by the fact that *H. pylori* can be found in regurgitated gastric juice, which would allow the organism to temporarily colonize the oral cavity. *H. pylori* has also been isolated from dental plaque, saliva, and vomitus where the organism can remain viable for hours.[56]

Although, the mechanism by which *H. pylori* is transmitted from one host to another remains speculative, the gastro-oral, oral-oral, and fecal-oral routes are the most likely means of transmission.[56,64,65] In developing countries, fecal/oral transmission of *H. pylori* appears to be a likely means of spread of *Helicobacter* where lack of sanitation may pose a greater risk.[64,65] Water has been proposed as a source of *Helicobacter* infection, since water biofilms have been suggested to provide the bacteria with a protective habitat enabling them to endure the water handling process.[66,67] This route of transmission has been supported by both epidemiologic studies which have shown *H. pylori* prevalence to be associated with water related sources, as well as with more rapid acquisition rate, and those that have detected or isolated *H. pylori* from water sources by using autoradiographic, molecular, culture and other methods.[68–79] Water may serve as a secondary transmission source in the fecal-oral transmission of *H. pylori*, acting as a reservoir for the organism, as well as a source of infection.[79]

Human infections with *H. heilmannii* and related species of gastric origin are generally considered uncommon, with prevalence rates ranging from less than 0.3–6%.[41,80] There have been reports of human infection with one or more species of zoonotic origin, notably, *H. salomonis*, *H. felis*, *H. suis*, and "*Candidatus H. bovis.*" This indicates that cats, dogs and swine may be possible sources of infection, although the mode of transmission is not yet known.[80–83]

Among the enterohepatic helicobacters, species such as *H. bilis*, *H. canadensis*, *H. canis*, *H. cinaedi*, *H. fennelliae*, *H. pullorum,* and *H. winghamensis*, are known to produce clinical symptoms in humans. See Table 30.2 The enterohepatic *H. mustelae*, which colonizes ferrets and minks, has a similar relationship of age-associated prevalence that mimics that of *H. pylori* in humans. Studies have shown that *H. mustelae* infection ranges from 0% in ferrets less than 1 month of age to 100% in adult animals over 1 year of age.[84,85] Fecal-oral spread of *H. mustelae* in the ferret population has likewise been proposed, as well as the possible zoonotic transmission of these gastric helicobacters to humans.[86] Naturally infected cats and sheep have been found to have *H. pylori* in their secretions and feces, also raising the possibility of transmission to humans.[87,88] Likewise, the zoonotic food-borne transmission of enterohepatic helicobacters to humans, such as *H. pullorum* and *H. canadensis,* has been reported.[45,89] Enterohepatic *H. pullorum*, is considered an emergent human pathogen and has been implicated in gastroenteritis, inflammatory bowel disease, and chronic liver diseases.[41] A high prevalence of *H. pullorum* has been found in chicken flocks, with strains of the bacterium isolated from chicken meat, which suggests this organism may be a foodborne pathogen.[42,90,91] The significance of enterohepatic helicobacters in transmission of disease and the true prevalence of these organisms in human and animal populations are yet to be determined. What has become apparent over the years is that *Helicobacter* species are commonly present as part of the gastric, enteric, and hepatobiliary microbiota in humans and other animals.[24,92] See Table 30.2.

Pathogenesis

The gastric helicobacters have evolved and acquired a number of traits that enable them to survive in a harsh environment, and the complex mechanisms used by these organisms to establish infection and maintain colonization is just beginning to be understood. Knowledge of the prevalence and natural history of *Helicobacter* infections as they occur in nature in nonhumans is likewise limited.[93] Gastric *Helicobacter* species exhibit different degrees of host specificity; hence, manifestations of disease are host specific in most cases. High levels of host specificity in gastric helicobacters are most evident in those species that adhere tightly to host tissues and are able to agglutinate red blood cells.[94,95] The wide range of *Helicobacter* infections seems to indicate that these bacteria may not always have a true pathogenic relationship with their host.[96] Although some *Helicobacter* strains clearly cause more damage to cells than others, much of the pathogenesis seen in *Helicobacter* infections such as *H. pylori* may be due to the host response to the bacterium, rather than any significant toxicity mediated by the bacterium itself. Some studies suggest that colonization of the stomach by this organism serves as a protective factor against gastroesophageal reflux disease and adenocarcinoma of the esophagus.[96] These types of pathology have increased at an alarming rate over the years and coincide with the dramatic decrease in gastric cancer and increased eradication of *H. pylori*.[97] This view of the role of *Helicobacter* is one of a commensal displaying a symbiotic host-parasite relationship.[6,98] Most of the pathology seen with gastric helicobacters such as *H. acinonychis,* and *H. felis* occurs when the organism is placed in an unnatural host or when the infection becomes chronic over time. Of course there are exceptions; for example, *H. cinaedi* and *H. fennelliae*

clearly produce disease in the primate model and have also been found to be associated with human disease.[41,99] Unlike *H. pylori*, *H. cinaedi* has been cultured from human blood and joint fluid, as has *H. fennelliae* from human blood.[100] It is believed that helicobacters that invade the bloodstream do so via colonization of the lower gastrointestinal tract.[101] *H. cinaedi* infection has been linked to possible animal human transmission, having been isolated for the first time in an adult who developed bacterial meningitis, after prolonged contact with her cat.[102] *H. heilmannii* and related gastric species have been associated with mild to moderate gastritis, peptic ulcer disease and gastric mucosa-associated lymphoid tissue (MALT) lymphomas in human adults.[41,103,104–106] Among the enterohepatic species of *Helicobacter*, *H. hepaticus*, *H. mustelae*, and *H. bilis*, exhibit carcinogenic potential in animals, and have been associated with numerous virulence genes, which might result in human disease as well.[39–41] For example, in the naturally infected ferret, infection with *H. mustelae* can also lead to precancerous lesions and has also been linked to gastric adenocarcinoma and MALT lymphoma in these animals.[107] Other enterohepatic species, such as *H. hepaticus, H. bilis,* and *H. ganmani*, have been detected by PCR in specimens from patients with hepatobiliary diseases.[30,31,108] However, such organisms have not yet been isolated from these patients. In addition, these organisms may be associated with Crohn's disease, inflammatory bowel disease and ulcerative colitis.[109,110] Similar helicobacters have also been found to colonize and cause inflammation in other mammalian species. This includes, for example, *H. cinaedi* in the rhesus monkey and *H. hepaticus* in mice.[111–113] *H. rodentium*, *H. typhlonius*, *H. bilis,* and *H. hepaticus* were recently found to be the most frequently detected enterohepatic species in wild house mice, suggesting that these animals serve as a potential reservoir for infection of both humans and other vertebrates.[114] *H. cinaedi, H. bilis,* and *H. canis* can cause severe infections, mostly in immunocompromised patients, such as bacteremia, cellulitis, cutaneous diseases, and fever of unknown origin.[115] Additional species of enterohepatic helicobacters have been implicated as causes of human gastroenteritis, in compromised patients such as *H. canadensis*, *H. pullorum,* and *H. winghamensis*.[44,45,62,89,116–119] *Helicobacter* species, such as *H. bilis*, *H. pullorum,* and *H. hepaticus* have also been detected in the human hepatobiliary tract.[109,120]

The role of enterohepatic helicobacters in veterinary and human medicine is increasingly recognized. However, more studies are still required to prove this association.[115]

In humans, natural infection with *H. pylori* is likely acquired quite differently from animal infection models, which require large and often repeated inocula.[121,122] It is widely believed that in the absence of treatment, *H. pylor*i infection, once established, persists for life. In the elderly, however, it is likely that infection can disappear. This is most likely due to the stomach mucosa becoming increasingly atrophic with age, rendering it inhospitable to colonization.[123] The proportion of acute infection that persists is not known. However, in studies that have followed the natural history of disease progression in populations, spontaneous elimination has been reported.[123,124]

Helicobacter can cause direct damage to epithelial cells in the gastric mucosa as well as induce an inflammatory response in the host. Both host factors and organism factors determine the phenotypic expression of the infection over time. Essentially, all persons colonized with *H. pylori* develop gastric inflammation, known as chronic superficial gastritis. The condition can develop into chronic inflammation of the gastric mucosa if the bacteria are not eradicated. However, this chronic inflammation is clinically silent in most infected persons.[38] This type of gastritis usually predisposes the host to hyperacidity and duodenal ulcer disease. In cases where the gastritis results from long-standing infection, it becomes more generalized and affects the corpus, leading to glandular atrophy and intestinal metaplasia. This is a recognized precursor state for gastric ulcer disease, gastric carcinoma, and MALT lymphoma.[125–128]

The role of *H. pylori* is less clear in chronic inflammation in coronary disease, inflammatory bowel disease, liver and biliary tract diseases and pancreatic cancer.[21,129–131] However other helicobacter species, such as *H. hepaticus, H. bilis,* and *H. cinaedi* are known to infect the intestines and biliary tract in humans and *H. bilis* has been found to be highly prevalent in patients with pancreaticobiliary maljunction.[21,132] Hence, additional studies are needed to determine the prevalence and capacity of non-*pylori* helicobacters to cause disease. Other medical conditions in which there is a suggested role for *H. pylori* include nonulcer dyspepsia, nonsteroidal anti-inflammatory drug-induced (NSAID) ulcer, gastroesophageal reflux disease (GERD), iron-deficiency anemia, and idiopathic thrombocytopenic purpura. There has also been a growing interest in the association of *H. pylori* with cardiovascular, neurologic, hematologic, dermatologic, head and neck, urogynecology diseases, diabetes mellitus and metabolic syndrome.[132–138]

Virulence Factors

Many virulence factors have been described in *Helicobacter* over the years, as summarized in Table 30.3. These factors enable the organism to survive the extreme acidic environment of the gastric tract, to reach the more neutral environment of the mucus layer, to colonize the gastric epithelium, and to evade the human immune response. This progression of events ultimately results in persistence of the organism, leading to possible infection and subsequent disease. Flagella, urease, and adhesins are essential colonizing factors. Among the other unique adaptations of *H. pylori* that enable the organism to survive in the hostile environment of the stomach are the presence of vacuolating cytotoxin (VacA) and oncogenic cytotoxin associated antigen A (cagA) protein. These virulence factors are discussed in greater detail in this section.[97,139–207,210]

Flagella and Motility

Movement is an important function of the gastric colonizers. First, it prevents the organisms from being washed out of the stomach and, second, allows the organisms to find suitable nutrients, while evading the local hostile environment. A fully functioning flagellum structure is essential for optimal survival. Studies involving the genes responsible for the flagella filament structure reveal that successful colonization and organism survival became compromised when these genes were disrupted.[210] Most of the gastric colonizers possess a spiral-shaped body with one exception, *H. mustelae,* which is a short rod. The morphology of the bacterium and the type of flagella dictate how the organism moves

TABLE 30.3

Virulence Factors of *Helicobacter*

Virulence Factor	Type	Proposed Function	Ref.
Flagella	Organelle	Promotes colonization; enhances bacterial penetration into the mucus layer and enables movement away from acidic environment.	[214–216]
Urease	Enzyme, immunogen	Colonization, neutralization, tissue damage (tight junctions). Causes gastric cancer progression	[143, 148–151]
Lewis Blood Group Antigen Adhesins: BabA (Binds to B and H-1 antigens) SabA (Binds with sialyl-Lex antigen)	ABO antigen-binding adhesins	Mediate bacterial attachment and colonization of gastric epithelium; Molecular mimicry and autoimmunity	[151, 210 220–223, 237–238]
Adhesins: OipA HopQ	Outer Membrane Protein (OMP)	Bacterial adherence to gastric epithelium; OipA also promotes a proinflammatory environment and damages mucosal layer. HopQ inhibits immune cell activities and facilitates CagA translocation.	[151, 210, 220, 221, 224–229]
Superoxide dismutase	Enzyme	Prevents phagocytosis and bacterial cell death	[151]
Catalase	Enzyme	Prevents phagocytosis and bacterial cell death	[151, 210]
Glycosulfatase	Proteolytic enzyme	Mucin degradation	[151, 210]
Phospholipase A	Enzyme	Tissue damage (cell membrane disruption)	[151]
Lipopolysaccharide (LPS)	Endotoxin	Affects macrophage-lymphocyte interactions; May contribute to *H. pylori* permanence; Epithelial cell apoptosis; molecular mimicry	[151, 153–155, 159, 164, 234–239]
Vacuolating cytotoxin A (VacA)	Cytotoxin	Causes cell vacuolization, cell necrosis and apoptosis.	[151, 166–168, 207–208, 210]
Cytolethal distending toxin (CDT)	Cytotoxin	Chronic inflammation and tissue damage (found in enterohepatic species of *Helicobacter*)	[151, 171–179]
Cytotoxin associated antigen (CagA)	Immunodominant cell surface antigen	Oncoprotein, which alters cell-signaling pathways; Induces chromosomal Instability, cell proliferation, and apoptosis; Causes IL-8 release and proto-oncogene activation.	[151, 188–194]
Coccoid forms	Morphological adaptation	Possible bacterial cell survival; May be associated with transmission and virulence.	[195–198, 201, 202]

and ultimately where in the gastric mucosa the organism will be located. For example, the movement of *H. felis* and *H. heilmannii* differs completely from that of *H. mustelae*, and, therefore, these bacteria are found in different regions of the stomach. These spiral organisms do not adhere to the cell surface, but instead are found free, tracking backward and forward along the mucus strands with their corkscrew motion.[209] The curved morphology of *Helicobacter* and the four to eight polar-sheathed flagella found in species such as *H. pylori,* create a screw-like motion, which may enable the organism to penetrate the mucin layer. The organism moves through the gastric mucosa epithelium layer to the basal layer where the pH value is close to 7.0.[210] Motility in helicobacters has been found to be pH dependent and becomes impaired at a pH below 4.0.[139] Mutations in any of the genes associated with the motility and the chemotaxis systems of *H. pylori* have been found to eliminate the bacterium's ability to infect the stomach and establish colonization.[210,211] Patients infected with *H. pylori* demonstrating increased motility were shown to also have increased bacterial density and a more intense inflammatory response in the upper stomach, and therefore potentially manifesting more severe pathological outcomes.[212] Therefore, flagella may be considered an early stage colonization virulence factor.[210] In addition to motility, flagella have been shown to play a role in bacterial adherence to mammalian host cells in a number of hosts.[213,214] However, a study by Clyne et al. indicated that flagella did not play a direct role in adhesion of both *H. pylori* and *H. mustelae* to gastric epithelial cells.[215] However, the genes involved in flagellar biosynthesis in *H. pylori* may also regulate the expression of adhesins, which are also important virulence factors associated with the bacterium.[215] Although many components of *H. pylori* flagella have been characterized and data regarding flagellar function and regulation are rapidly increasing, further studies are required to confirm the association between flagella an pathogenicity in *H. pylori*.[216]

Urease

Urease is a major virulence factor of gastric *Helicobacter* species. Among the proposed functions for the presence of urease in *Helicobacter* is the ability of the enzyme to protect the bacterium from the hostile acid environment of the stomach. Urease is also strongly immunogenic and chemotactic for phagocytes.[140] The enzyme catalyzes the breakdown of urea to alkaline ammonia and bicarbonate, which is further broken down to carbon dioxide and water (H_2O) molecules. These by-products provide the necessary environment for *H. pylori's* gastric survival, and continuous urease expression has been found to be necessary for colonization even after the organism's successful adaptation in the stomach.[142] Support for this theory has been demonstrated in studies with urease-negative mutants, which were shown to lack the ability to colonize the gastric mucosa at normal physiological pH.[141,142,217] *H. pylori* produces approximately 10% of its protein as urease enzyme.[143] The urease produced by *H. pylori* is of special interest as it is 10–100 times more active than other bacterial ureases and is located in the membrane, rather than the cytoplasm, of the organism. In addition, the Michaelis-Menten constant (K_m)

of the urease is much lower than that of other bacterial ureases, a finding consistent with the very low urea levels in the stomach.[144] Several *in vitro* studies have also linked urease to the associated pathology resulting from *H. pylori* infection. Ammonia production has been found to disrupt the tight cell junctions, breach the cellular integrity, and ultimately cause damage to the gastric epithelium.[145,146] Carbon dioxide protects *H. pylori* from the bactericidal activity of metabolic products like nitric oxide as well as intracellular killing of phagocytic cells.[147] Urease has also been reported to possibly contribute to tumor growth and metastatic dissemination by inducing new blood vessel formation from preexisting vasculature, or the process of angiogenesis. This process could play a role in gastric cancer progression.[148] Induction of hypoxia-inducible factor (HIF) has been associated with chronic *H. pylori* infection, and this transcription factor contributes to the development and progression of certain cancers.[149] *H. pylori* urease has also been shown to bind to major histocompatibility complex class II molecules and induce cell apoptosis.[150] The ureases of *H. pylori*, *H. felis*, and *H. heilmannii* are more closely related to one another than they are to the urease of *H. mustelae*.[218] Studies have shown that the enzyme of *H. heilmannii* might be different from those of other gastric *Helicobacter* species. However, there is also evidence to suggest that the *H. heilmannii* enzyme may be more similar to the urease of *H. felis*.[219] Unlike helicobacters that colonize the stomach, expression of urease in enterohepatic *Helicobacter* species is variable. See Table 30.1.

Adhesins

Adhesins are bacterial proteins, glycoconjugates, or lipids that are involved in the initial stages of colonization by mediating the interaction between the bacterium and the host cell surface.[151] Host cell receptors are composed of lipids, proteins, glycolipids, or glycoproteins. Adherence of bacteria to host cell receptors triggers cellular changes that include signal transduction cascades, which can lead to infiltration of inflammatory cells and to the local persistence of the organism. When the mucosal layer lining the gastric epithelium is colonized by *H. pylori*, the interaction between bacterial adhesins with cellular receptors ultimately protects the organism from displacement from the stomach due to peristalsis, gastric emptying, and mucus shedding. The bacterium also benefits by having access to nutrients for improved growth and enables bacterial toxin release and other effector molecules to gain entrance to host cells.[151,152] *H. pylori* adhesins are considered important virulence factors involved in many processes that occur both during the early and chronic phase of infection.[152] These adhesins belong to the outer membrane protein (OMP) family of *H. pylori*. The most well-known adhesins in this group include the blood group antigen-binding adhesin (BabA) and sialic acid-binding adhesin (SabA), the outer inflammatory protein (OipA) and *H. pylori* outer membrane protein (HopQ).[151] The OMP adhesins not only provide the bacteria attachment to host cells, but also augments the pathogenicity of *H. pylori*. BabA plays an important role in bacterial attachment and is associated with cellular pathogenicity. Two closely related paralogs, BabB and BabC have also been identified but their functions have not yet been elucidated.[151,220,221] BabA adhesin interacts with the difucosylated ABO/Lewis b (LeB) antigen present on red blood cells and gastrointestinal mucosa epithelial cells. Infection with BabA producing strains of *H. pylori* have been associated with an increased risk for peptic ulcer disease.[221] Also because of the preference of BabA *H. pylori* strains to bind to ABO blood group antigens, and especially to blood group O, infected individuals with this blood type are at higher risk for developing duodenal ulcer disease.[221] The SabA adhesin binds to Lewis X (sLex) and Lewis a (sLea) antigens, which are commonly found in the infected and inflamed gastric mucosa.[222] SabA expression has been found to respond to changing conditions in different regions of the stomach. This gives *H. pylori* the ability to quickly adapt to varying microenvironments or host immune responses, and results in long-term colonization and infection.[223] SabA production has also been reported to be associated with severe intestinal metaplasia, gastric atrophy, and development of gastric cancer.[222] Outer inflammatory protein (OipA) is another virulence protein comprising the *H. pylori* OMP family and is encoded by the *oipA* gene.[151] When the gene is expressed, OipA enables *H. pylori* to adhere to gastric epithelial cells and is associated with mucosal damage, host cell apoptosis, Interleukin (IL)-8 induction, duodenal ulcers, and development of gastric cancer.[151,224] *H. pylori* HopQ protein also contributes to bacterial adherence and interacts with the family of the carcinoembryonic antigen-related cell adhesion molecules (CEACAM), which are expressed on the gastric epithelium during gastritis and gastric cancer development.[151,224] In addition to the role played by HopQ in gastric colonization, recent studies have also shown its association with gastric ulcers, gastric cancer development, inhibition of immune cell activity, and the development of B-cell non-Hodgkin lymphoma.[151,225,226]

The attachment mechanisms of *H. pylori* to gastric epithelial cells that are associated with cytoskeletal rearrangements, and modification of host proteins, are also known to occur in enteropathogenic *Escherichia coli* adherence processes.[227] Similar structures have also been observed in ultrastructural studies of *H. mustelae* in its adherence to the ferret gastric mucosa.[228] The outer membrane proteins required for *in vitro* attachment of *H. pylori* to gastric epithelium have not been demonstrated in other gastric helicobacters such as *H. mustelae* and *H. felis*.[229] However, *H. mustelae* and *H. pylori* appear to bind common lipid receptors such as phosphatidylethanolamine (PE). The adhesion to intact eukaryotic cells has been found to correlate with the amount of PE present in the membrane.[230,231] Other cell surface properties, such as hydrophobicity, may also contribute to the gastric epithelial binding of helicobacters, as in the case of *H. mustelae*.[232] *H. heilmannii,* which is typically found in the mucus layer above surface epithelial cells, does not show the closely associated adherence structures seen in *H. pylori* adherence.[233]

Other Enzymes

Additional enzymes have been identified in the genus *Helicobacter* that enhance survival in the host environment. The action of superoxide dismutase, for example, breaks down the superoxide produced in polymorphonuclear leukocytes and macrophages, preventing their destruction of organisms. This enzyme has been isolated from *H. pylori*, for example, and is believed to play a role in its survival.[148] In a similar fashion, catalase is believed to protect *H. pylori* and other helicobacters from the damaging effects of hydrogen peroxide released from phagocytes.[149] Also, both

urease and catalase, when excreted into the surrounding environment, are believed to have a somewhat protective role against the humoral immune response.[148] Proteolytic enzymes such as glycosulfatase may cause degradation of gastric mucin, and the production of phospholipase A may contribute to the degradation of cell membranes by helicobacters.[150,151]

Lipopolysaccharide

The cell wall of most Gram-negative bacteria contains lipopolysaccharide (LPS) and which is typically composed of three layers: a hydrophobic lipid A (or endotoxin) that anchors the molecule to the outer membrane; a variable O-antigen extending from the cell to the external environment; and a core-oligosaccharide that links the O-antigen to the lipid A.[153] Each component of the LPS layer has its own unique function contributing to the bacteria's survival in the host. The LPS is known to play an essential role in inducing host activation of cytokine release and increased inflammatory response, resulting in a strong host immune response. The O-antigen of *H. pylori* LPS has been reported to contribute to the organism's virulence. *H. pylori* can imitate carbohydrate structures present within human blood cells, secretions and particularly epithelial cells by incorporating Lewis antigens into their O-chains.[154,159] Lewis antigens have been found to be expressed in over 80% of *H. pylori* strains tested.[237] To evade host immune surveillance, *H. pylori* constitutively modifies its Lipid A, allowing the organism to persistently colonize its host.[156] The unique lipid A structure of *H. pylori* enables the organism to resist cationic antimicrobial peptides (CAMPs), and to evade Toll-like receptor 4 (TLR-4) recognition.[154,156] Previous reports have shown that the LPS of *H. pylori* has a lower immunological activity when compared to other helicobacters and to other Gram-negative bacteria.[198] For example, *H. felis*-associated LPS appears to exert an inflammatory effect on host cells, whereas *H. pylori* endotoxin is a poor inducer of cytokine production by inflammatory cells *in vitro*.[235] This observation is explained in part by the unusual structure of lipid A in *H. pylori*.[153,154,156] The lower biological activity of the LPS, combined with host antigens on its surface, may be a mechanism for *H. pylori* to evade the host inflammatory response, and may explain why *H. pylori* infection is chronic and can last for decades.[236] Autoantibodies targeted against the bacterial Lewis antigens may also play a role in the pathogenesis of gastric disease.[237] This role is supported by studies that show that *Helicobacter* strains isolated from patients with ulcer disease express an increased number of Lewis antigens as compared to isolates cultured from patients with dyspepsia.[157,158] In contrast, the LPS of the gastric helicobacter *H. mustelae* does not express Lewis antigens, nor are the antigens expressed on ferret gastric epithelial cells. However, both ferret gastric epithelium and *H. mustelae* LPS express blood group antigen A. This antigenic expression may be considered a mechanism of molecular mimicry similar to the expression of Lewis antigens by *H. pylori*.[238,239]

Vacuolating Cytotoxin A

The toxins of *Helicobacter* species have been implicated in lesion formation associated with gastric and enterohepatic infections. The *H. pylori* VacA protein was the first of these toxins to be identified and characterized. This protein was initially described as inducing a vacuolating cytopathic effect in HeLa cell tissue cultures and is now known to play a crucial role in the pathogenicity of *H. pylori* due to its interaction with gastric epithelial cells.[151,161,162] VacA is an 88 kDa pore-forming toxin whose action on host cells is characterized by the formation of large vacuoles, which give the toxin its name.[151] The vacuoles formed are also believed to create an intracellular space for the survival of the bacterium.[205] The cellular morphologic changes induced by the protein as well as the resulting gastric epithelial cell necrosis, appear to create a nutrient-rich environment that optimizes organism survival.[163–165] The gene encoding VacA is present in all *H. pylori* strains and displays allelic diversity, which explains the variation in cytotoxic activity between strains.[163,164] The *H. pylori* strains most frequently associated with duodenal ulcer disease were found to produce toxigenic forms of VacA.[151] Both purified VacA protein and sonicated cell extracts of VacA-producing *H. pylori* were found to induce ulcer-like lesions when administered to mice, which supports the possible role of VacA in mediation of ulcer formation in the host.[240] Peptic ulcers have also been observed in gnotobiotic piglets and Mongolian gerbils that were colonized with *H. pylori*. Interestingly, these effects were also observed in mice, ferrets, and swine that were infected with non-*H. pylori* species.[94,241]

VacA has been found to promote the formation of acidic vacuoles in the cytoplasm of gastric epithelial cells.[163] This is believed to be caused by cellular collapse, resulting from the integrity of mitochondria, cytoplasmic membrane, and endomembranous structures, becoming destabilized.[163,165] In addition, the VacA protein is believed to be involved in the activation and suppression of the immune response through its effects on T-cells and antigen-presenting cells, which can result in immune tolerance and persistence of *H. pylori* infection.[163,166] The effects of this virulence factor have also been found to enhance *H. pylori* gastritis as well as ulcer and cancer development. This suggests that VacA could possibly be used as a biomarker for the prediction of disease development.[163–167,203,204] This is supported by studies that have shown that antibody produced against VacA is associated with increased risk for gastric cancer development and extra-gastric diseases, such as colorectal cancer, especially in African Americans.[203–208] Immunization of mice with VacA has been shown to prevent infection when mice were subsequently challenged with *H. pylori*.[208]

The *vacA* gene appears to be absent from other gastric helicobacters such as *H. felis*, and therefore, is not directly associated with damage to the gastric epithelium. Rather, the host T cell response, initiated by *Helicobacter* infection, is believed to be responsible for the resulting gastric pathology in *H. felis*.[242] Similarly, *H. mustelae* does not appear to produce vacuolating cytotoxin activity *in vitro*.[243] This observation suggests that there may be other factors involved in ulcer disease production among the other *Helicobacter* species.

Cytolethal Distending Toxin

The cytolethal distending toxin (CDT) is a bacterial virulence factor produced by several Gram-negative pathogenic bacteria, including some of the enterohepatic *Helicobacter* species implicated in several chronic infections.[171] The CDTs associated with these many organisms have been found to differ in their sequence

and structure, and are associated with the organism's pathogenicity, primarily by promoting persistent infection in their hosts. At the host level, CDTs cause cell distension, cell cycle block, and DNA damage, eventually leading to cell death.[171] In addition to these known *in vitro* effects of CDTs, there is also evidence that this toxin is involved in chronic inflammatory processes.[172,173] Among the enterohepatic helicobacters, CDT was first demonstrated in *H. hepaticus,* which produced a toxic effect in a murine liver cell line resulting in a granular appearance of the affected cells.[174] This latter CDT activity of *H. hepaticus* was found to closely resemble the CDT of *Campylobacter* species.[174,175] CDT-producing *H. hepaticus* closely resembles the human pathogen *H. pylori*, and is considered the prototype of enterohepatic helicobacters.[175] *H. hepaticus* infection induces chronic active hepatitis, hepatocellular tumors, typhlocolitis, and lower bowel cancer in susceptible mice.[175,178,179] This finding implicates CDT as having carcinogenic potential *in vivo*, although further studies using *in vivo* animal models are needed. The expression of CDT activity has also been observed in other enterohepatic *Helicobacter* species, such as *H. canis, H. bilis, H. cinaedi,* and in *H. pullorum,* which is considered an emerging human pathogen and implicated in several digestive pathologies.[41,42,177–179]

Cytotoxin-Associated Gene Antigen

One of the most intensely studied proteins of *H. pylori* is Cytotoxin-associated gene antigen (CagA). The *cagA* gene that encodes CagA is present within the *cag* pathogenicity island (*cag* PAI). The *cag* PAI is a 40 kb DNA segment that encodes for approximately 32 genes including components of the type IV secretion system.[164,180] The type IV secretion system (T4SS) is one of several types of secretion systems, which microorganisms use for the transport of macromolecules such as proteins and DNA across the cell envelope. Some T4SSs are used by pathogenic Gram-negative bacteria to translocate a wide variety of virulence factors into the host cell.[181] Upon infection, *H. pylori* utilizes this latter system to translocate CagA into host epithelial cells, which then localizes in the host cell plasma membrane. Once incorporated, a series of events occur, which starts with the kinase-mediated tyrosine phosphorylation of CagA.[164] In addition to CagA, *H. pylori* peptidoglycan is delivered into host cells, by the T4SS, which ultimately leads to the stimulation of pro-inflammatory cytokines such as interleukin-8.[151,182] Ultimately, the interaction between *cag* PAI positive strains and host cells results in the alteration of cell signaling pathways that regulate the cellular oncogenic response, induction of morphologic changes, chromosomal instability, cell proliferation, and apoptosis. This increases the risk for transformation and ultimately progression to gastric cancer.[151,183–187]

Both *cagA*-positive and *cagA*-negative *H. pylori* strains exist in nature. All *H. pylori* strains induce gastritis, however, those strains that are *cag* PAI positive, increase the risk for severe gastritis, atrophy, dysplasia, and gastric adenocarcinoma when compared to negative strains. The *cag* PAI is present in approximately 60% – 70% of Western *H. pylori* strains and close to 100% of East Asian *H. pylori* strains, which helps to explain the high gastric cancer incidence in that region.[187–193]

Negative *cag* PAI strains are located predominantly in the mucus gel layer of the stomach whereas positive strains are found adjacent or adherent to gastric epithelial cells, indicating the *cag* PAI genotype influences the colonization and distribution of the organism in the stomach.[194]

In animal hosts infected with non-*H. pylori* gastric helicobacters, such as *H. felis*, development of severe, chronic gastritis is known to occur. However, the presence of a *cagA* equivalent in these bacteria has not yet been definitively demonstrated. The induction of chronic gastritis in *Helicobacter*-infected animal hosts may therefore be independent of this cytotoxin.[242]

Coccoid Forms

H. pylori is typically recognized as a seagull-shaped or curved Gram-negative rod. However, when growing in either *in vitro* conditions or in suboptimal environments, the organism is capable of morphological transformation into an intermediate or transitional U-shaped and C-shaped cell (resting or dormant state), and a spherical or coccoid form (viable but unculturable form).[195] In addition, filamentous (elongated) forms of *H. pylori* have also been described.[195] This pleomorphism is not unique to *H. pylori* as this ability has been observed in many other Gram-negative rods. The coccoid form of *H. pylori* has been speculated to represent a dormant or stressed form of the organism, a resulting sign of cell adaptation, or a process of aging.[196] Since observing them in *H. pylori*, the coccoid forms and their viability, have been and continue to be a topic of debate. However, when the first observation of *H. pylori* coccoid forms were made in biopsy specimens, more emphasis and interest was generated in knowing their clinical importance and activity.[197] Coccoid forms are thought to play a potential role in relapsed or recurrent gastric disease and may even represent a form of antibiotic resistance.[195] Currently, it is believed that eradication therapies administered to patients, should aim at eliminating both bacilli and coccoid forms of *H. pylori*.[195,196] Other studies have indicated that adaptational changes in cell morphology are related to the virulence profile of *H. pylori*. Less virulent *H. pylori* strains have been found to have a lower potential for coccoid formation, than highly pathogenic strains, whereas strains of lower pathogenicity were more apt to form filamentous or elongated forms of the bacterium.[198–200] Reduction in cell size among *H. pylori* strains exposed to suboptimal conditions has been also found to be positively correlated with the presence of certain virulence genes, such as *vac*A, *cag*A, and *bab*A.[198] However, controversy still exists as to the infectivity of coccoid forms and their role in transmission, colonization, infection, and pathogenesis, and further studies are needed to better understand the importance of this pathogen morphotype.[201–202]

Culture of *Helicobacter*

The culture and isolation of *Helicobacter* in the laboratory is technically demanding and requires proper specimen transport, specific media, and growth conditions.[33,244] Given the effectiveness of currently available *Helicobacter* detection methods, it could be argued that culture is not an essential routine procedure in the diagnosis of *H. pylori* infections. However, there are many instances in which culture remains a valuable tool. For example, culture is indicated when evaluating antimicrobial resistance to prevent antibiotic treatment failures. There is also an increasing

need to fingerprint isolates of *H. pylori* and other *Helicobacter* species for epidemiological purposes. Many of these methods of molecular typing are relatively simple, well validated, and readily available, requiring pure cultures of newly isolated organisms.[60,61] Culture is also a basic research tool in the study of virulence factors such as urease and cytotoxin, among others. It is important to note that continuous passage on artificial media may cause isolates to lose properties essential for growth in the host and induction of disease. For this reason, those undertaking research with laboratory strains of *Helicobacter* isolates should repeat their studies using newly isolated organisms.[247]

Specimens for Culture of *Helicobacter*

Blood, feces, and gastric and tissue biopsies are sources for *Helicobacter* isolation. Although, *H. pylori* and other gastric helicobacters are rarely isolated from human blood, the enterohepatic helicobacters can often cause invasive infections. If bacteremia is suspected, peripheral venous blood should be collected as recommended by the manufacturer, in commercially available aerobic and anaerobic blood culture bottles.[247] The gastric helicobacters *H. pylori* and *H. heilmannii* are rarely isolated from human fecal specimens. However, enterohepatic helicobacters, like campylobacters, can be cultured routinely by modified stool culture, preferably within 4 hours of collection.[33] Glycerol-containing media can serve as both transport and storage media for biopsy specimens. Brucella broth with 20% glycerol is recommended as it is readily available commercially. Biopsy material should be minced or homogenized in 0.9% saline or 20% glucose prior to plating.[247]

Culture Techniques

In the laboratory, *Helicobacter* strains will typically grow under microaerophilic conditions (4% O_2, 5% CO_2, 5% H_2, and 86% N_2) at 37°C with increased humidity.[33,247] Microaerophilic environments can be created using a variable-atmosphere incubator, partially evacuated anaerobic jars with defined gas mixtures, or commercial gas-generating packets.[26] Growth does not occur in aerobic conditions, with the exception of species like the enterohepatic *H. rodentium,* which grows both in microaerophilic and anaerobic conditions. Although some species may take up to 10 days to grow, many others produce colonies in 3–4 days of incubation. *Helicobacter* can be grown on a variety of rich agar bases supplemented with 5–10% whole blood or serum.[33] These media include brain heart infusion agar, brucella agar, Wilkins-Chalgren agar, Trypticase soy agar, chocolate agar, Skirrow *Campylobacter* medium and Mueller Hinton agar.[33] Vancomycin, nalidixic acid, and amphotericin are common additives when a selective medium is required. When isolating *H. pylori*, the antibiotic cephalothin should be omitted, due to its susceptibility to this agent.[247,248] There are no recommended culture methods in the routine clinical laboratory for the isolation of *H. heilmannii* and other non-*H. pylori* gastric helicobacters, however, most media that will support the growth of *H. pylori* can be used to grow the gastric helicobacter *H. felis*.

Recently, a novel isolation method using high acidity and modified gaseous conditions has been developed for the isolation of *H. suis* from pig gastric tissue, but this medium's ability to isolate helicobacter from human gastric biopsy specimens has not been evaluated.[26] Fastidious species such as *H. bizzozeronii* and *H. salomonis* prefer very moist environments, and a thin broth layer can be poured on the top of the agar surface to stimulate growth.[249] Successful isolation of most enterohepatic helicobacters from feces requires a defined microaerophilic atmosphere with some strains requiring 5%–10% H_2 for optimum growth. Commercially available gas-generating packets may be inadequate in supplying the increased atmospheric hydrogen required by this group of helicobacters.[33] Certain species such as *H. bilis* and *H. hepaticus* have other specific growth requirements.[244]

Identification

Helicobacters produce varying colonial phenotypes on blood agar. *H. pylori* and other gastric helicobacters tend to produce entire gray and translucent colonies, whereas the intestinal helicobacters, such as *H. cinaedi, H. fennelliae, H. pullorum,* and *H. canadensis*, produce various swarming phenotypes as most isolates are motile. *H. pylori* cells have a curved or helical morphology, which is often lost on subculture, where the organism may subsequently appear as curved, "U" shaped or even as straight rods. Other gastric species are usually larger in size with a helical morphology that may be more pronounced.[33,245] The enterohepatic species morphologically resemble other Gram-negative spiral or curved bacteria.

Helicobacters cultured from blood may require special staining techniques to visualize the organisms. Such is the case when culturing *H. cinaedi,* which is generally not seen in a Gram stain preparation, but instead requires dark-field microscopy, Giemsa, or acridine orange staining for the best visualization of the bacterial cells.[100] When microscopically identifying helicobacters from biopsy material, Gram stains of histologic sections or smears of gastric mucus often can reveal the presence of the organisms. A modified Gram stain using carbol-fuchsin (0.5% wt/vol) counterstain has been found to augment detection of most helicobacters.[33] The Warthin-Starry and modified Giemsa stains can be used to identify the presence of the bacterial cells in tissue (Figure 30.1). Other non-*H. pylori* gastric helicobacters can be visualized by Giemsa stain and can be distinguished from *H. pylori* by their distinct, tightly spiral morphology.[245] Triple stains, which combine hematoxylin and eosin, Alcian blue, and a third stain such as the Genta or the El-Zimaity triple stain, have been found to be superior for identification of *H. pylori* and allow for easier delineation of gastric morophology.[250,251]

Helicobacters are routinely tested for cytochrome oxidase, catalase, and urease activity. All are oxidase-positive and most species, including *H. pylori,* are catalase-positive and urease-positive.[248] Susceptibility to nalidixic acid and cephalothin are also used as phenotypic markers of identification (Table 30.1). The enterohepatic species have several unique biochemical characteristics (Table 30.1). Biochemical and other testing should be carried out using recommended procedures.[246] Species such as *H. candidiasis*, *H. canis*, *H. fennelliae,* and *H. pullorum* that lack urease activity, resemble enteric campylobacters and therefore, definitive identification cannot be based on phenotype alone. Growth at 42°C and indoxyl acetate hydrolysis are examples of the useful tests that can be used to distinguish these species

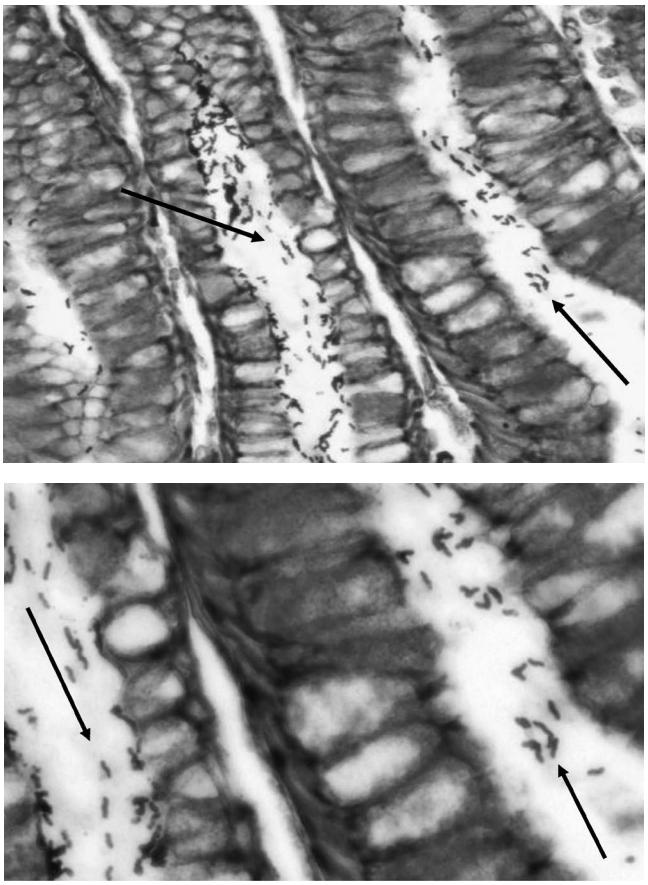

FIGURE 30.1 Panel A shows a Warthin Starry stain of *Helicobacter pylori* in the gastric mucosa demonstrating typical curved cell morphology. Panel B shows an enlarged portion of photomicrograph from Panel A. (Photomicrograph courtesy of Long Island Jewish Medical Center, Northwell Health System, Department of Pathology, New Hyde Park, New York.)

(Table 30.1). When culturing fecal specimens, it is important to note that samples may be co-colonized with multiple *Helicobacter* and *Campylobacter* species making organism identification challenging.[33]

There are currently several methods that can be used in the definitive identification of helicobacters, which include: nucleic acid amplification tests (NAATs) and matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry. NAATs are usually considered to be a good identification method due to their great sensitivity and specificity. PCR has been used for the rapid identification of *Helicobacter* species in clinical specimens, and has been used to identify *H. cinaedi* infections, as well as and for screening of carriers. [252–254] The advantage of MALDI-TOF when compared to other identification methods is the availability of results within a few hours.[255] This technique has also been used for the identification of *Helicobacter* species (*H. pullorum and H. pametensis*) and has helped to distinguish them from phenotypically similar *Campylobacter* species in clinical specimens.[256] However, this method has not been as successful for the identification of *H. pylori* because of its high intraspecies variability.[257] A variety of rapid typing methods have also been developed for clinical isolates, such as 16S rRNA gene sequencing, polymerase chain reaction-restriction fragment length polymorphism analysis (PCR-RFLP), and pulse field gel electrophoresis (PFGE). All of these methods enable subtyping of unrelated strains, but have differing accuracy, discriminatory power, and reproducibility.[258,259]

Antibiotic Susceptibility and Eradication Therapy

Various phenotypic and genotypic susceptibility testing methods are used to assess antimicrobial resistance in *Helicobacter.* Broth microdilution, disk diffusion, the Epsilometer test (E-test®), and agar dilution are among the phenotypic methods available used specifically for the susceptibility testing of *H. pylori.*[260–262] Several methods involving gene amplification, rapid sequencing by pyrosequencing, or fluorescent *in situ* hybridization, real-time PCR, PCR-restriction fragment length polymorphism among others have been developed for the rapid detection of mutations associated with antibiotic resistance in *H. pylori.*[263,264] The Clinical and Laboratory Standards Institute (CLSI) recommendations for antimicrobial susceptibility testing are currently available for *H. pylori* only. The CLSI recommends agar dilution susceptibility testing of clarithromycin when testing *H. pylori*. The treatment of *H. pylori* continues to be a much studied and debated topic. Increasing antibiotic resistance trends have become a stumbling block to current therapies and makes universal consensus on best treatment options challenging.[265] All patients who test positive for active infection should be treated, and the treatment that is chosen should provide an eradication rate of at least 90%.[266] Current *H. pylori* treatment regimens include: triple therapy, sequential therapy (where a patient is given one treatment followed by another), quadruple therapy, and levofloxacin-based triple therapy.[266,267] When choosing an appropriate treatment, other factors must be taken into consideration, which include: previous antibiotic exposure, regional antibiotic resistance patterns, and as noted above, eradication rates. It is believed that all of these factors may influence treatment outcome.[266,268] There are two suggested first-line triple therapy protocols, and they consist of clarithromycin, a proton pump inhibitor (PPI), and either amoxicillin or metronidazole.[266,267,269] Antacid medications such as proton pump inhibitors or H_2 antagonists are usually added to the regimen to reduce acid output and to encourage ulcer healing. Proton pump inhibitors suppress acid production by halting the mechanism that pumps acid into the stomach. H_2 blockers work by blocking histamine, which stimulates acid secretion. Historically, clarithromycin-based therapies were considered to be the most efficacious, best tolerated and safest to administer.[266] However, clarithromycin use has been threatened by increasing rates of antibiotic resistance, which have caused the eradication rate to fall below 80%.[263,264,266,270,271] Therefore it is recommended that this therapy choice be used in geographic areas where clarithromycin resistance rates are less than 15%, and for patients who have not had previous macrolide exposure.[263,264,266,267,269] Bismuth quadruple therapy has been found to result in eradication rates that are similar to clarithromycin-based regimens.[262,264,266,269] Bismuth-containing compounds, such as bismuth subsalicylate, can be added to the regimen to protect the stomach lining from acid damage. The compound also has some inhibitory effect on the organism. The first line bismuth

quadruple therapy is recommended in areas of high antibiotic resistance, in cases of prior macrolide exposure, and in patients where initial clarithromycin-based therapy has failed.[262,264,269] In addition, concomitant nonbismuth quadruple therapy administered for a recommended 14 days, is another first-line treatment choice for patients.[262,264,269] This regimen can also be used as salvage therapy in patients with persistent *H. pylori* infection, and where primary therapy has failed.[264,266] The College of American Gastroenterology (ACG) has recommended this latter approach based on a meta-analysis of 19 trials (>2,000 patients), which showed a mean eradication rate of 88%.[264,270] This eradication rate was also achieved in areas having high clarithromycin and metronidazole resistance. In the United States, levels of metronidazole resistance have been documented at 20–40% with similar levels seen in Europe.[264,268,270]

In cases of treatment failure using standard therapies, two other classes of antibiotics are recommended as a third choice for organism eradication. Levofloxacin and the antituberculosis agent, rifabutin, may be combined with a proton pump inhibitor and amoxicillin. This has been recognized as a promising regimen by the ACG based on results of international studies.[264,269] However, although levofloxacin-based therapy has been found to be comparable to clarithromycin triple therapy, *H. pylori* resistance rates to levofloxacin in the United States was found to be greater than 30% when isolates were tested from 2009 through 2011.[264] The use of rifabutin either in a triple regimen with a PPI and amoxicillin, or high dose dual therapy with a PPI and amoxicillin, are two other reported treatment options. However, there is insufficient efficacy data currently available for the rifabutin treatment options.[264,266,269] The limited antibiotic regimens used to treat *H. pylori* combined with the growing resistance of *H. pylori* to these antibiotics, is a cause for concern. lmproved local surveillance networks are needed to better select appropriate eradication regimens for each geographic region, in addition to long-term solutions for preventing infection with this pathogen.[263,264,266]

Optimal treatment regimens have not yet been established for other gastric helicobacters. However, there is evidence that treatment regimens used for *H. pylori* can resolve gastritis and peptic ulcer disease caused by these organisms as well as *H. heilmannii*-associated low-grade MALT lymphoma. There is no information regarding frequency of resistance to clarithromycin and other antibiotics and no PCR assays have yet been developed to determine antibiotic resistance in this group of organisms.[24,103,245] Although, *H. heilmannii* appears to be susceptible to triple therapy in humans, long-term eradication from animal hosts such as cats, dogs, and primates has not been as effective.[265,272] However, triple therapy has been shown to significantly reduce the burden of gastric helicobacters in experimentally infected mouse stomachs.[273] *H. felis*, which has been isolated from cats, dogs, and occasionally, the human stomach, is sensitive to a variety of antimicrobial agents. These compounds include metronidazole, cephalothin, erythromycin, ampicillin, and the antimicrobial agents used in triple therapy. Clearance of *H. felis* from mice using the triple therapy combination has led to the development of an animal model that can be used for the study of new antimicrobial regimens against *H. pylori*.[274] The antimicrobial therapy that is required to clear *H. mustelae* infection from ferrets is similar to that used for *H. pylori* in humans.[275] *H. acinonychis* is resistant to nalidixic acid and susceptible to ampicillin, penicillin, erythromycin, gentamicin, and chloramphenicol. *In vivo* triple antibiotic therapy has been found to be unsuccessful in totally clearing this organism from the cheetah host. This observation is also true for *H. salomonis* and *H. bizzozeronii,* which can be suppressed but not be totally eradicated from the stomach of dogs.[276]

There are currently no guidelines for the antimicrobial susceptibility testing of and recommended interpretive criteria for the enterohepatic helicobacters.[24,25] These organisms, which can be causative agents of bacteremia, often require combination antibiotic therapies that include aminoglycosides, such as amikacin or gentamicin. However, prolonged therapy is often necessary to eradicate infection. Treatment for *H. cinaedi*, for example, can include antibiotics such as erythromycin, ciprofloxacin, levofloxacin, gentamicin, tetracycline, and beta-lactams administered for at least a 2- to 3-week period.[80,100,276,277] Susceptibility testing of this latter species is probably warranted, as *in vitro* resistance has been correlated with treatment failures.[24,100] Although data are limited, gentamicin and ampicillin-sulbactam have been found to successfully treat bacteremia caused by *H. fennelliae*.[102,278] Likewise, limited information is available for treatment regimens for gastroenteritis caused by *H. canis, H. bilis*, and *H. pullorum*. However, bacteremia caused by *H. bilis* and *H. canis* were recently shown to be successfully treated with ertapenem, azithromycin, levofloxacin, doxycycline, and ceftriaxone.[279,280]

In addition to antibiotics, there is now evidence indicating that some natural compounds may have an inhibitory effect against *Helicobacter.* In particular, studies have shown that regular consumption of broccoli sprouts may eradicate *H. pylori*. Similarly, polyphenolics found in green and other teas have been shown to suppress *H. pylori* growth *in vitro* and in animal models.[281,282] Green tea extract has also been found to inhibit *H. pylori* adhesion to human epithelial cells *in vitro*.[283] Other nonantibiotic agents that have been reported to have anti-*H. pylori* activity include quince and cranberry juice, black caraway, garlic, and turmeric.[284,285] Recent interest has also been generated in the use of probiotic therapy, used as an adjunct to *H. pylori* eradication regimens. Reports and current meta-analyses have suggested that probiotic adjunct therapy resulted in an increased cure rate of approximately 10% – 4%.[265] Further studies are needed, however, to determine if these and other agents could potentially be used for prophylaxis or adjunct therapy for *Helicobacter* infection, and possibly help control the rising bacterial resistance of these organisms to antibiotics.[286]

Detection Methods

Historically, *H. pylori* testing was indicated for patients having clinical manifestations of infection, a history of peptic ulcer disease, or MALT lymphoma.[262,264,287,289] Recently, use of diagnostic testing has been expanded beyond gastrointestinal manifestations of *H. pylori* infection. Evidence now supports testing patients with nongastric diseases, such as unexplained iron-deficiency anemia or idiopathic thrombocytopenic purpura.[262,264,266,289]

There are several invasive and noninvasive approaches for the detection of *Helicobacter,* including *H. pylori*. Invasive methods require endoscopic biopsies and include rapid urease testing, histological examination, culture, and polymerase chain reaction.

TABLE 30.4

Methods for Detection of *Helicobacter*

Test Method	Principle	Comments	References
Histological examination	Direct observation of organism in tissue	Requires invasive procedures, such as endoscopy. Sensitivity is dependent on bacterial load present.	[250–251, 287, 289, 293]
Culture	Isolation of *Helicobacter* from specimens	100% specificity. Requires invasive procedures; technically demanding; Allows antibiotic susceptibility testing of isolates.	[244, 247–248, 257–258, 293]
Rapid urease	Indirect detection of *Helicobacter* by demonstration of urea breakdown products	Rapid results and easy to perform, False-positive results possible; endoscopy required.	[245–247, 293]
Radiolabeled C^{13} or C^{14} urea breath tests (UBT)	Measurement of labeled CO_2 in the breath; derived from urease hydrolysis of ingested C-labeled urea	Considered most reliable noninvasive test. Well tolerated; high sensitivity and specificity. Used in diagnosis of *H. pylori* infection and monitoring post treatment eradication.	[293, 300]
Serology	Measurement of *Helicobacter*-specific immunoglobulins IgG, IgA, and IgM by ELISA and latex agglutination	Noninvasive; good epidemiologic study tool; may not differentiate active vs. past infection. Widely available for *H. pylori* antibodies; not commercially available for *H. cinaedi* or other enterohepatic helicobacter; Method of choice for initial *H. pylori* detection due to cost efficiency and ease of performance.	[293, 297–298]
Fecal Antigen Test	Direct detection of *Helicobacter* antigen in feces using monoclonal antibodies by ELISA or immunochromatography assay (ICA) and antibodies.	Noninvasive; rapid assays available; high sensitivity and specificity; used in diagnosis and as an alternative method to UBT for eradication confirmation of *H. pylori* infection.	[292, 293]
DNA amplification	PCR assays are available for speciation, determination of resistance genes, 16S rRNA relatedness and for direct detection of *H. pylori* in stool and other specimens.	PCR is not available for all species; no suitable PCR assays available for fecal detection of enterohepatic *Helicobacter* species of clinical relevance.	[252–254, 259, 293, 295–296]

Noninvasive testing methods include serologic testing, the urea breath test, stool antigen test, and stool-based PCR assays.[288,289] Although the details of these test methods are beyond the scope of this chapter, additional information can be found in Table 30.4.[33,247–251,288–301]

Animal Models for the Study of *Helicobacter*

Much of the current understanding of *Helicobacter* pathogenesis, and especially that of *H. pylori*, has derived from *in vitro* studies. However, these methods often fail to demonstrate the true complexities of the host-pathogen relationship. The availability of small animal models has augmented and improved our understanding of the *in vivo* mechanisms of host adaptation by these organisms. Many different animal models, such as mice, ferrets, dogs, and cats, have been used over the years for studying *Helicobacter* organisms.[23] These animal models have generated important information that has also been physiologically relevant to human disease. Mice, rats, and rabbits were some of the first animal models used for the establishment of *H. pylori* infection, but they did not prove successful.[302] Animal models were then sought based on their natural infectivity with closely related *Helicobacter* species, such as the ferret or nonhuman primates, or by their ability to be experimentally infected with *H. pylori*, such as gnotobiotic piglets and dogs.[303–306] Experimental *H. pylori* infections have also been developed in Mongolian gerbils, guinea pigs, cats, and macaque monkeys.[307–310] Likewise, several animal models have been developed to study other gastric helicobacters, as well as the enterohepatic helicobacters such as *H. hepaticus*, *H. cinaedi*, *H. bilis,* and *H. fennelliae*.[242,311–318]

The ferret, having a stomach with anatomic and physiological similarities to that of humans, was also found to develop naturally occurring gastritis and gastric ulcer disease caused by *Helicobacter mustelae*.[303] As a result, the *H. mustelae* ferret model became one of the best-studied animal models of gastric *Helicobacter* infection in the natural host.[319,320] This model was instrumental in solidifying the role of *H. pylori* pathogenicity in humans. Although the ferret model is an excellent research tool, it is not always readily accessible.[320] Other animal models, such as the gnotobiotic piglets and primates, are likewise expensive and impractical for widespread use although they have been successfully utilized.[197,217,321]

Although there is no one model that is perfect for all aspects of research applications, the mouse model, based on cost and practicality, is the animal model of choice for *Helicobacter* studies. The use of mice models has been able to demonstrate the immune system modulation effects caused by gastric and enterohepatic *Helicobacter* species.[322–325] These models have also helped elucidate the importance of both intestinal and extraintestinal coinfection with regard to patient outcomes especially in terms of the degree of inflammation, and tumor development.[323,326,327] *H. felis,* which normally colonizes the gastric mucosa of cats and dogs, was found to readily colonize mice, particularly the gastric antrum.[328] This was an important finding because *H. pylori* could not be made to colonize early mouse models.[302] The first demonstration of the potential use of the *H. felis* mouse model was in studies with germ-free mice, where the bacterium was found to induce an active chronic gastritis and inflammatory effects similar to those induced by *H. pylori* in humans.[329] Subsequently, the *H. felis* mouse model provided an opportunity to study and understand an infectious process that resembled gastric pathological changes in human

H. pylori infection.[330,331] One limitation of the *H. felis* model is that it lacks the cag PAI found in *H. pylori*.[332] In spite of this, the ability of *H. felis* to induce severe gastritis and carcinoma in certain mice strains, makes this a valuable model to study inflammation-associated gastric carcinogenesis. With the availability of the *H. pylori* genome and recent advances in genetic engineering, *in vivo* imaging, and system-wide genomics and proteomics, the *H. felis* mouse model is being replaced with newer genetically engineered mouse study models.[54,160] The first published report of induced gastric carcinoma by *H. pylori* was reported using transgenic insulin-gastrin (INS-GAS) mice.[333,334] These mice overexpress pancreatic gastrin making them useful in the study of gastric cancer. This mouse model was also recently used to demonstrate the link between exposure to Swedish smokeless tobacco snuff and gastric cancer.[335] INS-GAS mice have a unique and important feature, i.e. male-predominant cancer expression, which mimics that seen in humans. Studies using these animals have shown that estrogen has a protective effect against cancer in both males and females infected with *H. pylori*.[334,336]

Other mouse models are being used to study the role of coinfection with other bacteria, viruses, and eukaryotic parasites and the modulation of *Helicobacter* disease. Such infections may augment or ameliorate gastric disease depending on location and the type of immune response elicited.[323,327] These findings help explain the high degree of regional differences seen in *H. pylori* disease outcomes among human populations, and which appear to depend on the incidence of endemic coinfections.[337] For example, in mice, helminth and protozoal parasites have been shown to impact the progression of gastritis and preneoplasia induced by *H. felis* and enterohepatic species of *Helicobacter* in the lower bowel. Such coinfections can impact the phenotypic disease induced by *H. pylori*.[322–324] In humans, infection with *Schistosoma mansoni* has been proposed to be one factor in the protection of individuals against concomitant *Helicobacter* gastritis in low-lying tropical regions.[338] Generally speaking, infectious agents that provoke a Th1 type immune response, regardless of tissue site, have been shown to augment disease induced by gastric helicobacters, whereas a Th2 type immune response may ameliorate disease.[337,339–341] This supports other animal studies that have shown that proinflammatory gut microbes such as *H. hepaticus* can promote extraintestinal cancers including mammary and liver carcinomas.[339]

Animal models and the use of sophisticated molecular tools will continue to yield new and pertinent information in our understanding of *Helicobacter* disease. In particular, new insights will continue to be unraveled regarding the complex host-pathogen mechanisms that influence clinical disease and its possible progression to cancer. This information will more importantly shed light on how these mechanisms might be therapeutically modulated to improve patient outcomes.

The Genus *Legionella*

Members of the genus *Legionella* are Gram-negative, aerobic bacilli that belong to the gamma-subgroup of proteobacteria. *Legionella* are facultative, intracellular bacteria that are ubiquitously found in freshwater ponds and streams where they colonize phagocytic protozoa. The relevance of these organisms to human health was first recognized following the eponymous 1976 outbreak at a meeting of the American Legion in Philadelphia. During the weeks following the convention, 221 attendees fell ill with unexplained, pneumonia-like symptoms; 34 of these patients later died (Garrett 1994). Legionnaires' disease was ultimately linked to infection by a bacterium that was named *Legionella pneumophila*. An examination of the air conditioning system at the convention site revealed high levels of *L. pneumophila*-laden protozoa, indicating that exposure to these bacteria via inhalation of contaminated aerosols could result in severe respiratory disease.

Subsequent outbreaks of *Legionella* infection have been traced to several types of man-made water reservoirs, including cooling towers, industrial air conditioners, hot water systems and fountains. If improperly maintained, biofilms may develop on the accumulated sediment in these structures, creating an ecosystem that supports both protozoa and *Legionella* growth. Members of the genus *Legionella* are found in numerous natural ecosystems proximal to human populations, but their ability to colonize human hosts depends upon inhalation of aerosolized water-borne bacteria. There has been one recorded case of *Legionella* human-to-human transmission stemming from the 2014 Vila Franca de Xira, Portugal outbreak that resulted in 400 cases and 14 deaths, one of the largest out breaks to date (Borges *et al.* 2016).

The diseases resulting from exposure to *Legionella*, collectively termed legionellosis, include Legionnaires' disease and Pontiac fever. Legionnaires' disease is a severe infection of the respiratory tract that is fatal in approximately 10% of cases (CDC 2018). Pontiac fever is a milder illness, with flu-like symptoms that may resolve within a few hours to a few days of onset. Whereas Legionnaires' disease is thought to result from an infection where bacteria are actively replicating in the lung, Pontiac fever may result from an acute exposure to high levels of bacteria without bacterial multiplication. All forms of legionellosis can be successfully treated with a range of antibiotics, including macrolides (erythromycin, azithromycin, clarithromycin), tetracycline (doxycycline), or broad-spectrum fluoroquinolones (Amsden 2005).

Legionella infection is one of the most common causes of community-acquired pneumonia (CAP) and is second only to bacteremic pneumococcal pneumonia in causing severe CAP that requires treatment in intensive care. *Legionella* has also emerged as a common nosocomial acquired pneumonia, a phenomenon of particular concern since mortality resulting from legionellosis is highest in elderly and immunocompromised patients (Amsden 2005). In the United States between 8,000 and 18,000 people are diagnosed with legionellosis each year; however, this number is estimated to be higher as many cases go undiagnosed (Amsden 2005).

Thus far, 65 *Legionella* species, consisting of more than 80 strains, have been identified (Gomez-Valero *et al.* 2019).

While many of these species can occasionally cause disease in humans, analysis of culture-confirmed cases of legionellosis indicates that *L. pneumophila* is responsible for greater than 90% of disease, with the exception of Australia and New Zealand, where 30–55% of cases are caused by *L. longbeachae* (Mercante and Winchell 2015). Other strains periodically isolated from immunocompromised patients include *L. bozemanii*, *L. micdadei*, *L. feeleii*, *L. dumoffii*, *L. wadsworthii*, and *L. anisa* (Yu *et al.* 2002). Of the 15 serogroups identified for *L. pneumophila*, the vast majority of disease results from infection by serogroup 1, with serogroups 4 and 6 periodically found in nosocomial outbreaks (Amsden 2005). Due to the marked clinical prevalence of *L. pneumophila* serogroup 1, the majority of scientific research has focused on these, commonly Philadelphia 1 and Paris strains.

Despite this historical focus on serogroup 1, the emergence of high-throughput sequencing technologies promises to shed new light on *Legionella* diversity and the evolution of disease. Early microarray-based comparisons between different genetic backgrounds of *L. pneumophila* have suggested that serogroup 1 clinical prevalence might derive from a unique lipopolysaccharide (Cazalet *et al.* 2008). Whole genome comparisons between a serogroup 6 strain *L. pneumophila* str. Thunder Bay and *L. pneumophila* serogroup 1 identified genetic differences within the serogroup 6 O-antigen biosynthetic cluster (Khan *et al.* 2013). Compared to serogroup 1 strains, Thunder Bay displayed reduced O-antigen decoration, increased susceptibility to complement-mediated killing, and reduced dissemination in a mouse model of disease. Whole genome sequencing revealed that the strain responsible for the first human-to-human transmission, *L. pneumophila* subspecies Fraseri, contained a rare 65 kb pathogenicity island carrying enzymes that mediate oxidative stress, an efflux pump-like homolog, as well as the unique lipopolysaccharides present in clinical strains of serogroup 1 (Borges *et al.* 2016). Additionally, some strains have developed the ability to infect human hosts through the acquirement of a diverse effector protein repertoire that will be discussed later.

L. pneumophila Growth in Nature and in the Laboratory

In freshwater ecosystems, *L. pneumophila* colonizes biofilms where they are phagocytized and replicate within free-living protozoa including *Acanthamoeba*, *Hartmonella,* and the model amoeba *Dictyostelium* (Moffat and Tompkins 1992; Fields *et al.* 1993; Solomon *et al.* 2000). To study the basis of human infection in the laboratory, *L. pneumophila* can be cultured within a range of mammalian cell lines. Primary macrophages derived from the bone marrow of laboratory mice, such as A/J and C57BL/6, have been used in numerous studies (Yamamoto, Klein, and Friedman 1991; Saito *et al.* 2001), in addition to macrophage-like cell lines such as THP1, U937, RAW, and J774 (King *et al.* 1991; Husmann and Johnson 1992; Cirillo, Falkow, and Tompkins 1994; Diez *et al.* 2000). *L. pneumophila* can also replicate within cells that are not inherently phagocytic, provided they have a means of internalization. For example, *L. pneumophila* that have been opsonized with a specific antibody can be internalized by Chinese hamster ovary (CHO) cells expressing the FcγRII receptor. Cell biological assays indicate that the intracellular life cycle events that unfold in this cell line parallel those seen in protozoan and phagocyte hosts (Kagan *et al.* 2004).

The nutrients required for *L. pneumophila* to establish and maintain its intracellular niche are yet to be fully described. Microarray analysis of differential gene expression in *L. pneumophila* growing extracellularly in broth culture or intracellularly in *Acanthamoeba castellanii* indicate that intracellular growth involves scavenging for amino acids by upregulation of factors governing amino acid uptake and catabolism. In addition, *L. pneumophila* may also acquire carbohydrate from its host, as intracellular growth also leads to an upregulation of the gene cluster encoding the Entner-Douderoff pathway, a putative glucokinase and a sugar transporter (Brüggemann, Cazalet, and Buchrieser 2006).

The growth medium commonly used for extracellular culture of *Legionella* spp. consists of yeast extract and ACES buffer, with potassium hydroxide added to adjust the pH to 6.9 (Feeley *et al.* 1979). This medium is then supplemented with cysteine and iron, and for solid medium, activated charcoal is added to chelate an unknown factor in agar that is toxic to *Legionella*. Bacterial growth is optimal at 37°C, but lower temperatures (20–25°C) are often required for studies involving protozoan host species. Streptomycin, chloramphenicol, gentamicin, and kanamycin are frequently used for antibiotic selection; however, *L. pneumophila* is resistant to even high doses of ampicillin.

Biphasic Life Cycle of *L. pneumophila*

Studies of *L. pneumophila* grown in broth or in protozoa have shown that this bacterium has (at least) two different stages in its life cycle. While growing exponentially in broth culture, and within the first several hours following host cell entry, *L. pneumophila* adopts a nonmotile, nonflagellated state, which is competent to replicate to high levels, but shows a low level of infectivity of new host cells. When cultured in broth to high density in post-exponential phase, *L. pneumophila* become motile due to the production of flagella and these bacteria are highly infectious. This phase roughly correlates with late time points of *in vivo* infection of host cells when *L. pneumophila* have completed several rounds of replication and exist within densely populated replicative compartments. With nutrient concentrations and host cell viability on the decline, these virulent, motile bacteria are primed to carry out new rounds of infection in neighboring host cells. In addition, the transition of *L. pneumophila* from its replicative form to infectious form is associated with increased resistance to osmotic and heat stress, sensitivity to sodium chloride, increased pigmentation and a reduction in bacterial cell size (Byrne and Swanson 1998).

These broadly defined stages of *L. pneumophila*'s life cycle have been termed the replicative and transmissive phases, and the regulatory mechanisms underlying this phase switch are beginning to be described. A screen for mutants that expressed low levels of flagellin during the during post-exponential growth conditions revealed that a two-component regulatory system, LetA/LetS, the sigma factor FliA, and the stationary phase sigma factor RpoS function in concert to regulate *L. pneumophila*'s transition from its replicative to transmissive form (Hammer, Tateda, and Swanson 2002; Lynch *et al.* 2003) . The LetA/LetS two-component system is thought to respond to

ppGpp, an alarmone produced as part of a stringent response under conditions of nutrient starvation such as low amino acid levels (Hammer and Swanson 1999; Jain, Kumar, and Chatterji 2006). In turn, LetA/LetS induces transition to the transmissive phase by relieving repression by CsrA (Molofsky and Swanson 2003). Csr regulatory systems are found in numerous bacterial species and are responsible for post-transcriptional regulation of gene expression on a global level (Romeo 1998; Majdalani, Vanderpool, and Gottesman 2008). However, the requirement for LetA/LetS signaling in *L. pneumophila* virulence appears to be host cell type-dependent. *LetA* mutants that showed a replication defect in the protozoan host *Acanthamoeba castellanii* were able to grow efficiently in A/J mouse bone marrow-derived macrophages (Hammer, Tateda, and Swanson 2002; Lynch *et al.* 2003).

The role of the sigma factor RpoS in phase switching is no yet fully understood. Due to the requirement for this transcription factor for intracellular survival and replication, RpoS function has been placed amidst a cascade of replicative phase regulatory events (McNealy *et al.* 2005; Abu-Zant *et al.* 2006). However, seemingly contradictory data reveal an upregulation of RpoS expression during the stationary phase as *L. pneumophila* prepares to transform into the transmissive phase (Hales and Shuman 1999; Bachman and Swanson 2001; Gal-Mor and Segal 2003; Molofsky and Swanson 2003).

Finally, the successful transformation of replicating *L. pneumophila* to virulent, motile, bacteria requires the signaling cascade of the flagella regulon. Upon entering the transmissive phase, the alternative sigma factor RpoN and the transcriptional activator FleQ positively regulate expression of *fleN* (FleN may be an antiactivator of FleQ), *fliM*, *fleSR*, and numerous other genes whose products are required for flagellum biosynthesis (Dasgupta and Ramphal 2001; Jacobi, Schade, and Heuner 2004; Brüggemann *et al.* 2006). RpoN and the FleS/FleR two-component system act in concert to trigger expression of the alternative sigma factor FliA, which controls the last stages of flagellum biosynthesis, including production of the FlaA flagellin subunit (Heuner and Steinert 2003; Brüggemann *et al.* 2006).

Intracellular Life Cycle of *L. pneumophila*

Bacterial Entry

Since *L. pneumophila* was identified as the causative agent of the fatal pneumonia outbreak in 1976, the intracellular life cycle events of this bacterium have been extensively dissected. Early work by Marcus Horwitz and colleagues provided an essential descriptive model of *L. pneumophila*'s intracellular trafficking within both protozoan and macrophage hosts (Horwitz 1983a; 1983b). Subsequent studies have revealed that *L. pneumophila* is able to evade the degradative endocytic compartments of the host cell (Berger, Merriam and Isberg 1994) and establish a replicative niche by remodeling its phagosome into a ribosome-studded vacuole that resembles the host cell endoplasmic reticulum (ER) (Tilney *et al.* 2001; Kagan and Roy 2002; Robinson and Roy 2006) (Figure 31.1).

L. pneumophila enter host cells by phagocytosis, engaging host cell surface receptors that appear to vary with host cell type. In mammalian monocytes, bacterial entry can be partially inhibited

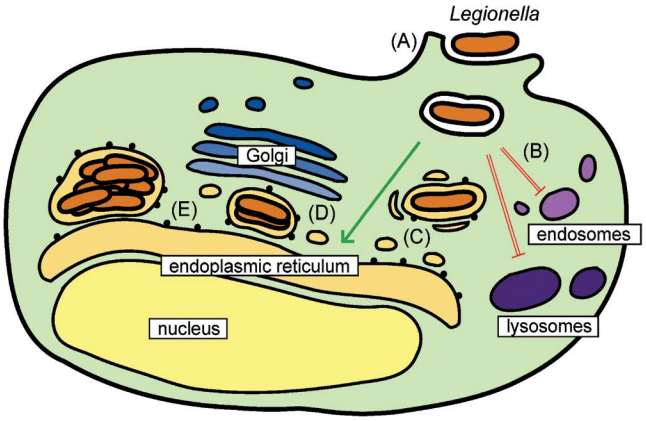

FIGURE 31.1 Intracellular life cycle of *Legionella pneumophila*. (A) *L. pneumophila* engage protozoan or mammalian host cell surface receptors and are internalized by phagocytosis. (B) The bacterium inhibits transport of its phagosome down the endocytic pathway to degradative lysosomes and (C) associates with membrane vesicles and mitochondria within minutes of internalization. (D) *L. pneumophila* completes remodeling of its vacuole and begins to replicate in a compartment that is morphologically indistinguishable from the ER. (E) Bacterial replication proceeds for several hours until the LCV is lysed and *L. pneumophila* exit host cells to initiate new rounds of infection. (Figure adapted from Roy and Tilney [2002].)

by the presence of antibodies specific for the C1 and C3 complement receptors on the host cell surface (Payne and Horwitz 1987). It has also been shown that opsonization of *L. pneumophila* with a bacteria-specific antibody allows for Fc-receptor mediated phagocytosis (Horwitz and Silverstein 1981) though the absence of *L. pneumophila*-specific IgG in the lungs of naïve human hosts renders this pathway of uncertain clinical relevance. In addition, levels of complement in the lung are normally low (Reynolds and Newball 1974), suggesting that *L. pneumophila* may also engage as yet unidentified surface receptors to induce uptake into mammalian host cells.

L. pneumophila's natural hosts—freshwater protozoa—lack both Fc and complement receptors. The bacteria infiltrate various protozoan host through predatory grazing of biofilms that *Legionella* has colonized (Boamah *et al.* 2017). The fate of the bacteria once it enters the cell is determined by the host infected. Members of the Cercozoa and Amoebozoa phylums such as *Cashia limocoides*, are efficient at digesting *Legionella* pathogens, while many protozoa such as the aforementioned *Acanthamoeba,* provide useful replication reservoirs (Boamah *et al.* 2017). Following adherence to host cells, internalization of *L. pneumophila* proceeds via conventional zippering phagocytosis that can be potently blocked by depolymerization of the actin cytoskeleton with Cytochalasin D (Elliott and Winn 1986). There is also evidence that *L. pneumophila* can induce a novel form of entry termed "coiling phagocytosis," in which the bacterium is enveloped in multiple layers of host cell membrane during internalization (Horwitz 1984). This phenomenon has been observed when professional phagocytes are infected with relatively high doses of live or heat-killed *L. pneumophila* and can be disrupted if the bacteria are pretreated with anti-*L. pneumophila* antibody. This suggests that high concentrations of a stable bacterial surface component may be required to perturb phagocyte membrane and induce coiling, a model supported

by the observation that only certain *L. pneumophila* serotypes induce coiling phagocytosis (Rechnitzer and Blom 1989).

The role of coiling phagocytosis during *L. pneumophila*'s life cycle is unclear. Bacterial viability has been shown to be required for all *L. pneumophila* virulence factors identified to date, including Type IV secretion (discussed below) and changes in morphology, motility, and gene expression associated with *L. pneumophila*'s transition from a replicating, noninfectious state to a stationary and transmissive one. Since heat-killed bacteria can induce coiling phagocytosis but are quickly delivered to lysosomes and degraded (Horwitz 1984), it is unlikely that this novel mode of entry plays a significant role in the later stages of *L. pneumophila*'s unique pattern of intracellular trafficking.

Intracellular Trafficking and Replicative Vacuole Formation

Once inside its host cell, *L. pneumophila* must quickly execute two essential tasks to successfully establish its intracellular niche. The bacterium must avoid the fate of most cargo internalized by phagocytic cells by preventing its rapid delivery to lysosomes, the degradative terminal compartment of the endocytic pathway. Concurrently, *L. pneumophila* must establish a subcellular niche that supports bacterial replication.

Early experiments by Horwitz and colleagues showed that phagosomes containing live *L. pneumophila* acquire lysosomal markers at greatly reduced levels compared to phagosomes containing fixed *L. pneumophila* or *E. coli* and this separation from the endocytic pathway is maintained for several hours following infection (Horwitz 1983a; 1983b). Subsequently, various lines of experimentation have generated conflicting data regarding late-stage fusion events of *L. pneumophila*'s compartment with acidic lysosomes and the importance of acidic pH for efficient bacterial growth.

Evidence supporting a need for acidification of the *L. pneumophila*-containing vacuole (LCV) is provided by the reduced numbers of bacteria recovered from host cells treated with the vacuolar ATPase inhibitor bafilomycin-A (BFA), which prevents acidification of endocytic compartments (Sturgill-Koszycki and Swanson 2000). However, BFA treatment has been shown to dysregulate a number of cellular pathways (Clague *et al.* 1994; Reaves and Banting 1994; van, Geuze and Stoorvogel 1997; Yamamoto *et al.* 1998), calling into question the ability to directly interpret these data as proof of *L. pneumophila*'s requirement for an acidified compartment. In addition, bacterial growth assays conducted in monocyte cell lines with differing capacities to acidify their endocytic compartments yielded indistinguishable levels of bacterial growth (Wieland, Goetz, and Neumeister 2004). Therefore, it is likely that the only prudent action that *L. pneumophila* may take relative to the endocytic pathway is to avoid it.

With the degradative effects of the lysosome held at bay, *L. pneumophila* conducts an extensive remodeling of its plasma membrane-derived phagosome. Within 15 minutes of internalization, the LCV is surrounded by numerous smooth vesicles and mitochondria (Horwitz 1983a). As the infection proceeds, these vesicles flatten and fuse with the limiting membrane of the LCV, which also becomes studded with ribosomes (Horwitz 1983a; Tilney *et al.* 2001; Robinson and Roy 2006). Localization of various ER proteins to this compartment shortly after infection, including calnexin, BiP, and KDEL epitope-containing proteins, indicate that these vesicles are derived from the ER (Swanson and Isberg 1995; Kagan and Roy 2002; Derre and Isberg 2004). Conversely, LCVs do not accumulate the Golgi protein Giantin (Kagan and Roy 2002), suggesting that *L. pneumophila* gains access to secretory membrane traffic directly, rather than circuitously through the Golgi as is seen with the trafficking of the Cholera and Shiga bacterial toxins (Sandvig and van Deurs 2002).

Disruption of early secretory traffic using chemical inhibitors has allowed for a further narrowing of the window in which *L. pneumophila* intercepts the membrane traffic used to remodel its phagosome. Brefeldin A inhibits ADP ribosylation factor 1 (ARF1)-dependent vesicle budding from the ER. The microtubule-based transport of these vesicles from the ER through the intermediate compartment (ERGIC) to the Golgi can be blocked with the microtubule disrupting agent nocodazole. The LCV is able to recruit the ERGIC protein p58 in the presence of nocodazole but not when cells are treated with Brefeldin A (Kagan and Roy 2002). Thus, following internalization, *L. pneumophila* remodels its phagosome into a ribosome-studded, ER-like vacuole by intercepting and fusing with ER vesicles before they are transported through the ERGIC to the Golgi.

The previously proposed model to describe the generation of *L. pneumophila*'s unique vacuole invoked the involvement of host autophagic machinery to convert the LCV into an autophagosomal compartment. Common features shared by autophagosomes and LCVs include a double membrane and the presence of ER proteins such as calnexin and BiP (Horwitz 1983a; Swanson and Isberg 1995; Tilney *et al.* 2001). The induction of autophagy in macrophages by either amino acid starvation or rapamycin treatment results in both the recruitment of autophagy proteins Atg7 and Atg8 to LCVs and an increase in colony-forming units recovered from autophagy-induced cells compared to untreated conditions (Amer and Swanson 2005). However, the discovery of the *Legionella* translocated protein, RavZ has complicated this model. RavZ directly inactivates Atg8 proteins of autophagosomal membranes through hydrolyzation of C-terminal amide bonds, preventing conjugation to Atg7 and Atg3, and similarly restricting the recruitment of ubiquitin, thus inhibiting autophagy (Choy *et al.* 2012; Kubori *et al.* 2017).

It has also been shown that *L. pneumophila* grown in wild type and autophagy-deficient *Dictyostelium discoideum* were similarly able to form normal vacuoles and replicate to comparable levels (Otto *et al.* 2004). Additionally, the *L. pneumophila* effector *Lp*SPL targets the host cell's sphingolipid metabolism through lyase activity. Sphingolipids are eukaryotic bioactive molecules that are central regulators of several intracellular processes, including autophagy and cell death. By preventing the accumulation of the sphingolipids, *Lp*SPL plays a role in *L. pneumophila* evasion of host detection (Rolando *et al.* 2016). A third effector protein, LegA9, has been shown to promote clearance of *L. pneumophila* infections in BMDMs and wild type mice. LCVs of mutants lacking LegA9 have decreased ubiquitin labeling, promoting the evasion of autophagy, although the exact function of LegA9 is currently unknown (Khweek *et al.* 2013). These findings taken together contradict the notion of autophagy's role in LCV formation and suggest that evasion of host defenses plays a larger part in *Legionella* intracellular replication.

Egress

Little is known about the final phase of *L. pneumophila*'s intracellular existence. At 12 to 24 hours after infection, vacuoles containing multiplying *L. pneumophila* have grown substantially, housing dozens of bacteria. Bacterial cells now in the transmissive phase of the biphasic life cycle egress through the formation of pores in the LCV membrane. The *icmT* gene appears to play a role in pore-mediated egress, as mutants defective in host cell release all feature identical point mutations on the 3'- end following a stretch of poly(T). Electron microscopy studies have revealed what appear to be cytosolic *L. pneumophila* at late stages of infection indicating that there may be a delay between rupture of the LCV and egress of bacteria from the host cell to go on to further rounds of infection (Molmeret *et al.* 2004).

Identification of the Dot/Icm Secretion System as a Key Component of *L. pneumophila*'s Intracellular Life Cycle

To determine the mechanisms underlying *L. pneumophila*'s unique intracellular life cycle, numerous screens have been conducted to identify the bacterial genes required for intracellular growth. Various mutagenesis strategies were used to generate *L. pneumophila* strains unable to replicate within and lyse host cells, to prevent fusion of bacteria-containing phagosomes with lysosomes, or to recruit host cell vesicles and organelles.

One such set of mutants was generated by repeated passage of *L. pneumophila* on suboptimal laboratory media to allow for the loss of genes that are not essential for extracellular replication (Marra *et al.* 1992). One mutant strain isolated by this method, named 25D, was unable to grow inside a macrophage-like cell line, to avoid delivery to lysosomes, to recruit host vesicle traffic, and to kill host cells—a read-out for host cell lysis. By transforming this mutant strain with a cosmid library of *L. pneumophila* genomic DNA, a locus of genes capable of complimenting all of these defects were defined and subsequently named the *intracellular multiplication* (*icm*) locus.

Another strategy seeking a similar category of intracellular growth-deficient mutants was devised using *L. pneumophila* thymine auxotrophs that are only viable if they are not replicating when cultured in the absence of thymine (Berger and Isberg 1993). Mutagenesis of this *thy* strain followed by several rounds of infection and bacterial recovery produced a pool of mutants enriched for strains that were deficient when tested in intracellular growth and phagosome trafficking assays. Complementation by transformation of these mutants with a *L. pneumophila* genomic library also identified a locus of relevant genes, which was subsequently called the *defect in organelle trafficking* (*dot*) locus.

The *icm* and *dot* loci defined by these screening techniques encompass similar though not identical sets of *L. pneumophila* genes (Figure 31.2). Sequencing of nearby open reading frames and further analysis of salt-sensitive mutants produced a list of 27 *dot/icm* genes that are essential for *L. pneumophila*'s intracellular growth and trafficking (Andrews, Vogel and Isberg 1998; Segal and Suman 1998). Homology found within *dotB*, *dotG*, *dotL*, and *dotM* to known components of *Agrobacterium tumefaciens* conjugation machinery led to the discovery that the *dot/icm* genes collectively encode the components of a type IVb secretion system (Vogel *et al.* 1998). Members of this family of specialized secretion systems are ancestrally related to bacterial conjugation systems and are found across a wide range of pathogenic bacterial species (Christie 2001). Indeed, the *L. pneumophila dot/icm* system can support conjugative plasmid DNA transfer (Vogel *et al.* 1998), though it remains unclear whether this activity serves a present role in the life-cycle of *L. pneumophila* or is merely a vestige of the Dot/Icm apparatus' evolutionary past. *Helicobacter pylori*, the causative agent of stomach ulcers, uses a type IV secretion system to deliver the effector protein CagA into mammalian cells (Odenbreit *et al.* 2000) via its type IV secretion system, the plant pathogen *Agrobacterium tumefaciens* injects both protein effectors as well as oncogenic T-DNA to produce the tumorous growth characteristic of infected plant tissues (Christie 2001).

Further studies have found that in addition to the Dot/Icm apparatus, *L. pneumophila* encodes a veritable laundry list of other secretion systems, including a second type IV system called *lvh*, a type II system called *lsp*, a type I system called *lss*, and numerous secretion systems with homology to the *tra* conjugation machinery. Analysis of the Paris strain

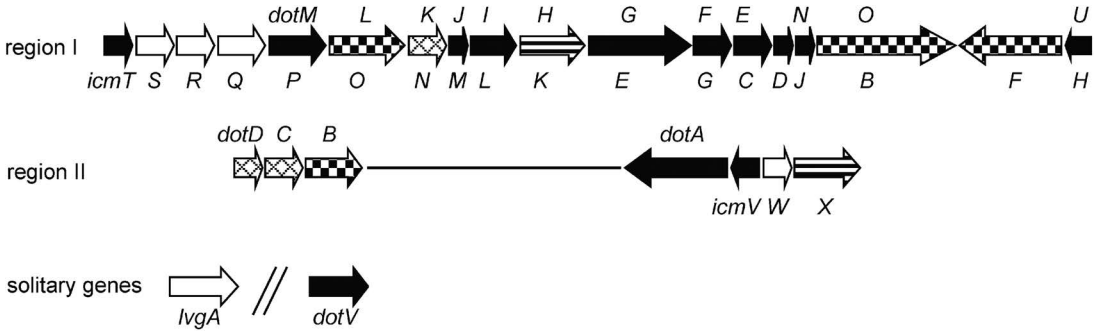

FIGURE 31.2 The *Legionella pneumophila dot/icm* locus encodes a type IVb secretion system. The 27 *dot/icm* genes are located in two regions of the *L. pneumophila* chromosome. Subcellular localization predictions for each gene product are indicated as follows: inner membrane (black), outer membrane (hatched), periplasmic (striped) or soluble (white). Proteins with predicted ATP/GTP binding sites are checkered. *Dot/icm* genes bearing homology to components of the *Agrobacterium tumefaciens* Ti plasmid Tra/Trb conjugation machinery include: *dotB* (*trbB*), *dotG* (*trbI*), *dotL* (*trbC*), and *dotM* (*trbA*). (Figure adapted from Segal and Suman (1998) and Nagai and Kubori [2011].)

of *L. pneumophila* has also revealed a type V secretion that serves as an autotransporter (Cazalet *et al.* 2004; Brüggemann *et al.* 2006). The *lsp* type II system has been shown to be important for efficient growth of *L. pneumophila* in protozoan and mammalian cells and is thought to control secretion of factors with protease, RNaseA and lipase activities, among others (Rossier, Starkenburg, and Cianciotto 2003). The role of the other secretion systems in *L. pneumophila*'s intracellular growth has yet to be studied in depth.

Identification of Dot/Icm Effector Substrates

Identification of a Large Arsenal

Proper functioning of the Dot/Icm secretion apparatus has been shown to be absolutely required for *L. pneumophila*'s intracellular replication. Therefore, it follows that the identification of the substrates of this transporter is essential for the understanding of *L. pneumophila* pathogenesis. However, the screens that successfully identified the Dot/Icm transporter as the predominant tool required for *L. pneumophila*'s intracellular growth failed to isolate mutants lacking individual Dot/Icm substrates. As an answer to this challenge, numerous novel strategies to hunt for Dot/Icm secreted proteins have been developed.

As described above, these original mutagenesis screens employed both gross intracellular growth and phagosome mistrafficking as phenotypic read-outs. Though the mutants isolated in this manner only contained lesions within individual *dot/icm* genes, it is probable that the absence of any one component of the apparatus results in a Dot/Icm complex that is misassembled, improperly functioning, or both. Therefore, the strong intracellular growth and trafficking defects displayed by these mutants most likely reflect their inability to secrete most if not all of *L. pneumophila*'s effector proteins into the host cell cytosol. Current research utilizes mutants deficient in the *dotA* component of the secretion system as a control as theses mutants lack the ability to secrete substrates into the host cell. Although the specific function of the DotA protein remains elusive, studies have found that the membrane protein is itself translocated by the Dot/Icm system (Nagai and Roy 2001).

Given the varied and complex aspects of its intracellular life cycle, it is probable that *L. pneumophila* requires the coordinate function of numerous effector proteins to establish its replicative vacuole. Within this repertoire, there may be proteins of redundant or overlapping function and proteins that mimic host cell activities. A mutation in any one of these genes may not cripple the bacterium sufficiently for it to be selected using such severe defects as overall intracellular growth or trafficking as a marker. Therefore, novel strategies to identify Dot/Icm substrates have allowed for the isolation of *L. pneumophila* genes whose products are responsible for more subtle phenotypes such as acquisition of a single cellular marker or minor perturbations of host cell pathways. In addition, strategies that permit the analysis of candidate genes in isolation have provided a means by which to sidestep the complications posed by functionally redundant effector proteins.

This more targeted approach was used to identify the *L. pneumophila* protein RalF as a secreted substrate of the Dot/Icm secretion apparatus (Nagai *et al.* 2002). This protein was identified using an *in silico* screen of the *L. pneumophila* genome based on the presence of a Sec7 domain, a catalytic motif conserved throughout the family of guanine nucleotide exchange factors for eukaryotic ARF proteins. Dot/Icm-mediated translocation of RalF into host cells was found to be required for the recruitment of detectable levels of host ARF1 to the *L. pneumophila* phagosome. However, when tested for growth in multiple host cell types, *L. pneumophila* lacking RalF showed no defect in their ability to grow compared to wild type bacteria, supporting the hypothesis that single effector mutants are unlikely to elicit gross defects in such assays.

Since the discovery of RalF, several additional strategies have been used to identify a growing list of Dot/Icm substrates. Bacterial two-hybrid screening using IcmG/DotF (predicted to be an inner membrane protein of the Dot/Icm complex that interacts with the carboxy terminus of RalF) was conducted and candidates were tested for translocation using the Cre/loxP system. These experiments yielded a large number of substrate of Dot/Icm transporter (Sid) proteins (Luo and Isberg 2004). *Saccharomyces cerevisiae* has been used in two different studies to identify *L. pneumophila* effectors based on their presumed ability to affect (and interfere with) host membrane transport when present in high levels. The VPS inhibitor proteins (Vip) were isolated using a well-established assay that measures perturbation of membrane transport via missorting of vacuolar cargo to the cell surface (Shohdy *et al.* 2005). Yeast lethal factors (Ylf) A and B are two Dot/Icm substrates that were identified based upon their ability to inhibit yeast growth when conditionally overexpressed (Campodonico, Chesnel, and Roy 2005). Yeast two-hybrid analysis using IcmW (a soluble protein predicted to mediate association of translocated effectors with the Dot/Icm apparatus) as bait isolated the IcmW interacting proteins (Wip) that were subsequently shown to be translocated into host cells in a Dot/Icm-dependent manner (Ninio *et al.* 2005).

In recent years, direct screens for translocation efficiency have been performed on large libraries of *L. pneumophila* proteins fused to reporter sequences, dramatically increasing the number of known Dot/Icm effector substrates. In one instance, *Legionella*-specific or eukaryotic-like genes were fused to a translocation-deficient N-terminal fragment of the substrate, sidC. A library of *L. pneumophila* strains expressing these fusions was then used to infect host cells and localization of each fusion protein to the *Legionella*-containing vacuole was measured by anti-sidC immunofluorescence (Huang *et al.* 2011). In another screen, a beta-lactamase reporter system was used to systematically measure the translocation of approximately 800 open reading frames during infection (Zhu *et al.* 2011). To date, more than 300 Dot/Icm translocated substrates have been identified in *L. pneumophila* str. Philadelphia-1, presenting researchers with the challenge of assigning function to each protein or family of proteins in the context of *L. pneumophila*'s intracellular life cycle.

The identification of such a large arsenal of Dot/Icm substrates in *L. pneumophila* str. Philadelphia-1 has also led to a greater understanding of the translocation signal required by the Dot/Icm system. Translocation of Dot/Icm substrates has been shown to be facilitated by glutamate-rich amino acid sequence located near the C-terminus of substrate proteins (Burstein *et al.* 2009;

Huang *et al.* 2011). This signal, together with other common features of translocated substrates, has been used to predict translocated substrates *in silico* in other species of *Legionella* and the closely related species, *Coxiella burnetii* (Lifshitz *et al.* 2013). Given that most large-scale screens for translocation efficiency to-date have been performed in only one strain of *L. pneumophila* (Philadelphia-1), the ability to predict effector proteins from primary sequence information will likely prove critical as access to affordable sequencing technologies continues to increase the number of genomes available for analysis.

Collectively Essential, Individually Dispensable

The extensive collection of Dot/Icm substrates in *L. pneumophila* and the essentiality of the translocation apparatus itself for intracellular replication speak to the importance of this arsenal to virulence. Nevertheless, the vast majority of translocated substrates are themselves are dispensable for intracellular replication in the standard host cells (mammalian and amoebal) used in the lab to model virulence. Current models suggest that the dispensability of individual translocated substrates derives from functional redundancy between these genes. The most striking example of substrate redundancy comes from a study in which the *L. pneumophila* genome was minimized through directed deletion of clustered nonessential genes (O'Connor *et al.* 2011). In this study, the simultaneous deletion of 31% of the known Dot/Icm substrates in one strain had little impact on its ability to replicate within primary mouse macrophages. Other multilocus deletions, spanning as few as 4% of the known Dot/Icm substrates, did display defects in one or more amoebal hosts. Some researchers have utilized transposon insertion sequencing (InSeq) to generate mutant libraries allowing for the screening of loss-of-function mutations that lead to enhanced or detrimental to *Legionella* intracellular growth in various hosts (Shames *et al.* 2017). The effector protein, LegC4, is one example of an effector protein that can promote replication in one host, while being detrimental in another. In the presence of a host immune system, LegC4 hinders intracellular replication by increasing cytokine-mediated host defenses (Ngwaga *et al.* 2019); however, LegC4 is required for wild-type replication of *L. pneumophila* within the natural host *Acanthamoeba castellanii* (Shames *et al.* 2017). This suggests that substrate function may be less redundant in some environmental hosts, which provides one possible explanation for the evolutionary maintenance of redundancy.

Evolution of *L. pneumophila* as an Intracellular Pathogen

Despite the threat the *L. pneumophila* poses to human health, only one human-to-human transmission of disease has ever been observed, and occurred between subjects with close interaction (Borges *et al.* 2016). In contrast, *L. pneumophila* persistence in nature depends upon its capacity to avoid predation by and replicate inside a diverse set of protozoan hosts (Fields 1996). Taken together, these observations suggest a critical role for bacteria-protist interactions in the evolution of *L. pneumophila* into an intracellular pathogen (Molmeret *et al.* 2005). Extended passage of *L. pneumophila* in a single host cell type has been shown to lead to specialization, suggesting that cycling through a diverse set of environmental hosts may play a critical role in maintaining the pathogen's broad host range (Ensminger *et al.* 2012). Given the importance of protozoa to the evolutionary trajectory of *L. pneumophila* and other intracellular pathogens, relatively little is understood about how the intracellular niche within individual hosts can vary; for instance, with respect to nutrient availability or vacuolar integrity.

A recent study uncovered over 18,000 effector proteins from 58 *Legionella* species that suggested horizontal gene transfer (HGT) and multiple eukaryotic crossover events have provided the bacterium with its impressive repertoire of Dot/Icm substrates (Gomez-Valero *et al.* 2019). Analysis of the sequenced genomes of three serogroup 1 species, Philadelphia-1, Paris and Lens, revealed that *L. pneumophila* displays a high degree of genome plasticity between species (Cazalet *et al.* 2004; de Felipe et al. 2005). Paris and Lens alone differ by three plasmids and approximately 13% genomic sequence (Cazalet *et al.* 2004). G-C content calculations for all three species indicate that *L. pneumophila* has likely acquired a large number of its predicted effector proteins from other organisms (Cazalet *et al.* 2004; de Felipe et al. 2005). The identification of a large group of *L. pneumophila* G-C biased open reading frames that encode proteins containing eukaryotic-like motifs strongly suggests that HGT from eukaryotic host cells themselves have supplied *L. pneumophila* with a number of these open reading frames.

De Felipe and colleagues have described a group of 46 genes termed *L. pneumophila* eukaryotic-like genes (*leg*) by screening the Philadelphia-1 genome for open reading frames baring eukaryotic sequences or motifs with a low prevalence in other prokaryotes. This strategy yielded a diverse collection of proteins containing common protein-protein interaction domains, including Ankyrin repeats, coiled coils, and Leucine-rich repeats. Several other genes encode proteins with motif or active site homology suggesting they may serve as serine-threonine kinases, lipid signaling factors, GDP-GTP exchange proteins and factors involved in ubiquitination. A number of these proteins are translocated into host cells in a Dot/Icm-dependent manner, providing evidence that *L. pneumophila*'s ability to manipulate its host cell is partially dependent upon effector proteins built using components of the host cell itself (de Felipe *et al.* 2005). Since this initial discovery, comparative genomics has been used to identify Dot/Icm substrates that display orthology to one or more amoebal proteins, providing further evidence that interdomain horizontal gene transfer has played an important role in expanding the arsenal of Dot/Icm substrates (Urbanus *et al.* 2016). The full potential of these approaches, however, remains largely unrealized given the limited number of sequenced protozoan genomes.

Affecting the Effectors

Somewhat exclusively to *Legionella* is the presence of meta-effectors. This class of effector proteins regulates the function of another effector or group of effectors. Many bacterial genuses produce protein antagonists that regulate the function of a proceeding protein in a toxin-antitoxin manner (Melderen and Bast 2009). *Legionella* meta-effectors are unique in they directly regulate their target effector through inactivation and/or

modification (Urbanus *et al*. 2016). The first observed case of this was the discovery of LubX and SidH in *L. pneumophila*. LubX is an E3 Ubiquitin Ligase that is secreted into the host cytosol in the late stages of infection and marks SidH for degradation (Quaile *et al*. 2015). The meta-effector, LupA, acts as a deubiquitinase to inactivate its cognate effector LegC3 (Urbanus *et al*. 2016). Interestingly, some meta-effectors have been found to be individually important for *Legionella* virulence (Liu and Luo 2007; Shames *et al*. 2017). *L. pneumophila* cells lacking the meta-effectors MesI or SidJ undergo attenuated growth due to unsuppressed toxicity of their effector targets. SidJ is a glutamylase that modulates the SidE family of ubiquitin ligases (Bhogaraju *et al*. 2019) while MesI specifically regulates the translation inhibitor SidI through unknown mechanisms (Shames *et al*. 2017; Joseph *et al*. 2020). In all, 143 effector pairs have been identified in *Legionella*, 19 of which have been found to have coevolved (Burstein *et al*. 2016). However, these analyses focused on pairs found in two or more species, and individual species of *Legionella* may harbor more effector pairs then currently recognized.

Conclusions

L. pneumophila is one of several facultative intracellular bacterial species that survive by subverting host defenses while engaging and co-opting other host pathways to create a replicative niche. With few exceptions, studies of *L. pneumophila* in both protozoan and mammalian host-cell systems have revealed remarkable parallels in the intracellular life cycle, indicating that the host proteins and pathways targeted by *L. pneumophila* to accomplish this feat are well conserved across Eukarya. In recent years, several groups have generated a long list of proteins that can be translocated by the Dot/Icm system into host cells. Characterization of these proteins will provide the mechanistic details underlying the unique phenomena observed during *L. pneumophila* infection, trafficking, replication, and egress. Additionally, the sheer number and diversity of *Legionella* effector proteins and their ability to infect and colonize a variety of eukaryotic hosts make the genus a valuable tool in the study of host-pathogen interactions.

Acknowledgments

This article is based on Chapter 35, *The Genus Legionella*, by Alexander W. Ensminger, Eva M. Campodonico and Craig R. Roy, in the third edition of this series. The previous contribution of these authors is very much appreciated and acknowledged.

Introduction

The genus *Listeria* belongs to the phylum Firmicute, the order Bacillales, the class Bacilli, and the family *Listeriaceae* together with the genus *Brochothrix*. The *Listeria* is Gram-positive bacteria with low G+C content closely related to *Bacillus*, *Clostridium*, *Enterococcus*, *Streptococcus*, and *Staphylococcus*. The natural habitat of these bacteria is thought to be decomposing plant matter, in which they live as saprophytes. The potential primary sources for the introduction of *L. monocytogenes* pathogenic to humans into the food chain and food-processing plants include livestock and produce farms. Isolation of *L. monocytogenes* has been reported from cattle, silage, animal feeds, manure, and growing grass, among others [1, 2] as well as from soil, water, and vegetation of natural and urban environments [3, 4].

Historically, Hülpers isolated bacteria from a liver necrosis in a rabbit in 1911 that were pathogenic for mice and called it *Bacillus hepatica* according to the isolation site [5]. In 1926, a bacterium was isolated from dead laboratory rabbits and guinea pigs exhibiting monocytosis by Murray, Webb and Swann who called it *Bacterium monocytogenes* [6]. Later, a similar bacterium was isolated from wild gerbils with "Tiger River Disease" in South Africa and named as *Listerella hepatolytica* to honor Lord Joseph Lister [7]. Nyfeldt reported the first confirmed isolation from humans in Denmark [8]. These two similar species were named *Listerella hepatolyticus* and finally renamed as *Listeria* in 1940 for taxonomic reasons [9].

Listeria monocytogenes contamination is one of the leading microbiological causes of food recalls, mainly of meat, poultry, seafood, and dairy products. More recently contamination of fresh fruit and produce has been associated with outbreaks of listeriosis. Prevention and control measures are based on hazard analysis and critical control point programs throughout the food industry, and on specific recommendations for high-risk groups.

Trends of listeriosis incidence differ around the world. This is related to dietary preferences and food safety policies [10–12]. High hospitalization and mortality rates worldwide, especially in high-risk groups such as the elderly, the newborns, and immunocompromised individuals as well as pregnant women have been associated with *L. monocytogenes* foodborne outbreaks. There were more foodborne outbreaks associated with *L. monocytogenes* between 2005 and 2015 in the EU (83) than in the United States (47), resulting in 757 and 491 cases, respectively [13, 14]. A new and significant source of infection is related to the use of antibiologicals to treat immune-related disease such as rheumatoid arthritis [15].

L. monocytogenes is morphologically indistinguishable from other *Listeria* species, and often causes nonspecific clinical symptoms; therefore, laboratory testing is required to differentiate *L. monocytogenes* from other *Listeria* species, and to diagnose listeriosis. Following recent advances in molecular genetic techniques, methods targeting unique genes in *Listeria* have been designed for the specific differentiation of *L. monocytogenes* from other *Listeria* species. These methods are intrinsically more precise and less affected by natural variation than the phenotypic methods. A great opportunity to use these tools toward the development of molecular subtyping techniques has been provided by the recent developments in the field of genomics to demonstrate occurrence and pinpoint circulation of strains. Whole genome sequence (WGS)-based typing provides higher discriminatory power, better data accuracy, and reproducibility thus allowing higher laboratory through-put at lower cost and has become indispensable to support a successful outbreak investigation by appropriate public health analysts and epidemiologists [16]. Classical epidemiological approach coupled with molecular subtyping and WGS techniques were used to identify and confirm a *Listeria* gastroenteritis outbreak associated with consumption of sliced cold beef ham in Italy [17].

Extensive research in recent decades has led to significant insights regarding *Listeria* species and listeriosis [18]. The establishment of animal models and *in vitro* cell culture systems for listeriosis has helped the delineation of key stages in *L. monocytogenes* infection and pathogenesis [19].

In-depth reviews on the taxonomy, isolation, identification, epidemiology, pathogenesis, virulence determinants and genomics of *L. monocytogenes* are available [20–26].

The Genus *Listeria*

With the description of several novel species, the genus *Listeria* includes 20 species now, *L. monocytogenes*, *L. seeligeri*, *L. ivanovii*, *L. welshimeri*, *L. marthii*, *L. innocua*, *L. grayi*, *L. fleischmannii*, *L. floridensis*, *L. aquatica*, *L. newyorkensis*, *L. cornellensis*, *L. rocourtiae*, *L. weihenstephanensis*, *L. grandensis*, *L. riparia*, *L. booriae* [27], *L. costaricensis* [28], *L. goaensis* [29], and *L. thailandensis* [30]. In 2012, *L. weihenstephanensis* was isolated from the water plant *Lemna trisulca* sampled from a fresh water pond [31] and *L. fleischmannii* isolated from cheese from a ripening cellar [32]. Sampling of seafood and dairy processing facilities in the north-eastern United States revealed two novel species, *L. booriae* and *L. newyorkensis* [33], while *L. floridensis*, *L. aquatica*, *L. cornellensis*, *L. riparia*, and *L. grandensis* were isolated from agricultural and natural environments [34]. *L. costaricensis* was isolated from a food processing drainage system in Costa Rica [28]. *L. goaensis* [29] was isolated from mangrove swamps in Goa, India, while *L. thailandensis* from fried chicken [30]. These novel species represent an important branching point in *Listeria* phylogeny. They also present a diagnostic challenge for clinical, food and public health microbiologists seeking to identify *L. monocytogenes*. *L. monocytogenes* is an opportunistic pathogen in human beings and various animal species, whereas *L. ivanovii* mainly affects ruminants, causing abortion, and only occasionally occurring in man. Phylogenetic analyses, based on the *16S* and 23S *rRNA* genes and the *iap*, *prs*, *vclA*, *vclB*, and *ldh* genes, indicate that *L. innocua* is highly related to *L. monocytogenes*, while *L. welshimeri* is more distant, exhibiting the deepest branching of this group. The second group has *L. ivanovii*, together with *L. seeligeri*, *L. grayi* seems to be very distant from these two groups [35]. The 16S rRNA gene sequence analysis confirmed close phylogenetic relatedness of *L. marthii* to *L. monocytogenes* and *L. innocua* and more distant relatedness to *L. welshimeri*, *L. seeligeri*, *L. ivanovii* and *L. grayi* [36]. Phylogenetic analysis of partial sequences of *L. marthii* for *sig*B, *gap*, and *prs* showed formation of a well-supported sistergroup to *L. monocytogenes* [36]. The 16S rRNA gene sequence analysis revealed a close phylogenetic similarity of *L. weihenstephanensis* to *L. rocourtiae* and a more distant relationship to other *Listeria* species [31] (Figure 32.1).

Characteristics

Listeria species are a small, Gram-positive, nonsporulating, facultatively anaerobic rod that measures 1–2 × 0.5 microns and shows characteristic tumbling motility at or around 25°C. *Listeria* is able to multiply at high salt concentrations (10% NaCl) and at a broad range of pH (pH 4.5 to 9) and temperature (0–45°C, optimum 30–37°C)[37]. The morphology of *Listeria* as seen by Gram staining and electron microscopy is depicted in Figures 32.2A and 32.2B, respectively.

Listeria species are closely related bacteria that share many morphological and biochemical characteristics. *Listeria* species are catalase and Voges-Proskauer reaction positive, and indole and oxidase negative. *Listeria* species can hydrolyze aesculin, but not urea or reduce nitrates. A rapid test strip for identification has been developed [38]. *Listeria* species show variations in their ability to hemolyze horse or sheep red blood cells, and in their ability to produce acid from L-rhamnose, D-xylose and a-methyl-D-mannoside [39].

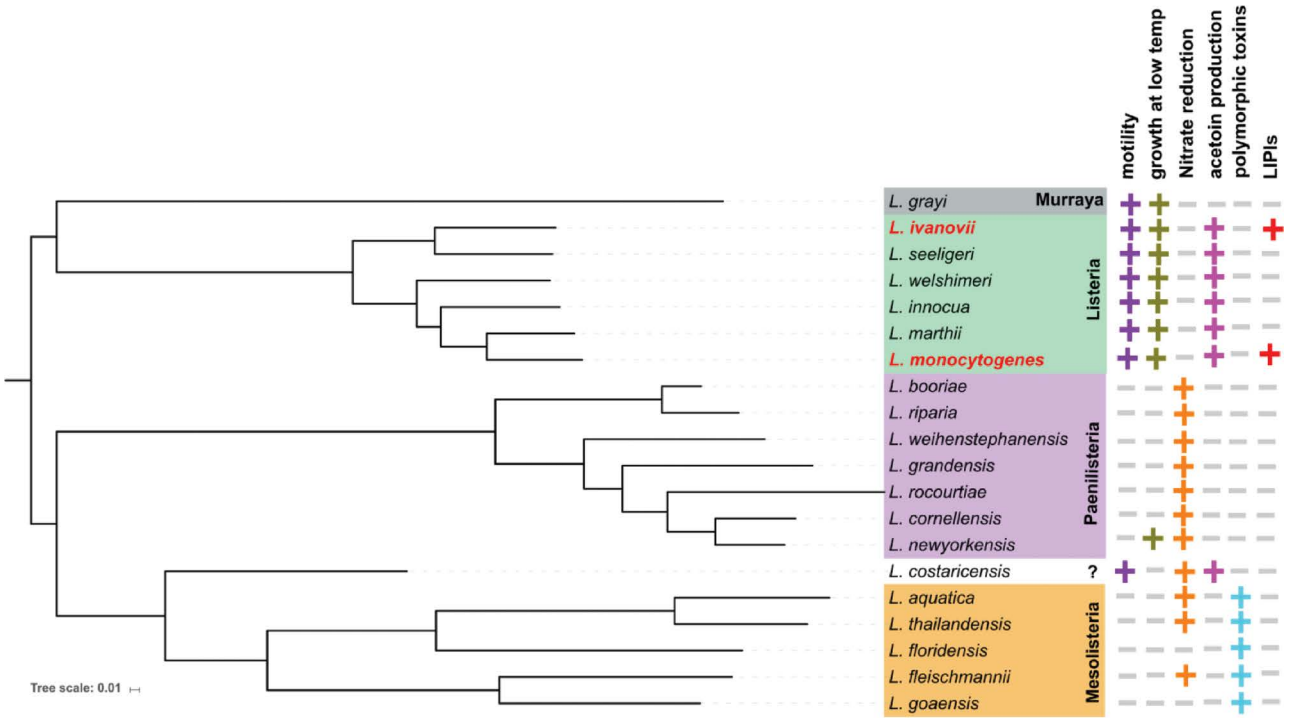

FIGURE 32.1 Phylogenetic tree of currently identified species of genus *Listeria*.

FIGURE 32.2A Gram-stained *Listeria monocytogenes* (magnification 100×).

Methods for Confirmation/Differentiation of *Listeria*

As *L. monocytogenes* is morphologically indistinguishable from other *Listeria* species additional, laboratory testing is required to differentiate *L. monocytogenes* from other *Listeria* species. Table 32.1 shows a scheme for identification of *Listeria* spp. *L. ivanovii* is differentiated biochemically from *L. monocytogenes* and other *Listeria* species by its production of a wide, clear or double zone of hemolysis on sheep or horse blood agar, strong lecithinase reaction with or without charcoal in the medium, a positive Christie-Atkins-Munch-Petersen (CAMP) reaction with *Rhodococcus equi* but not with hemolytic *Staphylococcus aureus*, and fermentation of D-xylose but not L-rhamnose [40]. *L. monocytogenes* requires charcoal for its lecithinase reaction [41]. *L. innocua* is distinguished from *L. monocytogenes* on the basis of its negative CAMP reaction and its failure to cause α-hemolysis or to show PI-PLC activity on chromogenic media [39].

An assay based on phosphatidylinositol-specific phospholipase C activity (PI-PLC) has been described for the discrimination of pathogenic and nonpathogenic *Listeria* species based on which hemolytic but nonpathogenic species, i.e., *L. seeligeri*, can be separated from the hemolytic and pathogenic species, i.e., *L. monocytogenes* and *L. ivanovii* [42]. The application of a multiplex polymerase chain reaction (PCR) assay that selectively amplifies a commonly shared region of the *iap* gene that facilitates the differentiation of all six *Listeria* species in a single test has been developed [43].

Biology of *Listeria*

L. monocytogenes is a remarkable bacterium that has acquired a diverse collection of virulence factors, each with unique properties and functions. Its life cycle reflects its remarkable adaptation to intracellular survival and multiplication in professional phagocytic and nonphagocytic cells of vertebrates and invertebrates.

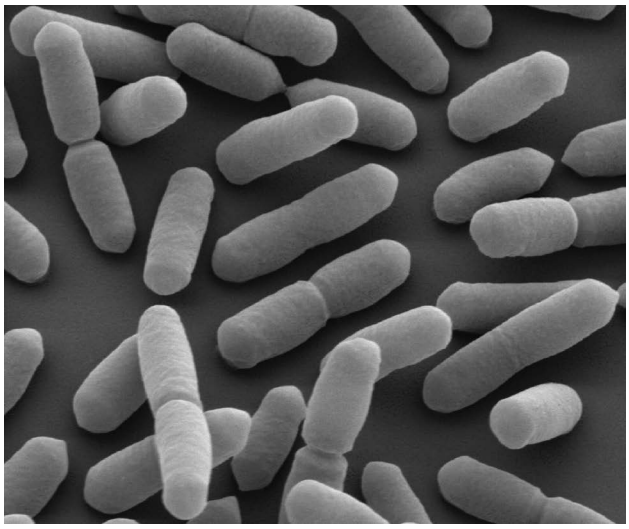

FIGURE 32.2B Scanning electron microscopy of *Listeria monocytogenes* (magnification 16,000×).

Pathogenic *Listeria* species are able to breach endothelial and epithelial barriers of the infected hosts including the intestinal, blood-brain and fetoplacental barrier, are able to invade and replicate in phagocytic and nonphagocytic cells [18]. Entry of the pathogen is mediated by internalins A and B, which are expressed on the surface of the bacterium. Two virulence associated molecules are responsible for lysis of the primary single-membraned vacuoles and subsequent escape by *L. monocytogenes*: listeriolysin O (LLO) and phosphatidylinositol-phospholipase C (PI-PLC). After lysis of the primary single-membraned vacuoles, *L. monocytogenes* is released to the cytosol, where it undergoes intracellular growth and multiplication. The bacterial surface protein ActA leads to the intracellular mobility and cell-to-cell spread, which is cotranscribed with PC-PLC and mediates the formation of polarized actin tails that propel the bacteria toward the cytoplasmic membrane, which enables the bacterium to infect the second cell [18]. Immunofluorescence staining of both bacteria and the host cell actin in infected cells reveals the unique ability of these bacteria to move intracellularly (Figure 32.2C).

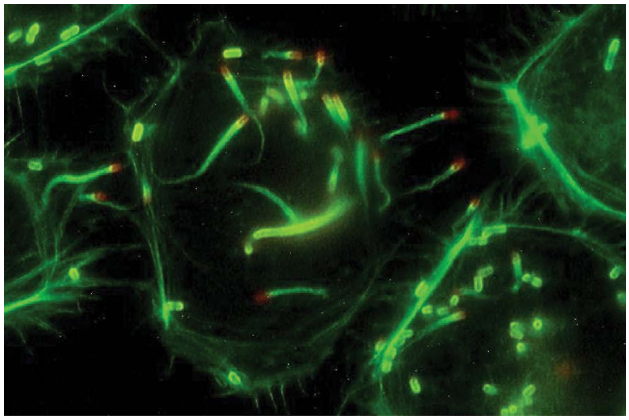

FIGURE 32.2C Immunofluorescence staining of intracellular motile *Listeria* (bacteria are stained red, while the actin tail of *Listeria monocytogenes* is stained green with FITC-labeled phalloidin).

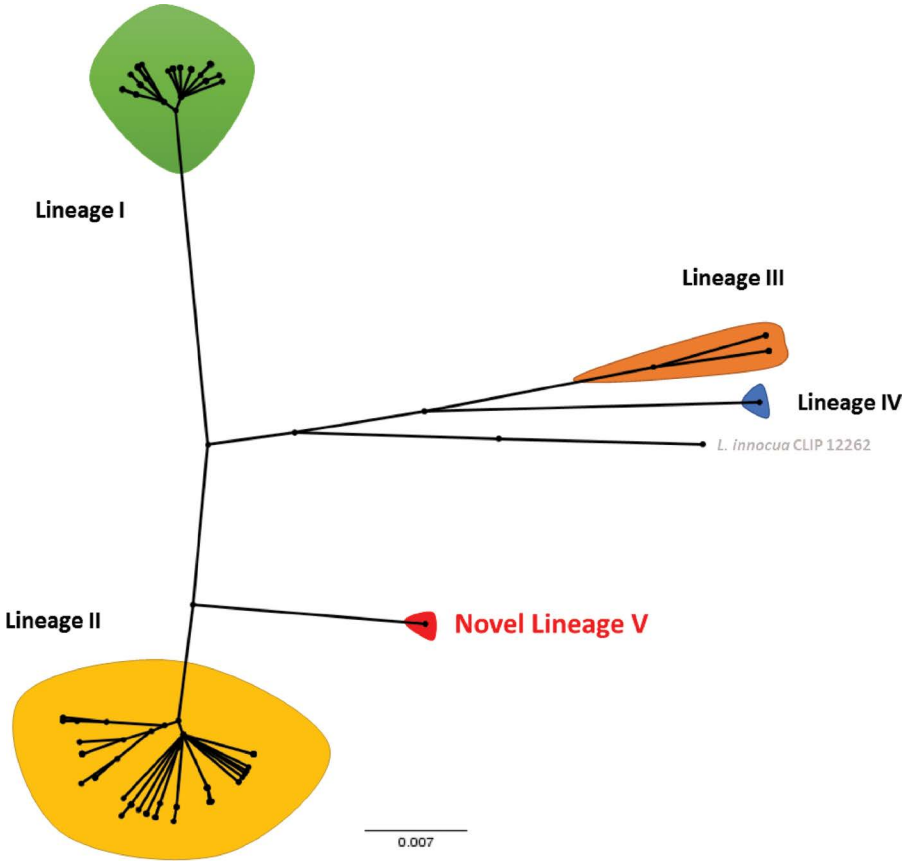

FIGURE 32.3 Phylogenomic lineages of *L. monocytogenes*.

The genes encoding the virulence-associated proteins PIPLC, LLO, Mpl, ActA and PC-PLC are located in a 9.6-kb virulence gene cluster [44], which is principally regulated by the pleiotropic virulence regulator, PrfA (a 27-kDa protein encoded by *prf*A). The various pathogenicity islands in *Listeria* species are shown in Figure 32.3. In addition to these virulence-associated genes and proteins, several other genes, such as *iap*, *bsh*, *vip*, *inlJ*, *auto*, *ami*, and *bilA*, are also involved in *L. monocytogenes* virulence and pathogenicity. The resistance of *L. monocytogenes* to acidic conditions and to bile salts makes it particularly adept at infecting the gastrointestinal tract [45].

Intracellular gene expression profiling of *L. monocytogenes* indicated that many of the genes are upregulated in the cytosol and allowed the identification of activation of several *L. monocytogenes* genes, including the *plc*A and *prf*A after infection of the host cells. Indeed, *L. monocytogenes* modulates the expression of 500 genes for its survival in this cellular compartment [46, 47].

A hybrid sublineage of the major lineage II (HSL-II) and serotype 4h of *L. monocytogenes* were discovered while characterizing the isolates from severe ovine listeriosis outbreaks from China [48]. HSL-II isolates were highly virulent and exhibited higher organ colonization capacities than well-characterized hypervirulent strains of *L. monocytogenes* in an orogastric mouse infection model. HSL-II isolates are the only known *L. monocytogenes* to carry virulence factors from a related species in the animal pathogen *L. ivanovii*. These isolates harbor a unique wall teichoic acid (WTA) structure essential for resistance to antimicrobial peptides and responsible for bacterial invasion and overall virulence phenotype [48] (Figure 32.4).

General Ecology of *Listeria*

Some *Listeria* strains have the ability to survive for long times under adverse environmental conditions and to persist in niches in food processing equipment, and associated drains, walls, and ceilings. Various compounds that are used to inhibit growth of the pathogen include organic acids, fatty acids, antioxidants, sodium nitrite, smoke, spices, and herbs.

Due to its environmental persistence *L. monocytogenes* is recognized as a problem for the food industry, because of its ability to form biofilms. Biofilms are microbial communities adhered to biotic or abiotic surfaces including polystyrene, polypropylene, glass, stainless steel, quartz, marble, and granite [49] coated by self-produced extracellular polymers, thereby conferring protection to bacterial cells from a variety of environmental factors, such as ultraviolet rays, toxic metals, acids, desiccation, salinity, and antimicrobials [50, 51] and decreasing the efficiency of cleaning and disinfection procedures [52].

Listeria spp. showed similar prevalence in samples from natural (23.4%) and urban (22.3%) environments. *L. seeligeri* and *L. welshimeri* were significantly associated with natural environments, while *L. innocua* and *L. monocytogenes* were significantly associated with urban environments [53]. Members of the genus *Listeria* were common in urban and natural environments

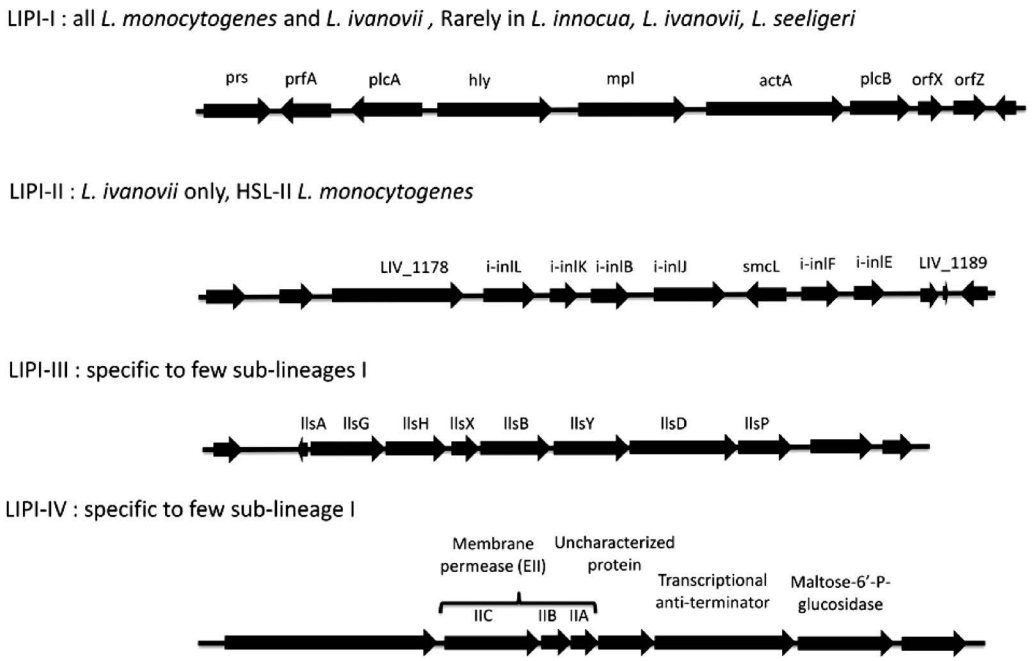

FIGURE 32.4 *Listeria* pathogenicity islands.

and showed species- and subtype-specific associations with different environments and areas (Figure 32.5). The study also indicated that *Listeria* species and subtypes within these species may show distinct ecological preferences suggesting development of molecular approaches for source tracking [53]. Sources of transmission of Listeria species between the natural environment, food industry, and humans are shown in Figure 32.6.

A study of the caged laying hens in France has shown that 29.5% are contaminated by *L. monocytogenes* [54]. Another study in five egg-breaking plants in Western France revealed the presence of *Listeria* spp. and *L. monocytogenes* in the environment of egg-breaking plants with 65.1% and 8.0% of contaminated samples, respectively. The typing of 253 isolates of *L. monocytogenes* by PFGE analysis using *Apa*I and *Asc*I enzymes identified a single dominant *L. monocytogenes* cluster that was better adapted to egg-breaking plants [55]. Analysis of strains revealed a high diversity with 46 different pulsotypes, and the raw material was implicated as a source of contamination of egg-breaking plants. One was dominant in the five egg-breaking plants during the four seasons studied.

Rodents have been reported to be capable of carrying pathogenic bacteria in their intestines, such as *Listeria*, and disseminating those pathogens into the natural environment and possibly transmit the pathogen between wild animals and humans. In a study, intestinal fecal samples of rodents were found to be positive for *L. monocytogenes* (3.22%) and for *L. ivanovii* (2.05%). Other species identified included *L. innocua*, *L. fleischmannii*, and *L. floridensis* [56]. In another study, *L. ivanovii* (3.7%) was isolated from wild rodents and the genetic diversity was relatively low [57]. Isolation of *L. monocytogenes* was reported

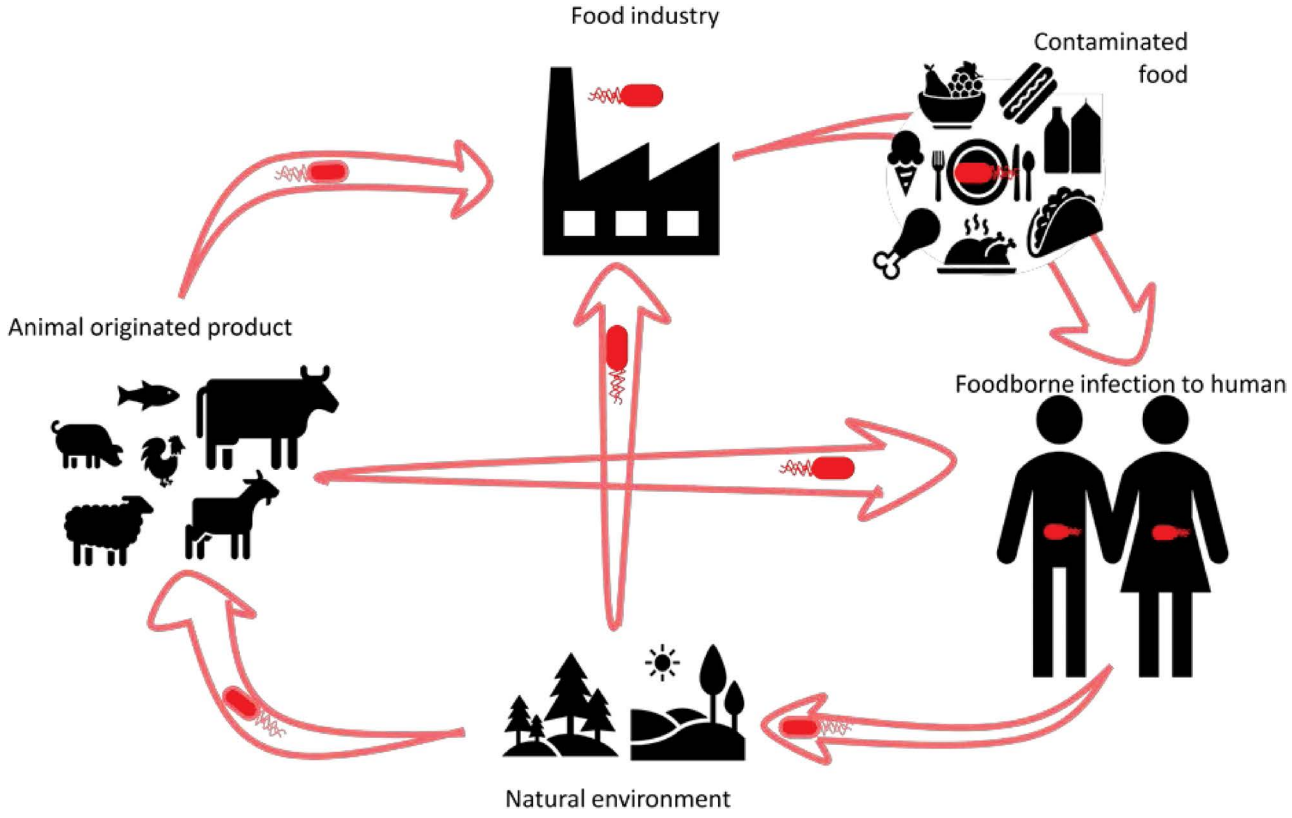

FIGURE 32.6 Sources of transmission of *Listeria* species between the natural environment, food industry, and humans.

from farm environment (soil) and invertebrates (fly and tick) [58]. Characterization of *L. monocytogenes* isolated from black-headed gulls in Dianchi Lake and other regions revealed potential public health risks in regions where the migratory birds passage and reside [59]. The occurrence of *L. monocytogenes* in black-headed gull feces in 2016, 2017, and 2018 was found to be 1.0%, 1.0%, and 0.6%, respectively.

Listeria and Biofilms

Biofilm formation by foodborne pathogens constitutes a grave concern in food industry. *L. monocytogenes* has the ability to form biofilms thereby persisting for a long-time favoring cross-contamination of foods. A number of studies have been conducted to better characterize the listerial biofilm extracellular matrix that represents the major component of a biofilm.

The biofilms represent structured communities of bacterial cells embedded in a self-produced matrix of extracellular polymeric substances (EPSs) leading to persistence of the pathogen in food processing environment. Exopolysaccharides, proteins, and eDNA are the main molecules composing the biofilm matrix of several bacteria [60]. Listerial biofilms were found to be abundant in proteins [61].

The formation of biofilms alters the phenotype and gene expression. The biofilm formation occurs on several surfaces employed in the food industry including stainless steel, polystyrene, and glass [62], signifying a serious concern for food safety. Upon maturity, microbial cells detach from the biofilm and scatter into the environment (in their planktonic form), thereby acting as a potential source of contamination [63]. Various areas in processing facilities, such as floors, waste water pipes, bends in pipes, conveyor belts, rubber seals, and stainless steel surfaces, are some of the most common sources involved in biofilm accumulation. As evidenced by electron microscopic studies, strong biofilm-forming isolates could synthesize a biofilm within 24 hours on surfaces important in food industries, such as stainless steel, ceramic tiles, high-density polyethylene plastics, polyvinyl chloride pipes, and glass [64]. Abundance of certain fatty acids such as iso-C15:0, anteiso-C15:0, and anteiso-C17:0 correlated with the biofilm-forming capability of *L. monocytogenes*. [64]. Cells within biofilms are reported to be more resistant to biocides and stress conditions [65, 66].

Temperature, the nature of adhesion surface, and its hydrophobicity play an important role in biofilm formation [62, 67]. Complex organization of *L. monocytogenes* biofilms was observed at both 22°C and 37°C in terms of cell number and EPSs produced [62]. *L. monocytogenes* form biofilms at 4°C and 12°C with higher levels on glass compared to stainless steel and polystyrene. Biofilm formation at low temperatures used during food processing and storage increases the likelihood of cross-contamination. Reports on a correlation between lineages and biofilm forming ability (with lineage II strains presenting higher levels of biofilm production) [68] have been reported.

In natural environments, such as in food industry, biofilms may be composed of multiple bacterial species, which are more resistant to disinfectants and sanitizers. An increase of number of listerial cells within biofilms was reported when cocultivated with *Flavobacterium* spp. [69]. Despite the great advances made over

the last few decades in the field of food safety, several outbreaks of foodborne listeriosis with high rates of morbidity and mortality have been reported [70, 71]. *L. monocytogenes-Escherichia coli* biofilms were effectively removed using DNase I followed by pronase and cellulose [72]. The antibiofilm strategies are focused on use of the enzymes [73], bacteriophages [74], or combined strategies [75]. Bacteriocinogenic lactic acid bacteria (LAB), their bacteriocins, and bioengineered bacteriocin derivatives have been proposed for controlling *L. monocytogenes* biofilms on different surfaces through inhibition, competition, exclusion, and displacement [76].

Disease in Humans

Listeriosis is considered an emerging health problem, especially among the elderly, including those with no underlying medical conditions [12]. In recent years, the trends of listeriosis incidence have been found to differ around the world, probably related to dietary preferences and food safety policies [11, 77–79]. Hence both an increase in incidence [80, 81] and a reduction in the number of cases of listeriosis have been reported [82, 83]. A recent report from the Centers for Disease Control and Prevention (CDC) estimates 1,600 cases and 255 deaths per year in the United States [84]. *L. monocytogenes* is the foodborne pathogen responsible for the majority of deaths in the United States after nontyphoid *Salmonella* spp. In Europe, statistically significant increasing trends in listeriosis notification rates from 2005 to 2009 were noted in Austria, Denmark, Hungary, Italy, Spain, and Sweden [85].

L. monocytogenes has great public health significance, and it is currently considered as one of the leading emerging pathogens associated with foodborne diseases [86].

The majority of cases in adults and juveniles occur among the immunosuppressed, i.e., patients receiving steroid or cytotoxic therapy or with malignant neoplasms. Other "at risk" groups include patients with AIDS, diabetics, elderly people, kidney dialysis patients, individuals with prosthetic heart valves, or replacement joints, and individuals with alcoholism or alcoholic liver disease. Approximately one-third of patients with listerial meningitis and around 10% with primary bacteremia are immuno-competent [87]. Rarer presentations in this patient group include meningoencephalitis and encephalitis, together with infections with identifiable foci, i.e., endocarditis, pneumonia, peritonitis, and deep-seated abscess formation. During the early stages of infection, human listeriosis often displays nonspecific flu-like symptoms (e.g., chills, fatigue, headache, and muscular and joint pain) and gastroenteritis. However, without appropriate antibiotic treatment, it can develop into septicemia, meningitis, encephalitis, abortion and, in some cases, death [18]. Minor skin infections, particularly in farmers or veterinarians after handling bovine calves or abortions, have been recorded. The symptoms such as vomiting and conjunctivitis have also been seen. A case of *L. monocytogenes* septic arthritis of the right hip in a 66-year-old male treated with mycophenolate mofetil for polyarteritis nodosa was reported [88]. *L. monocytogenes* was reported as a cause of fatal spontaneous bacterial peritonitis in a 51-year-old man with alcoholic cirrhosis with jaundice, ascites, and lower limbs edema [89]. Anti-TNF-α drugs blocking the host's response against various microorganisms, particularly intracellular agents like *L. monocytogenes*, increase the risk of disease. Two cases of *L. monocytogenes* meningitis in ulcerative colitis patients under infliximab plus steroids were reported [90].

Cases of *L. monocytogenes* endophthalmitis in human adults have also been reported [91]. A review of 38 consecutive patients with pleural infection, pneumonia, or both revealed *L. monocytogenes* as a rare but severe cause of pneumonia and pleural infection in older immunocompromised patients [92]. Endovascular listeriosis, manifested as vascular infections and endocarditis, mostly in older patients with vascular or cardiac valve prosthetic devices and co-morbidities, is a rare but severe infection. In addition, 71 cases with vascular aneurysms/prosthetic infections, endocarditis, or both were reviewed [93].

In South Africa, the world's largest listeriosis outbreak attributed to ready-to-eat processed meat products with a total of 1,060 confirmed cases was reported during 2017–2018 [94]. The clinical isolates were largely (91%) of sequence type 6 (ST6). Higher mortality was recorded in neonatal cohort probably due to more severe associated with ST6 and the predominance of early-onset disease [95]. An outbreak with *L. monocytogenes* ST2 clone lacking chitinase ChiB causing 163 cases of noninvasive listeriosis was reported in Germany in 2015 [96].

Interestingly in Europe, the incidence of listeriosis appears to have increased since 2000 [97]; in particular, the incidence among those >65 years old appears to have increased over the last years. Because of its high fatality rate, listeriosis ranks among the most frequent causes of death due to foodborne illness. *L. monocytogenes* infections are responsible for the highest hospitalization rates (91%) among known foodborne pathogens and have been linked to sporadic episodes and large outbreaks of human illness worldwide. Figures 32.5A and 32.5B show a stillborn with granulomatosis infantiseptica characterized by the presence of military-disseminated pyogranulomatous lesion on body surface and cut from the liver showing two subcapsular pyogranulomes, respectively.

Disease in Animals

The spectrum of the disease in animals is broad ranging from asymptomatic infection and carriage to uncommon cutaneous lesions or various focal infections such as conjunctivitis, urethritis, endocarditis, and severe disturbance of the gait, followed by death. Farm animals can be asymptomatic or cause encephalitis, septicemia, and abortions and may be a source of *L. monocytogenes* in the farm environment. *L. monocytogenes* causes invasive and often fatal disease including CNS infection in numerous animal species, including farm ruminants, horses, dogs, pigs, deer, South American camelids, and cats [98].

Abortions and perinatal deaths are common in cattle and sheep. *L. monocytogenes* is a well-recognized cause of mastitis, abortion, repeat breeding, infertility, encephalitis, and septicemia in cattle [99–100]. *L. ivanovii* has also been implicated as a cause of abortion in cattle and sheep but occurs less frequently than *L. monocytogenes*. Listeric infections and abortions usually develop in the late winter or early spring. Abortions are most commonly recognized in the last trimester of pregnancy, frequently in the absence of other clinical signs.

Immunity to *Listeria*

Listeria infection in mice has been exploited extensively as a model to study molecular mechanisms of early innate as well as adaptive immunity. Restriction of parenchymal and systemic spreading of *L. monocytogenes* is achieved by containment in granulomatous structures or abscesses containing cellular and acellular components. The major role in this process has been attributed to an intricate cooperation between macrophages, neutrophils, and T cells. During systemic *L. monocytogenes* infection in mice macrophages, neutrophils, natural killer (NK) cells, and dendritic cells are central to the early innate immune response, acting as both the host for and forming a major line of defense against this pathogen [101].

The development of a protective immune response to *L. monocytogenes* has been ascribed to the involvement of $CD4^+$ and $CD8^+$ T-cell populations. In this regard, class I MHC and class II MHC-restricted epitopes of LLO for $CD8^+$ and $CD4^+$ T-cells, respectively, have been identified [102]. $CD8^+$ cells have been shown to lyse macrophages infected with *L. monocytogenes* or pulsed with *L. monocytogenes* peptides, latter requiring additional *in vitro* stimulation for expressing significant cytolytic activity [103]. It is also now known that $CD4^+$ T-cell help is required during priming of $CD8^+$ T-cells to generate a life-long protective memory response to *L. monocytogenes* infection [104]. The increased levels of non-MHC-restricted cytotoxic activity, mediated by NK cells, have also been observed following *in vivo* challenge with *L. monocytogenes* in a mouse model [105].

Live, replicating bacteria that grow in the host cell cytosol induce acquired cell-mediated immunity to *L. monocytogenes*, whereas killed bacteria, or those trapped in a phagosome, fail to induce protective immunity [106]. It has been shown that three innate immune pathways are induced by infection with *L. monocytogenes*: expression of inflammatory cytokines through an MyD88-dependent pathway emanating from a phagosome; a STING/IRF3-dependent pathway; and low levels of a Caspase-1-dependent, AIM2-dependent inflammasome pathway, which results in proteolytic activation and secretion of IL-1β and IL-18 and pyroptotic cell death [106].

Activation of TH_1 cells, subset of $CD4^+$ T helper lymphocytes by various antigens, has been found to produce gamma-interferon [IFN γ] that stimulates macrophages [102]. Tumor necrosis factor and interferon gamma are essential for *in vivo* immune defense against primary infection with *L. monocytogenes* [107]. Full induction of protective immunity requires infection with live, cytosol-invasive *L. monocytogenes*. *L. monocytogenes* possesses many attributes that would make it a good antigen delivery system for vaccine strategies aimed at the induction of $CD8^+$ T-cell responses [104].

Surveillance of Listeriosis

Listeria spp., including *L. monocytogenes*, is ubiquitous. The presence of this organism has been reported in the environment including soil, water, sewage, vegetation (e.g., grass, meadows, forests, silage), wild animal feces, as well as on the farm and in food processing facilities [108]. Contamination of food along the food chain has always been shown as the cause of listeriosis. Outbreaks from *L. monocytogenes* are rare; however, they receive considerable attention due to high case fatality rate and seriously affected cases. The outbreaks are often the result of errors made by workers in manufacturing plants leading to major economic consequences, especially if the products affect international trade. In the EU in 2007, the notification rate was the highest in the elderly (53.1% of cases,1.0 case per population of 100,000) followed by children under the age of 5 (0.51 cases per population of 100,000) [109]. Surveillance programs are largely lacking in developing countries. There, it is assumed that listeriosis cases rarely are reported and traditional food storage and preparation situations preclude opportunities for growth of the pathogen in RTE foods. Cold foods are very popular in the Middle East with a tendency to keep the food refrigerated for a longer time. In, India and Africa, there is little refrigeration in homes. Therefore, a comprehensive study for contamination of RTE foods by *L. monocytogenes* in developing countries should be considered by WHO and FAO. The lessons learned from the study and earlier outbreak investigations can then be shared with food control agencies in developing countries. Surveillance of listeriosis and monitoring of *L. monocytogenes* over many decades in developed countries has demonstrated that the pathogen has become a major contributor to human foodborne disease because of its high hospitalization and death rates.

The global estimates of *L. monocytogenes* prevalence have been reported to be at 2.9% in deli meat, at 2.4% in soft cheese, and in packaged salad at 2.0% [110]. However, global summary prevalence estimates for risk assessments are not advisable owing to the high heterogeneity between studies.

Identification of the global trends in *L. monocytogenes* epidemiology using ProMED reports from 1996 to2018 revealed 123 *Listeria* events [111]. A total of 65% events were associated with two or more human cases, 11% with only one human case, and 24% were precautionary food product recalls due to the presence of bacterial contamination without associated human cases. The food vehicle implicated was identified in 85% outbreak events and in 77% sporadic case events. Educating high-risk individual, such as pregnant women and immunocompromised individuals, about safe food-handling practices is required [111].

The economic cost estimates associated with foodborne disease are important to inform public health decision-making. Costs associated with the cases and those incurred by the implicated plant and federal agencies responding to the outbreak were estimated to be nearly $242 million Canadian dollars [112], demonstrating the considerable economic burden at both the individual and population levels associated with foodborne disease and foodborne outbreaks in particular.

Antigens of *Listeria*

Conventional Antigens

Somatic (O) and flagellar (H) antigens of *L. monocytogenes* have been described and used for serological groupings. The conventional antigens employed in various serological assays include heat-killed suspensions to detect antibodies to somatic antigens and formalin-treated organisms for flagellar antigens [113–114].

These antigens exhibit cross-reactions with *Staphylococcus aureus*, *Corynebacterium pyogenes*, *Escherichia coli*, *Streptococcus faecalis*, and *Bacillus* species [115], when employed in serological tests like agglutination, complement fixation, and immunoprecipitation. Trypsinization of heat-killed antigen of *L. monocytogenes* has been reported to increase its specificity and sensitivity besides avoiding cross-reactions [113].

Listeriolysin O (LLO)

Of the various factors incriminated for the virulence of *L. monocytogenes*, listeriolysin O (LLO) is highly immunogenic and can serve as an important target for innate and adaptive immune responses in different animal models and humans [116].

LLO is a secreted 58-kDa protein belonging to the group of cholesterol-dependent cytolysins and is antigenically related to streptolysin-O [SLO], pneumolysin, and perfringolysin [117]. It contained 529 amino acids and exhibits strong regional homologies to SLO and pneumolysin [118]. The purification of LLO by column chromatography with cross-linked polydextrans and carboxymethyl cellulose has been described [119]. When expressed in *L. innocua*, expression of LLO had been found to increase 500-fold and purification of LLO by ion-exchange chromatography yielded a homogeneous protein free of p60 [120].

The demonstration that LLO could be detected in serum samples after absorption with SLO [121] has been suggestive of specific antigenic epitopes in LLO; therefore, an immunoassay based upon purified LLO would be a reliable indicator of listeric infection [122–123]. LLO has been shown to be a reliable indicator for serodiagnosis of listeriosis in sheep by enzyme-linked immunosorbent assay (ELISA) [40] and in human beings by dot-blot assay, especially when bacteria could not be isolated [121, 124].

Protein p60 (cwhA)

Antibodies directed against the major secreted protein of *L. monocytogenes*, termed p60, have been found to be more frequently than antilisteriolysin antibodies in sera of listeriosis patients [125], which were also found to recognize the native and denatured secreted p60 protein of all serotypes of this species [126]. Antibodies raised against synthetic peptides derived from p60 could be useful for the development of an immunological assay specific for the foodborne pathogen *L. monocytogenes* [126].

Surface Proteins/Outer Membrane Proteins

An approach in immunological detection of pathogenic *L. monocytogenes* has been the use of antibodies directed against specific cell surface proteins/outer membrane proteins of the microorganisms. Certain bacterial outer membrane proteins/antigens have been reported to be specific [127]. Characteristic banding patterns of the cell surface proteins of various *Listeria* spp. by SDS-PAGE and immunoblotting have been reported [128]. The cell surface proteins are specific for species and serovars with molecular weights of 64 and 68 kDa. Monoclonal antibodies associated with 66 kDa cell surface antigen specific for *L. monocytogenes* have been produced [129], which could be useful for detecting the organism in clinical samples and foods.

Phosphatidylinositol-specific phospholipase C (PI-PLC) is an essential determinant of *L. monocytogenes* pathogenesis and secreted by only pathogenic species of *Listeria* [42]. It has been purified to homogeneity [130]. It is a 33-kDa protein with isoelectric point of 9.4. Its secretion can be enhanced by the addition of divalent cations to the culture medium. Expression of PI-PLC in the host tissues may be studied by detection of specific antibodies against it, which in turn may be useful in the diagnosis of *L. monocytogenes* infection. The serodiagnostic efficacy of two recombinant antigens namely, rLLO and rPI-PLC, revealed rLLO to be a better antigen than rPI-PLC in ELISA for the serodiagnosis of listeriosis in animals [131]

A ≈77-kDa antigen that is associated with the cell surface of live *L. monocytogenes* serotype 4b cells was identified by mass spectrometry and N-terminal sequencing to be IspC [132]. The presence of IspC was shown to be highly conserved within *L. monocytogenes* serotype 4b. The monoclonal antibodies developed had high fidelity and affinity for the IspC protein and serotype 4b isolates making it a promising candidate for use in the development of a specific *L. monocytogenes* serotype 4b diagnostic test.

Diagnosis of Listeriosis

Listeriosis can be tentatively diagnosed on the basis of clinical symptoms and demonstration of the organisms in smear by Gram staining, or by immunofluorescence. The organism can be isolated from clinical specimens, such as blood, cerebrospinal fluid (CSF), and meconium of newborns or fetus in abortion cases, and feces, vomitus, food stuffs/animal feed, and vaginal secretions of infected individuals or animals.

Detection of soluble antigen in CSF especially in meningitis cases of humans may be useful, but it is not reliable. Serodiagnostic methods, such as serum agglutination, complement fixation test, hemagglutination test, hemagglutination inhibition test, antibody precipitation test, growth inhibition test, and ELISA exist, but crude antigens employed in the tests show cross-reactivity. Listeriosis should be differentiated from influenza, tuberculous meningitis (in humans), and rabies, brucellosis, pasteurellosis, toxoplasmosis (in animals), especially in abortion cases. In view of the high cost, more time and skills required by isolation procedures along with their impracticability for screening large numbers of samples, the serological, novel surface antigens, and pathogenicity marker-based methods play an important role in its rapid and reliable diagnosis.

Isolation of *Listeria*

Attempts to isolate and identify *L. monocytogenes* and to limit its proliferation in foods have been the focus of a significant international effort [133]. Historically, it has been challenging to isolate *Listeria* from food or other samples and this explains why it remained unnoticed as a major food pathogen until recently. The earliest method available was the cold enrichment technique [134], which remained the only available method for many years. This required inoculation of the sample into a nutrient broth lacking selective agents followed by incubation at 4°C for long periods primarily to isolate the pathogen from infected animal or human tissue.

The key issues, enrichment/isolation time and the recovery of stressed *Listeria* cells, were addressed when further methods of enrichment and isolation were developed. Owing to many food-borne outbreaks of listeriosis, a zero tolerance level (absence in 25 g of food) has been implemented. Therefore, the tests must be able to detect one *Listeria* organism per 25g of food if to be approved by the regulatory agencies. *Listeria* cells are fastidious and can be rapidly outgrown by competitors. The recovery of *L. monocytogenes* from food, animals/human beings, and environmental samples requires the use of enrichment cultures followed by selective plating and where injured organisms are likely to be present, a pre-enrichment step is required [135]. These methods are sensitive but often time consuming, laborious, and may take 5–6 days before the result is available. Two of the most widely-used culture reference methods for detection of *Listeria* in all foods are the FDA bacteriological and analytical method (BAM) and the International Organization of Standards (ISO) 11290 method.

In the FDA BAM method, a sample (25 g) is enriched for 48 hours at 30˚C in *Listeria* enrichment broth (LEB)[136] containing the selective agents acriflavine, nalidixic acid, and the antifungal agent cycloheximide, followed by plating onto selective agar (Oxford, PALCAM, MOX, or LPM) [10]. The ISO 11290 method employs a two-stage enrichment process: the first enrichment in half Fraser broth [137] for 24 hours, then an aliquot is transferred to full-strength Fraser broth for further enrichment followed by plating on Oxford and PALCAM agars. Fraser broth also contains the selective agents, acriflavine and nalidixic acid, as well as esculin, which allow detection of β-D-glucosidase activity by *Listeria*, observed as blackening of the growth medium [138]. Primary or pre-enrichment broths usually contain lower amounts of the selective agents to aid the resuscitation of possibly injured cells. Both primary and secondary broths contain a phosphate-buffering system.

The USDA and Association of Analytical Chemists (AOAC/IDF) methods use a modification of University of Vermont Medium (UVM) [139] containing acriflavine and nalidixic acid for primary enrichment, followed by secondary enrichment in Fraser broth and plating onto Modified Oxford (MOX) agar containing the selective agents, moxalactam and colistin sulfate [138].

The FDA method was designed for processing dairy products, whereas the USDA method was designed and has been officially recommended primarily for meat and poultry products [140], the latter being slightly superior for detection of *L. monocytogenes* in foods and environmental samples. The detection rate of *L. monocytogenes* in milk using the FDA method by changing the final Oxford and PALCAM plating agar to *L. monocytogenes* Blood Agar (LMBA) has been improved [141].

Selective or Differential Plating Media

Use of potassium tellurite to inhibit Gram-negative bacteria was the first significant step in producing a *Listeria* selective agar (LSA)[142]. Later on another LSA referred to as McBride *Listeria* agar (MLA) was formulated in 1960 by substituting phenyl ethanol agar containing lithium chloride, glycine, and blood [143].

Later, modified McBride *Listeria* agar (MMLA) [144] and LiCl-phenylethanol-moxalactam agar (LPMA) [135] were developed. The FDA method employed MMLA, while the USDA method used LiCl-phenylethanol-moxalactam agar (LPMA) as isolation agars [140].

A range of media has been developed, which include Oxford agar [145] LiCl-ceftazidime agar, modified (LCAM) [146], polymyxin-acriflavine-lithium chloride-ceftazidime-aesculin-mannitol (PALCAM), polymyxin-acriflavine-lithium chloride-ceftazidime-aesculin-mannitol egg yolk [147], Dominguez-Rodriguez isolation agar [148], Dominguez- Rodriguez *Listeria* selective agar medium, modified [149]; enhanced hemolysis agar (EHA) [145], modified Vogel Johnson agar (MVJ), [150],and MVJ modified further [151].

Chromogenic Media

Phosphatidylinositol-specific phospholipase C is an enzyme produced only by *L. monocytogenes* and *L. ivanovii*, which hydrolyses a specific substrate added to the medium, producing an opaque halo around the colonies. Substrates for the detection of β-glucosidase, common to all *Listeria* spp., may be used as elective feature for the detection of all *Listeria* colonies. Lithium chloride, nalidixic acid, and/or cyclohexamide are added to the media to obtain sufficient selectivity [152]. The chromogenic media that are commercially available include "Agar *Listeria* according to Ottaviani and Agosti," BCM *L. monocytogenes* detection system, CHROM agar, and Rapid'L.mono. Chromogenic media are simple, cost-effective, and easy to interpret [138]. Chromogenic media have been found to be a good supplementation to PALCAM agar [153].

Virulence Determination

Many *L. monocytogenes* strains are highly pathogenic, others are relatively avirulent and cause little harm in the host. A variety of methods have been developed to gauge the virulence of *L. monocytogenes* strains. Besides, hemolysin, mouse pathogenicity, tissue culture systems, and the detection of virulence-associated proteins and genes have been used to identify virulent *Listeria*.

Animal Inoculation

The mouse virulence assay has been frequently used for assessing *L. monocytogenes* virulence. This assay is done by inoculating groups of mice with varying doses of *L. monocytogenes* bacteria via the oral, nasal, intraperitoneal, intravenous, or subcutaneous routes [154]. Tests using oral inoculation in mice must be interpreted with caution since the main bacterial invasion protein internalin A does not bind to the mouse E-cadherin gene, resulting in inefficient translocation of these bacteria from the gastrointestinal tract to deeper tissues and organs [155]. The virulence of *L. monocytogenes* for man has been correlated with pathogenicity in mice [156], particularly in those made immunocompromised by treatment with carrageenan [157]. However, a large difference in the 50% of lethal doses (LD_{50}) between virulent and less virulent *L. monocytogenes* strains have been observed in immunocompromised model unlike the normal mice, which allows a clear and rapid means of distinguishing between the strains with a single dose inoculum and with the sole criterion being death of mice [158]. In some instances, the relatively high numbers of animals required have rendered LD_{50} determination

impracticable; therefore, it has been emphasized that criterion for assessing virulence of *Listeria* strains on the basis of death is wrong and should be replaced more appropriately with persistence of microorganisms in liver or spleen following inoculation [159]. Recently, relative virulence (%) has been described as an alternative to LD50 measurement of the mouse virulence assay for *L. monocytogenes* [160]. The relative virulence (%) is obtained by dividing the number of dead mice by the total number of mice tested for a particular strain, using a known virulent strain (e.g., *L. monocytogenes* EGD) as a reference. All the nonhemolytic species of *Listeria* (*L. innocua*, *L. welshimeri*, and *L. grayi*) and the weakly hemolytic *L. seeligeri* are avirulent in mouse pathogenicity tests [156].

Besides mice, Sprague Dawley rats pre-treated with cimetidine have also been developed as an experimental model for gastric intubation [161]. The chick embryo test has been reported to agree with the mouse bioassay for assessment of the pathogenicity of *Listeria* species [162] as embryos inoculated with pathogenic strains through chorioallantoic membrane (CAM) route died within 72 hours, whereas those inoculated with nonpathogenic strains survived [163]. The LD_{50} has been reported to be less than 6×10^2 cells for virulent strains [164]. Yolk sac challenge of 7-day-old chick embryos has been found to be less suitable than the CAM challenge for assessing virulence because of nonspecific deaths encountered in the former route [162].

Esophageal inoculation of juvenile rats with 10^6 cfu *L. monocytogenes* showed about a 50% infection rate in the liver or spleen [161]. An experimental keratoconjunctivitis test (Anton's eye test) can be performed in either guinea pigs or rabbits by inoculating a live bacterial suspension onto the eye [165].

Approximation of the infectious dose of *L. monocytogenes* in foods using cynomolgus monkey as a nonhuman primate model indicated that animals receiving 10^9 cells of *L. monocytogenes* became noticeably ill with symptoms of septicemia, irritability, loss of appetite, and occasional diarrhea [166].

The possibility of addressing aspects of mammalian innate immunity in invertebrates has opened a new arena for developing invertebrate models to study human infections [167]. The greater wax moth, *Galleria mellonella*, has been studied as a reliable model to investigate the *Listeria* pathogenesis [167, 168] and as a source of peptides exhibiting anti-*Listeria*-activity [167]. The *Galleria* model has been used to investigate the differences between infections caused by strains with different virulence potentials in the mouse infection model and revealed a strong correlation with virulence previously determined by the mouse model [167]. Using *Galleria* as a model, bacterial infection can be studied at 37°C as most of the human pathogens induce their virulence factors at this temperature. It has been shown that *G. mellonella* can be used to study brain infection and its impact on larval development as well as the activation of stress responses and neuronal repair mechanisms [169].

In vitro *Cell Assays*

L. monocytogenes is able to infect and grow intracellularly in a range of mammalian cell types growing *in vitro*, including enterocytes, macrophages, hepatocytes, neuronal cells, and fibroblasts [18, 170] as well as invertebrate, *Drosophila melanogaster*-derived cells [171]. These methods measure the ability of *monocyto genes* to cause cytopathogenic effects in the enterocyte-like cell line Caco-2 [172] to form plaques in the human adenocarcinoma cell line HT-29 [173] and L929 mouse fibroblast [174] and also help to study the heterogeneity of virulence factors. *L. monocytogenes*, *L. ivanovii*, and *L. seeligeri* show properties of invasion and spreading, but other *Listeria* species do not [172, 175].

The main advantages of *in vitro* cell assays include their relatively low cost and ease of use. However, these tests are time-consuming and occasionally variable, which has prevented them from being adopted in clinical laboratories for determining *L. monocytogenes* virulence and pathogenic potential [19]

Expression of Virulence-Associated Factors

In vitro demonstration of LLO, PC-PLC, and PI-PLC activities often provides general guidance on the pathogenic potential of *L. monocytogenes* strains. However, its reliability as a virulence indicator is not satisfactory. Detection of *L. monocytogenes* virulence-associated genes by PCR and genetic lineage analysis has not resulted in a clear correlation between these genes and the underlying virulence of *L. monocytogenes* [99, 176, 177]. Also, mutations in virulence-associated genes, resulting in the expression of truncated or nonfunctional proteins [178–179], can occur. Targeting these gene mutations as a means of differentiating *L. monocytogenes* virulence often experience difficulties. An optimal strategy for *L. monocytogenes* virulence testing should be the detection of virulence-specific gene[s] that are present only in virulent strains, but absent in avirulent strains [19].

Immunological Tests

Conventional Tests

Serological methods have been reported to be nonspecific because of antigenic cross-reactivity between *L. monocytogenes* and other Gram-positive bacteria, such as *Staphylococci*, *Enterococci*, and *Bacillus* spp. [115]. Such methods also lack sensitivity, and, therefore, cannot be used for reliable diagnosis of listeriosis [121].

Enzyme-Linked Immunosorbent Assay (ELISA)

ELISAs for *L. monocytogenes* detection are either based on polyclonal antibody [180] or on monoclonal antibodies (mAbs) [181]. There are a number of ELISA formats including direct ELISAs, sandwich ELISAs, and competitive ELISAs. MAbs based-ELISA and dot-blot assays have been reported to identify *Listeria* spp. in food [182–183] and clinical samples [184]. However, some of these mAbs have been shown to react with all species of *Listeria* [182–183].

The *Listeria*-Tek assay, an ELISA-based method, has been reported to be a rapid and simple procedure for determination of *Listeria* spp. in foods [185]. The ELISA and the USDA procedure have been proved to be equally sensitive for processing the food samples having *L. monocytogenes* count >3 cfu/g and had detection limits of approximately 10^6 cfu/ml and 10^4 cfu/mL in pure cultures, respectively [186]. The ELISA for detection of

L. monocytogenes in dairy, seafood, and meat products has been adopted first action by AOAC International [187].

The most commonly used immunoassays for the detection of the pathogen are based on the use of whole cells. Often for detection of *L. monocytogenes* from foods, the sample is enriched, heat-killed [188–189], or formalin-fixed [190]. However, many of the cell-surface antigens are genus-specific rather than *L. monocytogenes*-specific [191–192]. Detection of the flagella of the bacterium has also been attempted [193–194].

ELISAs using the O and H antigens [195], as well as whole-cell protein extracts [196], have also been used to detect the pathogen. Monoclonal antibodies are used in the Vitek Immunodiagnostic Assay System (VIDAS)-LMO (bioMerieux Vitek, Hazeltown, MO) and Lister test (Vicam, Watertown, MA) [188, 197]. For field application, a point-of-care-testing (POCT) version of ELISA was employed using the concept of cross-flow chromatography [198] and applied for the detection of *L. monocytogenes* [199].

Lateral Flow Assay

Recently, a lateral-flow enzyme immunochromatography coupled with an immunomagnetic step was developed for rapid detection of *L. monocytogenes* in food matrices [200] and was demonstrated to be highly sensitive, specific, and rapid compared with spectroscopic methods [201, 202]. The assay yielded a limit of detection of 95 and 97 ± 19.5 cfu/mL in buffer solution and 2% milk sample, respectively [200] with the separation and detection time within 2 hours. The system did not show cross-reactivity with other bacteria (e.g., *Escherichia coli* O157:H7, *Salmonella typhimurium*, and *Salmonella enteritidis*). The analytical procedure could be useful in the field for rapid screening for pathogenic and as a preventive measure to contain disease outbreak.

Immunomagnetic Separation (IMS)

Paramagnetic polystyrene beads possessing pathogen-specific antibodies covalently linked to the bead surface are used, to which the pathogen antigens binds in the presence of a magnetic field [203]. Immunomagnetic nanoparticles coated with rabbit anti-*Listeria monocytogenes* antibodies were used for the rapid detection of *L. monocytogenes* from milk samples in combination with real-time PCR with the limit of detection greater than 10^2 cfu/0.5 mL [204]. In another study, paramagnetic beads coated with recombinant *Listeria* phage endolysin-derived cell-wall-binding domain proteins specific for *Listeria* spp. were used to detect bacteria in artificially contaminated raw milk with a sensitivity of 10^2 to 10^3 cfu/mL [205].

Immunofluorescence Test

The fluorescent antibody technique for the detection of *L. monocytogenes* in smear—impression smears from dead tissues, meat, and milk—was described by Khan *et al.* [206]. However, they reported cross-reaction with micrococci and streptococci. Later, immunofluorescence tests based on monoclonal antibodies for detection of *L. monocytogenes* from the clinical specimens, such as necropsy tissue [184, 207] and specific-protein p60, have been developed [208].

Cellular Assays

Cell-mediated immune (CMI) effector functions have been shown to play important role in the host defense against different facultative intracellular bacterial pathogens through cytokine production and perhaps by recognition and lysis of macrophages and other cells infected with these pathogens including *L. monocytogenes* [209]. The measurement of CMI can be accomplished by several methods such as delayed type hypersensitivity, lymphocyte proliferation assay, cytotoxicity assay, and cytokine assay, which are either generalized or specialized in nature [210].

Delayed-type hypersensitivity (DTH) is characterized by a localized swelling occurring 48–72 hours after intradermal injection with the microbial antigen under test. DTH carried out with soluble crude antigen fractions of nonpathogenic *L. innocua* (serotype 6a) or *L. monocytogenes* (serotype 4 b) has been shown to be useful in detecting listeriosis at an early stage [211] using experimental mouse model.

Cytotoxicity assays are based on the measurement of the ability of lymphocytes to kill target cells. Cytotoxic T-lymphocytes have been found to play an important role in the immunity of hosts to facultative intracellular bacteria [212].

Cytokine released by activated lymphocytes have been assayed to serve as a measure of CMI. Cytokine assays might be in the form of bioassays or a direct concentration measurement as in ELISA, radio-immunoassays, or precipitation assays or detection of specific mRNA in lymphocytes [210]. IFNγ in the blood streams and spleens of mice has been detected from Day 1 to Day 4 postinfection with *L. monocytogenes* by double sandwich ELISA as well as immuno-histochemical techniques [213]. IFNγ appeared as early as Day 7 of an oral infection in bovines [214].

Molecular Methods

DNA Probes

The presence of a target sequence is detected using a single-stranded nucleic acid that is enzyme- or radiolabeled. Datta *et al.* [215] reported the first DNA probe wherein a *Hind*III-*Hind*II fragment of a presumptive hemolysin gene was used in a trial for specific detection of *L. monocytogenes*. Nonisotopic colorimetric detection has been applied in a rapid nucleic acid dipstick hybridization assay for detection of *Listeria* sp. in food and environmental samples [216]. Different DNA probes such as digoxigenin-labelled synthetic oligonucleotide probe [217] on a *16S r*RNA sequence [218] have been developed. DNA probes targeting the inlA and *plc*A [219–220], and the *prf*A [221] genes have also been developed. As this procedure exploits differences among *Listeria* species at the genetic level, it is more specific than biochemical and serological methods that are phenotype based.

Fluorescence in situ Hybridization

Fluorescence *in situ* hybridization (FISH) is used to study the presence and distribution of specific strains in microbial communities. FISH can be used in phylogenetic studies, and in assessing the spatial distribution of target microbes in communities such as biofilms [222]. FISH using oligonucleotide probes specific for the virulence gene transcript, *iap*-mRNA has been carried out

which allowed to analyze virulence gene expression of *L. monocytogenes* within a mixed microbial community [222].

Nucleic Acid Amplification

In the first reported PCR for identification of *L. monocytogenes*, the *hly* sequence published by Mengaud *et al.*[223] was used. This PCR was used to detect *L. monocytogenes* in water, whole milk, and human cerebrospinal fluid. Standard PCR followed by dot-blot hybridization has come out as an encouraging approach for the diagnosis of *Listeria* meningitis [224].

PCRs have been developed for the identification of *L. monocytogenes* in food samples [225–226] and in vegetables [227]. The minimum detection limits of *L. monocytogenes* in a 25-g sample after 48 hours incubation have been reported to be 10 cells [228] and 4–10 cells after overnight incubation [229]. Using a two-step PCR with nested primers, one colony-forming unit (CFU) *L. monocytogenes* could be directly detected in 25 mL of raw milk [230]. However, false-negative results have also been reported with PCR while analyzing foods containing high populations of *L. monocytogenes* [229].

As PCR has the ability to selectively amplify specific targets present in low concentrations, it offers exquisite specificity, unsurpassed sensitivity, rapid turnover, and ease of automation for laboratory detection of *L. monocytogenes* from clinical specimens [19]. The molecular differences within *16S* and *23S rRNA* genes, intergenic spacer regions, *hly*, *inlA*, *inlB*, *iap*, and other genes can be used to differentiate *L. monocytogenes* from other *Listeria* species and common bacteria [231]. Table 32.2 lists the genes employed for PCR-based identification of *Listeria*. The nested PCR protocol to detect the *hly*A gene has been used as a screening test to detect *L. monocytogenes* in Minas Frescal cheese, allowing earlier detection of the pathogen that can later be confirmed by the ISO standardized reference method [232].

Reverse Transcription (RT)-PCR

Testing of food or environmental samples for pathogenic *Listeria* should only target living organisms since only live *Listeria* cells can cause disease. The choice of RNA or mRNA as a target for food pathogen testing has gathered increasing favor since the presence of mRNA is an indication of the living state of the cell [233–234].

L. monocytogenes has been detected using RT-PCR in artificially inoculated meat samples [235] by targeting mRNA transcripts of the *hly*, *prf*A, and *iap* genes, in waste samples [236] by targeting the transcripts for *rRNA* genes, and also for the detection of heat-injured *monocytogenes* by targeting the *hly* transcript [237].

Real-Time PCR

Real-time PCR has been used to identify and quantify *L. monocytogenes* in foods and clinical samples in several studies [238–241]. Real-time PCR is quantitative, which is a significant advantage over other molecular methods, and so this technology is extremely attractive for food testing and epidemiological investigations. A combination of four qualitative SYBR®Green qPCR screening assays targeting two levels of discrimination, *Listeria* genus (except *Listeria grayi*) and *Listeria monocytogenes*, has been described [242] with the limit of detection of the SYBR®Green qPCR assays determined between two and five copies of target genes per qPCR reaction.

Other Techniques for Detection of *Listeria*

Biosensor-Based Techniques

The combined use of micro- and nanofabrication techniques in the area of biosensors holds a great promise in the area of detection of foodborne pathogens [243]. Aptamer-A8, specific for internalin A, was used in the fiberoptic sensor together with antibody in a sandwich format for detection of *L. monocytogenes* from food [244]. A mammalian cell-based biosensor, wherein the B-lymphocyte Ped-2E9 cell line embedded in a collagen matrix served as a sensing element, was developed and tested for detection of *L. monocytogenes* and its toxin, listeriolysin O, from artificially inoculated food samples [245]. It has a detection level of 10^2 to 10^4 cfu/g in artificially inoculated food and beverages. An internalin A probe-based genosensor that discriminates whole DNA samples of *L. monocytogenes* strains from other nonpathogenic *Listeria* species DNA has been developed [246].

Gold nanoparticles/horseradish peroxidase-encapsulated polyelectrolyte nanocapsule was developed for signal amplification in *L. monocytogenes* detection and demonstrated that the bioconjugate nanocapsules showed 30 times greater sensitivity and a shorter assay time (5 minutes) when compared to conventional ELISA using an HRP-labeled antibody, for a given quantity of antibody [247].

Loop-Mediated Isothermal Amplification (LAMP)

Loop-mediated isothermal amplification (LAMP) allows a rapid amplification of nucleic acids under isothermal conditions. LAMP can be combined with a rhodamine-based dual chemosensor for efficient, field-friendly detection of *L. monocytogenes*. The LAMP-chemosensor method was used to detect low levels of *L. monocytogenes* DNA. LAMP has the advantages of better sensitivity and speed and less dependence on equipment than the standard PCR and this can be useful in the field as a routine diagnostic tool [248].

LAMP assay targeting the *hly*A gene was developed and the amplification products were visualized by calcein and manganous ion and agarose gel electrophoresis. It has been opined that the LAMP assay can facilitate the surveillance for contamination of *L. monocytogenes* in food [249].

Spectroscopy-Based Techniques

Various spectrophotometric methods like Fourier transform infrared (FT-IR) and matrix-assisted laser desorption/ionization time-of-flight mass spectroscopy (MALDI-TOF MS) have been developed to detect foodborne pathogens [250]. A rapid method involving MALDI-TOF MS showed promise for identification of *Listeria* species and typing and even allowed for differentiation at the level of clonal lineages among pathogenic strains of *L. monocytogenes* [251]. The method examines the chemistry of major proteins, yielding profile spectra consisting of a series of peaks, a characteristic "fingerprint" mainly derived from ribosomal proteins. Mass spectra derived from *Listeria* isolates showed characteristic peaks, conserved at both the species and lineage levels.

The availability of reference databases such as MALDI Biotyper (Bruker Corporation) and SARAMIS (bioMérieux), which include reference spectra for numerous microorganisms, has made detection of microbes possible in a time-saving manner compared to the currently available screening and confirmation techniques for *Listeria* [252].

Other Methods

Other rapid methods for detecting *Listeria* spp. include the use of flow cytometry [95], nucleic acid sequence-based amplification [253], and electrical impedance [254].

Immunomagnetic separation used primarily to isolate strains of *L. monocytogenes* from pure cultures as well as from heterogenous suspensions has been viewed as a new approach for extraction and isolation of pathogenic bacteria directly from foods [255].

A fluorescent *in situ* hybridization (FISH] method in conjunction with fluorescein-labeled peptide nucleic acid (PNA) probes (PNA-FISH) for detection of *Listeria* species was developed [256]. Three PNA probes Lis-16S-1, Lm-16S-2, and Liv-16S-5 were suitable for specific identification of *Listeria* genus, *L. monocytogene*s, and *L. ivanovii*, respectively.

The Roka *Listeria* Detection Assay, in conjunction with a new media formulation (R2 Medium), allowed for the early detection of *Listeria* in ice cream and may be applied in other food matrixes and environmental samples [257].

Methods for Subtyping of *Listeria*

Subtyping plays an important role in epidemiology during outbreaks of *L. monocytogenes* and trace back investigations and also for understanding the pathophysiology of the organisms [258–259] and source attribution [260].

It is also useful to examine the epidemiology and population genetics of *L. monocytogenes* and is integral to control and prevention programs aimed at limiting listeriosis. A variety of conventional, phenotypic, and DNA-based subtyping methods have been described for differentiation of *L. monocytogenes* beyond the species and subspecies levels [261]. While phenotype-based methods have been used for many years to subtype *L. monocytogenes* and other foodborne pathogens, DNA-based subtyping methods are generally more discriminatory and amenable to inter laboratory standardization and are thus increasingly replacing phenotype-based subtyping methods [262]. Commonly used phenotype-based subtyping methods for *L. monocytogenes* and other foodborne pathogens include serotyping, phage typing, and multilocus enzyme electrophoresis (MLEE)[261, 263]. The genetic subtyping approach encompasses PCR-based approaches (e.g., random amplified polymorphic DNA and amplified fragment length polymorphism), PCR-restriction fragment length polymorphism (PCR-RFLP), ribotyping, pulsed-field gel electrophoresis, and DNA sequencing-based subtyping techniques, e.g., multilocus sequence typing (MLST) [264–267]. The phenotypic subtyping approach occasionally suffers from low discrimination and reproducibility, the genetic subtyping approach is highly sensitive, discriminatory, and reproducible. For improved subtyping discrimination, a combination of two or more subtyping techniques, be they gene or phenotype based, is often used in practice for epidemiologic investigation of *L. monocytogenes* outbreaks. The methods for subtyping of *Listeria* are listed in Table 32.3.

Phenotyping Typing Methods

Serotyping

Serotyping is a universally accepted subtyping method for *L. monocytogenes*. Identification of the strain serotype permits differentiation between important foodborne strains. *Listeria* species possess group-specific surface proteins, such as somatic (O) and flagellar (H) antigens that are useful targets for serological detection with corresponding monoclonal and polyclonal antibodies. While there are 15 *Listeria* somatic (O) antigen subtypes (I–XV), flagellar (H) antigens comprise four subtypes (A–D) [268–269] with the serotypes of individual *Listeria* strains being determined by their unique combinations of O and H antigens. An ELISA has recently been developed to improve efficiency of serotyping [195].

Serotyping may potentially be useful for tracking *L. monocytogenes* strains involved in disease outbreaks. Indeed, it has been observed that *L. monocytogenes* serotypes 1/2a, 1/2b, and 4b are responsible for 98% of documented human listeriosis cases, whereas serotypes 4a and 4c are rarely associated with outbreaks of the disease [270–271]. However, due mainly to the high cost of acquiring subtype-specific antisera, serotyping methods are

not routinely performed in clinical laboratories. Serotyping does not correlate with the species distinctions. Serotyping methods have largely been superseded by molecular procedures that are intrinsically more specific and sensitive for the identification and differentiation of *Listeria* species. The development of PCR-based serotyping procedures has provided additional tools for the identification and grouping of *L. monocytogenes* [272–273]. The multiplex PCR method, in combination with a simple slide agglutination assay, can be very useful in quickly identifying serotypes of major *L. monocytogenes* serotypes [274].

Phage Typing

Phage typing of *L. monocytogenes* has been used as a discriminatory typing system. Bacteriophages have the capacity to lyse closely related *Listeria* because of their host specificity independently of the species and serovar identities. *Listeria* strains can be separated into distinct phage groups and phagovars, which are useful for tracking the origin and course of listeriosis outbreaks [275]. With close to 10% of *Listeria* strains being untypable (especially serovar 3 and *L. grayi* strains), the usefulness of phage typing as an independent tool for epidemiological investigations is severely constrained.

Multilocus Enzyme Electrophoresis (MLEE)

MLEE is a protein-based, isoenzyme typing method that correlates specific protein-band patterns with genotypes. MLEE differentiates bacterial strains by detecting variations in the patterns of the electrophoretic mobilities of various constitutive enzymes. Based on the similar electrophoretic types detected in MLEE, *L. monocytogenes* serovars 1/2b, 3b, and 4b are classified into one distinct division, and serovars 1/2a, 1/2c, and 3a in another division [276–277]. The detection of a large number of electrophoretic types in *L. monocytogenes* strains by MLEE necessitates careful optimization and standardization of the test procedure so that run-to-run variations are minimized.

Genetic Typing Methods

DNA-based typing of *L. monocytogenes* can be divided into two broad categories. In the first approach, different fragments of genome generated either by cleaving with restriction enzymes are compared or amplified segments of DNA are visualized after gel electrophoresis separation [278]. The techniques include ribotyping (RT), pulsed field gel electrophoresis (PFGE), rep-PCR, and random amplification of polymorphic DNA. The second approach involves the sequence-based subtyping, which is faster and cheaper. The techniques include whole genomic sequencing (WGS), next-generation sequencing (NGS), multilocus variable tandem repeats analysis (MLVA), and DNA-based microarrays.

Pulse Field Gel Electrophoresis (PFGE)

PFGE is a highly reproducible, discriminatory and effective molecular typing method that is based on restriction fragment length polymorphisms (RFLPs) of bacterial DNA [12] and provides a "gold standard" for comparing isolates analyzed in different labs with different techniques. PFGE uses selected restriction enzymes to yield fewer and larger fragments of DNA, resulting in a higher level of fragment resolution. PFGE provides sensitive subtype discrimination and is often considered the standard subtyping method for *L. monocytogenes* [279]. However, this method is not automated and is labor intensive.

PulseNet, a national network of public health and food regulatory laboratories, is established in the United States to detect clusters of foodborne disease and respond quickly to foodborne outbreak investigations [265]. The laboratories use a highly standardized 1-day PFGE to subtype the bacteria and exchange normalized DNA fingerprint patterns via the internet. PFGE has become the mainstay in molecular subtyping activity. Using standard protocols, the CDC has initiated PulseNet USA to store, analyze, and share digital PFGE images on a real-time basis. This assists in outbreak and trace back investigations of outbreaks caused by foodborne bacterial pathogens [280–281].

Ribotyping

Ribotyping is similar to RFLP in that it uses restriction endonuclease digestion of DNA to create a pattern that can be analyzed. It involves the restriction enzyme digestion of chromosomal DNA followed by DNA hybridization using an *rRNA* gene probe. Weidmann et al. [282] used ribotyping on different isolates of *L. monocytogenes* to group different lineages and relate the pathogenicity of the organism. *Eco*RI ribotyping was used to demonstrate the level of genetic diversity among *L. monocytogenes* contamination of Gorgonzola cheeses [283]. Although several attempts have been made to use ribotyping as a standard tool for strain characterization, its usefulness was found to be limited because of its low discriminatory power [284].

RAPD and Arbitrarily Primed PCR (AP-PCR)

Randomly amplified polymorphic DNA (RAPD) and AP-PCR analysis make use of a short arbitrary primer (usually 10 bases long for AP-PCR, and 10–15 bases long for RAPD) that anneals randomly along genomic DNA to amplify a number of fragments within the genome at a relatively low temperature (around 36°C). RAPD was used to follow the incidence and typing of *L. monocytogenes* in both poultry [285] and vegetable [286] processing plants. RAPD is more economical and faster than other typing methods and is particularly suitable for testing fewer than 50 strains.

Amplified Fragment Length Polymorphism (AFLP)

AFLP is a modification of RFLP through the addition of adaptors to restriction enzyme-digested DNA, followed by PCR amplification and electrophoretic separation of PCR products [19]. AFLP can be used to differentiate strains of *L. monocytogenes* on a more discriminating basis than serotyping [242–243, 287–288]. AFLP is sensitive and reproducible, thus representing a valuable tool in the characterization of *L. monocytogenes* strains, and also in the identification of *Listeria* species [289–290].

PCR-RFLP

PCR-RFLP involves the PCR amplification of one or more *L. monocytogenes* housekeeping or virulence-associated genes (e.g., *hly*, *act*A, and *inl*A), digestion with selected restriction enzymes and separation by agarose gel electrophoresis. Subsequent examination of the distinct band patterns permits differentiation of *L. monocytogenes* subtypes [164]. Paillard et al. [291] used PCR–RFLP on the 23S rRNA gene to determine the species of *Listeria* in sludge samples. PCR-RFLP provides a sensitive, discriminatory, and reproducible method for tracking and epidemiological investigation of *L. monocytogenes* bacteria, if used in combination with other subtyping procedures.

REP-PCR

Repetitive extragenic palindromic (REP) and enterobacterial repetitive intergenic consensus (ERIC) sequences represent useful primer-binding sites for PCR amplification of the *L. monocytogenes* genome to achieve species and strain discrimination and divide *L. monocytogenes* strains into four clusters that match the origin of isolation, each consisting of multiple subtypes [292]. REP-PCR showed a higher discriminative potential than ERIC-PCR and a comparable discriminative potential as RAPD combining three to four primers [292].

MLST

DNA sequencing-based methods are being developed and increasingly used for subtyping and characterizing bacterial isolates. In these methods, complete or partial nucleotide sequences are determined for one or more bacterial genes or chromosomal regions, thus providing unambiguous and discrete data. The advantages of sequencing methods over DNA fragment size-based typing methods include their ability to generate unambiguous data that are portable through web-based databases and that can be used for phylogenetic analyses [293–294]. While a variety of DNA sequence-based subtyping strategies targeting virulence genes, housekeeping genes, or other chromosomal genes and regions are feasible, MLST, which is an extension of MLEE, represents a widely used strategy [295].

Multilocus sequence typing (MLST) is a reference method for global epidemiology and population biology of bacteria. The application of MLST to *L. monocytogenes* effectively allows isolate comparisons across laboratories (www.pasteur.fr/mlst). The existence of few prevalent and globally distributed clones has been shown following, genotyping of 300 isolates from the five continents and diverse sources, some of which include previously described epidemic clones [296].

The implementation of DNA sequence-based subtyping approaches for routine characterization of human, animal, and food *L. monocytogenes* isolates will not only allow for sensitive and standardized subtyping for outbreak detection, but it will also provide an opportunity for using subtyping data to probe the evolution of this foodborne pathogen and to track the spread of clonal groups [262]. With the cost of DNA sequencing decreasing rapidly, MLST is poised to play a more important role in *L. monocytogenes* subtyping and phylogenetic studies.

MLVA

Multilocus variable tandem repeats analysis (MLVA), based upon identifying a number of small repeats (5–10bp) at different genetic loci, is a sequence-based method. Each locus is PCR amplified by specific primers resulting in different fragment lengths and translated into to the number of repeats. These repeats are arranged in a string to form a pattern representing a strain. MLVA could be automated for high throughput and high reproducibility has been found to be useful in discriminating strains from a single outbreak from the unrelated strains. MLVA could be a very useful tool for discriminating pure cultures as well as food enrichment broths directly, thereby reducing the time for detection and subtyping [297]. A modified protocol using five loci has been evaluated and found to be slightly more discriminatory than single-enzyme PFGE [298]. A website, MLVA-NET (http://www.pasteur.fr/recherche/genopole/PF8/mlva/) proposing the five-loci method as the standard method for MLVA analysis of *L. monocytogenes*, is maintained by the Institute Pasteur [278].

Using various subtyping procedures, *L. monocytogenes* strains have been grouped into three genetic lineages (or divisions), with lineage I consisting of serotypes 1/2b, 3b, 4b, 4d, and 4e; lineage II of serotypes 1/2a, 1/2c, 3a, and 3c; and lineage III of serotypes 4a and 4c [299]. A recent classification describes four lineages of *L. monocytogenes* with coincident niches: lineage I encompasses serotypes 1/2b, 3b, 4b, and 3c; lineage II includes serotypes 1/2a, 1/2c, and 3a; lineage III comprises serotypes 4a, 4b, and 4c; and lineage IV comprises 4a, 4b, and 4c [300]. Most isolates belong to lineages I and II, comprising the serotypes most commonly associated with human clinical cases. Lineage II strains are commonly isolated from food and animals with listeriosis, whereas outbreaks of human listeriosis are associated with lineage I. Lineages III and IV strains are rare and mostly isolated from animal sources [300].

DNA Microarrays

Microarrays are composed of a number of discreetly located DNA probes corresponding to an oligonucleotide specific to a target DNA sequence fixed on a solid substrate, such as glass. DNA microarrays are used to investigate microbial evolution and epidemiology and can serve as a diagnostic tool for clinical, environmental, or food testing. Two approaches are used, one is based on sequence-specific oligonucleotides and the other employs specific PCR products.

Several microarray-based strategies were developed to differentiate between the six listerial species [219] and for discrimination among *L. monocytogenes* serovars [301–302] and phylogenetic lineages [303–304]. Microarray-based assays were also applied to investigate the genome evolution within the genus *Listeria* [299] and for identification of natural atypical *L. innocua* strains harboring genes of the LIPI-1 [305].

Oligonucleotide microarrays based on the *iap* and *hly* genes have been used simultaneously to detect and discriminate between *Listeria* species [219]. Borucki et al. [301] developed a mixed genome microarray to identify gene sequences that differentiate different serotypes of *L. monocytogenes*. The most attractive feature of microarrays is the capability of simultaneous identification and typing of several *Listeria* strains in one test.

Genome Sequencing

Since the 1990s, the genome sequencing methods have been developed for strain identification, strain characterization for epidemiological use and for establishing phylogenetic relationships and genetic evolution of organisms [278]. New generation sequencing techniques that are relatively cheap and fast have revolutionized the sequence-based subtyping and our understanding of the genome structure. More than 50,000 whole genome sequences are available as of the year 2020 in public databases representing several outbreak and nonoutbreak-associated strains [214].

The availability of genome sequences of *L. monocytogenes* serovars, *L. innocua*, *L. welshimeri*, and *L. seeligeri* [306–309], has provided insight into the molecular basis of the pathogenesis determinants of *Listeria* species. Further, sequencing of the strains from other species of this genus will provide a rich resource for understanding the sources of variation and evolutionary history. Comparative genomics could reveal genetic loci that confer specific pathogenic traits to epidemic strains. The information provides access to niche-specific candidate genes and proteins that will need to be evaluated by traditional physiological, biochemical, and genetic approaches, in turn enabling to develop novel ways to interrupt transmission and prevent foodborne transmission.

Prevention and Control

Listeriosis can be prevented in humans by taking care during handling of the abortion cases in both humans and animals, avoiding consumption of contaminated foodstuffs and cross-infections, especially among infants in hospitals. Culling infected animals should be advocated as they secrete the organisms in secretions and excretions, especially in the cases of mastitis. Care in the use and preparation of silage is important as the pathogen grows luxuriantly at a pH greater than 5, particularly when fermentation is ineffective and molds grow. So far, no vaccine is available against listeriosis.

The government, industry, and consumer are the most important parties in ensuring food safety. The government should establish standards and develop codes of practice and ensure that these will be followed. Food producers and food preparers should produce safe food, achieved by adequate hygiene standards, good manufacturing practices (GMP),and implementation of hazard analysis and critical control points (HACCPs). Consumers, in particular those who buy food and prepare meals, should have a basic knowledge of safe food preparation.

Treatment

The organism is, so far, usually sensitive to a wide range of antibiotics [310]. Ampicillin, amoxicillin, tetracyclines, chloramphenicol, β-lactam antibiotics, together with an aminoglycoside, trimethoprim, and sulfamethoxazole are recommended. The use of ampicillin plus gentamicin is recommended to treat CNS infections, endocarditis, and infections in immunocompromised patients [311–312]. As per the IDSA guidelines of *Listeria* encephalitis, the use of ampicillin plus gentamicin or SXT (evidence A-III) is recommended [313]. Based on the delayed *in vitro* bactericidal activity of ampicillin, the synergistic effect of both agents *in vitro*, and on results of animal models [314], an aminoglycoside was added. However, it has been opined that the potential benefit attained with the addition of an aminoglycoside may decrease due to the risk of nephrotoxicity and the possible teratogenic effect in pregnant women [315]. Use of combination of cotrimoxazole has been suggested as it is effective *in vitro* [316] and bactericidal, and when combined with ampicillin than the combination of ampicillin plus gentamicin (93.3% vs. 43%) [317].

Recently, it has been found that fosfomycin is extremely effective in controlling listerial growth in a mouse model of infection. The basis of this exquisite sensitivity has been elucidated by the finding that following entry of the bacteria to the cytoplasm, intracellularly growing *Listeria* express a permease for the uptake of hexose phosphates (UhpT), and that fosfomycin is preferentially translocated into growing bacteria via this transporter [318].

L. monocytogenes infections are usually treated with a single antimicrobial agent and drugs are only combined for treatment of immunocompromised patients [319]. Recently, reports have described clinical strains resistant to chloramphenicol, erythromycin, streptomycin, tetracycline, vancomycin, and trimethoprim [320–322]. Resistant *L. monocytogenes* strains have also been found in food samples [323]. Use of the disinfectants, Virkon®S 2.0%, H_2O_2 5.0%, and TH^{4+} 1.0%, loaded on silver nanoparticles composite had the strong bactericidal effect against *L. monocytogenes* [324]. Currently, for treatment of *L. monocytogenes* endocarditis penicillin G or ampicillin (AMP) monotherapy, or AMP + gentamicin combination therapy is often favored. In an investigation AMP + ceftriaxone (CRO) and AMP + daptomycin (DAP) were each found to have synergistic activity against a *L. monocytogenes* endocarditis isolate [325].

Biotechnological Applications

L. monocytogenes has become an important paradigm for immunological investigation and also an important model system for analysis of the molecular mechanisms of intracellular parasitism and pathophysiology [45]. For many years *L. monocytogenes* has been used as a model of host-disease immunology,

As a facultative intracellular bacterium, *L. monocytogenes* survive within cells after phagocytosis, it is an ideal vector for the delivery of antigens to be processed and presented through both the class I and II antigen-processing pathways. It is possible that the virulence factors released in cytosol can enhance the immunogenicity of tumor-associated antigens, which are poorly immunogenic [326]. In several mouse models, *Listeria*-based vaccines have been demonstrated to be an effective method of influencing tumor growth and eliciting potent antitumor immune responses [327]. Active immunotherapy targeting dendritic cells (DCs) have shown great promise in preclinical models and in human clinical trials for the treatment of malignant disease [328]. Live-attenuated *L. monocytogenes* found to target naturally the DCs *in vivo* and stimulate both innate and adaptive cellular immunity. *L. monocytogenes*-based vaccines engineered to express cancer antigens have demonstrated striking efficacy in several animal models and have resulted in encouraging anecdotal survival benefit in early human clinical trials [328]. Many synchronous and disparate action mechanisms stimulating innate and cell-mediated adaptive immunity and reducing immunosuppressive influences in the tumor microenvironment are utilized by *L. monocytogenes* immunotherapy [329].

LLO incorporated into liposomes can be used as an efficient vaccine delivery system carrying a viral antigenic protein to generate protective antiviral immunity [330].

Therapeutic vaccines of cancer including live vaccination strategies, having the capacity of breaking the immune tolerance and invoking long-term immune response targeting cancer cells without autoimmunity, have been emerged as an attractive approach [331]. Several bacterial strains including *L. monocytogenes* effectively colonize solid tumors and act as antitumor therapeutics. *Listeria* has been engineered to express a number of HIV/SIV antigens and has been tried as a live bacterial vaccine vector for the delivery of HIV antigens [332].

Listeria monocytogenes as a Vector for Cancer Immunotherapy

L. monocytogenes has been found to selectively infect antigen-presenting cells. It activates tumor-targeting CTL-mediated immunity through efficient delivery of tumor antigens to both the MHC Class I and II pathways [333–334]. *L. monocytogenes* is a versatile bacterial vector and has ability to induce therapeutic immunity against a wide-array of tumor-associated antigens (TAAs). Therefore, *L. monocytogenes*-based immunotherapies have delivered impressive therapeutic efficacy in preclinical models of cancer for two decades and are now showing promise clinically. The history leading up to the development of current Lm-based immunotherapies is extensively reviewed [333].

Incorporation of multiple epitopes from several antigens into a polyvalent vaccine has been suggested as an effective strategy going forward for *L. monocytogenes*-based immunotherapies to mitigate immune escape [335]. It has been suggested that in addition to the development of polyvalent *L. monocytogenes*-based vaccines, the new version could explore tumor tropism of their attenuated *L. monocytogenes* vaccines [336]. Treatment of stubborn malignancies such as pancreatic ductal carcinoma could be harnessed through the primary and metastatic tumor tropism and killing by *Listeria* [336]. Owing to this tumor tropism, a possible synergistic strategy of *L. monocytogenes*-based vaccines may go forward to deliver therapeutic proteins or expression plasmids to the tumor microenvironment [337]. This synergism of *L. monocytogenes*-based immunotherapies in combination with radiation, adjuvants, and therapeutic antibodies suggests versatile use [338–339].

L. monocytogenes infection has been known to induce robust $CD8^+$ T-cell responses having a critical role in resolving primary infection and provide protective immunity to reinfections [340]. The listeriolysin O peptide 91-99 (GNP-LLO_{91-99}) having antimetastatic properties, coupled with gold glyconanoparticles, are vaccine delivery platforms that facilitate immune-cell targeting and increase antigen loading [341] and have been proposed to function as immune stimulators and immune effectors and as safe cancer therapies, alone or in combination with other immunotherapies. *L. monocytogenes* immunotherapy with a broad effect on the immune system, axalimogene filolisbac (ADXS11-001), had shown promising results in Phase 2 studies for treatment of human papillomavirus-associated cancers, including cervical cancer [342].

Immunotherapy with $CD8^+$ T-cells activated by *Listeria* in young and old mice had shown an antitumor effect at young but not at old age; however, the metastases at old age were shown to be eliminated through different mechanism(s) [343].

Outlook and Perspective

Listeria remains among the deadliest known foodborne pathogen worldwide. Great progress has been made in eliciting the mechanisms leading to pathogenesis of this bacterium and a large battery of tests are now available to detect and diagnostically classify *Listeria* both at the species level and even permit discrimination between strains associated with human and animal infections or even sporadic from epidemic strains. The advent of functional listerial genomics is providing new possibilities to comprehensively catalogue genes and their products involved in the transition from life in the environment to life within infected cells. The availability of genome sequences will provide us with an opportunity to define the evolutionary paths taken to pathogenesis and help us understand the emergence of *Listeria* spp. as major foodborne pathogens. Recombinant *Listeria* is reported to be effective delivery vectors for the development of cancer vaccines, which needs to be explored further.

The discovery of isolates harboring pan-species virulence genes of the genus *Listeria* and novel species has opened new areas of research in genus *Listeria*.

We now have a good understanding of those listerial factors that predispose to biofilm formation and persistence. Thus, ability to determine hypervirulence properties of emerging *L. monocytogenes* variants has increased our understanding of virulence

potential that can now be translated to probiotic health and food safety measures. The increase of incidence causing both sporadic and epidemic disease worldwide suggests that increased vigilance must now be implemented, particularly in food-processing facilities.

Introduction

The genus *Mycobacterium* consists of more than 190 species and belongs to the family of *Mycobacteriaceae*, order Corynebacteriales, phylum/class Actinobacteria, and kingdom Bacteria (http://www.dsmz.de/bacterial-diversity/prokaryotic-nomenclature-up-to-date).[1] Mycobacteria are nonmotile, rod-shaped bacilli, characterized by an extremely lipid-rich cell wall comprising mycolic acids. These long-chain (C-60 to C-90) fatty acids make all mycobacterial species "acid-fast" as they resist acid-alcohol decolorization following staining with phenicated dyes like fuchsine, enabling their microscopic detection. Mycobacteria should not be confused with members of the closely related genera *Nocardia, Corynebacterium*, or *Rhodococcus*, which have shorter-chain (C-22 to C-64) mycolic acids and can be partially acid-fast.[1]

Based on phenotypic characters, the genus was proposed in 1896 by Lehmann and Neuman.[2] With the advent of DNA-based analysis, mycobacterial species were initially differentiated at <70% similarity by DNA-DNA hybridization,[3] and later by <98.8% 16SrRNA Sanger sequence similarity[4] with or without

inclusion of additional housekeeping genes like *hsp65* or *rpoB*.[5] These phenotypic and genotypic analyses are all in agreement with the initially described genus *Mycobacterium,* phylogenetically distinguishing five major groups.

Recently, the taxonomy of the genus *Mycobacterium* has been challenged based on a core protein analysis—identifying insertions/deletions of amino acids, or proteins exclusively found in evolutionarily-related groups of species—suggesting to split the genus in five monophyletic groups designated as the "Tuberculosis-Simiae," "Terrae," "Triviale," "Fortuitum-Vaccae," and "Abscessus-Chelonae" clades.[6] The five proposed genera exactly overlap the major clades of the classical taxonomy. Gupta et al. propose to keep the genus "*Mycobacterium"* for species belonging to the "Tuberculosis-Simiae" clade and to introduce four novel genera hosting the nontuberculous mycobacteria (NTM) of the above mentioned clades in "*Mycolicibacter*," "*Mycolicibacillus*," "*Mycolicibacterium*," and "*Mycobacteroides*," respectively. This reclassification has been debated and questioned for reasons of methodology and clinical relevance.[7,8] Tortoli and colleagues argue:

> NTM may be diverse in their genetics and biology, but they produce remarkably similar disease manifestations in distinct populations at risk. This uniformity and the lessons to be learned from it are important for both clinicians as well as the affected patients.

The newly proposed reallocation risks to cause confusion among clinicians and clinical microbiologists, while not being beneficial for the patient. Also, the novel genus "*Mycobacterium*" is said to include all of the major human pathogens[6] but does not comprise clinically important species like *M. abscessus*.[9] Regarding the methodological approach for this reclassification, while Tortoli and colleagues identified minor technical errors (mislabeling for some of the sequences used),[10] Meehan and colleagues questioned the correctness of the analysis in a more fundamental way.[8] Analyzing the percentage of conserved proteins (POCP) revealed that all 145 tested species in the original *Mycobacterium* genus fell within the 50% boundary of all others, while all 223 tested non-*Mycobacterium* species from the *Corynebacteriaceae* family had <50% POCP to all *Mycobacterium* species, strongly supporting retention of the classical genus *Mycobacterium*.[8] Given the equal taxonomic validity of both classification systems, the newly proposed genus and species names can be used as synonyms.[7] For sake of clarity in this handbook on clinical practice, we will stick to the classical genus "*Mycobacterium*" and related species names in this chapter.

With their generation time varying from 2 to 48 hours, mycobacterial species can be classified as slow growers—requiring more than 7 days to form visible colonies on solid medium—and rapid growers exhibiting visible growth in less than 7 days. This growth-rate-based separation is supported by phylogenetic trees constructed from 16S rRNA or whole genome sequences.[11] Combining growth rate with ability to produce pigmentation and clinical significance, Runyon classified members of the *Mycobacterium* genus into five groups,[12,13] a classification that is barely used nowadays.

According to their infectiousness, mycobacteria are classified in three categories: (1) strict pathogens, with members of the *M. tuberculosis* complex (MTBc) and *M. leprae* having the biggest public health impact; (2) opportunistic pathogens like *M. avium*, that are found in the environment and may cause disease in persons with predisposing conditions or compromised immunity; and (3) saprophytes like *M. gordonae*, that are ubiquitous and can be found in environmental sources, yet rarely or never cause infection and are considered overall nonpathogenic. Most (opportunistic) pathogenic mycobacteria are slow growers.

Clinical Importance of Mycobacteria

The clinical importance of mycobacteria cannot be overemphasized, especially for members of the MTBc, *M. leprae*, *M. ulcerans*, and some opportunistic NTM in specific vulnerable populations.

Mycobacterium tuberculosis Complex (MTBC)

Tuberculosis (TB) is caused by members of the *M. tuberculosis* complex (MTBC) comprising *M. tuberculosis sensu stricto*, *M. africanum*, *M. bovis*, *M. canettii, M. caprae, M. microti*, *M. mungi, M. pinnipedii*, *M. orygis*, and *M. surricatae*.[14] While *M. tuberculosis* and *M. africanum* are human-adapted species, the other species prefer (specific) animal hosts with possible zoonotic spill over to humans, mostly from *M. bovis* via cattle.[14] An attenuated strain of *M. bovis*, *M. bovis* BCG (Bacille Calmette-Guérin), is used as a vaccine in many high-burden countries to protect against acquiring TB, though its efficacy is questionable.[15]

The two human-adapted species comprise eight phylogenetic lineages (L1–L8),[16] with L1–L4 and L7–L8 being *M. tuberculosis sensu stricto*, and L5 and L6 *M. africanum*. As for their geographic repartition, L2 and L4 are the most widespread, while L1 and L3 are intermediately distributed, L5 and L6 are restricted to West Africa, and L7 is found only in Ethiopia.[17] *M. africanum* is responsible for up to 40% of TB in West Africa.[18]

Worldwide, TB is among the top 10 causes of death, and the first cause of death by a single infectious agent (above HIV/AIDS).[19] It was estimated that in 2018, worldwide, 10 million people developed TB, of whom 1.2 million died. Two-thirds of cases occurred in eight high-burden countries, with India (27%) and China (9%) ranking first. Only 6% of global cases were in the World Health Organization (WHO) European Region (3%) and the WHO Region of the Americas (3%). In terms of TB incidence, Africa ranked first with 231 per 100,000 population, which is almost twofold the worldwide incidence (132 per 100,000 population).[19] Likewise, the highest TB mortality rate was reported from Africa, where the TB epidemic is fueled by the HIV/AIDS epidemic. People living with HIV are 20–30 times more likely to develop active TB disease than people without HIV. Following huge TB control efforts, increased accessibility to antiretroviral treatment and availability of new anti-TB drugs, the worldwide TB incidence rate is falling at about 2% per year, with the fastest regional declines between 2013 and 2017 in the WHO European (on average, 5% per year) and African (3.8% per year) regions.[19] Nevertheless, TB continues to be a major public health problem in many countries.

Of added importance is the number of MTBC strains that are found resistant to one or more of the antitubercular agents.

TB disease is always treated with a combination therapy. The preferred regimen for treating adults with TB consists of an intensive phase of 2 months of isoniazid (INH), rifampin (RIF), pyrazinamide (PZA), and ethambutol (EMB) followed by a continuation phase of 4 months of INH and RIF. RIF, a strong bactericidal and sterilizing drug, is considered the core drug for standard TB treatment.[20] Patients infected with MTBC strains resistant to (at least) RIF or RIF and INH—defined as multidrug resistant (MDR)—should be treated with alternative drugs in so-called MDR-TB regimens. While these drugs are commonly known as "second-line" drugs, recent guidelines from the WHO classify these drugs in group A, B, and C.[21] Individualized MDR-TB regimens using three drugs from group A, complemented by one or two drugs from group B, and one or more from C, have been proposed for a duration of 18 months or more.[22] Alternatively, a standardized short MDR-TB regimen (9–12 months) has been shown to be noninferior compared to the long regimen,[22] and was successfully implemented under programmatic conditions in multiple African and Asian countries.[23,24] The short regimen includes a fourth-generation fluoroquinolone (gatifloxacin, moxifloxacin, or levofloxacin) as core drug.[20] Recently, the use of injectable aminoglycosides (amikacin or kanamycin) or polypeptides (capreomycin) has been discouraged, due to the irreversible ototoxicity.[21]

An MDR patient may further develop resistance to other drugs during the course of treatment. MDR combined with resistance to a fluoroquinolone and an injectable aminoglycoside or polypeptide is defined as extreme drug resistance (XDR). XDR-TB treatment regimens require further inclusion of less efficient, more toxic group C drugs[21] or new drugs like bedaquiline and delamanid. XDR-TB treatment is difficult and costly.

MDR- and XDR-TB are a major concern worldwide, with cases reported in all countries. According to the WHO, in 2018, globally 3.4% of new cases and 18% of previously treated TB cases had RIF-resistant/MDR disease, with three countries accounting for half of the world's cases of RIF-resistant/MDR-TB: India (27%), China (14%), and the Russian Federation (9%).[19] Among MDR cases 6.2% were estimated to be XDR, numbers that were slightly lower compared to 2018 data.[19]

Non-tuberculous Mycobacteria (NTM)

Mycobacterial species different from MTBC are grouped as NTM, also referred to as atypical or anonymous mycobacteria, or mycobacteria other than tuberculosis (MOTT).

Humans can acquire NTM infection from various sources in the environment such as natural and engineered water systems, mist, aerosols, dust, and soil,[25] or from contact with plants, birds, fish, and other animals.[26,27] In humans, NTM can be found as colonizers without clinical relevance—with chronic lung disease as predisposing factor—or they can be seen as mostly intracellular pathogens. Human-to-human transmission of NTM was not known to be a common route of transmission, till recent evidence documented human-to-human transmission in cystic fibrosis patients.[28–30]

While the frequency of clinical isolation of NTM is increasing in many countries with decreasing MTBC prevalence,[27,31–33] and even in countries endemic for TB,[34,35] their clinical relevance remains often unclear.

The diagnosis of NTM disease remains a clinical dilemma for clinicians as NTM exist in the environment, and mere isolation from an unsterile site could be a reflection of environmental contamination. Correctly identifying and determining the clinical relevance are however paramount, as the time-consuming and complicated treatment of NTM disease will vary depending on the species. NTM infections most commonly manifest as pulmonary disease (especially in adults), followed by skin and soft tissue infections, lymphadenitis (especially in children), or disseminated disease in severely compromised patients.[36]

General criteria for the diagnosis of pulmonary NTM disease as established by the American Thoracic Society (ATS) may guide on clinical decision-making.[37] One of the criteria states that two positive cultures should be obtained from subsequent sputum specimens OR a single positive culture from a bronchial aspirate. Nevertheless, single-sputum NTM isolation can provide evidence of true NTM-lung-disease, taking into account patient's characteristics like bronchiectasis, younger age, and more severe radiographic pulmonary lesions.[38]

It is to be noted that only around 20–25% of patients with pulmonary NTM isolates meet the ATS criteria,[32,35,39,40] which can increase up to 60% among patients at higher risk like cystic fibrosis patients.[41] Of note, a considerable proportion of patients with NTM pulmonary disease in Europe have no detected underlying lung disease or immunodeficiency.[42] In the United States, the annual rates of pulmonary NTM disease range from 1.4 to 13.9 per 100,000 inhabitants,[43] while in Europe rates seem to be lower ranging from 0.2 to 2.9 per 100,000 population.[42]

The probability of clinical relevance varies across species. NTM commonly found in patients with pulmonary symptoms are *M. avium, M. intracellulare*, *M. kansasii*, *M. xenopi*, *M. abscessus*, *M. fortuitum*, and *M. scrofulaceum.*[32,36,40,44] *M. abscessus* is increasingly seen as pulmonary pathogen.[39,40] While the less common *M. genavense* has a very high likelihood of being clinically relevant in pulmonary disease, *M. avium* and *M. kansasii* have a moderate odds, and *M. gordonae* is almost never involved in disease though frequently being isolated.[32,40] The frequency of isolated NTM species may vary across geographical regions and settings.[45] Also, the relative frequency of NTM species may change over time, as has been noticed in Europe with shifts of *M. kansasii* and *M. malmoense* frequency.[42]

Regarding extra-pulmonary NTM disease, the majority of lymphadenitis cases are seen in young children, and most often caused by *M. avium, M. scrofulaceum, M. simiae, M. haemophilum, M. malmoense*, or *M. marinum.*[32,46-48]

NTM species most commonly reported from skin and soft tissue infections are *M. fortuitum, M. abscessus, M. chelonae* among the rapidly growing mycobacteria, and *M. marinum, M. ulcerans, M. chimaera,* and *M. haemophilum* as slowly growing species.[27] Using inadequately disinfected medical equipment has been associated with outbreaks of NTM skin and soft tissue infections. Because of their lipophilic character, environmental mycobacteria are frequently found in biofilms, making them even more resistant to decontamination with standard antiseptics and biocides, including chlorhexidine and glutaraldehyde.[42,49] Recently, some compounds have been described to be active against NTM in biofilms.[50,51] Potable water systems have been proposed as an advantageous pre-infection niche for bacteria—including NTM-colonizing lungs of CF patients.[52] In a recent

comparison of Norwegian chlorinated and non-chlorinated drinking water distribution systems, it was found that residual chloramine may increase mycobacterial biomass, while it may also decrease mycobacterial diversity.[53] As a result, mycobacterial species have been associated with both pseudo-outbreaks and real outbreaks of nosocomial infections following surgery or cosmetic procedures. In the United States, cosmetic surgery tourism constitutes an increased risk for NTM soft skin tissue disease.[54,55] Molecular typing of the isolated strains during an outbreak with *M. abscessus* after breast augmentation surgery in Venezuela undoubtedly identified tap water as the source of infection.[56] Also from nonhospital/cosmetic settings, outbreaks have been reported, such as *M. marinum* infections following fish handling[57] or use of premixed ink as the common source of infection with *M. chelonae*.[58]

The NTM commonly found as causative agent in patients with disseminated disease are *M. avium, M. intracellulare*, *M. kansasii, M. haemophilum,* and *M. chelonae*.[36,59]

M. gordonae and *M. engbaekii* are among the NTM most frequently found as contaminants with no or very rare clinical implication.

Trying to ascertain the prevalence of NTM disease may be complicated by several factors. As opposed to TB, NTM disease is not notifiable to public health authorities at a national or an international level, with a few exceptions such as Oregon State (the U.S.A). Therefore, underreporting might occur, which can prohibit collection of systematic data and potentially lead to an underestimation of NTM disease. Conversely, overdiagnosis may occur when patients are diagnosed with (and treated for) nonpathogenic mycobacteria, and in those cases in which the clinical relevance of the potential pathogenic mycobacterium isolated has been misjudged. Finally, care must be taken with regard to the trend analysis of certain species, as the degree of taxonomical diversification is much higher in contemporary studies using molecular identification techniques, than it is in older studies based on phenotypic characteristics.[42]

Clinically Significant Species of Slowly Growing NTM

The following are some of the most important slow-growing NTM species that have been associated with clinical disease. An overview of the clinical relevance for additional slowly growing NTM species can be consulted at https://bccm.belspo.be/about-us/bccm-itm.

Mycobacterium leprae

This mycobacterium is an obligatory intracellular pathogen and the causative agent of leprosy or Hansen's disease. The disease mainly affects the skin, the peripheral nerves, mucosa of the upper respiratory tract, and the eyes. It can range from mild and self-limiting (tuberculoid type) to severely debilitating (lepromatous type). Leprosy is also classified as paucibacillary (PB) or multibacillary (MB), based on the number of skin lesions and the presence of nerve involvement. It is an ancient disease with cases depicted around 600 BC. There has always been a large social stigma associated with leprosy, which resulted in victims being segregated to leper colonies.

In humans, *M. leprae* is a very slow-growing organism with a long incubation period, it can take from 6 months to 20 years for an infected individual to develop symptoms after exposure (WHO fact sheet). *M. leprae* does not grow on laboratory media, likely due to the loss of important genes, with a reduced genome size of 3.3 Mbp compared to the 4.1 Mbp of MTBC.[60]

In its efforts to eliminate leprosy, the WHO recently introduced the concept of "one report for leprosy" by launching an online data collection tool to facilitate the gathering of epidemiological and programmatic indicators from member states. In 2018, there were 208,619 new leprosy cases registered globally, according to official figures from 159 countries from the six WHO Regions (https://www.who.int/news-room/fact-sheets/detail/leprosy). The majority of these cases were found in nine countries in Asia, Africa, and Latin America. In the United States, leprosy is seen in about 200 new cases every year, with nine-banded armadillos being an important reservoir.[61]

Current diagnosis of leprosy relies often solely on clinical findings, without microbiological confirmation. Microscopy for detection of acid-fast bacilli can confirm the diagnosis of more advanced leprosy, but it is less effective in the early stages or in paucibacillary cases. Nucleic acid-based detection techniques for *M. leprae* are becoming a standard of care for supporting the diagnosis of leprosy, with the repetitive sequence RLEP as a promising target for qPCR, allowing the detection of approximately one *M. leprae* genome in a sample (https://internationaltextbookofleprosy.org/chapter/pathogen-detection). No commercial molecular tests for *M. leprae* detection are available.

Clinical diagnosis of leprosy is based on the presence of at least one of three cardinal signs: (1) definite loss of sensation in a pale (hypopigmented) or reddish skin patch; (2) thickened or enlarged peripheral nerve with loss of sensation and/or weakness of the muscles supplied by that nerve; or (3) presence of acid-fast bacilli.[62]

Leprosy is now totally treatable with a free-of-cost multidrug therapy including dapsone, RIF, and clofazimine.

Mycobacterium ulcerans

This species is a close relative to *M. marinum,* but differs in its ability to produce a mycolactone toxin. It is the causative agent of Buruli ulcer (BU), a disease which occurs in at least 33 countries with mostly tropical and subtropical or temperate climates. Most cases are reported in West and Central Africa, while Australia remains an important non-African endemic country. In 2018, 2,713 suspected BU cases were reported from 14 countries, confirming the recent increase after years of decline from 2010 (5,000 cases) to 2016 (1,961 cases). The reasons for the initial decline and recent increase remain unclear https://www.who.int/news-room/fact-sheets/detail/buruli-ulcer-(mycobacterium-ulcerans-infection).

The disease begins as a painless nodule, but if left untreated, can progress to a debilitating skin ulcer or osteomyelitis, and can lead to permanent disfigurement and long-term disability.[63] It is the mycolactone that causes subcutaneous tissue destruction and local immunosuppression, aggravating the symptoms. Most of the lesions appear on the limbs, especially on the lower

extremities.[63] *M. ulcerans* is an environmental bacterium, and the exact means of transmission remain unknown, but most infections appear to be found adjacent to bodies of (stagnant) water. There is some indication that mosquitoes may be responsible for transmission of the disease in Australia,[64,65] although evidence of *M. ulcerans* positive mosquitoes remains limited.[66] In Africa, where BU is most prevalent, no environmental source has been identified so far, with one exception of a *M. ulcerans* isolate grown from a water strider in Benin.[67]

Although the disease can often be diagnosed on clinical presentation, this organism can grow on standard media suitable for mycobacterial growth, with a growth temperature optimum of 30°C. The most sensitive diagnosis for BU, however, is done by PCR targeting the insertion sequence IS*2404*.

Buruli ulcer is treatable with combination therapy using RIF and clarithromycin for 8 weeks. Surgical debridement is often required as well, especially for larger ulcers or advanced disease.[63]

Mycobacterium avium Complex (MAC)

Originally, *M. avium* and *M. intracellulare* were the only two species belonging to the *Mycobacterium avium* complex (MAC).[37] Sequencing studies of the 16S rRNA gene and 16S–23S internal transcribed spacer (ITS) confirmed the MAC as a diverse, yet relatively clearly defined and clustered group among the slowly growing NTM, comprising the species *M. avium, M. intracellulare** (including *M. chimaera**, *M. yongonense**, *M. paraintracellulare**), *M. colombiense, M. arosiense, M. vulneris, M. bouchedurhonense, M. timonense, M. marseillense*, and *M. lepraemurium*.[68–70]

M. intracellulare cannot be easily differentiated from *M. avium* through traditional physical and biochemical tests;[37] it requires genetic analysis.

Members of the MAC are ubiquitous in soil and many natural and man-made water systems.[25,71,72] Although usually not considered pathogenic in the general community, these organisms are the most commonly isolated causative agents of NTM-mediated lung disease with TB-like symptoms,[37,70] and they may cause lymphadenitis in children and/or other extrapulmonary and disseminated infections in immunocompromised pati ents.[37,68,73] Pulmonary disease attributed to the MAC is mainly caused by *M. avium* and *M. intracellulare*. Other MAC species have been increasingly reported as potential causative agents of NTM lung infections, but their full spectrum of diseases is not yet entirely known.[68] One member of the MAC, namely *M. lepraemurium*, is known as the etiologic agent of feline and murine leprosy.[74,75]

Infections are most probably acquired by inhalation or ingestion of the MAC species. Although frequently isolated from respiratory specimens, isolation of MAC does not necessarily imply clinical relevance in pulmonary disease.[37]

To date, there is still an ongoing debate on whether or not specific species should be assigned within the complex or if the MAC should be considered as a single entity. Moreover, the American Thoracic Society and Infectious Diseases Society of America (ATS/IDSA) stated that although the differentiation between *M. avium* and *M. intracellulare* may be important epidemiologically for research purposes and in the future for therapeutic use, the distinction is not yet clinically significant enough to routinely identify MAC isolates to the species level.[37] Also, disease caused by all members of the MAC is treated in a similar manner using a regimen specific to the MAC.[68]

Treatment regimens for MAC infections include combination therapy, typically with a macrolide (clarithromycin or azithromycin) as core drug, with RIF (or another companion drug), EMB and occasionally amikacin in cases of disseminated disease when a more aggressive therapy is required.[37,76] ATS recommends clarithromycin susceptibility testing for new, previously untreated MAC isolates.[37]

Mycobacterium avium

M. avium was originally divided into three subspecies corresponding to pathogenicity and host-range characteristics: *M. avium avium*, *M. avium paratuberculosis*, and *M. avium silvaticum*.[77,78] To elucidate the epidemiology of *M. avium*-associated disease, Mijs et al. clustered the isolates originating from humans and pigs together as a suggested fourth subspecies called *M. avium hominissuis*,[79] the most abundant etiological agent of *M. avium*-related disease in humans.[80,81] Additionally, Mijs and colleagues stated that the designation *M. avium avium* should be reserved for bird-type strains because of its association with avian TB.[79] *M. avium paratuberculosis* on the other hand is the causative agent of Johne's disease resulting in chronic granulomatous enteritis of ruminant livestock and wildlife and may have a similar—yet not proven—role in Crohn's diseases in humans.[82-84] Finally, *M. avium silvaticum* is highly related to *M. avium avium* and has been isolated primarily from wood pigeons wherein it can cause TB-like lesions.[78]

Tortoli and colleagues suggest combining these *M. avium* subspecies within a single taxon, and to regard them as synonyms based on their very high average nucleotide identity (ANI) and genome-to-genome distances (GG) values well exceeding the subspecies thresholds.[85] In consideration of their adaptation to specific hosts, the previously named subspecies should be reclassified as variants.[85] Subspecies status of *M. avium paratuberculosis* is proposed to be maintained due to the significant differences in clinical presentation between this subspecies and other variants of the MAC.[77,85]

This would result in *M. avium variant avium*, *M. avium variant hominissuis*, *M. avium variant silvaticum*, and *M. avium paratuberculosis*

M. avium grows at 30–37°C on media suited for mycobacterial growth. Primary isolation of both *M. avium paratuberculosis* and *M. silvaticum* requires adding mycobactin to the culture medium.[86] Besides, *M. silvaticum* is unable to grow on egg media and needs the stimulation of growth by pyruvate and at pH 5.5, gradually losing this phenotype upon subculture.[78]

Mycobacterium intracellulare and Closely Related Species

This mycobacterium is mainly a respiratory pathogen in humans, responsible for most MAC lung diseases in the United States, while an association with disseminated disease is less common.[35,77]

M. chimaera became well known for its association with contaminated heater-cooler devices used in open heart surgery during a worldwide outbreak.[87,88]

M. yongonense and *M. chimaera* were recently reclassified as subspecies of *M. intracellulare*, resulting in the designation of three new taxa: *M. intracellulare intracellulare*, *M. intracellulare yongonense*,[89] and *M. intracellulare chimaera*.[69] In 2019, *M. intracellulare chimaera* has even been proposed as synonym of *M. intracellulare yongonense*.[85]

Likewise, *M. paraintracellulare*[90] was proposed to represent a fourth subspecies or even a synonym of *M. intracellulare* rather than a separate species based on its average nucleotide identity (ANI) value being well within intraspecies values.[68,69] Also, the need to distinguish *M. paraintracellulare* from *M. intracellulare* is questioned as there is no reason of clinical relevance to do so.[68]

This would result in a new taxonomy to recognize only a single species, *M. intracellulare*, with two subspecies: *M. intracellulare intracellulare* and *M. intracellulare chimaera*.[85]

Mycobacterium haemophilum

This organism was first isolated in 1978 from a patient with Hodgkin's disease, and it was shown to cause skin lesions and disseminated infections in patients with AIDS in the early- to mid-1990s. Indeed, *M. haemophilum* has been described in immunosuppressed patients, including those with lymphoma, those who undergo bone marrow or cardiac transplantation, and patients receiving steroid therapy.[91] It has also been described as a cause of lymphadenitis in immunocompetent children.[92]

The growth requirement of these organisms is rather unique among mycobacteria as they require hemin or ferric ammonium citrate for growth, at an optimal temperature of 30°C.[93] This probably accounts for the relative infrequency of its isolation, especially in laboratories solely relying on culture at 37°C. It is advisable that all patients presenting with a skin lesion have their specimen cultured onto medium containing a source of hemin with incubation at 30°C.

There is no standard therapy for infections with *M. haemophilum* but regimens including clarithromycin, doxycycline, ciprofloxacin, amikacin, INH, and RIF have led to resolution of the disease,[94] while surgical intervention may be favored in case of cervicofacial lymphadenitis.[95]

Mycobacterium kansasii

This mycobacterium causes a disease that resembles pulmonary TB. The patients present with cough, fever, and night sweats as is seen in TB.[96] Typically, the patient is an older male with a prior history of TB, chronic obstructive pulmonary disease or other chronic lung diseases. Cavitary disease may be seen on x-ray. Extra-pulmonary disease caused by *M. kansasii* has also been described occasionally.[59,97] The odds of clinical significance for a positive *M. kansasii* culture is relatively high.[32] In a Korean study, 52% of all patients with *M. kansasii* respiratory isolates exhibited clinically significant disease.[98]

In the past, seven subtypes of *M. kansasii* have been reported based on target sequences such as *hsp65*. Recent WGS analyses support a reclassification of this polyphyletic group in separate species rather than subtypes,[99,100] with clearer separation of their clinical relevance (Table 33.1).

M. kansasii has similar growth conditions as *M. tuberculosis*. Standard treatment involves the use of first-line anti-TB drugs RIF, INH, and RMB, while RIF-resistant *M. kansasii* treatment can be based on drug-susceptibility testing data.[29]

TABLE 33.1

Reclassification Species Within the *Mycobacterium kansasii* Group

(New) Species Name[99,100]	Former *M. kansasii* Subtype	Pathogenicity	Isolation from Clinical Specimens
M. kansasii	1	Most pathogenic	Frequent
M. persicum	2	Pathogenic	Limited data
M. pseudokansasii	3	Rarely pathogenic	Frequent
M. species[a]	4		
M. innocens	5	Rarely pathogenic	Limited data
M. attenuatum	6	Nonpathogenic	Very rarely
No suggestion[b]	7		

[a] To be defined as soon as a Type strain is available; [b]Lack of Type strain and full genome.

Mycobacterium malmoense

This mycobacterium is rarely seen in the United States but is recognized as causing pulmonary disease in Northern Europe, with a frequency exceeding that of *M. kansasii*-isolation in some UK settings. In the United Kingdom, *M. malmoense* isolates had a moderate chance of being clinically significance,[40] while in the Netherlands *M. malmoense* was found to be clinically relevant at much higher (80% of cases) levels. These usually cause pulmonary disease with serious morbidity.[101] The typical patient is a male over his 50s with prior or underlying lung disease.[101,102] There have also been reports of—mostly pediatric—lymphadenitis caused by *M. malmoense*.[101,103]

M. malmoense has no specific growth requirements—even though growth on solid medium can remain very slight, with good growth at 37°C.[104]

Therapy includes the use of RIF and EMB, supplemented with a macrolide,[29] although some studies showed no additional benefit of adjunctive clarithromycin.[101,105]

Mycobacterium xenopi

Like most of the other slowly growing opportunistic pathogenic NTM, this species causes pulmonary disease, with various presentations (cavitary, nodular, or diffuse infiltrate).[106] *M. xenopi* disease has become prominent in Northern European and American countries with a low TB prevalence, yet is rarely or not seen in TB high prevalent countries (China,[107] Tanzania,[34] and Mozambique[35]). Nevertheless, *M. xenopi* is a fairly ubiquitous environmental bacterium found mostly in water, including the water supplies of hospitals. The typical patient is an older male with a prior history of TB or other lung disease. The patient often presents with cavitary lung disease. The probability of being clinically relevant was found to be moderate 40–60%.[32,39,40]

This organism is easily grown in culture but prefers an elevated growth temperature (42°C) and forms typical "bird's nest" colonies when grown on solid media.[108]

M. xenopi disease is hard to treat with around 30% success rate.[109] Variable success has been reported using a four-drug

regimen comprising RIF, EMB, a macrolide (clarithromycin or azithromycin), and a fluoroquinolone (cipro- or moxifloxacin) or INH.[29,106] For severe disease an injectable aminoglycoside (amikacin or streptomycin) can be added.[29]

Mycobacterium celatum

This mycobacterium was first described in the early 1990s as a causative agent of disseminated disease in AIDS patients with a very low CD4 count.[110] Subsequently, *M. celatum* has been identified as a cause of pulmonary disease in immunocompetent individuals as well, with disease resembling that of MTBC and other NTM species.[111] *M. celatum* isolates can be easily misidentified as *M. xenopi*, sharing many biochemical/phenotypic characteristics including a typical fatty acid pattern.[112] *M. celatum* can be differentiated from *M. xenopi* by its poor growth at 45°C, and production of larger colonies on 7H10 agar.[112] Using the AccuProbe assay—which detects MTBC-specific nucleic acids—*M. celatum* isolates can be falsely positive.[113]

There is no standard therapy for infections with *M. celatum*. Isolates of *M. celatum* are generally resistant to RIF. Successful treatment has been achieved by combining clarithromycin, EMB, and ciprofloxacin.[114]

Mycobacterium marinum

Mycobacterium marinum was first observed in 1926 causing infections in saltwater fish in the Philadelphia aquarium.[115] The first reported cases in humans were from an epidemic in Sweden in 1954. These patients, who all swam in the same swimming pool, developed lesions, which began as papules at the site of infection and mostly became ulcerated and/or exudative. *M. marinum* disease, often referred to as "swimming pool granuloma," has also been associated with fish tank ownership.[116] The infection usually occurs on the upper extremities, including the hands, where the organism gains entrance through scratches and abrasions, and generally remains localized at the site of infection.

M. marinum can be cultured on standard media used for mycobacterial growth, but with incubation at 30°C, the optimum growth temperature for this species.

Therapy with regimens containing EMB, RIF, clarithromycin, amikacin, or doxycycline is usually effective. In some instances, surgical intervention is required.[117]

Clinically Significant Species of Rapidly Growing NTM

At present, rapidly growing mycobacteria comprise approximately 50% of all recognized and validated species belonging to the genus *Mycobacterium*.[118,119] Although ubiquitous in environmental reservoirs, some rapidly growing NTM are frequently isolated in healthcare facilities and have emerged as important human pathogens.[120] They are commonly found in abscesses formed after an unintentional inoculation or puncture wound, through contamination of surgical wounds or via traumatic injuries.[27] *M. abscessus* is increasingly seen as pulmonary pathogen.[39,40] *M. abscessus*, *M. chelonae*, and *M. fortuitum* together embody more than 80% of clinical isolates of rapidly growing NTM.[119,121]

First-line TB drugs are ineffective against NTM disease due to rapid growers.

An overview of the clinical relevance for additional rapidly growing NTM species can be consulted at https://bccm.belspo.be/about-us/bccm-itm.

Mycobacterium abscessus

This organism was first identified in 1952 by Moore and Frerichs, who isolated it from a patient's knee abscess.[122] Species name designation was based on the mycobacterium's ability to cause human skin and soft tissue infection, producing deep subcutaneous abscesses.[123]

Over time, *M. abscessus*' taxonomy, particularly the identification of species and subspecies, has faced many challenges resulting in a cumbersome cascade of nomenclature changes. *M. abscessus* and *M. chelonae* were originally considered to be the same species as they present almost identical biochemical features.[10,121,123] After first being designated subspecies status in 1972,[124] Kusunoki and Ezaki re-elevated *M. abscessus* to species status in 1992 based on genomic DNA hybridization studies.[125] As a result, *M. chelonae* subspecies *chelonae* was also reinstated again to its former name *M. chelonae*. After *M. abscessus* was recognized as a distinct species, the mycobacterium has been further categorized into three distinct subspecies: *M. abscessus abscessus*, *M. abscessus bolletii*, and *M. abscessus massiliense*.[126-128]

Precise identification to subspecies level of the disease-causing strain in *M. abscessus* pulmonary infections is essential for diagnosis and management as the subspecies differ in clinical disease presentation as well as in susceptibility to drugs and in optimal therapeutic regimens.[129] *M. abscessus abscessus* and *M. abscessus bolletii* have an *erm* (erythromycin ribosomal methylase) gene that confers inducible macrolide resistance, whereas most *M. abscessus massiliense* strains have a dysfunctional *erm* gene, resulting in macrolide susceptibility.[130] Consequently, better treatment outcomes have been reported in patients with *M. abscessus massiliense* pulmonary infection than those with *M. abscessus abscessus* disease.[131]

M. abscessus abscessus is the most common pathogen of the three *M. abscessus* subspecies,[132] and typically it is associated with a wide range of skin and soft tissue infections in human hosts,[37,123,133] while being increasingly the cause of pulmonary infections in patients with underlying structural lung disease such as cystic fibrosis and bronchiectasis.[134]

Skin and soft tissue infections often develop after the use of equipment or injected substances contaminated with these rapid growing mycobacteria during medical, cosmetic, and plastic surgery (such as liposuction,[135] mammaplasty,[56] and mesotherapy[136]), pedicures,[137] and after trauma.[138,139] Also pseudoinfections due to contaminated bronchoscopes and endoscopes have been ascribed to *M. abscessus*[140] and *M. abscessus bolletii*.[141]

M. abscessus is a nonchromogenic rapidly growing NTM characterized by its inability to grow at 42°C.

Current guidelines recommend an initial treatment for 2–4 months consisting of two parenteral intravenous agents (such as amikacin, cefoxitin, imipenem, and tigecycline) and a macrolide antibiotic if the species is macrolide susceptible.[37,133] If not, the macrolide should be replaced by another agent based

on *in vitro* drug susceptibility testing data. Secondarily, an additional inhaled/oral antibiotic (fluoroquinolone, linezolid, or clofazimine) can be added during the continuation phase.[133]

Mycobacterium chelonae

As stated before, *M. chelonae* is closely related to *M. abscessus* but lacks the *erm* gene that confers macrolide resistance in *M. abscessus*.[142] *M. chelonae* is also highly resistant to cefoxitin, while *M. abscessus* is intermediately susceptible. Additionally, *M. chelonae* is only a rare cause of pulmonary infections and instead has a greater preference for skin and soft tissue infections.[27,143] Furthermore, *M. chelonae* has been associated with catheter-related, disseminated and bone infections, mainly in immunocompromised patients with risk factors such as organ transplantation, renal failure, surgery, long-term corticosteroid therapy, or chemotherapy.[144,145] Infections of *M. chelonae* can also be linked to ophthalmic surgery such as LASIK (laser in situ keratomileusis)[146] and cosmetic procedures (inoculations, plastic surgery, mesotherapy).[147]

This species of rapidly growing NTM is abundant in man-made environments, such as tap water, but has also been retrieved from natural environments, such as lakes, freshwater rivers, and seas.[148] Given its ubiquitous presence in the environment, exposure to *M. chelonae* is common and is often seen in clinical labs, contaminating solutions, medical equipment, and surgical wounds.

M. chelonae grows optimally at 30–32°C.

Treatment regimens of *M. chelonae* infections may include tobramycin, clarithromycin, linezolid, imipenem, or clofazimine. To avoid the development of macrolide resistance, clarithromycin will usually be combined with a second agent.[37]

Mycobacterium fortuitum Group

In 1938, da Costa Cruz (1938) proposed the name *M. fortuitum* for a strain isolated from a patient with a postinjection skin abscess.[121] More than 30 years later, Stanford and Gunthorpe showed that the isolate was identical to a formerly recognized species named *M. ranae*, isolated from a frog by Küster in 1905.[149,150] In 1972, the request of Runyon to maintain the species designation *M. fortuitum* was accepted, which to date still stands in nomenclature as such.[121]

The *M. fortuitum* group comprises the species *M. fortuitum*, *M. peregrinum*, *M. senegalense*, *M. alvei*, *M. houstonense*, *M. setense*, *M. neworleansense*, *M. boenickei*, *M. septicum*, *M. brisbanense,* and *M. porcinum*,[151,152] and its species are commonly found in drinking water, water distribution systems, and in a variety of soil worldwide.[148]

In a series of cases of extrapulmonary disease caused by the *M. fortuitum* group, Wallace et al. [153] reported that almost 80% of the infections were due to the single species *M. fortuitum*.

M. fortuitum has also been associated with a number of nosocomial pseudo-outbreaks,[154,155] and it has been linked to surgical site infections, skin lesions, postinjection abscesses, otitis media, and catheter-related infections.[156–160] Whirlpool pedicure footbaths in nail salons have also been identified as a potential source of *M. fortuitum*-associated furunculosis.[118,161]

M. fortuitum grows under the same conditions as MTBC.

Treatment of *M. fortuitum* infections consists of minimal 4 months of therapy with at least two agents with *in vitro* activity against the clinical isolate.[76] This regimen may include a combination of amikacin, fluoroquinolones, some tetracyclines, cefoxitin, imipenem, or sulfonamides.[153,162,163] In some cases where drug therapy is difficult, surgical intervention is required.[118]

Diagnosis

Clinical suspicion of mycobacterial disease (including x-ray or other imaging techniques) can be confirmed bacteriologically.

For decades, smear microscopy to detect acid-fast bacilli (AFB) and isolation of mycobacteria by culture were the most important diagnostic tools for mycobacterial disease, especially in low-resource settings where microscopy often was the only available and affordable method. Microscopy however lacks sensitivity (for pulmonary TB overall around 60% and only 22–43% in HIV-positive individuals; 10–60% for clinically significant NTM disease),[40] while culture is significantly more sensitive (80–95%) but can take weeks for *M. tuberculosis* complex and slowly growing NTM to become positive. With the advent of nucleic-acid amplification techniques in the 1990s, rapid, specific, and sensitive diagnosis became conceivable, but it was mostly restricted to well-equipped laboratories in high-income countries. Only with the introduction and roll out of the cartridge-based GeneXpert MTB/RIF assay (Cepheid, U.S.A), molecular diagnosis for TB—with simultaneous detection of rifampicin resistance—has become widely available and increasingly is the first test of choice in TB high prevalent settings.[164,165,166] TB-LAMP, another relatively easy isothermal DNA amplification assay to detect MTBC, has been endorsed in 2016,[167] but it has been rolled out in only a limited number of settings.[168,169]

The antigen-detection-based lateral flow-lipoarabinomannan (LF-LAM) assay has been recommended to assist in TB diagnosis in specific populations, namely adults, adolescents, and children living with HIV with signs and symptoms of TB and CD4 cell count under 200 in inpatient settings as well as in adults, adolescents, and children living with HIV with signs and symptoms of TB irrespective of the CD4 cell count in outpatient settings.[170,171] LAM, a lipopolysaccharide, is present in mycobacterial cell walls and is released from metabolically active or degenerating bacterial cells. An LF-LAM test is to be done manually on a urine sample.[170]

Regarding serodiagnostics, the WHO strongly recommended that commercially available assays should not be used for the diagnosis of pulmonary or extra-pulmonary TB.[172]

Despite progress in molecular diagnosis, culture remains important for subsequent phenotypic drug-susceptibility testing (especially for new drugs like bedaquiline), monitoring of patients during treatment, and as a gold standard test for most mycobacterial diseases. Once a culture becomes positive and is confirmed to yield AFB, the isolated bacteria can be identified by phenotypic or genotypic means prior to phenotypic drug-susceptibility testing.

Of note, two test systems are available for the identification of latent TB infection: the tuberculosis skin test (TST) and interferon-gamma assays (IGRAs). The TST consists of an intradermal injection of purified protein derivatives (PPD, tuberculin),

with a read-out by qualified staff after 48–72 hours. This assay, albeit cheap and not requiring any laboratory facility, is not specific because of cross-reaction due to prior BCG vaccination or exposure to NTM.[173] Efforts are ongoing to validate new skin tests using more specific RD1-antigens, not shared by *M. bovis* BCG, showing similar sensitivity.[174,175] IGRAs are *in vitro* blood tests to measure cell-mediated immune response, and make use of the same RD1-antigens.[173] Both test systems have limited value to predict progress to active TB.

Specimen Selection

Respiratory specimens constitute the most common type of specimen submitted for the culture and isolation of mycobacteria, with only 10–20% of clinical specimens originating from nonpulmonary sites.[176] For respiratory infections, sputum is to be obtained by preference early in the morning. The patient should be instructed to rinse his/her mouth with bottle water (tap water is not recommended), and cough up expectorate into a sterile sputum collection device specifically designed for mycobacterial culture. Multiple early morning sputum samples improve the chances to grow mycobacteria, especially NTM. If the patient can't produce sputum, which is often the case for children and very sick persons, a sputum induction can be performed. In this instance, the patient is either placed inside a special chamber or a hood is placed over the patient's head, and nebulized saline is introduced, causing the patient to cough up sputum.

In children or in presumptive patients having difficulty expectorating, specimens can also be obtained by the use of a bronchoscope, yielding a bronchial wash, bronchial alveolar lavage, or biopsy.[177] Bronchoscopy can assist in specifically sampling the affected area of the lung identified by x-ray. Alternatively, gastric lavage is used in patients who are not able to expectorate sputum and, hence, swallow it. Gastric lavage specimens need to be processed within 4 hours after collection.[178] Gastric lavage had higher positivity rates compared to induced sputum for TB diagnosis in children and adults.[177,179] Data on the isolation of MTBC and especially NTM from gastric lavage are scarce.[179] Recently, examination of stool by GeneXpert MTB/RIF (Cepheid, U.S.A) yielded good results and was superior compared to gastric lavage in individuals unable to produce sputum.[180] This application has however not yet been recommended by WHO.

For extrapulmonary disease, biopsies, or body fluids can be used for diagnosis. Biopsy specimens can be obtained from any site suspected of being infected with mycobacteria. Biopsies of an organ can be sampled either by ultrasound guidance or through general surgery. Skin lesions can be sampled by punch biopsy, scraping the margin of the lesion, or swabbing the ulcerated region. Drying of swabs should be avoided. It is rarely productive to collect samples from the necrotic center of the lesions. Body fluids can be obtained through aseptic fine needle aspiration. Urine samples are rarely positive for growth of mycobacteria. If indicated, early morning midstream urine should be collected. For the LF-LAM assay, any urine sample may do. Blood is not commonly used for detection of mycobacteria except for disseminated disease, especially in AIDS patients with low CD4 counts. Blood can be inoculated directly into special blood culture bottles of some of the automated mycobacterial culture systems.

Specimen Storage and Transport

Although mycobacteria can be recovered several days after sample collection, non-delayed processing will increase chances of successful isolation. Long delays in processing the sample increase the risk of overgrowth by microorganisms from the common mircroflora or environmental contamination. This risk can be reduced by ensuring refrigerated storage and transport (2–8°C), or in case of expected long delays from remote places (>7 days) and/or in the absence of an ensured cold-chain, transport medium can be added. To this end, a commercial medium like OMNIgene.SPUTUM (DNA Genotek, Canada) or the noncommercial cetylpyridinium chloride (CPC) can be added, allowing storage and transport at ambient temperature for up to 8 days or 28 days, respectively, prior to culture. Both reagents are also suited to conduct subsequent molecular analysis.[181] If only molecular analysis are to be done, addition of ethanol (final concentration ≥50%) allows for long-term storage (years) and shipping at ambient temperature.[181]

Isolation of Mycobacteria from Clinical Specimens (Culture)

Specimen Processing

Sputa and other specimens collected from the respiratory tract are "contaminated" with normal microflora. In addition, sputum is a viscous nonhomogenous specimen. Hence the need to process these specimens with a mucolytic agent and a decontaminating agent prior to inoculation on culture medium. If not, the normal flora will overgrow the more slowly growing species of mycobacteria, making their isolation from clinical samples impossible.

Several mucolytic and bactericidal/fungicidal reagents are used for this purpose.[178] The most commonly used are 4% NaOH or equal quantities of 4% NaOH solution and sodium citrate plus N-acetyl L-cysteine (NALC) solution. The 4% NaOH helps in liquefying the specimen as well as killing the normal flora of bacteria/fungi. NALC at concentrations of 0.5–2.0%, when combined with NaOH, facilitates decontamination by further digesting mucopurulent specimens, which allows the NaOH to penetrate; sodium citrate aids in the liquification by binding heavy metals, thus stabilizing NALC and allowing it to work properly. NALC can be used with reduced concentrations of NaOH (final concentration of 1% in sputum). For isolation of mycobacteria from specimens that are likely contaminated with Gram-negative organisms such as *Pseudomonas aeruginosa*, as observed in patients of cystic fibrosis and bronchiectasis, a combination of Nalc-NaOH processing with 5% oxalic acid treatment may be more successful.[178]

The optimal volume of sputum to be processed is 5–10 mL. An equal volume of the digesting/decontaminating solution is added to the specimen, vortexed, and allowed to stand for 15–20 minutes at room temperature. Then, the alkali are either neutralized by adding an equal volume of phosphate buffered saline (PBS; pH 6.8, 0.067 M) or HCl buffer (1N) till neutral pH as indicated by the phenol red indicator, or "washed" by adding an excess

(usually till 45 mL total volume) of PBS buffer.[178] PBS lowers the specific gravity of the specimen and gently neutralizes the specimen. The amount of NaOH used, the time allowed for decontamination, and the addition of neutralizing or washing buffer to the digested/decontaminated specimen are critical because both the common microflora and mycobacteria are affected by the exposure to the high pH of sodium hydroxide.

The specimen is then centrifuged at 3,000 × g for 15–20 minutes to concentrate the bacilli at the bottom.[182] The obtained sediment can be used to inoculate appropriate culture media, and—in case not yet done directly from the nonprocessed specimen—to prepare a smear for microscopic examination, or to perform a DNA extraction and subsequent molecular analysis.

Urine and other large volume samples should be concentrated (15 minutes at 3,000 × g), and nonsterile biopsies minced (sterile mortar and pestle) prior to processing. Specimens aseptically collected from normally sterile body sites do not need to be processed before inoculation into the appropriate media.

Smear Preparation

Smears can be prepared directly from clinical specimens (direct) or from the sediment of processed specimens in case culture is done as well (indirect).

Staining and Reading of Smears

Since the detection of TB bacilli by Robert Koch, the most commonly used dye for staining mycobacteria is basic fuchsine. This dye can stain all microorganisms, but only few will retain the dye in the cell wall after discoloration with an acid-alcohol solution. The composition of the mycobacterial cell wall (mycolic acids) of these organisms renders them resistant to discoloration of the primary dye, hence the term "acid-fastness."

The classic method, the Ziehl-Neelsen stain, uses carbolfuchsin (0.3%) as the primary dye. In this method, the stain is heated until steam arises (three times at intervals of 3–5 minutes) to allow optimal penetration of the cell wall. The modified or cold Kinyoun stain also uses carbolfuchsin as the primary dye but without heating and a contact time of 20–25 minutes. In both methods, acid-fast organisms will appear red against the background stain, which is usually methylene blue. Reading of the slides requires objective 100× and the use immersion oil.

Alternatively, fluorescent stains are used that consist of the fluorochrome stain auramine, alone or in combination with another fluorochrome, rhodamine. These stained smears must be read using a fluorescent microscope, where mycobacteria will fluoresce a bright yellow to orange. Fluorescence microscopy allows reading at a lower magnification (objective 25× or 40×), speeding up analysis. However, care must be taken to distinguish fluorescing artifacts from true organisms. The introduction of LED-based microscopes has enabled the roll out of fluorescence microscopy, even to remote places. In 2011, the WHO recommended that conventional fluorescence microscopy be replaced by LED microscopy, and that LED microscopy be phased in as an alternative for conventional Ziehl-Neelsen light microscopy.[183]

A minimum of 5,000–10,000 bacilli per mL specimen is needed to be observable in microscopy.

Isolation of Mycobacteria by Culture

For an optimal diagnosis of mycobacterial infection, their isolation from clinical specimens is considered as a gold standard. Digested, decontaminated, and concentrated specimen is inoculated on culture medium and incubated at 30°C and/or 37°C for 6–8 weeks to allow growth of mycobacteria. As a rule, media inoculated with specimens obtained from skin lesions should always be incubated at the regular 37 ± 1°C as well as at the lower 30 ± 1°C temperature. Once growth of AFB shows up and is confirmed, it is reported as positive. Traditionally one or more pieces of a solid medium or one solid and one liquid medium are inoculated.

Solid media used for mycobacterial culture can be divided into two main categories: egg-based and agar-based media. The egg-based media consist of (part of the) eggs, salts, potato flour, amino acids, glycerol, and malachite green as an inhibitor of bacterial growth from the common microflora persisting prior specimen processing. The media are solidified by heating the mixture to a temperature of 85°C for approximately 45 minutes in a process called inspissation. This process also sterilizes the medium. The most common form of egg-based medium used in the United States and many other countries is Löwenstein-Jensen (LJ) medium. Modified egg-based media may be more suited for the isolation of specific species. For example, *M. bovis* (BCG) grows better on medium without glycerol and supplemented with pyruvate (Coletsos or Stonebrink medium), while *M. haemophilum* needs addition of ferric-ammonium citrate for its growth. Agar-based media commonly employed are Middlebrook 7H10 and 7H11, both containing defined salt concentrations, growth factors such as oleic acid, albumin, catalase, glycerol, and a low concentration of malachite green. Medium 7H11 differs from 7H10 by the addition of pancreatic digest of casein to facilitate the growth of fastidious MTBC cultures.[184] Recently a new selective agar-based medium has been developed ("rapid growing mycobacteria" RGM), which enabled sensitive (98%) detection of NTM from CF patient samples.[185] Prolonged incubation up to 26 days further increased growth of MAC, with higher recovery compared to the classical medium for isolation of mycobacteria.[186,187]

Solid media can be prepared in house or purchased as ready-to-use from commercial companies. They may be supplemented with antibiotic mixtures to further reduce culture contamination rates. As, the optimal growth temperature for most NTM ranges between 28°C and 37°C, it is important to incubate at least one tube at 37°C and one at 30°C, especially in case of biopsies or pus from skin lesions.

In resource-poor settings, specimens can be cultured using only LJ medium, but for optimal isolation of mycobacteria from clinical specimens, both liquid and solid media should be employed to decrease the time to positivity and to increase the probability of a positive result (>10%).[188] The number of positive cultures for liquid is significantly higher than for any solid medium. Several automated systems using liquid medium for isolation of mycobacteria have been developed and are now used routinely in many laboratories, with the BACTEC 460 (BD Diagnostic Systems, U.S.) being the first introduced in the 1980s. This semiautomated system utilized a modified Middlebrook

7H9 broth containing a radiolabeled substrate that would be hydrolyzed by microorganisms growing in the medium, releasing radiolabeled carbon dioxide that was measured as an indicator of growth. The BACTEC 460 system has been discontinued due to concerns of radioactivity and its disposal and has been replaced by the nonradiometric BACTEC MGIT 960 system (BD Diagnostic Systems, Sparks, MD). This system builds on the principle of oxygen consumption by growing organisms. Oxygen present in the medium quenches the fluorescent indicator embedded in silicone at the bottom of the tube. When the oxygen is consumed by growing bacilli, the tubes will begin to fluoresce in the presence of UV light. Automated reading each hour, will flag these tubes as positive. The instrument provides the time to positivity and a growth-unit value (GU). Prior to specimen inoculation, a growth supplement including an antibiotic mixture (PANTA) must be added. MGIT 960 can be used for all types of specimens except for blood. Blood must be inoculated into a different type of bottle, the MYCO/F Lytic F, and incubated in a different instrument, the BACTEC 9240.

Bacterial contamination, which survives decontamination and grows in the presence of added antibiotics, can lead to a false-positive result. Unlike solid medium, liquid medium does not allow for the observation of colony characteristics, colony counts or mixed cultures. Any positive culture must therefore be confirmed by acid-fast staining, and, if possible, by purity check on a blood agar.

Scores of publications have verified MGIT 960 superior performance over solid media.

A couple of other commercial automated liquid systems have been introduced, such as VersaTREK Myco System (Trek Diagnostic Systems, U.S.A) and BacT/Alert (Biomérieux, France), but these systems are less commonly used.

Identification of Mycobacteria

It is imperative that MTBC can be immediately distinguished from NTM.

Upon isolation, initial mycobacterial species identification may rely on the observed growth rate (rapid versus slow), pigmentation, and colony appearance, the latter mainly observable from solid medium. They are described as either buff (white- to cream-colored colony) or a chromogen (yellow to orange pigmentation). The chromogens are classified as scoto- or photochromogenic, with scotochromogens being pigmented regardless of growing in the light or dark, whereas photochromogens will only develop pigment if exposed to light.[183] Most mycobacteria can be speciated by their biochemical profile,[183] which can be very tedious, requiring up to several weeks, and may not always allow for reliable (sub) species differentiation. Susceptibility to paranitrobenzoic acid (PNB; 500 µg/mL) has for long been a marker to differentiate MTBC from PNB-resistant NTM.[189] In most laboratories, however, molecular assays have displaced biochemical tests.

To rapidly differentiate MTBC from NTM growth, a lateral flow immunochromatographic assay detecting the presence of the MTBc-associated MPT 64 antigen has been developed. Three commercial tests are available: Capilia TB NEO (Tauns, Japan), BD MGIT™ TBc ID test (Becton Dickinson, U.S.), and SD Bioline TB Ag MPT64 Rapid (Standard Diagnostics, South Korea). In 15 minutes, the tests differentiate MTBC species from NTM in a positive culture. In a multicenter study, all three tests showed 100% sensitivity for detection of MTB from MGIT on the day of positivity. While the BD assay is not indicated for use with solid media cultures, the sensitivity of Capilia and SD Bioline assays was also 100% when applied on isolates grown on LJ cultures.[190] The SD Bioline assay may yield a weak false-positive result with *M. gastri*.[190] In a comparative study in Uganda, the SD Bioline assay performed equally well as the PNB assay.[191] Of note, not all MTBC lineages may be detected with a similar sensitivity, as evidenced by false-negative reactions for *M. africanum* in Benin and the Gambia.[192,193]

In case no MTBC is detected by an MPT64-based assay or an MTBC-specific molecular assay, most laboratories rely now on molecular testing for further NTM speciation. In house PCR- and sequencing-based identification of conserved genes is the reference method for the identification of mycobacteria.[5] This technology commonly targets a number of housekeeping genes, such as the ones encoding the 16S rRNA (*rrs*), the 65-kDa heat shock protein (*hsp65*), the RNA polymerase β-subunit (*rpoB*), bus is mostly restricted to reference laboratories. The vast majority of clinical laboratories will make use of commercially available assays.[5] While these can reliably differentiate MTBC from other mycobacterial species with very high sensitivity and specificity, they can identify only a limited number of NTM species. A comprehensive overview of various (molecular) assays for NTM species identification, discussing advantages, and shortcomings is provided by Misch and colleagues.[27] Some examples are discussed next.

The FDA-approved AccuProbe test (Gen-Probe, U.S.A) has single-stranded DNA probes that hybridize with ribosomal RNA from several mycobacterial species. It has probes specific for MTBC, *M. avium* complex, *M. kansasii*, and *M. gordonae*. The test can be used directly from positive cultures, within clinically relevant time frames (24–48 hours), with a sensitivity and specificity comparable to the lateral flow assay, yet requiring more complex manipulations.

Numerous assays based on the reversed hybridization line probe technology have been developed for the identification of mycobacteria: the InnoLiPA Mycobacteria (Innogenetics, Belgium) identifying 13 NTM species, and various GenoType assays from Hain Lifescience (Germany). The GenoType *Mycobacterium* CM and GenoType Cm*direct* both differentiate >20 common NTM species and MTBc, with the former requiring a positive culture, while the latter can also be used directly on decontaminated sputum. The GenoType NTM-DR allows for the same species identification as "CM," but in addition detects resistance mutations associated with clarithromycin and amikacin. For further identification of 19 less common NTM species, the GenoType *Mycobacterium* AS can be used on positive cultures.

In addition, molecular tests used for direct detection of MTBC in clinical specimens can also be used for identification of MTBC in grown cultures.

The cumbersome analysis of mycolic acid profiles using high performance (or pressure) liquid chromatography (HPLC), is nowadays rarely used in routine practice. The commercialized Sherlock Midi system (Midi Labs, Newark, DE), contains a database to which the profile of the unknown organism can be matched to speciate the isolate.

In clinical practice, matrix-assisted laser desorption/ionization time-of-flight (MALDI-TOF) mass spectrometry has shown value in replacing the more costly and time-consuming 16S rRNA gene PCR and sequencing-based approach as the primary method for identification of microorganisms.[194] In a recent multicenter study, two commercial databases (Bruker Biotyper with Mycobacterial Library v5.0.0 and bioMérieux VITEK MS with v3.0 database) showed comparable performance, with 92% and 95% of NTM strains identified at least to the complex/group level, and 62% and 57% to the highest taxonomic level.[195] Differentiation between members of *M. abscessus, M. fortuitum, M. mucogenicum, M. avium*, and *M. terrae* complexes/groups was problematic for both systems, as was identification of *M. chelonae* for the Bruker system.[195] Similarly, a seeded-culture study that incorporated clinically prevalent respiratory microbiota, achieved 99% correct identification of mycobacteria, indicating that residual patient microbiota in a positive liquid culture was reduced by the Vitek MS.[196] In another study, the MAC subtyper module using the MALDI Biotyper algorithm, allowed for correct identification of 100% of the *M. intracellulare* and 82% of the *M. chimaera,* two closely related species.[197] Forero-Morales and colleagues have described a novel mycobacterial inactivation and protein extraction protocol (MIPE), which provides reliable MALDI-TOF results from solid and liquid media, while ensuring laboratory safety.[198] Finally, MALDI-TOF MS is intended for the identification of pure cultures; mixed *Mycobacterium* cultures present a challenge, as both species may not be distinguishable, especially in case of closely related taxa.[199]

Finally, the next-generation sequencing based Deeplex Myc-TB assay (Genoscreen, Lille, France), can detect 156 mycobacterial species either directly from smear-positive clinical specimens or from positive cultures, using nucleotide identity at the *hsp65* gene.[200]

Direct Testing of Specimens for *Mycobacterium Tuberculosis* Using Molecular Methods

Molecular diagnostics can be used to test directly on clinical specimens. Several commercial assays for detection of MTBC are being used since the 1990s (Table 33.2), such as the isothermal MTD amplification test by Gen-Probe (San Diego, U.S.A), the ProbeTec ET *Mycobacterium tuberculosis* complex Direct Test (DTB) (Becton-Dickinson), or the COBAS Taq-Man MTB Test (Roche Molecular Systems, Indianapolis, U.S.A). These assays were approved for AFB smear-positive respiratory specimens, yet require large instruments, are expensive or can be cumbersome.

Among the most common newer commercial molecular tests are the GenoType MTBC (Hain Lifesciences, GmbH, Nehren, Germany) and the less commonly used INNO-LiPA Mycobacteria (LiPA Innogenetics, Ghent, Belgium). These tests detect MTBc in a clinical specimen. The sensitivity and specificity are good in smear-positive sputum specimens but low in smear-negative specimens.

The most recently introduced is the Gene Xpert MTB/RIF (Cepheid, California, U.S.A) automated test. It is the most simple and rapid test with results available within 2-hours' time. Specimen is mixed with a reagent in a measured quantity and is placed in the instrument. All the necessary molecular procedures are automatically carried out inside the instrument, and results for the presence or absence of the MTBc and presence of rifampicin resistance is displayed within two hours. Sensitivity and specificity for smear-positive is very high, but for smear-negative specimens is rather low. This system has been tried in the peripheral sites with encouraging results.[40] Detection from smear-negative and culture-positive specimens needs improvement while detection of rifampicin resistance at a low level may be a concern.[41]

Other less commonly used commercial CE-labeled real-time PCR systems are available:

- The artus *Mycobacterium tuberculosis* RG PCR (artus MTB) kit (QIAGEN, Germany) has also been approved by the FDA and detects MTBc and/or MAC.

TABLE 33.2

Overview of FDA-Approved Nucleic-Acid Amplification Techniques (NAAT) for the Detection and Identification of Mycobacteria

Target	Assay	Company
Mycobacterium tuberculosis	Xpert MTB/RIF Assay	Cepheid

- The Geno-Sen's MTC/MOTT Real-Time PCR (Corbett Research, Australia) detects the genus *Mycobacterium* and MTBC.
- The Abbott RealTime MTB (Abbott Diagnostics, U.S.A) detects MTBC, while the variant Abbott RealTime MTB RIF/INH allows for simultaneous detection of resistance to rifampicin and/or isoniazid.
- The Speed-oligo Direct *Mycobacterium tuberculosis* assay (Vircell, Spain) includes an automated or manual post-PCR strip hybridization (dipstick format).
- The Truenat MTB Plus (MolBio, India) allows for detection of MTBC, while the Truenat MTB-RIF Dx subsequently detects rifampicin resistance in *M. tuberculosis* in Truenat MTB/MTB Plus positive specimens.

More sophisticated micro-array or lab-on chip-based CE-approved systems comprise:

- The CapitalBio Mycobacteria Real-Time PCR Detection Kit (CapitalBio Corporation, China) detects and differentiates MTBC from NTM, while the CapitalBio M. tuberculosis Drug Resistance Array Kit in addition detects 14 of the most frequent mutations associated with resistance to isoniazid and rifampicin.
- The VereMTB™ Detection Kit (Veredus Laboratories, Singapore) simultaneously detects MTBC, resistance to rifampicin and isoniazid, as well as 14 NTM species.

A non-CE-IVD approved test includes the REBA Myco ID (YD Diagnostics, South Korea).

Drug-susceptibility Testing of Mycobacteria Species

Details of drugs effective against clinically important mycobacteria and procedures for drug-susceptibility testing (DST) can be found in the Clinical Laboratory Standard Institutes (CLSI) guidelines.[201]

Susceptibility testing of MTBc isolates is advisable even in newly diagnosed infections, as an individual may have been infected with a resistant strain (primary resistance),[202] and drug resistance rates vary widely across global regions and settings. The WHO therefore recommends "universal DST," i.e., the search and identification of RR-TB among new TB patients, wherever this is logistically feasible.[203] Universal DST in all presumptive TB cases in the GeneXpert-based algorithm in South Africa resulted in a higher overall proportion of MDR-TB cases being diagnosed.[164]

Regarding susceptibility testing of NTM, the U.S. CLSI provides clear guidance on when and how to test and how to interpret minimal inhibitory concentrations (MICs),[201] while the British Thoracic Society recommends to follow CLSI, admitting that evidence is poor and DST should only be carried out on isolates where there is clinical suspicion of disease.[29] In the absence of clear *in vitro/in vivo* associations and clear-cut test concentrations for most NTM and drugs, the British guidelines distilled some evidence statements that could guide patient management (Table 33.3).

Overall, there are two major approaches for testing drug resistance, using culture-based or phenotypic and molecular-based or genotypic methods, with NTM-DST being mostly limited to phenotypic DST, with preference for MIC determination and reporting.

Phenotypic Susceptibility Testing

Culture-based or phenotypic DST can be performed on solid or in liquid medium, the latter having the preference for MTBC in terms of speed, and for NTM in terms of reliability. TB-DST should always be carried out in a confined laboratory following at least the safety precautions recommended by WHO.[204]

Classically, TB drug susceptibility testing is performed on the same solid media as used for primary isolation, such as LJ or Middlebrook 7H10 and 7H11 agar medium. The proportion method is the most applied, establishing the proportion of bacilli growing on culture-containing medium as compared to drug-free slants, considering an isolate as clinically resistant if >1% of the bacterial population resists the drug. To this end, an appropriate bacterial suspension (e.g., 10^{-3} dilution MacFarland #1) of the isolated culture is inoculated on the drug-containing slants, while a 1:100 dilution of the same suspension is inoculated on ad drug-free control. Solid media for DST can be obtained commercially or prepared in house. The drugs are added to the medium prior to coagulation. With exception of pyrazinamide (PZA) all TB drugs can be tested on solid medium, with clearly defined critical concentrations, specific for the drug and medium used.[205] Of note, LJ medium should not be used for bedaquiline susceptibility testing, because of its high protein-binding capacity. Solid medium DST, while being reliable, requires at least 3–4 weeks of incubation, with preferably a second reading at 6 weeks,[205] which is not in keeping with current U.S. Centers for Disease Control recommendations.[202]

TABLE 33.3

Evidence-Based Impact of Drug Resistance on NTM Treatment Outcome

Species	Disease Presentation	*In Vitro* Resistance[a] to	Impact	Evidence Level[b]
MAC	Not specified	Macrolides & amikacin	Treatment failure	2++
M. kansasii	Not specified	Rifampicin	Treatment failure	2++
M. abscessus	Pulmonary	Macrolides	Treatment failure	2++
M. abscessus	Extrapulmonary	Cefoxitin, amikacin and co-trimoxazole	Treatment failure	2++

Source: Adapted from Ref. [28].

[a] determined by broth dilution.

[b] 2++ = High-quality. Systematic reviews of case–control or cohort studies, or high quality case–control or cohort studies with a very low risk of confounding, bias or chance, and a high probability that the relationship is causal.

The use of liquid medium for detection and drug susceptibility testing has been recommended by the U.S. Centers for Disease Control and WHO,[202,204] MGIT 960 is the most widespread used liquid culture system for susceptibility testing of isolated MTBC against first- and second-line drugs, as well as new drugs like bedaquiline[208] and delamanid.[209,210] The system also relies on the proportion method principle, and results can be reported as early as 5–7 days after primary isolation. Details of the MGIT DST procedure are covered in the MGIT Manual published by FIND.[211] First-line and some of the second-line drugs are available in ready-to-use lyophilized form, while others need to be purchased and dissolved/diluted in house. Although recommended by WHO and CDC, MGIT960 testing risks to miss some cases of rifampicin resistance.[212,213]

PZA testing requires a low pH (pH 5.0) which can be achieved using adapted MGIT medium (BACTEC™ MGIT™ 960 PZA Kit), the only recommended phenotypic assay, despite previous association with a high rate of false-resistance results.[201,207] Several studies have shown good agreement of MGIT-PZA testing with *pncA* sequencing, if done meticulously; careful inoculum preparation is essential for correctly performing PZA testing reliably.[214]

Regarding NTM susceptibility testing, a variety of methods have been proposed, including broth dilution tests, the E-test, and proportional- and absolute-concentration methods.[42] E-tests suffer from high intra- and interlaboratory variability, and the proportional method on solid media or in MGIT has its breakpoints not yet defined for NTM. Hence the preference for the broth microdilution method.[201]

Molecular-Based Drug-susceptibility Testing

In the last decade, several genotypic DST procedures have been introduced, detecting mutations in one or more specific genes associated with resistance to (a) particular (class of) drugs. Genotypic testing is significantly faster than phenotypic testing. Among the first-line drugs, molecular testing overall has an excellent sensitivity for rifampicin and a good sensitivity for isoniazid, while both having excellent specificity. Sensitivity and specificity for ethambutol and PZA are debatable. Regarding second-line drugs, both for injectables and fluoroquinolones a relatively high sensitivity is observed. Details of the likelihood of association with drug resistance can be found on the Relational Sequencing TB Knowledgebase (ReSeqTB) platform (https://platform.reseqtb.org/).[215]

The FDA-approved GeneXpert MTB/RIF is the most widely used assay, with a pooled sensitivity and specificity of 96.8% and 98.4%, respectively, to correctly identify rifampicin-resistance in clinical specimens.[216] False-resistant results have been associated with a low bacillary load,[217,218,219] or the presence of synonymous mutations not associated with resistance.[220] Therefore, it is recommended to repeat testing in case of a low pretest probability for rifampicin resistance or a very low bacillary load. The new version Xpert Ultra may be more specific as it includes melting temperatures to identify the mutation type.[221] Further roll out of this version will provide data on its performance as an initial diagnostic test in field settings.

Results for the clinical evaluation of the chip-based real-time micro-PCR Truenat MTB-RIF Dx (MolBio, India) are expected by 2020.

While not being FDA approved, the WHO has endorsed the GenoType MTBDR*plus* (Hain Lifesciences, Germany) and the Genoscholar NTM-MDR TB (Nipro, Japan) line probe assays for detection of resistance to rifampicin and isoniazid in cultures and smear-positive samples.[222] Likewise, the GenoType MTBDR*sl* (Hain Lifesciences, Germany) can detect resistance to fluoroquinolones and second-line injectables.[223] The only assay for rapid detection of PZA resistance (Genoscholar PZA-TB II) has not been endorsed yet.[224]

Finally, next-generation sequencing-based Deeplex Myc-TB assay (Genoscreen, Lille, France) can predict resistance to 13 anti-TB drugs/drug classes, directly from smear-positive sputum or from culture isolates.[225] This assay has not yet been CE or FDA approved. Likewise, whole genome sequencing can predict TB drug resistance with a good sensitivity and specificity for most drugs,[226] albeit with yet unclear genotypic-phenotypic associations for new drugs like bedaquiline and delamanid.[227,228]

Introduction

Mycoplasma spp. are members of the class *Mollicutes*, have the smallest cells among free-living eubacteria, and have genomes presumed to approach the minimal essential information for independent cellular life (1). Mycoplasmas and the other mollicutes evolved from Gram-positive ancestors (2) by reductive processes that resulted in obligate association with eukaryotic host cells. The distinguishing characteristics of mollicutes include absence of a cell wall, small cell size (200–500 nm), small genome size (580–2200 kbp), low G + C content (typically in the range of 23–34 mol%, but 40 mol% in *Mycoplasma pneumoniae*), 16S rDNA sequences clearly affiliated with the class (3), unique codon usage (e.g., UGA as a tryptophan codon) in some lineages, and minimal metabolic capabilities. Cells are bound only by a single membrane, resulting in a general cellular pleomorphism; however, cytoskeletal elements confer helicity or polarity in a small number of species. Some species exhibit rotatory, flexional, or gliding motility. The best-studied mollicutes are significant pathogens of humans, domesticated animals, or plants. Additionally, a small number of species are common contaminants of *in vitro* eukaryotic cell cultures (4). Scientific organizations devoted to the study of these unique organisms include The International Organization for Mycoplasmology (IOM-Online.org) and its International Research Programme on Comparative Mycoplasmology, The United States Organization for Mycoplasmology (USOMycoplasmology.org), The Asian Organization for Mycoplasmology (square.umin.ac.jp/aom/), European Society for Clinical Microbiology and Infectious Disease Study Group for Mycoplasma Infections, the International Committee for the Systematics of Prokaryotes subcommittee for the Taxonomy of *Mollicutes*, Australian Society for Microbiology (Division of Medical and Veterinary Microbiology, Special Interest Group for *Mycoplasmatales*), and Division G of the American Society for Microbiology (ASM.org). The purpose of this chapter is to introduce scientists who have been trained in other disciplines to Mycoplasma and related organisms, and to provide an entry to the literature of practical mycoplasmology with emphasis on vaccinology and methods of genetic manipulation for microbiologists who specialize in other species.

Species Concept for Mycoplasma and Related Organisms

The species concept for Mycoplasma and related organisms is similar to the general species concept for other bacteria (5–7). As with other bacteria, in Mycoplasma, the correlation between 16S rDNA

sequence similarity and gold standard DNA-DNA hybridization (DDH) values is practically useful although imprecise (7–9) for a few notable species. For example, *Mycoplasma gallisepticum* and *Mycoplasma imitans* have >99% 16S rDNA similarity, yet show only 40% DDH (10). Within-species variability among *Mycoplasma hominis* strains can generate as little as 50% intraspecific DDH, while maintaining >99% 16S rDNA similarity (11). Stackebrandt and Goebel (12) proposed an upper limit of 97% 16S rDNA similarity as a threshold, which if exceeded, would indicate a need for additional tests to determine whether strains should be regarded as a single or separate species. A contemporary interpretation of this guideline indicates that complete genome sequences should be derived to resolve ambiguity between closely related taxa. For Mycoplasma and related organisms, experience suggests that a frontier of about 94% 16S rDNA sequence similarity indicates either a spectrum of related species from which an isolate would have to be distinguished by additional means. Current mycoplasmology employing at minimum a combination of 16S rDNA sequence analyses and supplementary phenotypic data to identify species is consistent with standards established by the microbial systematics community for a species concept (13). However, novel species descriptions proactively avoid ambiguous taxonomic assignment and are greatly strengthened by the generation of a complete genome sequence and analyses of the average nucleotide identity (ANI) between pairs of genome sequences of closely related species (14). The accepted boundary between species of 70% DDH empirically equates to about 95–96% ANI also for species circumscription of Mycoplasma and related organisms (7, 15), but like DDH, the ANI is not suitable for the determination of supraspecific relationships among mollicutes (16).

Taxonomic Ambiguities

The order Mycoplasmatales presently contains the single family *Mycoplasmataceae*. About 130 species have been named. Its polyphyletic genus *Mycoplasma* is divided into two groups based on ribosomal RNA sequence, named for their most prominent human pathogens: hominis and pneumoniae (17). These groups are further subdivided into phylogenetic clusters, and this strategy was extended to include the anomalous mycoides cluster. This group consists of a few species, regrettably including the genus *Mycoplasma* type species (*Mycoplasma mycoides* subsp. *mycoides*), whose 16S rDNA sequences are affiliated unambiguously with those of the family *Entomoplasmataceae* rather than with the *Mycoplasmataceae*. The nomenclature of those species is a matter of continuing controversy. Renaming of this small number of species is not possible, as *M. mycoides* has taxonomic precedent over later-named species. Furthermore, multiple members of the mycoides cluster cause World Organization for Animal Health (OIE)-listed diseases, and their cultivation, transport, and reporting are tightly controlled. Alterations in nomenclature would introduce potentially catastrophic confusion.

Despite these practical challenges, several recent revisions were proposed to resolve the polyphyly within the class. Affected species include numerous organisms of clinical and/or regulatory significance. The proposed revisions are based on combinations of characteristic sequence polymorphisms and indels, which in some species' cases are based on as few as a single strain genome. For these logistic and technological reasons, the International Committee for the Systematics of Prokaryotes Subcommittee for the Taxonomy of *Mollicutes* has published a formal request for opinion on the preservation of the original names (18). In so doing, the committee has soundly rejected the inclusion of the proposed order name *Mycoplasmoidales*, the proposed family names *Metamycoplasmataceae* and *Mycoplasmoidaceae*, the proposed genus names *Malacoplasma*, *Mesomycoplasma*, *Metamycoplasma*, *Mycoplasmoides*, and *Mycoplasmopsis*, and all species names included therein (19, 20). It is therefore strongly recommended that the revised names not be adopted at this time.

Uncultivated *Mollicutes*

The International Code of Nomenclature of Prokaryotes (ICNP, also referred to as "the Bacteriological Code") states that valid publication of a novel taxon requires isolation in axenic culture. The indefinite rank *Candidatus* is used for those organisms that clearly represent extant taxa, yet are prohibited from fulfilling the standards for valid publication for technological reasons (20, 21). Major plant pathogens in the class *Mollicutes* have been described and most fall under the heading of "*Candidatus* Phytoplasma" spp. The phytoplasmas have not been readily cultivated *in vitro*, in part because among other biochemical lesions, they lack the capacity for ATP synthesis (22). A small number of reports of axenic phytoplasma cultivation using undefined medium are promising, but remain to be independently verified (23). At this time, these taxa retain the rank *Candidatus*, and infected plants are surveilled and detected using molecular techniques (24).

Hemotrophic mycoplasmas (colloquially referred to as "hemoplasmas") such as "*Candidatus Mycoplasma haemofelis*," which were historically affiliated to the rickettsial genera *Haemobartonella* or *Eperythrozoon* based on phenotypic traits, also remain uncultivated in artificial media. About a dozen different hemoplasmas are distinguishable by host origin and 16S rDNA sequences. A small number of hemoplasmas whose detection and description predate the introduction of the "*Candidatus,*" have full genus-species name combinations despite being uncultivatable. These include *Mycoplasma wenyonii*, *Mycoplasma coccoides*, *Mycoplasma ovis*, and *Mycoplasma suis* (1).

The rapid expansion of metagenomics datasets has allowed for the detection of numerous uncultivated *Mollicutes* through global 16S rDNA amplicon library sequencing. For example, Eckburg et al. (25) determined the 16S rRNA gene sequences of at least 10 novel phylotypes among the human intestinal microbiota that cluster distinctly enough to suggest the existence of a previously undiscovered order within the class *Mollicutes*. Similarly, the isolation or detection of 16S ribotypes in invertebrates (insects, shellfish) that appear to affiliate with the genus *Mycoplasma* question the previous genus description featuring vertebrate host habitats (26–29). As metagenomics continues to grow as a field, the number of discreet but uncultivated taxa belonging to the *Mollicutes* will undoubtedly expand.

Biology and Biochemistry of the Class *Mollicutes*

Mollicutes have been observed in close association with plants, invertebrates, and all classes of vertebrate hosts except amphibians. A flask-shaped cellular morphology, terminal adhesion-related

structures, and a complex cytoskeleton are common in the lineages of the *Mycoplasma pneumoniae* and *Mycoplasma sualvi* clusters, and helical morphology is distinct to members of the genus *Spiroplasma*. The general morphological and metabolic simplicity of mycoplasmas and related organisms is consistent with their limited genome size, and leads to few unique biochemical traits that can be exploited for rapid differentiation between species (30). The lack of anabolic pathways in mycoplasmas is compensated for by an overrepresentation of transport-associated proteins in their proteomes. Pathways for energy generation are also minimal, as mycoplasmas lack the tricarboxylic acid cycle and other mediators of oxidative phosphorylation (31). Sugar fermenting mycoplasmas generate much of their energy from glycolysis and the pyruvate dehydrogenase pathway. The acidic byproducts of these pathways cause a characteristic downward pH shift of the culture medium following growth of those species. Some mycoplasmas hydrolyze arginine as a means of energy generation through the relatively simple arginine dihydrolase pathway, which requires only three enzymes. Hydrolysis of arginine results in the accumulation of ammonia, resulting in the characteristic upward pH shift of the culture medium seen following growth. A small number of species (e.g., *Mycoplasma bovis*) do not cause any shift in pH of the culture medium following growth. Some mycoplasmas catabolize organic acids and alcohols, such as lactic acid, pyruvic acid, oxobutyric acid, ethanol, glycerol, or isopropanol (31–33). Catabolism of glycerol leads to the excretion of hydrogen peroxide, which is a critical mediator of pathogenicity for some species (34–36). The hydrolysis of urea for ATP synthesis is the defining trait of the genus *Ureaplasma*; however, it cannot be used to differentiate between species within the genus.

Growth Characteristics

Mollicutes spp. are aerobic or facultatively anaerobic (with the exception of *Anaeroplasma* spp.), and have been isolated from vertebrate, invertebrate, or plant hosts. Excluding the genera *Acholeplasma* and *Asteroleplasma*, they require cholesterol and/or other sterols for growth, a need that is usually met by adding serum to the culture medium. A variety of culture media have been described (37). Nonmotile species or species with only gliding motility, tend to form umbonate ("fried egg") colonies on solid media. Satellite colonies are often observed for motile species on agar. Most *Mycoplasma* spp. grow best at temperatures reflecting their usual habitat. Optimum growth at 37°C is a common feature of species isolated from homeothermic vertebrates, and the lower part of the permissive temperature range even of *Mycoplasma* spp. isolated from poikilothermic fish and reptiles is only 20–25°C. The differential utilization of glucose and arginine and the ability to hydrolyze urea (for *Ureaplasma* spp.) and esculin (for *Acholeplasma* spp.) are important diagnostic features of *Mollicutes* spp.

The nutritional requirements of mollicutes were reviewed extensively by Miles (38). Tully (37) described in detail the most commonly used complex media formulations for cultivation of *Mycoplasma* spp. and related organisms. American Type Culture Collection medium 988 (SP-4) is a rich undefined medium that has proven to be superior for meeting their comparatively fastidious nutritional requirements during primary isolation, and for the maintenance of many different mollicutes. It is prepared as an aqueous base, cooled to 56°C after autoclaving, to which is then added aseptically a mixture of serum, yeast extract, and other supplements that have been sterilized by sequential passage through 0.80 µm, 0.45 µm, and 0.22 µm filters. Penicillin G or other cell wall-targeting antibiotics are included to discourage the growth of other bacteria. The final pH of the complete medium, 7.6–7.8, facilitates phenol red-based detection of a pH shift caused by growth of mollicutes that excrete acidic end-products of fermentation, although not all species do so. Isolation and growth of arginine-hydrolyzing species can be enhanced by including 5 mL/L of a 42% w/v arginine solution in the supplements, in which case the final pH of the complete medium should be 7.0–7.2 to facilitate detection of an alkaline shift. Evaluation of clinical specimens wherein a novel *Mollicutes* species is suspected can be cultivated in SP-4 medium supplemented with both glucose and arginine. Some species, such as *Mycoplasma fermentans*, are capable of utilizing both sugars and arginine as carbon sources. An initial decrease in pH may reverse later during their course of growth in a complex medium (31). Quality control tests for the serum and yeast extract components and for complete SP-4 media are particularly important because serum quality is susceptible to variation and yeast extract contains labile components (37). Commonly used alternatives to SP-4, such as Frey's, Hayflick, and Friis media, differ mainly in the proportions of inorganic salts, amino acids, serum sources, and types of antibiotic supplements included. Urea must be supplied for primary isolation and cultivation of ureaplasmas, and they require a medium with pH 5.5–6.5. A variety of liquid and solid media formulations for *Ureaplasma* spp. culture from human and animal sources were described in detail by Shepard (39). Phenol red and bromothymol blue indicator broths have been developed to detect urease activity. Incorporation of calcium chloride in the differential agar medium A8 distinguishes *Ureaplasma* spp. colonies, which appear deep brown or brown-black in color (as a result of ammonia production through urease activity) from *Mycoplasma* spp., which remain colorless on A8 agar. Liquid and solid culture media for Spiroplasma spp. were described in detail by Whitcomb (40) and Hackett and Whitcomb (41). SP-4 or M1D media, which substitutes *Drosophila* tissue culture medium for CMRL 1066 and also includes fructose, sucrose, and sorbitol, are suggested for routine culture of a wide array of spiroplasmas from various serogroups. Sorbitol is used to adjust the osmolality to approximately 500 mOsm. Spiroplasmas have also been cultured in defined media or cocultured with mammalian or insect cells (42). Few *Mollicutes* species grow reliably well by 24 hours of incubation, especially at primary isolation from an infected host. The majority require multiple days before positive indicators of growth are observed, and clinical specimens should be left for up to one month without growth before being categorized as negative for growth.

Major Clinical Presentations

General Features of Mycoplasmosis and Phytoplasmosis

Mycoplasma and *Ureaplasma* species most commonly infect epithelial surfaces, and a small number of species can spread between distal tissues. Mycoplasmosis is a highly

inflammatory condition, and lesions in naturally and experimentally infected animals exhibit hallmarks of chronic inflammatory responses. Most manifestations cause significant morbidity and low mortality, with the notable exceptions of *M. mycoides* subsp. *mycoides*, *Mycoplasma capricolum* subsp. *capripneumoniae*, and *Mycoplasma alligatoris* (28). Phytoplasmosis similarly causes a general failure to thrive along with numerous species-specific clinical presentations. Disease states associated with specific *Mollicutes* species are detailed in Tables 34.1–34.3.

TABLE 34.1

Mollicutes Diseases of Animals[a]

Species	Host	Disease	Clinical Signs/Notes
Livestock Pathogens			
M. alkalescens	Cattle	URTD	Nasal discharge, lameness, decreased milk production
M. arginini	Cattle	RTI	Infertility
M. bovigenitalium	Cattle	LRTD, URTD, RTI	Nasal discharge, coughing, infertility
M. leachii	Cattle	Mastitis, arthritis	Lameness, decreased milk production
M. bovis	Cattle	URTD, LRTD	Coughing, head tilt, purulent discharge, lameness, decreased milk production
M. bovoculi	Cattle	Conjunctivitis	Ocular discharge
M. californicum	Cattle	Mastitis	Decreased milk production
M. canadense	Cattle	Mastitis	Decreased milk production
M. dispar	Cattle	LRTD	Coughing
M. leachii	Cattle	RTI	APO
M. mycoides mycoides	Cattle	CBPP	Coughing, fever, torticollis
M. verecundum	Cattle	Conjunctivitis	Ocular discharge
M. wenyonii	Cattle	Hemolytic anemia	Malaise, jaundice
M. gallsepticum	Galliform	CRD, IS, neurological disease, arthritis	Rales, coughing, fever, sinus swelling, ataxia, ocular discharge, lameness
M. synoviae	Galliform	Arthritis, LRTD, RTI	Rales, coughing, sinus swelling, PEQ, reduced hatchability, lameness
M. anatis	Duck	URTD	Nasal discharge
M. adleri	Goat	Arthritis	Lameness
M. agalactiae	Goat	LRTD, RTI, contagious agalactia	Coughing, ocular discharge, decreased milk production, lameness, APO
M. capricolum	Goat	Contagious agalactia, LRTD, encephalitis	Lameness, decreased milk production, coughing, sudden death
M. capricolum capripneumoniae	Goat	CCPP	Coughing, fever, torticollis
M. mycoides capri	Cattle	Contagious agalactia, LRTD	Lameness, decreased milk production, ocular discharge, coughing
M. putrefaciens	Goat	Septicemia, contagious agalactia	Fever, malaise, cataracts, blindness, lameness, decreased milk production
M. subdolum	Horse	RTI	APO, infertility
M. haemolamae	Llama	Infectious anemia	Malaise
M. haemosuis	Pig	Hemolytic anemia	Malaise, jaundice
M. hyopneumoniae	Pig	PEP	Coughing, malaise, arrhythmia
M. hyorhinis	Pig	URTD, LRTD	Nasal discharge, coughing, arrhythmia, lameness
M. hyosynoviae	Pig	Arthritis	Lameness
M. arginini	Sheep	LRTD, URTD	Nasal discharge, coughing, ocular discharge
M. conjunctivae	Sheep, chamois, ibex	Conjunctivitis	Cataracts
M. ovipneumoniae	Sheep	URTD, LRTD	Nasal discharge, coughing
M. ovis	Sheep	Hemolytic anemia	Malaise, jaundice
M. meleagridis	Turkey	LRTD, RTI	PEQ, reduced hatchability, Rickets, skeletal deformity
M. iowae	Turkey	Arthritis, osteitis, RTI	PEQ, reduced hatchability, ocular discharge, lameness, skeletal deformity
M. pullorum	Turkey	RTI	Reduced hatchability
S. eriocheiris	Chinese mitten crab	Tremor disease	Tremor, death
S. apis	Honeybees	May disease	Tremor, paralysis
S. melliferum	Honeybees	Colony loss	Sudden death of bees

TABLE 34.1 ***(Continued)***

Mollicutes Diseases of Animals

Species	Host	Disease	Clinical Signs/Notes
Wildlife Pathogens			
M. alligatoris	Alligator	LRTD, nephritis, ME, fulminant inflammatory disease	Rapid death, lethargy, rapid death, lameness
M. felifaucium	Cheetah, puma	Gastroenteritis	Emesis, wasting
M. agassizii	Desert tortoise	URTD	Nasal exudates
M. buteonis	Falcon	LRTD, unclear	Uncoordinated movement, lameness, skeletal deformity
M. gallsepticum	Passerines (primarily finches)	Conjunctivitis	Ocular discharge
M. pneumoniae	Hominids (chimpanzee, rhesus monkeys)	PAP, URTD	Coughing, malaise
M. iguanae	Iguana	Osteitis	Lameness
M. sphenisci	Jackass penguin	URTD	Halitosis, choanal discharge
M. crocodyli	Nile crocodile	LRTD	Lameness
M. haemodidelphidis	Opossum	Infectious anemia	Malaise
M. orale	Orangutan	URTD	Rales, nasal discharge
M. columborale	Pigeon	LRTD	Rales, coughing, lethargy
M. phocicerebrale	Seal, Human	Eye infection, Seal finger (hu)	Cataracts, blindness
M. phocirhinis	Seal	URTD	Rhinitis
M. zalophi	Sea lion	Necrotizing LRTD	Lameness, coughing
M. conjunctivae	Sheep, chamois, ibex	Conjunctivitis	Ocular discharge, cataracts
M. kahanei	Squirrel monkey	Hemolytic anemia	Malaise, jaundice, arrythmia
M. sturni	Starling	Conjunctivitis	Ocular discharge
M. mobile	Tench	Red gill disease	Ulceration, labored breathing
M. testudineum	Tortoise	URTD	Nasal discharge
M. corogypsi	Vulture	Abscess	Chronic exudate
M. vulturii	Vulture	LRTD	Rales, coughing
Companion and Laboratory Animal Pathogens			
M. oxoniensis	Chinese hamster	Conjunctivitis	Ocular discharge
M. cricetuli	Chinese hamster	Conjunctivitis	Ocular discharge
M. canis	Dog	RTI, UTI, URTD	Frequency, coughing
M. cynos	Dog	pneumonia	Coughing, malaise
M. edwardii	Dog	Septicemia	Fever, lameness
M. haemocanis	Dog	Infectious anemia	Malaise
M. maculosum	Dog	LRTD, UTI	Coughing, frequency
M. spumans	Dog	arthritis	Lameness
M. haemominutum	Domestic cat	Infectious anemia	Malaise
M. felis	Cat, Horse	URTD (Fe), LRTD (h)	Nasal discharge, labored breathing, ocular discharge
M. gateae	Cat	URTD	Anorexia, lethargy, ocular discharge, lameness
M. haemofelis	Cat	Infectious anemia	Malaise
M. equigenitalium	Horse	RTI	APO, infertility
M. equirhinis	Horse	Inflammatory airway disease	Nasal discharge, coughing, rales
M. coccoides	Mouse	Infectious anemia	Malaise
M. haemomuris	Mouse	Infectious anemia	Malaise
M. neurolyticum	Mouse	Rolling disease	Uncoordinated movement
M. pulmonis	Mouse, rat	Murine respiratory mycoplasmosis	Nasal discharge, coughing, anorexia, lameness
M. ravipulmonis	Mouse	Grey lung disease	Coughing
M. arthriditis	Rat	Septicemia, arthritis	Lameness
S. poulsonii	Drosophila spp.	Sex ratio abnormalities	Overabundance of males due to lethality in females

Abbreviations: URTD = upper respiratory tract disease; LRTD = lower respiratory tract disease; RTI = reproductive tract infection; CBPP = contagious bovine pleuropneumonia; CCPP = contagious caprine pleuropneumonia; CRD = chronic respiratory disease; IS = infectious sinusitis; PEP = porcine enzootic pneumonia; APO = adverse pregnancy outcomes; ME = meningoencephalitis; RTI = reproductive tract infection; UTI = urinary tract infection.

TABLE 34.2

Mollicutes Diseases of Humans

Species	Host Tissue	Disease	Clinical Signs/Notes
M. pneumoniae	Respiratory tract	PAP, encephalitis, meningitis, conjunctivitis	Postinfections inflammatory complications can occur; additional body sites are rarely implicated
M. genitalium	Urogenital tract	NGU, PID, cervicitis, orchitis	Infertility, preterm labor, APOs
M. hominis	Urogenital tract	BV, cerebral abscess, NGU	Infertility, APOs
M. amphoriforme	Respiratory tract	LRTI	Diagnostic differentiation from *M. pneumoniae* historically challenging
M. phocicerebrale	Skin	"seal finger" (ulcerative keratitis)	Occurs secondary to seal/marine mammal contact
Ureaplasma spp. (adult)	Urogenital tract	NGU, chorioamnionitis, endometritis, hyperammonemia	Strain-dependent pathogenicity, APOs, hyperammonemia occurs in immunocompromised patients only
Ureaplasma spp. (neonate)	Respiratory tract, CNS	BPD, encephalitis, meningitis	Premature infants born to infected mothers

Abbreviations: APO = adverse pregnancy outcome; BPD = bronchopulmonary dysplasia; BV = bacterial vaginosis; CNS = central nervous system; LRTI = lower respiratory tract infection; NGU = nongonococcal urethritis; PAP = primary atypical pneumonia; PID = pelvic inflammatory disease.

TABLE 34.3

Mollicutes Diseases of Plants

Species	Plant Host	Disease
S. citri	Citrus (orange; grapefruit)	Citrus stubborn
S. kunkelii	Corn/maize	Corn stunt
Candidatus P. asteris	Aster family plants	Aster yellows disease, corn stunt, cabbage proliferation disease, apple sessile leaf, strawberry green petal, blueberry stunt, tomato big bud, potato purple top, primrose virescence, hydrangea phyllody
Candidatus P. americanum	Potato	Potato purple top
Candidatus P. autralasia	Papaya	Papaya yellow crinkle disease
Candidatus P. allocasuarinae	Slaty sheoak	Sheoak (allocasuarina) yellows
Candidatus P. australiense	Grapevine; papaya; strawberry, peanut, apple, alfalfa, sweet potato	Australian grapevine yellows, papaya die-back, strawberry lethal yellows, peanut witches' broom, cocky apple witches' broom, sweet potato little leaf, alfalfa witches' broom
Candidatus P. mali	Apple	Apple proliferation disease
Candidatus P. vitis	Grapevine	Grapevine flavescence doree
Candidatus P. prunorum	Stone-containing fruits	European stone fruit yellows
Candidatus P. fraxini	Ash, lilac, alfalfa	Ash yellows, lilac witches' broom, alfalfa witches' broom
Candidatus P. lycopersici	Tomato	Hoja de perejil
Candidatus P. trifolii	Potato	Colombian potato purple top, potato witches' broom
Candidatus P. ziziphi	Cherry, nectarine	Nectarine yellows, cheery lethal yellows
Candidatus P. aurantifolia	Lime	Witches' broom disease of lime
Candidatus P. brasiliense	Alfalfa, hibiscus	Alfalfa witches' broom, hibiscus witches' broom
Candidatus P. fragariae	Strawberry	Strawberry lethal yellows
Candidatus P. japonicum	Coconut, sugarcane, strawberry	Coconut lethal yellows, sugarcane yellows, strawberry green petal
Candidatus P. pyri	Pear, peach	Peach yellow leafroll, pear decline
Candidatus P. phoenicum	Almond	Almond witches' broom
Candidatus P. oryzae	Rice, sugarcane	Rice yellow dwarf; sugarcane white leaf
Candidatus P. rhamni	Buckthorn	Buckthorn witches' broom
Candidatus P. spartii	Sweet potato	Sweet potato little leaf
Candidatus P. solani	Grapevine	Grapevine yellows
Candidatus P. omaniense	Blueberry, peach, sugarcane, grapevine, walnut, cherry, tea	Blueberry proliferation; Canadian peach X; little peach; sugarcane yellows; Virginia grapevine yellows; walnut witches' broom; cherry buckskin disease ("Western X"); weeping tea disease
Candidatus P. ulmi	Elm, Indian hemp	Elm yellows; hemp dogbane yellows

Transmission between hosts occurs primarily by direct contact (includes nose-to-nose contact, sexual contact, or milk feeding) (mycoplasmas, ureaplasmas, acholeplasmas, anaeroplasmas), fomite transmission (veterinary mycoplasmas, spiroplasmas [via plant surfaces]), or by insect vector (phytoplasmas, spiroplasmas, entomoplasmas, hemotropic mycoplasmas) (1, 28). Aerosol transmission of respiratory mycoplasmosis between humans or animals housed in high density (e.g., dormitory settings, military barracks, or livestock and poultry rearing) has also been observed (43–45). Vertical and perinatal transmission of mycoplasmas, ureaplasmas, and spiroplasmas has been reported (28). The clinical signs of vertically transmitted mycoplasmosis are distinct from those displayed by the infected mother, as congenital infection with *M. hominis* and *Ureaplasma* species can lead to pneumonia, bronchopulmonary dysplasia, meningitis, or encephalitis in (frequently premature) newborns born to mothers with either clinical or subclinical urogenital tract infections (46–48).

Impacts and Outcomes of Mycoplasmosis

The chronic nature of veterinary mycoplasmoses makes them diseases of concern for livestock, who often exhibit decreased production. Coinfections of mycoplasmas with additional pathogens notoriously exacerbate of disease over and above those of either pathogen alone (28). Mycoplasmosis of livestock species leads to billions of dollars of economic loss each year. Several mycoplasmal diseases are listed by OIE and the Food and Agriculture Organization of the United Nations (FAO) because of the potentially devastating impact on local and national economies and food security. Morbidity associated with mycoplasmosis results in decreased production for poultry, swine, cattle, and small ruminants in the forms of downgraded carcasses, lowered feed conversion, loss of egg or milk production, eggs or milk not suitable for sale, and infertility. The most common mycoplasmal livestock diseases worldwide include porcine enzootic pneumonia due to *Mycoplasma hyopneumoniae*, chronic respiratory disease/avian mycoplasmosis due to *M. gallisepticum* and/or *Mycoplasma synoviae*, bovine respiratory disease/mastitis/arthritis due to *M. bovis*, and bovine mastitis/contagious agalactia due to *Mycoplasma agalactiae*, *Mycoplasma mycoides* subsp. *capri*, *Mycoplasma capricolum* subsp. *capricolum*, and *Mycoplasma putrefaciens*. Over and above these classic manifestations of mycoplasmosis, contagious bovine pleuropneumonia (CBPP) and contagious caprine pleuropneumonia (CCPP) caused by *M. mycoides* subsp. *mycoides* and *M. capricolum* subsp. *capripneumoniae*, respectively, feature both high mortality and high morbidity in survivors. Outbreaks can thus cause catastrophic economic losses. Both diseases have been eradicated from the Americas, Australia, and Western Europe, and their import and cultivation are tightly regulated and highly restricted. The impact of CBPP and CCPP on the livelihood of sub-Saharan Africans, in particular, is widespread and multifaceted. Cattle with CBPP frequently die of disease or are culled to prevent the spread of infection. Survivors provide less meat, 90% less milk, and are far less able to perform production work (49–51). Quarantine is often implemented during CBPP and/or CCPP outbreaks, which severely restricts movement of infected herds and potentially prohibits animals from accessing grazing grounds or water sources. Both the health of uninfected animals in the herd and the ability of farmers to access the value of their cattle or goats (52) are thus negatively affected by quarantine. All mycoplasmal diseases of animals are described in Table 34.1.

Urogenital mycoplasmosis of humans has been linked to pelvic inflammatory disease, infertility, spontaneous abortion, and preterm labor. *M. genitalium*, a causative agent of nongonococcal urethritis, in particular is strongly associated with pelvic inflammatory disease, spontaneous abortion, and infertility (28, 46). Active infection is required to induce spontaneous abortion and preterm labor, but pelvic inflammatory disease and infertility persist even if infection is resolved. Preterm labor and/or premature rupture of membranes during ureaplasmosis of pregnant women is a significant risk factor neonatal respiratory tract or central nervous system infections, and chronic lung conditions can persist in infants following resolution of infection (28, 47). Respiratory mycoplasmosis caused by *M. pneumoniae* has been associated with asthma exacerbation, postinfectious reactive airway disease, and adult-onset asthma, and these conditions persist after successful elimination of the bacteria (53, 54). Impaired fertility, chronic pain, reactive airway disease, and lifelong complications from premature delivery can have significant impacts on economic livelihood and quality of life. All mycoplasmal and ureaplasmal diseases of animals are described in Table 34.1.

Several grain crops, fruit trees/bushes, nut trees, vegetables, and ornamental plants are affected by phytoplasmosis. General disease features of phytoplasmosis are variable and species-specific, but can include phyllody, greening (virescence), witches' broom formation, stunting, floral sterility, yellowing, leaf curling, purpling, cupping, vein clearing, and failure to thrive (28). Numerous diseases of important crop species are caused by phytoplasmas (Table 34.3). As with veterinary mycoplasmosis, numerous phytoplasmal diseases are listed by the International Plant Protection Convention (IPPC), and the import and reporting of infected plants is tightly controlled.

Detection and Surveillance

Growth in culture is often considered the gold standard for positive detection of an organism for most bacterial infections. In addition to detection by culture, nucleic acid amplification tests (NAATs) and metagenomics techniques have been used widely to detect mollicutes in clinical material, cell cultures, and environmental samples (55). Molecular techniques avoid the limitations of culturing, which include sometimes very slow growth, false-negative results due to the complex nutritional requirements of many species, or uninformative results due to overgrowth with fungal or other bacterial contaminants during primary isolation. Commercial NAATs have been developed for the human pathogens *M. pneumoniae* and *M. genitalium*, with the latter having the additional benefit of simultaneously detecting single nucleotide polymorphisms (SNPs) conferring macrolide resistance (Table 34.4). Serological methods of diagnosis were once preferred; however, NAATs have rapidly become the diagnostic method of choice for the major human mycoplasmoses (i.e., primary atypical pneumonia and nongonococcal urethritis). A qualitative method of detection in cell culture systems, based on mycoplasma-specific ATP synthesis activity present in tissue culture supernatant medium,

[e] Detects all members of the genus "Candidatus Phytoplasma."

is also available commercially with a standardized protocol for research purposes (MycoAlert®, Lonza Group Ltd.).

Because of the technical challenges to culturing certain species and the severely restricted usefulness of conventional metabolic diagnostic tests of isolates, diagnosis of veterinary mycoplasmosis often relies on enzyme-linked immunosorbent assays (ELISA) or NAATs. ELISA techniques have been described in detail for most major veterinary pathogens, and many are commercially available. Commercial NAATs are also available for most major agricultural mycoplasmas (Table 34.4), with the notable exceptions of *M. mycoides mycoides* and *M. capricolum capripneumoniae*. Additionally, many veterinary diagnostic laboratories have developed and validated in-house ELISA and/or NAATs for agricultural and companion animals available on a fee-for-service basis.

Treatment and Control

Antimicrobial Treatment

Mycoplasmas are intrinsically resistant to many antibiotics. Lacking a cell wall, mycoplasmas are not affected by β-lactams, vancomycin, or fosfomycin. In addition, mycoplasmas as a whole are resistant to sulfonamides and trimethoprim because they do not synthesize their own nucleotides; resistant to rifampicin because they express a form of RNA polymerase unrecognized by the antibiotic; and resistant to polymyxins (56). Individual species can exhibit even a broader spectrum of antibiotic resistance. Examples include the resistance to erythromycin and azithromycin exhibited by *M. hominis*, *M. fermentans*, *Mycoplasma hyopneumoniae*, *Mycoplasma flocculare*, *Mycoplasma pulmonis*, *Mycoplasma hyorhinis*, *Mycoplasma hyosynoviae*, *Mycoplasma meleagridis*, and *M. bovis*, which is apparently mediated by a change in sequence of the 23S RNA (57). Antibiotic treatment options for mycoplasmosis are therefore limited due to their intrinsic resistance and the toxicity of some of the antibiotics that are effective. Treatment of mycoplasmosis often involves the use of antibiotics that inhibit DNA replication or protein synthesis, such as tetracyclines, fluoroquinolones, aminoglycosides, certain macrolides or ketolides, and under rare circumstances chloramphenicol. Mycoplasmal infections require long-term antimicrobial therapy, as short-term treatment often results in recurrence of the infection. This is speculated to be due to sequestration of a small number of bacteria in privileged sites, potentially including inside host cells (28).

Macrolides are the treatment of choice for human mycoplasmosis based on their effectiveness and their minimal side effect

profile relative to tetracyclines. Macrolides less readily penetrate the blood-brain barrier, however, making them suboptimal treatments for disseminated mycoplasmosis. Fluoroquinolones exhibit a bactericidal effect on Mycoplasma spp. (12, 58, 59). Fluoroquinolones were historically less widely used to treat human mycoplasmosis, but their use is becoming more common due to increasing levels of macrolide resistance in both *M. pneumoniae* and *M. genitalium*. Factors leading to macrolide resistance differ for the two organisms. *M. pneumoniae* resistance is being driven largely by over-the-counter availability in many part of the world, and the emergence of resistant strains tends to occur in these areas (60, 61). In contrast, the single-dose azithromycin treatment given at the point-of-care (POC) recommended by the United States Centers for Disease Control and Prevention as of 2010 to combat nongonococcal urethritis is effective against *C. trachomatis*, but is insufficient to resolve *M. genitalium* infection. This treatment thus contributes to antibiotic resistance by *M. genitalium* in patients who are presumptively treated for chlamydia (62). The newly available near-POC diagnostic tests for *M. genitalium* should be an effective counter-measure against this source of developed macrolide resistance. Human mycoplasmosis is also responsive to tetracyclines, but the use of doxycycline is now preferred only in treatment-refractory cases due to its side effect profile. Chloramphenicol is used rarely, and is only recommended for central nervous system infections in neonates that are unresponsive to other antibiotics (37).

Tetracyclines and macrolides are used commonly to treat animal mycoplasmoses, based on their low cost and the fact that resistance is not intrinsic (56). Preference for tylosin and o-tetracycline is standard due to their limited use in human disease. The use of fluoroquinolones in veterinary medicine is growing, although the threat of generating resistant, nonmycoplasma zoonotic agents may dictate against their use (63). Aminoglycosides, pleuromutilins, lincosamides, and phenicols are also occasionally employed in veterinary medicine. As with human medicine, increasing reports of antimicrobial resistance among livestock pathogens emphasize the need to employ nonchemotherapeutic disease control approaches to veterinary mycoplasmosis (discussed later) (56, 64–66).

Antibiotic use to control phytoplasmosis has been carefully examined and found to be largely ineffective. Treatment with tetracyclines, phenicols, and thiazolides fails to transiently or permanently resolve signs of infection (67, 68). Application of potentially antimicrobial plant oils such as rose oil, clove oil, and eucalyptus oil were also ineffective (68). However, some efficacy toward alleviation of disease has been reported following treatment with organic acids such as salicylic acid and gibberellic acid (69, 70).

Infection Control Measures

Human mycoplasmosis is typically spread via droplet aerosol or by sexual contact. Accordingly, measures to control transmission are consistent with other respiratory or sexually transmitted pathogens. Patients exhibiting signs of community-acquired pneumonia associated with *M. pneumoniae* or *Mycoplasma amphoriforme* in an outpatient setting should be masked upon entry to a clinical setting to prevent spread to other patients in common areas. Prevention of *M. genitalium* transmission can be achieved through barrier protection such as condoms (71). There are no vaccines available to protect against human mycoplasmosis.

Control of phytoplasmosis can be an extraordinary challenge, as treatment is largely ineffective and plants cannot be vaccinated. Because phytoplasmas are vector-borne pathogens, the strongest preventative measures involve pest control, with a particular focus on eliminating leafhoppers and psyllids. Addition disease prevention can be achieved through management practices such as surveillance, import control, and roughing of infected plants (69).

Control of veterinary mycoplasmas is approached by a combination of vaccination and ancillary animal husbandry measures. Universal hygiene measures that prevent the spread of infection (e.g., disinfection of ear tagging equipment, milking equipment, and shearing tools; restriction of immediate movement between isolated groups of animals by farm personnel; and pest control) can reduce the incidence of mycoplasmosis. Additional management practices such as all in/all out production, use of artificial insemination over external breeders, minimizing herd/flock sizes, earlier weaning, periodic or continuous antibiotic use, and maintaining appropriate air quality within production facilities have all been shown to have additional benefits toward the prevention of mycoplasmosis (65, 66, 72, 73).

Vaccination is the most promising approach to the control of mycoplasma infections in animals, and several experimental vaccines have been described (reviewed in reference [74]). A number of vaccines are commercially available for the protection of livestock and poultry against infection by Mycoplasma spp. (Table 34.5). No subunit or nucleic acid-based vaccines against mycoplasmosis have been approved for use as of this writing, and only a single recombinant vaccine against *M. gallisepticum* employing a fowlpox vector has been approved (Vectormune FP MG, Ceva). Bacterins are the simplest vaccines to produce, and although many Mycoplasma spp. are capable of antigenic variation, potentially lowering the efficacy of a bacterin, many are commercially available. All other licensed vaccines are live, attenuated strains, despite their potential for residual virulence or the threat of reversion to pathogenic capabilities.

Several vaccines have been described for mycoplasmoses of small and large ruminants. Sonicated *Mycoplasma capricolum* subsp. *capripneumoniae* adjuvanted with saponin dramatically reduced endemic CCPP in goat herds (75), and a similar bacterin composed of lyophilized *M. capricolum* subsp. *capripneumoniae* adjuvanted with saponin was both completely protective and stable at ambient temperature, an important factor in the design of vaccines for diseases prevalent in developing countries (76). Commercial bacterins are also available against *M. bovis* and *M. agalactiae*, though their success is somewhat equivocal. Live, attenuated vaccines are available for CBPP and contagious agalactia due to *M. agalactiae*. The vaccine strain T1/44 of *M. mycoides* subsp. *mycoides* was generated by serial passage *in ovo*. The attenuating mutations of this strain are not clear, despite its recent genome sequence (77). T1/44 appears moderately efficacious and is commonly used in *M. mycoides* subsp. *mycoides* (SC)-endemic regions, despite the common occurrence of injection-site reactions ("Willem's reaction" and/or subdermal abscess) (51, 54, 78). Outbreaks of CBPP occurring in vaccinated herds, as well as T1/44 challenge studies, suggest that residual pathogenicity exists (79, 80). The vaccine strain of

[a] *Abbreviations:* ND = not described; N/A = not applicable; KeVeVaPI = Kenya Veterinary Vaccine Production Institute; BVI = Botswana Vaccine Institute; PVCI = Pendik Veterinary Control Institute.

M. agalactiae, AIK40, was generated by serial passage *in vitro*. Though not widely used, AIK40 appears to protect vaccinated sheep and goats against arthritis and keratoconjunctivitis (74). It was not completely protective against agalactia, however, as mild mastitis was observed in some challenged dams (81).

Many inactivated vaccines are available for the swine pathogen *M. hyopneumoniae*. Despite this, porcine enzootic pneumonia continues to be problematic in many countries, calling the efficacy of these preparations into question. Multiple studies have demonstrated their poor immunogenicity, and their inability to prevent colonization with *M. hyopneumoniae* (66, 82). Given the difficulty of eradicating *M. hyopneumoniae* from production facilities once introduced, there is understandable hesitation to hastily adopt live, attenuated vaccines. One such vaccine, Mycoplasma Hyopneumoniae Live Vaccine (strain 168, Tianbang Bio-Industry Co) has been described and is being used with apparent success in China (83, 84).

Many vaccines are commercially available targeting avian mycoplasmosis due to *M. gallisepticum*. A single bacterin (MG-Bac, Zoetis) is available, and the lone vectored vaccine against a member of the genus (Vectormune FP MG, Ceva) also targets this organism. However, both MG-Bac and Vectormune FP MG fail to fully prevent respiratory lesions and impacts on egg production, respectively (85, 86). Numerous live, attenuated vaccines are also available against *M. gallipseticum*, and are almost exclusively composed of either strains ts-11, 6/85, or F. Though these vaccines are largely successful, balancing the stronger safety versus poorer efficacy of 6/85, as opposed to the high efficacy but higher potential for residual pathology of F, can be challenging. A single live, attenuated vaccine strain (MS-H) has been described as protective against avian mycoplasmosis due to *M. synoviae*. Vaccination with MS-H does not prevent colonization with *M. synoviae*, but it does protect against clinical signs and minimize horizontal transmission between infected animals (44, 87, 88).

Molecular Biology and Genetic Manipulation

Mollicute Genome Characteristics

With their small genome size and diverse range of specialized hosts, mollicutes constitute a unique model organism for studying comparative genomics, and as economically important human, animal, and plant pathogens, understanding their molecular mechanisms is important for controlling their virulence (14, 89). Mollicutes have undergone reductive evolution, shedding nonessential genes, leading to small, high-density genomes with a core pool of genes and few extrachromosomal elements. The use of operon systems has also helped reduce the number of gene regulatory regions, but despite the shortage of space many duplicated and repeating sequences, and various nonchromosomal elements can also be found in their genomes. The 0.5–2 Mbp circular dsDNA chromosomes have low GC content (35% average, the lowest at 25%), and low number of rRNAs relative to other bacteria (89, 90).

While mollicute evolution has been influenced by gene loss, there is also increasing evidence for episodes of expansion via horizontal gene transfer. Indeed, comparative genomic methods show large chromosomal exchanges, high genome plasticity, and mosaics of mobile genetic elements (MGEs). The noncore accessory genomes of mollicutes are mostly contained in insertion sequence (IS) elements, integrative conjugative elements (ICEs), and a few phages and some plasmids (mostly in the spiroplasmas, phytoplasmas, and ruminant pathogens) (91). Phytoplasmas also contain sequence-variable mosaics (SVMs, evolutionary remnants of phages and other MGEs), and potential mobile units (PMUs), putative conjugative transposons that contain genes for recombination, replication, transposases, and effector virulence proteins that increase in expression in insect vectors (92, 93). Some mollicutes also have CRISPR elements in their genomes, as well as CRISPR-like structures that are smaller and less conserved (89). Reductive evolution and gene decay results in formation of pseudogenes (genes with coding sequence loss or change >20%), but these are found more often in the mobilomes than in the core genomes which contain the essential genes (89).

Genome Plasticity

Mollicute genomes are dynamic and their plasticity is evident in the variety of genetic elements they contain. Horizontal gene transfers (HGT) between related species and strains create the mosaicism and heterogeneity that is important for evolving with host defenses, avoiding genome stagnation, and adapting to new hosts, niches, and environments. While relative to other bacteria mollicutes have fewer MGEs, knowing the impacts of the mobilome on physiology, adaptation, evolution, and virulence are of critical importance, especially among pathogens of interest (28). MGEs, including ICEs, IS, phages, plasmids, integrative mobilizable elements (IMEs), PMUs, and Tra islands are highly heterogeneous and often restricted to specific species (94).

Mollicute ICEs (described in greater detail below) are important elements for HGT, in that they provide the conjugation machinery necessary for genetic transfer between cells. IMEs, also known as Genomic Islands, encode excision and integration machinery and depend on ICEs for conjugative transfer (89, 91, 95). A few mycoplasma species have Tra islands (one to two copies per genome), containing coding sequences for proteins with transmembrane domains, as well as phage- and plasmid-related gene homologs, such as helicases, methylases, machinery for replication-initiation and plasmid partition, and ssDNA binding proteins (ssb). Tra islands also contain a copy of *IS3*, and some ICE genes such as *traE*. Tra islands represent integrative elements, and although they are distinct from ICE, they do contribute to genome mosaicism by differential integration and genome rearrangement (89, 96, 97).

Compared to other bacteria, plasmids are rare in mollicutes, and mostly found in ruminant- and plant-pathogens, such as spiroplasmas, phytoplasmas, and mycoplasmas of the *mycoides* clade (98–112). However, the plasmids in these genera are different, despite their shared niche in plants. Mollicute plasmids are smaller than those of other bacteria, with 1–25 coding sequences within the 1 kbp–35 kbp plasmids (113). Although many of the plasmids are cryptic, some affect the host phenotype by expression of adhesins for transmission, conjugation machinery similar to ICE, and ssb for stabilizing the plasmids during rolling circle replication (99, 100, 105, 109, 114, 115). Plasmids can also be dynamic and undergo rearrangements and recombinations, but they retain their sequences and architecture distinct from mollicute chromosomes (103, 115, 116). As in comparative genomics, plasmids from different species can be compared for overall sequence, gene orders, and coding sequence similarities for evidence of shared lineage and HGT.

As with plasmids, phages are mostly found in spiroplasmas and phytoplasmas, and can be both ssDNA or dsDNA, (+) or (–) stranded, linear or circular free-phage-plasmids, and chromosome-integrated with truncated coding sequences (89, 117). Some phages resemble IS sequences in that they can encode excisionases and integrases, disrupting genes and reorganizing genomes, potentially altering the mycoplasma's virulence, antigen expression, lipoprotein expression, or encode their own novel surface proteins (117–122). Phages, combined with other mobile elements, can drive the formation of phytoplasma SVMs, increasing the differences between related strains (94).

Integrative Conjugative Elements (ICEs)

Relative to other bacteria, there is a lower frequency of conjugal DNA transfers in mollicutes (90). However, those species capable of HGT have greater phenotypic variation, with increased options for potential genes that may increase fitness (and gene decay for those that do not) (91, 113). HGT is important for evolution, adaptation, and acquiring new traits. The highest levels of HGT occur in ruminant mollicutes, with comparative genomic evidence of ~18% HGT between *M. agalactiae* and the *mycoides* cluster (28). Evidence of HGT is often observed in phenotypic changes, such as resistance to antimicrobial agents or degradative enzymes (91). HGT and mosaicism in the pathogens make diagnostics and identification of serovars difficult and may influence gain or loss of virulence (123–126). There is little evidence of HGT between mollicutes and nonmollicutes. Some sequence similarities can be found in *M. mobile*, *M. arthriditis*, and *M. hominis* with Gram(+) and proteobacteria, but these are likely due to shared ancestry. In ureaplasmas and mycoplasmas, there is evidence of evolutionary acquisition of the SOS system's *ruvB* gene from Gram(-) bacteria

in the same operon as *ruvA* that was inherited from a Gram(+) ancestor (127). There is evidence of HGT in Spiroplasmas, especially *S. mirum* and *S. citri*, but their mechanisms are still not yet elucidated (91, 128, 129). Spiroplasmas do have homologs of *Tra* genes for conjugation, and viral components for transduction (109, 130–132). The viral sequences found in Spiroplasmas can also cause genome rearrangement and facilitate incorporation of novel fragments of DNA (92).

In mycoplasmas, ICEs (also referred to as MICE or conjugative transposons) are large (20–30 kbp), modular, self-transmissible families of genetic elements that contain the genes for excision of the ICE out of the chromosome, the proteins for formation of the conjugative channel, proteins for replication of the complementary strand in the donor and the recipient, and for integration into the chromosomes at random (89–91). This conjugative HGT requires one of the two cells to contain at least one ICE, and the process is cell-cell contact dependent. ICEs are mainly found in the hominis and spiroplasma groups, and ICE homologs are found in the pneumoniae and ureaplasma groups. Some mycoplasmas species do not have ICEs, such as *M. genitalium* and *M. pneumoniae* in the pneumoniae clade, and *M. synoviae* and *M. pulmonis* in the hominis clade. These species have relatively stable genomes, both over time and over geographic distribution (91, 133). ICE in the hominis group have lower GC% than the rest of their chromosomes, while ICE in the mycoides group have the same GC% as their chromosomes (89). The same ICEs can be found in distant mycoplasma species, also making them useful tools for comparative genomics (134, 135). Vestigial ICE that have been disrupted by other elements (e.g., IS or transposons) also exist in mollicute genomes, and are often degraded over time, with smaller footprints and decayed pseudogenes (91, 97, 135).

The trigger for activating chromosomal ICE excision and gene expression is yet unknown, but ICE are often silent and expressed at low frequency in most mycoplasmas (91, 136). Upon excision, the ICE becomes a circular ssDNA, and the copy that is transferred is then replicated in the recipient cell, as is the ssDNA copy that remained in the donor (89, 96, 123, 137, 138). Large chromosomal transfers often occur during ICE conjugation, and interestingly, as the ICE transfers from ICE(+) to ICE(–), the chromosome fragment transfers from the ICE(–) to the ICE(+), and they have equal frequencies of transfer (139). The DDE recombinases encoded by ICE integrate the element randomly into the genome, but the chromosome fragments transferred to the ICE-donor integrate via homologous recombination, displacing that region from the host's chromosome (96, 140).

The types of DDE recombinase and inverted repeats that help the excised ICE circularize are unique to the type (family) of ICE. Multiple ICE can be found in the same organism, with either multiple copies of the same ICE or two difference ICEs (91). Separate but distinct ICE types exist, corresponding to the type of mycoplasma, often even if they share the same niche in the same host (96, 97, 123, 136, 138, 141–145). It is difficult to experiment with ICE for HGT because in the lab ICE are activated less frequently and may require specific stressors or host factors that are not yet known. Mycoplasma chromosomes can have their own non-ICE associated conjugative elements, but all observed conjugative transfers have required either the donor or recipient to have at least one ICE (91).

Insertion sequences (IS) are small and simple mobile genetic elements within mollicute genomes, which can be transposed within a genome, replicated via vertical transfer or potentially transferred between two cells during HGT (146–148). IS elements encode transposases (sometimes multiple), and often contain pseudogenes that have undergone gene decay (89, 97, 149). IS element genetic structures are used to classify them into families, and their copy number patterns and locations in the genome are used to identify mycoplasma strains (97, 123–125, 150–152). IS elements can disrupt genes and cause gene rearrangements, carry out tandem duplications or inversions, and carry restriction-modification systems (126, 145, 150, 153–156). While some mycoplasma species can contain few or no IS elements, the IS elements in *M. mycoides* subs. *mycoides* strain PG1 occupy 13% of the genome (89, 97, 149, 157). Some IS elements can also carry with them virulence genes, but their own distribution, copy number, and integration sites can directly contribute to the mollicute genome plasticity and dynamics (126).

Antigenic Variation

Mollicutes rely on structures on their surface to mediate targeted or nonspecific binding and motility on environmental surfaces, especially molecules on host cells required for successful infection and survival. These adhesion structures can thus provide ideal targets for immune recognition and response. Antigenic variations of these surface molecules by mollicutes can expand the repertoire of host targets to which they can bind, and to help evade the host's immune response (158). Although immune evasion is critical for survival, antigenic variation is not the function of the surface molecules, and the consequence of the variation (the cell's phenotypic change) is what is observed when the protein is absent or not in its primary form (159). Continued stress from the host can make the change in the new form of the antigen permanent, creating resistance and a new instance of the chronic infection (160). Sometimes, the protein that undergoes variability is not the target antigen, but the one performing the role of masking (161). Successful antigenic variations can result in worsened susceptibility to the immune system for an individual cell, but greater fitness for survival in a different way, such as the ability to bind new substrates for escape, or evasion via biofilm formation (162–165). Survival of the antigenic switch usually means either the variable protein or antigen is temporarily dispensable, or the new alternative form is still functional enough (166). Some antigenic variations that results from genetic switches provide protection due to more system-wide effects, such as genome-wide modifiers, or global changes in translation as ribosomes are altered (167). One antigen variation target can, itself, have two or more genetic switches associated with it, and one genetic switch can have effects on two different antigenic variation targets, attesting to the complexity of strategies available to organisms with limited coding capacities (158, 168–170).

Antigenic variations are stochastic events, even in a clonal population, and as they occur randomly, the individuals with the most optimal variation survive and thrive (171). The frequency of the antigenic variation likely corresponds to the frequency of changes in the host environment and the urgency of the mollicute to adapt. Due to selection pressures, the antigenic variations rely on the genetic switches to be fairly high-frequency to provide

the right combination in time for evasion. As such, the genomic elements that provide switching must be less rigid, such as areas of rapid point mutations, slipped-strand mispairings, and DNA rearrangements. In addition to genetic switches, epigenetic and postgenetic (post-transcriptional or post-translational) variation strategies can also occur. The resulting variations can be phase variations, where the genes are turned on or off, domain variations, where the gene is still expressed but in a new form, and epitope masking, where the susceptible area of the protein is hidden from threat (172).

Genetic switches can involve the coding sequence of a gene, the promoter, or both. Some switches can be simple, such as point mutations, additions, or deletions, resulting from template or synthesis strand slippage, usually at hot spots where there are numerous short nucleotide repeats. Switches can be inversion recombinations, caused by site-specific recombinations that require small, conserved inverted repeats around a target, a recombinase enzyme, and the proximity of the recombinase gene to its target can affect the frequency of the switch. Switches can be homologous recombination events that require larger areas of sequence homology, and the resulting crossover exchanges can happen across greater distances in the genome. Switches can also affect larger swaths of the genome caused by excisions or duplication events. Switches that result in epitope masking occur in the gene of a partner protein of the actual target antigen (172).

Specific examples of these antigenic variation strategies undertaken by different mollicute species have been reported. Genes with point mutations or strand slippage resulting from nucleotide repeats are common. In the *vlp* gene of *M. hyorhinis*, *vmc* genes of *M. mycoides* subs. *mycoides* SC and *M. capricolum* subs. *capricolum*, *vlhA* gene of *M. gallisepticum*, and *maa2* gene of *M. arthritidis*, the promoters all contain different variations of polynucleotide repeats, where if a mutation changes the number of repeats, the promoter stops functioning and the genes are turned off (173–176). These simple mutations can be seen in the coding sequences as well, for example in the *vaa* gene of *M. hominis*, and the *gapA* gene of *M. gallisepticum*, wherein short repeat sequences cause frameshift or nonsense mutation that form truncated transcripts (177, 178). The *gapA* gene of *M. gallisepticum* is also part of an operon system, and the mutation also inhibits the expression of the downstream gene (*pvpA*) (169).

In the *vpma* cluster of *M. agalactiae*, six downstream genes in a locus share one promoter, and an area of the 5' region of each gene is subject to inversion by the xerI recombinase, determining which of those genes is acted upon by the promoter and turned on at any one time (179, 180). In the *vsa* cluster of *M. pulmonis*, only one gene out of many in the cluster are transcriptionally active, determined by repetitive domains in each copy, that are inverted by HvsR recombinase and made available to a 5' signal region and the promoter (181, 182). Inverted repeat recombinations also affect the *mpl* cluster of *M. penetrans* and the *vlhA* cluster of *M. synoviae*, where recombinase-mediated inversions in the promoter or coding sequence, respectively, cause phase variation by turning the genes off (120, 183, 184). The *mba* locus of *U. parvum* undergoes inversions that switch genes adjacent to a promoter to turn them on and off, and in the *mpl* clusters of *M. penetrans*, each gene's own promoter can invert to turn the gene on or off (120, 185).

Homologous recombinations occur across greater distances in the genome and require larger homologous sequences for crossing over events. The *mgp* genes of *M. genitalium*, containing three copies of a three-gene operon, with two of them inactivated by truncation, can undergo homologous recombination to turn on different gene clusters by filling in the gaps of the truncation (186–188). The *vsp* loci of *M. bovis* undergo intrachromosomal homologous recombination between different copies to create new chimeric genes (158). *MgPa/MgPar* regions of *M. genitalium* and *M. pneumoniae* also undergo homologous recombination to create new antigen domains (186–188). Some of the masking events that have been reported include the P56 protein of *M. hominis* being masked by the phase variable P120 protein, and the maa1 protein of *M. arthritidis* being masked by a phase- and size-variable maa2 protein (161, 174).

There are also examples of multiswitching strategies. In the *mba* locus of *U. parvum*, a two-switch control combines strand-slippage in a poly-nucleotide repeat in the promoter for phase variation, and regional inversion events that change the number of open reading frames of the coding sequence downstream, leading to size variation (185, 189). A four-switch strategy exists in the *vsp* cluster of *M. bovis*, including: an inversion in a 5' UTR cassette that changes ribosomal binding; an inversion in a second 5' UTR region that prohibits the promoter's activity; tandem repeats in the coding sequence that create size variants, and homologous recombinations between the different loci, creating new chimeric proteins (158, 168, 170, 190). Finally, an epigenetic strategy was reported in the *hsd* locus of *M. pulmonis*, where inversions in the coding sequence of a methyltransferase enzyme in one of the restriction-modification system changes the DNA sequence affinity of the enzyme's binding site, potentially changing the global methylation landscape (167).

The functions of most of the antigens may be adhesion, but the larger consequence of their variation can be much more dynamic, such as growth alterations, quorum sensing, biofilm formation, or heme adsorption. It is also important to remember that the experimental laboratory environment has its own environmental pressures on mollicutes. Within the same population, there can be differences in metabolic conditions for growth, fitness advantages, regional differences in toxicity, population pressures, or nutrition pressures, all of which can influence antigenic variation (172).

Molecular Toolbox for Mollicutes

It is challenging to study mollicutes because many are difficult to cultivate, and sequence assemblies are complicated by the genomes' repeats and duplications. Endogenous restriction-modification systems often obstruct plasmids, phages, and other gene transfers, complicating the genetic manipulation of mycoplasmas. There are also a limited number of naturally occurring plasmids in mollicutes, complicating efforts to design vectors that can successfully and stably transform multiple species. Analysis of mollicute genes as clones in other model organisms (e.g., *E. coli*) is also hampered by the altered usage of the UGA codon for encoding tryptophan (all mollicutes except phytoplasmas and acholeplasmas), whereas otherwise UGA would be interpreted as a universal stop codon (89, 102, 135). Mollicutes have also lost their mismatch repair mechanisms, further complicating

attempts at molecular manipulation (90, 191). The use of antibiotic selection markers in mollicutes is also difficult due to the lack of a cell wall, limiting the options of both antibiotics and resistance marker genes. Nevertheless, a variety of genetic manipulation tools and methods have been developed to study mollicutes. For example, the UGA codon usage problem can be resolved by genetic construct synthesis or site-directed mutagenesis of the cloned gene, converting each instance of UGA to UGG (192, 193). The restriction-modification roadblock, too, can potentially be resolved, either by inactivation of the existing enzymes (if there are only a few), or by *in vitro* methylation of the introduced DNA to prevent restriction enzyme degradation (194). New plasmids and transposons are also being made for better targeting and replication of various mollicute species. Next-generation sequencing methods have also improved the understanding of mollicute genomes. This includes the potential for discovering novel extrachromosomal elements, better understanding of evolutionary and phenotypic traits, designing novel genetic tools corresponding to the right parts for the right species, and uncovering the pathogenic mechanisms for better molecular targeting.

An emerging useful tool in genetic manipulation of mollicutes has been yeast (194, 195). Many studies have used yeast (usually *Saccharomyces cerevisiae*) to replicate mollicute genomes, and this mechanism was indispensable for the generation of the multiple iterations of the synthetic mycoplasmas developed at the J. Craig Venter Institute (discussed in the next section). Expansion of synthetic and naturally occurring mycoplasma genomes has also facilitated the application of other molecular tools, such as cloning in *Cre/LoxP* cassettes, and manipulations of genes using the CRISPR-Cas system (196, 197).

The use of transposons to directly manipulate mollicutes has seen great improvement and yielded great results. The Tn916 conjugative transposon is a large transposon with site-specific conjugative properties, capable of being used as a delivery vector. Tn916 can be delivered using electroporation, polyethylene glycol, or transformation with the pAM120 plasmid (198–200). Tn916 also naturally encodes a *tetM* gene for tetracycline resistance. Another widely used transposon is Tn4001, often used to randomly transpose into mycoplasmas, creating mutant libraries for phenotypic analysis of interrupted genes. Modified versions of Tn4001 have improved upon its transformation efficiencies, and engineering in restriction sites to expand its function for gene delivery (201). Minitransposons have also been used as delivery vehicles, with the caveat that their transposase genes are outside of the transposable element, and excision from the primary site occurs only once (202–204).

Despite the lack of a cell wall, there are antibiotics to which mollicutes are sensitive, and for which resistance and selection options exist. As mentioned before, mollicutes are sensitive to tetracycline, and the Tn916 *tetM* gene confers resistance, with the added benefit that, as mollicutes are often intracellular microbes, tetracycline can penetrate eukaryotic membranes for *in vivo* experimentation (196, 205). Erythromycin resistance can be conferred via the *pAMb1* gene, chloramphenicol resistance via the *cat* gene (chloramphenicol acyltransferase from *E-coli* Tn9), puromycin resistance via *pac* (puromycin n-acetyl transferase), and gentamycin/tobramycin/kanamycin resistance via *aacA-aphD* (part of Tn4001). Resistance to fluoroquinolones can be generated by targeted mutations of the endogenous gyrase and topoisomerase genes, on the sites bound by the antibiotic (56).

Albeit transformation of mollicutes with plasmids has not been very stable or successful, improvements have been made in plasmids to increase efficiency. As new, naturally occurring plasmids are discovered, some have been found to be capable of acting as expression vectors in other species, such as pMyBK1, derived from *M. yeatsii*, capable of expressing in mycoplasmas of the *mycoides* cluster (206). Similarly, pKMK1 obtained from *M. mycoides* has successfully transformed *M. mycoides* subs. *capri*, and *M. capricolum* (207, 208). The efficiency of suicide plasmids in allele exchange via double crossover events have significantly improved by inclusion of the *recA* (recombinase) gene in the plasmid (209). Some of the best improvements in plasmid use in mollicutes have been seen in oriC plasmids. Extrachromosomal replication and stability of oriC plasmids had been a problem, and genomic integration of oriC improved its stability and expression. The oriC plasmid has been further improved by incorporation of DNA replication boxes from different species of mycoplasmas around the actual oriC site in the plasmid, making it extrachromosomally stable and replication competent when transformed into the mycoplasma with the homologous DNA box. OriC plasmids had also previously been used to transform spiroplasmas (with very few crossover events), but it is not known if the stability and efficiency of oriC can be improved by the use of cloning in natural spiroplasma plasmid DNA boxes into the oriC site, as was seen with mycoplasmas (209). However, some spiroplasmas naturally have multiple small extrachromosomal plasmids, each with a different replication region, and naturally occurring spiroplasma plasmids have been successfully used to transform other spiroplasma species that are resistant to artificial plasmids and oriC (109, 113).

Reporter transposons and plasmids have also been developed to determine the functions and activity of regulatory and promoter regions of mollicute genes, often using the *lacZ* gene as the reporter (211–213). While mutagenesis and gene knockout experiments can identify essential genes and phenotypes, the inability to positively regulate gene expression in mollicutes has been a roadblock. However, new plasmids and combination regulatory strategies have helped push these boundaries. One strategy combined the expression of the Cre enzyme, under the control of the tetracycline repressor promoter (*tetR*), regulating Cre expression (and targeting of desired *LoxP* targets in *M. genitalium*) via application of tetracycline (197). A newer inducible mechanism has utilized a CRISPR-Cas-mediated interference strategy for repression of endogenous gene expression in *M. pneumoniae* and *M. mycoides*. Once again, under the control of a tetracycline (*tetON*) promoter, a nuclease-defective Cas9 protein is guided to the gene of interest, tuneably suppressing its transcription (196).

Synthetic Biology

Mollicutes, as the smallest free-living organisms, are inherently good subjects for genome science. In 1995, owing to its size, the genome of *M. genitalium* was fully sequenced by J. Craig Venter's genome research group, uncovering 470 genes in the 580 kbp genome. In pursuit of identifying the minimal cell and the minimal essential genome, targeted deletions of the

470 genes helped identify ~100 genes that could be inactivated while maintaining life, leaving 350–400 genes (in this model) as the minimal essential genome.

To manufacture their own *M. genitalium* minimal essential genome, Venter's group designed a cassette-based artificial chromosome and took a strategy of iterative deletions of the nonessential genes. In 2008, his group chemically synthesized, ligated, and assembled a 583 kbp artificial version of *M. genitalium* G37 in yeast, with the addition of incorporated genetic barcodes for validation. This organism was dubbed JCVI 1.0 (214). Having proven the concept, and due to the slow rate of growth of *M. genitalium*, Venter's group switched to using the faster-growing *M. mycoides* subsp. *capri*, and in 2010, they chemically synthesized its 1.08 Mbp genome starting only with a digital sequence, assembling it as before in yeast, with a genetic barcode, protected it from restriction enzymes by methylation, and transplanted the *M. mycoides* subsp. *capri* genome into *M. capricolum* subsp. *capricolum* cells to prove the ability of this synthetic genome to maintain life (215). This organism was dubbed JCVI Syn1.0. Using transposon-mutagenesis methods, Venter's group subsequently identified essential gene pairs and essential genome regulatory regions, and further minimized the essential genome from JCVI Syn1.0 down to 531 kbp and 473 genes, capable of maintaining free-living and reproductive life as long as all of its nutrients were provided. This organism was dubbed JCVI Syn3.0 (216).

Although it is much easier to edit the genomes of existing organisms rather than synthesizing them *de-novo*, going forward, synthetic biology can serve many purposes, including genome recording and preservation, testing novel synthetic amino acids, creation of synthetic cells for industrial products and services, biodefense, production of medicines, electronics, biofuels, biomaterials, as well as creation of organisms for bioremediation, and biosensing and reporting (217, 218). As synthetic biology advances and new tools are developed, the possibilities are only limited by the imagination.

Taxonomy

The family of *Neisseriaceae* as defined by *Bergey's Manual of Systematic Bacteriology* consists of two separate rRNA super families that are not related. The true *Neisseriaceae* and two *Kingella* ssp. belong to the β-subclass of Proteobacteria, while false *Neisseria*, *Moraxella*, *Branhamella*, and the *Acinetobacter* genera belong to the γ-subclass of the Proteobacteria, which have been removed from the family of *Neisseriaceae*. In addition, genetic studies have shown that *Eikenella*, *Simonsiella*, *Alyseilla* EF-4a, EF-4b, M-5, and M-6 (CDC groups) are related to the true Neisseriaceae and two *Kinegella* ssp. The present classification of the family of Neisseriaceae contains *Neisseria*, *Kingella*, *Eikenella*, *Simonsiella*, *Alyseilla* EF-4a, EF-4b, M-5, and M-6 (1, 2). This chapter will only discuss *Neisseria gonorrhoeae* and *Neisseria meningitidis* because of their pathogenicity in humans. Species of the genus *Neisseria* found in humans and animals inhabiting mucous membranes are listed in Table 35.1 (3).

The *Neisseria* are Gram-negative diplococci, with adjacent sides that are flattened, giving the organisms a "coffee-bean" appearance. These organisms are aerobic, nonmotile, grow best in an atmosphere of 5–10% CO_2, produce cytochrome oxidase, and do not form spores. Acid from carbohydrates, nitrate reduction, polysaccharide from sucrose, presence of deoxyribonuclease (DNase), superoxol (30% hydrogen peroxide), pigment production, and the resistance to Colistin (10 µg) are used to differentiate the species (Table 35.2). Nongrowth-dependent rapid carbohydrate tests are available for the detection of acid production from carbohydrates for the speciation of *Neisseria* (3, 4).

Neisseria gonorrhoeae

N. gonorrhoeae (the gonococcus) is the causative agent of gonorrhea, a sexually transmitted infection, and for several other conditions that are sequelae to the infection. The organism infects only humans, and transmission is almost always by person-to-person contact. It is the second most commonly reported bacteria causing an infectious disease.

Microscopically, the organism is indistinguishable from other *Neisseria,* but, *N. gonorrhoeae* is the most fastidious in its growth requirements. The gonococcus requires the amino acid cysteine and a usable energy source (i.e., glucose, pyruvate, or lactose), and does not grow on blood agar. It will grow on supplemented chocolate agar. *N. gonorrhoeae* ferments glucose but not maltose, fructose, or sucrose.

Laboratory Diagnosis

Diagnosis of gonococcal infection can be made at two levels, presumptive and confirmed. The isolation of the organism and the diagnosis of the infection must be reported to the local public health authorities. There are serious medicolegal consequences for misdiagnosing gonorrhea or misidentifying *N. gonorrhoeae.*

Gram stain showing Gram-negative intracellular microorganisms is presumptive for the diagnosis of gonorrhea. This test has a sensitivity of 50–70% and generally used for symptomatic males. For symptomatic females, an endocervical smear has 40–60% sensitivity and its use discouraged. A definitive diagnosis for females must be made by the recovery of *N. gonorrhoeae* in culture from an endocervical specimen or by detection using a nucleic acid amplification procedure.

TABLE 35.1

Host Range of *Neisseria* Species in Humans and Animals

Humans	**Species**
Urogenital tract	*N. gonorrhoeae, N. meningitidis*
Oropharynx	*N. meningitidis, N. lactamica, N. cinerea, N. flavescens, N. subflava, N. sicca, N. mucosa, N. elongate, N. polysaccharea*
Animals	
Oropharynx	
Cat	*N. canis*
Dog	*N. weaveri*
Guinea pig	*N. denitrificans and N. caviae*
Iguana	*N. iguanae*
Rabbit	*N. cuniculi*
Monkey	*N. macacae*
Sheep and cattle	*N. ovis*

Source: Modified from *Identification of N. gonorrhoeae and Related Species*, Centers for Disease Control and Prevention, Sexually Transmitted Disease, Atlanta, GA, 2004.

The Gram stain has low predictive value and is not useful for the asymptomatic female (1, 2, 5).

The site of specimen collection depends on the gender and the patient's sexual practices. Sites for obtaining specimens include urethra, endocervix, rectum, oropharynx, joint fluid, blood, skin lesions, and conjunctiva, depending on the clinical impression. The gonococcus is the most sensitive of the *Neisseria* species to adverse conditions, such as drying and extremes in temperature (4).

The correct transportation of the specimen is very important in maintaining the viability of the gonococcus for definitive identification. The specimen must be collected with a Dacron or rayon swab that must be transported in Stuart's or Amies buffered semisolid transport media at room temperature. The specimen can also be inoculated directly onto culture medium immediately after collection. Culture media, such as Martin-Lewis, Thayer-Martin, and New York City medium in JEMBEC plates, can be used to transport the specimens (2). The medium, at room temperature, is inoculated and the CO_2-generating tablet is placed in the area provided. The inoculated agar is placed in a zip lock plastic bag and sent to the laboratory at room temperature. Upon receipt, the inoculated plate is placed in the incubator at 35–37°C with 3–5% CO_2.

Specimens submitted on swabs must be inoculated on an appropriate medium within 24 hours of collection. Specimens collected from sites with normal bacteria flora must be inoculated on a selection medium such as Thayer-Martin, Martin-Lewis, or New York City agar. Chocolate agar medium is used for specimens from normally sterile body sites. Inoculated media must be incubated in the atmosphere or 3–5% CO_2 at 35–37°C and examined every 24 hours for 72 hours. A higher concentration of CO_2 can inhibit the growth of some strains (2).

The colonies of *N. gonorrhoeae* are about 0.5 mm in diameter, glistening, and raised. A pinkish brown pigment is visible when sweeping the colonies with a cotton swab. For definitive identification, the organism must be Gram-negative diplococci, oxidase-positive, and ferment glucose, but not maltose, lactose, sucrose, or fructose. The test systems RapID™ NH System (Remel), API NH (bioMérieux) and Vitek 2 (bioMérieux) NHI

have replaced the slower carbohydrate tests. Definitive identification can also be made with direct fluorescent monoclonal antibodies, coagulation (Phadebact Monoclonal GC) and colorimetric test (GonoGen II).

Matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF MS) is being used by numerous laboratories because it is fast and gives accurate identification for clinically significant organisms. There is limited data on the accuracy of MALDI-TOF MS for the identification of *Neisseria* species (6).

Specimens from patients suspected of sexual abuse must be collected from the site of abuse for the recovery and definitive identification of *N. gonorrhoeae*. The identification of *N. gonorrhoeae* recovered from specimens in sexual abuse cases should be determined by at least two methods. The antimicrobial sensitivity pattern of the isolates from the alleged abuser and the patient are valuable in linking the isolate recovered from the victim and the alleged offender.

Nucleic acid amplification tests (NAAT) have a greater sensitivity than culture and almost the same specificity for the detection of *N. gonorrhoeae*. The specimens for the NAAT include urine (preferable for males), endocervical, urethral, self-collected vaginal, rectal, and pharyngeal specimens. Vaginal swabs have a greater sensitivity than endocervical swabs that are more sensitive than urine specimens. All FDA-approved NAAT for *N. gonorrhoeae* also include the target for *Chlamydia trachomatis* since infections with each of these organisms have similar clinical presentations. The advantages of the NAAT are longer specimen stability after collection, decreased turnaround time for results, and greater sensitivity than culture. Each of the NAAT has a unique system for the specimen transport and, except for the liquid Pap medium, they are not interchangeable. See Table 35.3 for a list of current FDA-approved NAAT with the specimen types (7).

There have been reports of cross-reactivity with genital saprophytic *Neisseria* species resulting in false NAAT-positive results. The Centers for Disease Control and Prevention (CDC) issued guidelines for NAAT when the positive predictive value is <90%. Repeat testing for positives specimens should be performed using a test that does not detect commensal *Neisseria* species. The limitations of NAAT include the high cost and the inability for antibiotic testing to monitor for resistance (7).

Because NAATs are significantly more sensitive with specificity almost equal to culture, they are recommended for rape and sexual abuse cases. Positive results should be confirmed by another method (7).

Gonococcal Disease

In the United States, gonorrhea is the second most commonly reported notifiable infection. There are 820,000 new gonococcal infections occurring each year based on the CDC estimates. The rate of reported gonorrhea cases increased 18.6% during 2016–2017, a 75.2% increased since the historic low in 2009 (3).

Acute anterior urethritis is the most common manifestation of gonorrhea. This usually appears in 90% of males 2–8 days after exposure and is manifested by a purulent discharge. Acute epididymitis is the most common local complication of the infection. In females, the endocervix is the primary site of infection. Urethral infection and infection of the Bartholin's glands are seen in women who have gonococcal cervicitis. Ascending infection occurs in 10–20% of females with a gonococcal infection. Asymptomatic infection can lead to pelvic inflammatory disease (PID), which can result in obstruction of the fallopian tubes and resulting sterility. Gonorrhea in women can facilitate the transmission of human immunodeficiency virus (HIV) (1, 8).

Manifestation of disseminated gonococcal disease in males and females includes dermatitis, arthritis-tenosynovitis syndrome, monoarticular septic arthritis, perihepatitis, endocarditis, and meningitis. Ophthalmia neonatorum, a disease of newborns, is prevented by prophylactic instilling in the eyes of the infant a solution of penicillin or silver nitrate immediately after birth.

Sulfonamides were used successful in the treatment of gonorrhea. During World War II, strains of *N. gonorrhoeae* resistant to sulfonamides appeared. Later, penicillin became the drug of choice; but with the acquisition of plasmid-mediated resistance, this treatment is now ineffective (9).

The CDC issued guidelines for treatment in 2015. For patients with uncomplicated genital, rectal, or pharyngeal gonorrhea, the CDC now recommends combination therapy with ceftriaxone, 250 mg as a single intramuscular dose, plus either azithromycin, 1 gram orally in a single dose, or doxycycline, 100 mg orally twice daily for 7 days. If ceftriaxone is not available, CDC recommends cefixime, 400 mg orally, plus either azithromycin, 1 gram orally, or doxycycline, 100 mg orally twice daily for 7 days. For patients with a severe allergy to cephalosporins, the recommendation is a single 2 g dose of azithromycin orally. In both circumstances, when ceftriaxone is not used, CDC recommends a test of cure for these patients one week after treatment. This is an important change in the treatment guidelines. Clinicians are encouraged to be vigilant for cephalosporin resistance (10). If a patient fails treatment with CDC recommended therapy, the clinician should collect a specimen for culture and sensitivity, re-treat the patient,

TABLE 35.3

Nucleic Acid Amplification Tests

Manufacturer		Instrumentation	Specimen
Roche Cobas® CT/NG	Roche Molecular Systems	Cobas 6800/8800	Vaginal (clinician or self-collected), urine in males only

Cepheid	Xpert CT/NG	GeneXpert®	Endocervix, vaginal (clinician or self-collected), urethra, urine, rectal, and pharynx

ensure the patient's recent partners are treated, and notify CDC through the local STD program within 24 hours (8).

To date, there are no documented treatment failures in the United States. However, Morbidity and Mortality Weekly Reports (MMWR), show that there are a number of international reports of cefixime treatment failures, and the bacteria's history of becoming resistant to antibiotics used for treatment, points to the increasing likelihood that gonococcal cephalosporin resistance and treatment failures are on the horizon in the United States. Refer to the current edition of Clinical Laboratory Standards Institute (CLSI) M100 Performance Standards for Antimicrobial Susceptibility for the recommended antimicrobials to be tested by the Bauer-Kirby method.

Test of cure is not recommended for individuals who receive the recommended therapeutic regimen. Culture for the recovery of *N. gonorrhoeae* should be performed if symptoms persist after therapy with an established regimen and antimicrobial susceptibility performed for the recovered N. gonorrhoeae isolate.

Neisseria meningitidis

Colonies of this species grow to be 1 mm in diameter after 18–24 hours of incubation and are usually gray and mucoid on primary isolation media. The organism grows very well on sheep blood or chocolate agar at 35–37°C and is enhanced by incubation in an atmosphere of 3–5% CO_2. Identification can be made by observing acid production from glucose and maltose, but not from sucrose, fructose, or lactose. The RapID NH System (Remel) and API NH (bioMérieux) have replaced the individual carbohydrate substrates (5, 3).

N. meningitidis is separated into 13 serologic groups (A, B, C, D, H, I, K, L, X, Y, Z, W135, and 29E) based on capsular polysaccharide. Encapsulated cells of freshly isolated organisms demonstrate the quellung reaction when mixed with homologous antiserum. Serogroups A, B, and C are usually isolated from epidemic and endemic cases (1, 11).

The pathogenicity of meningococcus is linked to a potent endotoxin, which comprises approximately 50% of the outer membrane of the organism. The endotoxin has been characterized as a lipooligosaccharide because it lacks the multiple repeating sugars of a lipopolysaccharide. The endotoxin has been implicated as the cause of septic shock seen in patients with meningococcemia (12).

Meningococcal Disease

Humans are the only natural host for *N. meningitidis*, and the disease is maintained and spread by carriers harboring the organism in their nasopharynx and pharynx. Infection commonly results from asymptomatic nasopharyngeal carriage. There is a 10–20% carriage rate in the population at any given time. The organism evades the immune system and enters the bloodstream to cause disease. Diseases caused by *N. meningitidis* include meningoencephalitis, meningitis with or without meningococcemia, meningococcemia without meningitis, and bacteremia without complications. Hematogenous spread of the organism can lead to endocarditis, pericarditis, arthritis, endophthalmitis, osteomyelitis, and peritonitis. Risk factors of meningococcal disease include individuals with complement or properdin component deficiencies, hepatic failure, systemic lupus erythematous, multiple myeloma, and asplenia. Meningococci have been implicated as the etiological agent of approximately 2–4% of community-acquired pneumonia. Pharyngitis is associated with recent contact with carriers of *N. meningitidis* and can be a prior symptom and sign of serious disease (1).

Laboratory Diagnosis

For the diagnosis of meningococcal disease, the organism should be isolated from cerebrospinal fluid (CSF), blood, or aspirates of petechiae. Synovial fluid, sputum, conjunctival and nasopharyngeal swabs should be obtained when clinically indicated. These specimens must be inoculated onto blood and chocolate media as quickly as possible. Gram-stained smears showing Gram-negative diplococci of CSF, aspirates, and other fluids can give the presumptive diagnosis. Latex agglutination and coagglutination tests are direct antigen tests to detect meningococcal capsular polysaccharide in CSF, urine, and serum, but have fallen into disuse (1, 2).

The significance of the recovery of *N. meningitidis* from rectal and genital specimens is unknown. The recovery of this organism from pharyngeal specimen identifies the individual as a carrier. Prophylaxis is considered during outbreaks of meningococcal disease.

Chemotherapy and Prophylaxis

With the introduction of sulfonamides, chemotherapy was the main method of treating meningococcal disease. The appearance of resistance to this agent in 1963, however, has made this treatment ineffective. Benzyl penicillin is the preferred agent for treatment of meningococcal meningitis as long as the strain does not produce β-lactamase with cefotaxime and ceftriaxone also being effective alternate agents.

Vaccines have been successful in reducing the incidence of disease in the military, containing epidemics and in individuals with complement disease. This protection is not long-lasting. Vaccines against *N. meningitidis* were available in the United States since 1981. Meningococcal polysaccharide vaccine (MPSV4 or Menomune®) and meningococcal conjugate vaccine (MCV4 or MenactraT) prevent four types of meningococcal disease. These vaccines prevent disease caused by two of the three most common serotypes in the United States (serogroups C, Y, and W-135) and serotype A that causes epidemics in Africa. Vaccines against serotype B were introduced in 2018. Meningococcal vaccines cannot prevent all types of the disease, but they can protect many people who might become sick if they do not receive the vaccine (12).

Meningitis due to *N. meningitidis* must be reported to state and/or local health departments to assure follow-up of close contacts and recognize outbreaks.

Laboratory Safety

N. meningitidis is now classified as a biosafety level 2 organism, which requires that all manipulations of specimens

suspected of containing this organism, and meningococcal culture, be conducted in a biological safety cabinet. It is recommended that laboratory personnel be offered the meningococcal vaccine. The vaccine will not decrease the risk of infection but can reduce the potential risk of laboratory-acquired disease (2).

Other *Neisseria* Species

The other *Neisseria* species listed in Table 35.1 are members of the microbiota of the pharyngeal and female urogenital tracts and are rarely associated with disease. *N. cinerea*, *N. elongate*, *N. flavescens*, *N. mucosa*, *N. sicca*, and *N. subflava* have been reported as the causative agents of endocarditis. *Neisseria lactamica*, *N. polysaccharea*, and *N. subflava* have been reported to be the etiological agent for septicemia and meningitidis.

Introduction

Members of the Gram-negative bacterial genus *Pseudomonas* are ubiquitous in soil and water ecosystems [1]. Their genetic flexibility, versatility in optimizing the usage of a vast array of organic and inorganic compounds, and innate capability to survive under diverse, often trying, environmental conditions are the key factors behind their successful inhabitation of most environmental niches found on our planet [2]. From the point of view of humankind, this genus is intriguing indeed. On the one hand, the ability of *Pseudomonas* to produce an arsenal of degradative factors makes it one of the most feared pathogens of plants and animals [3, 4]. On the other hand, this same feature, combined with biochemical proficiency for metabolizing toxic hydrocarbons and other compounds, have rendered it one of the most prized organisms for bioremediation of recalcitrant wastes [5–7]. This chapter briefly describes the current taxonomical position and general features of *Pseudomonas*. This discussion is followed by a section describing some of the prominent members of this genus, and their respective roles in pathogenesis, bioremediation, and plant symbiosis.

Taxonomy

Pseudomonas is part of the bacterial family *Pseudomonadaceae*, which is also composed of *Azotobacter*, *Azomonas*, *Cellvibrio*, and *Azorhizophilus*, among others [2]. *Pseudomonadaceae*

are commonly characterized as chemoorganotrophic, aerobic, and incapable of photosynthesis. There are also able to survive under a myriad of nutritional environments [8]. Classification and taxonomy of this genus has undergone numerous transitions since its inclusion in the first edition of *Bergey's Manual of Determinative Bacteriology* in 1923 [9]. Specifically, numerous species that were once classified in *Pseudomonas* are now recognized as distinct genera, through advances in molecular techniques. While the common methods of taxonomical organization of the *Pseudomonas* genus include cell morphology, pigment types, nutritional behaviors, and genetic organization, the widespread phenotypic characteristics mostly studied are carbon utilization patterns, antibiotic resistance, and antibiotic and amino acid synthesis [10].

There are currently more than 100 species in the genus *Pseudomonas* [11], and 13 species (and numerous strains thereof) are sequenced and annotated. Table 36.1 describes the various approaches used in the current era for *Pseudomonas* taxonomic studies. While the benefits of chemotaxonomic studies have been widely published [12, 13], gene sequencing and nucleic acid fingerprinting hold the greatest promise for solving *Pseudomonas* taxonomic issues [11]. In the past decade, clinical isolate identification has primarily been achieved based on protein analysis using matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF MS) [11]. Inclusion of new species in the genus *Pseudomonas* requires 16S rRNA sequencing, DNA-DNA hybridization, phenotypic analysis, fatty acid characterization, and multilocus sequencing analysis [11].

TABLE 36.1

Current Methods Used in *Pseudomonas* Classification

Approach	Illustrative Citation(s)	Comments/Description
Chemotaxonomic		
Whole fatty acid analysis	[256]	Has been used to examine the taxonomic position of certain *P. marginalis* strains included under the *P. fluorescens* group
SDS-PAGE profiling	[257]	Fingerprinting *Pseudomonas* strains (isolates from disparate phylogenetic groups) at the species level
Siderotyping and pyoverdine analysis	[20]	Involves isoelectrophoretic characterization of siderophores and often species-specific pyoverdines; mass spectrometry has greatly enhanced this approach
Use of stable low–molecular-weight RNA	[258, 259]	5S rRNA and tRNA are studied; staircase electrophoresis [260] has improved this technique
Fluorescent spectroscopy fingerprinting	[261]	Emission spectral analysis of intrinsic fluorophores like NADH, tryptophan
Matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF MS)	[262]	A type of bacterial fingerprinting that uses mass spectrometry to analyze protein composition.
Gene Sequencing Studies		
16S rRNA sequencing	[10, 263]	16S rRNA is widely used to determine phylogenetic relationships between organisms
Housekeeping genes as phylogenetic markers	[264]	Phylogenetic resolution of this method (using *rpoB* for instance) is often much more than can be obtained using 16S rRNA [265]
16S-23S rRNA intergenic spacer (ITS) marker	[266]	ITS has high sequence and size variability, and has phylogenetic resolution high enough to differentiate bacteria even at the strain level; the productivity of this method has been reported for *Pseudomonas* classification [267]

The Life of *Pseudomonas*

Cellular Characteristics

Pseudomonas species are Gram-negative, catalase positive, and either oxidase positive or negative, depending on the species. They are slightly curved or linear rod-shaped cells, having a maximum length of approximately 4 µm. *Pseudomonas* species sometimes exist as single cells and occasionally in pairs, or even short chains [2]. They are often motile via polar flagella, although lateral flagella are occasionally found, usually associated with swarming [2, 14, 15]. The flagellar number is decided by FleN, a putative ATP-GTP binding protein [2, 16].

Pili are also commonly reported and are particularly studied for their role in pathogenesis of clinically relevant species such as *P. aeruginosa* [17]; nevertheless, other typical nonpathogenic *Pseudomonas* species like *P. fluorescens* also possess pili [18]. Intriguingly, low G + C content of pilin genes, in relation to the higher average chromosomal G + C, indicates horizontal acquisition by *Pseudomonas* species [19].

There are several colored pigments produced by *Pseudomonas* species. For instance, under limiting iron conditions, some *Pseudomonas* species produce pigments that fluoresce under UV light, and these pigments facilitate bacterial iron uptake [20]. Others are nonfluorescent and participate in other processes. Common pigments characteristic of *Pseudomonas* are listed in Table 36.2.

Intracellularly, *Pseudomonas* species form inclusion bodies of various substances. For instance, under nitrogen deficient

TABLE 36.2

Common Pigments in *Pseudomonas*

Pigment	Bacterial Strain	Color
Pyoverdine	*Pseudomonas sp.*	Yellow-green, fluorescent
Pyocyanin	*P. aeruginosa*	Blue
Pyorubin	*P. aeruginosa*	Red
Oxychlororaphin	*P. aureofaciens*	Orange
Chlororaphin	*P. chlororaphis*	Green
Oxychlororaphin	*P. chlororaphis*	Orange

conditions, *Pseudomonas* accumulates poly-β-hydroxybutyrate (PHB) granules. When growing on gluconate or alkanes, *Pseudomonas* assembles polyhydroxyalkanoates.

Physiology and Metabolism

As mentioned, *Pseudomonas* exhibits great metabolic plasticity [2, 21], and extensive analysis has been performed to elucidate *Pseudomonas* metabolism [2, 22, 23]. The TCA cycle exists in all species of *Pseudomonas* and it is important for metabolism. The Entner-Doudoroff glycolytic pathway often prevails over the Embden-Meyerhof pathway due to the lack of 6-phosphofructokinase in many species. The pentose phosphate pathway, the glyoxylate shunt, and other important metabolic pathways, are also widespread in this genus.

Catabolite repression is also reported in *Pseudomonas* [24, 25], which allows *Pseudomonas* to utilize a medley of available carbon sources in a preferential and orderly manner [26, 27]. Organic and amino acids are preferred to glucose [28], followed by mannitol and histidine. Crc and other signal transduction proteins facilitate catabolite repression [29–32]. Intriguingly, in some cases, like during repression of phenol metabolism in *P. putida* [33], cells can mediate catabolite repression by discerning the redox state of respiratory chains.

Pseudomonas has a propensity to use amino acids as carbon and nitrogen sources. Specific membrane permeases translocate amino acids available in the environment into the cell cytoplasm [34]. The ability to use amino acids as nutrients poses a great advantage to *Pseudomonas*, because it can readily assimilate amino acids into the cell biomass with minimal processing. Alternatively, additional catabolic activity can funnel amino acids into central metabolism. Amongst amino acids, arginine metabolism, especially, is key in *Pseudomonas* biochemistry, with several catabolic pathways identified for breaking down this substrate [35, 36]. In *P. aeruginosa*, for instance, numerous arginine-responsive genes are controlled by the arginine regulatory protein ArgR [37].

Analysis of amino acid metabolism in *Pseudomonas* is important not only for biochemical elucidation, but also for taxonomical classification of the genus. For example, analysis of L-phenylalanine and L-tyrosine pathways has been used to classify members of *Pseudomonas* [38]. Furthermore, the multibranched pathways of aromatic amino acid synthesis have elucidated phylogenetic relationships in *Pseudomonas* [39–41].

Though typically considered a strict aerobe, particular *Pseudomonas* species perform fermentations and/or anaerobic respiration. Specifically, arginine [42, 43] and pyruvate [43] fermentation pathways have been reported. Additionally, *Pseudomonas* utilizes nitrogenous substances, like nitrate, as terminal electron acceptors for anaerobic respiration [44]. In addition to denitrification activities of some species, nitrogen fixing species like *P. stutzeri* have also been reported [45]. A few *Pseudomonas* species oxidize NO to nitrate [2], though generally considered as a detoxification or co-oxidation process rather than an energy yielding one. Another notable exception to the aerobic *Pseudomonas* species is *P. chloritidismutans*, which employs chlorate as an electron acceptor in conjunction with oxygen [46].

Habitat

Pseudomonas is ubiquitous in the environment, which is attributed to its metabolic versatility [47]. It can be found in soil and water environments, as well as plant and animal tissues and many other niches. *Pseudomonas* species have even been found in hospital saline solutions [48], Antarctic cyanobacterial mats [49], and water from plumbing fixtures [50]. *Pseudomonas* species grow over a temperature range of 4–42°C, and pH 4–8 is considered favorable. As mentioned, *Pseudomonas* species are generally strict aerobes, although *P. aeruginosa* and other denitrifying species exhibit fermentation and anaerobic respiration [51].

Though culture-dependent studies indicate *Pseudomonas* as an important soil microorganism [52], culture-independent methods, such as metagenomics, suggest a relative scarcity of *Pseudomonas* in the soil environment [53, 54]. Nevertheless, when growing in soil, *Pseudomonas* does so in conjunction with other bacteria, like *Streptomyces*, that supply monomeric carbon compounds [2].

Pseudomonas is considered extremely suited to thriving in the rhizosphere [55, 56], the territory impacted by vegetation [57]. *Pseudomonas* possesses numerous attributes necessary for optimizing its survival in this niche, like chemotaxis, adherence factors, and mechanism for evasion of plant defenses [2]. Importantly, *Pseudomonas* outcompetes other microorganisms to enhance its hold on the rhizosphere [58]. Different *Pseudomonas* species exert different effects on plants. Some species, like *P. syringae*, are epiphytic in nature and effectively colonize plant leaves and other plant surfaces to cause disease [59], while others benefit the plant by producing phytohormones [60]. However, many species neither harm nor hurt plants [2]. Generally, though, *Pseudomonas* species live a saprophytic or pathogenic lifestyle, scavenging organic matter [61, 62].

Laboratory Culture of *Pseudomonas*

Under laboratory conditions, *Pseudomonas* is generally grown in media containing organic compounds, at neutral pH and mesophilic temperatures (~30°C) [63–65]. These conditions yield a high growth rate. Media replete in peptides, like tryptic soy broth/agar, is preferred, especially by the saprophytic species of the genus; the peptide concentration of the media may be changed to optimize the amount and variety of species maintained in culture [66]. *Pseudomonas* generally requires media containing 0.1–1% (w/v) organic matter to maintain good growth. No separate mineral, vitamin, or growth factor is required in the media. Denitrifying *Pseudomonas* bacteria need nitrate, anaerobic conditions, and temperatures between 30 and 40°C for their enrichment [67].

As mentioned above, many *Pseudomonas* species produce fluorescent molecules. Differentiation of these species on laboratory media requires iron depletion to promote secretion of the fluorescent siderophores [2]. King's A and B media are commonly used for fluorescent *Pseudomonas* enrichment [68]. The antibiotic trimethoprim is often used to discern and isolate fluorescent species from nonfluorescent ones [69].

Although a few selective/differential media exist for *Pseudomonas* isolation (e.g., Pseudosel agar medium), highly selective media generally prohibit *Pseudomonas* growth [2, 70],

and it is often suggested not to use such media when isolating *Pseudomonas* from niches already exerting strong selection [2, 3]. Cetrimide is recommended [2] to inhibit accompanying microorganisms, enhance pigment production, and enrich for *P. aeruginosa*. A few unconventional methods of *Pseudomonas* isolation utilize toxic resin acids [71] or unorthodox terminal electron donors and acceptors [46].

Control of Gene Expression

Pseudomonas species have some of the largest genomes among sequenced bacteria, often containing more than 6 Mbp, and more than 5,000 genes. A complex network of transcriptional and post-transcriptional regulatory mechanisms controls expression of these numerous genes [72, 73]. Several of these regulatory mechanisms are discussed next.

Quorum Sensing (QS)

Pseudomonas species produce many different QS molecules to regulate gene expression. QS facilitates coordinated gene expression in response to environmental signals and bacterial population density. Thus, pseudomonads use QS to coordinate population-wide gene expression for pathogenesis, metabolism, and many other processes [74].

Two-Component Systems (TCSs)

All *Pseudomonas* species produce TCSs. These regulatory systems mediate a variety of functions for the microbes (Table 36.3).

Sigma Factors

Many sigma factors have been reported in *Pseudomonas* species, and these sigma factors are critical for optimal RNA polymerase-mediated gene transcription activity. Some important ones are described next.

σ^{70}

This sigma factor controls housekeeping gene transcription [75]. The consensus sequence found in σ^{70}-dependent promoters in *Pseudomonas* has similarity to that found in *Escherichia coli* [2].

Extracytoplasmic Function (ECF) Sigma Factors

This subgroup of σ^{70} family factors is important for control of extracytoplasmic stress [76]. An important ECF sigma factor is AlgU, which regulates biosynthesis of the secreted polysaccharide alginate [77]. It also influences expression of heat shock sigma factor σ^{32}, and hence serves as a global gene regulator [78]. PvdS, another prominent ECF sigma factor, regulates pyoverdine siderophore biosynthesis. A sequence at the –35 position, known as the "IS box," is critical for PvdS-dependent promoter functioning [79]. Orthologues of the *P. aeruginosa* PvdS exist in *P. putida* (strain KT2440) and *P. fluorescens* [80].

σ^{54}

This sigma factor is encoded by *rpoN* and is distinct from the σ^{70} family [81]. The number and function of σ^{54}-dependent genes varies greatly amongst various *Pseudomonas* species [82–84]. Some of the major functions of RpoN include regulation of glutamine synthetase and urease in *P. aeruginosa* and *P. putida*, as well as some virulence factors in *P. aeruginosa*, and regulation of the phytotoxin coronatine in *P. syringae*. In *P. aeruginosa*, RpoN regulates over 700 genes, and blocking this sigma factor can increase antibiotic sensitivity [85].

Other Transcriptional Regulators

Pseudomonas contains quite a few transcriptional regulator, including members of the AsnC, GntR, LacI, LuxR, and MarR families [2, 86]. For catabolism of aromatic hydrocarbons, various species use σ^{54}-dependent regulator families such as XylR, TouR, and DmpR [81, 87–90]. Table 36.4 summarizes some of the most common transcriptional regulators.

Post-transcriptional Regulation

Post-transcription regulation has also been reported in *Pseudomonas*. For example, in *P. aeruginosa*, the TCS GacAS and the response regulator RetS regulate transcription of two small noncoding regulatory RNAs: RsmY and RsmZ [91]. These RNAs control the intracellular concentration of free RsmA and RsmF, prominent members of the CsrA family of RNA-binding proteins [92]. Rsm regulons control almost a tenth of *P. aeruginosa* transcriptome and are important for activating the phenotypes

TABLE 36.3

associated with acute infections [92]. RsmA and RsmF control translation of certain transcripts by binding to conserved 5'-ANGGAN-3' motifs present within stem-loop secondary structures of target mRNAs, such as those for type three secretion system (T3SS) and type six secretion system (T6SS) [92, 93]. Such binding sites often overlap or are proximal to the Shine-Dalgarno sequence of these target mRNAs [94–98], and thus RsmA and RsmF binding blocks ribosome recognition and translation initiation [92]. RsmA can also act as a post-transcriptional stimulator of gene expression by affecting mRNA stability and secondary structure [97, 99]. RsmY and RsmZ each have 4-6 RsmA binding sites. Thus, presence of these regulatory RNAs controls the free concentration of RsmA and its ability to bind target mRNAs [91]. Recent studies uncovered two additional small noncoding regulatory RNAs, RsmV, and RsmW, that work in a GacAS-independent manner to sequester RsmA [100, 101]. Similarly, in *P. fluorescens*, the *hcnABC* operon (involved in expression of hydrogen cyanide synthase expression) is under control of the small noncoding RNAs RsmA and RsmE [102–105].

Examples of Prominent *Pseudomonas* Species

This section highlights four major *Pseudomonas* species: *P. aeruginosa*, *P. syringae*, *P. putida*, and *P. fluorescens*. These species are examples of *Pseudomonas* pathogenesis, bioremediation, or plant growth promotion.

Pathogenesis of *P. aeruginosa*

P. aeruginosa causes infection in a wide range of different host organisms, including humans. The importance of *P. aeruginosa* as an opportunistic pathogen stems from three major concerns: high incidence of infection, high morbidity and mortality, and recalcitrance to immune or antibiotic clearance [106]. Moreover, this pathogen can cause both acute infections and chronic infections (Figure 36.1). For instance, *P. aeruginosa* is the leading pathogen causing acute respiratory infections in mechanically ventilated and immunocompromised individuals and chronic infections in the airways of individuals with cystic fibrosis (CF) [107–109]. *P. aeruginosa* has also been implicated in other opportunistic diseases such as those of the urinary tract, eye, skin, and burn wounds [110].

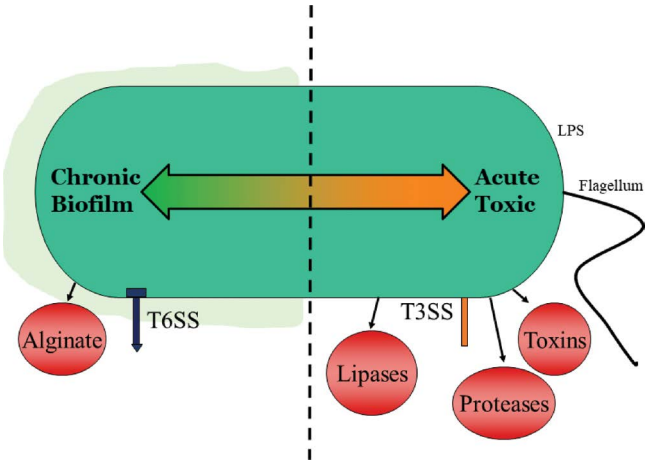

FIGURE 36.1 *P. aeruginosa* exhibits an acute infection lifestyle and a chronic infection lifestyle by alternate regulation of different sets of virulence factors. The dashed line separates these two lifestyles in this drawing, but, in reality, a continuum of phenotypes exists between these two extremes.

General Pathogenicity Attributes

During infection, *P. aeruginosa* is thought to be acquired from the environment, including, importantly, the hospital. Bacterial cell surface virulence factors, such as flagella, pili, and lipopolysaccharide (LPS), aid in initial adhesion to the host epithelial layer [106]. Attachment is followed by deployment of the T3SS by *P. aeruginosa* to inject effector molecules (ExoU, ExoS, ExoT, ExoY) into the host epithelium. These effectors facilitate host cell cytoskeleton rearrangement, escape from host cell phagocytic engulfment, and cytotoxicity leading to tissue necrosis [110]. Other secreted virulence factors involved in host cell cytotoxicity and tissue destruction include elastase, phospholipase C, and pigments such as pyoverdine and pyocyanin [111–119]. Production of this arsenal of virulence factors is tightly regulated by an intricate network of QS, TCSs, stress response systems, and other factors [110, 120–123]. This regulatory network controls the virulence phenotype of *P. aeruginosa*, producing an acute infection characterized by toxin production and other classical pathogenic activities, a chronic infection characterized by biofilm formation and exopolysaccharide secretion, or a continuum or phenotypes in between (depending upon the type and level of inputs the regulators receive) (Figure 36.1) [124].

Cell Surface Virulence Factors

As the name suggests, these factors are localized on the cell surface. They mediate bacterial motility and the early stages of infection, such as initial adhesion to the host cell surface.

Flagella: In addition to providing motility for *P. aeruginosa*, flagella bind to asialoGM1, a normal constituent of the host epithelial cell membrane [125]. They are also known to prompt an NFκB-mediated inflammatory reaction, such as production of interleukin (IL)-8, by interacting with TLR2 and TLR5 [126, 127]. Because flagella are immunogenic, they often are down-regulated during infection, especially in chronic infections like those in the CF airways (discussed later in this chapter). Immunogenicity of flagellar proteins has been exploited by researchers to develop immunological products targeted at them [128–130].

Pili: Pili are also critical for *P. aeruginosa* virulence [131–133], particularly for adherence to the host cell surface by binding to asialoGM1 [134, 135]. They are also involved in twitching motility, which is dependent upon retractile movement of the pili. This activity leads to "spreading," rather than "swimming," of the bacterial population on the host tissue surface. This kind of locomotion is especially prevalent in respiratory tract infections [136]. Because of the importance of pili for virulence, immunological targeting of pili is a major area of research [137–140].

LPS: LPS is crucial in *P. aeruginosa* pathogenesis [141]. LPS assists *P. aeruginosa* in binding to asialoGM1 [135] and it elicits pro-inflammatory cascades through interaction of lipid A with TLR4/CD14 [142, 143].

Type III Secretion System (T3SS)

T3SS is a complex molecular syringe that *P. aeruginosa* uses to inject four effector toxins (ExoU, ExoS, ExoT, and ExoY) into the host cell cytosol. Different strains contain different combinations of these effectors. Intriguingly, mutants that lack effectors, but still express the T3SS structure are still virulent [144], indicating that the T3SS needle complex by itself might be important in *P. aeruginosa* pathogenesis. PcrV is an important structural protein making up the tip of the T3SS "needle" [145], and immuno-therapeutics targeted at PcrV have achieved some success [146–150].

ExoU: ExoU is the most potent of the *P. aeruginosa* T3SS effectors [144, 151] and it is the predominant cytotoxin injected by the T3SS [151–153]. It destroys host cell membranes through its phospholipase/lysophospholipase activities [154–156]. Anti-ExoU immunotherapy has been generally unsatisfactory [106], but some success has been achieved with phospholipase A2 inhibitors in vitro [157]. As the mechanism of ExoU activity becomes clearer, newer therapeutic strategies will emerge.

ExoS: The ExoS cytotoxin [144, 158] disrupts the host cell cytoskeleton through two different activities [106]. The C-terminus, which requires a 14-3-3 cofactor protein, contains ADP-ribosyltransferase activity [151, 159, 160] and the N-terminal domain acts as a Rho GTPase-activating protein (GAP). ExoS provokes inflammatory responses through TLR2 and TLR4 [161].

ExoT: ExoT is regarded a minor effector [151]. This toxin contains domains similar to ExoS, although the ADP-ribosyltransferase domain in ExoT affects a more restricted subset of host cellular proteins, including Crk [162]. ExoT induces cytoskeletal rearrangements, leading to inhibition of *P. aeruginosa* internalization and stunted wound healing [163, 164]. Some literature sources have reported that ExoT production decreases ExoU-mediated cell cytotoxicity [144].

ExoY: ExoY functions as an adenylate cyclase [110], and upon being injected into the host cell cytoplasm, increases intracellular cAMP levels [165]. Increased host intracellular cAMP leads to increased tissue porosity, especially in lung infections [166].

Type VI Secretion System (T6SS)

T6SS acts as a contractile molecular syringe, consisting of a sheath and a needle-like structure anchored to the inner and outer membrane via a baseplate complex. *P. aeruginosa* contains three different T6SS loci named H1-, H2-, and H3-T6SS [167]. The main proteins that make up this structure including the needle, baseplate, and spike all show significant homology to the T4 phage tail structure [168]. T6SS primarily acts in bacterial defense but can also mediate intracellular host invasion [167]. T6SS enhances *P. aeruginosa* ecological fitness by reducing colonization of other bacteria present in the same ecological niche [168]. Once *P. aeruginosa* comes in contact with a neighboring bacterial cell, the tube inside the sheath will extend, penetrate through the prey's membrane, and inject effectors into the cell [168].

H1-T6SS: H1-T6SS primarily serves as an antibacterial weapon to outcompete other bacteria that may colonize the same ecological niche as *P. aeruginosa* [167]. Once in contact with other bacteria, it will inject the effectors Tse1-7 that cause a wide range of damage including dormancy and degradation of peptidoglycan and dinucleotides [167]. To reduce damage against other *P. aeruginosa* cells, immunity proteins Tsi1-6 directly interact with the effectors to render them inactive [167].

H2- and H3-T6SS: H2- and H3-T6SS mediate invasion of *P. aeruginosa* into pulmonary epithelial cells, likely via microtubules and actin [167]. Effector toxins released by H2- and H3-T6SS include phospholipases PldA and PldB that degrade the host cell membrane [167, 169].

TABLE 36.5

Secreted Virulence Factors of *P. aeruginosa*

Factor	Description/Function
Pyocyanin	Blue pigment; induces IL-8 expression and apoptosis of neutrophils; causes oxidative damage in host cells
Pyoverdine	Siderophore for iron chelation and uptake; virulence regulator controlling secretion of Exotoxin A and itself
Alkaline protease	Lyses fibrin in host tissue; secreted by type I secretion system; prevalent in corneal infections and in lung disease
Protease IV	Important in keratitis caused by *P. aeruginosa*; also implicated in airway infections due to destruction of lung surfactant proteins A, B, and D
Elastase	Metalloproteinase secreted by the type II secretion system (T2SS) into the extracellular space; destroys tight-junctions leading to porosity of airway epithelial tissue; induces inflammation by recruiting neutrophils and eliciting IL-8 response; also reported to disrupt lung surfactant proteins A and D
Phospholipase C	Secreted into the extracellular space by the T2SS; disrupts host cell membrane phospholipids, especially in acute lung disease; participates in surfactant destruction, inflammation induction, and inhibition of neutrophil oxidative burst
Exotoxin A (ExoA)	Toxin secreted by the T2SS; functions as an ADP-ribosyltransferase that blocks elongation factor 2, leading to impaired protein synthesis and host cell death; also diminishes host response to infection

Source: Data obtained from ref. [106].

Other Secreted Virulence Elements

P. aeruginosa secretes several other factors that contribute to disease progression. These factors, such as secreted pigments, enzymes, and proteases, destroy host tissues, increase tissue porosity, and induce host inflammatory reaction, among other functions (Table 36.5) [74, 106].

Quorum Sensing (QS)

In *P. aeruginosa*, there are three overlapping QS systems. Two of these systems, Las and Rhl, produce acyl homoserine lactone (AHL) autoinducers, while the third involves the quinolone molecule PQS [74]. QS controls expression of Type II Secretion (T2SS), T6SS, elastase, pyocyanin, and pyoverdine in *P. aeruginosa*, among other factors [74, 167].

P. aeruginosa Pathogenesis in the CF Lung Environment

CF is a congenital genetic disease, marked by improper chloride secretion across cell membranes [170]. Particularly in the airway

epithelium, this defect leads to unusually high amounts of mucus building up [171], which provides an excellent niche for microbes to proliferate. Though there are multiple pathogens that colonize the CF lung, *P. aeruginosa* predominates from adolescence though adulthood [171].

P. aeruginosa causes a persistent, lifelong infection in the airways of individuals with CF [63, 77, 109]. These chronic infections initiate as *P. aeruginosa* adjusts to the CF airway environment and transitions to a biofilm lifestyle [63, 74, 172, 173]. This biofilm infection in CF lungs is strikingly dissimilar to acute *P. aeruginosa* infections. Selective pressure from the host's immune system and complex genetic networks activate the switch from an initial acute (planktonic) infection to a chronic (biofilm) infection lifestyle (Figure 36.1) [124]. T3SS and expression of toxins like elastase are diminished. Likewise, virulence features that trigger host immunity, like flagella and pili, are down-regulated once the pathogen has established adherent contact with the host respiratory epithelium. On the other hand, biofilm bacteria produce vast amounts of the exopolysaccharide alginate, leading to a highly mucoid phenotype and upregulation of T6SS activity [124, 174].

P. aeruginosa biofilms in the context of CF airways hold serious clinical implications [77]. Firstly, CF biofilms are nearly impossible to eradicate due to elevated antibiotic resistance [172]. Secondly, despite intense host immune infiltration, the biofilm structure protects resident bacteria from destruction. Moreover, inflammation leads to damage of surrounding host tissues [175]. Thus, *P. aeruginosa* persists for the life of the individual, and it is recognized as the leading cause of morbidity and mortality in CF patients [171, 176]. Understanding the molecular cascades that enable *P. aeruginosa* to form biofilms has been the focus of much research [110].

Infrequent Pseudomonas *Species as Human Pathogens*

P. aeruginosa has been implicated as the foremost pathogenic strain for human infections. Nevertheless, other *Pseudomonas* species have been reported in human infection, including *P. putida*, *P. fluorescens*, *P. pseudoalcaligenes*, and *P. stutzeri* [177]. While very few infections involving *P. putida* bacteremia and *P. stutzeri* endocarditis have been reported, many of them involved immunocompromised patients and/or patients who had recently received invasive surgery prior to infection [178, 179].

The Phytopathogen *P. syringae*

P. syringae is the predominant plant pathogen in the *Pseudomonas* genus [180]. There are more than 60 defined pathovars of this bacterium [180, 181], and they infect a variety of plants, including lilac, maple, saucer magnolia, cherry, plum, apple, basswood, dogwood, and forsythia [182, 183]. Diseases caused by this pathogen range from bacterial specks on tomatoes, halo blight on beans, and bleeding cankers on horse-chestnuts [184]. *P. syringae* has been isolated from *Primula officinalis*, *P. grandiflora*, *P. elatior*, *Dodecatheon pulchellum*, *Silene acaulis*, *Hutchinsia alpina*, *Geranium sylvaticum*, and *Onobrychis montana*. Bacterial populations are minimal on emerging and developing plant tissues, but under favorable conditions, large CFUs have been reported [185–187]. In perennial plants, *P. syringae* manifestations are higher in spring compared to summer [186, 188–192].

Mechanism of Spread

P. syringae can exist in clouds and can be spread through snow and rain (Figure 36.2) [193, 194]. Water-borne *P. syringae* can then reach wild and cultivated plants, and eventually return to clouds as aerosols. At each step of this ecological cycle, strains diversify as selective pressures select for genetic modifications.

Pathogenic Properties and Genes

P. syringae is associated with ice nucleation [180, 195], which can lead to frost injury and destruction of plant tissues [182, 183]. *P. syringae* also regulates activities to enhance its survival on

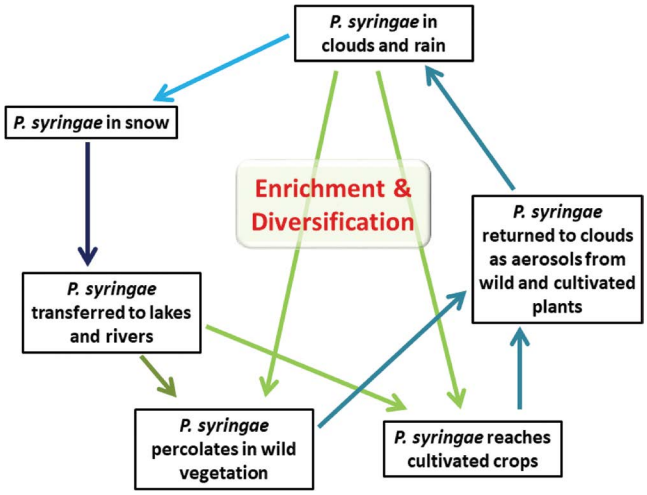

FIGURE 36.2 The transmission cycle of phytopathogenic *P. syringae*. See reference [195] for more information about this subject.

plants, including UV tolerance and production of extracellular polysaccharide to cope with dryness [180]. Alginate has specifically been reported as a virulence factor for *P. syringae* [196]. In some *P. syringae* pathovars (e.g., tomato), pili have been described as important virulence factors [197–202]. Additionally, genes of the *hrp* (hypersensitivity reaction (HR) and pathogenicity) regulon encode a T3SS involved in rapid crumpling and plant death [203].

Another important gene important for *P. syringae* pathogenesis is *gacS*, encoding a sensor kinase [180]. The utility and significance of *gacS* in *P. syringae* seems to be pathovar specific [204]. For example, it is associated with production of syringopeptin toxin in pathovar (pv.) *syringae*, while in pv. *coronafaciens*, it leads to expression of tabtoxin [205]. In addition to toxin regulation, *gacS* also affects production of proteases, QS molecules, alginate, and swarming motility [206–210]; multiple genes under the *gacS* regulon have been reported [207].

Bioremediation by *P. putida*

P. putida has been quite useful for environmental biotechnological applications. *P. putida* strain KT2440 [211, 212] is particularly utilized in environmental remediation applications. Additionally, it populates the rhizosphere of cultivated plants, and thus enhances plant growth [213].

Metabolic Potential for Bioremediation

P. putida can catabolize a wide array of compounds [213]. For this activity, it possesses a vast repertoire of degradative enzymes (mostly oxygenases and oxidoreductases) [214] to break down environmental pollutants (Table 36.6). Genetic modification has created *P. putida* strains capable of degrading many environmental pollutants such as hydrocarbons [215], naphthalene [216], and 1,2,3-trichloropropane (TCP) [217]. Some of its catabolic substrates are lignin derivatives produced during plant disintegration [218]. *P. putida* breaks these compounds down to precursors that are then fed into central metabolism [219, 220]. Importantly, this species contains excellent chemosensory mechanisms [213].

TABLE 36.6

Common Catabolic Enzymes Chromosomally Encoded in *P. putida*

Enzyme Type	Putative Number	References
Dioxygenase	18	[275, 276]
Monooxygenase	15	[213]
Oxidoreductase	80	[213]
XenB (PP0920: metabolizes trinitrotoluene (TNT))	1	[277, 278]
Hydrolase	51	[213]
Transferase	62	[213]
Dehydrogenase	40	[213]
Enzymes encoded by the *ssuFBCDAE* operon	6	[213]
Glutathione-S-transferase	12	[279]
Chlorohydrolase	3	[213]

In addition to its metabolic flexibility, *P. putida* has extensive transporter systems to facilitate transport of substrates and end products into and out of the cell [213], such as PcaK [221] for 4-hydroxybenzoate transport and members of the BenF/PhaK/OprD porin family [222, 223]. The presence of 11 LysE family amino acid efflux transporter proteins [213] helps alleviate deleterious levels of amino acids or their analogues.

P. putida *in the Rhizosphere*

ABC transporters facilitate *P. putida* survival in the rhizosphere [213]. As in other root associated microbes, *P. putida* KT2440 has a putative ABC family opine transporter [224] and other enzymes for metabolizing opine, which is a plant produced molecule. Additionally, *P. putida* can protect its host by expressing a type VI secretion system that injects toxins into a wide range of plant pathogens, thereby inhibiting their growth [225]. Additionally, it has an efflux mechanism for removal of fusaric acid, a toxin produced by plant pathogens like *Fusarium oxysporum* [226], suggesting that *P. putida* could be used as an effective biopesticide [213].

P. fluorescens, the Phyto-Benefactor

P. fluorescens is widely accepted as a promoter of plant health and productivity [227]. This microbe is metabolically versatile and adaptive [228], and it aids in crop growth and expansion [229, 230] by producing metabolites like phytohormones [231–233]. In some cases, it has been reported to produce proteins that limit frost injury in plants [234, 235], while in other instances, this species boosts plants' nutrition [236] by increasing the availability of key nutrients [237, 238]. Additionally, rhizosphere-dwelling *P. fluorescens* produce secondary metabolites like antibiotics [227] that limit the growth of deleterious populations of pathogenic organisms around the plant. Several phenazine compounds produced by *P. fluorescens* act as antimicrobial compounds against fungal, bacterial, and oomycete plant pathogens [239]. Altogether, the extraordinary ability of *P. fluorescens* to thrive in the rhizosphere yields great benefits to agriculture [227]. *P. fluorescens* strain Pf-5 has been well characterized for its role in aiding plant growth [227].

Fitness to Exist in the Rhizosphere

Pf-5 expresses a variety of factors that promotes its growth in the rhizosphere. For instance, it can metabolize a wide range of compounds commonly found in this environment, many of which are organic molecules exuded by roots or other plant tissues [240, 241]. Additionally, Pf-5 can outcompete other microbes in the environment, and this feature has rendered it a promising biocontrol agent [227]. Pf-5 exhibits resistance to a range of antibiotics [227] and toxins produced by plant pathogens [242], and it has a large repertoire of efflux pumps for removal of toxic compounds [243]. Furthermore, it expresses ten peroxidases, six catalases, and several superoxide dismutases to cope with oxidative stress [244].

Regulatory Mechanisms

P. fluorescens contains a multitude of regulatory genes in its large genome (7.06 Mb) to adjust to various environmental niches [227].

Among these are 68 putative sensor histidine kinases and 113 response regulators; also it has the highest count of ECF sigma factors (27) amongst all *Proteobacteria* [227]. Several antisigma factors [245] have also been reported in this species.

Role of Pf-5 in Biocontrol

P. fluorescens strain Pf-5 promotes plant growth because of its propensity to produce numerous antimicrobials [246] and other secondary metabolites [247]. Almost 6% of the Pf-5 genome encodes secondary metabolites [227]. Antibiotics produced by Pf-5 include pyoluteorin [248–250], 2,4-diacetylphloroglucinol (DAPG), and pyrrolnitrin [251]. HCN is also produced by Pf-5 [252]. The surfactant lipopeptide is effective against the phytopathogen *Phytophthora ramorum* [253]. Pf-5 also produces chitinase [254] and can thus serve to degrade chitin in fungal cell walls. Other prominent antimicrobials include bacteriocins [247] and exoenzymes [227]. To further strengthen its role as a biocontrol agent, Pf-5 has a homolog of the *mcf* (*m*akes *c*aterpillars *f*loppy) insect toxin gene also found in the bacterium *Photorhabdus luminescens* [255]. Moreover, Pf-5 is devoid of numerous virulence elements found in other *Pseudomonas* species, such as T3SS, toxins, and exoenzymes [227]. This lack of plant destructive factors enhances the agricultural suitability of *P. fluorescens*.

Conclusion

Pseudomonas is a genus that continues to fascinate microbiologists with its phenotypic and genotypic diversity. In some cases, as with the human and plant pathogens *P. aeruginosa* and *P. syringae*, respectively, this diversity and is highly detrimental, while in others, like *P. putida* and *P. fluorescens*, metabolic versatility can be exploited to our advantage. As additional genomic and transcriptomic data is revealed, we will likely discover novel properties of this extraordinary genus.

Introduction

Bacteria of the order Rickettsiales (*Alphaproteobacteria*) are Gram-negative, small, rod-shaped, and coccoid, with all described species existing as obligate intracellular parasites of a wide range of eukaryotic organisms (Gillespie et al., 2012a). Before the "DNA revolution," bacteria were assigned to Rickettsiales based primarily on chemical composition and morphology. Intraordinal classification employed a taxonomic system (i.e., generic characteristics) based on five major biological properties: (1) human disease and geographic distribution, (2) natural vertebrate hosts and other animal vectors, (3) experimental infections and serology reactions and cross-reactions, (4) strain cultivation and stability, and (5) energy production and biosynthesis. This pioneering systematic work resulted in a Rickettsiales hierarchy of three families containing nine obligate and facultative intracellular pathogenic genera: (1) *Rickettsiaceae*: genera *Rickettsia*, *Coxiella*, *Rochalima*, and *Ehrlichia*; (2) *Bartonellaceae*: genera *Bartonella*, *Haemobartonella*, *Eperythrozoon*, and *Grahamella*; and (3) *Anaplasmataceae*: genus *Anaplasma*. However, rickettsial classification has been substantially revised since the turn of the millennium, owing to the technological advances in molecular sequence generation and the advent of several new fields of study, including molecular systematics, phylogenomics, and bioinformatics. Contemporary Rickettsiales taxonomy is radically different from the traditional system, with such tremendous changes as the reassignment of the Q-fever agent (*Coxiella burnetii*) to *Gammaproteobacteria* (Williams et al., 2010) and the placement of the causative agents of several human diseases such as endocarditis, Trench fever, and Cat-scratch disease (*Bartonella* spp.) to the Order Rhizobiales (Williams et al., 2007).

This chapter primarily focuses on the family *Rickettsiaceae*, which is currently comprised well-studied species in the genera *Rickettsia* and *Orientia*, as well as candidate species in several provisional genera that are poorly understood (Castelli et al., 2019; Driscoll et al., 2013; Schrallhammer et al., 2013; Szokoli et al., 2016). *Rickettsia* and *Orientia* contain many known and potential pathogens of great concern as the causative agents of emerging and re-emerging human diseases (Table 37.1). However, this work also reviews other families that are either currently included in the order Rickettsiales (*Holosporaceae*, *Anaplasmataceae*, and *Midichloriaceae*) or were previously classified as Rickettsiales (e.g., *Bartonellaceae*). A summary of the current knowledge of rickettsial phenotypic and genotypic characteristics is presented, as well as a synopsis of the factors governing rickettsial virulence and pathogenicity. A perspective on the changing ecology of rickettsial pathogens is provided, illustrating the emerging and re-emerging properties of many pathogenic species. Finally, a discussion is given on the utilization of rickettsial pathogens as agents of bioterrorism.

TABLE 37.1

Some Epidemiological Features of Rickettsial Diseases

	Agent	Disease/dominant symptoms	Vector/Reservoir Host	Geographic Distribution
Typhus fevers	*R. prowazekii*	Epidemic typhus	Human body louse/Humans	Africa, Asia, America
		Sylvatic typhus	Flea and louse/Flying squirrels	USA (only)

Rickettsial Classification

Rickettsiaceae

Within *Rickettsiaceae*, only species of the genus *Rickettsia*, unique bacteria with highly reduced genomes (Andersson and Andersson, 1999; Andersson et al., 1998) and a close evolutionary relationship with the mitochondrial ancestor (Emelyanov, 2003), remain from the original four genera (Table 37.2). Of particular note, one former species of *Rickettsia*, the scrub typhus agent *R. tsutsugamushi*, is now placed in a novel genus, *Orientia* (Tamura et al., 1995). For the taxon *Coxiella*, a monotypic genus originally considered a sister lineage to *Rickettsia* species, reassignment to the *Gammaproteobacteria* was suggested based on phylogenetic analysis of 16S ribosomal DNA sequences (Weisburg et al., 1989). Robust phylogenomic analysis has confirmed the close relationship of *Coxiella* and *Legionella* species within the *Gammaproteobacteria* (Williams et al., 2010). Phylogenetic analysis of the genus *Rochalima* resulted in its unification with *Bartonella* species in the *Bartonellaceae*, with all species renamed as *Bartonella* spp. (Brenner et al., 1993). Finally, the genus *Ehrlichia* has been moved to the *Anaplasmataceae*, as its current described species share greater affinity with *Anaplasma* spp. than to species of *Rickettsia* (Dumler et al., 2001).

Species of the genus *Rickettsia* have traditionally been classified into either the Typhus Group (TG) or the Spotted Fever Group (SFG) rickettsiae. However, this classification is no longer valid for several reasons. First, many uncharacterized species of *Rickettsia*, particularly those with unknown pathogenicity and no known association with blood-feeding arthropods or vertebrates, are ancestral to the more commonly known pathogenic strains (Perlman et al., 2006). Second, several characterized species of *Rickettsia*, such as *R. bellii* (Stothard and Fuerst, 1995), *R. canadensis* (Gillespie et al., 2007) and *R. helvetica* (Driscoll et al., 2013), do not group within the TG or SFG based on robust phylogenetic analysis. Finally, a monophyletic clade that lies between TG and SFG rickettsiae, containing *R. felis*, *R. akari*, and *R. australis*, has been shown to share many traits similar to non-SFG rickettsiae (Gillespie et al., 2007, 2015a). This group was named Transitional Group (TRG) rickettsiae, with all other early diverging *Rickettsia* lineages assigned to provisional groups that need further classificatory attention (Murray et al., 2016). Recent advances in phylogenetic methods that accommodate base compositional biases in nucleotide and amino acid sequences, which are critical to employ for the highly AT-rich genomes of Rickettsiales, suggest that TRG and TG rickettsiae share a common origin relative to the other rickettsial lineages (Driscoll et al., 2013) (Figure 37.1).

TABLE 37.2

Pathogens That Are No Longer Associated with Rickettsiales and/or Rickettsiaceae

	Agent	Disease/dominant symptoms	Vector/Reservoir Host	Geographic Distribution
Coxiella	*C. burnetii*	Q-fever	Tick/Goats, sheep, cattle, domestic cats	Worldwide
Bartonella	*B. henselae*	Cat-scratch disease	Cat flea/Domestic cat	Worldwide
	B. quintana	Trench fever	Human body louse/ Humans	Worldwide
	B. bacilliformis	Oroya fever	Sand fly/?	Peru, Ecuador, Colombia

Neorickettsia	*N. sennetsu*	Sennetsu fever	Snail/Fish	Japan, Malaysia
Anaplasma	*A. phagocytophilum*	Anaplasmosis	Tick/Rodents, other small mammals	USA, Europe, Asia, Africa

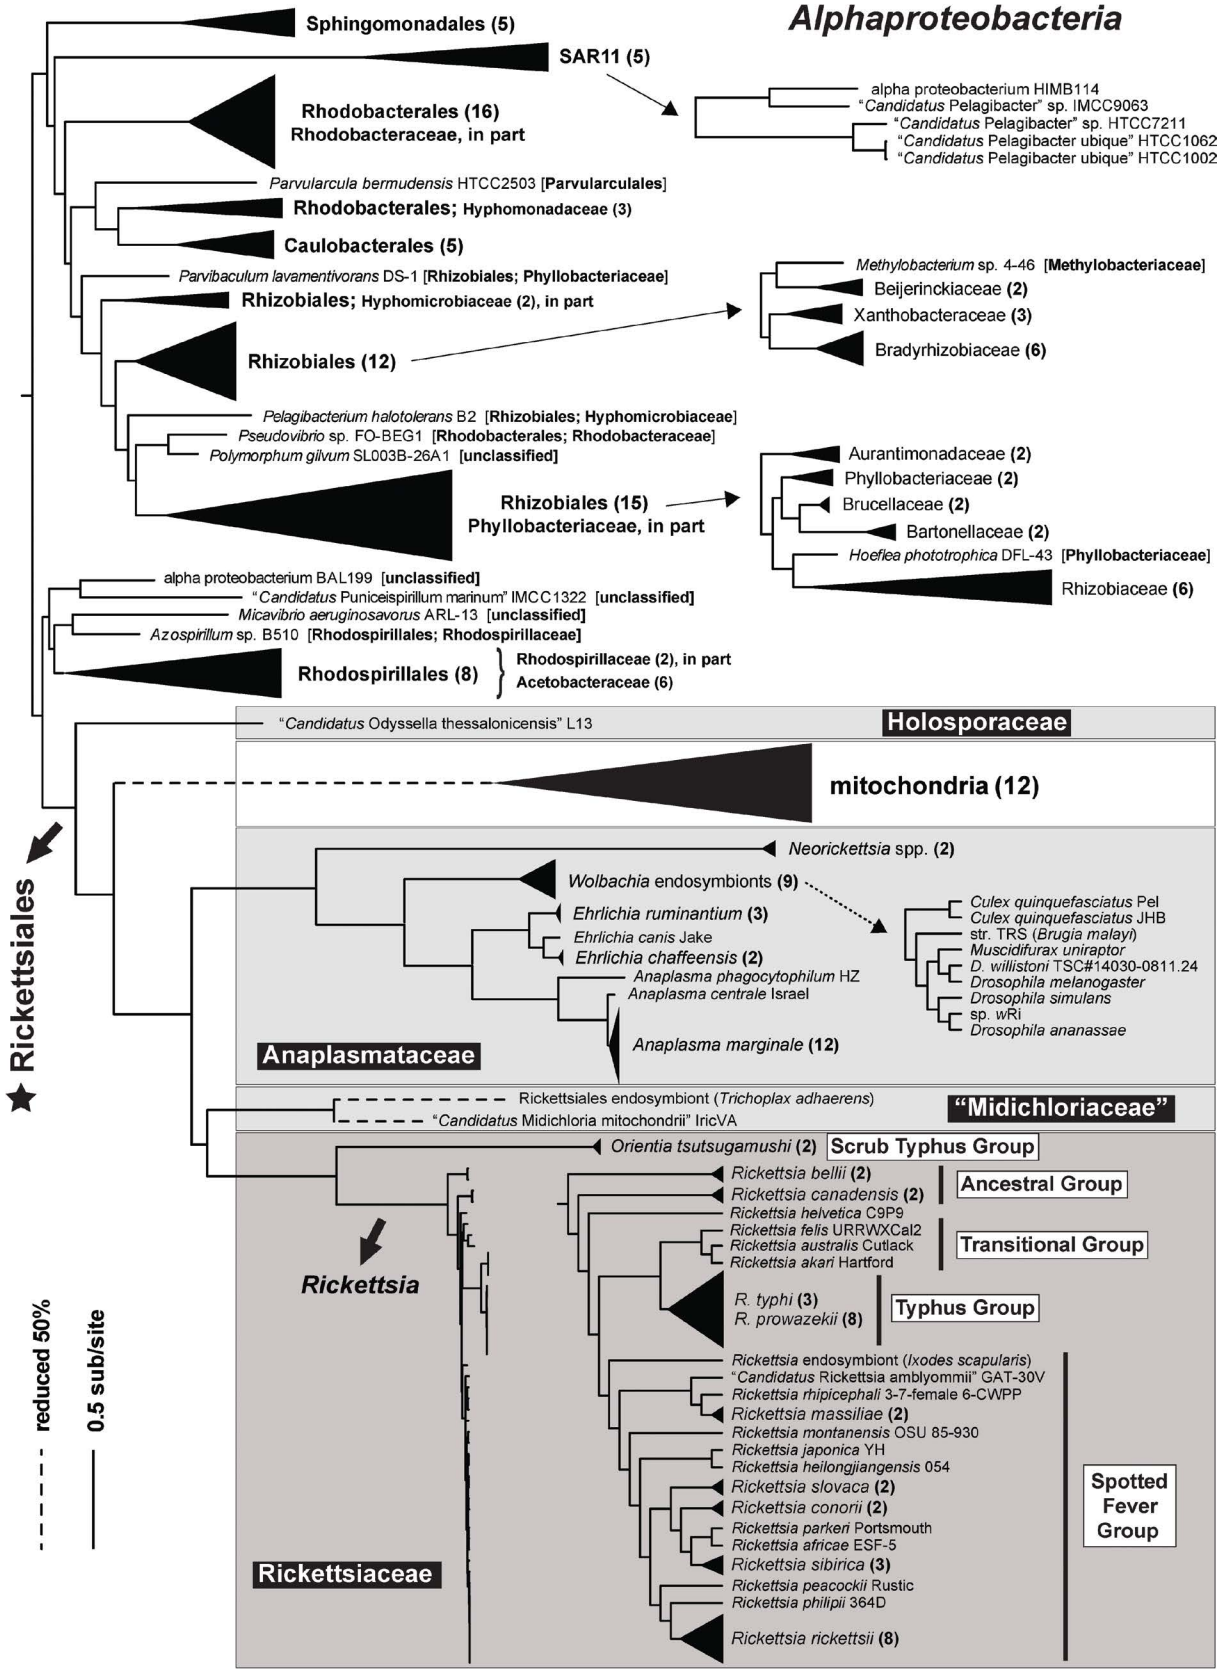

FIGURE 37.1 Genome-based phylogeny estimated for 164 alphaproteobacterial taxa, 12 mitochondria, and two outgroup taxa (not shown). The phylogenetic pipeline that entails orthologous protein group (OG) generation, OG alignment (and masking of less conserved positions), and concatenation of aligned OGs is described elsewhere (Driscoll et al., 2013). Tree was estimated using the CAT-GTR model of substitution as implemented in PhyloBayes v3.3 (Lartillot and Philippe, 2004, 2006). Tree is a consensus of 1,522 trees (post burn-in) pooled from two independent Markov chains run in parallel. Branch support was measured via posterior probabilities, which reflect frequencies of clades among the pooled trees (all branches were recovered at 100%). Rickettsiales is noted with a star. Mitochondria, boxed; rickettsial families *Holosporaceae, Anaplasmataceae* and *Midichloriaceae* boxed and shaded light gray; *Rickettsiaceae*, boxed and shaded dark gray. Classification scheme for *Rickettsia* spp. follows previous studies (Gillespie et al., 2007, 2008). More details such as taxon names, genome accession numbers, etc., are provided elsewhere (Driscoll et al., 2013).

An assemblage of 1) Scrub Typhus Group rickettsiae (STG), which currently comprises *Orientia tsutsugamushi* and *O. chuto* (Izzard et al., 2010), 2) *Occidentia massiliensis* (Mediannikov et al., 2014), 3) "*Candidatus* Megaira polyxenophila" (Lanzoni et al., 2019), and 4) many other uncharacterized environmental strains typically isolated from aquatic ciliates, hydra, etc. (Boscaro et al., 2019) form sister lineages to *Rickettsia* species or early branching lineages of *Rickettsiaceae*. The recently sequenced genome of "*Candidatus* Arcanobacter lacustris" indicates it is the most ancient lineage of *Rickettsiaceae*, as it contains chemotaxis genes and vertically inherited flagellar genes reflective of a once facultative obligate intracellular lifestyle (Martijn et al., 2015). Collectively, this reclassification of *Rickettsiaceae* has been continually supported in various robust phylogenomic analyses (Gillespie et al., 2008, 2009a, 2012a, 2015a; Kaur et al., 2012). The monophyly (common ancestry) of the reclassified *Rickettsiaceae* is indisputable, thus providing a final stability to the classification of this natural rickettsial group.

Rickettsiella

The genus *Rickettsiella*, originally described as a member of Rickettsiales (Weiss et al., 1984), comprises a group of intracellular pathogens of diverse arthropod species. Based on characteristics divergent from typical rickettsiae, such as unique cell morphology (Weiser and Zizka, 1968), mode of reproduction (Götz, 1971, 1972), and an unusual morphogenic cycle most similar to *Chlamydia* spp. (Federici, 1980), the placement of *Rickettsiella* within Rickettsiales was always considered tenuous. Phylogenetic analysis confirmed the erroneous taxonomic assignment of *Rickettsiella* (Roux et al., 1997), with an eventual reassignment to the *Coxiellaceae* (*Gammaproteobacteria*: Legionellales) (Garrity et al., 2005). Robust phylogenomic analysis has confirmed the close relationship of *Coxiella* spp. with *Rickettsiella* within the *Gammaproteobacteria* (Leclerque, 2008; Williams et al., 2010).

Anaplasmataceae

Molecular phylogenetic analysis revealed that the once monotypic *Anaplasmataceae* was comprised of four lineages containing five described genera: *Anaplasma*, *Cowdria*, *Ehrlichia*, *Neorickettsia*, and *Wolbachia*. In a landmark study, the majority of the species in these five genera were meticulously placed into the genera *Neorickettsia*, *Wolbachia*, *Anaplasma*, and *Ehrlichia*, with substantial revision of the latter two genera (Dumler et al., 2001). Robust phylogeny estimations have supported the monophyly of the contemporary *Anaplasmataceae*, and its sister relationship to the *Rickettsiaceae* within Rickettsiales (Driscoll et al., 2013, 2017; Gillespie et al., 2012a; Williams et al., 2007). A lineage containing *Neorickettsia* spp. and the recently discovered "*Candidatus* Xenolissoclinum pacificiensis," an endoparasite of the tunicate *Lissoclinum patella* (Kwan and Schmidt, 2013), is currently the most ancestral lineage within the *Anaplasmataceae* (Driscoll et al., 2017), followed by the *Wolbachia* endosymbionts and parasites, then the sister clade containing *Anaplasma* and *Ehrlichia* (Figure 37.1). The latter two genera are much less divergent from one another than any other generic comparisons within the Rickettsiales, suggesting their relatively recent divergence from one another (Driscoll et al., 2013).

Midichloriaceae

A novel rickettsial family, *Midichloriaceae*, was recently proposed based on the discovery of a large clade of species that is distinct from the *Rickettsiaceae* and *Anaplasmataceae* (Driscoll et al., 2013; Gillespie et al., 2012a; Montagna et al., 2013). This family includes many species with diverse eukaryotic hosts, which are predominantly aquatic (i.e., corals, sponges, placozoans, Hydra spp., and protists). *Midichloriaceae* was named after the tick symbiont "*Candidatus* Midichloria mitochondrii," which is known to invade and devour mitochondria (Sassera et al., 2006). Unique genomic traits define "*Candidatus* M. mitochondrii," particularly genes encoding flagella and cbb(3) oxidase (Sassera et al., 2011). However, the phylogenetic position of the "Midichloriaceae" within the Rickettsiales is still tenuous. Genome-based phylogenies have supported the sister relationship of *Midichloriaceae* with either *Rickettsiaceae* (Driscoll et al., 2013; Sassera et al., 2011), as depicted in Figure 37.1, or *Anaplasmataceae* (Driscoll et al., 2017). The latter is probably more accurate, provided that 16S rDNA-based phylogenies including far more environmental isolates suggest a closer relationship of "Midichloriaceae" with *Anaplasmataceae* (Driscoll et al., 2013; Gillespie et al., 2012a). The analysis of 16S rDNA sequences illustrates the extraordinary diversity within the *Midichloriaceae* and paves the way for future genome sequencing of additional taxa to better understand the proximate position of this natural group within the Rickettsiales (Figure 37.2). The position of the recently described "*Candidatus* Deianiraea vastatrix," a presumed obligate exoparasite of ciliates, is currently tenuous but stands to inform on the origin of obligate intracellularity in Rickettsiales (Castelli et al., 2019).

Holosporaceae

Family *Holosporaceae* was first added to the Rickettsiales in 2001 (Boone et al., 2001). This group is composed primarily of endosymbionts of protists, particularly amoebae, and was shown to form a distinct lineage basal to the derived rickettsial lineages (Baker et al., 2003). Much of the knowledge pertaining to these organisms comes from the described species of *Holospora*, particularly the paramecia associated *H. obtusa* (Gromov and Ossipov, 1981). Robust phylogenomics analysis of the first sequenced genomes for *Holosporaceae*, *H. undulata* (Dohra et al., 2013) and "*Candidatus* Odyssella thessalonicensis" (Birtles et al., 2000), placed *Holosporaceae* as a basal lineage to the three other rickettsial families and mitochondria (Driscoll et al., 2013) (Figure 37.1). While broader analysis of 16S rDNA sequences confirmed this arrangement of rickettsial families (Driscoll et al., 2013) (Figure 37.2), more recent studies argue that *Holosporaceae* is not a rickettsial family (Hess et al., 2016; Muñoz-Gómez et al., 2019; Szokoli et al., 2016). Like *Midichloriaceae*, the diversity encompassed within the *Holosporaceae* is extraordinary, necessitating the collection of more genome sequences from other species to bolster the taxonomic position at the root of the rickettsial phylogeny. This information will prove invaluable for further stabilization of

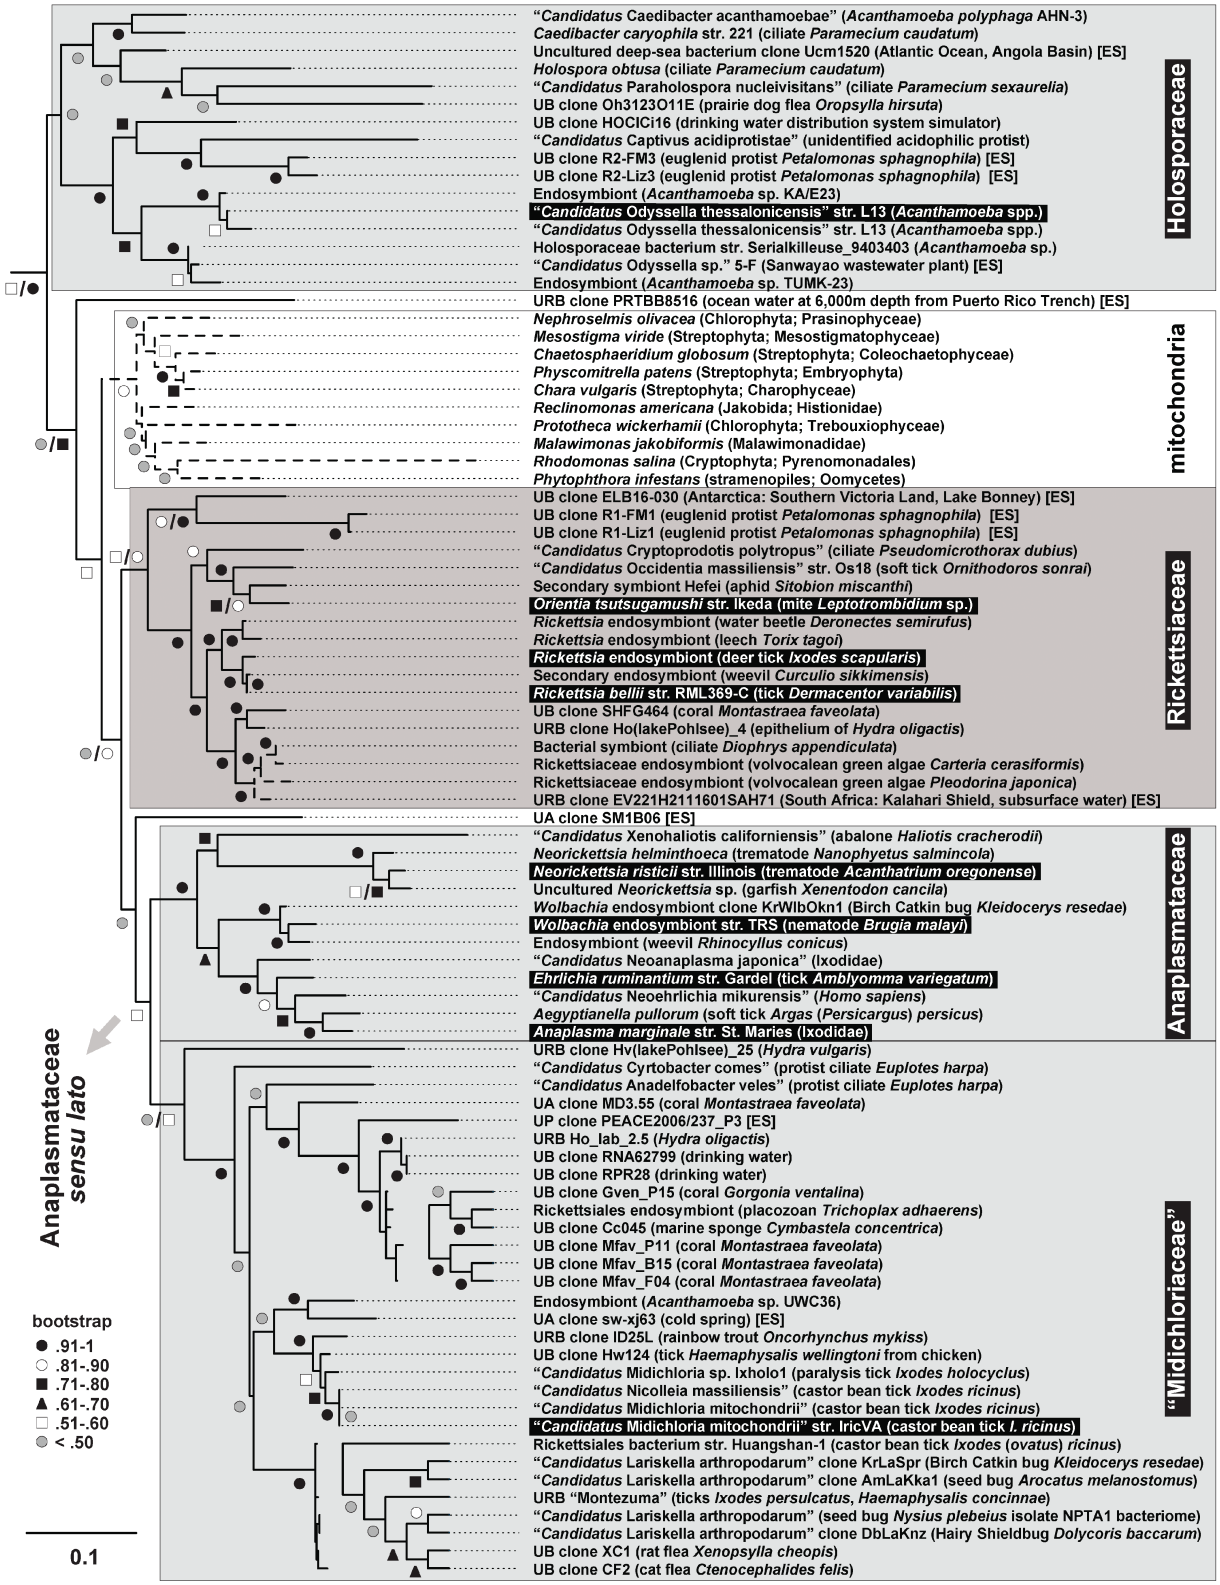

FIGURE 37.2 16S rDNA-based phylogeny estimation for Rickettsiales. Phylogeny of SSU rDNA sequences was estimated for 78 Rickettsiales taxa, 10 mitochondria, and five outgroup taxa (not shown). The phylogenetic pipeline that entails alignment and tree-building methods is described elsewhere (Driscoll et al., 2013). Tree is final optimization likelihood: (–22042.321923) using GTR substitution model with GAMMA and proportion of invariant sites estimated. Brach support is from 1,000 bootstrap pseudoreplications. For nodes represented by two bootstrap values, the left is from the analysis that included 10 mitochondrial sequences, with the right from the analysis without the mitochondrial sequences. All nodes with single bootstrap values had similar support in both analyses. Dashed branches are reduced 75% (mitochondria) or increased 50% (within *Rickettsiaceae*). Cladograms depict minimally resolved lineages within the "Midichloriaceae." For each taxon, associated hosts are within parentheses, with ES depicting an environmental sample.) Taxa within black boxes have available genome sequence data. More details such as taxon names, sequence accession numbers, etc., are provided elsewhere (Driscoll et al., 2013). (*Abbreviations:* UB, uncultured bacterium; UP, uncultured proteobacterium; UA, uncultured alphaproteobacterium; URB, uncultured Rickettsiales bacterium.

rickettsial classification and will also shed light on the evolution of diverse strategies of obligate intracellular lifestyle.

Rickettsial Genotypic and Phenotypic Characteristics

The first sequenced genome of a rickettsial species, *R. prowazekii*, revealed numerous pseudogenes and a highly reduced genome relative to facultative intracellular and free-living bacterial species (Andersson et al., 1998). Since then, dozens of additional genomes from species within all major genera have been sequenced, all being highly reductive yet encoding slightly different metabolic capacities (Driscoll et al., 2017; Gillespie et al., 2012a). Regarding Rickettsiaceae, by April 2014 three genome sequences of STG rickettsiae were available, coupled with 59 genome sequences from species of *Rickettsia* (Table 37.3). The genomes of two strains of *O. tsutsugamushi* possess a staggering proliferation of mobile genetic elements (MGEs), on par with that of the human genome (Cho et al., 2007; Nakayama et al., 2008). Still, these genomes contain several hundred core genes in common with *Rickettsia* genomes, though with slightly fewer encoding metabolic enzymes (e.g., an incomplete TCA cycle) (Driscoll et al., 2017; Nakayama et al., 2010). Analysis of the sequenced genomes of *O. chuto* (Izzard et al., 2010) and *Occidentia massiliensis* (Mediannikov et al., 2014) placed these species together with *O. tsutsugamushi* strains in a sister clade to all described *Rickettsia* species (Driscoll et al., 2017).

Importantly, the genome of *Occidentia massiliensis* does not encode the proliferated MGEs that characterize the *O. tsutsugamushi* genomes, suggesting the latter acquired these elements after diverging from the former (the *O. chuto* genome has not yet been analyzed for MGEs). It is tempting to speculate that these proliferated MGEs in *O. tsutsugamushi* genomes play a role in pathogenesis, possibly in providing the rickettsiae with a dynamic arsenal of surface antigens for avoidance of the host immune response (Cho et al., 2007; Gillespie et al., 2012b). Aside from several known host factors (i.e., fibronectin, α5β1 integrins and syndecan-4 receptors), three proteins have been shown to mediate attachment and entry of *O. tsutsugamushi* into host cells through a clathrin-dependent endosomal pathway (Ge and Rikihisa, 2011). Two of these proteins, TSA (47 kDa surface protein) and surface antigen ScaC, are unknown from *Occidentia massiliensis* (the *O. chuto* genome has not yet been scrutinized). The other protein, HtrA (47 kDa surface protein), is highly conserved across *Rickettsiaceae* genomes, with its function as a surface protein in *O. tsutsugamushi* possibly a moonlighting role that needs to be determined for other rickettsial species. Collectively, it is apparent that substantial genotypic differences underlay the STG rickettsiae genomes, illustrating the need to employ phylogenomics as a means to correlate pending characterized phenotypic traits with underlying genotype.

Substantial variation in size and gene number is seen across the 59 sequenced *Rickettsia* genomes (Table 37.3). The TG rickettsiae genomes are the smallest and encode the fewest number of genes, consequences of being the most degraded and rapidly evolving genomes of *Rickettsia* (Blanc et al., 2007). The TG rickettsiae genomes also contain a slightly higher AT-bias within their genomes. Outside of TG rickettsiae, such genome metrics do not consistently define other monophyletic groups. This is exemplified by the larger *Rickettsia* genomes, which are found in ancestral taxa (e.g., *R. bellii*), TRG rickettsiae (*R. felis*) and SFG rickettsiae (REIS, or now referred to as *R. buchneri* (Kurtti et al., 2015)). In fact, the larger *Rickettsia* genomes tend to have higher numbers of transposases and other MGEs relative to the smaller genomes, illustrating the role of lateral gene transfer in the evolution of *Rickettsia* species (Gillespie et al., 2012b; Hagen et al., 2018). The presence of plasmid(s) is also variable across species (and sometimes strains) (Gillespie et al., 2015a), yet it is likely that all species are able to harbor plasmids given that *R. prowazekii*, which does not encode plasmids, can stably maintain a transfected SFG-like plasmid (Wood et al., 2012). Notwithstanding these variable features across *Rickettsia* genomes, mapping of protein families over generated genome-based phylogenies strongly supports the three-group classification scheme (Gillespie et al., 2007), with each group having a distinct genetic profile that is predominantly of vertical descent (Gillespie et al., 2008, 2012a).

Phylogenomics has provided some clues for why certain species of *Rickettsia* do not fit well into the traditional TG and SFG rickettsiae. For instance, *R. canadensis* was previously associated with either TG or SFG rickettsiae until a robust phylogeny estimation suggested its closer affiliation with *R. bellii* (Gillespie et al., 2007). This result was consistent with only a few other reports (Stothard and Fuerst, 1995; Vitorino et al., 2007), as most other phylogenetic studies grouped *R. canadensis* erroneously based on the molecular marker being employed for phylogeny estimation. This instability of *R. canadensis* in analysis of different genes was clearly illustrated (Vitorino et al., 2007), and correlates with phenotypic traits that do not clearly delineate this species into TG or SFG rickettsiae. For example, like SFG rickettsiae, *R. canadensis* (1) infects ticks and is maintained transstadially and transovarially (Brinton and Burgdorfer, 1971; Burgdorfer, 1968); (2) grows within the nuclei of its host (Burgdorfer, 1968; Burgdorfer and Brinton, 1970); and (3) contains genes encoding both Sca0 and Sca5 surface antigens (Ching et al., 1990; Dasch and Bourgeois, 1981) (Figure 37.3). However, similar to TG rickettsiae, *R. canadensis* grows abundantly in yolk sac, lyses red blood cells, is susceptible to erythromycin, and forms smaller plaques relative to SFG rickettsiae (Myers and Wisseman, 1981). Genomic characteristics are just as ambiguous, as despite sharing roughly the same G + C% as TG rickettsiae (Eremeeva et al., 2005; Myers and Wisseman, 1981) and being more similar to TG rickettsiae in the percentage of coding sequence per genome and number of predicted genes (Table 37.3), *R. canadensis* shares more small repetitive elements with SFG rickettsiae than TG rickettsiae (Eremeeva et al., 2005). Collectively, these attributes for *R. canadensis* illustrate how a rigorous phylogenomic analysis is imperative for generating a robust systematic position for rickettsial species that defy older paradigms for classification into TG and SFG rickettsiae (Gillespie et al., 2007, 2009a).

Phylogenomics has also been employed to characterize the TRG rickettsiae (Gillespie et al., 2007, 2008, 2015a), as well as identify that *R. helvetica* does not currently fit within the four-group classification scheme (Driscoll et al., 2013, 2017). The emerging diversity of genus *Rickettsia* (Gillespie et al., 2012a; Murray et al., 2016; Perlman et al., 2006; Weinert et al.,

[a] All sequences were annotated with RAST (Aziz et al., 2008).

2009) suggests that additional groups of rickettsiae will likely be needed to further stabilize *Rickettsia* classification, though such endeavors must employ rigorous phylogenomic analysis. Additionally, phenotypic data is critical for understanding the underlining genetic attributes of *Rickettsia* genomes. Without such data, the results of phylogenomics cannot be effectively interpreted. For example, the analysis of 19 secreted proteins across 59 *Rickettsia* genomes shows some patterns that define the four groups of rickettsiae (Gillespie et al., 2015b) (Figure 37.3B). However, it is difficult to associate phenotypic traits with these genotypic maps, for several reasons. First, thorough and rigorously tested phenotypic traits are not available in the literature for all rickettsial species. Second, presence alone of a gene suspected to contribute to a phenotype is not enough; expression and other post-genomic data are necessary to determine if the gene is functional. Finally, and most concerning, is the poor quality of many genomes sequenced with short read sequencing technologies. It is apparent that most genomes sequenced since 2010 have not been manually curated for confirmation of automated annotation, and many genome projects have not published an assembly. The WGS "raw" data may contain areas of low sequence coverage that, unfortunately, result in misassembly or, even worse, errors in gene prediction and annotation. This results in apparently truncated genes, split genes, or pseudogenes; however, the probable full-length of these genes is masked by poor quality of data and a lack of manual evaluation.

Collectively, a vast treasure trove of genomic data is amassing for species of *Rickettsiaceae*. Phylogenomics is providing an invaluable tool for improving rickettsial classification and identifying genotypic features that define specific lineages of rickettsial species. Undoubtedly, the challenges highlighted above will be met with the careful fusion of experimental data and genomic data, with the latter manually processed to provide an accurate genotype for all species. Thus, the framework for scaffolding pathogenicity factors over rickettsial lineages, correlating phenotype with genotype, is set and provides an invaluable resource for future research.

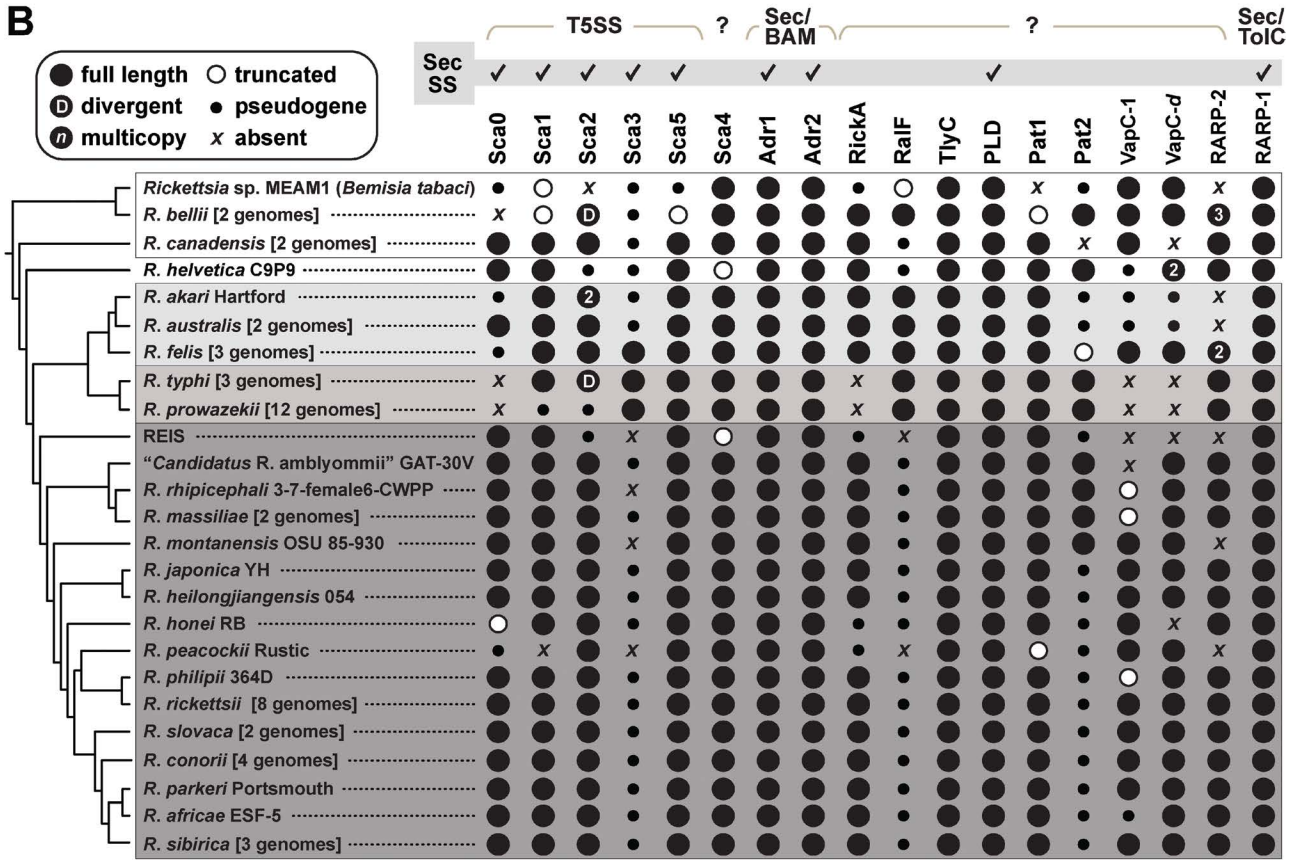

FIGURE 37.3 *Rickettsia* phenotypic and genotypic variability. (A) Variation in pathogenicity (decreasing left to right) and several phenotypic traits for nine well-studied *Rickettsia* species. For transmission: V, vertical (transovarial); H, horizontal (transstadial only). For *R. typhi*, "min" reflects the small actin tails responsible for erratic rickettsia movement (Heinzen et al., 1993; Van Kirk et al., 2000; Teysseire and Raoult, 1992). For *R. felis*, "C" denotes contradictory data. (B) Conservation and distribution across 59 *Rickettsia* genomes of genes encoding 18 secretory proteins. Phylogeny at left was estimated as previously described (Driscoll et al., 2013), with additional genomes annotated using RAST (Aziz et al., 2008). Classification scheme for *Rickettsia* spp. follows previous studies: white, ancestral group; light gray, transitional group; gray, typhus group; dark gray, spotted fever group (Gillespie et al., 2007, 2008). *Rickettsia helvetica* is unclassified (*incertae sedis*) following recent recommendations (Driscoll et al., 2013). Protein names are listed at top. Secretion pathway information is above protein names, with checkmarks depicting proteins with NT Sec secretion signals (Ammerman et al., 2008). Inset: large black circles, full-length proteins; medium-sized open circles, truncated proteins that may have additional fragments encoded by separate genes; small black circles, probable pseudogenes with one or more fragments that do not span the complete protein; Xs, absent genes with zero significant matches using BLASTP. For Sca2, D denotes divergent passenger domains fused to conserved Sca2 autotransporter domains. Numbers on other circles depict proteins encoded by multiple genes.

Rickettsial Virulence and Pathogenesis

The majority of extant, described species of *Rickettsia* and *Orientia* are associated with arthropods during some phase of their life cycle. Vector maintenance of rickettsiae involves either horizontal (arthropod-vertebrate cycle) or vertical (transovarial) transmission, or both, as is the case for many of the well-studied *Rickettsia* pathogens (Figure 37.3A). Aside from the spread of *R. prowazekii* via lice-feeding among tightly associated communities, humans are considered a dead-end host for rickettsiae, the result of accidental infection (Sahni et al., 2013). The rickettsiae transmitted via blood-feeding arthropods are found within all four phylogenetic groups (STG, TRG, TG, SFG rickettsiae) as well as certain ancestral *Rickettsia* species (e.g., *R. bellii* and *R. canadensis*) and include pathogens vectored by various species of ticks, fleas, lice, and mites. These rickettsial species have varying degrees of pathogenicity for eukaryotic hosts, including mammals and arthropods. For example, *R. prowazekii* and *R. rickettsii* produce severe and often fatal disease in humans, and their maintenance in their vectors (human body lice and tick, respectively) is lethal to the arthropod host (Azad and Beard, 1998). However, infection with *R. typhi*, while symptomatic and even fatal in humans, has no effect on the vector fleas. While both *R. prowazekii* and *R. typhi* infection are lethal to human body lice, infection with two pathogenic SFG rickettsiae (*R. rickettsii* and *R. conorii*) had no effect on louse fitness. In contrast to all described species of TG and TRG rickettsiae, not all species of SFG rickettsiae cause disease in vertebrate hosts; for example, *R. montanensis*, *R. peacockii*, and *R. rhipicephali* are proposed to be nonpathogenic for mammals and lack any apparent adverse effects on the survival and fitness of their tick hosts (Azad and Beard, 1998). Furthermore, the pathogenicity of species of ancestral *Rickettsia* species remains unknown, as does the ability of other poorly described species not associated with blood-feeding arthropod vectors (Gillespie et al., 2012a).

Over the past 20 years, the application of molecular biology tools, especially recombinant DNA technology for rickettsial diagnosis, resulted in the discovery of several new species of pathogenic rickettsiae. Of paramount importance was the sequencing of over 60 genomes of the members of *Rickettsiaceae* (Table 37.3). While this information revealed some intriguing information (e.g., close phylogenetic relationship to mitochondria, extensive numbers of pseudogenes in varying states of degradation, genome reduction and loss of many genes needed for free living life style), it also confirmed many features of rickettsial pathogens that were already known (e.g., ATP/ADP transporter system, absence of rickettsial bacteriophages, lack of genes for glycolysis and the biosynthesis of most amino acids, vitamins and cofactors) (Gillespie et al., 2012a). Aside from evolutionary studies and comparative metabolic profiling (Driscoll et al., 2017), more recent studies utilizing genomic data tend to focus on specific genes that potentially play a direct role in host pathogenicity. To this end, studies focusing on genes that define particular rickettsial groups are invaluable for understanding lineage-specific pathogenicity factors (Ammerman et al., 2009; Lehman et al., 2018; Rahman et al., 2010, 2013; Rennoll-Bankert et al., 2015).

For *Rickettsia* spp., genomics has driven the characterization of genes encoding secreted proteins involved in (or predicted to be involved in) adhesion, phagosomal escape, host actin polymerization, toxin secretion, and hemolysis (Gillespie et al., 2015b) (Figure 37.3B). The secretion systems themselves (Gillespie et al., 2009b, 2010, 2015c, 2016; Kaur et al., 2012; Rahman et al., 2003, 2005, 2007; Sears et al., 2012) as well as the factors mediating protein secretion (Ammerman et al., 2009, 2008; Lehman et al., 2018; Rennoll-Bankert et al., 2015), are also becoming better understood. Collectively, these components of the rickettsial secretome are highly targeted by researchers interested in identifying the mechanisms of rickettsial pathogenicity. Although rickettsial invasion and destruction of eukaryotic host cells is considered the basis for rickettsial pathogenicity, the precise role of presumed "virulence factors" requires further elucidation. The question that remains to be answered is: what are the underlying mechanisms that make some strains of *Rickettsia* so virulent and others avirulent? While the relevance of these findings to virulence is still an open question, a blend of advances in genetic manipulation, post genomic approaches, and phylogenomics (including more sequenced genomes) will undoubtedly provide insights into the underlying molecular basis of rickettsial virulence. It is only a matter of time before the genetic basis of rickettsial pathogenicity is illuminated.

Changing Ecology of Rickettsial Pathogens

Throughout modern history, the morbidity and mortality associated with rickettsial infections has been underestimated, primarily due to misdiagnosis. This unfortunate truth remains at present, with the significance and impact of rickettsioses greatly underappreciated worldwide, including in the United States. Fatalities associated with rickettsial infections continue to decline worldwide due to the effectiveness of antibiotics and physician awareness and improved rapid diagnosis. However, the "flu-like" symptoms presented by patients during early infection often delay the administration of appropriate antibiotics. Furthermore, the long incubation time (often greater than one week) allows rickettsiae to grow to large numbers and disseminate throughout the vascular system, compromising vascular integrity and setting the stages for more serious complications, including noncardiogenic pulmonary edema, acute respiratory distress, compromised central nervous system (CNS), and failure of multiple organ systems (Sahni et al., 2013). However, perhaps most important to the underestimation of rickettsial diseases is the growing number of emerging pathogens that were previously considered nonpathogenic, such as *R. massiliae*, *R. felis*, *R. parkeri*, *R. aeschlimannii*, *R. slovaca*, and *R. helvetica*. This occurrence, in conjunction with reemerging pathogens in novel focal areas, which in some cases are vectored by previously unrecognized arthropod species (Dumler and Walker, 2005), present a dire need to better understand the ecological landscapes of rickettsial pathogens and their ability to adapt to changing environments and maintain their virulence.

In recent decades, the improvement of molecular diagnostics and the importance of selected rickettsial pathogens as biothreat agents have rekindled interest in rickettsioses. Recent "serosurveys" have demonstrated a high prevalence of rickettsial

diseases worldwide, particularly in warm and humid climates. Additionally, new molecular diagnostic technologies helped to narrow the gap of the continental divide in rickettsial distributions. For example, several rickettsial species that were known only in the United States are now reported in Central and South America. The substantial diversity of rickettsial pathogens throughout the world, coupled with variable clinical manifestations, provides a daunting task to review the ecology of all rickettsial diseases. Thus, further description below is limited to four important rickettsial pathogens: 1) the louse-borne epidemic typhus agent *R. prowazekii*, 2) the flea-borne endemic typhus agent *R. typhi*, 3) the tick-borne Rocky Mountain Spotted Fever agent *R. rickettsii*, and 4) the mite-borne scrub typhus agent, *O. tsutsugamushi*.

Classic Epidemic Typhus

Epidemic typhus is one of the most virulent diseases known to humanity. Symptoms appear about 10 days after an infected body louse has bitten a person and include a high fever of about 42°C, extreme pain in the muscle and joints, stiffness, and cerebral impairment. During the second week, the patient may become delirious with neurological symptoms and may experience stupor. Gangrene and necrosis may occur due to thrombosis of the small vessels in the extremities. Mortality rate in untreated patients is approximately 20%. In severe epidemics, the mortality rate is often as high as 40%. The human body louse, *Pediculus humanus corporis*, is the principal vector for *R. prowazekii*. Although the head louse, *P. h. capitis*, is capable of maintaining *R. prowazekii* experimentally, its role in the transmission of this rickettsiosis is not well established. Body lice feed only on humans, although the laboratory-adapted colony can be maintained on rabbit or artificially fed on defibrinated blood, and all three stages of the louse life cycle (i.e., eggs, nymphs, and adults) may occur on the same host. The lice prefer a lower temperature (20°C) and are normally found in the folds of clothing. The body louse will abandon a patient with a temperature greater than 40°C to seek another host. This attribute is a major factor in the transmission of typhus within the susceptible population. Humans serve as host to *R. prowazekii* and lice and are reservoirs of the rickettsiae. In addition, humans serve as a mobile component of the louse-borne typhus cycle, such that behavior influences the pattern of typhus transmission. The conditions that allow for the coexistence of body lice and a susceptible population could be the starting point for an epidemic of *R. prowazekii* to flare in refugee camps.

Louse-borne epidemic typhus is still endemic in highlands and cold areas of Africa, Asia, Central and South America, and in parts of Eastern Europe. Another face of typhus, hardly studied in depth, is recrudescent typhus (Brill-Zinsser disease), in which the symptoms are less pronounced, and the mortality rate is less than 1%. However, these patients could serve as a long-range source of *R. prowazekii*, permitting transmission of rickettsiae to occur months to years after the primary infection. In the United Sates, *R. prowazekii* is maintained in the sylvatic form involving the flying squirrel and its fleas and lice. Fortunately, immunity to typhus rickettsiae develops after recovery from infection. Furthermore, successful treatment with tetracycline and doxycycline is the approach of choice to reduce morbidity and eliminate mortality in susceptible populations. Although vaccination against *R. prowazekii* has been partially achieved with inoculation of inactivated rickettsiae or attenuated strains (e.g., str. Madrid E), these vaccine approaches have unfortunately been accompanied with undesirable toxic reactions and difficulties in standardization.

Endemic Typhus

In the United States, a major concern is the changing ecology of endemic typhus, hereafter referred to as murine typhus. For instance, in both south Texas and southern California, the classic cycle of *R. typhi*, which involves commensal rats and primarily the rat flea (*Xenopsylla cheopis*), has been replaced by the Virginia opossum (*Didelphis virginiana*)/cat flea (*Ctenocephalides felis*) cycle. Curiously, however, infected rats and their fleas are difficult to document within Texas and California's murine typhus foci (Azad and Beard, 1998; Azad et al., 1997). Similarly, the association of 33 cases of locally acquired murine typhus in Los Angeles County with seropositive domestic cats and opossums was also confirmed. Additionally, based on serological surveys, *R. typhi* infections also occur in inland cities in Oklahoma, Kansas, and Kentucky, where urban and rural-dwelling opossums thrive. Thus, the maintenance of *R. typhi* in the cat flea/opossum cycle is of potential public health importance and a major health risk considering the distribution of opossum, which spans the United States, Mexico, Central America, and Canada. A previous search for the rural reservoir of murine typhus also resulted in the discovery of *R. felis*, the second flea-borne associated rickettsial species in opossums (Azad and Beard, 1998; Azad et al., 1997). Urban rat/flea populations are still the main reservoir of *R. typhi* worldwide and particularly in many cities where urban settings provide a constellation of factors for the perpetuation of the *R. typhi* cycle, including declining infrastructures, increased immunocompromised populations, homelessness, and high population density of rats and fleas.

Rocky Mountain Spotted Fever (RMSF)

RMSF is one of the most virulent human infections in the United States. *R. rickettsii*, the causative agent of RMSF, is a true zoonotic bacterium that cycles between ixodid ticks and wildlife populations, not only in the United States, but also in Mexico and in Central and South America. RMSF, like all rickettsial infections, is classified as a zoonosis requiring a biological vector such as tick to be transmitted between animal hosts (and accidentally to humans). Human infection occurs via the bite of an infected tick. Initial signs and symptoms of the disease include fever, headache, and muscle pain. This is followed by rash and organ-specific symptoms such as nausea, vomiting, and abdominal pain. Delayed treatment results in hospitalization and sequelae, such as amputation, deafness, and permanent learning impairment. The disease can be difficult to diagnose in the early stages due to nonspecific presentations and, unfortunately, in the absence of prompt and appropriate treatment, it often kills the infected patient. Mortality of up to 75% had been reported before antibiotic discovery, and even today 5–10% of

children and adults die from RMSF, with many more requiring intensive care. RMSF is a reportable disease in the United States, although the number of reported cases annually ranges between 250 and 1,200.

All SFG rickettsiae are transmitted by ixodid ticks (Azad and Beard, 1998; Parola et al., 2005). In addition to *R. rickettsii*, the etiologic agent of RMSF, several other tick-borne rickettsial species are also human pathogens (Table 37.1). In the United States, at least five other SFG rickettsiae, namely *R. amblyommii*, *R. montanensis*, *R. peacockii*, *R. buchneri*, and *R. rhipicephali*, are routinely isolated only from ticks yet cause limited or no known pathogenicity to humans or certain laboratory animals. *R. parkeri*, which was originally considered nonpathogenic, is now widely considered a human pathogen (Paddock et al., 2004); thus, the other five rickettsial species could also be etiologic agents of as-yet-undiscovered, less severe rickettsioses. However, the genome sequences of *R. peacockii* (Felsheim et al., 2009) and *R. buchneri* (Gillespie et al., 2012b) reveal the proliferation of mobile elements that have interrupted many genes, some of which are candidate virulence factors, suggesting that these species may be restricted to their arthropod vectors.

Distribution of SFG rickettsiae is limited to that of their tick vectors. In the United States, a high prevalence of SFG species in ticks cannot be explained without the extensive contributions of transovarial transmission. The transovarial and transstadial passage of SFG rickettsiae within tick vectors in nature ensures rickettsial survival without requiring the complexity inherent in an obligate multi-host reservoir system (Azad and Beard, 1998). Although many genera and species of ixodid ticks are naturally infected with rickettsiae, *Dermacentor andersoni* (Rocky Mountain wood tick) and *D. variabilis* (American dog tick or Wood tick) are the major vectors of *R. rickettsii* in the United States.

Scrub Typhus

Scrub typhus is an acute, febrile, infectious illness caused by *O. tsutsugamushi* (formerly *Rickettsia tsutsugamushi*, as previously discussed) (Salje, 2017). Long considered a monotypic genus, it is now apparent that substantial diversity exists within the sister clade to genus *Rickettsia* (Figure 37.2), with a recently described novel species of *Orientia*, *O. chuto* (Izzard et al., 2010). Additionally, novel strains of *O. tsutsugamushi* continue to be discovered in geographically isolated regions worldwide (Jiang et al., 2013; Kelly et al., 2009; Odorico et al., 1998; Yang et al., 2012). Like *Rickettsia* spp., *O. tsutsugamushi* is an obligate intracellular Gram-negative bacterium. However, as compared to *Rickettsia* spp., *O. tsutsugamushi* possesses a different cell wall structure, lacking canonical peptidoglycan and any component of lipopolysaccharide (Atwal et al., 2017; Driscoll et al., 2017), and also has a slightly different composition of metabolic genes (Driscoll et al., 2017; Gillespie et al., 2012a; Min et al., 2008). Humans acquire scrub typhus via the bite of infected larval stages of numerous species of trombiculid mites (*Leptotrombidium* spp.). Scrub typhus is endemic in regions of eastern Asia and the southwestern Pacific (Korea to Australia), and also from Japan to India and Pakistan. While no significant morbidity or mortality occurs in patients who receive appropriate treatment, pneumonia, myocarditis, disseminated intravascular coagulation, and death can occur in 0–30% of untreated patients or those infected with antibiotic resistant *O. tsutsugamushi* strains.

The contemporary urban and rural cycles of rickettsial pathogens present a potential for future outbreaks amid the drastic increase in housing construction, urban sprawl and related developmental expansion, all of which provide mammalian reservoirs and their blood-sucking ectoparasites ample harborage and proximity to human habitations. Considering the existing trends in global population expansion, rickettsial agents will continue to be introduced into human populations, with susceptible populations the primary targets for emerging and re-emerging pathogens. To this end, the advancements in classification and diagnostics brought about by the molecular technologies described above have a broader impact, reshaping the knowledge of the eco-dynamics and compositional patterns of rickettsial species worldwide.

Rickettsial Pathogens as Biothreat Agents

Throughout modern history, the epidemics of louse-borne typhus have been important in the molding of human destiny, being credited with causing more deaths than all the wars in history (Azad, 2007; Azad and Radulovic, 2003). For example, more than 30 million cases of louse-borne typhus occurred during and immediately after World War I, causing an estimated 3 million deaths. In the wake of war, famine, flood, and other disasters, the explosive spread of the brutal epidemic of louse-borne typhus within crowded human populations made a deep impression on the commanders of the Russian Red Army, and by 1928, *R. prowazekii* was transformed into a battlefield weapon. Many years later, the Japanese Army successfully tested "biobombs" containing *R. prowazekii*, causing outbreaks of typhus. Thus, the precedent exists for utilizing pathogenic rickettsiae in warfare, and recent increased risk of misuse of bacterial pathogens as weapons of terror is no longer fiction (Azad, 2007; Azad and Radulovic, 2003).

The rickettsial diseases vary from mild to very severe clinical presentations, with case fatality ranging from 2% to more than 30% (Table 37.4). The severity of rickettsioses has been associated with age, delayed diagnosis, hepatic and renal dysfunction, CNS abnormalities, and pulmonary compromise. Despite the variability in clinical presentations, pathogenic rickettsiae cause debilitating diseases and sometimes death, and several rickettsial pathogens could be used as a biological weapon. Realistically, only *R. prowazekii* and *R. rickettsii* pose serious problems, especially when some salient features of pathogenic rickettsial species are compared with those from several category A agents (Table 37.4). Despite the fact that effective chemotherapy is available and effective control measures are known, rickettsial diseases continue to be a problem in the United States and many other parts of the world.

Introduction

This chapter focuses on the pathogenic spirochetes, highlighting their unique basic biological properties and the important epidemiologic, clinical, pathologic, and diagnostic entities and immune phenomena associated with the diseases caused by them. Major emphasis is placed on the causative agents of Lyme disease (*Borrelia burgdorferi* and related strains) and syphilis (*Treponema pallidum*), because these represent the most common spirochetal diseases worldwide, including North America, and have generated the most interest and discussions among clinicians, scientists, patients, and other members of the lay public. In addition, their social, behavioral, as well as biomedical implications have long been recognized and these have led to considerable scientific and political debate, and unfounded misconceptions.

Basic Biology of the Spirochetal Bacteria

Spirochetes are a highly specialized group of motile Gram-negative spiral-shaped bacteria (Table 38.1), usually having a slender and tightly helically coiled structure. They range from 7 µm to 50 µm in length and about 0.5 µm in width. One of the unique features of spirochetes is their motility by a rapidly drifting rotation, often associated with a flexing or undulating movement along the helical path. Such locomotion is due to the presence of axial fibrils, also known as flagella, that are wound around the main body (protoplasmic cylinder) and enclosed by the outer cell wall or sheath of these organisms. These bacteria belong to the order Spirochaetales, which includes two families: Spirochaetaceae and Leptospiraceae. Important members of these groups include the genera *Borrelia, Leptospira,* and *Treponema*.

The spirochetes generally comprise a fastidious group of bacteria; that is, they can be difficult to grow (and therefore to study) in the laboratory, often requiring highly specialized media and culture conditions (such as low oxygen tension) to optimize their replicating capabilities. Some, such as *Treponema pallidum*, can only be maintained consistently in a replicating state by *in vivo* passage in rabbits, although a recent breakthrough in culture techniques may change the need for this long-standing procedure. The spirochetes live primarily as extracellular pathogens, rarely (if ever) growing within a host cell. A few reports have claimed finding spirochetes inside host cells but there is no evidence indicating that these are live or replicating organisms. Unlike most bacteria, spirochetes do not stain well with aniline dyes such as those used in the Gram stain procedure. However, their cell walls do resemble,

TABLE 38.1

Unusual Features of the Pathogenic Spirochetes

- Large bacteria: up to 50 μ in length, but very thin in diameter compared with other bacteria (e.g., cocci and rods are 1–3 μ in length), red blood cell diameter is 6–8 μ; they also exhibit a unique spiral, helical shape (Figure 38.1).
- Most of them require special staining techniques and microscopy for visualization, such as silver stain, fluorescence, or dark-field microscopy.
- They are nutritionally fastidious and exhibit a slow rate of growth: estimated 24–33 hour division time *in vivo* and slightly less *in vitro*; compare with *Escherichia coli*: 20 minutes.
- They are extremely sensitive to elevated temperatures (≥38°C). Except for one recently reported successful attempt, pathogenic treponemes *cannot* be cultivated on artificial media; other spirochetes, such as the *Borrelia* and *Leptospira* can be grown with some difficulty or with special media.
- They cause chronic, stage-related, and sometimes extremely debilitating or crippling disease in the untreated host.
- They do *not* seem to produce toxins.
- The interplay or interrelationship between the invading spirochetes and the subsequent host response as factors in the disease process have yet to be clearly or fully defined.
- They have endoflagella intertwined between the cell wall and protoplasmic cylinder—also called axial fibrils. Most bacterial flagella are extracellular.
- Most pathogenic spirochetes (*Borrelia, Treponema)* are microaerophilic (once thought to be anaerobes).
- *Borrelia burgdorferi* and its related strains are perhaps the most unique of the spirochetes, by having linear plasmids that code for outer-surface proteins.

both structurally and biochemically, those of other Gram-negative bacteria and are thus classified within this very large group of bacteria. Other staining procedures, such as silver, Giemsa, or the Wright stain, may be useful. The best way to visualize spirochetes, especially when they are alive and motile, is through the use of dark-field or phase-contrast microscopy or after staining with a fluorochrome dye, such as acridine orange, and then viewing under a microscope equipped for fluorescence microscopy (Figure 38.1). When present, their appearance in tissue specimens can often be revealed best by the silver-staining technique.

The infections caused by the spirochetes are important public health problems throughout the world, leading to such diseases as Lyme and the relapsing fever borrelioses, syphilis and the other treponematoses, and leptospirosis (Table 38.2). A better understanding of the molecular biology, pathogenesis, and immunobiology of the disease-causing spirochetes has become crucial in efforts to try to develop effective vaccines because there has been no significant modification in excessive sexual activity or in consistently practicing "safe sex" (for syphilis), personal hygiene practices (for some of the treponemal diseases), or vector or reservoir control (for Lyme disease and the other related borrelioses). Further knowledge of immune responses to spirochetes is essential for their eventual control by immunization, and studies of the host-spirochete relationship have led to important new insights related to the immunobiology of these pathogens. Serologic techniques have long been used as indispensable diagnostic tools for the detection of many of the spirochetal diseases, especially Lyme disease and syphilis. Unfortunately, as may occur in other infectious processes, the host response to the spirochetes, as part of the normal protective mechanisms, may paradoxically cause an immunologically induced disease in the affected individual, leading to the complications of carditis, arthritis and the neuropathies of Lyme disease, as well as aortitis, immune-complex glomerulonephritis, neurologic anomalies and the gummatous lesions of syphilis.

Lyme Disease

General Features

In the mid-1970s, a geographic clustering of an unusual rheumatoid arthritis-like condition, involving mostly children and young adults, occurred in northeastern Connecticut. This condition proved to be a newly discovered disease named Lyme disease, after the town of its origin.[1] The arthritis was characterized by intermittent attacks of asymmetric pain and swelling, primarily in the large joints (especially the knees) over a period of a few years. Epidemiological and clinical research showed that the onset of symptoms was preceded by an insect bite and unique skin rash probably identical to that of an illness following a tick bite, first described in Europe in the early 1900s.[2]

The beneficial effects of penicillin or tetracycline in early cases suggested a microbial origin (likely bacterial) for what was initially called Lyme arthritis. According to the U.S. Centers for Disease Control and Prevention (CDC), each year, approximately 25,000 to 30,000 cases of Lyme disease are reported to the CDC by state health departments and the District of Columbia (Figure 38.2). However, this number is believed to be a sizable

TABLE 38.2

Epidemiology of Spirochetal Infections

Pathogenic Spirochete	Human Disease	Vector or Source of Infection
Borrelia		
B. burgdorferi (sensu lato)[a]	Lyme disease or	Ixodid ticks
B. burgdorferi (sensu stricto)	Lyme borreliosis	*I. scapularis* or *pacificus*
B. afzelii		*I. ricinus*
B. garinii		
B. recurrentis	Epidemic relapsing fever	Body louse, *Pediculus humanus*
B. hermsii		
B. turicatae	Endemic relapsing fever	Ornithodoros ticks
B. parkeri		
B. miyamotoi		Various species of Ixodid ticks
Leptospira		
Leptospira interrogans	Leptospirosis (Weil's disease)	Exposure to contaminated animal urine
Treponema		
T. pallidum subspecies *pallidum*	Syphilis	Sexual contact, transplacental
T. pallidum ssp. *endemicum*	Bejel (endemic syphilis)	Direct contact with contaminated eating utensils
T. pallidum ssp. *pertenue*	Yaws	Direct contact with infected skin lesions
T. carateum	Pinta	

[a] Sensu stricto strains are found almost exclusively in North America, while *B. afzelii* and *B. garinii* are found only in Europe.

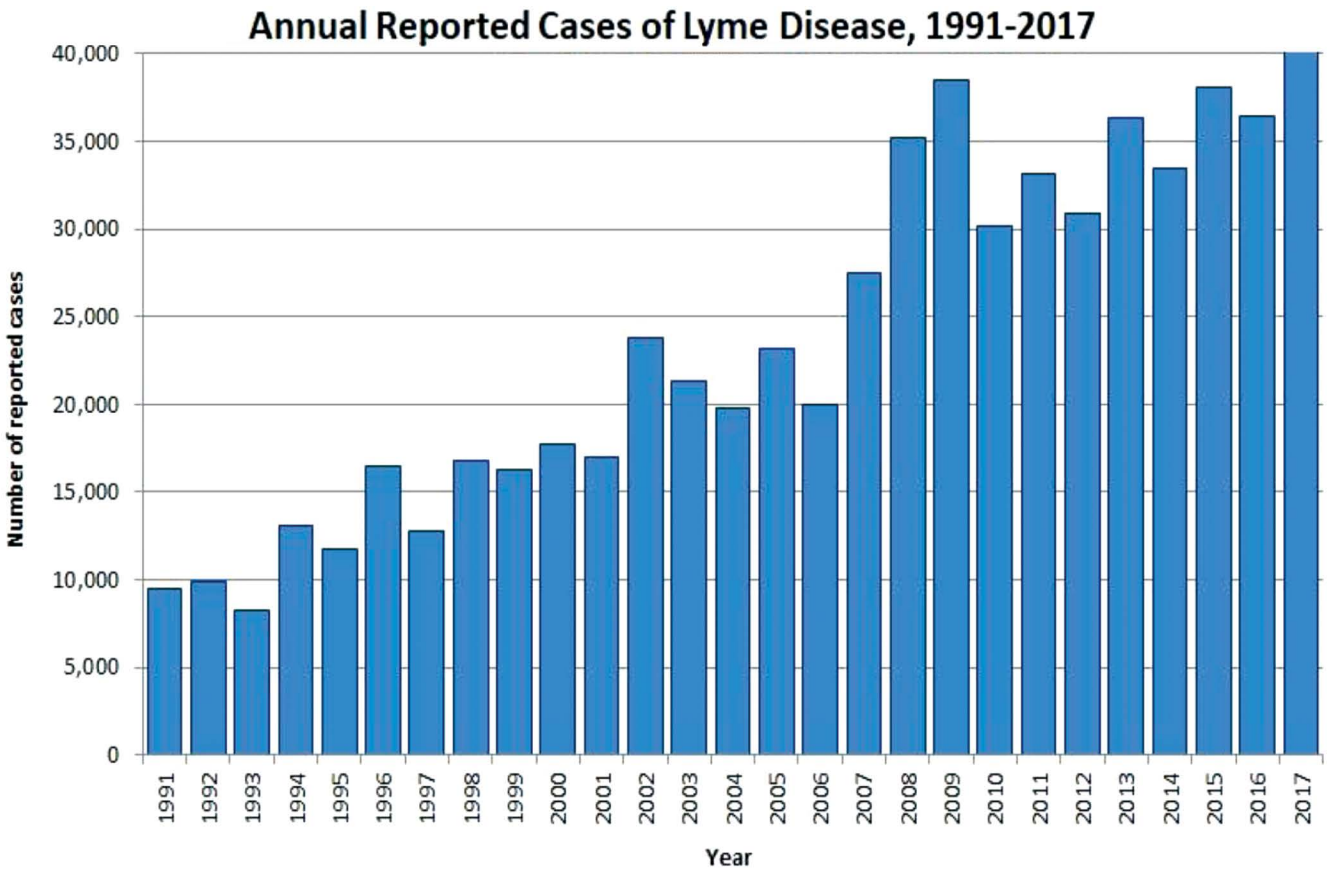

FIGURE 38.2 The graph displays the number of cases of Lyme disease reported to CDC which have increased steadily over the past 26 years. (From Centers for Disease Control and Prevention website: https://www.cdc.gov/lyme/why-is-cdc-concerned-about-lyme-disease.html.)

underestimate of the actual cases of Lyme disease that occur in the United States every year. It was announced in the summer of 2013, by the CDC, that the number of Americans diagnosed with Lyme disease each year is probably around 300,000. This preliminary estimate is based on studies conducted by the CDC and published a year later[3] that analyzed medical claim information, test results from clinical laboratories, and self-reported cases derived from a survey of the general public. The validity of such findings, however, still require scrutiny and further analysis, especially in terms of delineating laboratory-confirmed cases in relation to only probable cases having little or no confirmatory laboratory test results.

Lyme disease is now the most common tick-transmitted illness, and it has been reported in almost all the contiguous states of the United States and in numerous countries worldwide. However, it occurs primarily in three geographic regions in North America: (1) the coastal areas of the Northeast from Maine to Maryland, (2) the Midwest in Wisconsin and Minnesota, and (3) the far West in parts of California and Oregon. These geographic areas parallel the location of the primary tick vector of Lyme disease in the United States—*Ixodes scapularis* (formerly called *I. dammini)* in the east and Midwest and *I. pacificus* in the far west. Outside North America, Lyme disease is most prevalent in western Europe, especially in Austria, Germany, and the Scandinavian countries, corresponding to the distribution of *I. ricinus* ticks. The greatest concentration of cases is in the northeastern United States, particularly in Connecticut, Pennsylvania, and New York state, where the disease is endemic on eastern Long Island and just north of New York City in neighboring Westchester and Putnam counties.

In the early 1980s, spirochetal organisms were isolated and cultured from the midguts of *Ixodes* ticks taken from Shelter Island, NY (an endemic focus), and shortly thereafter they were cultured from the skin rash site, blood, and cerebrospinal fluid of patients with Lyme disease. This newly discovered spirochete called *B. burgdorferi* is microaerophilic, resembles other spirochetes morphologically, and is larger and not as tightly coiled than the treponemes. Recently, the Lyme disease spirochetes have been given updated taxonomic designations under the broad category of *B. burgdorferi* (sensu lato) (Table 38.2). Unlike most of the pathogenic treponemes, *B. burgdorferi* and related strains can be readily cultivated *in vitro* in a highly fortified growth media.[4]

Protection to *B. burgdorferi* may develop slowly, and it is unclear whether resistance to reinfection occurs. Experimental animal studies have shown that immune sera, that was derived from untreated patients having high titer antiborrelial antibodies, can transfer protection to normal recipients challenged with *B. burgdorferi*.[5] Monoclonal antibodies to borrelial outer surface proteins are also protective,[6] and these were the major target antigens for the first vaccine that became available for human use. It should be noted that, for a variety of reasons, the vaccine was withdrawn from the market by the manufacturer in 2002, after its initial approval in 1998.

Clinical Aspects

Lyme disease is an illness having protean manifestations with various signs and symptoms that include the following: (1) an erythematous-expanding red annular rash with central clearing; (2) fever, headache, stiff neck, nausea, and vomiting; (3) neurologic complications such as facial nerve (Bell's) palsy and meningitis; and (4) arthritis in about 50% of untreated patients.[7] These symptoms occur most frequently from May to November when ticks are active and numerous, and people are engaged in many outdoor activities. The most characteristic feature of early Lyme disease is a skin rash, often referred to as erythema migrans (EM), which appears shortly (3–32 days) after a bite from an infected tick. The lesion typically expands almost uniformly from the center of the bite and is usually flat or slightly indurated with central clearing and reddening at the periphery. It is noteworthy, however, that many Lyme disease victims either do not recall being bitten by a tick, or they do not notice a rash developing at an unrecognized tick bite, or possibly they do not go on to develop a classic EM at all. On the other hand, at various intervals after the initial rash, some patients develop similar but smaller multiple secondary annular skin lesions that last for several weeks to months. Due to the expanding nature of this rash and its originally described chronic form in European patients, it was initially referred to as erythema chronicum migrans. However, this term is rarely used now, with the term EM or multiple EM being the current descriptor. Biopsy of these skin lesions reveals a lymphocytic and plasmacytic infiltrate, and *Borrelia* can be cultured from them but not always. Various flu-like symptoms such as malaise, fever, headache, stiff neck, and arthralgias are often associated with EM. The serious extracutaneous manifestations of Lyme disease may include migratory and polyarticular arthritis, neurologic and cardiac involvement with cranial nerve palsies and radiculopathy, myocarditis, and arrhythmias. Lyme arthritis typically involves a knee or other large joint. It may enter a chronic phase, leading to destruction of bone and joints if left untreated. Interestingly, Lyme arthritis is less common in Europe than in the United States, but neurologic complications are more prevalent in Europe. Another geographic consideration involves the later-stage chronic skin condition known as acrodermatitis chronicum atrophicans, which can occur in Europe but has rarely been observed in North America. Unique strain variations expressing antigenic sub-types between European and North American isolates of *B. burgdorferi*[8] probably explain these dissimilarities, and this has led to additional species designations for other related Lyme disease-causing spirochetes, such as *B. afzelii* and *B. garinii,* which are not found in North America. Also, several other species within the senso-lato geno-complex, such as *B. lusitaniae* (found in Portugal) and *B. japonica* (found in certain parts of the Far East), have been identified but their pathogenic capabilities, as possible causes of Lyme disease, have yet to be well characterized.

In most cases, humoral and cell-mediated immune responses are activated during borrelial infection.[7,9,10] Antibody, mostly of the IgM class, can be detected shortly after the appearance of EM; thereafter, a gradual increase in overall titer and a switch to a predominant IgG antibody response occurs for the duration of an untreated infection. Most notably, very high levels of antibody have been found in serum and joint fluid taken from patients with moderate to severe arthritis, making this the most actively invasive and debilitating form of Lyme disease. Although the presence of such high antibody titers against *B. burgdorferi* may reduce the spirochete load somewhat, they appear not to

ameliorate the disease process completely and, indeed, may actually contribute to some of the pathologic changes. These consistent serologic responses have led to the development of laboratory tests designed to aid in the diagnosis of Lyme borreliosis. For cellular immunity, lymphocyte transformation assays have shown that peripheral blood T cells from Lyme disease patients respond to borrelial antigens primarily after early infection and following successful treatment.[9,10] Also, addition of antigens to synovial cells *in vitro* from infected patients triggers the production of interleukin-1, which could account for many of the harmful inflammatory reactions associated with this disease.[11] Other *in vitro* studies[12,13] have shown that human mononuclear and polymorphonuclear phagocytes can both ingest and presumably destroy *Borrelia*. Thus, borrelial antigen-stimulated T cells or their products may activate macrophages, limiting dissemination and resulting in enhanced phagocytic activity and the eventual clearance of spirochetes from the primary lesion.

Diagnosis

Clinically, Lyme disease mimics other disorders, many of which are not infectious and therefore would ordinarily not be responsive to antibiotic therapy. Because *B. burgdorferi* is the causative agent, finding the organism, or any of its key detectable components, in suspected cases is the most definitive diagnosis. However, in the vast majority of cases, the Lyme spirochete cannot be consistently isolated or identified due to its transient presence in blood and other body fluids and various tissues, coupled with its highly fastidious growth requirements for in vitro culture. Accordingly, immune responses (antibody production) specific for *B. burgdorferi* must be used to confirm the diagnosis.[14] Unfortunately, the antibody response is often not detectable in the early treatable stage, and the clinical impression cannot always be confirmed.

Isolation of the spirochete unambiguously confirms the diagnosis of Lyme borreliosis. Recovery of *Borrelia burgdorferi* is possible but the frequency of isolation from the blood or other body fluids of acutely ill patients is very low.[15,16] Better success rates in isolating *Borrelia* have been achieved after culturing skin biopsy specimens of clear-cut EM rashes.[17] Despite such success, borrelial cultivation can usually only be done in a few laboratories or institutions because the medium is expensive and very complex, and cultures can take up to several weeks of incubation before spirochetes are detected,[15,16] but most are positive within 4 weeks.

Visualization of the spirochetes in tissue or body fluids also has been used to diagnose Lyme borreliosis.[18] In the early stage of the disease, when EM is present, the Warthin-Starry or modified Dieterle silver stain can identify spirochetes in half or more of skin biopsies obtained from the outer portion of the lesion.[19] However, few microorganisms are present and they can be confused with normal skin structures or tissue breakdown products by inexperienced laboratory personnel. Immunohistologic examination of tissue has rarely been successful in determining the presence of *Borrelia* and, in chronic Lyme disease, spirochetes are rarely detectable by any microscopic technique.[20]

Serologic tests are, for all practical purposes, the only detection systems routinely available for the confirmation of Lyme borreliosis. One of the standard serological tests, either an enzyme-linked immunosorbent assay (ELISA) or an indirect immunofluorescence assay (IFA),[14] is available in many public and private laboratories. Blood samples obtained within 3 weeks of the onset of EM are frequently serologically negative in both assays.[21] In the past, these assays were not standardized, with laboratories using different antigen preparations and *cut-off* values. Workers, using the same set of sera, have reported interlaboratory variation in results and interpretations.[22] There is also considerable variability in the serologic response pattern of patients with Lyme disease. Nonetheless, over the past several years there has been considerable progress in development of better antibody detection systems. Currently, there are several commercially available serologic test kits that claim to have improved sensitivity (e.g., the C6 ELISA) without sacrificing specificity. Finally, if antibiotics are administered during early illness, antibody production can be aborted or severely curtailed,[7,14] although this is not always the case, particularly when convalescent sera are analyzed.[23]

The existence of antigenically different strains of *B. burgdorferi* sensu lato throughout the world[8] may account for some of the variability in antibody response patterns. In addition, assays currently either use the whole spirochete or a crude bacterial sonicate as antigen, or a mixture of recombinant-derived proteins. While the latter results in greater specificity, they tend to be less sensitive. With these assays, cross-reactions have been observed with other spirochetes, in particular *T. pallidum* and the relapsing fever *Borrelia* species.[24] For all of these assay systems, false-positive reactions are relatively rare except possibly in hyperendemic areas, where considerably more testing (often unnecessary) would be expected because of heightened awareness of Lyme disease within the general community. The cause of these positives is not always clear but they can occur if a patient has certain other disorders, such as syphilis (active or inactive), infectious mononucleosis, lupus, or rheumatoid arthritis. In the absence of a clear-cut EM rash, laboratory testing plays a vital role in establishing or confirming the diagnosis.

Attempts to improve antibody detection have used Western (immunoblot) analysis for the detection of IgM and IgG antibodies and have used purified flagellin antigen or the VlsE (or C6) peptides in the ELISA. Immunoblots are more sensitive and more specific than ELISAs. Although not standardized, commercial immunoblot test kits are now being offered to further verify a routine ELISA-based serologic test result, especially in troublesome cases, in conjunction with the two-tiered testing algorithm recommended by the CDC,[25] as well as for further confirmation of a true serologic response to specific borrelial antigens and possible infection. Some studies have shown, however, that immunoblotting could not overcome the inability to detect antibody during the first 3 weeks of infection.[26] The performance of the ELISA can also be improved using purified flagellin protein as antigen.[27] Antibodies to the 41-kDA, flagellum-associated component peak at 6–8 weeks, and often appear very early (<4 weeks) during an initial infection. Unfortunately, epitopes on this antigen are shared by many other spirochetes, and neither IgM nor IgG antibodies to this antigen are specific for *B. burgdorferi*.[26] It is noteworthy, however, that the initial development of an ELISA using recombinant VlsE (or C6) peptides showed considerable improvement in both specificity and sensitivity over prior assay systems.[28]

The prevailing sentiment within (as well as outside) the Lyme disease research and diagnostic community is that serological verification of this disorder is still fraught with difficulties. False-negative results are likely to occur if serum is obtained within 4 weeks of initial infection, or if the patient has been treated with antibiotics soon after a tick bite or a recognized EM rash. False-positives occur if large numbers of patients with a low *a priori* probability of having Lyme borreliosis are examined. Interlaboratory agreement on what constitutes a positive result varies, in part because of the diversity of detection systems being used by diagnostic testing facilities, which contain different antigen preparations and cut-off values developed by various manufacturers for serodiagnostic purposes. Compounding this problem, diagnosis of initial infection can be clinically difficult because only 60–75% of patients with Lyme borreliosis present with or recall having developed an EM rash, or have a clear and consistent epidemiologic history.[7]

The initial attempts in developing nonserologic based assays that were meant to address these apparent shortcomings in serologic testing have led to the development of alternative or supplemental diagnostic procedures such as the polymerase chain reaction (PCR) and the lymphocyte proliferation assay. Using the PCR and selective probes, it is possible to detect a single organism in a serum or tissue sample, and such gene amplification procedures show great promise for the early detection of *B. burgdorferi*.[29] In this regard, using primers directed at the rRNA genes of *B. burgdorferi*, it is possible to find the Lyme disease spirochete directly from skin biopsy material[30] as well as from short-term cultures of tissue extracts.[31] From a realistic standpoint, however, and because it may be technically demanding and not cost-effective for most diagnostic labs handling just a few specimens, PCR may continue to be primarily a research tool rather than a routine diagnostic procedure. Other limitations include its relatively poor sensitivity beyond the infected skin site and its inability to distinguish live organisms from remnants of dying organisms that may be present in a patient sample.

Additionally, some attention had previously been given to a cell-mediated immune (CMI)-based assay system[9,10] designed to measure past or current exposure to *B. burgdorferi* by virtue of the patient's lymphocytes to respond *in vitro* to undergo DNA synthesis (aka lymphocyte transformation or proliferation) in the presence of specific borrelial antigens. This laboratory procedure is generally considered a good *in vitro* correlate of the classic delayed type hypersensitivity (DTH) reaction,[32] analogous to what is found when measuring *in vivo* tuberculin sensitivity following a Mantoux skin test using a purified protein derivative (PPD) of *Mycobacterium tuberculosis*. For purposes related to Lyme disease, it was found that these lymphocyte proliferation assays have been helpful in identifying patients with active disease in the absence of detectable antibody (serologic) responses. However, as was the case with the early development of serologic tests, this assay has yet to be standardized and there is concern over the evidence[9] for elevated responses occurring in some healthy controls, thereby limiting the usefulness of this technique. Another *in vitro* correlate of the DTH reaction, which is currently being developed and is an extension of the lymphocyte proliferation assay, is based on Quantiferon technology.[33] This assay system relies on the ability of a patient's T cells to be stimulated to produce interferon-gamma after *in vitro* culture with peptide antigens of *B. burgdorferi*. So far there is only preliminary data showing that this assay system would be a significant alternative or supplement to serologic testing.

Finally, apart from PCR- and CMI-based techniques, another nonserologic detection system has used the newly developed metabolomics approach for the purpose of identifying unique biomarkers that appear in the blood of patients with early Lyme disease. Using this approach, it has been shown[34,35] that certain serum and urine small molecule metabolites can accurately distinguish patients with early Lyme disease from healthy controls and from patients with other diseases. The results of such analyses involved the use of liquid chromatography-mass spectrometry instrumentation which could be a serious limiting factor in the routine implementation of this diagnostic approach.

While PCR- and metabolomic-based procedures seem promising as exquisite and novel diagnostic tools for selective stages of Lyme disease, serological testing, for a variety of reasons (cost, standardization, need for sophisticated equipment and technical skill), will continue to be the mainstay for the laboratory detection of the vast majority of Lyme disease cases, as it currently is for syphilis (caused by the related spirochete, *T. pallidum*) and for certain other infectious and noninfectious disorders. Nonetheless, continued refinements along these lines will be needed and should be geared toward developing as economical a system as possible combined with one having optimal sensitivity and specificity.

Prophylactic Measures

Avoiding *Borrelia*-infected ticks or tick-infested areas will guarantee protection against Lyme infection. For those living in endemic areas, a few simple precautions will help minimize possible exposure. These include wearing clothing that fully protects the body and using repellents that contain DEET (diethyltoluamide). If a tick does attach to the skin, careful removal with tweezers shortly after it attaches, followed by application of alcohol or another suitable disinfectant, will make borrelial transmission unlikely.

In the early 1990s, considerable attention turned toward the development of a vaccine for Lyme disease. For a few years already, a canine vaccine consisting of whole inactivated organisms (Bacterin) was available, and still is, for veterinary purposes,[36] primarily for preventing *B. burgdorferi* infection in dogs. Those that had been developed for humans consisted of recombinant outer surface proteins (Osp) of *Borrelia burgdorferi*. In 1998, the FDA gave final approval to the first Lyme disease vaccine (called LYMErix®), which was shown to be safe and effective in extensively conducted clinical trials. It consisted of DNA-derived OspA of B31—a well-characterized tick isolate of *B. burgdorferi*—incorporated with an adjuvant.[37] However, in less than 4 years, the vaccine was withdrawn by the manufacturer, mostly due to concerns over its safety and unfavorable publicity resulting from claims of purported serious side effects in a select group of vaccines. Although studies continue with other vaccine candidates (especially in Europe), it is unclear when they may be available for widespread use.

Since the Lyme vaccine is no longer marketed and a number of substantive limitations exist to the use of oral doxycycline for prophylaxis shortly after a documented tick bite (cited below, under treatment) including the fact that the drug is contraindicated

in young children (<8 years of age) and pregnant or lactating women, consideration has been given to using topical antibiotic preparations instead that might have antiborrelial activity. In this regard, a variety of topical antimicrobials are in wide general usage for treatment of common conditions, both infectious and noninfectious. These preparations are well accepted and safe and because *B. burgdorferi* remains at the site of deposition in the skin after an *I. scapularis* tick bite for ≥2 days, perhaps the timely application of topical formulations of active antibiotics at the tick bite site could eliminate the infection. In the first published study[38] to test this hypothesis, several topical antimicrobial preparations (tetracycline hydrochloride, doxycycline, penicillin G, amoxicillin, ceftriaxone, and erythromycin) were shown to be highly effective (nearly 100%) in preventing *B. burgdorferi* infection in a mouse model when these preparations were applied within 48 hours after the spirochete-infected ticks had detached and the drug was given in the appropriate concentration and for the appropriate duration of time. However, none of the antibiotic preparations studied by these investigators is commercially available for use topically in the United States. Also, these investigators dissolved all the antibiotics studied, except for erythromycin, in dimethyl sulfoxide for improved absorption, but this compound is unsatisfactory, based on the formulation used, for routine use in humans. Unfortunately, as a follow-up to these initial seemingly promising results, in carefully controlled studies[39] using the murine model for experimental Lyme disease, topical applications of 2% erythromycin and 3% tetracycline preparations, that are acceptable for use in humans, were found to be ineffective in eliminating *B. burgdorferi* from the tick bite site or in preventing dissemination to other tissues.

Treatment

In general, early Lyme disease is readily treatable with a 2–3 week course of antibiotics, such as amoxicillin and doxycycline.[40] Later complications, such as arthritis and the neuropathies, may require more intense and prolonged antibiotic therapy, including intravenous treatment, with ceftriaxone being the preferred parenteral drug. Based on an extensive and well controlled study, showing favorable outcomes in treating patients with a single dose of doxycycline soon after a documented tick bite,[41] consideration should be given to following this treatment strategy, especially in highly endemic areas and this practice has recently been endorsed by the CDC, after meeting certain criteria, for the prevention of Lyme disease but not for other tick-borne diseases.[42]

Relapsing Fever Borreliosis

Relapsing fever is an acute febrile disease of worldwide distribution and is caused by arthropod-borne spirochetes belonging to the genus *Borrelia*.[43,44] Two major forms of this illness are louse-borne relapsing fever (for which humans are the reservoir and the body louse *Pediculus humanus* is the vector) and tick-borne relapsing fever (TBRF, for which rodents and other small animals are the major reservoirs and ticks of the genus *Ornithodoros* are the vectors). *B. recurrentis* causes louse-borne relapsing fever and is transmitted from human to human following the ingestion of infected human blood by the louse and subsequent transmission of spirochetes onto the skin or mucous membranes of a new host when the body louse is crushed. The disease is endemic in parts of central and east Africa and South America. The causative organisms of tick-borne relapsing fever are numerous and include *B. hermsii, B. turicatae,* and *B. parkeri* in North America; *B. hispanica* in Spain; *B. duttonii* in eastern Africa; and *B. persica* in Asia. Ticks become infected by biting and sucking blood from a spirochetemic animal. The infection is transmitted to humans or animals when saliva is released by a feeding tick through bites or penetration of intact skin.

After an individual has been exposed to an infected louse or tick, *Borrelia* penetrate the skin and enter the bloodstream and lymphatic system. After a 1- to 3-week incubation period, spirochetes replicate in the blood and there is an acute onset of shaking chills, fever, headache, and fatigue. Concentrations of *Borrelia* can reach as high as 10^8 spirochetes per milliliter blood, and these are clearly visible after staining blood smears with Giemsa or Wright's stain. During the febrile disease, *Borrelia* are present in the patient's blood but disappear prior to afebrile episodes and subsequently return to the bloodstream during the next febrile period. Jaundice can develop in some severely ill patients as a result of intrahepatic obstruction of bile flow and hepatocellular inflammation; if left untreated, patients can die from damage to the liver, spleen, or brain. The majority of untreated patients, however, recover spontaneously. They produce borrelial antibodies that have agglutinating, complement-fixing, borreliacidal, and immobilizing capabilities, and that render patients' immune to reinfection with the same *Borrelia* serotype. Serologic tests designed to measure these antibodies are of limited diagnostic value because of antigenic variation among strains and the coexistence of mixed populations of *Borrelia* within a given host during the course of a single infection. Diagnosis in the majority of cases requires demonstration of spirochetemia in febrile patients.

A partial account of an interesting clinical case pertaining to relapsing fever borreliosis was published recently in the *New England Journal of Medicine*[45]. It discusses a 13-year-old girl who presented with recurrent fevers, with temperatures up to 104°F (40°C), over a 3-week period, with associated headache, chills, and malaise. She and her family had stayed in a cabin in the eastern Sierra Nevada Mountains 10 days before she first had a fever. The patient's brother had similar symptoms. The siblings were febrile for 5 days and then symptom-free for 7 days. During a relapse of the girl's fever, blood was drawn; on examination of a blood smear, a *B. hermsii* spirochete was detected (Figure 38.3; arrow). Because of their symptoms and recent travel to an area where tickborne relapsing fever is endemic, the siblings were treated with doxycycline for presumed *B. hermsii* infection. Tests for serum IgG and IgM antibodies to *B. hermsii* were subsequently positive. After the first dose of doxycycline, defervescence occurred in both patients and associated symptoms resolved.

Borrelia miyamotoi is a newly recognized, culturable agent of human disease, and may be prevalent in areas where Lyme disease is endemic in the United States.[46] Using specialized media, *B. miyamotoi* isolates from certain parts of Japan and North America have been cultured but the reported yields of cultures for a North American isolate were lower than that expected for *B. burgdorferi* and several other *Borrelia* species. Based on recent DNA sequencing studies, it has been established that *B. miyamotoi* is a relapsing-fever group species. It is a spiral-shaped

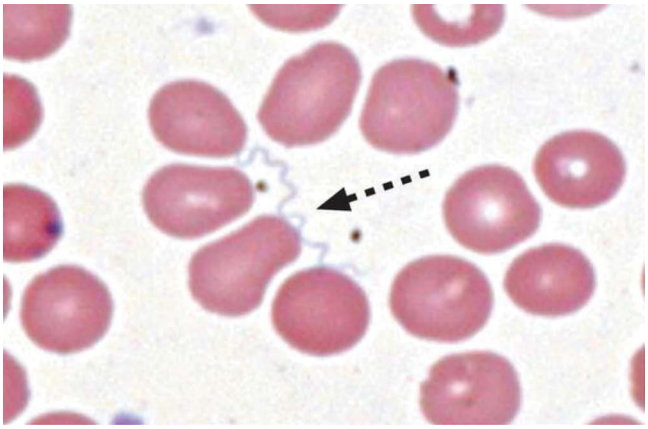

FIGURE 38.3 Giemsa-stained peripheral blood smear confirming a diagnosis of relapsing fever borreliosis.

bacterium that is only distantly related to the spirochete that causes Lyme disease. First identified in 1995 in ticks from Japan, it has since been detected in two species of North American ticks, the deer tick that transmits Lyme disease and the Western black-legged tick (*I. pacificus*), which is also known to transmit several diseases, including Lyme disease, anaplasmosis, and babesiosis. Human infections with *B. miyamotoi* were first described in 2011 in a report from Russia. Most of the patients had fever, headache, and muscle aches—the symptoms typical of TBRF. Symptoms similar to those of Lyme disease, such as the erythema migrans rash (bull's-eye rash), arthritis, or facial palsy, were uncommon.

Since the first three cases of human infection with *B. miyamotoi* were identified in the United States,[46] subsequent studies have identified several more cases. Examples of these patients include an elderly, immunocompromised woman with confusion and an unsteady gate. The bacteria were seen in samples of the patient's spinal fluid, and she recovered when treated with antibiotics. The two other patients had fever, chills, and muscle aches, similar to the symptoms of the patients in Russia.

Blood tests based on detection of antibodies appear to be useful indicators of active infection,[43] but still require further validation. Diagnosis currently relies on the use of tests to detect DNA of the organism in whole blood using the polymerase chain reaction or by serology. Serologic testing for *B. miyamotoi* is done using a recombinant glycerophosphodiester phosphodiesterase (rGlpQ) protein.[47] These tests are under continuous development and refinement, and only a few laboratories perform these tests. Culturing *B. miyamotoi* from whole blood of suspect patients is not routinely done due to the need for a highly specialized growth media, and the limited number of laboratories having the capability to isolate this difficult-to-culture spirochete on a routine basis. It should be noted that blood tests for Lyme disease are unlikely to be helpful in diagnosing *B. miyamotoi* infections. Physicians have successfully treated patients infected with *B. miyamotoi* with a 2-week course of doxycycline. The key signs and symptoms of this infection have not been clearly defined and some of them could easily be confused with other abnormal conditions. Most studies have focused on hospitalized patients and may have overestimated the severity of a typical infection. It is also unclear how common this infection is in the United States.

Leptospirosis (Weil's Disease)

Leptospiral infections are zoonoses widely distributed throughout the world. Human disease is somewhat more common in tropical than in temperate areas, and infection occurs more in the summer or autumn in temperate regions.[48] Most humans are infected by leptospires in water used for drinking, washing, bathing, or swimming primarily after contact with contaminated urine, from leptospiruric animals, that has entered the water supply. The most common sources of organisms are chronically infected rats and other rodents, cattle, horses, pigs, and dogs. Numerous wild animals and even reptiles and amphibians may be carriers. In North America, unvaccinated dogs are the major reservoir for exposure of humans to this disease. The routine vaccination of dogs against *Leptospira* is probably an important preventive measure. Leptospirosis is an occupational hazard for rice and sugar cane field workers, military personnel during field exercises, people who swim in contaminated ponds or streams, farmers, veterinarians, and sewer and abattoir workers. In tropical rainforests, infected rodents contaminate stream banks as well as the water. Rainstorms raise the level of the water, which washes leptospires into streams and makes swimming very hazardous. Related to this concern, large outbreaks of leptospirosis were reported among athletes participating in triathlon events held within the past 20 years in both the United States in 1998[49] and Malaysia in 2000.[50] More recently in the winter of 2018, a very small and brief outbreak occurred in the Bronx section of New York City (a large urban area) that involved three people who contracted leptospirosis. Although New York City typically sees only about one to three cases of leptospirosis per year, this is the first time that health officials identified a cluster of leptospirosis cases (meaning more than a single case occurring in the same place around the same time) in the city. All three people were hospitalized with kidney and liver failure, and one person died as a result of complications from their infection. It is believed that all three victims were exposed to infected rat urine. Such an outbreak points to the sometimes unpredictable epidemiologic nature of this disease.

Leptospirosis is an acute, febrile disease caused by various serotypes of *Leptospira* (there exist about 170 serovars in 20 serologic groups). Often referred to as Weil's disease, infection with *Leptospira interrogans* causes diseases that are extremely varied in their clinical presentations and that are also found in a variety of wild and domestic animals. After entering the body through the mucosal surface or breaks in the skin, leptospiral bacteria cause an acute illness characterized by fever, chills, myalgias, severe headaches, aseptic meningitis, rash, hemolytic anemia, uveitis, conjunctival suffuseness, and gastrointestinal problems. Most human infections are mild and anicteric, although in a small proportion of victims, severe icteric disease can occur and be fatal, primarily as a result of renal failure, myocarditis, and damage to small blood vessels. After infection of the kidneys, leptospiras are excreted in the urine. Liver dysfunction with hepatocellular damage and jaundice is common. Antibiotic treatment is curative if begun during early disease, but its value, thereafter, is questionable.

Diagnosis of leptospirosis depends on either seroconversion or the demonstration of spirochetes in clinical specimens. The

macroscopic slide agglutination test, which uses formalized antigen, offers safe and rapid antibody screening. Measurement of antibody for a specific serotype, however, is performed with the very sensitive microscopic agglutination test involving live organisms. This method provides the most specific reaction with the highest titer and fewer cross-reactions. Agglutinating IgM-class-specific antibodies are produced during early infection and persist in high titers for many months. Protective and agglutinating antibodies often persist in sera of convalescent patients and may be associated with resistance to future infections.

Syphilis

General Features

The origins and history of syphilis are filled with many mysteries and hypotheses. Biblical references suggest its presence in early civilization. Other evidence points to its prevalence primarily after Columbus and his crew returned to Europe from the New World in 1493. From that point on, syphilis spread throughout Europe, affecting all levels of society including political and religious leaders. Indeed, the dementia and insanity associated with late-stage syphilis that may have occurred in certain afflicted rulers or monarchs probably changed the course of history during the 16th and 17th centuries. Before antibiotics, many toxic drugs were used for treatment; as early as 1905, a blood test was developed for the diagnosis of syphilis—the so-called Wasserman test—the prototype for the current nonspecific serologic tests designed to measure antibodies to cardiolipin.

Syphilis is still a significant worldwide problem, and after herpes, gonorrhea, and chlamydial infections, it is the fourth or fifth most commonly reported sexually transmitted disease in the United States. The most recent rise in both same-sex and heterosexual infection occurred in the mid-1980s to the early 1990s (Figure 38.4), which coincided and co-factored with the huge number of newly diagnosed HIV cases. At the same time, this also paralleled an alarming increase in congenital syphilis in many urban areas where drug abuse and the frequent exchange of sexual services for drugs were common practices among those using illicit drugs.

Treponema pallidum subspecies *pallidum* is the spirochetal bacterium that causes syphilis and was once referred to as "The Great Imitator" (or "Mimicker"), due primarily to the myriad clinical presentations often associated with this disease.[51,52] If left untreated, syphilis can have severe pathologic effects, leading to irreversible damage to the cardiovascular, central nervous, and musculoskeletal systems.[51,52] This treponeme's genome was sequenced in 1998, yet up until very recently,[53] it had remained nonculturable on artificial media for more than a century. Despite this extraordinary achievement, it remains to be seen if other laboratories are able to grow this pathogen on a consistent basis. Prior to the successful *in vitro* cultivation of *T. pallidum*,[53] it had to be passaged *in vivo* using rabbits to maintain sufficient numbers of live organisms needed for conducting meaningful laboratory studies. It is also highly motile, infectious, and replicates extracellularly and very slowly *in vivo*. Because of its uniqueness, it has taken many years of research to acquire our current understanding of the treponemal bacteria, such as *T. pallidum* and this has probably delayed efforts toward any possible vaccine development. *T. pallidum*, unlike some of the other spirochetes, is shorter and more tightly coiled than the *Borrelia* and *Leptospiras*.

With the institution of antibiotic therapy in the mid-1940s, the incidence of syphilis fell sharply from a high of 72 cases per 100,000 population in 1943 to about 4 per 100,000 in 1956. During the late 1970s and early 1980s, syphilis increased rapidly within the homosexual community. Such findings can be attributed, in part, to changing lifestyles, sexual practices, and other factors such as an unusually high prevalence and reduced efficacy of antibiotics in patients with acquired immunodeficiency syndrome (AIDS). Syphilis continues to rank annually in the top five of the most frequently reported communicable disease in the United States, although its overall prevalence pattern has remained almost unchanged for the past several years (Figure 38.4).

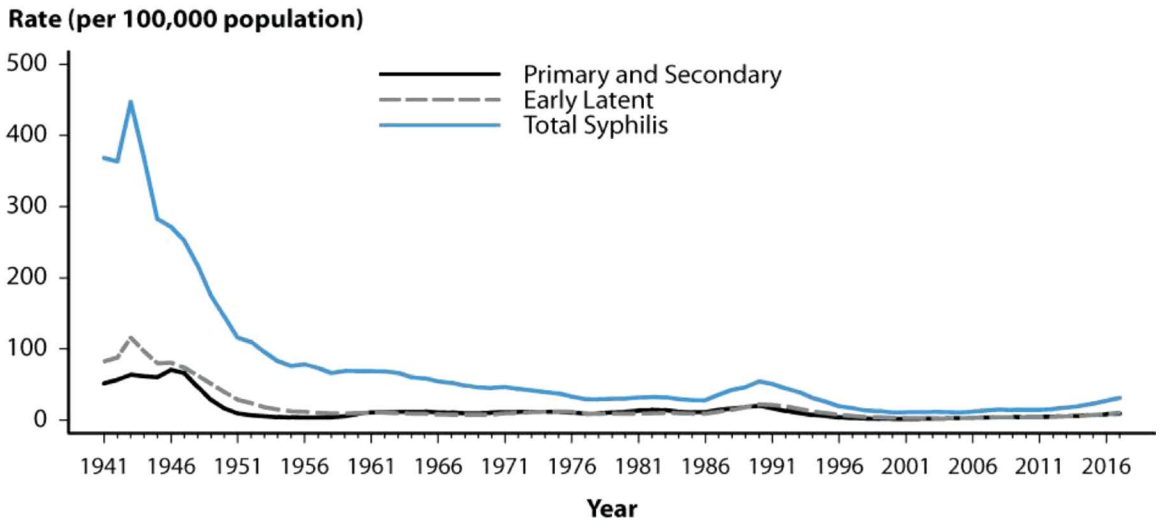

FIGURE 38.4 Rates of reported syphilis cases by stage of infection, United States, 1941–2017. (Based on data from Centers for Disease Control and Prevention. https://www.cdc.gov/std/stats17/syphilis.htm; accessed on July 8, 2019.)

The course of syphilis in humans is marked by several interesting phenomena. Without treatment, the disease will usually progress through several well-defined stages (somewhat resembling Lyme disease). This is unlike most other infectious diseases, which are ultimately eliminated by the host's immune system or, in severe cases, result in death. The relatively slow generation time of treponemes, which is estimated at 30–33 hours, contributes to this unique course. During the first two stages (primary and secondary syphilis), there is almost unimpeded rapid growth of *T. pallidum*, leading to an early infectious spirochetemic phase of the disease. The third stage (tertiary syphilis) occurs much later, following a prolonged latency period. Alterations in this stage are due primarily to tissue damaging immune responses elicited by small numbers of previously deposited or disseminated spirochetes.

Syphilis activates both humoral and cell-mediated immunity, but this protection is only partial. The relative importance of each type of immune response is not fully known. Protective immunity against re-exposure is incomplete, especially during early stages when it develops relatively slowly.

Clinical Aspects

The severe late manifestations or complications of syphilis occur in the blood vessels and perivascular areas. However, sexual contact is the common mode of transmission that follows inoculation of infectious treponemes onto the mucous membranes of genital organs or of the oropharynx.

The first clinically apparent manifestation of syphilis (primary syphilis) is an indurated, circumscribed, relatively avascular and painless ulcer (chancre) at the site of treponemal inoculation. Spirochetemia with secondary metastatic distribution of microorganisms occurs within a few days after onset of local infection but clinically apparent secondary lesions may not be observed for 2–4 weeks. The chancre lasts 10–14 days before healing spontaneously.

The presence of metastatic infection (secondary syphilis) is manifested by highly infectious mucocutaneous lesions of extraordinarily diverse description as well as headache, low-grade fever, diffuse lymphadenopathy, and a variety of more sporadic phenomena. The lesions of secondary syphilis ordinarily go on to apparent spontaneous resolution in the absence of treatment. However, until solid immunity develops (a matter of about 4 years), 25% of untreated syphilitic patients may be susceptible to repeated episodes of spirochetemia and metastatic infection.

Following the resolution of secondary syphilis, the disease enters a period of latency with only abnormal serologic tests to indicate the presence of infection. During this time, persistent or progressive focal infection is presumably taking place, but the precise site remains unknown in the absence of specific symptoms and signs. One site of potential latency, the central nervous system, can be evaluated by examining the cerebrospinal fluid in which pleocytosis, elevated protein levels, and a positive serologic test for syphilis are indicative of asymptomatic neurosyphilis.

Only about 15% of patients with untreated latent syphilis go on to develop symptomatic tertiary syphilis. Serious or fatal tertiary syphilis in adults is virtually limited to disease of the aorta (aortitis with aneurysm formation and secondary aortic valve insufficiency), the central nervous system (tabes dorsalis, general paresis), the eyes (interstitial keratitis), or the ears (nerve deafness). Less frequently, the disease becomes apparent as localized single or multiple granulomas known as *gummas*. These lesions are typically found in the skin, bones, liver, testes, or larynx. The histopathologic features of the gumma resemble those of earlier syphilitic lesions, except that the vasculitis is associated with increased tissue necrosis and often frank caseation. With its myriad organ-system involvement and symptomatology, syphilis, it's not surprising to have long been called the *The Great Imitator.*

Congenital syphilis is the direct result of treponemes crossing the placenta and fetal membranes, especially during midpregnancy, leading to spirochetemia and widespread dissemination after entering the fetal circulation. Fetal death and abortion can occur. Surviving babies with the disease have prominent early symptoms of hepatosplenomegaly, multiple long bone involvement, mouth and facial anomalies (e.g., saddle nose), and skin lesions. Treponemal antibodies (especially IgM) found in the newborn's blood is highly diagnostic.

Diagnosis

In its primary and secondary stages, syphilis can be diagnosed by dark-field microscopic examination of material taken from suspected lesions. This rather delicate and cumbersome procedure is now rarely done in most clinical settings and confirmatory tests rely solely on serology. Diagnostic serologic changes do not begin to occur until 14–21 days following acquisition of infection. Serologic tests provide important confirmatory evidence for secondary syphilis but are the only means of diagnosing latent infection. Many forms of tertiary syphilis can be suspected on clinical grounds, but serologic tests are important in confirming the diagnosis. Spirochetes are notoriously difficult to demonstrate in the late stages of syphilis.

Two main categories of serologic tests for syphilis are available: (1) tests for nonspecific reaginic (or anticardiolipin) antibody and (2) tests for specific treponemal antibody. In the United States, testing for syphilis traditionally has consisted of initial screening with the relatively inexpensive nonspecific test, then retesting reactive specimens with the specific, and slightly more expensive, treponemal test (both types of tests are explained next). When both test results are reactive, they indicate present or past infection. However, for economic reasons and because of variable response patterns exhibited by some suspect patients (such as with false-positives associated with the nontreponemal tests), some high-volume clinical laboratories have begun using automated treponemal tests, which has led to reversing the previously established and more traditional testing sequence by first screening with a treponemal test and then retesting reactive results with a nontreponemal test. This approach has introduced complexities in test interpretation that did not exist with the traditional sequence. Specifically, screening with a treponemal test sometimes identifies persons who are reactive to the treponemal test but nonreactive to the nontreponemal test. No formal recommendations exist regarding how such results derived from this new testing sequence should be interpreted, or how patients with such results should be managed thereby making the attending physician to have to rely on using sound judgement and expertise in deciding how to deal with a suspect patient in the context

of the clinical picture. If they have not been previously treated, patients with reactive results from treponemal tests and nonreactive results from nontreponemal tests should be treated for late latent syphilis.

Tests for Reaginic or Anticardiolipin Antibody

This is an unfortunate and confusing designation; there is no relationship or connection between *T. pallidum*-related reaginic antibody and IgE reaginic antibody (the antibody associated with immediate hypersensitivity reactions or anaphylaxis). Patients with syphilis develop an antibody response to a tissue-derived substance (from beef heart) that is thought to be a component of mitochondrial membranes and is called *cardiolipin*. Antibody to cardiolipin antigen is known as the Wassermann, or reaginic antibody. Numerous variations (and names) are associated with tests for this antigen. The simplest and most practical of these are the VDRL test (a test originally developed, many years ago, by the Venereal Disease Research Laboratory of the U.S. Public Health Service), which involves a slide microflocculation technique and can provide qualitative and quantitative data, and the rapid plasma reagin (RPR) circle card test (a simplified version of the VDRL test). Positive tests are considered to be diagnostic of syphilis when there is a high or increasing titer or when the medical history is compatible with primary or secondary syphilis. The tests may also be of prognostic aid in following response to therapy because the antibody titer will revert to negative within 1 year of treatment for seropositive primary syphilis or within 2 years of that for secondary syphilis. Because cardiolipin antigen is found in the mitochondrial membranes of many mammalian tissues as well as in diverse microorganisms, it is not surprising that antibody to this antigen should appear during other diseases, leading to a false-positive test result. A positive VDRL or RPR test may be encountered, for example, in patients with infectious mononucleosis, leprosy, hepatitis, or systemic lupus erythematosus, and various other conditions. Although the VDRL test lacks specificity for syphilis, its great sensitivity and simplicity, along with being cost-efficient, makes it extremely useful.

Tests for Treponemal Antibody

The first test used for detecting specific antitreponemal antibody was the *Treponema pallidum* immobilization (TPI) test. Although highly reliable, it proved too cumbersome for routine use. In its place and used initially as a major test, until recently, was the fluorescent *T. pallidum* antibody (FTA) test (Figure 38.5). If virulent *T. pallidum* grown from an infected rabbit testicle is placed and fixed on a slide and then overlaid with serum from a patient with antibody to treponemes, an antigen-antibody reaction will occur. The bound antibody can then be detected by means of a fluoresceinated antihuman immunoglobulin antibody. The specificity of the test for *T. pallidum* is enhanced by first absorbing the serum with nonpathogenic treponemal strains. This modification is referred to as the FTA-ABS test. (If specific fluoresceinated anti-IgM antibody to human gamma globulin is used, the acuteness of the infection or the occurrence of congenital syphilis can be assessed. However, this test may sometimes be falsely positive or negative in babies born of mothers with syphilis.)

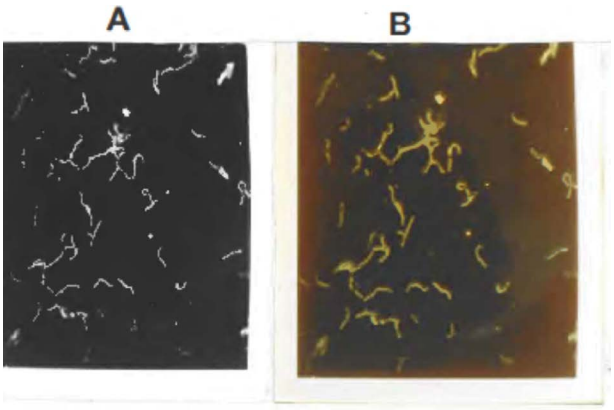

FIGURE 38.5 Indirect fluorescent antibody (IFA) method for detecting antibodies against *T. pallidum*. Image A shows *T. pallidum* organisms viewed under darkfield microscopy. Image B shows the same *T. pallidum* organisms reacting with serum from an immune patient, followed by treatment with fluorescein-tagged goat antihuman immunoglobulin, and then viewed using fluorescence microscopy.

The FTA-ABS test is reactive in approximately 80% of patients with primary syphilis (vs. 50% for the VDRL test). Both tests are positive in virtually 100% of patients with secondary syphilis. Whereas the VDRL test shows a tendency to decline in titer after successful treatment, the FTA-ABS test may remain positive for years. It is especially useful in confirming or ruling out a diagnosis of syphilis in patients with suspected biologic false-positive reactions to the VDRL test. However, even the FTA-ABS test may be susceptible to false-positive reactions, especially in the presence of lupus erythematosus (an autoimmune disorder of unknown etiology).

The microhemagglutination-*Treponema pallidum* (MHA-TP) test, a simple passive hemagglutination test, has been used as a satisfactory substitute for the FTA-ABS test. Treponemal antigens are coupled onto animal erythrocytes and, in the presence of specific antibody, agglutination or clumping occurs, indicative of a positive reaction. Its principal advantages are economy of technician time, low cost and it can be read visually without the need for any sophisticated Instrumentation. Its results correlate closely with those of the FTA-ABS test, except during primary and early secondary syphilis when both the VDRL and FTA-ABS tests are more likely to show reactivity. An alternative version of the MHA-TP test, that is in current use, is the *Treponema pallidum* particle agglutination assay which is also an indirect agglutination assay used for detection and titration of specific antibodies directed against a collection of *T. pallidum* antigens. In the test, gelatin particles are sensitized with *T. pallidum* antigens. Patient serum is mixed with the reagent containing the sensitized gelatin particles. The particles aggregate to form clumps when the patient serum is positive for syphilis. A negative test shows no clumping of gelatin particles. More recently, commercially available ELISA detection systems for measuring specific treponemal antibodies have been developed that can also be used for aiding in the diagnosis of syphilis. In addition to serum, cerebrospinal fluid can also be analyzed for treponemal antibodies, and be used to confirm a case of neurosyphilis. It should be noted, however, that the VDRL test is the only one that can be used with reliability in the evaluation of cerebrospinal fluid.

As noted previously, the interpretation of serologic data from patients with syphilis may be extremely complex in some cases. For example, a prozone phenomenon may be encountered in secondary syphilis; serofastness may characterize late syphilis; and the VDRL test may be negative in up to a third of patients with late latent syphilis.

Prophylactic Measures

As is the case with other sexually transmitted infections, prevention of syphilis requires the practice of safe sex techniques such as the use of condoms. These, if used properly, can be an effective barrier against the sexual transmission of *T. pallidum*. Early treatment with antibiotics is the only known way to prevent the later ravages of syphilis. Experimental vaccines have proven impractical or fail to afford complete protection, based primarily on animal studies involving the use of the experimental rabbit model for syphilis.

Treatment

Penicillin is the drug of choice for syphilis in all its stages. For those allergic to penicillin, alternative antibiotics such as doxycycline and erythromycin (azithromycin) can be used. Because the lesions of tertiary syphilis may be irreversible, it is crucial to identify and treat the disease before tertiary lesions or damage to key organ sites begin to occur. AIDS patients with syphilis must be treated more intensively with penicillin.[54] This reinforces the notion that curing syphilis depends on interactions between an intact immune system and the treponemicidal effects of antibiotics. So far there is no evidence that drug-resistant strains exist, unlike what has been found many other nonspirochetal bacteria.

Nonvenereal Treponematoses

The causes of yaws (*Treponema pallidum* ssp. *pertenue*), pinta (*T. carateum*), and bejel (*T. pallidum* and *endemicum*) are human pathogens responsible for this group of contagious diseases, which are endemic among rural populations in tropical and subtropical countries.[55] Unlike syphilis, these diseases are not transmitted by sexual activity but arise when treponemes are transmitted primarily by direct contact, mostly among children living under poor sanitary conditions. These three treponemal species are morphologically and antigenically similar to *T. pallidum* but give rise to slightly different disease manifestations. Pinta causes skin lesions only, yaws causes skin and bone lesions, and bejel (so-called endemic syphilis) affects the mucous membranes, skin, and bones. They do resemble venereal syphilis by virtue of the self-limiting primary and secondary lesions, a latency period with clinically dormant disease, and late lesions that are frequently highly destructive. The serologic responses for all three diseases are indistinguishable from one another and from that of venereal syphilis, and there is the same degree of slow development of protective immunity associated with prolonged untreated infection.

The spirochetes that cause yaws and pinta are transmitted through broken skin after close contact with infected people. The diseases are most prevalent in rural tropical areas where hygiene is poor and living conditions are crowded. Yaws occurs most often in 2- to 5-year-olds, and pinta occurs most often in older children and adolescents. During global campaigns in the 1950s and 1960s, both diseases were nearly eradicated, but their prevalence has increased in the absence of continuous control measures. Indeed there is now much concern over the most recent resurgence of yaws primarily in the Papua New Guinea/Melanesia areas.[56] Yaws could easily be included in that long list of neglected tropical diseases that are currently getting significant worldwide attention by the World Health Organization and a few nongovernmental organizations including certain philanthropic foundations for improved methods of control and access to treatment. However, except for the WHO and one pharmaceutical company that plans to donate massive quantities of azithromycin as part of an eradication effort, no other response against yaws has occurred.

With yaws, there is usually an incubation period of 2 weeks to 3 months before a papular-type lesion appears on the face, arms, and legs and persists for weeks or months. This papilloma expands slowly to form multiple papular or raspberry-like lesions that may ulcerate in the center. The primary papillomas heal spontaneously within months. Similar secondary lesions may erupt, heal, and spread in successive crops. Also, painful papillomas and hyperkeratosis may appear on the palms and soles, along with lymphadenopathy, and destructive osteitis and periosteitis of the long bones. A variety of skin lesions can appear in the late stage of the disease, with gummatous lesions at several sites. Yaws cripples and deforms but is rarely fatal.

With pinta, 1–8 weeks after infection, a scaling papule appears on the hands, legs, face, or dorsum of the feet. The papule may be accompanied by lymphadenitis. In 3–12 months, a maculopapular erythematous rash appears at the sites of the primary lesions. It may change color from blue to violet to brown and finally become depigmented. The rash and pigmented lesions can recur for years, and the depigmented lesions can cause considerable disfigurement.

Spirochetes can be found in early skin lesions in patients having either yaws or pinta. Serologic tests for syphilis become positive during the early stages of either disease. Small dose of an antibiotic such as penicillin cures the infection. Improved sanitation, including increased use of soap and water, will prevent transmission. Case monitoring and antibiotic treatment control these diseases.

Spirochetal Infections During Pregnancy and Transfusions

Except for syphilis, there is little evidence or few well-documented cases for other maternally acquired spirochetal infections that lead to congenital disease.[57] Nonetheless, syphilis was probably the first infectious disease where transplacental transmission was first recognized, and which could lead to serious outcomes to the mother or the developing fetus, involving miscarriages, stillbirths, or neonatal disease. Syphilis is now a relatively rare occurrence in the newborn, except in certain large urban settings such as New York City. *T. pallidum* bacteria are

usually acquired transplacentally, although intrapartum acquisition is possible. A mother with untreated primary or secondary syphilis is unlikely to have normal children; about half will be premature or suffer perinatal death, and the remainder will have congenital disease. These proportions decrease to 10% perinatal death and 10% congenital syphilis when maternal infection is acquired during late gestation. About 50% of infected newborns are initially asymptomatic. Babies with congenital infection may have a vesicular or bullous rash that includes the palms and soles; they may have rhinitis (sniffles), a maculopapular rash, pneumonia, condylomata lata, hepatosplenomegaly, generalized lymphadenopathy, and/or abnormal CSF. These manifestations may not be apparent at birth but may develop during the first few weeks of life. Radiographs often reveal bony lesions at 1–3 months postnatally, and these are characteristic for symmetric metaphyseal involvement with elevation of the periosteum, and osteomyelitic lesions, most often involving the humerus and tibia. These bone changes occur in 90% of infants who manifest with congenital syphilis. The osteochondritis and periostitis may be painful and may be manifested by the pseudoparalysis of a limb due to pain. Diagnosis may be problematic and usually depends on serologic confirmation of clinically based suspicions.

Infected infants are often asymptomatic at birth; and if infection was late in the pregnancy, they may be seronegative. Either the VDRL/RPR tests or the specific treponemal tests may be used, but it should be noted that any maternal serologic reactivity, in the form of IgG antibodies, will be transmitted to the newborn. All these tests measure both IgG and IgM. However, for measuring IgM only (produced by the newborn), recently developed ELISAs and the FTA-IgM test can be used. This would be helpful in identifying an actual congenital infection because IgM is not transferred across the placenta. Problems exist, however, in the overall sensitivity and specificity of these newer assays. The infant's passively acquired VDRL reactivity gradually decreases by 3 months, and passive TPPA/ELISA reactivity should decrease significantly by 6 months.

All infants suspected of having congenital syphilis on the basis of maternal history or physical findings should be carefully examined, investigated by serology, and have a lumbar puncture to collect cerebral spinal fluid for routine analysis, a possible dark-field exam, and a VDRL/RPR test. The placenta should be examined for focal villitis and other possible abnormalities. If the serologically positive mother did not receive adequate therapy or received nonpenicillin therapy, or if adequate follow-up is not assured, the child should be treated with penicillin at birth. Infants with neurosyphilis should be seen at follow-up at 3 months, then at 6-month intervals for repeat serology, CSF exam, and clinical reevaluation, until it is clear that VDRL/RPR titers are falling.

Prior to there being sophisticated screening techniques, various pathogens were known to cause infections following a blood transfusion. These included the spirochetes, *T. pallidum* and *B. recurrentis*, the protozoans *Babesia* and *Plasmodia*, and several viruses. Currently, transfusion-associated infections with spirochetes are practically nonexistent, due to the use of up to date screening procedures, but this was not always the case, as was the situation, even fairly recently with other infectious diseases, such as hepatitis B and HIV infections. Historically, there had always been a concern that the spirochetemic phase of an infection with *T. pallidum*, resulting from extracutaneous spread of the organism, could be a source of transfusion-associated syphilis, especially if a prospective donor was asymptomatic. Likewise, with Lyme disease, there is ample evidence, based primarily on blood culture studies,[16,17] that the spread of *B. burgdorferi* organisms from the EM rash to the various extracutaneous sites occurs mainly through the hematogenous route. Currently however, the CDC does not include *B. burgdorferi* as one of the pathogens to be tested for its possible presence in donated blood. Fortunately, it is highly unlikely that Lyme disease patients would want to donate blood during their symptomatic, and presumably spirochetemic phase, and thus it would be highly remote that blood containing *Borrelia* bacteria would be unwittingly transferred to a prospective recipient.[58] Still, it is important that blood collecting agencies nationwide and throughout the world, such as the American Red Cross, remain vigilant and continue to use the most sensitive test procedures in the screening for these diseases in potential blood donors.

Summary

The spirochetes are a unique group of bacteria that can be distinguished morphologically from most other bacteria based on their large size and helical or corkscrew-shaped appearance. They also possess flagella that are internal rather than extracellular, which is more characteristic of most other motile organisms. They include numerous species belonging to the *Borrelia*, *Leptospira,* and *Treponema* genera. Infection with most of the spirochetes occurs initially in the skin before they disseminate to extracutaneous sites. Spirochetes usually cause diseases that are nonacute upon initial exposure of a susceptible host to the infectious agent, but they can have devastating consequences on the human body later on, in the absence of curative antibiotic therapy, or when treatment is delayed.

The sexually transmitted treponemal disease, syphilis, has been with us for many centuries, perhaps as far back as Biblical times, whereas the tick-borne borrelial-caused illness, Lyme disease, was initially described as a serious clinical entity only about 40 years ago. Both of these pathogens can cause a variety of multisystem disorders that can be easily confused with other infectious or noninfectious illnesses. Early diagnosis of syphilis and Lyme disease is essential so that effective antibiotic treatment can be given leading to the prevention of chronic debilitating sequelae. Other spirochetal infections caused by various other *Borrelia, Leptospira,* and *Treponema* are uncommon in developed countries but still can cause significant morbidity in various other parts of the world, especially in poor, underdeveloped and tropical regions.

All spirochetal infections rely heavily on serologic techniques for verifying or establishing the diagnosis, although molecular techniques and other nonserologic laboratory tests can be helpful under certain circumstances. Nonmedical preventive measures include avoiding contact with (1) the appropriate insect vector, (2) an infected sex partner or body fluid, and (3) contaminated fomites or skin lesions. Although vaccines for human use are currently unavailable, there is hope that continuing research along these lines will lead to the development of safe and effective ones.

Introduction

Staphylococcus aureus was first characterized as a human isolate in the late 19th century. Sir Alexander Ogston in his lecture at the Ninth Surgical Congress in Berlin in 1880 reported the presence of "Micrococci" associated with pus in surgical wound infections. Later, Sir Ogston would use the word staphylococci to refer to these organisms (1). He used eggs to isolate pure cultures of staphylococci and showed that rabbits inoculated with these cultures developed abscesses thereby fulfilling Koch's postulates for the identification of the etiological agent of suppurative abscesses (1). *S. aureus* is a physiological commensalism of the human skin, nares, and mucosal surfaces, and bacteriological culture of the nose and skin of healthy humans invariably reveals staphylococci. In 1884, Rosenbach isolated two colony types of staphylococci found on humans and, based on their pigmentation, proposed the nomenclature *S. aureus* and *S. albus* for the yellow and white isolates, respectively (2). The latter species is now named *S. epidermidis* and until the early 1970s, *S. aureus*, *S. epidermidis*, and *S. saprophyticus* were the only three species in the genus *Staphylococcus*. Genotypic properties and refined taxonomy have led to the distinction of over 40 species during the last four decades (3, 4). This review will describe *Staphylococcus* species briefly and provide a more detailed account on laboratory manipulation of *S. aureus* and *S. epidermidis*.

Classification, Natural Habitat, and Epidemiology

Classification and Natural Habitat

The genus *Staphylococcus* is in the bacterial family *Staphylococcaceae*, which includes the lesser known genera, *Gemella, Jeotgalicoccus*, *Macrococcus*, and *Salinicoccus* (5). Nearby phylogenetic relatives include members of the genus *Bacillus* and *Listeria* in the family *Bacillaceae* and *Listeriaceae*,

†Deceased May 26, 2019

respectively (5). More than 60 species and subspecies of the genus *Staphylococcus* are distinguished based on biochemical analysis, DNA-DNA hybridization studies and sequencing analyses of the conserved genes *gap*, 16S rRNA, *hsp60*, *rpoB*, *sodA*, and *tuf* (3–8). Various species are often distinguished as coagulase-positive and -negative, and novobiocin susceptible or resistant (4).

Members of the genus *Staphylococcus* inhabit the skin, skin glands, and mucous membranes of humans, animals, and birds. Staphylococci found on the skin are either resident or transient. Transient bacteria are encountered upon exposure with exogenous source and upon contact between different host species. Such transient organisms are mostly eliminated unless the normal defense barriers of the host are compromised. Yet, host switching represents an important mechanism in the evolution of *Staphylococcus* (*vide infra*) (7). *S. epidermidis* is the most prevalent and persistent *Staphylococcus* species on human skin. Although it is present all over the body surface, it prefers hydrated sites such as the anterior nares and apocrine glands. Similarly, *S. aureus*, *S. hominis*, and *S. haemolyticus* and to a lesser extent *S. warneri* share the same habitat although as a result of its adaptability *S. hominis* colonizes drier regions on the human skin. *S. aureus* is found in the nares and other anatomical locales of humans and can exist as a resident or transient member of the natural flora. *S. aureus* can also colonize domestic animals and birds. *S. capitis* colonizes the human scalp following puberty and large populations may be found in areas with numerous sebaceous glands. *S. auricularis* demonstrates a strong preference for the adult human external auditory meatus. Some subspecies of *S. auricularis* preferentially colonize the ears of nonhuman primates. *S. intermedius* and *S. felis* are major species of the domestic dog and cat, respectively. The host range of these staphylococci is however not restricted to the skin of dogs and cats and may encompass other animals or even humans. Other staphylococci including *S. xylosus*, *S. saprophyticus*, and *S. cohnii* are more prevalent on lower primates and mammals while *S. delphini, S. caprae*, and *S. lutrae* have been specifically isolated from dolphins and domestic goat with suppurative skin abscesses, and dead otters, respectively. Interestingly, pigmented *S. xylosus* strains are used as fermenting agents in production facilities, and the activity of nitrate reductase contributes to the development of the red color characteristic of dried sausages or the orange color that coats some cheeses. General taxonomic, environmental, and genetic information about staphylococci can be found at https://bacdive.dsmz.de/.

Epidemiology of Staphylococcus Infections

S. aureus and *S. epidermidis* are always found associated with humans and bear the greatest pathogenic potential. Likewise, they are the best and most studied species. Among the other human commensals, *S. haemolyticus*, *S. simulans*, *S. cohnii*, *S. capitis*, *S. warneri*, and *S. lugdunensis* are occasional causative agents of infections in humans and *S. saprophyticus* is often associated with urinary tract infection (reviewed in Refs. [9, 10]). Similarly, commensals of animals such as *S. intermedius, S. hyicus*, or *S. sciuri* display virulence traits in infected animals. Because they colonize the human skin continuously, staphylococcal strains are exposed to all antibiotic therapies (11). *S. aureus* is a major cause of nosocomial and community-acquired infections. Whenever drug-resistant microbes emerge, these strains can spread by direct contact very rapidly among human populations, as exemplified by the threat of methicillin-resistant *S. aureus* (MRSA) worldwide and vancomycin-resistant *S. aureus* (VRSA) (12–14). New antibiotics (daptomycin, linezolid, mupirocin) have been developed with the concomitant emergence of resistance mechanisms with dire consequences for the clinical management of such infections (15). *S. aureus* isolates collected during outbreaks were traditionally characterized by a phage-typing method based on phenotypic markers in the envelope. This typing method requires maintenance of many phage stocks and is technically challenging. Various molecular typing methods are used for the epidemiological analysis of MRSA strains since such strains encode defined genetic markers. Molecular typing relying on plasmid analysis is often used but often lacks accuracy, as plasmids are easily lost, especially when strains are grown in laboratory media. Pulsed field gel electrophoresis, whereby genomic DNA is cut with a restriction enzyme that generates large fragments of 50–700 kbp, represents a reliable method for genetic characterization. Recently, whole-genome sequencing has been used to characterize MRSA outbreaks and to define transmission pathways (16–18). In these approaches, high-throughput sequencing technology is used to construct a phylogenetic tree by comparing single-nucleotide polymorphisms (SNPs) in the core genome to a reference genome (an epidemic MRSA clone versus a sequenced MRSA clone). It is expected that the time and cost associated with sequencing analyses will eventually be reduced to levels where the technology will represent the standard of clinical care (17, 19).

Staphylococci should always be considered potential pathogens as the difference between commensal and pathogen is tenuous, or at least difficult to define at the molecular or genetic level. The spectrum of diseases caused by staphylococci ranges from soft tissue infections, abscesses in organ tissues, osteomyelitis, endocarditis, toxic shock syndrome, to necrotizing pneumonia (20–22). The ability to replicate in different pathological-anatomical sites (23) is enabled by a long list of virulence factors, including cell-wall anchored proteins, secreted toxins such as hemolysins, leukocidins and enterotoxins, capsular- and exopolysaccharides, iron-transport systems, and modulators of host immune functions in addition to antibiotic-resistance genes (20, 24–26). Production of toxins is not limited to *S. aureus*. For example, some strains of the fermenting *S. xylosus* isolated from milk of cows with mastitis produce several enterotoxins (27). Many staphylococci encode all the attributes to form biofilms, attaching effectively to surfaces and developing into antibiotic recalcitrant community structures (28). Biofilm-based infections caused by *S. aureus* and coagulase-negative staphylococci represent a significant burden on the healthcare system, in particular infections of medical devices and surgical wounds (29). An appreciation of staphylococci-host interactions can be gained through the exploitation of animal models of infections (see reviews Refs. [30–35]). In these models, the ability to colonize, replicate, disseminate and either persist or precipitate lethal disease can be compared between wild-type bacteria and isogenic mutants or in the presence of candidate therapeutics. The mouse remains the preferred model for studying *S. aureus* (31). However, some *S. aureus* virulence factors have a restricted

human tropism. Examples include staphylococcal superantigen-like (SSL) proteins, phage-encoded immune evasion molecules staphylokinase (SAK), chemotaxis inhibitory protein (CHIPS) and staphylococcal complement inhibitor (SCIN), as well as Panton-Valentine leukocidin (PVL) and γ-hemolysin CB (HlgCB) (36–38). Thus, the contribution of these factors to disease cannot be evaluated in animals. It is interesting, for example, that epidemiological studies attribute the predominance of the highly virulent community-associated MRSA strain USA300 to PVL (39, 40). PVL and HlgCB belong to the family of bicomponent pore-forming toxins that target and kill phagocytes. PVL is a prophage-encoded, pore-forming exotoxin composed of subunits LukS-PV and LukF-PV (41, 42). Each subunit binds a different receptor on human phagocytes; LukS-PV binds human complement C5a receptor 1 (C5aR1), while LukF-PV binds human CD45 independently of the S-component. HlgC, the S component of HlgCB, also binds hC5aR1 (43–45). The identification of these receptors explains the cellular tropism and human specificity of these two leukocidins; the development of a human C5aR1 knock-in mouse model substantiates the contribution of HlgCB during infection (45).

Biochemical Properties

General Properties: Appearance and Metabolic Properties

Members of the genus *Staphylococcus* are Gram-positive cocci with sizes ranging between 0.5 and 1.5 µm in diameter. Staphylococci divide in two perpendicular planes and new daughter cells may remain associated in irregular grape-like clusters, a feature that distinguishes them from the slightly oblong streptococci that divide in one plane and usually grow in chains. Cocci also occur singly, in pairs, tetrads and short chains. Staphylococci are nonmotile, nonspore-forming, and although genes encoding for capsule formation are found in the genus, usually staphylococci grow nonencapsulated. Most species are facultative anaerobes that grow by aerobic respiration or by fermentation yielding principally lactic acid. Staphylococci grow more rapidly under aerobic conditions with the exception of *S. saccharolyticus* and *S. aureus* subsp. *anaerobius*. This latter subspecies is the etiological agent of abscess disease in sheep, also known as Morel's disease, which was first described by Morel in 1911 (46, 47). Aerobic respiration is achieved by the presence of a- and b-type cytochromes and electron transfer in the membrane is mediated by menaquinones. Thus far, c-type cytochromes, where heme is covalently attached to cysteine residues, have only been identified in *S. lentus*, *S. sciuri*, and *S. vitulus*.

Carbohydrate uptake and metabolism have been best characterized for *S. aureus* and *S. xylosus* or may be deduced from genome analysis of *S. aureus* and *S. epidermidis* strains. Two types of carbohydrate transport systems have been investigated, the phosphoenolpyruvate (PEP):sugar phosphotransferase system (PTS) and the PTS-independent carbohydrate transport whereby sugars taken up by a dedicated permease are subsequently phosphorylated by an ATP-dependent kinase (instead of PEP-dependent phosphorylation). Both systems have evolved to take up glucose as demonstrated in *S. aureus* and *S. xylosus* (48). Glucose oxidation is mediated by the fructose 1,6-bisphosphate and the oxidative pentose phosphate pathways. There is no evidence for the existence of the Entner-Doudoroff pathway and, in the absence of oxygen, staphylococci will behave like facultative anaerobes. Enzymes of the entire tricarboxylic acid (TCA) cycle are encoded in the genome of *S. aureus* and reduced cofactors generated by the TCA cycle are re-oxidized by an electron transport chain containing a- and b-type cytochromes. A typical F0F1-ATPase is encoded in the genome of staphylococci. In addition to glucose, *S. aureus* may use D-galactose in a pathway that converts it to D-galactose 6-P and next tagatose. Tagatose-6-P kinase, the key enzyme of the tagatose pathway is inducible by growth on galactose or lactose and is found in *S. aureus*, *S. epidermidis*, and *S. hominis*, but absent in *S. intermedius*, *S. saprophyticus*, and *S. xylosus*. In these organisms, galactose is oxidized via the Leloir pathway (49). Other sugars can be metabolized by staphylococci and a summary of these other metabolic pathways can be found in reference (4). Upon glucose depletion, *S. aureus* cells growing in aerobic conditions will oxidize acetate, succinate, and malate (50). Most strains examined thus far encode a lactate dehydrogenase that is activated by fructose-1,6-bisphosphate, itself upregulated during anaerobic conditions in the presence of glucose. Staphylococci may use nitrate as an electron acceptor in the absence of oxygen, a metabolic activity that has broad application in food technology, however little is known about the biochemistry and genetic requirement for nitrate reduction with the exception of *S. carnosus* (51).

Most *Staphylococcus* species are oxidase-negative (exceptions include *S. lentus*, *S. sciuri*, and *S. vitulus*) and catalase-positive (exceptions include the anaerobic *S. saccharolyticus* and *S. aureus subsp. anaerobius*). The catalase test helps distinguish the catalase-negative streptococci from staphylococci. The test is performed by adding 3% hydrogen peroxide to a colony on an agar plate or slant. Catalase-positive cultures produce O_2 and bubble. Most staphylococci are susceptible to lysostaphin (*vide infra*). Most staphylococci are also susceptible to furazolidone (100 µg on disk; see Ref. [52]), display low resistance to erythromycin (0.04 µg/mL) and produce acid from glycerol oxidation (53).

Major Differences Between *S. aureus* and Other Staphylococci

Strains of *S. aureus* are classified into sequence type (ST) following a multilocus sequence typing (MLST) scheme based on sequences of internal fragments of seven housekeeping genes (*arcC*, *aroE*, *glpF*, *gmk*, *pta*, *tpi*, and *yqiL*) (54). Strains that are only different at one or two of the seven MLST sites are grouped into a so-called clonal complex (19, 54). *S. aureus* forms fairly large, yellow colonies on rich medium due to the production of the orange carotenoid staphyloxanthin (55, 56). Production of this membrane-bound pigment helps scavenge reactive oxygen species and protects *S. aureus* from neutrophil killing (57). *S. aureus* clonal complex 75 (CC75) has been described as the distinct species *S. argenteus*; both species share the same virulence factors and antibiotic resistance genes but *S. argenteus* conspicuously lacks the genes for staphyloxanthin production (reviewed by Ref. [58]). Surprisingly, *S. argenteus* exhibits comparable morbidity and health care-associated infection rates as *S. aureus* (reviewed by Ref. [58]).

Hallmark of *S. aureus* is its ability to clot human or animal blood even in the presence of coagulation inhibitors (warfarin, heparin, hirudin, or calcium chelators) (59, 60). Coagulation is caused by two secreted proteins, Coa and vWbp, that bind to prothrombin to promote its non-proteolytic activation (reviewed by Ref. [61]). The coagulation test is used extensively as a diagnostic tool to differentiate *S. aureus* from other staphylococci (22). Prothrombin in complex with Coa or vWbp cleaves fibrinogen but not with other thrombin substrates (clotting factors FV, FVIII, FXI, protein C, antithrombin, and plasmin) (reviewed by Ref. [61]). Thus, by secreting Coa and vWbp, *S. aureus* usurps the zymogen of one clotting factor (FII) to modify the coagulation cascade of human or animal blood, causing exuberant, uncontrolled polymerization of fibrin without activating the other clotting and inflammatory factors. Another diagnostic tool, the slide agglutination test, monitors the agglutination of *S. aureus* immersed in calcium-chelated plasma (62). Recently, the biochemical attributes and physiological relevance of staphylococcal agglutination have been shown to require Coa and vWbp as well as clumping factor A (ClfA) (63). ClfA is a surface protein that promotes precipitation of staphylococci through association with soluble fibrinogen (clumping reaction) (64, 65) but can also bind to coagulases-polymerized fibrin cables, thereby tethering fibrin cables to the staphylococcal surface (63). Importantly, Coa, vWbp, and ClfA have been shown to be important virulence factors during the pathogenesis of *S. aureus* infections, enabling the formation of abscesses for staphylococcal replication and the depletion of clotting factors from blood (63, 66). Most other staphylococci and thus cannot manipulate blood hemostasis for virulence. Protein-ligand interaction studies have shown that surface proteins Fbl, SdrG, and SpsD of *S. lugdunensis*, *S. epidermidis*, and *S. pseudintermedius*, respectively, bind human fibrinogen *in vitro*. *S. pseudintermedius* also displays SpsL in its envelope (67). SpsL binds canine fibrinogen with high affinity and may promote bacterial aggregation, biofilm formation, and resistance to neutrophil phagocytosis, suggesting a role similar to *S. aureus* ClfA during pathogenesis (68).

S. aureus secretes α-hemolysin, which causes complete lysis of red blood cells (this lysis is referred to as β-hemolysis). Lack of hemolytic activity around colonies on blood agar is referred to as γ-hemolysis. *Staphylococcus* species are either β- or γ-hemolytic. Most *S. aureus* strains encode *hla*, the structural gene for α-hemolysin (α-toxin), on their chromosome (69, 70). Occasionally *S. aureus* appears nonhemolytic on blood agar. This has been attributed to mutations in the *agr* or *sae* loci (*vide infra*) or in other regulatory loci that control globally the expression of secreted proteins. The *hla* gene encodes a 293 amino acid long protein secreted as a water-soluble monomer (71), which represents the founding member of bacterial pore-forming β-barrel toxins (72). Hla engages surface receptors of sensitive host cells, thereby promoting its oligomerization into a heptameric prepore and insertion of a β-barrel with 2 nm pore diameter into the plasma membrane (73). Hla pores form in lymphocytes, macrophages, type I alveolar cells, pulmonary endothelium, and erythrocytes, whereas granulocytes and fibroblasts are resistant to lysis (71, 74). Instillation of purified Hla into rabbit or rat lung tissue triggers vascular leakage and pulmonary hypertension (74–76). ADAM10 serves as the receptor for α-toxin (77). ADAM10 contains a zinc-dependent metalloprotease domain displayed on the surface of many host cells. This extracellular domain cleaves the ectodomain of several host proteins including members of the cadherin family (reviewed in Ref. [78]). E-cadherin of epithelial cells, such as pneumocytes and keratinocytes, is a principal substrate for ADAM10. Epithelial cells are also key targets of α-toxin (78). Cleavage of E-cadherin by ADAM10 is enhanced in the presence of α-toxin and results in a loss of the homotypic interaction of the cadherin molecules on adjacent cells at the adherens junction (79), thereby injuring the epithelial tissue barrier function and promoting *S. aureus* virulence (80, 81).

S. aureus is the only staphylococcal species that displays Staphylococcal protein A (SpA; Protein A) on its surface. Protein A has been exploited commercially for its ability to bind antibodies. Protein A binds the Fcγ region of immunoglobulins as well the V_H3 region of IgM molecules of B lymphocytes, i.e., B cell receptors (82–84). Binding to Fcγ results in the coating of bacteria with immunoglobulins, which blocks phagocytosis by immune cells. Protein A released by *S. aureus* binds to Fab and crosslinks V_H3 clan IgM promoting B cell superantigen activity and the futile production of V_H3 antibodies that cannot neutralize *S. aureus* (84, 85). Consequently, mutants that no longer produce protein A display reduced virulence in animals (86–88).

Cell Wall Envelope

The Gram stain broadly differentiates bacteria into Gram-positive and Gram-negative groups. Staphylococci have a thick (60–80 nm) continuous cell wall also called the murein sacculus. The cell wall is composed largely of peptidoglycan also known as muropeptide or murein. Peptidoglycan also functions as a scaffold for the immobilization wall teichoic acids (WTA) (89, 90), capsular polysaccharides (91, 92), and proteins (93) (*vide infra*). Eighty percent of all capsular types found in clinical isolates of *S. aureus* strains are serotypes 5 and 8 (92). Polysaccharide intercellular adhesin (PIA) may also be found in the envelope (94). The genes responsible for PIA synthesis were first revealed in *S. epidermidis* and designated *icaABC* (94). PIA is a polymer of *N*-acetylglucosamine, a surface carbohydrate involved in biofilm formation (94) that contributes to the pathogenesis of biomaterial-associated infections (95). The *ica* genes are also found in other staphylococci including *S. aureus* where it also contributes to formation of biofilms on the surfaces of biomedical implants (96). Detailed information on capsular polysaccharides and PIA can be found in the following reviews (4, 92, 97).

The cell wall presents a unique problem in cellular architecture, as new incoming units must be inserted into a peptidoglycan sheet that is held together by covalent bonds. Random openings in the wall would otherwise result in cell lysis. Further, the cell wall must grow into a specific shape. This process is achieved by a regulated pattern of enzymatic activities that controls opening and closure of covalent bonds in particular during cell division. Distinct morphological features of the cell wall have been revealed by electron microscopy of the newly emerging cross walls of dividing cells, revealing "murosomes," i.e., small puncture sites along the division plane of future daughter cells (98, 99).

Peptidoglycan

Composition

Most bacterial peptidoglycans, with the exception of archaebacteria, have a very similar structure. The peptidoglycan consists of a backbone of glycan chains of the repeating disaccharides N-acetylglucosamine (NAG) and its lactic ether N-acetylmuramic acid (NAM). Each disaccharide carries a tetrapeptide substituent of alternating L and D amino acids. A peptide bridge links the terminal COOH of D-alanine of one tetrapeptide to an NH_2 group of a tetrapeptide on a neighboring glycan chain (Figure 39.1). In *S. aureus*, each interbridge peptide consists of a pentaglycine (Figure 39.1) and peptidoglycan crosslinking is extensive (100). In rapidly growing cells, more than 95% of the subunits are crosslinked and bear almost no free carboxyl groups, since the D-glutamic acid α-carboxyl group is amidated (101). *S. aureus* peptidoglycan is extensively modified on the *N*-acetylmuramic acid residues with *O*-acetyl substituents such as the 4-*N*, 6-*O*-diacetyl derivative (102). This modification renders the peptidoglycan resistant to egg-white lysozyme and other muramidases (103). In *S. aureus*, the enzyme *O*-acetyltransferase A is responsible for modification of peptidoglycan and resistance to lysozyme (104). During infection, phagocytosis and lysozyme-based cell-wall degradation of *S. aureus* favors inflammasome activation and IL-1β secretion (105). Thus, acetylation of peptidoglycan endows pathogenic staphylococci with a specific subversion mechanism against host defenses.

Biosynthesis

Peptidoglycan synthesis is initiated in the cytoplasm by modifying the uridine nucleotide of NAM (UDP-NAM) with the pentapeptide at its lactic carboxyl end. This product is also named UDP-NAM-pentapeptide or Park's nucleotide and accumulates in *S. aureus* inhibited by penicillin (106, 107). It is formed by

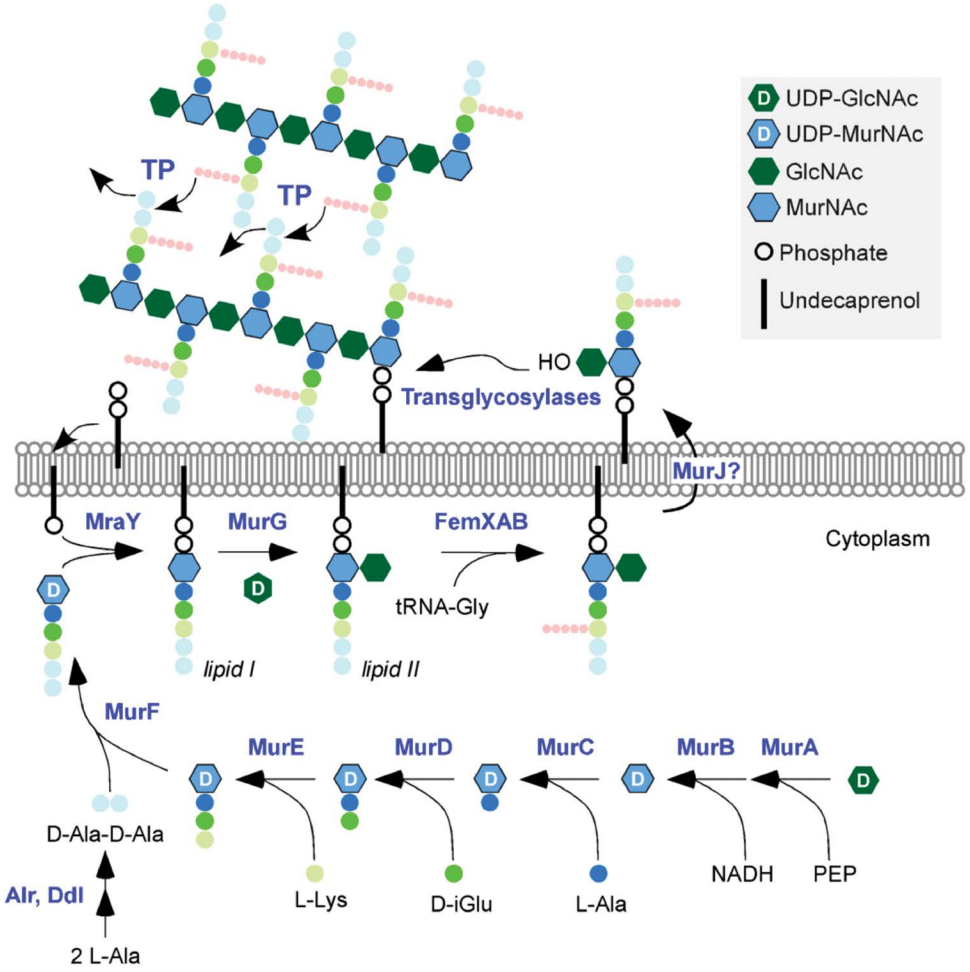

FIGURE 39.1 Model of peptidoglycan biogenesis. The generation of cell wall precursors begins in the cytoplasm, resulting in the synthesis of the soluble intermediate UDP-MurNAc-L-Ala-D-*i*Glu-L-Lys-D-Ala-D-Ala (Park's nucleotide). The peptidoglycan precursor subunit is transferred to the bactoprenol lipid carrier in the membrane to generate lipid I and further converted to the lipid II intermediate following addition of GlcNAc and the penta-Gly cross-bridge in *S. aureus*. Lipid II is translocated to the outer leaflet of the plasma membrane and transglycosylases link peptidoglycan precursors in a processive manner possibly onto bactoprenol. A murein hydrolase (SgtB) cleaves glycan strands to physiological sizes (not shown). Transglycosylation causes the concomitant displacement of the lipid carrier which must be dephosphorylates and retransported to the cis side of the membrane (not shown). The terminal D-alanine of the wall pentapeptide is subject to substitution by cross-linking to other wall subunits catalyzed by transpeptidases or can be removed by the action of carboxypeptidases (not shown). Enzymes known to be involved in distinct steps of this pathway are shown in blue. (*Abbreviations:* PEP, phosphoenolpyruvate; TP: transglycosylase.)

the sequential addition of L-alanine, D-glutamic acid, L-lysine and D-alanyl-D-alanine to the D-lactyl group of UDP-NAM and each step is catalyzed by a specific synthetase (106, 108) (see Ref. [109] for a review). Further, as for *Escherichia coli,* the enzyme MurI converts the L-Glu to D-Glu (110), while L-Ala is converted to D-Ala by the alanine-racemase Alr in *S. aureus* (111). A dedicated ligase generates a D-Alanyl-D-alanine dimer (108). The final soluble intermediate is UDP-NAM- L-Ala-D-*iso*-Glu-L-Lys-D-Ala-D-Ala. This intermediate is transferred onto the membrane carrier lipid, undecaprenol-P (also called bactoprenol-P or C55-P) by the conserved enzyme MraY to yield lipid I (112–115). Lipid I faces the cytoplasm and UDP-NAG is linked to the muramoyl moiety at the expense of UPD by the conserved enzyme MurG to generate the disaccharide lipid II precursor (Figure 39.1) (116, 117). Lipid II precursors are modified by sequential addition of glycine to the ε-amino group of lysine, using glycyl-tRNA as donor, in a ribosome independent fashion (118). *S. aureus* encodes three species of glycyl-tRNA for cell-wall biosynthesis and one for protein synthesis (119). The factors essential for methicillin (Fem) resistance (120) catalyze the incorporation of glycyl residues in the cross bridge. FemX links the first glycine residue to the ε-amino group of lysine, FemA incorporates glycyl residues 2 and 3 and FemB, glycyl residues 4 and 5 (100, 121, 122). The pentaglycine bridges is essential for cell integrity of *S. aureus* (123) and is also the target of anti-staphylococcal endopeptidases such as lysostaphin, secreted by *S. simulans* biovar *staphylolyticus* (124), and Ale-1, secreted by *S. capitis* EPK1 (125). To protect themselves from the lytic activity of lysostaphin and Ale-1, *S. simulans* and *S. capitis* encode the lysostaphin immunity factors (Lif) and endopeptidase resistance (Epr), respectively (126, 127). In *S. epidermidis,* four different pentapeptide cross-bridges have been isolated (128). Each contains glycine and L-serine residues in the ratio 3:2 in a characteristic sequence where glycine is always the initial substituent of the ε-amino group of L-lysine.

The completed lipid II-pentaglycine intermediate is flipped across the membrane by a mechanism that is not completely resolved, possibly involving MurJ or FtsW (129, 130) (Figure 39.1). MurJ is a member of the MOP (multidrug/oligosaccharidyl-lipid/polysaccharide) exporter superfamily and has been suggested to be the lipid II flippase in *E. coli* (131). In *S. aureus*, the essential gene SAV1754 (SACOL1804) has been proposed to serve as a functional MurJ ortholog (132) and microscopy studies suggest that MurJ is recruited to the septum by divisome proteins, driving peptidoglycan incorporation to midcell (133). FtsW is a member of the SEDS (sporulation, elongation, division, and synthesis) protein family, also suggested to be a lipid II flippase (134). More recently, SEDS proteins were shown to be peptidoglycan transglycosylases that may work together with a cognate penicillin-binding protein (PBP; *vide infra*) (135, 136). Following translocation of the lipid II-pentaglycine intermediate, glycan polymerization is carried by highly processive transglycosylases. The presence of uncrosslinked peptidoglycan in the cell wall suggests that transglycosylation reaction precedes transpeptidation reaction. The released carrier undecaprenol-PP then loses a P, thereby regenerating the form that can accept a precursor. Lastly, peptide cross-linking between adjacent glycan chains is catalyzed by transpeptidases that are sensitive to β-lactams and thus referred to as penicillin binding proteins (PBP) (137). Most organisms encode multiple PBPs that are involved in peptidoglycan growth, cell shape and septum formation. Some PBPs encode D,D-carboxypeptidases that release the terminal D-Ala from a pentapeptide and thus generate a tetrapeptide with a free terminus (that cannot enter a cross-link). These enzymes also have endopeptidase activity on existing cross-links. They function to guide morphogenesis and can be eliminated without loss of viability. *S. aureus* contains only four PBPs, PBP1-4, and MRSA strains contain a fifth known as PBP2A. The low affinity of PBP2A for β-lactams makes it the determinant factor for resistance (138). PBP1 is an essential transpeptidase involved in cell division and separation (139, 140). PBP2 is the only bifunctional PBP with both transpeptidase and transglycosylase activities. This protein is essential in MSSA strains, but dispensable in MRSA strains owing to the presence of PBP2A, unless β-lactams are present (141). Interaction between the SEDS protein FtsW (transglycosylase) and PBP1 (transpeptidase) may be critical for initiating septum formation upon FtsZ assembly, while later processive peptidoglycan synthesis is carried out by PBP2 (136). PBP3 and PBP4 are nonessential proteins. The exact function of PBP3 is unknown but loss of PBP4 results in highly cross-linked peptidoglycan (142). *S. aureus* also encodes two proteins with monofunctional transglycosylase domains, and two transpeptidase-like proteins, but none are essential for growth (142).

The so-called autolysins play an important role during cell division when new cell wall synthesis must take place and be added to the preexisting wall (143). Autolysins catalyze amidase and glycosidase activities that split bonds between tetrapeptides and glycan chains, respectively. In *S. aureus,* and *S. epidermidis*, the major murein hydrolases involved in cell separation are named AtlA (144) and AtlE (145), respectively. Both proteins bear a conserved modular organization encompassing a signal peptide for secretion, followed by propeptide, amidase, three repeat (R1-R3) and glucosaminidase domains. Secreted autolysins are proteolytically cleaved after the propeptide and repeat R2, leading to the formation of two processed hydrolases that bind to the septum sites of dividing cells (146–148). The repeat sequences are responsible for the targeting of the enzymes to the septum of dividing cells (149, 150). Presumably, wall teichoic acid (WTA) present in the old cell wall but not yet accessible in the septum region prevents binding of repeat-containing peptides (150), whereas lipoteichoic acid (LTA) present at the septum favors binding of the hydrolases (151) thereby restricting the activity of these enzymes.

Glycan chain length of peptidoglycan is constant in staphylococci (152, 153). In *S. aureus*, glycan chain length is regulated by SagB, a membrane-associated N-acetylglucosaminidase, that cleaves polymerized glycan strands to their physiological length (154). Loss of *sagB* perturbs growth, cell morphology, and protein trafficking into and across the envelope (154). All these defects can be explained by the exaggerated length of peptidoglycan strands (154, 155).

Protoplasts

The cytoplasmic membrane is pressed against the wall by an internal osmotic pressure (turgor pressure) that exceeds that of the external environment. Digestion of the wall or inhibition of its synthesis in growing cells leads to cell lysis. Cell

wall of Gram-positive bacteria can be destroyed by digestion of the peptidoglycan using lysozyme, a protein that breaks the 1,4-glycosidic bonds between N-acetylglucosamine and N-acetylmuramic acid. Because of extensive peptidoglycan modification, staphylococci are insensitive to lysozyme (102, 103) and the glycyl-glycine endopeptidase lysostaphin is used to digest the cell wall. This procedure is necessary for the extraction of cytoplasmic components such as DNA, RNA, and proteins. Cell lysis will not occur in the presence of lysostaphin when the medium is sufficiently hypertonic. Typically, a solute such as sucrose 0.5 M in the buffer solution, will balance the concentration of solutes inside the cell. This leads to the formation of an osmotically sensitive sphere called a protoplast. Such sucrose-stabilized bodies can grow briefly without cell division. However, if placed in hypotonic solution, lysis occurs immediately.

Peptidoglycan Biosynthesis Steps Inhibited by Antibiotics

Penicillin interferes with wall formation by inhibiting the transpeptidation reaction. Electron microscopy reveals that penicillin-treated cells accumulate amorphous material between the membrane and the wall (98). There is a close structural analogy between the D-Ala-D-Ala and the β-lactam ring of penicillin or other β-lactam antibiotics. This ring reacts with the transpeptidase to forms a stable covalent bond that inactivates the enzyme. Cycloserine, a structural analog of D-Ala is a competitive inhibitor of both racemization of L-Ala to D-Ala and conversion of the latter to the dipeptide D-Ala-D-Ala. Fosfomycin, an analog of P-enolpyruvate, irreversibly inhibits the conversion of P-enolpyruvate to the ether-linked lactyl group of UDP-NAM. Neomycin blocks transfer of muramyl peptide to the growing chain. Vancomycin blocks transpeptidation by binding to D-Ala-D-Ala in several intermediates and in the peptidoglycan form. Bacitracin also binds to a substrate instead of an enzyme. It binds undecaprenol-PP blocking its dephosphorylation and thereby preventing its recycling to undecaprenol-P. In response to vancomycin selective pressure, some staphylococcal strains acquired mutations that trigger altered cell wall envelope structures and low-level vancomycin resistance (14, 156). Other strains such as VRSA acquired the *vanA* resistance gene from enterococci (13, 157). VanA ligates β-hydroxy carboxylic acids, for example D-lactate, to D-Ala and the product, D-Ala-D-Lactate is then incorporated into wall peptides (158). The net result of staphylococcal *vanA* gene acquisition, vancomycin resistance, stems from the reduced affinity of the glycopeptide antibiotic to the depsipeptide bond between D-Ala-D-Lactate (159).

Resistance to methicillin by MRSA results from the acquisition of the oxacillin/methicillin-resistance gene *mecA* that encodes PBP2A. *mecA* was possibly acquired from *S. sciuri* by an unknown mechanism (160). *mecA* is located on a mobile genetic element called staphylococcal cassette chromosome (SCC) in *S. aureus (*21–67 kb fragment) (161). Because MRSA and VRSA strains have also acquired macrolide, tetracycline, aminoglycoside, chloramphenicol and fluoroquinolone resistance mechanisms (162), pharmaceutical, scientific, and medical communities have suddenly begun to realize that the therapeutic arsenals are close to depletion causing a threat for infectious disease therapy (163).

Teichoic Acids

Cell wall teichoic acid (WTA) and lipoteichoic acid (LTA) are secondary wall polymers that traverse the envelope of Gram-positive bacteria (164). WTA is tethered to peptidoglycan whereas LTA is retained in the outer leaflet of the plasma membrane through attachment to a glycolipid. *S. aureus* WTA is a polymer of 30 to 50 ribitol-phosphate (Rbo-P) subunits connected via 1,5-phosphodiester bonds (165). The repeating ribitol units may be further substituted with D-alanine and GlcNAc via α- or β-glycosidic linkages (166, 167). Rbo-P_n is tethered to peptidoglycan via the murein linkage unit, GlcNAc-ManNAc-(Gro-P)$_{2\text{-}3}$ (168). Synthesis of the murein linkage unit is initiated by TagO (also referred to as TarO), which links UDP-GlcNAc onto undecaprenol-P (Figure 39.2) (169–171). Next, TagA adds ManNAc (168, 172), TagBDF adds Gro-P, and TarILJ adds Rbo-P (173–175). The product of this pathway, C_{55}-PP-GlcNAc-ManNAc-(Gro-P)$_{2\text{-}3}$-(Rbo-P)$_{30\text{-}50}$, is flipped across the plasma membrane by the TagGH transporter (176). Attachment of WTA polymers to the C6-hydroxyl of *N*-acetylmuramic acid within peptidoglycan requires genes encoding LytR-CpsA-Psr (LCP) proteins (177, 178). *S. aureus* encodes three LCP enzymes and a mutant lacking all three genes does not harbor WTA in the cell wall envelope (179) and instead releases these polymers in the medium (89).

The first two genes of the WTA pathway (*tagO tagA*) can be deleted without abolishing staphylococcal growth (172, 180, 181). In contrast, *tagBDFGHtarIJL* cannot be deleted unless staphylococci carry inactivating mutations in *tagA* or *tagO* (182). This synthetic viable phenotype is explained as the limited availability of bactoprenol and its undecaprenyl-phosphate derivatives (C_{55}-PP and C_{55}-P) for peptidoglycan cell wall biosynthesis (182).

Unlike WTA, LTA is composed of 1,3-polyglycerolphosphate (poly[Gro-P]) linked to the C-6 of the non-reducing glycosyl within the glycolipid anchor ß-gentiobiosyldiacylglycerol (Glc[α1-2]Glc (α1-3)-diacylglycerol (Glc$_2$-DAG) (328). Assembly of LTA can be divided into three steps: (1) synthesis of the glycolipid anchor diglucosyl-diacylglycerol (Glc$_2$-DAG) by PgcA, GtaB, and YpfP; (2) polymerization of the poly(Gro-P) chain by LtaS; and (3) D-alanylation of poly(Gro-P) by Dlt enzymes (183–190). When Glc$_2$-DAG cannot be synthesized because of mutations in the *pgcA*, *gtaB,* or *ypfP* genes, the poly(Gro-P) is tethered to DAG, instead of Glc$_2$-DAG (187, 191). In staphylococci, *ypfP* is located in an operon with *ltaA*, a gene that encodes a polytopic membrane protein and has been proposed to translocate Glc$_2$-DAG (Figure 39.3) (191). Polymerization of the poly(Gro-P) chain, is catalyzed by LtaS, a polytopic membrane protein with a large C-terminal domain on the outer surface of the bacterial membrane (Figure 39.3). LtaS transfers *sn*-glycerol 1-phosphate from phosphatidylglycerol onto Glc$_2$-DAG with subsequent stepwise addition of Gro-P at the distal end of the polymerizing chain (183). *S. aureus ltaS* mutants display a severe cell division defects and grow poorly, suggesting that LTA synthesis is required for growth (192, 193). Incorporation of D-alanine esters confers positive charges onto otherwise negatively charged polymers (194) and requires genes of the *dltXABCD* operon (195). Two models have been proposed to account for the biochemical activity of DltABCD proteins (the *dltX* gene is not conserved in

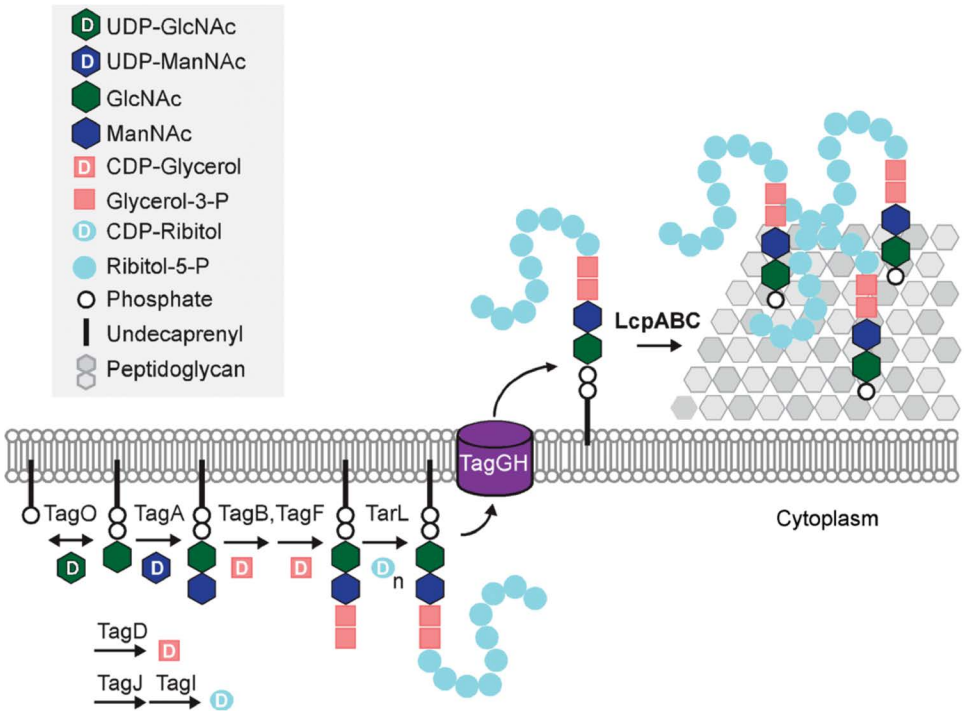

FIGURE 39.2 Model of wall teichoic acid biogenesis in *S. aureus*. The complete synthesis of WTA is catalyzed on bactoprenol P on the *cis* side of the plasma membrane. The assembled molecule is translocated by the membrane transporter (TagG, TagH), and ligated to peptidoglycan by Lcp enzymes. The WTA can be further glycosylated and modified with d-alanyl residues (not shown, see text for details).

bacteria and it has no assigned function so far). In the first model, DltB transfers D-alanine from DltC to undecaprenol-phosphate and flips the lipid-linked intermediate across the membrane, whereas DltD, acting on the *trans* side of the membrane, transfers D-alanine to LTA (196, 197). In the second model, DltD promotes transfer of D-alanine between DltA and DltC in the cytoplasm. Alanylated-DltC is translocated across the membrane by DltB and may then transfer D-alanine directly onto LTA (194). The Dlt enzymes transfer D-alanine onto LTA but not onto WTA. D-alanyl esters are transferred from LTA to WTA in a manner that may not involve any further catalysis (198, 199).

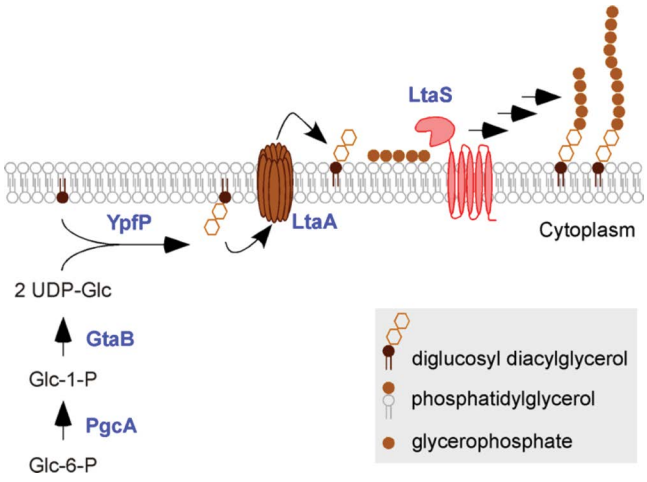

FIGURE 39.3 Model of lipoteichoic acid biogenesis in *S. aureus*. PgcA, GtaB, and YpfP synthesize the glycolipid anchor diglycosyl-diacylglycerol (Glc_2DAG). The 12-transmembrane-domain permease LtaA (brown) transports the glycolipid anchor to the *trans* side of the membrane. Next, LtaS (red) cleaves glycerophosphate (Gro-P) subunits from phosphatidyl glycerol (PG) and polymerizes Gro-P onto Glc_2DAG. Polymerization of Gro-P by LtaS occurs at the distal end of the extending polymer, up to 50 PG molecules may be added.

S. aureus mutants lacking WTA such as *tagO* mutants have been shown to be unable to colonize cotton rat nares (181); the exact function of LTA is unknown although the presence of LTA at the dividing septum may favor the recruitment of autolysins for cell separation (151). In *S. aureus,* the growth defect caused by loss of *ltaS* can be rescued by inactivation of *gdpP* (200). GdpP is a phosphodiesterase that hydrolyzes the signaling molecule cyclic-di-AMP (327). Increased cyclic-di-AMP in the *gdpP* mutant was shown to be associated with increased peptidoglycan crosslinking that could somehow compensate for the lack of LTA (200). Cyclic-di-AMP was also found to regulate the production of the potassium transporters Kdp and Ktr (201, 202). Neuhaus and Baddiley referred to LTA as a polyelectrolyte that forms a "continuum of anionic charges" (194). Thus, it is tempting to speculate that osmotic homeostasis in *S. aureus* caused by loss of LtaS may be compensated by the regulatory activity of cyclic-di-AMP (201, 202). The contributions of D-alanyl esterification and glycosylation of TAs are better appreciated. *Dlt* mutants of *S. aureus* are more susceptible to cationic antimicrobial host factors, antibiotics, bacteriocins and neutrophils (203, 204). In contrast, several glycosyltransferases modify WTA to generate anomeric heterogeneity that results in altered ability of WTA to elicit specific antibody responses, bind bacteriophages, and resist methicillin (205, 206).

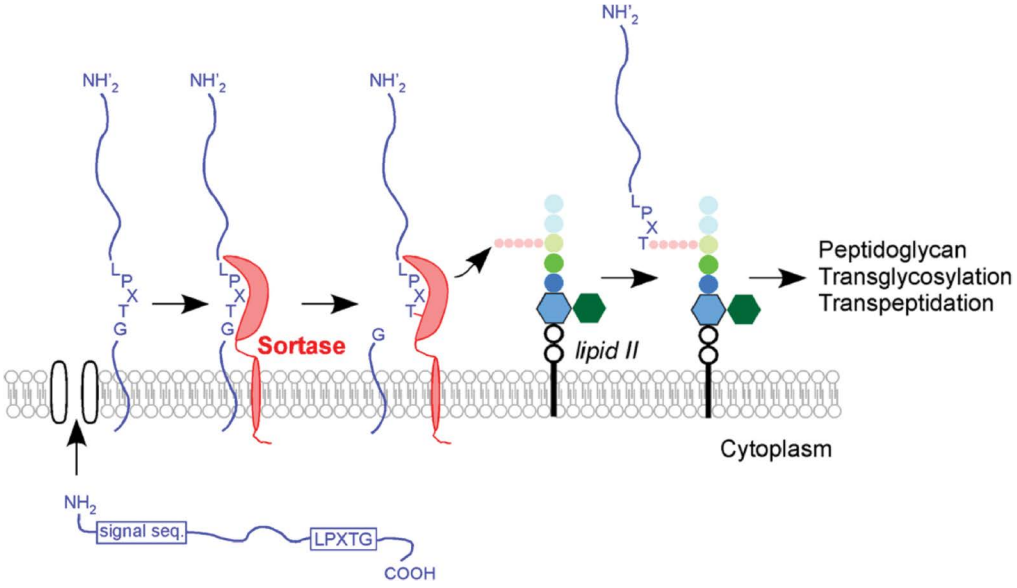

FIGURE 39.4 Sortase-mediated anchoring of proteins to the cell wall envelope of *S. aureus*. Precursor proteins bear an N-terminal signal sequence and C-terminal sorting signal with the conserved LPXTG motif. Precursor proteins are first secreted across the plasma membrane (Sec machinery) and the signal sequence is cleaved to yield a new N-terminus (NH'_2). The C-terminal is retained in the membrane. Sortase A cleaves the LPXTG motif to form an acyl-enzyme intermediate that is resolved by lipid II. The cell-wall anchored protein-linked to lipid II is then incorporated into the cell wall via the transpeptidation and transglycosylation reactions as shown in Figure 39.1.

Cell-Wall Anchored Surface Proteins

Staphylococci display several surface proteins in the envelope, some of which are covalently attached to peptidoglycan following secretion through the canonical secretory pathway (207). The mechanism responsible for protein attachment (anchoring) was first solved for *S. aureus* protein A. Protein A can be released as a homogeneous molecule following lysostaphin treatment (208). However, mechanical treatment of cells releases Protein A with incremental mass increases that can be attributed to the amino sugars *N*-acetylglucosamine and *N*-acetylmuramic acid, suggesting that protein A is linked to peptidoglycan when immobilized in the envelope (208). Protein A contains two hydrophobic domains, one at the N-terminus and one at the C-terminus. The C-terminus carries the LPXTG sequence that is an almost invariant motif shared by most cell wall anchored proteins, where X is any amino acid, followed by a C-terminal hydrophobic domain and a tail of mostly positively charged residues (209). The LPXTG motif and C-terminal tail are necessary for cell wall anchoring (210). Following translocation, the LPXTG motif sorting signal is cleaved between the threonine (T) and the glycine (G) residues (211) by the enzyme sortase A (Figure 39.4) (93). Sortase A also catalyzes the transpeptidation reaction between the carboxyl of threonine and the free amino group of pentaglycine cross-bridges in the staphylococcal cell wall (212) by using lipid II peptidoglycan intermediates as a substrate (213). A second sortase, SrtB is responsible for the anchoring of Isd factors (iron-regulated surface determinant) of *S. aureus* but recognizes a slightly different sorting signal. Isd factors are responsible for hemoglobin binding and passage of heme-iron to the cytoplasm and act as an import apparatus that uses cell wall-anchored proteins to relay heme-iron across the bacterial envelope (214).

Sortase A-anchored surface proteins can be identified following a genome wide search for candidate polypeptides bearing a predicted signal sequence for secretion at the N-terminus and the LPXTG motif at the C-terminus. Between 18 and 22 genes encoding substrates of Sortase-A can be identified in the genomes of *S. aureus* (25). The function of cell wall anchored proteins is not exhaustively known, nonetheless many of them function as microbial surface components recognizing adhesive matrix molecules (MSCRAMMs) and thus represent bacterial elements of tissue adhesion and immune evasion (67, 86, 207, 215, 216).

Virulence Factors and Regulation

S. aureus is the leading cause of hospital acquired infections (22). The spectrum of human diseases caused by staphylococci ranges from soft tissue infections, deep-seated abscesses, osteomyelitis, endocarditis, toxic shock syndrome to necrotizing pneumonia all of which can be tested using small animal model of infection (20, 22, 23, 31). Research over the past several decades identified *S. aureus* cell wall anchored proteins, secreted toxins, capsular- and exo-polysaccharides, iron-transport systems, and modulators of host immune functions in addition to antibiotic-resistance genes as important virulence factors (20, 25, 26, 84). Such versatility is enabled by complex regulatory pathways that include sigma factors, two-component systems, metabolite-responsive regulatory proteins, RNA-binding proteins, and regulatory RNAs (217, 218).

Many staphylococci perform a bacterial census via the secretion of auto-inducing peptides known as AgrD. Auto-inducing peptides are processed and secreted via AgrB, and bind to a cognate histidine kinase (AgrC) at threshold concentration, thereby activating phospho-relay reactions and activation of the AgrA transcription factor (217, 219). The so-called accessory gene regulator (*agr*) is one of 16 two-component systems in *S. aureus*. Activation of AgrA leads to the production of RNAIII, the main

intracellular effector of the quorum-sensing system (217, 219). RNAIII encodes the small δ-hemolysin in *S. aureus*, as well as antisense RNAs that regulate the translation or stability of mRNAs encoding transcriptional regulators, major virulence factors, and cell-wall metabolism enzymes (217). During infection, Agr-mediated bacterial census ensures massive secretion of virulence factors when staphylococcal counts are high, presumably increasing the likelihood of bacterial spread in infected tissues and/or systemic dissemination (217, 220, 221).

Virulence factor synthesis is also metabolically controlled. Three major metabolic regulators, CodY, CcpA, and Rex proteins, regulate dozens of metabolism and virulence genes (222). CodY activity is controlled by the branched-chain amino acids isoleucine, leucine, and valine; CcpA, a member of the LacI family, responds to the availability of preferred carbon sources; Rex is a global regulator of genes whose products interconvert NADH and NAD^+ (222). More directly, the tricarboxylic acid (TCA) exerts a metabolic regulation over the synthesis of capsular polysaccharide by providing phosphoenolpyruvate for gluconeogenesis (223). However, the level of activity of the TCA cycle may lead to transcriptional repression of the *icaADBC* operon encoding the enzymes of polysaccharide intercellular adhesin (PIA) (224). The interconnection between virulence and metabolism is particularly intriguing when staphylococci switch from planktonic to biofilm lifestyles and develop "persister" cells in a metabolically quiescent state (see Ref. [225] for a review on this subject).

Genome and Genomic Variability

Comparative and pan-genomic analyses of staphylococcal genomes revealed interesting genomic variabilities and strain-specific features linked to virulence, hospital adaptation, or commensalism (226–229). Most extensive studies have been performed for *S. aureus* and *S. epidermidis*. Their pan-genome is subclassified into three major sections: the core genome, the accessory genome, and the unique genome (227). While the unique genome encompasses genes that can be assigned to a single genome, the core genome comprises a shared set of genes found in all isolates (227). In *S. aureus*, the core genome (approximately 1,400 genes) is composed of essential genes involved in DNA and RNA biosynthesis, replication, and metabolism along with genes required for virulence, including those encoding for surface proteins, sortase, α-hemolysin, several exotoxins and the *agr* regulon. On the contrary, the accessory genome is highly diverse and contains an array of varying mobile genetic elements (MGE) such as pathogenicity islands, prophages, plasmids, transposons, integrative and conjugative elements, and the staphylococcal cassette chromosome (SCC) (230, 231). Most of these elements have been acquired by horizontal gene transfer events and typically encode for proteins affecting virulence, antibiotic resistance, host-adaptation, and specificity (230, 231). For example, all MRSA strains carry the *mecA*-encoding SCC*mec* element always inserts into *orfX* (231). However, not all SCC elements harbor *mecA*. Non-*mec* SCC elements contain fitness and resistance determinants such as resistance to fusidic acid (SCC*476*) or mercury chloride (SCC*mercury*) (232, 233). Strains with SCC*mec* elements such as the hypervirulent and pandemic isolate USA300 (ST8) or the emerging MRSA lineage ST239 carry the arginine catabolic mobile element (ACME) gene cluster (234, 235). ACME affects skin colonization, survival in acidic environments, and evasion from host immune cell responses (236–238).

Earlier work identified bacteriophages as important contributors to pathogenesis and the evolution of staphylococcal genomes (231, 239, 240). For example, virtually all sequenced *S. aureus* genomes carry at least one and up to four prophages (241). Certain *S. aureus* bacteriophages encode the previously mentioned innate immune modulators chemotaxis inhibitory protein (*chp*), staphylokinase (*sak*), and staphylococcal complement inhibitor (*scn*) (239, 242). Other bacteriophages bear coding sequences for potent toxins including enterotoxins, exfoliative toxin, or PVL (231, 240), and are associated with severe soft tissue infections and fulminant necrotizing pneumonia (243–245). The φSPβ-like prophage found in widespread Asian MRSA isolates, harbors SasX, a sortase-anchored surface protein speculated to promote nasal colonization and immune evasion (246). In addition, clinical strains bear bacteriophage-related *S. aureus* pathogenicity island (SaPI) (231, 247). These elements are 14–27 kbp DNA in size and occupy constant positions in the chromosomes of toxigenic strains (231, 247). SaPIs encode for various enterotoxins, multidrug resistance transporters, toxic-shock-syndrome toxin-1, and an array of T-cell superantigens (247, 248). Secreted T-cell superantigens cause massive cytokine release that leads to fatal toxic shock (249). SaPIs rely on helper bacteriophages for mobilization as they lack genes encoding for structural phage elements (247, 250, 251). In this manner, SaPIs can be transferred across species boundaries thereby substantially contributing to bacterial evolution and the emergence of new epidemic clones (252–254). Although uncommon, host switching also contributes to the evolution of *Staphylococcus*. For example, human-to-poultry and bovine-to-human host switches have been observed for *S. aureus* (255, 256). Host switching may occur through single nucleotide change (*S. aureus* adaptation to rabbits) as well as horizontal gene transfer (257).

Practical Growth and Manipulations

Growth in Laboratory Media

Under laboratory conditions, most staphylococci can be grown in nonselective and rich media including, but not limited to, trypticase soy broth (TSB), brain heart infusion, or Luria Bertani broth. For optimal growth, a temperature of 37°C should be considered although most staphylococci replicate at temperatures ranging from 15°C to 45°C. In addition, *S. aureus* and related species can be cultivated in high-salt media (up to 20% NaCl) or synthetic media mimicking natural niches such as human nares (258–260). In routine processes, specific media are often used to select for *S. aureus*. For example, direct enumeration of *S. aureus* from human swabs can be made on Baird-Parker agar containing rabbit plasma-fibrinogen tellurite, lithium chloride, and egg yolk (261). Clear halos develop around gray-black colonies of *S. aureus*. Coagulase-negative staphylococci typically do not develop the characteristic halo zones. Because the presence or absence of coagulase is a distinctive feature of staphylococci, several coagulase tests have also been developed. Here, isolated colonies are grown in 0.2 mL of brain heart infusion for 18–24 hours

at a temperature of 37°C. After incubation, 0.5 mL of reconstituted coagulase plasma with ethylenediaminetetraacetic acid (plasma is commercially available and reconstituted according to manufacturer's directions) is added to the culture, followed by another subsequent incubation step at 37°C. Samples are examined for clot formation in 6-hour intervals. Other media, often derived from Baird-Parker medium, are used for the nonselective isolation and enumeration of coagulase-positive staphylococci from food sources. Moreover, Schleifer-Krämer agar can be used for enrichment of staphylococci from foods. Methods and recipes for specific media can also be found in (259, 262).

Biosafety Measures

S. aureus is an opportunistic and adaptable pathogen with the ability to infect, invade, persist, and replicate in any human tissue including skin, bone, visceral organs, or vasculature. Manipulation with most *Staphylococcus* species should be performed following biosafety level 2 measures. General guidelines for BSL-2 practice can be obtained from the latest edition (5th edition) of Biosafety in Microbiological and Biomedical Laboratories available via the following web link: https://www.cdc.gov/labs/BMBL.html.

Molecular Biology and Genetic Manipulation

Staphylococcal Cloning Plasmids

Many staphylococcal plasmids have been developed for genetic manipulation and cloning purposes. These plasmids are grouped in families based on replication initiation mechanisms. Representative prototype vectors, which are copied via a rolling circle mechanism, are pC194, pT181, pSN2, and pE194 (263–265). Other vectors such as pSK1 or pI258 utilize a theta (θ)-type replication mechanism (263, 265). Derivatives of these vectors carrying mutations with conditional replication phenotypes have been isolated. For example, pTS1, a temperature-sensitive (*ts*) *E.coli*/*S. aureus* shuttle plasmid, carries a chloramphenicol resistance determinant for plasmid selection and the pE194*ts ori* (origin) for propagation in staphylococci (266). PTS1 is frequently used for allelic replacement (*vide infra*). A set of inducible expression systems, some of which are derived from pI258, have also been developed (265). Integrative vectors with an *E. coli* replicon for cloning, but unable to replicate in staphylococci, have been developed taking advantage of staphylococcal phages. Genes carried by these plasmids can only be expressed following site-specific recombination onto the bacterial chromosome. Of note, stable integration does not require selection and facilitates single copy gene-dosage analysis. Lee and colleagues developed an array of prototype single-copy integration vector systems, most of which are based on the site-specific recombination of bacteriophage L54a (267–269). In *S. aureus*, these vectors integrate into the *attB* attachment site located within the *geh* gene encoding for lipase (267–269). Vectors pLL29 and pLL39 contain a second attachment site derived from lysogenic bacteriophage φ11 that facilitates integration into an alternative genomic locus and can be used to preserve an intact lipase (270). In addition, numerous pCL83/84-based integration plasmids have been engineered (271–273).

Allelic Replacement

Allelic replacement is frequently used to generate chromosomal mutations (Figure 39.5). Generally, shuttle vector systems such

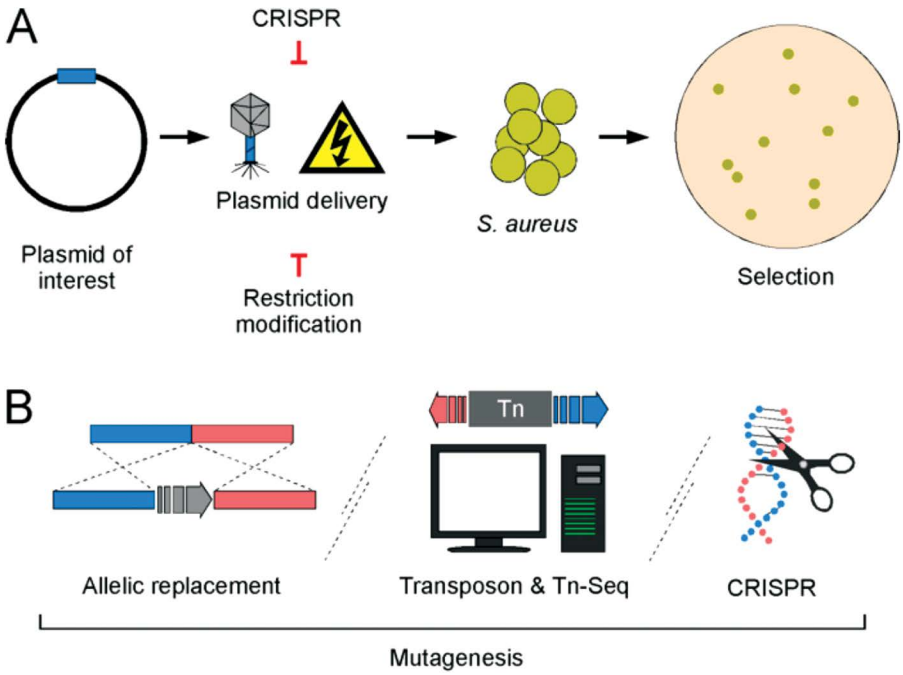

FIGURE 39.5 Genetic engineering of staphylococci. Panel A: A plasmid of interest carried by *S. aureus* RN4220 is typically transferred to clinical staphylococci via electroporation or phage-mediated transduction. Restriction modification systems or CRISPR/Cas9 loci may interfere at this stage. Panel B: Following transformation (or transduction), various technologies can be applied for subsequent mutagenesis.

as pTS1 carrying replication-defective conditional mutations are used. Under nonpermissive condition, i.e., temperature shift, plasmid integration into the bacterial chromosome occurs via homologous recombination (274). As a result of single cross-over recombination events, merodiploid cells bearing both wild-type and mutant alleles may develop and can be resolved under permissive conditions, in which recombination and vector excision are thought to be triggered by a rolling-circle mechanism. In case of double cross-over recombination, wild-type or mutant alleles reside in the genome while the reciprocal alleles replicate with the excised vector.

Cloning design for successful allelic replacement should include genomic sequences of 0.4–1.0 kbp flanking the gene of interest or target sequence to be deleted or modified. When desired, an antibiotic resistance marker (i.e., *ermC*) may be inserted between the flanking sequences to accelerate the identification of recombinants (Table 39.1). Selection takes place at the permissive temperature of 30°C on agar plates containing chloramphenicol. Further selection with chloramphenicol (and erythromycin) and a shift to a nonpermissive temperature, typically 43°C, ensures integration of the vector into the staphylococcal chromosome. Next, variants are grown under the permissive temperature (30°C) and plated on agar supplemented with erythromycin. Several colonies are patched onto non- and antibiotic-containing agar plates (chloramphenicol). Colonies that grow in the absence of chloramphenicol, but not in its presence, should be further analyzed for plasmid loss and the presence of the mutated allele (274).

Arnaud and coworkers developed pMAD for allelic replacement in Gram-positive bacteria (275). pMAD contains sequence fragments of pBR322 and the pE194*ts ori* along with *bgaB* derived from *Bacillus stearothermophilus* (275). *bgaB* encodes for a thermostable β-galactosidase which facilitates cleavage of the chromogenic substrate X-gal (5-bromo-4-chloro-3-indoyl-β-d-galactopyranoside) in *S. aureus*. Depending on the integration status of pMAD, *S. aureus* colonies may appear blue (episomal), light-blue (single cross over), or white (double cross over) thereby providing a rapid screening tool for excision and loss of the plasmid (275). In addition, Bae and Schneewind designed pKOR1 (another pTS1 derivative) taking advantage of antisense *secY* RNA expression for counter-selection during the allelic replacement procedure (276). In pKOR1, expression of the antisense *secY* RNA is controlled by $P_{xyl/tetO}$, an anhydrotetracycline (ATc)-inducible module. Since SecY is essential, expression of *secY* antisense RNA efficiently prevents colony formation on solid media (277). Following plasmid transfer to *S. aureus* via electroporation, replication of pKOR1 requires a permissive temperature of 30°C. Similar to pTS1, a thermal shift to 43°C (nonpermissive

TABLE 39.1

Preparation of Electrocompetent *S. aureus* and Their Transformation with DNA

1. Streak *S. aureus* strain to be transformed from a frozen stock on a tryptic soy agar (TSA) plate and incubate overnight at 37°C.
2. Pick an isolated colony with a sterile loop and inoculate 25 mL tryptic soy broth (TSB) in a 100-mL flask.
3. Incubate overnight at 37°C with shaking (160–200 rpm)
4. Dilute the overnight culture in 200 mL TSB to a final $OD_{600} = 0.1$; the use of a large 2-L flask is recommended.
5. Grow cells at 37°C to early-log phase ($OD_{600} = 0.5$) with vigorous shaking (approximate incubation time is 90–120 minutes).
6. Transfer the culture into sterile spin bottles and collect cells by centrifugation at 5,000 x g for 10 minutes and 4°C.
7. Discard the supernatant and suspend the cell pellet in 40 mL of ice-cold sterile 0.5 M sucrose in deionized water.
8. Transfer the suspension to a prechilled 50 mL sterile centrifuge tube; keep sample on ice.
9. Collect cells by centrifugation at 8,000 x g (10 minutes, 4°C).
10. Discard supernatant and suspend the cell pellet in 20 mL of the ice-cold 0.5 M sucrose solution as above.
11. Collect cells by centrifugation at 8,000 x g (10 minutes, 4°C).
12. Repeat steps 10 and 11 once more.
13. Resuspend the pellet in 2 mL ice-cold 0.5 M sucrose solution. Keep samples on ice.
14. Transfer 100 µl aliquots of the prepared electrocompetent cells into microcentrifuge tubes chilled on ice.
15. Freeze tubes by plunging them in a dry ice-ethanol bath; store cells at –80°C until use.
16. For electroporation with plasmid DNA, retrieve a tube of competent cells from the freezer and place tube on ice.
17. Add 500–1,000 ng of purified plasmid to thawed cells.
18. Incubate the DNA/cell mixture for 30 minutes at room temperature.
19. Transfer the DNA/cell mixture into a 0.1-cm prechilled electroporation cuvette
20. Electroporate the cells using the following parameters: voltage = 2.5 kV, resistance = 100 Ω, capacity = 25 µF.
21. Subsequently, add 1 mL TSB kept at room temperature and transfer the entire content to sterile 2 mL reactions tubes.
22. Incubate for 1 hour at 37°C (no shaking required). In case temperature-sensitive plasmids are transformed, incubate sample at 30°C accordingly.
23. Plate 50–200 µl aliquots on multiple TSA plates containing the appropriate antibiotic for plasmid selection.
24. Incubate plates at 37°C (or 30°C) for at least 16 hours (or until colonies are visible).
25. Extract plasmid DNA from potential *S. aureus* clones using lysostaphin digestion and a commercially available plasmid isolation kit
26. Validate plasmid via agarose gel electrophoresis.

temperature) and homologous recombination facilitate integration of the vector into the staphylococcal chromosome. Next, plasmid eviction is triggered by growing cells to permissive temperature (30°C) and subsequent plating of 10^4-fold dilutions (100 µl) onto plates containing 0, 1, or 2 µg/mL ATc. ATc-induced expression of the *secY a*ntisense RNA suppresses growth of cells containing pKOR1 thereby selecting against co-integrants that are not resolved (refer to Ref. [276] for a more detailed protocol). *SecY* antisense RNA has also been used for counterselection in other vector systems. The $P_{xyl/tetO}$-inducible *secY* antisense element of pKOR1 was transferred into pIMAY with the temperature-sensitive replicon of the lactococcal plasmid pWV01*ts* (278). Elements of pKOR1 and pBT2 have also been combined to generate pBASE6, another vector system that employs *secY* antisense RNA for counterselection (279). All plasmids, pKOR1, pIMAY and pBASE6 have been successfully used for allelic replacement procedures in *S. aureus* and coagulase negative staphylococci such as *S. epidermidis* and *S. lugdunensis*.

Transposon Mutagenesis and Tn-Seq

Transposons can be adapted for random genetic mutagenesis of bacteria including staphylococci (Figure 39.5). Most transposons are delivered using vectors with temperature sensitive replicons. In some instances, two plasmids are used to deliver the transposon and its cognate transposase, other technologies rely on single vector systems. For example, pTV1 harbors a transposon *Tn*917 (280) that has been used for insertional mutagenesis of various Gram-positive microbes including *S. aureus* (281–283). Another single vector system is pBTn, which takes advantage of a *himar1* transposase driven by a xylose-inducible promotor (284). The transposon system *bursa aurealis* developed by Bae *et al*. consists of two plasmids with temperature-sensitive replicons, pBursa (transposon) and pFA545 (transposase *himar1*) (281). *Bursa aurealis* was used to generate a large collection of *S. aureus* mutants, the ΦNΞ (Phoenix) library (284), as well as the publicly available Nebraska Tn Mutant Library, a transposon library generated in USA300-derived MRSA strain (285). Detailed instructions on the use of the *bursa aurealis* technology can be found in (281, 286).

Transposons insertional mutagenesis has also been combined with next-generation sequencing technologies in staphylococcal research (Figure 39.5). This experimental approach, known as Tn-Seq, relies on genome-wide transposon mutagenesis coupled to high-throughput sequencing to define the contribution of crucial genes to certain phenotypes. In general, *himar1 mariner*-based transposon insertion systems are used to generate a saturated transposon mutant pool. Following library generation, the mutant pool is subjected to a strong selection procedure designed with specific goals. Ultimately, PCR, massive sequencing, and bioinformatics are used to identify transposon insertion sites and mutational lesion frequencies. For example, such a pooled *S. aureus* transposon library was used to isolate genes for replication in whole human blood, aqueous fluid, and vitreous fluid to discover 426 genes presumably required for *S. aureus* survival and growth under infection-associated conditions (287). Several other studies employed similar approaches to identify staphylococcal genes contributing to antibiotic resistance (288), temperature stress (289), or virulence (290, 291).

Genome Editing Via CRISPR/Cas9 Mutagenesis

Clustered regularly interspaced short palindromic repeat (CRISPR)/Cas9-powered genome editing is a powerful genetic tool that facilitates rapid and efficient disruption of genomic loci. While initially designed to edit mammalian genomes, an array of vector systems has been developed for manipulation of bacterial and staphylococcal chromosomes (Figure 39.5). For example, Chen and colleagues designed pCasSA suitable for gene deletion, gene knock-down, insertion, and single-base substitution mutation in *S. aureus* (292). PCasSA harbors the *cas9* gene from *Streptococcus pyogenes* (SpCas9), which is driven by the *S. aureus rpsL* promoter (292). Expression of the single guide RNA (sgRNA; sequence targeted for mutagenesis) is controlled by the *cap1A* promotor (292). Moreover, pCasSA contains a temperature-sensitive origin (*repF*), thus facilitating efficient curing of the vector after successful mutagenesis (292). Based on pCasSA, Gu *et al.* developed pnCasSA-BEC, an elegant base-editing system that can be used for gene inactivation or introduction of point mutations in *S. aureus* (293). The system relies on a *S. pyogenes*-derived Cas9 nickase fused to a cytidine deaminase (rat APOBEC1) thereby enabling highly efficient C to T conversion in staphylococcal genomes (293). The genome editing toolbox for staphylococci has further been expanded by Liu *et al.* who designed another single vector system (pLQ-$P_{xyl/tet}$-*cas9*-P_{spac}-sgRNA) (294). This plasmid carries the sgRNA under the control of the P_{spac} promotor while *cas9* is placed under the constitutive promotor $P_{xyl/tet}$ (294). pLQ-$P_{xyl/tet}$-*cas9*-P_{spac}-sgRNA also includes a temperature-sensitive origin and target gene-flanking elements required to repair Cas9-mediated double-strand breaks (294). Detailed protocols on the use of these tools can be found in references (292–294).

Bacteriophage-Mediated Transduction

Many naturally occurring *S. aureus* bacteriophages facilitate rapid exchange of mobile genetic elements between clonal complexes thereby representing excellent tools for genetic manipulations. All known *S. aureus* bacteriophages have double-stranded DNA genomes and belong to the order of *Caudovirales* (295, 240). According to their morphology, staphylococcal bacteriophages are further subdivided into three major families: *Siphoviridae* (long, noncontractile tails), *Myoviridae* (contractile tails), and *Podoviridae* (short, noncontractile tails) (241, 240). Lytic *Myoviridae* and *Podoviridae* cannot be used for genetic manipulations. However, *Siphoviridae*, with three main serological groups (A, B, F), are temperate phages that have the capacity to transduce genetic material between staphylococci (240, 296, 297). For example, φ11, a serogroup B transducing phage has a burst size of approximately 250 plaque-forming units and exhibits a low lysogenization frequency (1–10%) (298). Use of φ11 is ideal for transducing alleles linked or marked with a selectable trait between staphylococcal isolates. Here, phage lysates are generated by infecting a donor strain grown in TSB containing 5 mM $CaCl_2$ at a multiplicity of infection of 1. Addition of $CaCl_2$ favors phage adsorption. Lysis, which can be performed on both soft agar and liquid broth, is achieved after 16 hours of incubation at 37°C. To remove cellular debris and potential bacterial survivors, recovered phage lysates must be centrifuged

and sterilized by filtration. For transduction experiments, a multiplicity of infection of 1 phage particle to 10 bacteria is recommended. Samples should be incubated at 37°C for 30 minutes, followed by a centrifugation step to separate bacteria and phage particles. Supernatants containing phages are discarded and bacterial pellets washed twice with TSB containing the calcium chelating agent, sodium citrate (40 mM). Selection of transductants is performed by plating bacteria are onto media with the appropriate antibiotic and sodium citrate (40 mM). Transductants typically arise within 48 hours of incubation at 37°C and should be streaked at least twice on sodium citrate-containing plates to eliminate residual lytic phage. Likewise, phages may also be used to transfer plasmid DNA among staphylococci (Figure 39.5) (299, 300). Not all strains are susceptible to φ11 or can be transduced by other serogroup B phages as the host range of staphylococcal phages largely depends on their cognate cell surface receptor: WTA (254, 301). Differences in phage susceptibility can also be accounted for by postadsorption events, such as genetic barriers that limit or prevent phage replication (*vide infra*).

Barriers to Genetic Manipulation in Staphylococci and Technical Solutions

Genetic barriers such as restriction modification systems (R-M systems) or CRISPR/Cas9 loci substantially contribute to bacterial and staphylococcal evolution (230). Such barriers also interfere with laboratory procedures employed for genetic manipulation of *S. aureus* and related staphylococci (Figure 39.5) (230). For example, R-M systems limit or completely prevent transfer of plasmid DNA to staphylococci from exogenous sources (302–304). Three major types of R-M systems (types I, II, and IV) have been identified in *S. aureus* (302–306), where type I and IV systems mainly impede plasmid transfer events (302–304). Thus, *E. coli*-derived plasmid DNA is often passaged in the *S. aureus* laboratory strain RN4220 (307). RN4220 accepts *E. coli*-propagated plasmid DNA due to nitrosoguanidine-induced mutation(s) in its R-M systems (308), recently mapped to the *hsdR* and *sauUS1* genes (302, 303). Plasmids extracted from strain RN4220 can be electroporated into most *S. aureus* isolates (Table 39.1). Alternatively, a set of specifically engineered *E. coli* strains lacking the *dcm* gene required for cytosine methylation of DNA may be used to overcome the type IV restriction barrier (278). Plasmid DNA derived from these *E. coli* strains can be electroporated directly into some clinical isolates without using strain RN4220 (278). To bypass both type I and IV R-M systems, Jones *et al.* generated *E. coli dcm* mutants with a plasmid artificial modification (PAM) system, which ensures protection of the vector from the restriction endonuclease in the target *S. aureus* strain (309). In this manner, clinical isolates belonging to clonal complexes 1, 5, and 8 can be transformed with plasmid DNA derived from *E. coli* (309).

Exogenous DNA is also rapidly recognized and destroyed by CRISPR/Cas9 systems (310). These loci facilitate adaptive immunity against bacteriophages and other foreign DNA elements such as plasmids, thus interfering with genetic engineering of bacteria (Figure 39.5) (310–312). However, CRISPR/Cas9 systems are typically not found in *S. aureus* genomes as only a few isolates carry CRISPR/Cas9 modules (313–315). These systems may play a more important role in coagulase-negative staphylococci and hamper their genetic manipulation (316). Accordingly, genetic engineering of most coagulase-negative staphylococci continues to be laborious and complex (278, 317–319).

The Challenge in Staphylococcal Research

Invasive infections caused by Gram-positive pathogens such as Staphylococci, Streptococci, or Enterococci represent a serious public health threat (320–322). Specifically, the emergence of rapidly spreading hyper-virulent and multidrug-resistant clones is a daunting task for clinicians, pharmaceutical companies, and the research community (321–323). While warranted, the development of new antimicrobials to combat the emergence of drug-resistant strains is laborious, time- and cost-intensive, and such efforts are often deemed unprofitable. To circumvent this problem, many well-conceived approaches have been initiated to develop a vaccine, or alternative anti-infective therapeutics against *S. aureus* (324). A large body of studies has been conducted to understand the composition and biogenesis of staphylococcal cell wall envelope and to identify valuable targets for vaccines and therapeutics. However, attempts to design vaccines that target cell envelope structures such as capsular polysaccharide, or LTA, or the IsdB protein have failed in various clinical trials (325). Clearly, the wide array of virulence and immune evasion factors, the genetic variability of clinical *S. aureus* isolates have prevented linear progress toward vaccine development (84, 324–326). Yet, this genetic variability, versatility to adapt to new hosts and environment, and expandable immune subversion attributes make staphylococci an endless treasure-trove for the avid microbiologists.

Introduction

Streptococci will appear under the microscope as round bacteria arranged in pairs or in chains. By the Gram-staining technique, they will be Gram-positive. The chaining characteristic is best observed when organisms are grown in liquid media or isolated from infected body fluids such as blood. Streptococci are differentiated as alpha, beta, and gamma types based on their activity on the surface of blood agar, which could differ somewhat based on the species and age of the red blood cells. Alpha-hemolytic streptococcal colonies are surrounded by a narrow zone of hemolysis that shows green discoloration based on the hemolysin's action on the hemoglobin; beta-hemolytic streptococci show a well-defined clear zone of hemolysis around the colony; gamma-hemolytic streptococci have no effect on the red blood cells. *Streptococcus pyogenes* are nearly always beta-hemolytic, whereas closely related Groups B and C streptococci usually appear as beta-hemolytic colonies, but different strains can vary in their hemolytic activity. Nearly all strains of *Streptococcus pneumoniae* are alpha-hemolytic but have been shown to exhibit beta-hemolysis during anaerobic incubation. Most oral streptococci and enterococci are nonhemolytic, and thus considered gamma types. The property of hemolysis is used in rapid screens for identification of *S. pyogenes* and *S. pneumoniae* but may be unreliable for general differentiation of other streptococci. In general, strains that produce a hemolysin are professional pathogens, responsible for direct human and animal diseases, whereas nonhemolytic streptococci are mostly opportunistic pathogens.

Hemolytic Streptococci

Hemolysins are considered virulence determinants, and as such, hemolytic streptococci are found to be human and animal pathogens. Most clinical isolates appear as beta-hemolytic streptococci when grown on blood agar. *S. pyogenes*, groups B and C streptococci and *Streptococcus pneumoniae* (described below in more detail), are the most prevalent streptococcal pathogens isolated from humans. The human oropharynx is the sole known natural reservoir for *S. pyogenes* in the environment. These organisms are maintained in the throats of humans (usually children) in a

"carrier state," with up to a 30% frequency [1]. Group B streptococci are predominantly found colonizing the human vagina, but it is also associated with animal infections. Although resistance to penicillin-based antibiotics has yet to emerge in *S. pyogenes*, infections caused by this organism continue to occur with occasional widespread outbreaks.

Classification

The classification of hemolytic streptococci was considerably simplified when Lancefield showed that surface antigens (carbohydrates) extracted with heat from the cell wall of streptococci could react with carbohydrate-specific antisera prepared in rabbits. Lancefield's group A, for example, are the *S. pyogenes* strains responsible for human diseases such as scarlet fever, streptococcal pharyngitis, erysipelas, puerperal sepsis, and wound infections. N-acetylglucosamine is the group A-specific carbohydrate, whereas N-acetylgalactosamine is the group C streptococcal determinant. Extended studies of the cell wall carbohydrates of streptococci from several sources have shown at least 13 different serologic groups encompassing human and animal pathogens and commensals.

The group A streptococci may be subdivided into more than 150 different types based on a highly variable region of a fibrillar surface protein, called M protein. While M protein was used as a serologic determinant for early classification of group A strains (M serotypes), recently, the sequence of the variable region of the M protein gene (*emm*) has been used instead (emm-type) with identical results. M and *emm* typing are generally used for epidemiologic purposes in studying the spread of streptococcal strains and the diseases they cause.

Capsular serotyping has been used to differentiate different strains of group B streptococci (*S. agalactiae*). To date, 10 capsular serotypes have been described (Ia, Ib, II-IX). Worldwide, serotype III strains are of particular importance, since they are responsible for the majority of infections, including neonatal meningitis.

S. pyogenes Extracellular Products

S. pyogenes produce a wide array of extracellular products, many of which are considered virulence factors (reviewed in refs. [2, 3]).

Streptococcal pyrogenic exotoxins (Spes) are produced by most *S. pyogenes* strains. The most potent of which, SpeA, is responsible for the rash in cases of scarlet fever and its gene is carried by a prophage [4]. Currently, up to 13 different Spes have been reported [5]. In all cases, Spes are superantigens, or mitogenic proteins with the capacity to crosslink the V_b domain of the T-cell receptor and the major histocompatibility complex of class II molecules on the surface of an antigen-presenting cell. This T-cell stimulation results in high systemic levels of proinflammatory cytokines and T-cell mediators, causing hypotension, fever, and shock. As a result, Spes have been suggested to be the prime mediators in streptococcal toxic shock syndrome. Interestingly, except for SpeB (a cysteine protease), Spes are not part of the bacterial genome but are carried on prophages widely found in streptococci.

Streptolysin O (SLO) is an oxygen-labile protein with the capacity to lyse red blood cells under anaerobic conditions. It is highly antigenic such that the antibodies produced during infection could be quantified in relation to their capacity to neutralize the hemolytic activity of SLO. It has been shown that the titer of antibodies to streptolysin O (ASO) is related to a recent *S. pyogenes* infection. Streptolysin S (SLS) on the other hand is stable in air and is the molecule responsible for the hemolytic zone around streptococcal colonies on blood plates. SLS is a nonantigenic 2.8 kD peptide that is tightly associated with the bacterial cell surface with potent toxic effects on experimental animals in vivo and on leukocytes in vitro [6].

Streptokinase is a secreted molecule with no intrinsic enzymatic activity, however when bound to plasminogen it initiates its conversion to plasmin, the active protease with fibrinolytic activity. Because of this activity, streptokinase has had some success in human medicine as an agent to lyse fibrin clots in coronary arterial thrombosis, acute pulmonary embolism, and deep venous thrombosis. However, because of its antigenicity, it has appreciated limited use.

Hyaluronidase is an enzyme that acts on hyaluronic acid, the ground substance in connective tissue. Because of this activity, hyaluronidase is considered the "spreading factor" for these streptococci. Surprisingly, the structurally identical hyaluronic acid is also the composition of the capsule found on many strains of *S. pyogenes,* a capsule that enables the organism to resist phagocytic attack by human leukocytes [3]. While the capsule is found on the organism during log-phase growth, it quickly falls off during stationary phase.

S. pyogenes also produce four enzymes that can cleave nucleic acids, specifically DNA. These DNases, or sometimes referred to as streptodornase A through D, all possess deoxyribonuclease activity while streptodornase B and D possess ribonuclease activity as well. It has been suggested that by digesting the DNA released from dead mammalian cells at an infected site, the enzyme reduces the local viscosity allowing the organism to spread more easily through the tissues and as such are considered to be virulence factors. As such, DNAses have also been referred to as "spreading factors."

Surface Proteins on *S. pyogenes*

In addition to secreted molecules, *S. pyogenes* express a variety of molecules that are displayed on the cell surface, which are critical for colonization and infectivity (reviewed in refs. [2, 7, 8]). Among these are M protein, IgA binding protein, IgG binding protein, C5a peptidase, serum opacity factor, fibronectin binding protein, plasmin binding protein, and five glycolytic enzymes (glyceraldehyde-3-phosphate dehydrogenase, alpha-enolase, phosphoglycerate mutase, phosphoglycerate kinase, trios phosphate isomerase) to name a few. All these proteins have been implicated in some way with streptococcal pathogenesis; however, here we will discuss the major virulence determinant, the M protein, in detail.

M Protein

The streptococcal M protein is probably one of the best-defined molecules among the known bacterial virulence determinants. It was discovered more than 90 years ago by Rebecca Lancefield [9], and it is clear that protective immunity to

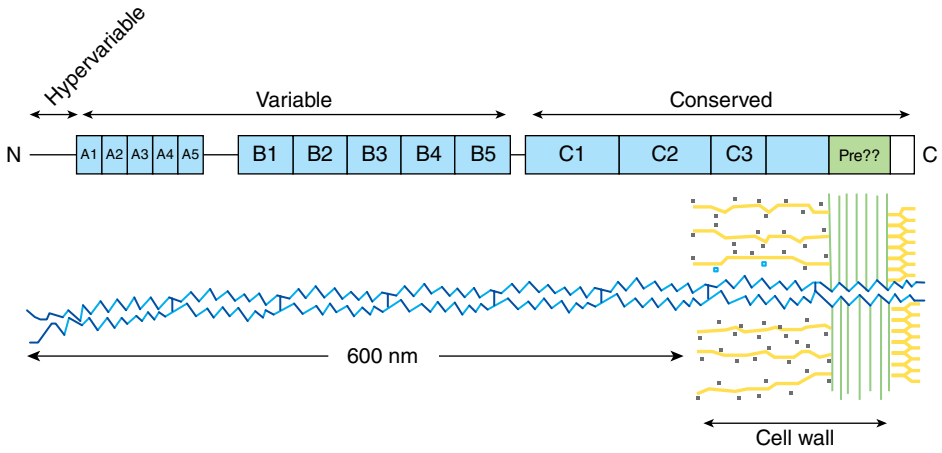

FIGURE 40.1 Sequence repeat and other regions of the M protein molecule (top) and the corresponding coiled-coil M protein situated in the bacterial cell wall (bottom).

group A streptococcal infection is achieved through antibodies directed to the M protein [10]. The M molecule is a fibrillar coiled-coil molecule composed of sequence repeat regions extending from the cell wall surface. The A- and B-repeats located within the N-terminal half of the molecule are antigenically variable among the >150 known streptococcal types with the N-terminal nonrepetitive region and A-repeats exhibiting hypervariability (Figure 40.1). The C-terminal C-repeats, the majority of which are still surface exposed, contain epitopes that are highly conserved among the identified M proteins [11]. Because of its antigenically variable N-terminal region, the M protein provides the basis for the Lancefield serological typing scheme for group A streptococci [10].

The M protein is considered the major virulence determinant because of its ability to prevent phagocytosis when present on the streptococcal surface and thus, by this definition all clinical isolates express M protein. This function may in part be attributed to the specific binding of complement factor H to both the conserved C-repeat domain [12] and the fibrinogen bound to the B-repeats [13], thus preventing the deposition of C3b on the streptococcal surface. It is proposed that when the streptococcus contacts serum, serum factor H binds to the M molecule and inhibits or reverses the formation of C3b, Bb complexes, helping to convert C3b to its inactive form (iC3b) on the bacterial surface, thus preventing C3b-dependent phagocytosis. This is supported by studies showing that antibodies directed to the B- and C-repeat regions of the M protein are unable to promote phagocytosis [14] while antibodies to the N-terminal type-specific region opsonize the organism. This may be the result of the ability of M-bound factor H to also control the binding of C3b to the Fc receptors on these antibodies, resulting in inefficient phagocytosis [15]. Antibodies directed to the hypervariable N-terminal region are opsonic, perhaps because they cannot be controlled by the factor H bound to the distantly located B- and C-repeat regions. Thus, it appears that the streptococcus has devised a method to protect its conserved region from being used against itself by binding factor H to regulate the potentially opsonic antibodies that bind to these regions. Both the N-terminal hypervariable region and the conserved region are targets for vaccine development (discussed later) [16].

Streptococcal Diseases

S. pyogenes are responsible for several diseases including, pharyngitis, otitis media, impetigo, meningitis, necrotizing fasciitis, scarlet fever, erysipelas, rheumatic fever, and acute glomerulonephritis, to name a few [2, 17]. The latter two, rheumatic fever, and acute glomerulonephritis, are sequelae of an *S. pyogenes* infection. Although a great deal of research has focused on these diseases, little is known regarding their etiology except that an *S. pyogenes* infection preceded the disease, suggesting that an immune component may be responsible for the observed symptoms.

The latent period for rheumatic fever is about three weeks after a streptococcal pharyngitis [17]. Curiously, none of the other *S. pyogenes* infections culminates in this disease, only acute pharyngitis ultimately results in damage to the mitral heart valve. It has been proven that aggressive treatment of the streptococcal pharyngitis with penicillin within 10 days of its onset will significantly reduce and even prevent cardiac damage. However, if untreated, recurrent rheumatic attacks following streptococcal pharyngitis may occur resulting in further cardiac damage ultimately necessitating valvular replacement surgery. It should be emphasized that *S. pyogenes* are never isolated from the damaged heart, strongly suggesting that based on the timing of the disease, an immunological component is responsible for the observed damage.

Acute glomerulonephritis may follow a *S. pyogenes* infection by about one week, resulting in malfunction of the kidney glomeruli. However, in this disease the patients usually undergo spontaneous recovery. Treatment is usually managing the reduced kidney function until the condition resolves itself. Whether this is a toxic or an immunological disease has not yet been resolved.

In recent years, streptococcal toxic shock syndrome (STSS) has been a concern worldwide. It is a severe illness associated with invasive or noninvasive *S. pyogenes* infection. The disease may result from an infection at any site but most often in association with infection of a cutaneous lesion. In some cases, a traumatic injury without any external breaks has been the focus, suggesting that organisms circulating in the blood of carriers

could bind to the site of the trauma to initiate the localized infection. Toxicity and a rapid progression of the clinical course (24–48 hours) are characteristic, having a case-fatality rate of >50%. In most instances, patients present with shock-like symptoms and a necrotic lesion or painful abscess. However, in cases where no injury is obvious, these are more difficult to diagnose and rapidly become serious. Treatment is usually management of the shock, debridement of the lesion, and intravenous antibiotics. Fortunately, *S. pyogenes* are not resistant to penicillin-based antibiotics, making this the drug of choice. In more severe cases, amputations may be necessary due to the manifestations of septic shock.

More than 100 years ago, scarlet fever was considered a deadly disease, and a severe complication of a streptococcal infection, usually pharyngitis. Today, perhaps due to changes in the bacteria and treatment options, scarlet fever is not as serious, but still results in a body rash during a pharyngitis. Erysipelas (cellulitis with fever and toxicity) is also less common today again perhaps due to changes in the bacteria, the host, and the availability of antibiotics. Neonatal meningitis is a disease that has been increasing in the past few decades. This disease, caused by group B streptococci (GBS), results from the contamination of newborns of mothers vaginally colonized with GBS during natural childbirth. The organism and its pathogenic program are discussed later in this chapter.

Vaccine Development

To date, no vaccine is available to prevent infections by *S. pyogenes*, making pharyngitis one of the only childhood diseases for which no vaccine exists. This could be due to several factors. The first being that the M protein is the major virulence determinant for which type-specific antibodies were shown to be neutralizing. However, since there are >150 different serotypes identified, a polyvalent vaccine directed to the most prevalent types would need to be developed. This was accomplished after years of testing [18, 19]. In a second approach, it was discovered that antibodies directed to the conserved C-repeat region of the M protein while not opsonic, could protect mice from colonization by multiple *S. pyogenes* serotypes when delivered to the oral mucosa [20, 21]. Unfortunately, both apparently effective vaccine approaches have yet to be licensed for human testing and use. The major reason for this could be that the streptococcal antigen/s responsible for the observed heart-reactive antibodies seen in rheumatic fever patients has yet to be identified, so companies are reluctant to administer a streptococcal product as a vaccine for fear of inducing the disease it is designed to prevent.

Laboratory Diagnosis

The hemolytic reaction and colonial morphology exhibited on blood agar has been used as the standard to classify streptococci. *S. pyogenes* is associated with beta-hemolysis, or complete lysis of blood cells around the colony. *S. pyogenes* are nearly always beta-hemolytic as opposed to group *B streptococci*, which can exhibit alpha-, beta- or gamma-hemolysis. Serological identification is the most accurate method of streptococcal identification; however, these reagents are for research purposes and are unavailable for routine use. Because *S. pyogenes* are sensitive to bacitracin, and most other beta-hemolytic streptococci are not, using a bacitracin disk on a blood agar plate can be used for identification.

Rapid Tests

There are several rapid test kits for *S. pyogenes* in use today that rely on the group-specific carbohydrate found in the cell wall of this organism [22]. These test kits, which are routinely employed in doctor's offices and hospitals, use acid to extract the carbohydrate determinant (N-acetylglucosamine) from the streptococci on a swab and antibodies to that released sugar are used for positive identification. Since *S. pyogenes* is the only streptococcus with this determinant, most of these rapid tests are >95% specific and about 90% sensitive for these bacteria.

Other Beta-Hemolytic Streptococci

Groups C and G Streptococci

According to recent taxonomic studies, large colony-forming groups C and G streptococci that infect humans are classified as *Streptococcus dysgalactiae* subsp. *equisimilis* [23], the others infect animals. These human and animal species have been isolated from severe systemic infections in humans that are usually associated with food born contamination (primarily from milk and cheese). More commonly however, groups C and G streptococci may be found colonizing the human nasopharynx and have been associated with outbreaks of acute pharyngitis. Because of the specificity of antigen-specific tests for the group A streptococci, group C and G streptococci colonizing and infecting the nasopharynx are usually missed. Recently, group G streptococci have been identified as an important opportunistic and nosocomial pathogen. In certain tropical climates (Caribbean and northern Australia), group G as well as group C streptococci have been associated with cases of rheumatic fever, a disease that for decades has only been associated with group A streptococcal pharyngitis [24]. Since both groups C and G streptococci have surface M protein, they can be subtyped based on the antigenic and sequence differences in this molecule.

Group B Streptococci (GBS)

GBS are Gram-positive encapsulated organisms found predominantly in pairs or short chains. They not only share the Lancefield group B polysaccharide antigen, but they are discriminated based on their type-specific capsular polysaccharides which separate them into ten antigenically unique types (Ia, Ib, II-IX) [25]. The capsule is a major virulence factor for GBS. It is an antiphagocytic molecule, which helps the organism evade phagocytic attack except when type specific antibodies are present [25]. "Nontypeable" strains have also been identified, which account for ~1% of isolates from neonatal infections. On blood agar, GBS appear beta-hemolytic with a narrow zone of hemolysis, however ~2% of isolates are nonhemolytic. All beta-hemolytic isolates

produce a red-orange pigment, granadaene, when cultured under certain conditions [26]. An additional important surface protein is the immunogenic protein Sip, which is shared by all GBS isolates [16]. Pilus-like structures have also been described which are composed of three subunits and used by the organism as an adhesin [27].

As mentioned above, this human pathogen is responsible for neonatal meningitis and is a leading cause of neonatal sepsis, which presents within the first 24–48 hours after birth. The organism, which colonizes the genitourinary or gastrointestinal tracts of 10–30% of pregnant women, is acquired vertically after the amniotic sac ruptures, but can also invade through intact amniotic membranes. The bacterium is aspirated into the lungs of the neonate, resulting in sepsis, pneumonia, and, less commonly, meningitis. The resulting infection is a leading cause of early neonatal death [28].

It is essential, prior to giving birth, that maternal carriers be identified by culture-based screening and treated with intravenous antibiotic prophylaxis during labor and delivery [26]. Past studies have shown that intrapartum antibiotic prophylaxis is ~88% effective in preventing these neonatal infections [29, 30]. A more recent study [31] has shown that intrapartum treatment with β-lactam antibiotics (penicillin or ampicillin) for 4 hours or more before delivery was most effective at preventing neonatal infections. Although screening for potential carriers has become standard practice, for those mothers who have not been identified prior to presenting in labor, risk-based screening is essential, which evaluates a number of other factors that correlate with increased risk of neonatal infections including intrapartum temperatures >100.4°C, amniotic rupture >18 hours, and delivery <37 weeks gestation [32].

Identification

Vaginal and rectal cultures from pregnant women (35–37 weeks gestation) are now the standard practice for screening potential carriers of GBS. Specimens are collected and transported in commercially available media [33] and held at 4°C until processed. Within 24 hours of collection, specimens are inoculated into enrichment media, and this step, rather than direct plating, has been shown to decrease the incidence of false-negative results. Enrichment broths include TransVag broth (ToddHewitt supplemented with 8 μg/mL gentamicin and 15 μg/mL nalidixic acid) and Lim broth (essentially TransVag broth in which gentamicin is replaced by colistin [10 μg/mL]) [34].

Enrichment is followed by traditional subculturing on blood agar or chromogenic agar, followed by the CAMP test, hippurate hydrolysis assays, or latex agglutination with antisera against group B–specific carbohydrates. While DNA probes and PCR-based assays are commercially available, the necessity of performing enrichment culture to decrease false-negative results makes these assays less feasible in a hospital setting to screen intrapartum women who were not screened earlier in their pregnancy. In those instances, postpartum cultures or risk-based screening may prove more beneficial. While the CDC does not recommend any of the rapid nucleic acid-based techniques on nonenriched samples in the intrapartum setting, nucleic acid amplification techniques on enriched samples have been shown to be 92.5–100% sensitive [32].

Other Streptococci

Viridans Streptococci

The viridans streptococci are a heterogeneous group, which includes both alpha-hemolytic and nonhemolytic streptococci. Many species are components of the normal flora of humans and animals; however, the members of this group can cause human disease if given access to normally sterile sites in the body. These opportunistic pathogens are primarily associated with the formation of dental caries (*Streptococcus mutans)*, infective endocarditis (*S. sanguis*) and bone, joint, and liver abscesses (*S. anginosus*) [35].

Viridans streptococci include approximately 30 species that belong to one of five general groups: Mutans, Salivarius, Sanguinis, Mitis, and Anginosus [36]. The members of the viridans group are historically considered difficult to differentiate on the species level, as they do not contain C-carbohydrate antigens in their cell walls, they cannot be serologically identified using the traditional methods described for the beta-hemolytic streptococci. It is generally accepted that the viridans group are first differentiated from other streptococci by exclusion: all members are bile insoluble, nonbeta-hemolytic, pyrrolidonyl arylamidase (PYR) negative, cannot grow in 6.5% NaCl, and with the exception of the Salivarius group, are bile-esculin negative.

The differentiation of the viridans streptococci into groups or species requires a combination of molecular and biochemical tools. Several species-specific biochemical characteristics may prove useful (https://www.cdc.gov/streplab/other-strep/general-methods-section2.html#table2). For example, the Voges-Proskauer reaction assists in the differentiation of the viridans streptococcal species and is a key reaction for the identification of the Anginosus group. Members of the *S. mutans* species/group produce acid in nearly all carbohydrate broths, and the strains belonging to the *S. salivarius* group are the only viridans to hydrolyze urea. The *S. mitis* group members are the only viridans that are negative for the following biochemical reactions: mannitol or sorbitol fermentation, arginine or urea hydrolysis, and Voges-Proskauer and bile esculin tests. The species within each of the major groupings can be further differentiated by additional biochemical characteristics [36, 37]

The clinical significance of viridans group members is generally species-dependent and as such, accurate species differentiation is the first step in properly diagnosing the etiologic agent of an infection to prescribe the proper treatment course. Commercially available kits for biochemical identification of streptococci are available, such as the API 20 Strep kit and Rapid ID 32 Strep kit (both from bioMérieux, Hazelwood, MO). These tests, however, are generally more reliable for the nonviridans streptococci, and do not always provide accurate results for the identification of individual viridans group species [38, 39]. In addition to biochemical analyses, several molecular assays have been developed for viridans identification, including PCR-based techniques, ribotyping, and sequence comparisons of various target genes including 16s rRNA [40], manganese-dependent superoxide dismutase, and *groESL* genes [41].

Various automated systems are now used to identify clinical isolates of the viridans group, including VITEK 2 (bioMérieux) and Phoenix systems (Becton Dickinson Diagnostic Systems,

Sparks, MD). The VITEK system, however, has recently been reported [40, 42] to often be unreliable for the viridans group (particularly *S. mitis* and *S. sanguinis*), with only about 40% of clinical isolates correctly identified at the species level. The performance of the Phoenix system for identification of *Streptococci* and *Enterococci* was recently evaluated for reproducibility and reliability in comparison to the API system [43]. Phoenix correctly identified 67% of clinical isolates of viridans streptococci at the species level, with most accurate results obtained for *S. anginosus* (100%) and *S. sanguinis* groups (75%), and the least correct results for the *S. mitis* group (53%). The discrepancies resulting from all automated systems, however, can generally be resolved with further testing using molecular techniques or other biochemical tests.

Streptococcus pneumoniae

S. pneumoniae are Gram-positive cocci often arranged in pairs (diplococci) or in short chains that commonly asymptomatically colonize the human nasopharynx. Like other streptococci, pneumococci are nonmotile, catalase-negative, facultative anaerobes that ferment glucose to lactic acid. *S. pneumoniae* produce a large polysaccharide capsule, which is considered to be one of the major virulence factors (reviewed in [44]), as it confers antiphagocytic properties on the organism, and was recently shown to limit mucus-mediated clearance of the organism from human mucosal surfaces [45]. The composition of the polysaccharide capsule forms the basis for pneumococcal serotyping by the Neufeld Quellung reaction, which involves agglutination of the organism with type-specific capsular antibodies [46]. To date, at least 90 serotypes have been identified [44].

Pneumococci (and other streptococci in the mitis group [47]) contain phosphorylcholine that is covalently linked to teichoic acid in the cell wall and to the lipoteichoic acid component of the cell membrane [48]; thus, choline is an absolute growth requirement of the organism. A group of surface-exposed choline-binding proteins (as many as 15 in some strains [49]) interact noncovalently with the choline residues in the cell wall, and exhibits a number of different functions essential to the overall biology of the organism, including host tissue adherence and autolysis sink [50].

Pneumococcal Diseases

S. pneumoniae cause a wide variety of illness including lobar pneumonia, meningitis, otitis media, bacteremia, and sinusitis. Of great importance to human health, it is worth noting that in 2016, *S. pneumoniae* was the leading cause of global mortality from pneumonia and was responsible for more deaths than all other causes combined [51]. Most deaths occurred in African and Asian countries, where vaccination programs (discussed later) are less robust or altogether absent.

The elderly and children under the age of 2 years carry the major disease burden and the World Health Organization estimates that nearly 500,000 children (most of whom are from underdeveloped nations) die each year of pneumococcal infections (https://www.cdc.gov/pneumococcal/global.html). Recently, the Centers for Disease Control (www.cdc.gov) estimated that *S. pneumoniae* caused over 175,000 cases of pneumonia requiring hospitalization, 6–7 million cases of otitis media, 50,000 cases of bacteremia (13,000 of which are children) and 3,000–6,000 cases of bacterial meningitis (700 of whom were children) (http://www.cdc.gov/vaccines/pubs/pinkbook/pneumo.html).

Pneumococci produce several virulence determinants that contribute to the overall pathogenicity of the organism, and the antiphagocytic polysaccharide capsule has long been considered one of the most important. There are however, numerous cell-surface associated and secreted proteins involved in various disease processes including (but not limited to) hyaluronate lyase, pneumolysin, choline binding proteins, two neuraminidases, autolysin LytA, pneumococcal surface antigen PsaA, and pneumococcal surface proteins PspA and PspC (reviewed in [52, 53]). Also contributing to virulence is the ability of pneumococci to undergo spontaneous phase variation between an opaque and a transparent colony phenotype. Although the mechanisms of this process are still not fully understood, opaque variants have more capsular polysaccharide than the transparent phenotype and are more commonly associated with invasive infections. The transparent phenotype is generally better able to colonize the nasopharynx than the opaque variants [54, 55].

The pathogenic program of pneumococci is a complicated, multifaceted process that depends on the interaction between host and bacterium, as well as the genetic and physiological characteristics of both. Recent findings [56, 57] indicate that the capsular types, as well as the overall genetic background of the pneumococci located at specific infection sites, contribute to the degree to which isolates are virulent. Furthermore, a relationship has been shown to exist between capsular type and risk for, and outcome of, invasive pneumococcal disease.

Identification

S. pneumoniae are fragile organisms, lysing within 18–24 hours after the start of growth due to the production of autolysin, a cell-wall degrading lytic enzyme [58, 59]. Pneumococci are fastidious, growing best in 5% CO_2 on agar containing blood as a source of catalase. On blood agar, colonies are round and about 1 mm in diameter. Colonies initially appear raised, but over time, become flattened and shiny (or mucoid) in appearance, with depressed centers (resulting from the action of autolysin) [60]. In 5% CO_2, colonies are surrounded by large zones of alpha-hemolysis (resulting from the production of pneumolysin); a characteristic that helps to distinguish pneumococci from the beta-hemolytic group A streptococci.

Further tests are necessary to distinguish *S. pneumoniae* from the alpha-hemolytic viridans streptococci, and classically include differentiation based on colony morphology, bile (deoxycholate) solubility [61] and optochin (cuprein hydrochloride) sensitivity [62]. The latter two tests are still considered generally reliable for initial identification, with reported sensitivities of >98% and 90–100%, respectively [60]. The bile solubility test is based on the observation that broth cultures of *S. pneumoniae* lyse (solubilize) when treated with a 2% solution of the bile acid salt, sodium deoxycholate. This assay remains one of the most sensitive and specific tests for the identification of pneumococci [60]. Optochin (ethylhydrocupreine hydrochloride) sensitivity is determined using disks impregnated with the compound that are

placed on a freshly streaked agar plate of bacteria. After incubation, a zone of inhibition (>14 mm) surrounding the disk indicates that the organism is a pneumococcus [36]. Growth of other alpha-hemolytic streptococci in the area surrounding the disk will not be inhibited. For cases in which discrepancies in either test occur, other identification methods should be included, as there have been reports of optochin-susceptible viridans group streptococci as well as bile-insoluble *S. pneumoniae* [63]. The traditional Quellung (capsular swelling) reaction for identification is cumbersome and labor-intensive and has been generally restricted to specialized laboratories.

Newer diagnostic tests, including identification and typing methods are now available for *S. pneumoniae* (reviewed in [52]) that facilitate rapid identification of pneumococci. An overview of several such tests is provided here.

Detection of the polysaccharide capsule by latex agglutination forms the basis of a number of the currently available serological tests, including Pneumoslide (Becton-Dickinson Diagnostic Systems, Sparks, MD), Directigen (Becton-Dickinson), and Pneumotest-Latex (Statens Serum Institut, Copenhagen, Denmark); however, many false positives involving alpha- and nonhemolytic streptococci have been reported with both Pneumoslide and Directigen [60]. In contrast, the Pneumotest-Latex method has recently been shown to detect 90 different pneumococcal serotypes with 95% accuracy [64]. Serological tests that detect capsular antigens by coagglutination techniques are also available, including Phadebact (Bactus AB, Huddinge, Sweden), which, in independent tests, correctly identified 98% of pneumococcal isolates [60]. Obviously, the major limiting factor for all these serological tests is that they can only be used on encapsulated isolates.

Several diagnostic methods have been developed that are based on specific virulence factors of *S. pneumoniae*. Pneumolysin-derived peptides can be detected immunologically (enzyme-linked immunosorbent assays [ELISA] and agglutination) and genetically (nested-PCR, real-time PCR and multilocus sequence typing [MLST]). PCR-based assays targeting autolysin are also available. These methods (reviewed in [53]) have facilitated the identification of the organism from cultured specimens and clinical samples such as urine, sputum, and pleural fluid. More recently, Pimenta et al. [65] have developed a real-time PCR-based assay for detection of 21 different capsular polysaccharides.

Importantly for diagnostics, the CDC has recently noted that the serotypes of *S. pneumoniae* involved in invasive diseases have changed greatly since the heptavalent vaccine was introduced in 2001 and provides up-to-date primer sequences for PCR assays and MLST analysis on their website. Recent studies [66] to evaluate such methods have shown that real-time PCR assays to detect the *lytA* gene in cerebrospinal fluid, together with Gram stains of the CSF, were sensitive and specific (>90% for both) in diagnosing pneumococcal meningitis.

For clinical cases in which it is difficult to obtain isolates of *S. pneumoniae* (low recovery after antibiotic treatment, negative subcultures, sampling procedures that are too invasive), an immunochromatographic membrane assay (Binax NOW, Binax, Portland, ME) is available that, with great rapidity, sensitivity, and specificity (80–95%), detects the presence of the C polysaccharide cell wall antigen (common to all serotypes) in urine [67, 68], blood culture bottles [69], bronchoalveolar lavage fluid [70], and cerebrospinal fluid [71]. The main drawback of this methodology is reduced accuracy in children, as it also detects pneumococcal carriage [72].

Treatment and Vaccines

For most hospital and outpatient settings, penicillin, erythromycin, and tetracycline have been recommended for the treatment of pneumococcal infections; however, in 2017, the CDC estimated that nearly one-third of pneumococcal strains from pneumonia patients are resistant to common antibiotics [73]. Specifically, data from the Active Bacterial Core Surveillance project at the CDC (http://www.cdc.gov/abcs/reports-findings/survreports/spneu17.html) revealed that 2.4% of *S. pneumoniae* strains were resistant to penicillin (a decline from 2012 when approximately 6.8% of isolates were resistant and from 2005 when 34% were resistant) and 29% were resistant to erythromycin (no change from 2012 reports). The 2017 prevalence of resistance to tetracycline was reportedly 11.3% and trimethoprim-sulfamethoxazole resistance was 6.9% (a decrease from the 20% reported in 2012).

There are currently two pneumococcal vaccines, both based on capsular polysaccharides, which are licensed for use in the United States. The 13-valent pneumococcal conjugate vaccine (PCV13, Prevnar 13®) was introduced in the United States in 2010 for the prevention of systemic infections in children and replaced the original heptavalent pneumococcal conjugate vaccine (PCV7, Prevnar®) approved in 2000. The 13-valent vaccine is recommended for children aged 2–59 months and for children aged 60–71 months who are at increased risk for pneumococcal disease [74, 75]. In 2012, it was approved for use in adults aged 50 years and older [76].

The second vaccine, PPSV23, a 23-valent polysaccharide vaccine was initially recommended only for adults aged 65 or older; however, in 2010, the Advisory Committee on Immunization Practices (ACIP) at the CDC published new recommendations for the PPSV23 vaccine to include adult asthmatics, adult cigarette smokers, and adults with asplenia or other immunocompromising conditions [74]. Although this vaccine is not particularly immunogenic in children under 2 years of age, it is recommended for children over 2 who have underlying immunocompromising medical conditions. In 2014, the ACIP further recommended that PCV13 be given in series with PPSV23 for all adults over 65 years old [77].

It is of great significance that after the introduction of the heptavalent vaccine in 2001 the CDC's Bacterial Surveillance Program reported a significant decrease in invasive pneumococcal diseases (IPD) in the United States (https://www.cdc.gov/pneumococcal/surveillance.html). In 1998, there were an estimated 95 cases of IPD per 100,000 children less than 2 years old, while in 2008, the reported numbers of infected children dropped to 21 per 100,000 children. After the replacement of the heptavalent vaccine with PCV13, the reported cases of IPD have dropped even further to seven children per 100,000 in 2017 (https://www.cdc.gov/abcs/reports-findings/survreports/spneu17.html). For adults less than 65 years of age, the reported number of cases of IPD has been reduced by 50% (16 per 100,000 in 1998 to seven per 100,000 in 2016). Adults over 65 years of age demonstrated an even greater reduction in cases, falling from 61

cases to 26 cases per 100,000 (https://www.cdc.gov/abcs/reports-findings/survreports/spneu17.html). Furthermore, Tomczyk et al. recently reported two interesting findings after tracking the occurrences of antibiotic-resistance cases of IPD in the 3 years following the introduction of PCV13 [78]. First, they noted large decreases in the rates of antibiotic-nonsusceptible IPD caused by the serotypes included in PCV13 vaccine (but not in PCV7 vaccine). Second, they found a decrease in cases of multidrug-nonsusceptible IPD across all age groups, particularly among children younger than 5 years old and adults aged 65 years or older [78]. The role that conjugate vaccines have on decreasing antimicrobial resistance, while indirectly allowing resistant non-vaccine-serotype clones to continue to emerge and expand, was recently extensively reviewed [73].

S. pneumoniae is a naturally transformable organism, and as such, during a physiological state known as competence [79–81], the bacterium can readily acquire exogenous DNA, thereby increasing its genetic plasticity. This trait is one of the underlying factors that contribute to capsular switching, increased antibiotic resistance and virulence factor exchange [82]. Furthermore, pneumococci harbor bacteriophage, and recent reports indicate that at least 70%, and as many as 90%, of the pneumococcal genomes from clinical isolates contain prophages or phage remnants. Therefore, through both transformation and transduction, pneumococci can readily exchange and acquire genetic material, including novel capsular genes, antibiotic resistance markers and encoded virulence determinants: factors that may potentially compound our ability to treat and to prevent infections caused by this organism.

Enterococci

Members of the genus *Enterococcus,* once included in genus *Streptococcus* [83, 84], are catalase-negative Gram-positive cocci that appear in short chains, in pairs or as single cocci. Most strains react with Lancefield group D typing serum, grow in 6.5% NaCl and produce pyrrolidonyl arylamidase. Colonies on agar plates are generally larger than streptococci, growing to 2–3 mm in diameter within 2 days, and appear raised and gray/white in color.

Enterococci share a few characteristics with other Gram-positive cocci and as such, a battery of biochemical tests (reviewed in Murray [85]) can be performed to differentiate enterococcal isolates from less commonly encountered Gram-positive cocci. Examples of such tests include growth on bile-esculin media (most enterococci are positive), production of gas from glucose (most enterococci are negative), and the ability to grow at both 45°C and 10°C (enterococci generally grow at both temperatures).

Enterococci are components of the flora of the intestinal tract, oral cavity and vaginal canal of humans and animals, and have historically been considered commensals with low pathogenic potential. The past two decades, however, have seen an increase in enterococcal infections, including those of the urinary tract, burn wounds, surgical incisions, and heart valves. Enterococci colonize catheters and implanted medical devices, which often results in endocarditis and septicemia. At least 12 different species have been associated with various illness; however, two species, *E. faecalis* and *E. faecium*, have emerged in recent decades as major causes of nosocomial infections (reviewed in Mundy [86], with *E. faecalis* responsible for the vast majority (80–90%) of the infections caused by this genus.

As most human infections are caused by either *E. faecalis* or *E. faecium*, it is often necessary to specifically differentiate these two species. Clinical laboratories use automated and rapid identification systems such as the VITEK II system (bioMérieux), BBL Crystal kits (Becton Dickinson, BD) and more recently, the Phoenix system (Becton Dickinson, BD). Given reported concerns about the reliability of such systems [83], molecular techniques and species-specific biochemical differences (e.g., using API®20 Strep tests, bioMérieux) can facilitate the identification process. In terms of simple biochemical differences, *E. faecalis*, but not *E. faecium,* will grow on medium containing 0.4% telluride, reduce tetrazolium to formazan and most isolates will produce acid from sorbitol, glycerol, and D-tagatose. On the other hand, most strains of *E. faecium*, but not *faecalis* will produce acid from L-arabinose and melibiose [85].

PCR-based techniques for the amplification and downstream sequencing of the 16S rRNA genes have been used for several years to distinguish enterococci from lactococci and to identify specific enterococcal species [84]. Similar techniques involving the sequencing of species-specific regions of other genes have been described (e.g., heat shock protein 60 and manganese-dependent superoxide dismutase, *sodA,* genes) [58]. Recently, a novel multiplex PCR technique, incorporating both 16S rRNA and *sodA* specific primers, has been developed that allows for the simultaneous identification of both genus and species from a variety of sample types (feces, retail foods, animal carcasses). Additionally, peptide nucleic acid fluorescent in situ hybridization (PNA FISH®) tools have been introduced to differentiate *E. faecalis* from other enterococcal species in blood cultures within 3 hours (AdvanDX, Inc.).

E. faecalis and *E. faecium* elaborate virulence factors that contribute to the infection process. Although both species have acquired antibiotic resistance determinants (discussed below), the best-studied virulence factors are predominantly associated only with *E. faecalis*. For example, this species elaborates a cytolytic toxin (hemolysin), gelatinase, aggregation substance, and an enterococcal surface protein, Esp; each of these enhance virulence, but they are not (or very rarely) produced by *E. faecium* [86]. The enterococcal cytolysin is a proinflammatory, acutely lethal, hemolytic toxin, which also functions as a bacteriocin against other Gram-positive bacteria. The aggregation substance is a surface protein that is multifunctional: it not only promotes aggregate formation during bacterial conjugation to facilitate efficient contact between donor and recipient strains for plasmid transfer, it is also associated with binding to, and subsequent intracellular survival within, human neutrophils. The role of this virulence factor as well as the numerous others elaborated by *E. faecalis* are reviewed extensively elsewhere [86].

The organism is spread through direct contact with stool, contaminated urine, and blood, and indirectly via healthcare workers and contaminated hospital surfaces. The clinical relevance of enterococci has increased due to the emergence of vancomycin resistant strains (VREs) and multidrug resistant

isolates, and it is now the second most isolated bacteria in nosocomial infections (second to *Staphylococci*). Data from the CDC report entitled *Antibiotic resistance threats in the United States, 2019* (https://www.cdc.gov/drugresistance/pdf/threats-report/2019-ar-threats-report-508.pdf) indicate that there are an estimated 54,500 healthcare associated VRE infections in the United States. In the years prior to 1990, VRE accounted for less than 0.5% of hospital acquired infections (www.cdc.gov). In 2017, the WHO ranked VRE (more specifically, vancomycin-resistant *E. faecium*) as a "high priority" due to the dearth of antibiotics to treat such infections and the economic impact of health care costs associated with such infections (https://www.who.int/medicines/publications/global-priority-list-antibiotic-resistant-bacteria/en/).

The proportion of VRE infections differs by species, with over 77% attributed to *E. faecium* and 9% caused by *E. faecalis*. The numbers from the SENTRY antimicrobial surveillance program agree with those from the CDC, as SENTRY reports that 80.7% of all bloodstream VRE infections are caused by *E. faecium* (a marked increase from the 57% in 2000) and 5.3% are attributed to *E. faecalis*. SENTRY further reported that the vancomycin-resistant *E. faecalis* strains also showed resistance to amoxicillin (close to 95%), levofloxacin (94%), and erythromycin (94%). The CDC has determined that vancomycin-resistant *E. faecalis* strains are a *serious threat* and calls for prompt action (compliance to CDC guidelines for detection, prevention, tracking, and reporting) to ensure the problem does not escalate.

The explanation for the rapid emergence of VRE is markedly different in different parts of the world. In Europe, for example, the emergence of vancomycin resistance has been associated with avoparcin, a vancomycin-related antibiotic, used as a growth promoter in various agricultural processes and added to animal feed until it was banned in 1997 [84]. Colonization of humans with vancomycin resistant strains likely occurred after ingestion of meat products resulting from such practices. In the United States, where avoparcin was never approved for use in animal feed, the major reservoirs for VRE are hospital staff and patients [86]. A root cause of vancomycin resistance appears, at least in part, to be the improper use of antimicrobial agents, and VRE spread seems to be directly linked to clinical settings where the organism is most prevalent.

The recent emergence of multidrug resistance in enterococci presents an even bigger challenge to the health care profession. Multidrug-resistant isolates generally emerge from intrinsic baseline resistance to antibiotics or by acquiring resistance through mobile genetic element transfers (transposons and plasmids) [86, 87]. Studies have found a link between ampicillin and vancomycin resistance, particularly in *E. faecium*, and it has been suggested that β-lactam exposure is a predisposing factor for multidrug resistance. Never has the need to control the spread of VRE in nosocomial settings been more apparent than after a recent report detailing the horizontal transfer of one such vancomycin resistance gene (*vanA*) from *E. faecalis* to methicillin-resistant strains of *Staphylococcus aureus* (MRSA) [87]. Not only are the reports of multidrug-resistant VRE increasing, but the danger of such strains is no longer restricted to other *Enterococci*, as the passage of resistance markers to other genera is now a documented reality.

Lactococci

Lactococci are Gram-positive, catalase-negative cocci that grow in chains and produce lactic acid from the fermentation of lactose. The two major species, *L. lactis* subsp. *lactis* and *L. lactis* subsp. *cremoris* were previously categorized as lactic acid streptococci until they were moved to their own genus in 1985 [88]. They can be distinguished from other similar cocci by specific phenotypic characteristics: they do not produce gas from glucose fermentation, most strains can grow in 6.5% NaCl, grow poorly at 45°C (distinguishing them from enterococci) but well at 10°C, and exhibit positive reactions on bile-esculin media. Further differentiation from the enterococci relies on additional biochemical tests (reviewed by Facklam and Elliott [89]): lactococcal strains do not produce acid in arabinose broth (as do *E. faecalis*), but will produce acid in mannitol broth (unlike *E. durans* and *E. hirae*).

Lactococci are common environmental bacteria that are most notable for their use in the food industry for food preservation and flavor. The biochemical process that produces lactic acid during carbohydrate fermentation has several specific applications: the byproducts of the fermentative pathway can enhance food flavor; the decrease in pH during lactic acid production can precipitate proteins that help to change or improve food texture. The increased acidity (which can be as low as 4.0) inhibits the growth of many microorganisms, thereby increasing the shelf life of such fermented foods. *L. lactis* is used in the production of fermented milk products (such as buttermilk) and is the major starter bacterium in the cheese industry.

Beyond the food industry, *L. lactis* has an important place in the biotechnology industry due to the production of nisin, a 34 amino acid potent bacteriocin with broad-spectrum activity against several bacterial species (reviewed in [90, 91]). The lactococci are also involved in other applications, including the expression of antigens for the development of mucosal vaccines, gene expression systems (NICE), and the production of human proteins such as cytokines for in situ applications [92].

The Genus Vibrio *and Related Genera*

Seon Young Choi, Anwar Huq, and Rita R. Colwell

CONTENTS

Introduction 579
Genus *Vibrio* Pacini, 1854 579
Vibrios as Human Pathogens 581
References 583

Introduction

Vibrios are short curved or straight cells, which are single or united into spirals. They grow well and rapidly on the surfaces of standard culture media and can be readily isolated from estuarine, marine, and fresh-water samples. These heterotrophic organisms vary in their nutritional requirements; some occur as parasites and pathogens for animals and for humans. The short curved, asporogenous, Gram-negative rods that are members of the genus *Vibrio* are most commonly encountered in the estuarine, marine, or fresh-water habitat. Distinguishing species of the genus *Vibrio* from other related genera can be presumptively accomplished by examining Gram stains of carefully prepared specimens, followed by electron microscopy to confirm morphology. *Vibrio* species are short rods with a curved axis, motile by means of a single polar flagellum. *Vibrio* species may be short, straight rods (1.5–3.0 µm × 0.5 µm), or they may be S-shaped or spiral-shaped when individual cells are joined. Possession of two or more flagella in a polar tuft has also been demonstrated in *Vibrio* species, as have lateral flagella in *Vibrio parahaemolyticus*. Thus, to identify and classify vibrios, physiological and biochemical taxonomic tests are done.[1] *Vibrio* species are facultatively anaerobic, with both a respiratory (oxygen-utilizing) and a fermentative metabolism. Related genera may be aerobic or microaerophilic, with a strictly respiratory metabolism (oxygen is the terminal electron acceptor).

Since the eighth edition of *Bergey's Manual of Determinative Bacteriology*,[1] the genus *Vibrio* was placed among the Gram-negative facultatively anaerobic rods in the family *Vibrionaceae*. The family *Vibrionaceae* comprises several genera including *Vibrio, Photobacterium,* and *Salinivibrio. Vibrio* species are fermentative, producing acid in carbohydrate-containing media without formation of gas, and possess a DNA with G + C in the range from 39 to 49 moles %. Vibrios require 1–3% NaC1 for growth and the salt requirement is absolute. Vibrios, including *Vibrio cholerae,* are autochthonous to the aquatic environment. Molecular genetic and genomic sequence data have proved useful in establishing relationships among the genera *Plesiomonas*, *Aeromonas,* and *Vibrio*.[2] In the latest edition of *Bergey's Manual*, *Plesiomonas* and *Aeromonas* are classified in other families, although they are oxidase positive genera of fermentative bacteria as are *Vibrio* and *Photobacterium*.[3]

Genus *Vibrio* Pacini, 1854

The type species for the genus *Vibrio* is *Vibrio cholerae* Pacini, 1854. The genus *Vibrio* has been expanded to include many more species than the 40 species of *Vibrio* listed in the latest edition of *Bergey's Manual*.[3] The intense studies of the genus *Vibrio* performed over the years resulted in considerable changes. Many *Vibrio* species have been reclassified and transferred to other or new genera. Strictly anaerobic species have been removed from the genus and no cultures of obligately anaerobic *Vibrio* species are extant. Microaerophilic species, including *Vibrio fetus* and *Vibrio bubulus*, have been transferred to the genus *Campylobacte*r and another microaerophilic species, *Vibrio succinogenes,* is now the type species of the genus *Wolinella*.[4,5] Also the pink-pigmented methanol-oxidizing bacterium, *Vibrio extorquens*, is reclassified in the genus *Methylobacterium*.[6]

The number of characterized and defined species resident in the genus *Vibrio* has been significantly increased, with many novel species having been described.

Description of the genus *Vibrio*, as amended by the Subcommittee on Taxonomy of Vibrios, International Committee on Nomenclature of Bacteria, is concise and remains a reasonably good working definition:

> Gram-negative, asporogenous rods which have a single, rigid curve or which are straight. Motile by means of a single, polar flagellum. Produce indophenol oxidase and catalase. Ferment glucose without gas production. Acidity is produced from glucose by the Embden-Meyerhof glycolytic pathway. The guanine plus cytosine in the DNA of *Vibrio* species is within the range of 40 to 50 moles per cent.

The genus *Vibrio* has been a subject of many polyphasic studies. The genus *Listonella,* proposed by MacDonell and Colwell,[7] is polyphyletic and belongs to the genus *Vibrio* on the basis of 16S rRNA phylogeny (Figure 41.1).[8] *Listonella anguillarum* and

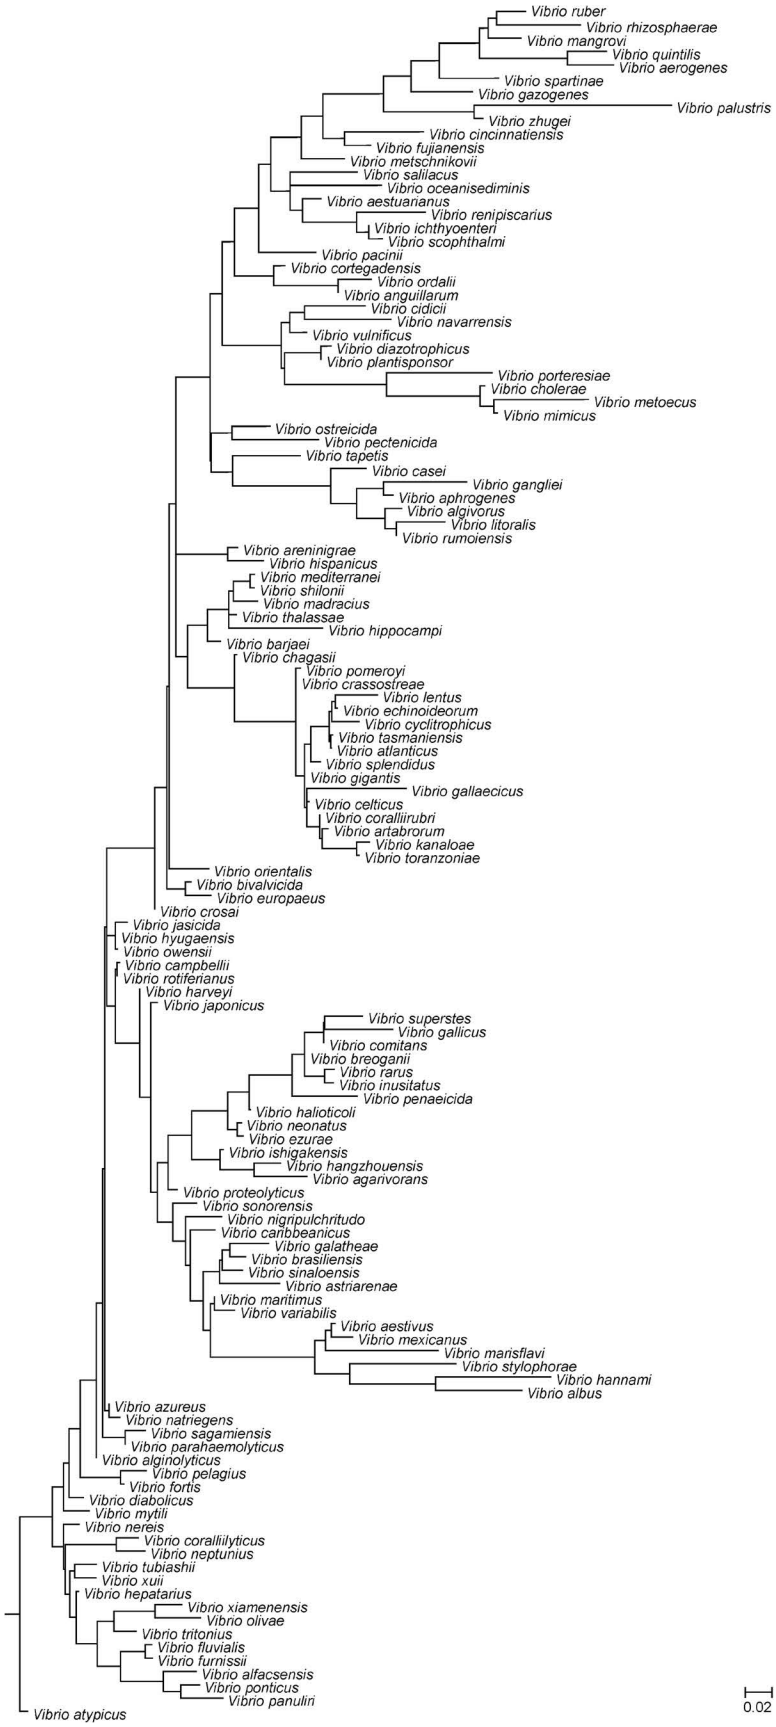

FIGURE 41.1 *Listonella anguillarum*.

Listonella pelagius are included in the genus *Vibrio* in the latest edition of the *Bergey's Manual*. Most of the present members of the genus *Vibrio* form a monophyletic group except for *Vibrio calviensis,* which should be transferred to the genus *Enterovibrio*.[9]

The type species of the genus, *Vibrio cholerae* Pacini 1854, can be succinctly described as follows: producing L-lysine and L-ornithine decarboxylases; not producing L-arginine dihydrolase and hydrogen sulfide (Kligler iron agar). The G + C content in the DNA of *Vibrio cholerae* is approximately 48 ± 1%. *Vibrio cholerae* includes strains that may or may not elicit the cholera-red (nitroso-indole) reaction, may or may not be hemolytic, may or may not be agglutinated by Gardner and Venkatraman O group I antiserum, and may or may not be lysed by Mukherjee *Vibrio cholerae* bacteriophages I, II, III, IV, and V.[10]

Vibrio cholerae strains possess a common H antigen and can be serologically grouped into many serotypes according to their O antigens. Strains agglutinated by Gardner and Venkatraman O group I antiserum are in serotype I and were the principal cause of cholera in man until the emergence of *Vibrio cholerae* serotype O139. An M antigen can obscure the agglutinability of mucoid strains of *Vibrio cholerae*.

In the past, many cholerae-like vibrios were given separate species status because they had been isolated from patients suffering diarrhea, not cholera, or from water and foods. Among these, *Vibrio albensis* can be considered to be a biotype of *Vibrio cholerae*. The so-called nonagglutinable (NAG) or noncholera (NCV) vibrios, including *Vibrio eltor*, were shown many years ago by Citarella and Colwell,[11] using DNA-DNA hybridization, to be *Vibrio cholerae* and this conclusion has been substantiated.

Since its initial isolation by Fujino and Fukumi[12] in 1953, *Vibrio parahaemolyticus* has received considerable attention and rightfully, as it is a major cause of seafood borne illness. *Vibrio parahaemolyticus* (syn. *Pasteurella parahaemolytica*, *Pseudomonas enteritis*, *Oceanomonas parahaemolytica*) is the causative agent of food poisoning arising from ingestion of contaminated seafood and is autochthonous to the marine and estuarine environment.

The species *Vibrio alginolyticus*, although previously considered by some investigators to be synonymous with *Vibrio parahaemolyticus*, is a separate species.

According to results of DNA-DNA hybridization and other techniques, *Vibrio mimicus* is highly related to *Vibrio cholerae*. With *Vibrio cholerae*, the species *Vibrio mimicus* will be the basis for the definition of the genus *Vibrio*.[3,13]

Other species of *Vibrio* that should be considered are listed in Figure 41.1 and Table 41.1. Vibrios are naturally occurring in the aquatic environment and are found in sea water and associated with human and marine animals.[14,15]

Distinctions can be made among the species of the genus *Vibrio* and useful differentiating characteristics are given in Table 41.1. Some species of *Vibrio* may demonstrate sheathed flagella—i.e., a flagellum with a central core and an outer sheath—and, under certain conditions of growth, peritrichous flagella.[16] "Round bodies" or spheroplasts are commonly present during various stages of growth,[17,18] and fimbriae (pili) have been observed in strains of *Vibrio cholerae*.[19]

Vibrios as Human Pathogens

Many species of the genus *Vibrio* are commensals or pathogenic for fish, shellfish, mollusks, Crustacea, and other aquatic animals. Among all the major bacterial foodborne pathogens (e.g., Salmonella, Listeria, Shiga toxin–producing *Escherichia coli* (STEC), and Campylobacter), vibrios are a distinct group that is increasing in incidence in the United States.[20–22] Many are associated with foodborne outbreaks and of significant importance are *Vibrio cholerae*, *Vibrio parahaemolyticus*, and *Vibrio vulnificus,* three well-characterized human pathogenic bacterial species.[23]

V. cholerae is responsible for seven historical cholera pandemics since 1817. Cholera outbreaks occur throughout the world, from Southeast Asia, Africa, the Middle East, to South and Central America. In the past decade, a cholera outbreak in Haiti occurred after the earthquake of 2010 and in October 2016, another outbreak was reported in Yemen after war. Also many countries in Sub-Saharan Africa suffer recurrent cholera outbreaks.[24–28] This bacterium can cause severe, dehydrating diarrhea in otherwise healthy people, resulting in approximately 100,000 deaths annually.[29] The major virulence factors of *V. cholerae* are cholera toxin (CT, *ctxAB*) and type IV pilus toxin coregulated pilus (TCP) encoded by a lysogenic bacteriophage (CTXϕ), and the *tcpA-F* operon located in the Vibrio pathogenicity island 1 (VPI-1). In regard to antimicrobial resistance, ICE (integrative conjugative element) of the SXT/R391 family was originally reported in *V. cholerae* O139 strain MO10 and it encodes resistance to sulfamethoxazole (*sul2*), trimethoprim (*dfr*), chloramphenicol (*floR*), and streptomycin (*strA* and *strB*).[30] Since the report of O139 strain MO10, the number of reports of SXT-related ICEs is increasing in Asia and Africa. Also, various types with a difference in antibiotic-resistant genes have been reported and ICEs play a critical role in acquiring antimicrobial resistance genes by vibrios.[31–36]

Human-illness-associated strains, harboring CT, are generally associated with the *V. cholerae* O1 or O139 serogroups. *V. cholerae* O1 serogroup is further classified into two biotypes, classical and El Tor, based on a number of phenotypic characteristics, including Voges-Proskauer reaction and sensitivity to polymyxin B. Classical biotype strains were responsible for the first six cholera pandemics in the early 19th century, while El Tor biotype strains producing El Tor type CT are responsible for the current seventh cholera pandemic since 1961. Beginning in the early 1990s, new variants of the *V. cholerae* O1 serogroup, hybrid and altered strains have emerged and have replaced El Tor strains in Asian countries, but also have been reported in Africa.[37–39] Comparative genomics and genome sequencing analysis show VPI-1, VPI-2, Vibrio seventh pandemic island 1 (VSP-1) and VSP-2 to be present in the *V. cholerae* genome, findings reported after the complete genome sequence of *V. cholerae* O1 El Tor N16961 was published.[40,41] Serotype O139 first emerged in South India and Bangladesh during 1992 and can cause epidemics of cholera. Since first emergence in India, it has been reported in the Southeast Asia and China subsequently.[42–45]

In the 1950s, *V. parahaemolyticus* was isolated and described as an important seafood-borne bacterium and subsequently shown to be the primary cause of human acute gastroenteritis worldwide. *V. parahaemolyticus* also can cause wound

infections and septicemia. With *V. vulnificus*, *V. parahaemolyticus* is the major cause of seafood-borne infections and mortality in the United States.[22,46,47] Until 1996, *V. parahaemolyticus* infections were associated with diverse serovars of the pathogen, but after 1996 the most common serotype has been *V. parahaemolyticus* O3:K6, associated with the pandemic clonal complex (CC) 3 and the multilocus sequence typing (MLST) sequence type (ST) 3, with specific genetic markers (*tdh* positive, *toxRS/new*, and/or *orf8* from the f237 filamentous phage, *trh* and urease negative).[48–50] An outbreak of *V. parahaemolyticus* O3:K6 that began in Kolkata, India in 1996, rapidly spread throughout Southeast Asia, the Atlantic and Gulf coasts of the United States, as well as in Europe, Africa, and Central and South America.[51–54] Subsequently, there have been reports of more than 20 serovariants of O3:K6, including O4:K68, O1:K25, O6:K18, O4:K12, and O1:KUT (untypable).[53–56] Potentially virulent strains of *V.*

parahaemolyticus are commonly distinguished from virulent strains by the presence of two hemolysins, namely thermostable direct hemolysin (*tdh*) and Tdh-related hemolysin (*trh*).[57–59] Pathogenic strains of *V. parahaemolyticus* can produce either TDH, TRH, or both. The finding of *tdh* gene was also reported in several other vibrios, including *V. hollisae*, *V. mimicus,* and *V. cholerae* non-O1, suggesting horizontal transfer of that gene to other species.[60] Genomic sequencing of *V. parahaemolyticus* RIMD 2210633 revealed two pathogenicity islands encoded T3SS1 and some cognate effectors and Vp-PAI, also referred to as VPaI-7, encoding T3SS2, its known effectors and the *tdh* genes.[61–64] Comparative genomics analysis revealed additional genomic islands.[65–67] The complete genome of *V. parahaemolyticus* RIMD 2210633 O3:K6 serotype strains and many other strains of *V. parahaemolyticus* have been sequenced, including *V. parahaemolyticus* AQ3810 serotype O3:K6, strain 10329 serotype O4:K12, and the serotype O4:K68 strains AN-5034, K5030, and Peru-466. The *V. parahaemolyticus* isolate PCV08-7 *tdh+/trh-* and prepandemic strain BB22OP have also been sequenced.[51,61,64,68,69]

V. vulnificus is a dangerous pathogen, with a case-fatality rate exceeding 50% and now recognized as the most virulent of the pathogenic vibrios in the United States. Indeed, this single bacterial species is responsible for 95% of all seafood-borne deaths and is capable of causing gastroenteritis, wound infections, and fatal septicemia in humans.[23,70,71] Cases where skin or wounds have been contaminated with *V. vulnificus* have been described in Belgium, Denmark, Germany, Spain, Sweden, and the Netherlands.[23,72,73] Especially, the infection of *V. vulnificus* shows an obvious gender disparity with males making up around 85% of reported infections.[74] Strains of *V. vulnificus* are classified into three biotypes, based on their biochemical and serological characteristics, as well as host range. Strains of biotype 1 are responsible for most human infections and biotype 2 is primarily pathogenic for eels (genus *Anguilla*), but may also act as an opportunistic human pathogen. *V. vulnificus* biotype 3 possesses biochemical properties of both biotypes 1 and 2 and recently emerged in Israel, associated with an outbreak of human wound infections.[75–78] Strains of *V. vulnificus* can be divided into two groups based on alleles of the virulence correlated gene *vcg* (environmental and clinical types *vcgE* and *vcgC*), the *pilF* gene that encodes a protein required for pilus type IV assembly, and by comparison of 16S rRNA sequences (A-type and B-type).[79–81] Following genome sequencing of two clinical strains of *V. vulnificus* C-type, and utilizing comparative genomics based on results of genome sequencing projects, many more strains have been described, including E-type strains, providing interesting genomic diversity.[82–87] *V. vulnificus* possesses many virulence determinants, one of which is a polysaccharide that confers resistance to phagocytosis and serum complement. An important characteristic of *V. vulnificus* is that it produces a variety of iron uptake systems, including siderophore (vulnibactin), and utilizes hemoglobin and hemin as iron sources via the heme receptor HupA. *V. vulnificus* possesses exoenzymes and exotoxins, including metalloprotease (VvpE), phospholipase A, cytolytic hemolysin (VvhA), and repeats-in-toxin (RtxA1). Flagella and pili have been described in *V. vulnificus* to be important virulence factors.[88–98]

These three *Vibrio* spp. are the dominant human pathogenic species of the genus Vibrio. However, it is also reported in the Cholera and Other Vibrio Illness Surveillance (COVIS) system of the Centers for Disease Control and Prevention that more than 20% of patients with diagnosed illness are concluded to have their disease condition caused by *V. alginolyticus*, *V. fluvialis, V. mimicus*, *V. hollisae* (formerly *Grimontia hollisae*) and related species, including *Photobacterium damselae* subsp. *damselae* (formerly *V. damsela*), *V. furnissii,* or *V. metschnikovii*.[74] In human clinical specimens worldwide, the cases of *Vibrio cincinnatiensis* and *Vibrio harveyi* (*V. carchariae*) are shown rarely as well.[3,99–101] The status of the latter as human enteric or wound pathogens is less clear, but nevertheless significant. Among non-cholera vibrios, *V. alginolyticus*, formerly regarded as biotype 2 of *V. parahaemolyticus*, is gradually recognized as an emerging human pathogen responsible for more than 10% of patient cases. *V. alginolyticus* is reported the causative agent of wound and ear infections, intracranial infection, peritonitis, and osteomyelitis.[74,102] The incidence of *V. alginolyticus* infection significantly increases during summer months and most reports of *V. alginolyticus* wound infections result from exposure of cuts or abrasions to contaminated seawater.[22,103,104]

Including *V. cholerae*, *V. parahaemolyticus*, *V. vulnificus*, and *V. alginolyticus*, vibrios are ubiquitous bacteria in estuarine and marine environments and an important cause of diseases in human and aquatic animals. Their abundance in the natural environment mirrors the ambient environmental temperature and, with climate change, especially warming of the sea surface, which is strongly associated with spread of vibrio pathogens in the environment. In an aquatic environment, most notably infectious disease outbreaks will depend on climate change, including warm air with low river flows, heavy rainfall, and also extreme weather events.[47,105–111] Discovering the link between growth and spread of Vibrio spp. in the oceans and climate change should be widely investigated as a potential emerging issue.

Introduction

The genus *Yersinia* comprises Gram-negative rod-shaped bacteria that inhabit diverse ecosystems and includes several pathogens of humans and other animals. The most notorious species, *Yersinia pestis*, is the causative agent of plague, which is one of the oldest recorded infectious diseases. Plague has caused at least three major pandemics at approximately 600-year intervals starting in the 6th century AD. This pandemic began in Egypt and spread through the Middle East to Europe. The second pandemic occurred during the 14th century AD and was called The Black Death. It began in the area of the Black Sea, spread to Europe, and was responsible for the death of more than a quarter of Europe's population. The third plague pandemic, termed the Third Pandemic, began in 1855 in China and spread to India, Egypt, Portugal, Japan, Paraguay, Eastern Africa, Manila, Scotland, Australia, the United States, and several other countries. This infection is believed to have caused more than 150 epidemics of varying degrees until the 1950s.[1–3]

Because The Black Death was, according to historical accounts, characterized by swollen lesions (buboes) in the groin and elsewhere on the body, as was the Third Pandemic, scientists and historians have assumed that the earlier pandemic was an outbreak of the same disease. This led to the conclusion that The Black Death was caused by the bacterium *Y. pestis*, which is spread by fleas with the help of rodent reservoirs. However, because buboes are features of other diseases, too, this view has been questioned by some.

Taxonomy

The genus name *Yersinia* was coined by van Loghem in 1944 in honor of the French bacteriologist Alexandre Yersin who, in 1894, first isolated the causative agent of plague, "*Pasteurella pestis*."[4] This organism was subsequently renamed *Yersinia pestis*. In 2016, the genus *Yersinia*, along with the genera *Chania*, *Ewingella*, *Rhanella*, and *Serratia*, was assigned to the new family *Yersiniaceae*.[5] Later, the genera *Chimaeribacter*, *Nissabacter*, *Rouxiella*, *Samsonia*, and *Candidatus* Fukatsuia were also included in this family. Previously, these organisms were classified among the *Enterobacteriaceae*. This systematics change does not impact the binomial species names of any members of the genus *Yersinia*, and is not expected to affect diagnostic testing (e.g., interpretation of antimicrobial susceptibility test data) or regulations concerning disease reporting, biological containment, isolate transportation, biological safety, and biological security.

To date, there are 19 named *Yersinia* spp. and numerous as-of-yet unnamed isolates. Of the former, three species are important human pathogens: *Yersinia enterocolitica*, *Y. pestis*, and *Yersinia pseudotuberculosis*. The extremely high ribosomal RNA sequence identity and disparate clinical presentations (and consequent biocontainment controls) between *Y. pestis* and *Y. pseudotuberculosis* are a frustrating taxonomic paradox. The logistical challenges associated with altering the nomenclature of *Y. pestis* make resolving this instance of polyphyly impractical, as first measured and articulated by Bercovier *et al.*[6] *Y. pseudotuberculosis* has taxonomic precedent over *Y. pestis*, and therefore the informal designation "*Y. pseudotuberculosis* complex" was created to address this ambiguity. This group consists of *Y. pseudotuberculosis*, *Y. pestis*, *Yersinia similis*, and *Yersinia wautersii*.[7,8]

Other species in the genus include *Yersinia frederiksenii*, *Yersinia intermedia*, *Yersinia kristensenii*, *Yersinia aldovae*, *Yersinia bercovieri*, *Yersinia mollaretti*, *Yersinia aleksiciae*, *Yersinia hibernica*, *Yersinia entomophaga*, *Yersinia massiliensis*, *Yersinia nurmii*, *Yersinia pekkanenii*, *Yersinia ruckeri*, *Yersinia rohdei*, *Y. similis*, and *Y. wautersii*.[9,10] The status of these organisms as primary or opportunistic pathogens is equivocal, with the exception of *Y. ruckeri*, the unambiguous etiologic agent of enteric redmouth disease (ERM) of farmed fish.[11] Significant polyphyly still exists within *Y. enterocolitica* and *Y. kristensenii*, suggesting that further resolution of informal groups into extant novel species is likely.

Epidemiology

The natural reservoirs of *Y. pestis* are rodents (e.g., rats, mice, rabbits, prairie dogs, and ground squirrels). Organisms are usually spread from a reservoir to humans by fleas. Much less frequently, the organisms can be spread to humans through direct contact with infected animals. The Oriental rat flea, *Xenopsylla cheopis* (Figure 42.1), is considered the classic vector of plague; however, other flea species can be major vectors of endemic plague in the western parts of the United States. For example, ground squirrel fleas (*Oropsylla montana*) have been found to be vectors in California, and prairie dog and rock squirrel fleas (*Oropsylla hirsuta*, *O. montana*, and *Hoplopsyllus anomalus*) have been found to be vectors in New Mexico.[12,13]

Flea-mediated transmission of *Y. pestis* depends on masses of the organism blocking the flea's proventriculus foregut. This blockage causes the flea to be unable to feed, and the effect of which is the flea repeatedly biting a host in an attempt to obtain a blood meal, which optimizes transmission of *Y. pestis* from the flea to the host (e.g., a human). Should infection progress to the lungs (pneumonic plague; discussed later), aerosol-based transmission between humans is possible. Direct transmission from infected companion animals or wildlife to humans has also been reported.[14,15] The cat flea, *Ctenocephalides felis*, is a poor vector for plague, and cats usually become infected by eating an infected rodent rather than by a flea bite. Infected cats can transmit plague to humans through bites, scratches, and aerosols. Dogs rarely develop clinical signs during *Y. pestis* infection, but have played a role in transmission by bringing infected fleas into the proximity of their owners.[16] Because *Y. pestis* is often low on the diagnostic index of suspicion for dogs with severe pneumonia, untreated canine pneumonic plague has, in rare cases, lead to widespread human exposure.[17]

FIGURE 42.1 *Xenopsylla cheopis*, the Oriental rat flea, the primary vector of *Y. pestis*. Original magnification, 4x.

Prairie dogs have also emerged as important sources of human plague cases, both as wildlife reservoirs and as pets.[18,19] Plague is still endemic in many countries, most of which report at least some human cases each year. Madagascar has had notably high levels of seasonal plague each year since its introduction in 1990, with most cases occurring between September and April. The plague season of 2017–2018 was dramatically intense, with that year's suspected and confirmed case total exceeding 2,400.[20] This epidemic consisted largely of urban cases and a higher proportion of pneumonic plague, whereas most of the world's cases occur in rural settings and are bubonic plague. These differences likely led to the higher incidence and are evidence of the potential for higher-than-expected plague case-loads under certain circumstances.

Y. enterocolitica is also found in a wide variety of animals, including humans, but the primary reservoir for this species is swine.[3] In addition, as *Y. enterocolitica* can survive for a time in the environment, contaminated soil, water, and vegetation can be a part of the chain of transmission to animals and humans.[3] *Y. enterocolitica* is an infrequent cause of disease in the United States, but is common in northern Europe.[21,22]

Y. pseudotuberculosis is the most uncommon of these three human pathogens. It is found in a wide variety of domestic and wild animals, including fowl. The main reservoirs for this organism are rodents, rabbits, and wild birds. Most cases of disease associated with *Y. pseudotuberculosis* are reported in European children. Although *Y. enterocolitica* and *Y. pseudotuberculosis* are found worldwide, they are primarily seen in the warmer areas of Europe. They can also be found in Asia, South Africa, Australia, and the United States.[21,22]

Characteristics of Pathogenic *Yersinia* spp.

Cellular Morphology

Yersinia spp. are nonspore-forming Gram-negative bacilli measuring 0.5–0.8 µm wide by 1–3 µm long.[3] They appear in Gram-stained smears as small, individual cells when cultures on solid media are used to prepare smears (Figure 42.2). In smears from broth (e.g., blood culture broth), they can form short chains.[3] Staining with either Wright or Wayson stains can demonstrate bipolar staining, a phenomenon in which the cell poles stain, but the center of the cell does not. Note that bipolar staining is not a defining characteristic of *Yersinia* and it is not always obvious. *Y. pestis* is nonmotile, but all other species are motile by peritrichous flagella at 22–30°C; all species are nonmotile at 37°C.[3]

Culture

Yersinia spp. will grow on a variety of nonselective and selective media under aerobic conditions. Optimal growth temperatures range from 25–28°C, but many species can grow at temperatures as low as 0°C to as high as 45°C. In clinical microbiology laboratories, cultures for *Y. enterocolitica* are often incubated at room temperature to optimize recovery of this organism; however, growth will still occur at 35–37°C.[3] Unlike other closely related bacteria, *Yersinia* spp. grow slower, so colonies are often tiny (<1 mm) after 24 hours of incubation at their optimal growth temperature.

On sheep blood agar, colonies are nonhemolytic and tiny (<1 mm) after 24 hours of incubation. Following 48 hours of incubation, colonies are larger (~2 mm in size), have an irregular edge, and are often gray-white and opaque (Figure 42.3A). Older cultures (>48 hours) of *Y. pestis* exhibit a fried-egg morphology; the central mass of the colony is more opaque than the peripheral growth. On MacConkey agar, colonies are small and colorless, as lactose is not fermented. Cefsulodin-Irgasan®-novobiocin (CIN) agar is a medium developed specifically to selectively isolate *Yersinia* spp. from stool and other contaminated specimen types. The growth of most other Gram-negative bacilli is inhibited by CIN agar, but some, including *Morganella* spp. and *Serratia* spp., can grow and appear similar to *Yersinia* colonies.[3] Although colonies of these organisms are often larger than those of *Yersinia*. On CIN agar, *Y. enterocolitica* often develops characteristic "bull's eye" colonies that have a dark red center surrounded by a lighter periphery (Figure 42.3B).

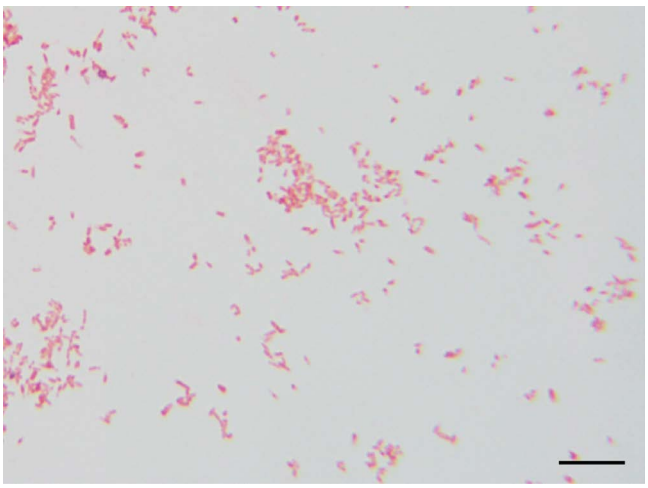

FIGURE 42.2 Gram stain of *Y. pestis* prepared from a blood agar culture that was incubated for 48 hours. Cells are small, plump, and stain Gram-negative. Scale bar, 10 µm.

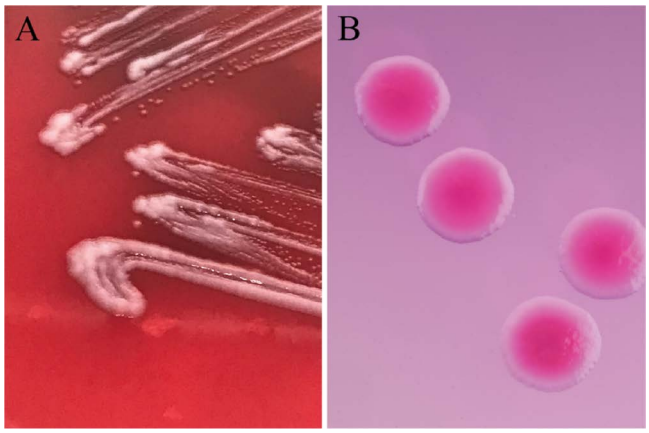

FIGURE 42.3 Colonial characteristics of *Y. pestis* grown on blood agar after 48 hours of incubation (A) and *Y. enterocolitica* growing on CIN agar (B). On CIN agar, isolates of *Y. enterocolitica* often display the characteristic "bull's eye" appearance in which the center of the colony is more red than its lighter periphery. (Image courtesy of Hardy Diagnostics, www.HardyDiagnostics.com.)

Identification of Isolates

Physiochemical identification of isolates requires the use of a variety of biochemical media or multisubstrate panels, such as those used with manual (e.g., analytical profile index [API]) and automated (e.g., VITEK 2, MicroScan WalkAway) phenotypic identification systems. In general, all *Yersinia* spp. ferment glucose, are cytochrome oxidase-negative, and reduce nitrate to nitrite. Table 42.1 lists distinguishing biochemical test results for human-pathogenic yersiniae.

Note that *Y. pestis* is often misidentified as *Y. pseudotuberculosis* by automated phenotypic identification systems, so all isolates identified as such should be tested further to rule out *Y. pestis* as the true identity. Sentinel-level laboratories (e.g., clinical microbiology laboratories) should perform a minimal amount of testing on suspected *Y. pestis* isolates to avoid excessive amplification and manipulation of cultures, which could inadvertently lead to laboratory-acquired infections. If laboratories cannot rule out *Y. pestis* as the identity of an unknown isolate, it should be referred to a Laboratory Response Network (LRN) Reference Laboratory (e.g., a state public health laboratory) for additional testing and then to a National Laboratory for further characterization. Guidelines for ruling out are available from the American Society for Microbiology's LRN Sentinel Level Clinical Laboratory Protocols website: https://www.asm.org/Articles/Policy/Laboratory-Response-Network-LRN-Sentinel-Level-C.

Newer identification technologies, including nucleic acid amplification tests that enable detection of *Yersinia* spp. DNA directly from clinical specimens (e.g., *Y. enterocolitica* DNA from stool specimens) and matrix-assisted laser desorption/ionization time-of-flight mass spectrometry that permits rapid

identification of cultured isolates, have supplanted traditional biochemical testing methods in many diagnostic laboratories. In doing so, these technologies have increased the accuracy and precision of *Yersinia* spp. detection and identification and, in the majority of cases, have substantially decreased the turnaround time for disease diagnosis.[23] A number of publications describing the performance characteristics of these technologies applied to the identification of *Yersinia* spp. are available.[24–28]

Laboratory Safety

Extreme care should be used when handling cultures suspected of being, or confirmed to be, *Y. pestis*. Currently, *Y. pestis* is classified as a CDC/USDA Animal and Plant Health Inspection Service Tier 1 Select Agent that requires biosafety level (BSL)-3 containment, security, and work practices for handling, storage, and inactivation of specimens and cultures containing virulent *Y. pestis*. All manipulations of virulent *Y. pestis* strains, including, but not limited to, cultivation, storage, transfer, inactivation, animal inoculation, and disposal, requires documentation to ensure compliance with Select Agent rules, which are available on the Federal Select Agent Program website, https://www.selectagents.gov/index.html. *Y. pestis* strains containing deletions in the *pgm* locus, which are designated Pgm^-, including strain EV and its various substrains, are excluded from Select Agent rules and regulations.[29] For these strains, standard BSL-2 containment, security, and work practices are appropriate for manipulation of cultures.

Other *Yersinia* spp., including *Y. enterocolitica* and *Y. pseudotuberculosis*, can be safely handled at BSL-2; however, a thorough laboratory risk assessment must be conducted prior to any diagnostic or experimental work to ensure that all appropriate procedures (e.g., spill cleanup and emergency response procedures), engineering controls (e.g., biological safety cabinet [BSC]), and personal protective equipment (PPE; e.g., gloves and laboratory coats) are in place prior to commencement of work.

Parcels containing cultures of virulent strains of *Y. pestis* must be shipped in accordance with the International Air Transport Association's (IATA) Dangerous Goods Regulations and, if cultures are shipped within the United States, the U.S. Department of Transportation's (U.S. DOT) Hazardous Materials Regulations.[30,31] According to both IATA and the U.S. DOT, *Y. pestis* cultures must be shipped according to Category A Infectious Substance Affecting Humans (UN 2814) packaging and shipping regulations.[30,31]

Diseases

Plague

Bubonic Plague

Following a bite from an infected flea, *Y. pestis* travels to the nearest lymph node where they are ingested by macrophages. Once inside, they rapidly multiply to high levels. The ensuing inflammatory reaction causes the formation of buboes, which are, although not specific to bubonic plague, a hallmark of this disease. Buboes are hot, red, and painful oval swellings of the skin and surrounding tissue that range in size from 1 cm to 10 cm in length.[32] Patients also usually present with fever.

Septicemic Plague

Y. pestis can spread to the bloodstream and cause septicemic plague. Bloodstream infections often result in the dissemination

of *Y. pestis* to various organs and, as a result, patients can develop disseminated intravascular coagulation, bleeding, organ failure, and irreversible shock. Infected patients often develop necrotic lesions on the skin, which turn black, which is why this disease was named "The Black Death." Blockage of vessels in the fingers, toes, ears, and nose can lead to gangrene. In cases of primary septicemic plague, buboes may be absent, leading to clinical misdiagnosis.[3]

Pneumonic Plague

Primary pneumonic plague is seen when a person inhales *Y. pestis* and the organisms proliferate within the lungs. Persons with either the primary or secondary form of pneumonic plague are very contagious and can easily spread the infection from person to person via aerosols. Pneumonic plague is rapidly fatal, which makes rapid diagnosis critical.[3] These patients normally present with cough, hemoptysis, and may or may not have buboes.[3]

Miscellaneous Plague Manifestations

Plague meningitis is a rare complication of infection that occurs as acute early disease or as a result of inadequate treatment for bubonic plague. This syndrome is characterized by headache, fever, meningismus, and cerebrospinal fluid (CSF) pleocytosis. *Y. pestis* can also manifest as pharyngeal plague, which is characterized by a painful, inflamed pharynx and associated local lymphadenopathy, which may mimic acute tonsillitis. This form of disease can rarely follow either ingestion or inhalation of the bacteria. Plague can also rarely manifest as gastrointestinal symptoms, including nausea, vomiting, diarrhea, and abdominal pain, which may precede the formation of buboes.[3]

Yersinia enterocolitica Infections

Yersiniosis

Gastrointestinal infections caused by *Y. enterocolitica* are associated with consuming contaminated food or water. Yersiniosis, which is caused by *Y. enterocolitica*, is most often transmitted by consumption of raw or undercooked pork products (e.g., chitterlings) and unpasteurized milk, but other meats and beverages are also implicated in transmission.[3] Symptoms of yersiniosis in children include watery and occasionally bloody diarrhea, fever, and abdominal pain. Mesenteric lymphadenitis is a potential complication of yersiniosis, and its symptoms (fever and right-sided abdominal pain) mimic those of appendicitis.[3] These symptoms can last for 2–3 weeks and normally occur in children. A reactive polyarthritis may also develop in patients after 2 to 14 days of infection. This process involves two to four joints (knees, ankles, toes, fingers, wrists), and symptoms can persist for up to 4 months. Less commonly seen complications associated with *Y. enterocolitica* infections include ankylosing spondylitis, reactive arthritis, erythema nodosum, exudative pharyngitis, pneumonia, empyema, lung abscess, septicemia, endocarditis, and mycotic aneurysms.[3]

Yersinia pseudotuberculosis Infections

Far East Scarlet-Like Fever

Like *Y. enterocolitica*, *Y. pseudotuberculosis* causes self-limited mesenteric lymphadenitis; however, in Japan and Russia, *Y. tuberculosis* is associated with sporadic outbreaks of a disease characterized by severe systemic inflammation. This condition is called Far East scarlet-like fever. Signs and symptoms often include hyperemic skin covered in a punctate rash, submandibular lymphadenopathy, hyperemic tongue, pale nasolabial triangle, and tonsillitis, mimicking those of scarlet fever.[33]

Diagnosis, Treatment, and Prevention

For diagnosis of plague, aspirates of buboes and blood should be cultured.[3] Additional specimens can include sputum, bronchial washes, swabs from skin lesions or the pharyngeal mucosa, and CSF. Aspirates of buboes are obtained using sterile saline and a small needle and syringe. A small amount (up to 2 mL) of sterile saline is infused into the bubo and is then aspirated. Gram-stained or Wayson-stained direct smears of bubo aspirates often reveal an acute inflammatory infiltrate, characterized by the presence of abundant polymorphonuclear neutrophils, and small, plump Gram-negative bacilli. Wayson stain will demonstrate bipolar staining; however, as mentioned before, this attribute is not always apparent and is not specific to *Y. pestis* or other *Yersinia* spp. Refer to laboratory safety and federal Select Agent mandates for ruling out and reporting *Y. pestis*.

Serological diagnosis of plague is also possible, and in the United States, a number of commercial reference laboratories offer testing. The passive hemagglutination test using F1 antigens from the organism is performed on acute and/or convalescent serum samples. A four-fold rise in IgG titer from acute to convalescent samples, or a single titer of greater than 1:16, is presumptive evidence for disease, and a titer of 1:128 is diagnostic for infection.[3] Most patients will have antibodies by the second or third week after infection. Additional diagnostic techniques include polymerase chain reaction (PCR) for detecting the nucleic acids of the organisms, and enzyme immunoassay for the detection of antigens associated with the organisms.[4]

Diagnosis of *Y. enterocolitica* and *Y. pseudotuberculosis* infections normally depends on the isolation of the organisms from stool, mesenteric lymph nodes, peritoneal fluid, blood, or abscesses. Rapid, multiplex real-time PCR assays are now commercially available to clinical laboratories for detecting *Y. enterocolitica* in stool specimens. These syndromic panels permit the simultaneous detection of several pathogens that are frequently associated with specific disease syndromes, including enteritis.

If indicated, antimicrobial susceptibility testing (AST) of isolates can be performed by disk diffusion or methods that determine the minimal inhibitory concentration of a drug or drugs (e.g., microbroth dilution testing). AST of *Y. pestis* should not be attempted by routine clinical microbiology laboratories; instead, isolates should be referred to an LRN Reference Laboratory or National Laboratory for this testing. Frequently updated breakpoints for interpretation of AST results are available from the Clinical and Laboratory Standards Institute and other sources.

If left untreated, plague can result in a 50% mortality rate. Streptomycin is the drug of choice for treatment of all types of plague.[3] Alternatively, gentamicin or gentamicin in combination with doxycycline can be used.[3] Chloramphenicol can be used when high tissue concentrations are necessary, as with cases of meningitis. Resistant strains of *Y. pestis* have rarely been encountered, and treatment does not seem to select for a resistant population of organisms, as relapses do not occur.

Infections caused by *Y. enterocolitica* can be treated with aminoglycosides, chloramphenicol, tetracycline, trimethoprim-sulfamethoxazole, piperacillin, ciprofloxacin, and the third-generation cephalosporins.[3,22] *Y. pseudotuberculosis* is normally susceptible to the aminoglycosides, chloramphenicol, tetracycline, and cephalosporins; although, therapy is usually not warranted in patients with mesenteric adenitis.[3] Septicemia caused by either of these organisms is usually greater than 50% fatal despite appropriate therapy.

A formalin-killed plague vaccine exists, but is only available currently from a manufacturer in Australia. It is not protective against the pulmonary form of the disease, and immunity requires several doses. It is rarely used today except for personnel in research laboratories who work with *Y. pestis*. Research is currently underway to produce a vaccine that will be effective against the pulmonary form of the disease, as concerns mount over this organism potentially being used as a biological weapon.

Persons living in endemic areas should take precautions against becoming infected with the plague bacteria. Protective measures against exposure to rodents and their fleas are of utmost importance. Public health measures aimed at curbing the transmission of infections caused by *Y. enterocolitica* and *Y. pseudotuberculosis* include appropriate sanitation measures in food preparation and not eating undercooked pork.[3]

Introduction

Anaerobic bacteria live in environments with reduced oxygen levels and include both commensals microorganisms and microbial pathogens. Anaerobic pathogens are frequently components of the resident (normal) microflora. They are opportunistic pathogens that can cause disease if, for example, they are traumatically inoculated into adjacent sites or by elimination of microbial competitors following antibiotic therapy. Resident anaerobic bacteria can also become pathogenic by gaining access to the bloodstream and being transported from their normal ecologic niche to distant sites in the body. Anaerobic bacteria that normally reside in the human oral cavity—members of the genera *Porphyromonas* and *Prevotella*— can be found in atherosclerotic plaques (Haraszthy et al., 2000; Kozarov et al., 2006; Zhong et al., 2008; Chhibber-Goel et al., 2016). A number of oral species have been associated with atherosclerotic plaques including *A. actinomycetemcomitans, C. pneumoniae, C. rectus, E. corrodens, E. hormaechei, F. necrophorum, F. nucleatum, H. pylori, M. pneumoniae, P. aeruginosa, P. endodontalis, P. gingivalis, P. intermedia, P. luteola, P. nigrescens, S. gordonii, S. mitis, S. mutans, S. oralis, S. sanguinis, T. denticola, T. forsythia, and Veillonella* (Chhibber-Goel et al., 2016). Many species, including *Porphyromonas gingivalis* and *Prevotella intermedia*, have been identified by polymerase chain reaction (PCR) amplification of bacterial 16S rDNA and species-specific DNA probes. Consequently, anaerobic species such as these that have their primary ecologic niche in dental plaque in the human oral cavity are thought to gain access to the blood stream and become part of atherosclerotic plaques, possibly playing a role in their formation.

As in the case of *P. gingivalis* and *P. intermedia* in atherosclerotic plaques, anaerobic infections are typically mixed infections comprising several species almost evenly divided between anaerobes and facultative species. The microbial ecology of these mixed anaerobic infections is mutually sustaining with facultative species reducing oxygen levels sufficient to permit the growth of the anaerobic species, while anaerobic species inhibit phagocytosis by host immune cells and provide metabolic end products that are necessary for the growth of the facultative species (Styrt and Gorbach, 1989). The importance of mixed infections in human disease is well known and was shown in studies by Smith in 1930. He found that individual bacterial species isolated from what at the time was known as Vincent's infection, and is now called necrotizing gingivitis, were individually unable to cause disease in animal models, but could cause disease when two or more species were used.

Environments with reduced oxygen tension favor anaerobes. Certain diseases or traumatic injuries can reduce oxygen levels in tissues favoring anaerobic infection. Certain disease processes or traumatic injuries can diminish blood flow to a tissue and consequently reduce tissue oxygen levels favoring anaerobic infection. For example, microvascular changes associated with diabetes mellitus can diminish blood flow, particularly to the extremities, and make them susceptible to anaerobic infections as frequently seen in diabetic foot ulcers. In a study of 900 clinical isolates

collected from patients with intra-abdominal and diabetic foot infections, 61% were anaerobes, of which 56% were *Bacteroides* (Edmiston et al., 2004). Similarly, a prominent feature of chronic periodontitis is the development of epithelial-lined soft tissue pockets around the teeth, sometimes approaching 1 cm in depth. In the depth of these pockets, oxygen is decreased and the proportion of anaerobes in the biofilm is increased (Mombelli et al., 1996; Tanaka et al., 1998). Certain anatomic sites have decreased vascularity with aging favoring the growth of anaerobic bacteria. This occurs in the dental pulp in teeth where blood flow is reduced over time as the pulp chamber narrows with the deposition of secondary dentin. Carious lesions in the dental pulp can become infected with strict anaerobes such as *Porphyromonas endodontalis*, leading to odontogenic abscess (Siqueira et al., 2001; Narayanan and Vaishnavi, 2010).

Culture and identification of anaerobic microorganisms is expensive and limited in clinical settings (Ortiz and Sande, 2000). It is often reserved for situations in which empirical therapy has failed to produce a satisfactory result. Clinical microbiological tests for anaerobes often have limited effect on therapy. Less than 1% of anaerobic blood cultures are associated with clinically significant anaerobic bacteremia. Although mortality for these infections is high, patients frequently receive presumptive treatment with appropriate antibiotics based not on the results of anaerobic culture, but on clinical presentation suggestive of an anaerobic infection (Byrd and Roy, 2003). The results of blood cultures of patients with community-acquired pneumonia rarely alter the empiric choice of antibiotics (Ramanujam and Rathlev, 2006).

DNA-based technologies have largely supplanted traditional methods for the identification of bacterial pathogens, including anaerobic bacteria. These methods depend on the determination and use of nucleic acid sequences specific for the target microorganism or microbial taxon. They generally require traditional microbial culture and sequencing of the microbial nucleic acids. That is, the microorganism must be cultivable in order to isolate and sequence the nucleic acids. The species or group-specific sequence can then be employed in a number of different formats such as real time PCR, cloned, sequenced and compared to a database of nucleic acid sequences such as GenBank of the National Center for Biotechnology Information (United States), European Molecular Biology Laboratory Nucleotide Sequence Database, or the DNA Databank of Japan. The direct amplification of microbial nucleic acids, sometimes referred to as broad-range PCR, can identify both cultivable and noncultivable bacteria (Relman, 2002; Johnson et al., 2019). This method is based on the highly conserved nature of 16S ribosomal RNA within species and genera. Analysis of the 16S rRNA sequence facilitates the classification of bacteria and defines phylogenetic relationships between species. For example, *Bacteroides splanchnicus*, which can be phenotypically distinguished from other members of the genera by its production of *n*-butyric acid, is distinct from the genus *Bacteroides* as shown by analysis of 16S rRNA (Olsen and Shah, 2003). Conversely, bacteria that are phenotypically indistinguishable from other species are identified as novel species based on 16S rRNA sequence. Thus, nucleic acid sequencing has greatly increased the number of bacterial species, including many previously never-cultured anaerobic bacteria among the *Bacteroides* and *Fusobacteria*. Consequently, while the identification and characterization of cultivable anaerobic bacteria, including *Bacteroides* and *Fusobacterium*, have previously relied on phenotypic features, biochemical tests, % G + C, and DNA–DNA hybridization, the identification of both cultivable and noncultivable microorganisms is based on nucleic acid analysis (Clarridge, 2004).

Bacteroides, Porphyromonas, and Prevotella

Of the genera within the family *Bacteroidaceae* (class: Bacteroidetes; order: Bacteroidales), only a few genera have been associated with significant disease in humans. These include *Bacteroides, Porphyromonas, Prevotella,* and *Fusobacteria*, the latter genus to be considered separately.

Bacterial species within the genera *Bacteroides*, *Porphyromonas*, and *Prevotella* are Gram-negative, obligately anaerobic (sometimes strictly anaerobic, sometimes exhibiting various degrees of aerotolerance), nonmotile (some with twitching motility), and nonspore-forming. The bacterial cells generally range in size from coccobacillus to long rods. The species grow at 37°C, particularly on blood agar. Colonies are generally 1–3 mm in diameter, circular, with an entire edge, low convex, smooth, and shiny. Strains are generally not hemolytic, but some strains produce small amounts of hemolysin and some are beta hemolytic. Strains generally ferment carbohydrates although, as described later, sugar fermentation has been a major feature in distinguishing species and in the taxonomy of this group of microorganisms. They can produce gas and acid, including volatile fatty acids such as acetic and succinic acids. The genera vary in the guanine and cytosine contents of the DNA. For the genus *Bacteroides*, the G + C content is 40–48 mol%. For the *Porphyromonas*, the G + C content is 40–55 mol%; and for the *Prevotella*, the G + C content is 40–60 mol%.

Both *Bacteroides* and *Prevotella* have a cell-wall peptidoglycan based on mesodiaminopimelic acid, similar to other Gram-negative bacteria, and as distinguished from the *Porphyromonas*, which have a cell-wall peptidoglycan based on lysine (Shah et al., 1976).

In the human body, species in these three genera colonize a variety of mucosal surfaces—oral, pharyngeal, gastrointestinal, and genitourinary—where they exist as part of the normal (resident) microflora and where they can cause opportunistic infections. As resident species, they are important in stabilizing the microbial ecology on mucosal surfaces and in preventing colonization by exogenous pathogens, a process referred to as colonization resistance (van der Waaij et al., 1972). These species, particularly the *Bacteroides*, are major constituents of the microflora throughout the human gastrointestinal tract where they exist in close contact with the mucosa of the small and large intestines. They outnumber aerobic bacteria in the intestine by 1,000:1 and are associated with diseases of the colon. These genera, particularly the *Porphyromonas* and the *Prevotella*, rarely the *Bacteroides*, are also found in the upper gastrointestinal tract. Like *Bacteroides* in feces in the intestine, *Porphyromonas* and *Prevotella* are major components of supragingival and, especially, subgingival dental plaque in the human oral cavity. These genera are associated with oral infectious diseases such as chronic periodontitis, periodontal abscess, endodontic infections, periapical abscess, and sometimes life-threatening soft tissue infections of the head and neck region. In the oropharynx, *Bacteroides*, *Porphyromonas*, and *Prevotella* can be found in tonsillar crypts where they can cause peritonsillar

abscess (Kuhn et al., 1995) and in the fissures sometimes found on the dorsal surface of the tongue (Faveri et al., 2006) where they have can cause oral halitosis. Infection with these bacteria in the oropharynx can also be associated with chronic (but not acute) sinusitis and chronic (but not acute) otitis media. These bacteria are present in the upper (but not lower) respiratory tract where they are associated with community-acquired aspiration pneumonia, necrotizing pneumonia, lung abscess, and empyema (Pryor et al., 2001; Johnson and Hirsch, 2003; Brook, 2004a). They are present in the urogenital tract, particularly the vagina, where they can cause bacterial vaginosis, a disease that significantly increases the risk for preterm, low-birth-weight babies. Bacterial vaginosis is characterized by an alteration in the microbial ecology with decreased numbers of lactobacilli and increased numbers of *Prevotella*. Specific bacteria implicated in bacterial vaginosis include *Bacteroides ureolyticus* (reclassified as *Campylobacter ureolyticus* [Vandamme et al., 2010]), and *Prevotella bivia* (Boggess et al., 2005). Finally, *Bacteroides*, *Porphyromonas*, and *Prevotella* are not usually found on the human skin except in the case of human and dog bite wounds (Talan et al., 1999).

Taxonomy of *Bacteroides*, *Porphyromonas*, and *Prevotella*

The taxonomy of the *Bacteroides*, *Porphyromonas*, and *Prevotella* has undergone numerous revisions reflective of changing methodology. Originally, all three genera were classified within a single genera—*Bacteroides*—based on phenotypic and biochemical tests. The bacterial cells were described as Gram-negative, nonspore-forming, anaerobic, often pleomorphic bacilli (usually with rounded or pointed ends, sometimes fusiform or filamentous). Growth is stimulated by bile, hemin, and vitamin K. Steroid hormones, such as estradiol and progesterone, can also stimulate growth. This is important in that people with elevated serum hormone levels, such as pregnant women or children during the time of puberty, can have oral infections with these species as a result of steroid hormone- stimulated growth (Kornman and Loesche, 1982; Rawlinson et al., 1998).

These bacteria are chemoorganotrophs, which ferment carbohydrates to produce mixed acid fermentation end products, including acetate, succinate, lactate, formate, or propionate. Distinct in this regard is *B. splanchnicus*, which produces butyric acid, including isobutyrate and isovalerate. Comparative nucleic acid sequence analysis has shown that *B. splanchnicus* is not a member of the genus (Olsen and Shah, 2003). The absence of butyric acid production differentiates *Bacteroides*, *Porphyromonas*, and *Prevotella* from *Fusobacterium*, which do produce butyric acid.

Prominent among the *Bacteroides* is the species *Bacteroides fragilis*, which at one time consisted of five subspecies: *distasonis*, *fragilis*, *ovatus*, *thetaiotaomicron*, and *vulgatus*. These were subsequently shown by DNA–DNA homology to be poorly related and were then defined as individual species:

B. distasonis, *B. fragilis*, *B. ovatus*, *B. thetaiotaomicron*, and *B. vulgatus* (Cato and Johnson, 1976). *Bacteroides merdae*, *B. splanchnicus*, and *Bacteroides stercoris* were identified as closely related species. Recently, 16S rRNA sequence analysis has shown that *B. distasonis*, *B. merdae*, and *Bacteroides goldsteinii* should not be classified within *Bacteroides*.

Bacteroides that produce darkly pigmented colonies constituted an easily distinguishable group that provided the impetus for further taxonomic revisions as well as a relatively easy method for assessing their importance in various diseases, such as human chronic periodontitis and, most recently, canine periodontitis (Hardham et al., 2005). Species within the original definition of *Bacteroides* included those within the human oral cavity that produce black or brown pigmented colonies when cultured on blood agar media (sometimes referred to as *black-pigmenting Bacteroides*). Colonies from some species exhibit brick-red fluorescence when exposed to UV light. Like the darkly pigmented colonies, fluorescence has been used as a way of differentiating these species.

In 1921, Oliver and Wherry isolated bacteria producing black or beige pigmented colonies and named them *Bacterium melaninogenicum* (*melanin producing*), mistakenly believing that the pigment in the colonies was melanin. Chemical analysis has since demonstrated that, rather than melanin, the pigments responsible for the dark coloration of the bacterial colonies are protohemin and protoporphyrin, the latter responsible for the brick-red fluorescence of colonies exposed to UV light (Shah et al., 1979; Slots and Reynolds, 1982).

The pigmented *Bacteroides* originally classified as *B. melaninogenicum* were subdivided by Moore and Holdeman into three subspecies based on sugar fermentation: *Bacteroides melaninogenicus* ssp. *melaninogenicus* for strong fermenters, *Bacteroides melaninogenicus* ssp. *intermedius* for bacteria with intermediate fermentative ability, and *Bacteroides melaninogenicus* ssp. *asaccharolyticus* for nonfermenting species. Subsequently, these subspecies were elevated to species level as *B. melaninogenicus*, *B. intermedius*, and *B. asaccharolyticus* (Moore and Holdeman, 1974). The sugar-fermenting species *B. melaninogenicus* was divided into *B. loescheii*, *B. denticola*, and *B. melaninogenicus* (Holdeman and Johnson, 1982). The intermediately sugar-fermenting species *B. intermedius* became two species: *B. intermedius* and *B. corporis* (Johnson and Holdeman, 1983). The sugar nonfermenting strains from the gastrointestinal tract could be distinguished from the sugar nonfermenting strains from the oral cavity both by DNA analysis and by phenotypic traits. Oral strains produced phenylacetic acid, while the gastrointestinal strains did not (Kaczmarek and Coykendall, 1980). The asaccharolytic species found in dental plaque around the gingiva were first defined as *Bacteroides gingivalis* (Coykendall et al., 1980) and then placed into a new genus *Porphyromonas* as *P. gingivalis* (Shah and Collins, 1988). Asaccharolytic species from the oral cavity associated with the root canals of teeth were likewise first defined as *Bacteroides endodontalis* (van Steenbergen et al., 1984) and then placed into the genus *Porphyromonas* as *P. endodontalis* (Shah and Collins, 1988). Two weakly fermentative species originally categorized within *B. intermedius* were later categorized in the genus *Porphyromonas* as *P. levii* (Shah et al., 1995) and *Porphyromonas macacae*.

Bacteroides

Bacteroides fragilis

B. fragilis is the type species and the most important species in the genus *Bacteroides* (Table 43.1) by virtue of its distribution

TABLE 43.1

and its pathogenic potential. It is the leading human anaerobic pathogen. The cells are 0.5–0.8 μm in diameter, 1.5–4.5 μm long with rounded ends, and most strains are encapsulated. It is present as part of the normal gastrointestinal microflora (i.e., a commensal) in proportions of about 0.5–2% of the gastrointestinal bacteria, and it constitutes about 10% of all fecal *Bacteroides*. However, it causes clinical problems in a disproportionately high number of cases relative to its numbers, pointing to the presence of virulence factors in some strains. *B. fragilis* is the most frequently isolated anaerobe from clinical specimens of the gastrointestinal tract of both humans and animals. *B. fragilis* recently has been shown to evolve within individuals in response to factors, such as diet, enabling the bacterium to persist in the intestine (Zhao et al., 2019). It is isolated particularly from intra-abdominal abscesses and from cases of peritonitis usually following perforation of the intestines due to pathological processes, trauma, or abdominal surgery. As in other mixed anaerobic infections, it is often isolated together with other anaerobes and facultative species. In contrast to its presence mainly in the gastrointestinal tract, two other members of the genus—*Bacteroides bivius* and *Bacteroides disiens*—are found mainly in the female genital tract. *B. fragilis* shares the same cellular and colonial morphology as the *Porphyromonas* and *Prevotella*, but it can be distinguished in that its growth is stimulated by the presence of 20% bile.

B. fragilis is typically nonhemolytic, but 10 hemolysin genes have been described (Robertson et al., 2006). *B. fragilis* is unusual among *Bacteroides* in possessing a polysaccharide capsule, seen especially in fresh isolates, but which is lost on repeated subculture (Kasper, 1976). Like capsules in other bacterial species, the *B. fragilis* capsule can inhibit phagocytosis by host immune cells and can also play a role in abscess formation as demonstrated in animal models (Nakatani et al., 1996). Two types of capsular polysaccharides have been described (Tzianabos et al., 1992). *B. fragilis* also has a lipopolysaccharide notable for a lipid A component chemically distinct from other species; the glucosamine lacks attached phosphate groups and the amino sugars have fewer attached fatty acids. The lipopolysaccharide also lacks beta-hydroxymyristic acid. This accounts for its much lower biological activity as compared to other lipopolysaccharide endotoxins (Weintraub et al., 1989; Hofstad, 1992).

Strains of *B. fragilis* can produce an enterotoxin (enterotoxigenic *B. fragilis* [ETBF]) causing watery diarrhea, especially in children between 1 and 5 years of age (Pantosti et al., 1997). While it is present in 6.5% of otherwise healthy people, ETBF accounts for up to 20% of cases of diarrhea. ETBF has also been associated with diarrheal disease in livestock, with inflammatory bowel disease, and with colorectal cancer, the latter thought to occur through modulation of mucosal immune responses and induction of changes in epithelial cells. The *B. fragilis* enterotoxin (*B. fragilis* toxin [BFT]) is a 20 kDa zinc metalloprotease. There are three subtypes encoded by the *B. fragilis* toxin (bft) gene (Kato et al., 2000). The enterotoxin binds to intestinal epithelial cells facilitated by pili present on the cell surface of some *B. fragilis* strains. The enterotoxin cleaves the protein E-cadherin, which is responsible for intercellular adhesion (Sears, 2001; Wu et al., 2007). ETBF-infected mice develop colitis and colonic tumors while nontoxin-producing *B. fragilis*-infected mice do not (Wu et al., 2007) and ETBF is found more frequently in colon-cancer patients (Toprak et al., 2006). The frequency of *B. fragilis* in patients with colorectal cancer is about twice that in control subjects (Haghi et al., 2019).

B. fragilis together with other species in the *B. fragilis* group—*B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, and *B. vulgatus*—frequently produce beta-lactamase and are resistant to penicillins, but they are generally susceptible to metronidazole, carbapenems, and beta-lactam antibiotics. There has been a marked increase in antibiotic resistance among *Bacteroides* as well as *Porphyromonas* and *Prevotella* species in recent years. Multidrug-resistant *B. fragilis has been reported* including an

isolate resistant to resistance to penicillin, clindamycin, metronidazole, cefoxitin, meropenem, imipenem, piperacillin/tazobactam, and tigecycline (Sherwood et al., 2011).

Bacteroides thetaiotaomicron

B. thetaiotaomicron is another important member of the genus *Bacteroides*. It is a nonspore- forming, Gram-negative anaerobic bacillus, which may be motile or nonmotile. It is the dominant bacteria in the distal human gastrointestinal tract (Moore and Holdeman, 1974). Next to *B. fragilis*, it is the most important cause of subdiaphragmatic infections in humans including intra-abdominal sepsis as well as bacteremia. It also has an important symbiotic relationship with its human host. It stimulates both the development of the human gastrointestinal tract and host immune functions (Hooper et al., 2002). Studies of *B. thetaiotaomicron* have been key to understanding the role of the gut microflora in carbohydrate metabolism. *B. thetaiotaomicron* metabolizes the contents of the intestine—otherwise indigestible, mainly fibrous, dietary carbohydrates as well as carbohydrates produced by humans, such as mucins—releasing sugars for its own metabolism and for other gut microorganisms (Gilmore and Ferretti, 2003).

B. thetaiotaomicron is also the first bacterium in this group to be completely sequenced (Xu et al., 2003). The type strain of *B. thetaiotaomicron* (VPI-5482 = ATCC 29148) originally isolated from feces taken from a healthy adult has a 6.26 Mb genome. The genome encodes 4,776 proteins and has a G+C content of 42.8%. Consistent with its role in metabolizing carbohydrates in the gut, a large portion of the *B. thetaiotaomicron* genome encodes enzymes involved in polysaccharide uptake and degradation such as glycosyl hydrolases, carbohydrate-binding proteins, and glycosyltransferases involved in capsular polysaccharide formation.

Porphyromonas

Porphyromonas are part of the phylum Bacteroidetes (previously the Cytophaga-Flavobacteria- Bacteroides group [Boone and Castenholtz, 2001]), order Bacteroidales, family *Porphyromonadaceae*. *Porphyromonas* are named after the porphyrin pigment—protoheme—that results in the colonies becoming darkly pigmented. The *Porphyromonas* include Gram-negative nonspore-forming anaerobic nonmotile rods, which are sometimes short or coccobacillary rods that produce smooth, shiny, circular, convex colonies with an entire edge. Growth is optimum at 37°C, and most species, but not all, produce the protoheme pigment that causes the colonies on blood agar to darken from edge to center over a period of 3–6 days. They are asaccharolytic species. The G + C content of the DNA ranges from 40 mol% to 55 mol%. They are primarily found in the oral cavity of humans, nonhuman primates, and other animals. Species of *Porphyromonas* are shown in Table 43.2. *Porphyromonas asaccharolytica* is the type species of the genera and, like *Bacteroides*, is found in the normal human intestinal tract and the human vagina. It is found in mixed infections, including superficial abscesses and ulcers of the genitalia and perineum (Duerden, 1993).

Porphyromonas gingivalis

P. gingivalis (formerly *Bacteroides gingivalis*) is an anaerobic, nonfermenting, Gram-negative short rod frequently found in the human oral cavity where it is part of the normal microflora. *P. gingivalis* is nonclonal with variable pathogenicity between strains (Tribble et al., 2013). For example, *P. gingivalis* strains W50 and W83 induce alveolar bone loss in mice, while strain A7A1-28 does not (Marchesan et al., 2012). *P. gingivalis* virulence factors include capsule, gingipains (cell surface cysteine proteinases that regulate host inflammatory responses (Huq et al. (2013), hemagglutinins, hemolysin, iron uptake transporters, and toxic outer membrane blebs. The genome of *P. gingivalis* strain W83 has been sequenced (Nelson et al., 2003) and is closely related to *B. fragilis* and *B. thetaiotaomicron*. It contains six putative hemagglutinin-like genes, 36 previously unidentified peptidases, and genes to produce toxic metabolic end products that may contribute to periodontal disease.

P. gingivalis can be isolated from dental plaque, particularly subgingival dental plaque in adults. An anaerobe, *P. gingivalis*, is found in higher numbers in the depths of periodontal pockets where the oxygen tension is lower and, which, consequently, favors its growth. *P. gingivalis* is less frequently found in dental plaque in children, and it appears to become established in the human oral cavity following puberty. *P. gingivalis* can also be found, but in fewer numbers, in parts of the oral cavity contacting dental plaque, such as in saliva, the buccal mucosa, the lateral borders of the tongue, and the tonsils, particularly if the tonsils are cryptic.

P. gingivalis is one of the major etiological agents in the pathogenesis and progression of the inflammatory events of periodontal disease (Hajishengallis et al., 2014). As described next, there are several factors in its pathogenesis including the fact that it is found in high prevalence in dental plaque in humans with chronic periodontitis. That is, when *P. gingivalis* is present in the dental plaque, periodontal pockets will often become deeper and there will be greater loss of the connective tissue attachment of the gingiva to the teeth and loss of alveolar bone. *P. gingivalis* is considered one of a group of "red complex" bacteria, each of which is found in cases of progressing periodontitis (Socransky et al., 1998). Conversely, healthy gingiva is associated with the absence of *P. gingivalis*. Interestingly, bacteria similar to *P. gingivalis* that infect the oral cavities of other animals, such as monkey, dogs, and cats, are also associated with periodontitis in those animals. *P. gingivalis* produces a number of virulence factors including:

1. Cell surface fimbriae that facilitate bacterial adherence to tooth surfaces and to epithelial cells, such as those present in the gingival sulcus or periodontal pocket. *P. gingivalis* can agglutinate red blood cells, bind and invade gingival epithelial cells via integrin host cell receptors, and induce cytokine expression resulting in alveolar bone resorption. *P. gingivalis* produces two types of fimbriae, Mfa1 and FimA, the latter long fimbriae from the *fimA* gene. There are six genotypic variants based on nucleotide sequence differences in the *fimA* genes—types I–V and Ib. Type II fimA exhibit greater adhesive and invasive

TABLE 43.2

Species of *Porphyromonas*

Species	Subclusters	Features	G + C mol%	Growth Characteristics	Type Strain	References
Found mainly in humans						
P. asaccharolytica	1	Type species of the genus (1970) Intestinal flora Vaginal flora Diabetic ulcers and gangrene Genital ulcers	52–54	Darkly pigmented colonies Inhibited by bile and bile salts Fluorescence with UV light	ATCC 25260	Moore and Holdeman (1974); Shah and Collins (1988); Duerden (1993)

P. crevioricanis	3	Cat dental plaque Feline periodontal disease Dog gingiva	44–45	Fluorescence with UV light Darkly pigmented colonies	ATCC 55563	Norris and Love (1999); Hirasawa and Takada (1994)
P. denticanis *P. gingivicanis*	1	Periodontal disease in dogs Most closely related to *B. splanchnicus* by 16S rRNA Dog gingiva	41–42	Darkly pigmented colonies Darkly pigmented colonies	ATCC 55562	Hardham et al. (2005); Hirasawa and Takada (1994)
P. gulae	3	Periodontal disease in dogs Dental plaque in animals	51	Darkly pigmented colonies	ATCC 51700	Fournier et al. (2001)
P. levii	2	Bear, cat, coyote, dog, wolf, and monkey Canine periodontal disease Intestinal tract of cattle	45–48	Darkly pigmented colonies	ATCC 29147	Hardham et al. (2005); Johnson and Holdeman (1983)
		Cow rumen		Weakly fermentative		Shah et al. (1995)
P. macacae	4	Periodontitis in monkeys	43–44	Fluorescence with UV light Differentiable from *P. macacae* based on phenotypic differences	ATCC 33141	Slots and Genco (1980)
P. salivosa		Cat bite wounds in humans Feline periodontal disease	42–44	Darkly pigmented colonies Weakly fermentative Differentiable from *P. salivosa* based on phenotypic differences	NCTC 11362	Love (1995); Love et al. (1987, 1992); Love (1995)
		Canine periodontal disease				Citron et al. (1996); Norris and Love (1999)

capabilities (Nagano et al., 2013) and predominate in chronic periodontitis (Amano et al., 2004; Moon et al., 2012; Fabrizi et al., 2013). *P. gingivalis* fimbriae degrade integrin-related signaling molecules, thereby disrupting cellular proliferation, which enables it to persist in the gingival epithelium (Amano, 2007) where it becomes resistant to antibiotic treatment (Irshad et al., 2012).

2. A bacterial collagenase capable of degrading type I collagen and thought to be responsible for the connective tissue destruction seen in periodontitis (Houle et al., 2003). *P. gingivalis* collagenase is a therapeutic target for low-dose doxycycline therapy used to treat chronic periodontitis (Vernillo et al., 1994), and it is the basis for a diagnostic test for *P. gingivalis* and oral bacteria with similar trypsin-like activities able to hydrolyze *N*-benzoyl-dl- arginine-2-naphthyl-amide (Lee et al., 2006).
3. A lipopolysaccharide endotoxin associated with alveolar bone loss (Millar et al., 1986), but, which like the LPS from *B. fragilis*, has relatively weak biological activity based on the chemical structure of the lipid A moiety (Ogawa et al., 2007).
4. A capsular polysaccharide encoded by a glycosyltransferase (Davey and Duncan, 2006), which, like the capsule in *B. fragilis*, can inhibit phagocytosis by host immune cells and complement-mediated killing (Slaney et al., 2006) as well as a hemagglutinin, hemolysin, hyaluronidases, phospholipase, alkaline phosphatase, and acid phosphatase (Kantarci and Van Dyke, 2002).
5. Bacterial proteases including trypsin-, thiol-, and caseinolytic proteinases (Curtis et al., 2001). The *P. gingivalis* proteases are important factors in colonization of the periodontal pocket (Dubin et al., 2013). *P. gingivalis* proteases fall into two general classes; the cysteine proteinase (also known as "trypsin-like" enzymes) and the serine proteinase (Bostanci and Belibasakis, 2012). The cysteine proteinases are commonly knowns as gingipains and cleave polypeptides at the C-terminal after arginine-gingipain R, of which there are two types, RgpA and RgpB, or lysine-gingipain K, of which there is one type, Kgp. Gingipain R degrades integrin-fibronectin-binding cytokine, immunoglobulin, and complement factors.

The complete bacterial genome from *P. gingivalis* strain W83, originally isolated from a human oral infection by H. Werner (Loos et al., 1993), has been sequenced and found to exhibit similarities to other *Bacteroides* species, such as *B. fragilis* and *B. thetaiotaomicron*, to the Cytophaga- Flavobacteria-Bacteroides phylum, and to the green-sulfur bacteria (Nelson et al., 2003). It exhibits 2,343,476 base pairs and 2,053 genes, of which 96.83% are protein encoding. It also exhibits a large number, at least 96, mobile insertion sequences and genes similar to those found in other *Bacteroides*, including immunoreactive surface proteins and proteins for aerotolerance (Duncan, 2003). Whole-genome comparison between virulent *P. gingivalis* strain W83 and avirulent *P. gingivalis* strain ATCC 33277 shows 93% similarity, with 7% composed of variant or missing genes, including insertion sequences, the immunoreactive surface protein RagA, enzymes involved in polysaccharide capsule synthesis, and pathogenicity islands possibly acquired by lateral gene transfer (Chen et al., 2004).

P. gingivalis has been recently associated with extraoral diseases including rheumatoid arthritis, Alzheimer's disease, and pancreatic cancer. Patients with rheumatoid arthritis have a higher prevalence of severe periodontitis than patients without rheumatoid arthritis (Ogrendik, 2012; Totaro et al., 2013). *P. gingivalis* DNA, as well as that of Prev*otella intermedia*, *Prevotella melaninogenica*, and *Tannerella forsythia,* can be detected in the synovial fluid of arthritic joints and correlated with the number of missing teeth, which is a measure of the severity of periodontal disease (Reichert et al., 2013). Patients with both severe periodontitis and rheumatoid arthritis have higher antibody titers to *P. gingivalis* than patients with severe periodontitis who did not have rheumatoid arthritis (Smit et al., 2012). Autoimmunity to citrullinated proteins is a feature of rheumatoid arthritis, and anticitrullinated antibodies are found in gingival crevicular fluid from inflamed gingiva. *P. gingivalis* is unique among oral bacteria in having an enzyme, peptidylarginine deiminase, capable of citrullinating proteins (Janssen et al., 2013; Quirke et al., 2013). It can also be shown to cause rheumatoid arthritis in animals by other mechanisms including induction of NETosis, osteoclastogenesis, and Th17 proinflammatory response (Perricone et al., 2019)

Postmortem examination of the brains of patients with Alzheimer's disease demonstrates lipopolysaccharide from *P. gingivalis* (Poole et al., 2013), and Alzheimer's patients have elevated levels of serum antibodies to *P. gingivalis* compared to control subjects (Sparks Stein et al., 2012). Similarly, subjects exhibiting elevated levels of *P. gingivalis* antibodies were at twice the risk of pancreatic cancer compared to controls (Michaud et al., 2012).

Porphyromonas endodontalis

P. endodontalis is a bacterium that is closely related to *P. gingivalis* and causes dental root canal infections and endodontic abscesses together with other species (van Steenbergen et al., 1984). *P. endodontalis* infections are characterized by acute symptoms, such as pain, swelling, and purulence. As opposed to the aerotolerance exhibited by *P. gingivalis*, *P. endodontalis* is a strict anaerobe whose intolerance for atmospheric oxygen has made it difficult to detect on routine culture. For example, *P. endodontalis* can be detected more than twice as frequently in chronically infected dental root canals by the PCR than it can be detected by anaerobic culture (Tomazinho and Avila-Campos 2007). The lipopolysaccharide from *P. endodontalis* can stimulate cytokine production, and the bacterium can induce dental pulp to produce matrix metalloproteinases (Chang et al., 2002).

Prevotella

The genus *Prevotella* (Shah and Collins, 1990; family: *Prevotellaceae*), named after the French anaerobic microbiologist Prevot, includes species previously classified as *Bacteroides*.

As described earlier, these species are obligately anaerobic, nonspore-forming, nonmotile, Gram-negative rods. They produce gray, brown, or black colonies that are shiny, circular, and convex with an entire edge, although there are also nonpigmenting species within the genus. They *moderately* ferment sugars, require hemin and menadione for growth, and are bile sensitive. The cell walls contain mesodiaminopimelic acid. The G+C content ranges from 40 mol% to 60 mol%. There are 45 cultured species of which 38 have been isolated from humans (Alauzet et al., 2010, Table 43.3) and of which 31 have been isolated from the oral cavities of humans and other species. Only one species, *Prevotella paludivivens*, has been isolated from the environment of rice plants.

In humans, *Prevotella* are predominantly oral species (Table 43.3) that can be found in infections of the head and neck regions, including the oral cavity where they can cause periodontal diseases and oral halitosis (Krespi et al., 2006), sinus infections (Brook, 2005a), and infections of the tonsils and middle ear (Brook, 2005b). They can also be found in the gastrointestinal tract (Brook, 2004b) and the urogenital tract, particularly *P. bivia* and *Prevotella disiens*, which can cause gynecologic infections, including bacterial vaginosis—a risk factor for preterm low birth weight (Marrazzo, 2004). In animals, *Prevotella* comprise the most numerous Gram-negative species in the gastrointestinal tract (Peterka et al., 2003). *P. melaninogenica* has been associated with oral cancer as specific for tumorigenic tissues, and together with *Capnocytophaga gingivalis* and *Streptococcus mitis* as a salivary marker for the early detection of oral squamous cell carcinoma (Mager et al., 2005). Other species of *Prevotella* include *Prevotella heparinolytica* and *Prevotella zoogleoformans*, which are closely related to *Bacteroides* species and may represent a new genus within the family *Prevotellaceae*.

Prevotella intermedia

Prior to reclassification in the genus *Prevotella*, this species of intermediately fermentative *Bacteroides* was known as *B. intermedius*. It can be distinguished on primary culture plates from other darkly pigmented colonies by the brick-red fluorescence observed in the colonies exposed to UV light. *P. intermedia* can also be distinguished from other darkly pigmented colonies by its production of galactosidase. *P. intermedia* is associated with different forms of human periodontal disease, including moderate to severe gingivitis, chronic periodontitis, and necrotizing gingivitis.

Tannerella

Most oral species once categorized as *Bacteroides* have been placed into the genus *Porphyromonas* or *Prevotella* as described earlier. One notable exception is an organism originally isolated by Anne Tanner of the Forsyth Institute from dental plaques in adults with progressing advanced periodontitis (Tanner et al., 1986). It has subsequently been isolated from gingivitis, periodontitis, endodontic infections, and infections around dental implants. This microorganism was first described as *fusiform Bacteroides* based on its cellular appearance—tapered (fusiform) ends with central swellings. The species, originally named *Bacteroides forsythus*, was found to be distinct from *Bacteroides*—it is not resistant to bile—and from *Porphyromonas* based on 16S rRNA phylogenetic analysis. It was placed into a new genus as *Tannerella*, first as *Tannerella forsythus* (Sakamoto et al., 2002) and then as *T. forsythia* (Maiden et al., 2003) It is a slow-growing, strict anaerobe with unique growth requirements. The colonies are tiny and opaque, and appear on primary culture often as satellites of *Fusobacterium nucleatum* colonies, where they appear as speckled pale pink, circular, entire, convex, and sometimes with a depressed center. *T. forsythia* requires media containing *N*-acetylmuramic acid (Wyss, 1989), and it is one of a few oral species from among the up to 1,200 bacterial species that can inhabit the human oral cavity, such as *Aggregatibacter actinomycetemcomitans* and *P. gingivalis,* for which there is significant evidence for its role in the etiology of human periodontitis.

T. forsythia along with *P. gingivalis* and *T. denticola are* routinely isolated from subgingival plaques in patients with chronic periodontitis. Although *T. forsythia* is the only member of the genus cultured to date, other members of the genus have been detected by their 16S rRNA sequence. *Tannerella* sequences have been identified in the gut flora from insects, such as termites and scarab beetle (Tanner and Izard, 2006). The full sequence of the *T. forsythia* type strain ATCC 43037 has been determined. It contains 3,405,543 base pairs, 3,034 predicted open reading frames, 15 pathogenicity islands, and a G+C content of 46.8 mol% (Chen et al., 2005).

T. forsythia produces several virulence factors, including trypsin-like and PrtH proteases, SiaH and NanH sialidases, a hemagglutinin, alpha-d-glucosidase and *N*-acetyl-beta-glucosaminidase, epithelial cell-adhering and invasion-promoting S-layer, and an apoptosis-inducing activity (Sharma, 2010). It has demonstrated virulence in animal models causing skin abscesses and alveolar bone loss enhanced by coinfection with *F. nucleatum* or *P. gingivalis* (Kesavalu et al., 2007). Along with *P. gingivalis*, it has been associated with esophageal cancer (Malinowski et al., 2019). *Tannerella forsythia* can be detected in the synovial fluid of arthritic joints.

Fusobacterium

Fusobacterium (Table 43.4) is a genus of Gram-negative nonspore-forming anaerobic bacteria that has a distribution similar to *Bacteroides*. Similar to the species described earlier, *Fusobacterium* lives on mucous membranes in both humans and other animals. Like *Bacteroides* and related species, some species of *Fusobacterium* are pathogenic and are found in purulent infections and in gangrene. Fusobacterium cells are filamentous or spindle-shaped, varying in size and motility, and its major metabolic end product is butyric acid.

Fusobacterium has been implicated in the etiology of colorectal cancer as have some other microorganisms in the gastrointestinal tract. Studies in animal models have pointed to potential mechanisms. Fusobacterium could promote oncogene transcription and induce immune suppression. Fusobacterium is associated with epigenetic changes of malignant epithelial cells (Zhou et al., 2018).

TABLE 43.3

Prevotella Species

Species	Isolated From	G + C mol%	Growth Characteristics	Type Strain	References
P. albensis	Rumen. Previously *Prevotella ruminicola* subsp. *ruminicola*	39–43	Nonpigmented	NCTC 13060	Avgustin et al. (1997)

TABLE 43.4

Taxonomy of *Fusobacteria*

Phylum XIX: Fusobacteria	Class I: Fusobacteriia	Order I: Fusobacteriales	Family I: Fusobacteriaceae	Genus: Fusobacterium	Species:	Subspecies:
						F. nucleatum
						F. nucleatum subsp. nucleatum
						F. nucleatum subsp. animalis
						F. nucleatum subsp. fusiforme
						F. nucleatum subsp. polymorphum
						F. nucleatum subsp. vincentii
					F. canifelinum	
					F. equinum	
					F. gonidiaformans	
					F. mortiferum	
					F. naviforme	
					F. necrogenes	
					F. necrophorum	
						F. necrophorum subsp. necrophorum
						F. necrophorum subsp. funduliforme
					F. perfoetens	
					F. periodonticum	
					F. russii	
					F. simiae	
					F. ulcerans	
					F. varium	

Source: Adapted from Bergey's Manual of Systematic Bacteriology, Volume 4.

F. nucleatum is the type species of the genus. It is indigenous to the human oral cavity (where it can cause periodontal disease) and can be found in dental plaque in association with other Gram-positive and Gram-negative species. The cells are spindle shaped, 5–10 µm long, and often paired end to end. *F. nucleatum* can be found in mixed infections from the head and neck, as well as infections in the chest, lung, liver, and abdomen. It is associated with colorectal cancer, pancreatic cancer, oral cancer, and premature and term stillbirths (Shang and Liu, 2018). The complete genome of *F. nucleatum* strain ATCC 25586 has been sequenced (Kapatral et al., 2002). It has a 27 mol% G+C content and 2.17 Mb encoding 2,067 open reading frames.

Fusobacterium necrophorum is also a component of the normal human oropharyngeal, gastrointestinal, and urogenital tract flora. The otogenic variant can cause abscesses, otitis, sinusitis, sinus thrombosis, mastoiditis, and meningitis (Creemers-Schild et al., 2014). There is some evidence that *F. necrophorum* disease is increasing (Brazier et al., 2002). The cells are filamentous, curved, with spherical enlargements. *F. necrophorum* is responsible for about 10% of sore throats, second only to group A streptococci (Aliyu et al., 2004), and can cause a particularly serious disease in healthy young adults known as Lemierre's syndrome—a life-threatening infection that follows an initial sore throat. *F. necrophorum* can also cause meningitis, gastrointestinal and urogenital infections, and a number of clinical syndromes known as necrobacillosis (Hagelskjaer Kristensen and Prag, 2000). *F. necrophorum* causes disease through the production of several virulence factors, including a leukotoxin, proteolytic enzymes, lipopolysaccharide, and hemagglutinin.

Gram-positive Anaerobic Cocci

Previously classified as *Peptostreptococcus* (phylum: Firmicutes—Gram-positive bacteria; class: Clostridia; order: Clostridiales), the Gram-positive anaerobic cocci (GPAC) are slow-growing and

nonspore-forming cocci that are 0.3–1.8 µm in diameter and usually arranged in chains, pairs, tetrads, or clumps. They were a poorly described group of bacteria previously referred to as *anaerobic cocci*, *anaerobic streptococci*, *anaerobic Gram-positive cocci*, and *Peptococcus* although they have been the subject of increasing study in recent years. The genera and species of the GPAC are listed in Table 43.5. In addition to *Peptostreptococcus* (species include *P. anaerobius*, *P. stomatis*, and *P. russellii*), the GPAC include the genera *Finegoldia (F. magna)*, *Parvimonas* (species include *P. olsenii* and *P. gorbachii*), *Anaerococcus*, *Peptococcus*, *Peptoniphilus* (species include *P. ivorii*, *P. harei*, *and P. niger*), *Gallicola* (species include *G. barnesae)*, *Murdochiella* (*M. asaccharolytica)*, *Atopobium*, *Anaerosphaera* (*A. aminiphila*), *Coprococcus*, *Sarcina*, *Ruminococcus*, and *Blautia* (*B. product*) (Murphy and Frick, 2013). Studies of the *Peptostreptococcus* like the larger GPAC group have been hampered by taxonomic uncertainties, slow bacterial-cell growth, and oxygen sensitivity. They are part of the normal flora on mucosal surfaces of the oral cavity, gastrointestinal tract, and urogenital tract, and account for 25–30% of all anaerobic bacteria isolated from clinical specimens. They are the most frequently isolated group of anaerobic microorganisms isolated from clinical infections followed by *Prevotella* species and the *B. fragilis* group (Mikamo et al., 2011). They are commensals and opportunistic pathogens recovered from oral infections, deep organ abscesses, obstetric and gynecological sepsis, and chronic wounds, such as leg ulcers. They are components of mixed anaerobic infections but may also be found as the sole infecting microorganism. As more is known about the GPAC, their importance in certain infections such as bacteremias and infected joints has increased.

The most commonly isolated GPAC from infections are (using the revised taxonomy) *F. magna*, *M. asaccharolytica*, *Anaerococcus prevotii*, and *Parvimonas micra*. *F. magna* (formerly *Peptococcus magnus* and *Peptostreptococcus magnus*) is the most pathogenic of the GPAC and is isolated from skin lesions, soft tissue abscesses, joint infections, pleural empyema, vaginosis, and infective endocarditis. *F. magna* has been isolated from infected orthopedic joints (Söderquist et al., 2017). *F. magna* virulence factors include protein L, which binds to immunoglobulin light chains. Protein L is thought to enhance *F. magna*'s ability to colonize host tissues (Ricci et al., 2001), and it induces the synthesis and release of IL-4 and IL-13, making protein L a bacterial superantigen (Genovese et al., 2003). *F. magna* also produces a peptostreptococcal albumin-binding protein (de Château and Björck, 1994) that facilitates nutrient access, increases growth rate, and inactivates antibacterial peptides (Egesten et al., 2011). *Anaerococcus sp. A20* was isolated from the skin of the human axilla and is responsible for axillary odor as it releases 3-hydroxy-3-metyl-hexanoic acid, the main component of axillary odor (Fujii et al., 2014). *M. asaccharolytica* is the sole species in the genus *Murdochiella* and has been isolated from human wounds (Ulger-Toprak et al., 2010). *A. prevotii* is a component of the resident flora of the skin, oral cavity, and gut but is also isolated from vaginal discharges, ovarian, peritoneal, sacral, and lung abscesses (Labutti et al., 2009), diabetic foot ulcers, and pressure ulcers (Dowd et al., 2008). *P. micra* (formerly *Peptostreptococcus micros* and *Micromonas micros*) is part of the resident gastrointestinal flora including the oral cavity and is a pathogen in oral infections including chronic periodontitis and endodontic lesions as well as extraoral chronic wounds, burns, and surgical infections. *P. micra* virulence factors include proteases, gelatinases, collagenase, and hemolysins (Grenier and Bouclin, 2006; Ota-Tsuzuki and Alves Mayer, 2010).

Introduction

Gram-negative bacteria do not retain the crystal violet stain during classical Gram staining methods to differentiate between bacterial pathogens. Gram-negative bacteria do not follow a monophyletic, phylogenetic pattern, and thus, the designation is primarily of importance in the determination of which antimicrobial to use when treating bacterial infections. For example, the Gram-negative outer cell membrane makes them resistant to several classes of antibiotics. This chapter briefly discusses species of the following Gram-negative genera in the phylum Proteobacteria: *Acinetobacter*, *Burkholderia*, and *Moraxella*.

Genus *Acinetobacter*

The genus *Acinetobacter* is a heterogeneous group of organisms, including strains associated with both the natural environment and human infection. *Acinetobacter* is in the class Gammaproteobacteria and the family *Moraxellaceae*, where there are 63 named species and several unnamed species (http://www.bacterio.net/acinetobacter.html) (1).

While organisms in *Acinetobacter* generally inhabit soil and water environments, some are nosocomial pathogens and others are opportunistic human pathogens. In the clinical setting, *Acinetobacter* infections are classified as either nosocomial or community acquired, although the majority of cases are community acquired (2). *Acinetobacter baumannii* is the primary organism identified in nosocomial infections, particularly in intensive care units, where it has been associated with 20% of all infections (3). However, other species have also been associated with nosocomial infections, including genomic species 13 (*Acinetobacter nosocomialis* [4]) and 3 (*Acinetobacter pittii* [4]). These three species are closely related according to DNA-DNA hybridization studies and are difficult to distinguish phenotypically and thus are often grouped together into the *Acinetobacter calcoaceticus-baumannii* (*Acb*) *complex*. The complication with this complex designation is that a fourth species, *A. calcoaceticus*, is included in the complex, but is a soil bacterium not associated with human disease (1). Also included in the *Acb* complex is *Acinetobacter oleivorans*, a species not associated with pathogenesis that can grow solely on diesel fuel (5). A recent clinical study in the United States demonstrated that most *Acinetobacter* bloodstream infections were caused by *A. baumannii* (63% of cases), *A. nosocomialis* (21% of cases), and *A. pittii* (8% of cases) (6). Species outside of the *Acb* complex, including *Acinetobacter ursingii*, have also been associated with nosocomial infection (7).

Acinetobacter spp. are difficult to differentiate experimentally, even with commercial typing systems (8, 9). A range of methods have been investigated to classify and discriminate between *Acinetobacter* species. One study assessed a variety of methods and found pulsed-field gel electrophoresis (PFGE) to be the most discriminating method in the differentiation of *Acinetobacter* spp (10). However, the PFGE protocol must be strictly standardized (11), and even then, the results are not always reproducible (12). Additional methods, including optimal growth temperature, cannot accurately distinguish between species within the *Acb* complex (13). Additional analyses applied to the identification of *Acinetobacter* spp. include amplified 16S rDNA restriction analysis (14), amplified fragment length polymorphism (AFLP) (15), and *rpoB* gene sequence analysis (16). However, many of these methods can either not be compared between studies or cannot differentiate between related species in the *Acb* complex. Core genome phylogenetics has recently been used to differentiate between *Acinetobacter* spp. and will likely be the most accurate method moving forward to differentiate between species (17, 18).

A. baumannii is the most clinically relevant species of *Acinetobacter* (9) and causes a range of negative interactions with the human host, from asymptomatic colonization (19) to septicemia and death (20–22). One of the primary human health concerns of *A. baumannii* infection is the organism's potential resistance to all known antibiotics (9, 21). Multidrug-resistant (resistant to at least three classes of drugs specifically

cephalosporin, fluoroquinolones, and aminoglycosides) (23) and extensively-drug-resistant (MDR plus resistant to carbapenems) (24) isolates of *A. baumannii* have been identified in hospitals around the world (25). The combination of desiccation resistance (26), antibiotic resistance, and attachment to abiotic surfaces (27), including surfaces used in joint replacements (e.g., titanium), has made *A. baumannii* a pathogen of great concern in the hospital environment.

Genus *Burkholderia*

Originally, a member of the genus *Pseudomonas*, the genus *Burkholderia* has species that occupy a wide range of ecological niches, including soil, water, the rhizosphere, animals, and humans. *Burkholderia* is a member of the class Betaproteobacteria, family *Burkholderiaceae*, and consists of 122 named species (http://www.bacterio.net/burkholderia.html).

The *Burkholderia cepacia* complex (Bcc) consisting of at least 17 species, is a group of organisms consisting of extraordinary metabolic diversity that enables the inhabitants to colonize a wide range of environments (28). Some members of this complex have been leveraged for bioremediation applications, because of their ability to degrade pollutants in water and soils (29). There are also several strains in the Bcc that produce antifungal compounds and fix atmospheric nitrogen (28, 30). While the Bcc was originally identified as a plant pathogen (31), species in this complex generally have ecologically beneficial interactions with plants (32). Because of the ability of several species within the Bcc to colonize the rhizosphere on economically important crops, there has been interest in using Bcc isolates for plant-growth promotion (30). Issues with their use have arisen due to the fact that many species in *Burkholderia* have emerged as important human pathogens. These environmental organisms in the Bcc have been implicated as opportunistic pathogens for cystic fibrosis (CF) and immunocompromised patients.

Bcc species can cause severe respiratory infections in CF patients (33) and currently there is no distinction between environmental and clinical isolates, implying that the natural environment is the source of infections (34). Identified in 1984 as an increasing problem among CF patients and noting multiresistance to antibiotics, Bcc species were concluded to cause the *cepacia syndrome* (35). Although this syndrome is not common, it presents a high fatality rate and affects the ability of the patient to qualify for a lung transplant (33). Several strains within the Bcc are shown to be highly transmissible among patients through social contact (36, 37). Because these are ecologically diverse species, they can often survive in a variety of environments that can put human health in danger. Contaminated pharmaceuticals, cosmetics, disinfectants, and preservative products are a major source of Bcc bacteria. Furthermore, in the clinical setting, bacteria from this complex have been isolated from tap water, dialysis machines, nebulizers, catheters, blood gas analyzers, thermometers, ventilators, temperature sensors, solutions, and intravenous fluids (38, 39). One issue associated with the Bcc complex is their intrinsic resistance to most of the clinically available antimicrobials including aminoglycosides, quinolones, polymyxins, and β-lactams (40).

Another complex within *Burkholderia* is the *Burkholderia pseudomallei* complex (Bpc), which contains *B. singularis*, *B. oklahomensis*, *B. humptydooensis*, two putative novel species (41), *B. thailandensis*, and the Select Agents: *B. pseudomallei* and *B. mallei*, which can cause serious disease in humans and animals (42). *B. pseudomallei*, an organism found naturally in soil and water, causes the disease melioidosis in Southeast Asia, northern Australia, the Middle East, China, India, and South America (43, 44). The highest number of human cases is in Thailand, where it accounts for up to 20% of community-acquired septicemias. Melioidosis mostly affects adults, often with underlying predisposing conditions that result in an impaired immune response (42). There are a variety of clinical manifestations, both acute and chronic, although asymptomatic colonization has also been observed (45). *B. pseudomallei* is also recognized as a major veterinary pathogen, causing disease in many animal species, and is especially a concern for zoos (42). The other Select Agent, *B. mallei* causes the disease glanders (42), mainly a disease of equines, but can be transmitted to humans. The disease can be either acute or chronic, and the organism cannot persist outside its host. *Burkholderia mallei* is a clone of *B. pseudomallei*, which has gone through significant genomic reduction (46, 47). Both *B. mallei* and *B. pseudomallei* have been identified as pathogens of interest for many years, and knowledge on the mechanisms underlying their virulence has recently advanced (48).

Genus *Moraxella*

The genus *Moraxella* contains species that are coccoid or rod-shaped, but are all genetically related (49–51). *Moraxella* is in the class Gammaproteobacteria and the family *Moraxellaceae*, where there are 22 named species (http://www.bacterio.net/moraxella.html).

Several species within *Moraxella* cause clinical disease, while others are found as part of the natural human flora. *Moraxella lacunata* (52), *M. nonliquefaciens*, and *bovis* (53) have been associated with eye infections. Additionally, *M. nonliquefaciens* can cause septicemia in leukemic patients (54), but may also be found as part of normal airway flora (50, 55). The most clinically important species of this genus is *Moraxella catarrhalis*, which originally was thought of as a commensal of the upper respiratory tract but, as of late, has been identified to cause disease of the eye, ear, and sinus in children (56).

Only recently has there been clinical interest in *M. catarrhalis*, and as such, not much is known about the pathogenesis of the species. Phenotyping strategies have been developed for epidemiological typing, although none have been accepted internationally. Electrophoretic profiling of outer membrane proteins (57), typing of lipopolysaccharide (58), and isoelectric focusing of β-lactamase proteins (59) have all been proposed for typing this species. DNA techniques have also been developed, but there are no universally adopted techniques. Restriction endonuclease analysis (60, 61), macrorestriction enzyme (62), PFGE (63), strain-specific DNA probes (64), AFLP, and ribotyping (65, 66) have all been typing procedures discussed in the literature. As genetic studies are being conducted, the possibility of frequent horizontal gene transfer has become evident (67) allowing for the sharing of important genetic material potentially linked to

antibiotic resistance. There are greater than 100 whole-genome sequences for *M. catarrhalis* (68) and additional sequencing may lead to the identification of an appropriate and comprehensive typing system.

Historically, there is an inverse relationship between patient age and colonization of *M. catarrhalis* that is still present today (69, 70). While carriage rates are high in children, *M. catarrhalis* is also an opportunistic pathogen causing sinusitis, otitis media, tracheitis, bronchitis, and pneumonia, and can cause systemic disease (e.g., meningitis and sepsis) (51). *M. catarrhalis* is one of the top three pathogens in acute otitis media, which is a major cause of morbidity in early childhood (51). Infections in adults include laryngitis, bronchitis, and pneumonia, and a rare but serious infection is endocarditis. *Moraxella catarrhalis* can also manifest as a nosocomial pathogen, but without a reliable typing system, the conformation of the spread of the organism is difficult (51, 71). This species produces β-lactamase and thus has almost universal β-lactamase-mediated resistance to penicillins. *Moraxella catarrhalis* is also inherently resistant to trimethoprim; however, it is universally sensitive to most antibiotics used in respiratory infection treatments (72–74).

Conclusions

The *Acinetobacter*, *Burkholderia*, and *Moraxella* genera contain a mix of important human pathogens and environmental bacteria. The study of pathogenesis in these organisms is important not only to control the spread of infection but also in understanding the genetic effects that allow soil bacteria to transition to the colonization of the human host. A comprehensive study of environmental and clinical isolates will allow researchers to better understand the evolution of these clinically important genera. These studies will help guide more accurate diagnostics for human pathogens and will also help to understand the acquisition of antimicrobial resistance mechanisms, which will focus targeted treatment therapeutics.

Introduction

Zoonosis is described as an infectious disease that is transmitted primarily from animals to humans. More than 950 of some 1,500 known pathogens have been categorized as zoonotic[1], and, therefore, present a significant public health risk. Consequently, the World Health Organization is engaged to address the diseases caused by existing and emerging zoonoses. In addition, One Health Initiative has been launched to emphasize that both human and animal health are inextricably linked.[2] Zoonotic bacteria have assumed additional importance since more than two-thirds of all emerging pathogens during the last three decades are zoonotic in origin. These pathogens are represented by diverse taxa and are not restricted to any particular class or group of bacteria. Data from the European Union member states have shown zoonotic bacteria with high levels of antimicrobial resistance in humans, animals, and food, which is a concern for European food safety authorities.[3] Climate change may also affect the emergence of new zoonotic diseases particularly caused by pathogens whose life cycle exists partly outside of their human hosts.[4] Furthermore, effects of climate and climate changes, particularly on the vector-borne diseases, including the ones caused by the zoonotic bacteria, is a concern since rise in temperatures, precipitation, and climate-change driven changes in the animal hosts could help establish and spread zoonotic pathogens to newer geographical areas.[5] Zoonotic pathogens maintain either an ongoing reservoir life cycle in animals or arthropod vectors without maintaining a permanent life cycle in humans; in some cases the pathogens can jump the species barrier and maintain a permanent life cycle in humans, possibly not needing the animal reservoir. Figure 45.1 shows the potential for emerging new zoonotic pathogens as a consequence of increased interactions between humans, vectors, and companion and wild animals. Climate change, including higher precipitation and global warning, may also contribute to the emergence and/or enhanced virulence of zoonotic pathogens. These interactions allow species to jump hosts, get adapted and become opportunistic pathogens. The parasitic vectors and wild animals further aid in the maintenance and spread of potential zoonotic microbial agents. Zoonotic pathogens' ability to colonize human organs and their disease-causing capability varies considerably. Because these pathogens have evolved to live in multiple hosts including both vertebrates and invertebrates to maintain their enzootic lifestyle, their genomes have evolved to help them sustain life in different host environments. Some of them have a diminished ability to synthesize essential proteins because they can be acquired from the host. However, many of them retain their ability to make specific cofactors and vitamins to sustain efficient growth. These pathogens probably exploit receptors that are common in multiple hosts to colonize and/or gain entry into human hosts. Several groups of pathogens with representatives that can cause zoonotic disease are described in their own chapters in this book. In this chapter, we briefly discuss the pathogens of the following zoonotic genera: *Anaplasma, Bartonella, Borrelia, Brucella, Coxiella, Francisella*, and *Pasteurella*.

Anaplasma

The family *Anaplasmataceae* includes several tick-borne zoonotic pathogens. The genus *Anaplasma* is one of four genera placed in the newly organized family *Anaplasmataceae*. The other three genera in this family are *Ehrlichia*, *Neorickettsia*, and *Wolbachia*. However, this section will primarily focus on *Anaplasma phagocytophilum*. In the newly proposed taxonomic reclassification of the order *Anaplasmatales* by Dumler et al. in 2001, the three previously described species, *Ehrlichia equi*,

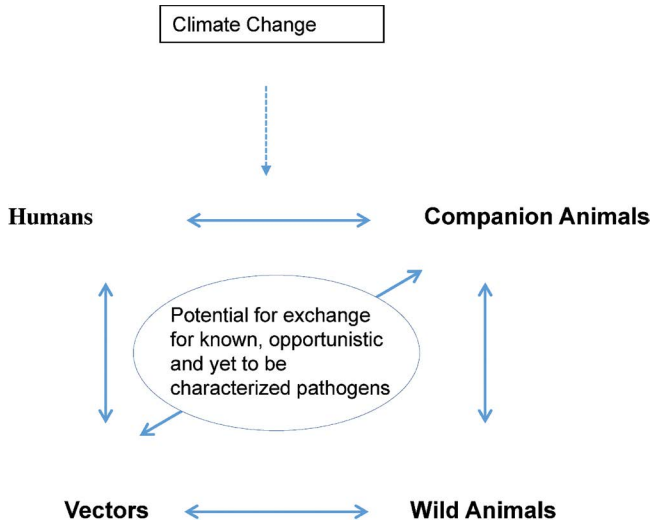

FIGURE 45.1 A schematic diagram of potential for emerging new zoonotic pathogens as a consequence of increased interaction among humans, companion animals, disease vectors, and wild animals. The relative likelihood of transmission and bacterial species jump in these hosts may vary.

Ehrlichia phagocytophila, and human granulocytic agent were combined and named as *A. phagocytophilum*.[6] This regrouping was justified by Dumler and colleagues following a molecular taxonomic approach that showed at least 99.1% nucleotide similarity in their 16S rRNA genes and identical GroESL amino acid sequences.[6]

A. phagocytophilum are pleomorphic, Gram-negative, small, obligate intracellular, zoonotic bacterium that are 0.5–1.5 µm in size. They reside and replicate in membrane-bound vacuoles of neutrophils of eukaryotic cells but can also infect bone marrow progenitors and endothelial cells.[7,8] The other rickettsia that infects granulocytes is *Ehrlichia ewingii*, but it is primarily confined to dogs even though it has been reported to cause infection in humans as well.[9] Some of the common natural hosts for *A. phagocytophilum* are humans, deer, horses, sheep, cattle, bison, and wild rodents. This pathogen cannot be transmitted transovarially in the invertebrate hosts.[10] *A. phagocytophilum* exhibit leukocyte-specific tropisms and infect granulocytes; hence the disease it causes was named granulocytic anaplasmosis. A wide range of vertebrate animals including horses, sheep, and humans can develop granulocytic anaplasmosis. It is a relatively uncommon zoonotic disease in humans and was first recognized in the upper midwestern United States in 1994.[11,12] However, equine granulocytic anaplasmosis has been described as early as 1968 in the western United States and Canada[13] and in dogs in 1982.[14] *A. phagocytophilum* infections have been described in California, the upper midwestern and northeastern regions of the United States, British Columbia, Great Britain, and Europe.

This pathogen multiplies in granulocytes and forms membrane-bound, intracytoplasmic colonies known as morulae,[15] which could be seen in the peripheral smear of the blood upon staining with Giemsa stain. The symptoms of granulocytic anaplasmosis are not remarkable and overlap with other tick-borne diseases. Symptoms include undifferentiated febrile illness, rigors, headache, myalgia, and malaise often accompanied by leucopenia and thrombocytopenia. Elevation of liver enzymes such as alanine aminotransferase and aspartate aminotransferase has also been reported but the presence of skin rash is not common.

Since granulocytic anaplasmosis is a tick-borne disease, it is seasonal and often coincides with tick and human outdoor activities (hiking, camping, etc.) in tick-endemic wooded areas. Due to the seasonality of the disease, its transmission and dissemination is intertwined with the 2-year life cycle of the tick vectors, specifically their activities in spring and summer. The disease could be acquired when an *A. phagocytophilum* infected tick of the *Ixodes ricinus* complex transmits the pathogen to the host during a blood meal. Tick vectors differ in different geographic areas. It is transmitted by *Ixodes pacificus* in the western United States, *Ixodes scapularis* in the midwestern and eastern United States,[16,17] *I. ricinus* in Europe, and *Ixodes persulcatus* in Asia. The tick life cycle could be considered starting with a newly hatched tick larvae parasitizing on white-footed mice in spring. The larvae feed on the mice over the summer and then molt to the nymphal stage. At the nymphal stage, ticks typically acquire the pathogen from the blood meal of their hosts, which could be rodents, deer, or humans. Over winter, nymphs engage in another blood meal before falling off from the host and molting into an adult stage. Adults, both males and females, then search for another host, such as white-tailed deer, and mate there. Subsequently, females drop off and lay eggs. The eggs hatch and repeat the life cycle next spring. The risk of human infestation is higher when the nymphal tick is searching for a new host, although larvae and adults are capable of feeding on humans as well. Humans can get infected via a blood meal by an infected tick. Studies on mice suggested that infected nymphs may transmit the pathogen within 24 hours of attachment to the host.[18] The main mammalian reservoir for *A. phagocytophilum* is the white-footed mouse (*Peromyscus leucopus*), although white tailed deer (*Odocoileus virginianus*) also play a role in the maintenance of the pathogen. Other reported vertebrate hosts included humans, cats, sheep, cattle, horses, llamas, bison, etc., whereas ticks are the invertebrate hosts. Granulocytic anaplasmosis is rarely a fatal disease, although it could be fatal in immunocompromised individuals.

A probable diagnosis for granulocytic anaplasmosis includes a febrile illness with a history of tick exposure/bite, the presence of intracytoplasmic morulae in a blood smear (Figure 45.2), more than four times *A. phagocytophilum* antibodies than the cutoff, or a positive polymerase chain reaction (PCR) result for the pathogen using *Anaplasma*-specific primers. Since *A. phagocytophilum* is an obligate intracellular pathogen, it is quite difficult to culture this pathogen in the laboratory routinely. However, it could be cultured in HeLa cells[19] and has been successfully

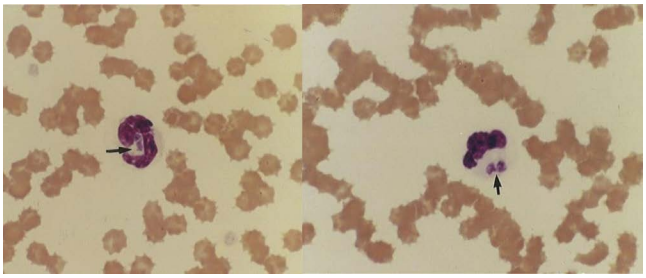

FIGURE 45.2 *Anaplasma phagocytophilum* morulae within the cytoplasm of a cat granulocyte.

cultured in a tick cell line as well.[20] Availability of the culture grown *Anaplasma* cells have advanced our knowledge of the pathogen's physiology and genomics. The genome size of *A. phagocytophilum* strains has been found to be remarkably consistent in size, conserved in genomic content, and ranges between 1.47 Mb and 1.51 Mb.[10] The genome, despite numerous repeats, shows flexibility and harbor genes that allow them to have a dual existence (as invertebrate symbionts and human/animal pathogens).[6] The genome contains 1,369 open reading frames including genes for major vitamins, co-factors and nucleotides, but with a limited ability to make amino acids.[10] Since this pathogen lacks the genes for biosynthesis of lipopolysaccharide and most of the genes of peptidoglycan biosynthesis,[21] it does not trigger a robust immune response.[22] A significant percent of its genome is dedicated to nucleotide, co-factor and vitamin biosynthesis, and protein synthesis, but less for the regulatory and metabolic functions.[10] Limited genotypic studies on the pathogen suggests that not all *A. phagocytophilum* strains are equal. Disparities exist in disease incidence in different endemic areas, clinical severity, seroprevalences and disease manifestation in humans, horses, cattle, ruminants, etc. from both North America and Europe, suggesting there may be yet-to-be-understood genotypic differences that exist among strains of this species.[16,23,24] Several 16S rRNA gene-based variants of *A. phagocytophilum* have been described from animal isolates.[16,25–27] Based on the genetic variants found in Rhode Island and Connecticut, Massung et al. have hypothesized that some variants are incapable of infecting humans. Further, in areas where these variants are predominant in ticks, a lower incidence of human infection causing strains would be expected in ticks in these areas and consequently a lower number of human cases.[16,25–27]Although 16S rRNA gene of the human isolates are found to be identical, genetic divergence in *A. phagocytophilum* has been noted when comparing their ankyrin gene, *ankA* or membrane surface protein 4 gene, *msp4*.[28,29] Cows with granulocytic anaplasmosis could be infected with multiple variants of *A. phagocytophilum* at the same time.[30] High levels of IFN-γ, IL-10, IL-12, and serum ferritin have been observed in patients with *A. phagocytophilum* infection. However, the severity of infection could be correlated with the level of IL-12 and ferritin and the ratio of IL-10 to IFN-γ in serum.[31,32] A pathophysiological role for proinflammatory response in human anaplasmosis have been proposed recently. In a case control study that measured select cytokines in sera from patients with human anaplasmosis (HA) and healthy control subjects, it was observed that proinflammatory cytokines, particularly, IFN-γ, on average were 7.8 times higher in HA patients. In addition, IL-1β, IL-8, IL-6, TNF-α, and IL-10 were significantly associated with severity of thrombocytopenia. Higher concentrations of IL-13 and IL-5 were associated with diarrhea and vomiting symptoms.[33] In laboratory study, sarolaner (Simparica™) prevented the transmission of *A. phagocytophilum* in dogs after being challenged with infected ticks.[34]

Additional immune-response studies in humans are needed to assess their complete biological significance, specifically with respect to in the pathogen's virulence potential and differences in host susceptibility. A conserved membrane protein, VirB10 of *A. phagocytophilum* type 4 secretion has shown promise as a vaccine candidate in mouse model. This vaccine showed partial protection against *A. phagocytophilum* challenge through the production of IFN-γ CD^+ T cells.[35] Doxycycline and rifampin are the most effective drugs based on the susceptibility testing[28]; most people do recover if a timely therapy is instituted. Since this pathogen is present in blood, there is a potential risk for anaplasmosis if a recipient received *A. phagocytophilum*-infected blood from a donor. Interestingly, mechanisms used by the *A. phagocytophilum* to infect and multiply in ticks, and in vertebrate host cells, appear to be conserved across all tick species and vertebrate hosts.[36]

Bartonella

Members of the genus *Bartonella* are small, Gram-negative, aerobic α-proteobacteria, which also includes genera such as *Agrobacterium, Brucella*, *Rhizobium*, and *Rickettsia*.[37] Many *Bartonella* species are potential zoonotic pathogens including *B. bacilliformis, B. henselae, B. quintana, B. elizabethae, B. grahamii, B. koehlerae, B. vinsonii*, and *B. washoensis*.[38,39] The first species characterized was *B. bacilliformis* that was associated with infections in the Peruvian Andes.[40] *B. quintana* was isolated in 1960 and identified as the causative agent of trench fever, a disease that infected over a million soldiers during World War I.[41] The more extensive recognition of *Bartonella* species causing a wider range of infections occurred following the beginning of the AIDS epidemic, where immunocompromised individuals developed various diseases manifestations that were tied to *Bartonella* infections.[42] One of the challenges to earlier recognition of *Bartonella* serving as a source of human infections was the challenge in culturing the fastidious pathogens that often required weeks to grow for primary culture. With the advent of improved molecular detection (PCR, DNA sequencing, etc.) and serological methods there was a wider understanding of the diseases associated with the genus.[43] In tissues, the organisms are visible with Warthin-Starry silver impregnation stain as tightly compacted clumps. In red blood cells, the organisms can be identified by May-Grünwald-Giemsa staining.[44]

The current, most common species associated with human infections is *B. henselae*, the causative agent of cat-scratch disease (CSD).[45] Based on insurance claim data, there are approximately 12,500 CSD infections diagnosed in the United States each year, with the majority of the cases being relatively mild, producing a lesion at the bite/scratch site and regional lymphadenopathy; however, ~500 cases required hospitalization.[46] Zoonotic transmission of *B. henselae* to humans generally occurs through a cat scratch, cat flea bite, or possibly less likely through a tick bite.[39] The organisms are present in flea feces and are transmitted to humans following disruption of the epithelial barrier during scratching or biting.

The prevalence of *B. henselae* in cats is generally higher in areas of warmer and more humid climates and lower in colder climates; for example, in the Philippines the prevalence was 68% and 0% in Norway.[44] Likewise in the United States, the highest incidence of infections is in the southern states and lower in the northern and western mountain states. This distribution is likely due to the numbers of cat fleas present throughout the year in the different locations. Cats were generally found to be asymptomatic carriers of the organism in experimentally infected conditions, although the bacterium was able to persist for up to

32 weeks.[47] The organism can persist in the feline bloodstream within erythrocytes and potentially invade blood vessel endothelial cells. Endothelial invasion has been noted *in vitro*, but not yet identified *in vivo*.[48] The vast majority of cases of bartonellosis in immunocompetent individuals present as typical CSD with limited regional lymphadenopathy and red-to-brown papules at the site of infection. However, 10–20% of patients may have multiple lymph nodes affected during the disease course. In addition to the skin lesions and lymphadenopathy, many patients report low-grade fever, malaise, headache, or sore throat. Atypical CSD occurs in 11–12% of patients and involves additional disease manifestations including granulomatous conjunctivitis, hepatitis and splenitis, osteitis, pneumonitis, and neurological pathologies.[37] In addition, patients infected with *B. henselae* or *B. quintana* may develop endocarditis or bacillary angiomatosis (BA), a proliferative disease of the vascular tissue that can lead to papular lesions of the skin or impact a number of different internal organs. BA is most commonly seen in immunocompromised patients, such as those with HIV infections or who have had a transplant.[48] *B. quintana*, which is carried by fleas and lice, is the causative agent of trench fever that impacted several troops during World War I. People who develop trench fever often have high fevers, severe headache, especially behind the eyes, and pain in the legs and back.[49]

Typical CSD infections are primarily diagnosed clinically based on the history of a cat bite or scratch and the detection of enlarged lymph nodes and the granulomatous lesion at the infection site. The detection of atypical *B. henselae* infections relies on diagnostic testing including serology, PCR-based detection, or direct culture of the pathogen, which is often problematic due to the fastidious nature of the organism and the long incubation period for growth.[44] Direct culture is important however since some patients with BA do not generate a detectable antibody response. Antimicrobial therapy for *B. henselae* infections generally includes macrolides such as erythromycin, azithromycin or clarithromycin, doxycycline, and rifampin.[48] A meta-analysis of the treatment for CSD, found that antimicrobial therapy did not reduce the cure rate or duration of infection in most patients.[50] Prevention of infection appears to be the most effective way to limit the impact of *B. henselae* on human health. For example, immunocompromised individuals that choose to have pets should adopt those that are serologically negative for *Bartonella* exposure and work to limit flea infestation on the animals to break the chain of transmission of the pathogen.[44]

Borrelia

Although our understanding of the genetics and pathophysiology of *Borrelia* has been significantly better now due to tools available in genomics, proteomics, and bioinformatics, an effective vaccine for humans remains elusive. The genus *Borrelia*, which presently consists of 11 genospecies, belongs to the family *Spirochaetaceae*. However, not all species are present in all endemic locations and of the 11 genospecies only *Borrelia andersonii*, *Borrelia bissettii*, and *Borrelia burgdorferi* sensu stricto have been identified in North America. Seven species, including *Borrelia garinii*, *Borrelia afzelii*, *Borrelia valaisiana, Borrelia japonica*, *Borrelia tanukii*, *Borrelia turdi*, and *Borrelia sinica* have been identified from Asia. The five European species are *B. burgdorferi* sensu stricto, *B. garinii*, *B. afzelii*, *B. valaisiana,* and *Borrelia lusitaniae*.[51] This pathogen is transmitted by vectors of the *I. persulcatus* complex (also called the *I. ricinus* complex). *I. scapularis* is the principal vector for this pathogen in the northeastern and north-central United States, whereas *I. pacificus* is the primary vector in the western United States. *I. ricinus* and *I. persulcatus* are the principal vectors for Europe and Asia, respectively. Interestingly, not all *Borrelia* species are known to cause infections. Based on several genetic and immunologic considerations, all *Borrelia* species could be placed into three phylogenetic distinct genomic clusters: *B. burgdorferi* sensu stricto, *B. garinii*, and *B. afzelii*. In the United States, *B. burgdorferi* sensu stricto used to be the only species that caused infection in humans but in 2014 another species, named as *B. mayonii* has been reported to cause Lyme disease and it can be detected by a PCR test from blood.[52–54]

The full syndrome of Lyme disease was initially recognized as juvenile rheumatoid arthritis in Connecticut, United States in 1975. However, this spirochetal bacterium was discovered by Willy Burgdorferi and colleagues in 1981 from the nymph of the tick, *I. scapularis*[55] that was subsequently linked to Lyme disease as recognized by Steere et al. and others.[56,57] *Borrelia* are highly motile, corkscrew shaped, endoflagellated bacterium with cells 10–30 µm long and 0.2–0.5 µm wide. It has a relatively small genome of ~1.5 Mb, which consists of a linear chromosome (~0.91 Mb) and 21 plasmids (nine circular and 12 linear) with a G + C content of 28.6%. The genome contains ~1,701 predicted genes. However, a whole genome sequence comparison of 13 *B. burgdorferi* isolates suggested the range of genome size between 1.35 Mb and 1.52 Mb and the number of plasmids in strains can vary between 13 and 21.[58] Some plasmids are essential and are considered as mini chromosomes. Unlike other prokaryotic genomes, the *B. burgdorferi* genome is unique because of its linear chromosome and multiple linear plasmids. A 16S rRNA gene-based PCR assay based on the two highly conserved segments of the gene has been developed to detect *Borrelia*.[59] Its genomic novelty is also due to the presence of over 150 lipoprotein-encoding genes, including a surface exposed lipoprotein called VlsE that undergoes extensive antigenic variation.[60] Analysis of the plasmid sequence suggests evidence of recent genomic rearrangement.[53] *B. burgdorferi* genome encodes for a limited number of biosynthetic proteins and therefore has to depend on its host for many of its nutritional needs. Since this pathogen makes no known toxins, it causes infection by attaching to the host cells and migrating through the tissues.

B. burgdorferi sensu lato maintains a complicated enzootic life cycle in nature, which involves one of ticks of the *I. persulcatus* complex and a range of animal hosts. Both the transmission vectors and the animal hosts vary depending upon geographic locations. Its incidence in 2012 in the United States was 7.0 cases per 100,000 persons. However, the incidence is higher in the eastern coastal states, i.e., New Hampshire: 75.9, Maine: 66.6, Vermont: 61.7 per 100,000 persons.[61] Lyme disease can be acquired after being bitten by a *B. burgdorferi*-infected tick that engages in a blood meal from the host. Small mammals serve as the reservoir for this pathogen for the vector's larva and nymphs, whereas the white-tailed deer is the reservoir for the adults. Once infected with the pathogen, larvae can maintain the agent during molting

to nymph and adult stages. Lyme disease has multiple phases and typically starts with a spreading skin lesion (*erythema migrans*) at the tick bite site (phase 1). This typically happens in spring and/or summer months when tick activity is usually high. In phase 2, which could occur within days to weeks of phase 1, the pathogen may cause additional skin lesions or infect other organs such as the heart, joints or even the nervous system. In phase 3, which may begin within months to years after the initial bite, is a stage where manifestation of the latent infections takes place. Recently, cases of cardiac bradydysrhythmia have been reported in cats from Lyme borreliosis[62] and this disease was consistent with what has been reported in humans and dogs.

As expected for vector-borne pathogens, *B. burgdorferi* sensu lato genome expresses different genes in response to different microenvironments as part of its multiple-host associated life cycle. Not all genes that are expressed in mammalian hosts are expressed in tick vectors or vice versa.[63] Outer surface proteins (Osp), which are lipoproteins, are among the major antigens of this pathogen. OspA and OspB are expressed in the midgut of the tick vector, whereas OspC is expressed in the salivary gland of the tick once the pathogen migrates there.

The presence of *B. burgdorferi* in a clinical sample could be determined in a laboratory by several approaches, including the direct observation of the pathogen under a microscope. Biopsy material from skin lesions or cerebrospinal fluid or blood samples may be used to isolate the agent in the original Kelly medium[64] or its modified versions such as Barbour-Stoenner-Kelly II medium (BSK-II), BSK-H, Kelly–Pettenkofer (MKP) medium.[53] *B. burgdorferi* sensu lato has a long generation time of 7–20 hours, which necessitates a long incubation period, often up to 12 weeks to detect a positive culture. However, daily microscopic examination of the culture supernatant could facilitate detection within a week in many cases.[65] The time to infer a positive culture could be further reduced by testing the culture supernatant by PCR even before it is suspected to be positive by microscopic examination.[66] In general, recovery of the *B. burgdorferi* was best achieved from skin lesion biopsy followed by plasma, serum and whole blood, respectively. The latter three are poor clinical samples for a Lyme PCR assay probably because of the low number of the organisms present or the presence of PCR inhibitors. A number of qualitative and quantitative PCR-based diagnostic assays have been developed and these assays could target either chromosomally encoded genes (such as the 16S and 23S rRNA genes, 5S-23S rRNA intergenic region, *recA*, *flab*, *p66*, etc.) or the plasmid encoded gene *ospA*, and not each target gene has the same level of sensitivity.[67] To confirm Lyme arthritis, PCR-based assays rather than the culture method are recommended from the synovial fluids of the affected joints.[51]

Immunologically, Lyme borreliosis is frequently diagnosed by detecting antibodies in the host's serum against a panel of *B. burgdorferi* antigens that are available as part of the Lyme borreliosis detection kits. Both IgG and IgM antibodies could be detected against *B. burgdorferi* FlaB (41 kDa) and FlaA (37 kDa) antigens within days of exposure to the Lyme agent.[68] Plasmid encoded OspC, which is heterogeneous in nature (21–25 kDa), is another immunodominant antigen during the early stage of the disease.[39] Some of the other commercially available Lyme antibody detection kits use indirect immunofluorescent-antibody assay, enzyme-linked immunosorbent assay, or Western immunoblots or their variations. For the immunofluorescent-antibody assay, diluted serum titers of 128 or 256 that react with fixed Lyme antigen on the glass slide are considered a positive reaction.[69]

Western immunoblots are useful in determining the different stages of Lyme borreliosis as antibody response to different antigens varies. This assay is somewhat variable due to the different strain types and different geographic sources of strains used in the preparation of antigens. Newer enzyme immunoassays, which use recombinant antigens of OspC, vlsE, FlaA, P66, etc., have also been developed but their relative sensitivity and reactivity to corresponding IgM and IgG vary.[53] Borreliacidal antibody assays have also been developed to detect Lyme borreliosis by exploiting the killing properties of OspC in combination with a complex of complements that act upon the pathogen's outer surface proteins. The borreliacidal assay makes use of flow cytometry and/or staining dyes to distinguish the dead bacterial cells from the viable ones.[70] Overall, all diagnostic tests for Lyme borreliosis should be interpreted in the context of the endemicity of the pathogen in that geographic area, relevant travel history, clinical samples tested, duration of the infection following tick-bite and the type of assay used. *Borrelia*-induced monocyte and T-cell derived cytokines profile showed that they were influenced by both genetic and nongenetic factors.[71] Notably, age strongly impaired the IL-22 responses; activation of HIF-1 alpha was observed along with the increase in glycolysis derived lactate in Lyme disease patients.[71]

Lyme disease can be effectively treated with appropriate antibiotics during the early stage of infection whereas Lyme arthritis and neuroborreliosis can be effectively treated with third generation cephalosporins. However, prevention of exposure and early treatment should be the strategy for an effective management.[72] Vaccine development for Lyme disease has been fraught with frustration and technical challenges. Vaccines made from outer surface proteins, OspA, OspC, and OspA and OspC in combination has met with limited success. The recombinant OspA vaccine LYMErix had promise, but was withdrawn due to poor sales, need for a multiple booster shots, and the potential for an autoimmune response against human lymphocyte function associated antigen -1.[73] Using the combination of omics and bioinformatics approaches, an interactome of *Borrelia* proteins suggested two proteins, ErpY and ErpX, as potential targets for vaccine development.[74]

Brucella

Brucella species are important zoonotic pathogens that cause infections that manifest in different disease syndromes.[75] Several different species of livestock and other animals are normal hosts for members of the genus *Brucella*. Members of the genus have a high degree of genetic similarity, but are currently separated into multiple species, based largely on the animal hosts where they normally reside.[76] *Brucella abortus* is predominantly associated with cattle, *B. canis* with dogs, *B. ceti* and *B. pinnipedialis* with marine mammals, *B. melitensis* with goats, *B. neotomae* with rats, *B. ovis* with sheep, and *B. suis* with swine.[77,78] The most commonly associated species with zoonotic disease are *B. melitensis*, *B. abortus*, and *B. suis*.[79] The number of cases of brucellosis is

hard to determine, but it is likely that there are nearly 500,000 new cases each year worldwide.[80] Part of the challenge in determining the infection is that the symptoms of the acute phase of disease are the fairly nondescript "flu-like symptoms" that are associated with multiple infections.[78] The chronic phase of infection is more severe, in that after a 2- to 4-week latency period postinfection, the organism can be disseminated throughout the body where they infect tissues leading to endocarditis, meningitis, spondylitis, arthritis, or potential reproductive-system problems, such as inflammation of the epididymis and testes or spontaneous abortion if the disease occurs during pregnancy.[81] In more developed countries, the number of cases is relatively small, e.g., in the United States, the average number of infections reported annually is ~100.[81]

Brucella are Gram-negative, facultative, intracellular bacteria that are members of the α-proteobacteria along with organisms such as *Agrobacterium, Anaplasma, Bartonella*, *Rhizobium*, and *Rickettsia*. A distinctive feature of some *Brucella* species is the presence of two chromosomes in their genome. Species with two chromosomes include *B. abortus, B. melitensis*, and some biotypes of *B. suis* (others contain a single larger chromosome)[62] and there appears to be some duplication of genes between each chromosome. *Brucella* also lack several of the virulence factors that are characteristic of other Gram-negative pathogens, including many toxins and type 3 secretion systems. Due to this genetic reductionism in prototypical virulence factors, *Brucella* have evolved other characteristics that facilitate intracellular pathogenesis. The bacteria have acquired genes associated with acid tolerance that allow for transversion of the upper gastrointestinal and within phagocytic vesicles and they have modified lipopolysaccharide (LPS) antigens that make *Brucella* less immunogenic than that of most Gram-negative organisms.[79,82], The modified LPS layer limits the activation of the alternative complement pathway and production of certain cytokines, as well as decreasing the susceptibility to bactericidal substances produced by the host. The mild immune response and resistance to toxic substance likely allows for the persistence of the organism in a host.[77] Additionally, *Brucella* express a VirB type 4 secretion system (T4SS) that allows for the transfer of effector molecules to the host cells allowing for protection during the intracellular phase of infection.[78,83]

The zoonotic transmission of *Brucella* occurs primarily through direct contact with or consumption of contaminated animal products or inhalation of aerosolized particles containing infectious bacteria. The most common cause of infection in the United States is associated with the consumption unpasteurized dairy products originating from *Brucella* endemic areas.[81] However, infections associated with occupational exposure of animal caretakers, veterinarians, and laboratory personnel have also been reported. A recent systemic review of the literature has shown that there have been isolated reports of human-to-human transmission of *Brucella*, most commonly through breast feeding, as well as through sexual contact, aerosol exposure, and via blood transfusion or bone marrow transplantation.[84] During the infectious process, the organisms penetrate the nasal, oral, or pharyngeal mucosa and enter phagocytes that are transferred to regional lymph nodes.[77] The exact mechanism by which *Brucella* enter the cells is not fully understood. However, the organisms that enter phagocytes are able to survive in a *Brucella*-containing vacuole (BCV) and avoid fusion with the lysosome[79] and a key contributor to the ability to survive and persist in the BCV is the expression of the VirB T4SS factors that impact intracellular trafficking and persistence.[79,83] After the postinfection latency period, the organism may be released from the phagocytes and widely disseminated throughout the body leading to debilitating disease.[80]

The most effective way to limit brucellosis is to prevent human infections by preventing infection in livestock and through the pasteurization of dairy products.[85] Currently there are effective veterinary vaccines against *B. melitensis* and *B. abortus,* which have helped to limit the number of human infections in the United States. Consequently, many of the human brucellosis cases are likely associated with the consumption of unpasteurized dairy products illegally brought in from countries where brucellosis in animals remains a problem. The recommended treatment of brucellosis is a multidrug approach that includes doxycycline, streptomycin, and rifampin. Other agents effective against *Brucella* include gentamicin, trimethoprim/sulfamethoxazole, and the fluoroquinolones.[81,86]

Coxiella

Coxiella burnetii is the causative agent of Q fever, a disease found throughout the world. The microorganisms are Gram-negative coccobacilli that are obligate intracellular pathogens. Genetically, the organisms are closely related to *Legionella pneumophila* and are members of the γ-proteobacteria.[87] *C. burnetii* is a clonal pathogen and its genetic variation is achieved through single nucleotide polymorphisms, and many of them are nonsynonymous.[88] Some *C. burnetii* cells exist as relatively dormant small colony variants. These organisms tend to be more resistant to chemical agents and heating. Small colony variants are more resistant to the environmental stresses of the external environments and are the primary form of inhaled microorganisms.[89] Other cells are transformed into large cell variants that are able to multiply within macrophages and monocytes. As *C. burnetii* are taken up by the phagocytes, they enter the phagosome. As the small colony variants enter the phagosome, they appear to delay lysosomal fusion and are transformed into the large cell variant state prior to the formation of the phagolysosome. The low pH environment of the phagolysosome serves as the site of cellular reproduction.[90] *C. burnetii* also can undergo antigenic phase variation following isolation. Organisms recently isolated from humans or other animals display a phase I type antigenic profile consisting of a thick lipopolysaccharide layer capable of blocking antibodies from binding to the surface of the organism. The enhanced lipopolysaccharide layer is one of the major virulence factors employed by *C. burnetii*. Upon repeated passage of the microorganisms in cell culture or embryonated eggs, *C. burnetii* can shift to displaying the phase II antigenic structure, which is characterized by having an altered lipopolysaccharide structure and reduced infectivity.[91]

Several different animal species may be infected with *C. burnetii*, including many mammals, birds, fish, and arthropods such as ticks. Among mammals, cattle, sheep, goats, cats, and dogs are potential sources of human infections. Spread to humans is generally through direct contact with infected animals, their

byproducts, or through the inhalation of microorganisms that are aerosolized or associated with dust. In infected animals, such as sheep, the placenta may have a very high level of *C. burnetii* that can be aerosolized following birth and serve as a source of infection. Additionally, the hides of infected animals are also a potential source of infection, especially for abattoir workers.[87] Multiple genotypic tools including comparative genome hybridization have identified eight genogroups (genogroup I–VIII),[92] but not all genomic groups of *C. burnetii* are equally virulent.[93]

C. burnetii infections can present as either an acute illness or as a chronic disease. Many patients with an acute form of Q fever present with a fever that may be associated with pneumonia and hepatitis. However, in some cases, fever may not be present, while in others, it can last a week or more. In one preantibiotic era study, the length of fever ranged from 5 to 57 days with a median of 10 days.[87,94] There is a high level of variation in patient presentation, which can confound the diagnosis. The mortality rate of acute infections is around 1–2% and is often associated with more severe manifestations of Q fever such as myocarditis. In addition to fever, many patients with acute Q fever also have severe headaches, night sweats, muscle and joint pain, and anorexia, leading to rapid weight loss. The early treatment of patients with an antibiotic, such as doxycycline, appears to reduce the length of fever and decreases the recovery time in patients with pneumonia. Patients who develop pneumonia are characterized by having fever, a nonproductive cough that often expels blood and a severe headache. Radiographic findings are often nonspecific and of limited value for diagnosing Q fever.[95]

In patients who develop chronic disease, endocarditis is the major manifestation, accounting for 60–70% of the cases and the detection of endocarditis is often delayed up to a year or more from onset to symptoms, which is associated with significant morbidity. Patients who do not receive antimicrobial therapy for the endocarditis have a high level of mortality. Primary risk factors for patients to develop endocarditis include having an underlying condition, such as a heart valve abnormality, or being immunocompromised.[87] In addition to endocarditis, other presentations can occur, including bone and joint infections, infections of the kidney, liver, or lungs, or a recrudescence of disease during pregnancy. Pregnancy related infections have been associated with premature birth, miscarriage, and neonatal mortality.[94]

The clinical diagnosis of Q fever can be difficult due to the variable nature of disease presentation. Due to the zoonotic nature, a history of animal exposure to animals known to be associated with Q fever may be helpful. Laboratory testing for *C. burnetii* antibodies is the current best diagnostic tool and the primary detection method is through indirect fluorescence detection.[91] Other serological tests based on complement fixation and enzyme immunoassays are available, but appear to lack the desired specificity and sensitivity for detection. Interestingly, the antibodies against the phase II antigens are generally higher in acute infections and phase I antigens are elevated in chronic infections. Other detection methods are available that utilize PCR detection of the organisms or rely on histological changes in infected tissue. Presently, neither PCR, nor histological testing appears to be as valuable as serology for the detection of Q fever.[87]

The treatment of Q fever is dependent on the type of infection. For acute infections, doxycycline treatment for 2 weeks is valuable in reducing the length of fever and/or pneumonia.[91] In children who are infected, treatment with trimethoprim/sulfamethoxazole is preferred. Treatment for patients with chronic endocarditis is controversial with some advocating lifelong antibiotic treatment while others recommending shorter courses of 1.5–2 years with combination therapy.[87] Combination of doxycycline with hydroxychloroquine appears to be effective in the treatment of chronic endocarditis. Hydroxychloroquine raises the pH of the phagolysosome, allowing the doxycycline to function with greater efficiency in clearing the infection. The use of trimethoprim/sulfamethoxazole to treat *C. burnetii* infections during pregnancy limits the risk for spontaneous abortion and neonatal infections and may prevent recrudescence.[87,96] In some countries, there are effective vaccines available to prevent Q fever. However, in the United States, there is only an investigational vaccine available for laboratory workers who handle live microorganisms. When available, people who are at greatest risk for exposure (abattoir workers, laboratory personnel, animal handlers) should receive the vaccine to limit infection.[94,96]

Francisella

The genus *Francisella* is part of the γ-proteobacteria along with genera such as *Escherichia, Pseudomonas, Salmonella, Yersinia*, and *Vibrio. Francisella tularensis* is a small Gram-negative coccobacillus-shaped organism that is the causative agent of the disease tularemia.[97] Multiple animal species are known to host *F. tularensis*, including rabbits, ground squirrels, muskrats and other rodents.[98] In addition, the bacterium can be carried by many arthropod vectors, including several species of ticks, mosquitoes, and biting flies.[99] *F. tularensis* is divided into three subspecies, *tularensis, holarctica*, and *mediasiatica,* each having varying degrees of virulence in rabbits and humans, with *tularensis* and *holarctica* being most virulent to humans.[100,101] A second species, *F. novicida* is a the cause of a limited number of human infections, predominantly in immunocompromised patients.[101]

While the incidence of tularemia in the United States has been declining since the 1930s, there are concerns about the potential use of *F. tularensis* as a bioterrorism agent.[100,102] Cases of tularemia are likely under diagnosed, since many strains lack the significant virulence factors that are associated with severe disease. In highly virulent strains, an infectious dose of less than 10 colony-forming units can cause significant illness with mortality rates of up to 5–10%, without appropriate antimicrobial therapy.[103] The spectrum of disease associated with *F. tularensis* infections is quite varied depending on the route of infection. The most common manifestation is ulceroglandular tularemia, which is characterized initially by chills, fever, headache, and body pain that develop 3–6 days postinfection. Transmission of the pathogen to humans can occur through handling infected wild game, being bitten by an insect vector that recently fed on an infected mammal, or through contaminated water.[99] With ulceroglandular infections, an ulcer often develops at the site of infection that can persist for months. The bacteria can also enter the lymphatic system and migrate to the regional lymph nodes, causing swelling of the nodes. Glandular infections can progress without the development of the ulcerative skin lesion. In some

cases, the bacteria can infect other tissues of the body leading to increased morbidity.

Other routes of infection include the eye, pharynx, gastrointestinal (GI) tract, and lungs leading to different disease syndromes and clinical outcomes. Oculoglandular infections, or Parinaud's syndrome, originate in the conjunctiva of the eye and progress with ulceration of the cornea and regional lymph node involvement.[99] Oropharyngeal and GI tularemia typically occurs after the consumption of contaminated food or water and may result in a painful infection of the throat, with tonsillitis and enlargement of the cervical and mesenteric lymph nodes that can drain into the GI tract.[100,103] Patients may also develop bowel ulceration and accompanied by GI bleeding, diarrhea, and vomiting that can lead to shock. Consequently, the case fatality rate may be as high as 60% with GI involvement.[99] Patients can also develop typhoidal tularemia, which can be problematic to diagnose due to the lack of distinct signs and/or apparent routes of infection common to other types of tularemia infections. Most patients have a high-grade fever, but other signs may be more variable.[97,100] Pneumonic infections can also develop through hematogenous spread during the progression of ulceroglandular tularemia[97] and the fatality rate of pneumonic infections is nearly 40%.[99] Pneumonic tularemia is typically the most acutely severe form of tularemia occurring following inhalation of the bacteria. Those with the greatest risk of pneumonic tularemia include farmers, landscapers, and laboratory workers who come in contact with aerosols or dust containing *F. tularensis*.[99]

Tularemia diagnosis is often dependent on the signs and symptoms associated with the different types of disease manifestation. For example, ulceroglandular tularemia is characterized by the ulcerative lesion that develop at the site of infection and the corresponding enlargement and tenderness of the adjacent lymph nodes to the site of infection.[97,100] Culturing of the infecting *F. tularensis* is the most definitive method of confirming an infection, however there are challenges as the culture media needs enrichment with cysteine to facilitate growth, however blood culture is often negative for growth of the organisms.[99] Serological testing has also been shown to have diagnostic utility for the detection of tularemia, however there is the potential for cross reactivity with other bacterial pathogens that can confound the interpretation of results.[99] Another drawback of serological testing is the delay of 2–4 weeks postinfection required to develop a high enough antibody titer to be detected efficiently.[98,100] PCR has also been shown to have utility in the detection of *F. tularensis* in certain samples, for example PCR has shown to be effective in the detection of *F. tularensis* from ulceroglandular primary lesions, blood, and respiratory specimens.[100,104]

Early and appropriate antimicrobial therapy is important for the treatment of severe cases of tularemia to avoid potential septic shock and respiratory distress. The primary antibiotic recommended includes the aminoglycosides, including streptomycin (first line), gentamicin, or kanamycin for 7–14 days. Other agents with efficacy include the tetracyclines and the fluoroquinolones. Relapse of infection is possible in some cases, especially if the antimicrobial prescribed is bacteriostatic, thus a longer course of therapy may be required.[97,100] Work continues on the development of an effective vaccine against *F. tularensis*. Such a vaccine would be most beneficial for people living in highly endemic areas involved in activities that put them at elevated risk for exposure, including laboratory personnel, hunters, outdoors people, and people working with potentially contaminated soils, such as landscapers and farmers.[97,105]

Pasteurella

Members of the genus *Pasteurella* are Gram-negative facultative anaerobes that are part of the γ-proteobacteria that are carried in the oral and gastrointestinal tract of many animal species.[106] The most common species associated with zoonotic disease is *P. multocida*.[107] *P. multocida* was first identified by Louis Pasteur as the causative agent of the poultry disease, fowl cholera, and has subsequently found to be a potential pathogen to a variety of animal species.[108] Other *Pasteurella* species associated with human disease include *P. canis, P. stomatis*, and *P. dagmatis*.[109] As many as 90% of cats and 66% of dogs carry *Pasteurella* asymptomatically and most of the human cases of pasteurellosis are due to animal bites or scratches. However, transmission can occur following contact with saliva from infected animals or inhalation of the agent.[110,111] It is estimated that between 20% and 50% of cat and dog bites become infected by *Pasteurella*.[111] *Pasteurella* can also be isolated from the upper respiratory tract of many livestock species as well and serve as a source of zoonotic transmission.[109,112] Many of these nonbite infections can lead to severe manifestations, including infections of the bone and joints, skin, soft tissue, meningitis, peritonitis, pneumonia, endocarditis, and septicemia. The initial exposure is through the oral/respiratory route leading to an initial colonization of the upper respiratory tract, followed by hematogenous spread to the affected organ system.[107,109,110,113,114] Between 16% and 31% of *Pasteurella* infections occur without apparent direct animal contact, which may be indicative of human-to-human transmission of the pathogens.[115]

The initial symptoms of skin and soft tissue infections, such as from animal bites, involves swelling and tenderness at the site of infection, followed by regional lymphadenopathy, wound discharge, and fever, which occur in approximately 20–40% of cases.[109] More severe manifestations may include septic arthritis and/or osteomyelitis, especially when the bite wound involves the periosteum where there is spread from soft tissue adjacent to the bone.[116] Additionally, patients receiving corticosteroids due to underlying arthritis are at increased risk of developing septic arthritis.[109] In rare cases, patients can develop *P. multocida*-associated septicemia that can lead to development of endocarditis and meningitis.[114,116,117] Most patients that develop septicemia often have pre-existing health conditions that predisposes them to the invasive disease.[113]

In the majority of non soft-tissue infections, the initial *Pasteurella* colonization often occurs through fimbriae-associated adherence in the upper respiratory tract to the mucosal epithelial cells. After skin and soft tissue, the respiratory tract is the most common site of infection, with the tonsils likely the primary site of colonization.[109] *P. multocida* cause upper respiratory disease such as sinusitis and bronchitis and lower respiratory tract infections, including empyema and pneumonia. Patients that develop lower respiratory illnesses typically have underlying pathologies.[116] There have also been reports of *Pasteurella*-associated urinary tract infections, endocarditis, and peritonitis.

Urinary tract infections are likely due to direct infection of urinary tract colonization rather than hematogenous spread.[110] A number of virulence factors have been identified in *Pasteurella* strains including those that encode the production of fimbriae, toxins, polysaccharide capsules, lipopolysaccharide, and iron acquisition proteins.[108] Toxins detected within virulent strains likely aid in the invasion of different host tissues,[109] while the capsule aids in resistance to complement and phagocyte-mediated killing, adherence and resistance to drying.[108]

The typical diagnosis of *Pasteurella* infections involves the clinical presentation and culture of the organisms from the site of infection or from the patient's blood.[112] Additionally, diagnostic technologies, such as the matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) can be used to identify *P. multocida*.[117] Penicillin or amoxicillin-clavulanic acid are the primary recommended therapies for most forms of *Pasteurella* infections.[109,118] If penicillins are contraindicated, macrolides, such as clindamycin, are recommended for use.[119] The treatment regimen is dependent on the severity of disease, with mild soft tissue infections treated with antibiotics on an outpatient basis, whereas more severe infections with deeper tissue and/or bone and joint involvement may require hospitalization and more aggressive antimicrobial and surgical interventional therapy.[118] The use of antimicrobial prophylaxis following animal bites remains somewhat controversial, however many clinicians recommend a short course of antimicrobials to reduce the risk of infection of the wound.[109]

Conclusions

The taxonomic diversity of zoonotic pathogens is quite substantial and ranges from mycobacteria, to Gram-positive to Gram-negative organisms. Some are obligate intracellular bacteria while others are not. Many zoonotic pathogens are spread by direct contact with another vertebrate host through contact or bite wounds, while others are transferred through an arthropod vector, such as a tick or mosquito. The number of potential zoonotic pathogens is also quite substantial but our understanding of many of them is quite limited. In this chapter, we focused on seven genera of zoonotic pathogens that were not covered in other chapters in this book. Some zoonotic pathogens, such as *Bacillus anthracis, F. tularensis*, and *Brucella abortus* have garnered renewed interests because of their potential role as bioterror agents. The list of new zoonotic pathogens is likely to grow as integration of MALDI-TOF mass spectrometry for bacterial identification in clinical microbiology laboratories has the potential to identify new and clinically relevant zoonotic pathogens from animal sources. Additionally, the "One Health" laboratory practice where clinical microbiologists overseeing both human and animal microbiological specimens may play a greater role in making zoonotic connections.

While a number of zoonotic pathogens are likely to increase, their control and prevention will be complicated due to high degree of diversity among these pathogens and many modes of transmission. Steady surveillance of infectious diseases in wild and domesticated animals, animal reservoirs, known vectors, and monitoring human exposure will not only enhance our understanding of the ecology of many of the zoonotic pathogens, but also zoonotic pathogen prevalence and their transmission dynamics. Knowledge of the ecological factors that promote the emergence of zoonotic pathogens will help us create ways to reduce or break the transmission cycles. Zoonotic pathogens and diseases remain a significant cause of morbidity and mortality throughout the world and an increased understanding of these pathogens and their ecology is warranted.

Acknowledgment

Authors would like to acknowledge Krishna Ganta for proofreading the manuscript. SKS would like to acknowledge the support from Marshfield Clinic Research Institute. The material described in this manuscript is not a formal dissemination of information by FDA and does not represent agency position or policy.

The Fungus Kingdom Mycota

The Mycota is one of the taxonomic kingdoms of life, and all members of the kingdom share a set of characteristics that separates them from the other kingdoms. Genomic evidence shows that this kingdom has a closer evolutionary relationship to the animal kingdom than to any other eukaryotic kingdom, which is a factor with clinical implications that will be addressed later in this chapter [1–4].

Based on genomic and ultrastructural evidence, various Mycologists have subdivided the Mycota into at least a dozen phyla, and this chapter describes the 11 that appear to be the most valid (some very briefly) [2–5]. All 11 are treated as separate phyla for consistency, even though there is uncertainty about the status of some of them. The names of these phyla refer to some unique feature of the phylum or to a representative member of the phylum, and (with one exception) these names end with the suffix -mycota.

The Mycota include four phyla with swimming zoospores, a primitive feature that reflects the aquatic ancestry of this kingdom: the Chytridiomycota, Blastocladiomycota, Neocallimastigomycota, and Olpidiomycota [2, 3, 5, 6]. These four phyla are given the informal name "Lower Fungi with Zoospores" in this chapter, and some of the more notable activities of organisms in this group are described within the section with that name. There are another five phyla given the informal designation "Lower Fungi without Zoospores," since they appear to be relatively primitive as well, but they do not produce motile zoospores: the Glomeromycota, the Mucoromycota, the Zoopagomycota, the Entomophthoromycota, and the Microsporidia [2, 3, 5, 7]. Several of these phyla had originally been classified within a phylum known as the Zygomycota because of similarities in their reproductive cycles that included the formation of a zygospore, but more recently they have been recognized as different phyla based on genomic data, making that earlier phylum name invalid [7, 8]. Several species within these phyla are of clinical importance, while others are significant for economic or ecological reasons. Finally, the Ascomycota and Basidiomycota are the most highly evolved and specialized phyla in many respects, identified collectively by some authors as the Dikarya (to be explained later) but more commonly referred to as the Higher Fungi, and these are covered in detail in their own section of this chapter with that title [9, 10].

Each of these phyla is subdivided into fungal classes, orders, families, genera, and species following the standard taxonomic system of classification. (Note that some Mycological texts refer to each subdivision of the fungus Kingdom as a Division, but an increasing number of publications utilize the term Phylum, so that term is employed in this chapter for consistency.)

Within this standard taxonomic system the species name is a Latin binomial (capitalized genus and lower-case specific epithet, written as a Latin name), with priority given to the first valid binomial that was assigned to any given organism. However, there are certain challenges regarding the naming of fungi that have complicated the definition of the first valid binomial, as explained in more detail below.

Biology of Fungi

The Mycota consists of heterotrophic, eukaryotic organisms that are functionally single-celled, absorbing nutrients directly into their protoplasm through a chitinous cell wall and a cell membrane, that have a relatively simple growth form known as a thallus (never forming true tissues or organs), and that typically reproduce by means of spores [2, 4, 11, 12].

Fungal Cell Structure

The cells of all fungi are enclosed in a cell wall that is permeable to gases and dissolved solutes. This cell wall consists of molecules of chitin, chitosan, glucans (glucose polymers), glycoproteins, and mannans and/or galactomannans. Each of these macromolecules is extruded into the cell wall space by plasma membrane-associated synthases. These macromolecules are cross-linked by extracellular enzymes to create the wall matrix that provides a protective layer against osmotic and other stresses, as shown in Figure 46.1 [13, 14].

Additional components are deposited into the wall structure that creates an amorphous layer that covers and encloses the cross-linked matrix, and this layer is quite variable depending on the adaptations of the fungus. Two examples of functions of this layer are to provide adhesion to a substrate or to mask antigenic wall components in the case of species adapted to infect humans and other animals [13].

The protoplasm of fungi contains nuclei and other eukaryotic organelles, but plastids (the category of organelles that include chloroplasts) are absent from the protoplasm of the members of this kingdom. The nuclei in the growing and metabolizing cells of many of the fungi are haploid, meaning that the only time when a diploid nucleus occurs in such fungi is at one specific point in its life cycle, after which that diploid nucleus divides by meiosis. However, diploid nuclei are common in other fungi (especially the yeasts), and polyploid and aneuploid chromosome numbers can occur as well. The haploid nuclei are approximately 2 microns in diameter, which are relatively small among eukaryotic organisms (and difficult to study microscopically), and the number of chromosomes in those that have been studied ranges from 3 to 15 [11, 12, 15].

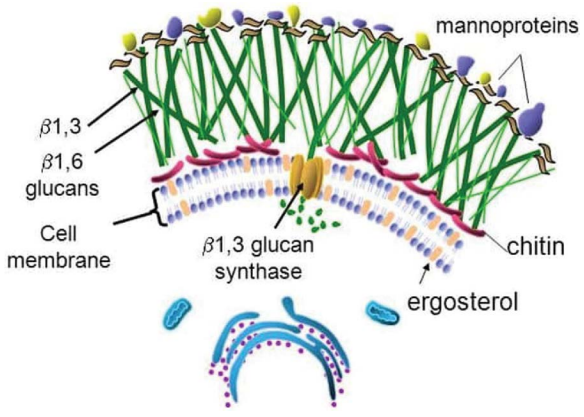

FIGURE 46.1 Ultrastructure of fungal cell walls.

The selectively permeable fungal plasma membrane has the typical phospholipid bilayer with membrane-bound proteins that is characteristic of all eukaryotic organisms. However, the sterol component of the membrane is ergosterol, contrasting with the cholesterol in animal plasma membranes and phytosterols in plant plasma membranes. This difference in membrane sterol composition has been targeted in the development of some antifungal therapeutic agents. One of these is amphotericin B, which binds with ergosterol and creates a polar pore in the plasma membrane that has lethal effects on the fungus, but this agent unfortunately causes significant side effects in treated patients. The azoles, another type of antifungal therapeutic agent, inhibit the synthesis of ergosterol, and include fluconazole and miconazole. Ergosterol is also found in the plasma membranes of certain Protista, such as *Trypanosoma* (the cause of African sleeping sickness), so the same therapeutic agents may be utilized to treat infections by these organisms [13, 16].

Fungal Physiology and Nutrition

Most fungi are capable of aerobic respiration at atmospheric concentrations of oxygen, but many are facultatively anaerobic, utilizing various fermentative pathways at very low oxygen levels or in the complete absence of oxygen; very few are obligate anaerobes. There are a few species of fungi that are thermophilic (capable of growth at temperatures of 45–60°C), many that are psychrotrophic (capable of growth at 0°C but with optimum growth above 20°C), and very few that are psychrophilic (capable of growth at 0°C but unable to grow above 20°C) [17, 18]. Many fungi are osmophilic, and some of these are associated with spoilage of sugary food products, while a small number are halophilic, capable of growth in hypersaline environments. Other extremophiles among fungi include acid-tolerant species, many of which can grow in environments with a pH of 3–4, while a small number have been detected at a pH below 3.0 [17–21].

The nutrients for the heterotrophic nutrition of fungi must be absorbed in solution through the permeable cell wall, so fungi are dependent on a damp or moist environment that provides such solutions. Fungi typically release enzymes through the cell wall into their surroundings that digest complex organic compounds into soluble molecules, and they also release waste products including various metabolites through their cell walls into their surroundings [22].

Sources of Fungal Nutrition

The nutritional requirements of fungi are met through several different kinds of interactions with their surroundings and other organisms. Many fungi are saprotrophs, absorbing their nutrients from nonliving organic matter, thus functioning ecologically as decomposers, and their impact on human affairs can be beneficial or harmful. Fungi of medical and agricultural importance are often necrotrophic, invading a living host with the release of toxins and enzymes that kill the host tissues, releasing soluble nutrients that are absorbed by the fungus, and typically creating a disease condition in the host. A few fungi are biotrophic (often referred to as obligate parasites), absorbing nutrients while maintaining an intimate relationship with host tissues that does not cause tissue death immediately, or at all, and the effect of this interaction on the host can be harmful or beneficial. Those necrotrophic and biotrophic fungi that cause disease in a host organism are identified as pathogens infecting a host to create that diseased condition. The disease cycle leading to such an infection is closely related to the life cycle and means of dispersal of the pathogenic fungus [22, 23].

Symbiotic Associations of Fungi

A beneficial biotrophic relationship with plants (known as a symbiosis) has evolved in several different phyla of fungi in the form of mycorrhiza (literally "fungus-root"), which occurs as endomycorrhizae or ectomycorrhizae. Endomycorrhizae consist of an invasion of the outer cortex layer of a plant root by the fungus, leading to penetration of individual plant cell walls by the hyphae without killing the host protoplast, since the hyphae neither penetrate the host plasma membrane nor release any products that injure the protoplast. The most commonly occurring endomycorrhiza is the arbuscular form involving the Glomeromycota, which is described later in the section about that phylum, but there are also other types of endomycorrhiza associated with the Ericaceae (the heath family of plants) and with the Orchidaceae. In an ectomycorrhiza, the fungal hyphae do not penetrate the host plant cell walls, but instead grow in the intercellular spaces between the cortex root cells. In all types of mycorrhizae, the hyphae of the fungus extend outside the root into the surrounding soil or other substrate, and in the case of ectomycorrhizae the hyphae create a mantle of mycelium around the root known as a "hartig net." The diagram in Figure 46.2 illustrates the relationship between fungus and root in each of these kinds of mycorrhizae. In most cases, the symbiotic relationship involves enhanced absorption of inorganic nutrients (and in some cases water) by the fungus, which are delivered to the plant, and transfer of carbohydrate food from the plant to the fungus. However, in the case of orchid endomycorrhizae, the fungus typically transfers carbohydrates to the plant [24–28].

Lichens consist of a biotrophic relationship between a fungus (almost always a member of the Ascomycota, although a very small number of Basidiomycota are also involved) and an "alga" that is either one of the Cyanobacteria or one of the Chlorophyta. Although this relationship is traditionally included among examples of symbiosis, it is actually closer to a case of cultivation of an autotroph by a heterotroph, with the "alga" performing photosynthesis (and nitrogen fixation in some Cyanobacteria) and thus providing food to the fungus, while it gets mineral nutrients, exposure to light, and a chance to grow in unusual locations in return. All the algae in this relationship are capable of growing independently in aqueous environments, whereas the fungal component is highly dependent on its autotrophic partner. The fungal component makes up 90–95% of the mass of a lichen, determines is shape, and reproduces with its typical sexual or asexual spore stages. The algal component is in the upper layers of the structure, with its cells essentially caged in by fungal hyphae and supplying either glucose or sugar alcohols to the fungus. A type of vegetative propagation occurs in some lichens by the release of powdery soredia (clusters of a few algal cells surrounded by fungal hyphae) or other comparable structures [29, 30].

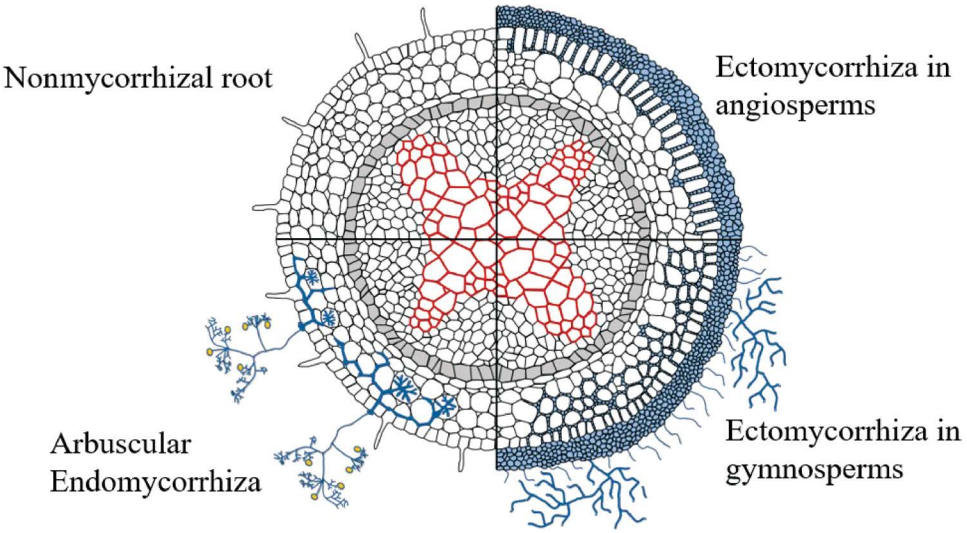

FIGURE 46.2 Comparisons of mycorrhizal types.

Fungal Growth Forms

The two most common growth forms of fungi are branching hyphae and single-celled yeasts. Branching hyphae occur in nearly all the major fungal phyla, while the yeast form of growth occurs in several of them, especially among the Ascomycota and to a lesser extent in the Basidiomycota.

The Branching Hyphae Growth Form

This growth form is created as a result of the tubular extension and branching of the growing hypha as the turgor pressure within the protoplasm pushes against the cell wall, stretching those regions of the cell wall at the tips where there is the least cross-linking [14]. The branching hyphae grow continuously and function in nutrient absorption, while a fungus is metabolically active, except when they function in the formation of sexual or asexual spores, and for convenience this growing and feeding stage is described as "vegetative." Mitosis of the hyphal nuclei occurs simultaneously with hyphal growth so that nuclei are distributed throughout the growing protoplasm. The diameters of most fungal hyphae range from 2 to 5 µm, although in some of the Mucoromycota they can be as much as 15 µm in diameter, as shown in Figure 46.3 [12].

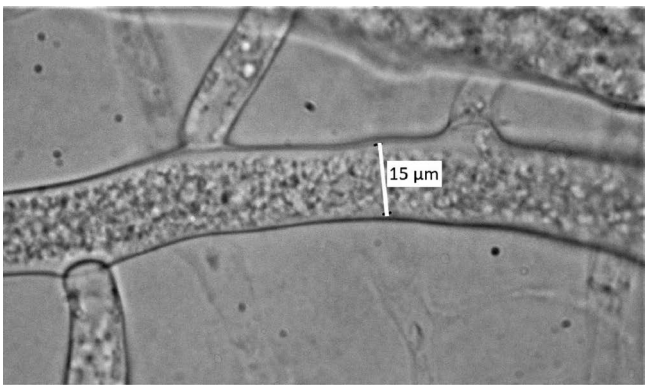

FIGURE 46.3 Nonseptate hypha of *Mucor plumbeus*.

In several of the fungal phyla—primarily the Ascomycota and Basidiomycota—there is a development of septa (internal cross-walls) at regular intervals within the hypha, and the presence or absence of septa in various groups of fungi can be readily observed by light microscopy, as shown in Figure 46.4. There are usually either one or two nuclei within each segment of the hypha created by septa, depending on various factors described in a later section of this chapter, and a function of these septa in some fungi is to prevent nuclear migration within the hypha that would alter this number. A complete septum without a pore is produced in all fungal phyla in the process of forming reproductive structures. The septa in actively functioning hyphae are perforated by various types of pores that allow the passage of ribosomes and other smaller cytoplasmic components, and the plasma membrane of adjacent cells is continuous through the margins of the pore. The septa of most Ascomycota have a round pore in the center and associated with each septum is a type of cytoplasmic microbody known as a Woronin body on either side of the pore. The Woronin body quickly plugs the pore if the hypha is damaged, preventing leakage of protoplasm from adjacent sections of the hypha. The septal pores of Basidiomycota are more complex, with either a dolipore septum (consisting of a barrel-shaped structure in the center of the pore with a portion of the endoplasmic reticulum described as a "parenthesome" on either side of it), or a "pulley wheel occlusion" suspended in the middle of the pore, nearly blocking it. The ultrastructure of hyphal pores and associated structures is illustrated in Figure 46.5 [12, 31, 32].

Hyphae can extend for considerable lengths and develop into macroscopic arrays that are easily visible without a microscope,

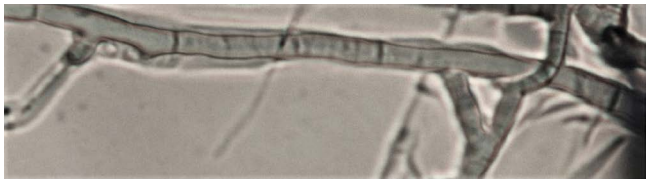

FIGURE 46.4 Septate hypha of *Helminthosporium solani*.

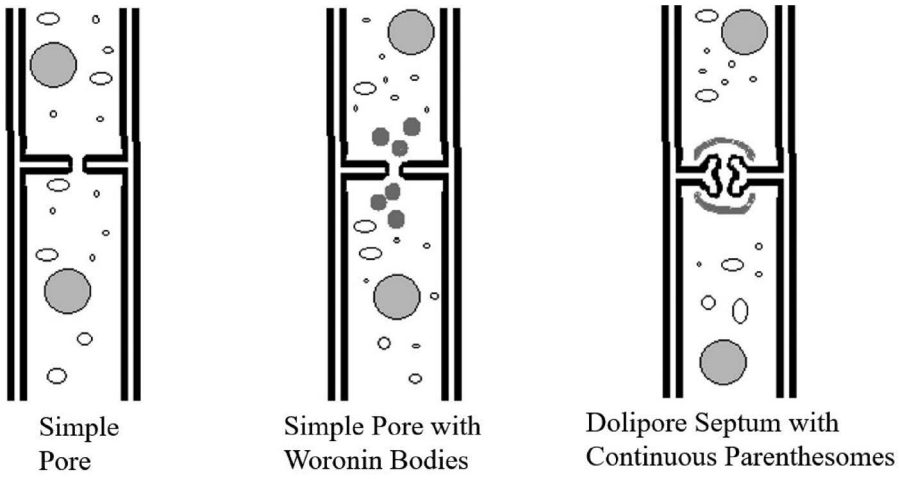

FIGURE 46.5 Simplified diagrams of septal pore types occurring in fungal hyphae.

in which case the growth is described as "mycelium." Such growth is seen in the familiar forms known as molds and in the interwoven structure of such fruiting bodies as mushrooms. Because of the growth of hyphae into the substrate from which the fungus obtains its nutrients, a fungal colony is strongly adherent to that surface. When grown in culture on solid medium, fungal colonies display colors and textures that are characteristic of the species involved [12].

The Yeast Growth Form

The yeasts are an alternate growth form that occurs in some fungi that are essentially metabolically active spores (compared to the temporarily dormant state that is typical of most fungal spores). Many of the familiar yeasts are fairly small (4–6 µm), have round to elliptical shapes and have relatively thin cell walls. Most yeasts are dependent on outside forces for their dispersal beyond the site of a local population, and enter a metabolically inactive state until they are exposed to a wet or moist environment containing dissolved nutrients to support their metabolism [12, 33].

Population increase in most yeasts occurs by the formation of a blastospore, commonly described as "budding," which is essentially a smaller sister cell created when one of the nuclei formed by mitosis migrates into a ballooning portion of the cell wall until a separate cell is created, isolated from the original cell by a septum, as illustrated in Figure 46.6. However, there are other modes of reproduction in certain yeasts (such as the "medial fission" of fission yeasts described later in this chapter) [33, 34].

Rapid population growth of yeast cells in a favorable environment creates the characteristic macroscopic appearance of a yeast culture, which can resemble a bacterial colony on solid media. There are some fungi (described as dimorphic) that can transition between hyphal and yeast forms depending on their environmental conditions, such as *Histoplasma capsulatum* (causal agent of the human infection known as histoplasmosis), which is filamentous when growing saprotrophically at room temperature, but has a yeast growth form when growing necrotrophically inside the human body at 37°C [35].

Blastospores can also be formed directly on hyphae of certain fungi, which can create the macroscopic appearance of a yeast even though the organism is filamentous, and there are some yeasts that take on a hypha-like shape known as pseudohyphae (sometimes described as "pseudomycelium") when individual cells become unusually elongated or cling together in a linear arrangement, shown in Figure 46.7 [36].

Sexual and Asexual Reproductive Stages of Fungi

The traditional name for the sexual spore stage in the field of Mycology had originally been the "perfect stage," but this has been replaced by the term teleomorph ("end form"). Parallel with this terminology, the traditional name for the asexual spore stage had been the "imperfect stage," and this has been replaced by the term anamorph, which describes all structures (including hyphae) that are not involved in the sexual stage of the organism. Finally, the term holomorph describes the complete picture of

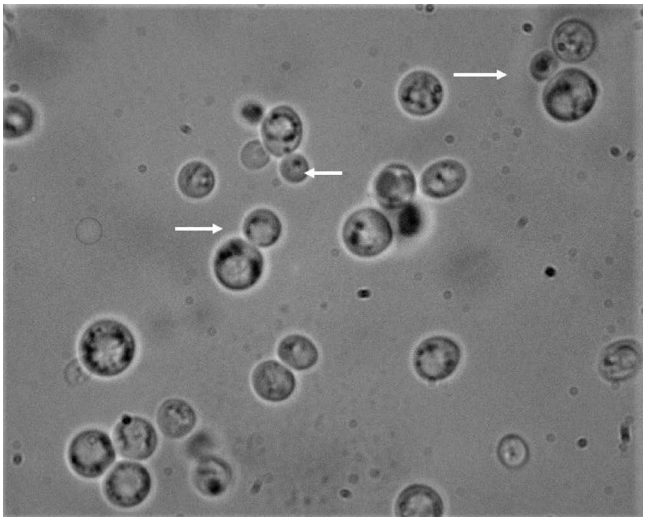

FIGURE 46.6 Blastospore formation ("budding") in *Saccharomyces cerevisiae*.

FIGURE 46.7 Pseudohyphae of *Aureobasidium pullulans*.

both the sexual and asexual stages of a fungus, so it is a combination of the teleomorph and the anamorph [9, 10].

Sexual Spore Stage

The sexual stage of a fungus life cycle consists of the events leading up to the fusion of two compatible haploid nuclei to form a diploid zygote and its subsequent division by meiosis to produce haploid nuclei typically packaged within spores. The fusion of the compatible haploid nuclei is more accurately known as karyogamy ("nuclear marriage") than "fertilization," since there are no equivalents to male or female gametes among fungi [37–39]. Some fungi employ elaborate methods for bringing together the two compatible haploid nuclei in this process, often having mating types that prevent karyogamy of nuclei within the same colony or between closely related strains. A fusion of fungal cells is therefore necessary to bring these two compatible haploid nuclei together, whether these are two hyphae, a hypha and a specialized spore, two spores, or other specialized structures, and this cell fusion is known as plasmogamy ("cell marriage"). Following meiosis of the diploid zygote (or comparable cell), the resulting haploid nuclei, or their mitotic products, are immediately or eventually packaged into characteristic spores that are associated with the sexual stage of the fungus. The events of plasmogamy, karyogamy and meiosis are so unique to each phylum of Mycota, and to each of the various taxonomic subgroups within each of those phyla, that they are a dependable basis on which to identify and classify these organisms [37–39].

Asexual Spore Stage

Those spores that are produced by mitosis from various hyphal structures are known as zoospores, sporangiospores, or conidia depending on their properties and the structure in which or on which they are formed. There is a tremendous variety of asexual spore morphology, and also in the modes of asexual spore formation and dispersal, all of which are utilized in recognizing fungal species. However, the asexual spore stage is much less reliable than the sexual spore stage for establishing the identity and taxonomic placement of an unknown fungus. Since their mitotic origin results in cloning, the reproductive function of zoospores, sporangiospores and conidia is asexual [40–42].

Practical Challenges Caused by the Teleomorph/Anamorph Duality of Many Fungi

A recurring theme in the field of Mycology has been the difficulty in making the connection between the teleomorph and the anamorph of a large number of fungi in several of the phyla of the Mycota, especially those in the Ascomycota. One of the reasons for this is that the sexual and asexual spore stages are typically quite dissimilar, and often produced at different times during the development of a fungus in its natural habitat. Also, the successful initiation and outcome of the sexual spore stage in many fungi requires the interaction of two compatible mating types which may not always be present in the same location at the same time, so the teleomorph may occur rarely or never. The mitotically produced spores associated with the anamorph of most fungi function effectively as a means of asexual reproduction, and they can also function as an effective means of initiating host infections by necrotrophic and biotrophic fungi of clinical or agricultural importance. Because of this characteristic of many fungi that have an impact on human affairs, these fungi have been historically recognized by their anamorph stage, have been given Latin binomials based on that stage, and are described in the scientific literature by those binomials [5, 9].

At the same time, the teleomorphs of many of these same fungi have been identified as unique species and given Latin binomials, but the connection with the corresponding anamorph may or may not have been recognized at the time they were first described. As a result, there are many fungi that have two Latin binomials, one for the anamorph and one for the teleomorph. Advances in mycological techniques, including both the availability of genomic data and methods of ultrastructural analysis, have resulted in the publication of increasing numbers of teleomorph binomials that are linked to their corresponding anamorph binomial [9].

While the publication of two different binomials for the same fungal species would appear to be cause for confusion, most scientists investigating these organisms in the context of agricultural, clinical, and industrial applications have recognized the basis for these binomials and have cited them appropriately in the scientific literature. However, there is a debate arising from the principle of "one fungus one name" that is consistent with the current interpretation of the International Code of Botanical Nomenclature, the recognized authority on scientific naming of fungi. While the use of both the teleomorph binomial and anamorph binomial was originally considered to be acceptable, the current standard being advocated is to utilize only the teleomorph binomial, even in cases when the anamorph binomial was published first. In practical terms, much of the scientific literature regarding clinical, agricultural, and industrial investigations of fungi has identified these organisms by the anamorph binomial, since that is the stage that is relevant to these fields. The exclusion of the anamorph binomial from future publications in these fields would appear to be a more significant source of confusion than following the earlier convention of identifying the organism with both binomials when appropriate [43–45].

Spore Structure and Germination

Whether produced sexually or asexually, each fungal spore is basically a package (or set of packages) of protoplasm containing at least one nucleus, and is typically capable of initiating the growth of the organism in a location or at a time that is separate from its point of origin.

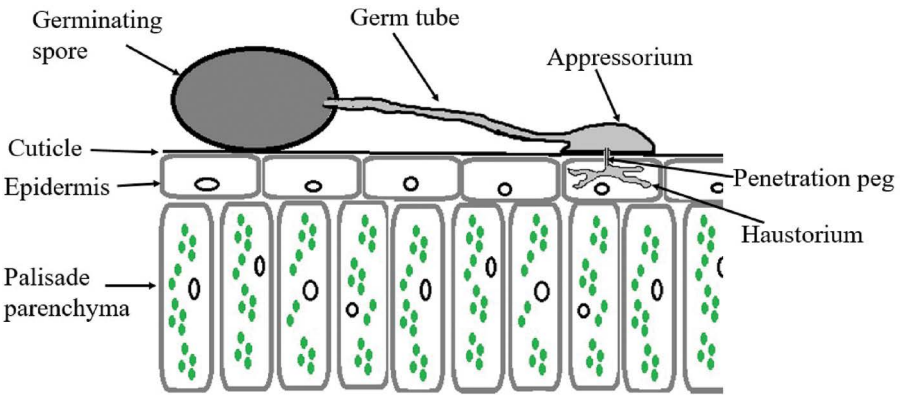

FIGURE 46.8 Germ tube with appressorium penetrating the host leaf epidermis.

Spore Germination

In most cases, the contents of the spore have a low level of metabolic activity until they are stimulated to germinate by conditions that are favorable for the growth of the organism that they can potentially develop into. Most fungal spores produce at least one germ tube that emerges through the spore wall and that essentially functions as the first hypha of the organism. The fungus at the time of spore germination is highly vulnerable to conditions that are unfavorable for its continued growth and development, and in the case of plant pathogenic fungi this is the stage that is most susceptible to disease control measures such as fungicide application. For a germ tube of a plant pathogenic fungus to be successful in initiating an infection, it must penetrate the surface of the plant, which in a few groups is accomplished by growing into a stoma (gas exchange pore on the surface of leaves and young stems). However, in most cases the penetration involves the expansion of the hyphal tip into an appressorium that adheres to the plant cuticle, while a thin infection peg pushes through the cell wall with a combination of mechanical pressure and enzymatic action, as shown in Figure 46.8. Once inside the plant cell or tissue, the hypha expands to its typical diameter and begins the internal invasion of the plant by whatever mechanism is characteristic for that kind of fungus [46–49].

There are some exceptions to the above description of spore production and function, including the blastospores ("buds") produced by yeasts as described above that are metabolically active at the time of formation, the behavior of flagellated zoospores produced by several small phyla of Lower Fungi with Zoospores described below, and certain specialized spores that only function in bringing compatible mating types together, as in the case of "spermatia" produced at one point in the life cycle of the Pucciniales (the rust fungi), also described in more detail within the Higher Fungi later in this chapter [34, 50].

Lower Fungi with Zoospores

The production of zoospores by the four phyla in this category reflects the aquatic evolutionary origins of the fungus kingdom. Although they have relatively less impact on human affairs than the fungi in the next sections of this chapter, the activities of some members of the zoospore-producing fungi are associated with economic losses as well as ecological damage [51].

Phylum Chytridiomycota

The fungi in this phylum are primarily aquatic, occurring in fresh water, salt water, and moist soil. Many of the species are saprotrophic, functioning as decomposers in the ecosystem. However, there are several biotrophic species (obligate parasites) that can cause economic loss, and there is also a significant necrotrophic pathogen of amphibians in this phylum [51].

Characteristics of the Phylum

Hyphae in the Chytridiomycota (known as "chytrids") are nonseptate when present, but some members of the phylum absorb nutrients directly into a thallus consisting only of a developing zoosporangium, and some absorb nutrients with rhizoids (thin, branching extensions that do not contain nuclei). A typical chytrid thallus with rhizoids is shown in Figure 46.9. Cleavage of multinucleate protoplasm inside a zoosporangium results in the formation of zoospores, and these zoospores may escape through an opened operculum (lid) or through pores or slits in the zoosporangium. Zoospores display chemotactic behavior that favors their migration toward a suitable substrate, and once contact is made, they form a single-celled cyst (with or without retraction of the flagellum), which develops a chitinous cell wall and then germinates with a germ tube that penetrates the substrate [6, 51].

In those Chytridiomycota in which the sexual stage has been observed, there are several methods by which compatible haploid nuclei are brought together, including fusion of two zoospores,

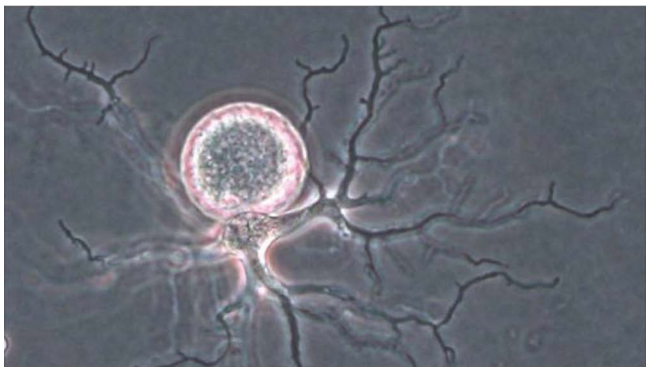

FIGURE 46.9 Chytrid thallus with rhizoids.

fusion of a zoospore with a nonmotile cell, and fusion of rhizoids of compatible strains. The zygote often functions as a survival structure during periods when the nutrient source is unavailable or conditions are unfavorable for growth. Meiosis of the zygote is typically followed by the development of haploid zoospores within a zoosporangium [51].

Class Chytridiomycetes

This class within the phylum Chytridiomycota is notable because of agricultural losses caused by some of its species and because one genus in this class has had a highly negative ecological impact in recent years.

One of the genera within this class is *Synchytrium*, a biotrophic parasite of flowering plants, ferns, mosses, and algae, and the species *Synchytrium endobioticum* is a well-known plant pathogen in this genus. This species infects epidermal cells of developing potato tubers, stimulating them to overgrow, resulting in the symptoms of potato scab or potato wart. When the fungus produces its zygotes toward the end of the growing season, additional disruptive host cell divisions occur, leading to decay of the potato tuber [52].

Also included in the class Chytridiomycetes is the genus *Batrachochytrium* causing an infection known as chytridiomycosis in amphibians that has come to be recognized as a significant cause of population decline of many species in this class of animals. This fungus is a necrotrophic pathogen, capable of releasing enzymes that digest the epidermis of various frogs and salamanders, leading to the death of the infected animal. The zoosporangia of the fungus develop in the invaded epidermis, leading to release of additional generations of zoospores that initiate infections of increasing numbers of amphibians. This chytridiomycosis of amphibians has resulted in the extinction of several species, although some species are naturally resistant (including bullfrogs, that appear to be help disperse the zoospores of the parasite through their activities) [6, 53, 54].

Phylum Blastocladiomycota

An economically important species within this phylum is the plant pathogen *Physoderma maydis*, which causes brown spot and stalk rot of maize; other species in this genus cause similar diseases of other crop plants. Plant disease caused by these pathogens is more severe during periods of high rainfall during the growing season, since free water favors the dispersal of their zoospores to above-ground portions of the plant [6, 55].

Phylum Neocallimastigomycota

The organisms within this phylum are unusual among fungi in that they are anaerobic, lacking mitochondria. These organisms are part of the microbiome of the digestive tracts of herbivorous animals that consume a high-fiber diet. The polysaccharide-degrading enzymes released by these fungi function in hydrolyzing resistant plant polymers, making the resulting carbohydrates available for the nutrition of their host animal [6, 56, 57].

Phylum Olpidiomycota

An economically important member of this phylum is the genus *Olpidium,* which infects a number of plants, animals, protists, and other fungi. Plant pathogens in this genus initiate an infection by means of zoospores that are released from zoosporangia on roots of infected plants and that migrate to roots of neighboring plants. Although the infection symptoms caused by *Olpidium* are relatively minor, it is the migration of its zoospores from one plant to another that can cause economic loss in crop plants. If a plant is suffering a virus infection in addition to an *Olpidium* infection, the migration of *Olpidium* zoospores from the double-infected plant can serve as a virus vector, introducing the virus into a neighboring healthy plant as the zoospores encyst, germinate, and penetrate the roots of that plant with their germ tubes [6, 58, 59].

Lower Fungi Without Zoospores

This informal collection of phyla includes fungi that may be entirely microscopic, or if they have visible mycelium it is never organized into complex structures like mushrooms. The hyphae are nonseptate when present, and the structures associated with their sexual stages (if known) are microscopic [7].

Phylum Glomeromycota

The Glomeromycota are a unique phylum of fungi with a relatively small number of species, but this phylum is vast in terms of its distribution and presence among nearly all plant populations of the world. These are the arbuscular mycorrhizal fungi that have a mutualistic biotrophic relationship with most photosynthetic organisms growing on land—primarily members of the Angiosperms (flowering plants), but also with the Bryophyta (mosses and their relatives), and even some Cyanobacteria, in which case the Cyanobacteria are inside the fungus. The symbiotic relationship with land plants began at least 400 million years ago, as observed in fossil evidence, and appears to have been a major factor that contributed to the survival and evolution of plants on land into the highly successful kingdom that now supports much of the animal life on the planet [7, 24, 26].

The Glomeromycota reproduce asexually with multinucleate spores that can be as large as 0.5 mm in diameter. The asexual spores in this phylum may be formed individually by expansion of the hyphal tip followed by cutting off of the spore or, in some cases, by cleavage of multinucleate protoplasm to form several spores within a type of sporangium. No sexual stage has been identified in this phylum [7, 25].

Spore germination in this phylum may occur when conditions are favorable, but is often stimulated by root exudates of compatible plant species. A germ tube develops that penetrates through the root epidermis into the root cortex (the outer layer of tissue that surrounds the central vascular cylinder). As the hyphae grow into this tissue, they penetrate the walls of living host cells and grow and branch inside each cell space but outside the host cell plasma membrane, developing into an arbuscule (named for the treelike appearance of their branching arrangement), as shown in Figure 46.10 [7, 26].

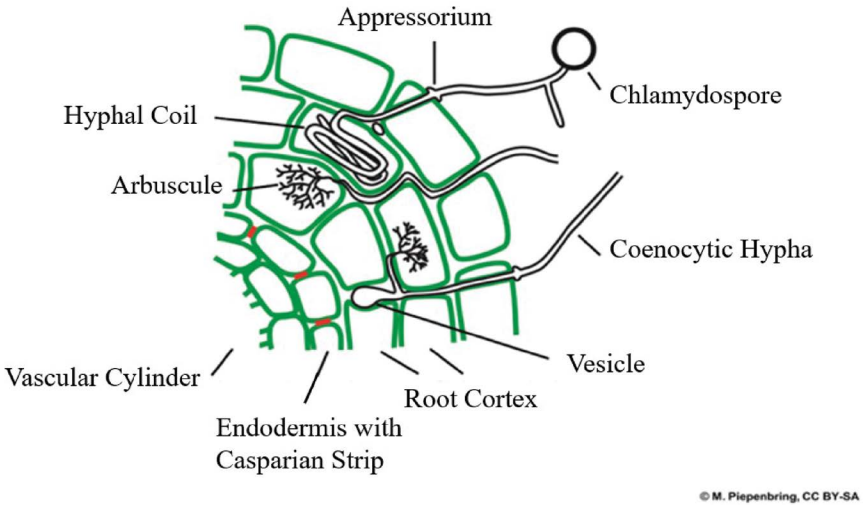

FIGURE 46.10 Glomeromycota infection on a host root with development of arbuscules.

At the same time, the hyphae of this fungus grow into the soil surrounding the root, creating a large absorbing surface area that functions in taking up various inorganic ions, including phosphate and nitrate ions, and transporting these into the root-invading hyphae that connect with the arbuscules. This intimate contact between fungus plasma membrane and host plasma membrane facilitates the transfer of carbohydrate from the plant to the fungus and the transfer of essential nutrients (inorganic ions) from the fungus to the plant [7, 27, 28].

Phylum Mucoromycota

This is one of three phyla of fungi that had previously been included in a larger phylum known as the Zygomycota. That identity is now considered invalid because it had included three similar-looking groups of fungi that are now recognized as a three separate phyla based on genomic and ultrastructural data [7, 8].

Characteristics of the Phylum

Many of the members of the Mucoromycota develop into macroscopically visible colonies and conspicuous spore-producing structures, so these are more familiar than the preceding phyla of fungi described in this chapter.

In some but not all members of the phylum, colony expansion may be augmented by the formation of long horizontal aerial hyphae known as "stolons" that arch over the surface until they make contact with the substrate. In those species producing such stolons, the hypha is anchored to the substrate at the point of contact by sprouting rhizoids (thin, branching extensions that do not contain nuclei) that penetrate the surface and function in the saprotrophic nutrition of the fungus. The macroscopically visible growth of mycelium in this phylum has a woolly appearance because of the profuse development of aerial hyphae [7].

Sexual Spore Stage

The characteristic structure associated with the sexual stage of fungi in this phylum is the zygospore. The development of the zygospore begins with the fusion of compatible haploid nuclei that are brought together by modified hyphal branches, known as zygophores, that arise from hyphae of compatible mating types of the organism, illustrated in Figure 46.11. The zygophores in most of the genera in this phylum are aerial hyphae that

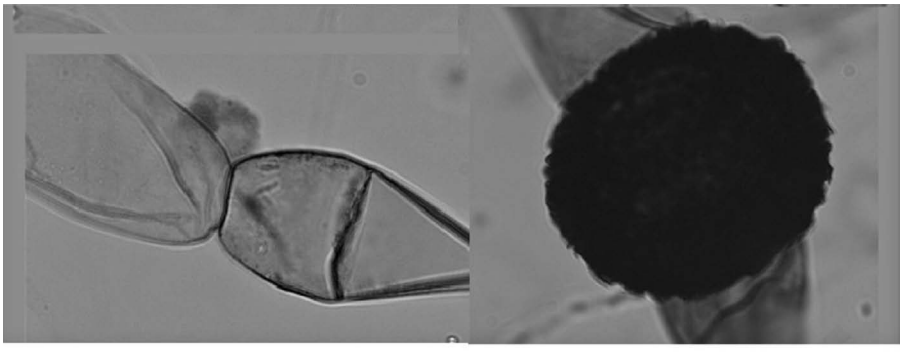

FIGURE 46.11 *Rhizopus oryzae*: Representative images of the sexual stage.

release pheromones into the air that attract the growth of the corresponding structure of the opposite mating type. Once the two zygophores make contact, they flatten and adhere in the region of contact, then each one becomes enlarged by expansion of its surrounding cell wall. A septum cuts off the terminal portion of each zygophore, resulting in the creation of two adhering cells that contain one or more of the haploid nuclei of that mating type, known as gametangia (literally "gamete vessels"). The cell wall substance in the region of contact between these two gametangia becomes hydrolyzed, resulting in the plasmogamy of the two gametangia, representing the next stage of zygospore development. That portion of the zygophore below each gametangium is known as a suspensor, and each one continues to maintain a functional connection to the gametangia and to the developing zygospore, enabling the transfer of metabolites to these structures from the supporting hyphae of the "parent" organisms [7, 39].

A notable feature of zygospore development in this phylum is the formation of a thick wall with conspicuous warty projections surrounding the nucleus or nuclei that are contained inside, and this protective wall has been described as a zygosporangium with a zygospore inside. There are dense deposits of melanin in this thick zygosporangium wall, making the contents invisible to both light microscopy and electron microscopy, but cryofracturing of the zygosporangium wall has allowed the visualization of its contents in some studies [7, 39].

The zygospore is the site of karyogamy and meiosis, leading to the formation of haploid nuclei. There is some variation among different members of this phylum in terms of the timing of these events and whether all potential gamete nuclei participate in the process, or if some remain haploid (therefore remaining part of the population of haploid nuclei prior to germination of the zygosporangium). As would be expected for this type of structure, the zygospore functions as a survival structure, remaining dormant until it is stimulated to germinate by conditions favorable for the growth of the fungus. Zygosporangium germination typically results in the development of a sporangium containing sporangiospores, although, in some cases, the germ tube from the zygosporangium just continues growth as a new hypha. The sporangium that develops following the germination of the zygosporangium is indistinguishable from a sporangium of the type that the same organism produces in the process of asexual reproduction, so the characteristics of these sporangia are described in the following section dealing with asexual reproduction in this phylum [7, 39].

Asexual Spore Stage

As in the case of sporangia in other phyla described previously, sporangiospores in the Mucoromycota are typically created by cleavage of multinucleate protoplasm within a sporangium. Most sporangia range in size from 40 µm to 350 µm in diameter, and the sporangiospores can be from 4 µm to 11 µm in diameter with globose or angular shapes. The wall of the sporangium becomes fragile and easily disrupted at maturity in most species, allowing the sporangiospores to be released, as shown in Figure 46.12. Depending on the species, the sporangiospores may be dry and released into the surrounding air, or they may be slimy or become suspended in a spore droplet. Following the disintegration of a sporangium wall, the basal portion may persist in the form of a "collarette." Some sporangia with air-borne spores are produced on relatively tall sporangiophores (as much as several centimeters in some species) that raise the released spores above the level of surface laminar air flow and into a more turbulent zone, increasing the probability of wide dispersal of the sporangiospores [7, 8].

The sporangiophore terminates in a dome-shaped or globose columella that extends into the sporangium and persists after the sporangium wall disintegrates. In some species, the sporangiophore is expanded in the region below the columella, a feature known as an apophysis. The presence and appearance of the columella, apophysis, and the collarette described previously can be useful identifying features of some species [7, 8].

The sporangiophores in some members of the phylum are branched, producing a sporangium on each branch as in *Mucor plumbeus* shown in Figure 46.13, while others are unbranched. There is also wide variation in the arrangement and number of sporangiospores within each sporangium, including some (known as sporangioles) that contain only one sporangiospore or a few sporangiospores, and some (known as merosporangia) that contain 5–10 merosporangiospores in a row [7, 8].

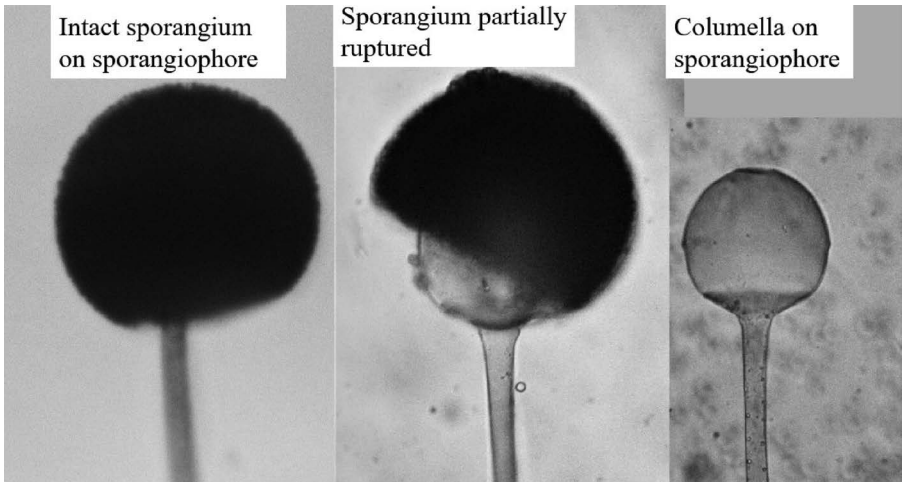

FIGURE 46.12 *Rhizopus oryzae*: Representative images of the asexual stage.

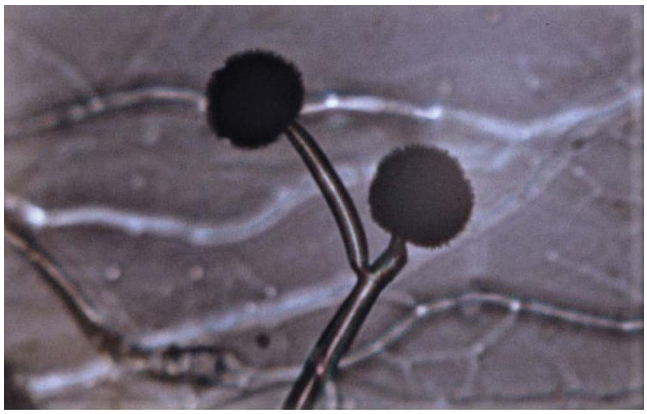

FIGURE 46.13 *Mucor plumbeus*: Sporangia borne on branching sporangiophores.

Impact of Mucoromycota on Human Affairs

The members of this phylum are all saprotrophic, but several also function as necrotrophs when susceptible host tissue is available.

Mucormycosis in Humans

Several species of Mucoromycota are associated with mucormycosis of humans (also known in earlier literature as zygomycosis because of the previous use of "Zygomycota" as the name for this phylum). The genera most commonly associated with human infections are *Rhizopus* and *Mucor*, with *Rhizopus oryzae* and *Rhizopus microsporus* being the two most common causal agents, but there are species in several other genera that may also be involved [60].

The spores of these organisms are common in the environment, especially in soil, but most people are resistant to mucormycotic infections. These infections are mostly limited to individuals with uncontrolled diabetes or certain cancers, those who are taking immune-suppressing treatments following organ transplant, those with immune deficiency diseases, those taking broad-spectrum antibiotics or corticosteroids for an extended period of time, and in those suffering from severe burns and other injuries that become contaminated with the fungal spores [60, 61].

Types of mucormycosis that occur include rhinocerebral (moving from infected sinuses into the brain), pulmonary, gastrointestinal, cutaneous (developing after skin trauma in otherwise healthy individuals), and disseminated when spread through the bloodstream. Available antifungal treatments, such as amphotericin B and the azoles (which target the ergosterol component of the fungal plasma membrane as described previously) have very limited effectiveness, so the mortality rate from these infections is approximately 50% [61].

Mucormycosis in Domesticated Animals

Mucormycosis has also been reported in domesticated animals including cats, dogs, cows, and pigs, commonly causing pneumonia and enteritis. As in the case of humans, healthy animals are generally not susceptible, while those with extended treatment with corticosteroids or broad-spectrum antibiotics, or with certain virus diseases, are more susceptible [62].

Economic Loss and Plant Disease Caused by Mucoromycota

Familiar examples of economic loss caused by the activity of species in this phylum include "black bread mold" growth on baked goods (saprotrophic) and the damage to harvested fruits sometimes observed on overripe or bruised produce. Various species of both *Rhizopus* and *Mucor* have been reported as the causal agents of postharvest "soft rot" of a wide range of fruits and certain vegetables, such as sweet potatoes and white potatoes. "Head rot"—when flower heads are destroyed before they are ready for harvesting—is a significant loss in sunflower cultivation caused by several species of *Rhizopus* [63, 64].

Economically Beneficial Mucoromycota

There are beneficial uses of fungi in this phylum, including the involvement of *Rhizopus oligosporus* and *Rhizopus oryzae* in the aerobic fermentation of the Indonesian soy product tempeh. Besides creating a desirable texture and flavor in this product, the enzymatic action of the fungal growth hydrolyzes the oligosaccharides that are associated with undesirable side effects of eating soybeans, and also reduces the level of phytic acid that tends to interfere with absorption of phosphorus and inositol by the human digestive system [65–67].

Rhizopus oryzae is also widely utilized in the field of industrial microbiology as a source of enzymes, organic acids, and ethanol that are useful in the pharmaceutical and food processing industries and as a source of industrial raw material [68].

Phylum Zoopagomycota

This is the second of the phyla of fungi that had previously been considered a member of the now-invalid phylum Zygomycota and consists of microscopic fungi without any clinical or economic impact on human affairs. All of its members are parasitic, with most of them obtaining their nutrition biotrophically. Their hosts include soil nematodes, rotifers, protozoa (such as amoebae), and some Mucoromycota [69].

Phylum Entomophthoromycota

This is the third of the phyla of fungi that had previously been considered a member of the now-invalid phylum Zygomycota, and—as reflected in its name ("insect destroyer")—is a group known for parasitizing insects. This phylum also includes some fungi with clinical significance as parasites of humans and some domesticated animals [70].

Although it has nonseptate hyphae and zygospores that look similar to those of the Mucoromycota, its asexual spores are quite different, consisting of sporangia that are forcibly discharged from the sporangiophore on which they are formed. According to some reports, the mechanism involves the formation of a gas bubble at the point of contact of sporangium and sporangiophore, contained within the outer cell wall that surrounds both structures, leading to sufficient pressure to break the outer cell wall and to propel the sporangium several millimeters away from the sporangiophore. In most cases, the sticky sporangium surface favors contact with the exoskeleton of a susceptible host insect. Germination of a sporangium can lead to penetration

of the insect exoskeleton and invasion of the insect hemocoel (inner fluid-filled body cavity). The resulting internal infection often includes production of additional sporangiophores growing out of the body of the insect while it is still alive, favoring the dissemination of sporangia to other potential hosts [70].

Most of the other species within this phylum are saprotrophic, utilizing dead plant material as a food source, or in some cases living in the intestinal tract of reptiles, amphibians, and some fish. However, *Basidiobolus ranarum* is a species that can parasitize human and other animal tissues as a necrotrophic pathogen, causing a granuloma [71]. Most human infections are associated with tropical climates, while reported animal hosts include horses, dogs, and sheep. The closely related *Conidiobolus coronatus* is associated with rhinofacial "zygomycosis" (another case of naming according to the original name of the phylum in which it had been classified). This infection begins in the nasal passages and leads to destructive subcutaneous involvement. As in the case of *Basidiobolus*, most human infections occur in the tropics, and this species causes similar infections in some domesticated animals [62].

Phylum Microsporidia

The atypical name of this fungal phylum reflects the historically uncertain classification of these organisms, which had been considered to be protozoa of one type or another prior to their recognition as fungi. These organisms are essentially single-celled intracellular biotrophs that lack mitochondria, having an anaerobic metabolism. They are capable of forming resistant spores that have a chitinous layer, a feature demonstrating that they are fungi. Parasitism of a host by these organisms is generally initiated by the germinating spore by means of a penetration apparatus that allows the organism to pass through the intestinal lining to initiate an infection, illustrated in Figure 46.14. Many of the species in this phylum cause a chronic infection of insects that disrupts the host physiology. This phylum is of particular clinical importance because some species can infect the intestinal lining of immunocompromised humans, causing a chronic wasting condition [72, 73].

The Higher Fungi

Both phyla in this category, the Ascomycota and the Basidiomycota, have septate hyphae. Almost all holomorphs in these two phyla exist as a dikaryon for at least a portion of their life cycles, this being the state in which two compatible haploid nuclei coexist within the same cell (defined in this case as the segment of a hypha between two septa) without fusing to become a zygote. To create this dikaryotic hypha, there must be plasmogamy without karyogamy, resulting in two haploid nuclei sharing the same body of cytoplasm and potentially providing the same genetic function as a diploid nucleus. Because of this shared nuclear condition, which is not found in any other phyla of fungi, these two phyla are described by some authors as being within the subkingdom Dikarya [9, 10].

Phylum Ascomycota

This is an extremely large phylum of fungi that includes saprotrophic, necrotrophic, and biotrophic members, among which are a number of adaptations for these modes of nutrition. Most of the organisms in this phylum occur as septate hyphae containing one haploid nucleus per cell. There are also a number of yeasts in this phylum, and in some of these yeasts the nuclear condition in nonreproductive cells may be diploid. As described above, there is a small round pore in the middle of each septum of most filamentous Ascomycota and there is a Woronin body on either side of the pore that functions in plugging the pore if a hypha is damaged. Many species in this phylum produce macroscopic structures that house the phases of the sexual stage, some of which are comparable to mushrooms in their size, complexity, and potential edibility by humans. There is also a wide assortment of conidial shapes and means of production of the asexual spores of these fungi, with some species being known only by their anamorph because of the rarity or absence of the sexual stage [74].

Sexual Spore Stage

Although there are some variations among different classes within this phylum, the typical sexual spore stage in the Ascomycota results in the formation of eight ascospores inside an ascus (plural asci). The process begins with plasmogamy achieved by specialized hyphal structures known as gametangia, identified as such because they contain haploid nuclei of compatible mating types that could potentially function as gametes in karyogamy. Two kinds of gametangia are formed: the ascogonium, a receiver of gamete nuclei, and the antheridium, a donator of gamete nuclei. The process of plasmogamy begins in many Ascomycota by the expansion of the ascogonium cell wall on the surface facing the antheridium, creating an extension of this cell into a thread like (or hair like) tube known as the trichogyne. This structure grows toward and penetrates the antheridium, after which haploid nuclei migrate from the antheridium into the ascogonium through the trichogyne. In some Ascomycota, a conidium (asexually-produced spore) can take the place of an antheridium as the source of compatible haploid nuclei that migrate into the ascogonium [9, 37].

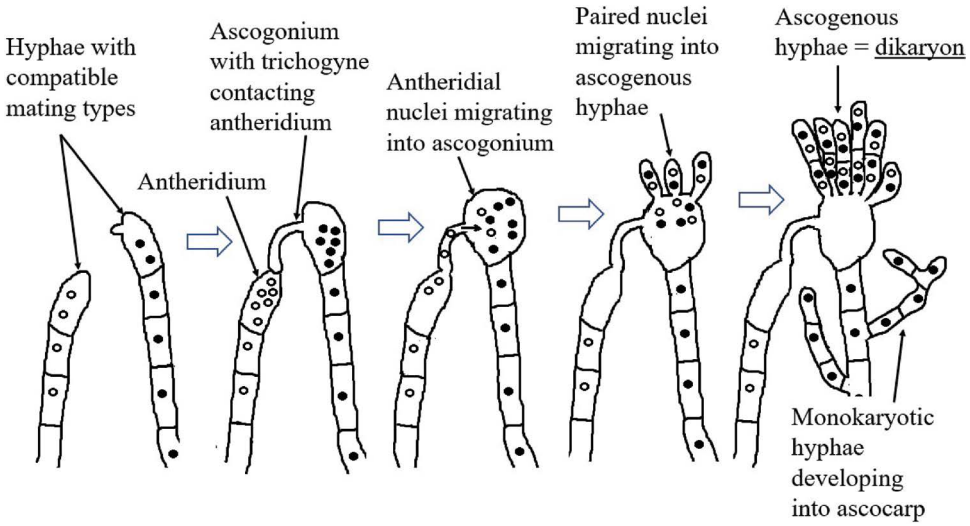

FIGURE 46.15 The Ascomycota sexual stage from ascogonium/antheridium to ascogenous hyphae.

Once the haploid nuclei from the antheridium are inside the ascogonium, the haploid nuclei of compatible mating types pair up, but do not fuse, thus, no zygote is formed yet in this process. These pairs of nuclei divide synchronously by mitosis, resulting in many pairs of compatible haploid nuclei within the ascogonium. Numerous narrow septate hyphae containing these nuclei then grow out of the ascogonium with a pair of compatible nuclei contained within each cell; these nuclei divide by mitosis as each new cell is formed, resulting in dikaryotic ascogenous hyphae. Figure 46.15 illustrates the stages that occur up to this point. The formation of these dikaryotic hyphae is the basis for the inclusion of the Ascomycota in the subkingdom Dikarya [9, 37].

The terminal portion of each of these narrow hyphae bends back on itself forming what is known as a crozier. The two nuclei located within this crozier divide by mitosis synchronously with parallel division figures, resulting in one set of daughter nuclei arriving at the bend of the crozier and the other set of daughter nuclei located away from the bend. Two septa typically form across the crozier, one cutting off the "apical cell" containing one haploid nucleus and the other cutting off the basal "stalk cell" containing the other haploid nucleus, leaving the pair of compatible haploid nuclei alone in the "penultimate cell," as shown in Figure 46.16 [9, 37].

It is at this point when this pair of haploid nuclei finally forms a diploid zygote by the process of karyogamy. Meiosis of this zygote occurs immediately, resulting in four haploid nuclei, and in nearly all Ascomycota each of these haploid nuclei divides by mitosis, resulting in the formation of eight nuclei inside of what is now the ascus. Cleavage of the cytoplasm around each nucleus creates eight ascospores inside the expanding ascus, a feature that occurs in the sexual stage of nearly every member of the Ascomycota (the only exceptions being some that form just four ascospores out of the products of meiosis, as in the case of the yeasts, or that have different structural arrangements leading to larger numbers of ascospores) [9, 37].

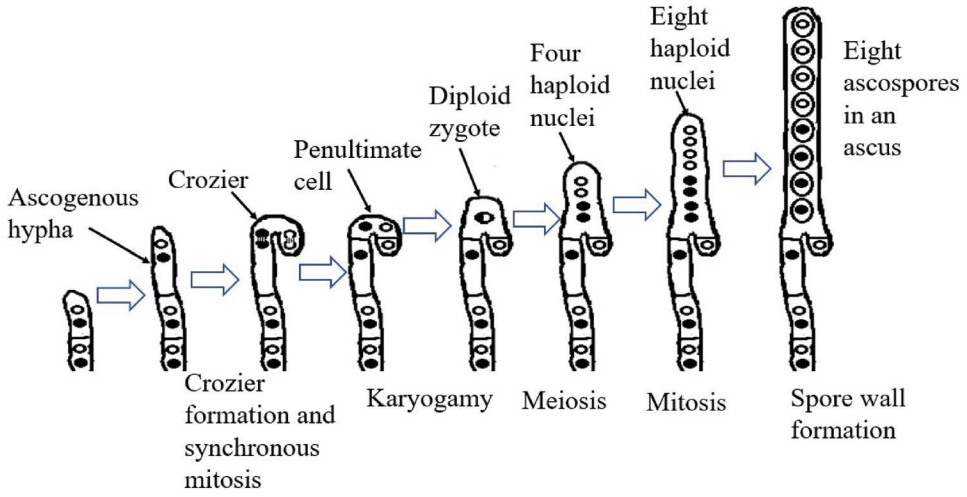

FIGURE 46.16 The Ascomycota sexual stage from crozier to ascus.

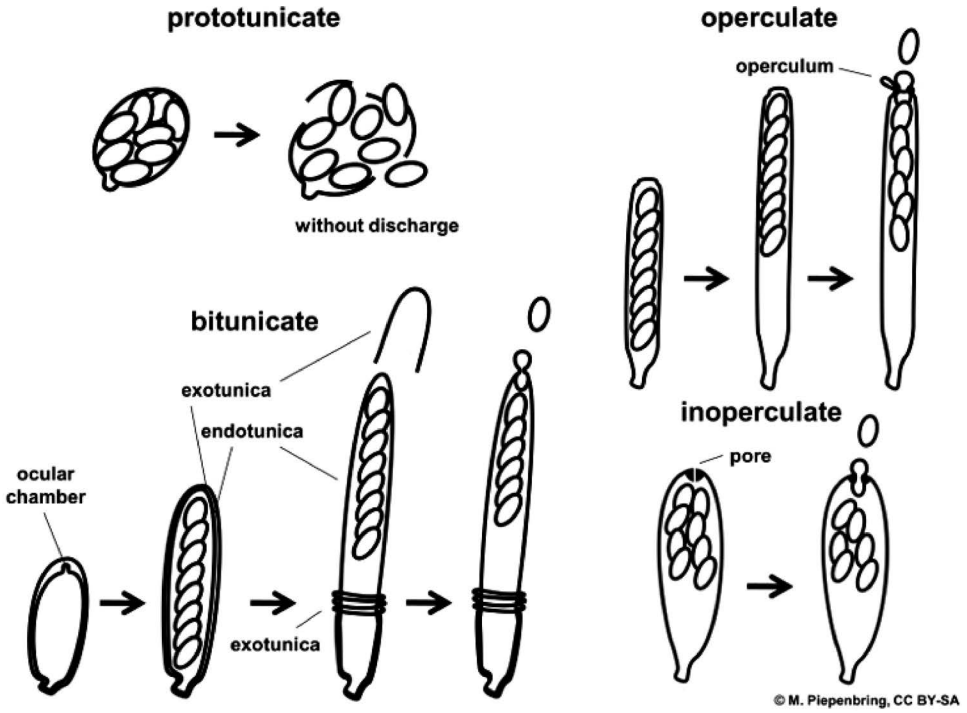

FIGURE 46.17 Types of ascus morphology.

Variation in Ascus Morphology

In many of the Ascomycota, the ascospores are ejected through the tip of the ascus by the sudden release of osmotic pressure that has built up because of a high concentration of glycerol and other solutes within the ascus, although there are some asci that have more passive ascospore release mechanisms. The process of ascus formation in various classes of Ascomycota results in one of four distinctly different ascus structures related to the mode of ascospore release. Terms used to describe these forms include "tunicate" referring to the nature of the wall of the ascus and "operculate" referring to the nature of the opening (if any) of the ascus. As indicated by the labels in Figure 46.17, these four types of ascus structure are as follows:

a. Unitunicate-operculate asci: Elongated asci having a single functional wall and a pre-existing operculum at the tip that opens at a sufficient pressure to allow the ascospores to be ejected.
b. Unitunicate-inoperculate asci: Elongated asci having a single functional wall but no pre-existing operculum, but instead having a ring of cell-wall material at the tip that is stretched open at a sufficient pressure to allow the ascospores to be ejected.
c. Bitunicate asci: Elongated asci with a thin inelastic outer wall and a thick elastic inner wall. The inner wall absorbs water by imbibition while the ascus takes up water by osmosis, resulting in expansion of the ascus leading to rupture of the thin outer wall, and continued lengthwise expansion until the ascus extends above its surrounding structures and finally bursts at the tip to allow the ascospores to be ejected.
d. Prototunicate asci: More or less spherical asci that do not eject their ascospores under pressure, with a wall that may dissolve at maturity to allow ascospores to ooze out, or that may depend on outside forces to rupture the wall and disperse the ascospores. This type of ascus has evidently evolved independently in several different classes of Ascomycota from one of the three ascus categories described above; therefore, it represents a reduction of a previously more complex structure typical for each group [9, 75].

Variation in Ascocarp Morphology

In most of the Ascomycota, there is extensive growth of the surrounding "parent" monokaryotic hyphae (having only one haploid nucleus per cell) that originally gave rise to the ascogonium and the resulting asci of one of the above categories. This hyphal growth produces the supporting and more or less enclosing ascocarp ("ascus fruit") of various forms, and of which there are also four commonly observed categories (correlated with one or more of the four categories of asci described previously). The four commonly observed ascocarp categories are:

a. Apothecium: An open fruiting body in the form of a cup- or bowl-shaped supporting structure that forms under a developing layer of upward-pointing asci that are packed together on the exposed surface as shown in Figure 46.18. This fertile layer of asci is known as a "hymenium," and the species that produce this type of ascocarp are commonly known as cup fungi. Most of the asci in this layer mature simultaneously and release all their ascospores at once. This is the only category of ascocarp formed

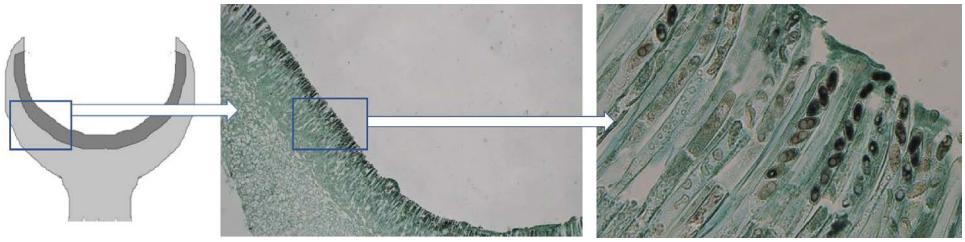

FIGURE 46.18 *Peziza cerea* apothecium diagram (left), magnified detail of hymenium (center) and asci with ascospores (right).

by species that have unitunicate-operculate asci, while some of the species that produce unitunicate-inoperculate asci also produce an apothecial ascocarp.

b. Perithecium: A flask-shaped fruiting body that develops around a developing group of asci, with a narrow aperture that allows only one or a few asci at a time to get through the opening to release their ascospores, shown in Figure 46.19. The only kind of Ascomycota that form this kind of ascocarp are those that produce unitunicate-inoperculate asci.

c. Pseudothecium: This as also a flask-shaped fruiting body that requires its asci to take their turns in releasing their ascospores. However, it differs from the true perithecium because its hyphal structure begins growing before the asci develop, so that the developing asci must find their way through pre-existing hyphae as they expand, rather than being surrounded as they develop (thus the reasoning for the "pseudo-" prefix for its name). Figure 46.19 also shows an example of this structure. Only those species that produce bitunicate asci form this type of ascocarp.

d. Cleistothecium: These fruiting bodies form around a developing group of asci, but they have no opening, as shown in Figure 46.19. In some groups, the asci inside are not adapted for ejecting their ascospores into the air and would meet the definition of prototunicate asci described previously; in others, the cleistothecium opens at a certain point, allowing the asci inside to eject their ascospores [9].

Asexual Spore Stage

The majority of species in the Ascomycota produce conidia as the asexual spore stage, and these are typically adapted for rapid and efficient dispersal of the organism to new substrates and sources of nutrients. After the conidia separate from the hypha of origin, they are capable of germinating with a germ tube in a different location or at a different time from their place and time of origin. In a few species the anamorphic stage may involve the formation of survival structures such as chlamydospores or sclerotia. Chlamydospores are a type of asexual spore with a greatly thickened wall, while sclerotia are dense masses of hyphae with an outer layer consisting of dead cells with thickened walls and an inner core of viable but dormant cells. Melanin is commonly deposited in the walls of both structures as an additional protective feature [76–78].

In several species of Ascomycota with highly successful asexual reproduction, the teleomorph is rarely encountered or is still unknown. In the case of these species, it is difficult or impossible to identify the corresponding holomorph, given the need for the teleomorph for a definitive answer. Many economically important fungi—both beneficial and harmful—are known only by their anamorph, therefor it has been necessary to construct an artificial classification system based largely on the mode of conidial formation or other anamorphic features. Because of the earlier tradition of referring to the asexual spore stage as the "imperfect stage," the fungi that are studied in this artificial classification system were known as the Fungi Imperfecti. A more authentic-sounding title for the same category of fungi is "Deuteromycetes," but this has no more validity than Fungi Imperfecti. [76, 78, 79].

Classification of Anamorphic Ascomycota Based on Organization of Conidiophores

An example of a classification system that is employed in the identification of anamorphic fungi that continues to be useful (even though it may not reflect the "true" holomorphic identity

of the fungi that are organized within it) relates to the organization of the conidia-forming hyphae (conidiophores). This system is based on whether the fungus produces its conidia on hyphae that are uncovered and exposed to the air as they form conidia (in which case it is referred to as a hyphomycete) or if its conidia are produced in a complex more or less closed structure (referred to as a coelomycete) [9, 74, 76].

Those fungi commonly known as molds (in which individual exposed conidiophores are distributed throughout the growing colony) are familiar examples of hyphomycetes. However, this category also includes some fungi in which the conidiophores are clustered together into a tight bundle (a synnema) that produces a mass of conidia at the top (slimy and adapted for insect dispersal), and there are other fungi in which the conidiophores are packed together on top of a cushion of supporting hyphae (a sporodochium) adapted for rain-splashing of the conidia [9].

Coelomycetes include plant parasitic fungi that form closely packed conidiophores within host plant tissue (at the epidermal layer or deeper) in a disc-shaped structure known as an acervulus that has a superficial similarity to an apothecium; large numbers of conidia arising from these conidiophores create sufficient pressure to rupture the plant tissues, allowing the conidia to be dispersed (often by rain-splashing). There are other coelomycetes that form tightly-packed conidiophores within a flask-shaped structure that has a superficial similarity to a perithecium but is known as a pycnidium; conidia arising from these conidiophores are extruded through the opening of the pycnidium in a slimy mass in wet weather, also adapted for rain-splashing of conidia. Representative hyphomycete organization of conidiophores is illustrated in Figure 46.20, and coelomycete organization of conidiophores is shown in Figure 46.21 [74, 78].

Classification of Anamorphic Ascomycota Based on Conidial Morphology and Details of Conidiogenesis

Most conidia are globose to elliptical in shape or, in some cases are short cylinders, and these are known as amerospores, while a two-celled conidium divided by one septum is a didymospore. A conidium consisting of several cells in a row separated by two or more transverse septa is a phragmospore, while a conidium in which there are both transverse and longitudinal septa creating multiple cells is a dictyospore. Variations in conidial shape include scolecospores, which are long and thin (with the length more than 15 times the width), staurospores that have radiating arms, and helicospores that are curved through more than a half-circle. Conidia are often hyaline, but some of the larger conidia with septations are dark because of melanin deposition in the wall. Some varieties of conidial morphology are shown in Figure 46.22 [9, 80].

In most of the Ascomycota with a hyphal growth form, conidia develop by one of two basic mechanisms known as thallic or

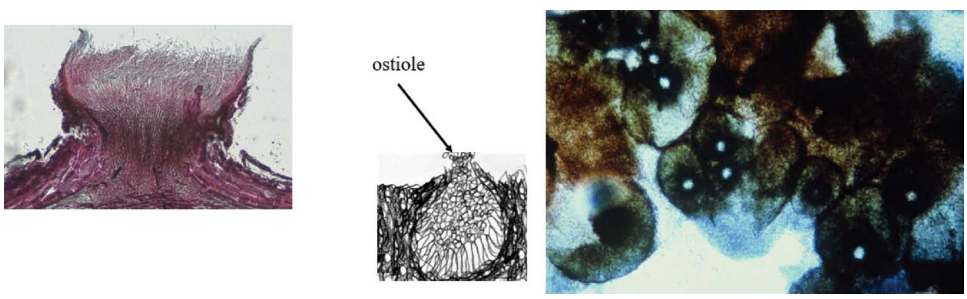

FIGURE 46.21 Representative modes of organization of conidiophores among Ascomycota coelomycete anamorphs. Left: *Nectria cinnabarina*, acervulus erupting through three bark. blastic. Thallic conidiogenesis occurs by the conversion of sections of hyphae that were located between adjacent septa (or at the end of a hypha) into the resulting conidia, with more or less modification of the shape of the original hyphal sections as they mature, and the resulting amerospores are likely to have a short cylindrical shape rather than an elliptical or globose shape. Blastic conidiogenesis occurs by budding of a conidium from its hypha of origin and is comparable to the blastospore formation described in the introductory section of this chapter in which the yeast growth form was explained. As the bud develops into the conidium, it takes on the shape that is characteristic for the conidia in that species as genetically determined regions of the cell wall balloon out [74, 76].

In most species of Ascomycota with blastic conidiogenesis, the hypha of origin is modified for conidial production and is recognized as a conidiophore. Both thallic conidia and blastic conidia are separated from the hypha of origin or from each other by the formation of either a double septum or by the formation of a separating cell between the conidium and its hypha of origin, followed by the breakdown of cell wall material to release the conidium. The separation of a conidium by wall breakdown at a double septum is known as schizolytic, while the release of a conidium by breakdown of a separating cell is known as rhexolytic [74, 78, 81, 82].

Compared with thallic conidiogenesis, there is much more variety in the modes of blastic conidiogenesis, depending on whether there is a chain of conidia or individual conidia, whether the newest conidia in a chain are at the base or at the tip of the chain, whether or not the hypha of origin is modified into a conidiophore, what shapes, septations, and colors occur in the conidia that are produced, in addition to the distinction between hyphomycetes and coelomycetes described previously [9, 74].

Several commonly observed modes of conidiogenesis in anamorphic Ascomycota are listed next and illustrated with examples in Figure 46.23.

a. Arthric: Thallic conidiogenesis in which the hyphal cells develop into conidia that separate schizolytically into a chain that appears jointed, thus the basis for the name.

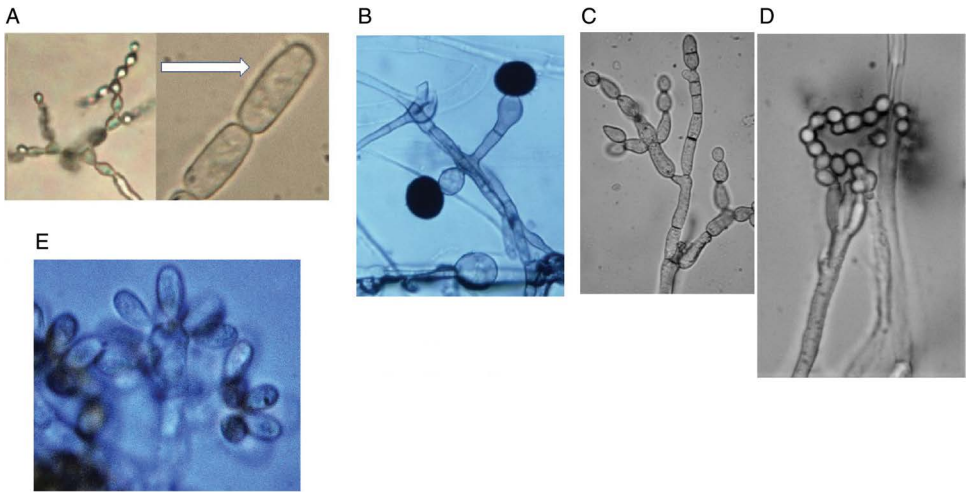

FIGURE 46.23 Modes of conidiogenesis among anamorphic Ascomycota. A: Arthric conidia of *Neurospora intermedia*. B: Solitary conidia of *Nigrospora sphaerica*. C: Acropetal conidia of *Cladosporium cladosporioides*. D: Phialidic conidia of *Penicillium notatum*. E: Synchronous conidia of *Botrytis cinerea*.

b. Solitary: Thallic conidiogenesis in which the terminal cell of the hypha becomes modified into a conidium, often becoming enlarged before it separates schizolytically.
c. Acropetal: Blastic conidiogenesis occurs at the tip of a hypha, and is followed by blastic conidiogenesis of an additional conidium arising from the first conidium, then from the second and third conidium, with the process repeating (with double conidia formed on some of the conidia, resulting in branching) until there is a branching chain of conidia, with the oldest at the base and the youngest at the tips of the branches.
d. Phialidic: Blastic conidiogenesis occurs from within an elongated flask-shaped cell at the tip of the conidiophore, with each new conidium pushing the previous one farther away from the phialide as it emerges. In some fungi, each conidium may cling to the previous conidium so that a chain develops with the oldest conidium at the tip and the youngest at the base, while in others, the conidia may accumulate around the phialide. Since new cell-wall material is laid down around each conidium as it is budded from the phialide, this may result in an internal thickening of the phialide until it no longer functions, at which time a new phialide develops next to the original phialide.
e. Synchronous: Blastic conidiogenesis occurs at several points over the surface of an enlarged terminal cell of the conidiophore, resulting in simultaneous formation of many conidia [9, 74, 78].

Classes and Representative Orders of Ascomycota of Importance in Human Affairs

The holomorphs of many of the Ascomycota have been identified and their relationships have been analyzed on the basis of genomic and ultrastructural evidence, leading to the recognition of three subphyla: the Taphrinomycotina, the Saccharomycotina, and the Pezizomycotina [3, 9, 74].

Taphrinomycotina

The members of this subphylum do not produce ascogenous hyphae or ascocarps and occur as a yeast form for part or all of their life cycle. This subphylum is distinct from the "true" yeast subphylum Saccharomycotina that includes the more familiar species utilized as leavening agents and brewing and is apparently descended from the ancestors of the entire phylum. The three classes of significance in this subphylum are the Schizosaccharomycetes, Taphrinomycetes, and Pneumocystidomycetes [9].

Schizosaccharomycetes

This is the class of "fission yeasts" in which the organism consists of rod-shaped cells 7–14 µm in length that elongate at the cell tips until they divide by mitosis at their medial region to produce two daughter cells of equal size (a process known as "medial fission," which is quite different from the budding process in other yeast-forming fungi). Typical cells of this group are shown in Figure 46.24. The economic significance of the genus *Schizosaccharomyces* is that of a fermenting organism utilized in the production of some alcoholic beverages, but the species *Schizosaccharomyces pombe* is also of importance as a model organism that has been the subject of extensive research into cell cycle regulation and genetics, and its genome was fully sequenced in 2002 [9, 83].

Taphrinomycetes

This class includes the one order Taphrinales and is unusual among Ascomycota in that the growing hyphae are diploid rather than haploid or dikaryotic. Although these organisms form ascogenous hyphae, the asci are produced at the surface of the tissues of a host organism without any supporting ascocarp, and the mature asci release their ascospores by splitting open at the tip rather than having an operculum or expanding ring of cell wall material, as illustrated in Figure 46.24. The ascospores bud to form yeast cells that form additional cells by budding, representing the yeast stage in this order. The best-known species in this class is *Taphrina deformans*, the causal organism of a leaf curl disorder in peaches and almonds. This disease can cause significant damage to the leaves of infected plants and the loss

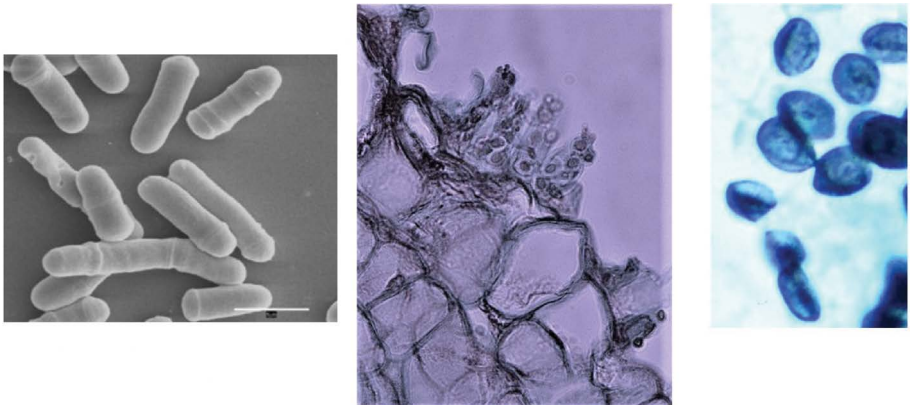

FIGURE 46.24 Three classes within the Taphrinomycotina. Left: Schizosaccharomycetes, *Schizosaccharomyces pombe*. Middle: Taphrinomycetes, *Taphrina deformans*. Right: Pneumocystidomycetes, *Pneumocystis jirovecii*.

of developing fruit. The various species in this class are fairly host-specific and cause abnormal developmental symptoms in the plants that are infected [9, 84].

Pneumocystidomycetes

This class includes the one order Pneumocystidales that contains the one family *Pneumocystidaceae* that contains the one genus *Pneumocystis* in which the species now known as *Pneumocystis jirovecii* is the causal organism of pneumocystis pneumonia. This organism was previously considered to be a protozoan with the name *Pneumocystis carinii*, but it was subsequently recognized as a member of the Ascomycota, and as such the species name was officially changed to *P. jirovecii*. However, it should be noted that the well-established name *P. carinii* has been retained in much of the clinical literature on this disease. This organism appears to be fairly ubiquitous and is readily cleared by a competent immune system if there is an exposure to it, but it has been recognized in recent years as a biotrophic parasite, causing disease in immunocompromised individuals. The organism occurs as an extracellular parasite in lung tissue, as shown in Figure 46.24, but it has not yet been grown in culture. An increase in the number of parasitic cells by mitosis during infection is comparable to the asexual reproduction of other Ascomycota, and the formation of globular cysts with a thick cell wall, followed by their rupture to release eight spores, is seen as evidence that this is a type of ascus in which karyogamy and meiosis take place. Until the development of therapies to control this infection, the disease caused by this organism contributed to the death of many individuals infected by the human immunodeficiency virus [85–87].

Saccharomycotina

These are the true yeasts that reproduce asexually by budding, and that produce neither ascogenous hyphae nor an ascocarp. Their growth forms include septate hyphae, pseudohyphae, and typically budding yeast cells. The hyphal septa in this subphylum differ from those of other Ascomycota in that they are perforated by many micropores, and there are no Woronin bodies associated with them. This subphylum includes the one class Saccharomycetes that contains the one order Saccharomycetales. Of the 13 families described in this order, the *Saccharomycetaceae* is most familiar in that it includes both the well-known "baker's/brewer's yeast" genus *Saccharomyces* and the diverse genus *Candida* that includes species of clinical importance.

The Genus Saccharomyces

There is considerable variation in the chromosome number in *Saccharomyces* populations, including the common occurrence of metabolically active diploid cells arising through the plasmogamy ("mating") of compatible haploid cells and of aneuploid and polyploid forms. These cells reproduce asexually by budding, but in *Saccharomyces cerevisiae* certain conditions may trigger the meiosis of the diploid nucleus of a cell, resulting in the formation of four ascospores in an ascus derived from the mother cell in which meiosis took place. Such ascospores typically have a thick resistant wall, and function in survival rather than in dispersal of the organism [15, 88, 89].

The commercial and biopharmaceutical utilization of *Saccharomyces* species is based on technology developed in the production of beer and wine. *Saccharomyces cerevisiae* is utilized in the production of ale, while *S. carlsbergensis* is involved in the production of lager. *S. cerevisiae* var. *ellipsoideus* is the most common wild yeast from grape skins that is associated with the production of grape wines. With the development of techniques for genetic recombination, *S. cerevisiae* has been successfully utilized in the production of enzymes, biomass, and a number of pharmaceutical products such as hepatitis B subunit vaccine, Leukine, platelet derived growth factor, and Gardasil [88, 90–93].

Although the teleomorph of *Candida albicans* is *Saccharomycopsis*, this species and other pathogenic *Candida* species are primarily known by their anamorph name and morphology in clinical practice. *Candida albicans* is normally a harmless part of the intestinal microbiome, but under certain conditions it can infect the mucous membranes (causing thrush or vaginal candidiasis) and skin (cutaneous candidiasis). In individuals who are immunocompromised or otherwise compromised by metabolic disorders or long-term utilization of catheters or intravenous delivery of nutrients, candidiasis can extend throughout the alimentary canal or become disseminated as a septicemia. *Candida auris* (named for its original isolation from the ear) has been recognized in recent years as the causal agent in increasing numbers of systemic infections, complicated by its resistance to most antifungal treatments [94–97].

Candida species display dimorphism by switching from a yeast form to a filamentous form (pseudohyphae) at 37°C, neutral pH, elevated CO_2 levels, and serum presence, then switching back to the yeast form at lower temperatures, acidic pH, and rich nutritional conditions. Both forms occur in culture as shown in Figure 46.25. This property evidently enhances the ability of pathogenic species to pass through tissue barriers until they reach circulatory pathways leading to systemic invasion [95, 97].

Pezizomycotina

This is the largest of the subphyla of Ascomycota, and the teleomorph (when present) forms its asci within some type of ascocarp. The holomorphic species are classified into six classes, 18 orders, and a great number of families and genera. In addition to the known holomorphs, there remain many anamorphs that

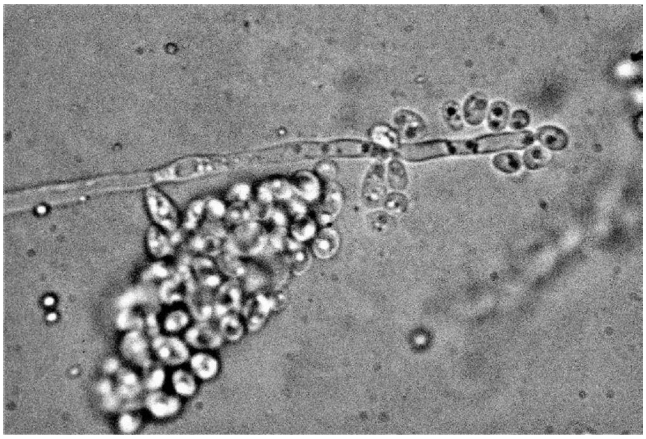

FIGURE 46.25 Candida albicans growth form.

can only be indirectly correlated with the holomorphic species. Representative examples of some of the holomorphs and anamorphs of importance in human affairs are described here.

Class Pezizomycetes

This class includes the one order Pezizales, the group in which the asci are unitunicate-operculate, and in most of the genera the asci appear on above-ground apothecia, as represented in Figure 46.18. Most of the members of this order are saprotrophs, although some are biotrophs that have an ectomycorrhizal relationship with tree roots. The apothecia of these fungi are often seen in wooded areas, including those of the genus *Morchella* in which a large edible ascocarp known as the "morel" is produced. The asci of the morel are on multiple apothecia that form in pits on the surface of a ridged conical head supported by a hollow stalk. A second type of edible ascocarp is produced by the genus *Tuber*, which has evolved into an entirely closed underground structure containing prototunicate asci surrounded by a dense mass of hyphae. There are various colors, flavors, and fragrances of these ascocarps in different species of *Tuber*, which are well known as the edible truffles. The fragrance and edibility of truffles function in attracting animals (primarily mammals, such as pigs) that disperse the ascospores during their feeding activity. *Tuber* is also notable because its mycelium grows in association with roots of trees with which they have an ectomycorrhizal relationship [98–101].

Class Dothideomycetes

All members of this class produce bitunicate asci, and the ascospores typically become septate internally to form either phragmospores or dictyospores. Although most of the fungi within this class are saprotrophic, many them are also necrotrophic plant pathogens. The order Dothidiales includes the family *Venturiaceae*, which includes the causal organism of apple scab disease, *Venturia inaequalis*. The major damage in this disease results from necrotic spots on the leaves and disfiguring scabs on the fruit. During the growing season, its anamorph *Spilocaea pomi* produces blastic conidia on exposed conidiophores (thus is a hyphomycete), and these conidia initiate new infections during the growing season. The teleomorph consists of pseudothecia that develop from mycelium in dead leaves on the ground in the spring, as shown in Figure 46.19, leading to the release of ascospores that begin the next disease cycle [9, 102].

The Capnodiales are another order in the Dothideomycetes of importance as plant pathogens, and they include the family *Mycosphaerellaceae* containing the genus *Pseudocercospora*, which is the anamorph of *Mycosphaerella*. The conidia are elongated phragmospores produced in an acervulus on short conidiophores. Species in this genus cause of variety leaf and fruit spots and blights of many tropical fruit crops, including sigatoka disease of bananas, something that represents a significant threat to banana production in many regions [103].

The Pleosporales are a third order of economic significance in the class Dothideomycetes and include the families Pleosporaceae and Didymellaceae that include teleomorphs of several plant pathogenic species. However, these plant pathogens are better known by the names assigned to their anamorphic forms (some of which have no known teleomorph), represented by the following examples.

a. *Alternaria* is a hyphomycete anamorph in the family Pleosporaceae, and it produces branching acropetal chains of conidia that become darkened dictyospores through internal septations and accumulation of melanin as they mature, as shown in Figure 46.26. The numerous species of this genus are typically necrotrophic, causing leaf spots as well as lesions on fruits and stems, and they attack a very wide host range of cultivated plants. The conidia in this genus are also important as an airborne allergen [9, 104].
b. *Stemphylium* is another hyphomycete anamorph in the family Pleosporaceae, associated with the holomorph *Pleospora*, but the sexual stage has not been observed in nature. Its conidia are produced blastically on short conidiophores and become darkened dictyospores through internal septations and accumulation of melanin as they mature, similar to those of *Alternaria*, except that its conidia are solitary, also shown in Figure 46.26. It is a necrotrophic plant pathogen often attacking the leaves of vegetable and field crops [105].
c. A third example of a destructive plant pathogen in the Pleosporaceae is the genus *Bipolaris*, a hyphomycete producing long elliptical (15–20 µm × 70–160 µm) phragmospores blastically on simple conidiophores that have a geniculate appearance, bending back and forth at the points where the conidia arise. There are several plant pathogenic species in this genus, many of them identified in the older literature as *Drechslera* or *Helminthosporium*. The species *Bipolaris maydis* (of which the teleomorph is *Cochliobolus heterostrophus*) is the cause of southern corn blight, a disease that caused major losses of the corn crop during 1969–1970 because most of the hybrid corn at that time shared a genotype that made it susceptible to this infection [106].
d. *Phoma* is a coelomycete anamorph in the family Didymellaceae, and the holomorph associated with most species in this genus is *Didymella*. The conidia of *Phoma* are produced on short phialides lining the interior of a pycnidium and are extruded in a slimy mass that is adapted for rain splashing of conidia, as illustrated in Figure 46.21. Species of *Phoma* are necrotrophic pathogens of numerous cultivated plants, causing leaf spots, blights, and stem cankers [48, 107, 108].

Class Eurotiomycetes

Most of the members of this class have prototunicate asci enclosed in a cleistothecial ascocarp. One of the orders in this class is the Onygenales that is of considerable clinical importance. One of the medically important families in this order is the Arthrodermataceae, known for the ability of many of its members to digest keratin. As with the Pleosporaceae described above, the fungi represented by teleomorphs in this family are better known by the names assigned to their anamorphic forms (some of which have no known teleomorph). Only nonliving tissues of the skin, hair, and nails are invaded by these dermatophytes, but the metabolites of the fungi create the familiar symptoms and host tissue responses, including shedding of thickened keratinized epithelium that tends to favor dispersal of

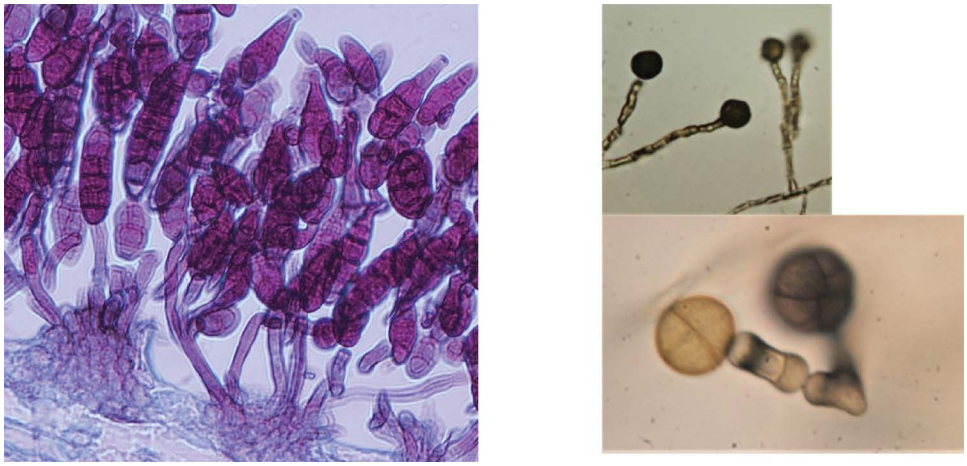

FIGURE 46.26 Plant pathogenic members of the Pleosporaceae known only by their anamorphs. Left: *Alternaria alternata*. Right: *Stemphylium sarcinaefome*.

conidia of these fungi to additional hosts. The anamorphic characteristics of three commonly encountered dermatophytes are as follows:

a. *Microsporum* is identified based on its large septate macroconidia with echinulate to verrucose (more or less spiny and roughened) cell walls, formed by thallic conidiogenesis. No microconidia are produced in this genus.
b. Several species of *Trichophyton* produce pyriform/globose microconidia by blastic conidiogenesis directly on growing hyphae, as shown in Figure 46.27, and some produce macroconidia that are similar to those produced by *Microsporum* except they are smooth-walled.
c. *Epidermophyton* produces both septate macroconidia and arthric conidia by thallic conidiogenesis, but it does not form blastic microconidia, in contrast with *Trichophyton* [94, 95, 109].

Two other families of clinical significance in the Onygenales are the Onygenaceae and the Ajellomycetaceae. The Onygenaceae includes the clinically important anamorphic genus *Coccidioides*, of which the species *Coccidioides immitis* is the cause of coccidiosis in humans. This organism is placed into this holomorphic family based on genomic and ultrastructural evidence, even though its teleomorph is unknown. It grows as a filamentous fungus in nitrogen-rich soil and produces small (3–5 µm) arthric conidia by thallic conidiogenesis as shown in Figure 46.27. If the conidia are inhaled by a human, they parasitize the lung tissue as a necrotrophic pathogen, switching to a yeast form under physiological conditions. During the infection, the fungal cells become enlarged into spherules in which large numbers of nuclei are formed by mitosis, after which cytoplasmic cleavage results in the formation of numerous endospores. The endospores can continue the lung infection, or if released into the environment can germinate to form the hyphae of the filamentous saprotrophic stage [94, 110].

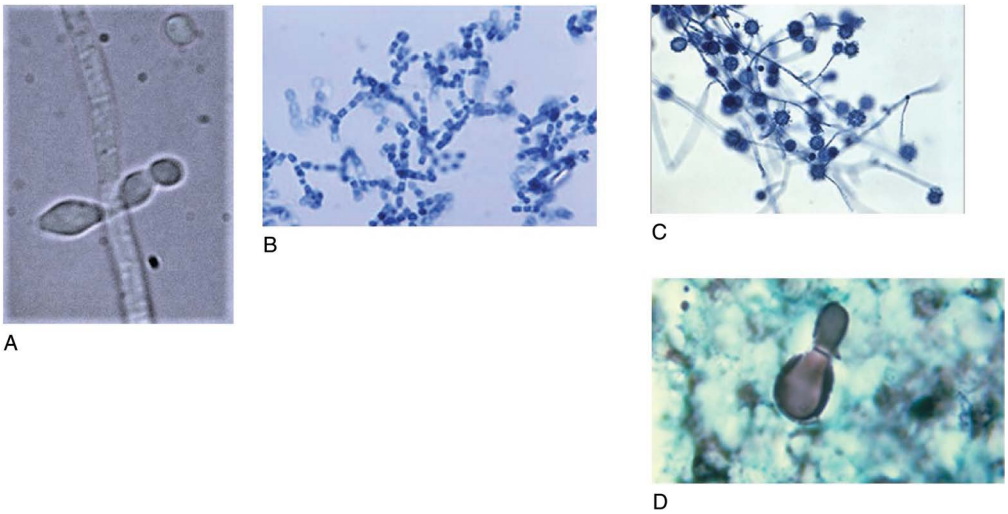

FIGURE 46.27 Human pathogens in three of the families in the order Onygenales. A: *Trichophyton mentagrophytes* in the Arthrodermataceae. B: *Coccidioides immitis* in the Onygenaceae. C: *Ajellomyces capsulatus* (*Histoplasma capsulatum*) in the Ajellomycetaceae. D: *Ajellomyces dermatitidis* (*Blastomyces dermatitidis*) in the Ajellomycetaceae.

The Ajellomycetaceae includes the clinically important genus *Ajellomyces* in which there are two species causing human infections, but much of the literature regarding these infections refers to the anamorph names, and the clinical terms for these infections are also based on the anamorph names. The anamorph of *Ajellomyces dermatitidis* is *Blastomyces dermatitidis*, which forms short conidiophores that produce small (2–10 µm) blastic conidia that are readily airborne and inhaled, shown in Figure 46.27. The infection is known as blastomycosis, and typically begins as granulomas in the lungs showing up as pneumonia, but can become disseminated to other organs, especially the skin, bones, joints, and the genitourinary tract. This disease is endemic to eastern North America, including Eastern Canada and the United States, and is apparently associated with high organic-matter soil with an acidic pH and high moisture levels created by nearby waterways [94, 111–113].

The anamorph of *Ajellomyces capsulatus* is *Histoplasma capsulatum,* which forms short conidiophores that produce two types of conidia blastically: ovoid microconidia (2–4 µm) and globose macroconidia (8–15 µm) with finger-like projections on the cell wall, also shown in Figure 46.27. This species occurs widely in nitrogen-rich soil and is common in central and eastern North America.

The microconidia are readily airborne and inhaled, but when phagocytized they remain active within the phagocytes, leading to a condition known as histoplasmosis. This organism is dimorphic, switching to a yeast form when growing necrotrophically inside the human body at 37°C [35].

The Eurotiomycetes are also of considerable importance because of the inclusion in this class of the order Eurotiales, in which the known teleomorphs produce a thick-walled cleistothecium surrounding several spherical prototunicate asci (shown in Figure 46.28) containing distinctive ascospores (many of them oblate with an equatorial ridge, or "pulley-wheel" shape). The family of most importance to humans within this order is the Trichocomaceae, given that it includes the teleomorphs of the highly significant anamorphic genera *Aspergillus* and *Penicillium* (although some anamorphic species in these genera have no known teleomorph). Some of the holomorphic genera that are associated with *Aspergillus* species are *Emericella, Eurotium,* and *Neosartorya*; holomorphic genera associated with *Penicillium* species include *Carpentales, Eupenicillium*, and *Talaromyces* [9, 91, 114–116].

The Trichocomaceae also includes the holomorphic genus *Byssochlamys,* which is primarily known as a genus containing heat-resistant spores that germinate leading to growth within containers of canned fruits and bottled fruit juices resulting in their spoilage. A common anamorph of *Byssochlamys* is *Paecilomyces*, a very diverse genus found on a wide variety of substrates, and the necrotrophic infections of fruit crops that it causes may explain its presence in canned fruit products [117–120].

The asexual spores of *Aspergillus*, *Penicillium*, and *Paecilomyces* are formed blastically on phialides from which they are produced in basipetal succession, and they tend to cling together in chains until they are dislodged and become airborne. The conidiophores of *Aspergillus* species arise from a vesicle supported by an unbranched conidiophore. The phialides in *Penicillium* species develop in parallel bundles supported by hyphae with various levels of branching, creating the familiar "paint brush" form. Conidiophores of *Aspergillus* and *Penicillium* are shown in Figure 46.28. The phialides of *Paecilomyces* species may be solitary, in pairs, as verticils, or in penicillate heads [9].

Several *Aspergillus* species have a beneficial impact on human affairs, and examples include the use of *Aspergillus oryzae* in the production of soy sauce, miso, and saké, the use of *Aspergillus niger* in the production of citric acid, and the production by this and other *Aspergillus* species of enzymes and organic acids utilized in processing of food and animal feed [121, 122].

Growth of *Aspergillus* species can also have a negative impact, including the production of carcinogenic aflatoxins in stored grains and nuts by *Aspergillus flavus* and *Aspergillus parasiticus*, as well as spoilage of stored foods. *Aspergillus fumigatus* (with *Neosartorya* identified as its teleomorph) is a species of clinical importance because of its ability to colonize the pulmonary system as an opportunistic pathogen, which can include growth within a lung cavity created by a previous occurrence of Mycobacterial tuberculosis (known as an aspergilloma), leading to breakdown of the cavity wall [94, 123].

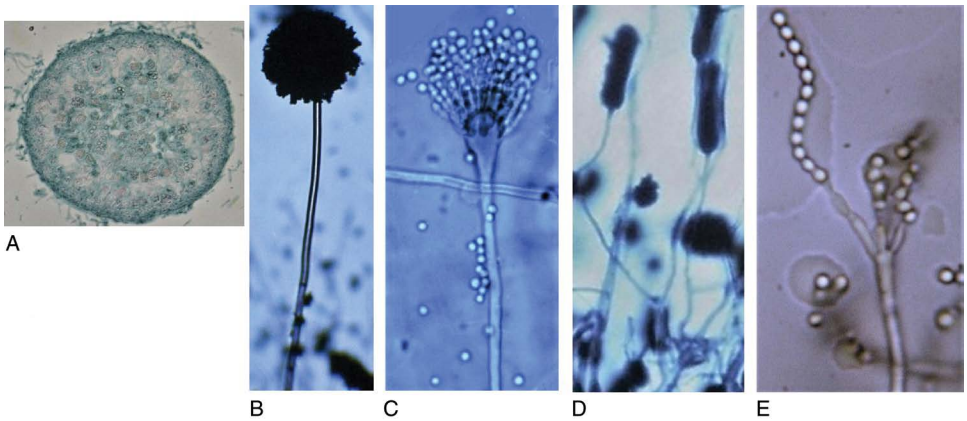

FIGURE 46.28 Teleomorph and anamorph stages of significant genera in the Trichocomaceae. A: Cleistothecium of teleomorph stage of *Aspergillus* sp. Note the ascospores within prototunicate asci. B: *Aspergillus niger* conidiophore. C: *Aspergillus oryzae* conidiophore. D: *Aspergillus fumigatus* conidiophores. E: *Penicillium notatum* conidiophore.

Penicillium is the genus well-known for the production of penicillin by some of its species, as discovered and published by Sir Alexander Fleming in 1929 (but not produced in large quantities until the 1940s). Fleming originally described the antibiotic from *Penicillium notatum*, but *Penicillium chrysogenum* became the major source of this antibiotic during the years in which it was first utilized for treating bacterial infections. Griseofulvin is an antifungal antibiotic produced by *Penicillium griseofulvum*. Various *Penicillium* species are also utilized for their production of enzymes and organic acids for industrial use, and the growth of species such as *Penicillium caseiolum, Penicillium camemberti*, and *Penicillium roqueforti* on certain cheeses creates desirable modifications of those foods. However, there are also species of *Penicillium* that produce mycotoxins in stored food products, including patulin formation in stored apples by *Penicillium expansum* [91, 121, 122].

Class Leotiomycetes

All members of this class have unitunicate-inoperculate asci formed within various types of ascocarps, including apothecia and cleistothecia. The holomorph is well known for most of the fungi in this class, although different names continue to be used for the holomorph and anamorph stages of most of these organisms since a number of plant diseases are associated with the anamorph stage [9].

The order Helotiales within this class include several necrotrophic plant pathogens that cause significant economic loss, most of them in the family Sclerotiniaceae, but there are destructive pathogens in other families as well. Three examples of plant pathogens in the Sclerotiniaceae are:

a. *Sclerotinia sclerotiorum*, which is known for producing sclerotia (but not conidia) and causing such diseases as stem rot, crown rot, and blossom blight of field crops. Apothecia develop from overwintering sclerotia at the beginning of the next growing season, releasing ascospores that are the inoculum for the next disease cycle [48].
b. *Monilinia fructicola*, which causes soft rot of peaches and other stone fruits. Apothecia develop from mummified fruit containing mycelium from the previous season, releasing ascospores at the time fruit trees are flowering to initiate new infections. Blastic acropetal conidia are produced on the infected plant tissues during the growing season as inoculum for additional infections, and this anamorphic stage has the name *Monilia fructicola* [48].
c. *Botryotinia cinerea*, which represents the teleomorph of the anamorph *Botrytis cinerea*; the anamorph name of this organism is most widely used, given that the blastic synchronous conidia are the only commonly observed stage of this fungus, and the primary overwintering structures are sclerotia that germinate to produce new mycelium. This organism is a necrotrophic pathogen with an extremely wide host range, commonly described as "gray mold." It frequently causes a soft rot of mature plant structures such as fruits, storage organs, and flowers, but it can also attack susceptible leaves and seedlings. Its conidiophores are branched with multiple denticles on a terminal cell (shown in Figure 46.23) on which many individual conidia are produced by synchronous blastic conidiogenesis [9, 48].

Another order in the Leotiomycetes that includes significant plant pathogens is the Erysiphales—the powdery mildews that attack a wide range of cultivated plants. The members of this order are biotrophic pathogens, dependent on a parasitic relationship with a host plant. The hyphae of a powdery mildew remain outside the host plant except for the penetration of the cell wall of individual epidermal cells by an appressorium and the development inside each cell of a fungal haustorium that typically branches within the host cell and absorb nutrients through the plasma membrane of the living host cell. The anamorph genus for most powdery mildews is *Oidium*, which develops unbranched conidiophores on the external hyphae on the surface of the host as shown in Figure 46.29. These conidiophores produce basauxic chains of conidia (with the youngest conidium at the base of the chain) that function as the inoculum during the growing season. The conidia have a powdery appearance on the surface of the plant (the basis for the common name), and are airborne to new host plants; they are unique in their specific requirement for a dry surface but high humidity for successful germination on the surface of the new host. Cleistothecia typically develop on the surface of the infected plant late in the season (as shown in Figure 46.29) and serve as overwintering structures. The cleistothecia often have distinctive appendages that may play a role in the dispersal of the cleistothecia themselves and serve as an identifying feature.

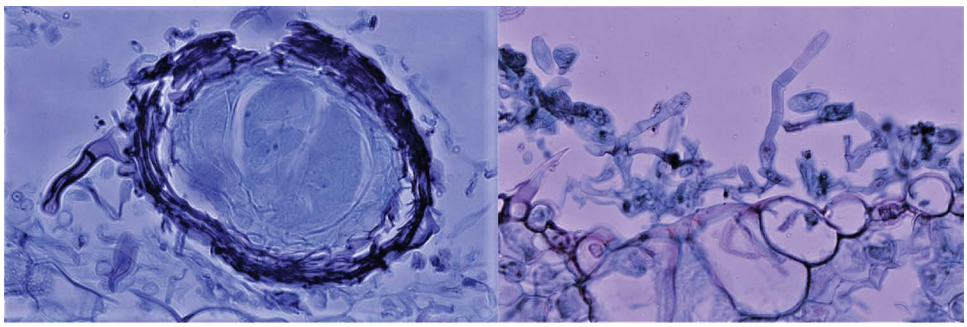

FIGURE 46.29 Teleomorph and anamorph of powdery mildew. Left: Cleistothecium; note the broken appendage. Right: Conidiophores with conidia nearby; note haustoria penetrating epidermal cells.

They open to allow the asci to eject ascospores that have the same germination requirements as the conidia [9, 124].

Class Sordariomycetes

Members of this class with a known teleomorph have unitunicate-inoperculate asci that develop inside perithecial ascocarps. Most of the seven orders in this class are saprotrophic, although they also include necrotrophic or biotrophic plant pathogens, some parasites on arthropod hosts, and one species that causes a necrotrophic infection of humans. Selected examples are described next:

a. Hypocreales: This order includes several holomorphic families of significance along with one related anamorphic genus for which the teleomorph has not yet been identified.

   The Nectriaceae include the holomorphic genus *Nectria* that is known as a necrotrophic pathogen of tree species, causing cankers and dieback, as illustrated in Figures 46.19 and 46.21. The anamorph of *Nectria haematococca* is *Fusarium solani*, a significant necrotrophic pathogen of numerous commercially important plants. Fusarium species produce canoe-shaped phragmospores with a distinctive "foot cell" at one end (macroconidia) as shown in Figure 46.30, as well as single-celled microconidia on short slender phialides; chlamydospores often develop from one or more cells of a macroconidium. *Fusarium solani* and other species in this genus attack seedlings and roots, and also cause a wilt disease when they invade the vascular tissue of a plant host, releasing a toxin into the vascular stream that causes necrotic symptoms above the infection site. A mycoprotein food product known as "Quorn" has been developed in recent years through the culturing of *Fusarium venenatum* [125–127].

   The Hypocreaceae include the holomorphic genus *Hypocrea* which is known as a saprotroph on wood, but species in its anamorphic genus *Trichoderma* (which forms conidia on phialides on branching hyphae as seen in Figure 46.30) are often mycoparasitic (attacking other fungi). This trait makes *Trichoderma* of interest as a candidate for biological control of plant pathogenic fungi, and the cellulases produced by these fungi are also of value in digesting cellulose [9, 128, 129].

   The small anamorphic family Stachybotryaceae includes the saprotrophic species *Stachybotrys chartarum* (in addition to some plant pathogenic species). A corresponding teleomorph of *Stachybotrys* has been reported to be *Melanopsamma* in the holomorphic family *Niessliaceae* in the Hypocreales, but the anamorph binomial *Stachybotrys chartarum* is the name most associated with the fungus that produces trichothecenes that have been reported as contributing to sick building conditions. These mycotoxins can be released into the air from growth of colonies of *Stachybotrys chartarum* on interior surfaces of cellulose-containing building material (such as wallboard), which has become wet from flooding damage. The conidia of this species are dark, elliptical amerospores, produced singly on swollen phialides that develop in a cluster at the tip of the conidiophore, as shown in Figure 46.30. The conidia tend to collect into a slimy mass and would only be released into the air if the interior surfaces of the colonized building material were exposed through demolition activity, thus these conidia would not normally be found at high levels in indoor air [130–134].

   The family *Clavicipitaceae* includes the holomorphic species *Claviceps purpurea* that is a biotrophic parasite of rye. The rye flowers are inoculated by ascospores released by this species in the spring, leading to fungal growth in place of the normal rye ovary tissue. The anamorphic stage known as *Sphacelia* forms conidia in phialides on a mycelial mat that produces a sugary nectar, and this nectar attracts insects that disseminate the conidia to new hosts. Later in the season the mycelial mats develop into an ergot, which is a type of sclerotium formed on the rye plant. The ergots typically fall to the ground as an overwintering structure, and in the spring each one sprouts several

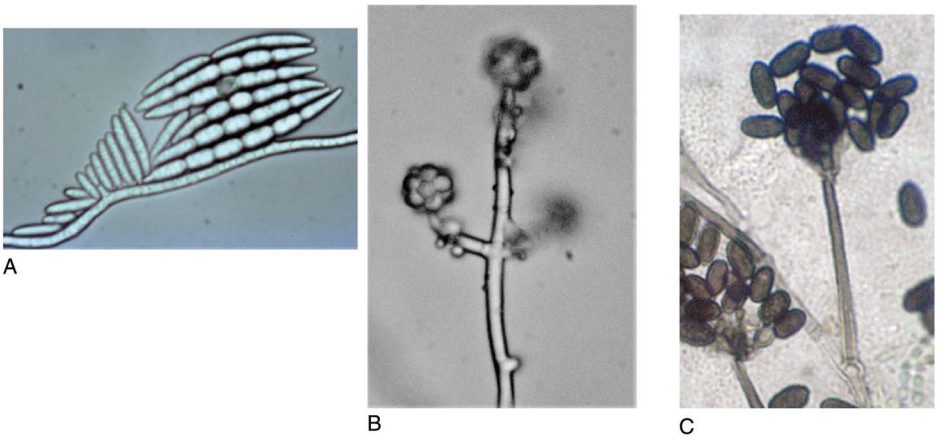

FIGURE 46.30 Anamorphic stages of members of three families in the Hypocreales. A: Nectriaceae: *Fusarium roseum* conidia from pure culture. B: Hypocreaceae: *Trichoderma viride*. C: Stachybotryaceae: *Stachybotrys chartarum*.

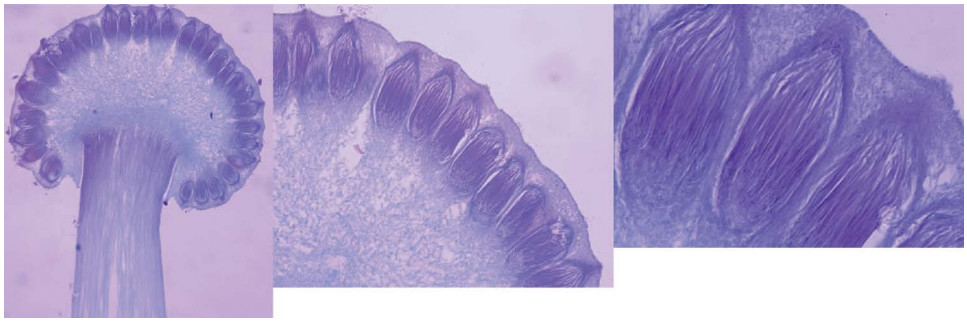

FIGURE 46.31 *Claviceps purpurea* stroma with multiple perithecia, magnified to show needle-shaped ascospores. Left: Terminal knob on stroma with imbedded perithecia. Middle: Detail of perithecia showing openings to the surface of the terminal knob. Right: Needle-shaped ascospores within asci contained within perithecia.

upright stalks made up of interwoven hyphae, each with a terminal knob. Perithecia develop on the surface these knobs, leading to the formation and release of the ascospores that begin the disease cycle again, as shown in Figure 46.31. If the developing ergots become harvested with rye grain instead of falling on the ground, the alkaloids in the ergots can produce the symptoms of ergotism if edible products made from the rye grain are consumed. Ingestion of ergot alkaloids leads to extreme smooth muscle contractions, which result in interrupted circulation and gangrene in affected tissues. This property of the alkaloids has been used pharmaceutically to induce uterine contractions and to control postpartum bleeding [9, 135].

Cordyceps is another genus in the family *Clavicipitaceae* that is of interest because of a highly beneficial pharmaceutical product derived from one of its anamorphs. While the holomorphic species *Cordyceps subsessilis* parasitizes beetle larvae, its anamorph *Tolypocladium inflatum* is the source of cyclosporine, the immunosuppressant that has become of great importance in minimizing organ transplant rejection as well as controlling some autoimmune disorders [91, 136].

Verticillium is apparently a member of the Hypocreales based on its characteristics, but its teleomorph is unknown at this time. The fungi in this genus invade plant hosts through natural wounds in the roots and enter the vascular tissue where they create a severe wilt disease because of xylem blockage. *Verticillium* produces blastic conidia on phialides that are arranged in whorls ("verticils") around an upright conidiophore, and the conidia tend to accumulate in a slimy cluster around each phialide in culture, but are carried by the xylem stream in a host plant to initiate infections at higher locations in the stem or trunk. Some *Verticillium* species produce microsclerotia as survival structures in the soil, some produce chlamydospores, and some survive in the soil as mycelium [137].

b. Sordariales. The species in this order are typically saprotrophic, which can lead to economic loss as in the case of the genus *Chaetomium* in the *Chaetomiaceae*, known for is cellulose-decomposing activity affecting canvas and other fabrics. The species *Neurospora crassa* in the *Sordariaceae* has been of particular importance in genetics research, and one of the factors that made it suitable for such research is its ability to grow on minimal media, making it possible to connect biochemical changes to genetic factors [138].

c. Ophiostomatales. Several genera and species in the family *Ophiostomataceae* are associated with beetles that tunnel through tree bark and function as vectors of fungi that invade the sapwood of trees, often causing a wilt disease or staining of the wood. The asci in this order break down to release their ascospores in a slimy mass that oozes out of the long tubular neck of the perithecium where they are picked up by tunneling beetles. *Ophiostoma ulmi* has caused the death of many American elms by the misnamed Dutch elm disease since its introduction to North America from Asia by way of the Netherlands. The conidiophores of its anamorph *Graphium* are bundled into a synnema that retains the conidia in a slimy droplet accessible to passing beetles. Another species in this genus that causes sapwood staining is *Ophiostoma stenoceras*, and its anamorph *Sporothrix schenckii* is associated with a subcutaneous infection in humans known as sporotrichosis when its conidia in soil or peat moss are introduced into a superficial wound. It responds to the higher temperature of a human host by transforming into a yeast that can become disseminated, leading to a significant medical condition in immunocompromised patients [94, 139, 140].

d. Glomerellales. Several species of necrotrophic plant pathogens attacking a wide range of hosts are within the holomorphic family *Glomerellaceae*, primarily in the holomorphic genus *Glomerella*, but the causal organisms are primarily known as the anamorphic genus *Colletotrichum*. The members of this coelomycete genus produce single-celled conidia (amerospores) within an acervulus (a disc-shaped mass of conidiophores originating under the surface of the host plant). When the cuticle or epidermis of the host ruptures from the pressure of the accumulating conidia, the resulting lesions are recognized as an anthracnose. [141].

Phylum Basidiomycota

Like most of the Ascomycota, the Basidiomycota typically have septate hyphae containing haploid nuclei, although there are a few members of the phylum that occur in a yeast form. Many Basidiomycota produce macroscopic basidiocarps that house the phases of the sexual stage, and many of them have anamorphs that produce conidia or sclerotia. A significant feature of the Basidiomycota is the common occurrence of dikaryotic vegetative hyphae, compared with the brief dikaryotic phase of most Ascomycota that is represented only by the ascogenous hyphae developing from an ascogonium. A hyphal structure associated with these dikaryotic hyphae in many of the Basidiomycota is the "clamp connection," which consists of the growth of a narrow tubular hypha extending from the new terminal cell to the adjacent cell concurrently with the simultaneous mitosis of the two nuclei in that cell. The clamp connection delivers one of the two resulting nuclei back to the adjacent cell so that both cells have one of each the two original nuclei, as shown in Figure 46.32. There are three subphyla in the Basidiomycota—Agaricomycotina, Pucciniomycotina, and Ustilaginomycotina—all of which produce basidiospores at the conclusion of their sexual stage, but the processes associated with this stage are unique to each of the three subphyla [10].

Agaricomycotina

Most of the members of this subphylum produce readily visible basidiocarps, comparable to the ascocarps described for the Ascomycota, and among these are the familiar mushrooms, bracket fungi, and puffballs along with the other less commonly seen earthstars, stinkhorns, and bird's nest fungi. The nutrition of most of the fungi in this subphylum is saprotrophic, with only a small number parasitic toward plants. Although the holomorph basidiocarp structure is most often recognized in this subphylum, conidia are produced by the anamorphs of several members of this group. The class Agaricomycetes includes most of the members of the Agaricomycotina subphylum, with a smaller number of species in two smaller classes known as the Dacrymycetes and Tremellomycetes [10].

The dikaryotic condition of fungi in this class originates through anastomosis of monokaryotic hyphae with compatible mating types and is maintained by the formation of clamp connections described earlier in this section. Dolipore septa (having a round pore with a barrel-shaped structure in the center, and bracketed by endoplasmic reticulum "parenthesomes" on either side, as shown in Figure 46.5) are also common in the Agaricomycotina [10, 142].

The two compatible nuclei of the dikaryotic hyphae typically form a diploid zygote by karyogamy within the club-shaped basidium (known as a holobasidium) that is characteristic of this subphylum. This is followed immediately in most members of this subphylum by meiosis, and the four resulting haploid nuclei are typically packaged into four basidiospores that form outside the basidium, created blastically on sterigmata, to which the basidiospores are attached asymmetrically. This sequence is illustrated in the series of diagrams in Figure 46.33. The basidiospores are propelled off the sterigmata by a mechanism that depends on the condensation of water vapor and osmosis of that water into a droplet containing mannitol and monosaccharides that is located at the base of each basidiospore. The basidiospores also accumulate a film of water by condensation on their hygroscopic surfaces, and at a certain point the basal droplets shift and merge with the water film on each spore, resulting in a force that separates the basidiospores from their sterigmata. This force is sufficient to carry the basidiospores far enough horizontally to reach a vertical space within the basidiocarp, allowing them to fall until they reach the turbulent air zone underneath and become dispersed by air currents. The basidia are typically packed together into a hymenium on the surface of the basidiocarp structure (commonly on gills or within pores), which are maintained in the necessary vertical orientation for basidiospores to escape from the structure [143].

There are exceptions to the typical dikaryotic state of the mycelium of the Agaricomycotina, such as the genus *Armillaria* in which karyogamy occurs immediately after plasmogamy, resulting in diploid vegetative hyphae. Basidiospores are produced as usual by meiosis of the diploid nuclei in the basidia that are formed on basidiocarps of such fungi [143].

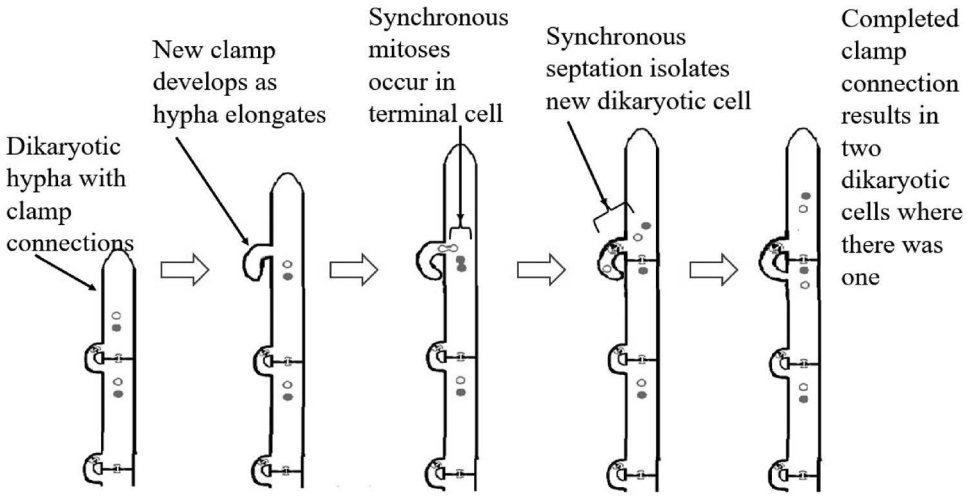

FIGURE 46.32 Clamp connection function in maintaining dikaryotic condition in Basidiomycota.

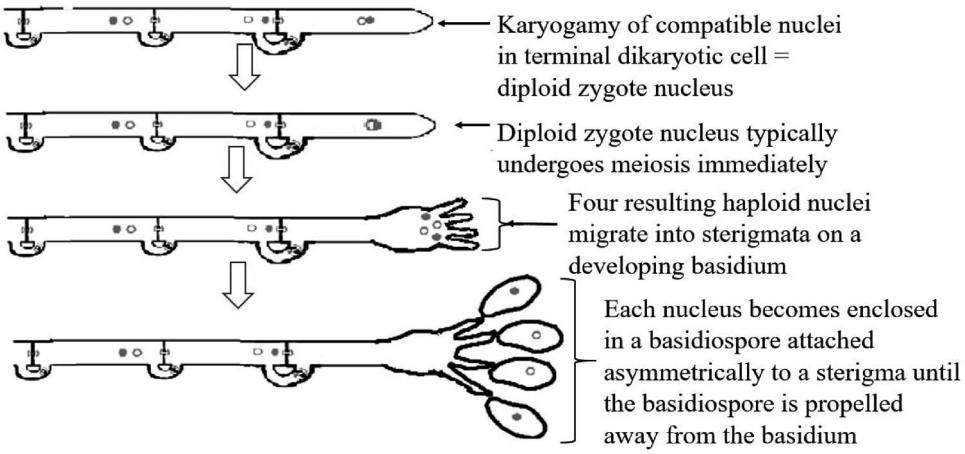

FIGURE 46.33 The sexual stage associated with the Agaricomycotina subphylum of Basidiomycota.

Based on molecular data, many of the Agaricomycetes have been classified into one of two subclasses—the Agaricomycetidae and the Phallomycetidae—but there are a number of other members of this class that are given the Latin designation "*Incertae sedis*" (uncertain position). The Agaricomycetidae is the group in which the members produce the mushrooms, brackets, and puffballs as their basidiocarps, developing from mycelium that obtains nutrients from a substrate (or host) [10].

The morphology of most basidiocarps in this subclass is adapted for the type of basidiospore dispersal described above, with a central stipe (stalk) supporting the pileus (cap) that commonly has its hymenium on the surface of gills or a porous structure underneath. A protective membrane-like layer known as a veil sometimes encloses all are part of the basidiocarp during its development, and remnants of this veil may persist on the fully opened structure in the form of a volva (surrounding the base of the stipe), patches on the surface of the cap, an annulus ringing the stipe, or a cortina (curtain-like remnants) hanging down from the edge of the pileus [144].

The two major orders within this subclass are the Agaricales and the Boletales. Although the Agaricales include the more familiar mushrooms with their basidia on gills, this order also includes the puffball *Lycoperdon* in which basidiospores are not propelled off of sterigmata, but are retained within the basidiocarp until it ripens to release the basidiospores in the powdery puff that occurs when raindrops (or other forces) strike the outer wall. There are a vast number of families, genera, and species within this subclass, and some representative examples are the edible *Agaricus* (the familiar grocery store mushroom) and *Lentinula* (the shiitake mushroom), the hallucinogenic *Psilocybe*, the tree pathogen *Armillaria* that attacks the roots and kills the tree, and numerous poisonous genera and species such as *Amanita*. Figure 46.34 shows cross sections of the pileus of a representative basidiocarp at different magnifications, revealing basidiospores arising from basidia lining the hymenium of the gills. Many members of this subclass are ectomycorrhizal on tree roots, primarily those of conifers. The Boletales produce fleshy basidiocarps similar to those of the Agaricales, but the hymenium is more often located within a porous structure than on gills, although gills also occur in some genera. Most of the Boletales are associated with ectomycorrhizae with tree roots [9, 28, 145–147].

Of the orders in the *Incertae sedis*, the Polyporales are significant as a large, economically destructive order since it includes numerous wood-rotting fungi. As the name indicates, the basidiocarps of the Polyporales typically have pores on the underside lined with basidia, as shown in the series of cross sections through the hymenium on the gills of a porous basidiocarp in Figure 46.35. Although some are fleshy and temporary like those of the Agaricales, many of them are corky or woody

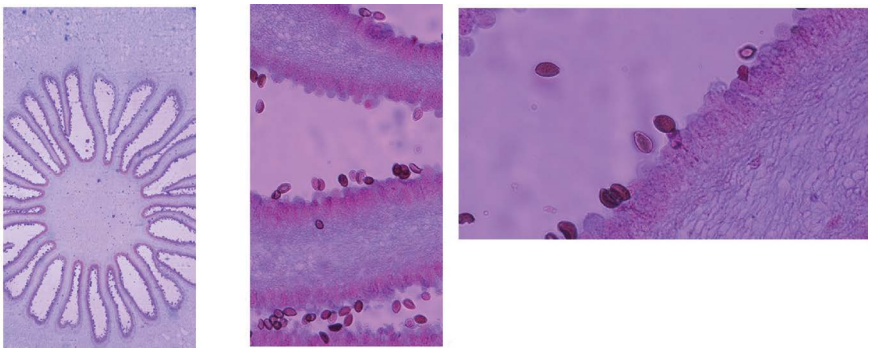

FIGURE 46.34 *Agaricus campestris* basidiospores on basidia in a hymenium on gills of basidiocarp. Left: Basidiocarp cross-section with gills radiating from the central stipe. Middle: Hymenium of basidia on the gill surface with basidiospores. Right: Magnified view of middle panel.

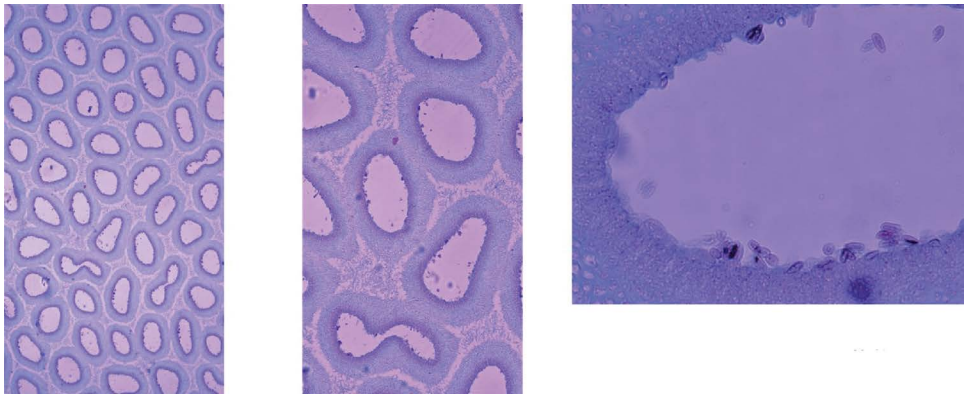

FIGURE 46.35 *Polyporus sp.* Basidiospores on basidia in a hymenium on surface of pores of basidiocarp. Left: Basidiocarp cross-section with pores on lower surface. Middle: Hymenium of basidia on pore surface with basidiospores. Right: Magnified view of middle panel.

perennial structures in which a new layer of pores is added to previous layers each year. Some members of this order (such as *Heterobasidion* and *Fomes*) are pathogenic, causing the weakening or death of host trees, while others such as *Polyporus* and *Ganoderma* are saprotrophic, growing on exposed heartwood of trees or on structural lumber. Fungi in this order are differentiated by the type of enzymatic digestion of wood they cause (brown rot fungi digest cellulose but not lignin, while white rot fungi digest lignin but not cellulose), the kinds of hyphae that make up the basidiocarp (whether they consist of only generative hyphae that create basidia or also contain thick-walled skeletal hyphae that create a hardened basidiocarp or thin-walled binding hyphae or both, along with other microscopic features). Anamorphs of these fungi may have thallic arthric conidia or blastic conidia produced on a vesicle [9, 48].

The subclass Phallomycetidae contains a relatively small number of orders, including the Phallales that rely mostly on flies for basidiospore dispersal. The members of this group release their basidiospores into a slimy mass with an odor of decaying animal flesh or feces, typically presented on upright basidiocarps that are often colorful and conspicuous [9, 80].

The class Dacrymycetes represents the jelly fungi that grow on decaying wood and that produce a gelatinous matrix through which their basidia elongate until they reach the surface where the basidiospores are propelled into the air.

The class Tremellomycetes also produces gelatinous basidiocarps, but differ from the Dacrymycetes in having vertically septate basidia with long sterigmata on which the basidiospores develop. Most of the anamorphs in this class are budding yeasts, and the basidiospores also germinate as budding yeast cells in most species. All teleomorphs in this class are mycoparasites, attacking both Ascomycota and Basidiomycota that occur on wood. The family Tremellaceae within the order Tremellales contains the genus *Filobasidiella neoformans* that is better known by its anamorph name *Cryptococcus neoformans*, which is of clinical importance as the cause of cryptococcosis. This species grows saprotrophically as a yeast on pigeon droppings and similar high-nitrogen substrates, and the cells are coated with a polysaccharide capsule that has a gelatinous consistency, as illustrated in Figure 46.36. This capsule functions as a virulence factor when the cells are inhaled and become established in a necrotrophic lung infection in individuals who are immunocompromised. The *Cryptococcus* yeast cells can become disseminated and initiate infections in multiple organs, including a meningitis with a very high mortality rate [148].

Pucciniomycotina

This subphylum consists of several classes and orders of fungi that are related to each other according to genomic data, but there is just one order in just one class that is of most importance as a category of plant pathogens: the Pucciniales in the Pucciniomycetes that cause rust diseases of plants. These fungi are biotrophic pathogens, with an obligately parasitic relationship with their hosts, and many of the rust fungi alternate between two host plant species, in which case they are described as being heteroecious; those that only occur on one host species are autoecious. The entry of the parasite into the host plant is initiated by spores that germinate on the surface and penetrate the epidermis with an appressorium. This leads to mostly localized infections of the host by the growth of hyphae within the tissues but between the cells, except for haustoria that penetrate individual cells and absorb nutrients through the plasma membrane of the host cells that the haustoria are in contact with. An overwintering spore known as the teliospore takes the place of the basidiocarp in the

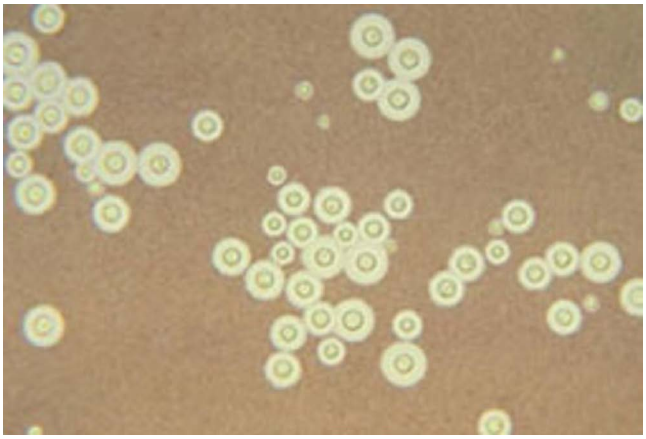

FIGURE 46.36 *Cryptococcus neoformans* suspended in India ink to reveal the capsule around each cell.

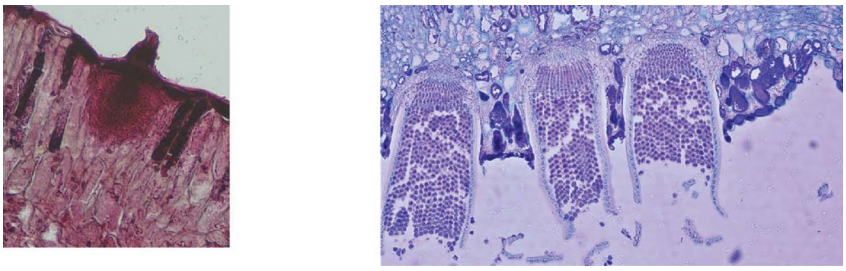

FIGURE 46.37 *Puccinia graminis* spore stages on *Berberis vulgaris*. Left: Spermatia with receptive hyphae extending above the surface of an infected leaf. Right: Aecia breaking through the lower epidermis and releasing aeciospores that function in inoculating wheat *Triticum aestivum*.

teleomorphic stage of the members of this order, and the anamorph of these fungi is represented by a series of conidial stages that are distinctive and characteristic of members of this order. If the teleomorphic teliospores are included, there can be as many as five spore stages in the life cycle of macrocyclic rust fungi, but microcyclic rust fungi have fewer than five spore stages. Both monokaryotic and dikaryotic phases occur in the life cycle, and the dikaryotic hyphae have a unique septal pore structure among Basidiomycota: a simple round pore in the center of which is suspended a "pulley wheel occlusion." The dikaryotic hyphae in this subphylum do not have the clamp connections that are common in the other two subphyla [10, 149].

The stem rust of wheat caused by *Puccinia graminis* subspecies *tritici* is widely cited as a representative macrocyclic heteroecious rust because of its economic impact as well as its well-defined spore stages, so it is described here for the same reasons. The annual disease cycle of this pathogen begins with airborne basidiospores that function as the inoculum that initiates the infection of the leaves of barberry (*Berberis*) by monokaryotic hyphae, leading to a fairly minor leaf spot disease. As the barberry leaf infection progresses, the fungus produces a specialized type of single-celled conidia known as spermatia, by phialidic conidiogenesis, within a droplet of nectar, along with several receptive hyphae, all of which are formed within a pycnidium-like structure known as a spermagonium, as shown in Figure 46.37. These conidia do not function as additional inoculum leading to additional barberry leaf infections, but instead are adapted for dispersal to other spermagonia by nectar-feeding insects where they function in the delivery of nuclei to receptive hyphae if they are of the opposite mating type, resulting in the establishment of dikaryotic hyphae. On the underside of the same leaf, the resulting dikaryotic hyphae create an acervulus-like structure under the epidermis known as an aecium in which unbranched conidiophores produce dikaryotic conidia known as aeciospores by arthrosporic conidiogenesis, also shown in Figure 46.37. Once the host epidermis ruptures to expose the aeciospores, they become airborne as the inoculum that initiates an infection of wheat plants (*Triticum aestivum*). As in the barberry host, the wheat infection is biotrophic, with an intercellular invasion that involves penetration of host cells with haustoria. The wheat infection leads to the formation of acervulus-like structures on wheat stems known as uredinia, within which conidiophores produce dikaryotic urediniospores on unbranched conidiophore in "pustules" under the epidermis that have a rust-red color, shown in Figure 46.38. The color of these urediniospores is the basis for the name of the disease (and for the ancient Roman festival of Robigalia that was held to appease the Roman god Robigus to protect the wheat fields against this disease). Once the host plant epidermis ruptures to release the urediniospores, they become airborne to other wheat plants and function as the inoculum for new stem rust infections, which can rapidly become widespread in a wheat-growing region, leading to considerable economic loss. Both the physiological effects of the infection and the damage to the wheat stems by this spore production causes reduced yields, excessive water loss, disruption of water transport, and weakening of stem tissue leading to stem breakage known as lodging. Toward the end of the growing season, the same stem lesions mature into telia in which the

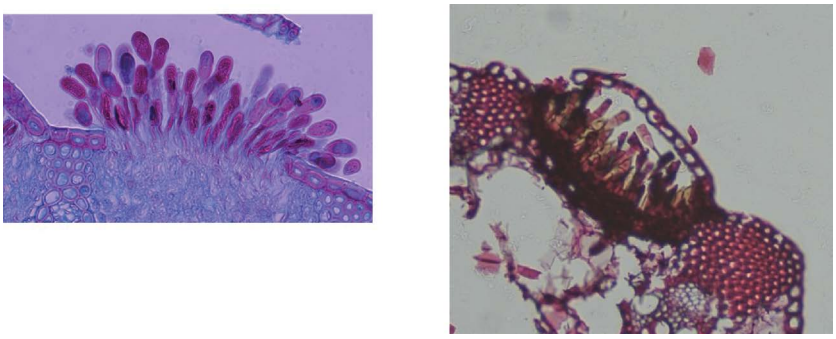

FIGURE 46.38 *Puccinia graminis* spore stages on *Triticum aestivum*. Left: Uredinia breaking through the epidermis of wheat and releasing urediniospores that function in inoculating wheat plants. Right: Telia developing on dead wheat stems and producing teliospores that overwinter until they germinate in the spring, leading to basidiospore production.

conidiophores produce terminal dikaryotic, pigmented, thick-walled, two-celled teliospores that remain attached to the stem tissue, shown in Figure 46.38. Karyogamy occurs within each cell of the teliospore while it functions as an overwintering structure very much like a sclerotium. At the beginning of the next growing season, at the time when barberry leaves have opened, each cell of the teliospore germinates with a short germ tube that develops into a septate four-celled basidium with a sterigma on each cell bearing a basidiospore. The basidiospores are propelled into the air by the same mechanism described above for other basidia, resulting in their being dispersed by wind, and those that land on barberry leaves may germinate and penetrate the leaf tissue to initiate a new infection [50, 150, 151].

Another macrocyclic heteroecious rust pathogen causing economic loss is *Cronartium ribicola*, causing blister rust of eastern white pine (*Pinus strobus*) and western white pine (*Pinus monticola*). The disease cycle begins with the infection of pine needles and twigs by basidiospores in the spring, followed by development on the twigs of spermagonia that form spermatia and receptive hyphae in a nectar droplet leading to dikaryotization as nectar-feeding insects serve as vectors for the spermatia, corresponding to the same events described above for stem rust of wheat. The aecia that subsequently develop on the bark of the pine twigs release aeciospores that function as the inoculum for the infection of wild currant (*Ribes*), but the persistence and expansion of these aecia causes permanent damage to the bark of these trees. When this damage extends to the main trunk of the tree, its bark becomes girdled (the term for the destruction of the bark around the entire circumference of the tree), which kills both the food-conducting phloem and the meristematic vascular cambium that functions in creating new layers of wood and bark, and results in the death of the tree. Once the wild currant plants are infected, uredinia are formed during the growing season that release urediniospores that can inoculate other wild currants, followed by the formation of telia that produce the overwintering teliospores in which karyogamy and meiosis lead to the release of basidiospores in the spring [152, 153].

Coffee rust is a microcyclic autoecious rust disease caused by *Hemileia vastatrix*, which produces only three spore stages in the disease cycle: Urediniospores that function as the inoculum that initiates infections of leaves of coffee trees, teliospores in which karyogamy and meiosis occur, and the basidiospores that form on septate basidia following meiosis in the teliospore. The urediniospores function in inoculating leaves of coffee trees and are produced by conidiophores that emerge through leaf stomata. The infection causes severe defoliation of the coffee trees, leading to the decline and death of the trees. Although teliospores and their resulting basidiospores are produced in the same lesions, there is no known alternate host that is inoculated by these basidiospores.

There are numerous rust diseases of economically important plants that display various disease cycles such as the ones described above. An example of another variation is represented by the rust diseases of members of the bean family (Fabaceae) caused by *Uromyces* species which are both macrocyclic and autoecious. All five spore stages are produced on the same host plant by fungi in this genus. The disease primarily causes a leaf spot that may cause defoliation but may also extend to a blight of young plants [154, 155].

Ustilaginomycotina

As in the case of the Pucciniomycotina, no basidiocarp is produced in this subphylum, and the teleomorph is represented by either a basidium developing directly from dikaryotic hyphae or by a basidium developing from a germinating teliospore. Nearly all of the members of this subphylum are plant parasites, primarily attacking flowering plants, and the commonly recognized diseases they cause are known as smuts (a reference to the "dirty" appearance of a black mass of teliospores) and bunts (a term reportedly arising from a contraction of the original "burnt ears" describing the affected grain). In most of the orders within this subphylum the organism is dimorphic, growing as saprotrophic monokaryotic budding yeasts and as biotrophic dikaryotic septate hyphae at different stages of the life cycle. Two classes have been identified within this subphylum, the Exobasidiomycetes and the Ustilaginomycetes [10, 156].

Exobasidiomycetes

Of the eight orders in this class, the Tilletiales (containing the one family *Tilletiaceae*) contains several destructive plant pathogens. It is the only order in this class that is not dimorphic, occurring entirely as dikaryotic hyphae, and it has dolipore septa similar to those of the Agaricomycotina. The teleomorph in the *Tilletiaceae* consists of overwintering dikaryotic teliospores in which karyogamy and meiosis leads to the formation of a type of holobasidium (nonseptate but elongated rather than club shaped) that forms 8–16 terminal basidiospores. These basidiospores immediately undergo dikaryotization through plasmogamy between compatible basidiospores by the connection of outgrowths from the spores themselves that results in an H-shaped arrangement of connected spores. The resulting dikaryotic hyphae may function in the inoculation of seedlings of the host plant (often members of the *Poaceae* (grass family), or they may produce ballistoconidia (propelled into the air by various mechanisms) that function as the inoculum. The *Tilletiaceae* grow intercellularly within the apical meristem of the plant until it produces an inflorescence, at which time the fungus typically replaces the normal ovary tissue of the flower with its own hyphae. These hyphae become converted into a mass of black or brown teliospores known as a sorus when the structure is mature. A representative pathogen in this family is *Tilletia caries*, causing common bunt of wheat, also known as stinking smut because of the release of trimethylamine with the odor of decayed fish from the sorus [156–158].

Ustilaginomycetes

Members of this class are dimorphic, with a budding yeast anamorph, while the teleomorph consists of an overwintering teliospore in which karyogamy and meiosis lead to the formation of a septate basidium, producing four basidiospores on sterigmata. The basidiospores give rise to the yeast anamorph that grows saprotrophically, and neither the basidiospores nor the yeast function as inoculum in the disease cycle. After dikaryotization occurs through anastomosis of yeast cells of compatible mating types, the resulting dikaryotic hyphae are capable of initiating an infection of a host plant (primarily members of the *Poaceae*) with an appressorium, leading to an intracellular invasion of the host tissue. This infection has a limited impact on the physiology of the host plant until an inflorescence develops, at which

time the fungus typically occupies the normal ovary tissue of the flower with its own hyphae. When the structure is mature, a gelatinization of hyphal cell walls occurs, resulting in an arthritic formation of black teliospores when the structure is mature, thus following a developmental pattern similar to that of the *Tilletiaceae* described previously. An unusual feature of the Ustilaginales is the absence of septal pores in physiologically inactive hyphae. A representative pathogen in the *Ustilaginaceae* is *Ustilago maydis* causing corn smut, in which some of the kernels on a developing ear of corn become converted to smut sori that become much larger than normal corn kernels, eventually disintegrating to release the black smut teliospores. Prior to the maturation of a sorus into teliospores, the enlarged sori consisting of fungal hyphae growing within the original ovary tissue are utilized as an edible product known locally as "cuitlacoche" or "huitlacoche." While corn smut creates the enlargement of kernels described above, smut diseases of a wide range of hosts in the *Poaceae* are caused by various genera and species in the *Ustilaginaceae*, typically involving replacement of the reproductive structures of the infected plant by teliospores without such a conspicuous sign of the disease [10, 156, 159, 160].

Introduction*

The focus of this chapter is on human parasites, particularly those that are major pathogens. The word "parasite" is derived from the Greek *para*, meaning eating and *sitos* meaning by the side of. Parasitism is a biological niche in which one organism derives benefit at the expense of another.

Parasites can be unicellular or multicellular organisms, ranging in size from protozoa of microscopic dimensions to tapeworms that can attain a length of 20–30 feet. They can be classified based on where they live: ectoparasitic if they live on the body, e.g., lice, or endoparasitic if they live inside the body.

This chapter describes a limited number of parasitic diseases as representative of major groups of parasitic organisms. The major groups of parasites included in the chapter are the protists (protozoan) and helminths. Insects (mosquitoes, flies, etc.) and acarids (ticks), while human parasites, are dealt with only in the context of their role as disease vectors.

Global Dissemination of Parasites

The numbers of people suffering and dying from parasitic diseases is staggering. It is estimated that annually, there are more than 200 million cases of malaria [1], almost 1 billion cases of soil-transmitted helminths [2], and 8 million infections of *Trypanosoma cruzi* [3]. These diseases have mortalities ranging from the hundreds of thousands to thousands annually, with children representing a large number of deaths. While the vast majority of the disease burden lies in developing countries, increased international travel and climate change mean that the developed world is not immune.

Adaptations for Parasitism as a Way of Life

Parasite Life Cycles: Definitions

The *definitive* host of a parasite is the one in which the parasite becomes sexually mature. Thus, for the malaria parasite, the mosquito is the definitive host, and the human is the intermediate host. The *intermediate* host (e.g., snails, fish) is one that harbors the developmental stages of the parasite and serves as a food source for the definitive host, thus completing the cycle from human to human. Some parasites may have a primary, secondary, and even a tertiary intermediate host. The *vector* is the means by which a parasite is spread. In African sleeping sickness, the tsetse fly is the vector and, in its quest for blood, transmits the parasite from animal to animal, animal to human, or from human to human. Water may also serve as a vector, transmitting water-borne infections. A *mechanical* vector is one that can transmit a parasite, but in which no parasite development occurs. Flies and roaches as purveyors of filth may serve as *mechanical* vectors by transmitting disease organisms from fecal waste to food waiting to be consumed. A *reservoir* is an animal, other than human, that harbors the parasite and can serve as a source of human infections.

Mechanisms of Pathogenesis

A parasite inflicts damage upon the host (Table 47.1). Competition with the parasite for nutrients may lead to malnutrition, slowed development of the host, or vulnerability to other infections. Some parasites, such as *P. falciparum* and *T. brucei*, cause death if left untreated. In well-fed, otherwise healthy individuals, parasites may cause illness but only rarely death. A tapeworm may even have an advantageous effect on its host. It has been suggested that a benign tapeworm can, by its presence in the intestine, present a target for the immune system, making it less likely that lymphocytes (see later) would cause autoimmune diseases [4]. In a mixed malarial infection, the presence of *Plasmodium malariae* may moderate symptoms caused by *P. falciparum* [5]. Parasites living in the intestinal tract, such as tapeworms, compete with the host for nutrients passing through the gut. Physical damage can result from attachment by hooks to the intestinal wall (some tapeworms) or migration of helminth larvae through body tissues and organs. Some parasitic worms (e.g., *Ascaris*) can, by their numbers, physically obstruct the intestine. Destruction of cells or tissues can be a consequence of feeding by the parasite such as when *Entamoeba histolytica* attaches to the intestine and ingests epithelial cells. The malarial parasite, *Plasmodium* develops within the host's erythrocytes, causing them to lyse and leading to anemia. Toxins or waste products of the parasite can also cause damage to the host, as well as activating an intense immune response from the host that can have harmful consequences, akin to what occurs in toxic shock syndrome. The presence of a parasite or its secretions may cause an allergic response. In many helminth infections, a large part of the disease pathology is caused by the human immune response. Parasites produce a variety of enzymes, including proteases, peptidases, hydrolases, lipases, and phospholipases that can damage the integrity of host tissues and cell membranes, providing nutrients and shelter for the parasite and avenues for parasite expansion.

* This article is based on Chapter 45 in the second edition of this series, and Chapter 49 in the third edition, "Introduction to Parasites" by Fred Schuster (second edition), and Purnima Bhanot and Fred Shuster (third edition). The previous contributions of Dr. Shuster (deceased) are very much appreciated and acknowledged.

TABLE 47.1

Protistan Parasites of Humans

Parasite Genus	Species	Disease	Area Affected	Geographic Distribution	Transmission	Diagnosis
			Amoebozoa (Amoebae)			
Acanthamoeba	Several species: *A. castellanii, A. culbertsoni, A. healyi, A. polyphaga, A. hatchetti*	Granulomatous amoebic encephalitis	Cutaneous lesions, CNS	Cosmopolitan	Contact with soil, water, air-blown cysts, immunocompromised status	IFA, brain/skin biopsy, culture, PCR
		Amoebic keratitis	Cornea		Corneal trauma, contact lens use	Corneal scraping, serology, culture, PCR
Balamuthia	*B. mandrillaris*	Granulomatous amoebic encephalitis	Cutaneous lesions, CNS	Cosmopolitan	Contact with soil, water, air-blown cysts	Brain/skin biopsy, culture, serology, PCR
Entamoeba	*E. histolytica*	Amoebiasis; amoebic dysentery	Colon, liver, brain	Cosmopolitan	Fecal-oral route, sewage-contaminated uncooked foods	Stool samples for trophic amoebae or cysts, immunoassay, serology for tissue stages
			Opisthokonta (Protists with fungal affinities/origins)			
Microsporidia	*Encephalitozoon cuniculi* *Enterocytozoon bieneusi*	Microsporidiosis	Intestinal tract, brain	Cosmopolitan	Fecal-oral transmission, immunocompromised status	Tissue biopsy, H&E, trichrome, and IFA staining, ELISA
Pneumocystis	*P. jirovecii*	*Pneumocystis (carinii) jirovecii* pneumonia (PCP)	Lungs	Cosmopolitan	Airborne transmission, immunocompromised status	Bronchoalveolar lavage
			Chromalveolata (Protists with apicoplasts; ciliates)			
Babesia	*B. divergens* *B. microti*	Babesiosis	Blood	Europe, United States, Africa, Asia	Zoonotic disease, insect transmission (tick), blood transfusions	Blood films, PCR, ELISA, animal inoculation
Balantidium	*B. coli*	Balantidiosis	Intestine; mostly in pigs	Tropical to subtropical	Fecal-oral route	Trophic ciliates or cysts in stool sample
Cryptosporidium	*C. hominis*	Cryptosporidiosis	Small intestine	Cosmopolitan	Fecal-oral route, water, contaminated foods, immunocompromised status	Stool, sputum, urine samples for oocysts, modified acid-fast (positive), IFA, PCR
Cyclospora	*C. cayetanensis*	Cyclosporiasis	Small intestine	Cosmopolitan	As for *Cryptosporidium*	As for *Cryptosporidium*
Plasmodium	*P. falciparum*	Malignant tertian malaria (48-hour periodicity)	Blood, brain	Africa, Asia, South America	Mosquitoes (*Anopheles* spp.)	Blood films, PCR, IFA, ELISA
	P. vivax	Benign tertian malaria	Blood	Asia, North Africa		Blood films, PCR, IFA
	P. malariae	Quartan malaria (72 periodicity)	Blood	SE Asia, Central America, Pacific area		Blood films, PCR, IFA
	P. ovale	Mild tertian malaria	Blood	West Africa, Pacific area, India		Blood films, PCR, IFA
Toxoplasma	*T. gondii*	Toxoplasmosis	Fetus	Cosmopolitan	Fecal-oral route, infected meat, cat feces, immunocompromised status	ELISA, PCR, IFA, culture, commercial kits available

(*Continued*)

TABLE 47.1 ***(Continued)***

Protistan Parasites of Humans

Parasite Genus	Species	Disease	Area Affected	Geographic Distribution	Transmission	Diagnosis
			Excavata (Flagellate or amoeba-flagellate protists)			
Giardia	*G. duodenalis*	Giardiasis	Small intestine	Cosmopolitan	Fecal-oral route	Stool sample, ELISA, IFA, commercial kits available
Leishmania	*L. tropica* *L. major*	Old World leishmaniasis (Oriental sore)	Cutaneous ulcerated lesions	Africa, Middle East, Asia Minor, India	Sandfly (*Phlebotomus* et al.)	Presence of Leishman-Donovan bodies in aspirates (non-flagellate [amastigote] stages in tissue aspirates), ELISA, PCR, clinical ID
	L. donovani	Visceral leishmaniasis (Kala azar)	Enlarged liver and spleen cutaneous lesions	India, Africa, Mediterranean area		
	L. braziliensis	Mucocutaneous leishmaniasis (Espundia)	Cutaneous lesions	Latin America north to Mexico		
	L. mexicana	New World leishmaniasis (Chiclero ulcer)	Cutaneous lesions	South and Central Americas		
Naegleria	*N. fowleri*	Primary amoebic meningoen-cephalitis	CNS	Cosmopolitan	Swimming, water sports (fresh water)	Microscopic examination of CSF, culture, PCR
Trichomonas	*T. vaginalis*	Trichomoniasis	Urogenital tract of females and males	Cosmopolitan	Sexually transmitted disease	Vaginal discharge (wet-mount), commercial kits, PCR
Trypanosoma	*T. brucei rhodesiense,* *T. brucei gambiense*	East and West African sleeping sickness	CNS	Africa	Tsetse fly (*Glossina* spp.)	Blood films, CSF, culture, lymph node aspirate, ELISA, card agglutination test
	T. cruzi	American trypanosomiasis (Chagas' disease)	Cardiovascular, gastrointestinal systems, brain	Argentina north to Mexican border	Reduviid bug (*Triatoma* spp.), blood transfusions	Blood films, IFA, culture, clinical ID, PCR, xenodiagnosis (in triatomid bug)

Abbreviations: CSF = cerebrospinal fluid; ELISA = enzyme-linked immunosorbent assay; H&E = hematoxylin-eosin stain (tissue); IFA = immunofluorescent antibody staining; IIF = indirect immunofluorescent staining (tissue); PCR = polymerase chain reaction.

The course of parasitic infections can be influenced by factors such as the infective dose of the parasite, the virulence of the particular strain or species, the ability of the parasite to circumvent the host's immune system, and the immune status and/or health of the host. Immunosuppressed individuals, the elderly, and the young are more vulnerable to many diseases, parasitic or otherwise.

Host Factors

The Immune Response

The Humoral Pathway

There are two major immune responses of the host. One is the *humoral* pathway resulting in antibody production by B-lymphocytes specifically targeted at the invading parasite, also called adaptive or inducible immunity. Immunity can be conferred to a neonate by transplacental transfer of maternal antibodies and provide protection for several months after birth before it begins to fade and before the child's own immune system becomes functionally mature. This offers a window of opportunity for parasites to infect and cause disease or death. Falciparum malaria has its greatest impact on children between 1 and 5 years of age. Antibodies produced during parasitic disease remain for varying lengths of time even after the disease has been cleared, conferring weak or strong immune protection against reinfection. Immunoglobulin M (IgM) is associated with the initial stage of infection, and IgG with postacute to convalescent or later stages of infection, protection against recurrent infection, and placental transfer. IgA is a secretory antibody released from mucosal surfaces (intestinal, pulmonary and urogenital tracts, corneal surface), and has a role in antiparasite activity. IgE is linked to allergic responses and parasitic infections and causes degranulation of eosinophils, with release of hydrolytic enzymes, peroxidases, and a core cationic protein granule. Eosinophils can adhere via antibodies to the surface of intestinal helminths and release granule contents that aid in attacking the worm's surface, allowing other immune molecules to penetrate and destroy the worm.

Cell-Mediated Immunity

The second type is the *cell-mediated* immune response (innate or nonspecific immunity) leading to the activation of T-lymphocytes, activated macrophages, killer T-cells, and other cell types that are functionally equipped to destroy the parasite, particularly those parasites that are intracellular and sheltered from contact with antibodies. The cell-mediated response can activate the *complement system* (alternative and classical pathways) that may or may not damage and/or lyse the parasite. Cell-cell communication between immune response components is the function of interleukins, cytokines, and other molecules such as tumor necrosis factor and interferon. *Plasmodium* toxins stimulate T-cell proliferation, which leads to overproduction of interferon and tumor necrosis factor. An excess of these proinflammatory cytokines can be as damaging to the host as the disease itself, affecting erythrocyte formation and a possible cause of malaria-associated anemia [6]. Other parasites have evolved mechanisms to neutralize these activators. Tapeworms of various species can inhibit production of interferon and interleukins, thus muting the immune response [4].

Parasite Evasion of the Immune Response

Parasites have intrinsic and extrinsic ways of avoiding the host's immune response. Chief among these is antigenic variation that is well developed in several protozoa. *T. brucei, P. falciparum* and *Giardia lamblia* are all capable of shedding their antigenic coat to which the host has developed antibody sensitivity, and replacing it with a new coat requiring a build-up of new antibody by the host. This delay enables the parasites to remain within the host and prolong periods of transmission.

Leishmania spp. and *Trypanosoma cruzi* develop safely within the host's macrophages, activist components of the antiparasite response. Other parasites (e.g., schistosome worms) cloak themselves with host molecules to escape detection as foreign antigen. Components of the complement pathway can be neutralized by some parasites by preventing complement activation and subsequent lysis. Still other parasites may shed complement activation components as they bind to the parasite surface, or produce substances that activate and deplete complement, but at a safe distance from the surface of the parasite.

Human Parasitic Diseases

Protists and helminths are two major groups of organisms that are parasites of humans (Tables 47.1 and 47.2). The insects and ticks include human parasites but they will be treated in this review with regard to their role as vectors of parasitic diseases (Table 47.3). These tables are not comprehensive and include the more familiar human parasites as well as those responsible for the more devastating diseases, causing both morbidity and mortality in large numbers of individuals. There are less than 400 species of protists and helminths that are parasitic in humans: approximately 300 species of worms and greater than 70 protist species [7].

Protists

Disease agents belonging to this group are responsible for some of the most widespread and fatal diseases of humans and other mammals. Malaria is the deadliest parasitic disease. The World Health Organization (WHO) estimates that there were about 220 million cases of malaria in 2010 causing almost 600,000 deaths [1]. Most of these deaths are of children in sub-Saharan Africa. African sleeping sickness or trypanosomiasis is another major killer disease, not only of humans but also cattle and wild game—which serve as reservoirs of disease—preventing the raising and grazing of cattle in vast areas of Africa.

Falciparum Malaria

An abundant literature on falciparum malaria exists and this capsule summary is insufficient to convey all that is known of the disease. *Plasmodium falciparum* is the most lethal of the human malarial parasites, and the only one to affect the CNS, causing

TABLE 47.2

Helminth Parasites of Humans

Parasite Genus	Disease	Body Area Affected	Distribution	Transmission
		Trematodes (Flukes)		
Clonorchis sinensis	Clonorchiasis	Liver, bile duct	Asia	Eating raw or undercooked fish
Schistosoma haematobium	Schistosomiasis (bilharziasis)	Bladder	Africa, Middle East	Aquatic larvae (cercariae) penetrate through skin
S. japonicum		Veins draining small intestine	Japan, China, SE Asia	
S. mansoni		Veins draining large intestine	Middle East, Africa	
		Cestodes (Tapeworms)		
Diphyllobothrium latum	Diphyllobothriasis (fish tapeworm)	Intestine	United States, Europe	Eating raw or undercooked fish
Echinococcus granulosus	Hydatid cyst (larval stage)	Brain	Cosmopolitan	Acquiring ova from infected dogs
saginatus	Taeniasis (beef tapeworm)	Intestine	Cosmopolitan	Eating raw or undercooked beef
Taenia solium	Taeniasis (pork tapeworm)	Intestine	Cosmopolitan	
	Cysticercosis (larval stage)			
		Brain		
		Nematodes (Round Worms)		
Ancylostoma duodenale	Hookworm	Small intestine	SE Asia, northern Africa, Europe	Terrestrial larvae penetrate through skin
Ascaris lumbricoides	Ascariasis	Intestine	Cosmopolitan	Contact with worm ova
Baylisascaris procyonis	Baylisascariasis	Migrating larvae	United States	Transmitted via raccoon feces (geophagia)
Dracunculus medinensis	Dracunculiasis (guinea worm)	Females release ova in subcutaneous sites (legs, feet)	Middle East	Intermediate host (crustacean) present in drinking water
Enterobius vermicularis	Enterobiasis	Colon, perianal area	Cosmopolitan	Contact with worm ova
Gnathostoma spinigerum	Gnathostomiasis	Migrating larvae	Asia, SW Pacific	Eating raw or undercooked fish
Necator americanus	Hookworm	Small intestine	SE Asia, United States, SW Pacific	Terrestrial larvae penetrate through skin
Onchocerca volvulus	Onchocerciasis (river blindness)	Eyes	Africa, Central and South Americas	Transmitted by black fly (*Simulium*)
Trichinella spiralis	Trichinellosis	Muscle tissues, migrating larvae	Cosmopolitan	Eating raw or undercooked pork
Wuchereria bancrofti	Filariasis (elephantiasis)	Lymphatic system	SE Asia, Pacific area, Central Africa	Transmitted by mosquitoes (Anopholes Culex, Aedes)

TABLE 47.3

Insects and Acarids Important as Vectors of Human Parasitic Disease

Insect	Genus	Disease	Transmission
Black fly	*Simulium*	Onchocerciasis	Injection from salivary glands
Cockroach	All species	None	Mechanical transmission
House fly	*Musca domestica*	None	Mechanical transmission
Mosquito	*Anopheles*	Malaria	Injection from salivary glands
Sandfly	*Phlebotomus*	Leishmaniasis	Injection
Tick	*Ixodes*	Babesiosis	Injection
Triatomid bug (kissing bug)	*Triatoma*	Chagas' disease	Defecation at site of insect bite
Tsetse fly	*Glossina*	Trypanosomiasis	Injection

cerebral malaria [8]. The disease is actually two infections: malaria as the blood disease and as a fulminant cerebral infection. Cerebral malaria is more likely to develop in naive children than in adults with some immunity to the disease. Following injection of the infective stage (sporozoite) from *Anopheles* spp., the organism invades hepatic cells where asexual reproduction occurs. Infected liver cells release merozoites, which penetrate erythrocytes, reproduce asexually, and cause their hemolysis at approximately 48-hour intervals. The cycle of infection and lysis is synchronous. At lysis, there is release of toxins and wastes from the erythrocytes that causes the chills and fever typifying the disease. Infected erythrocytes become sequestered in the microvasculature of the brain. They bind to the endothelial walls of the blood vessels by parasite-induced knobs on the erythrocyte surface, and form rosettes of erythrocytes facilitating vessel occlusion [8]. The consequences of this blockage are oxygen insufficiency, necrosis, edema, hemorrhage, and inflammation in the brain. Overproduction of proinflammatory cytokines stimulated by *Plasmodium* antigens may aggravate the condition [9, 10]. Prevention includes screens, netting, mosquito repellent, and prophylactic drugs if traveling in malaria-endemic areas.

Plasmodium vivax

P. vivax is most geographically wide-spread human malaria species [11]. It is most common in Asia and South and Central America. In these areas, *P. falciparum* and *P. vivax* malaria have roughly equal prevalence. Importantly, intrahepatic stages of *P. vivax* can form dormant stages known as *hypnozoites*. Hypnozoites can stay dormant for weeks up to a year before reactivating to cause the relapses characteristic of *P. vivax* infection. The primary receptor for *P vivax* on the erythrocyte surface is the Duffy antigen receptor for chemokines (DARC). West Africans carry the Duffy-negative phenotype [12] and are resistant to *P. vivax* malaria. *P vivax* preferentially invades immature red blood cells and parasitemias are usually lower than in *P. falciparum* infections [11].

Diagnosis and Assessment

The gold standard for malaria diagnosis is the microscopic examination of blood smears. However, simple and sensitive antibody tests that detect specific parasite proteins are now widely used. Some these tests can distinguish between different *Plasmodium* species.

African Sleeping Sickness

The subspecies *Trypanosoma brucei gambiense* is an etiologic agent of African trypanosomiasis, also known as Gambian sleeping sickness in West and Central Africa. The tsetse fly, *Glossina* spp., is the vector of the disease and, once infected, remains infected for its life. The fly acquires the parasite while obtaining blood from a human and passes it on to another host after the transmissive stage of the parasite enters the fly's salivary glands. In both the fly and the human, the parasite passes through several pleomorphic stages, ranging from a slender swimming form with an elongate undulating membrane and free flagellum (Figure 47.1) to a shorter stage lacking the free flagellum that is found in the salivary glands

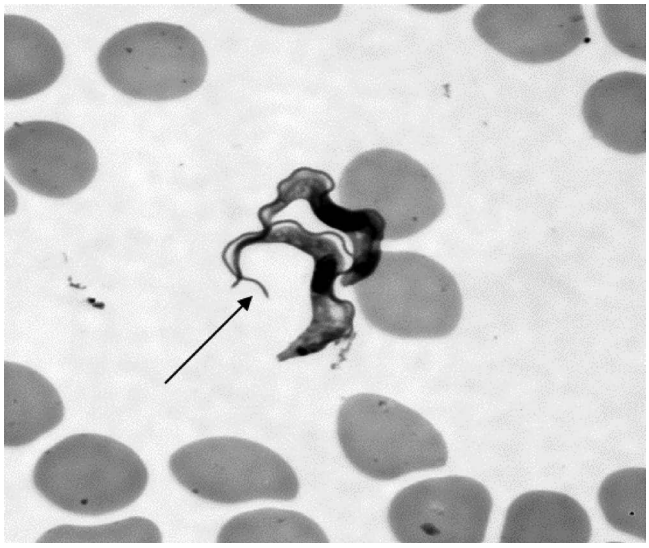

FIGURE 47.1 Trypanosomes seen in a stained blood film. The two organisms (trypomastigote stage) have a wavy outline due to undulating membrane that runs the entire length of the body. A free flagellum projects beyond the undulating membrane. Giemsa stain. (Courtesy of DPDx Parasite Image Library at the Centers for Disease Control and Prevention.)

of the tsetse fly. *T. b. gambiense* causes a chronic form of sleeping sickness affecting the central nervous system, while a related subspecies, *T. b. rhodesiense*, causes a similar but fulminant infection in humans. Of diagnostic importance is elevated protein (and IgM) and leukocyte levels in the central nervous system (CNS). *T. b. rhodesiense* occurs in eastern and Central Africa and is also found in wild game animals that serve as reservoirs for the parasite. *T. brucei brucei* infects cattle and wild animals (nagana), but not humans. Sleeping sickness is biphasic: an early blood phase and a later CNS phase, and different drugs are used for the different stages (Table 47.4).

American Trypanosomiasis

American trypanosomiasis is caused by *Trypanosoma cruzi*, and transmitted by a triatomid ("kissing") bug. Transmission from insect to human occurs when the bug defecates on the skin while feeding. The deposited fecal material contains the infective parasites and is usually rubbed into the break in the skin caused by the bite or into the eyes.

Babesiosis

This is a zoonotic blood infection transmitted by the bite of an infected tick, and similar to malaria in intraerythrocytic location and malaria-like symptoms (fever, chills, aches, and anemia). Two species are involved in human infections: *Babesia microti* in North America and *B. divergens* in Europe, with the latter species being the more virulent (5% vs. 42% mortality, respectively) [13, 14]. Coinfected ticks can spread both babesiosis and Lyme borreliosis disease (caused by the bacterium *Borrelia burgdorferi*) simultaneously. Splenectomized and immunosuppressed individuals are at high risk for developing fulminating disease if infected. Rodents, deer, elk, and cattle serve as reservoir hosts. Diagnosis can be difficult, and hamster inoculation (xenodiagnosis) is useful to boost parasitemia

TABLE 47.4

Drug Therapy for Protistan and Helminthic Infections

Disease	Recommended Drug Therapy
Protistan Diseases	
Acanthamoebiasis	Keratitis: Polyhexamethylene biguanide, chlorhexidine gluconate with or without Brolene® Amoebic encephalitis: Empirical therapy—pentamidine isethionate, sulfadiazine, flucytosine, fluconazole, or itraconazole
Balamuthiasis	Encephalitis: Empirical therapy — pentamidine isethionate, sulfadiazine, clarithromycin (or azithromycin), fluconazole, flucytosine
African sleeping sickness, west (*Trypanosoma b. gambiense*)	Human infection Early stage: Pentamidine isethionate or suramin Late stage (CNS involvement): Melarsoprol, eflornithine
African sleeping sickness, east (*Trypanosoma b. rhodesiense*)	Human infection Early stage: Suramin Late stage: melarsoprol
Entamoebiasis (amoebic dysentery)	Iodoquinol or metronidazole or tinidazole
Chagas' disease	Benznidazole or nifurtimox
Giardiasis	Metronidazole or tinidazole
Leishmaniasis	Cutaneous, mucosal, and visceral disease: Sodium stibogluconate
Microsporidiosis	Albendazole plus fumagillin
Naegleriasis (primary amoebic meningoen-cephalitis)	Amphotericin B plus miconazole
Plasmodium falciparum (malaria)	Malaria acquired in chloroquine-resistant area: Atovaquone-proguanil or quinine sulfate plus doxycycline or mefloquine or artesunate plus mefloquine
Plasmodium vivax (malaria)	Malaria acquired in chloroquine-resistant area: Quinine sulfate plus doxycycline or mefloquine
Plasmodium spp. (other human malarias)	Malaria acquired in chloroquine-sensitive area: Chloroquine phosphate or quinidine gluconate (oral), quinidine dihydrochloride (parenteral) or artemether For prevention of relapse: Primaquine phosphate General prevention: Chloroquine-sensitive areas—mefloquine, doxycycline, chloroquine-resistant areas—chloroquine phosphate or atovaquone proguanil
Pneumocystis pneumonia (PCP)	Trimethoprim-sulfamethoxazole
Toxoplasmosis	Pyrimethamine plus sulfadiazine
Trichomoniasis (*Trichomonas vaginalis*)	Metronidazole or tinidazole

to make a diagnosis. *In vitro* cultivation is possible but exacting [15]. Prevention includes wearing protective clothing (long sleeves, full-length pants) and applying tick repellent when working or recreating in areas where ticks are abundant (particularly in the Northeast, upper Midwest, West, and Northwest coast of the United States).

Cryptosporidiosis and Cyclosporiasis

Caused in humans by *Cryptosporidium hominis*, *C. parvum,* and *Cyclospora cayetanensis*; spread by fecal-oral contamination, usually of drinking water but also food (raw shellfish, uncooked vegetables, salad greens). Person-to-person spread can occur among children (nurseries and day care) and among the elderly in nursing facilities. Infective oocysts are shed in stools; they are visible with modified acid-fast staining. Oocysts of *Cryptosporidium* are smaller (~5 µm) than those of *Cyclospora* (~9 µm) [16]. A major outbreak of cryptosporidiosis occurred in Milwaukee, Wisconsin, in 1993 that resulted in more than 400,000 infections was caused by a contaminated water supply.

Cyclospora outbreaks have been traced to imported produce. In 2013, a cyclosporiasis outbreak sickened more than 600 people in 25 states. Some cases were traced to salad mixes and fresh cilantro. Symptoms are typical of gastrointestinal infection and can be particularly serious in HIV/AIDS patients. Diarrhea is self-limiting (~2 weeks) in immunocompetent individuals. Antibiotics are not helpful in treatment except, perhaps, in HIV/AIDS patients. Prevention: avoid possibly contaminated drinking water (bottled water for HIV/AIDS patients), uncooked fruits and vegetables, and contact with farm animals.

Toxoplasmosis

Caused by *Toxoplasma gondii* and transmitted to humans in undercooked meat (horse meat, pork, lamb, beef) and by cat feces containing oocysts [17]. The domestic cat is the definitive host. In humans, the main pathway of infection is via meat, and the cat is unnecessary in transmission of *Toxoplasma* to humans. Symptoms are flu-like and pass quickly, but congenital infections (leading to hydrocephalus, microcephaly, chorioretinitis, cerebral calcification, and mental retardation in the neonate and juveniles) can develop in pregnant women who are not immune from earlier exposure; the risk of fetal infection increases with the gestation period. The organism is also an opportunistic pathogen of HIV/AIDS patients and other immunosuppressed individuals. Reactivation of latent infections can occur in individuals who secondarily become immunosuppressed. Toxoplasmosis is more common abroad (20–40% of adult Americans are seropositive for *Toxoplasma* antibodies vs. approximately 70% in France

and about 70–90% in Latin America) and in immigrants to the United States [18]. Prevention includes avoiding raw or undercooked meats that may transmit parasite. Pregnant women in particular should avoid eating undercooked meats or contact with cat litter boxes.

Leishmaniasis

Leishmaniasis is caused by different species of the genus, *Leishmania*, each with a distinct geographic distribution. They are transmitted by certain species of the sandfly. It occurs primarily as either cutaneous or visceral leishmaniasis. Cutaneous leishmaniasis is caused mostly by *L. major*, *L. tropica,* and *L. Mexicana*. Visceral leishmaniasis is caused mostly by *L. donovani* and *L. chagasi*. The parasites infect macrophages and undergo asexual development within the cell. In cutaneous leishmaniasis, the parasites remain at the site of infection causing a skin lesion. The skin ulcer is often self-healing and leads to long-term immunity against cutaneous leishmaniasis. In visceral leishmaniasis, the parasites infect the reticuloendothelial system compromising the patient's immune system. Domestic dogs and rodents are the major reservoirs of human disease. Prevention relies on control of the sandfly.

Giardiasis and Amoebiasis

Giardiasis is caused by *Giardia lamblia*, an amitochondriate, flagellated protozoan. It is transmitted through water contaminated with environmentally resistant cyst forms. Beavers are the major reservoir. After encountering low pH in the stomach and pancreatic enzymes, the ingested cysts excyst to form two motile trophozoites in the small intestine. The trophozoite has two nuclei, eight flagella and an adhesive disc on its ventral surface. The adhesive disc allows the trophozoites to attach to epithelial cells of the intestinal villi. The trophozoite then divide through binary fission. Some trophozoites eventually encyst in the small intestine and pass out with feces.

Infection with *G. lamblia* is often symptomatic. Clinical disease consists of severe diarrhea. Flattening of the villi as a result of infection also leads to malabsorption. The parasite is able to evade the host's immune reaction through variation of its major surface protein, the cysteine-rich variant surface protein. Prevention of Giardiasis consists of proper disposal of fecal matter and filtering drinking water.

Amoebiasis is caused by the pseudopod forming protozoan, *Entamoeba histolytica*. Infection can lead to liver abscess and amebic colitis. *E. histolytica* life cycle consists of the infectious cyst form and the invasive trophozoite form. Cysts are generally ingested by eating fecally infected food or water. In the intestine, the cyst forms eight trophozoites. Trophozoites can either invade the intestinal mucosa forming flask-shaped ulcers or colonize the liver.

Helminths

The helminths are a group of parasitic organisms that includes flatworms and round worms. Flatworms have a dorsoventrally flattened body and include cestodes such as tapeworms and trematodes (also known as flukes) such schistosomes. Roundworms include soil-borne nematodes and filarial worms such as those that cause lymphatic filariasis.

FIGURE 47.2 Scolex ("head") of an adult tapeworm, *Taenia solium*. The scolex has a ring of hooks (rostellum) and below that are four suckers (acetabula). The scolex tapers to form the neck, which is the generative region where proglottids are formed. (Courtesy of DPDx Parasite Image Library at the Centers for Disease Control and Prevention.)

Cestodes (Tapeworms)

Tapeworms are best known as intestinal parasites but, as larval stages, can penetrate the intestinal wall and migrate through tissues and organs. Damage by the migration of the larvae and the final site of the larvae can cause life-threatening conditions. In a "normal" infection of the human, the larval stage (in beef, pork, or fish) is digested free in the intestine, grows, and reaches sexual maturity (Figure 47.2).

Pork Tapeworm

The human, as the definitive host, contracts the disease by eating undercooked pork. The pig, as the intermediate host, becomes infected with ova when it has access to human fecal matter containing proglottids and/or eggs. This occurs in areas of the world where human waste is used as fertilizer or in rural areas where pigs forage on refuse. In the pig intestine, the eggs hatch and produce larvae that penetrate the intestinal wall and migrate to muscle tissue where they become encapsulated. Pork flesh containing these larvae (bladder worms), which can be seen as lustrous beads, is called measly pork and can be identified with the naked eye. In the human small intestine, the bladder worm is digested free from its capsule, attaches to the intestinal wall, and develops into the adult worm. The human can inadvertently become a dead-end intermediate host for the larva if the tapeworm egg itself is ingested. The freed larva (cysticercus) then migrates through host tissue, coming to rest in muscle or organs and causing a condition known as cysticercosis, or neurocysticercosis if the traveling larva ends its journey in the brain. The latter condition which is accompanied by seizures can be fatal. In the

United States, most cases of cysticercosis occur in foreign-born Hispanics (Mexico and Latin America), while it is relatively rare in native-born citizens [19]. An outbreak of cysticercosis among Orthodox Jews—proscribed from eating pork or pork products—was traced to Hispanic household employees. Prevention includes avoiding undercooked pork products, particularly in developing countries where swine have access to garbage and other waste materials. Emphasize importance of hand washing to food handlers.

Trematodes (Flukes)

The fluke body is unsegmented. The adult worm may have one or two suckers, one ventrally located and the second a sucker that surrounds the mouth leading to a sac-like gut but lacking an anal opening. Most flukes are monoecious (have male and female sex organs in the same individual) although *Schistosoma* spp. are dioecious (the sexes in separate individuals). Intestinal flukes can be identified by the shapes of their ova as seen in stool samples (Figure 47.3).

Schistosomiasis

Schistosomiasis (also called bilharzia or snail fever), caused by *Schistosoma* spp., is transmitted by water contaminated with the parasite's larval forms. Chronic schistosomiasis causes delays in physical growth and cognitive development in children. The schistosomes are found in the circulatory system of humans. Three of the medically important species recognized in this chapter are *S. haematobium;* which is found in veins associated with the urinary bladder and lower abdomen; *S. japonicum;* which is found in veins about the small intestine; and *S. mansoni,* which is found in veins associated with the large intestine.

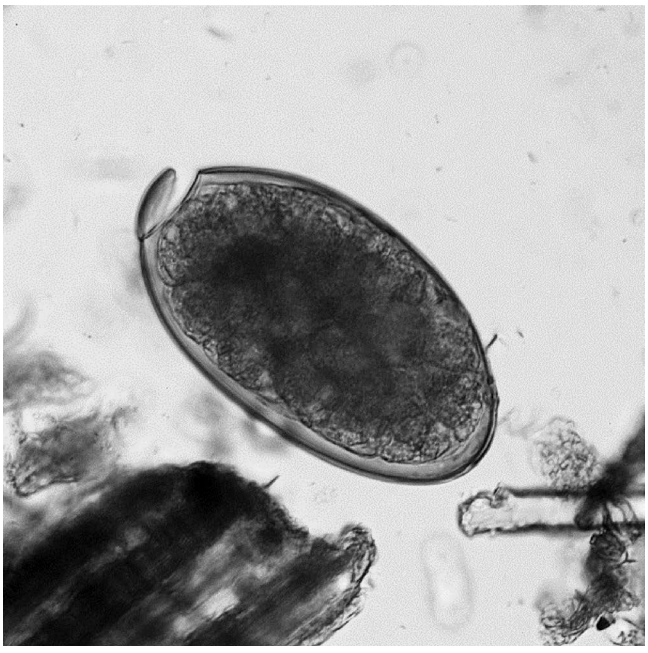

FIGURE 47.3 Ovum of a flatworm (*Fasciola hepatica*, liver fluke). The eggs are shed in the stool and identifying them is probably the chief way in which diagnosis is made. The egg has a distinctive operculum at one end through which the larva (miracidium) will emerge. (Courtesy of DPDx Parasite Image Library at the Centers for Disease Control and Prevention.)

The female is harbored within a groove of the male worm, ensuring close contact and fertilization of ova. Depending on the site of the adults in the body, eggs can be found in the urine or in the stool. Ova that do not pass out of the body can penetrate the venule walls, causing granuloma formation. Once in water, the egg hatches to release a ciliated miracidium that infects a snail as secondary host. The snail host is specific for each of the three different species. After undergoing development in the snail, a cercarial stage is released which can infect humans by penetrating the skin. They then enter the circulatory system and are carried to the lungs and liver, and finally to their specific sites in the venous circulation. Prevention calls for avoidance of streams, lakes, and ponds in endemic areas for washing and swimming because of cercariae in the water.

Helminth Infections: Nematodes

Nematode worms are among the most numerous organisms in the world. The group includes many free-living forms as well as medically significant parasites.

Onchocerciasis

The disease, also called river blindness, is caused by the filarial worm *Onchocerca volvulus*, and is transmitted by the black fly (*Simulium* spp.). The fly becomes infected with larvae (microfilariae) when it feeds on the blood of an individual with onchocerciasis. The microfilariae migrate from the fly's stomach to its proboscis. Once inoculated into the human host, the male and female worms accumulate in cutaneous nodules. Following mating, the larvae appear in the circulatory system. The disease is found in Central and South America, Mexico, the Middle East, and Africa, with distribution to the Americas a consequence of the slave trade. Microfilariae can also enter the eye where damage is done in large part by the host's immune response to the larvae. Prevention includes water filtration in endemic areas, insecticide use to eliminate black flies.

Lymphatic Filariasis

The disease, also called elephantiasis, is caused by the filarial worms *Wuchereria bancrofti* and *Brugia malayi*, transmitted to humans via mosquito bite. Infected mosquitoes deposit worm larvae on the skin. The larvae enter the lymphatics and mature into adults. Adult living worms can suppress the host's immune response. Dead or dying worms can elicit an immunopathology that can lead to an occlusion of lymphatics resulting in lymph accumulation in tissues or lymphedema in the affected region of the body. Elephantiasis is a consequence of long-term infection. Prevention requires the use of netting and mosquito repellant.

Nematode Infections

Ascariasis

One of the most common nematode infections, it is caused by *Ascaris lumbricoides*. It is acquired by ingesting food contaminated with Ascaris eggs. The adult worm is found in the human

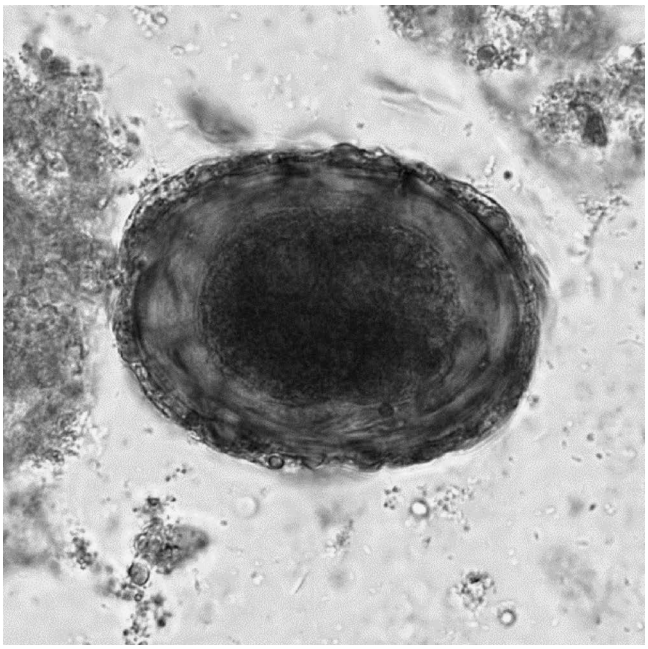

FIGURE 47.4 Ovum of the nematode worm *Ascaris lumbricoides*. The egg with an embryo inside has a thick, protective, and mammilate wall that can withstand long-term environmental exposure. (Courtesy of DPDx Parasite Image Library at the Centers for Disease Control and Prevention.)

intestine and eggs are shed into the feces (Figure 47.4). The thick-walled eggs are highly resistant to environmental extremes and can remain viable for months after being shed. Large numbers of worms can cause blockage of the intestinal lumen, requiring surgical removal. Ascariasis is more likely to occur in rural farming areas where there is close contact between humans and pigs, both of which share the worm infection (*A. lumbricoides* in humans and *A. suum* in swine). Prevention requires proper disposal of human waste and avoiding soil containing human or swine excrement, particularly for children who are more likely to transfer eggs on their fingers after playing in or eating soil.

Trichuriasis

Trichuriasis is caused by *Trichuris trichiura*, commonly known as the whipworm. It is transmitted to humans through ingestion of *T. trichiura* eggs. Ingested eggs hatch into larvae in the small intestines, where they develop into adults. Adults *T. trichiura* migrate into the colon and permanently attach to the mucosa by embedding their anterior portion in the tissue. Adult females release eggs that are passed out in feces. Heavy infections can lead to dysentery and colitis in children. Severe cases may lead to rectal prolapse. Prevention calls for proper disposal of human waste and avoiding soil containing human excrement.

Parasite Epidemiology

Epidemiology: Ways That Parasites Spread

Parasite epidemiology attempts to explain how diseases are spread from person to person. Epidemiology has moved well beyond its beginnings in hand washing and the fundamental principles of hygiene. Modern epidemiology focuses more on the parasite genome, enabling identification of parasite strains and the presence of genes that confer drug resistance. The tools of the trade include evolutionary analyses and construction of phylogenetic trees, mapping the genomic composition of parasite populations, and, not forgetting the vectors, the genomes of the insects that transmit disease [20]. Molecular studies of parasite distribution and spread are the counterpart of studies tracing outbreaks of bacterial infections through plasmids and antimicrobial resistance genes that have revolutionized prokaryote epidemiology. In this chapter, however, more attention is given to the classic approach to epidemiology. Categories recognized below are not mutually exclusive and there much is overlap between them.

Insect Transmission

Elimination of insects as vectors—a desirable goal but not always possible—can reduce incidence of disease. Controlling populations of *Plasmodium*-carrying mosquitoes using insecticides or protecting susceptible children in malarious areas from being bitten by use of insecticide-impregnated bed netting, can reduce deaths due to malaria. Mosquitoes, however, have developed resistance to some insecticides (e.g., DDT), reducing their efficacy in controlling insect populations. As noted earlier, insects such as roaches and flies can transmit protistan cysts and helminth ova on mouthparts, legs, and feet as well as within their digestive tract. Regurgitation of gut contents prior to feeding and fecal deposition are other ways in which infectious material can be transferred [21].

Fecal-Oral Transmission

Human or animal feces transmit many parasitic diseases by parasite ova and protistan cysts. Such transmission can occur where feces are used as fertilizer ("night soil") or contaminate water used for bathing, drinking or irrigation. This is particularly the case with cysts of *Entamoeba histolytica*, *Giardia duodenalis,* and *Balantidium coli* that can contaminate the water supply in countries lacking water treatment standards. Feces-contaminated vegetables, eaten without cooking, are another result of fecal-oral transmission. This has become increasingly common in recent years as such foods, sometimes from abroad but also from "safe" farms, come on the market.

Direct Blood Transmission

This route is perhaps a consequence of human ingenuity that allows for blood collection for transfusions. Although the blood supply is monitored for HIV and prion diseases (bovine spongiform encephalopathy), etiologic agents of parasitic diseases are usually not looked for. Malaria and babesiosis, both blood infections, have been transmitted by human blood transfusions, as has Chagas' disease and toxoplasmosis.

Zoonotic Transmission

A zoonotic disease is one that is spread from animal to human. Some of the zoonotic diseases include babesiosis (from rodents, cattle, deer, elk, and sheep) to humans via ticks; trypanosomiasis

(from game animals and cattle via the tsetse fly); toxoplasmosis (from cats, pigs, lambs, and horses to humans), ascariasis, and echinococcosis. The transition from a mobile hunter-gatherer society to a settled life on farms, and ultimately communities, encouraged domestication of cattle, pigs, and other animals, offering opportunities for animal parasites to jump from one host to a new and virgin host. Nomadic people leave their wastes behind them but as communities increased in numbers, human and animal excreta would accumulate. Some was undoubtedly used as fertilizer as in areas of Asia today, but the cumulative build-up of waste would also contaminate water supplies, affording a means of disease transmission.

Sexual Transmission

Two protistan parasites can be transmitted via sexual contact. *Trichomonas vaginalis* can be spread as a sexually transmitted disease by intercourse, with transmission from male to female or female to male. *Entamoeba histolytica* has been spread by anal intercourse among male homosexuals.

Person-to-Person Transmission

Most parasitic diseases require an intermediate host before cycling to the human host. Pinworms, highly resilient intestinal parasites, can be spread directly from an infected child to other children and adults as a result of poor sanitary habits (careful hand washing). *Cryptosporidium* can be spread directly in high-risk groups such as children in daycare centers and institutionalized individuals.

Food and Food Handler Transmission

Food may serve as a vehicle for transmission of many parasites, including those found in feces. Food contaminated with human or animal waste, particularly if not cooked (e.g., salad greens, fruits), can transmit *Entamoeba histolytica*, *Cryptosporidium,* and *Cyclospora*. Food handlers indifferent to washing hands after toileting have also been implicated in transmission.

Undercooked pork, beef, or fish can carry larval stages of tapeworms or *Trichinella* (pork) (Figure 47.5). In Asia, intermediate hosts of some parasites (e.g., fish, crabs) may be eaten raw or lightly cooked and pass on larval stages to humans and other mammals as definitive hosts.

Water Transmission

Perhaps the simplest and most common vehicle for disease transmission is water, either directly or indirectly. Contaminated drinking water can transmit amoebic dysentery and giardiasis (discussed previously: fecal-oral transmission). Numerous efforts have been made to provide water to water-scarce areas of Africa for drinking, irrigation, and hydroelectric power through the construction of dams. The resultant lakes and irrigation canals, however, have also attracted snails, in particular those that are intermediate hosts for schistosome worms, resulting in a sharp increase in schistosomiasis [22]. The water also provides a breeding ground for mosquitoes that spread malaria.

FIGURE 47.5 Section through muscle tissue showing an encysted larva of *Trichinella spiralis*. If not killed by cooking, the larvae are digested free of their capsules and develop into sexually mature adults. Larvae produced in the lumen penetrate the intestinal wall to encyst in muscle tissues. (Courtesy of DPDx Parasite Image Library at the Centers for Disease Control and Prevention.)

Diagnostic Techniques

As with all infectious diseases, a critical factor in initiating appropriate therapy is early identification of the etiologic agent. After decades of testing, the protocols for detection of many parasitic disease agents are well established. Cultivation of protist parasites from a clinical sample is helpful in some diagnoses. Helminth parasites, however, are not cultured.

Clinical Diagnosis

Some parasitic infections can be recognized based on the patient's symptoms, recent travel history, occupation, contact with domestic and wild animals, unusual diets, immune status, insect bites, and place of birth (i.e., immigrant or native-born). Amoebic dysentery would be a logical diagnosis for a patient with diarrhea who had recently returned from a vacation in a developing country. Examination of a stool sample for amoebic cysts or trophozoites could verify the diagnosis and treatment could be started. Visceral leishmaniasis (kala-azar) would be a differential diagnosis for a child with an enlarged spleen and liver who emigrated from the Middle East (Table 47.1). Many other parasitic diseases have vague symptoms, are difficult to identify, and may require extensive testing. The clinician also has information from the standard panel of diagnostic tests, including the complete blood count (CBC); analysis of CSF (protein, white blood cells, and glucose in the CSF); and radiographic imaging (CT scans, MRIs). Neurocysticercosis, in which the larval stage of the pork tapeworm develops in the brain and eventually becomes encapsulated, will show up in an MRI. Other parasitic infections where calcification facilitates diagnosis are dracunculiasis, balamuthiasis, and baylisascariasis. Infection by

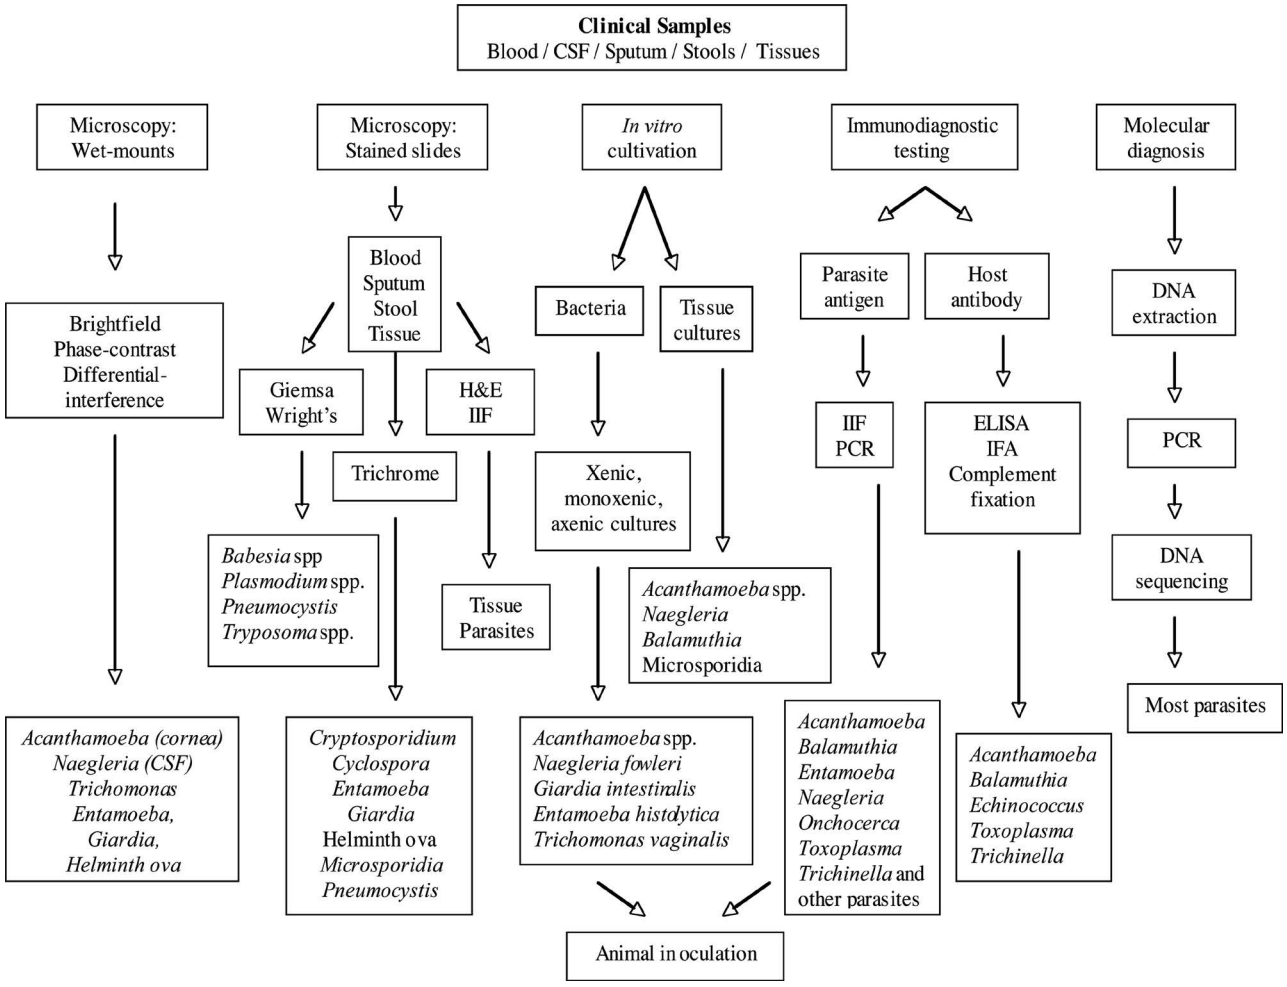

FIGURE 47.6 An algorithm based on the types of clinical samples and the various techniques that can be applied in identification. The same organisms can appear in several pathways, indicating that there is more than one way for identification of the parasite. It is assumed in this algorithm that most parasitic organisms can be identified by the PCR technique.

parasites can lead to elevated IgE levels and eosinophilia. If the blood sample is counted electronically instead of using a stained blood film, eosinophils may not be differentiated from other leukocytes and might be missed. In malaria infections, a drop in erythrocyte numbers and anemia are to be expected and, coupled with a stained blood film, can confirm a diagnosis.

Laboratory Diagnosis

Where testing is based on established criteria, such as cysts in a stool sample or *Plasmodium*-infected erythrocytes in a blood film, a rapid diagnosis is possible. Many parasitic diseases, however, are more difficult to identify. Symptoms may be vague or nonspecific and may mimic a number of other conditions.

Clinical Samples

The most common samples for testing include whole blood (malaria, trypanosomiasis), serum for serological testing (toxoplasmosis), stool samples for gastrointestinal parasites (worm ova), cysts of amoebae (dysentery), tissue samples for hematoxylin-eosin or other types of staining, sputum for lung parasites (*Paragonimus, Pneumocystis*), vaginal smears (trichomoniasis), and sigmoidoscopic (pinworms), or lymphatic aspirates (trypanosomes). Based on the type of specimen, special handling may be required. Although serum samples for antibody testing can be frozen and stored for prolonged periods of time, whole blood for blood film staining must be processed immediately. With other types of specimens, the integrity of the parasite might be damaged should the sample be kept at or near 37°C for prolonged time periods or, at the other extreme, placed in a refrigerator or freezer. Delayed transit of a sample to the laboratory can also reduce the chance of detecting more fragile parasites. Figure 47.6 presents an algorithm for the testing of clinical samples.

Specific Techniques

Direct and Indirect Testing for Parasites

Testing for the presence of parasites covers a broad range of techniques. Direct testing aims to visualize the parasite with a microscope in a blood film, stool, urine, or bronchoalveolar sample or biopsied tissue. Even with these long-established

techniques, however, the parasite can elude the technician. For many parasites, multiple samples must be taken over several days because of periodicity in the presence of parasite stages in the clinical sample. The names characterizing the different malarial diseases (Table 47.1) denote differences in the time intervals at which the acute phase of disease occurs (i.e., approximately 48 hours in tertiary malaria; approximately 72 hours in quartan malaria). Early erythrocytic ("ring") stages of *Plasmodium falciparum* are infrequently seen in circulating blood or blood films because these infected erythrocytes are likely to bind to the walls of blood vessels in the brain. The filarial worm *Wuchereria bancrofti* (cause of elephantiasis) appears in circulating blood at night, corresponding to the time that mosquito vectors would be most actively feeding.

In indirect testing, where testing for antibodies is involved, samples from the acute as well as the convalescent phases of the disease are needed to detect changes in antibody titer or in types of antibodies present (IgM vs. IgG). Antibodies in the patients' blood samples may cross-react with the "wrong" antigens, leading to misdiagnosis and unnecessary or inappropriate therapy. Some immunoserology tests may give problematic results (e.g., for neurocysticercosis) and may need corroboration by some other technique to get a definitive diagnosis.

Cultivation of Parasites

In vitro cultivation of parasites is useful in confirming identification, obtaining yields of parasites for molecular and biochemical studies, for assessing virulence, for electron microscopy, and for testing antimicrobial efficacy in treating infections. Many protist parasites can be cultured, although often requiring complex media, demanding growth conditions, and inconvenient transfer schedules to keep cultures from dying out. Some media are available commercially and the American Type Culture Collection (www.ATCC.org), in addition to having active cultures or frozen strains of parasitic protists available for purchase, can also provide media formulations and prepared media. Bacteria generally accompany protists established in culture from clinical samples, the number depending on the site in the body from which they were taken. CSF, for example, should be sterile and anything isolated (e.g., *Naegleria fowleri*) from it would be significant. Cultures with undefined bacteria are referred to as xenic or polyxenic cultures (from *xenos* [Greek], meaning stranger). The next step would be to establish the protist in monoxenic (single "stranger") culture with a defined bacterial species using antibiotics to eliminate unknown or unwanted microbes. The goal is eliminating all bacteria to obtain an axenic culture (without "strangers," or bacteria-free). Antibiotics frequently used for eliminating bacteria are penicillin-streptomycin, gentamycin, and amphotericin B for fungal contaminants.

Naegleria fowleri and *Acanthamoeba* can be cultured by transfer of clinical samples (*Naegleria*: brain tissue, CSF; *Acanthamoeba* spp.: brain or cutaneous tissues, corneal scrapings for amoebic keratitis) to nonnutrient agar plates with a film of bacteria as a food source (any of the following: *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter* spp.) spread over the agar surface and incubated at 30–37°C. Amoebae will grow out within 24–72 hours [23]. *Balamuthia*, another free-living amoeba causing cutaneous and CNS infections, can be cultured from brain tissue (often obtained at autopsy) on tissue culture cells. Monkey kidney cells are a good source for growth, but other tissue culture lines have been used [24]. *Entamoeba histolytica*, *Giardia duodenalis*, and *Trichomonas vaginalis* require complex media and are often accompanied by a mixed population of indigenous bacteria that can overgrow in the enriched medium [25]. An *Entamoeba histolytica* look-alike, *E. dispar*, may also be present in cultured stool [26], as well as several other commensal amoebae from the intestine (*Entamoeba coli, Endolimax nana*).

The hemoflagellates (trypanosomes, *Leishmania*) are medically important protists that can be isolated from blood and tissues samples, and needle aspirates of cutaneous lesions. The media used for these organisms are varied and complex [27]. *Plasmodium* and *Babesia*, both intraerythrocytic blood parasites, can be grown in culture but are especially challenging in terms of media and growth conditions, requiring skills that are usually restricted to research laboratories [28, 29]. Microsporidia, intracellular parasites that can be isolated from urine, corneal scrapings, and bronchoalveolar lavage, can be maintained in a variety of tissue culture lines [30]. *Toxoplasma* can be identified by inoculation of clinical samples (e.g., CSF) into tissue cultures. *Pneumocystis jirovecii*, although an important opportunistic parasite, has yet to be cultured *in vitro*, beyond mere maintenance.

Animal Inoculations (Xenodiagnosis)

Mice, rats, hamsters, or guinea pigs can be inoculated with infectious material from a clinical sample or with isolated etiologic agents themselves if in culture and observed for signs of disease. An advantage of this technique is that if parasitemia is low in the host and diagnosis is uncertain (as in *Babesia* infections), animal inoculation can allow for an increase under *in vivo* conditions and aid in diagnosis. The disadvantage with the technique is that it may take days or even weeks for results to develop. Some isolates such as amoebae (*Balamuthia mandrillaris, Acanthamoeba* spp.) from culture can be inoculated in mice via an intranasal or intracranial route and cause death of the animal within a week [31]. Insect vectors for parasitic diseases (*Anopheles* mosquitoes, triatomid bugs, etc.) can be inoculated by allowing them to feed on an infected human or animal. Some pathogenic strains lose virulence with prolonged *in vitro* culture and may require animal passage to maintain or up-regulate their virulence.

Immunofluorescent Testing for Antibodies (IFA)

Patient serum is prepared in a series of dilutions. Antibodies in the serum bind to the antigen (the parasite) that is fixed and dried on a slide. This, in turn, is treated with anti-human fluorochrome-conjugated antibody raised in goats or rabbits. Fluorescence resulting from binding of the fluorescent antibody to the human antiparasite antibody can be visualized using a fluorescence microscope. The antibody titer is that serum dilution (e.g., 1:64), beyond which fluorescence can no longer be detected. The technique is useful for determining antibody titers at different stages of disease.

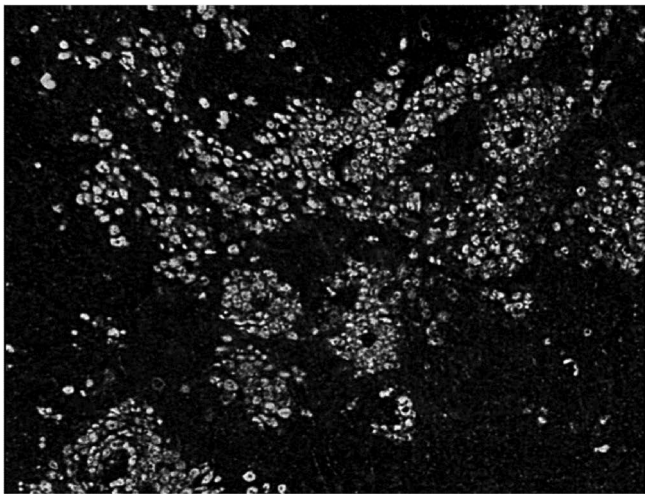

FIGURE 47.7 Section through brain stained with immunofluorescent antibody specific for *Balamuthia mandrillaris*. The amoebae fluoresce brightly against unstained parenchymal background. (Courtesy of Dr. G. S. Visvesvara.)

Immunofluorescent Staining for Parasites in Tissue (IIF)

IIF (indirect immunofluorescence) is a qualitative test for the presence of the parasite in tissue. Biopsy or necropsy tissue sections on slides are exposed to goat or rabbit antiparasite serum, followed by fluorochrome-conjugated antirabbit or antigoat serum. Parasites in tissue will fluoresce when the slide is examined with a fluorescence microscope, but not surrounding host tissue (Figure 47.7). The immunostaining is highly specific, making this a particularly reliable diagnostic test.

Enzyme-Linked Immunosorbent Assay (ELISA)

Enzyme immunoassay for antibody is widely used for diagnosis of many parasitic diseases. Commercial ELISA kits are available, precluding the do-it-yourself, time-consuming preparation of plates and assembling necessary reagents, thus simplifying the procedure. Because of considerations such as cost of the kits, the number of tests being performed in the laboratory, and the shelf life of the kit, it may not be feasible to perform ELISA testing, but rather to send samples to state or national reference laboratories.

Microscopic Diagnosis

For many diagnostic procedures, the microscope remains an important and affordable tool, especially in laboratories where more sophisticated testing and equipment are not available. A major use is in the examination of blood smears in conjunction with staining, using Giemsa or Wright's stains for blood smears. Stained blood films are useful in determining parasitemia, the percentage of infected erythrocytes. Changes in parasitemia can be used to check response to drug therapy or determine if a particular therapy is effective. Stained films are also effective in distinguishing between infection with *Plasmodium* or *Babesia* (pear-shaped in erythrocytes).

The microscope is used with a variety of clinical samples: Fixed and stained with hematoxylin-eosin (tissue sections), or iron hematoxylin or trichrome for stool samples. Lugol's iodine, used in moderation, can also be a useful stain, enhancing the appearance of ova in stools and the presence of flagella on protists, although more conventional staining should be used to corroborate observations. A compendium of stains, formulas for preparation, and directions for their use can be found in Garcia [16]. In some instances, unstained material can be examined directly (e.g., CSF, lymph node aspirates) as wet-mounts.

A phase-contrast or differential-inference microscope can enhance the appearance of unstained specimens in wet-mounts and facilitate parasite identification. For extended viewing of wet-mounts, a combination of petroleum jelly and paraffin can be used to seal the coverslip to the slide, thus slowing drying. Fresh, unfixed wet-mounts are particularly useful for observing protist motility. Examination of CSF wet-mounts for the presence of active, rapidly moving amoebae is essential in the diagnosis of amoebic meningoencephalitis caused by *Naegleria fowleri*. In old or refrigerated CSF samples, leukocytes may be mistaken for amoebae, causing misdiagnosis. Flagellated trichomonads from vaginal discharge in a wet-mount typically show a wobbly movement, similar to that of a spinning top that is about to topple.

Concentrating the clinical sample is often useful for increasing the chance of detecting parasites or parasitic stages that may be sparse in samples. Thick versus thin blood films can be helpful in detecting and identifying malaria parasites. A thick film offers a better chance of seeing parasites in the blood film, while a thin film is better able to identify the different species of *Plasmodium*. Helminth ova in stools may be obscured by fecal debris, and separating them using flotation (zinc floatation) or sedimentation (formal-ethyl acetate), the former being more reliable and easier to use than the latter, is frequently done [16].

Histopathology

Sectioned tissue from biopsies, whether brain, liver, or intestine, stained with hematoxylin-eosin stain can provide definitive evidence for the identification of parasites (Figure 47.8).

Molecular Diagnostic Techniques: PCR

Once a highly specialized technique used only in research and reference laboratories, the polymerase chain reaction (PCR) is now available to a wider audience of diagnosticians. Its basis is the use of primer sets containing base pairs unique for strands of parasite nuclear or mitochondrial DNA, giving an amplified product that can be visualized on a gel. The resulting bands identify the DNA as coming from a particular parasite whose DNA is present in host tissues or body fluids. Many, if not most, parasites can be identified by the PCR. In conventional PCR, the amplified DNA extract from a clinical sample is run on a gel and identified by the number of base pairs in the amplification product and by comparison with positive and negative controls. The identification can be further confirmed by DNA sequencing. Nested PCR is a modification of the conventional PCR technique in which sequential primer sets are used in producing an amplification product. Real-time PCR is an alternative technique that is more sensitive than conventional PCR and has additional advantages.

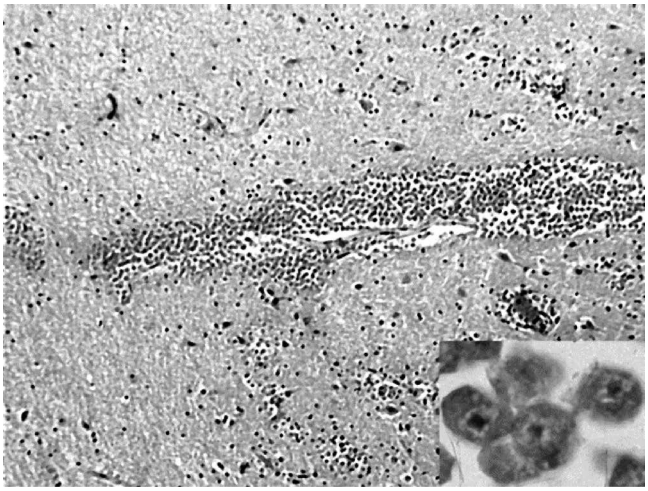

FIGURE 47.8 Section through brain with primary amoebic meningoencephalitis caused by *Naegleria fowleri*. A heavy concentration of amoeba is seen in the perivascular space. Hematoxylin-eosin stain. Inset: high-magnification image of *Naegleria* amoebae showing nucleus with large centrally located nucleolus in each amoeba. (Courtesy of Dr. G.S. Visvesvara.)

The amplification and detection (fluorescent probe) steps occur in a closed tube, reducing the chance of contamination and environmental spread of DNA [32]. Additionally, the products are analyzed in real-time using a thermal cycler. The technique is faster (hours vs. overnight) and requires no post-amplification handling. Real-time PCR can identify DNA from different organisms simultaneously as, for example, *Naegleria fowleri*, *Acanthamoeba*, and *Balamuthia mandrillaris,* free-living amoebae responsible for amoebic encephalitis [33]. It has also been used for differentiating between species of *Plasmodium* more effectively than stained blood films and has shown evidence of mixed human infections [34].

PCR cannot distinguish between DNA from living versus dead organisms, which can make a difference in deciding to treat or not treat a disease with drugs. PCR can be useful in retrospective studies of disease by analysis of archival slides and formalin-preserved tissues, but is less reliable in identifying DNA from parasite tissue samples because of fragmentation of the DNA caused by formalin fixation.

Drug Therapy

As with all infectious diseases, the ideal drug for use against an etiologic agent is one that will specifically target a particular function or metabolic pathway in the parasite that is either absent from the host's cells or less sensitive to the drug. Drug treatment is dynamic; new drugs come on the market, new variations of existing drugs become available, the U.S. Food and Drug Administration may approve drugs that were previously unavailable for use in the United States, or resistance to a particular drug therapy (e.g., use of chloroquine in areas where chloroquine resistance is common) may preclude its use in treatment and the cost of the drug, particularly when considering widespread use in endemic regions. Additionally, there are other considerations that will affect drug choice and dosage: dosage adjusted for age, oral versus parenteral administration, stage of disease, drug use for prophylaxis, drug allergies or negative interactions with other medications, drug safety during pregnancy, disseminated or localized infections, and patient compliance with the recommended drug therapy.

A consequence of drug therapy is death of parasites. Although this is a desired effect, massive release of antigens from disintegrating parasites may present more of a problem to the immune system than the presence of the living organisms. Large-scale death of helminths in tissue can elicit an allergic reaction from the host caused by an immune response to the dying parasites. Antihistamines and corticosteroids can mute the drug-initiated immune reaction, but in some instances palliative measures may be the preferred course of action. Table 47.4 presents general information about drugs for protistan and helminthic diseases. The reader should seek medical advice regarding current guidelines [35, 36] for drug use against specific diseases.

Mechanisms of Action of Selected Drugs

Several drugs that are used against a number of different parasites are examined for their mechanisms of action. The general effects include interference with parasite metabolic pathways, inhibition of microtubule assembly preventing mitosis or disorganizing cell structure, alteration of permeability of the parasite tegument, and damage to parasite DNA.

Selected Drugs Effective in Treating Protistan Diseases

1. *Artemisinin and derivatives.* These antimalarial compounds are derived from the medicinal herb *Artemisia annua* that has been used for centuries in China as a treatment for malaria [37]. Derivatives of the compound include artemether and artesunate. The drugs themselves are effective for relatively short time periods and, to extend their duration of efficacy, they have been coupled with other drugs (e.g., artesunate-mefloquine).
2. *Chloroquine.* Chloroquine was used successfully for many years in the treatment of malaria until drug resistance began to show up in malarial parasites. Now its use is restricted to parts of the world where malarial strains remain sensitive to the drug. The drug is a weak base and is taken up into acidic food vacuoles of the intracellular parasite. Several mechanisms of action have been reported for the drug: prevention of detoxification of internalized heme (from host erythrocyte hemoglobin) accumulated by the malarial parasite, formation of drug-heme complexes, or interference with nucleic acid biosyntheses. Chloroquine-sensitive strains accumulate the drug, while chloroquine-resistant strains do not.
3. *Metronidazole (Flagyl®) and tinidazole (Tindamax®; Fasigyn®).* Metronidazole is a synthetic nitroimidazole antiprotistan drug. When taken up, it is reduced by the parasite's electron transport system, resulting in production of free radicals. A gradient is established across the parasite membrane between the reduced molecule

within the parasite and its normal oxidized molecular state outside the membrane, enhancing uptake of the drug. It has also been shown to damage the parasite's DNA and is a mutagenic agent (in rodents). It is particularly useful in treating infections caused by anaerobic or microaerophilic protists such as *Entamoeba histolytica, Giardia intestinalis,* and *Trichomonas vaginalis*. Tinidazole is similar to metronidazole in its action and the organisms effected, but is reportedly faster acting.

4. *Miltefosine (hexadecylphosphocholine).* Miltefosine is an alkylphosphocholine developed as an anticancer drug but has been shown effective in the treatment of leishmaniasis, including visceral [38], cutaneous, and mucocutaneous [39] forms. It is available as a pill for oral administration and has limited side effects (diarrhea, vomiting) in patients. The drug produces an apoptosis-like effect on the parasite, resulting in membrane breakdown and lysis.

Selected Drugs Effective in Treating Helminth Diseases

1. *Praziquantel (Biltricide®).* Praziquantel alters the intracellular calcium levels of sensitive flat worms [40]. Among its effects on helminths, at low concentrations it causes spastic paralysis leading to expulsion of the worm from the host. At high concentrations, it leads to damage to the worm's tegument, alters permeability, and causes its disintegration, opening the tegument to the host's immune system. Both these events are triggered by an increase in calcium ions. It has also been used in treating neurocysticercosis. Although praziquantel is used in treating many fluke and cestode diseases, nematodes do not respond to treatment with this drug.
2. *Albendazole (Albenza®) and Mebendazole (Vermox®).* Both drugs are benzimidazole broad-spectrum antihelminthics. Their effects include preventing glucose absorption across the worm tegument, interfering with mitochondrial activity, and inhibiting microtubule formation by binding to tubulin. A concentration differential exists between sensitivity of nematode tubulin and host tubulin to benzimidazoles, the former being more sensitive to lower drug concentrations. Their use is primarily against nematodes: pinworm, hookworm, and mixed infections. They are used in the treatment of inoperable neurocysticercosis in conjunction with corticosteroids, the latter to prevent an inflammatory response to the disintegrating cysticercoid larvae.

Conclusions and Perspectives

Parasites are well adapted to their ecologic niche, and in many diseases have achieved détente with their hosts. The parasites have had millennia to perfect their way of life; the host has decades to adjust. As the result of living in a disease-endemic region, the host may develop some immunity against the parasite (e.g., falciparum malaria in individuals older than 5 years), allowing survival.

Although major efforts are underway to eliminate specific parasitic diseases, problems remain:

1. Prohibitive cost of medication in developing countries.
2. Patient compliance in taking necessary antiparasite medications despite unpleasant side effects or prolonged use
3. Development of resistance to drugs of choice
4. Prevention of reinfection in endemic areas

Progress on vaccines against the most devastating of the parasitic diseases, malaria, has been slow and the successes once envisioned have yet to be realized, with antigenic variation as a major obstacle to overcome; any vaccine, to be successful, has to protect against all stages of the parasite life cycle. With continued sequencing studies of parasite DNA and identification of gene products, new drugs aimed at specific functions in parasites may prove more effective in combating diseases than those in the current pharmacopoeia.

Looking ahead to the generally accepted effects of global climate change, conditions may become more favorable for survival and dissemination of human parasites. Resource-starved developing nations will likely bear the burden of increased parasite loads. As a result of global warming, water may become scarcer in areas of the world, further concentrating peoples around water sources leading to their contamination with enhanced development of larval stages and vectors.

Introduction

The Nature of Bacteriophages

Bacteriophages are viruses that only infect bacteria. They are like complex spaceships (Figure 48.1), each carrying its genome from one susceptible bacterial cell to another in which it can direct the production of more phage. Each phage particle (virion) contains its nucleic acid genome (DNA or RNA) enclosed in a protein or lipoprotein coat, or capsid; the combined nucleic acid and capsid form the nucleocapsid. The target host for each phage is a specific group of bacteria. This group is often some subset of one species, but several related species can sometimes be infected by the same phage.

Phages, like all viruses, are absolute parasites. Although they carry all the information to direct their own reproduction in an appropriate host, they have no machinery for generating energy and no ribosomes for making proteins. They are the most abundant living entities on earth, found in very large numbers wherever their hosts live—in sewage and feces, in the soil, in deep thermal vents, and in natural bodies of water. Their high level of specificity, long-term survivability, and ability to reproduce rapidly in appropriate hosts contribute to their maintenance of a dynamic balance among the wide variety of bacterial species in any natural ecosystem. When no appropriate hosts are present, many phages can maintain their ability to infect for decades, unless damaged by external agents.

Some phages have only a few thousand bases in their genome, whereas phage G, the largest sequenced to date, has 497,513 base pairs—as much as an average bacterium, though still lacking the genes for such essential bacterial machinery as ribosomes. Over 95% of the phages described in the literature to date belong to the Caudovirales (tailed phages). Their virions are approximately half double-stranded DNA and half protein by mass, with icosahedral heads assembled from many copies of a specific protein or two. The corners are generally made up of pentamers of a protein, and the rest of each side is made up of hexamers of the same or a similar

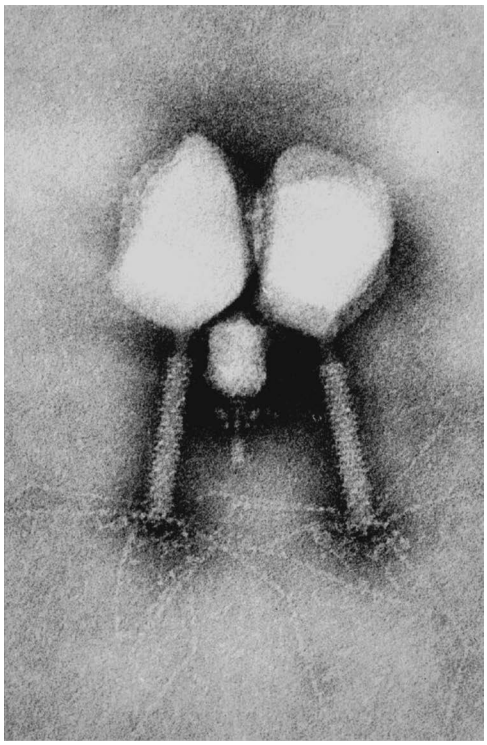

FIGURE 48.1 A "family portrait": Bacteriophages φ29 and T2. (Electron micrograph provided by Dwight Anderson.)

protein. The three families are defined by their very distinct tail morphologies: 60% of the characterized phages are *Siphoviridae*, with long, flexible tails; 25% are *Myoviridae*, with double-layered, contractile tails; and 15% are *Podoviridae*, with short, stubby, tails. The latter may have some key infection proteins enclosed inside the head that can form a sort of extensible tail upon contact with the host, as shown most clearly for coliphage T7.[3]

Bacteriophage T4, a myovirus, is the most extensively studied[2b] of the larger phages at the genetic, molecular, and functional levels (Figure 48.2). T4 and its close relative T2 played key roles in the development of molecular biology: The identification of DNA as the genetic material, the discovery of messenger RNA (mRNA), the triplet nature of the genetic code and the deciphering of that code. Their use of a noncanonical base, 5-hydroxymethylcytosine, rather than cytosine, in their DNA was crucial for establishing that viruses encoded enzymes, and for totally shutting off all host transcription, including that of ribosomal RNA (rRNA). Until then, the enormous amounts of rRNA had masked the existence of the labile messenger RNAs (mRNAs), which mediate the transfer of the information from the nucleotide sequence of each gene in DNA to the protein it encodes.

Archaea have their own set of infecting viruses, sometimes called *archaephages*. Many of these have unusual, often pleomorphic shapes, that are unique to the Archaea. However, many viruses identified to date for the Crenarchaeota kingdom of Archaea look like typical tailed bacteriophages.[4] See Chapter 21 in this book for more information on Archaea.

The 10 families of tailless phages described to date each have very few members. They are differentiated by shape (rods, spherical, lemon-shaped, or pleomorphic); by whether they are enveloped in a lipid coat; by having double- or single-stranded DNA or RNA genomes, segmented or not; and by whether they are released by lysis of their host cell or are continually extruded from the cell surface. Their general structures, sizes, nucleic acids, adsorption sites, and modes of release are described in detail in recent books,[1,5] as well as the basic infection processes of the *Inoviridae*, *Leviviridae*, *Microviridae*, and *Tectiviridae*. Relatively little is known about most of the others, which generally have been isolated under extremes of pH, temperature, or salinity, and have only been observed in Archaea.

Phages can also be divided into two classes based on lifestyle: obligatorily/professionally *virulent* and *temperate*. Professionally virulent phages can only multiply by means of a lytic cycle; the phage virion adsorbs to the surface of a host cell and injects its genome, which takes over much of host metabolism and sets up molecular machinery for making more phages. The host cell then lyses minutes or hours later, liberating many new phages. *Temperate phages*, in contrast, have a choice of reproductive modes when they infect a new host cell. Sometimes the infecting phage initiates a lytic cycle, resulting after a given short time in lysis of the cell and release of new phage, as just described. The infecting phage may alternatively initiate a *lysogenic* cycle; instead of replicating, the phage genome assumes a quiescent state called a prophage, generally integrated into the host genome but sometimes maintained as a plasmid. It remains in this condition indefinitely, being replicated as its host cell reproduces to make a clone of cells all containing *prophages*; these cells are said to be lysogenized or lysogenic (i.e., capable of producing lysis) because one of these prophages occasionally comes out of its quiescent condition and enters the lytic cycle. The factors affecting the choice to lysogenize or to reenter into a lytic cycle are described below. As discussed by Levin and Lenski,[6] the lysogenic state is highly evolved, requiring co-evolution of virus and host that presumably reflects various advantages to both. Temperate phages can help protect their hosts from infection by other similar phages and can lead to significant changes in the properties of their hosts, including restriction systems and resistance to antibiotics and other environmental insults. As discussed later in this chapter, they may even convert the host to a pathogenic phenotype, as in diphtheria or enterohemorrhagic *Escherichia coli* (EHEC) strains. Bacteriophages lambda (λ), P1, Mu, and various dairy phages are among the best-studied temperate phages. (Note that mutation of certain genes can create virulent derivatives of temperate phages; these are still considered members of their temperate phage families, especially since they can pick up various genes through recombination with their integrated relatives.)

The larger virulent phages generally encode many host-lethal proteins. Some of them disrupt host replication, transcription, or translation; they may also degrade the host genome, destroy, or redirect certain host enzymes, and/or alter the bacterial membrane. There have also been found many small host-lethal early phage genes that could be exploited to develop new antimicrobials or other modulators of bacterial physiology.[6b] The temperate phages, in contrast, generally do much less restructuring of the host, and they carry few if any host-lethal proteins that would need to be kept under tight control during long-term lysogeny. They always encode a *repressor* protein, which acts at a few *operator* sites to block transcription of other phage genes. This

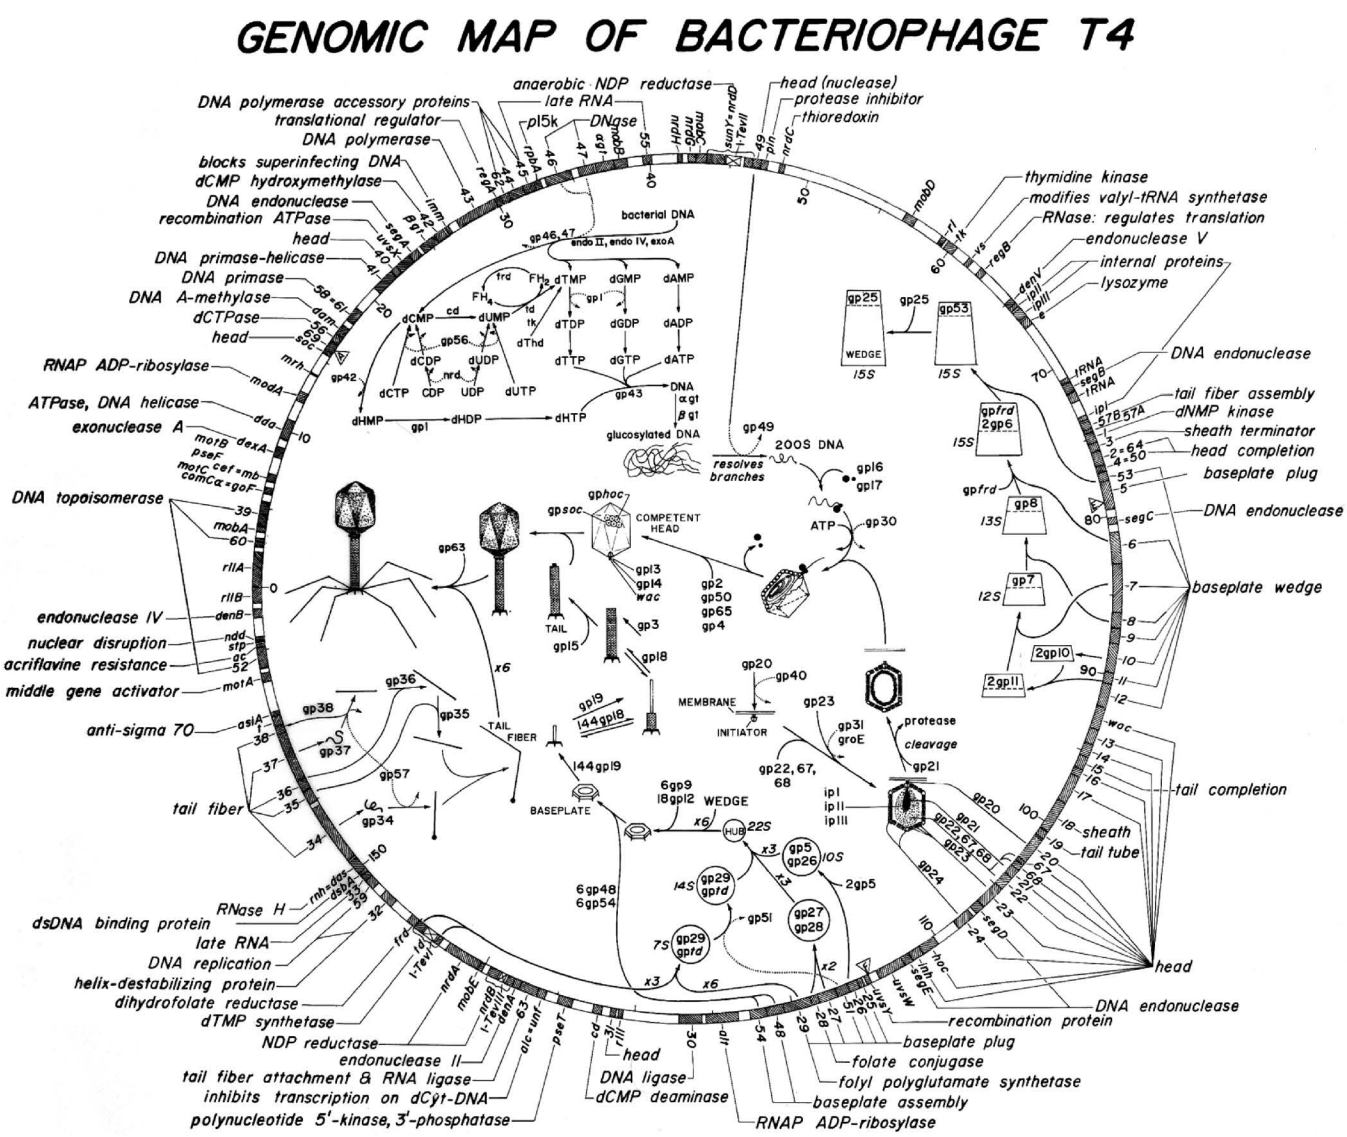

FIGURE 48.2 This genomic map of bacteriophage T4, incorporating detailed illustrations of the pathways of DNA biosynthesis and phage particle construction, has been updated multiple times by Burton Guttman and Elizabeth Kutter from the version originally drawn as the frontispiece for the 1983 book "Bacteriophage T4." That book, which grew out of the 1981 biennial Evergreen International Phage Meeting and involved 71 members of the T4 community, was the first monograph ever published by ASM press.

repressor may be the only phage-encoded protein produced during the lysogenic state, but often a few other genes that may be beneficial to host survival are also expressed from the prophages. The repressor also blocks lytic infection by other phages of the same immunity group—that is, other phages whose genes can be regulated by the same repressor. In this way, a temperate phage generally protects its host bacterium from infection by several kinds of phages.

Antigenic Properties of Phages

Phages, like other protein structures, can elicit an antibody response, and antiphage antibodies have been used in a variety of ways since early phage researchers first showed that rabbits injected with phage lysates produced phage-neutralizing antibody; in 1926, d'Herelle,[7] and in 1959 Adams,[8] reviewed early studies in the field. For most phages, the neutralization follows first-order kinetics to an inactivation of about 99%, with the survivors then generally being more resistant and often having smaller plaque size. The activity of a given preparation at a standard temperature and salt concentration is denoted by a velocity constant, K, which is related to the log of the percent of phage still infectious after a given exposure time t. As emphasized by Adams, such factors as salt concentration are very important in titering antibody activity. Some phages require specific divalent cations but monovalent cations above 10^{-2} M and divalent cations above 10^{-3} M are generally inhibitory. He cites an example of anti-T4 serum with an inactivation constant (K value) of over 105 min^{-1} under optimal conditions but only 600 min^{-1} in broth. Also, somewhat surprisingly, different assay hosts may give different estimates of the fraction of nonneutralized phage. Adams suggested this may be due to minor differences in the receptors

recognized on various hosts, leading to differences in bonding strength. We also know now that some phages can use totally different receptors on different hosts, as described for T4 later in this chapter. Once determined for a given set of conditions, the *K* value can be used to calculate the appropriate antibody dilution for any given experiment.

With the aid of noted Russian electron microscopist Tamara Tikhonenko,[9] such techniques as immunoelectron microscopy were used to carry out particularly detailed studies of the process of inactivation by antibodies.[10] Implications of phage antigenicity for human therapy are discussed in chapter 54.

Recent experiments have shown that phage can elicit antiviral immune responses in mammalian cells, which turn out to protect a bacterial pathogen, *Pseudomonas aeruginosa*, from being cleared from infected patients.[10b]

Susceptibility of Phages to Chemical and Physical Agents

Phages vary greatly in their sensitivity to various chemical and physical agents, in ways that are generally unpredictable and need to be determined experimentally in each case. For example, no one has yet explained the stability of phage T1 to drying, a stability that has led to much grief in the biotech industry as well as in phage labs from contamination by ubiquitous T1-like phages. There are, however, certain general principles. For example, almost all phages are very susceptible to UV light in the range of 260 nm as well as in the far UV; in addition to the general effects of sunlight, there are multiple reports of phage collections being lost to fluorescent-lighted refrigerators. Other factors potentially affecting phage infectivity include pH, ascorbic acid, urea, urethane, detergents, chelating agents, mustard gas, alcohols, and heat inactivation. The most extensive summary of the known effects of chemical and physical agents on phages is found in Adams[8]; there is also very good information in Ackermann and Dubow.[11]

Phages generally are stable at pH 5–8, and many are stable down to pH 3 or 4; each phage needs to be specifically characterized. Phage are often quite sensitive to protein-denaturing agents such as urea and urethane, but the level of inactivation depends on both concentration and temperature and differs for different phages. Not surprisingly, detergents generally have far less effect on phage than they do on bacteria, although the few phages that are enveloped in membranes are quite susceptible, while chelating agents have strong effects on some phages but not on others; this apparently depends mainly on ionic cofactor requirements for adsorption. Chloroform has little or no effect on nonenveloped phages; in fact, one needs to be very careful not to get phage contaminants into the chloroform being used to produce phage lysis. However, contaminants toxic to phage in high concentrations are found in some commercial chloroform. Mutagenic agents such as mustard gas, nitric oxide, and ultraviolet light inactivate phage and can induce the lytic cycle in many lysogens. Lytic phages can generally still infect cells recently inactivated with UV or other mutagens, because they do not require ongoing synthesis of host proteins after infection. In fact, UV inactivation of the host just prior to infection is sometimes used to virtually eliminate residual synthesis of host proteins for experiments using pulse labeling to examine patterns of phage protein synthesis.

Interaction of Phage with the Host Cell

Virtually every structure on the outer surface of a bacterial cell is likely to serve as a receptor for some phage. See Chapter 18 in this book.

The properties of the distinctive outer membrane of Gram-negative cells have been reviewed in detail by Nikaido[12,13] and Ghuysen[14] and are shown in Figure 48.3a. The inner face of the outer membrane has a phospholipid composition similar to that of the cytoplasmic membrane, to which is attached the peptidoglycan layer. In contrast, the lipid part of the outer face is mainly a unique substance called lipopolysaccharide (LPS), seen nowhere else in nature. LPS is composed of three parts: a hydrophobic lipid A membrane anchor, connected by a core polysaccharide, to a complex distal polysaccharide O-antigen. The O-antigens play important roles in bacterial interactions with mammalian hosts and in virulence; they are often indicated in strain names, such as *E. coli* O157. They can also serve as efficient phage receptors; obviously, such phages are likely to have very narrow host ranges. Many common lab strains, including *E. coli* K-12, lack any O-antigen; *E. coli* B, used extensively for phage work, even lacks the more distal part of the LPS core, but they are found in most clinical strains. The outer membrane also contains several families of general porins—proteins that form large β-barrel channels with charged central restrictions that support nonspecific rapid passage of small hydrophilic molecules but exclude large and lipophilic molecules, and are generally present in high quantity. It also contains various high-affinity receptor proteins that catalyze specific transport of solutes such as vitamin B12, catechols, fatty acids, and different iron derivatives. There are about 3 million molecules of LPS on the surface of each cell, plus 700,000 molecules of lipoproteins, and 200,000 molecules of the porins. The concentrations of the specific other outer membrane proteins used as receptors vary considerably, depending on environmental conditions and the general need for the particular compound each one transports; sex pili and other such structures are also used as sites of initial attachment by some phages, leading, for example, to phages that are male-specific. Some filamentous phages actually inject through the pili.

Appropriate positioning of the phage tail on the cell surface[14b] triggers irreversible events leading to DNA delivery into the host. There is some evidence supporting that phage T4 can actually "walk" along the surface of the bacterium to find its receptor (Liefting W, Dreesens L, Aubin-Tam ME, Beaumont H, personal communication). In Gram-negative cells, DNA delivery includes getting its DNA safely across the periplasmic space (periplasm), which appears to be a sort of viscous gel that contains many nucleases and proteases, in addition to transport across the outer and inner membranes. In some phages, it has been shown that lipopolysaccharide alone is capable of triggering DNA release from phage particles.[14c] There are few phages where much is known about the mechanism or energetics of DNA delivery, but it is clear that it can differ substantially from phage to phage.

Proteins TonB and TolA, which are anchored to the inner membrane but span the periplasmic space and are particularly important to various uptake systems, are also crucial to infection by such phages as T5. A detailed review by Letellier et al.[15] focuses primarily on three coliphages that have been best studied

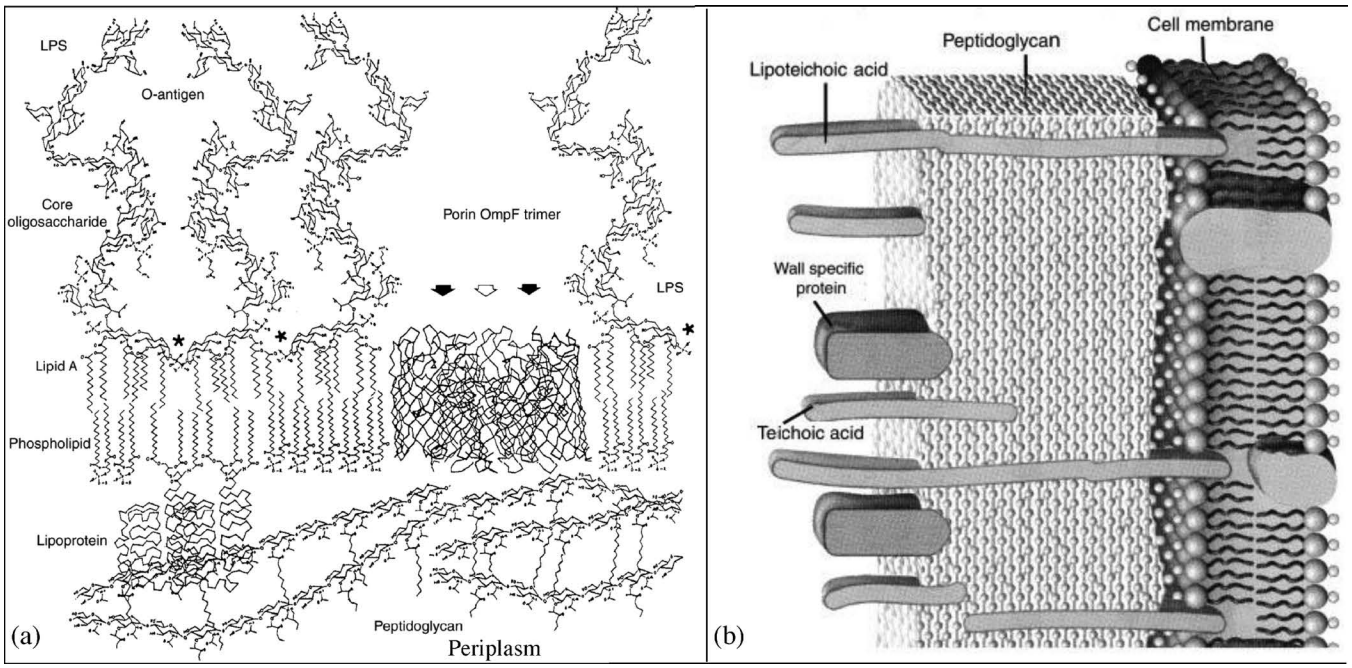

FIGURE 48.3 (a) Details of the outer membrane structures of Gram-negative bacteria. (With permission, from Hancock, R.E.W., Karunaratne, D.N., and Bernegger-Egli, C. Molecular Organization and Structural role of Outer Membrane Macromolecules, *The Bacterial Cell Wall*, J.M. Ghuysen, Hackenbeck, R. (Eds.). Elsevier, Amsterdam, 1994, 263–279.) (b) General structure of the cell wall of Gram-positive bacteria (from Kutter et al.[2]). Recent work indicates that there is actually an inner wall zone between the peptidoglycan and the cell membrane in *S. aureus*.[72]

regarding the DNA transfer process: myovirus T4, siphovirus T5, and podovirus T7. For each, a very long polyanionic genome—50 times the cell length for T4—must penetrate unscathed across two hydrophobic barriers, the outer and inner membranes, as well as the peptidoglycan sheath and the nuclease-containing periplasmic space. As they discuss, the rate of transfer can be as high as 3,000–4,000 base-pairs/second, in contrast to the 100 base-pairs/second seen for conjugation and natural transformation. Furthermore, the very high efficiency of infection for phages like T4 indicates that the process almost always occurs without significant damage to the infecting DNA molecule. The mechanisms are highly varied; often, ATP, a membrane potential, or enzyme action is involved, but some phages, such as T5, can enter cells in the absence of metabolic energy sources—it is here that TolA and TonB are involved for T5, but not used for T4 or T7.

The volume of the rigid phage capsids does not change as the DNA is injected into the cell, and the simple release of energy from metastable packing in the particle does not provide sufficient energy to transport a DNA molecule several micrometers long through the very narrow channel inside the tail tube. For *B. subtilis* phage SP82G, McAllister[16] showed that the rate of DNA transfer into the cell is constant over the whole genome and is highly temperature dependent, and the second-step transfer of the major part of coliphage T5 DNA proceeds normally even in experiments where the DNA has already been released from its capsid.[15] Though the myoviruses have contractile tails, it does not appear that their tail tubes actually pierce the inner membrane and a potential gradient is still required for DNA entry into the cell. All in all, as discussed by Molineux,[3] it is clear that the widely invoked "hypodermic syringe" injection metaphor is generally inaccurate and the mechanisms providing energy for the transfer differ from phage to phage. In the case of T7, for example, the energy for transfer is largely supplied by transcription of the incoming DNA, starting from a promoter near the unique beginning of the molecule and depending on the fact that all of the transcription is in the same direction. The relatively slow speed of this process allows time for T7-encoded mechanisms to block damage to the DNA by host nucleases.

The interactions of phage with Gram-positive hosts have been much less well studied. Here, the phage recognize parts of the peptidoglycan layer and/or other molecules embedded in it (Figure 48.3b); for example, particular teichoic acids are involved for myoviruses like *B. subtilis* phage SPO1, listeria phage A511, and *Staphylococcus aureus* phages ISP and Twort. Specific interactions with the cell membrane appear to also be involved in the final, irreversible step. Little is yet known about the specific adhesins of most phages infecting Gram-positive bacteria or about the various receptors to which they bind. Phage specificity may relate to the substantial variations in the amino acids used for the cross-linking peptides in the exposed thick peptidoglycan structure; there are also variations in the teichoic acids protruding from it. A variety of cell-wall-associated proteins are also bound to the cell either via a specific C-terminal anchor sequence or as N-terminal lipoproteins, and interact in various ways with the environment; staph protein A, which binds the constant region of IgG and has been implicated in pathogenesis, is the most famous of these.

Duplessis and Moineau[17] published the first identification and characterization of a phage gene involved in recognition of Gram-positive bacteria, for the sequenced phage DT1 and six related virulent phages with different host ranges on *Streptococcus*

thermophilus. They confirmed that *orf18* encodes the adhesin, which has a conserved N-terminal domain of nearly 500 amino acids, a collagen-like sequence, and a largely conserved C-terminal domain with an internal 145 amino acid variable region (VR2). Using DT1 to infect a host in which MD4 genes *17–19* had been cloned, they generated five recombinant phages that now had the MD4 host range; all five contained the MD4 version of the VR2 region, but were otherwise largely like DT1.

Ravin et al.[18] showed that the specificity of adsorption of the isometric-headed phage LL-H and the prolate-headed JCL1032 to their host *Lactobacillus delbrueckii* involves a conserved C-terminal region in LL-H Gp71 and JCL 1032 ORF 474. Stuer-Lauridsen et al.[19] showed that four virulent prolate-headed phages (c2 species) of *Lactococcus lactis* with different host ranges first reversibly recognize a specific combination of carbohydrates in the outer cell wall. They then bind irreversibly with a host surface protein called PIP (phage infection protein), with no other known function, triggering DNA release from the capsid. Using the fully sequenced phages φc2 and φbIL67 and the sequenced least-conserved late regions of the other phages, the authors showed that the host-range-determining element is in the central 462 bp segment of a gene designated *115, 35*, and *2* in three different phages, with 65–71% pairwise similarity between them. While most genes in this region show no homology with unrelated phages, parts of this host-range-determining element resemble genes from phages of *S. thermophilus* and *L. lactis* that have also been implicated in host range determination processes. The product of a neighboring gene, *110/31/5*, with 83–95% similarity, had earlier been shown to bind to the tail spike and apparently to be involved in the infection process; they could not clone this second gene in their shuttle vector, perhaps because it is the one responsible for binding to PIP and helping transfer the DNA into the cell.

The phage infection process is very much dependent on the host metabolic machinery, so in most cases it is highly affected by what the host was experiencing shortly prior to infection, as well as by the energetic state and what nutrients and other conditions are present during the infection process itself.[20] Note that the phages that efficiently turn off host gene function, such as coliphages T4 and T5 and *B. subtilis* phage SPO1, generally render their hosts incapable of responding to substantial environmental changes after infection. For temperate phages, the energetic state of the cell also generally has significant effects on the probability of establishing lysogeny and, in some cases, on the reactivation of phages from lysogens.

Most bacteria used in phage studies use two basic kinds of metabolic pathways to get the energy they need: Fermentation and respiration. In both cases, electrons are withdrawn from an oxidizable molecule, freeing energy which is then stored as ATP, NADH, or similar coenzymes. These electrons, now at a lower potential, must, in turn, be removed by reducing some final acceptor. In fermentation, electrons removed from substrates such as glucose are transferred to breakdown products of the glucose to produce wastes such as ethanol or lactic acid, and only a small fraction of the energy in the glucose can be used. In respiration, the electrons are eventually passed through a membrane-bound electron transport system (ETS) and are carried away by reducing oxygen to water (in ordinary aerobic respiration), or, in anaerobic respiration, by reducing ferric to ferrous iron, sulfate to sulfide, fumarate to succinate, or nitrate to nitrite or N2. The electron transport system is oriented in the cell membrane so as to transport protons, H^+, to the outside of the cell membrane. This builds up an electrochemical potential, known as the proton motive force (PMF), across the cell membrane. This PMF is critical for infection by most phages. As discussed by Goldberg,[21] the PMF is separable into two parts: a pH gradient and a membrane potential that is due to the general separation of charges. For many (but not all) phages, DNA transfer into the cell requires the membrane potential.

The Infection Process

Overview

The general lytic infection process for tailed phages is presented here, with some examples from model phages. More detail on these subjects can be found in Abedon and Calendar's *The Bacteriophages*,[5] in Kutter and Sulakvelidze's *Bacteriophage: Biology and Applications*, or in Granoff and Webster's *Encyclopedia of Virology*,[22] as well as in books and articles on the individual phages.

Since the early studies of d'Herelle, the details of phage-host interactions have been studied by use of the single-step growth curve (Figure 48.4a), as systematized in 1939 by Ellis and Delbrück.[23] Phage are mixed with appropriate host bacteria at a low multiplicity of infection. After a few minutes for adsorption, the infected cells are diluted (to avoid attachment of released phage to uninfected cells or bacterial debris) and samples are plated at various times to determine infective centers. An infective center is either a single phage particle or an infected cell that bursts on the plate to produce a single plaque (see Chapter 7 for a discussion of bacteriophage plaque assays). The number of plaques generally remains constant at the number of infected cells for a characteristic time, called the *latent period*, and then rises sharply, leveling off at many times its initial value as each cell lyses and liberates the completed phage. The ratio between the numbers of plaques obtained before and after lysis is called the burst size. Both the burst size and the latent period are characteristic of each phage strain under particular conditions, but are affected by the host used, medium, and temperature. As first shown by Doermann,[24] if the infected cells are broken open at various times after infection, the phage seem to have all disappeared for a certain period. This eclipse period was a mystery until the nature of the phage particle and of the infection process was determined and it was realized that during this period only naked phage DNA is present in the cell. Using chloroform-induced lysis followed by plating, both the eclipse period and the subsequent rate of intracellular synthesis of viable phage particles are now routinely measured. Infecting at a high multiplicity (5–10 phage/cell) allows one to also measure the effectiveness of killing (i.e., the number of bacterial survivors) and the impact of the phage infection in terms of continued expansion of cell mass and eventual cell lysis, as reflected in the absorbance or optical density (Figure 48.4b).

The infection process involves several tightly programmed steps, as diagramed in Figure 48.5. The efficiency, timing, and other aspects of the process may be very much affected by the

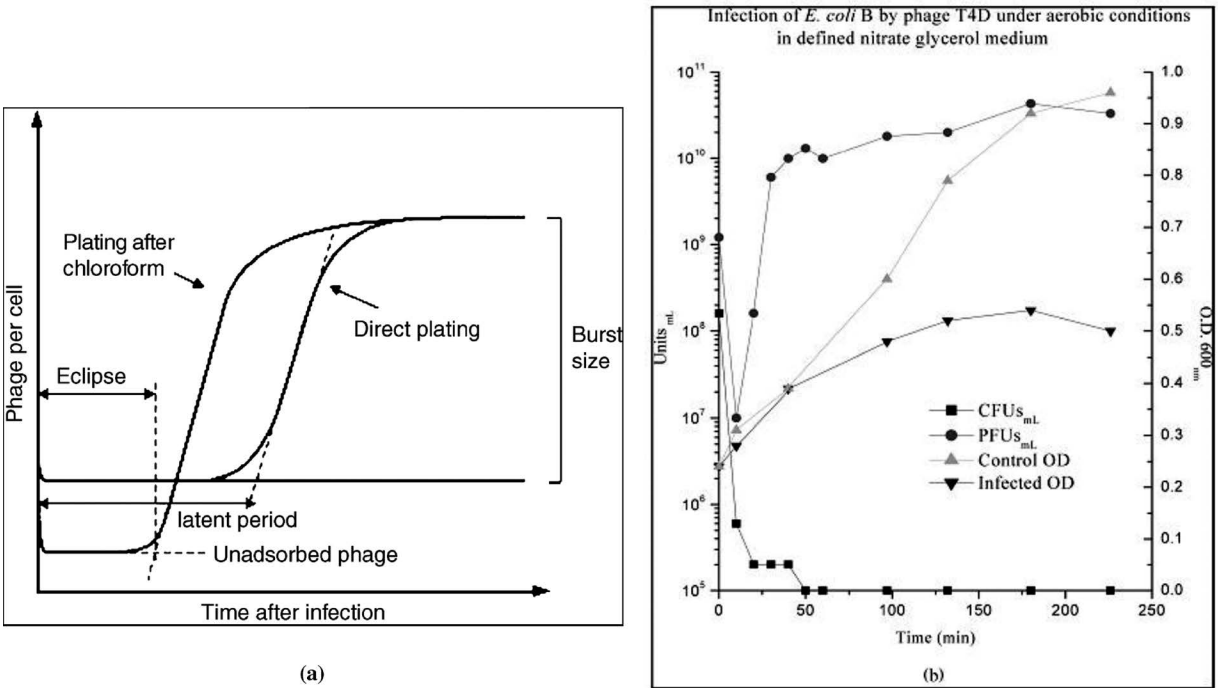

FIGURE 48.4 (a) Classical single-step growth analysis of phage infection. (b) Infection of *E. coli* B by T4D at an MOI of 9 in a minimal medium. Note the very rapid initial drop in both surviving bacteria and unadsorbed phage, the doubling of the cell mass even after infection, as measured by absorbance (OD600), and the fact that there is a long delay before lysis actually occurs under these conditions; this phenomenon of "lysis inhibition" is discussed in the text.

host metabolic state, and in many cases the host can no longer adapt to major metabolic changes once the phage has taken over the cell. Thus, for example, studies on anaerobic infection can only be carried out in host cells that were themselves grown anaerobically.

Most research on phage have utilized bacteria growing exponentially. However, in nature, phage may be more likely to encounter bacteria in the stationary phase. This condition has not been studied very much. Research has revealed that phage T4 can infect and kill stationary phase hosts but enter what has been termed a "hibernation" mode between middle and late gene expression. Phage morphogenesis is delayed until additional nutrients are added to the medium, after which infection resumes and goes to completion. Not all phage-infected stationary cells

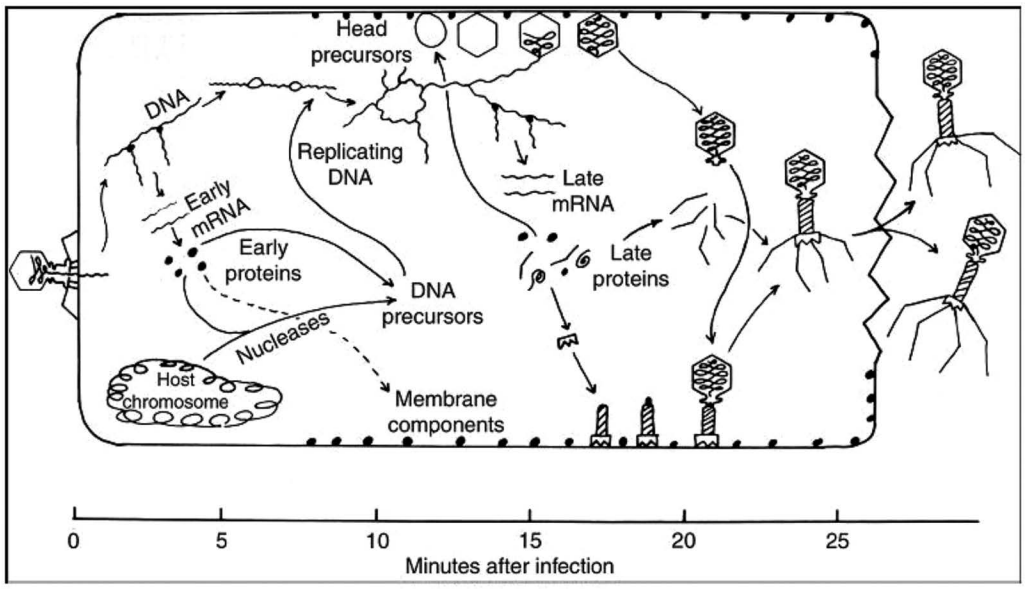

FIGURE 48.5 An overview of the T4 infection cycle. (From Mathews, C.K., Kutter, E., Mosig, G. and Berget, P.B. [Eds.] Bacteriophage T4. American Society for Microbiology, Washington, D.C., 1983, as reproduced in Kutter et al.[1])

follow this prototype—there is also an alternate "scavenger" response, where the phage uses whatever nutrients are available to generate a very low burst of progeny, only about one phage per infected cell.[24b]

Adsorption

Infection by tailed phages starts when specialized adsorption structures, such as fibers or spikes, bind to specific surface molecules or capsules on their target bacteria. In Gram-negative bacteria, virtually any of the proteins, oligosaccharides, and lipopolysaccharides can act as receptors for some phage. The more complex murein of Gram-positive bacteria offers a very different set of potential binding sites. Many phages require clusters of one specific kind of molecule that is present in high concentration to properly position the phage tail for surface penetration. However, coliphage N4 manages to use a receptor called NfrA, which is only present in a few copies per cell. The attachment of phages often involves two separate stages and two different receptors. T4-like phages, for instance, must bind at least three of their six long tail fibers to primary receptor molecules to trigger rearrangements of baseplate components, which then bind irreversibly to a second outer-membrane receptor that is involved in actual cell-surface penetration, eventually leading to the triggering of DNA release into the cell. Different members of the T4 family use very different primary receptors, but they seem to all use the heptose residue of the LPS inner core for the secondary receptor.

Adsorption velocity and efficiency are important parameters that may vary for a given phage-host system depending on external factors and host physiological state. For example, the lambda receptor is only expressed in the presence of the sugar maltose. Many phages require specific cofactors, such as Ca^{2+}, Mg^{2+}, or simply any divalent cation. T4B strains (but not T4D strains) require tryptophan for binding, but can bypass this requirement for a short "nascent" period when they are first released from the prior host and still attached to the inside of the membrane by their baseplates.[25–27] A nascent-phage period with broader adsorption properties was also observed for *Staphylococcus* phage in early work, and described for a *Streptococcus* phage by Evans,[28] but the mechanism(s) of nascent-phage interaction to give the extended host range is not known.

Bacteria commonly develop resistance to a particular phage through mutational loss or alteration of receptors used by that phage. However, losing some receptors offers no protection against the many other kinds of phage that use different cell-surface molecules as receptors. Furthermore, in most cases, the phage can acquire a compensating adaptation through appropriate host range mutations, which alter the tail fibers so they can recognize the altered cell-surface protein or bind to a different receptor. This is likely less efficient than bacteria acquiring resistance, since phage adaptation to new receptors requires establishment of a new functional interaction, while development of host resistance is a "negative" event, requiring loss of function.[29] Still, some such mutants seem to be present in every substantial phage population. Furthermore, some phages, such as P1 and Mu, encode multiple versions of the tail fibers. Others can recognize multiple receptors; for example, T4 tail fibers bind efficiently to an *E. coli* B-specific lipopolysaccharide, to the outer membrane protein OmpC found on K strains, and to OmpF.[30] The adhesion regions of the tail fibers are highly variable between related phages, with high rates of recombination that facilitate the formation of new, chimeric adhesins. Not surprisingly, there is much interest in engineering new receptor-recognition elements into the tail fibers of well-characterized phages so they can infect taxonomically distant hosts.

The physiological state of a cell can substantially change the concentration of particular cell-surface molecules and thus the efficiency of infection by certain phages. Many of the surface molecules that particular phages use as receptors are crucial to the bacterial cell, at least under some environmental conditions, so resistance may lead to loss of important functions and reduction in competitiveness. Such phages are particularly useful for phage therapy applications.

Penetration

After irreversible attachment, the phage genome passes through the tail into the host cell. This is not actually an "injection" process, as has often been depicted, but involves mechanisms of DNA transfer specific for each phage. In general, the tail tip has an enzymatic mechanism for penetrating the peptidoglycan layer and then touching or penetrating the inner membrane to release the DNA directly into the cell; the binding of the tail also releases a mechanism that has been blocking exit of the DNA from the capsid until properly positioned on a potential host. The DNA is then drawn into the cell by processes that generally depend on cellular energetics but are poorly understood except for a few phages. For example, as noted earlier, in T7 the entry of the DNA is mediated by the process of its transcription, but that is an unusual case. No host mutants have yet been identified that specifically block phage DNA transport across the cell membrane for any phage. That process thus probably involves host components, which are indispensable to the viability of the host, at least for those phages like T4 where it is very rapid and generally complete.

Once inside the cell, the phage DNA is potentially susceptible to host exonucleases and restriction enzymes. Therefore, many phage circularize their DNA rapidly by means of sticky ends or terminal redundancies, or have the linear ends protected; T4 encodes a special protein, gp2, for this purpose. Many also have methods to inhibit host nucleases (T7, T4) or use an odd nucleotide in their DNA such as hydroxymethyldeoxycytidine (hmdC: T4-related coliphages) or hydroxy methyldeoxyuridine (hmdU: SPO1-related phages infecting Gram-positive bacteria and ViI-like phages infecting enteric bacteria). In other cases, their genomes have been selected over evolutionary time to eliminate sites that would be recognized by the restriction enzymes present in their common hosts (staphylococcal phage Sb-1, coliphage N4).

The Transition from Host to Phage-Directed Metabolism

The initial step generally involves recognition by the host RNA polymerase of very strong phage promoters, leading to the transcription of immediate early genes. The products of these genes may protect the phage genome and restructure the host appropriately for the needs of the phage; they may inactivate host

proteases and block restriction enzymes, directly terminate various host macromolecular biosyntheses, and/or inactivate some host proteins. The large virulent phages such as T4, SPO1, and Sb-1 encode many proteins sometimes referred to as "monkey wrenches," which are lethal to the host even when cloned individually and which appear to participate in this process of host takeover. A set of middle genes is often then transcribed, producing products that synthesize the new phage DNA, followed by expression of a set of late genes that encode the components of the phage particle and factors needed for assembly. For some phages, these transitions involve the synthesis of new sigma factors or DNA-binding proteins to reprogram the host RNA polymerase; other phages encode their own RNA polymerase(s) for one or more of these stages. Degradation of host DNA, inhibition of host replication, and inhibition of transcription and translation of host mRNAs are other mechanisms that can contribute to reprogramming the cell for the synthesis of new phage. For lytic development of temperate phages and for some lytic phages, the programmed synthesis of phage proteins is superimposed on the host pattern. At the other extreme, 2-D gel analysis of proteins radioactively pulse-labeled after T4 infection shows that synthesis of host proteins is totally inhibited during the first couple of minutes after infection.[31]

New techniques, such as RNA-seq, are now being used to look more carefully at the details of host and phage gene expression after infection by a variety of phages, with very different results being seen for different phages.[32,33] Unexpectedly, RNA-seq technology has revealed that host transcription, and even phage mediated transcription of host genes, occurs during lytic infections with many *Pseudomonas aeruginosa* lytic phages.[33b,33c] This may function to allow the bacterium to respond to stresses during the infection.

Morphogenesis

The DNA is packaged into preassembled icosahedral protein shells called procapsids. In most phages, their assembly involves complex interactions between specific scaffolding proteins and the major head structural proteins, followed by proteolytic cleavage of both the scaffolding and the N-terminus of the main head proteins. Before or during packaging, the head expands and becomes more stable, with increased internal volume for the DNA. Located at one vertex of the head is a portal complex that serves as the starting point for head assembly, the docking site for the DNA packaging enzymes, a conduit for the passage of DNA, and, for myoviruses and siphoviruses, a binding site for the phage tail, which is assembled separately. The assembly of key model phages provides the best-understood examples in biology of morphogenesis at the molecular level.[33] It also has provided the models and components for several key developments in nanotechnology.

Cell Lysis

The final step—lysis of the host cell—is a precipitous event whose timing is tightly controlled.[34] If lysis happens too quickly, too few new phages will have been made to effectively carry on the cycle; if lysis is delayed too long, opportunities for infection and a new explosive cycle of reproduction will have been lost.[35,36] As discussed in Chapter 18, the shape-determining rigid wall that protects virtually all bacteria from rupture in media of low osmolarity (and must be ruptured to release phage) is actually one enormous molecule, forming a peptidoglycan or murein sack that completely encloses the cell; the sack grows and divides without losing its structural integrity and is the site of attack of antibiotics like penicillin (see Chapter 51 in this book). The glycan warp of this sack consists of chains of alternating sugars—*N*-acetylglucosamine (NAG) and *N*-acetyl muramic acid (NAM)—wrapped around the axis of the cylinder for rod-shaped bacteria. These chains are cross-linked by short peptides to make a two-dimensional sheet. The tailed phages all use two components for lysis: a lysin (an enzyme capable of cleaving one of the key bonds in the peptidoglycan matrix) and a holing (a protein that assembles pores in the inner membrane at the appropriate time to allow the lysin to reach the peptidoglycan layer and precipitate lysis). The timing is affected by growth conditions and genetics; mutants with altered lysis times can be selected. The T4-like phages often have an additional mechanism for adapting to host availability. If other phages of the same species try to enter the cell more than a few minutes after T4 infection, the infected cell interprets that as a sign that there is more phage around than available hosts, and substantially delays lysis. This phenomenon, termed "lysis inhibition," may last many hours; the precise length is characteristic of the specific phage involved and the environmental conditions.[35] For T4 grown aerobically at 37°C, it typically lasts about 6 hours and can be instigated even when the superinfection by the secondary phages occurs just a minute or two before the normal time of lysis. The general mechanisms and wide variety of holins and lysins are discussed by Young and Wang[37] and by Kutter et al.[2].

Mechanisms of Host Survival of Phage Attack

Phage are the most abundant biological form on earth and have been estimated to outnumber their bacterial hosts by at least an order of magnitude. Nevertheless, bacterial species survive and even flourish despite being so heavily outnumbered by their predators. Obviously, it is essential for phage to not obliterate their bacterial hosts since they would then not have a vehicle for their own growth. The evolution of lysogeny and temperate phages (discussed later) are one major solution to this issue, along with immunity to superinfection conferred by many prophages (a result of several alternate mechanisms, including the lysogenic repressor protein repressing expression of the superinfecting phage genome). Those bacterial species capable of forming spores represent another solution to this issue, as spores are resistant to many environmental insults, including phage attack. In addition, bacteria have themselves evolved several mechanisms for surviving in an environment heavily populated with phage predators.[38] As mentioned above, one common mechanism for bacterial survival to phage attack is mutation of a receptor for phage adsorption, where the altered receptor won't support phage attachment and penetration. Given the large populations involved, it is virtually to be expected that in a susceptible bacterial population subjected to phage attack, there will reside one or more random variants to which the phage cannot attach. If the phage kills most of their wild-type brethren, these variants

will now take over the population in what could be described as a textbook exercise in Darwinian evolution. Some bacteria also produce molecules that hinder access to, alter, or block phage receptors when challenged with a phage predator.

A potential variation on this theme is that bacteria can, in some small proportion of the population, enter a state of quiescence, where the cell is not growing but not dead. This is believed to be the mechanism by which some bacteria survive exposure to antibiotics.[39] It is also possible (though not yet demonstrated, to our knowledge) that if infecting phage require growing cells to support their own reproduction, some quiescent cells will survive the phage attack and later be able to regenerate the bacterial population when conditions are suitable for survival. In the case of T4, phage entering stationary-phase cells show the option of going into a so-called hibernation mode, capable of delaying completion of the infection process until needed nutrients become available, while others follow a scavenger pathway, using the limited nutrients available to make a few phage but unable then to respond to nutrient addition. The balance between the two pathways is affected by both host and phage genetics as well as environmental conditions.

Also mentioned above, many phage have evolved mechanisms to protect their DNA from bacterial host restriction enzymes that would otherwise destroy the invading DNA. Nevertheless, the existence of these restriction enzymes thus represents another mechanism by which bacteria are able to survive despite being so outnumbered by phage. Restriction enzymes are not without risk: they are capable of destroying host bacterial DNA as well as foreign (invading) DNA. The risk is tolerated because most restriction enzymes co-evolved with modification enzymes, generally referred to as "restriction/modification" systems. In these systems, modification enzymes chemically alter the host DNA (e.g., by methylation), and the altered host DNA is refractory to degradation by the co-evolved restriction enzyme.[40] Therefore, this restriction/modification pair confers an epigenetic alteration of the cellular DNA that allows the DNA to remain intact in the presence of the restriction enzyme, whereas any foreign DNA that is not decorated with the same chemical modification will be destroyed.

A bacterial population may also survive a phage attack if the specific cells infected by phage undergo an abortive infection; that is, the infected cells die before the phage have had the time to reproduce. This could be considered "altruistic" on the part of the cells that die, since they take the phage down with them before the phage have emerged to kill their bacterial brethren. While there are several known mechanisms that accomplish this (including drastic reduction of ATP levels, or cleavage of protein synthesis components such as EF-Tu or $tRNA^{Lys}$), one interesting basis for abortive infection has recently been analyzed to result from a toxin-antitoxin (TA) system. Originally identified as a mechanism for plasmid maintenance, and later shown to exist in bacterial genomes as well, TA systems comprise pairs of elements, a stable toxin that can kill the cell harboring it, and an unstable antitoxin that protects the cell from the lethality of the toxin. While these systems are tightly controlled, the underlying principle is that if the antitoxin, or the gene encoding the antitoxin, is lost, the toxin kills the cell because it is stable and the unstable antitoxin is not regenerated to protect the cell. In one reported case of cells using this mechanism to abort phage infection,[41] the antitoxin is an RNA, while the toxin is a protein. The phytopathogen *Erwinia carotovora* subspecies *atroseptica* encodes the toxin, triggering abortive infections of many different phages. The phage infection is thought to prevent replenishment of the antitoxin, so the toxin then kills the cell before the phage have had the time to reproduce. The consequence of this bacterial apoptosis is the death of both the cells that were infected, and the phage that infected them, while the rest of the bacterial population survives.

With the advent of widespread DNA sequencing of many genomes, another mechanism of bacterial resistance to phage infection has been recognized. This is a kind of adaptive immunity, in which the bacteria acquire specific sequence information from their predators and incorporate this sequence information as spacers into a specialized genetic element named CRISPR (Clustered Regularly Interspaced Short Palindromic Repeats). CRISPR sequences are transcribed and processed by CRISPR-associated (Cas) systems, leading to production of short interfering RNAs (crRNAs) that then function in a manner similar to that of eukaryotic RNA interference (RNAi). The interfering RNAs target foreign nucleic acid, preventing expression and causing degradation of the foreign genetic material.[42] Presently, about half of eubacterial species, and 85% of archaebacterial species, have been identified as harboring CRISPR-Cas systems, though these numbers may increase in the future. CRISPR-Cas systems have been developed as general tools for editing genomes. See Chapter 16 in this volume for details.

Identified sequences in the systems studied to date stem from temperate phages (which are discussed in detail later) rather than from the obligatorily/professionally lytic phages, which is not surprising since bacteria infected by such lytic phages generally don't survive to pass on any such sequence information to their progeny. In the case of temperate phages, the CRISPR-Cas systems may help control both infection by new phages and the activation of prophages carrying the target sequences.

An interesting question about CRISPR systems is how do bacteria obtain the pieces of phage nucleic acid that are then incorporated into CRISPR elements? One possibility is that defective phage particles produced during a lytic infection contain portions of the phage genome that are insufficient to support productive infection in a recipient host. This would be similar to the principle of transduction, described later. The defective phage particle is then the vehicle for delivering phage genetic material that becomes incorporated into CRISPR elements. Another possibility is that acquisition of phage sequences for CRISPR spacers may be accomplished by some bacterial cells managing to survive a phage attack, even though the phage genetic material has entered the cell, that is, a kind of abortive infection that does not result in the death of the cell. Perhaps quiescent cells[39] (as mentioned previously) could provide a mechanism for this kind of abortive infection, allowing cell survival even in the presence of a phage genome. Upon leaving the quiescent state, portions of that phage genome could then be incorporated as spacers in CRISPR elements. This would probably not apply to the professionally lytic phages, whose genomes contain host-lethal genes that would kill the cell upon leaving the quiescent state.

At the end of the day, phage have to balance their need to reproduce with their need to allow the vehicles for their reproduction to remain available. A summary of the major mechanisms discussed here is in Chart 48.1. The balancing act between

bacteria and their phage predators is a fascinating area of study that continues to reveal sometimes surprising new information.

CHART 48.1
Major Mechanisms of Bacterial Survival to Phage Attack

1. Blocking phage adsorption
   This can be accomplished by alteration of the phage's receptor, hindering phage access to the receptor, or by mutation of the receptor to a resistant phenotype.
2. *Restriction/modification systems*
   Host DNA is chemically modified to be resistant to a restriction enzyme, while foreign DNA not decorated with that modification will be destroyed by the restriction enzyme.
3. *Abortive infection*
   A kind of "altruistic" action on the part of some cells that die from the phage infection before the phage can reproduce. Mechanisms include membrane alteration, loss of ATP, degradation of components of the protein synthesis apparatus, and toxin-antitoxin systems.
4. *CRISPR adaptive immunity*
   Cells incorporate DNA sequences of the phages that attack them into CRISPR genetic elements and transcribe these sequences into interfering RNAs that block phage gene expression and lead to degradation of the invading phage genome.

Lysogeny

The concept of lysogeny has had a checkered history. Early phage investigators in the 1920s and 1930s claimed to find phages irregularly associated with their bacterial stocks and believed that bacteria were able to spontaneously generate phage, which were thus long considered by many to be some sort of "ferment" or enzyme rather than a living virus. When Max Delbrück and his companions began their work, they confined themselves to the classical set of coliphages designated T1–T7, none of which showed this property, and Delbrück attributed the earlier reports to methodological sloppiness. However, the phenomenon could no longer be denied after the careful work of Lwoff and Gutmann[43]; through microscopic observation of individual cells of *Bacillus megaterium* in microdrops, they demonstrated that cells could continue to divide in phage-free medium with no sign of phage production, but that an occasional cell would lyse spontaneously and liberate phage. Lwoff named the hypothetical intracellular state of the phage genome a prophage and showed later that by treating lysogenic cells with agents such as ultraviolet light, the prophage could be uniformly induced to come out of its quiescent state and initiate lytic growth. The prophage carried by a bacterial strain is given in parentheses; thus, K(P1) means bacterial strain K carrying prophage P1.

Esther Lederberg[44] showed that strains of *E. coli* K-12 carried such a phage, which she named lambda (λ). Meanwhile, Jacob and Wollman[45] had been investigating the phenomenon of conjugation between donor (Hfr) and recipient (F^-) strains of *E. coli*. They found that matings of F^- strains carrying λ and nonlysogenic Hfrs proceeded normally, but that reciprocal matings yielded no recombinants and, in fact, produced a burst of lambda phage. A mating of Hfr(λ) with nonlysogenic F^- would proceed normally if it were stopped before transfer of the *gal* (galactose metabolism) genes, but if conjugation proceeded long enough for the *gal* genes to enter the recipient cell, the prophage would be induced (zygotic induction). These experiments indicated that the λ prophage occupies a specific location near the *gal* genes; that a lysogenic cell maintains the prophage state by expression of one λ gene, encoding a specific repressor protein, which represses expression of all other λ genes; and that if the *gal* genes—and thus the λ prophage—are transferred into a nonlysogenic cell during mating, the prophage finds itself in a cytoplasm lacking repressor and therefore expresses its other genes and enters the lytic cycle.

Typical plaques made by phage λ are turbid, due to lysogenization of some bacteria within the plaque. Mutants of λ producing clear plaques are unable to lysogenize. Analysis of these mutants revealed three genes, designated cI, cII, and cIII, whose products are required for lysogeny. The cI gene encodes the repressor protein. Allen Campbell demonstrated that the sequence of genes in the prophage is a circular permutation of their sequence in the phage genome. He therefore postulated that the prophage is physically inserted into the host genome by circularization of the infecting genome followed by crossing-over between this genome and the (circular) bacterial genome. We now know that the genome in a λ virion has short, complementary single-stranded ends; as one step in lysogenization, it circularizes through internal binding of these ends and is then integrated (by means of a specific integrase) at a point between the *gal* and *bio* (biotin biosynthesis) genes.

The mechanism of the molecular decision between lytic and lysogenic growth has been worked out in most detail for phage λ,[46] but Dodd and Egan[47] found great similarities for the unrelated temperate phage 186. In each case, lysogeny is governed by a repressor protein, CI, which binds to a set of operators in the lysogenic state and represses the expression of all genes except its own (Figure 48.6). Both phages have critical promoter regions, one promoting lysogeny and the other lysis, which are closely associated, and lysogeny is promoted by binding of the CI protein to these sites in such a way as to inhibit lytic growth. DNA looping contributes to stability of the repression,[47b] similar to the role of DNA looping in repression of several catabolic operons. The CI proteins of both phages are strongly cooperative, forming tetramers or octamers. In the λ case, CI is involved in a molecular competition with another protein, Cro, which promotes the lytic cycle. The transition toward lysogeny in λ is also promoted by two other proteins, CII and CIII, which bind to critical promoters and stimulate transcription of the *cI* gene and others. The stability of CII is determined by factors that measure the cell's energy level. A cell with sufficient energy has little cyclic AMP (cAMP); when the cell is energy-starved (leading to low intracellular glucose), the cAMP concentration is high. A high level of cAMP promotes CII stabilization and thus lysogeny. It is clearly adaptive for a phage genome entering a new cell to sense whether there is sufficient energy to make a large burst of phage or whether the energy level is low, so its best strategy for survival is to go into a prophage state.

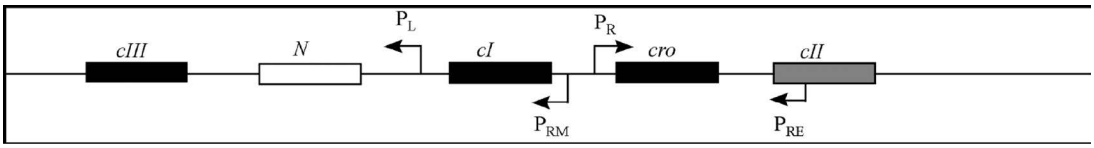

FIGURE 48.6 The regulatory region of the phage λ genome where the decision is made between lysis and lysogeny. The heart of the matter is competition between two proteins, CI and Cro. Initially, lysogeny is promoted by the combined action of the cII and cIII proteins, which act at P_{RE} (promoter right for establishment) and promote transcription of the *cI* gene; the cI protein then binds to various operator/promoter sites and represses them. In particular, cI prevents transcription of the *N* gene whose product acts at other sites in the genome to promote expression of genes required for lytic growth. Also, cI binds to P_{RM} (promoter right for maintenance) and promotes further transcription of its own gene. These lysogeny-directed processes are in competition with transcription from P_R of the *cro* gene and other genes to the right needed for lytic growth. Cro and cI compete for binding sites in the complex promoter/operator region that includes both P_{RM} and P_R where the lysis/lysogeny decision is ultimately made.

Notice that the critical event in establishing lysogeny is regulation of the phage genes. Integration of the phage genome into the host is secondary, and so it is understandable that other temperate phages, such as P1, can establish lysogeny with their prophages functioning as plasmids in the cytoplasm. Many interesting variations on lysogeny and temperate phages have been discovered.

Transduction

Generalized Transduction

As noted previously, bacteriophage package their genomes into phage capsids. Also noted above, the host's bacterial DNA is often subject to degradation during phage infection. The consequence of these two phenomena is that capsids of many phages occasionally package pieces of host DNA instead of phage DNA, making a transducing particle, that is, a vehicle that transmits a piece of DNA from one bacterium to another. This is because the phage particle containing the piece of bacterial DNA can attach to an uninfected bacterium and have its DNA contents taken up by the recipient cell. If the introduced donor DNA recombines with the chromosome of the recipient cell, then genes carried on the donor DNA will be incorporated into that recipient.

Originally discovered in 1952 by Zinder and Lederberg,[48] this process is called generalized transduction, because any portion of the genome can, in principle, be packaged and transferred to a recipient cell. In practice, some phages are much better than others in carrying out transduction, which is a consequence of the characteristics of the specific phage life cycle. Phage T4, for example, is not a very good transducing phage because it is too effective in degrading host DNA, whereas some integrity of host DNA is required for effective transduction, especially by a phage designed to package as long a DNA molecule as T4 does (about 180 kb). By contrast, phage P1 is a workhorse of transduction, very widely used by researchers, because it generates capsid-size chunks of host DNA and is capable of effectively packaging them in transducing particles. The frequency of P1 transduction of any given gene is generally taken to be about 10^{-6}. Multiplicity of infection (MOI) needs to be considered in transduction experiments, because too high an MOI will make it unlikely that a recipient cell will only receive a transducing particle and not be killed by a co-infecting virulent phage particle as well. An illustration of the principle of generalized transduction is shown in Figure 48.7.

Specialized Transduction

Temperate phages have the alternate lifestyle choice of lysogenizing the hosts they infect, integrating into the host chromosome or, like phage P1, forming a plasmid and keeping their genomes largely dormant. But when adverse conditions activate a lysogen, the phage enter a lytic cycle. Rarely, excision of temperate phage DNA from the chromosome is imprecise, resulting in an excised piece of DNA that contains most of the phage genome but also part of the host chromosome that was physically adjacent to the prophage DNA on the chromosome (Figure 48.8). When this excised piece of DNA is packaged in a phage capsid, it becomes a vehicle for transmitting these adjacent host gene(s) to a recipient cell. Because of the imprecise excision, the partial phage genome is usually defective, so the recipient cell will not be subject to a lytic cycle of the phage; instead, the defective phage DNA, carrying the adjacent host DNA, will recombine with the recipient cell's chromosome and thereby transfer genetic material from donor to recipient.

First characterized in 1956 by Morse et al.,[49] this process is called specialized transduction because it can transfer only genes that were physically adjacent to the prophage when it resided in the chromosome of the donor (prior to induction). The host genes transferred can be from either side of the prophage DNA in the lysogen and, depending on the extent of imprecise excision, can include one or a few genes.

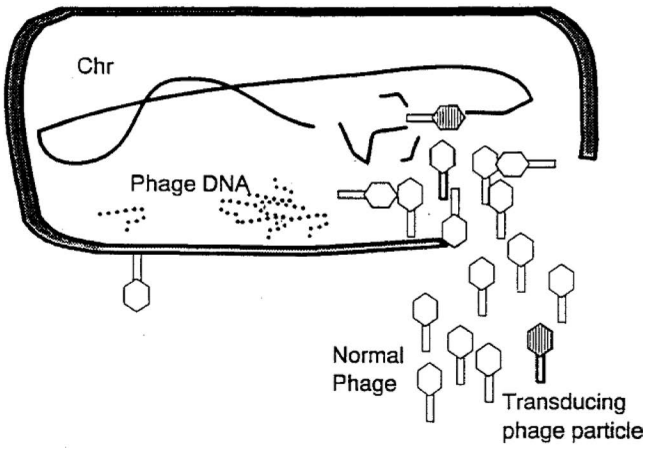

FIGURE 48.7 Generalized transduction. During a lytic phage infection, host chromosomal DNA is degraded. Occasionally, a fragment of the host chromosome is inadvertently packaged into a phage capsid. This "transducing phage particle" can transfer the packaged part of the donor chromosome to a recipient cell. (Illustration courtesy of M. Zafri Humayun.)

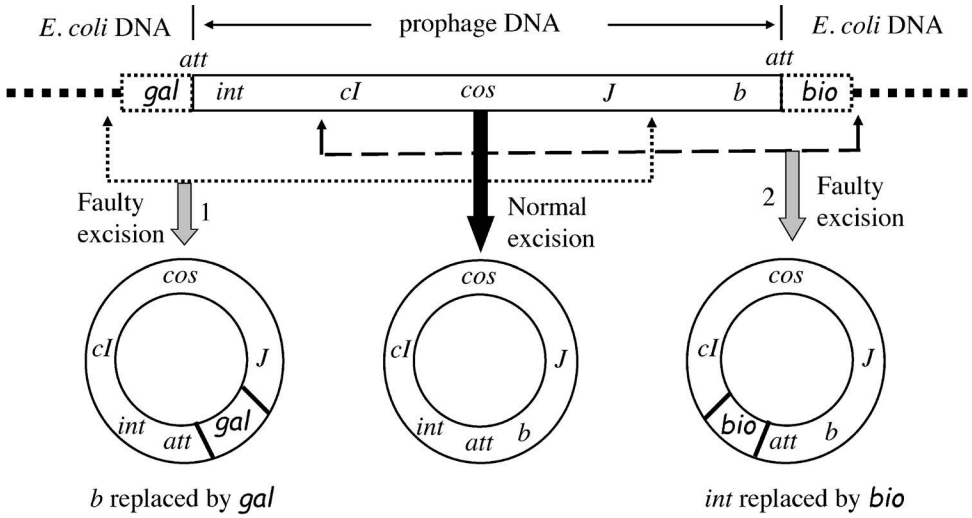

FIGURE 48.8 Specialized transduction results from faulty excision of the lambda prophage. The linear lambda phage DNA (not shown) has cohesive ends (*cos*) that lead to formation of circular lambda DNA. The attachment site (*att*) in the circular lambda DNA recombines with the *E. coli* chromosome between the *gal* and *bio* genes, integrating the lambda prophage DNA to make a lysogen. When the lysogen is induced to a lytic cycle, prophage DNA is excised, and the restored circular lambda DNA will act as a template for virus growth. As a rare event, excision of the prophage is faulty, generating circular lambda DNA containing either the adjacent *E. coli gal* gene (excision 1 in the figure) or the adjacent *E. coli bio* gene (excision 2), in place of lambda genes. Transfer of these *E. coli* genes to recipients in subsequent infections constitute examples of specialized transduction. Representative lambda genes: *int*, integrase; *cI*, repressor; *J*, tail fiber; *b*, region of lambda chromosome that can be deleted with phage retaining viability. (Based in part on ideas described by Campbell.[109])

Many temperate phages have their own specific sites of integration, so the genes they transfer are characteristic of the phage and are a consequence of the specific integration sites. However, some phages, like Mu (for "mutator"), integrate randomly into the genome and a piece longer than the phage genome is packaged directly from the host, so they always carry some neighboring host DNA with them during the packaging process when they are induced. Thus, they are able to affect a generalized transduction of short segments from throughout the genome, and the transducing phage is still fully capable of carrying out a normal infection cycle.

Transduction plays important roles in bacterial genetics, both in the lab and in the wild, and is one of the three major mechanisms for gene transfer between bacteria (the other two being conjugation and transformation). Briani et al.[50] have emphasized the importance of temperate phages as "replicons endowed with horizontal transfer capabilities," and they have probably been major factors in bacterial evolution by moving segments of genomes into new organisms. Broudy and Fischetti[51] have reported *in vivo* lysogenic conversion of Tox– *S. pyogenes* to Tox$^+$ with lysogenic streptococci or free phage in a mammalian host. Thus, this process presumably goes on all the time in nature.

In a variation on transduction, some phages do not degrade host DNA, leaving intact plasmids capable of altering other bacteria by transformation. These phages have been termed "superspreaders",[51b] and they could be significant contributors to the spread of antibiotic resistance as well as other properties.

Role of Bacteriophage in Causing Pathogenesis

Although most phage genes are dormant in a lysogen, particularly genes responsible for lytic growth of the phage, there are a few genes that continue to be expressed from the integrated phage genome. These include, of course, genes like the lambda repressor, which prevents expression of the lytic cycle. However, other phage-specific genes may also be expressed that direct synthesis of one or more products to change the cell's phenotype; the new product(s) did not exist in the cell prior to lysogeny and are often beneficial to host survival in some environments, giving the lysogenized host a selective advantage. This phenomenon is known as phage conversion.

Bacterial toxins, such as diphtheria, cholera, and Strep A toxin, and new antigens, such as *Salmonella* O antigen, are medically important examples of phage conversion, which led a famous bacterial geneticist, William Hayes (1918–1994), to remark "We incriminate the bacteria for the sins of its viruses." Table 48.1 lists a few prominent examples of phage-encoded pathogenesis factors. As an introductory chapter to the field, we will only briefly describe three of the very many known instances of temperate phage-determined virulence. Extensive coverage of this topic may be found in recent publications.[52,53]

Diphtheria Toxin

For an excellent review on diphtheria toxin (DT), see Holmes.[54] When *Corynebacterium diphtheriae* are lysogenized by phage β, the prophage expresses the *tox* gene, leading to the production of a precursor form of DT, which is then processed to the mature toxin. DT inhibits eukaryotic protein synthesis by inactivating elongation factor EF-2. It accomplishes this by covalent attachment of an ADP-ribosyl group to a unique residue in EF-2, a modified form of histidine called diphthamide.

Expression of the *tox* gene is controlled by an iron-regulated repressor encoded by the *dtxR* gene on the *C. diphtheriae* chromosome. In the presence of iron, the DtxR protein is active as a repressor and prevents transcription of the *tox* gene. In the

TABLE 48.1

Examples of Bacteriophage-Encoded Pathogenesis Factors

Pathogenesis Factor	Bacteria	Phage
O antigen[72–76] (immune system evasion)	*Salmonella* species	ε15, ε34
SopE[77] (invasion, type III secretion)	*Salmonella typhimurium*	SopEϕ
SodC[78] (superoxide dismutase)	*Salmonella typhimurium*	Gifsy-2
Cholera toxin[55]	*Vibrio cholerae*	CTXϕ
Diphtheria toxin[79]	*Corynebacterium diphtheriae*	Converting β–phage
Shiga-like toxin–I and –II[80,81]	Enterotoxigenic *E. coli*	Stx converting phage
Serum resistance[82]	*Escherichia coli*	λ
Enterotoxin A and staphylokinase[83]	*Staphylococcus aureus*	ϕ13
Streptococcal pyrogenic exotoxins A&C[84]	Group A *Streptococci*	T12 and 3GL16

absence of iron, the repressor is inactive and there is no repression of *tox*, leading to production of DT (Figure 48.9). Since iron concentrations tend to be low in mammalian hosts, pathogenesis occurs when β-phage-carrying *C. diphtheriae* colonize the throat of an affected individual. See Chapter 27 of this volume for a full discussion of *Corynebacteria*.

Cholera Toxin

Recognition that cholera toxin (CT) is encoded by a lysogenic phage was relatively recent,[55] perhaps in part because the phage involved, CTXφ, is a filamentous phage that does not kill the host bacterial cell during productive growth. CT, comprised of one "A" subunit and five "B" subunits, inactivates a GTP-binding protein needed to control cellular cyclic-AMP synthesis, causing overproduction of cAMP and massive fluid and electrolyte loss from intestinal cells.[56]

Vibrio cholerae ordinarily occupy a salt-water habitat, which is not the environment of a mammalian gut. Thus, one can argue that a bacterial sensor system of a low-salt environment activates synthesis of CT, and the profuse resultant diarrhea facilitates the release and spread of the bacteria from the affected individual. It is known that environmental conditions affect *V. cholerae* virulence.[57] Chapter 41 in this volume presents a full discussion of *Vibrio* species.

The sensor system for activation of CT synthesis is complex, with many cellular components[58] as well as a recently discovered lysogenic satellite phage, RS1.[59] The regulator ToxT activates transcription of the *ctxA* and *ctxB* toxin genes from a single promoter; there is much greater synthesis of the B subunit compared to the A subunit, which is probably controlled at the translational level. The *toxT* gene, as well as other virulence genes activated by ToxT (toxin coregulated pilus [tcp] and accessory colonization factors [acf]), are located on the Vibrio pathogenicity island (VPI) region of the *V. cholerae* chromosome. This region was also thought to represent a lysogenic phage genome, but evidence for this was not compelling and this view is generally no longer current.[60]

Synthesis of ToxT itself is activated by other *V. cholerae* genes, *toxR, toxS, tcpP*, and *tcpH*. The products of these genes are located in the cell membrane, where they may play a role in sensing a low salt level in the environment, activating ToxT synthesis, which in turn, activates CT production from the lysogen.

Recently, the satellite phage RS1 was shown to be another lysogen of *V. cholerae* and to play a role in CT production. RS1 itself is defective and only grows during growth of CTXφ. The *ctxAB* genes can also be transcribed in the lysogen from an upstream promoter for phage growth, which is repressed by the RstR repressor. Phage RS1 encodes an antirepressor, RstC, which inactivates repression by RstR, leading to increased synthesis of the CT genes. RstC itself is also repressed by the RstR repressor; therefore induction of the prophage by DNA damage (the "SOS"

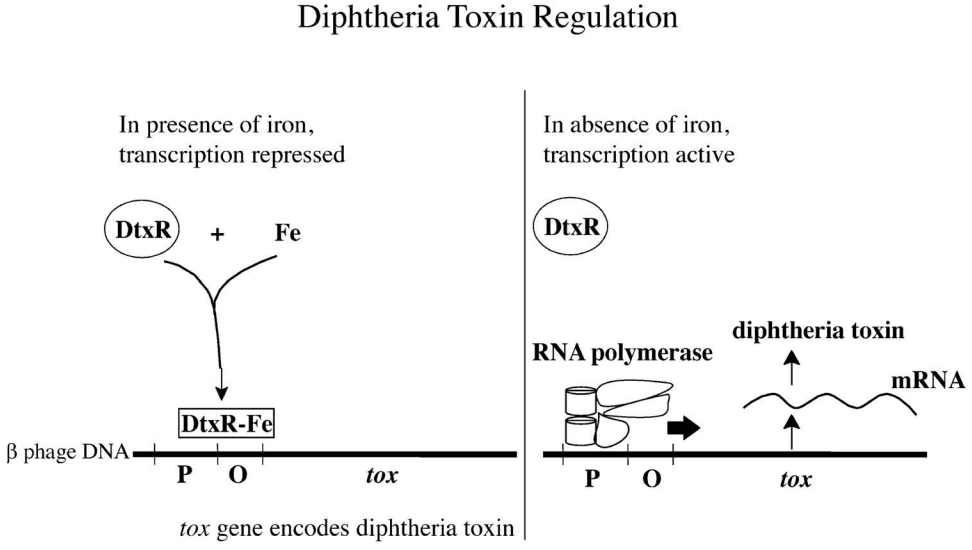

FIGURE 48.9 Negative control of diphtheria toxin by a repressor protein. The toxin is encoded by a phage gene in a lysogen. The DtxR repressor protein is encoded in the *C. diphtheria* genome. (*Abbreviations:* P, promoter; O, operator; Fe, iron.)

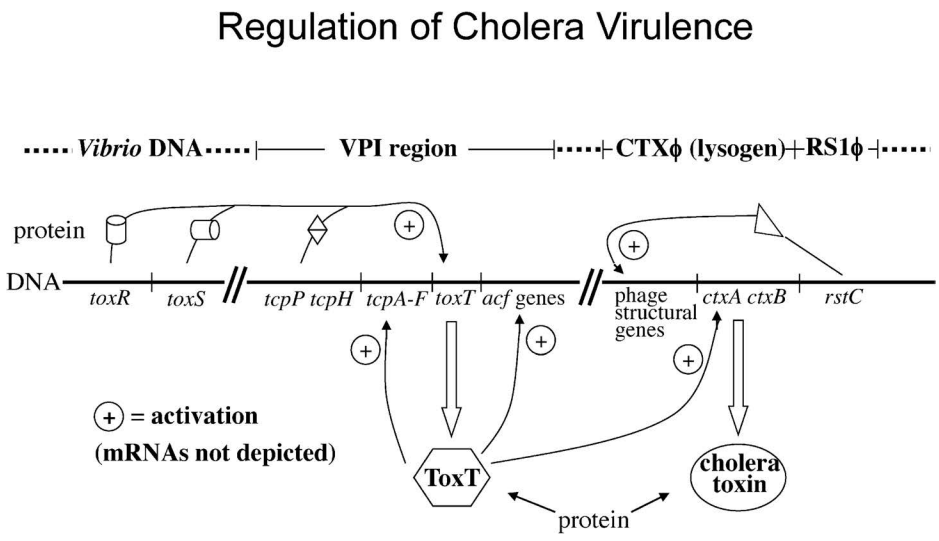

FIGURE 48.10 Regulation of virulence gene expression in *Vibrio cholerae*. TcpP/tcpH and toxR/toxS are located in the cell membrane and cooperate in activating transcription of *toxT*. ToxT activates transcription of *tcpA-F, ctxAB*, and *acf* genes. Genes for toxR/toxS are encoded on the ancestral *V. cholerae* chromosome and regulate genes other than those on CTXφ and VPI (formerly thought to be a lysogen). Satellite phage RS1φ encodes the RstC antirepressor, which inactivates the RstR repressor (not shown) of CTXφ growth. Inactivating the RstR repressor also leads to transcription of the *ctxAB* genes. Synthesis of RstC follows an SOS response.

response), which inactivates RstR, is necessary to obtain production of RstC.[60] Thus, there is also a second mechanism available, mediated by satellite phage RS1, to stimulate synthesis of CT.

A schematic diagram of the regulatory circuits for production of CT is shown in Figure 48.10. For simplicity, the effect of RstC is shown only as activation of transcription upstream of the *ctxAB* genes (whereas the actual mechanism involves the intermediate step of inactivation of the RstR repressor).

Shiga-Like Toxins

Escherichia coli, ordinarily a commensal universally found in the gut, can become highly pathogenic following lysogeny with Stx-converting phages. Pathogenicity is generally associated with the serotype O157:H7, although there are some other serotypes as well, resulting in hemorrhagic colitis, hemolytic uremic syndrome, and kidney failure. See Chapter 28 of this volume for a discussion of Enterobacteriaceae, including *Escherichia coli*.

The Shiga-like toxins, so-named due to similarity to toxins from *Shigella dysenteriae*, are also comprised of one "A" subunit and five "B" subunits. They inhibit protein synthesis by attacking eukaryotic ribosomal RNA.

The phages responsible for this are of the lambda family, and carry genes, *stxA* and *stxB*, that encode the two toxin subunits. Of the two prominent toxin types, type 1 is regulated by iron, while type 2 is not. Type 2 is repressed in the lysogen, and expression follows induction of the lysogen to a lytic cycle.[61] Expression of Type 1 in the lysogen, under conditions of low iron concentration, is enhanced following induction of the lysogen to a lytic cycle.[62] The involvement of lambdoid phages in pathogenesis is why they are not good choices for phage therapy (see Chapter 54).

A simplified schematic diagram illustrating regulation of expression of Shiga toxin-type 2 is shown in Figure 48.11.

Practical Information about Selected Phages

Tailed Phages

Table 48.2 lists, in alphabetical order, selected tailed phages that have been extensively studied. Pathogenesis-causing phages previously listed in Table 48.1 are not included. All of these phage have linear double-stranded DNA genomes. Many exhibit terminal redundancy with (e.g., P1, P22, T4, ViI, SPO1, K,) or without (e.g., λ, P2, P4, T5, T7) circular permutation.[63] Some key characteristics of the phages are presented, and the "comments" column highlights especially interesting or unique features.

More in-depth general resources include Granoff and Webster's *Encyclopedia of Virology*,[22] both editions of *The Bacteriophages*,[64,65] Ackermann and DuBow[11] and Adams.[8] The complete genomic sequences of hundreds of phages have now been determined and are available in the bacteriophage section of the genome sites at the National Center for Biotechnology Information <http://www.ncbi.nlm.nih.gov>, as are the sequences of many of the prophages determined in the course of microbial genome projects.

Phages of *E. coli* and *B. subtilis* have generally been the best studied regarding genetics and the physiology of the infection process, taking advantage of and contributing to the broad knowledge about these two key model organisms. Coliphage T4 in particular has provided the data used to identify the probable functions of many apparently related genes in genetically unstudied phages (Figure 48.2).

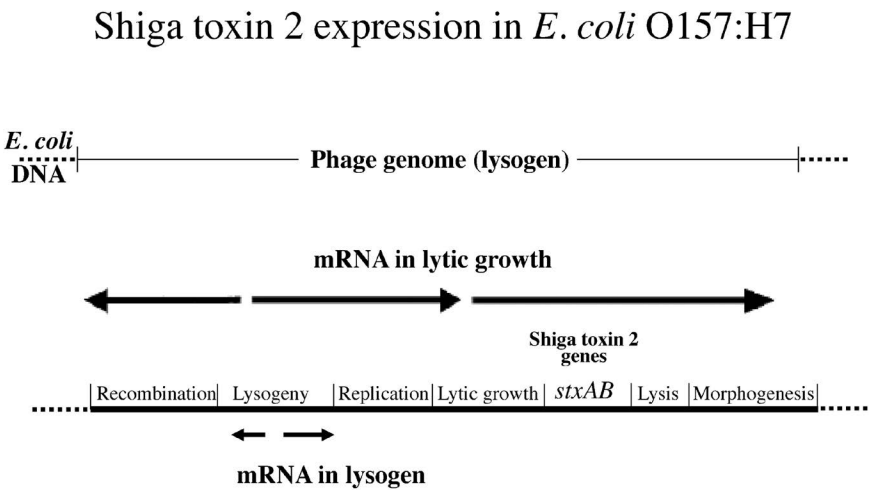

FIGURE 48.11 Shiga toxin 2 expressed following λ-family prophage induction in *E. coli* O157:H7. Putative genome organization (not to scale) and transcription of Stx2-encoding phage is based on known lambda-family phage. Shown are relevant functional genes clusters, as indicated. *stxAB* represents the genes encoding the pathogenic Shiga toxin 2. Below is shown the pattern of transcription initiating at the early promoters in the lysogen. Above is shown the patterns of transcription initiating at the early and late promoters during lytic growth.

TABLE 48.2

Survey of Selected DNA-Containing Tailed Phages (Caudovirales)*

Phage	Family[a]	Host(s)	Size[b]	Temperate[c]	Transduction	Comments
		Gram-Negative Bacteria				
Lambda (λ)	Sipho	*Escherichia coli*	48.5[85]	+	specialized	Genetic engineering vector
Mu	Myo	*E. coli, Salmonella,* others	36.7[86]	+	generalized	Random integration in host DNA
N4	Podo	*E. coli*	70.2[87]			RNA polymerase used in biotech
N15	Sipho	*E. coli*	46.3[88]	+		Prophage a linear plasmid
P1	Myo	broad host range	93.6[89]	+	generalized	Prophage a circular plasmid
P2	Myo	*E. coli*	33.6[90]	+		DNA packaged from monomeric circles
P4	Myo	*E. coli*	11.6[91]	+		Defective; satellite of phage P2
P22	Podo	*Salmonella typhimurium*	41.7[92]	+	generalized	Transduction via lytic cycle; modifies O antigen
phiKZ(ϕKZ)	Myo	*Pseudomonas*	280[93]		generalized	Transduction at very low frequency
T1	Sipho	*E. coli*	48.8[94]			Viable even after dried out
T4[d]	Myo	*E. coli*	169[95]			5-hmdC replaces C in DNA
T5	Sipho	*E. coli*	122[96]			Encodes tRNAs for all 20 amino acids
T7[e]	Podo	*E. coli* (F^- only)	39.9[97]			Many biotech applications
		Gram-Positive Bacteria				
C_1	Podo	group C *Streptococci*	16.7[98]			Potential medical use of "lysin"
G	Myo	*Bacillus megaterium*	497.5[99]			Largest characterized virus
L5	Sipho	*Mycobacteria*	52.3[100]	+	specialized	Useful for *Mycobacterial* genetics
MM1	Sipho	*Streptococcus pneumoniae*	40.2[101]	+		NOT coliphage MM1; many unknown genes
phi11(ϕ11)	Sipho	*Staphylococcus aureus*	43.6[102]	+	generalized	Closely related to pathogenic phage ϕ13
phi29(ϕ29)	Podo	*Bacillus subtilis*	19.3[103]			Biotech use of DNA polymerase
phi105(ϕ105)	Sipho	*B. subtilis*	39.3[104]	+	specialized	Similar to lambda
Sb-1	Myo	*S. aureus*	120[105]			Resistance rare; therapeutic use
SPβ	Sipho	*B. subtilis, B. globigii*	134[106]	+	specialized	Secretes betacin, kills nearby cells
SPO1	Myo	*B. subtilis*	140[107]			Transcriptional sigma cascade; hmdU replaces T

* For more detailed discussion of most of the phages in this table (and related phages), see Chapter 3 in *Bacteriophages: Biology and Applications*[1]

[a] Virus type[108]: Myoviridae, viruses with contractile tails; Siphoviridae, viruses with long noncontractile tails; Podoviridae, viruses with short noncontractile tails.

[b] genome size in kbp.

[c] + = known to be capable of lysogeny.

[d] T2 and T6 are very closely related to T4.

[e] T3 is very closely related to T7.

Note that, in general, the designation of phage names has been quite arbitrary, giving little or no information about phage properties or relationships.

Nontailed Phages

phiX174 (ϕX174): The prototype member of the *Microviridae*, with a 5.4-kb circular single-stranded DNA genome[66] and an icosahedral virion. The DNA is a positive (+) strand (i.e., sequence is in the same orientation as its mRNA) with overlapping genes. Infects *Enterobacteriaceae* such as *E. coli, Salmonella* and *Shigella,* and has been extensively used in studies of DNA replication.

M13: The prototype member of the *Inoviridae*, with a 6.4 kb circular positive single-stranded DNA genome,[67] and an amorphous, filamentous virion. Infects male *E. coli* by adsorbing to the tip of the pilus; nonlytic, but turbid plaques can be discerned due to slower growth of infected bacteria. Has been extensively used for cloning and DNA sequencing, and in "phage display" technology, described in detail in Chapter 9 in this book.

MS2: The prototype member of the *Leviviridae,* with a 3.6 kb linear single-stranded highly structured RNA genome[68] and an icosahedral virion. Infects male *E. coli* by adsorbing to the sides of the pilus; lytic virus but does not shut off host metabolism. Positive-strand RNA genome functions as an mRNA. High affinity of coat protein to specific sequences in RNA has been exploited in biotechnology.

phi6 (ϕ6): The prototype member of the *Cystoviridae,* with a genome of three double-stranded RNAs of 6.4, 4.1, and 2.9 kb (reviewed in Mindich[69]) and an enveloped virion. Infects the plant pathogen *Pseudomonas syringae* by initially adsorbing to the pilus, though other family members do not use the pilus for entry.

PRD1: The prototype member of the *Tectiviridae,* with a 14.9-kb linear double-stranded DNA genome,[70] and an icosahedral virion coating an internal lipid membrane. Infects Gram-negative bacteria including *Enterobacteriaceae* (*E. coli, Salmonella*, etc.) and *Pseudomonas*. Certain conjugative plasmids required for phage adsorption to the cell wall (not pili).[71] Has garnered attention as a model for human adenovirus.

Introduction

Viruses are simple infectious agents and yet, as they parasitize our bodies, they can cause devastating disease. Viral diseases range from the common cold and diarrhea to life-threatening encephalitis, hemorrhagic fever, and smallpox. Several different viruses may cause a single disease, as determined by the tissue or organ that is affected, or one virus may cause different diseases due to the nature of its interaction with the body. Ultimately, the nature of the disease caused by the virus is a function of the tissue that is infected, the nature of the virus, and the host immune response to the virus. Interestingly, each of these parameters is determined by the structure and mode of replication of the virus. This chapter introduces the basic viral structures and modes of replication and presents the consequences of these properties for the different virus families. *In many cases, knowing the structure of the virus allows prediction of many of the other properties of the virus.* This introduction also includes a discussion of general mechanisms of viral pathogenesis and disease production, epidemiology, antiviral drugs, vaccines, and viral detection before a synopsis of each of the virus families is presented. References to other basic reviews on virology by the author (1–4) are provided.

Definition of a Virus

Unlike bacteria, fungi, or parasites, a virus does not replicate by binary fission but rather by synthesis and assembly. Viruses neither have organelles nor can they make energy. Viruses are obligate intracellular parasites that depend on the biochemical machinery of the infected cell for replication. As obligate parasites, viruses must continue to find new host cells and individuals and be able to use the biochemical machinery of the cell to replicate or the virus will disappear. The virus uses different molecular tricks to manipulate the cell and its host to replicate and spread.

Structure

Although we may think of a virus as having characteristics of a living microbe, it is not alive. The virion particle is a very large biochemical complex consisting of a nucleic acid genome protected and carried within either a protein shell, termed a capsid, or within a membrane envelope. (Although prions were considered atypical viruses at one time, they are rogue, infectious proteins and not viruses). The basic virion particle consists of a genome of either RNA or DNA (but only one or the other) that is packaged for protection in a protein capsid or a membrane envelope. Some viruses may carry auxiliary RNA or proteins within the virion particle to facilitate replication in the host.

Human viruses range in size and complexity from the tiny Norwalk virus (22 nm), which causes outbreaks of diarrhea, to the poxviruses, which are almost visible under a light microscope (Tables 49.1 and 49.2). They may be as simple as the rabies virus, which has only five proteins, or as complex as the cytomegalovirus, which encodes approximately 110 proteins. The larger viruses have more space to hold a larger genome and encode more proteins. These "extra" proteins may facilitate the replication of the virus; allow replication in difficult cells, such as neurons; or facilitate escape from host protective innate and immune responses. Larger viruses also require larger aerosol droplets for transmission through the air.

The viral genome is the core of the virus and acts like a computer memory to store the genetic information for the virus. Like computer memory (e.g., a hard drive, CD-ROM, or USB memory device), the viral genome can take different forms. It can consist of DNA—either linear, circular, single or double stranded—or double- or single-stranded RNA of positive or negative sense. Most DNA genomes can establish themselves in the nucleus and utilize the nuclear machinery for mRNA synthesis and replication of the genome, whereas RNA genomes are more temporary. Most RNA viral genomes replicate in the cytoplasm (where RNA belongs) and must provide and encode the enzymes to make mRNA and replicate their genome. DNA and positive strand RNA (other than retroviruses) genomes are sufficient to infect cells when microinjected into the cells.

The outer structures of the virus are a package that protects the genome, delivers it from host to host, and provides the means for interacting with and entering the appropriate target cell (Figure 49.1). Capsids are protein shells usually in symmetrical icosahedral or icosadeltahedral shapes (soccer balls)

TABLE 49.1

DNA Viruses

Family	Genome	Virion	Virion Size (nm)	Example(s)
Parvoviridae	ss, linear	Capsid	18–26	B19, Boca
Papillomaviridae	ss, circular	Capsid	45–55	Human papilloma
Polyomaviridae	ss, circular	Capsid	45–55	JC, BK, Merkel
Hepadnaviridae	ds, circular	Enveloped	42	Hepatitis B
Adenoviridae	ds, linear	Capsid with fibers	70–90	Adenovirus
Herpesviridae	ds, linear	Enveloped	120–130	HSV, VZV, EBV, CMV, HHV6-8
Poxviridae	ds, linear	Enveloped, brick	300 × 200 × 100	Smallpox, Molluscum contagiosum

Abbreviations: ss = single stranded; ds = double stranded; HSV = herpes simplex virus; VZV = varicella zoster virus; EBV = Epstein Barr virus; CMV = cytomegalovirus; HHV = human herpes virus.

TABLE 49.2

RNA Viruses

Family	Genome	Virion	Virion Size (nm)	Example(s)
Caliciviridae	ss, positive	Capsid	35–40	Norovirus
Hepeviridae	ss, positive	Capsid	27-34	Hepatitis E virus
Picornaviridae	ss, positive	Capsid	25–30	Polio, echo, parecho, entero, HAV, rhino
Coronaviridae	ss, positive	Enveloped	80–130	Corona, SARS, MERS, SARS-CoV-2
Paramyxoviridae	ss, negative	Enveloped	150–300	Measles, mumps, parainfluenza, respiratory syncytial virus, metapneumovirus
Orthomyxoviridae	ss, negative	Enveloped	80–120	Influenza A, B, C
Rhabdoviridae	ss, negative	Enveloped	180 × 75 bullet	Rabies
Filoviridae	ss, negative	Enveloped	800 × 80 fiber	Ebola, Marburg
Reoviridae	Double stranded	Double capsid	60–80	Rotavirus, Colorado tick fever
Togaviridae	ss, positive	Enveloped	60–70	Rubella, EEV
Flaviviridae	ss, positive	Enveloped	40–50	West Nile encephalitis, Yellow fever, dengue, zika
Bunyaviridae	ss, negative	Enveloped	90–100	Ca. encephalitis, hantavirus
Arenaviridae	ss, ambisense	Enveloped	50–300	Lassa fever, LCMV
Retroviridae	ss, positive	Enveloped	80–110	HIV, HTLV

Abbreviations: ss = single stranded; ds = double stranded; SARS = severe acute respiratory syndrome; MERS = middle eastern respiratory syndrome; EEV = eastern equine encephalitis virus; LCMV = lymphocytic choriomeningitis virus; HIV = human immunodeficiency virus; HTLV = human T lymphotropic virus.

(Table 49.3). Like hardboiled eggs, the protein of the capsid forms a shell that is impervious to drying, acids, and detergents. In contrast, enveloped viruses are surrounded by a membrane consisting of phospholipids and proteins, which must stay wet and can be disrupted by detergents and harsh environments, including the acids and bile of the gut. Of course, there are exceptions to these generalizations and they will be identified throughout the text.

The nature of the viral disease, the means by which it spreads, the type of immune response necessary to control the viral infection, and the types of antiviral drugs that can be used to combat the infection are determined to a large extent by the viral structure and mechanism of replication (discussed later). The impervious shell of capsid viruses allows them to be transmitted by the fecal-oral route and resist drying and disinfection with detergents and

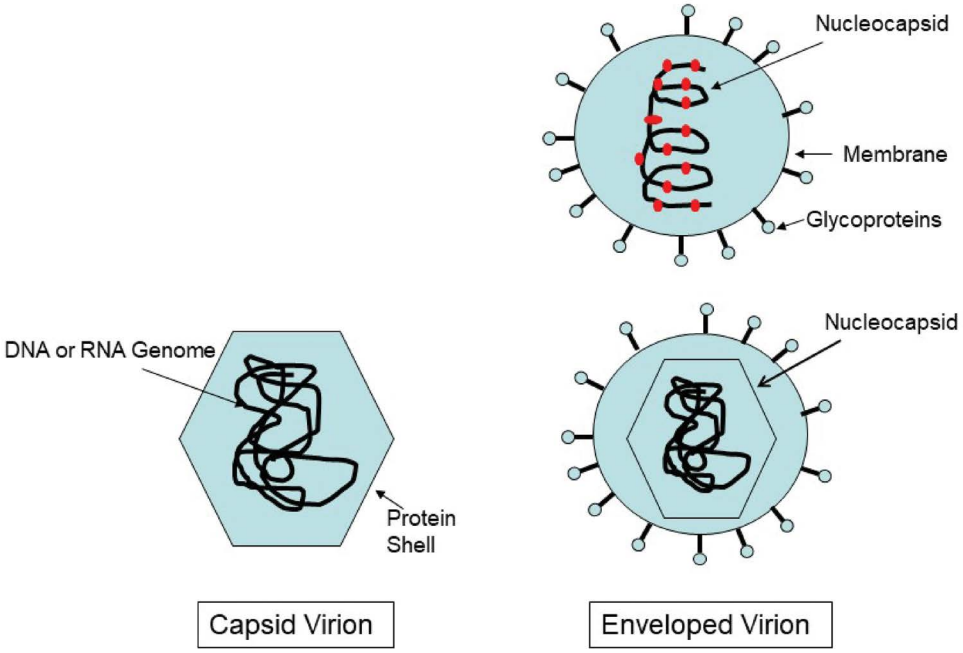

FIGURE 49.1 Virion structure. The virion particle consists of a DNA or RNA genome surrounded by either a protein shell (called a capsid) or a cell-like membrane (called an envelope). The genome may be associated with or enclosed by protein to form the nucleocapsid. The virion may also contain other structures and proteins that will facilitate the replication of the virus within the cell. The outside structures of the capsid or the glycoproteins of the envelope mediate the interaction of the virus with the cell and are the primary targets of protective neutralizing antibodies.

[b] Coronavirus glycoprotein forms an exoshell around its envelope to resist detergents, acid, and allow fecal-oral spread.
[c] Some capsid viruses (hepatitis A) can be released through exocytosis.

solvents. This is not so for enveloped viruses. Rhinovirus (common cold) is an exception and is susceptible to acid pH. This is the basis for incorporating citric acid into tissues to kill these common cold viruses. As discussed later, antibody is usually sufficient to control most naked capsid viruses. This is why inactivated virus vaccines, which generate primarily an antibody response, are usually effective for capsid viruses but may not be effective for enveloped viruses. In contrast, enveloped viruses cannot withstand the harsh conditions of the gastrointestinal (GI) tract; they are readily disinfected by soap or solvents and are more sensitive to heat and dryness. Enveloped viruses are transmitted in fluids (e.g., aerosols, saliva, blood, semen, and tissue transplants). The exceptions are coronaviruses and hepatitis B virus, which can withstand the GI tract. A combination of cell-mediated and antibody immune responses are important to control enveloped viruses.

Replication and Consequences

Every virus must replicate and produce more viral progeny or disappear. In many respects, a virus utilizes host cells as a factory that provides the raw materials, energy, and most of the synthetic machinery to produce the genome and structural components of new viruses. For every infecting virus, the cell can produce 100 to 100,000 new infectious virions and many times more noninfectious (defective) particles. Viruses are notorious for making mistakes, but when there are a million siblings, even 10% infectious virus is a lot. The virus can kill the cell quickly, slowly, or not at all. The outcomes depend on the type of virus and how it interacts with the cell.

All viruses follow a similar set of steps to generate new viruses (Figure 49.2). The basic steps for replicating the virus include:

1. Recognition and attachment
2. Entry into the cell
3. Uncoating
4. Synthesis of the macromolecular components, including the genome and the structural parts of the virion particle
5. Assembly of the new virion particles
6. Exit from the cell

Each of these steps is performed differently by different viruses, depending on the structure of the viral genome and whether the virion has a naked capsid or an envelope.

Recognition, Attachment, and Entry

Finding and binding to the appropriate cell is mediated by the surface structures of the naked capsid virus or by the glycoproteins that decorate the envelope. These viral attachment proteins (VAP) are the keys that interact with cell surface receptors and open the doors of entry into the cell. Some of these structures are like skeleton keys and bind to many different cell types, whereas others are very specific for certain cell types. A canyon on the surface of the rhino or polio virus (picornaviruses) acts as a keyhole that can be filled by specific receptors from the cell which are members of the immunoglobulin family of glycoproteins. The glycoproteins on the Epstein-Barr virus bind to the receptor for the C3d component of complement (CD21), identifying the B lymphocyte as the principal target for the virus. The HIV gp120 glycoprotein binds to the CD4 molecule to target subsets of T cells and myeloid cells (dendritic cells and macrophages), but can switch target cells by mutating and changing the portion of the gp120 that binds to a chemokine receptor present on either myeloid cells and activated T cells (CCR5) or one that is present on other T cells (CXCR4).

The mechanism of virus entry into the cell depends on the virion structure. Binding of the picornavirus receptor to the canyon on the virion surface opens the capsid structure and creates a hydrophobic portal for injection of the viral genome into the cytoplasm. Some enveloped viruses, including herpes, retro-, and paramyxoviruses will fuse their membrane envelope with the plasma membrane of the cell to deliver their genome into the cell. Many viruses bind to receptors on the cell surface that trigger the internalization of the virus by receptor-mediated endocytosis, the same pathway that cells use to take up transferrin or low-density lipoprotein. Although one would think that the normal acidification of the endosomal vesicle would be detrimental to a virus, they use this as a trigger to enter the cytoplasm. Acidification activates the fiber protein of the adenovirus capsid to lyse the vesicle and break into the cytoplasm. Acidification changes the conformation of the viral attachment glycoproteins of enveloped viruses, such as influenza or rabies virus, to expose regions that promote fusion of their membrane

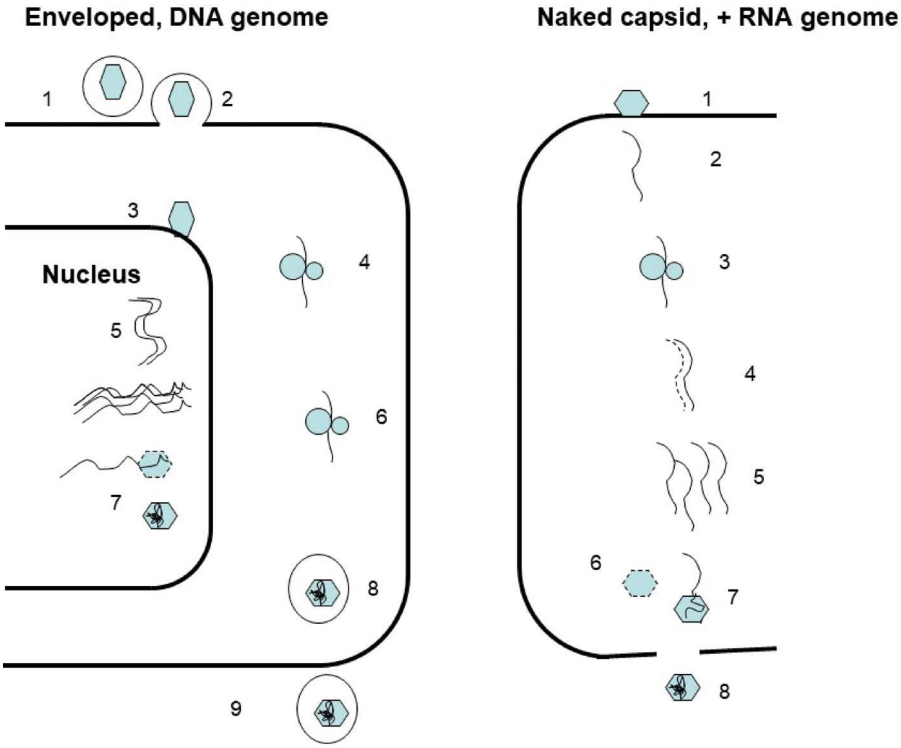

FIGURE 49.2 Virus replication. Virus replication proceeds in an ordered, sequential fashion. Left: The steps in virus replication for an enveloped virus with a DNA genome, like a herpes virus, are (1) binding, (2) fusion and entry, (3) delivery of genome to nucleus, (4) immediate early and early mRNA and protein synthesis, (5) replication of the genome, (6) late mRNA and protein synthesis, (7) capsid assembly and filling, (8) envelopment of genome-filled capsid, and (9) exit of cell by exocytosis or cell lysis. Right: The steps in virus replication for a capsid virus with a positive-sense RNA genome, like a picornavirus (polio or rhino), are (1) binding, (2) entry and uncoating, (3) protein synthesis, (4) production of an RNA template, (5) genome replication, (6) capsid assembly, (7) filling capsid with genome, and (8) cell lysis and release.

with the vesicular membrane of the cell to deliver their genome into the cytoplasm.

Viral mRNA and Protein Synthesis

Once inside the cell, the viral genome inserts into the cell's machinery to promote the synthesis of viral mRNA and protein (Table 49.4). DNA viruses, except poxviruses, deliver their genome to the nucleus where it will be mistaken for cellular DNA. The sequences of the viral genes must contain the same genetic passwords as cellular DNA so that they can use the cell's machinery for making and processing mRNA. RNA will be made by the host DNA-dependent RNA polymerase and modified to make the viral mRNAs look and act like cellular mRNAs. The RNA will be processed into mRNA by removal of introns (if present), become stabilized by the addition of a 3'-polyadenosine tail, and pick up the recognition structure for attachment to the ribosome and protein synthesis with the addition of a 5'-methylated (7-methylguanosine) cap. Poxviruses are the DNA virus exception because they replicate in the cytoplasm. The poxviruses pay the price for being more independent of the nucleus by having to provide their own molecular tools for mRNA synthesis.

Most DNA viruses divide protein synthesis into early and late phases. The proteins made during the early phase convert the cell into a more efficient factory for replicating virus. Once the cell has been subverted and new viral genomes are being produced, then the late genes are turned on and the cell churns out large amounts of viral structural proteins and glycoproteins to make the capsid or envelope proteins. Activation of the late genes and synthesis of the structural proteins of a DNA virus is usually a death sentence for the cell.

Most RNA viruses replicate in the cytoplasm, which provides easy access to the ribosome for protein synthesis. However, using RNA as the genetic information carrier is foreign to the cell because the cell has no polymerases to copy RNA from RNA, and cannot make mRNA or replicate the genome from an RNA template. Hence, most RNA viruses must encode and/or carry their own RNA-dependent RNA polymerases within the virion particle. In addition, these viruses must develop a way to acquire a 5' cap or an alternative way to bind to the ribosome for protein synthesis.

The viruses with a genome that looks like mRNA (positive-sense), except retroviruses, can immediately bind to ribosomes and initiate protein synthesis. The resulting protein, called a polyprotein, includes proteases to cleave itself or is cleaved by other proteases into the individual viral proteins. Viruses with a negative-sense RNA (like a photographic negative) cannot be deciphered by the cell's ribosome. The genome of these viruses is decorated by enzymes (RNA-dependent RNA polymerase), as part of the nucleocapsid, that will convert the genome into individual mRNAs for each of the viral proteins when released from the virion particle. The orthomyxoviruses (influenza) are exceptional because their proteins are encoded by individual segments of negative-stranded RNA, and these segments are converted

[a] *Memory aid*: P for petite, parvo-, polyoma-, and papilloma viruses.
[b] Poxviruses are the exception to most rules since they replicate in the cytoplasm, hepadnaviruses replicate through an RNA intermediate and are not included in table.
[c] Influenza mRNA and replication occur in the nucleus.

into mRNA in the nucleus. Influenza steals the 5' cap from cellular mRNA, and the 3'-polyadenosine is attached before leaving the nucleus so that their viral mRNA will look like cellular messenger RNA. The reo- and rotaviruses have a segmented double-stranded RNA genome surrounded by components of the polymerase (an inner capsid) that will convert the negative strands of the genome into individual mRNAs.

Although the retroviruses, including HIV, have a positive sense RNA genome, they carry a reverse transcriptase enzyme that converts the RNA genome into DNA and then another viral protein promotes the integration of the viral DNA into the host chromosome. The integrated retroviral DNA becomes a very active gene within the host chromosome to produce viral mRNAs and new copies of the viral genome are transcribed as if it were a cellular gene.

Once the virus has manipulated the cell into making mRNA, the viral proteins are synthesized by the cell's ribosome and glycoproteins are processed by the same machinery as cellular glycoproteins. Different viruses have different ways to regulate when early and late proteins are made. The herpesviruses (DNA viruses) have three phases of protein synthesis, the immediate early genes are activated by viral and cellular proteins and the early and late genes are activated by viral proteins. The early proteins of the togaviruses and coronaviruses (positive RNA genome) are translated directly from the infecting genome while the mRNA for the late proteins is made from the negative RNA template that is used to replicate the genome. During the late phase of protein synthesis, the cellular machinery is likely to be devoted to production of viral proteins to the exclusion of cellular proteins.

Genome Replication

The new genome of DNA viruses is replicated like cellular DNA, in a semiconservative manner. The amounts of deoxyribonucleotides and DNA polymerase in a resting cell are limited and this can prevent or retard the replication of a virus. The smaller DNA viruses get around this problem by replicating in growing cells (B19 parvovirus in erythrocyte precursors) or by removing or blocking the action of inherent cellular growth inhibitors (p53 or RB growth suppressor proteins). The larger viruses encode their own tools for viral replication, a viral DNA polymerase and even scavenging enzymes for deoxyribonucleotides, which provide more independence from the cell and speed up the replication of the genome.

Most RNA viruses replicate their genome using an RNA-dependent RNA polymerase that is carried into the cell or encoded by the virus and made soon after infection. This polymerase makes an RNA template from the genome and uses it to synthesize positive- or negative-sense RNA genomes. During some point during the production of an mRNA or a new genome, a double-stranded RNA structure will be generated between the template and the new copy. The double-stranded RNA replicative intermediate is the most powerful activator of Type 1 interferons and activates other innate responses through Toll-like (TLR) and other receptors.

The retroviruses and hepatitis B virus utilize both RNA and DNA in their replication. During the early steps in retrovirus infection, the incoming RNA genome is converted into DNA by the viral encoded and virion carried reverse transcriptase enzyme (RNA-dependent DNA polymerase) and another viral enzyme (integrase) facilitates the integration of the genome into the host chromosome. Viral mRNA and new genomes are produced by the cell's DNA-dependent RNA polymerase as if it were making mRNA. For hepatitis B virus, the cell makes different sizes of mRNA, including a longer than full genomic length RNA copy from the DNA genome. The RNA circle that results is transcribed into the circular hepatitis B virus DNA genome using the viral reverse transcriptase.

The viral polymerase is the major target for antiviral drugs. Nucleotide analogs inhibit virus replication or promote hypermutation.

Virus Assembly

Ultimately, all parts of the virus must be assembled into the virion particle so that it can move to new target cells and hosts. At first thought, the process seems analogous to assembling a jigsaw puzzle by shaking the parts in a box. However, the process is not as random as the shaken puzzle box. For some capsid viruses, individual proteins associate into larger and larger complexes that eventually become empty capsid shells. The large number of viral proteins within the cell promotes enough collisions between the proteins to drive the process to completion. Many of these structures are built on scaffolds made of cellular membranes or other viral proteins. Some proteins must be cleaved before they become fully functional and fit into the assembly.

To finish the process, the genome can be inserted into an assembled capsid shell, or the capsid proteins can assemble around or associate with the genome. For enveloped viruses, the protein-coated genomes (nucleocapsid) associate with proteins on the inside of the cellular membrane and the structure wraps itself in the membrane to bud from the cell. The viral encoded proteases of retroviruses finalize the assembly process after envelopment and are a target for antiviral drugs.

Virus Release

Most capsid viruses accumulate in the cytoplasm and must cause the cell to lyse in order to be released. Lysis of the cell may be a consequence of toxic viral proteins, the build-up of viral material, an inability to rebuild cellular structures, or induction of apoptosis or necrosis. Most enveloped viruses are more subtle and acquire their envelope from the plasma membrane as they push their way out of the cell without killing the cell. Herpesviruses are released by vesicular transport mechanisms, similar to those used to release proteins as well as by cell lysis.

Upon release, the viruses can spread to other cells and expand the infection. Some viruses (e.g., herpes simplex virus (HSV) can move between cells (intercellular spaces) to infect neighboring cells without exposing themselves to antibody detection. Other viruses (HSV, varicella zoster, measles and other paramyxoviruses, and HIV) recruit large numbers of cells into their factory by fusing them together into multinucleated giant cells (syncytia). Syncytia formation is also a diagnostic characteristic of these viruses.

Host Protective Responses

Antiviral immune responses are a part of viral disease. They are essential for control of infection and yet they contribute to the pathology of the disease. Most viruses encode proteins and mechanisms to escape or shut off the host protections. Antiviral host protective responses are based on the following military-like rules:

1. Keep them out and they can cause no harm.
2. Prevent them from establishing a toehold.
3. If they acquire a toehold, then prevent them from spreading.
4. Eliminate the invaders and their factories at all cost.

The initial antiviral protection consists of barriers such as skin and mucus; unfavorable conditions such as the acid and detergent-like bile found in the gut; and antimicrobial peptides such as the defensins, which are found in many parts of the body and especially the mouth. Body temperature and fever are deterrents to many viruses; for example, the rhinoviruses are restricted to the upper respiratory tract because they cannot replicate at body temperature in the lower lung.

Innate responses react quickly in response to microbial components and prevent the establishment of a toehold. These responses include the type 1 interferons, natural killer (NK) cells, macrophages, and dendritic cells. Neutrophils and complement have less important protective roles in antiviral responses than antibacterial responses but contribute to pathogenesis.

The cell has sensors for cytoplasmic RNA, double stranded RNA and cytoplasmic DNA produced during viral replication that activate antiviral responses, including type 1 interferon production. Enzymes, such as APOBEC3 (apolipoprotein B mRNA editing enzyme), promote mutagenesis of single stranded DNA in the cytoplasm, as would be produced during retrovirus infection. HIV counteracts this enzyme with its vif protein.

Type 1 interferons (IFN) include more than 20 different IFN alphas, and one type of IFN beta. They received their name because they "interfere" with virus replication. The type 1 IFNs are produced in response to viral DNA, RNA, and especially the double-stranded RNA replicative intermediate generated during RNA virus replication. Plasmacytoid dendritic cells produce large amounts of type 1 IFNs in response to viruses in the blood. Type 1 IFNs are distinguished from interferon-γ (IFN-γ), the only type 2 IFN, which is produced by NK and T cells in response to activation of immune responses (discussed later).

IFN produced and released from a virus-infected cell acts as an early warning system to surrounding cells. The IFN binds to cell surface receptors and induces the production of antiviral proteins, which become activated upon virus infection of the cell. These antiviral proteins are part of the "antiviral state" and include a protein kinase (PKR), which when activated by double-stranded RNA will phosphorylate a key controlling protein in the ribosome assembly to prevent protein synthesis. Another protein indirectly activates an RNase in response to virus infection. Both of these interferon-induced and virus-activated responses work together to prevent protein synthesis and hence block virus replication. IFN also activates NK cells and other body defenses. These actions act locally to stop the progression of the infection but also provide an early warning system in case the virus does spread. Unfortunately, these protections cause the flu-like symptoms associated with many viral infections.

NK cells can recognize and kill viral-infected cells as well as produce IFN-γ. IFN-γ acts as a cytokine to activate macrophages and dendritic cells. Activated macrophages also have killer cell activity. Activated dendritic cells initiate the antigen-specific antiviral immune response.

The goal of the protective innate and immune responses is to completely eliminate the virus (resolve the infection) by eliminating infectious virus and virus-producing cells. Some virus infections can be controlled by antibody, whereas others require both antibody and cell-mediated responses. The rule is that if the virus kills the cellular factory as part of virus replication, then

antibody is sufficient to resolve the infection. If the virus does not kill the infected cell, then cell-mediated immune responses must kill the cell to resolve the infection.

Antibody-mediated protection acts primarily to limit the spread of the virus. It is directed against the proteins and structures that bind to the cell surface receptor, the viral attachment proteins, or structures. The antibody coats the virus and prevents it from being able to bind and infect cells and promotes the uptake and destruction of the virus by macrophages (opsonization). Antibodies to other viral proteins are not protective but provide serological evidence of the infection.

T-cell responses help the antiviral response with cytokines and provide killer cells to destroy the viral infected cell factories. The killer CD8-T cell responses are directed against viral peptides that decorate the major histocompatibility antigens (MHC-I) on the surface of the infected cell. CD8-T cells and CD-4 T cells can also make IFN-γ to maintain the cytolytic response. Cell-mediated responses usually cause flu-like symptoms, inflammation, and tissue damage contributing to the disease presentation. More description of the antimicrobial immune response can be obtained in Ref. [1–4] and other sources.

Mobilization of the antigen-specific immune response takes longer to activate than the local militia of innate responses, especially if it is the first challenge with this strain of virus. Maturation of new antigen-specific immune responses takes at least 7–10 days, sufficient time for the virus to spread, reach the target tissue for the disease (e.g., for polio virus, to the central nervous system), and cause damage. As a result, there is more virus and infected cells and a much stronger immune response is necessary to resolve the infection of an immunonaive individual and this may result in greater immunopathology (discussed later). Prior immunization, either by natural infection or vaccination, shortens the time to approximately three days and the infection is usually stopped before signs of disease begin.

Pathogenesis and Disease

Most viral diseases are caused by a combination of viral pathogenesis and immunopathogenesis.

For some viruses, such as polio, the viral pathogenesis is the primary cause of disease as the virus kills the infected cell and targets motor neurons of the anterior horn and brainstem. For rhinoviruses (common cold) and the more serious influenza and herpes viral diseases, disease results from a combination of viral and immunopathogenesis whereas for measles, mumps, hepatitis viruses, and hantaviruses, immunopathogenesis is the primary cause of disease.

Viral Pathogenesis

Viral pathogenesis is caused by changes in the cell that are induced by viral replication and viral replication-induced cell death. The type and extent of viral pathogenesis is determined by the nature of the virus-cell interaction. Many viruses, especially the larger viruses, encode proteins that can manipulate the cell and the host to promote virus replication. Only half of the approximately 80 genes encoded by HSV are necessary to replicate the virus in tissue culture; the other genes support virus replication in difficult cells, like neurons, and help the virus spread or escape the immune response.

Viral disease is primarily determined by the cell type and tissue (tropism) that are infected by the virus and the consequences of the virus-cell interaction (e.g., hepatitis, encephalitis). The expression of virus receptor molecules on the target cell is the initial and most important determinant of the nature of the viral disease.

Once the virus has picked, attached, and entered the target cell, there are several different possible outcomes: replication and viral-induced cell death, replication without cell death (chronic infection), latency, or transformation. Most naked capsid viruses are cytolytic because they must kill the infected cell to be released and spread to other cells, whereas many enveloped viruses leave the cell without killing the cell as they acquire their envelope from the cell membrane and bud away from the cell. For a DNA virus, the outcome can be determined by the ability of the cell to make the viral proteins. For example, HSV establishes a latent infection without apparent effect on neurons because only one RNA (latency-associated transcript (LAT) is transcribed in these cells, and this RNA does not encode a detectable protein. For simian virus 40 (SV40), the early gene, T antigen, stimulates cell growth, which facilitates replication of the DNA viral genome; but if the late genes for the capsid proteins cannot be transcribed, as in rodent cells, the stimulation of cell growth becomes uncontrolled, and can lead to oncogenic transformation. The T antigen protein prevents the function of the p53 and RB cellular growth suppressors and cell growth and mutation ensues. SV40 replicates and kills monkey cells, a situation that is inconsistent with oncogenic transformation. Similarly, the E6 and E7 proteins of the high risk for cancer human papilloma virus types, including Types 16 and 18, also prevent the function of the p53 and RB. When the HPV DNA genome becomes circularized or integrated into the host chromatin, a gene important for virus replication is inactivated and the cell grows out of control. HPV 16, 18 and several other types are associated with human cervical carcinomas and other cancers.

Although the virus may not kill the cell, it may cause characteristic changes to cellular structures within the cell. These changes may be seen as histological staining aberrations, including inclusion bodies, or syncytia formation (multinucleated giant cells due to cell-cell fusion). For example, herpes simplex virus causes syncytia formation, margination of the chromatin, and a Cowdry Type A intranuclear inclusion body. More examples are presented in Table 49.5.

TABLE 49.5

Visual Examples of Viral Pathogenesis

Example	Virus
Cytolysis	Most viruses, especially herpes, picorna, adeno, pox
Syncytia formation	HSV, VZV, paramyxoviruses, HIV
Inclusion bodies:	
Cowdry type A intranuclear	HSV
Owl's eye intranuclear	CMV
Intranuclear basophilic	Adenovirus
Intracytoplasmic acidophilic	Poxvirus
Negri bodies intracytoplasmic	Rabies
Perinuclear cytoplasmic acidophilic	Reoviruses

The incubation period for disease will be short if the primary site of infection is also the target tissue. The incubation period is longer if the virus must be amplified and then spread to the target tissue through the blood stream (viremia) or the disease is due to immunopathogenesis (e.g., hepatitis). Oftentimes, a prodrome of flu-like symptoms occurs while the virus spreads by viremia to the disease related target tissue.

Immunopathogenesis

Although the immune response is essential to control the virus infection, it is also a major contributor to the disease signs and symptoms. It takes energy to combat a viral infection, and many protective immune responses also cause cell damage. Interferon and cytokines not only mobilize the body's defenses against the virus, but also cause the flu-like symptoms of fever, malaise, headache, muscle ache, and lack of appetite. Inflammation, rashes, and tissue destruction may be a consequence of cell-mediated immune killing of infected cells to combat the virus. However, insufficient immune responses can result in chronic infections, as with hepatitis B virus infection of children ("no pain, no gain"). Immune complexes between viral antigen and antibody can lead to hypersensitivity reactions as with the rash following infection of children and the arthritis that accompanies adult infection by the B19 parvovirus. Similarly, the large amount of viral antigen particles (HBsAg) during hepatitis B infection can cause glomerulonephritis.

Laboratory Detection

This section is not a replacement for a chapter on the subject but provides a summary. An overview of laboratory diagnosis of microbial diseases, including viruses, was developed by the IDSA (5).

Choice of the appropriate sample for analysis is the first step in viral laboratory analysis. The patient's symptoms and the source and nature of the clinical sample are the first clues to the proper sample and to identification of the virus. Virus isolation was the gold standard for detection of viruses but this is not possible in all cases and is being replaced by genome amplification techniques, such as polymerase chain reaction (PCR) for DNA and reverse transcriptase PCR (RT-PCR) for RNA. Growth of the virus isolate in appropriate cell cultures and the cytopathological effects induced by virus replication (see Table 49.5) can provide important clues to the trained eye. Due to the expense, difficulty, and risk, most laboratories have minimized the use of virus isolation and are identifying viruses by detection of the viral genome or antigens using molecular biological or immunological techniques. Enzyme-linked immunosorbent assays (ELISA), immunofluorescence, and related tests are useful for detecting viral antigen in serum or other sample and in infected tissue culture cells. *In situ* hybridization, PCR, RT-PCR, and related approaches can detect and quantitate the viral genome. Newer gene amplification techniques and DNA sequence analysis have made quantitation of the virus load for HIV, Hepatitis C (HCV), and other viruses, the standard analytical tool to follow the patient's disease progress and antiviral drug compliance. Multiplex PCR techniques are available for different diseases to allow rapid screening for multiple agents. This approach can provide rapid distinction of a treatable bacterial from an untreatable viral cause of pneumonia as well as the type and strain of the virus (e.g., influenza type). New, cheaper, and more rapid DNA sequencing techniques allow rapid definitive identification of the agent and can distinguish the mutations that may be associated with antiviral drug resistance or immune escape mechanisms. (A full description of these techniques can be found in Chapters 10 and 11).

Serological analysis provides a history of a patient's infections. The presence of IgM (immunoglobulin M) to viral antigen indicates ongoing disease, and a fourfold increase in antibody titer between acute and convalescent serum indicates recent infection. Analysis of antibody responses to specific viral antigens can also be used to follow the course of some viral diseases, especially for Hepatitis B virus and Epstein-Barr virus. ELISA tests are important for screening the blood supply for HIV, HCV, HBV, and HTLV-1. In addition to the ELISA and immunofluorescence tests mentioned earlier, antibody neutralization of virus infection and inhibition of hemagglutination (for those viruses that bind to erythrocyte structures and agglutinate the cells), termed hemagglutination inhibition (HI), can be used to evaluate serum for antiviral activity. HI is used to validate the annual influenza vaccine activity.

Epidemiology

Similar to infectious disease, which studies the consequence of viral infection of the body and its control by the immune response, epidemiology studies the viral infection of the population and the control of its spread by immunization of the populace. Specifically, viral epidemiology studies the mechanisms and modes of transmission of the virus, including vectors; the risk factors; the at-risk groups; seasonal, geographical, and environmental considerations for infection; as well as modes of controlling virus spread. The personal history provides epidemiologic data and is a gold mine of information for making the diagnosis of a viral disease.

Transmission

The most common means of virus transmission are the respiratory and fecal-oral routes. Other transmission routes include contact with fomites carrying the virus (e.g., paper tissues), contaminated secretions (e.g., saliva, semen) or blood upon sex, at birth, by transfusion or organ transplant, and from insect or animal vectors.

Some viruses are zoonoses, capable of infecting insects or animals other than humans. A bird, rodent, or monkey may be a reservoir for maintaining the virus and an arthropod, such as a mosquito or tick, may be the vector for transmitting the virus. The arthropod would acquire the virus while taking a blood meal and transmit the virus to its next host. To be a good reservoir, the animal must maintain a sufficient viremia for the vector to acquire the virus. Humans are primarily at risk for infection when they encroach on the environment of the reservoir or vector.

The route of transmission is determined by several factors, but primarily what the virion structure can withstand and the tissue

that replicates the virus. As indicated earlier, capsid viruses can be transmitted by most routes, but enveloped viruses must remain wet during transmission to be functional, and most enveloped viruses are destroyed in the GI tract. Viruses released in respiratory aerosols replicate in the lung. For fecal-oral transmission, the virus can replicate in mucosal epithelium or lymphoid tissue of the intestines or the pharynx; most of these viruses are capsid viruses. Transmission in blood, by a mosquito or in a transfusion, requires that the virus infect blood cells or the cells lining the blood vessels, establish a sufficient viremia and be in the bloodstream when the blood bank or the arthropod takes its blood.

Sexual transmission requires an additional criterion. Sexually transmitted viruses replicate on the genitalia or within secretory cells and virus transmission must occur prior to, or in the absence of symptoms. Aches, pains, lesions, or other symptoms are a deterrent to the transmission of STDs (sexually transmitted diseases).

Geography and Season

Many viral diseases have worldwide distribution. The geographic limitations to virus spread have dissolved due to global transportation. Passengers and freight can carry a virus or an infected mosquito to new geographic regions within a day. A perfect example of this was the outbreak of severe acute respiratory syndrome (SARS) in 2002. SARS spread from Vietnam to China to Hong Kong and then to Toronto, Canada. The spread of, and outbreak of measles in the United States is a more recent example. Vector-borne viral diseases are endemic to the habitat of the insect or animal vector. This is especially true for many of the mosquito-borne encephalitis and hemorrhagic fever viruses. Influenza spreads throughout the world in infected birds as well as infected people.

The reasons for the seasonal occurrence of viral infections are sometimes obvious—for example, outbreaks of arboviral (arthropod-borne virus) encephalitis occur during the summer when mosquitos are prevalent. The seasonal nature of influenza outbreaks may be due to the increased proximity of people during the fall and winter, or that the temperature and humidity of the air may stabilize or promote transmission of the virus-loaded aerosol.

Who is at Risk

There are many different risk factors in addition to geography that determine whether an individual is likely to come into contact with a virus and the severity of the resulting infection. These include the age, health, and immune status of the individual, as well as occupation, travel history, lifestyle, sexual activity, and interactions with children, especially daycare facilities.

Vaccines and Antiviral Drugs

Vaccines

Vaccination is probably the most beneficial treatment that a physician can provide because the immune response is the only therapy for most viral diseases (6, 7). Passive immunization can be used as a temporary therapy to prevent or ameliorate the course of viral disease. The use of human antibodies is preferable to avoid the possibility of developing serum sickness upon a second administration of animal antibody. For example, rabies immunoglobulin is injected around the site of an animal bite to neutralize any potential infecting virus. Varicella zoster immunoglobulin (VZIG) can be given to children with leukemia because they are at risk for serious outcomes of infection.

Active immunization with an attenuated (nondisease causing) virus, inactivated, or subunit vaccine is preferable to passive immunization because it initiates a longer-term immune response in the individual (Table 49.6). Live attenuated vaccines utilize virus variants that cause mild or no disease in humans. The vaccine viruses cannot grow efficiently at human body temperature, they have been adapted to animal or tissue culture cells rather than human cells, or they are a related animal virus that does not grow well in humans but shares antigens with the human virus (e.g., smallpox and rotavirus vaccines). These live vaccines elicit a natural, long-lived immunity with effective cellular and antibody responses. For example, the live attenuated vaccine for influenza is dripped into the nose, grows efficiently at 25°C but very poorly at 37°C and elicits IgG, secretory IgA, T cell responses, and longer immune memory. However, there is a minor risk of disease with some live vaccines in the immunocompromised individual or upon mutation of the vaccine virus (e.g., poliovirus). Inactivated vaccines consist of purified viral components or virion particles that are heat, radiation, or chemically treated to destroy the infectivity of the virus. The hepatitis B virus and the human papillomavirus vaccines are produced by genetic engineering and consist of virus-like particles (VLPs) containing one of the viral proteins. Inactivated vaccines produce a more short-lived and mainly antibody, not cell-mediated immunity. Adjuvants, larger amounts, and booster immunizations enhance the response to inactivated vaccines.

New approaches to vaccines being developed for dengue, HIV, HCV, and other very difficult viruses include the use of new adjuvants, immunization with hybrid viruses, DNA vaccines, and even self-replicating RNA vaccines, which resemble RNA viruses. Newer adjuvants enhance the potency and stimulate cell-mediated immunity to the vaccine proteins. Hybrid virus vaccines for HIV incorporate HIV genes into adenovirus, poxvirus, or other vectors. DNA vaccines incorporate genes for cell mediated and antibody responses into plasmids that can be utilized by human cells. Safe and more efficient methods of DNA and RNA vaccine delivery have been developed to make this approach viable.

Vaccine immunization of the community reduces the number of virus susceptible individuals and is termed “herd immunity.” Routine immunization programs are available for infants and children and for individuals at risk of infection due to their vocation or travel into an endemic region. Immunization programs have led to the elimination of smallpox throughout the world; natural polio in most of the world; measles, mumps, and rubella except in the Third World; and reduction of rotavirus and influenza infections and disease. Complacency and misinformation have compromised the delivery of these programs in many parts of the developed world as evidenced by outbreaks of measles. Measles is so contagious that outbreaks will occur if less than 10% of the population is unimmunized, which includes

TABLE 49.6

Most Common Viral Vaccines

Vaccine	Type of Vaccine	Who Should Receive Vaccine[a]
Measles	Live, attenuated	1-year-olds, booster at 4–6 years
Mumps	Live, attenuated	1-year-olds, booster at 4–6 years
Rubella	Live, attenuated	1-year-olds, booster at 4–6 years
Varicella Zoster Virus *Varicella*	Live, attenuated	1-year-olds, booster at 4–6 years
Varicella Zoster Virus *Zoster*	• Stronger version of live attenuated[b] • Adjuvanted subunit	>60-year-olds
Polio	• Killed, intramuscular • Live, attenuated, oral[b]	2-, 4-, and 6-month-olds 2-month-olds
Influenza	• Inactivated • Live, attenuated, aerosol	Adults, annually Ages 2–49 year-olds
Hepatitis A	Inactivated	12-month-olds, Travelers and at-risk population
Hepatitis B	Virus-like particle	2-, 4-, and 8 months old and at-risk population
Rabies	Inactivated	Infected individuals, veterinarians, and others at risk
Rotavirus	• Live attenuated, oral • Live reassortant, oral	2-, 4-, 6 months old
Human papillomavirus	Virus-like particle	Teen and young adult women Teen boys

[a] As per "Recommended Immunization Schedules for Persons Aged 0 Through 18 Years."
[b] No longer recommended in the United States.

individuals who are less than 1 year of age, the minimal age for measles vaccination.

Antiviral Drugs

A summary of antiviral drugs will follow, but the subject is discussed in depth in Chapter 53.

The best antiviral drug targets are the DNA polymerase of herpes viruses, the reverse transcriptase polymerase of retroviruses and hepatitis B virus, and other polymerases. Other targets include the protease of HIV and HCV, the integrase, fusion and attachment steps of HIV, the neuraminidase of influenza A and B, and the M2 protein of influenza A. Inhibitors of viral polymerases include nucleotide/nucleoside analogs such as acyclovir, penciclovir, and azidothymidine (AZT). The anti-HSV and varicella zoster virus drugs (acyclovir and penciclovir) and their prodrugs (valacyclovir and famciclovir) are very safe drugs because they require activation by a viral enzyme called thymidine kinase. There are also nonnucleos(t)ide inhibitors that bind outside of the active site of the enzyme, such as for the HIV reverse transcriptase. The HIV and HCV proteases are also good targets for antiviral drugs because they are essential for the proper assembly of an infectious virion and activation of the viral proteins. Inhibitors of the influenza neuraminidase, such as zanamivir and oseltamivir, cause the virus to clump and stick to the cell surface and this prevents virus release. Blockage of the M2 protein channel of influenza A by amantadine and rimantadine prevent the release of the genome into the cytoplasm. Ribavirin is a guanosine analog that induces hypermutation and inactivation of viral genomes as well as inhibiting other important processes.

Description of Virus Families

DNA Viruses

Parvoviruses

The parvoviruses are the smallest DNA viruses and include the B19, bocavirus, and adeno-associated viruses (8–10). Parvoviruses have a single-stranded DNA genome contained in a naked capsid. They require growing cells to provide DNA nucleotides and polymerase for replication. B19 targets erythroid precursor cells. During replication, the single-stranded genome is converted into double-stranded DNA.

B19 causes erythema infectiosum (fifth disease—one of the five childhood exanthems) in children and polyarthritis without rash in adults (11). In children, a period of high fever is followed several days later by a maculopapular rash caused by immune complexes. B19's predilection for erythroid precursor cells can cause an aplastic crisis in a person with chronic hemolytic anemia (e.g., sickle cell anemia) and neonatal infection may be fatal due to hydrops fetalis. There are neither vaccines nor antiviral drugs. Bocavirus may cause acute respiratory disease (12). Adeno associated viruses do not cause disease but are good vectors for genetic engineering (13).

Papillomaviruses

There are at least 100 types of the wart-causing human papillomavirus (HPV) that infect cutaneous or mucosal tissues (14, 15). HPVs are naked capsid viruses with a double-stranded DNA genome. These viruses can stimulate the cell to grow but utilize

cellular polymerases for replication of the genome. The virus is transmitted by contact. In addition to the benign common and other warts of the skin, other HPV types can cause growths on mucosal epithelial surfaces of the throat, conjunctiva, and anogenital regions. High risk HPV strains, including HPV 16, 18, 31, 33, 45, 52, and 58, inhibit cellular growth suppressor proteins p53 and RB105, integrate into the host chromosome, and can promote cell progression to cancer. HPV 16, 18, and some other types are common sexually transmitted diseases that can lead to dysplasia and cervical carcinoma. These high-risk HPV types are also associated with anal, penile, and oropharyngeal cancers. Genome detection methods such as PCR and *in situ* DNA analysis are used to detect and identify the virus. Surgical removal of the wart or growth is the most common therapy. A nucleotide analog, cidofovir, and an immunomodulator, imiquimod, are FDA-approved therapies. A virus-like particle vaccine formulation including HPV 6, 11, 16, 18, 31, 33, 45, 52, and 58 is recommended for young women and boys to prevent infection and cancer.

Polyomaviruses

The three human polyomaviruses, JC, BK, and Merkel Cell polyomavirus (MCV), are close cousins of the papillomaviruses. JC and BK are ubiquitous but only cause disease in immunocompromised individuals (16). The JC virus causes progressive multifocal leukoencephalopathy (PML), a disease of multiple neurologic symptoms; and the BK virus causes hemorrhagic cystitis. MCV is associated with Merkel cell carcinoma, a highly aggressive skin cancer. There are neither vaccines nor antiviral drugs.

Adenoviruses

The adenoviruses are larger double-stranded DNA viruses (17, 18). Their naked icosadeltahedral capsid has a fiber at each of the 12 vertices that serves as the viral attachment protein. These viruses encode a DNA polymerase and replication is divided into early and late phases. Respiratory diseases and pharyngoconjunctival fever (pink eye with a sore throat) are most common but adenovirus can cause other syndromes. Immunocompromised patients are at risk to serious adenovirus disease. The virus is spread in aerosols, in contaminated water (e.g., swimming pools), fecal contact, and by contact with fomites. There are live attenuated vaccines to adenovirus types 4 and 7 for military (but not civilian) use. Adenovirus infections may be treated with cidofovir. These and other adenovirus types are also used as gene delivery vehicles for gene replacement therapy and hybrid vaccines.

Herpesviruses

The herpesviruses are large viruses with a double-stranded DNA genome packaged in an icosadeltahedral capsid that is surrounded by an envelope. Cell-mediated immune responses are essential for control of the herpesviruses. Herpesvirus replication progresses through immediate early, early, and late phases of mRNA and protein expression but transition through these phases depends on the type and state of the infected cell. The herpesviruses establish latent infection within specific cell types of the host, different for each of the viruses. All the herpesviruses can reactivate upon immunosuppression and HSV reactivates upon stress—emotional as well as physical.

There are eight different human herpesviruses, all but HHV8 are ubiquitous. They include herpes simplex virus (HSV) types 1 and 2 (19, 20), both of which cause oral and genital herpes, encephalitis, keratoconjunctivitis, and severe neonatal infections; varicella zoster virus (VZV) (21), which causes varicella (chicken pox) and upon recurrence, zoster (shingles); Epstein-Barr virus (EBV) (22, 23), which causes heterophile-positive infectious mononucleosis and is associated with Burkitt's, other lymphomas and nasopharyngeal carcinoma; cytomegalovirus (CMV) (24–26), which can cause a mononucleosis-like disease, causes several different opportunistic diseases in immunocompromised individuals and is the most common viral cause of congenital disease; HHV6 and 7 (27, 28), which cause exanthema subitum (roseola), a rash in children, and is integrated into the chromosome of 1% of the population with neurologic consequences upon recurrence; and HHV8, which causes Kaposi's sarcoma, multicentric Castleman disease, and primary effusion lymphoma (29, 30). Kaposi's sarcoma can affect normal individuals, but is usually an opportunistic disease associated with AIDS. Immune and inflammatory responses to silent recurrences of HSV, EBV, CMV, and HHV6 and 7 have been implicated to trigger different neurologic and inflammatory diseases.

HSV and CMV can be isolated in tissue culture but these methods are being replaced by immunological and genome detection methods that are used for the other herpesviruses. Serology is commonly used to detect and follow the progression of EBV-associated infectious mononucleosis. EBV infection of B cells induces production of heterophile antibodies, which distinguish the resulting mononucleosis from those caused by CMV, HIV, or toxoplasma. Detection of antibodies to the EBV MA (membrane antigen) and VCA (viral capsid antigen) are present during disease and antibody to EBNA (Epstein-Barr nuclear antigen) indicates convalescence from infectious mononucleosis or prior infection.

Acyclovir, valaciclovir, penciclovir, and famciclovir are available for treatment of HSV and VZV. Ganciclovir, valganciclovir, cidofovir, and foscarnet are available for CMV. Passive immune protection with VZIG and prophylactic protection with a live vaccine is available for varicella and an adjuvanted subunit vaccine is available for zoster.

Poxviruses

Poxviruses are the largest viruses that cause human disease. Poxviruses have a double-stranded DNA genome that is enclosed in an ovoid to brick-shaped enveloped virion with a complex structure. The poxviruses are the exception to most of the rules for virus replication because they are DNA viruses that replicate and assemble in the cytoplasm. As such, their genome encodes the polymerase and other enzymes necessary to transcribe mRNA as well as replicate its genome.

This virus family includes the deadly smallpox, animal pox viruses (31) that cause similar vesicular diseases, and molluscum contagiosum (32). Through a very effective vaccination program and careful epidemiology, the smallpox virus was eradicated from all parts of the Earth except for the biowarfare factories of

the former Soviet Union and the deep freezers of the CDC in the United States. Molluscum contagiosum is a wart-like skin disease. The smallpox vaccine consists of a related virus, vaccinia, which shares immunogenicity with smallpox but usually causes benign disease in immunocompetent humans. The vaccine is only administered to military and at-risk personnel. Vaccinia is a good vector for genetic engineering and has been used to develop hybrid vaccines for HIV and other viruses.

RNA Viruses

Caliciviruses and Hepeviridae

The caliciviruses are small naked capsid viruses with a positive-sense RNA genome. The most well-known of this genus are the noroviruses (33–35). Most caliciviruses cause outbreaks of gastroenteritis. Norovirus is the most common cause of foodborne gastroenteritis, is very resistant to inactivation and infected individuals shed large amounts of virus in their stool and vomit even after recovery. Norovirus has a predilection to infect and cause more serious disease in individuals with cell surface carbohydrates of the type O (not A or B) blood group.

Hepatitis E virus (HEV) was classified as a calicivirus but now has its own family, *Hepeviridae* (36). HEV causes acute hepatitis similar to hepatitis A virus (HAV) but the mortality rate is 1–2% (10 times greater than for HAV) and up to 20% for pregnant women. HEV is detected by ELISA.

Picornaviruses

The picornaviruses (pico-small, RNA viruses) are the prototypical naked capsid viruses with a positive-sense RNA genome (37–39). This family includes the enteroviruses, which cause all kinds of different diseases except gastroenteritis, and the rhinoviruses, which cause the common cold. A canyon on the surface of these viruses binds to a receptor on the target cell and the RNA genome is injected into the cell. The positive-sense RNA genome binds to a ribosome and a polyprotein is made that becomes proteolyzed into individual proteins including an RNA-dependent RNA polymerase, capsid subunits, and other proteins. A negative-sense RNA template is made, from which more mRNA and new genomes are produced by the viral-encoded polymerase. An empty procapsid shell is filled with the RNA genome, and the virus kills and then leaves the cell.

The most famous member of the enteroviruses is poliovirus, infamous for causing paralytic disease. Fortunately, effective immunization programs with the attenuated-oral or the inactivated vaccines have led to the elimination of natural polio in most parts of the world. Other members of this family include the Coxsackie A viruses, which cause hand, foot and mouth disease, herpangina, common cold-like, polio-like, and other diseases; Coxsackie B virus (B is for body), which causes pleurodynia and myocardial infections; echoviruses; parechoviruses; and some of the higher-numbered enteroviruses, which normally are benign, but can cause viral meningitis in children younger than 1 year. Coxsackie B virus infection can lead to type 1 diabetes. Hepatitis A virus, which causes acute hepatitis, is also an enterovirus. The enteroviruses are transmitted by the fecal-oral route, but some are also transmitted in aerosols and on fomites.

The rhinoviruses cause the common cold and are distinguished from the enteroviruses because they are disrupted by acids, cannot be transmitted by the fecal-oral route, and cannot grow efficiently at temperatures above 34°C. These conditions restrict the virus to the upper respiratory tract and aerosol dispersion.

Live attenuated and killed polio vaccines are composed of two or three poliovirus types. Although the live vaccine is cheaper, easier to administer, and has other benefits, the killed vaccine is safer and currently preferred where risk of exposure is minimal. The hepatitis A virus vaccine used in most parts of the world is also inactivated, but a live vaccine is used in China. Pleconaril is an antiviral drug that binds to the cell receptor binding canyon on the virion surface, prevents uncoating of the virus but is no longer available.

Coronaviruses

Coronaviruses are enveloped viruses with a positive-sense RNA genome. The virus derives its name from the "corona" seen in electron micrographs around the virion created by the viral glycoproteins (40, 41). This structure also protects the virion from harsh conditions and allows this enveloped virus to be transmitted by the fecal-oral route in addition to the respiratory route. Like rhinoviruses, most of these viruses do not replicate well at 37°C, are restricted to the upper respiratory tract and cause the common cold. The severe acute respiratory syndrome coronavirus (SARS-CoV-1 and SARS-CoV-2) and Middle Eastern respiratory syndrome virus (MERS-CoV) can grow at 37°C and cause severe lung disease. SARS-CoV, MERS-CoV, and SARS-CoV-2 originated as animal (bats) viruses and have animal reservoirs. SARS-CoV-1 caused an outbreak of deadly severe acute respiratory syndrome, which started in Vietnam and China and spread to Toronto, Canada (42). An outbreak of MERS-CoV occurred in 2013 in Saudi Arabia. As this book goes to press, December 2020, the world is in the grips of a new coronavirus pandemic (COVID-19) caused by SARS-CoV-2. Based on the extensive tissue expression of the angiotensin converting enzyme 2 (ACE2) receptor for SARS-CoV-2 and inflammatory responses, disease can affect many organs and range from asymptomatic to lung and multisystem organ failure (42a). Careful quarantine limited the spread and disease caused by SARS-CoV-1. Vaccines and antiviral drugs for SARS-CoV-2 are available.

Paramyxoviruses

The paramyxoviruses include the well-known measles and mumps viruses, as well as very common parainfluenza, respiratory syncytial, and metapneumo respiratory disease viruses (43). The paramyxoviruses are large enveloped viruses with a negative-sense RNA genome. As negative-strand RNA viruses, they carry their polymerase in the virion wrapped around the genome as part of the nucleocapsid. Individual mRNAs and a genomic-length positive-sense RNA are transcribed from the genome and the latter form of RNA is used as a template to make new genomes. The paramyxoviruses express a fusion protein that allows them to enter the cell by fusion of the envelope with the plasma membrane, and the fusion protein also promotes cell-cell fusion into multinucleated giant cells (syncytia). These viruses exit the cell without killing the cell.

Paramyxoviruses are good inducers and responsive to type 1 interferons. Cell-mediated immunity is essential for controlling paramyxoviruses but the resulting "flu-like" symptoms and inflammation contribute to the production of disease.

As respiratory viruses, the paramyxoviruses are very contagious. Parainfluenza and respiratory syncytial viruses (RSVs) (44–46) are ubiquitous, causing anything from a serious cold to bronchiolitis or pneumonia. In young children, parainfluenza causes croup and RSV causes a serious pneumonia. The severity of RSV infections in newborns, especially those born prematurely, prompted the development of antiviral therapy with aerosolized ribavirin or treatment with anti-RSV immunoglobulin.

The classic symptoms of measles (47–50) are cough, coryza (runny nose), conjunctivitis, rash, and Koplik spots (small vesicular lesions in the mouth). The more serious outcomes include pneumonia, encephalitis, and post-infectious encephalitis. Most of the disease symptoms are due to immune pathogenesis. Measles is very contagious and remains a major killer especially for vitamin A deficient individuals. Sequelae of measles may include post measles encephalitis and subacute sclerosing panencephalitis (SSPE). Mumps infects glandular tissue and the immune response causes swelling that can result in parotitis, orchitis, and meningoencephalitis. Fortunately, there are very effective live, attenuated vaccines for protection against measles and mumps that are administered as part of the MMR (measles, mumps, rubella) or MMRV (with varicella) vaccines to children after 1 year of age and again at 4-6 years of age. Unfortunately, increasing numbers of individuals are opting out of vaccination programs and large outbreaks of measles and mumps have returned.

Orthomyxoviruses

The orthomyxoviruses include influenza A, B, and C (51–56). These are medium sized enveloped viruses that have a segmented, negative-strand RNA genome. Most of the RNA genome segments encode individual viral proteins. The virions are decorated with hemagglutinin (HA or H) and neuraminidase (NA or N) glycoproteins. The HA binds to a sialic acid cellular receptor, which is on epithelial cells and on erythrocytes. The NA cleaves sialic acid from virion glycoproteins and mucus to prevent the virus from binding to itself and facilitates exit from the infected cell and spread. Having a segmented genome allows the influenza to reassort their segments when a cell is infected with more than one strain of influenza to create hybrid viruses.

Influenza A is a zoonose, a virus that infects animals and humans. Reassortment of gene segments during a mixed animal-human influenza virus infection or mutation can create new human viruses that can spread worldwide. These greatly feared pandemics usually originate in the Far East, although the most recent "swine flu" originated in Mexico. Influenza viruses are named for their type, place of original isolation, date of original isolation, and type of hemagglutinin and neuraminidase (for example, A/Bangkok/1/79(H3N2) virus). Influenza B is strictly a human virus. Influenza B can also change, but primarily by mutation and less drastically than Influenza A. Influenza C causes mild disease. Influenza can be assayed by its ability to agglutinate erythrocytes (hemagglutination) but detection of antigen by ELISA tests or the genome by RT-PCR are preferred procedures. Anti-influenza antibody generated by the annual vaccines is validated by hemagglutination inhibition as a surrogate of protection.

Oseltamivir (Tamiflu), zanamivir (Relenza) and peramivir (Rapivab) inhibit the neuraminidase of influenza A and B. Amantadine and rimantadine are antiviral drugs that inhibit a channel formed by the M2 protein of influenza A (not B or C) to prevent the initial release of the genome from the virion particle within the cell to block replication, but these drugs are no longer recommended due to the prevalence of resistant strains. An annual vaccine program utilizes a mixture of three or four inactivated viruses or their HA and NA produced in fertilized eggs or tissue culture or the HA produced by genetic engineering comprising the influenza A and B types that are predicted to occur during that year. A live attenuated inhaled vaccine (LAIV) (FluMist) is also available for persons aged 2–49 years.

Rhabdoviruses, Filoviruses, and Bornaviruses

These viruses have similar structures and were once considered to be in the same viral family. These are enveloped viruses with single-stranded, negative-sense RNA genomes. The rhabdoviruses have a characteristic bullet shape, whereas the filo- and bornaviruses are filamentous. The most famous and only rhabdovirus to affect humans is rabies (57). Reservoirs of this virus are present in raccoons, foxes, skunks, other forest wildlife, bats, and even farm animals. Infected dogs are still a common vector in countries that lack pet immunization programs. Infection of humans is always fatal unless the individual is treated with anti-rabies immunoglobulin and immunized with an inactivated vaccine prepared in human diploid fibroblasts or chick embryo cells. Rabies takes a long time to progress from the site of the bite to the brain and does not cause signs of disease until it reaches the salivary glands and the brain. The characteristic fear of drinking water (hydrophobia) is due to the pain upon swallowing due to infection of the salivary glands. Infection of the highly innervated salivary glands and mental changes in animals (e.g., mad dog) provides the source of virus and the attitude (madness) for transmitting the virus. Analysis of brain tissue from an infected animal will show Negri inclusion bodies in the cytoplasm, but virus infection is usually detected by immunofluorescence or genome detection. As mentioned, there is an inactivated vaccine that is administered to people at risk for infection, such as veterinarians, and to people who have been bitten by an animal that is a possible carrier of rabies. A hybrid vaccine consisting of the rabies virus glycoprotein gene genetically inserted into the vaccinia virus is infused into blocks of food and airdropped into the forest to immunize wild animals.

The Marburg and Ebola filoviruses cause severe or fatal hemorrhagic fevers and are endemic in regions of Africa (58). These viruses are so virulent that they often burn out their susceptible population by killing their human cohort before they can spread to another community. Recent outbreaks of Ebola have occurred in the Democratic Republic of the Congo. These infections may be responsive to ribavirin or immunoglobulin from survivors. A hybrid virus vaccine has been developed for Ebola. Bornaviruses have been implicated to trigger psychiatric diseases.

Reoviruses

The reoviruses derive their name as the acronym for "respiratory enteric orphan" viruses because no human disease was associated with them until the rotaviruses were identified. The Colorado tick fever virus is also a reovirus. Reoviruses have a double capsid and a double-stranded segmented RNA genome. Partial protease digestion exposes the viral attachment proteins and allows the virion to disassemble when inside the target cells of the GI tract. Like the orthomyxoviruses, the individual negative-strand segments of the double stranded genome are transcribed into positive-sense mRNA. An early set of proteins are made that corral the positive-sense segments into an inner capsid, late proteins are made, the double-stranded RNA is recreated, the outer virion capsid acquired, and the virus is released.

Rotaviruses are the most common cause of infantile diarrhea and a major cause of death due to dehydration of infants in underdeveloped countries (59–61). Rotaviruses are usually detected in stool by ELISA. A live, attenuated human virus or a bovine reassorted vaccine is administered at 2, 4, and 6 months of age to prevent this disease.

Togaviruses

The togaviruses consist of the alphaviruses, which are zoonoses that are transmitted by mosquitoes and considered arboviruses (arthropod-borne viruses), and rubella virus, which is transmitted by aerosols. The togaviruses are small with an envelope that is tightly wrapped around a nucleocapsid containing a positive-strand RNA genome. After entering the cell by receptor-mediated endocytosis, the genome is released, binds to ribosomes, and a polymerase and other early proteins are cleaved from the initially translated polyprotein. After a negative-strand RNA template is made for new genomes, smaller mRNAs are also made that encode a polyprotein for the capsid and envelope glycoproteins.

The alphaviruses are zoonoses, which usually have a bird or rodent reservoir and a mosquito vector (62). These viruses, which include Western, Eastern, and Venezuelan equine encephalitis viruses, cause either systemic flu-like symptoms or encephalitis in humans. Chikungunya causes systemic, arthralgia and arthritic disease (63).

Rubella virus is not a zoonose, is transmitted in aerosols, only infects humans, has one serotype, and causes rubella (German measles), a childhood rash with possible arthritic symptoms due to immune pathogenesis. Rubella was a major cause of congenital defects (deafness, mental retardation, and cataracts) until vaccine programs limited the spread of and infection by this virus. The vaccine is live and attenuated and administered with the measles and mumps (MMR) and potentially VZV (MMRV) vaccines.

Flaviviruses

The flaviviruses are arboviruses, except for the hepatitis C virus (HCV). These viruses are small and enveloped with a positive-strand RNA genome that replicates like the picornaviruses, except with an envelope surrounds its nucleocapsid. The arboflaviviruses (64–70) cause mild systemic flu-like symptoms, systemic disease (zika), hemorrhagic disease (dengue, yellow fever), or encephalitis (St. Louis, West Nile, Japanese encephalitis viruses). Zika virus remains in the blood for long periods after infection and can be transmitted in semen and in utero to the fetus where it can cause congenital anomalies. St. Louis and West Nile encephalitis and dengue and yellow fever viruses establish urban cycles of human-mosquito-human infection based on the habitat of the mosquito vector. Vaccines are available for the yellow fever and Japanese encephalitis viruses.

Hepatitis C (HCV) virus is transmitted in blood, semen, and vaginal fluids (71–76). HCV usually causes chronic hepatitis (70%), which can progress to cirrhosis (20%), liver failure (6%), or hepatocellular carcinoma (4%). There are 6 different HCV types, type 1 being the most common. They differ in their sensitivity to antiviral drugs. ELISA is used for serological screening to protect the blood supply and RT-PCR is used to follow the progression of disease and treatment. HCV disease is treated with a combination of drugs that inhibit the polymerase, polymerase/virulence enhancer, or protease. Treatment has the potential to cure the HCV infection. Previous therapy utilized ribavirin and interferon alpha.

Bunyaviruses

The bunyaviruses are enveloped viruses with a negative-strand RNA genome. There are many different bunyaviruses with exotic names that are indicative of where in the world they were discovered. Most bunyaviruses are transmitted by arthropods, including mosquitoes, flies, or ticks, depending on the virus (77–79). The hantaviruses infect rodents and are spread in their urine and stool (80, 81). The California encephalitis viruses and hantaviruses occur in the United States. These viruses cause encephalitis and hemorrhagic disease, respectively. There is no treatment or vaccine for these viruses.

Arenaviruses

The arenaviruses (*arena* is Greek term for "sandy") get their name because they incorporate ribosomes into the virion particle and this gives them a sandy appearance in electron micrographs (82). These enveloped viruses contain two circular RNA genome segments; the larger segment is a negative-sense RNA while the other is ambisense. Early mRNA from the ambisense segment is copied from the entering genomic negative-sense RNA. Later, when positive RNA templates are made to replicate the genome, another mRNA is also made for the late structural proteins. The arenaviruses are transmitted in urine from mice and other rodents and Lassa fever is also transmitted in secretions and fluids from infected humans. Lymphocytic choriomeningitis virus is seen in rodent infested areas around the world (83). Lassa fever (84), Machupo, and Junin viruses, in Western Africa, Argentina and Bolivia, respectively, cause deadly hemorrhagic fever. Lassa fever has been treated with immunoglobulin and ribavirin.

Retroviruses

The retroviruses include two human disease viruses—human immunodeficiency virus (HIV) (85–95) and human T-leukemia virus (HTLV) (96)—as well as oncogenic animal viruses, some nonpathogenic viruses, and many endogenous viruses that are

carried in our chromosomes. The retrovirus envelope encloses a nucleocapsid that contains two copies of the positive-sense RNA, two transfer RNAs, an RNA-dependent RNA polymerase (reverse transcriptase), and other enzymes. The basic retrovirus genome consists of three genes: The gag (capsid proteins), pol (polymerase, integrase and protease), and env (glycoprotein) genes. HTLV and HIV encode other genes to facilitate the replication and pathogenesis of the virus. HIV binds to CD4 molecules and a chemokine receptor as a co-receptor on T-cells, macrophages, dendritic and other cells. Initially, the virus uses the CCR5 chemokine receptor and then later in the disease, some of the virus mutates to utilize the CXCR4 receptor. Persons lacking the CCR5 protein are naturally resistant to HIV. The virus fuses its envelope with the cell membrane to enter the cell, releasing the genome and proteins into the cytoplasm. The positive-strand RNA is converted into a negative-strand cDNA and then a circular double-stranded DNA by the reverse transcriptase enzyme carried in the virion. The HIV polymerase is extremely error prone and readily generates new versions of the virus through mutation. An integrase enzyme, carried into the cell, facilitates the integration of the genome into the host chromosome of growing cells and several mRNAs and a genomic-length, positive-sense RNA are transcribed by cellular enzymes as if from very active genes. A polyprotein, consisting of the capsid and enzymatic proteins, associates with viral glycoprotein modified plasma membranes. A pair of RNA genomes and tRNAs then associates with the protein-modified membrane and the virion buds out of the cell. After leaving the cell, the virion protease cleaves the polypeptide into functional proteins. Eventually, the cell will die. HTLV-1 also binds to CD4 molecules on T cells, its cDNA gets integrated into the host chromosome, but the virus stimulates the growth of the cell. There is a long latent period prior to the onset of acute T cell lymphocytic leukemia in infected individuals.

Many articles and books have been written about HIV and its disease, acquired immunodeficiency syndrome (AIDS). In summary, HIV infects the controlling cells of the immune response, the CD4 expressing macrophage, dendritic cell, and CD4 T-cell, to eventually deplete the person's immune response and cause the individual to die of opportunistic infections. Soon after HIV infection, the activated CD4 T cells of the intestinal and other systems are eliminated. Initial symptoms of acute disease may resemble mononucleosis. After a variable period of subclinical immune dysfunction and a switch in viral specificity to the CXCR4 chemokine receptor, CD4 T cell numbers drop precipitously followed by a drop in CD8 T cell numbers, resulting in significant immunodeficiency. Individuals are plagued by opportunistic diseases caused by mycobacteria and other bacteria, fungi and parasites, and recurrences of herpesviruses.

Virus infection can be detected by genome analysis and serology and the blood supply is screened by ELISA. Western blot analysis was necessary for confirmation but has been replaced by newer ELISA assays that detect an early viral protein (p24) as well as anti-HIV antibodies. Virus load, the number of viral genomes in the blood, is quantitated by real-time reverse transcriptase PCR analysis or other genome detection methods. These tests are more sensitive than serology and allow early detection and quantification of the infection and the ability to follow the course of disease and compliance with antiviral therapy. The high mutation rate of the virus promotes escape from antibody control and single antiviral drug treatment. A cocktail of antiviral drugs (highly active antiretroviral therapy [HAART]) consists of nucleotide and/or non-nucleotide analog inhibitors of the reverse transcriptase, inhibitors of the protease, integrase, binding to CCR5, and/or virus fusion. Prophylactic therapy (PrEP (pre-exposure prophylaxis)) or (PEP [post-exposure prophylaxis]) are suggested for individuals at risk for infection.

HTLV infection is usually asymptomatic but can progress to adult acute T-cell lymphocytic leukemia (ATLL) over the course of many years. HTLV can also cause tropical spastic paraparesis, a nononcogenic neurologic disease.

Up to 8% of the human chromosome is made up of retroviral sequences. Human endogenous retroviruses (HERV) are quiet but may influence body functions, immune and other responses. A retroviral protein, syncytin, is induced during pregnancy and promotes placental formation.

Hepadnaviruses and Hepatitis D Virus

Hepatitis B virus (HBV) is the only member of the hepadnaviruses that infects humans (97–100). The hepadnaviruses are enveloped DNA viruses but, like the retroviruses, encode a reverse transcriptase and replicate through an RNA intermediate. HBV replicates in hepatocytes without killing the cell. The DNA genome of the virus is transcribed in the nucleus into several mRNAs and one RNA that is larger than the genome is used as a template for making the genomic DNA. The negative DNA strand is synthesized from the template RNA by the viral encoded reverse transcriptase and as the positive DNA strand is being made, the RNA is degraded and the genome is enclosed in a capsid structure that causes synthesis to stop prior to completion. The virus acquires its envelope by budding from the plasma membrane without killing the cell. Large amounts of the glycoproteins of the virus are produced, and these form particles (HBsAg) that are present in the blood of infected individuals.

Hepatitis B, also known as serum hepatitis, has an insidious onset and usually will resolve, but it can also cause chronic disease in 10% of patients. Interestingly, the symptoms of disease are caused by the immune resolution of the infection and a mild case of HBV is likely to become chronic. This is especially true for infants and children. Chronic HBV can result in primary hepatocellular carcinoma (PHC) after 20 or more years. The course of the disease is followed by detection of viral proteins and serology. The presence of the HBsAg with another viral antigen, HBeAg, is indicative of active disease and virus production, while just HBsAg can indicate chronic disease. Antibodies to HBsAg (anti-HBsAg) are detectable only after HBsAg disappears from the blood and indicates resolution of infection or a vaccinated individual. IgM for the HBcAg (capsid antigen) indicates recent infection and may be present after HBsAg ceases to be produced but before anti-HBsAg can be detected ("the window"). HBV is transmitted in blood, semen, vaginal secretions, and saliva. Antiviral drugs target the viral reverse transcriptase polymerase and include lamivudine, entecavir, tenofovir, adefovir dipivoxil, and telbivudine. The HBV vaccine consists of virus-like particles that form from the HBsAg. Originally, the vaccine was purified from the blood of chronic carriers of the disease but is now prepared by genetic engineering. In addition

to reducing the incidence of hepatitis, vaccination also reduces the risk for PHC.

Hepatitis D virus (HDV) is somewhat of a parasite of hepatitis B virus. HDV can only replicate in HBV-infected cells and the HDV RNA genome is packaged in HBV envelopes. HDV exacerbates HBV disease, promoting fulminant hepatitis and cirrhosis.

Prions

Prions, by definition, are infectious proteins and not really viruses. The prion protein, called PrP^{SC}, is a structural variant of a normal and natural cell surface protein (101). Binding of the prion protein to the natural analog changes its configuration to resemble the prion protein, adds it to the aggregate to extend the prion structure. Prions are very resistant to inactivation by detergents, disinfectants, heat, autoclaving, and irradiation. Prions cause spongiform encephalopathies, including Creutzfeldt-Jakob disease (CJD), Kuru, Gerstmann-Straussler-Scheinker syndrome, and fatal familial insomnia, which can be infectious or inheritable diseases. CJD has an incubation period that could last for decades prior to the onset of a progressive degenerative neurologic disease. A variant CJD (vCJD) has a more rapid onset. After a long incubation period, the spongiform encephalopathies are characterized by a loss of muscle control, shivering, myoclonic jerks, and tremors, rapidly progressive dementia, and death. Prions are very difficult to detect, but an assay has been developed (102). There is no vaccine or treatment other than supportive care for these diseases.

Introduction

Emerging viruses are classified as those viruses that are new to human hosts, rising significantly in incidence, or have established endemicity in a new geographic location. In contrast, re-emerging viruses are those that were largely controlled and whose incidence is rising again. Emerging viruses that are of primary concern to human health, as of this writing, belong to a relatively small number of viral taxa, and almost exclusively feature RNA genomes. This chapter aims to introduce general principles that drive viral emergence, identify several prominent emerging viruses (Table 50.1) and note their clinical presentations (Table 50.2), recommended treatment and control (Table 50.3), diagnostic approaches and recommendations, competent transmission vectors (Table 50.4), synonyms and diagnostic codes (Table 50.5), and geographic distributions (Figures 50.1–50.13). This chapter will only briefly discuss re-emerging diseases (Table 50.6) and will defer discussions of novel pandemic influenza virus strains and human immunodeficiency virus (HIV) to more specialized resources due to the depth and broad scope of these topics. We have also declined to include additional viruses that are at times included in the category of emerging viruses due to either their current global ubiquity and disease burden following re-emergence (e.g., dengue virus) or the ambiguity surrounding their causal role in disease outbreaks (e.g., Bas-Congo virus, Bornavirus) [1, 2].

Principles and Drivers of Virus Emergence

New, emerging, and re-emerging viruses are a perpetual threat to human health. Since the dawn of recorded history, there have been records of sudden and unexpected plagues, some of which recede just as suddenly and some of which continue to circulate quietly, with sudden outbreaks recurring every so often [3, 4]. The overwhelming majority of emerging viruses are zoonotic, meaning they are existing viruses of animals that are introduced into the human population or develop the capacity to infect humans [5]. The circumstances of emergence for each virus are somewhat unique, but there are several features that are common to the phenomenon.

Disease ecology, a collective consideration of the intersections between host, pathogen, and environment, has shown to be a very useful framework around which to consider emerging pathogens. Emergence or re-emergence of viruses often feature changes to the environment of humans, viruses and their reservoirs and/or vectors, or some combination thereof [6]. Notable examples of such changes include the expansion of building and construction, shifting ecologies due to climate change, population density, wildlife and livestock densities, and sanitation. These factors often intersect and amplify each other. For example, rapid development of a country on the edges of historical climate zones would lead to extensive construction, which can create sources of standing water, lead to deforestation, or disrupt watersheds or habitats in ways that displace wildlife that reservoir and/or transmit human-pathogenic viruses. The subsequent increase in the human and livestock densities, perhaps in the absence of strict regulatory controls, can lead to increased travel and transit to other parts of the world, which, in turn, can promote the introduction of foreign arthropod vectors from neighboring climate zone. These actions can lead to increases in populations of arthropod vectors, allow the introduction of vectors previously not present to the area, bring humans into closer contact with animals, or a combination thereof. Surveillance for, and prediction of, disease emergence is best performed by integrating wildlife carriage, vector distribution, wildlife/livestock interactions, and human infection incidence.

Many viruses are biologically primed to evolve more rapidly than their hosts, and viruses that emerge in new hosts often undergo a period of rapid diversification as they adapt to their new habitat. Such viruses often encode their own polymerases with poor or absent proofreading capacity, resulting in high rates of nucleic acid substitutions. While these error-prone polymerases often result in replication inefficiencies because lethal mutations can occur, their overall contribution to fitness for many

TABLE 50.1

Notable Emerging Viruses

Virus	Abbrev.	Genus	Family	Reservoir Species[a]
Alkhurma (aka Alkhumra) virus	ALKV	*Flavivirus*	*Flaviviridae*	Ruminants
Andes virus	ANDV	*Orthohantavirus*	*Hantaviridae*	Rodents
Banna virus	BFV	*Coltivirus*	*Reoviridae*	Livestock
Barmah Forest virus	BAV	*Alphavirus*	*Togaviridae*	Marsupials
Bayou virus	BAYV	*Orthohantavirus*	*Hantaviridae*	Rodents
Black Creek Canal virus	BCCV	*Orthohantavirus*	*Hantaviridae*	Rodents
Bourbon virus	BRBV	*Thogotovirus*	*Orthomyxoviridae*	Cervids; procyons
Bundibugyo virus	BDBV	*Ebolavirus*	*Filoviridae*	Bats (?)
Chikungunya virus	CHIKV	*Alphavirus*	*Togaviridae*	NHPs; bats
Colorado tick fever virus	CTFV	*Coltivirus*	*Reoviridae*	Small mammals
Crimean-Congo hemorrhagic fever virus	CCHFV	*Orthonairovirus*	*Nairoviridae*	Livestock; artiodactyls
Dobrava virus[b]	DOBV	*Orthohantavirus*	*Hantaviridae*	Rodents
Eastern equine encephalitis virus	EEEV	*Alphavirus*	*Togaviridae*	Birds
Ebola virus	EBOV	*Filovirus*	*Filoviridae*	Bats (?)
Eyach virus	EYAV	*Coltivirus*	*Reoviridae*	Rodents
Hantaan virus	HTNV	*Orthohantavirus*	*Hantaviridae*	Rodents
Heartland virus	HRTV	*Phlebovirus*	*Phenuiviridae*	Cervids; procyons
Hendra virus	HEV	*Henipavirus*	*Paramyxoviridae*	Bats
Jamestown Canyon virus	JCV	*Orthobunyavirus*	*Peribunyaviridae*	Cervids
Japanese encephalitis virus	JEV	*Flavivirus*	*Flaviviridae*	Birds
Junin virus[b]	JUNV	*Mammarenavirus*	*Arenaviridae*	Rodents
Kyasanur Forest disease virus	KFDV	*Flavivirus*	*Flaviviridae*	NHPs
La Crosse encephalitis virus	LACV	*Orthobunyavirus*	*Peribunyaviridae*	Sciurids
Lassa virus	LASV	*Mammarenavirus*	*Arenaviridae*	Rodents
Lujo virus	LUJV	*Mammarenavirus*	*Arenaviridae*	Unconfirmed
Machupo virus	MACV	*Mammarenavirus*	*Arenaviridae*	Rodents
Marburg virus	MARV	*Marburgvirus*	*Filoviridae*	Bats
Mayaro virus	MAYV	*Alphavirus*	*Togaviridae*	NHPs
Middle East respiratory syndrome coronavirus	MERS-CoV	*Betacoronavirus*	*Coronaviridae*	Bats
Monkeypox virus	MPV	*Orthopoxvirus*	*Poxviridae*	Mammals
Monongahela virus	MGLV	*Orthohantavirus*	*Hantaviridae*	Rodents
Murray Valley encephalitis virus	MVEV	*Flavivirus*	*Flaviviridae*	Birds
Nipah virus	NIV	*Henipavirus*	*Paramyxoviridae*	Bats
O'nyong'nyong virus	ONNV	*Alphavirus*	*Togaviridae*	Unknown
Orf virus	ORFV	*Parapoxvirus*	*Poxviridae*	Ruminants
Oropouche virus	OROV	*Orthobunyavirus*	*Peribunyaviridae*	NHPs; birds; rodents
Powassan virus	POWV	*Flavivirus*	*Flaviviridae*	Birds
Puumala virus	PUUV	*Orthohantavirus*	*Hantaviridae*	Rodents
Rift Valley fever virus	RVFV	*Phlebovirus*	*Phenuiviridae*	Mammals
Ross River encephalitis virus	RRV	*Alphavirus*	*Togaviridae*	Mammals; birds
Saaremaa virus	SAAV	*Orthohantavirus*	*Hantaviridae*	Rodents
Saint Louis encephalitis virus	SLEV	*Flavivirus*	*Flaviviridae*	Birds
Seoul virus	SEOV	*Orthohantavirus*	*Hantaviridae*	Rodents
Severe acute respiratory syndrome coronavirus	SARS-CoV	*Betacoronavirus*	*Coronaviridae*	Bats
Sever acute respiratory syndrome coronavirus 2	SARS-CoV-2	Betacoronavirus	Coronaviridae	Bats
Severe fever with thrombocytopenia syndrome virus.[b]	SFTSV	*Banyangvirus*	*Phenuiviridae*	Livestock; rodents
Sin Nombre virus[b]	SNV	*Orthohantavirus*	*Hantaviridae*	Rodents

TABLE 50.1 ***(Continued)***

Notable Emerging Viruses

Virus	Abbrev.	Genus	Family	Reservoir Species[a]
Sudan virus	SUDV	*Ebolavirus*	*Filoviridae*	Bats
Tai Forest virus	TAFV	*Ebolavirus*	*Filoviridae*	Bats
Tick-borne encephalitis virus	TBEV	*Flavivirus*	*Flaviviridae*	Rodents
Usutu virus	USUV	*Flavivirus*	*Flaviviridae*	Birds
Venezuelan equine encephalitis virus	VEEV	*Alphavirus*	*Togaviridae*	Rodents
West Nile virus	WNV	*Flavivirus*	*Flaviviridae*	Birds
Western equine encephalitis virus	WEEV	*Alphavirus*	*Togaviridae*	Birds
Yellow fever virus[c]	YFV	*Flavivirus*	*Flaviviridae*	NHPs
Zika virus	ZIKV	*Flavivirus*	*Flaviviridae*	NHPs

[a] Reservoir species listed are the primary source of infection; "NHP" = nonhuman primate.
[b] Taxonomic revisions are as follows: New York virus has been reclassified as a variant of Sin Nombre virus (SNV).
[c] YFV is endemic in several parts of Africa, but is considered an emerging/re-emerging disease in parts of the Western Hemisphere.

TABLE 50.2

Clinical Presentations Associated with Emerging Viruses[a]

[a] *Abbreviations*: C – cough; D – diarrhea; E – elevated liver enzymes; H – hematuria; HCPS – Hantavirus cardiopulmonary syndrome; HFRS – hemorrhagic fever with renal syndrome; HPS – hantavirus pulmonary syndrome; J – jaundice; MBFM – morbilliform; MP – maculopapular; N – nausea; P – popular; PET – petechial; RDS – respiratory distress syndrome; TTP – thrombocytopenia; V – vomiting; VES – vesicular; VHF – viral hemorrhagic fever

[b] Mortality classifications: LOW = 0–1%; MODERATE = 2–10%; HIGH = >10%.

[c] Mortality is high in patients presenting with encephalitis, but low in patients presenting subclinically or with mild febrile illness.

[d] Mortality is low in pregnant women but high in developing fetuses, leading to stillbirth or spontaneous abortion.

TABLE 50.3

Emerging Viruses, Disease Names, and Clinical Interventions

Virus	Common Disease Name	Treatment	Vaccine Available?
ALKV	Alkhurma hemorrhagic fever	Supportive care	NO
ANDV	Hantavirus pulmonary syndrome	Supportive care	NO
BAV	Banna virus encephalitis	Supportive care	NO
BAYV	Hantavirus pulmonary syndrome	Supportive care	NO
BCCV	Hantavirus pulmonary syndrome	Supportive care	NO
BDBV	Ebola virus disease	Supportive care; mABs	NO[a]
BFD	Barmah Forest disease	Supportive care	NO
BRBV	Bourbon virus disease	Supportive care	NO
CHIKV	Chikungunya	Supportive care	NO
CCHFV	Crimean-Congo hemorrhagic fever	Supportive care, ribavirin?	NO

USUV	Usutu fever	Supportive care	NO
VEEV	Venezuelan equine encephalomyelitis	Supportive care	NO
WNV	West Nile fever; West Nile encephalitis	Supportive care	NO
WEEV	Western equine encephalomyelitis	Supportive care	NO
YFV	Yellow fever	Supportive care	YES (17D; YF-VAX)
ZIKV	Zika virus disease; Zika congenital syndrome	Supportive care*	NO

[a] The VSV-EBOV vaccine may provide cross-protection.
[b] The Candid#1 JUNV vaccine may provide cross-protection.
[c] An efficacious veterinary vaccine is available against RVFV, which has not be utilized in humans.

TABLE 50.4

Major[a] Competent Vectors for Emerging Viruses

Arthropod Vector	Type[b]	Viruses Transmitted	Geographic Distribution
Aedes aegypti	M	CHIKV, ZIKV, MAYV, YFV	Tropics worldwide
Aedes albopictus	M	CHIKV, ZIKV, WNV, USUV, YFV	Rethink
Aedes africanus	M	CHIKV, YFV, WNV, RVFV	Africa
Aedes camptorhynchus	M	RRV, BFV	Australia
Aedes furcifer-taylori	M	CHIKV	Africa
Aedes luteocephalus	M	CHIKV, YFV	Africa
Aedes mcintoshi	M	RVFV	Africa
Aedes notoscriptus	M	RRV	Australia, USA (West Coast)
Aedes normanensis	M	BFV	Australia
Aedes ochraceus	M	RVFV	Africa
Aedes triseriatus	M	LACV	USA, Canada
Aedes vigilax	M	RRV, BFV	Australia
Amblyomma americanum	T	BRBV, HRTV	USA (East, Midwest)
Anopheles funestus	M	ONNV	Africa
Anopheles gambiae	M	ONNV	Africa
Anopheles punctipennis	M	JCV	North America
Coquillettidia perturbans	M	JCV, EEEV, WNV, BFV	Worldwide
Coquillettidia venezuelensis	M	OROV	South America, Central America
Culex annulirostris	M	RRV, MVEV	Australia
Culex annulus	M	BAV	Southeast Asia
Culex pipiens	M	WNV, LACV, RVFV, USUV	Worldwide
Culex quinquefasciatus	M	OROV, WNV, SLEV, WEEV	Tropics/subtropics worldwide
Culex tarsalis	M	WNV, WEEV,	North America
Culex tritaeniorhynchus	M	JEV, BAV	Eastern Hemisphere
Culicoides paraensis	Mi	OROV	Western Hemisphere
Culiseta melanura	M	EEEV, WEEV	North America
Dermacentor andersoni	T	CTFV	Western North America
Haemagogus janthinomys	M	MAYV, YFV	South America
Haemaphysalis spinigera	T	KFDV	India, Sri Lanka, Vietnam
Haemaphysalis longicornis	T	POWV	Central/East Asia, Australia
Hyalomma anatolicum	T	CCHFV	Central Asia, Southern Europe
Hyalomma asiaticum	T	CCHFV	Middle East
Hyalomma marginatum	T	CCHFV	Southern Europe, North Africa
Hyalomma rufipes	T	CCHFV, ALKV	Southern Europe, Africa
Ixodes cookie	T	POWV	USA, Eastern Canada
Ixodes ovatus	T	TBEV	Southeast Asia
Ixodes persulcatus	T	TBEV	Europe, Asia
Ixodes ricinus	T	TBEV, EYAV	Europe
Ixodes scapularis	T	POWV	USA (East), Canada (Southeast)
Ochlerotatus abserratus	M	JCV	USA
Ochlerotatus canadensis	M	JCV, EEEV	Eastern North America
Ochlerotatus cantator	M	JCV	Canada (East), USA (Northeast)
Ornithodoros savignyi	T	ALKV	Africa, Asia
Sabethes chloropterus	M	YFV, SLEV	South America, Central America

[a] Vectors showing transmission under experimental settings are not included.

[b] *Vector abbreviations:* M = mosquito; Mi = mite; T = tick.

TABLE 50.5

Diagnostic Codes and Synonyms

Virus	ICD9	ICD10	Synonyms
ALKV	063.8	A98.8	Alkhurma disease; Fakeeh; Kadam
ANDV	078.89	B33.4	Hantavirus respiratory distress syndrome; Hantavirus cardiopulmonary syndrome

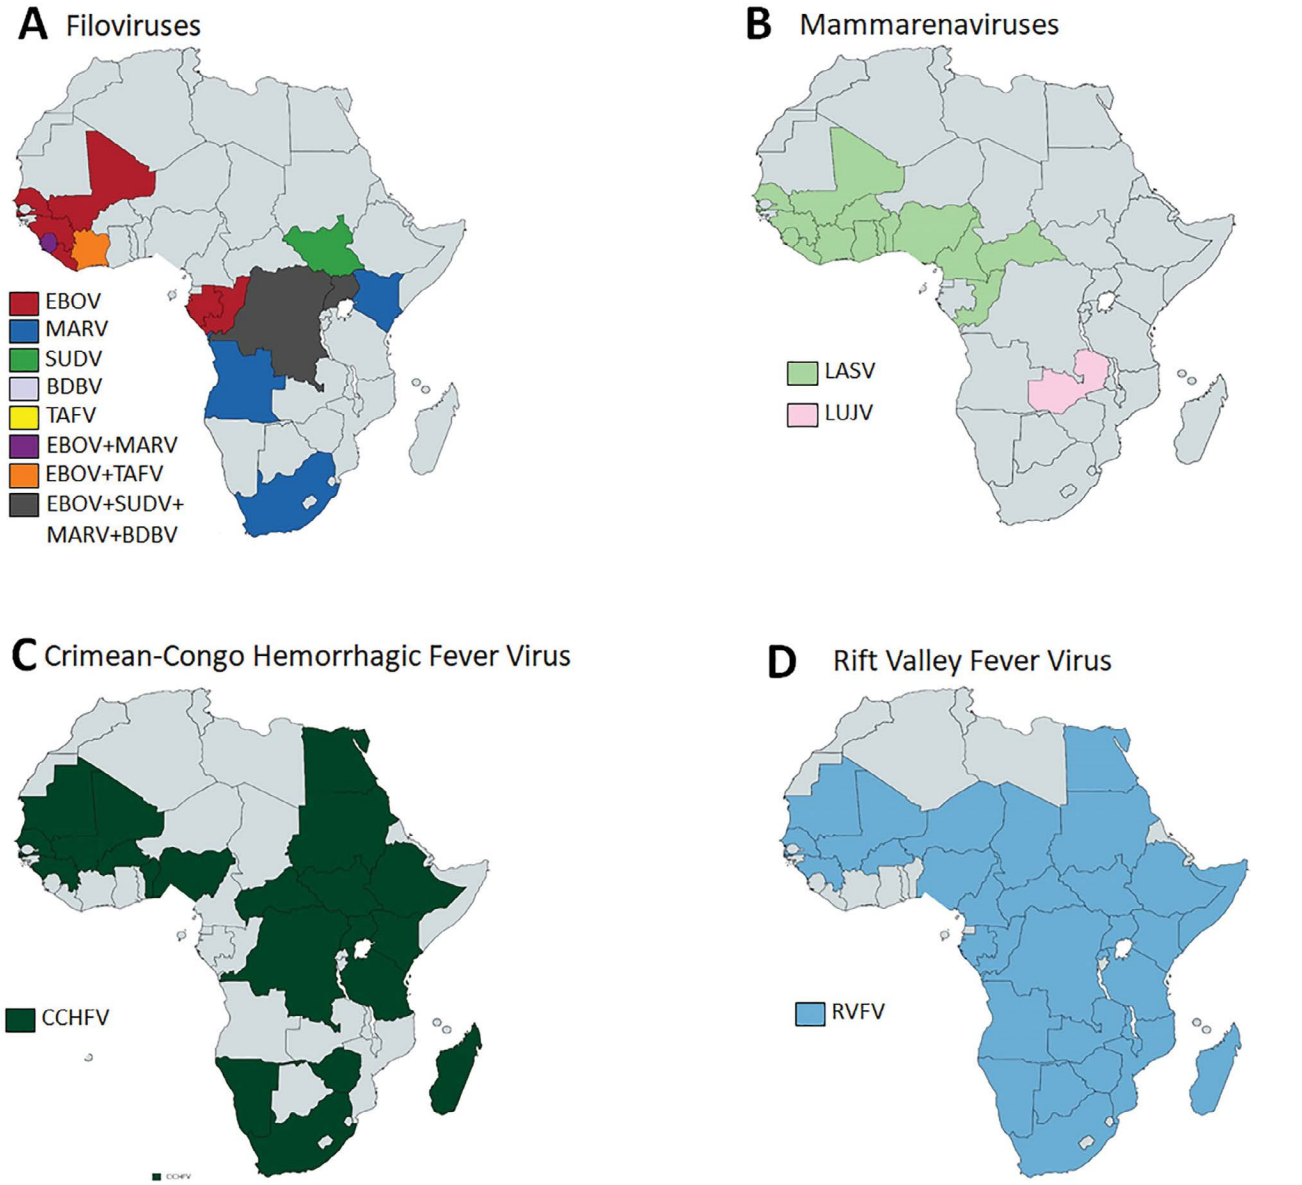

FIGURE 50.1 Emerging hemorrhagic fever viruses in Africa. Filoviruses (Panel A) are colored as follows: red (EBOV), blue (MARV), green (SUDV), purple (EBOV and MARV), orange (EBOV and TAFV), and dark gray (SUDV, EBOV, MARV, and BDBV). Mammarenaviruses (Panel B) are colored as follows: light green (LASV) and pink (LUJV). Crimean-Congo hemorrhagic fever virus distribution (Panel C) is shown in dark green, and Rift Valley fever virus distribution (Panel D) is shown in light blue.

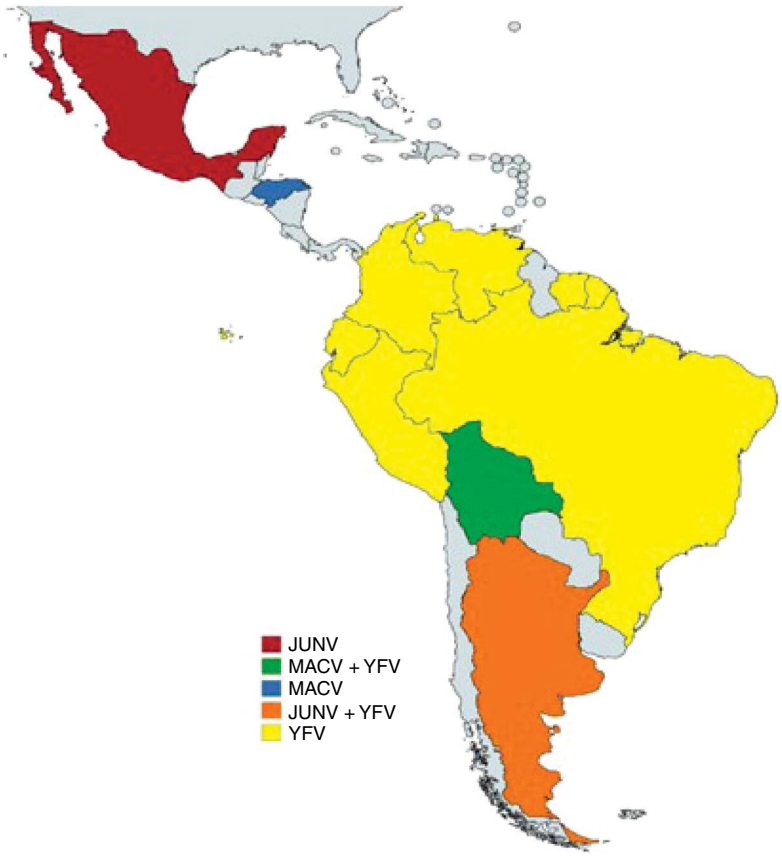

FIGURE 50.2 Emerging hemorrhagic fever viruses in the Americas. Viral distributions are shown by color coding as follows: red (JUNV), blue (MACV), yellow (YFV), green (MACV and YFV), and orange (JUNV and YFV).

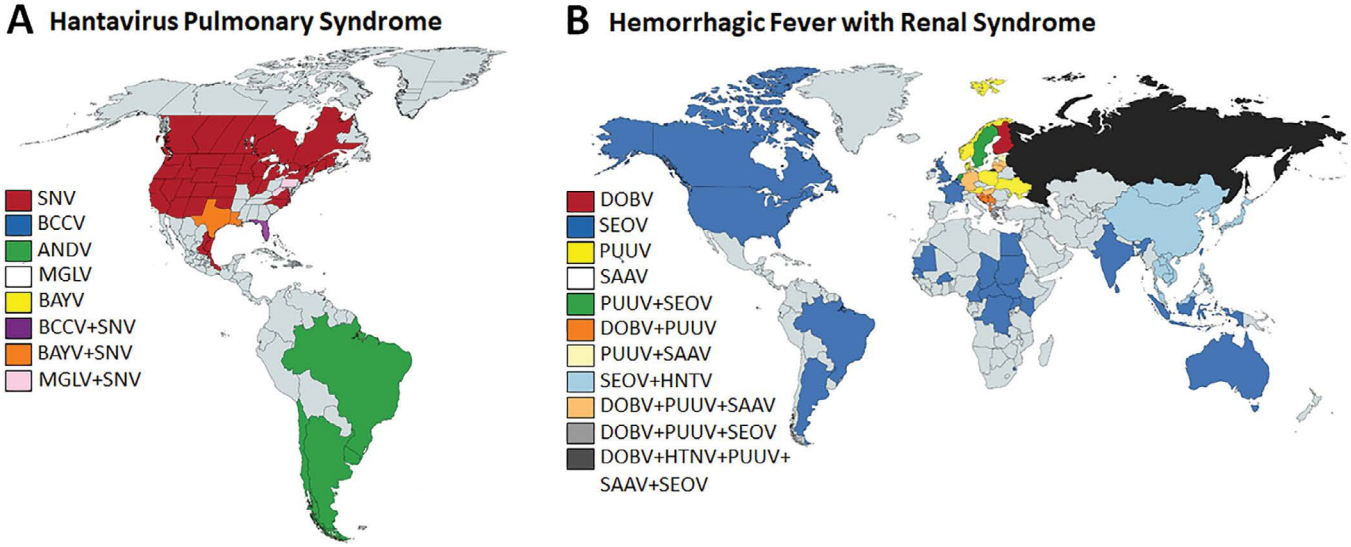

FIGURE 50.3 Global distribution of hantaviruses. Viruses causing hantavirus pulmonary syndrome (Panel A) are colored as follows: red (SNV), green (ANDV), orange (BAYV and SNV), purple (BCCV and SNV), and pink (MGLV and SNV). Viruses causing hemorrhagic fever with renal syndrome (Panel B) are colored as follows: blue (SEOV), red (DOBV), yellow (PUUV), white (SAAV), orange (DOBV and PUUV), pink (DOV and SAAV), light yellow (PUUV and SAAV), green (PUUV and SEOV), light blue (PUUV and SAAV), light orange (DOBV, PUUV, and SAAV), light gray (DOBV, PUUV, and SEOV), and dark gray (DOBV, HTNV, PUUV, SAAV, and SEOV).

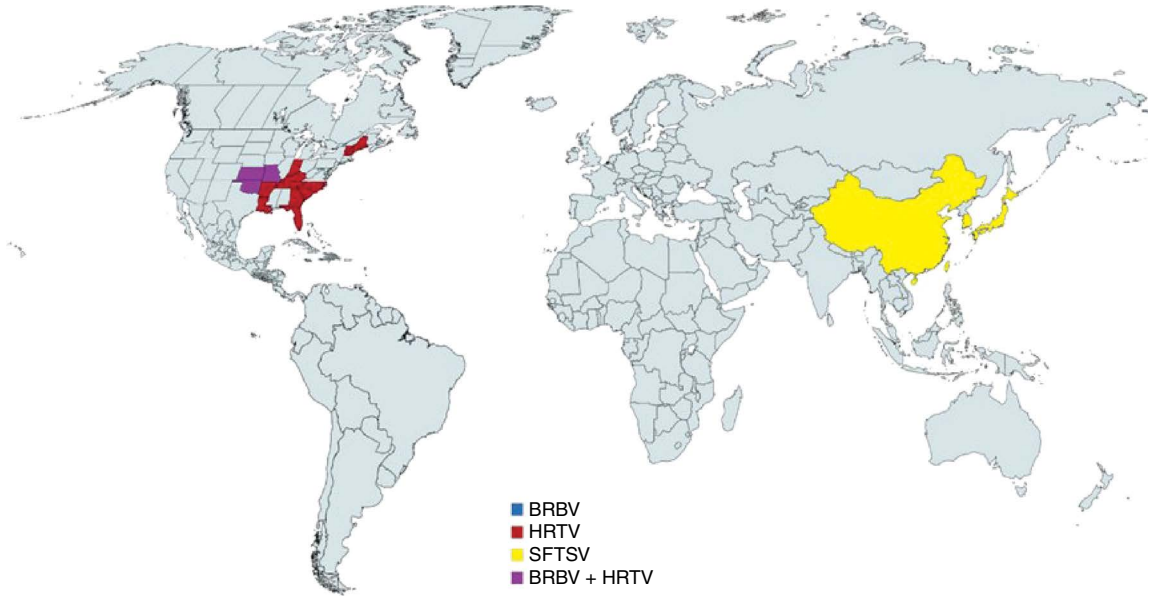

FIGURE 50.4 Emerging viral causes of febrile thrombocytopenia. Viral distributions are shown by color coding as follows: red (HRTV), yellow (SFTSV), and purple (HRTV and BRBV).

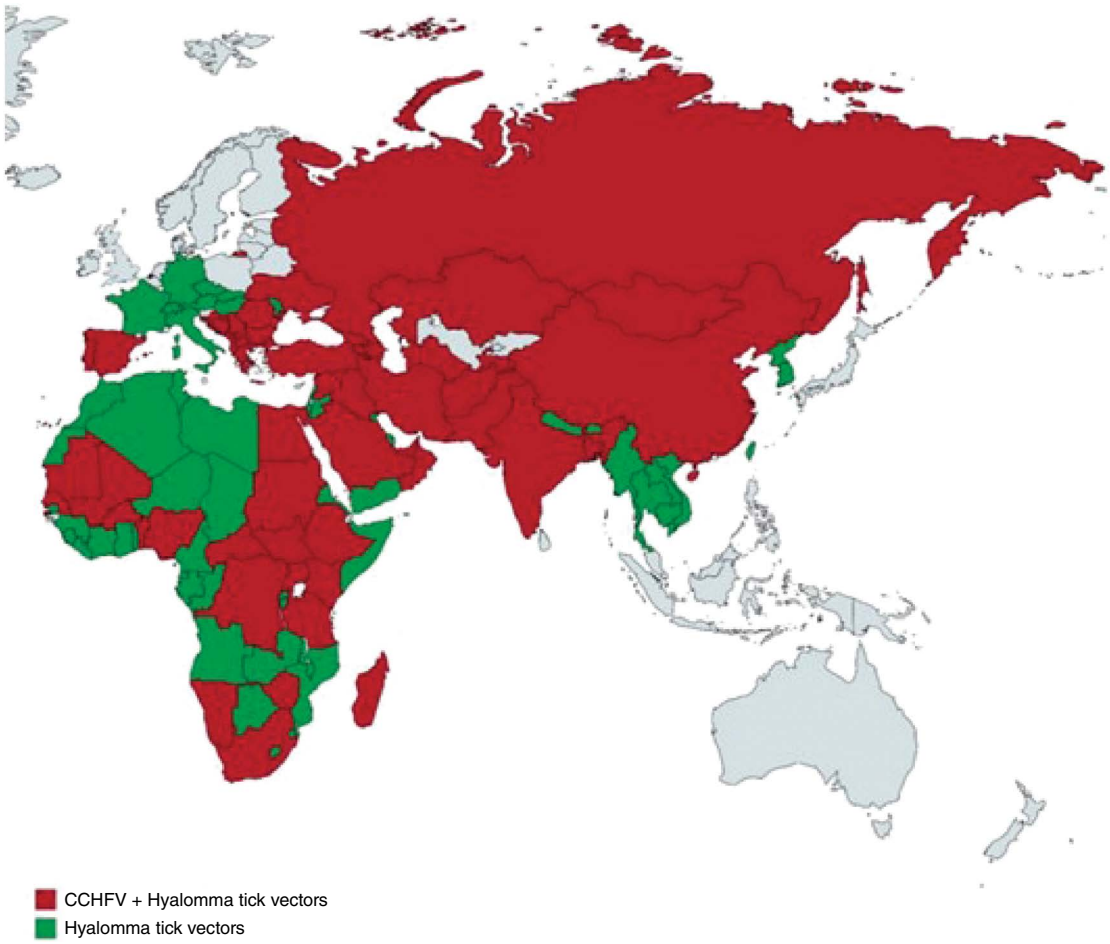

FIGURE 50.5 Crimean-Congo hemorrhagic fever virus activity and vector distribution. The distribution of CCHFV and *Hyalomma* tick vectors are shown in red, and areas with *Hyalomma* ticks where autochthonous transmission of CCHFV has not been documented are shown in green. Green areas should be considered potential sites of future CCHFV activity.

TABLE 50.6

Notable Re-Emerging Viruses

Virus	Abbreviation	Disease	Drivers of Re-Emergence
Rubeola virus	MV	Measles	Vaccine coverage; international travel
Rubula virus	MuV	Mumps	Vaccine escape; vaccine coverage
Yellow fever virus	YFV	Yellow fever	Primate ecology; vector control; vaccine coverage
Rubella virus	RuV	Rubella/CRS (?)	Vaccine coverage; international travel
Dengue virus	DENV	DF/DHF	Population growth; urbanization; vector control

viruses is clear. Additional diversity can be rapidly achieved by genome reassortment for segmented viruses, many of which fall into the category of emerging viruses (Table 50.7). Both point mutations and genome segment reassortment can produce viral variants with novel abilities to interact with different tissues, new hosts, or new vectors, allow viruses to escape immune responses raised against parallel strains, and, arguably, to escape clinical interventions that curb transmission such as vaccines or diagnostic tests [2, 5, 7].

Spectrum of Disease Presentation, Diagnostic Approaches, Treatment, and Prevention Strategies

Many emerging and re-emerging human-pathogenic viruses cause acute febrile disease processes that exhibit overlapping clinical signs and symptoms. In general, arthropod-borne viruses (arboviruses) cause disseminated diseases that are characterized either by a nonspecific prodrome accompanied by rash, arthralgia, myalgia, malaise, and/or gastrointestinal symptoms. Meningitis and/or encephalitis are not infrequent complications of infection with some arboviruses, including members of the genera *Alphavirus*, *Orthobunyavirus*, and *Phlebovirus*. Infection with the same or other arboviruses can cause severe organ disease (*e.g.*, hepatitis) and systemic infections characterized by coagulopathy that can lead to bleeding diatheses; this syndrome is referred to as viral hemorrhagic fever. Arboviruses associated with systemic diseases accompanied by coagulopathy or hemorrhagic fever include members of the genera *Banyangvirus*, *Flavivirus*, *Orthonairovirus*, *Phlebovirus*, and *Thogotovirus*. Specific viruses and their associated disease presentations are given in Tables 50.1 and 50.2 and arthropod vectors are listed in Table 50.4.

Many emerging and re-emerging nonarthropod-borne zoonotic viruses cause diseases similar to those caused by arboviruses.

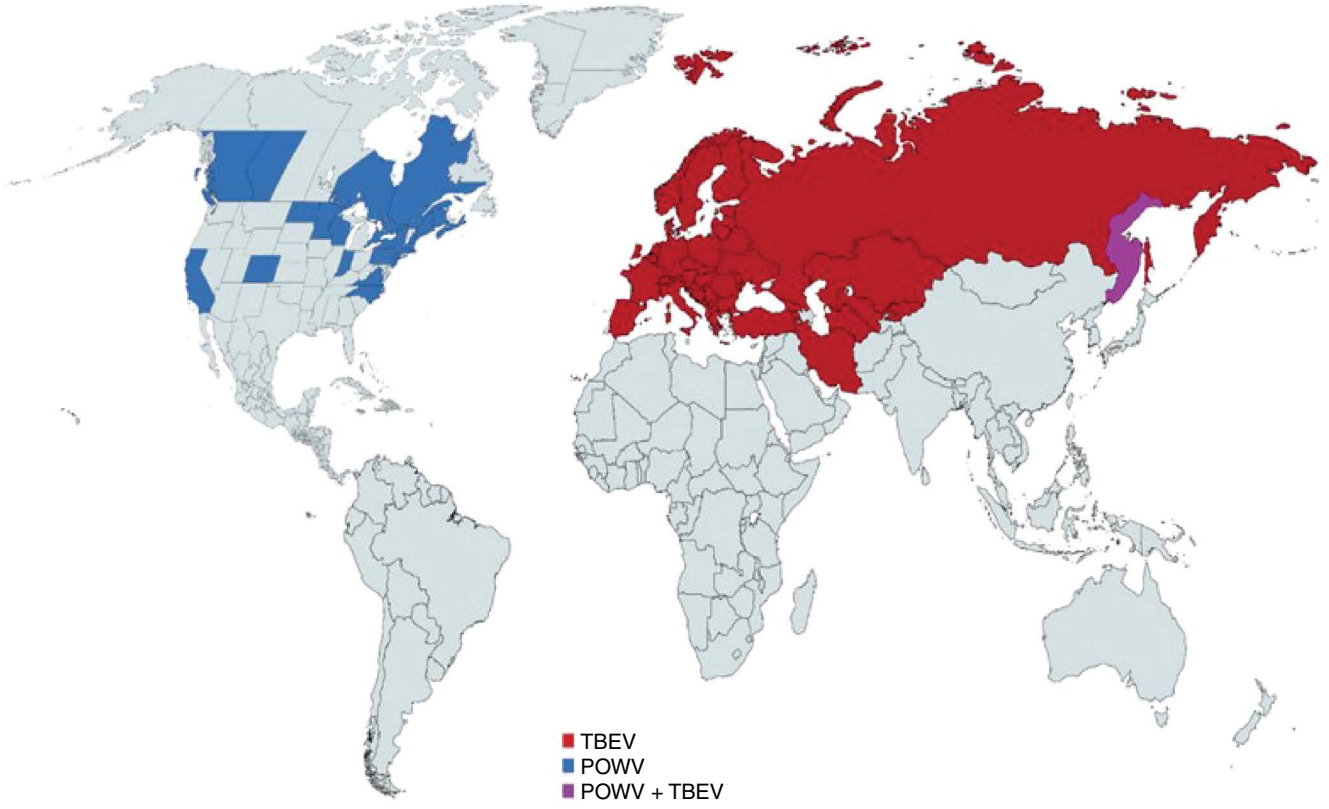

FIGURE 50.6 Emerging tick-borne viral encephalitides. Viral distributions are shown by color coding as follows: red (TBEV), blue (POWV), and purple (TBEV and POWV).

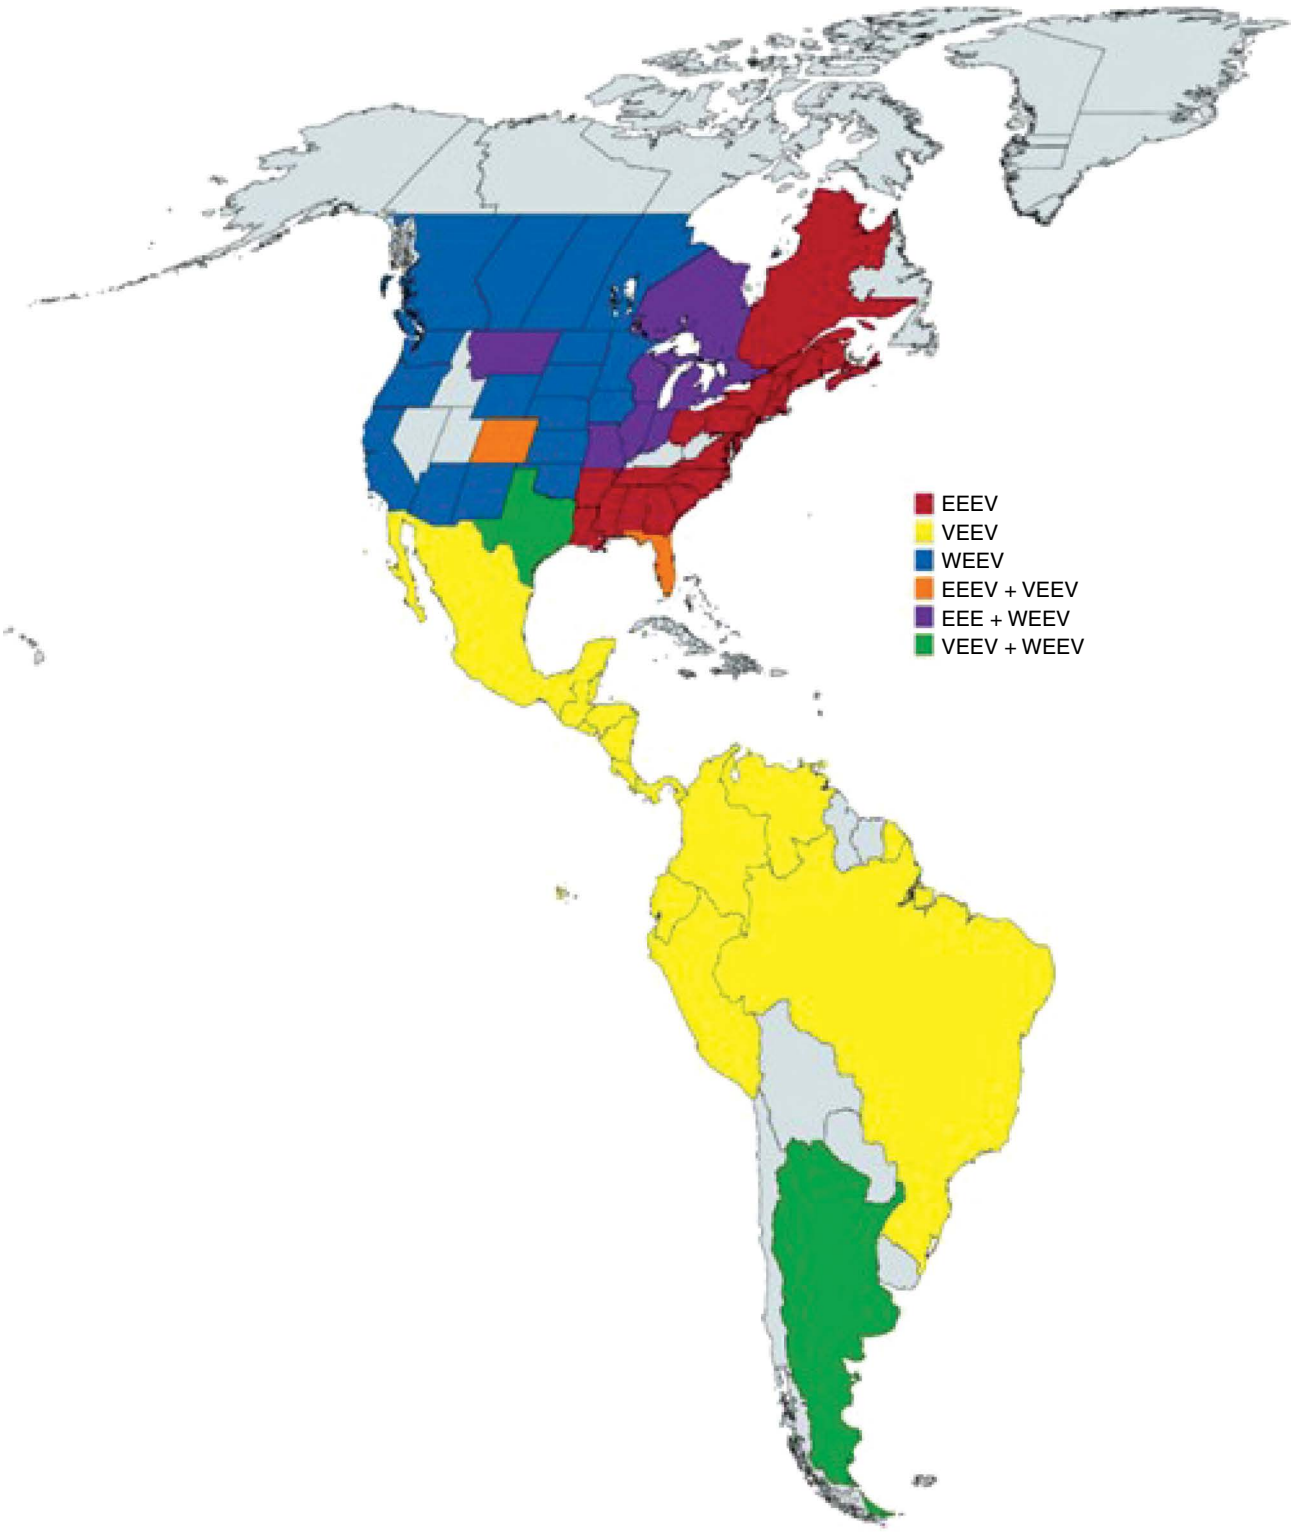

FIGURE 50.7 Equine encephalitis viruses. Viral distributions are shown by color coding as follows: red (EEEV), blue (WEEV), yellow (VEEV), green (VEEV and WEEV), orange (EEEV and VEEV), and purple (EEEV and WEEV).

In addition, some of these viruses cause severe respiratory disease that, depending upon the virus, may be followed by invasive and often fatal central nervous system disease. Rodent-borne viruses, primarily members of the genera *Mammarenavirus* and *Orthohantavirus*, are frequently implicated in outbreaks of hemorrhagic fever, hemorrhagic fever with renal syndrome, or cardiopulmonary disease. Viruses reservoired by bats that are either directly transmitted from bats to humans or are indirectly transmitted from bats to humans through one or more other animal hosts are among the deadliest viruses known.

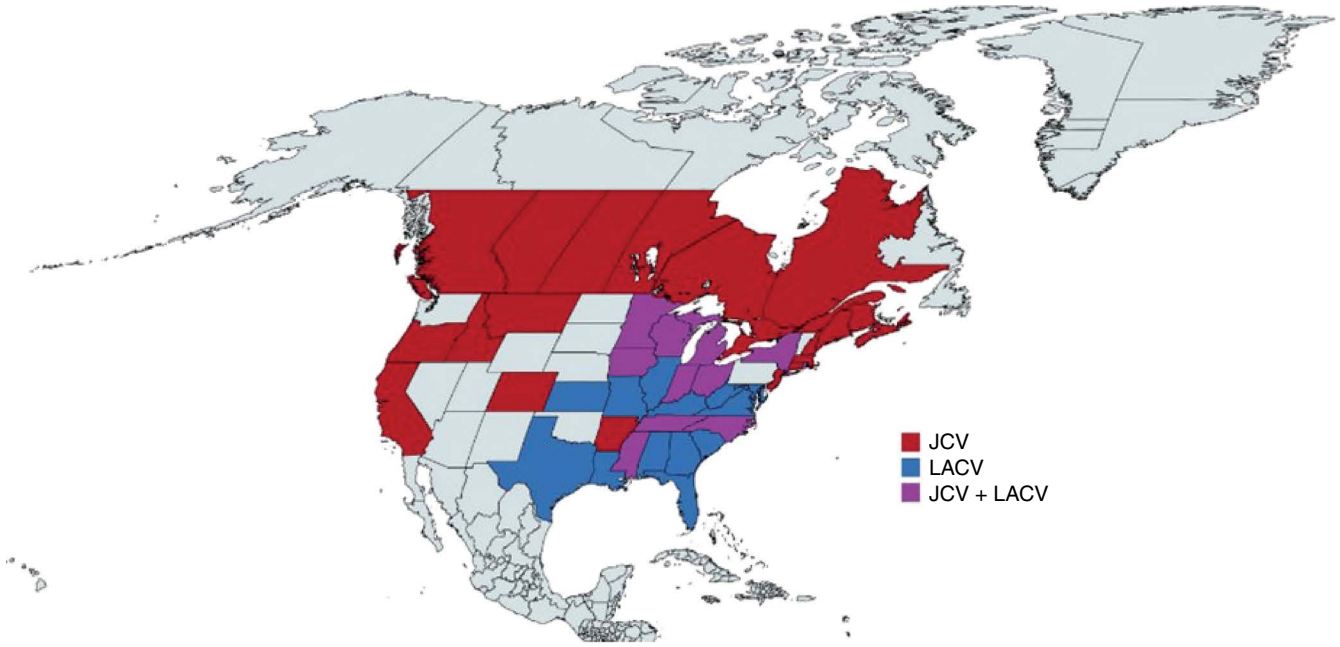

FIGURE 50.8 Distribution of California serogroup viruses. Viral distributions are shown by color coding as follows: red (JCV), blue (LACV), and purple (JCV and LACV).

Four members of the genus *Ebolavirus,* family *Filoviridae* (e.g., Bundibugyo virus, Ebola virus, Sudan virus, and Tai Forest virus), which are believed to be carried by Old World fruit bats, cause severe human systemic infections that can progress to hemorrhagic fever and often death. These viruses are also highly contagious, so large outbreaks associated with single-index cases are not uncommon [8]. Infection caused by the related filovirus Marburg virus (genus *Marburgvirus*) shares disease symptomatology, ecology, epidemiology, and transmission dynamics with ebolaviruses, and case fatality rates can also be quite high (up to ˜90% in some outbreaks) [9].

Two species comprising the genus *Henipavirus* (Hendra virus and Nipah virus) are the causative agents of severe respiratory and central nervous system diseases (encephalitis); Nipah virus is frequently associated with outbreaks in Bangladesh and India [10]. Case fatality rates with Nipah and Hendra viruses range from 40–90% [11]. These two viruses are carried by large fruit bats belonging to the genus *Pteropus*, which are commonly

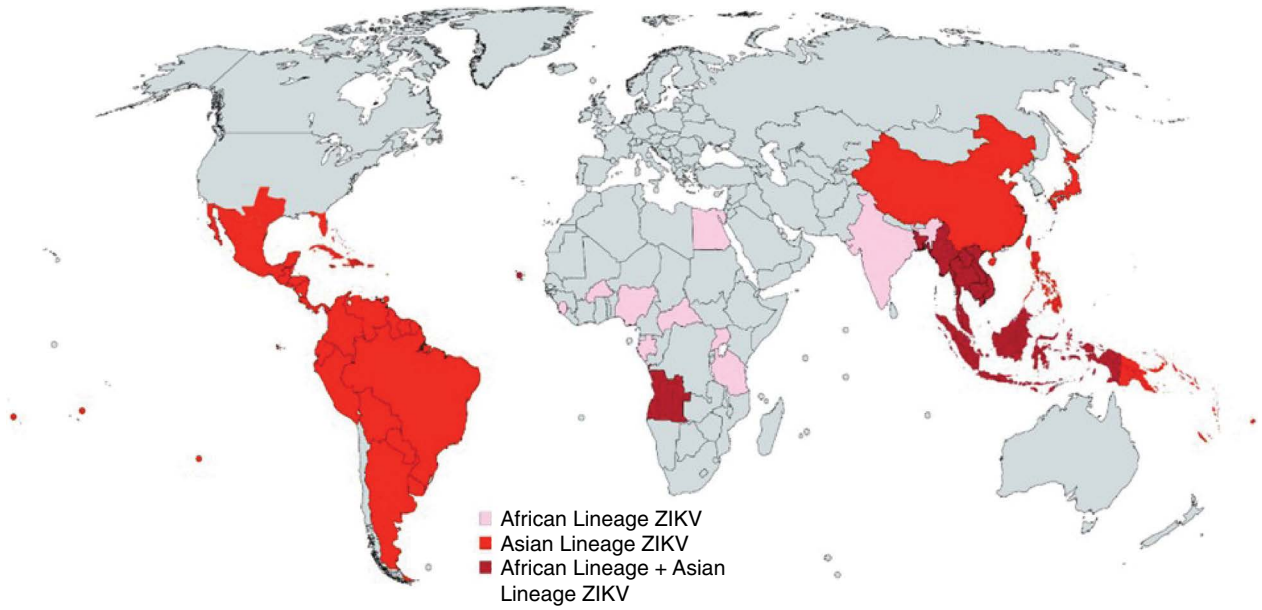

FIGURE 50.9 Zika virus distribution by lineage. The distributions of African lineage, Asian lineage, and both African and Asian lineage ZIKV strains are shown in pink, orange, and red, respectively.

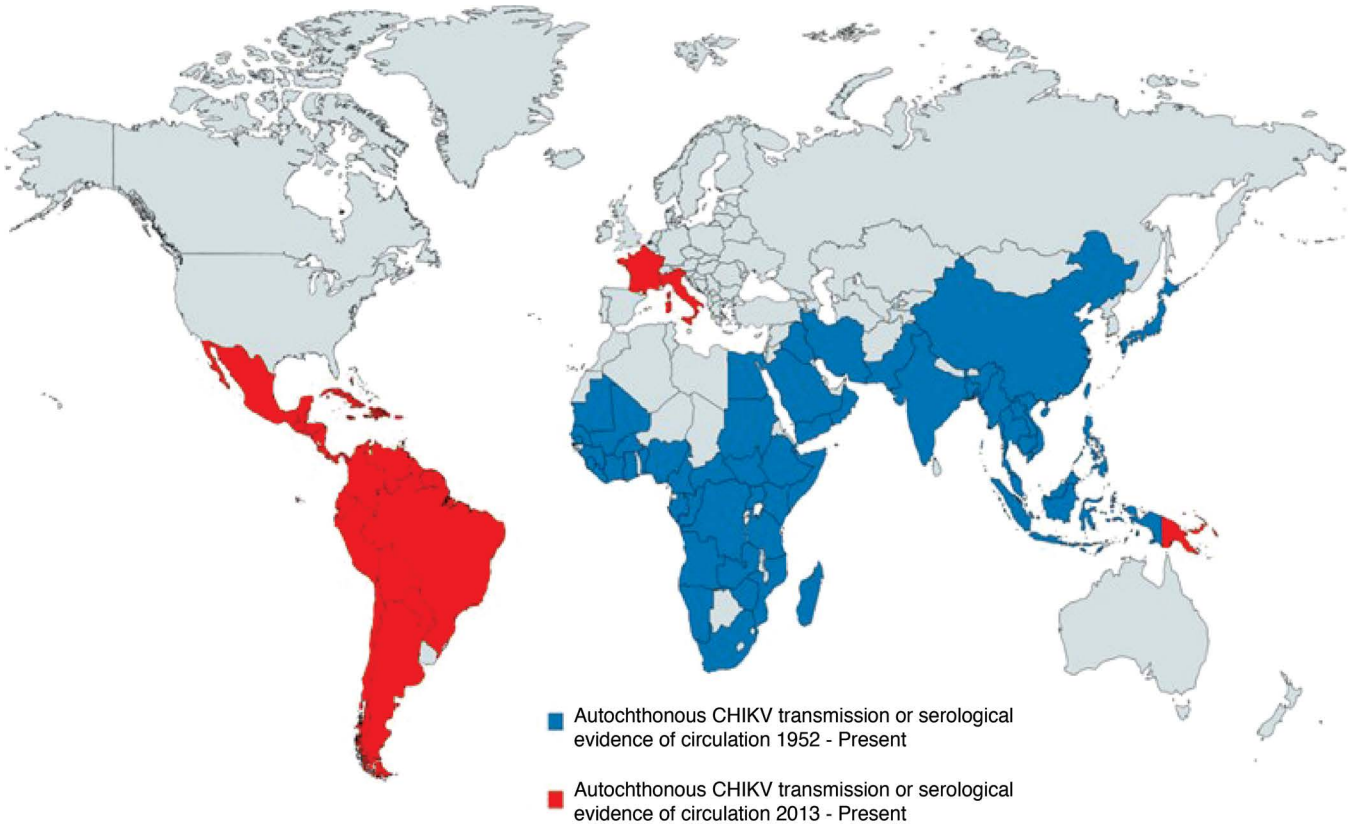

FIGURE 50.10 Global chikungunya distribution. Areas with autochthonous transmission of CHIKV as early as 1952 are shown in blue, whereas areas with local transmission beginning in 2013 are shown in orange. All shaded areas continue to have CHIKV activity at this time.

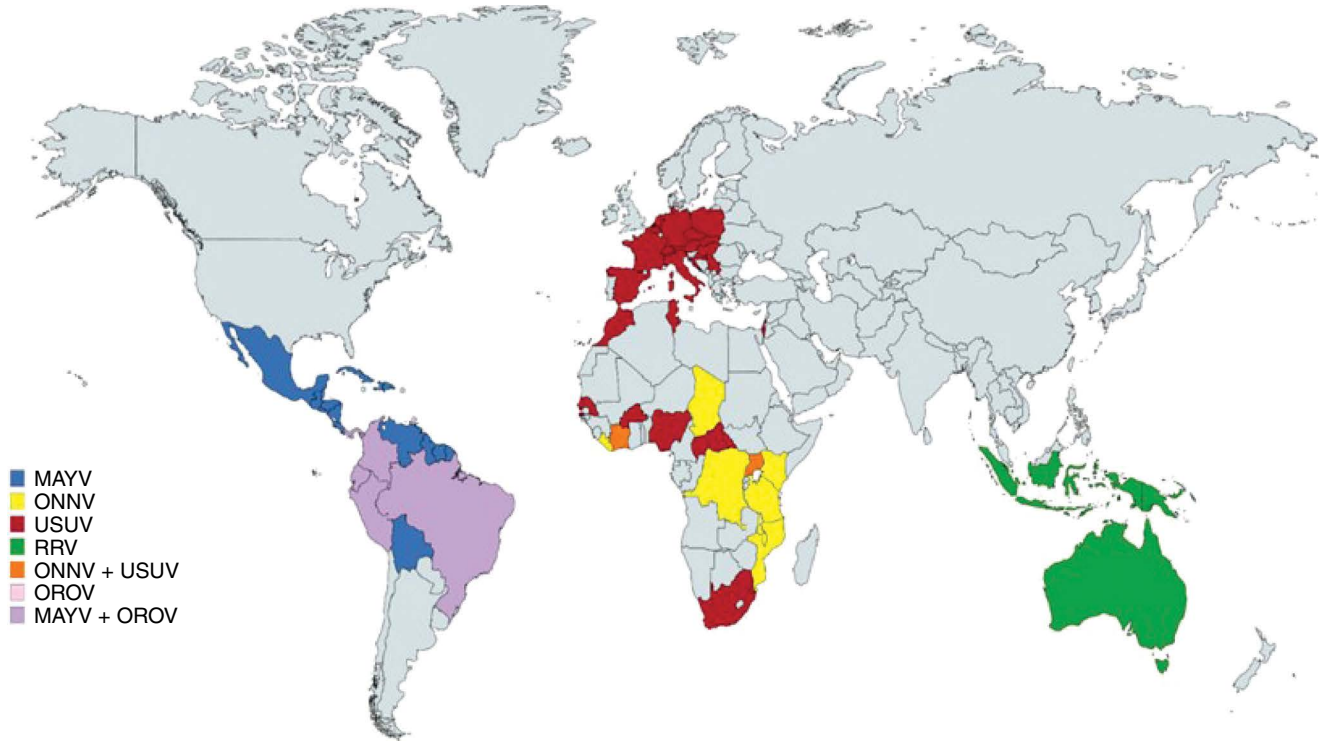

FIGURE 50.11 Emerging viruses causing febrile arthralgia. Viral distributions are shown by color coding as follows: red (USUV), blue (MAYV), yellow (ONNV), green (RRV), orange (ONNV and USUV), pink (OROV), and purple (MAYV and OROV).

called flying foxes [12]. Outbreaks of both viruses usually involve transmission of the virus from bats to horses to humans (Hendra virus) or bats to pigs to humans or bats to humans through bat-urine/excrement-contaminated foodstuffs (Nipah virus); however, some Nipah virus outbreaks have undetermined sources [12, 13]. The human-pathogenic filoviruses and henipaviruses are geographically spread across Africa, Asia, and Australia; to date, these viruses have not been found to naturally occur in the Western Hemisphere. However, cases of filoviral disease have been exported to the United States and Europe.

The betacoronaviruses associated with severe acute respiratory syndrome (SARS; SARS-CoV) and Middle East respiratory syndrome (MERS; MERS-CoV) have emerged in the 21st century and have proven to be formidable public health threats. SARS-CoV appeared in 2003 in China and resulted in a pandemic that caused more than 8,000 human cases of lower respiratory tract infection and 774 deaths, globally [14]. This pandemic is believed to have originated from one or more spillover events from infected palm civets to humans in Guangdong Province, China during 2002; however, the exact source has not been identified [15]. The discovery of related viruses from Chinese bats (e.g., Chinese horseshoe bats, genus *Rhinolophus*) suggests a bat reservoir of SARS-CoV [16]. MERS-CoV, which was first recognized in the human population in 2012, has since caused over 2,400 cases and nearly 860 deaths [17]. All cases have been traced back to exposures that took place on the Arabian Peninsula; however, cases have been exported from this region to Europe, Asia, and North America. Most severe and fatal cases have occurred in individuals with underlying health conditions, including structural lung disease, chronic heart disease, and diabetes [18]. Like with SARS-CoV, investigations of bats indicate a likely chiropteran source for MERS-CoV [19]. Dromedary camels appear to serve as the main source of human infections; although, human-to-human transmission via inhalation of infectious aerosols acquired at close proximity to patients is documented [20]. In 2019 a novel coronavirus emerged in Wuhan,

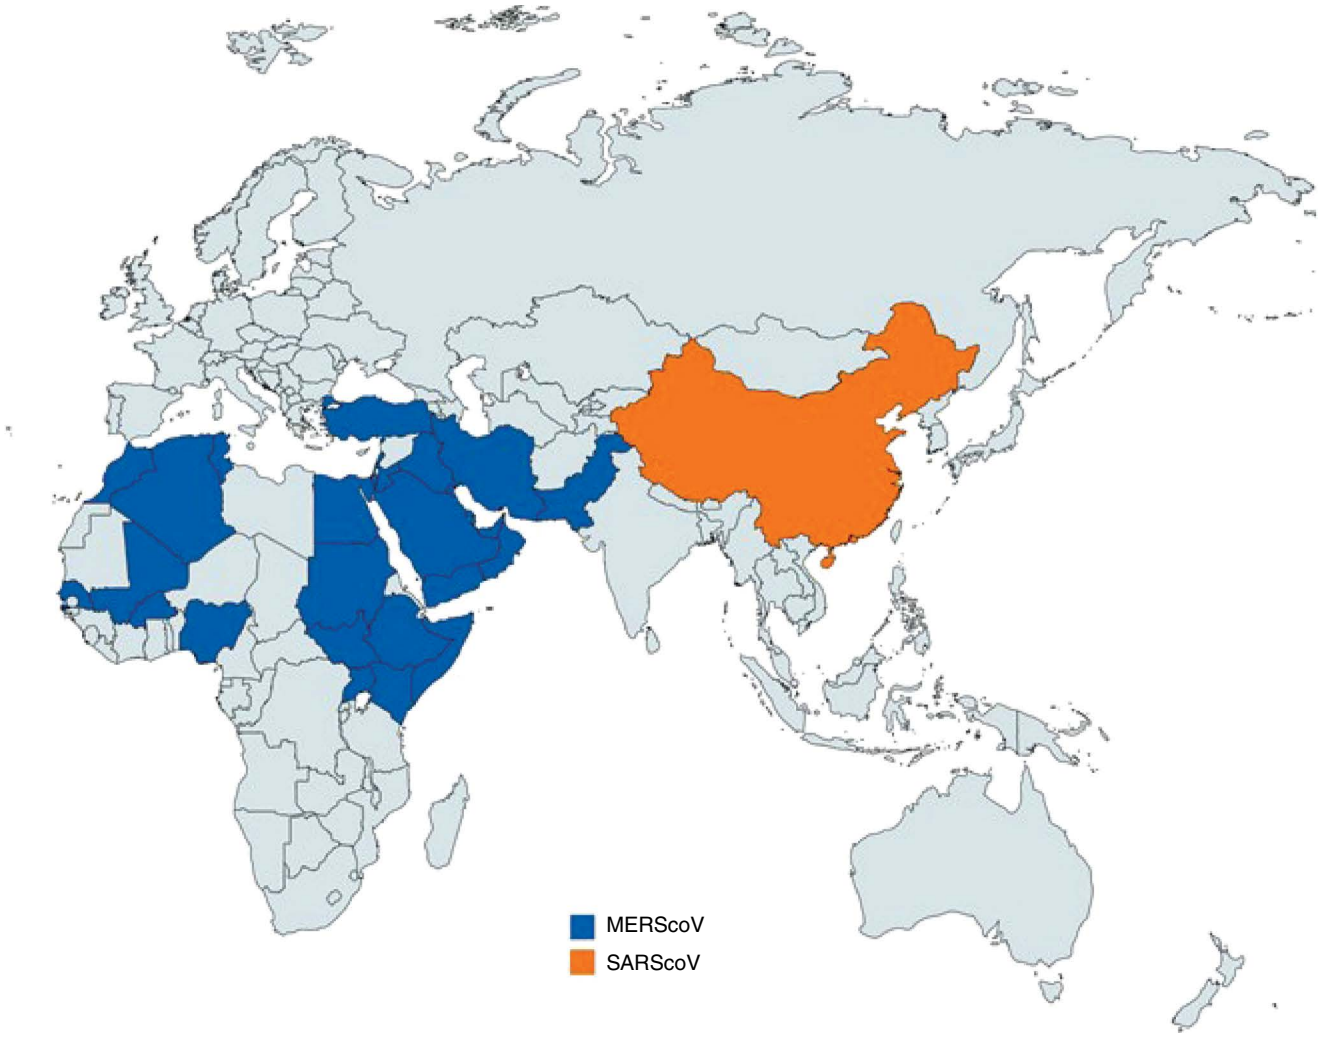

FIGURE 50.13 Distribution of emerging coronaviruses causing respiratory distress syndrome in humans. Areas with MERS-CoV activity are shown in blue, and areas with presumed local reservoirs of SARS-CoV are shown in orange. At this time, SARS-CoV-2 has been detected worldwide and is therefore not depicted.

China (SARS-CoV-2) and has spread around the world. As of this writing (November, 2020), it has affected more than sixty million people worldwide, and caused more than 1.5 million deaths [21]. Cases outside of China were originally among travelers from Wuhan.

Because the early clinical signs and symptoms of emerging and re-emerging viral diseases are often vague and overlap with each other and with other infectious diseases (e.g., malaria, leptospirosis, etc.), their diagnosis requires a high index of clinical suspicion. In areas outside of endemic regions, clinicians should obtain a thorough travel history, animal and vector exposure history, and sick-contact exposure history from patients to assess their risk of infection with specific emerging agents. Care providers must also be aware of ongoing or recent outbreaks of specific pathogens and must be cognizant of dangers posed to them by treating patients with diseases caused by high-consequence pathogens. In response to the 2014–2016 West African Ebola virus disease (EVD) epidemic, healthcare facilities throughout the world implemented questionnaires to gauge a patient's risk for having EVD prior to clinical assessment. In addition, dedicated patient containment rooms or units were constructed throughout many hospitals in the United States and abroad to permit the isolation and care of patients with EVD and other high-consequence pathogens. Barrier precautions, including the use of full-body personal protective equipment, became standard for the care of persons under investigation of EVD or other viral hemorrhagic fevers.

Clinical laboratory testing of patients should include general health screening (e.g., complete blood count, biochemical markers of renal and hepatic function, and markers of hemostasis [D-dimer, prothrombin time/international normalized ration]) and agent-specific testing. Because of the general nature of the prodromal signs and symptoms of most emerging viral diseases, testing for common pathogens (e.g., influenza, malaria, etc.) should also be performed to rule out the involvement of such pathogens. If high-consequence pathogens are suspected, clinical specimens should be handled according to recommendations

TABLE 50.7

Emerging Viruses Featuring Segmented Genomes

Virus	Segments	Names	Encoded Proteins
ANDV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
BAV	12	1 - 12	1: VP1 polymerase; 2–8: VP1–VP8; 9: VP9, VP9′; 10–12: VP10–VP12
BAYV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
BCCV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
BRBV	6	1 - 6	1: PB2 pol; 2: PB1 pol; 3: PA pol; 4: envelope; 5: nucleoprotein; 6: M protein
CCHFV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
CTFV	12	1 - 12	1: VP1 polymerase; 2-8: VP1 - VP8; 9: VP9, VP9′; 10-12: VP10 – VP12
DOBV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
HTNV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
HRTV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
JCV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
JUNV	2	S, L	S: nucleocapsid, glycoproteins; L: polymerase
LACV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
LASV	2	S, L	S: nucleocapsid, glycoproteins; L: polymerase
LUJV	2	S, L	S: nucleocapsid, glycoproteins; L: polymerase
MACV	2	S, L	S: nucleocapsid, glycoproteins; L: polymerase
MGLV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
OROV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
PUUV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
RVFV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
SAAV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
SEOV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
SFTSV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase
SNV	3	S, M, L	S: nucleocapsid; M: glycoproteins; L: polymerase

published by various professional societies (e.g., American Society for Microbiology) and public health agencies (e.g., CDC). If the healthcare institution supports biocontainment patient care rooms or units, testing should be performed in the containment suite, if space permits.

For the detection of specific agents in human clinical specimens, one or more serological, cultivation-based, molecular, and/or histopathological methods can be used; specific methods for individual viruses are described elsewhere. Serological tests include assays designed to detect virus-specific antibodies (IgM and IgG) and antigens and are usually enzyme immunoassays, such as enzyme-linked immunosorbent assays (ELISA). Because IgM is produced soon after infection with a pathogen, IgM-based assays are among the first to be used to attempt diagnosis. Several IgM-based assays have been developed to assist with the diagnosis of an array of viral pathogens, and many are available from commercial suppliers; however, assays for most high-consequence and esoteric viruses are limited to public health and research laboratories. Testing for pathogen-specific IgG is often diagnostic: a fourfold increase in IgG titer between paired acute and convalescent serum specimens indicates infection [22]. Immunochromatographic tests designed to detect either viral antigens or antiviral antibodies have also been developed to aid in the diagnosis of some emerging or re-emerging viral diseases (e.g., EVD) and offer a rapid answer when patients initially present for treatment; however, the performance characteristics of many of these tests have not been well-established because of the relatively low prevalence of many of the diseases they have been designed to diagnose.

Major shortcomings of serological tests include potential cross-reactivity of assays and the length of time often required to obtain a definitive diagnosis. Because closely related viruses share antigenic similarity, antibodies generated against common antigens can cross-react with those of one or more related viruses. Assays designed to detect pathogen-specific antibodies usually cannot readily distinguish the exact specificity of the antibodies present in clinical specimens (e.g., serum), so arbitration is required to determine their specificity. The most common arbiter is plaque reduction neutralization testing, which is described in-depth elsewhere. The length of time required to obtain a definitive diagnosis using serological tests is also an issue, as serum obtained at both the acute phase and convalescent phase (if the patient survives the disease) must be tested together to detect a fourfold rise in IgG titer. Although serum specimens are readily obtainable at the time of initial patient presentation to a healthcare facility, which generally occurs during the acute phase of the illness, obtaining a serum specimen 10–14 days or more later, during the convalescent phase, is sometimes problematic. In addition, this attribute makes some serological tests impractical for clinical use, as the diagnosis is only available

long after acute infection, a therapeutically relevant timeframe, and/or death [22].

Cultivation-based detection of viral pathogens has traditionally been regarded as the gold standard for the diagnosis of infections caused by culturable viruses. Viral culture requires procurement of clinical specimens that are the most likely to contain viable viruses: selection of specimens should be guided by published recommendations for specific agents. Although viral culture is a very sensitive method for diagnosing many viral infections, it is slow, laborious, requires highly skilled laboratory scientists to perform and interpret, and can pose a significant biohazard to laboratory personnel if exposures occur. Because many emerging and re-emerging viruses are classified as either risk group-3 or risk group-4 pathogens, which require biosafety level (BSL)-3 and BSL-4, respectively, containment and work practices, cultivation attempts should not be made unless appropriate containment facilities are available. To that end, cultured isolates are needed to thoroughly characterize novel viruses and variants of known viruses.

Molecular methods, including nucleic acid amplification tests such as the polymerase chain reaction (PCR) and its variations (e.g., real-time PCR), have supplanted most traditional diagnostic testing approaches such as viral culture. PCR and other molecular methods usually require smaller clinical specimen volumes, offer superior analytical sensitivities and specificities, and significantly reduce the result turnaround time, often from days or weeks to hours [23]. In addition, some molecular methods such as next-generation nucleotide sequencing permit rapid characterization of viruses and other pathogens present in clinical specimens. Among other benefits, the information gleaned from nucleotide sequencing permits discovery of new viruses, detection of novel viral variants, and provides insight into the evolution and phylogeny of viruses. Although these methods have become commonplace in diagnostic laboratories throughout the world, most often, molecular diagnostics for emerging viruses are not. Instead, hospitals and other healthcare facilities must rely upon specialized laboratories, including commercial reference laboratories or public health laboratories, to meet testing needs.

The analysis of human tissues by light microscopic and immunohistochemical methods is uncommon for the diagnosis of acute emerging viral infections, except for diseases caused by poxviruses [24]. Instead, histopathological analyses are most commonly performed on tissues collected at autopsy. Microscopic examination of 5-μm-thick, hematoxylin and eosin-stained sections of formalin-fixed, paraffin-embedded tissue is essential for the description of the microscopic effects of emerging viral diseases. Features such as inflammation, alteration of tissue architecture, necrosis, hemorrhage, and others become apparent. Localization of viral antigens and nucleic acids within tissue specimens is possible using virus-specific immunohistochemical and *in situ* hybridization methods, respectively. Observation of positive results permits pathologists to determine the identity of the virus present within the tissue. In cases of death associated with a novel virus, histopathological examination permits characterization of the pathology of the disease process caused by the virus. Electron microscopy is also applicable to viral detection and characterization, as the high magnification afforded by transmission electron microscopy permits visualization of viruses.

Due to a paucity of effective antiviral therapeutics, treatment of emerging viral diseases consists largely of supportive care measures. Supportive treatments for most mild emerging arboviral diseases (e.g., non-neuroinvasive La Crosse virus infections) include antipyretics, analgesics, and antinausea medications. If patients are dehydrated due to diarrhea and/or vomiting, oral hydration, if tolerated, should be emphasized. If oral hydration is not tolerated, intravenous fluid administration is required. If mild infections affect underlying health conditions (e.g., diabetes), additional disease-specific treatments (e.g., insulin) may be needed. For more serious arboviral infections, such as encephalitis and hemorrhagic fever, hospitalization is needed to closely monitor signs and symptoms and to provide intensive care and laboratory-guided assessment of patient status. Additionally, if patients are infected with high-consequence arboviral pathogens (e.g., Crimean-Congo hemorrhagic fever virus), isolation of the sick is paramount to limiting further spread. Similar isolation and supportive treatment measures are used for the care of patients afflicted with most other emerging viral infections. For those viruses that cause respiratory diseases, care may also include mechanical ventilation or extracorporeal membrane oxygenation, if available.

Some antiviral medications such as ribavirin have proven useful for the treatment of arenaviral hemorrhagic fevers, including Lassa fever and Venezuelan hemorrhagic fever [25]. Experimental antiviral drugs such as favipiravir offer promise that better treatments for at least some emerging viral diseases are within reach [26]. However, what is known regarding the antiviral efficacy of this and other experimental drugs is mostly derived from *in vitro* and animal model studies. Data concerning the efficacy of these drugs in treating human cases is severely lacking. Recently, the novel antiviral drug remdesivir (GS-5734) was shown to protect African green monkeys from experimental infection with Nipah virus, showing promise that another effective drug may be added to the antiviral armamentarium used to combat emerging infectious diseases [27]. The EVD drug ZMapp and other biopharmaceuticals offer potential alternatives to conventional antiviral compounds, as these drugs comprise monoclonal antibodies or other biological molecules that effect virus neutralization or inhibit viral infectious cycles [28]. Significant research is still needed to prove the utility of these drugs for combating human infections, but what little data has been generated is promising.

Prevention of emerging viral diseases using vaccines and other prophylactics has already proven useful for abating outbreaks of some diseases, including Japanese encephalitis, yellow fever, Kyasanur Forest disease, and, most recently, EVD [29–32]. The use of genetic engineering has permitted researchers to create recombinant rhabdoviruses (e.g., vesicular stomatitis virus [VSV]) that express immunodominant antigens (e.g., viral peplomers) of viruses that can stimulate production of a humoral antiviral response. These recombinant viruses can be used to vaccinate susceptible hosts. One example is rVSV-ZEBOV, a vaccine licensed by Merck and approved by the United States Food and Drug Administration for the prevention of EVD. This vaccine is highly effective and has been in wide use throughout the 2018–2020 EVD epidemics in the Democratic Republic of the Congo [33]. Additional vaccines using recombinant VSV are expected to be produced in the years to come. Another area of vaccine research is that involving the development of veterinary

vaccines against emerging viruses. Because animals serve as sources of many human infectious diseases, the idea of vaccinating animals is to prevent infection in them, thereby eliminating the risk of animal-to-human transmission. Such a vaccine is already available for the prevention of Hendra virus disease in horses [34].
