Part II Survey of Microorganisms

17. Taxonomic Classification of Bacteria 161
J. Michael Janda

18. Bacterial Cell Wall: Morphology and Biochemistry 167
Stefania De Benedetti, Jed F. Fisher, and Shahriar Mobashery

19. The Human Microbiome in Health and Disease 205
Sandra B. Andersen, Menghan Liu, and Martin J. Blaser

20. The Phylum *Actinobacteria* 215
Alan C. Ward, Nagamani Bora, Jenileima Devi, Alexander Escasinas, and Nicholas Allenby

21. Archaea 229
Nina Dombrowski, Tara Mahendrarajah, Sarah T. Gross, Laura Eme, and Anja Spang

22. The Genus *Bacillus* 249
Daniel R. Zeigler and John B. Perkins

23. The Genus *Bordetella* 279
Rita Austin and Tonya Shearin-Patterson

24. The Genus Campylobacter 297
Collette Fitzgerald, Janet Pruckler, Maria Karlsson, and Patrick Kwan
Updated 2021: Janet Pruckler, Lavin Joseph, Hayat Caidi,
Mark Laughlin, Rachael D. Aubert

25. Chlamydiae 311
Lourdes G. Bahamonde

26. The Genus *Clostridium* 325
Peter Dürre

27. The Genus *Corynebacterium* 339
Lothar Eggeling and Michael Bott

28. The Family *Enterobacteriaceae* 353
J. Michael Janda and Denise L. Lopez

29. *Haemophilus* Species 363
Elisabeth Adderson

30. The Genus *Helicobacter* 375
Ernestine M. Vellozzi and Edmund R. Giugliano

31. The Genus *Legionella* 399
Ashley M. Joseph and Stephanie R. Shames

32. The Genus *Listeria* 411
Sukhadeo Barbuddhe, Torsten Hain, Swapnil P. Doijad, and Trinad Chakraborty

33. The Genus *Mycobacterium* 443
Leen Rigouts and Sari Cogneau

34. Mycoplasma and Related Organisms 465
Bahman Rostama and Meghan A. May

35. The Family *Neisseriaceae* 487
Yvonne A. Lue

36. The Genus *Pseudomonas* 493
Layla Ramos-Hegazy, Shubham Chakravarty, and Gregory G. Anderson

37. The Family *Rickettsiaceae* 511
Timothy P. Driscoll, Victoria I. Verhoeve, Magda Beier-Sexton, Abdu F. Azad, and Joseph J. Gillespie

38. Microbiological and Clinical Aspects of the Pathogenic Spirochetes 527
Charles S. Pavia

39. Staphylococcus aureus and Related Staphylococci 543
Volker Winstel, Olaf Schneewind, and Dominique Missiakas

40. Streptococcus 567
Vincent A. Fischetti and Patricia Ryan

41. The Genus *Vibrio* and Related Genera 579
Seon Young Choi, Anwar Huq, and Rita R. Colwell

42. Yersinia 587
Ryan F. Relich and Meghan A. May

43. Other Anaerobic Bacteria: Bacteroides, Porphyromonas, Prevotella, Tannerella, Fusobacterium, and Gram-positive Anaerobic Cocci 595
Joseph J. Zambon and Violet I. Haraszthy

44. Other Gram-Negative Bacteria: *Acinetobacter*, *Burkholderia*, and *Moraxella* 613
Rebecca E. Colman and Jason W. Sahl

45. Selected Zoonotic Pathogens 619
Sanjay K. Shukla and Steven L. Foley

46. Fungi 631
Charles Adair

47. Introduction to Parasites 665
Purnima Bhanot

48. Introduction to *Bacteriophages* 683
Elizabeth Kutter and Emanuel Goldman

49. Introduction to Virology 703
Ken S. Rosenthal

50. Emerging Viruses 723
Meghan A. May and Ryan F. RelichContents

Part III Applied Practical Microbiology

51. Mechanisms of Action of Antibacterial Agents 747
Ammara Mushtaq, Joseph Adrian L. Buensalido, Carmen E. DeMarco, Rimsha Sohail, and Stephen A. Lerner

52. Mechanisms of Action of Antifungal Agents 777
Jeffrey M. Rybak and P. David Rogers

53. Mechanisms of Action of Antiviral Agents 789
Guido Antonelli, Francesca Falasca, and Ombretta Turriziani

54. Phage Therapy: Bacteriophages as Natural, Self-Replicating Antimicrobials 801
Naomi Hoyle and Elizabeth Kutter

55. Emergence of Antimicrobial Resistance in Hospitals 825
Paramita Basu, Joshua Garcia, and Priyank Kumar

56. Emerging Antimicrobial-Resistant Microorganisms in the Community 841
Negin Alizadeh Shaygh, Divya Sarvaiya, and Paramita Basu

57. Overview of Biofilms and Some Key Methods for Their Study 857
Paramita Basu, Michael Boadu, and Irvin N. Hirshfield

58. Biofilms in Healthcare 873
Rebecca K. Kavanagh, Arindam Mitra, and Paramita Basu

59. The Business of Microbiology 879
Michael C. Nugent and Lorrence H. Green

60. Launching a Microbiology-Based Company 887
Leonard Osser

61. Microbiology for Dental Hygienists 891
Victoria Benvenuto and Donna L Catapano

62. Microbiology for Pre-College Teachers 899
Madge Nanney and Scott Sowell

63. Microbiology for Home Inspectors 905
William E. Herrmann

Survey of Selected Clinical, Commercial, and Research-Model Eubacterial Species 907

Index 913

Preface

As the Practical Handbook Series has gone from Dr. O'Leary's original first edition published in 1989 to the editions published in 2009 and 2015, we have tried to expand the group of people we are trying to help with our book. Dr. O'Leary's first edition was geared toward people generally trained as microbiologists. In the second edition, we added a second group; people that had been trained in other disciplines, but now found that they were using microorganisms as simply another tool or "chemical reagent." The third edition added yet another group, business people requiring assistance in understanding the microbiology-related companies they were considering supporting.

The fourth edition broadens our audience even further to include people in occupations and trades that might have limited training in microbiology, but who require specific practical information about their field. We hope that adding these chapters will give everyone who reads this book a sense of the importance of microbiology is in our everyday lives.

We salute all our authors, especially Dr. Rita Colwell and Dr. Stephan Lerner who have contributed to all four editions, for sharing their knowledge and expertise and helping to make the *Practical Handbook of Microbiology* an essential resource for the field.

About the Editors

Emanuel Goldman is a professor in the Department of Microbiology, Biochemistry, and Molecular Genetics of the New Jersey Medical School (NJMS), Rutgers Biomedical and Health Sciences (RBHS), a division of Rutgers University, Newark, New Jersey. He graduated with honors from the Bronx High School of Science in 1962, received a BA (cum laude) from Brandeis University in 1966, where he was a chemistry major and music minor, and completed his PhD in biochemistry at the Massachusetts Institute of Technology in 1972. He performed postdoctoral research at Harvard Medical School and at the University of California, Irvine, before joining the faculty of the New Jersey Medical School in 1979, where he rose through the ranks to professor in 1993. Among his awards and honors, Dr. Goldman was a Damon Runyon fellow, a Lievre senior fellow of the California Division, American Cancer Society, and a recipient of a Research Career Development Award from the National Cancer Institute. Among his service activities, he was an officer and organizer of the New York–New Jersey Molecular Biology Club, served as a full member of an American Cancer Society Study Section, and continues to serve on the editorial boards of *Protein Expression and Purification* and *Applied and Environmental Microbiology*. He was also twice elected by his colleagues to serve as the president of his university's chapter of the American Association of University Professors, and he was elected to serve as the president of the Faculty Organization of NJMS. Among several areas of research activity, he has focused on the role of tRNA in the elongation of bacterial protein synthesis, including uncharged tRNA, codon bias, and programmed translational frameshifts. In addition to numerous scientific peer-reviewed publications and publications in the lay press, he has contributed a chapter to Zubay's *Biochemistry* textbook and four chapters to the *Encyclopedia of Life Sciences*. His recently published Comment in *Lancet*, "Exaggerated risk of transmission of COVID-19 by Fomites," has attracted significant international attention.

Lorrence H. Green, PhD, President of Westbury Diagnostics, Inc., earned his PhD in Cell and Molecular Biology from Indiana University, Bloomington, Indiana, in 1978. He followed this with 3 years of recombinant DNA and genetic research at Harvard University. In 1981, he moved into Industry by joining Analytab Products Inc., a major manufacturer of *in vitro* diagnostic test kits. During the next 12 years he helped to invent and manufacture over 40 diagnostic test kits, and rose to become the Director of New Product Development and Product Support.

In 1993, Dr. Green founded Westbury Diagnostics Inc., a microbiology-biotechnology-based contract research and development laboratory also offering consulting services. Mixing his love of business with his love of teaching, Dr. Green has served as an adjunct associate professor of microbiology at the New York College of Osteopathic Medicine, and is currently an adjunct assistant professor of biology at Farmingdale State College and Director of the Fundamentals of the Bioscience Industry Program at Stony Brook University of the State University of New York.

Dr. Green is on the steering committee, and is a former Chairman, of the Microbiology Section of the New York Academy of Sciences. He was also the long-time Treasurer of the NYC Branch of the ASM. From 2001 to 2004 he was a member of the Advisory Committee on Emerging Pathogens and Bioterrorism to the New York City Commissioner of Health. In 2013 he was appointed to the Board of Directors of the Long Island Advancement of Small Business.

His main interests involve using technology in the development of commercial products and in being an entrepreneur who invests in and develops companies. He enjoys providing mentorship and career advice to students at all levels. He has spoken at many career day events, judged many regional science fairs, and has helped dozens of young people with applications to medical school, nursing school, physician's assistant school, and with starting companies.

Most recently, he has become involved in government and is currently the Chairman of the Town of Mamakating Planning Board.

Background

The techniques to control the growth of microorganisms have been shaped by both cultural and scientific advances. From the days of early food preservation—fermentation of milk products and smoking of meats—to extend the shelf life of foods, practical needs have contributed to the development of techniques and tools required for sterilization, disinfection, and antisepsis.

Formal development of clinical medical settings led to an awareness of the causes and effects of disease. This awareness contributed to the development of infection-prevention practices and techniques by Joseph Lister, Oliver Wendell Holmes, Ignaz Semmelweis, and Florence Nightingale, each making formal contributions to the mitigation of disease transmission among patients.

Society continues to shape the infection prevention needs of today. In the last 65 years, we have witnessed the rampant evolution of drug-resistant microbes, a steady increase to the nosocomial-infection rates in healthcare facilities, and the development of exploratory (e.g., endoscopes) and permanently inserted medical devices that have resulted in types of infections never before witnessed. These coupled with a threat from emerging pathogens, as consequence of habitat disruption and destruction, global climate change, modern transportation, and possible bioterrorism, brings together the potential for the introduction of pathogenic microbes into environments not considered in the past.

Our requirements for sterilization, antisepsis, and disinfection thus go beyond the historical needs of research and clinical laboratories and production requirements of commercial facilities. This chapter will review commonly used laboratory techniques, specifically addressing their limitations when used to reduce or eliminate bacteria on materials that were not originally designed to be sterilized or disinfected, and will introduce us to no-touch solutions for the elimination of microbes to mitigate the risk of transference of these microbes to susceptible hosts.

Methods of Sterilization

Sterilization is a process that results in the complete inactivation of all microbes, including endospores; it can be achieved by mechanical means, heat, chemicals, electromagnetic radiation, or sonic energy (Table 1.1). When using heat, its application may be either moist or dry. Traditionally, moist heat requires increased pressure to facilitate the transfer of energy. This is routinely accomplished with autoclave; dry heat can be applied using an oven (see Table 1.1). However, the dead microbes and their associated cellular debris remain, making even sterilized material a potential hazard.

Disinfection is the process that inactivates most or all microorganisms with the exception of endospores and some acid-fast bacilli. Disinfectants can be subcategorized as high-level disinfectants, which kill all microorganisms with the exception of endospores with an exposure time of less than 45 minutes; intermediate-level disinfectants, destroy the majority of bacteria and viruses but fail to inactivate endospores; and low-level disinfectants, kill the majority of vegetative bacteria, some fungi, and some viruses typically with exposure times of less than 10 minutes (1). Disinfectants are primarily used on inanimate objects and can be sporostatic but are typically not sporicidal (2). Antiseptics, a subset of disinfectants, destroy or inhibit the growth of microorganisms within or present on living tissues and are often referred to as biocides (2).

Steam sterilization and dry heat inactivation of infectious microbes can be monitored using biological indicators or by chemical test strips that turn color upon having met set physical

TABLE 1.1

Routine Methods of Sterilization[a]

Method [Ref.]	Temperature	Pressure	Time	Radiation (Mrad)
Dry heat (119)	150–160°C 302–320°F		>3 hours	
Dry heat (119)	160–170°C 320–338°F		2–3 hours	
Dry heat (119)	170–180°C 338–356°F		1–2 hours	
Moist heat[a]	135°C 275°F	31.5 psig	40 minutes

parameters. Usually the spores of species of *Geobacillus* or *Bacillus* are used in either a test strip or suspension, as these organisms are more difficult to kill than most organisms of clinical interest (3). Growth of the spores in liquid media after the cycle of sterilization is complete indicates the load was not successfully processed and should not be considered sterile.

In the days following September 11, 2001, letters containing the spores and cells of *Bacillus anthracis* were mailed to several news media offices, and two U.S. senators resulting in the death of 5 people and the infection of 17 others. This introduced a pathogen into locations where methods of safe handling and eradication of such pathogens were not defined nor anticipated. Further complicating matters was that the microbes contained within the packaging were optimized for airborne dispersal resulting in substantial contamination of the built environment necessitating isolation and/or closure of the buildings.

As a consequence of the Anthrax attacks of 2001, a number of laboratories have conducted experiments on the potential dispersal, detection, and eradication of organisms spread by these unconventional methods. Lemieux and others (4) conducted experiments with simulated building decontamination residue (BDR) contaminated with 10^6 spores of *Geobacillus stearothermophilus* to simulate *Bacillus anthracis* contamination. A single cycle did not effectively decontaminate the BDR. Only an autoclave cycle of 120 minutes at 31.5 pounds per square inch gauge, relative to atmosphere (psig) [2.17 bar]/275°F (135°C) and 75 minutes at 45 psig [3.10 bar]/292°F (144°C) effectively decontaminated the BDR. Two standard cycles at 40 minutes and 31.5 psig/275°F run in sequence were found even more effective. The authors state that the second cycle's evacuation step probably pulled condensed water out of the pores of the materials, allowing better steam penetration. It was found that both the packing density and material type of the BDR significantly impacted the effectiveness of the decontamination process.

CONVERSION FACTORS FOR COMMON MEASURES USED TO EXPRESS PRESSURES

Pounds per square inch (psi) or precisely, pound-force per square inch (lbf/in^2) is a unit of pressure or stress expressed using the avoirdupois system of measurement resulting from one pound-force of pressure applied to an area of one square inch. Using the International System of Units (SI) 1 PSI is approximately equal to 6,895 N/m^2.

Pounds per square inch absolute (psia) is a term used to delineate a pressure value being reported relative to vacuum rather than ambient atmospheric pressure. Given that 1 atmosphere of pressure at sea level is 14.7 psi, any value need expressed using psia requires the addition of the barometric relative to psia.

Pounds per square inch gauge (psig) the converse to **psia** expresses the pressure value relative to atmospheric pressure. Consequently, gauge pressure takes into consideration the effects of changes to barometric pressure or as a consequence of pressure changes due to altitude differentials.

Other common units used to express pressure are:

1 psi = 0.068046 atmospheres
0.689476 Bar
6,894.76 Pascals
51.7149 Torr
2.03602 inches of Hg
27.7076 inches of water column 6,895 N/m^2

When materials made of unusual substances and/or densities are to be sterilized, the method of sterilization must be monitored and adapted according to the material. Common strategies include alterations of placement and/or lower packing densities within the autoclave. Other common methods of sterilization of problematic materials and substance include use of gases such as ozone or ethylene oxide, radiation, or less commonly, electronic accelerators (see Table 1.1).

Solutions containing heat-labile components require a different approach. Filtration is generally the most accepted and easiest method. The Food and Drug Administration of the United States (FDA) and industry consider 0.22-µm filters to be sterilization grade based on logarithmic reductions of one of the smallest bacteria *Brevundimonas diminuta*, a nonlactose fermenting environmental Gram-negative rod (5). Usually an incubation

TABLE 1.2

Filter Sterilization

Size(μm)	Purpose
0.1	Mycoplasmal removal
0.22	Routine bacterial removal
0.45	Plate counts of water samples
>0.45	Removal of particulates, some bacteria, yeast, and filamentous fungi

period of at least 48 hours is required for colony development of *Br. diminuta* before the colonies are large enough to be viewed for counting. Griffiths and others (6) describe a Tn5 recombination method in which *Br. diminuta* is augmented with the genes for bioluminescence (luxABCDE) and fluorescence (*gfp*). Use of the modified microbe enabled detection within 24 hours of incubation by either bioluminescence or fluorescence. They state that this method may aid in preventing quality control backlogs during filter manufacturing processes.

A 0.22-μm filter will adequately sterilize the majority of heat labile solutions used for molecular biology and microbiology. Labile tissue culture reagents might also require to be certified free from mycoplasma contamination. A 0.1-μm filter is used to remove mycoplasma from tissue-culture solutions (7) (Table 1.2). Today, with the widespread availability of PCR machines, routine testing for *Mycoplasma*, *Acholeplasma*, and *Ureaplasma* via the amplification of sentinel genes has become the established method of choice for highest sensitivity detection of contamination of filtered liquids by these microbes. Detection limits of less than 1 cfu/mL are easily achieved within a few hours. This has transformed filtration-based sterile product release; rather than waiting on results from a 28-day biological culture test, manufacturers can now easily rely on this established methodology taking less than a few hours to complete.

The removal of contaminants from air may be necessary in the case of fermentation, drug manufacturing, or chemical reactions requiring some form of gas. Various types of filters are available for the removal of organisms from air. One such filter is the Aerex 2 (Millipore). It can withstand 200 steam-in-place cycles at 293°F (145°C), it can resist hydraulic pressures of 4.1 bar (60 psig), and has the ability to retain all phages when challenged with the ΦX-174 bacteriophage at 29 nm in diameter at a concentration of between 10^7 and 10^{10} bacteriophages per cartridge (8). In this particular scenario, the operator must assess their needs for how critical the product be free of contaminating materials (i.e., drugs versus topical cosmetics), as well as the ability of the product to withstand pressure, heat, flow-rate, and other parameters of the manufacturing process, and select an appropriate filter.

In some cases, a filter is used to recover bacteria from dilute solutions such as environmental water samples. The organisms of significance whose retention on the filter is most important should determine the filter pore size. The smaller the filter pore size, the slower the sample flow rate and throughput. Standard methods define an acceptable recovery rate for filter-based recovery of bacteria as being 90% of the number of bacteria (colony-forming units, [CFU]) recovered from the same sample by the spread plate method under typically aerobic conditions. In one study performed by Millipore, filtration with a 0.45-μm pore-size filter provided 90% recovery of 12 microorganisms used, ranging in size from *Br. diminuta* to *Candida albicans* (Table 1.2).

It is important to note that all filter sterilization is relative. Filter integrity for sterilization is usually done by a bubble test to confirm the pore size of the manufactured filter (5, 9). The bubble point is based on the fact that liquid is held in the pores of the filter (usually membrane) by surface tension and capillary forces, and the bubble pressure detects the least amount of pressure than can displace the liquid out of the pores of the filter (9). While a 0.22-μm filter will remove most bacteria, it will not remove viruses, mycoplasma, prions, and other small contaminants, including toxins. Every sample type and the level of permissible substances in the filtrate must be assessed on a case-by-case basis. For example, filter-sterilization of water or solutions used in atomic force microscopy might still allow sufficient numbers of small viruses and other particulates to pass through the filter and impede sample interpretation; under such conditions ultrapure water (UPW) may be needed. UPW comprises H_2O, H^+, and OH^- ions in equilibrium with an electrical conductivity of approximately 0.055 μS/cm at 25°C, which may be alternatively expressed by its resistance coefficient of 18.2 MOhm (10).

Ultrasonic Energy

Ultrasonic energy in the range of 20–500 kilohertz (kHz) makes use of physical and chemical phenomena induced by an interaction of the ultrasonic energy with the structures and chemical constituents within the microbial cell. Principally, the sonic energy generates a wave front within the liquid medium. Alternating regions of compression and expansion occur causing pressure changes resulting in cavitation and bubble formation. During the expansion phase within the wave front the expanding bubbles reach a state where they implode resulting in rapid condensation. The condensed molecules collide violently with the subsequent formation of a high-pressure shock wave of approximately 50 MPa resulting in a localized temperature of 5,500°C (11). These rapid changes in localized pressure and extremes of temperature serve to inactivate the microorganisms with temperature being the main contributor to the cell's inactivation (11).

In a study of the use of high-energy ultrasound in the range of 24 kHz over 1 hour where the nominal energy administered was applied at 1,500 W/L or 5,400 kJ/L, the mean killing observed for typical Gram-negative microbes found associated with wastewater, such as total coliforms, fecal coliforms, and/or *Pseudomonas* spp., was 99.5%, 99.2%, and 99.7%, respectively (12). Gram-positive microbes were found to be more recalcitrant to the sonic inactivation using this power density (W/L) and frequency (kHz) of energy, where the mean inactivation observed for *Clostridium perfringens* and fecal streptococci was 66% and 84%, respectively. Sonic inactivation of microbes was found to follow first-order kinetics with respect to the bacterial population and was not affected significantly by the medium in which they were suspended (12). The addition of 5 g/L of TiO_2 particles generally enhanced the destruction of Gram-negative bacteria, yielding a 3–5 log fold reduction in viability, while the addition of the titanium particles to Gram-positive microbes was found to be only mildly more effective. Nevertheless, the application of ultrasonic energy at 4,000 kJ/L in the presence of 5 g/L of TiO_2 particles

was able to meet the United States Environmental Protection Agency required limit, $<10^3$ CFU/100 mL total coliforms for water reuse (12).

Other workers have found similar antimicrobial effects when using sonic irradiation to inactivate microbes. Mesophilic aerobes and fungi suspended in orange juice were inactivated within 15 minutes through an application of 240 W of power at a frequency of 500 kHz under ambient temperature conditions (13). The coapplication of heat with and without pressure was found to accelerate the rate with which the population of microbes could be inactivated. For *Escherichia coli* suspended in a phosphate buffer, using a frequency of 20 kHz at a power setting of 100 W using temperature ranges between 40°C and 61°C and 100–500 kPa of pressure was found to be bactericidal between 0.25 minutes and 4 minutes (14).

Disinfectants and Antiseptics

The regulation of disinfectants and antiseptics falls under the jurisdiction of different agencies, depending on where the chemical will be used. In the United States, the Environmental Protection Agency (EPA) regulates disinfectants used on environmental surfaces (e.g., floors, laboratory surfaces, patient bathrooms), and the FDA regulates liquid high-level sterilants used on critical and semicritical patient-care devices.

Labeling terminology can also be confusing, as the FDA uses the same terminology as the United States Centers for Disease Control and Prevention (CDC) (critical [sterilization], semicritical [high and intermediate], and noncritical [low-level disinfection]), while the EPA registers environmental disinfectants based on the claims of the manufacturer at the time of registration (i.e., EPA hospital disinfectant with tuberculocidal claim = CDC intermediate level disinfectant) (15). In addition, the use of disinfectants varies globally. For example, surface disinfectants containing aldehydes or quaternary ammonium compounds are less often used in American, British, and Italian hospitals than in German ones (16), thus making it difficult to define overall best methods or practices. Whatever method is employed—mechanical, heat, chemical, or radiation—a method of assessment must be in place to test the initial effectiveness of the method on either the organism of the highest level of resistance to the method or a surrogate; and a standard must be included to monitor the effectiveness of the method for its regular use by general staff. While such forms of assessment are common for daily runs from the autoclave, they are used less often when general low-level disinfection occurs on noncritical surfaces. A number of commonly used disinfectants, along with some of the microbes against which they have activity, may be found in Table 1.3.

Disinfectants are often tested against cultures of the following bacteria: *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Salmonella typhimurium*, *Mycobacterium smegmatis*, *Prevotella intermedia*, *Streptococcus mutans*, *Aggregatibacter actinomycetemcomiticans* (formerly *Actinobacillus actinomycetemcomitans)*, *Bacteroides fragilis***,** and *Escherichia coli* (17). One common approach is to use the broth dilution method, wherein a standard concentration of the organism is tested against increasing dilutions of the disinfectant. The minimum inhibitory concentration (MIC) is defined as the lowest concentration of the disinfectant that prevented visible growth of the microbe.

While there are many reports of liquid disinfectant activity against liquid/planktonic cultures, biofilms of the aforementioned organisms have survived when the liquid/planktonic culture of the same organism has been killed (17). Therefore, biofilm disinfection must be evaluated separately. Better efficacy in biofilm prevention and removal has been demonstrated by the

TABLE 1.3

Partial Listing of Some Useful Disinfectants

Substance[a]	Concentration	Time	Types of Organisms Killed	Ref.
Inorganic hypochlorite (bleach)	6,000 ppm	5 minutes at 22°C	Adenovirus 8	(125)
	5,000 ppm	10 minutes at 23–27°C	Bacteria, viruses, and fungi, hepatitis A and B, HSV-1 and 2	(1)
	2,000 ppm	pH 7, 5°C, 102 minutes	*Bacillus anthracis* Ames (spores)[b]	(126)
	1,000 ppm	pH 7, 5°C, 68 minutes	*Bacillus anthracis* Sterne (spores)[b]	(127)
		10 minutes at 20 ± 2°C	*Feline calicivirus* (norovirus surrogate)	(128)
Peracetic acid[b]	0.3%		Sporocidal, bactericidal, viricidal, and fungicidal	(2)
Glutaraldehyde	2.65% in hard water (380–420 ppm calcium carbonate)	5 minutes at 22°C	Adenovirus 8	(125)
Ethyl alcohol	70%	5 minutes at 22°C	Disinfectant	(125)
Surfacine	Manufacturer's instructions		VRE	(19)
R-82 (quaternary ammonium compound)	856 ppm (1:256 dilution)	10 minutes at 20°C ± 2°C	*Feline calicivirus* (norovirus surrogate)	(128)
Ozone disinfection of drinking water	0.37 mg/L	Contact-time 5 minutes at 5°C	Noroviruses	(122)
Acidic sodium dodecyl sulfate	1% SDS plus either 0.5% acetic acid and 50 mM glycine (pH 3.7) or 0.2% peracetic acid	30 minutes at 37°C	Prions: specifically PrP^{Sc}, see Ref. for details	(129)

[a] Highest concentration given for use with most resistant organism tested. See cited reference for refined values for each organism.

[b] The authors observed $\log_{10}$ inactivation of populations of spores, the inactivation increasing with contact time, but not sterilization.

use antibiofilm products as compared to detergent disinfectants containing quaternary ammonium compounds (18).

One problem with most disinfectants and antiseptics is their short effective life span. Hospitals and laboratories today are challenged with multiple drug-resistant organisms that may be transmitted from surfaces. These surfaces may be routinely recontaminated by either patient, visitor, or staff activity. A new agent, a combination of antimicrobial silver iodide and a surface-immobilized coating (polyhexamethylene biguanide), Surfacine™, is both immediately active and has residual disinfectant activity (19). Additionally, it can be used on animate or inanimate objects. In tests on Formica™ with vancomycin-resistant *Enterococcus*, Surfacine™ was found to be 100% effective on surface-challenge levels of 100 CFU per square inch for 13 days (19). Rutala and Weber (19) also state that the manufacturer's test data demonstrated inactivation of bacteria, yeast, fungi, and viruses with inactivation time varying by organism. Similarly, Schmidt and colleagues reported on the *in situ* clinical evaluation of a persistently active disinfectant, *Firebird F130*™ (70% ethanol and <1% mixed quaternary ammonium chloride compounds along with proprietary agents designed to maintain activity for 24 hours subsequent its application) (Microban, Huntersville, NC) (20). Here, they learned that this new formulation of two agents known for their ability to disinfect the built clinical environment performed significantly better and for longer than the individual agents by themselves; this particular compound's persistently active material was found superior for all time points when compared to a dilutable quaternary ammonium agent, and it was significantly better for controlling bioburden for two of the three time points for the disinfectant with ethanol and quaternary ammonium as its agent (20).

Inducing a Viable but Nonculturable State upon Exposure to Sublethal Concentrations of Disinfectants and Other Environmental Stressors

Essential to measuring the effectiveness of sterilization and/or exposure to disinfectants is the ability of a microbe to form a colony after exposure to proper growth conditions on routine bacteriological medium on which the microbe would normally grow. Failure of some microbes to form a colony under all circumstances is not always the result of the microbe being killed but rather being in a state referred to as viable but nonculturable (VBNC) (21). This was first appreciated by Xu and colleagues in 1982 in the human pathogen *Vibrio cholerae*, and then during the ensuing period by other workers who investigated how exposure of populations of other microbes to environmental stressors triggered the VBNC condition. Upon entering a VBNC state, the community confers an impression that materials treated have fewer viable bacteria than they actually do. Unfortunately, many of the routine treatment processes used to render materials free or possessing reduced concentrations of bacteria (e.g., preparation of "ready to eat" salads and other produce by subjecting the produce to submersion into a dilute concentration of sodium hypochlorite [3–100 ppm] followed by drying) are in themselves responsible for triggering the VBNC phenotype (22–25). This is especially problematic as presumably treated materials retain substantial concentrations of bacteria capable of causing disease (23, 26–30). In addition to dilute sodium hypochlorite, many factors have been reported to induce the condition. They include many common household cleaners and inorganic salts (28), nutrient deprivation (31), growth outside the preferred/normal range of temperatures (31–34), alterations to the osmotic pressure exerted by the growth environment (35, 36), oxygen tension (37), commonly used food preservation materials (38), metals (39), exposures to thermosonication (40), and electromagnetic radiation in the visible (41) and ultraviolet spectra (42). Regardless of how the cells achieved a VBNC state, culture-based assessment of a product's sterility may lead to an underestimation in the number of microbes removed from the material and should be accounted for prior to the release of the "sterile" lot.

To address the limitation imposed by the presence of VBNC microbes in products, a nonculture-based system should be used to estimate the concentration of microbes remaining in the treated material. Commonly used methods include those that measure membrane integrity with redox sensitive dyes. As an example, one product marketed under the trade name of Live/Dead®*BacLight*™ assesses whether the microbes have a compromised membrane. Damage to the membrane of bacteria results in their death via a multifactor mechanism. Often commencing with the collapse of the membrane potential, the bacterial cell faces an accumulation of free oxygen radicals secondary to the effects of routine metabolism that are responsible for membrane damage leading to loss of integrity with cytoplasmic leakage and destruction of the nucleic acid within the microbe. Such dead bacterial cells stain red, while those with an intact membrane stain green. The disadvantage of methods relying on membrane integrity to assess life is the need to visualize what fraction of the population is live vs. those dead. Alternatively, total nucleic acid may be recovered from the treated materials whereupon RNA is isolated, subjected to reverse transcription, using a primer targeted against a routinely transcribed messenger RNA, where its presence signals the cell is still alive. This technique draws from the fact that since the average bacterial mRNA has a half-life of 3–5 minutes, those cells continuing to transcribe their genome are considered to be alive. Each of the alternate methods requires time, often specialized equipment, and skilled personnel to accomplish the tests.

Disinfection and Sterilization of Prion-Contaminated Materials

Prions are infectious agents composed solely of protein in a nonnative or misfolded form. Clinically these agents are considered transmissible spongiform encephalopathies (TSEs) and result in a family of rare progressive neurodegenerative disorders that affect both humans and animals. In humans they have been implicated in neurodegenerative diseases ranging from Alzheimer's, Creutzfeldt-Jakob (CJD), variant Creutzfeldt-Jakob (vCJD), Gerstmann-Straussler-Scheinker syndrome, fatal familial insomnia, to Kuru (laughing sickness) (43). This nonliving, but infectious proteinaceous material manifests disease by affecting the structure of the brain or other neural tissue of the central nervous system. In the United States, the incidence of CJD is approximately one case per million population (44–46). Unlike other infectious agents, TSEs do not elicit an immune

response (43). To date, they are untreatable and universally fatal following a long incubation period and a noninflammatory pathologic progression of disease within the central nervous system (43, 47). CJD occurs both sporadically, accounting for approximately 85% of the cases, and can also be inherited (15%) (43). However, there have been estimates that approximately 1% of the CJD in the United States may result from a healthcare-associated exposure from contaminated tissues, grafts, or via transmission from contaminated instruments (43).

Prions that cause CJD and other TSEs are recalcitrant to traditional means routinely used for the inactivation of fungi, bacteria, and viruses. The infectious material is introduced to the instrument as a by-product of the medical procedure. Tissues at high risk of containing infectious concentrations of these proteinaceous agents implicated in TSEs include the brain, spinal cord, pituitary gland, and the posterior eye (43). Critical and semicritical devices, as defined by Spaulding (48), must be rendered prion-free prior to their reuse. Presently, there are no antimicrobial products registered with the U.S. EPA having a registration specifically for the inactivation of prions on environmental surfaces, and there is no sterilization processes cleared by the FDA for sterilization of reusable surgical instruments (43). With that caveat, operationally, inactivation of a prion is defined when the infectious concentration has been reduced by 5–6 $\log_{10}$ in the number of prion particles associated with the critical/semicritical item (43). Rutala and Weber, writing the guidelines for the disinfection and sterilization of prion contaminated medical instruments for the *Society for Healthcare Epidemiology of America*, summarized data from the literature suggesting that autoclaving at 134°C for at least 18 minutes (prevacuum) or 132°C for 60 minutes (gravity displacement) was effective for the inactivation of prions (43). Further, the addition of chemicals in concert with heat such as sodium hydroxide (0.09N or 0.9N) for 2 hours with subsequent steam sterilization at 121°C for 1 hour was sufficient for the partial or complete loss of infectivity (49–53). The addition of proteolytic enzymes to the disinfection protocol may also facilitate the removal with subsequent inactivation of the infectious material. To enable the removal of the infectious protein, suspect instruments should be subjected to decontamination with subsequent sterilization as soon as possible after coming in contact with suspect tissues. Dilution to extinction remains an adjunctive method to facilitate the mitigation of the risk of exposure to prions. Thus, keeping the instruments wet or damp until they are subjected to decontamination might help mitigate the risk of prion exposure by facilitating removal of the agent from the suspected or contaminated instruments or devices.

Ding and colleagues described the kinetics of ozone inactivation of infectious prion proteins (54). Ozone possesses the property of having the highest oxidation potential among the majority of chemical disinfectant used for the treatment of water (55) and was found to inactivate the prion PrP^{sc} (scrapie 263K) as quantitatively assessed by measuring the templating properties using the protein misfolding cyclic amplification assay (PMCA) (56). Here they learned that pH and temperature, in addition to the concentration of ozone, was able to effectively reduce the concentration of PrP^{sc} by 2-$\log_{10}$, 3-$\log_{10}$, and 4-$\log_{10}$ increments. This led them to conclude in systems using ozone-demand-free water that ozone is effective for prion inactivation (54).

Similarly, hypochlorous acid (HOCL) commonly referred to as bleach was able to inactivate prions and other self-propagating protein amyloid seeds (57). Here, a weekly acidic aqueous formulation of hypochlorous acid, suitable for application directly to skin and mucous membranes or aerosolization to treat entire rooms without harmful effects, was able to eliminate all detectable prion seeding activity of the human Creutzfeldt-Jakob disease, bovine spongiform encephalopathy, cervine chronic wasting disease, sheep scrapie, and hamster scrapie with reductions seen between $\geq 10^3$ and 10^6 fold as measured by real-time quaking-induced conversion assays (RT-QuIC; for more information see refs. (58, 59)). Briefly, this type of assay exploits the self-propagating activity of these proteins or prion seeds by coupling their ability for self-amplification as much as trillionfold with the evolution of a fluorescent signal through the conversion of a recombinant prion protein in the assay medium (rPrP) into detectable amounts of a misfolded, aggregated form of rPrP. The rPrP-aggregates then interact with a specific dye, causing a measurable change in the dye's fluorescence emission spectrum, enabling use of multiwell plates and a fluorescent detection system to reveal the presence of a prion seed with greater sensitivity than animal bioassays (58, 59).

What has been hindering the adoption of a universal method for the inactivation of prions has been the absence of a rapid method, with sufficient sensitivity and specificity, to validate that prion "sterilization" method was indeed effective at rendering the material prion free. To date, alkaline and enzymatic detergents that mineralize proteins have been found to be the most effective at eliminating the infectious potential of prions associated with the instruments (60). The European Community Notified Body (CE) has independently certified some of the protein degrading agents, but recommends that their use remain at the discretion of the user who, in concert with the manufacturer, will assess the scientific qualities of the product (61).

Disinfection of Hands

One of the most important areas for infection control is debulking of the built environment with subsequent disinfection of the hands of their resident microbial flora. Usually, mechanical methods such as scrubbing with a brush are most used, but alternatively, alcohol-based rubs may also be used for hand disinfection. Widmer (62) states in the year 2000, the compliance rate for handwashing was less than 41% and speculated that understaffing may further complicate the problem. The proper methodology for handwashing includes wetting the hands and wrists with water, dispensing a dose of soap with the forearm or elbow, rubbing the hands and wrists with the soap for 10–15 seconds, rinsing the hands, and then drying the hands without rubbing. Additionally, the faucet is turned off while holding the paper towel, so as not to contaminate the hands (62).

Many authors now advocate waterless alcohol rubs. Kampf et al. (63) advocate a 1-minute handwashing at the beginning of the day, a 10-minute drying time, and then unless visibly soiled, a rub-in, alcohol-based hand disinfectant for routine disinfection throughout the remainder of the day. Gupta et al. (64) compared an alcohol-based waterless and an alcohol-based water-aided scrub solution against a brush-based iodine solution under conditions encountered in community hospital operating rooms. The

brush-based iodine solution performed best on the first day of the study; but when colony-count reductions were studied between the three options over the course of 5 days, no significant difference was found. The participants found the alcohol-based waterless solution the easiest of the three to use with the lowest complaints of skin irritation. Another reason to advocate non-abrasive hand sanitizing methods is the fact that brush-based systems can damage skin and cause microscopic cuts that can harbor microbes (64).

Cooper et al. (65) found that even small increases in the frequency of effective hand washes were enough to bring endemic nosocomial infective organisms under control in a computer model. Raboud et al. (66), using a Monte Carlo simulation, determined factors that would reduce transmission of nosocomial infection. The factors that were relevant included reducing the nursing patient load from 4.3 (day) and 6.8 (night) to 3.8 (day) and 5.7 (night), increasing the hand-washing rates for visitors, and screening patients for methicillin-resistant *S. aureus* (MRSA) upon admission.

In spite of the publication of guidelines for hand hygiene in healthcare facilities in 2002 (67), the subsequent widespread adoption of hand-hygiene compliance protocols, advances in understanding the mechanics and utility of new products for increased convenience and efficacy, hand hygiene remains a substantial problem for modern healthcare. McGuckin and colleagues reported in 2009 that the three most frequently reported methods for measuring hand hygiene compliance were (1) direct observation, (2) self-reporting by individual healthcare workers (HCWs), and (3) an indirect calculation based on the consumption of products directly tied to hand hygiene compliance (68). Their results showed that hand-hygiene compliance rates at baseline within intensive care units (ICU) were at an extremely low rate of 26%, while the average rate for non-ICU units was found to be only slightly better with a rate of 36% (68). Upon monitoring the usage of the products employed in hand-hygiene compliance protocols in concert with providing feedback to the staff, they witnessed a significant increase in compliance to 37% for the ICUs and 51% for the non-ICUs (ICU, $p = 0.019$; non-ICU, $p < 0.001$) leading them to conclude that in the United States, hand-hygiene compliance can increase with monitoring combined with feedback (68).

In 2018 an alarm within the infection control community sounded loudly enough to be heard by the general public when it was appreciated that some hospital isolates of *Enterococcus faecium* developed a tenfold higher tolerance against alcohol inactivation (69). This observation is especially troubling in that the microbe acquiring tolerance to this vital infection control intervention is also one of the leading causes of healthcare acquired infections. The natural selection of alcohol-tolerant strains of *E. faecium* was not unexpected given the emphasis that the infection control community has placed on the ubiquitous placement of point-of-care disinfection stations in order to facilitate convenient hand-hygiene compliance. While strains of *Enterococcus* have yet to "break-through" becoming tolerant to the concentration of alcohols used in the majority of hand rubs, the genetic modifications accumulating as heritable mutations within genes involved in carbohydrate uptake and metabolism (69) are sufficiently concerning to worry that it is only a matter of time before natural selection succeeds with an emergence of an *Enterococcus* completely tolerant to the lethal effects of exposure to short-chained alcohols used in alcohol-based disinfectant hand hygiene products.

No-Touch Disinfection Technologies

Hospital-associated infections (HAIs) continue to be one of the most common and significant complications associated with hospitalization. There is significant interest in learning how to manage and provide best-practice applications for infection control for hospitals (70–73). Microbes have an intrinsic ability to survive and ultimately colonize common touch surfaces where acquisition and transport from surfaces to humans is common. HCWs have the potential to transfer these microbiological contaminants not only from patient to patient but among themselves and back to surfaces, refreshing or adding to the complexity of the microbial reservoir involved in transmission. There have been many studies looking at the control of contamination of common hospital touch surfaces both from hand to surface contact and vice versa. Investigators have shown that the gloves of nurses frequently collected viable methicillin-resistant *S. aureus* (MRSA) after touching inanimate objects near colonized patients (74). In concert with aggressive hand-hygiene campaigns, recent hygiene guidelines specifically recommend that particular attention be paid to the disinfection of patient-care surfaces, especially surfaces designated "high touch objects" (HTOs) as a target of infection prevention and control (75). The guidelines note that such objects could potentially contribute to secondary transmission by contaminating hands of HCWs or by contacting medical equipment that subsequently contacts patients (1, 70, 76–80). Routine or daily cleaning coupled with cleaning immediately after patient discharge (terminal cleaning) of the surfaces and objects within the room with subsequent application of a hospital grade disinfectant has been an accepted method for controlling and limiting the spread of infectious agents. (81) A concentration of less than 250 aerobic colony-forming units (CFUs) per 100 square centimeters has been proposed as the benchmark, where bacterial levels below this value are considered low risk, while concentrations greater are suggestive of an increased infectious risk to patients (82, 83).

No-touch solutions for the disinfection of at-risk environments within healthcare settings are quickly gaining acceptance as the technologies have been found to be an effective and comprehensive addition to systems-based solutions for infection control. To date, they have not been studied in concert with aggressive hand-hygiene campaigns, appropriate routine and terminal cleaning of patient-care environments, or an active surveillance and isolation protocol for patients entering care who are already colonized with VRE, MRSA, *Clostridioides* (formerly, *Clostridium*) *difficile* (CDI or C-diff) or other multidrug-resistant microbes such as *Klebsiella pneumoniae* carbapenemase (KPC). Since the time of the drafting of the previous edition, studies have yet to be completed to learn the outcome from this call to action, again leading us to wonder whether the antimicrobial effectiveness will have an additive effect or whether it will act synergistically. Only through careful studies will we come to know the answer to this question.

As the name suggests, no-touch technologies do not come in direct contact with colonized, contaminated, or soiled surfaces.

Rather, they distribute their microbiocidal activity through the atmosphere by either delivering a lethal concentration of electromagnetic energy in the ultraviolet spectrum or by the real-time distribution of reactive oxygen species, such as hydrogen peroxide, singlet oxygen, hydroxyl radical, or oxyanions. In general, both systems have been found to effectively reduce the concentration of microbes by at least 4 $\log_{10}$ (84). Both systems have their limitations. Each requires skilled labor to place the equipment and commence the disinfection cycle in the location subjected to disinfection. While studies report on the effectiveness of ultraviolet-C (UV-C) to save healthcare institutions on the costs associated with infections the studies often fail to consider the cost of the intervention (85, 86). In general, the cost associated with UV-C disinfection per room for a typical healthcare institution, at prevailing labor rates for 2019 for the United States, is approximately $9.50 per room. The bulk of the cost, 64%, results from the skilled labor required to operate the equipment (~$15 per hour in 2019 wages), where the estimated time per room subsequent to discharge-based cleaning and routine terminal disinfection is approximately 30 minutes with 30 rooms being serviced per day (assuming two shifts per day). The remaining 36% of the cost results from amortization of the capital cost of the device, including maintenance, service, and supplies (capital equipment ranges $82,000–$124,000 per unit and monthly recurring costs of $3,000–$3,500 for maintenance, service, and supplies [bulbs]).

The disinfection reach of ultraviolet light is subject to the effects of shadowing and "cornering" where the light is unable to reach objects not within the sight lines of the device emitting the disinfecting irradiation. This typically requires that the equipment be placed in the center of the room to ensure uniform coverage. Additionally, rooms must be vacant of patients, staff, and visitors as any associated ultraviolet energy needs to be prevented from leaching into areas occupied by people as UV light energy can cause damage to sight and result in burns to exposed skin. The energy can also shorten the life of equipment in the room as routine exposure to UV light can accelerate the decay of the materials by increasing the brittleness of many of the plastics used in the fabrication of equipment associated with the delivery of healthcare.

Despite the limitations of ultraviolet-assisted disinfection, in one comprehensive study, Anderson and colleagues learned that an automated UV-C emitter was capable of decreasing the bioburden of significant pathogens in hospital rooms (87, 88). In their pragmatic, cluster-randomized, crossover trial at nine hospitals in the southeastern United States, they learned that a contaminated healthcare environment is an important reservoir from which patients can acquire pathogens and, importantly, that enhanced terminal-room disinfection decreases HAI risk. Post hoc analysis of their data showed that after the discharge of a previous occupant with a *C. difficile* infection, there was a decrease in multidrug-resistant microbes (primary outcome for their study) as a result of the inclusion of ultraviolet light to the cleaning regimen (88). Similarly, Rutala and colleagues concluded that an enhanced form of disinfection, here again UV-C energy, can lead to a reduction in both the microbial burden in the built environment with a subsequent decrease in patient colonization and infection by four epidemiologically relevant pathogens (MRSA, VRE, *C. difficile*, and multidrug-resistant *Acinetobacter*) (89).

In 2015, Ghantoji and colleagues assessed the noninferiority of pulsed xenon UV-C energy against the effectiveness of bleach for its ability to reduce the concentration of *C. difficile* resident on high-touch services in rooms housing isolation patients with *C. difficile* infections. Here they similarly learned that for high-touch surfaces in rooms previously occupied by patients with *C. difficile* infections, both methods were essentially equivalent in their ability to decrease environmental contamination by spores of *C. difficile* (90).

The cost of enhanced disinfection via vapor-phase disinfection of a built environment is approximately an order of magnitude greater than the cost of UV-C energy with an estimated cost of approximately $107 per single-patient room, again controlling for the capital investment, labor, and supplies. Like UV-C disinfection, this form of enhanced disinfection of the built environment similarly has limitations in that ventilation/air flow to the room must be controlled/and or limited for the duration of the disinfection cycle. This time can vary depending upon the concentration of peroxide or disinfecting gas used. Nevertheless, the two technologies have been found to be effective for the disinfection of inanimate objects and surfaces. However, neither technology is intended as a substitute for cleaning or for the removal of soil from the resident objects and surfaces within the built patient-care environment. An appropriately trained environmental service team must accomplish cleaning, with subsequent disinfection of the built environment.

Recently, we have begun to witness the incorporation of another no-touch technology. However, unlike UV and vapor-phase oxygen radicals (H_2O_2) that distribute their antimicrobial activity through the atmosphere, this technology requires the microbe come in contact with the material in order to exert its antimicrobial activity. Additionally, once placed, such no-touch systems relying on contact for killing do not require any further user intervention. One such example of this type of no-touch technology is solid antimicrobial copper. The resident microbial burden associated with the built environment is continuously reduced through the strategic placement of solid copper surfaces onto critical high-touch surfaces within the patient-care setting (91). Copper has been used by humans for millennia, first as tools and then as a measure to fight the spread of infectious agents. Metallic copper intrinsically displays a strong antibacterial activity both in aquatic systems (92, 93) and on dry surfaces (94–98). In 2008, the EPA registered five families of copper-containing alloys as antimicrobial, establishing that products manufactured from one of the registered alloys kill 99.9% ($\log_{10}$ 2.0) of bacteria within 2 hours of exposure (99). It is anticipated that the solid antimicrobial copper surfaces will remain microbiocidal for the life of the product (>10 years). A variety of controlled studies have looked at the antimicrobial activity of copper surfaces against specific human pathogens (95, 97, 98, 100–102). Copper has been used to limit the bacterial burden found on commonly touched surfaces and objects in active healthcare environments. In a recent hospital trial, bacterial reductions up to one-third were recorded using copper alloys in place of plastic or aluminum surfaces on light switches, door knobs, and push plates (103). Casey and others (104) observed a median microbial reduction of between 90% and 100% ($\log_{10}$ 1.95 and 2.0) on copper surfaced push plates, faucet handles, and toilet seats, while Schmidt and colleagues demonstrated significantly lower bacterial burdens on six HTOs,

averaging an 83% ($\log_{10}$ 1.93) reduction for all of the objects over the course of a 43-month multicenter trial (91).

Current cleaning methods can effectively remove pathogens from surfaces, but studies have shown that more than half of the trial surfaces were not adequately terminally cleaned and may become recontaminated within minutes (105, 106). The rails of hospital beds, as a consequence of coincident interactions with patients, HCWs, and visitors, are one of the most frequently touched items found in the built patient-care environment. Schmidt and colleagues found when they quantitatively assessed the bacterial burden present on bed rails, metallic copper was able to continuously limit the concentration of bacteria resident on frequently touched surfaces before and after routine cleaning (107).

Environmental monitoring of bed frames has shown that beds exceed the suggested bacterial burden more than any other object in patient's rooms (108, 109). The bacterial burden observed was consistently lower on copper surfaced bed rails before and after cleaning. Thus, the copper surfaces were able to augment cleaning by continuously limiting the concentration of aerobic bacteria associated with the rails of beds. This observation was consistently maintained despite the kinetic nature of care present in the environment of the ICU. Low-risk concentrations were associated with 77% of the sampled beds (107). Further, MRSA, VRE, and Gram-negative bacteria were absent from all of the copper samples, arguing that the risk mitigation provided by copper surfaces might be greater than the data suggest (107).

Weber and Rutala (110) in their commentary of the evaluation of no-touch copper conducted by Karpanen and colleagues argued that it was impractical or impossible to coat each of the environmental surfaces with copper (111). However, the data provided by Schmidt and colleagues suggest that the strategic placement of copper in key, high-touch areas offers a novel strategy to limit the bacterial burden on a continuous basis (91). The other no-touch methods for room disinfection rely on discontinuous modalities of application to reduce the environmental bacterial burden (84). Hydrogen peroxide vapor (HPV) is introduced as a gas into a sealed room. Ultraviolet light (UV) achieves its effectiveness through the transient transmission of germicidal radiation within an unoccupied room. Consequently, like the EPA registered disinfectants regularly used to disinfect patient rooms, subsequent to cleaning, both UV and HPV will likely suffer from the same limitations of the rapid restoration of the bacterial burden intrinsic to HTOs. In contrast, copper-alloyed surfaces offer a continuous way to limit and/or control the environmental burden. Hospital and environmental services need not perform additional steps, follow complex treatment algorithms, obtain "buy-in" from other providers, or require additional training or oversight.

In addressing the question of whether or not the strategic placement of copper might ameliorate the rate with which HAIs are acquired, Salgado and colleagues (112) found from the conduct of a multicenter trial that the limited placement of copper as described by Schmidt and colleagues (91) resulted in a significant reduction to the HAI rate and/or MRSA or VRE colonization rate in medical intensive care rooms (ICU). The collective rate for HAI infection or MRSA/VRE colonization was found to be significantly lower 42% (7.1%) in the copper arm of the study when compared against the (12.3%) rate observed in the control rooms ($p = 0.020$). When the data were considered separately for HAI alone, the rate of infection was significantly reduced (58%) from 8.1% to 3.4% ($p = 0.013$). The investigators also were able to demonstrate that burden and infection were directly linked. In the analysis of the quartile distribution of HAIs stratified by microbial burden measured in the ICU rooms during the patient's stay they learned that there was a significant association between burden and HAI risk ($p = 0.038$), with 89% of HAIs occurring among patients cared for in a room with a burden of more than 500 colony-forming units (CFUs) (112).

The results of the effectiveness of antimicrobial copper surfaces being able to debulk the built environment have been confirmed in a number of subsequent trials (113–115). The first was a trial conducted in a pediatric ICU (115, 116). Here, copper surfaces were found to be equivalently antimicrobial in pediatric settings to activities observed in adult medical ICUs. In a companion trial to the one of Salgado and colleagues (112), copper surfaced bed rails were found to limit and continuously reduce the microbial burden to levels 99% lower than the equivalent control areas, leading the authors to conclude that copper surfaces warranted serious consideration when contemplating the introduction of no-touch disinfection technologies for reducing burden to limit acquisition of HAIs (113). In another trial, set in the medical-surgical suites for a 49-bed rural facility, 20 surfaces and components were outfitted with continuously active antimicrobial copper surfaces for 12 months (114). All of the components fabricated using copper alloys were found to have significantly lower concentrations of bacteria, at or below levels targeted upon completion of terminal cleaning (2.5 cfu/cm^2). Surprisingly vacant, control rooms were found to harbor significant concentrations of bacteria, whereas those fabricated from copper alloys were found to be at or below those concentrations prescribed subsequent to terminal cleaning, leading the authors to conclude that such an intervention using copper alloys can significantly decrease the burden resident on high-touch surfaces implicated in HAIs, and thus warrant inclusion as component for an integrated infection control strategy for rural hospitals (114).

Taken collectively, the data from the no-touch technologies support an argument that any method to minimize the patient's exposure to potentially infectious microbes, whether it be hand hygiene, routine cleaning, or the deployment of no-touch disinfection technologies will likely translate into better patient outcomes. Of the no-touch technologies, the demonstration that antimicrobial activity of copper surfaces was continuous in its effectiveness likely offers the best explanation as to its effectiveness at reducing the rate with which HAIs were acquired.

Hazard Analysis Critical Control Point and Risk Assessment Methods

Food-related industries have used Hazard Analysis Critical Control Point (HACCP) as a method to identify critical control points where lack of compliance or failure to meet standards is where foodborne illness or contamination of a manufactured product may occur.

The HACCP can be used to promote two positive outcomes. First, a well-designed HACCP can be used as a diagnostic tool to find points in a system where failure might occur. For example, if a certain floor disinfectant has a maximum disinfectant activity at 80°F, a critical control point on the HACCP would be that the temperature was measured and remained at that temperature

throughout use. The second area of use is in education, where those using the disinfectant could be asked during regular and routine surveys if they were measuring and using the disinfectant at that temperature. Meeting compliance standards by writing elegant in-house documents of required methods, and actually monitoring that those standards are maintained by all staff regardless of station, are two different goals—both of which have equal importance.

The HACCP is a qualitative rather than a quantitative tool. Larson and Aiello (117) list the seven steps of HACCP as follows:

1. Analyze the hazards.
2. Identify the critical control points.
3. Establish preventative measures with critical limits for each control point.
4. Establish procedures to monitor the critical control points.
5. Establish corrective actions to be taken when monitoring shows that a critical limit has not been met.
6. Establish procedures to verify the system is working properly.
7. Establish effective record keeping for documentation.

When more quantitative measures are required, a microbial risk assessment model may be the method of choice. Larson and Aiello (117) use four categories of environmental site-associated contamination risks and need for contamination based on the work of Covello and Merkhoffer (118). These include:

1. Reservoirs (e.g., wet sites: humidifiers, ventilators, sinks) with a high probability (80–100%) of significant contamination and an occasional risk of contamination
2. Reservoir/disseminators (e.g., mops, sponges, cleaning materials) with a medium risk (24–40%) of significant contamination and a constant risk of contamination transfer
3. Hand and food contact surfaces (e.g., chopping boards, kitchen surfaces, cutlery, cooking utensils) with a medium risk (24–40%) of significant contamination and a constant risk of contamination transfer
4. Other sites (e.g., environmental surfaces, curtains, floors) with a low risk (3–40%) of significant contamination and an occasional risk of contamination transfer

Covello and Merkhoffer (118) use six criteria in the evaluation of a risk-assessment-based framework: logical soundness, completeness, accuracy, acceptability, practicality, and effectiveness.

Whether a formal HACCP or risk-assessment or a site-specific method/process-specific model developed by the operator is used, a formal method of assessment of structure, appropriate use, compliance, education, and record-keeping is needed. The methods must be kept current with the practices of the laboratory, hospital, or manufacturing entity, and also with the evolution of resistance in microbes and introduction of new microbes into the environment.

The tables in this chapter represent a selective starting point for choosing a method of sterilization or disinfection. Many of the cited articles contain in-depth information and should be consulted for further details, as there are space limitations herein. New methods are also being developed daily.

Quantitative Microbial Enumeration

This chapter provides general information on the various methods used to estimate the number of microorganisms in a given sample. The scope of this chapter is limited to methods used for the enumeration of microbial cells and not the measurement of microbial cellular mass.

Most Probable Number (MPN) Method

General

The most probable number (MPN) method is a microbial estimate method used to enumerate viable cell counts by diluting the microorganisms, followed by growing the diluted microorganisms in replicate liquid medium dilution tubes. An example of a MPN dilution scheme used to prepare the various dilution

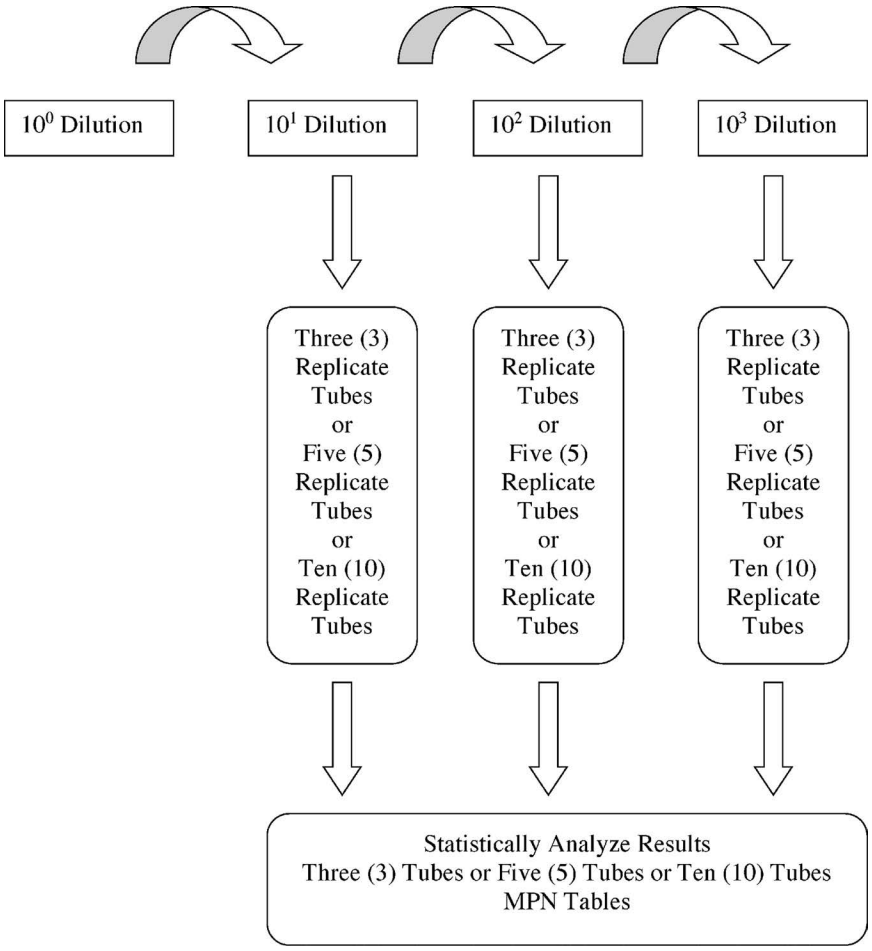

FIGURE 2.1 MPN serial dilution scheme.

test tube replicates is shown in Figure 2.1. After optimal microbial growth incubation, the positive and negative test results are based on the positive (visible turbidity) and negative (clear) replicate dilution tubes. The MPN method can also be referred to as the multiple tube fermentation method if fermentation tubes (Durham tubes) are also used inside the serial dilution tubes to measure gas production. The viable cell counts are then compared to a specific MPN statistical table to interpret the test results observed. There are also several versions of statistical tables used based on the sample matrix tested, test dilutions used, number of replicates per dilution used, and the statistical considerations used.[1–7] Table 2.1 and Table 2.2 provide two examples of MPN statistical tables for three tenfold dilutions with three or five tubes at each dilution, respectively.[8] The confidence limits of the MPN are narrowed when a higher number of replicate dilution tubes is inoculated in the dilution series. A number of assumptions are also considered when using the MPN method of microbial estimation. The microorganisms to be estimated are distributed randomly and evenly separated within the samples tested in the liquid dilution tubes. The microorganisms to be estimated are also separated individually and are not clustered together, nor do they repel each other in the liquid dilution tubes. In addition, the utilization of optimal growth medium, incubation temperature, and incubation period is needed to allow any single viable cell to grow and become quantifiable in the liquid dilution tubes used. Primary equipment and materials used for this method are serial dilution tubes (may include use of Durham fermentation tubes), dilution replicate tubes, pipettes, specific growth medium/reagents, and incubator with appropriate optimal temperature setting. Sources of error using this method are improper or inadequate preparation of the test samples, serial dilution or dilution factor calculation error, and statistical interpretation error of observed results.

Applications

The MPN method is useful in the estimation of low microorganism counts where particulate matter or turbidity is present in the sample matrix, such as in milk, food, water, and soil. The MPN method is not particularly useful in the enumeration of fungi. It is mainly used in the enumeration of samples with low bacteria concentrations or bacteria that does not grow well on solid medium or use in the enumeration of total aerobic bacterial counts. MPN methods are used in the areas of food,[8–17] pharmaceutical,[18–21] environment,[22–24] water,[25–31] agriculture,[32,33] petroleum,[34–36] and poultry[37,38] applications. Modified or alternate versions of the MPN method have also been developed to further expand the use of the standard MPN method to estimate bacteria by utilizing

Turbidimetric Method

General

The turbidimetric method is used to measure the turbidity in a suitable liquid medium inoculated with a given microorganism.[67–71] Turbidimetric measurement is a function of microorganism cell growth. This method of microbial enumeration is based on the correlation between the turbidity observed and changes in the microbial cell numbers. Standard optical density (O.D.) or turbidimetric curves constructed may be used to estimate the number of microbial cells for the observed turbidity values using a turbidimetric instrument. This is achieved by determining the turbidity of different concentrations of a given species of microorganism in a particular liquid medium using the standard plate count method to determine the number of viable microorganisms per millimeter of sample tested. The turbidimetric calibration standard curve generated is subsequently used as a visual comparison to any given suspension of that microorganism. The use of this method assumes that there is control of the physiological state of the microorganisms. It is based on the species of microorganism and the optimal condition of the turbidimetric instrument used. Primary equipment and materials used for this method are the turbidimetric reading instrument, turbidimetric calibration standards, optically matched tubes or cuvettes, appropriate recording instruments, dilution tubes, pipettes, specific growth medium and reagents, and incubator with appropriate optimal temperature setting. The turbidimetric reading instrument can be, for example, be a spectrophotometer or turbidimeter (wavelength range of 420–615 nm). The typical turbidimetric standard used is the McFarland turbidimetric standard. These standards are used as a reference to adjust the turbidity of microbial suspensions to enable the number of microorganisms to be within a given quantitative range. These standards are made by mixing specified amounts of barium chloride and sulfuric acid to form a barium sulfate precipitate that causes turbidity in the solution mixture. If *Escherichia coli* is used, the 0.5 McFarland standard is equivalent to an approximate concentration of 1.5×10^8 colony forming units (or CFUs) per mL. The 0.5 McFarland standard is a commonly used standard, which is prepared by mixing 0.05 mL of 1% barium chloride dehydrate with 9.95 mL of 1% sulfuric acid. There are other turbidimetric standards that can be prepared from suspensions of latex particles that can extend the expiration use and stability of these suspensions.[72,73] Sources of error for this method include using a noncalibrated instrument, damaged or misaligned optical matched tubes or cuvettes, color or clarity of the liquid suspension medium used, condition of the filter or detector used, and quality of the turbidimetric instrument lamp output. Sources of error for this method can also be microbial related, such as clumping or settling of the microbial suspension, inadequate optimal growth condition used; or analyst related, such as lack of understanding the turbidimetric technique used, sample preparation error, and incorrect use of the turbidimetric standards.[74,75]

Another recent use of the turbidimetric technique is the use of the turbidimetric method in combination with the use of modern digital photography method.[76]

Applications

Turbidimetric methods are used where a large number of microorganisms is to be enumerated or when the inoculum size of a specific microbial suspension is to be determined. These areas include antimicrobial, preservative, or biocide susceptibility assays of bacteria and fungi,[77–91] growth of microorganisms,[92–96] effects of chemicals on microorganisms,[97,98] and control of biological production.[99]

Plate Count Method

General

The plate count method is based on viable cell counts. The plate count method is performed by diluting the original sample in serial dilution tubes, followed by the plating of aliquots of the prepared serial dilutions into appropriate plate count agar plates by the pour plate or spread plate technique. The pour-plate technique utilizes tempered molten plate count agar poured into the respective plate and mixed with the diluted aliquot sample in the plate, whereas the spread-plate technique utilizes the addition and spreading of the diluted aliquot sample on the surface of the preformed solid plate count agar in the respective plate.[100] An example of a plate count serial dilution scheme is shown in Figure 2.2. These prepared plate count agar plates are then optimally incubated and the colonies observed on these plate count agar plates are then counted as the number of colony forming units (CFUs). The counting of CFUs assumes that every colony is separate and founded by a single viable microbial cell. The total colony counts obtained in CFU from the incubated agar plates and the respective dilution factor used can then be combined to calculate the original number of microorganisms in the sample in CFU per mL. The typical counting ranges are 25–250 CFU or 30–300 CFU per standard plate count agar plate. Additional considerations for counting colony forming units (or CFUs) are counting of plate spreaders, too numerous to count (TNTC) reporting and statistics, rounding and averaging of observed plate counts, limit of detection, and limit of quantification of plate counts.[101–103] There are also optimal condition assumptions for the plate count method as changes to the plate count agar nutrient level or temperature can affect the surface growth of bacteria.[104,105] Primary equipment and materials used for this method are serial dilution tubes (bottles); petri plates or dishes; pipettes; specific growth medium, diluents, and reagents; incubator and water bath with appropriate optimal temperature setting; commercial colony counter (manual or automated); and plate spreader or rod. Total bacteria and fungi can be enumerated separately using the plate count method based on the type of culture medium utilized.[106–111] Specific or selective culture medium can also be used in place of the standard plate count agar media more specific microbial enumeration.[112,113] Sources of error using this method are improper or inadequate preparation of the test samples, serial dilution error, suboptimal incubation conditions, undercounting due to cell aggregation or clumping, and analyst error in the colony counting or calculation of observed results.

Applications

The plate count method is used primarily in the enumeration of samples with high microorganism numbers or microorganisms that do not grow well in liquid media. Plate count methods are used in the areas of food,[106,107,114–117] pharmaceutical,[19–21] environmental including drinking water applications,[30,118–122] and biofilm testing.[123,124] Modified or alternate versions of the plate count methods have also been developed to further enhance the use of the standard plate count method approach to estimate bacteria or fungi by utilizing the roll-tube method,[125–128] drop-plate method,[129–131] spiral plate count method,[132–135] Petrifilm™,[136–151] SimPlate™,[54,152–157] RODAC™ (replicate organism detection and counting plate) for environmental surface sampling,[158–165] dipslide or dipstick paddle method,[166–170] and adhesive sheet method.[171–177]

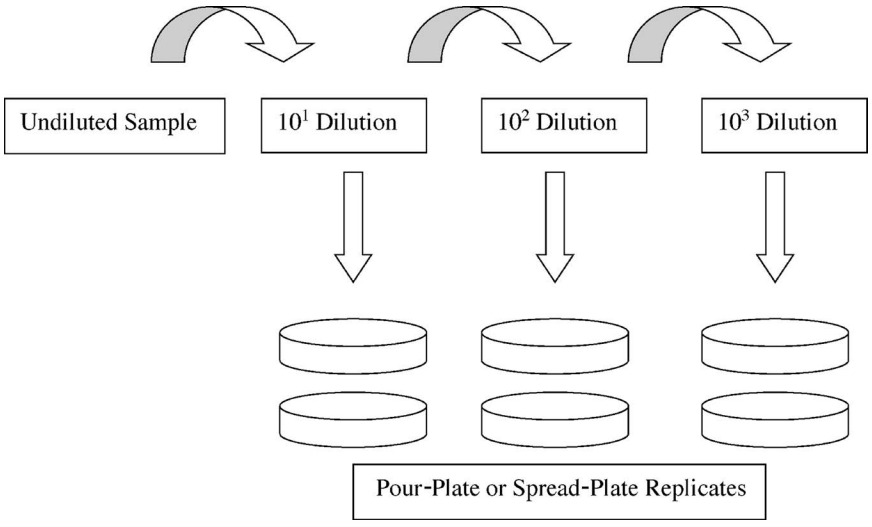

FIGURE 2.2 Plate count serial dilution scheme.

Membrane Filtration Method

General

The membrane filtration (MF) method is based on viable cell enumeration. The MF method is conducted by filtering a known volume (typical volumes range from 100 mL to 1,000 mL) of liquid sample through a sterile membrane filter (0.22 µm or 0.45 µm pore size). The filter membrane will retain microorganisms during membrane filtration of the liquid sample. After filtration, the membrane filter is placed onto a membrane filter agar medium plate or membrane filter medium pad. These membrane filter plates or pads are then optimally incubated and the colonies observed on these membrane filter plates or pads are counted as the number of colony forming units (CFUs). The total colony counts obtained in CFU from the incubated membrane filter plates and pads and the respective membrane filtered sample volume used can then be combined to calculate the original number of microorganisms in the sample volume used (in CFU per mL). The typical counting ranges are 20–80 CFU per membrane filter used. Primary equipment and materials used for this method are the membrane filtration manifold unit (single or multiple); specific membrane filter with an appropriate membrane pore size and membrane material; filter funnels; pipettes; serial dilution tubes; specific growth medium; sterile buffers or diluents, and reagents, incubator with appropriate optimal temperature setting; vacuum pump; and sterile forceps. Sources of error using this method are improper or inadequate preparation of the test samples, sample dilution error, suboptimal incubation conditions, solid particles and membrane-adsorbed chemicals may interfere with microbial growth, and analyst error in the colony counting or calculation of observed membrane filtration results.

Applications

The membrane filtration method is used to concentrate the number of microorganisms from large volumes of liquid sample with low numbers of microorganisms. This flexible sample volume range allows for the use of larger sample volumes and increases in the sensitivity of microbial enumeration. The membrane filtration method is not particularly useful with turbid or highly particulate samples that may block the membrane pores. Membrane filtration methods are used in the areas of food,[178,179] pharmaceutical,[19–21,180,181] and environmental including drinking and recreational water application.[30,182–190] Modified or alternate versions of the membrane filtration estimate have also been developed to further enhance the use of this method in estimating bacteria by utilizing the defined substrate medium membrane filtration method (selective and/or differential medium)[191–197] and the higher microbial enumeration range hydrophobic grid-membrane filtration (HGMF) method.[198–209]

Direct Count Method

General

The number of microbial cells can be determined by direct microscopic examination of the sample within a demarcated region or field of the microscopic slide and counting the number of microbial cells observed per field under the microscope. The enumeration of microbial cells in the original sample can be rapidly calculated using an aliquot of known volume used for direct enumeration under the microscope slide (numbers of cells counted per field and number of microscopic fields counted) in number of microbial cells per milliliter or by using a counting standard.[210,211] This direct count method requires a higher number of microorganisms per milliliter for enumeration, and there is the potential for counting both dead and living microbial cells. An extension of the direct count method is the use of fluorescent stains with the epifluorescence microscope or the direct epifluorescence filtration technique (DEFT).[212–219] Primary equipment and materials used for this method are the microscope (light or phase contrast or epifluorescent), microbial counting chambers (Petroff-Hauser, Helber, or Nebauer) or membrane filter, microscope slide support, internal counting standards (latex particles), biological stains or fluorochromes for certain applications, and capillary tubes. Sources of error using this method include the experience of the analysts performing the microbial cell count observed under the microscope, cell aggregation or clumping, inadequate staining, and inadequate microscopic slide sample preservation or preparation.

Applications

Direct count methods are used in the areas of food,[220,221] biocides,[222,223] metal working fluids,[224] and environmental including soil, air, water, or terrestrial ecological applications.[225–232] Modified or alternate versions of the direct count method have also been developed, such as the direct viable count method (DVC),[233–242] fluorescence *in situ* hybridization (FISH) method,[239–242] and combined DVC-FISH method.[243–246]

Particle Counting Method

General

The coulter counting method, or electrical sensing zone (ESZ) method, is a particle count method in which microbial cells suspended in a weak electrolyte pass through an electric field of standard resistance within a small aperture. The measured resistance changes as the microbial cells pass through the aperture. The voltage applied across the aperture creates a sensing zone. If a constant voltage is maintained, a microbial cell passing through will cause a transient decrease in current as the resistance changes. A transient increase in voltage will occur if constant current is maintained. These transient impedance changes in the sensing zone can then be amplified and recorded electronically, thus allowing one to enumerate the number of microbial cells flowing through the aperture opening. The estimation of the total number of microbial cells in a given sample can be correlated with the microbial cell counts obtained for either a metered sample volume or a fixed time period for flow under constant pressure.[247–251]

The flow cytometry method is another particle count method that analyzes the light scatter and fluorescence emitted from individual microbial cells as these cells flow in a single-file manner through an intensely focused laser light source. The sample is injected into a pressurized fluid-delivery system or sheath that forces the suspension of cells into laminar flow and aligned in single file along the central core through the sensing zone. As the

cells pass through the sensing zone, a laser light source generates a light-scatter pulse that is collected at small forward angles and right angles to the cell. The collected light pulse from the single cell is converted to an electrical signal (voltage) by either a photodiode or a photomultiplier. The captured data can then be analyzed as two-parameter histograms or by using multiparametric analysis. Fluorescent dyes or stain can be used to further enhance the use of the flow cytometry to discriminate between live or dead microbial cells. A combination of internal calibrating counting beads used per test, the number of events in a region containing microbial cell population and bead population, dilution factor used, and test volume will provide the estimated total number of microbial cells in a given sample.[252–259]

Primary equipment and materials used for the particle count method are commercially available counters (coulter counters or flow cytometry counters), internal liquid bead counting standards (polystyrene beads with or without fluorophores), biological stains or fluorochromes for certain applications, specific reagents (electrolyte solutions or sheathing liquids or preservatives), disposable test tubes, micropipettes plus pipette tips, and vortex mixer. Sources of error using this method include the presence of bubbles or foreign particles while cell counting, which causes high background noise; partial blocking of the counting aperture; a higher number of cells, which may lead to higher probability of the coincident passage of two or more cells through the aperture; and background noise, which will become higher for enumerating low concentrations of cells.

Applications

Particle counting methods are used in the areas of food,[260–265] pharmaceutical or dental,[266–270] and environmental or water treatment applications.[270–281] Flow cytometry methods can also be used for virus enumeration.[282–286] Modified or alternate versions of the standard particle counting methods have also been developed, including the solid state laser cytometry method.[287,288]

Focal Lesion Method

General

The focal lesion method considers an infection of a suitable host by a specific virus to produce a focal lesion response that can be quantitated if it is within an appropriate range of the dilution of the viral sample used. The average number of focal lesions is a linear function of the concentration of virus employed. This method is used to enumerate the number of viruses because each lesion formed is focused at the site of the activity of an individual viral particle. The relationship between the lesion counts obtained and the virus dilution used is also statistically consistent. Primary equipment and materials used depend on the test system employed. Focal lesions can be generated on the skin of whole animals, on the chorioallantoic membrane of chicken embryo, or in cell culture monolayers. Focal lesions can also be produced in agar plate cultures of bacterial viruses and on the leaves of a plant rubbed with a mixture of virus plus abrasive. Sources of error using this method are nonspecific inhibition of focal lesion response by unknown factors, dilution or counting errors, overlapping of focal lesions, size of focal lesions and the numbers countable on the surface area tested, and insufficient viral replication to provide statistical significance.

Applications

The focal lesion method can be used for the enumeration of animal, plant, and bacterial viruses.[289–291]

Quantal Assay Method

General

The quantal assay method uses a statistical method with an all-or-none (cell culture mortality or cytopathic effect or death of experimental animals) response or outcome to enumerate the number of viruses in a given sample. Using a serial dilution approach, the endpoint of activity or infectivity is considered the highest dilution of the virus at which there is 50% or more positive response of the inoculated host. The exact endpoint is determined by interpolation from the cumulative frequencies of positive and negative responses observed at the various dilutions. The endpoint of the quantal titration is the viral dilution that has 50% positive and 50% negative responses. The reciprocal of the dilution yields an estimate of the number of viral units per inoculum volume of the undiluted sample and is expressed in multiples of the 50% endpoint. Primary equipment and materials used for the quantal assay method will depend on the test system employed either as groups of animals, use of chick embryo, or tubes/flasks of cell cultures. Sources of error using this method include dilution or counting errors and insufficient replication to provide statistical significance, and sample titration.

Applications

The quantal assay method is used in infectivity assays in animals or tissue-culture-infectious-dose assay applications in which the animal or cell culture is scored as either infected or not infected. The infectivity titer is proportionately measured by the animal or tissue culture infected. The main use of this method is in the enumeration of culturable waterborne viruses.[292–295]

Plaque Assay Method

General

The plaque assay method utilizes serial dilution of a given viral suspension sample that is inoculated onto a confluent monolayer of a specific host cell culture. Following the adsorption or attachment step, the monolayer is overlaid with either a semisolid or solid medium to restrict the movement of the progeny virus in the vicinity of the infected host cells. After incubation, the infectious plaque plate is enumerated and examined for plaque formation. Each virus unit makes one plaque (an observed localized focus of infected and dead cells) after the cell monolayers are stained with general cellular stain or dye. The infectivity titer of the original viral suspension sample is recorded as plaque-forming units (PFUs) per milliliter. Primary equipment and materials used for this method include serial dilution tubes (bottles), petri plates or dishes, pipettes, specific growth medium, specific cell culture or

bacterial host, diluents, reagents, membrane filtration setup, stains/dyes as needed, and incubator and water bath with appropriate optimal temperature setting. Sources of error using this method include improper or inadequate preparation of the test samples, serial dilution error, suboptimal incubation conditions, and analyst error in the plaque counting or calculation of observed results.

Applications

The plaque assay method can be used for the enumeration of animal, plant, and bacterial viruses.[296–310]

Rapid Methods

General

There are several types of rapid microbiological technologies that fall into one or sometimes overlap into two of three general categories: Identification, qualitative (i.e. presence/absence), or quantitative (i.e. countable). Quantitative rapid technologies specifically can be further subdivided into colony forming units (CFU), countable (growth-based), or cellular countable technologies.

Growth-based rapid methods typically require several hours or up to a day or longer to yield final results because these technologies rely on the detection of microcolonies using ATP bioluminescence, cellular fluorescence, or high magnification images. These technologies often have a sensitivity of one CFU. A benefit of these technologies is the ability to continue incubation after detection of growth to yield larger colonies to perform subsequent identification. They also align well with compendial sample preparation methods such as membrane filtration.

Cellular countable-based rapid methods can generate results in seconds to minutes. Due to the speed at which these results can be generated, these methods can be particularly useful when continuous monitoring is desired, such as in active air or purified water systems. One example is the use of Raman spectroscopy to compare microscopic particulate spectral signatures to a library of known microorganisms. Another example is the cleavage of enzymatically fluorescent substrates by metabolically active cells combined with solid phase cytometry, Mie scattering or flow cytometry (see Particle Counting Method section). When samples pass through a flow cell, a laser diode illuminates the sample. Mie scattering sizes any particles present while fluorescence detects biological metabolites like NADH (nicotinamide adenine dinucleotide [NAD] + hydrogen [H]) and riboflavin. These technologies can be sensitive to the single-cell level. An advantage for some cellular-based rapid methods have over growth-based rapid methods is that they can detect microbes that are viable but not culturable using traditional growth media.

Primary equipment and materials used for rapid methods are commercially available including reagents and instruments. Sources of error using these methods vary depending on the instrument being used. Regardless of instrument being used, user training should be a primary consideration.

Applications

Different rapid methods vary in their application, but as a whole they allow for a broad spectrum of detection of bacteria, yeast, and mold in raw material in addition to finished product bioburden testing, environmental monitoring, water analysis, and sterility testing. Some technologies are applicable across multiple types of sample analysis, such as air monitoring or water monitoring. It is common for a single piece of equipment to be dedicated to a certain type of analysis, such as air monitoring or water analysis, even though the underlying technology being used in different pieces of equipment may be essentially the same.[311–323]

Summary

There are a number of test methods used for the quantitative enumeration of microorganisms. A more formal validation approach can also be used to compare new or alternate test methods for the quantitative enumeration of microorganisms.[324–331] This may include rapid test methods for the quantitative enumeration of microorganisms compared to the above standard microbial enumeration test methods.[332–339] Methods for quantitative enumeration of microorganisms will continue to be developed and validated to meet the various industry demands and the associated microbial quantitative enumeration applications, as evidenced by more recent statistical approaches to quantitative microbial estimation or counting methods and the uncertainty associated with microbiological testing.[340–347]

Introduction

The use of culture as a diagnostic technique is described in Chapter 10. The purpose of this chapter to discuss only the principles of enrichment culture. This technique has been in use for more than 120 years.[1,2] It consists of incubating a sample in a medium that encourages the growth of an organism of interest, while inhibiting the growth of others. In this way, it can assist the technician in isolating pure colonies of microorganisms from mixtures in which the organisms represent only a very small percentage of the overall flora, and in which isolation by streaking may not be practical. In some cases, as in the isolation of salmonella, first growing a sample in an enrichment culture is a necessary first step to increase the relatively small number of organisms usually found in the primary sample.[3] While the use of enrichment broths in food and environmental microbiology has been demonstrated, their use in clinical microbiology has not fully been established.[4] In some cases, the use of enrichment broths has done little more than add unnecessary cost and extra testing.[5]

Designing an Enrichment Medium

Introduction

While the media used to enrich for specific microorganisms might differ greatly, they should all contain an energy source, a carbon source, and a source of major and trace elements. Factors such as the pH, temperature, and oxygen tension should be appropriate to enhance the growth of the microorganism of interest.[1] In addition to providing components that select for specific microorganisms, enrichment media may also contain antibiotics or other compounds that inhibit the growth of microbiological competitors. In the case of autotrophic microorganisms, such as cyanobacteria or algae, enrichment media may lack the carbon sources required by heterotrophic microorganisms.

Historically, enrichment cultures have been developed by selecting chemically defined components, and empirically testing their ability to enrich for the organism of interest. While this might be useful in some settings, recent studies have found that the microbial interactions during the enrichment process can be important. This interaction can be either positive in that some microorganisms will only grow in culture if they can interact with others; or negative in that the presence of other organisms normally found in the same biosphere might inhibit growth.[6–8]

In recent years, molecular methods have been employed in the development of enrichment media. This is especially true in environmental studies in which the biome may have hundreds of different species in a starting sample. Mu et al. performed an initial enrichment culture of marine sediment and obtained isolated colonies. These were then subjected to 16S RNA analysis. By altering the parameters of the enrichment process, they were able to affect the relative ratios of 16S RNA sequences that they observed.

In addition to providing an enrichment method, this technique also allowed them to identify viable but dormant microorganisms.[9]

Energy Source

Most microorganisms are heterotrophs, and as a result, obtain their energy by ingesting organic molecules. When these molecules are broken down, energy contained in the chemical bonds is liberated.[10] Some microorganisms are autotrophs and are capable of obtaining energy either by oxidizing inorganic chemical compounds (chemoautotrophs) or by directly utilizing light (photosynthetic).[10] Chemoautotrophs derive energy from reduced inorganic molecules or ions, which can include H_2, NH_4^+, Fe^{2+}, and S^0.[1,11,12] Photosynthetic microorganisms derive their energy directly from light sources, with bacteria and photosynthetic eukaryotes favoring light in the red portion of the spectrum, while cyanobacteria favor light in the blue portion.[1]

Source of Carbon

Because autotrophic organisms derive their energy from light, this usually requires little more than a source of simple carbon, such as bubbling CO_2 gas into the media or by adding a solid carbonate source. Heterotrophic organisms can obtain their carbon from a wide variety of sources. The most common of these are carbohydrates. Many of these are actually used as the component parts of biochemical tests used to identify microorganisms. These include carbohydrates (i.e., glucose, maltose, lactose, sucrose, etc.), acids found in the TCA cycle (i.e., succinic, oxaloacetic, malic, α-ketogluaric, etc.), amino acids (i.e., alanine, arginine, glycine, serine, etc.), and fatty acids (i.e., lactic, pyruvic, butyric, propionic, etc.).

In the past few years, it has been realized that microorganisms exist that are capable of using toxic compounds as carbon sources. Xu et al. have recently reviewed the use of microorganisms in bioremediation.[13]

Trace and Major Elements

All microorganisms require varying amounts of certain elements. Major elements such as nitrogen, potassium, sodium, magnesium, and calcium can be found as salts. These can include chlorides (NH_4Cl, KCl, NaCl), sulfates ($MgSO_4.7H_2O$, Na_2SO_4, $(NH_4)_2SO_4$), carbonates ($MgCO_3$, $CaCO_3$), nitrates ($(CaNO_3)_2.4H_2O$), and phosphates (K_2HPO_4, KH_2PO_4).[1] Other elements may also be required in trace amounts. These can include nickel, iron, zinc, manganese, copper, cobalt, boron, molybdenum, vanadium, strontium, aluminum, rubidium, lithium, iodine, and bromine.[14]

pH

While most organisms prefer to grow in a neutral pH environment, the pH level can be used as an enrichment method. Acidophiles, for instance, can be enriched by lowering the pH in the media.[15]

Physical Components

Although researchers usually tend to focus on ingredients that can be added to a liquid medium, it should be remembered that manipulating the physical environment in which the culture is placed for temperature, oxygen tension, and even pressure, may offer some microorganisms a competitive advantage in reproduction. The levels of these agents will be determined by which organism the technician is trying to isolate.[16] Thermophiles, such as *Thermogladius shocki*, for, instance can be enhanced by growing cultures at temperatures as high as 80–95°C.[17] Selective enrichment can also be obtained by varying the concentrations of media.[18]

Antimicrobial Agents

Enrichment for specific groups or species of microorganisms can not only be achieved by defining conditions that will preferentially allow them to grow, but can also be achieved through the use of agents that will inhibit the growth of competing organisms. In some instances, fast-growing organisms can be inhibited, giving fastidious or slower-growing organisms an advantage in a particular sample. An interesting clinical consequence of the use of antimicrobial agents as a method of enrichment is the observation of resistant organisms in patients who have been hospitalized. Hui et al.[19] have found that previous antibiotic exposure of nosocomial patients using mechanical ventilation can lead to an increase in antibiotic resistance. Antibiotics can also be used for enriching specific resistant strains. It is not known if this technique provides any advantages over the standard methods of testing isolated colonies (i.e., MIC or KB) for antibiotic resistance.[20]

Preservation of Microorganisms

Introduction

Many laboratory test procedures require the use of microorganisms as reagents. Many of these are naturally occurring, but advances in biotechnology have also resulted in the creation of engineered microorganisms. In both instances, to obtain consistent results, these organisms must be preserved in a manner that will allow for their genetic stability and long-term survival. Preservation of microorganisms can be accomplished by a variety of methods. These can include subculturing them, reducing their metabolic rate, or putting them into a state of quasisuspended animation.[21] The chosen method will usually depend on which organism one is trying to preserve. Despite the introduction of newer methodologies, many of the techniques that are used have not changed much since the previous editions of this book. Most still involve the use of drying, lyophilization, or storage in freezing or subfreezing temperatures. A flowchart as well as specific techniques for preservation can be found at www.cabri.org (accessed January 29, 2020).

Methods

Serial Subculture

This is a simple method in which the cultures are periodically passed in liquid or agar media. Some cultures can be stored on agar media in sealed tubes and survive for as long as 10 years.[22] This method has been used extensively for fungi, but usually requires storage under mineral oil.[21] Despite its simplicity and

applicability for cultures that cannot survive harsher preservation methods, serial subculture is not a very satisfactory method. In our hands we have had problems with contamination, culture death, and the unintended selection of mutants. This has been particularly difficult in cases in which we were trying to develop new products for the identification of microorganisms. It was imperative to periodically confirm the identity of the organisms being used in the database.

Storage at Low Temperatures

Some species are capable of being stored for long periods at 4–8°C on agar plates or on slants. Sorokulova et al. have found that the use of acacia gum in storage media will allow long-term storage of organisms even at room temperature.[23]

In our lab, we have been able to store cultures at –20°C for extended periods. We have found that this can be accomplished by growing the cultures in liquid media for 24–48 hours and then mixing one part sterile glycerol to three parts culture. While this does not work for all organisms, it allows the use of a standard refrigerator for preserving cultures. Many laboratories store organisms at –70°C to –80°C by first mixing them with 10% glycerol.[24] Cultures can also be stored indefinitely in liquid nitrogen. While the use of liquid nitrogen is a good method for storing microorganisms, for most laboratories, it requires the expense of constantly refilling a specialized thermos. Tedeschi and De Paoli in their review of cryogenic methods of preserving microorganisms point out that in this era of being able to manipulate the microorganism genome, that it is important to pick a cryogenic preservation method that will preserve the genotype and phenotype of the original organism.[25]

Freeze-Drying

This is a widely used method in which a suspension of microorganisms is frozen and then subjected to a vacuum to sublimate the liquid. The resulting dried powder is usually stored in vials sealed in a vacuum. Many factors can affect the stability of the culture. These include the growth media, the age, phase and concentration of the organisms, lyoprotectant added, and the mass of the cotton added to the storage ampule.[21,26–28]

The length of sample viability can vary substantially, but cultures surviving for up to 20 years have been reported.[29] Freeze-drying requires a cryoprotective agent to provide maximal stability. Usually, the organisms are suspended in 10% skim milk.[30]

Storage in Distilled Water

This was cited as a method of preservation of *Pseudomonas* species and fungi in the first edition of this book.[21] Recent studies have found that it is still an effective method of preserving fungi,[31] as well as a wide variety of bacteria (including *Pseudomonas fluorescens, Erwinia* spp., *Xanthomonas campestris, Salmonella* spp., *Yersinia enterocolitica, Escherichia coli O157:H7, Listeria monocytogenes*, and *Staphylococcus aureus*).[32] Stationary-phase organisms grown on agar media and then suspended in 10 mL of sterile water were found to be stable when sealed with parafilm membranes and then stored at room temperature in the dark. Even greater stability could be obtained by suspending the organisms in a screw-capped tube with phosphate buffered saline (PBS) at pH 7.2, containing 15.44 µM KH_2PO_4, 1.55 mM NaCl, and 27.09 µM Na_2HPO_4.[24]

Drying

Sterile soil or sand has been used for preserving spore-forming organisms by adding suspensions and then drying at room temperature. In addition, bacterial suspensions have been mixed with melted gelatin and then dried in a desiccator. Both methods have produced samples that are stable for long periods of time.[21] A newer method involves using a microliter quantity of a bacterial suspension that is mixed with a predried activated charcoal cloth-based matrix contained within a resealable system. This can then be stored. Experiments with *Escherichia coli* have found that viability of over a year at 4°C can be obtained.[33]

Recovery and Viability of Preserved Microorganisms

Several factors can affect the viability of microorganisms that have been stored by either freezing or drying. These can include the temperature at which microorganisms are recovered, the type and volume of the media used for recovery, and even how quickly microorganisms are solubilized in a recovery medium.[21] Once reconstituted, microorganisms should be evaluated for cell survival.

Usually, the losses of preservation can be overcome by initially preserving large numbers of microorganisms. In doing this, one must be careful to avoid two problems. The first is that if only a very small fraction of organisms is recovered, this can result in the selection of biochemically distinct strains. The second is that if a culture has inadvertently been contaminated with even a few microorganisms, the preservation technique may lead to a selection for the contaminant.[34]

Drying and freeze-drying have been known to cause changes in several characteristics of preserved microorganisms. These can include colonial appearance and pathogenicity.[21] After revival from a frozen or dried state, many protocols usually advise subculturing the organisms at least two or three times in an attempt to restore any characteristics that may have been lost, and to confirm the genetic identity.[21]

The following is a selection of staining methods that may be of assistance to microbiologists.

Gram Stain[1–5]

Background for the Gram Stain

The Gram stain was developed by Christian Gram in 1884 and modified by Hucker in 1921. The Gram stain separates bacteria into two groups: (1) Gram-positive microorganisms that retain the primary dye (crystal violet) and (2) Gram-negative microorganisms that take the color of the counterstain (usually safranin O). These results are due to differences in the structure of the cell wall. Crystal violet is attracted to both Gram-positive and Gram-negative microorganisms. The second step (Gram's iodine, a mordant) stabilizes the crystal violet into the peptidoglycan layer of the cell wall. The peptidoglycan layer is much thicker in Gram-positive bacteria than in Gram-negative bacteria; hence, the crystal violet is more extensively entrapped in the peptidoglycan of Gram-positive bacteria. The third step (alcohol decolorization) dissolves lipids in the outer membrane of Gram-negative bacteria and removes the crystal violet from the peptidoglycan layer. In contrast, the crystal violet is relatively inaccessible in Gram-positive microorganisms and cannot readily be removed by alcohol in Gram-positive microorganisms. After the alcohol step, only the colorless Gram-negative microorganisms can accept the safranin (counterstain). Carbolfuchsin and basic fuchsin are sometimes employed in the counterstain to stain anaerobes and other weakly staining Gram-negative bacteria (including *Legionella* spp., *Campylobacter* spp., and *Brucella* spp.). The *Bacillus-Butyrivibrio-Clostridium* groups can be considered to stain Gram-variable because of changes in their cell wall, which is linked to the growth curve. They typically stain Gram-positive during the lag and exponential phases of growth and then usually stain as a Gram-negative beginning in the stationary growth phase. The S-layer of the cell wall becomes substantially thinner and diffuse as the growth cycle proceeds, which results in more fragile cells that usually stain as a Gram-negative. *Gardnerella vaginalis* has a very thin Gram-positive wall so that it can stain as either a Gram-positive or negative. Mycoplasma lacks a cell wall and stain as a Gram-negative bacterium. Details of the three-step Gram stain by Meszaros and Strenkoski are available.[6]

The three-step method simultaneously decolorizes and counterstains Gram-negative bacteria. Most clinical laboratories are currently using the four-step Gram stain. A modified Brown and Brenn Gram stain can be used to detect Gram-negative and Gram-positive bacteria in tissue.[7] In this method, Gram-positive bacteria stain blue, Gram-negative bacteria stain red, and the background color is yellow.

Standard Gram Stain Procedure

1. Fix the specimen with heat or use 95% methanol for 2 minutes.
2. Apply the primary stain (crystal violet) for 1 minute. Wash with tap water.
3. Apply the mordant (Gram's iodine) for 1 minute. Wash with tap water.
4. Decolorize for 5–15 seconds. Wash with tap water.
5. Counterstain with Safranin for 1 minute. Wash with tap water.

Gram Stain Reagents

1. Primary stain: 2 g crystal violet, 20 mL 95% ethyl alcohol, 0.8 g ammonium oxalate, and 100 mL distilled water
2. Gram's iodine: 2 g potassium iodide, 1 g iodine crystals, and 100 mL distilled water

3. Decolorizer: 50 mL acetone and 50 mL ethanol
4. Counterstain: 4.0 g Safranin, 200 mL 95% ethanol, and 800 mL distilled water

Decolorizer/Counterstain for the Three-Step Gram Stain

Combine 0.40% safranin, 0.30% basic fuchsin, 90% ethanol, and 10% distilled water, and acidify to pH 4.5.

Variations for Gram Stain Reagents

Many variations exist for the Gram stain. The Gram iodine mordant can be stabilized using a polyvinylpyrrolidone–iodine complex. Slowing the decolorizing step is accomplished using only 95% ethanol. Some laboratories prefer to decolorize with isopropanol/acetone (3:1 vol/vol).

Technical Concerns When Gram Staining

The optimum age for staining microorganisms is 18–24 hours. Bacteria that are more than 48 hours old are more likely to have cell wall damage, and this is one reason why Gram-positive bacteria may stain a pink color and appear to be Gram-negative bacteria. Additionally, excessive heat fixing may also damage the cell wall and this renders the bacteria to decolorize excessively. The end result can be that a Gram-positive will stain as Gram-negative bacteria. Occasionally, a smear is uneven in its thickness with the middle portion containing a heavy concentration of bacteria. The end result is that the heavy center portion may not properly decolorize sufficiently. This is the major reason why the bacteria on the edge of a Gram smear are more likely to give true results, and those in the center are often unreliable for reading a Gram stain. Clinical samples that contain bacteria are sometimes damaged by either an inflammatory response or antibiotics. The bacteria may have an atypical morphology and Gram staining can give atypical results. Additional information on the pitfalls and technical trouble spots was discussed by McCelland[3] and Sutton.[4]

Automated Staining Instruments

There are automated Gram-staining instruments available for use in the laboratory that have been found to produce adequate Gram-stain slides as compared to manual staining. Advantages to automated staining were reported to be more uniform, a reduction in hands-on staining time, and conservation of reagent.[8]

Acridine Orange Stain[1,2,14,16]

Background for the Acridine Orange Stain

The acridine orange stain is a sensitive method for detecting low numbers of organisms in cerebrospinal fluid (CSF), blood, buffy coat preparations from neonates, and tissue specimens. The acridine orange stain can be employed in rapidly screening normal sterile specimens (blood and CSF) where low numbers of microorganisms usually exist. Acridine orange is a fluorochrome that binds to nucleic acids. Bacteria and yeasts stain bright orange/red, and tissue cells stain black to yellowish green. The filter system used on a fluorescent microscope can affect the observed colors. Because red blood cells are not fluorescent, acridine orange stain can be useful for screening blood cultures for the growth of microorganisms. The stain maybe useful in interpreting thick purulent specimens that failed to give clear results with the Gram stain. With experience and training, acridine orange can also be used for detection of malarial parasites in the blood.[7] Acridine orange may also be useful for staining miscellaneous microorganisms such as *Mycoplasma*, *Pneumocystis jiroveci* trophozoites, *Borrelia burgdorferi*, *Acanthamoeba*, *Leishmania*, and *Helicobacter pylori* purulent specimens. Additional information on the acridine orange stain can be found at www.histonet.org.

Acridine Orange Standard Staining Procedure

1. Fix the smear in methanol for 2 minutes.
2. Stain with acridine orange for 1 minutes.
3. Rinse with tap water.

Paraffin Acridine Orange Staining Procedure

1. Deparaffinize and hydrate to distilled water.
2. Stain sections with acridine orange for 30 minutes.
3. Rinse sections in 0.5% acetic acid in 100% alcohol for about one minute.
4. Rinse sections 2 × in 100% alcohol.
5. Rinse sections 2 × in xylene.
6. Mount sections in Fluoromount.

Reagents for Standard Stain

1. 0.2 M sodium acetate buffer (pH 3.75)
2. Add acridine orange to buffer (0.02 g)

Reagents for Paraffin Procedure

1. Add 5 mL acetic acid to 500 mL distilled water.
2. Add 0.05 g acridine orange to the diluted acetic acid.

Macchiavello Stain Modified for *Chlamydia* and *Rickettsia*

Background for the Macchiavello-Gimenez Stain

Chlamydia and *Rickettsia* will stain red, whereas cellular material stains blue. A longer exposure than 1 or 2 seconds with citric acid may stain the organisms blue instead of red. Pinkerton's adaptation of Macchiavello's stain is used to detect *Rickettsia* in tissue samples. *Legionella* can also be stained by this method.

Macchiavello Stain Procedure (Modified) for *Chlamydia*

1. Heat-fix the smear or air-dry.
2. Stain the slide with basic fuchsin for 5 minutes.

3. Wash in tap water and then place the slide in a Coplin jar that contains citric acid. The slide should remain in the citric acid for a few seconds. Decolorization of the *Chlamydia* will occur if the citric acid is left on too long.
4. Wash the slide thoroughly with tap water.
5. Stain the slide for 20–30 seconds with 1% methylene blue.
6. Wash the slide with tap water and air-dry.

Pinkerton's Adaptation of Macchiavello's Stain for *Rickettsia* in Tissues

1. Deparaffinize and hydrate to distilled water.
2. Stain overnight with methylene blue (1%).
3. Decolorize with alcohol (95%).
4. Wash with distilled water.
5. Stain for 30 minutes with basic fuchsin (0.25%).
6. Decolorize 1–2 seconds in citric acid (0.5%).
7. Differentiate quickly with alcohol (100%).
8. Dehydrate with alcohol (95%), followed by 3 × alcohol (100%).
9. Clear in xylene 3 × and mount in Permount.

Reagents for the Macchiavello Stain

1. Basic fuchsin: Dissolve 0.25 g basic fuchsin in 100 mL distilled water.
2. Citric acid: Dissolve 0.5 g citric acid in 100 mL distilled water. Some procedures use 0.5 g in 200 mL distilled water. This reagent must always be fresh.
3. Methylene blue: Dissolve 1.0 g in 100 mL distilled water.

Acid-fast Stains[1,2,8,11]

Background for the Acid-Fast Stain

The cell wall of mycobacteria contains a large amount of lipid that makes it difficult for aqueous-based staining solution to enter the cell. Gram staining is not acceptable because the results are often Gram-variable, beaded Gram-positive rods, or negatively stained images. In contrast, the acid-fast stains contain phenol, which allows basic fuchsin (red) or auramine (fluorescent) to penetrate the cell wall. The primary stain will remain bound to the cell wall mycolic acid residues after acid alcohol is applied. The resistance of the mycobacteria group to acid alcohol decolorization has led to the designation of this group as acid-fast bacilli (AFB). A counterstain such as methylene blue is applied to contrast the mycobacteria (red) from the non-AFB organisms (blue). Detailed information on acid-fast stains can be found at the Centers for Disease Control and Prevention (CDC) *Acid Fast Direct Smear Microscopy Manual*. The CDC also supplies detailed information on the use of fluorochrome staining for the detection of acid-fast mycobacteria.

Ziehl-Neelsen Staining Procedure (Hot Method)

1. Fix the prepared slide with gentle heat.
2. Flood the slide with carbolfuchsin and heat to steaming only once.
3. Leave for 10 minutes.
4. Rinse with distilled water.
5. Decolorize with acid alcohol for 3 minutes.
6. Rinse with distilled water.
7. Counterstain with methylene blue for 1 minute.
8. Rinse with distilled water, drain, and air-dry.

Ziehl-Neelsen Staining Reagents

1. Primary stain: 0.3% carbolfuchsin. Dissolve 50 g phenol in 100 mL ethanol (95%) or methanol (95%). Dissolve 3 g basic fuchsin in the mixture and add distilled water to bring the volume to 1 L.
2. Decolorization solution: Add 30 mL hydrochloric acid to 1 L of 95% denatured alcohol. Cool and mix well before use. Alternate decolorizing reagent (without alcohol): Slowly add 250 mL sulfuric acid (at least 95%) to 750 mL distilled water. Cool and mix well before using.
3. Counterstain: 0.3% methylene blue. Dissolve 3 g methylene blue in 1 L distilled water.

Kinyoun Staining Procedure (Cold Method)

1. Fix and prepare the slide with gentle heat.
2. Stain with Kinyoun carbolfuchsin for 3–5 minutes.
3. Rinse with distilled water.
4. Decolorize with acid alcohol until the red color no longer appears in the washing (about 2 minutes).
5. Rinse with distilled water.
6. Counterstain with methylene blue for 30–60 seconds.
7. Rinse with distilled water, drain, and air-dry.

Kinyoun Staining Reagents

1. Primary stain: Dissolve 40 g basic fuchsin in 200 mL of 95% ethanol. Then add 1000 mL distilled water and 80 g liquefied phenol.
2. Decolorizer: 3% acid. Mix 970 mL of 95% ethanol and 30 mL concentrated hydrochloric acid.
3. Counterstain: 0.3% methylene blue. Dissolve 3 g methylene blue in 1 L distilled water.

Reporting System for Acid-Fast Stains Using Bright Field Microscopy

Table 4.1 follows the CDC recommendation and should be used to report the results of the Kinyoun acid-fast stain.

Truant Fluorochrome Staining Procedure

1. Air-dry the smears and fix on a slide warmer at 70°C for at least 2 hours. A Bunsen burner may be substituted.

TABLE 4.1

Result Reporting of AFB Smear for Bright-Field Microscopy

Read at Total Magnification (1000×)	Report
0 AFB/300 fields	No AFB seen on smear
1–2 AFB/300 fields	Report actual count and suggest a repeat test
1–9 AFB/100 fields	Sparse (1+)
1–9 AFB/10 fields	Few (2+)
1–9 AFB/field	Moderate (3+)
>9 AFB/field	Numerous (4+)

2. Stain with auramine O–rhodamine B solution for 15 minutes.
3. Rinse the slide with distilled water.
4. Decolorize with acid alcohol for approximately 2 minutes.
5. Rinse with distilled water and drain.
6. Counterstain with potassium permanganate for 2 minutes. Applying the counterstain for a longer period may quench the fluorescence of the *Mycobacterium* species. Acridine orange is not recommended as a counterstain by the CDC.
7. Smears are scanned with a 10× objective. It is sometimes necessary to use the 40× objective to confirm the bacterial morphology.
8. Examine at least 30 fields when viewing the slide under a magnification of 200× or 250×. Examine at least 55 fields when viewing the slide under a magnification of 400×. Examine at least 70 fields when viewing the slide under a magnification of 450×.
9. If only one or two AFB are observed in 70 fields, the results are reported as doubtful and should be repeated.

Truant Staining Reagents

1. Auramine O–rhodamine B: Dissolve 0.75 g rhodamine B and 1.5 g auramine O in 75 mL glycerol.
2. Decolorizer: Add 0.5 mL concentrated hydrochloric acid to 100 mL of 70% ethanol.
3. Counterstain: 0.5% potassium permanganate. Dissolve 0.5 g potassium permanganate in 100 mL distilled water.

Reporting System for Acid-Fast Stains Using Fluorescent Microscopy

Table 4.2 follows the CDC recommendation and should be used as a guide for result reporting acid-fast stains using fluorescent microscopy procedures.

Modified Acid-Fast Stain for Detecting Aerobic Actinomycetes (Including *Nocardia*), *Rhodococcus*, *Gordonia*, and *Tsukamurella*

The actinomycetes are a diverse group of Gram-positive rods, often with branching filamentous forms, and are partially acid fast. A modified acid-fast stain using 1% sulfuric acid rather than the usual 3% hydrochloric acid can be used if Gram-positive branching or partially branching organisms are observed.

TABLE 4.2

Result Reporting of AFB Smear for Fluorescent Microscopy

Read at Total Magnification (200× to 250×)	Read at Total Magnification (400× to 450×)	Report
0 AFB/30 fields	0 AFB/55 fields	No AFB seen on smear.
1–2 AFB/30 fields	1–2 AFB/70 fields	Report actual count and suggest a repeat test.
1–9 AFB/10 fields	2–18 AFB/50 fields	Sparse (1+)
1–9 AFB/field	4–36 AFB/10 fields	Few (2+)
10–90 AFB/field	4–36 AFB/field	Moderate (3+)
>90 AFB/field	>36 AFB/field	Numerous (4+)

Modified Acid-fast Stain for Detecting *Cryptosporidium*, *Isospora*, and *Cyclospora*

The modified acid-fast stain is used to identify the oocysts of the coccidian species, which are difficult to detect with the trichrome stain. Fresh or formalin-preserved stools as well as duodenal fluid, bile, and pulmonary samples can be stained.

Modified Acid-Fast Staining Procedure

1. Prepare a thin smear by applying one or two drops of sample to a slide. The specimen is dried via a slide warmer at 60°C and then fixed with 100% methanol for approximately 30 seconds.
2. Apply Kinyoun carbolfuchsin for 1 minute and rinse the slide with distilled water.
3. Decolorize with acid alcohol for about 2 minutes.
4. Counterstain for 2 minutes with malachite green. Rinse with distilled water.
5. Dry (a slide warmer can be used) and apply mounting media and a cover slip.
6. Examine several hundred fields under 40× magnification and confirm morphology under oil immersion.
7. The parasites will stain a pinkish-red color.

Modified Acid-Fast Staining Reagents

1. Kinyoun carbolfuchsin: See earlier procedure.
2. Decolorizer: 10 mL sulfuric acid and 90 mL of 100% ethanol.
3. Counterstain: 3% malachite green. Dissolve 3 g malachite green in 100 mL distilled water.

Mycology Preparations and Stains

Potassium Hydroxide and Lactophenol Cotton Blue Wet Mounts[11–13]

Wet mounts using 10% KOH (potassium hydroxide) will dissolve keratin and cellular material and unmask fungal elements that

may be difficult to observe. Lactophenol cotton blue (LPCB) preparations are useful because the phenol in the stain will kill the organisms and the lactic acid preserves fungal structures. Chitin in the fungal cell wall is stained by the cotton blue. The two wet mount preparations (KOH and LPCB) can be combined. Additional variations include using KOH and calcofluor white (CFW) or KOH and dimethylsulfoxide for thicker specimens of skin or nail. An extensive online *Mycology Procedure Manual* (Toronto Medical Laboratories/Mount Sinai Hospital Microbiology Department) is available at http://www.mountsinai.on.ca/education/staff-professionals/microbiology/microbiology-laboratory-manual/MYCOLOGY.doc. Additional staining procedures for the fungi can be found at doctorfungus.org.

KOH Procedure

1. Thin smear scrapings from the margin of a lesion are placed on a slide.
2. Add one or two drops of KOH, place on a cover slip, and allow digestion to occur over 5–30 minutes. Alternately, the slide can be gently heated by passing it through a flame several times. Cool and examine under low power. The fungal cell wall is partially resistant to the effects of KOH. However, the fungi may eventually dissolve in the KOH if left in contact with the reagent for an excessive period.

KOH Reagent

Dissolve 10 g KOH in 80 mL distilled water and then add 20 mL glycerol.

LPCB Procedure

1. Place a thin specimen on the slide and add one drop LPCB. Mix well and place a cover slip over the slide. Nail polish can be used to make a semipermanent slide.
2. Observe under the microscope for fungal elements.

LPCB Reagent

Dissolve 0.5 g cotton blue in 20 mL distilled water and then add 20 mL lactic acid and 20 mL concentrated phenol. Mix after adding 40 mL glycerol.

10% KOH with LPCB Procedure

1. Place a thin specimen on a slide and add one or two drops KOH. Place a cover slip over the preparation and wait for 5–30 minutes at room temperature or gently heat for a few seconds.
2. Add one drop LPCB and add a cover slip; examine under the microscope.

India Ink or Nigrosin Wet Mount

India ink or nigrosin will outline the capsule of *Cryptococcus neoformans*. The stain is far less effective than the latex agglutination procedure when examining CSF. In addition, human red or white blood cells can mimic the appearance of yeast cells. A drop of KOH can be added because human cells are disrupted and yeast cells remain intact. A positive India ink preparation is not always definitive for *C. neoformans* because additional yeasts such as *Rhodotorula* may be encapsulated.

Capsule Detection with India Ink

Mix one drop of the specimen with one drop India ink or one drop nigrosin on a slide. Place a cover slip over the preparation, and let it rest for 10 minutes before examining under the microscope.

Calcofluor White Stain[12–14]

Background for the Calcofluor White Stain

The calcofluor white (CFW) stain can be used for the direct examination of most fungal specimens. This stain binds to cellulose and chitin in the fungal cell wall. CFW is used in conjunction with KOH to enhance the visualization of the fungal cell wall. Positive results are indicated by a bright green to blue fluorescence using a fluorescent microscope. A nonspecific fluorescence from human cellular materials sometimes occurs. A bright yellow-green fluorescence is observed when collagen or elastin is present. The CFW staining technique usually provides better contrast than lactophenol aniline blue stains. The CFW stain can be used for the rapid screening of clinical specimens for fungal elements.[14] Furthermore, a CFW preparation subsequently can be stained with Grocott-Gomori methenamine silver (GMS) and periodic acid-Schiff (PAS) stain without interference.

General CFW Staining Procedure

1. Mix equal volumes of 0.1% CFW and 15% KOH before staining.
2. Place the specimen on the slide and add a few drops of the mixed CFW–KOH solution. Place a cover slip over the material.
3. The slide can be warmed for a few minutes if the material does not clear at 25°C.
4. Observe the specimen under a fluorescence microscope that uses broadband or barrier filters between 300 nm and 412 nm. The maximum absorbance of CFW is at 347 nm.
5. A negative control consists of equal mixtures of CFW–KOH. A positive control consists of a recent *Candida albicans* culture.

CFW Staining Reagents

1. 0.1% CFW (wt/vol) solution. Store the solution in the dark. Gentle heating and/or filtration is necessary to eliminate precipitate formation. CFW is available as a cellufluor solution from Polysciences (Washington, PA) or as fluorescent brightener from Sigma (St. Louis, MO).

2. 15% KOH. Dissolve 15 g KOH in 80 mL distilled water and add 20 mL glycerol. Store both reagents at 25°C.

CFW Stain for *Acanthamoeba* spp., *Pneumocystis Jiroveci*, *Microsporidium*, and *Cryptosporidium*

This procedure is used only as a quick screening method and not for species identification. The CFW stain is not specific because many objects other than fungi and parasites will fluoresce. Fresh or preserved stool, urine, and other types of specimens can be used in the following procedure (https://www.cdc.gov/dpdx/diagnosticprocedures/index.html). In 2009, Harrington[15] modified the succeeding procedure to detect *Cryptosporidium* oocytes in fecal smears. The modified procedure detected *Cryptosporidium* as well as coinfections with *Microsporidium*.

CFW Staining Procedure for *Acanthamoeba* and other Genera

1. Use approximately 10 µL of preserved or fresh fecal, or urine specimen to prepare a thin smear.
2. Fix the smear in 100% methanol for 30 seconds.
3. Stain with CFW solution for 1 minute. A 0.01% CFW solution in 0.1 M Tris-buffered saline with a final pH of 7.2 constitutes the staining reagent.
4. Rinse with distilled water, air-dry the slide, and mount.
5. Examine under a UV fluorescence microscope using a wavelength at or below 400 nm.
6. The spores of *Microsporidium* will also exhibit a blue-white fluorescent color.

Histopathologic Stain for Fungi: Periodic Acid-Schiff (PAS) Stain[1,2,12,13]

Background for the PAS Stain

Some laboratories prefer to use phase contrast microscopy in place of the periodic acid-Schiff (PAS) stain because similar results are often obtained. In the PAS stain, carbohydrates in the cell wall of the fungi and carbohydrates in human cells are oxidized by periodic acid to form aldehydes, which then react with the fuchsin-sulfurous acid to form the magenta color. Identification of fungal elements in tissue can be enhanced if a counterstain such as light green is used. The background stains green and the yeast cells or hyphae will accumulate the magenta color. The online *Surgical Pathology-Histology Staining Manual* discusses several PAS methods.[16]

PAS Staining Procedure

1. Deparaffinize and hydrate to distilled water.
2. Treat slides with 0.5% periodic acid for 5 minutes, followed by a rinse in distilled water.
3. Stain in Schiff's reagent for 15–30 minutes at room temperature. An alternate method is to microwave on high power for 45–60 seconds. The solution should be a deep magenta color. *Schiff's reagent requires extreme caution because it is a known carcinogen.*
4. Wash in running water (about 5 minutes) to develop the pink color.
5. Counterstain in hematoxylin for 3–6 minutes. Light green can be substituted when fungi are suspected. Go to step 8 if using light green.
6. If using hematoxylin, wash in tap water, followed by a rinse in distilled water.
7. Place in alcohol to dehydrate and apply a cover slip and mount.
8. If using light green, wash in tap water followed by 0.3% ammonia water.
9. Place in 95% alcohol and later in 100% alcohol (2×), followed by clear xylene (2×), and then mount.

Reagents

1. Periodic acid: Dissolve 0.5 g periodic acid in 100 mL distilled water. The reagent is stable for 1 year.
2. Harris' hematoxylin: Dissolve 2.5 g hematoxylin in 25 mL of 100% ethanol. Dissolve 50 g potassium or ammonium alum in 0.5 L heated distilled water. Mix the two solutions without heat. After mixing, the two solutions are boiled very rapidly with stirring (approximate time to reach a boil is 1 minute). After removing from the heat, add 1.25 g mercury oxide (red). Simmer until the stain becomes dark purple in color. Immediately plunge the container into a vessel containing cold water. Add 2–4 mL glacial acetic acid to increase the staining efficiency for the nucleus. The stain must be filtered before use.
3. Light green reagent: Dissolve 0.2 g light green in 100 mL distilled water. Dilute 1:5 with distilled water before use. Determining optimum concentration of light green often requires several attempts.

Grocott-Gomori Methenamine Silver Stain (GMS)[11]

Background for the GMS Stain

Silver stains are useful in detecting fungal elements in tissues. The fungal cell wall contains mucopolysaccharides that are oxidized by the Grocott-Gomori methenamine silver (GMS) stain to release aldehyde groups, which later react with silver nitrate. Silver nitrate is converted to metallic silver, which becomes visible in the tissue. *P. jiroveci* can be detected by several staining techniques, including toluidine blue O, CFW, GMS, and Giemsa. Multiple studies have compared the ease and accuracy in detecting *Pneumocystis* with these stains. A single stain has not emerged as being consistently superior to the others. The procedure described uses the microwave method and employs 2% chromic acid. The conventional method employs 5% chromic acid. The chromic acid solution must be changed if it turns brown. Additional information is available online.[17]

GMA Staining Procedure

1. Deparaffinize and hydrate to distilled water.
2. Oxidize with chromic acid (2%) in a microwave set at high power for 40–50 seconds and wait an additional 5 minutes.
3. Wash in tap water for a few seconds and then wash in distilled water 3×.
4. Rinse the slide in sodium metabisulfate (1%) at room temperature for 1 minute to remove the residual chromic acid.
5. Place the working methenamine silver solution in the microwave (high power) for 60–80 seconds. Agitate the slide in the hot solution. The fungi should stain a light brown color at this stage.
6. Rinse the slide in distilled water 2×.
7. Tone in gold chloride (0.5%) for 1 minute or until gray.
8. Rinse in distilled water 2×.
9. Remove the unreduced silver with sodium thiosulfate (2%) for 2–5 minutes.
10. Rinse in tap water, followed by distilled water.
11. Counterstain with diluted light green (1:5) for 1 minute. The optimal dilution of light green can vary.
12. Rinse in distilled water.
13. Dehydrate, clear, and mount.

Reagents

1. Chromic acid (2%): Dissolve 2.0 g chromium trioxide in 100 mL distilled water.
2. Sodium metabisulfate (1%): Dissolve 1.0 g sodium metabisulfate in 100 mL distilled water.
3. Borax (5%): Dissolve 5.0 g sodium borate in 100 mL distilled water.
4. Stock solution of methenamine silver: Add 5 mL silver nitrate (5%) to 100 mL of methenamine (3%). Store the reagent in the refrigerator in a brown bottle.
5. Working solution of methenamine silver: Add 25 mL distilled water and 2.5 mL borax (5%) to 25 mL methenamine silver stock solution.
6. Gold chloride (0.5%): Dissolve 0.5 g gold chloride in 100 mL distilled water.
7. Light green (0.2%): Dissolve 0.2 g light green in 100 mL distilled water and add 0.2 mL glacial acetic acid.

Trichrome Stain[1–22]

Background for the Trichrome Stain

The Wheatley trichrome stain is the last part of a complete fecal examination, and it usually follows a direct iodine wet mount and/or parasite concentration technique. The Wheatley procedure is a modification of the Gomori tissue stain. The procedure is the definitive method for the identification of protozoan parasites. Small protozoa that have been missed on wet mounts or concentration methods are often detected with the trichrome stain. The trichrome stain detects both trophozoites and cysts and documents a permanent record for each observed parasite. The background material stains green; the cytoplasm of the cysts and trophozoites stain blue green; and chromatoidal bodies (RNA), chromatin material, bacteria, and red blood cells stain red or purplish-red. Larvae or ova of some metazoans also stain red. Thin-shelled ova may collapse when mounting fluid is used. The fecal specimen may be fresh, fixed in polyvinyl alcohol (PVA), Schaudinn, or sodium acetate-acetic acid-formalin (SAF). The CDC has used various components of the trichrome stain to detect *Microsporidium* spores from the fecal component. The complete chromotrope staining procedures are available at the CDC's website (https://www.cdc.gov/dpdx/diagnosticprocedures/index.html).

Trichrome Staining Procedure

1. Place the PVA smears in 70% ethanol/iodine solution for 10 minutes. This step can be eliminated if the fixative does not contain mercuric chloride.
2. Transfer slide to 70% ethanol for 5 minutes. Repeat with a second 70% ethanol treatment for 3–5 minutes.
3. Stain in trichrome for 10 minutes.
4. Rinse quickly in 90% ethanol, acidified, with 1% acetic acid, for 2 or 3 seconds.
5. Rinse quickly using multiple dips in 100% ethanol. Repeat the dipping in a fresh 100% ethanol. Make sure that each slide is destained separately using fresh alcohol. The most common mistake is excessive destaining.
6. Transfer slides into 100% ethanol for 3–5 minutes. Repeat a second time.
7. Transfer slide to xylene for 5 minutes. Repeat a second time.
8. Mount with Permount.
9. A 10× objective can be used to locate a good area of the smear. Then examine the smear under oil immersion and analyze 200–300 fields.

Reagents

1. 70% ethanol with iodine: Add sufficient iodine to 70% ethanol to turn the alcohol a dark tea color (reddish brown). If the ethanol/iodine reagent is too weak, the mercuric chloride will not be extracted from the specimen. The end result will be the formation of a crystalline residue that will hamper the examination of the specimen.
2. D'Antoni's iodine: Dissolve 1 g potassium iodide and 1.5 g powdered iodine crystals in 100 mL distilled water.
3. Trichrome stain: Add 1 mL glacial acetic acid to the dry components of the stain, which are 0.60 g chromotrope 2R, 0.15 g light green SF, 0.15 g fast green, and 0.70 g phosphotungstic acid. The color should be purple. Dissolve all the reagents in 100 mL distilled water.

Iron Hematoxylin Stain[11,18,21–23]

Background for the Iron Hematoxylin Stain

The iron hematoxylin stain is used to identify the trophozoites and cysts of the protozoa group. It is less commonly used than the trichrome stain. The cysts and the trophozoites stain a blue gray to black, and the background material stains blue or pale gray. Helminth eggs and larvae are usually difficult to identify because of excessive stain retention. Yeasts and human cells (red blood cells, neutrophils, and macrophages) are also detected by the stain. The stain can be used with fixatives that include PVA, SAF, or Schaudinn. Good fixation is the key in obtaining a well-stained fecal preparation. The simplest variation of the iron hematoxylin stain is the method of Tompkins and Miller. A modified iron hematoxylin stain that incorporates a carbolfuchsin step will detect some acid-fast parasites (including *Cryptosporidium parvum* and *Isospora belli*).

Iron Hematoxylin Stain Procedure

1. Prepare a thin layer of fecal smear and place it in a fixative. If SAF is used, proceed to step 4. Mayer's albumin can be used to ensure that the specimen will adhere to the slide.
2. Dehydrate the slide in ethanol (70%) for 5 minutes.
3. Transfer slide in iodine ethanol (70%) for 2–5 minutes. The solution should have a strong tea color.
4. Transfer the slide to 50% ethanol for 5 minutes.
5. Wash the slide in a constant stream of tap water for 3 minutes.
6. Transfer the slide into 4% ferric ammonium sulfate mordant for 5 minutes.
7. Wash the slide in a constant stream of tap water for 1 minutes.
8. Stain with hematoxylin (0.5%) for 3–5 minutes.
9. Wash in tap water for about 1 minutes.
10. Destain the slide with 2% phosphotungstic acid for 2 minutes.
11. Wash the slide in a constant stream of tap water.
12. Transfer the slide to 70% ethanol that contains several drops of lithium carbonate (saturated).
13. Transfer the slide to 95% ethanol for 5 minutes.
14. Transfer the slide to 100% ethanol for 5 minutes. Repeat a second time.
15. Transfer slide to xylene for 5 minutes. Repeat a second time.
16. Mount with Permount.

Reagents

1. Seventy percent ethanol/iodine: Add sufficient iodine to 70% ethanol to turn the alcohol a dark tea color (reddish brown).
2. D'Antoni's iodine: Dissolve 1 g potassium iodide and 1.5 g powdered iodine crystals in 100 mL distilled water.
3. Iron hematoxylin stain: Dissolve 10 g hematoxylin in 1000 mL of 100% ethanol. Store the reagent at room temperature.
4. Mordant: Dissolve 10 g ferrous ammonium sulfate and 10 g ferric ammonium sulfate in 990 mL distilled water. Add 10 mL concentrated hydrochloric acid.
5. Working hematoxylin stain: Mix (1:1) the mordant and the hematoxylin stain.
6. Saturated lithium carbonate: Dissolve 1 g lithium carbonate in 100 mL distilled water.

Preparation of Blood Smears for Parasite Examination[3,11,18–20]

Trypanosoma, *Babesia*, *Plasmodium*, and *Leishmania*, as well as most microfilariae, are detected from blood smears. Identification of these parasites is based on the examination of permanent blood films. The blood samples from malaria and *Babesia* patients are best collected toward the end of a paroxysmal episode. Blood samples can be collected randomly from patients with trypanosomiasis. Blood samples should be collected after 10 p.m. on those microfilariae that exhibit nocturnal periodicity (*Wuchereria* and *Brugia*). Blood samples should be collected between 11 a.m. and 1 p.m. if *Loa loa* (diurnal periodicity) is suspected. Thick blood smears are typically used as a screening tool, and thin blood smears are used to observe detailed parasite morphology. Blood parasites are usually identified from the thin films. The Giemsa, Wright, and Wright-Giemsa combination can be used to stain the blood smears. The Giemsa stains the cytoplasm of *Plasmodium* spp. blue, whereas the nuclear material stains red to purple, and Schuffner's dots stain red. The cytoplasm of trypanosomes *Leishmania* and *Babesia* will also stain blue and the nucleus stains red to purple. The sheath of microfilariae often fails to stain but the nuclei will stain blue/purple.

Giemsa Staining Procedure for Thin Films

1. Fix the blood films in 100% methanol for 1 minute.
2. Air-dry the slides.
3. Place the slides into the working Giemsa solution. The working solution is one part Giemsa stock (commercial liquid stain) and 10–50 parts phosphate (pH 7.0–7.2) buffer. Experimentation with several different staining dilutions/times is often required to obtain optimum results.
4. Stain for 10–60 minutes.
5. Briefly wash underwater or in phosphate buffer.
6. Wipe the stain off the bottom of the slide and air-dry.

Reagents

1. Stock Giemsa commercial liquid stain: Dilute 1:10 with buffer for thin smears.
2. Phosphate buffer, pH 7.0: Dissolve 9.3 g Na_2HPO_4 in 1 L distilled water (solution 1), and dissolve 9.2 g NaH_2PO_4 H_2O in 1 L distilled water (solution 2).

Add 900 mL distilled water to a beaker and 61.1 mL solution 1 and 38.9 mL solution 2. This reagent is used to dilute the Giemsa stain.

3. Triton phosphate buffered wash: Add 0.1 mL Triton X-100 to 1000 mL of the pH 7.0 phosphate buffer. This is the wash; tap water can also be used.

The Giemsa stain has been the recommended stain for identification of malarial parasites because it reliably shows the red staining Schuffner's dots in the infected erythrocytes when present.[24]

Variations of the traditional Giemsa and Wright stains, including Wright-Giemsa combination stains, have been commercially developed in response to the urgent nature of staining and reading blood films quickly in the clinical laboratory setting. These variations are based on multiple modifications of the classic formulas and involve repeated dips of a dry thin blood film into each of the three solutions. The first is a methanol fixative solution containing malachite green or fast green. The second solution contains buffer and eosin. The third is a mixture of buffer and thiazine dye. Use of a commercially modified staining procedure can result in a more rapid reporting of blood films because of the shortened staining times that can range from 15 seconds to 10 minutes depending on the actual product used. It is suggested that the staining characteristics of any polymorphonuclear leukocytes in the blood film can help to monitor the quality of these nontraditional staining methods.[25,26] As a good laboratory practice, control slides should be stained as directed.

Introduction

Human infections caused by Gram-positive organisms have increased over the years, both as nosocomial infections and community acquired infections, so it is imperative that these organisms are identified as expeditiously as possible. However, because of the sheer multitude of Gram-positive organisms implicated in disease, identification can be challenging. Certainly the advent of the matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF MS) has given clinical laboratories the tool to quickly identify organisms, but this technology is expensive and may not be suited for midsize to smaller clinical microbiology laboratories. What follows is a synopsis of identification tests for Gram-positive organisms that can make the process easier.

Gram-Positive Cocci

Staphylococcus

Colony morphology: Colonies of *Staphylococcus* on sheep blood agar present themselves as smooth, yellow, white, or off-white colonies somewhere in the area of 1–2 mm in diameter.[1] Colonies may exhibit β-hemolysis and may show varying degrees of growth. Sometimes the β-hemolysis is not evident after 24 hours of incubation and requires further incubation. Because of the varying degrees of colony size and color that may mimic other Gram-positive organisms, such as streptococci and micrococci, identification of *Staphylococcus* can sometimes be problematic. CHROMagar (CHROMagar Company) and ChromID (bioMerieux) are types of media that can alleviate this problem. They contain chromogenic substrates that yield a certain colony color.[2]

Quick tests: Perhaps the most common quick test employed to help identify colonies of *Staphylococcus* is the catalase test. This simple test can differentiate off-white or gray colonies of *Staphylococcus* from *Streptococcus* and is an invaluable tool. The modified oxidase test is another quick test that can differentiate *Staphylococcus* from *Micrococcus* as is the lysostaphin test (Remel). Differentiation among the staphylococci can be achieved by the coagulase test, testing for both bound and free coagulase. Alternatively, there are a multitude of latex agglutination tests available. Slidex Staph Plus (bioMerieux), Staphy Latex (Tulip Diagnostics),

Staphtex (Hardy Diagnostics), Staphyloslide (Becton-Dickinson), and Staphaurex (Remel) are all latex agglutination tests for the identification of *Staphylococcus aureus*.[3,4]

Conventional methods: *S. aureus* can further be identified by its ability to produce DNase and ferment mannitol. Both DNase agar and mannitol salt agar are readily available. When needed to speciate coagulase negative staphylococci (CNS), there are a number of tests that can be employed. Carbohydrate utilization such as sucrose, xylose, trehalose, fructose, maltose, mannose, and lactose as well as such tests as urease, nitrate reduction, and phosphatase will all aid in the identification of CNS. *Staphylococcus saprophyticus* is a frequent cause of urinary tract infections and can be identified by its resistance to novobiocin. Bacitracin and acid production from glucose are tests that can be employed to differentiate *Staphylococcus* from *Micrococcus*.[5]

Identification strips: There are a number of manufacturers that have developed identification strips containing many of the aforementioned biochemicals. API STAPH (bioMerieux), ID 32 Staph (bioMerieux), BBL Crystal Gram-positive ID (Becton-Dickinson), and RapID Staph Plus (Remel) utilize a number of biochemical tests on their strips and are reliable in identifying most strains of CNS.[6]

Automated methods: The VitekII GPID card (bioMerieux-Vitek), the MicroScan Rapid Pos Combo Panel and Pos ID Panels (Dade/MicroScan) and the Phoenix Automated Microbiology System (Becton Dickinson) are a few of the more common automated identification panels for staphylococci as well as other Gram-positive organisms.[3,7,8]

Molecular methods: Molecular methods have gained widespread popularity in the field of medical microbiology. GenProbe introduced their AccuProbe for *S. aureus* culture confirmation a number of years ago and Roche Molecular Systems has a RT-PCR test for the direct detection of the *mecA* gene for use on their LightCycler.[9,10] Table 5.1 summarizes all of the available tests for *Staphylococcus* species.

Micrococcus and Related Species

Colony morphology: *Micrococcus* presents as dull, white colonies that may produce a tan, pink, or orange color. They are generally 1–2 mm in diameter and can stick to the surface of the agar plate.[1] A Gram stain will assist in the preliminary identification as micrococci appear as larger Gram-positive cocci arranged in tetrads. Other related species that have a microscopic morphology similar to *Micrococcus* include *Kocuria* species, *Kytococcus* species, and *Arthrobacter agilis*. They all appear as Gram-positive cocci in tetrads and their colony morphology is characterized by pigmentation. *Kocuria* species have been implicated in bacteremia and peritonitis and have a yellow to orange to pink pigment.[11,12] *Kytococcus* species have caused cases of endocarditis and appear as a creamy white to yellow colony.[13] *A. agilis* appears as a red colony and is predominately found in soil.[14]

Quick tests: The catalase test and the modified oxidase test are invaluable tools in helping to differentiate micrococci from staphylococci.

Conventional tests: Glucose fermentation, nitrate reduction, lysostaphin, furazolidone and bacitracin can all be used to separate micrococci from staphylococci.[15]

Identification strips: The API STAPH identification strip (bioMerieux) and RapID Staph Plus (Remel) can be utilized to identify *Micrococcus* species.

Automated methods: MicroScan has 2-hour rapid Gram-positive panels that can identify *Micrococcus* species.

Table 5.2 summarizes the available tests for *Micrococcus* and related species.

Streptococcus, Including *Enterococcus*

Colony morphology: *Streptococcus* colonies are typically smaller on sheep blood agar than *Staphylococcus* colonies and measure about 1 mm. Agar such as Columbia CNA and PEA can enhance the growth of streptococci resulting in larger colony size. Perhaps the one characteristic that can aid in the separation of *Streptococcus* species is hemolysis. ß-hemolysis, α-hemolysis, α-prime hemolysis, and γ-hemolysis are all produced by members of the genus.

Quick tests: The catalase test is very useful in differentiating *Staphylococcus* colonies from *Streptococcus* colonies, especially γ-hemolytic streptococci. After the colony has been tentatively identified as strep, there are several latex agglutination and coagglutination tests that can provide a definitive identification. Kits include Phadebact (MKL Diagnostics), Streptex (Remel),

Streptocard (Becton-Dickinson), Patho-Dx (Remel), and Slidex Strepto Plus (bioMerieux).[3] Two useful tests to help aid in the identification of enterococci are the pyrrolidonyl arylamidase (PYR) and leucine aminopeptidase (LAP) tests. These are available as discs (Remel) and can be inoculated directly with colonies for a rapid identification. The DrySpot Pneumo (Oxoid), PneumoSlide (Becton-Dickinson), and Slidex Pneumo (bioMerieux) are rapid tests for the identification of *Streptococcus pneumoniae*.

Conventional tests: Because there are a multitude of *Streptococcus* species implicated in human disease, there so exist a number of conventional tests to aid in the identification of streptococci. Conventional tests that aid in the identification of ß-hemolytic strep include the bacitracin disc, CAMP test, susceptibility to SXT, hippurate hydrolysis, Vogues-Proskauer (VP), and PYR. Alpha-hemolytic strep can be identified by using the optochin disc, bile solubility, esculin hydrolysis, 6.5% NaCl, arginine hydrolysis, and acid from mannitol. Enterococci can be identified by utilizing bile esculin, 6.5% NaCl, SXT susceptibility, motility, pigment production, and VP.[15]

Identification strips: The API 20 Strep and API Rapid ID 32 Strep (bioMerieux) and RapID STR strips (Remel) provide a number of biochemicals for the identification of streptococci, enterococci, and nutritionally variant strep.[16] The Remel BactiCard Strep is a card that has PYR, LAP, and ESC reactions encompassed on it.

Automated methods: The MicroScan Pos ID panel and the Vitek II GPID card can be utilized for identification of strep.

Molecular methods: The AccuProbe *S. pneumoniae* system is available.

Table 5.3 summarizes the available tests for *Streptococcus* and *Enterococcus* species.

Aerococcus

Colony morphology: Aerococci appear as α-hemolytic colonies that closely resemble enterococci and the viridans streptococci.

Quick tests: Two tests that aid in the identification of *Aerococcus* species are PYR and LAP.

Conventional tests: Laboratory tests utilized for the identification and speciation of *Aerococcus* include bile esculin, 6.5% NaCl, hippurate hydrolysis, and acid production from sorbitol, lactose, maltose, and trehalose.[17]

ID strips: The API 20 Strep and Rapid ID 32 Strep strip contain biochemical that can identify *Aerococcus*.[18]

Automated methods: The Vitek II GPID can be used to identify *Aerococcus*.[15]

Leuconostoc

Colony morphology: *Leuconostoc* are small, α-hemolytic colonies.

Quick tests: The PYR and LAP discs can be utilized.

Conventional tests: Arginine dihydrolase, gas from glucose, resistance to vancomycin, lack of growth at 45°C, and esculin hydrolysis are all useful tests in the identification of *Leuconostoc*.[15,19,20]

ID strips: API 50 CHL.

Automated methods: Vitek II GPID card.

Pediococcus

Colony morphology: Pediococci are small, α-hemolytic colonies that resemble viridans strep.

Quick tests: The PYR and LAP discs can be used.

Conventional tests: Conventional tests include acid production from glucose, arabinose, maltose, and xylose; lack of gas production in glucose; growth at 45°C; and resistance to vancomycin.[15,19]

ID strips: API 50 CHL.

Automated methods: Vitek II GPID card.

Table 5.4 summarizes the available tests for *Aerococcus*, *Leuconostoc*, and *Pediococcus*.

Lactococcus

Colony morphology: Lactococci are small, α-hemolytic colonies that resemble enterococci and viridans strep.

Quick tests: LAP and PYR discs.

Conventional tests: Bile esculin, 6.5% NaCl, arginine dihydrolase, hippurate hydrolysis, and acid from glucose, maltose, lactose, sucrose, mannitol, raffinose, and trehalose are all conventional tests that can be used.[15,19]

ID strips: The API Rapid ID 32 Strep strip contains biochemicals for the identification of *Lactococcus* species.

Automated methods: Vitek II GPID card.

Gemella

Colony morphology: Colonies of *Gemella* closely resemble colonies of viridans streptococci.

Quick tests: The PYR disc can be used to aid in identification.

Conventional tests: Conventional tests include esculin hydrolysis, reduction of nitrite, arginine dihydrolase, and acid production from glucose, mannitol, and maltose.[15,19]

ID strips: The API Rapid ID 32 Strep, RapID STR, and API 20A (bioMerieux) can be used to identify *Gemella*.

Automated methods: The Vitek II GPID card

Table 5.5 summarizes the available tests for *Lactococcus* and *Gemella*.

Miscellaneous Gram-Positive Cocci

There are a number of Gram-positive cocci whose implication in human disease is questionable. *Alloiococcus* has been isolated from tympanocentesis fluid[21]; *Abiotrophia* has caused endocarditis[22]; *Rothia* (*Stomatococcus*) has been isolated from blood cultures[23]; *Globicatella* has been implicated in bacteremia[24]; *Helcococcus* has been isolated from abscesses[25]; *Facklamia*, *Granulicatella*, *Dolosigranulum*, *Ignavigranum*, and *Dolosicoccus* have caused disease in humans, such as endocarditis, keratitis, pneumonia, and synovitis[26–32]; and *Vagococcus* is primarily zoonotic. Biochemical tests are included in Table 5.6.[19,23]

Gram-Positive Bacilli

Corynebacterium

Colony morphology: Colonies of *Corynebacterium* on 5% sheep blood agar appear as tiny, gray-to-white colonies that are generally nonhemolytic. Special media such as cysteine tellurite blood agar and Tinsdale agar should be utilized whenever *Corynebacterium diphtheriae* group are to be isolated.

Quick tests: The Gram stain can be an invaluable tool for the identification of *Corynebacterium* as they can be differentiated from *Bacillus* by their coryneform shape and size and lack of spores. The catalase test is useful in differentiating *Corynebacterium* from *Erysipelothrix* and *Lactobacillus*.

Conventional tests: Useful tests for the identification of *Corynebacterium* include motility, lack of H_2S production in a TSI slant; esculin; nitrate reduction; urease; as well as the carbohydrates glucose, mannitol, maltose, sucrose, xylose, and salicin.[33,34]

ID strips: API Coryne strip (bioMerieux) and RapID CB Plus (Remel) are identification strips that can be used for the identification of *Corynebacterium*.[35,36]

Automated methods: Vitek II GPID card.

Table 5.7 summarizes the available tests for *Corynebacterium*.

Microgen Bacillus

Bacillus

Colony morphology: *Bacillus* species can have many variations in colony morphology. For example, *Bacillus anthracis* appear as nonhemolytic medium-to-large gray, flat colonies with irregular swirls; *Bacillus cereus* appear as large, spreading ß-hemolytic colonies; and *Bacillus subtilis* appear as large, flat colonies that may be pigmented or ß-hemolytic.

Quick tests: The Gram stain and spore stain are useful tools in identification.

Conventional tests: Motility; gas from glucose; starch hydrolysis; growth in nutrient broth with 6.5% NaCl; indole; nitrate reduction; VP; citrate; gelatin hydrolysis; esculin hydrolysis; growth at 42°C, and various carbohydrate fermentations such as glucose, maltose, mannitol, xylose, and salicin. Susceptibility to penicillin can also help in the identification of *B. anthracis*.[37]

ID strips: Microgen Bacillus ID (Microgen Bioproducts) and the API 50 CHB (bioMerieux).

Table 5.8 summarizes the available tests for *Bacillus*.

Listeria

Colony morphology: Colonies appear on sheep blood agar as small, translucent, and gray with a small zone of β-hemolysis.

Quick tests: Catalase and motility on a wet mount are useful.

Conventional tests: Growth at 4°C, esculin hydrolysis, motility, fermentation of glucose, trehalose, and salicin; lack of H_2S production; CAMP test.[38] *Listeria monocytogenes*, chromogenic agar (bioMerieux) is available.

ID strips: API 20 Strep, API Listeria strip, Rapidec L. mono (bioMerieux), API Rapid ID 32 Strep, API Coryne strip (bioMerieux), and Microgen Listeria ID (Microgen Bioproducts).[39]

Automated methods: Vitek II GPID card.

Table 5.9 summarizes the available tests for *Listeria*.

Lactobacillus

Colony morphology: *Lactobacillus* can have a variety of colony morphologies ranging from tiny, pinpoint, α-hemolytic colonies resembling viridans strep to small, rough, gray colonies.

Quick tests: Gram stain and catalase tests are two tests that are useful in aiding in the identification.

Conventional tests: Fermentation of glucose, maltose, and sucrose as well as urease and nitrate reduction tests are helpful.[3]

ID strips: API 20A and API 50 CHL (bioMerieux) can be used to identify some strains of *Lactobacillus*.

Automated methods: Vitek II ANC ID card.

Table 5.10 summarizes the available tests for *Lactobacillus*.

Actinomyces, Nocardia, Streptomyces

Colony morphology: Colonies of *Nocardia* can vary but are commonly dry, chalky white in appearance, and can sometimes be ß-hemolytic on sheep blood agar with a late-developing pigment. *Streptomyces* can appear as waxy, glabrous, heaped colonies. *Actinomyces* appear as white colonies with or without ß-hemolysis.

Quick tests: Modified acid-fast stain and catalase tests.

Conventional tests: Casein; tyrosine; xanthine; urease; gelatin hydrolysis; starch hydrolysis; nitrate reduction; lactose, xylose, rhamnose, and arabinose fermentation. The BBL Nocardia ID Quad Plate (Becton-Dickinson) combines casein, tyrosine, xanthine, and starch on one plate.[3,40–42]

ID strips: *Actinomyces*: API Coryne and API 20A (bioMerieux); BBL Crystal rapid Gram-positive (Becton-Dickinson); RapID ANA II (Remel); Rap ID CB Plus (Remel).[43–45]

Nocardia species can be identified with additional tests by the API Coryne strip.

Automated methods: Vitek II ANC ID card.

Gardnerella

Colony morphology: Special media such as V agar and HBT agar must be used to isolate *Gardnerella vaginalis*. Colonies appear as tiny and β-hemolytic after 48 hours.

Quick tests: Gram stain; catalase; oxidase.

Conventional tests: Hippurate hydrolysis; urease; nitrate reduction; a zone of inhibition with trimethoprim, sulfonamide, and metronidazole; fermentation of glucose, maltose, and sucrose.[46]

ID strips: The API Rapid ID 32 C strip can be used to identify *Gardnerella*.

Automated methods: MicroScan Rapid HNID panel (Dade/MicroScan) and Vitek II NH ID card (bioMerieux).

Table 5.12 summarizes the available tests for *Gardnerella*.

Miscellaneous Gram-Positive Rods

Arcanobacterium, Erysipelothrix, Kurthia, Rhodococcus, Gordonia, Oerskovia, Dermatophilus, Actinomadura, Nocardiopsis, Arthrobacter, Paenibacillus, Cellulomonas, Actinobaculum, Brevibacterium, Cellulosimicrobium, Dermabacter, Microbacterium, Turicella, and *Tsukamurella* have all been implicated in human disease.[40,47–61] Identification tests for these organisms appears in Table 5.13.

Anaerobic Gram-Positive Organisms

Clostridium, *Bifidobacterium*, *Peptostreptococcus*, *Finegoldia*, *Peptococcus*, *Micromonas*, *Eggerthella*, *Eubacterium*, *Pseudoramibacteri*, and *Propionibacterium* are all organisms that have been implicated in human disease.[62–69] Identification tests are listed in Table 5.14.

Introduction

Aerobic Gram-negative bacteria are ubiquitous. Many are found throughout the environment and distributed worldwide. Others are established as normal flora in human and animal mucosa, intestinal tract, and skin. Many of these bacteria are typically harmless, and several are even beneficial. Others account for a large percentage of foodborne illness, and some have been identified as potential weapons of bioterrorism. The identification of these organisms is necessary in many circumstances. The clinical microbiologist identifying the pathogen responsible for the severe, bloody diarrhea of a hospitalized young child; the environmental laboratorian identifying the bacterial contaminant that forced a recall of a commercial product; and the researcher identifying and characterizing the bacteria that are degrading chemical pollutants in a river all find themselves faced with the task of identifying aerobic Gram-negative bacteria. This task can be accomplished using a variety of methods. It often involves a combination of conventional phenotypic tests based on biochemical reactions, commercial kits or systems, and/or molecular analysis.

This chapter addresses the Gram stain and cellular morphology of bacteria, which are key features for preliminary identification of the Gram-negative genera. Descriptions are given of some fundamental phenotypic characteristics including growth on trypticase soy agar (TSA) with 5% sheep blood, pigment production, growth on MacConkey agar, glucose fermentation, and production of oxidase.

In general, aerobic Gram-negative bacteria can be divided into two groups based on their ability to ferment glucose and produce acid in triple sugar iron (TSI) agar or Kligler's iron agar as shown in Figures 6.1 and 6.2. Descriptions of some additional conventional biochemical tests that can be used to further characterize an aerobic Gram-negative bacterium are included in this chapter: motility, acid from carbohydrates, catalase, citrate, decarboxylases, esculin hydrolysis, gelatin liquefaction, indole, methyl red (MR), Voges-Proskauer (VP), urease, and nitrate reduction. However, there are many bacteria that are difficult to identify solely by conventional biochemical tests. Reference laboratories may utilize mass spectrometry or polymerase chain reaction (PCR) assays to assist in the identification of aerobic Gram-negative bacteria.

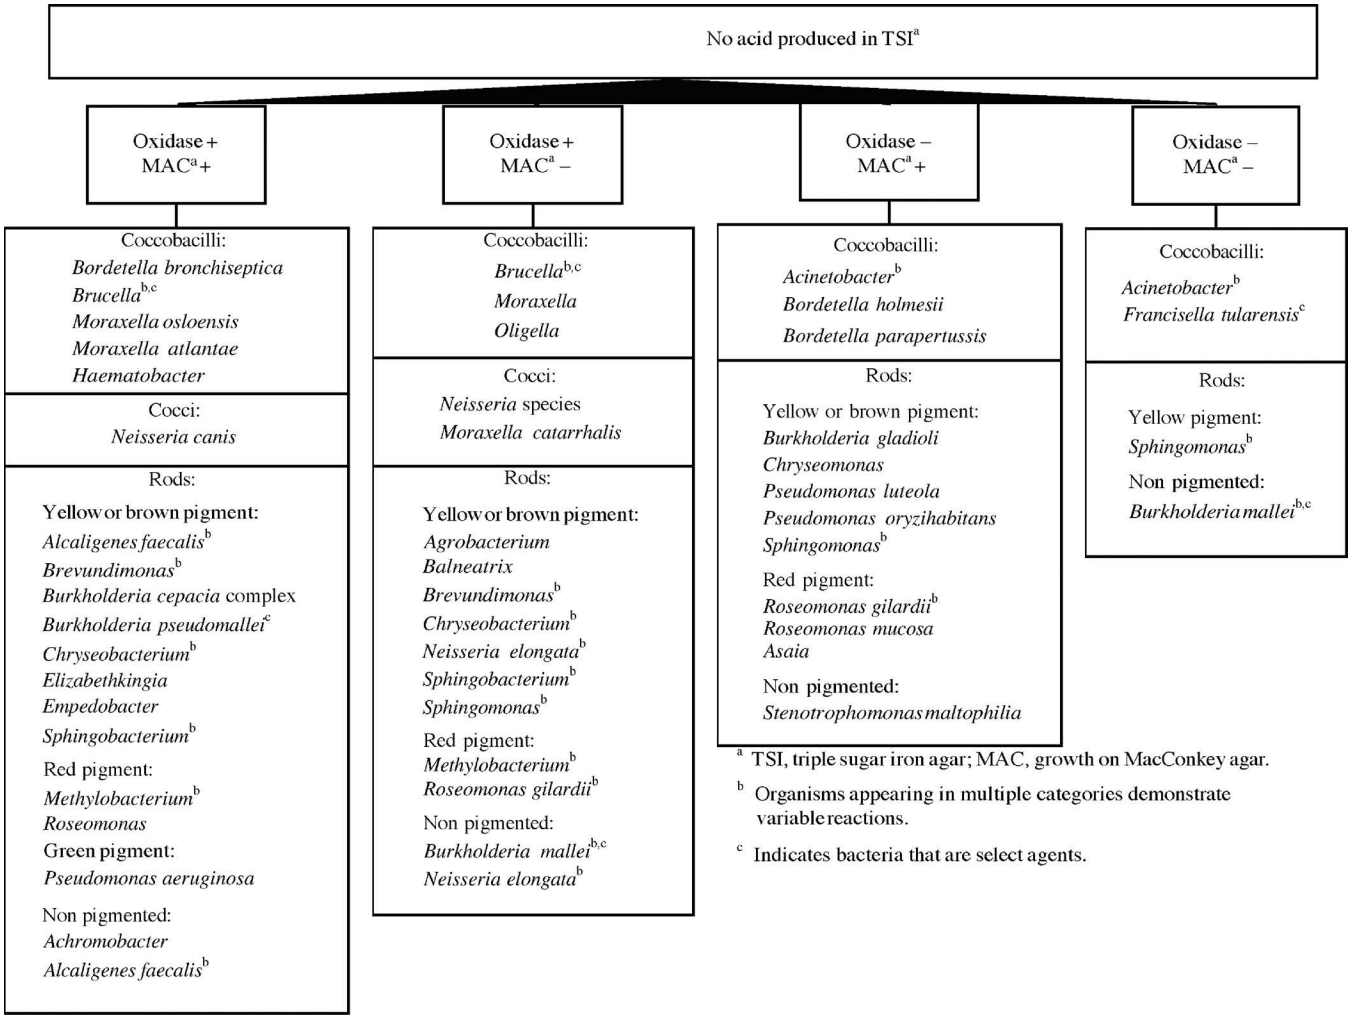

FIGURE 6.1 Gram-negative organisms that grow on TSA with 5% sheep blood and do not ferment glucose. (Data from Refs. [8, 9, 11, 15, 20–24, 27, 28].)

Additionally, 16S rRNA gene sequence analysis can be used to identify unusual members of this group that give problematic results.

The identification algorithms in Figures 6.1 and 6.2 do not include those aerobic Gram-negative bacteria that are incapable of growing on TSA with 5% sheep blood. For example, most *Haemophilus* species will grow only on chocolate agar, *Legionella* species require l-cysteine and will grow on buffered charcoal yeast extract media, and growth of *Bordetella pertussis* requires the supplements contained in Bordet-Gengou or charcoal-horse blood agar. The reader can consult Edelstein and Wadlin,[1] Leber,[2] Ledeboer and Doern,[3] Konig et al.,[4] and Edelstein and Luck[5] for identification algorithms for these organisms.

Laboratory protocols for the identification of unknown aerobic Gram-negative bacteria should also include procedures for the safe handling of potential pathogens. If a select agent (potential bioterrorism threat agent), such as *Francisella tularensis*, *Burkholderia mallei*, *Burkholderia pseudomallei*, *Brucella* species, or *Yersinia pestis*, is suspected at any point during the identification process, culture work on the open lab bench should cease immediately, and a biological safety cabinet should be used if further testing is necessary. An appropriate reference laboratory should be contacted to arrange the shipment of the specimen for complete or confirmatory identification.

Characteristics for Initial Identification

Identification schemes for aerobic Gram-negative organisms that grow on TSA with 5% sheep blood agar begin with performing a Gram stain, observing colony morphology, and assessing the organism's ability to ferment glucose and grow on MacConkey agar. Figures 6.1 and 6.2 show a strategy to divide aerobic Gram-negative organisms based on Gram-stain cellular morphology, TSI reaction, cytochrome oxidase production, pigment production, and growth on MacConkey agar. Detailed algorithms for the preliminary identification of aerobic Gram-negative bacteria have been published by Schreckenberger and Wong[6]; York, Schreckenberger, and Church[7]; Weyant et al.[8]; and Wauters and Vaneechoutte.[9]

Gram Stain

Performing a Gram stain of bacterial growth from isolated colonies should be one of the first steps in identifying an unknown bacterium. Gram-negative organisms have a cell wall composed of a single peptidoglycan layer attached to a lipopolysaccharide-phospholipid bilayer outer membrane with

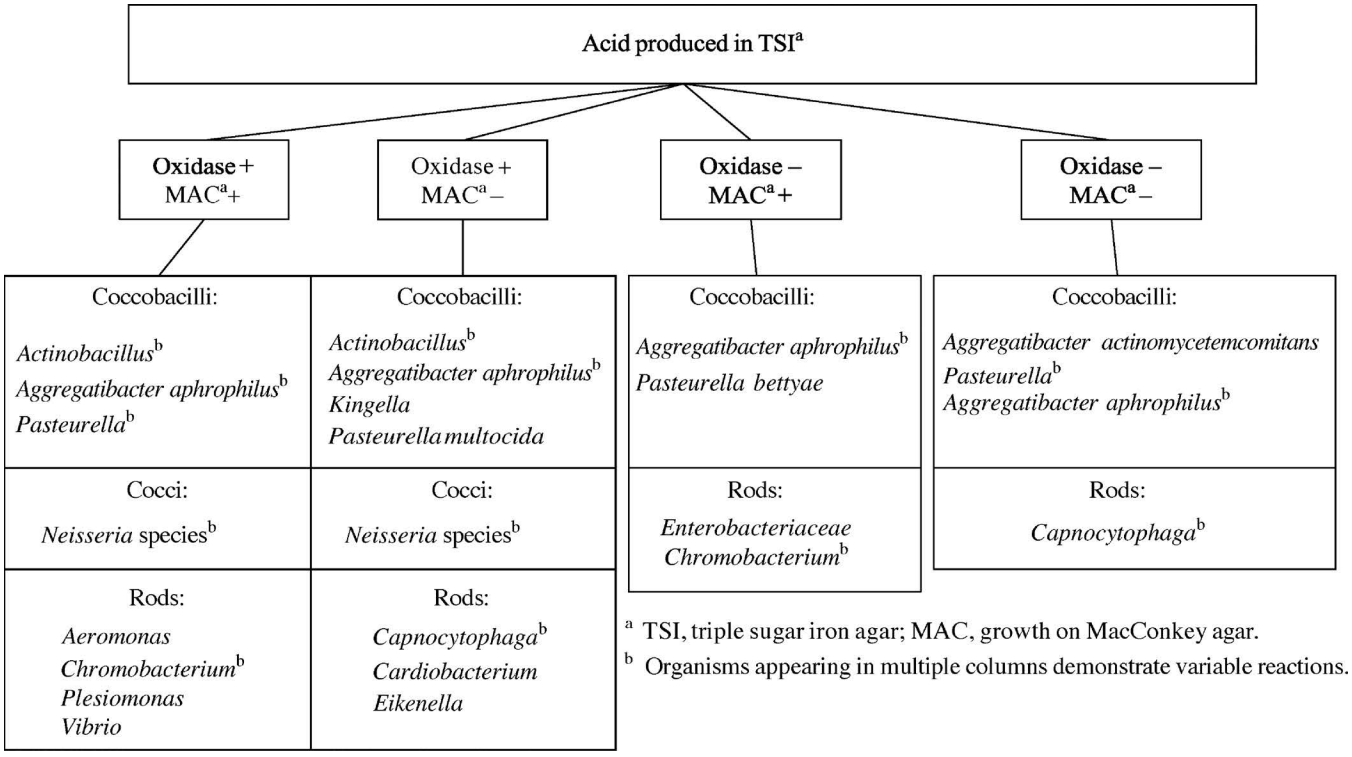

FIGURE 6.2 Gram-negative organisms that grow on TSA with 5% sheep blood and ferment glucose. (Data from Refs. [8, 11, 14, 19, 20, 27, 28, 78].)

protein molecules interspersed in the lipids. Decolorizing with alcohol damages this outer membrane and allows the crystal violet-iodine complex to leak out. The organism then takes up the red color of the safranin counterstain.[10] Once proven to be Gram-negative, bacteria can be further differentiated based on their cellular morphology. They may appear as pronounced rods as seen in most *Enterobacteriaceae* and many *Pseudomonas* species; as Gram-negative cocci, such as most *Neisseria* species and *Moraxella catarrhalis*; or as oval coccobacilli, as seen in *Haemophilus*, *Aggregatibacter*, *Francisella*, and *Acinetobacter* species.

Even an experienced microbiologist might have difficulty distinguishing between true cocci and coccobacilli in some cases. Growth of cultures in the presence of low levels of penicillin can cause the bacteria to reveal their true form. Organisms that normally divide and produce short rods will instead continue to grow and produce filaments when exposed to penicillin. Gram stains made from growth at the edge of the zone of inhibition around a 10µg penicillin disk will show either enlarged cocci if the organism is a true coccus or long filaments if the organism is a Gram-negative coccobacillus or rod.[8]

Colony Morphology

Another key feature for preliminary identification of aerobic Gram-negative organisms is observation of the size, shape, and texture of bacterial colonies growing on agar media. Colonies of most members of the *Enterobacteriaceae* family tend to be large and moist and grow well on TSA with 5% sheep blood after 24 hours of incubation. *Neisseria* species have smaller but distinct colonies after 24 hours. Nonfermentative Gram-negative rods and fastidious fermenters may require 48 hours or more of incubation before growth is evident. Many Gram-negative organisms produce extracellular enzymes that lyse the red blood cells in the agar. *Escherichia coli*, *Morganella morganii*, *Pseudomonas aeruginosa*, *Aeromonas hydrophila*, and commensal *Neisseria* species can be recognized by the presence of complete clearing of the red blood cells around the colonies (beta-hemolysis) on blood agar. Colonies of *Eikenella corrodens* and *Alcaligenes faecalis* produce only partial lysis of the cells, forming a greenish discoloration (alpha-hemolysis) around the colony.[11] Colonies of *Proteus mirabilis* and *Proteus vulgaris* are distinctive because of their swarming edges that can spread to cover the entire plate. *Photorhabdus* species, usually associated with nematodes but recently reported to cause human infections, are bioluminescent: the colonies emit light when examined under conditions of total darkness.[12,13]

Pigment Production

Gram-negative bacteria can produce several pigments that are helpful in establishing identification. Some pigments are water insoluble and give color to the bacterial colonies. These include carotenoids (yellow-orange), violacein pigments (violet or purple), and phenazines (red, maroon, or yellow). Other pigments, such as pyocyanin and pyoverdine, are water-soluble and diffusible. They confer color to the medium surrounding the colonies as well as to the colonies themselves. Media formulations developed specifically to detect pigment production contain special peptones and an increased concentration of magnesium and sulfate ions.[11] Pigment can also be observed in growth on TSA with 5% sheep blood, brain heart infusion agar, and Loeffler's agar.

Enterobacter species, most strains of *Cronobacter sakazakii*, *Pantoea agglomerans*, *Leclercia adecarboxylata*, and the nonfermentative Gram-negative rods *Chryseobacterium*, *Elizabethkingia*, *Myroides*, *Flavobacterium*, *Balneatrix*, *Empedobacter*, and *Sphingomonas* species can be distinguished from related organisms by their yellow pigment. *Burkholderia cepacia* complex or *Burkholderia gladioli* can be suspected when a colony of a nonfermentative Gram-negative rod displays a yellow-brown pigment. *Chromobacterium violaceum* produces violet pigment, while colonies of *Roseomonas*, *Methylobacterium*, *Asaia*, *Azospirillum*, and some species of *Serratia* appear pink to red. The fluorescent *Pseudomonas* group is distinguished from other nonfermentative Gram-negative rods by the production of the fluorescent pigment pyoverdine. *P. aeruginosa* isolates may produce both pyoverdine and blue-green pigment pyocyanin.[11,14,15]

Growth on MacConkey Agar

The ability of an organism to grow and to ferment lactose on MacConkey agar offers clues to the organism's identification. MacConkey agar contains crystal violet and bile salts, which are inhibitory to most Gram-positive organisms and certain Gram negatives.[16] *Enterobacteriaceae* will grow on MacConkey agar in 24–48 hours, while fastidious fermenters and nonfermentative Gram-negative organisms may take up to 7 days for growth to appear. Most *Moraxella* species and most species of *Neisseria* can be distinguished from related organisms by their inability to grow on MacConkey agar. MacConkey agar also contains lactose and a neutral red indicator, which can further help characterize the organism. Gram-negative organisms that ferment lactose, such as *Klebsiella pneumoniae* and strains of *E. coli*, will develop into purple colonies as the neutral red indicator changes due to the production of acids. Organisms that do not ferment lactose, such as *Proteus* or *Pseudomonas* species, appear colorless or transparent.

Triple Sugar Iron Agar

Triple sugar iron (TSI) agar can be used to determine whether an organism is capable of fermenting glucose. This medium contains glucose, lactose, and sucrose in a peptone and casein base with a phenol red pH indicator.[11,17,18] An agar slant is inoculated by first stabbing through the center of the medium and then streaking the surface of the slant, using an inoculum of 18–24 hours growth. If the organism ferments glucose, acid will be produced in the agar, lowering the pH and changing the color of the medium from red to yellow. If gas is produced during fermentation, bubbles will form along the stab line, fracturing or displacing the medium. Most species of *Enterobacteriaceae* and *Aeromonas* will produce an acid reaction, often with the production of gas, after 24 hours of incubation at 35°C–37°C. *Pasteurella*, *Eikenella*, and other fastidious fermentative Gram-negative rods will produce a weak acid reaction that may take up to 48 hours to appear, and typically will have no gas formation. *Pseudomonas* species, *Moraxella* species, and other nonfermentative Gram-negative organisms will show no color change on TSI medium or will produce a pink, alkaline reaction as the bacteria break down the peptones in the agar base.

TSI agar also contains iron salts and sodium thiosulfate to detect the ability of a Gram-negative organism to produce hydrogen sulfide (H_2S). H_2S, if produced, will react with the iron salts to form a black precipitate in the butt of the TSI tube.[11] The ability to produce H_2S is a key test to differentiate *Salmonella*, *Proteus*, *Citrobacter*, and *Edwardsiella tarda* from other members of the *Enterobacteriaceae*. H_2S production helps to separate the genus *Shewanella* from other similar nonfermenters.[9]

Oxidase

The oxidase test determines the ability of an organism to produce cytochrome oxidase enzymes. A phenylenediamine reagent is used as an electron acceptor. In the presence of atmospheric oxygen and the enzyme cytochrome oxidase, the reagent is oxidized to form a deep blue compound, indole phenol. Two different reagents are commercially available: (1) tetramethyl-*p*-phenylenediamine dihydrochloride (Kovac's formulation) and (2) dimethyl-*p*-phenylenediamine dihydrochloride (Gordon and McLeod's reagent). The tetramethyl derivative is the more stable of the two, is less toxic, and is more sensitive in detecting weak results.[8,11] Oxidase can be detected by adding drops of the test reagent directly onto 18–24 hours old growth on a culture plate. Colonies will become blue if cytochrome oxidase is produced. An alternate, more sensitive oxidase test method uses filter paper saturated with reagent. A loopful of organism from an 18–24-hour-old culture is inoculated onto filter paper. Growth should be taken from a medium that contains no glucose. Development of a blue color at the site of inoculation within 10–30 seconds indicates a positive reaction. Care must be taken to avoid using metal loops, which can give a false-positive reaction.[8] All members of the *Enterobacteriaceae* except *Plesiomonas shigelloides* are negative for oxidase. *Aeromonas*, *Vibrio*, *Neisseria*, *Moraxella*, and *Campylobacter* are all positive for oxidase, as are most *Pseudomonas* species. *Acinetobacter* species can be distinguished from similar nonfermentative Gram-negative rods by a negative oxidase reaction.

Additional Conventional Biochemical Tests

Gram-negative organisms can be further characterized phenotypically using a battery of media and substrates. The pattern of reactions is then compared with charts in the literature [8,11,12,19–28] to arrive at a definitive identification. What follows is a brief description of some key tests used for identifying Gram-negative organisms to the species level. More detailed descriptions of these test methods have been published elsewhere.[11,17,18,29]

Acid from Carbohydrates

Many identification schemes for Gram-negative organisms rely on the determination of the organism's ability to produce acid from a variety of carbohydrates. Acid can be produced by either fermentation or oxidation. Fermentative organisms are tested

using a 1% solution of carbohydrate in peptone water containing a pH indicator. Different media formulations may incorporate bromocresol purple, phenol red, or Andrade's indicator with acid fuchsin.[8,11,18,29] Selected carbohydrates are inoculated with a suspension of the organism in saline or in broth without glucose. After 1–5 days of incubation at 35°C–37°C, if the organism ferments the carbohydrate, the resulting acid will change the color of the pH indicator. The medium will become yellow if bromocresol purple or phenol red is used as an indicator, or pink if Andrade's indicator is used.

Nonfermentative organisms may produce acid from carbohydrates by oxidation. This can be detected using Hugh and Leifson's oxidation–fermentation basal medium, a semisolid peptone base with a bromothymol blue indicator and 1% concentration of carbohydrates. Two tubes of each carbohydrate are inoculated with the test organism by stabbing an inoculation needle into the center of the semisolid medium. The medium in one tube of each set is overlaid with sterile mineral oil. The second tube is left with the cap loosened. Both tubes are incubated at 35°C–37°C for up to 10 days. If the isolate oxidizes the carbohydrate, acid will be produced in the presence of oxygen, causing a yellow color change in the tube with no oil. If the isolate ferments the carbohydrate, an acid change will occur in the tube overlaid with oil. An organism that is neither oxidative nor fermentative may produce an alkaline (blue) reaction in the open tube if the organism breaks down peptones in the medium base.[8,11,18,29]

Catalase

The enzyme catalase breaks down hydrogen peroxide to form oxygen gas and water. When drops of 3% hydrogen peroxide are added to 18–24 hours of growth of an organism, bubbles will form if the organism is producing the catalase enzyme. Any medium containing whole blood should not be used for catalase testing because red blood cells contain catalase and can cause a false-positive result. Although it contains blood, chocolate agar can be used for the catalase test because the red blood cells have been destroyed during media preparation.[17] The catalase reaction is useful to differentiate *Kingella* species, which are catalase negative, from most other fastidious fermenters and from *Moraxella* species, which are catalase positive. *Neisseria gonorrhoeae* is strongly positive when 30% hydrogen peroxide (superoxol) is used. This characteristic is often included as part of a presumptive identification for *N. gonorrhoeae* from selective media.[19,29]

Citrate Utilization

The ability of a bacterium to use citrate as a sole source of carbon is an important characteristic in the identification of *Enterobacteriaceae*. Simmons citrate medium formulation includes sodium citrate as the sole source of carbon, ammonium phosphate as the sole source of nitrogen, and the pH indicator bromothymol blue. The agar slant is inoculated lightly and incubated at 35°C–37°C for up to four days, keeping the cap loosened because the reaction requires oxygen. If the organism utilizes the citrate, it will grow on the agar slant and break down the ammonium phosphate to form ammonia. This will cause an alkaline pH change, turning the pH indicator from green to blue.[11,17,18] *E. coli* and *Shigella* species are citrate negative, while many other *Enterobacteriaceae* are citrate positive. Among nonfermentative Gram-negative rods, *A. faecalis* and *Achromobacter xylosoxidans* are consistently positive for citrate utilization, while *Moraxella* species are consistently negative. A positive citrate reaction helps to distinguish *Roseomonas gilardii* from *Methylobacterium* species.

Decarboxylation of Lysine, Arginine, and Ornithine

This test determines whether an organism possesses decarboxylase enzymes specific for the amino acids lysine, arginine, and ornithine. Moeller's decarboxylase medium is commonly used. This medium contains glucose, the pH indicators bromocresol purple and cresol red, and 1% of the l (levo) form of the amino acid to be tested. A control tube containing the decarboxylase base with no amino acid is inoculated in parallel. All tubes are overlaid with oil because decarboxylation requires anaerobic conditions. If the organism possesses the appropriate enzyme, hydrolyzation of the amino acid will occur, forming an amine and producing an alkaline pH change. A positive reaction will result in a purple color change. A negative reaction will retain the color of the base or become acidic (yellow) due to fermentation of glucose in the medium.[11,17,18,29] Fermentative Gram-negative rods require a light inoculum and 24–48 hours of incubation at 35°C–37°C. Nonfermenters, however, may produce a weaker reaction and often need a heavy inoculum and prolonged incubation at 35°C–37°C before a color change occurs. Decreasing the volume of substrate used can also enhance reactions in weakly positive organisms.[11]

Lysine, arginine, and ornithine reactions are key tests that help differentiate among the genera and species of the *Enterobacteriaceae*. For example, many species of *Citrobacter* and *Enterobacter* are positive for arginine and ornithine, while *Klebsiella* species are often only positive for lysine, and *Yersinia* species are typically positive for ornithine. *Leclercia adecarboxylata* is unable to decarboxylate any of the three amino acids, while *Plesiomonas shigelloides* is positive for all three. Among nonfermentative Gram-negative rods, a positive arginine dihydrolase reaction is characteristic of *P. aeruginosa* and the select agents *Burkholderia mallei* and *Burkholderia pseudomallei*. A positive arginine reaction also helps differentiate *Haematobacter* species from *Psychrobacter phenylpyruvicus*.[15] A positive lysine decarboxylase reaction is useful in distinguishing *Stenotrophomonas maltophilia* and members of the *Burkholderia cepacia* complex from most other nonfermenting Gram-negative rods.

Esculin Hydrolysis

Esculin agar formulations consist of 0.1% esculin in a heart infusion basal medium containing ferric citrate. Agar slants are inoculated with isolated growth and incubated at 35°C–37°C for 24 hours, or up to seven days for slowly growing Gram-negative rods. Hydrolysis of esculin forms glucose and esculetin.

The esculetin reacts with ferric ions to form a black compound in the media. Esculin is also a fluorescent compound that appears white-blue under long-wave ultraviolet light at 360 nm. When esculin is hydrolyzed, fluorescence is lost. The development of a black color in the agar or the loss of fluorescence after incubation is interpreted as a positive test. If the agar remains fluorescent or there is no black color formed, the test is interpreted as negative. Gram-negative organisms that produce H_2S may cause a false-positive reaction as H_2S also reacts with ferric ions to produce a black complex. The esculin hydrolysis reaction for these organisms should be interpreted by checking for loss of fluorescence.[11,16,18,29]

Esculin hydrolysis is a key reaction in the identification of *Chryseobacterium* and *Sphingobacterium* species. *Pseudomonas (Chryseomonas) luteola*, *Brevundimonas vesicularis*, *Stenotrophomonas maltophilia*, and *Ochrobactrum anthropi* are all positive for esculin hydrolysis as are some members of the *Burkholderia cepacia* complex and the select agent *Burkholderia pseudomallei*.[11]

Gelatin Liquefaction

The gelatin test detects an organism's ability to produce the proteolytic enzyme gelatinase. Nutrient gelatin is incorporated into a semisolid basal medium. The medium is stabbed with a heavy inoculum of the bacteria to be tested. An uninoculated control tube is included. Both tubes are incubated for up to two weeks. *Enterobacteriaceae* and *Pseudomonas* species should be incubated at 22°C. Nonfermenting Gram-negative organisms are incubated at 30°C. Other organisms are incubated at 35°C.[17] If gelatinase is produced, the inoculated media will become liquefied as the enzymes break down the gelatin present. Since the basal medium is a liquid at incubation temperatures, the tubes must be moved from the incubator to the refrigerator before a final reaction can be assessed. A positive reaction will remain liquid at refrigerator temperature, while a negative reaction will return to a semisolid state.

Alternatively, strips of undeveloped x-ray film coated with gelatin can be used to test for gelatinase production. The strip is placed in a suspension of the organism to be tested. A positive reaction will cause the coating of the strip to be hydrolyzed so that a clear plastic strip remains. The x-ray method requires 4–48 hours of incubation at 35°C.[17,29]

Gelatin is a key reaction in distinguishing *Pseudomonas fluorescens* group (positive) from *Pseudomonas putida* (negative). Among the *Enterobacteriaceae*, *Serratia* species, *Pantoea agglomerans*, and several species of *Proteus* are gelatin positive. A positive gelatin reaction helps to differentiate *Acinetobacter haemolyticus* from other *Acinetobacter* species and distinguishes *Capnocytophaga sputigena* from gelatin-negative *Capnocytophaga* species such as *C. canimorsus*, *C. cynodegmi*, and *C. gingivalis*.[17,29]

Indole Production

The indole production test distinguishes organisms that produce tryptophanase, an enzyme capable of splitting the amino acid tryptophan to produce indole. Aldehyde in the test reagent reacts with indole to form a red-violet compound.[11,29] The test can be performed in a variety of ways. A spot indole test is useful for rapid indole producers such as *E. coli*. A drop of Kovac's reagent, containing 5% *p*-dimethylaminobenzaldehyde, is placed on the colony on an agar surface or on a colony picked up on a swab. The colony will form a red to pink color if positive.

Liquid or semisolid media with a high-tryptone content can be used for a tube test for indole. The medium is inoculated and incubated for 24–48 hours. A few drops of Kovac's reagent are added. If the organism produces tryptophanase, a pink color will develop at the meniscus.[11,17,29] *E. coli* and several other *Enterobacteriaceae* are indole positive and can be tested using this method.

For weakly reacting nonfermenters and fastidious organisms, Ehrlich's reagent, containing 1% *p*-dimethylaminobenzaldehyde, can be used. In this method, 0.5 mL xylene is added to the organism growing in tryptone broth to extract small quantities of indole, if present. The mixture is vortexed and allowed to settle. Six drops of Ehrlich's reagent are then added to the tube. If positive, a pink color will form below the xylene layer.[11,17,29] *Cardiobacterium hominis* and several nonfermentative Gram-negative rods, including *Chryseobacterium indologenes*, will be indole positive by this method.

Motility

Motility is demonstrated macroscopically by making a straight stab of growth into semisolid medium, incubating for 24–48 hours at 35°C–37°C, and then observing whether the organism migrates out from the stab line, causing visible turbidity in the surrounding medium.[17] Various formulations of motility medium are available. *Enterobacteriaceae* can be tested in a 5% agar medium with a tryptose base. Incorporation of 2,3,5-triphenyltetrazolium chloride (TTC) into this medium can help in visualizing the bacterial growth. TTC causes the bacterial cells to develop a red pigment that can aid in the interpretation of the motility reaction. Nonfermentative Gram-negative organisms that fail to grow in 5% agar medium can be tested using 3% agar in a base containing casein peptone and yeast extract. Fastidious organisms may demonstrate motility better in a 1% agar base containing heart infusion and tryptose.[16] *Shigella* species and *Klebsiella* species are always nonmotile. *P. aeruginosa* and *Achromobacter xylosoxidans* are both motile. *Yersinia enterocolitica* is often nonmotile at 35°C–37°C, but motile at 28°C.

Motility may be difficult to demonstrate in semisolid medium if the organism grows slowly. Use of a wet mount made from a suspension of growth in water or broth may enable weak motility to be detected. The mount is observed with the 40× or 100× objective of a light microscope to determine whether the organisms move and change direction.[8]

Methyl Red (MR) and Voges-Proskauer (VP) Tests

The methyl red (MR) test is used to determine an organism's ability to both produce strong acid from glucose and to maintain a low pH after prolonged (48–72 hours) incubation. MR–VP medium formulated by Clark and Lubs is inoculated and incubated for

at least 48 hours. Five drops of 0.02% MR reagent are added to a 1 mL aliquot of test broth. Production of a red color in the medium indicates a positive reaction.[11,17,29]

The Voges-Proskauer (VP) test determines an organism's ability to produce acetylmethylcarbinol (acetoin) from glucose metabolism. MR–VP broth is incubated for a minimum of 48 hours, followed by the addition of 0.6 mL of 5% alpha-naphthol and 0.2 mL of 40% potassium hydroxide to a 1 mL aliquot of test broth with gentle mixing. The 40% potassium hydroxide causes acetylmethylcarbinol, if present, to be converted to diacetyl. Alpha-naphthol causes the diacetyl to form a red color.[6,11,17]

The MR and VP tests are used as part of the identification of *Vibrio* and *Aeromonas* species and help to differentiate among the genera and species of the *Enterobacteriaceae*.

For example, *E. coli*, *Citrobacter*, *Salmonella*, and *Shigella* species are positive for MR but negative for VP, while some species of *Enterobacter* are positive for VP but negative for MR. Several species of *Serratia* and *Klebsiella* can be distinguished from other *Enterobacteriaceae* because they are positive for both MR and VP. The tests are usually performed at 35°C–37°C, but *Yersinia enterocolitica* is VP positive at 25°C and variable at 35°C–37°C.

Nitrate Reduction

The ability of an organism to reduce nitrate (NO_3) to nitrite (NO_2) or to nitrogen gas is an important characteristic used to identify and differentiate Gram-negative bacteria. The organism is grown in a peptone or heart infusion broth containing potassium nitrate. An inverted Durham tube is included in the growth medium to detect the reduction of nitrites to nitrogen gas. After 2–5 days of incubation, five drops each of 0.8% sulfanilic acid and 0.5% *N,N*-dimethyl-naphthylamine are added to the test broth. If the organism has reduced the nitrate in the medium to nitrites, the sulfanilic acid will combine with the nitrite to form a diazonium salt. The dimethyl-naphthylamine couples with the diazonium compound to form a red, water-soluble azo dye. If there is no color development and no gas in the Durham tube, zinc dust can be used to determine whether nitrate has been reduced to nongaseous end products. Zinc dust will reduce any nitrate remaining in the medium to nitrite, and a red color will develop. If no red color develops after the addition of zinc, all nitrate in the medium has been reduced, indicating a positive nitrate reduction reaction. The development of a red color after the addition of zinc dust confirms a true negative reaction.[11,17,18,29] All members of the *Enterobacteriaceae*, except for certain biotypes of *Pantoea agglomerans* and certain species of *Serratia* and *Yersinia,* are able to reduce nitrate. *P. aeruginosa*, *Moraxella catarrhalis*, *Neisseria mucosa*, and *Kingella denitrificans* are characterized by a positive nitrate reaction. *A. faecalis* can be distinguished from similar nonfermentative Gram-negative organisms by its inability to reduce nitrate.

Urease

Detection of the ability of an organism to produce the enzyme urease can be accomplished using either broth or an agar medium containing urea and the pH indicator phenol red. Urea medium is inoculated with isolated, 24 hours old colonies and incubated at 35°C–37°C. If the organism produces urease, the urea will be split to produce ammonia and carbon dioxide. This creates an alkaline pH, causing the phenol red indicator to become bright pink.[18,29] Some bacteria, such as *Proteus* species, *Brucella* species, and *Bordetella bronchiseptica*, are capable of producing a strongly positive urease reaction in less than 4 hours. A rapidly positive urease reaction is useful in differentiating the select agent *Brucella* species from other oxidase-positive, slow-growing, aerobic Gram-negative coccobacilli. Other organisms must be incubated 24 hours or longer before a positive urease reaction becomes visible. Among the *Enterobacteriaceae*, *Proteus*, *Providencia*, and *Morganella* species are urease positive, as are some *Citrobacter* and *Yersinia* species. A positive urease reaction helps distinguish *Psychrobacter phenylpyruvicus*, *Haematobacter* species, and *Oligella ureolytica* from related organisms.[15] Urease is also a key test in the identification of *Helicobacter pylori* in gastric and duodenal specimens.

Commercial Identification Systems

There are several commercial systems available for the identification of aerobic Gram-negative organisms. The Vitek® System (bioMerieux, Inc., Hazelwood, MO), Sensititre Automated Reading and Incubation System (Thermofisher Scientific, Waltham, MA), MicroScan Walkaway (Beckman Coulter, Brea, CA), and the Phoenix™ System (BD Biosciences, Sparks, MD) are miniaturized, sealed identification panels containing 30–51 dried biochemical substrates, depending on the particular test kit chosen. The systems incorporate modifications of conventional biochemicals and also test for hydrolysis of chromogenic and fluorogenic substrates and for utilization of single carbon source substrates. A standardized inoculum is used, and the panels are continuously incubated in an automated reader. Reactions are detected by the instrument via various indicator systems. Results are compared with known bacteria in the system's database to arrive at a final identification.[11,30–33]

Semiautomated systems such as MicroScan® panels (Beckman Coulter, Brea, CA) and the BBL Crystal Identification System (Becton Dickinson Microbiology Systems, Sparks, MD) use substrates similar to the fully automated methods. They can be placed in an automated reader for interpretation or read visually by the operator. API® kits (bioMerieux, Inc., Hazelwood, MO), TREK Sensititre plates (Thermofisher Scientific, Waltham, MA), and BD BBL Enterotube II (Becton Dickinson Microbiology Systems, Sparks, MD) also use miniaturized modifications of conventional biochemicals, but the systems are open, allowing reagents to be added by the operator. The wells are read manually, giving the opportunity for visual confirmation of biochemical results. For the semiautomated and manual systems, a 5–10 digit code is generated as the biochemical reactions are interpreted. The code is translated into an identification using a code book or software provided by the manufacturer.[11,32–34]

The Biolog MicroPlate™ system (Biolog, Inc., Hayward, CA) identifies aerobic Gram-negative organisms by testing their ability to utilize 95 separate carbon sources. Reactions are based on the exchange of electrons generated during respiration, leading to a tetrazolium-based color change. Biolog microplates can be read

visually, achieving a reaction pattern that can be classified using database software,[11,32,34] or used as part of the fully automated OmniLog ID System (Biolog, Hayward, CA). The OmniLog system allows the user to choose different incubation temperatures to enable maximum growth.[11,32,34]

There are two FDA-cleared identification systems that rely on matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF MS) technology, Bruker Biotyper MALDI-TOF MS platform (Bruker Daltonics Inc., Billerica, MA) and the Vitek MS system (bioMerieux, Inc., Durham, NC). MALDI-TOF MS is a form of mass spectrometry that employs a soft ionization technique. Soft ionization keeps the molecules intact with minimal fragmentation during ion formation, which enables the analysis of proteins.[35] MALDI-TOF MS allows for the identification of microorganisms by analyzing the expression of their intrinsic proteins, particularly the ribosomal proteins that are stable under various culture conditions.[36,37] The proteins present in the sample are separated by mass and charge to yield a spectrum. This spectrum functions as a fingerprint for the particular species that is then compared to a reference database to identify the bacteria (or yeast).[37] This technology provides a fast, reliable, low-cost method for identifying bacterial organisms.

Commercial systems are useful when a large number of isolates must be processed because such systems offer a decreased turnaround time and decreased hands-on time, as compared to conventional biochemical schemes. The biochemical-based commercial platforms perform with high levels of accuracy when identifying metabolically active organisms such as the *Enterobacteriaceae*, *P. aeruginosa*, or *Stenotrophomonas maltophilia*. However, some systems are not designed to detect weak or delayed reactions, which can result in false-negative results. Some fastidious aerobic Gram-negative organisms may not grow well in commercial systems and may require the use of additional testing methods. The MALDI-TOF MS–based platforms are based on ribosomal proteins and often perform as well on inert organisms as on metabolically active organisms. Commercial kits and systems may be limited by the range and number of bacteria included in the particular system's database. Organisms that are not included in the database will not be recognized and may be misidentified.

A number of references provide detailed descriptions and evaluations of biochemical-based commercial systems,[11,32,38] MALDI-TOF MS systems that can be used on bacterial isolates,[39–42] and MALDI-TOF MS identification performed directly from blood cultures.[43–48]

Molecular Testing and Analysis

Molecular analysis is becoming an increasingly important tool for the clinical bacteriologist, especially in the identification of aerobic Gram-negative bacteria. PCR and real-time PCR assays offer specific and rapid identifications that can be the key to the detection of pathogens. This is particularly true for specimen types where classical approaches may be compromised due to a delay in transport or the initiation of antimicrobial therapy prior to specimen collection.

Molecular analysis can quickly provide identification to the species level for certain genera of aerobic Gram-negative bacteria that cannot be differentiated by commercially available systems, or that would require the use of highly specialized, time-consuming, and labor-intensive protocols. Examples include species determination for organisms of the *Burkholderia cepacia* complex[49] and the genera *Bordetella*,[50] *Brucella*,[51,52] *Achromobacter*,[53] *Yersinia*,[54] and *Campylobacter*.[55] PCR and real-time PCR assays offer specific and rapid identification of foodborne pathogens in clinical specimens as well as in food and other environmental samples.[56,57] Further, many Gram-negative bacteria, such as *Legionella*, *Bordetella*, *Neisseria*, and *Haemophilus*,[58–61] are difficult to cultivate; PCR analyses offer superior sensitivity in identifying these organisms. Additionally, molecular typing and the rapid characterization of antibiotic resistance, pathogenic plasmids, or toxin genes can be achieved. Examples include the typing of *E. coli*,[62] *Salmonella*,[63] and *Neisseria meningitidis*[64] and the detection of genes associated with *Klebsiella pneumoniae* carbapenemase-mediated carbapenem resistance in *K. pneumoniae*[65] and other *Enterobacteriaceae*,[66] the virulence plasmids of *Yersinia pestis*,[54] and the presence of Shiga toxins in *E. coli*.[57] Finally, molecular analyses are utilized for ruling in or out the presence of Gram-negative bacterial select agents in clinical and environmental samples; in such a situation, rapid issuance of test results by a reference laboratory can be crucial in detecting and averting the intentional dissemination of potentially deadly pathogens.[67]

When working with a primary specimen or an unknown aerobic Gram-negative bacterium, the use of syndromic panels, 16S rRNA gene sequence analysis, or other broad-range PCR may be successful.[68] There are a number of commercially available molecular assays that can detect numerous microorganisms simultaneously, including Gram-negative bacteria. There are assays that can detect Gram-negative bacteria directly from clinical specimens such as stool (*E. coli*, *Campylobacter*, *Shigella*, *Yersinia*, *Salmonella*),[69–71] respiratory specimens (*N. meningitidis*, *Haemophilus influenzae*, *Legionella pneumophila*, *Acinetobacter baumannii*),[72–74] and blood or blood cultures (*A. baumannii*, *Enterobacter*, *E. coli*, *H. influenzae*, *Kingella kingae*, *Klebsiella*, *Neisseria*, *Proteus*, *P. aeruginosa*, *Salmonella*, *Serratia marcescens*, *Stenotrophomonas maltophilia*, *Bacteroides fragilis*, *Campylobacter*).[75–78] A number of these assays are FDA-cleared, including the xTAG Gastrointestinal Pathogen Panel (Luminex Corp., Austin, TX), the Prodesse ProGastro SSCS (Hologic Gen-Probe Inc., San Diego, CA), and FilmArray Blood Culture Identification Panel and Respiratory Panel (BioFire Diagnostics, Inc., Salt Lake City, UT), with more to follow in the future. These assays provide more rapid results without the need to wait for bacterial growth. Additionally, broad-range PCR tests are useful when conventional methods provide inconclusive results or if a result is needed rapidly. Broad-range PCR tests are based on the fact that some genes present in all bacterial organisms contain both regions of highly conserved sequence and regions of variable sequence. The highly conserved regions can serve as primer binding sites for PCR, while the variable regions can provide unique identifiers enabling the precise identification of a particular strain or species. These sophisticated PCR applications require adequate laboratory facilities, trained and experienced staff with expertise in the use of molecular databases, and protocols in place to avoid contamination.[79,80] Although such tests are time-consuming and

costly, and may only be available at specialized laboratories such as reference laboratories, they can provide an answer when other modes of testing give problematic results or are not feasible.

History

The plaque assay, an indispensable tool for the study of bacteriophage, was described in the earliest publications on the discovery of these viruses. Felix d'Hérelle, credited as co-discoverer of phage (along with Frederick Twort) described, in effect, the first plaque assay in 1917 [1], when he wrote the following:

> …if one adds to a culture of *Shiga* as little as a millionfold dilution of a previously lysed culture and if one spreads a droplet of this mixture on an agar slant, then one obtains after incubation a lawn of dysentery bacilli containing a certain number of circular areas of 1 mm diameter where there is no bacterial growth; these points cannot represent but colonies of the antagonistic microbes: a chemical substance cannot concentrate itself over definite points." (Translation from Stent [2].) The "antagonistic microbes" were then named "bacteriophage."

Subsequently, the technique was refined by Gratia [3] and Hershey et al. [4], by pouring onto an agar plate a top layer of molten agar containing a phage-bacteria mixture. The molten agar solidified, fixing the phage particles in the semisolid agar substrate, and as the bacteria grew during incubation to cover the plate as a lawn of bacterial growth, the embedded phage particles killed those bacteria in their vicinity, with the progeny phage infecting other bacteria in the vicinity to produce a zone of clearing, or a "plaque," on the lawn of bacterial growth. This method was described by Delbrück [5] as follows:

> In this technique a few milliliters of melted agar of low concentration, containing the bacteria, are mixed with the sample to be plated. The mixture is poured on the surface of an ordinary nutrient agar plate. The mixture distributes itself uniformly over the plate in a very thin layer and solidifies immediately. We used about 20 mL of 1.3 per cent agar for the lower layer and 1.5 mL of 0.7 per cent agar for the superimposed layer on petri plates of 7 cm diameter. With this technique 60 samples can be plated in about 20 minutes. The plaques are well-developed and can be counted after 4 hours' incubation.

The plaque assay was validated as showing that a single phage infecting a bacterium was sufficient to initiate formation of a plaque, because there was linear proportionality between the plaques observed and the dilution of the phage sample [6]. Electron microscopy later indicated that under optimal conditions, there was a close approximation between physical phage particles and the presumptive phage particles that initiated plaque formation [7].

However, the "efficiency of plating" of a bacteriophage preparation can vary extensively depending on conditions, especially the bacterial host strain. Varying susceptibility of different bacterial strains to different bacteriophage in fact was exploited for many years in the identification of bacteria, in a procedure called "phage typing." Although this procedure is not used as extensively today as in the past, a brief description of the principle will be provided later in this chapter. Current use of phage for identification of bacteria, including phage typing, is discussed in Chapter 8.

Methodology

A suspension of bacteriophage of unknown titer is first subjected to serial dilution, illustrated in Figure 7.1. A small portion (0.1 mL) of the suspension is added to 9.9 mL of dilution fluid, for a 100-fold dilution. A small portion (0.1 mL) of this dilution, in turn, is added to a fresh tube containing 9.9 mL of dilution fluid, for another 100-fold dilution. At this point, the original phage suspension has been diluted by a factor of 10,000. The process is repeated two more times, to a fourth tube where the dilution factor is 10^{-8}. Dilutions, of course, do not always have to be 1:100; other dilutions are perfectly acceptable, as long as the dilution factor is duly noted, since this is needed to obtain the titer of the original stock. In Figure 7.1, there is a fifth dilution tube with the addition of 1–9 mL of dilution fluid, to provide a 1:10 dilution, bringing the overall dilution factor to 10^{-9}. The need for large dilutions is because phage titers can be quite high.

Dilution fluid can be the growth medium for the host bacteria, but since this would be wasteful and expensive, in practice a simpler liquid diluent is used. Sterile saline solution can serve this

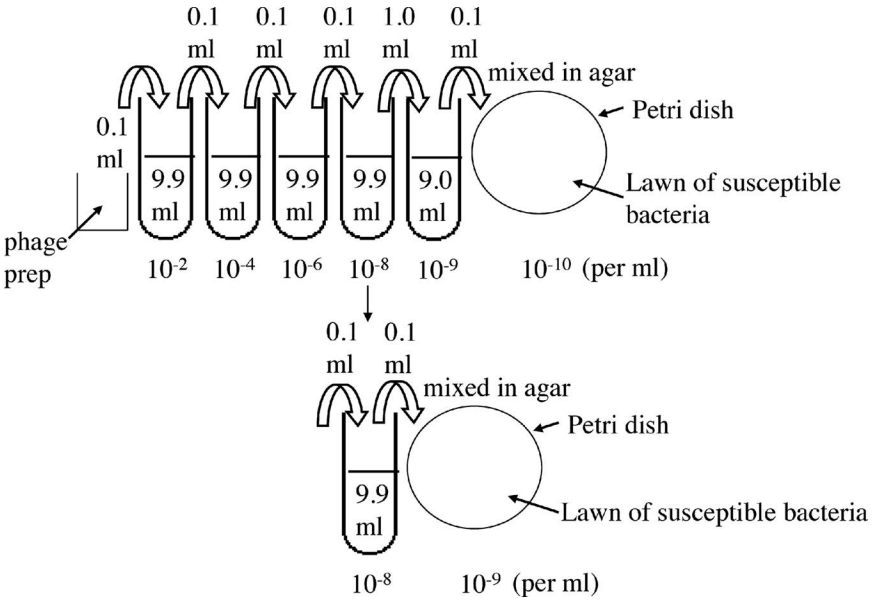

FIGURE 7.1 Serial dilutions.

purpose, or variations of saline with lower salt and a small addition of a growth nutrient, for example, sterile 0.25% (w/v) sodium chloride, 0.1% (w/v) tryptone.

Once the last dilution is made, 0.1 mL is added to tubes containing 2.5 mL soft agar that has been melted in a boiling water bath and equilibrated to ~45°C. Tubes can be kept in a water bath or, more commonly, a dry-block heating unit. The dry block is preferable to avoid unwanted contamination of water-bath water from the outside of the tubes when the contents are poured onto plates. Tubes should be plated fairly soon after addition of the phage dilution, to avoid incubating the phage at the high temperature for an extended period of time. The soft agar contains the nutrients for growth of the bacteria (and can be a minimal media) with 0.65% (w/v) agar. Two drops of a fresh saturated bacterial suspension (about 0.1 mL, ~10^8 bacteria total) are added to the tubes, which are then mixed and poured onto nutrient agar (1–1.5% w/v) petri plates (100 × 15 mm) that have been previously prepared (bottom agar) and are at room temperature. The plate is briefly rocked to facilitate uniform distribution of the top agar across the surface of the bottom agar before the top agar solidifies. If the plates have been refrigerated and are not at room temperature, top agar may solidify too quickly and not distribute uniformly, which will make plaque counting more difficult. The plates are then incubated at 37°C for several hours, usually overnight, to allow the bacteria to make a lawn and for the plaques to develop.

A recent report demonstrated improved visibility and consistency of plaques when a small volume of liquid suspension of the phage dilution was applied to the top agar layer after it had solidified, by a spreading technique with a glass rod (as opposed to mixing the phage in the molten top agar before pouring onto the bottom agar) [8].

Because the titer is unknown at the outset, more than one dilution of the phage stock is plated in this way, so that a reasonable (countable) number of plaques will be obtained at least at one of the dilutions tested. Figure 7.1 illustrates two dilutions that are plated, 10^{-8} and 10^{-9}. If one obtained, for example, 15 plaques from the 10^{-9} dilution (and ~150 plaques from the 10^{-8} dilution), the titer of the original phage stock would be 1.5×10^{11} phage/mL in the original stock suspension. This number of phage is the reciprocal of the dilution factor and is derived by taking into account that only 0.1 mL of the dilution was added to the plate, which represents an additional dilution factor of 10^{-1} when considered on a per mL basis. Hence, 15 plaques obtained from 0.1 mL of a 10^{-9} dilution = 15×10^{10} phage/mL in the original stock.

An example of actual plaques of a lytic phage grown on *Escherichia coli* is shown in Figure 7.2. The lawn is shown as a black background, although in an actual assay it would likely be tan or brown, and the plaques are shown as clear white circular spots on the lawn. If this plate resulted from plating 0.1 mL of a 10^{-8} dilution (as in Figure 7.1, bottom), then the titer of the stock would be ~1.5×10^{11}, since there are about 150 plaques on this plate. It is important to remember that each plaque represents the progeny phage from a single individual phage that was embedded in the top agar. The plaque as a whole may contain in the order of

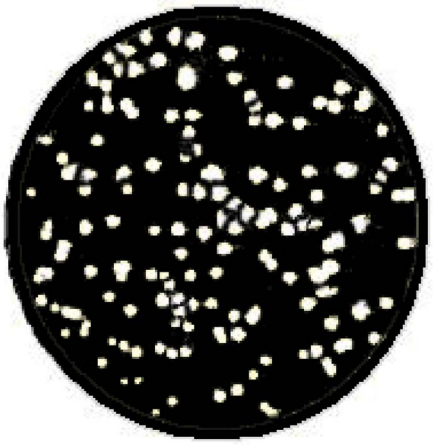

FIGURE 7.2 Bacteriophage plaques.

10^6 phage. A good description of preparation of phage and plaque assays can be found in a laboratory manual by Miller [9].

Different phage exhibit different morphologies in plaque assays. Some plaques are small and clear, with sharply defined borders. Some are large and can be more diffuse. A recent study compared isogenic phage mutants for differences in plaque morphologies and found that differences could be ascribed to specific alleles in the phage [10]. Some phage exhibit turbid plaques, in which there is some bacterial growth within the plaque, as if those bacteria had developed resistance to the phage. This is the hallmark of a temperate (lysogenic) phage, which, at low frequency, integrates its genome into the bacterial host and renders the host immune to reinfection by phage of the same type (see Chapter 48 in Part II). This characteristic appears to make plaque assays more difficult for some temperate phages, for example with *Lactococcus* species. However, improved methodology of plaque assays for temperate lactococcal phages has been reported, with a major enhancement of plaque size and visibility resulting from addition of glycine (between 0.25% and 1.25%) to the medium [11]. New approaches replacing the plaque assay for quantitating phage have been tested, using either of two alternative methods: quantitative PCR (polymerase chain reaction), and NanoSight Limited technology (using laser optical microscopy to visualize nanoparticles) [12]. However, these alternate techniques cannot confirm the viability of phage in the sample.

Application to Phage Typing

The ability of phage to form plaques on a lawn of susceptible bacteria was exploited to develop systematic methods for identifying strains of bacteria by their susceptibility to known stocks of individual phages, a technique known as "phage typing." A chapter of the first edition of this Handbook was devoted to this method [13], which was particularly useful for identifying strains of *Staphylococcus aureus* and *Salmonella typhi*, among others. An update on contemporary use of phage typing is included in Chapter 8.

The method requires a standard set of typing phages that are different for each species to be typed. A culture of the bacteria to be identified is spread over the surface of a nutrient agar plate. Drops from a set of typing phages are placed in a grid pattern on the surface of the plate, which is then incubated to allow the bacteria to form a lawn and for the phage to produce plaques. Following incubation, those phage in the set that can inhibit growth of the bacteria will form plaques. Since the phages were applied in a grid pattern, one can identify which phages the bacterial host is susceptible to, which will then be given a "phage-type" designation.

This principle is illustrated in Figure 7.3. The plate on the left shows a grid pattern of 12 individual phage that are spotted on a surface containing the bacteria to be identified. The plate is incubated to allow the lawn (and phage) to grow. Following incubation, plaques are observed at the locations where phages 2, 5, and 11 were spotted, and not at the locations of the other 9 phages in the set. If the bacteria to be identified had been a strain of

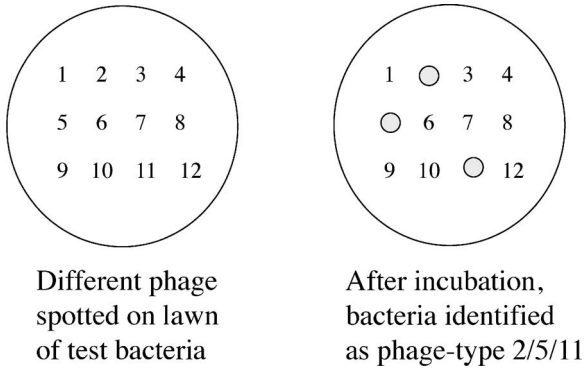

FIGURE 7.3 Phage typing.

Neisseria meningitidis, for example, the strain would thus be identified as *Neisseria meningitidis* phage type 2/5/11.

Introduction

As the name suggests, bacteriophage (literally "bacteria eating" from the Greek) were discovered as lytic agents that destroyed bacterial cells by Edward Twort and Felix D'Herelle (see [1] for a review of the history of their discovery and application). Bacteriophage* are in fact viruses that specifically infect members of the Bacterial kingdom [2]. In the Eukaryotic kingdom, the visible diversity of biological forms makes it unsurprising that viruses have a specific host range, since it is clear that the organisms affected by the different viruses are very different. However, in the Bacterial kingdom, differences between bacterial genera are not as easy to detect and differentiation between members of a species is often only reliably determined at the molecular level. Hence, in the field of bacteriology, the fact that viruses have evolved to specifically infect only certain members of a genus or species seems to be surprising. However, as the molecular recognition events involved in Eukaryotic virus infection are elucidated, it is clear that even subtle difference in cell surface proteins have profound effects on binding and infection of Eukaryotic viruses (see [3] for a review), and this is also true for the bacteria-virus interaction.

Historically, it was in 1926 that D'Herelle first reported the fact that not all members of a species could be infected by the same phage when he was investigating the use of bacteriophage to treat cholera [4]. He divided isolates of *Vibrio cholerae* into two groups on the basis of phage sensitivity. Until molecular methods of cell discrimination became more widely adopted, differentiation of cell type on the basis of phage sensitivity (or phage typing) was one of the best ways to discriminate between different isolates within a species and much research was put into developing and refining the phage typing sets for a range of different bacteria. Antibody typing (serotyping) is also able to differentiate strains at the subspecies level but, as phage isolation and propagation is easier and cheaper than characterization of polyclonal or monoclonal antibodies, phage typing has often been the first subspecies typing method developed for bacterial pathogens. Where robust and widely adopted phage-typing schemes exist, their use has continued, and phage typing is still used in some settings to subtype isolates of both Gram-negative and Gram-positive bacteria. However, since DNA-based typing methods have become more widely adopted, new phage typing sets are not being developed since generally, WGS analysis is found to be more discriminatory than the use of phage-typing to subspeciate strains, especially when tracking outbreaks of disease [5, 6]. However, so that historical data can be linked to modern methods of whole genome sequence analysis, the genetic differences that underlie phage types are now being derived from genome sequences, and linking phage sensitivity profiles to information gained from WGS continues to inform our understanding of the bacterial cell (e.g., see [7–11]).

In contrast to the use of phage typing, methods for the detection of bacteria using bacteriophage continue to be developed. This has resulted in the emergence of commercial tests, employing

* There is an ongoing debate about the plural form: bacteriophage or phages. For a discussion see [2].

a variety of assay formats, for use in both medical and environmental applications. This chapter will provide an overview of these technologies and describes some of the newer findings that may be developed into practical applications in the near future.

Phage Typing

Choice of Phage

Bacteriophage can be divided into two broad groups on the basis of the biological outcome of infection. Virulent, or lytic, phage always lyse the host cell at the end of the replication cycle. Temperate, or lysogenic, phage may cause lysis of the host cell after completing a lytic replication cycle or, alternatively, they may enter a dormant phase of replication where their genome is maintained within the host cell without causing harm to that cell so that the virus is replicated as part of the cell during cell division. Because of this choice of replication pathway, infection with temperate phage will not always result in the formation of plaques (lytic areas of clearing in a lawn of bacteria), and therefore these are often not chosen for use in phage typing schemes. Much work has been put into the isolation of virulent phage that can be evaluated for use in phage typing sets, and these are often found in the natural environment of the target bacterium (for instance, sewage is a good source of bacteria specific for enteric pathogens) [see 12–19]. However, other workers have chosen to try and identify phage variants or mutants (adapted phage) of previously isolated phage that have a new or altered host range. The fact that it was possible to select for such mutants was first shown by Craigie and Yen [20] as early as 1938. These workers identified the fact that phage could be selected from an infection that were now more lytic against that same strain on which they were last propagated and the practice of phage adaptation is still used to improve the discriminatory power of phage sets [18, 21]. More recently, this process has been taken further by the use of genetic engineering to develop recombinant phage with new host ranges that can be rapidly built and selected using high-throughput screening methods [22, 23].

Perhaps more important for science as a whole was the observation that phage host range could be affected by the host strain used to propagate the phage. This led to the discovery of phage restriction barriers (see next section and [24, 25]) and ultimately to restriction enzymes [26–28], which revolutionized the study of cellular molecular biology. In the same vein, more recently, the discovery of the host-encoded CRISPR-Cas phage immunity system has led to the development of an efficient, targeted genome engineering tool that has been widely adopted in many fields [29, 30].

Factors Affecting Phage Infection

There are many factors that influence the ability of a phage to infect a particular cell type. For successful infection, the phage needs to recognize its host by binding to primary surface receptors (see [31]). These are often molecules containing carbohydrates such as lipopolysaccharides [32] (O antigen) in Gram-negative bacteria, teichoic acids [33, 34] (O antigen) in Gram-positive bacteria, or capsular polysaccharides [35] (K antigen). The fact that structural variations in these molecules occur with a relative high frequency, which is used to distinguish cell types on the basis of serology, begins to explain why phage bind to different host cell types with variable efficiencies (see [36, 37]). In addition to carbohydrates, different cell surface proteins can be utilized as receptors such as flagella or pili [38–41], sugar uptake proteins [42], membrane proteins [43, 44], or S-layer proteins [45]. Again, variations in these proteins occur that can be detected using specific antisera (for instance, flagella represent H antigens), and accordingly phage binding occurs with a different affinity depending on the match between phage and host receptor molecules. Another level of variation can occur depending on the pattern of expression of the receptor by the host cell, which may be regulated by environmental conditions. This is particularly true for the expression of flagella and sugar transporters, and therefore the particular culture conditions used can determine whether or not a phage can infect a cell.

Once the phage has penetrated the cell envelope, replication may be prevented by a variety of mechanisms. For instance, if the cell contains a prophage (a dormant lysogenic phage), the regulatory proteins that suppress the lytic replication of the phage may also suppress replication of the newly infecting phage (see [46]).

Cells that possess DNA restriction-modification systems may reduce levels of infection by the destruction of incoming foreign DNA (the restriction barrier [47]) and host cell genes (abortive phage infection genes [48–50]) have been described that specifically block phage replication (for more details see [51]). Most recently, the role of acquired immunity through the CRISPR systems has been recognized as a major driver of phage resistance (see [52]). In effect then, phage typing is an indirect way of investigating variations in cell structure and genetics using the ability of a phage to infect cells (or not) as a biological indicator of the differences that can exist in closely related bacterial cells. Therefore, even though phage typing methods have fallen out of regular usage, the methods used for phage typing are still valuable research tools. In particular, these basic phage typing methods are used to determine the host range of newly isolated phage to be included in phage therapy trials [53].

Phage Typing Methods

Determining Phage Titer and RTD

To determine phage titer, 10-fold serial dilutions of the phage are prepared in a buffer that contains divalent cations (often Mg^{2+}), to facilitate phage binding to the cell surface, and gelatin, to stabilize phage particle structure. Commonly used buffers are Lambda buffer (50 mM Tris-HCl [pH 7.5], 100 mM NaCl, 1 mM MgSO4, 0.2% gelatin) [54] or SM buffer (50 mM Tris-HCl [pH 7.5], 100 mM NaCl, 8 mM $MgSO_4$, 0.01% gelatin) [54]. Alternatively, the broth used for host cell infection can be used. Host cells are freshly grown in broth (usually overnight), diluted into fresh broth, and grown to mid-exponential phase of growth to approximately 1×10^8 cfu mL^{-1}. This broth is often supplemented with Ca^{2+} to promote phage binding. The cells are then spread over an agar plate, allowed to air dry and then 10–20 µl samples [55] of each phage dilution spotted onto the lawn of the bacteria to produce discrete areas of infection (see Figure 8.1). Once the samples have dried, the plates are incubated at the appropriate temperature overnight and the numbers of plaques counted only

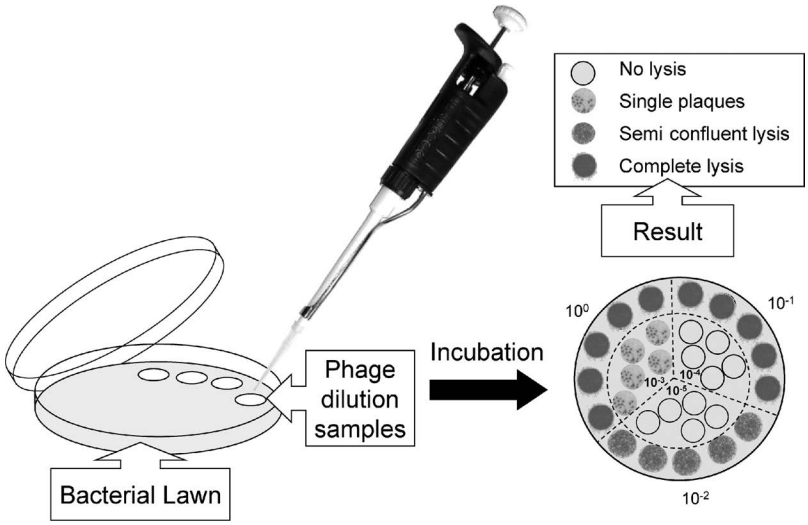

FIGURE 8.1 Phage titration and interpretation of results.

in samples where discrete plaques are seen. This value is then used to either determine the titer of the phage stock, or the routine test dilution (RTD, [56]). The RTD is defined as the highest titer that just fails to produce confluent (complete) lysis of the cells within the sample area. The appearance of semiconfluent lysis indicates that the number of phage present are reaching a point of dilution where numbers are low enough to allow individual infection events to be detected and the growth of plaques from a point of infection can be visualized. This is an important point since the applications of high numbers of phage to a lawn of bacteria can produce confluent lysis even though productive infection does not occur. This phenomenon can be due to the process of "lysis from without" [57]; in essence, large numbers of phage binding to the cell surface damages the cell wall integrity and cells lyse before the phage have replicated. Alternatively, phage preparations may contain defective phage particles or bacteriocins [58] that again can cause complete cell lysis, or the phage suspension itself can contain chemical residues that inhibit lawn growth, giving the appearance of confluent lysis in the area where a sample has been applied. Any of these possibilities may lead to false areas of confluent lysis but are ruled out by dilution of the phage sample to the point where semiconfluent lysis occurs which will not occur unless phage infect their host cells and grow.

Freshly grown host cells are spread over an agar plate to form a bacterial lawn. A 10-fold serial dilution of the phage is prepared and then 10–20 µl samples of each phage dilution spotted onto the lawn and allowed to air dry. After incubation, numbers of plaques are counted only in samples where discrete plaques are formed. The RTD [42] is defined as the highest titer that just fails to produce confluent (complete) lysis of the cells within the sample area.

The phage concentration to produce semiconfluent lysis depends on plaque morphology (phage producing fast growing, large plaques will require fewer numbers to form semiconfluent lysis than phage that produce small discrete plaques) but is generally between 5×10^4 and 2×10^5 pfu mL^{-1} [58] and should be 2- to 10-fold lower than the concentration required to produce confluent lysis. The bacterial strain used to determine the RTD is always that used to propagate the phage so that host adaptation (discussed previously in this chapter) does not affect the titer results.

Determining Efficiency of Plating

Due to the subtle differences in cell surface components and cellular biochemistry that influence phage binding (described in section Factors Affecting Phage Infection), even without host adaptation, the efficiency with which a particular phage will infect different strains of a bacterium will vary. This basically reflects the tightness of the interaction between the phage and host receptors, with stronger binding leading more often to productive infection events and weaker binding leading to fewer, and hence a lower titer. By comparing the titer of a phage preparation when tested against different strains of bacteria, a ratio of productive infection events can be determined. This value is termed the efficiency of plating (or EOP) with a value of 1 representing 100% efficiency (i.e., the titer on the two test strains is the same) and 0.9 representing 90% efficiency or a titer of one $\log_{10}$ lower. Since the binding of the phage to the cell can also be influenced by the differential expression of surface proteins and carbohydrates (see section Factors Affecting Phage Infection), and this is influenced by the particular growth state of the cell, some variation in titer of phage on the same strain can occur when the experiment is performed on different days. Therefore, a consistent difference of at least 5- to 10-fold in titer is required before a reliable difference in EOP can be established. This degree of variability in expected titer is another reason for choosing semiconfluent lysis as the RTD when performing phage typing (see next section). If a dilution were chosen that gave in the range of 10–20 discrete plaques, sometimes a result would be positive, and sometimes negative. The use of a higher phage dilution takes this inherent variation into account and allows a more robust typing result to be achieved.

Phage Typing Methods

For phage typing, a panel of phage characterized to have a discriminating host range is chosen and strains are infected with each phage at standard concentration (the RTD). The method is similar to that for determining phage titer, in that a bacterial lawn is prepared and samples of phage are applied to the surface

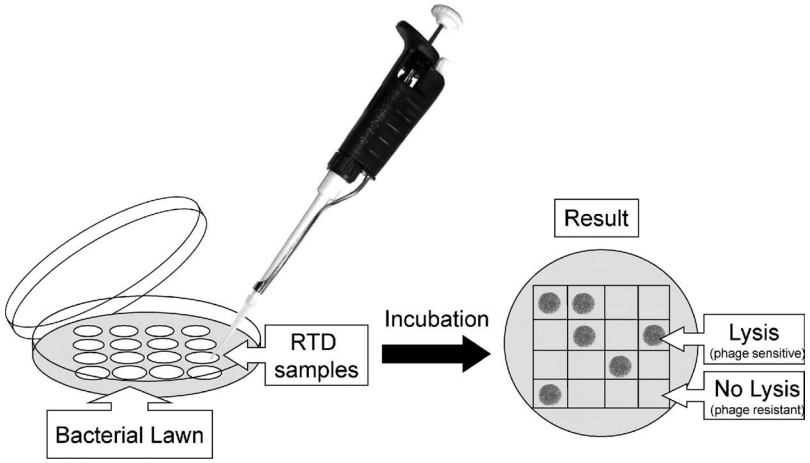

FIGURE 8.2 Phage typing.

(see Figure 8.2). Now samples of different phage from the phage typing set, each diluted to the RTD, are spotted onto the lawn in a grid pattern. In some typing schemes, both the RTD and 100× the RTD are tested. After incubation of the plates, infection is detected by the presence of plaques and patterns of susceptibility to individual phage are determined, leading to the determination of a phage type based on the pattern of sensitivity (see Figure 8.2). The results are not only scored as negative or positive, but are also given a semiquantitative description that in some way reflects the EOP (i.e., at the RTD; if the phage infects with the same efficiency that it infects the host strain, semiconfluent lysis should occur; if confluent lysis is seen on the test strain, then the EOP is greater than 1; if single plaques appear, the EOP is less than 1). Different phage typing schemes use different conventions of scoring; commonly letter descriptors are used for confluent lysis (CL), semiconfluent lysis (SCL), and opaque lysis (OL; this refers to the situation where growth of the lawn occurs within the zone of lysis so that the area is not cleared). These can be combined with < symbols to indicated intermediate degrees of lysis (e.g., <CL or <SCL) and then ± to +++ to indicate increasing numbers of discrete plaques. In typing schemes where more than one phage dilution is used, the scoring is more directly related to the EOP where 5 = ++ reaction in the same dilution as on the propagating strain, 4 = ++ reaction in a dilution 10- to 100-fold more concentrated that that giving ++ on the propagating strain, 3 = ++ in a dilution 10^3- to 10^4-fold more concentrated that that giving ++ on the propagating strain, 2 = in a dilution 10^5 to 10^6 fold more concentrated that that giving ++ on the propagating strain, 1 indicates very weak lysis, and a minus symbol (–) for no reaction. The number 0 is used to record evidence of lysis from without. The typical reaction patterns for a variety of phage can be found in the published literature and Public Health Agencies (e.g., see *Salmonella enterica* [59, 60, 72], *Escherichia coli* O157 [61, 62], *Shigella* [12, 13], *V. cholerae*[63, 64], *Staphylococcus aureus* [58, 65], *Listeria monocytogenes* [66–68], and *Bacillus* spp. [69–71]).

A panel of phage with discriminating host range is each diluted to the RTD. Ten to twenty microliters of each diluted phage are applied to the surface of a bacterial lawn of the test strain in a grid pattern. After incubation of the plates, infection is detected by the presence of plaques and patterns of susceptibility to individual phage are determined. See text form more details of qualitative scoring schemes used.

The Use of Phage Typing

In the past, these phage typing sets have been successfully used in epidemiological studies to monitor changes in the predominant organism causing disease in a population and the emergence of new dominant clones. For *S. enterica*, the phage typing system described by Callow [72] still provides a useful reference for the differentiation of strains from within the same serovar, although WGS methods have replaced them in epidemiological studies [5, 6]. However, phage typing has been historically used worldwide to investigate a variety sources of bacterial contamination, environmental spread of the organism, and outbreaks of food poisoning involving not only *S. enterica* [73–77] and other members of the *Enterobacteriacae* [77] but also to follow the dissemination of strains *V. cholerae* in India [18, 78] and for studies of the spread of clones *Staphylococcus* in hospital populations [79–80]. The effectiveness of these studies demonstrates the usefulness of this simple microbiological method that can still be a useful tool in settings where access to WGS is not readily available.

Phage-Based Rapid Detection Methods

Traditional culture-based methods of detection exploit the specific growth requirements or cellular biochemistry of particular bacteria to achieve selective growth and detection of specific phenotypic traits through careful formulation of diagnostic media. Further identification can then be achieved using a variety of techniques including antibodies (or phage typing) to reveal more information about variation in cell surface structures or molecular analysis to interrogate the genome structure. However, to carry out this process of identification, single cells present in a sample must be separated from the sample matrix and then grown until discrete colonies are formed. This is inevitably time consuming, and the drive in both the fields of medical microbiology and food microbiology is for rapid, more sensitive diagnostic tests that can provide detection and identification without the need for culture. Using phage to detect the presence of their host

cells is an obvious way to address this need. Phage-based tests use the specificity of the interaction between the virus and the host cell as a diagnostic tool, and in this sense is not so different to the use of phage in typing schemes. However, the specificity of the phage-host interaction also means that the target cell can be detected in the presence of competitive flora, thus reducing the need for selective growth of the target bacterium before it is detected. Finally, the fact that the replication of the phage is so much faster than that of the host cell also allows methods to be developed that are more rapid than traditional culture.

Unlike phage selected for typing sets, phage with the widest host range are chosen for rapid detection methods, preferably those that can encompass all members of the genus or species to be detected. There are many examples of well characterized broad host-range phage, but one that has been used more than most to develop these assays is *Salmonella* phage Felix 01, which has been shown to infect more than 95% of *Salmonella* isolates [81]. Similarly, two broad host-range phage have been identified for *Listeria*, A511 [82] that infects 95% of those serotypes most commonly associated with human disease (1/2a and 4b) and P100 [83] that can infect and lyse more than 95% of serotypes 1/2 and 4 (*L. monocytogenes*) and 5 (*Listeria ivanovii*). Both phage have been used to develop rapid methods for the identification of *Listeria* in food samples. Broad host-range phage specific for other bacteria can be readily isolated, often from those environments where the host cells are found naturally [52, 84–86]. Using these broad host-range phage, many different phage-based assay formats have been described, but in this section we will review the three approaches that have been developed into commercial assays. For an in-depth review of the broader use of methods used to engineer bacteriophages and their use in a range of applications see [87–90].

Reporter Phage

In the reporter phage assay, phage are genetically engineered to deliver a reporter gene into the target bacterium. While the specificity of the assay comes from the phage host range, the speed and sensitivity of the assay come from the fact that the reporter genes are inserted into the phage in a way that they are expressed at high level following phage infection, and sensitive instrumentation means that the production of the reporter gene signal can be detected at very low levels.

Reporter phage were first described in 1987 [91] when the principle of reporter phage assays was demonstrated using a Lambda cloning vector containing the bacterial *lux* operon that was used for detection of *E. coli* in milk samples. Even this simple model was able to detect as few as 10 *E. coli* cells within 1 hour using a luminometer to detect the light produced by the infected cells [92]. This group simply created wild type *lux* phage by introducing the reporter genes by random mini Tn*10-luxAB* mutagenesis. These reporter phage were used to detect enteric pathogens on swab samples from abattoir, meat-processing factory surfaces, and animal carcasses [93]. In this study, light levels were compared with viable count, and a good correspondence between the two measurements was found. The phage assay allowed detection of 10^4 cfu g^{-1} or cm^{-2} within 1 hour or <10 cfu g^{-1} or cm^{-2} following a 4-hour enrichment, demonstrating good sensitivity and that a far faster result could be achieved than by conventional culture. A similar level of sensitivity was also reported using a Lambda *lux* phage to detect enteric bacteria without enrichment [94]. These early studies highlight one of the biggest advantages of the phage assays over many modern molecular tests which is that to generate the signal detected, the host cell must be viable to allow the reporter genes encoded by the phage to be expressed. This allows the same live/dead differentiation achieved using conventional culture techniques, which is an important factor when carrying out analysis of processed foods which may contain bacteria that have been inactivated during production of the product; detecting DNA or cell components alone in this case would give a false-positive result.

After these early experiments proved the value of reporter phage, more recently, reporter phage have been created in a more directed manner, by using homologous recombination to introduce the reporter gene into a precise location in the phage genome. For instance, the *luxAB* genes have been introduced into the *Salmonella* phage that infect groups B, D, and some group C serovars using this method [95]. A mixed-phage preparation was used to detect as few as 10 cfu mL^{-1} of *Salmonella* cells with 6 hours of preincubation. However, without preincubation the limit of detection was only 10^8 cfu mL^{-1} in 1–3 hours, indicating that the enrichment phase allowed the number of bacteria to reach a critical threshold that allowed the signal to be detected. The same method was used to introduce *luxAB* genes into the late gene region of the broad host range *Listeria* phage A511 [96]. When this *lux* phage was tested in a range of different food types, detection levels of between 0.1 cells g^{-1} and 10 cells g^{-1} were achieved after 20 hours of selective enrichment (giving a total assay time of 24 hours), depending on the food type tested [97]. This work highlighted the fact that the nature of the matrix that contains the bacteria is an important factor in determining test sensitivity, as clearly the efficiency of phage infection was affected by either the food components or the high levels of competitive microflora present. Thouand et al. [98] also reported that the sensitivity of the P22::*lux* reporter phage assays was affected by the nature of the sample matrix when trying to develop a rapid method to detect the presence of *Salmonella* in samples taken from poultry houses. As the binding to phage to host cell surfaces is essentially a specific protein-ligand interaction, it is not that surprising that complex, organic samples can interfere with the kinetics of binding, and therefore care must be taken before extrapolating proof of concept data using pure laboratory cultures to results that can be obtained when testing more complex samples.

Nevertheless, these early proofs of principle experiments have led to the successful engineering of bacterial bioluminescence genes into a number of different bacteriophage to create reporter phage with specificity for range of different bacterial hosts and different types of application. For instance, the *luxAB* genes have been introduced into the broad host range *Bacillus anthracis*-specific Wβ phage and shown to be able to specifically detect as few as 10 *B. anthrax* spores inoculated into pond water within 8 hours using a simple sampling process without needing to first extract spores from the sample [99, 100]. However, again the effect of the sample on assay sensitivity was noted, and the limit of detection increased to 100 spores when lake water was used that had a higher salt content and higher levels of competitive microflora [100]. The same group also introduced the *luxAB* genes into engineered phage φA1122 used by the CDC

as a diagnostic tool for the identification of *Yersinia pestis* [101]. When this was used to test clinical blood samples, it could successfully detect samples containing $<10^2$ CFU mL^{-1} within 5 hours and importantly excluded samples where the infection was due to species typically associated with bacteremia or those relevant to plague diagnosis [102]. A *luxA*B reporter phage that could be used to detect dysentery caused by *Shigella flexneri* has also been described by this group, and although the limit of detection was reduced to ~10^3 CFU g^{-1} when detecting the pathogen in spiked stool samples this is more than sufficient to detect the levels of pathogen normally found in clinical samples in the early stages of infection [103]. Outside the area of human pathogens, *luxAB* reporter phage have also been developed for the detection of economically important plant pathogens such as *Pseudomonas cannabina* pv. *Alisalensis*, which causes bacterial blight of cruciferous vegetables [104], and *Erwinia amylovora*, which is the causative agent of fire blight, with the latter of these being shown to be able to detect the pathogen in natural infected plant samples within 1 hour [105].

Bioluminescence is a particularly good signal when testing biological samples as there is very little background signal generated from the material, producing good signal-to-noise ratios so that sensitive detection can be achieved. The majority of the bioluminescent reporter phage described so far have utilized just the *luxAB* genes that are approximately 2 kbp in size and encode the bacterial luciferase enzyme. This produces light by the conversion of an aldehyde substrate which is converted to carboxylic acid in a reaction that also produces a photon of light. In bacteria, these two genes are part of the larger *lux* operon that also encodes three other genes (*luxCDE*) that produce the aldehyde substrate that drives bioluminescence production (see [106] for more details). However, the full operon is ~6 kbp in size, which is too large to easily introduce into bacteriophage genomes unless some phage genes are deleted [91]. Hence, for these reporter phage assays, the aldehyde is added after phage infection has been allowed to proceed. As the ability to sequence and analyze phage genomes has improved, and more methods for phage engineering have become available (see [89]), full *lux* operon reporter phage have been developed [107–109] in the hope that introducing the full operon would allow fewer cells to be detected and reduce the limit of detection of phage assays. However, more recently, there has been a move toward using the newly discovered eukaryotic enzymes such as NanoLuc, which is a single subunit 19 kDa enzyme derived from sea shrimp. This is 100 times more active than other bioluminescent enzymes and when incorporated into a T7 phage, less than 20 *E. coli* E cells could be detected in a 100 mL sample of drinking water within 5 hours [110]. Similarly, NanoLuc was chosen as the best enzyme to introduce in the *Listeria* phage A511, and in this case, the reporter phage was able to detect one *L. monocytogenes* cell in 25 g of artificially contaminated milk, cold cuts, and lettuce within less than 24 hours and successfully detected *Listeria* spp. in potentially contaminated natural food samples without producing false-positive or false-negative results [111].

In addition to the *lux* genes, a number of other reporter genes have been introduced into phage. Early examples included the green fluorescent protein, favored because its small size (~800 bp) made it easy to introduce into phage genomes when little genetic analysis had been performed. For instance, *gfp* was introduced into the *E. coli* O157:H7-specific phage PP01 to create a fluorescent reporter gene phage that was shown to be able to specifically detect *E. coli* O157:H7 cells in the presence of other competitive *E. coli* cells [112]. The same group also introduced the *gfp* gene into phage T4 that was unable to lyse the *E. coli* host cells at the end of the replication cycle, leading to sustained expression of the *gfp* gene within the infected cells. These highly fluorescent cells could then be detected by automated methods moving toward the production of integrated biosensor assays [113]. Another reporter phage assay for *E. coli* O157:H7 has been developed by inserting the *lacZ* gene into phage T4 [114]. In this case, the specificity of the assay does not come from the phage alone, but it has been combined in a three-step assay comprising enrichment, immunomagnetic separation (IMS), and the use of a colored enzyme substrate in a simple to use sample tube format (Phast Swab [115]). The advantage here is that by using traditional culture and separation methods, they have overcome the requirement to find a phage with a defined specificity. The advantage of the Phast Swab assay format was that the phage were packaged into a unit that does not require dispensing of liquids or opening once the sample has been added to the tube. This type of practical consideration made the assay more accessible to workers in routine Quality Assurance labs. However, despite promising trials, this format did not result in a fully commercial product. Hagens et al. [116] investigated the use of an extremely thermostable glycosidase (CelB) as an alternative to *lacZ* to try and improve the sensitivity of the *Listeria* A511::*luxAB* phage [96]. In this case, the thermostable properties of the reporter protein were used to allow heating of the samples to try and remove background noise from endogenous enzymes, but even though the more sensitive fluorescent substrate methylumbelliferyl-α-D-glucopyranoside (MUG) was used, no increase in sensitivity in real food samples was achieved. However, this group also found that combining reporter phage with selective enrichment of the target bacteria improved the sensitivity of reporter phage assays [117]. In this case, they took advantage of another aspect of phage biology, in this case the high affinity of the carbohydrate-binding domains (CBDs) of the phage lysin enzymes for the unique carbohydrate components of *Listeria* cell wall peptidoglycan that can be utilized as efficient cell capture agents [118].

A similar idea of IMS concentration of cells and reporter phage technology was also used to detect *Salmonella*, this time using phage P22 containing the ice nucleation reporter gene (*ina*) as a reporter [119, 120]. As few as 10 *Salmonella* Dublin cells mL^{-1} could be detected in the presence of a high level of competitor organisms using the phage alone, but the sensitivity of the assay for food samples was further increased by using it in combination with *Salmonellae*-specific immunomagnetic bead separation [121]. This method was developed into a commercial assay by the Idetek Corporation but is also no longer available.

The most extensively studied reporter phage are those produced for the rapid detection of *Mycobacterium tuberculosis*, since circumventing the need to culture this slow-growing organism reduces detection times from weeks to days. There is also less concern in the area of medical diagnosis about GM, and accordingly, the reporter phage have been extensively evaluated, although no commercial product has been produced. Reporter phage produced for the detection of *Mycobacteria* containing the reporter gene firefly luciferase (*luc* or *Fflux*) [114] have been

produced using the lytic phage TM4 [122, 123] and the temperate phage L5 [124], which was surprisingly effective at detecting cells despite the fact that it could form lysogens. However, the most effective *luc* reporter phage (or LRP) has been developed using phage TM4 and this has been extensively modified to optimize reporter gene expression [123]. Using these phage in combination with refinements of the sample preparation, mycobacteria were successfully detected in smear-positive human sputum samples within 24–48 hours [125] and, when compared with other standard microbiological testing methods, was found to perform favorably in the detection of positive clinical samples [123, 126]. Similarly, fluorescent (*gfp*, ZsYellow and *mCherry*) reporter phage based on the broad host range mycobacteriophage TM4 for the detection of *M. tuberculosis* have been developed [127, 128]. Due to the natural fluorescence of many different biological molecules, a different color of fluorescent reporter will be more appropriate for specific sample types. In this case, the *mCherry* $_{bomb}\Phi$ was shown to be a promising tool for fluorescence microscopy-based methods of diagnosing tuberculosis infections in low income settings [129].

In response to some concerns about the use of GM viruses in routine diagnostic laboratories, nonreplicative forms of reporter phage have become favored since they minimize any possible risk of release of the GM phage. An example of this is the *lux* phage created by random mini Tn*10-luxAB* mutagenesis of phage NV10 [62] that is specific for *E. coli* O157:H7. In this case, the insertion of the *lux* genes into the phage genome created a defective phage that could infect but not replicate [130]. Using this reporter phage, *E. coli* O157:H7 cells were detected within 1 hour of infection. Rather than relying on random mutagensis effects, Kuhn et al. [131] created a genetically "locked" phage that can express the luciferase gene after infecting any wildtype *Salmonella* cells but can only replicate in specially engineered host cells. However, this type of engineering program requires a considerable amount of genetic analysis of the phage to be used and is probably not practicable for a large number of different phage, and is only a concern for nonclinical applications as medical diagnostic laboratories do not have the same regulatory constraints as food or environmental testing laboratories. Another problem facing the food industry is that in addition to speed of identification of contamination problems to prevent release of contamination product, manufacturer also needs to isolate the organism from the product for possible epidemiological trace-back investigations at a later date. Hence, although *lux* reporter phage were launched as a commercial testing service by the Sample 6 company based in the United States, which offered near online testing results for *Listeria* during food production runs [132], the product is no longer available after the company restructured.

Phage Amplification

In contrast to the reporter phage, this technology uses nonengineered phage and so does not suffer from any of the complications surrounding the release of GM organisms. This also makes the development of new assays easier and less expensive, as demonstrated by the fact that one of the earliest publications describes the simultaneous development of tests for *Pseudomonas aeruginosa*, *Salmonella typhimurium*, and *S. aureus* [133]. The other components of the assay are also standard microbiological materials and so there is no need for the purchase of specialist equipment or for highly trained staff to carry out the assay. Although termed the phage amplification assay, as growth of the phage is used to indicate the presence of the target bacterium, the test is effectively a phage protection assay. Samples to be tested for the presence of a target bacterium are mixed with phage and incubated to allow phage infection to occur. A virucide is then added to the sample to destroy any phage that have not infected its host cell. Next, the virucide is neutralized, the infected cells mixed with more bacteria that will support phage replication (helper or sensor cells), and the whole sample is plated out using soft agar. During incubation of the plates, the phage finish their replication cycle, lyse the target cell, and the released phage go on to form plaques by infecting the helper cells present in the lawn. Each plaque represents a phage that was protected from the action of the virucide by infecting its specific target host (see [134]). To develop an assay, all that is required is a phage with an appropriate host range and a virucide that will inactivate the phage while not damaging the host cell. This latter point is key to the assay; the phage must be protected within the cell and the cell must be viable to allow phage replication to be completed [135]. Hence, like the reporter phage assays, phage amplification assays also provide live/dead differentiation.

The test still requires overnight incubation to allow growth of the helper cells to form a lawn and because of this, although this assay method can be used to detect any bacterial cell, it is in the detection of slow growing organisms—such as pathogenic *Mycobacteria*—that the biggest advantage is gained. A phage amplification method for the detection of *M. tuberculosis* in human sputum samples has been developed that only takes 2 days, compared to several weeks for other methods of detection, and was previously sold as the commercial test FAST*Plaque*TB® [136, 137]. To achieve rapid detection using this assay, the phage chosen was D29 that has a broad host range and can infect both *M. tuberculosis* and also *Mycobacterium smegmatis*, a member of the fast growing group of *Mycobacteria* that can form colonies in 18 hours. *M. smegmatis* is used as the helper cells and lawn develops for plaque visualization after overnight incubation. The limitation of this assay is that, because the broad host range of the phage, it will detect any type of *Mycobacterium*, including nonpathogens. However, when used to test human sputum samples, it is unlikely that high levels of nonpathogenic Mycobacteria will be present and detection of high numbers of Mycobacterial cells indicated that the patient requires treatment. A range of workers have carried out evaluations of this test and generally it performs as well as other culture-based tests [138, 139]. However, the main use of the assay was in clinical settings in developing countries where it is difficult to afford the reagents and machines required for automated culture-based rapid methods, such as MGIT [140].

The broad host range of this phage has made its application in this assay format problematical for samples where both pathogenic and nonpathogenic, environmental Mycobacteria may be present. However, the broad host range of the phage means that it can be used to detect other Mycobacteria if it is used in combination with other tests that improve the specificity of the assay. To this end, the FAST*Plaque*TB® reagents have been used for the detection of viable *Mycobacterium bovis* or *Mycobacterium avium* subsp. *paratuberculosis* (*Map*) by combining the phage

amplification assay with PCR confirmation of cell identity [141]. To do this, DNA is extracted from plaques at the end of the phage assay and then PCR used to detect signature IS elements (IS900 for *Map* and IS1081 for *M. bovis*). This combined Phage Amplification PCR assay was shown to be able to detect viable *Map* in milk samples from infected cattle within 24 hours and has been used to conduct surveys of a range of retail dairy products [142–144]. More recently, methods to detect the presence of mycobacterial pathogens in blood samples have been described and used to detect *Map* in cattle suffering from Johne's disease [145], *M. bovis* in the blood of cattle [146]. This assay has been further refined in to a 6-hour test that has been commercialized as the Actiphage® test by PBD Biotech Ltd. Actiphage is a one tube assay that removes the need for virucide, agar plates and overnight incubation of samples and, in addition to being able to rapidly detect *Map* and *M. bovis* in animal samples [147], has been shown to be able to detect *M. tuberculosis* in the blood of human tuberculosis patients, including those in the early stages of disease [148].

A different approach to improve specificity of the phage amplification assay has been to selectively remove the mycobacterial cells from the sample by immunomagentic separation methods prior to performing the phage assay [149, 150]. However, there have been variable reports of the robustness of this approach, as the efficiency capture by the magnetic beads seems to influence the positivity rate of the test [151, 152].

Another combined assay that uses a variation of the phage amplification assay has been described for the detection of *Salmonella* [153]. Immunomagnetic separation is used to separate the target bacteria the food sample and then the concentrated *Salmonella* cells are then infected with phage. Phage that have not infected a target cell are removed by washing, which also separates the *Salmonella* from the magnetic beads. These infected cells are incubated so that the phage can complete their replication cycle and then they are added to a culture of a phage propagating strain (signal amplifying cells or SACs). The optical density of the culture is monitored and cell lysis indicates that phage, protected within an infected cell, have been carried through the washing steps, indicating the presence of *Salmonella* in the original sample. Using this method, a detection limit of less than 10^4 cells mL^{-1} was achieved in 4–5 hours.

Phage Growth Assays

In this form of assays, the detection event is an increase in the number of phage particles present in a sample indicating that a suitable host strain is present to support phage replication. Typically low numbers of phage are added to the sample which is below a threshold of detection, after a period of incubation, the increase in phage particles in the sample is then detected either by an antibody-based assay or by qPCR. Confusingly, these phage growth assays are also referred to as phage amplification assays, but the two methods are very distinct.

The most successful example of this type of assay is the one that was developed and marketed commercially as MicroPhage as the KeyPath™ MRSA/MSSA Blood Culture Test which both allowed identifying of *S. aureus* in blood samples and also differentiated between MSSA (methicillin-susceptible *S. aureus*) and MRSA (methicillin-resistant *S. aureus*). The test required a short (5 hours) period of incubation with a mixture, or cocktail, of phage that specifically infect a wide range of *S. aureus* cell types. To determine antibiotic sensitivity, parallel samples were inoculated into tubes with or without the addition of cefoxitin. If after incubation the phage levels in the sample reached the threshold level (1.4×10^8 phage particles per mL), a positive detection result was indicated. If a positive result also occurred in the sample containing the antibiotic, this indicated that the bacterial growth (and therefore phage growth) was not inhibited, and therefore the strain detected was antibiotic resistant (MRSA). In trials, the method had 100% specificity and good levels of sensitivity [154].

Other more complicated assays have been described that rely on specifically detecting only newly synthesized phage molecules. For instance, a method that uses isotopically labeled ^{15}N bacteriophage and matrix-assisted laser desorption/ionization-time-of-flight mass spectrometry (MALDI-TOF MS) has been described. To discriminate between phage added to the assay and those newly synthesized as part of the tests, input phage were isotopically labeled with ^{15}N. After 90 minutes of incubation, MALDI-TOF MS was then used to specifically detect ^{14}N capsid proteins produced in the phage-amplified culture, which indicated the presence of the host bacteria that supported phage growth [155]. This approach overcomes the problem associated with methods that rely on detecting phage growth alone which cannot distinguish the phage used to inoculate the sample from the new progeny phage produced after phage replication has occurred, and causes a high background noise level that reduces test sensitivity.

A similar method of identifying the production of new phage particles combined phage engineering with phage growth assays. In this case, phage capsid proteins were engineered to display a small biotinylation peptide on the surface of the phage protein by fusing it to the major capsid protein. The engineered phage are produced in a specialized strain that lacks the biotin ligase, and therefore input phage are not biotinylated. If new phage are produced in a wildtype strain that naturally encodes this enzyme, the phage produced will have been biotinylated. These phage are then mixed with streptavidin-functionalized Quantum Dots that can then be sensitively detected using flow cytometry. Using this approach and an engineered T7 phage, it was possible to detect less than 10 *E. coli* cells in the presence of a 10^5-fold excess of competitor organisms in as little as 1 hour [156].

An alternative method of measuring phage growth is qPCR, where an increase in the number in phage genomes is monitored after incubation with a sample [157, 158]. Two such assays have been described for the detection of *Brucella abortus* [159] and *Y. pestis* [160] in blood samples and, since both of these organisms require growth at BS level 3, any method that removes the need for culture is a clear benefit. In both cases, the methods were shown to be sensitive and compatible with detection in blood without the need to perform extractions, which inevitably reduces the sensitivity of any DNA-based detection method. Recently, a variant of this method was described, where rather than detecting the increase in bacteriophage genomes, transcription of phage-encoded genes was monitored by reverse transcriptase qPCR [161]. In this case, only a short period of incubation is required because highly transcribed phage genes are targeted, so the number of mRNA molecules increases rapidly after infection, shortening the time required for this to reach a threshold level

of detection. In addition, as there is no transcription of phage genes prior to infection, there is no background signal from phage added to the assay which reduces the signal-to-noise ratio, and hence increases sensitivity. The simplicity of this approach is that very little information is required about phage molecular biology before a new assay can be developed, and accordingly in their proof of concept paper, the authors were able to demonstrate successful detection of both *S. aureus* and *B. anthracis* within 5 hours.

Phage Capture Assays

Since phage have evolved to interact very specifically with the surface of their target host cells, proteins that make up phage receptors and enzymes have the same type of specific interaction with bacterial surface molecules as antibodies have with their cognate antigens. Exploiting the specificity of the CBD of phage lysin has already been described, but Galikowska et al. [162] have demonstrated that phage can replace specific antibodies in a standard enzyme immunoassay (EIA) for the detection of *S. enterica* and *E. coli* (see Chapter 10 for figures demonstrating the steps of an EIA assay). In their technique, phage that are specific for the pathogen are adsorbed to the polystyrene surface of microtiter plate wells. The sample is then added, and if the pathogen is present, it binds to the phage. Following this, an antibody raised in rabbits is added, which binds to the pathogen. Detection is achieved by using a biotinylated antirabbit secondary antibody followed by an avidin-alkaline phosphatase conjugate, and the appropriate substrate. This technique offers the advantage of having a reagent that is very stable and - unlike antibodies—the detection agent is self-propagating, thus making it a very inexpensive reagent to produce. The assay can detect as few as 1×10^5 bacteria, which gives it a sensitivity in line with standard EIA assays [162].

In a more simple approach, phage can be linked to carboxylic acid-functionalized magnetic beads and then used to separate and concentrate target bacteria from samples, in the same way, that IMS concentration of samples has already been described. An example of this is the use of the *E. coli* O157-specific phage ECML-117 (ATCC PTA-7950) and ECML-134 (ATCC PTA-7949) to recover *E. coli* O157 from water samples [163]. It was found that the capture efficiency of the coupled assay under extreme conditions was approximately 20% higher than that of antibody-based separation, suggesting that phage binding to host cell is less susceptible to environmental perturbation than are antibody-antigen interactions, which is perhaps not surprising given that phage and host bacterial cells will encounter one another is a range of different environmental conditions and so the host cell binding event must have a certain degree of robustness.

Overview

The history of phage typing has been a little like phage therapy; since its discovery it has gone through different phases of popularity, but even today it continues to be a useful and sensitive tool for rapid discrimination of bacterial cell types. The advances in sequencing technologies means that phage typing *per se* has been superseded by molecular typing methods for routine subspecies identification of strains, but the technique remains a useful and sensitive method of investigating differences in cell structure, and in particular is of interest when identifying which phage are best to include in phage therapy cocktails. Rapid methods of detection have also shown promise and then fallen out of favor, probably because no one phage can provide the Holy Grail of identification—the one test that detects all target cells with 100% specificity and sensitivity. However, the recent trend of combining these with other rapid methods of bacterial detection to improve the speed and specificity of phage-based test shows promise in producing assays that do indeed meet the requirements of the consumer; that is simple, rapid tests with a high degree of discrimination. Phage identification methods have been in use for some 90 years now, and this recent revival of its fortunes in the form of commercial tests that are beginning to emerge suggests that they will continue to be used for some time to come.

Introduction

One of the principal modes of cell-cell communication, as well as control of biochemical processes in cells, relies upon proteins binding to a ligand. The ligand could be another protein, a nucleic acid, or a small molecule. Phage display is a tool that makes possible both presentation of large repertoires of naturally occurring proteins, and the derivation of protein ligands that have never previously been known to exist in nature. The very essence of phage display is that the displayed protein is encoded in the nucleic acid encapsulated by the phage particle, hence creating a physical coupling between genotype and phenotype [1]. Different protein sequences can be displayed by cloning the genes of interest as they occur in nature, or simply modifying the sequence of the DNA through molecular engineering. The simultaneous display of many different molecules on a population of phage then collectively makes what is called a phage library.

The power of phage display is derived from the fact that an extremely large number of displayed ligands in the form of a library can be studied in a single experiment. This is possible due to the fact that the filamentous phage strains such as f1, M13, and fd, of *Escherichia coli* (*E. coli*) are the most prolific phages in nature, giving rise to titers of up to 10^{13} particles per milliliter culture [2]. Thus, libraries with diversities exceeding 10^{10} unique members have been made. All library members then compete for binding to a defined target, allowing for the identification and characterization of binders with desired specificity and affinity, in a process often termed panning. During panning, the noninteracting library members are removed by washing, and the identity of those interacting with the target is subsequently decoded by virtue of sequencing the DNA encapsulated by the retrieved phage particles. This large combinatorial power, combined with the extreme robustness exhibited by the phage particle, which allows it to withstand the physicochemical challenges during different selection regimens, is the main reason for its success [3, 4].

The most common form of phage display is based on fd and M13, and their two coat proteins, minor protein pIII and major coat protein pVIII. Both have been appended with random peptides or engineered proteins to create phage libraries. In 1985, George Smith was the first to demonstrate that a protein, can be displayed on the filamentous phage particle fused to pIII and selected for in an enrichment experiment from among a large excess of ordinary phage [1]. Five years later, in 1990, he and coworker Jamie K. Scott reported on the construction of the first true phage library, which comprised more than 10 million

members, all displaying six amino acid-long random peptides [5]. They panned this library toward two monoclonal antibody targets and identified specific peptide ligands. The significance of this discovery quickly became clear to the scientific community, and the new field of phage display was established with explosive growth following.

Despite its early introduction more than 30 years ago, phage display is still the most important molecular evolution technology available [4, 6, 7], at least in part due to its major contribution to design of new therapeutics [8, 9]. Consequently, a variety of protein scaffolds have been displayed on the phage and served as starting point for a multitude of library designs [3]. Thus, phage display technology has found applications within both basic and applied biological research, as well as in combinatorial chemistry and material sciences [2, 10, 11]. One of the most important events was the report that showed functional display of antibody fragments, which opened the field of antibody discovery by use of this method [12–14]. Today, phage display is an important source of therapeutically and diagnostically useful antibodies, and the complexity of libraries have increased from 10^6 clones early on to now more than 10^{11} clones [15].

The importance of the birth of phage display technology and the achievement of merging it with antibody technology can hardly be underrated with respect to impact it has had on modern life science. Acknowledging this, The Royal Swedish Academy of Sciences awarded the 2018 Nobel prize in Chemistry with one half to Frances H. Arnold and the other half jointly to George P. Smith and Sir Gregory P. Winter exactly for these reasons as given in their statement:

> The 2018 Nobel Laureates in Chemistry have taken control of evolution and used it for purposes that bring the greatest benefit to humankind. Enzymes produced through directed evolution are used to manufacture everything from biofuels to pharmaceuticals. Antibodies evolved using a method called phage display can combat autoimmune diseases and in some cases cure metastatic cancer.

The transition from phage vector systems that rely on the large and genetically unstable phage genome, into the genetically stable low valence phagemid display system greatly improved the performance of phage display [16]. Thus, heterologous capsid fusion proteins may be encoded either in a phage genome or by a phagemid; in the latter case, complementation by a helper phage is needed to support virion production [16]. Thus, a critical component for the effective use of phagemids was the construction of interference-resistant helper phages, such as M13K07, that allowed for high phage titer production and preferential phagemid packaging [17, 18]. Easy manipulation and high transformation frequencies are additional assets that have made the phagemid format the most popular display system for folded domains [13, 14].

In addition, theoretical approaches to biopanning have emerged, guiding investigators in how to implement the most efficient techniques for selecting binders [19–22], as well as evaluating the characteristics of the isolated binders [23–25]. Of particular importance is the emergence of next generation sequencing, a very powerful tool when evaluating panning experiments [26, 27]. Most notable, several excellent books [28–30] and review articles [7, 31–35] that focus on different aspects of phage display have been published.

Filamentous Phage Biology

The filamentous bacteriophages belong to a group of viruses that harbor a circular single-stranded DNA carried in an elongated protein capsid cylinder. The genus is termed *Inoviridae* (UniProtKB taxon identifier 10861) and comprises 22 strains of which seven belong to the group of Enterobacteria phage, namely f1, fd, l2-2, If1, IKe, M13, ZJ/2, Pf1, and Pf3. Based on X-ray diffraction studies, the viruses have been divided into two morphologically distinct classes, and the *E. coli* viruses M13, fd, f1, If1, and IKe belong to class I [36, 37]. Infection depends on the presence of specific pili encoded by conjugative plasmids carried by the host cell. M13, fd, and f1 only infect *E. coli* strains that harbor the conjugative plasmid F, hence the common annotation Ff for F-specific filamentous phage. The nucleotide sequences of M13, fd, and f1 show that these viruses are very closely related (homology ~97%) and, therefore, rather recently evolved from a common ancestor [38].

The Ff class of filamentous phages is by far dominating the phage display field in combination with its natural host *E. coli* (Figure 9.1). Though pIII grafting experiments show that the host range can be expanded in that the phages can become M pili specific, this has yet to be implemented in phage display [39]. A complete list of phage proteins and the genes encoding them is provided in Table 9.1.

M13 Virion

The filamentous phage genome consists of a 6,407 nt single-stranded DNA and encodes 11 proteins. Five structural proteins include a minor coat protein pIII, the major coat protein pVIII, and three other proteins, pVI, pVII, and pIX (Figure 9.2). Proteins pIII and pVI cluster on the adsorption end of the virion, while proteins pVII and pIX cluster on the maturation end. These proteins are present in very few (three to five) copies in the virion, in sharp contrast with pVIII (2,700 copies). The six nonstructural proteins are replication proteins pII and pX, single-stranded DNA binding protein pV, and morphogenic proteins pI, pIV, and pXI (arabic numerals are sometimes used to designate the proteins and genes instead of roman numerals).

Information about the virion structure comes primarily from x-ray diffraction studies and electron micrography. The M13 genome is packaged into a phage capsid 65 Å in diameter and 9,300 Å in length (Figure 9.3). The main building block for the capsid is the 50 amino acid residue-long protein pVIII, oriented at a 20° angle from the particle axis and assembled in a shingle-type array. The assembly of pVIII proteins leaves a cavity of diameter

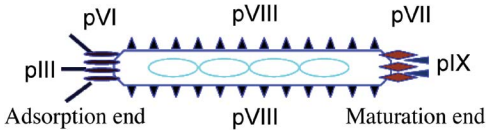

FIGURE 9.1 Schematic of coliphage M13 virion.

TABLE 9.1

F-specific Filamentous Phage Genes/Proteins and Properties

Gene	Protein	Size (aa)	Location	Function	Display Mode/Valence
gI	pI	348	Inner membrane	Assembly	*NA*
	pXI	108	Inner membrane	Assembly	*NA*
gII	pII	409	Cytoplasm	Replication (nickase)	*NA*
	pX	111	Cytoplasm	Replication	*NA*
gIII	pIII	406[a]	Virion tip (end)	Virion component	Yes (N-term)/1-5
gIV	pIV	405[a]	Outer membrane	Assembly (exit channel)	*NA*
gV	pV	87	Cytoplasm	Replication (ssDNA bp)	*NA*
gVI	pVI	112	Virion tip (end)	Virion component	Yes (C-term)/1-5
gVII	pVII	33[b]	Virion tip (start)	Virion component	Yes (N-term)/1-5
gVIII	pVIII	50[a]	Virion filament	Virion component	Yes (N- and C-term)/>50
gIX	pIX	32[b]	Virion tip (start)	Virion component	Yes (N-term)/1-5

of 25–35 Å, filled with phage DNA throughout the length of the virion. The phage DNA is oriented in the particle, determined by the packaging signal (PS), which forms an imperfect hairpin and is positioned at the maturation end of the phage particle. The PS is necessary and sufficient for incorporation of the DNA into the phage particle. The bulk of the pVIII protein (residues 6–50) forms an alpha helix. Five N-terminal residues are surface-exposed, while residues near the C terminus interact with the genomic DNA. The amino terminus of pVIII has been a subject of extensive engineering in the process of creating phage libraries.

The ends of the particle have different appearance in electron micrographs. The pointed end (also known as the adsorption, proximal, or infectious end) consists of about five copies each of pIII and pVI. The 406-residue pIII consists of three domains, N1, N2, and CT, separated by two glycine-rich linkers (Figure 9.3, Panels B and C). Domains N1 and N2 appear in electron micrographs as knobby structures emanating from the pointed end of the particle into the medium and are key for infectivity. The crystal structure of a polypeptide comprising both domains has been determined (Figure 9.3, Panel C). The C-terminal 132 residues of the CT domain are proposed to interact with pVIII and form the proximal end of the particle; they are also thought to be buried. Most importantly, they are necessary and sufficient for pIII to be incorporated into the phage particle and for termination of assembly and release of phage from the cell.

The role of the 112 amino acid long protein pVI is not fully understood. It may interact with pVIII at the tip of the particle and is partially buried. The C-terminus of pVI has been used to display heterologous proteins [40], suggesting that it is accessible on the surface of the phage particle. For this reason, pVI appears particularly fit for the display of cDNA libraries [41].

The other phage particle end, also known as the distal or maturation end, appears blunt in electron micrographs. It has approximately five copies each of two small proteins pVII (33 amino acids in length) and pIX (32 amino acids in length). While protein interactions at this particle end are not fully understood,

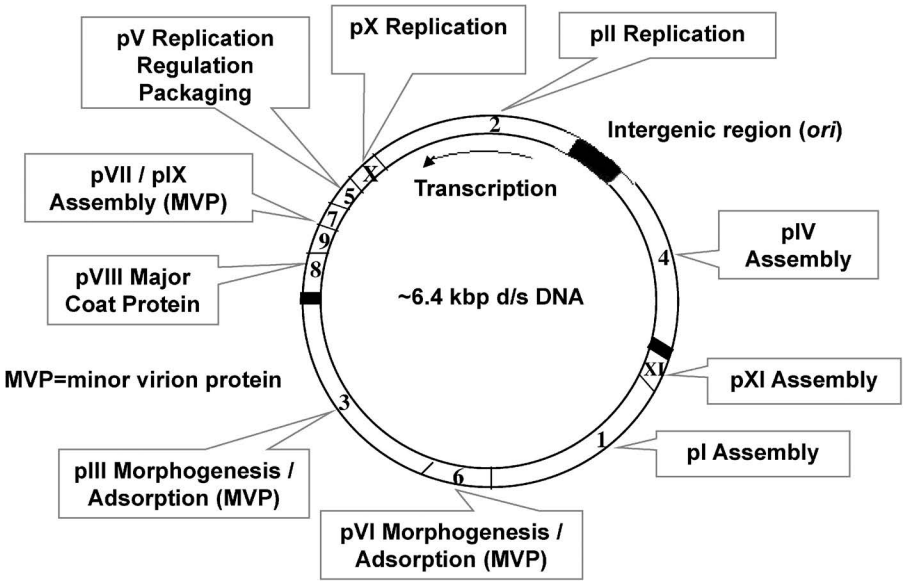

FIGURE 9.2 Phage M13 genome. The replicative form DNA (RF DNA) is depicted. The genes are designated by Arabic numerals, while the proteins they encode by Roman numerals. Proteins X and XI are not encoded by separate genes, but are derived from gene *2* and gene *1*, respectively, as discussed in the text. Modified from a GP Smith PowerPoint slide.

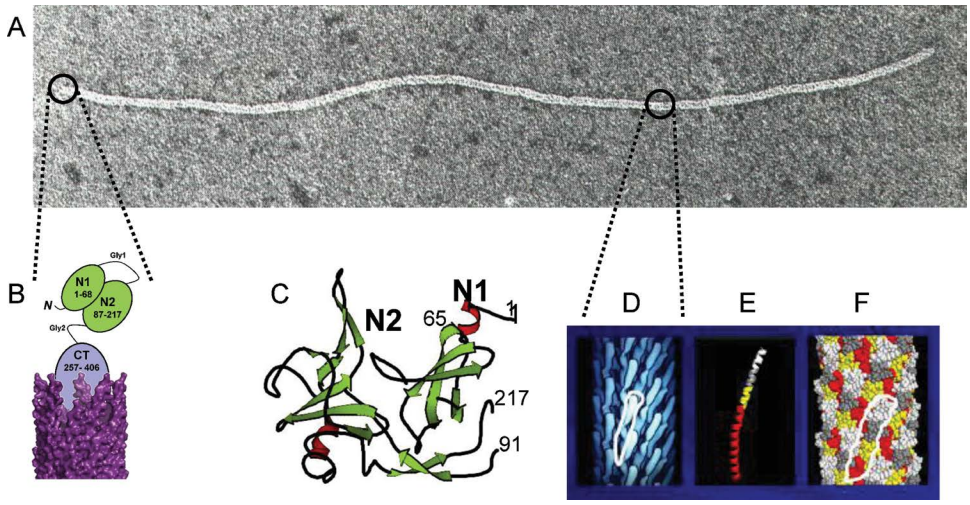

FIGURE 9.3 Panel A: Structure and electron micrograph of a filamentous ssDNA phage. The orientation that the DNA molecule is thought to have within the elongated filamentous particle is indicated by gene numbers; the morphogenetic signal sequence is believed to be in the intergenic (IG) region at the right, possibly bound to gene VII and IX proteins. The diagram also shows how the major coat protein is polymerized in helical array around the DNA. Panel B: Cartoon of the pIII structure, including domains N1, N2, and CT, and glycine-rich linkers Gly1 and Gly2. Numbers indicate amino residues comprising the domains. The pVIII virion body structure (purple) was made by PyMOL (PDB: 1IFJ) and the pIII-CT unit arbitrarily positioned—the real stoichiometry of pIII per phage is about 5. Panel C: Crystal structure of the N1 and N2 domains of pIII [84]. The image was generated using KiNG software (PDB: 1GP3). Numbering is according to the amino acid residues: 1-amino terminus and the site for display of peptides and proteins fused to pIII; 1–65–N1 domain; 91–217–N2 domain. The structure of the 66–90 region, a glycine linker, has not been determined. Panel D: Computer rendering of the electron density map of M13 based on x-ray diffraction studies [85]. The elongated rod-like structures are pVIII subunits forming the phage coat. The highlighted structure corresponds to a single pVIII subunit. Panel E: Model of the alpha-helical domain of pVIII [86] based on x-ray fiber diffraction and solid-state NMR data [87]. Four differently shaded areas are as follows (from top to bottom): (1) the foreign peptide fused to the amino terminal region of pVIII; (2) amino acids 6–11 of pVIII; (3) amino acids 12–19 of the engineered pVIII; and (4) buried residues of pVIII (amino acids 20–50). Panel F: Space-filling model of the phage. About 1% of the phage length is shown. The highlighted structure corresponds to a single pVIII subunit. ([A] Courtesy of Professor R. Webster. Source: GP Smith PowerPoint slide; [D] with permission, from Lee Makowski and the publisher, ©1992 Elsevier; [E] with permission, from Valery Petrenko and the publisher, © 2008 Elsevier; [F] with permission, from Valery Petrenko and the publisher, © 2008 Elsevier.)

it has been shown that the amino termini of both proteins can be used for heterologous protein display [42], which has been exploited for efficient peptide and antibody discovery [43–45].

M13 Life Cycle

In describing the M13 life cycle, we will focus on the aspects of direct significance for experimentation with phage display. More detailed descriptions are available[2].

To infect the bacterium, the bacteriophage uses the tip of the F conjugative pilus of *E. coli* as the receptor. The three bacterial proteins required during phage infection are TolQ, TolR, and TolA, which appear to form a complex anchored in the cytoplasmic membrane; the complex protrudes into the periplasm of *E. coli*. Infection starts with the binding of the N2 domain of the phage pIII protein to the tip of the F pilus, followed by a retraction of the pilus, which brings the adsorption end of the particle to the periplasm. As a result of this binding, the N1 domain of pIII is released from the N2 domain and allowed to interact with TolA. Thus, the tip of the pilus can be considered a receptor, and TolA, a coreceptor. The processes of phage particle disassembly and entrance of the single stranded phage DNA into the cytoplasm that follow are not well understood. Phage pVIII protein is reused in the making of the new phage, and DNA, which is a (+) strand (same orientation as phage mRNA), undergoes replication.

The (+) strand becomes a template for synthesis of the complementary (–) strand. The synthesis by bacterial enzymes and the introduction of negative supercoils by a gyrase produces a covalently closed, supercoiled double-stranded DNA called the parental replicative form DNA (RF DNA). This RF DNA serves a triple role: initially it is a template for transcription of mRNA and for synthesis of additional RF DNA, and after the accumulation of sufficient amounts of phage protein, it serves as a template for synthesis of the (+) strand to be packaged into new phage. Phage protein pII is necessary for nicking/closing of the DNA to be replicated, while the accumulation of pV results in formation of a complex between pV and (+) strands, thereby preventing the conversion of the (+) strand to RF DNA. The RF DNA/pV complex serves as a substrate for phage assembly. An additional protein, pX, created by an in-frame translational start within the p*II* mRNA and thus having a sequence identical to the 111 carboxy terminal residues of pII, helps to regulate the replication of phage DNA.

Phage assembly is a complex process requiring five structural proteins (pIII, pVIII, pVI, pVII, and pIX), three assembly proteins (pI, pIV, and pXI), and at least one bacterial protein, thioredoxin. Protein pXI is created by an in-frame translational start within the p*I* mRNA and thus has a sequence identical to the 108 carboxy terminal residues of pI. At the core of the assembly process is the removal of pV from the pV/RF DNA complex and the association of structural proteins around double-stranded phage DNA in the periplasm, where the inner and outer membranes are in close contact. At the final stages of phage assembly, the phage emerges from the bacterial cell without killing the cell.

Phage Proteins Used for Display

While all five phage coat proteins have been used for display of heterologous peptides or proteins, only two have been widely used, pIII and pVIII. As a result, there are a large amount of data on the design of display experiments and library construction using these proteins.

Protein pIII

Of the two proteins, pIII and pVIII, pIII is by far the most commonly used (alternatively referred to as 3 and 8 type display) (Figure 9.4). Regarding pIII display, the insert location of choice is the amino terminus—that is, the heterologous gene is cloned between the p*III* gene regions that correspond to the signal peptide of pIII and domain N1. Upon secretion of pIII into the periplasmic space of the cell, the signal peptide is removed, and the heterologous peptide ends up as a fusion to the amino terminus of the mature pIII protein.

There are several reasons for this cloning site preference. First, the replication process of the phage seems to tolerate a wide range of insert sizes. This can be rationalized by realizing that insertion places the heterologous peptide at the adsorption end of the phage particle, which creates less steric hindrance during phage maturation; pIII emerges last during the transport of the particle from the bacterial cell into the medium. Proteins as large as alkaline phosphatase have been expressed as fusions to pIII [46]. On the other hand, many experiments with fusions of short peptides to pIII have also been quite successful.

Second, the structure of the amino-terminal half of pIII, comprising the N1 and N2 domains (Figure 9.3, Panels B and C) is highly conducive to phage display experimentation. Both domains, but particularly the amino terminus, are exposed on the surface of the phage particle. Thus, one can expect that the foreign peptide will be able to adopt its native fold and be exposed to the medium, which would allow for successful selection experiments.

Third, the purpose of many phage experiments is the selection of high-affinity binders to a biomolecule of choice. Under such conditions, a monovalent display is often desired, with expression on pIII being closer to this ideal (five copies) than a clearly polyvalent (up to 2,700 copies) display on pVIII. In real life, the valence of display is difficult to measure; it cannot be excluded that due to unavoidable proteolysis, only a small fraction of phage coat proteins, whether pIII or pVIII, display a foreign peptide. Thus, pIII display might be closer to monovalent than the number of pIII molecules in the virion might indicate. However, it is still most often alluded to as high valence display, to distinguish it from low valence display, which is achieved by phagemid display (discussed later in this chapter).

Alternative display locations in pIII, namely between the N1 and N2 domains and between the N1 and CT domains, have been also explored [47]; however, they have not been widely used.

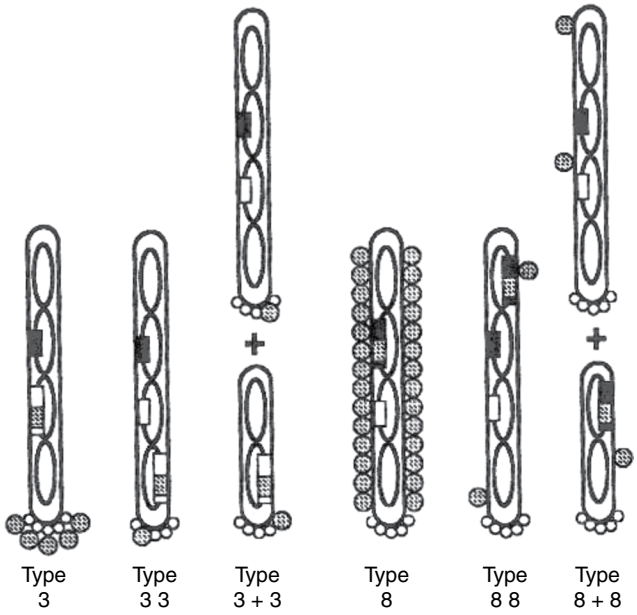

FIGURE 9.4 Types of phage vectors for display experiments. A Type 3 vector has a single recombinant gene *III* (open box) bearing a foreign DNA insert (hatched segment): all five copies of pIII are decorated with the foreign peptide encoded by the insert (hatched circles at the tip). The other phage genes, including *VIII* (black box), are normal. Type 33 vectors provide two genes *III*, one wild-type, the other an insert-bearing recombinant. The virions display a mixture of pIII molecules, only some of which are fused to the foreign peptide. Type 3 + 3 vectors resemble Type 33 in having two genes *III*; in this case, however, the recombinant gene is on a phagemid, a plasmid that contains, in addition to a plasmid replication origin and an antibiotic resistance gene, the filamentous phage "intergenic region." Type 8, 88 and 8 + 8 vectors are the gene-*VIII* counterparts of the gene-*III* vectors. (With permission from GP Smith [*Gene* 128, 1-2] and the publisher [© 1993 Elsevier].)

Protein pVIII

Display experiments on pVIII target the amino terminus of pVIII. That is, the heterologous gene is inserted between the region corresponding to the signal peptide and the mature pVIII protein. Unlike pIII display, there is a significant length limit of six to eight amino acid residues on the size of the peptide displayed; this size limit seems to be connected to the interference of larger peptides with phage packaging and in particular with the transport of the phage particle through the pIV channel. Display of larger peptides fused to pVIII is only possible with hybrid phage display systems (see "Phagemid and Helper Phage," discussed later in the chapter).

Examples of Strategies to Alleviate pIII and pVIII Display Constraints

Even though a large variety of different proteins have been successfully displayed on phage [3], there are still many that are refractory to functional display due to their folding characteristics, a notion that is relevant both to peptide and domain display. Such constraints may be alleviated by manipulating the periplasmic chaperone environment [48, 49], altering the periplasmic targeting propensity [50], route [51, 52], or even by modifying the zwitterionic characteristics of the phage particle [53]. Capsid engineering has also been explored to improve functional display of heterologous fusion proteins. This involves trimming of pIII as in CT display [54], or removing the N1–N2 cysteines of the full length pIII [55]. With the exception of the latter approach, it is notable that all these avenues rely on hybrid display systems (see "Phagemid and Helper Phage," later in this chapter). An additional exception here is some types of pVIII display where modifying the solvent exposed *N*-termini may increase display levels [56].

Nomenclature of Phage Display Experiments

As alluded to above, it is desirable in many phage display experiments to reduce the number of foreign peptides displayed on the phage, relative to the native number of pIII or pVIII proteins (five or 2,700 each, respectively). This is done by introducing into the *E. coli* cell additional copies of the wild-type pIII or pVIII genes; the gene can reside on the same phage vector that harbors the heterologous gene, in which case the system is called 33 or 88, respectively. Alternatively, the gene can be harbored on another vector, and such systems are called 3+3 or 8+8. The single-gene systems are known as type 3 (pIII only) or type 8 (pVIII only). The systems are depicted in Figure 9.4. Because the expression level of the wild-type genes can be controlled, the ratio of the heterologous to wild-type coat protein can be adjusted as needed.

Protein pVII and pIX

The use of pVII and pIX have emerged in recent years [7]. Both peptides and folded-protein domains have been successfully displayed and applied in selection experiments, and in both 7 and 9 as well as 7 + 7 and 9 + 9 versions. Results equal to or better than those obtained with classical pIII and pVIII have been achieved, and both pVII and pIX are now attractive fusion partners (insert PMID reference 27966617). They have some distinct advantages compared to pIII (see "Common difficulties" below).

Phagemid and Helper Phage

A popular implementation of the hybrid system involves the use of a phagemid, which is a cloning vector based on a plasmid (such as pBR322) and containing the replication origin of a filamentous phage as well as either gene *III* or gene *VIII* modified to accept gene inserts for display. The phagemid can be readily propagated in *E. coli* leading to the accumulation of the pIII or pVIII fusion protein. To allow formation of viable phage, a coinfection with so-called M13 helper phage is required. Compared with the wild-type phage, the helper phage has a compromised origin of replication and is unable to be propagated efficiently under normal conditions. However, an *E. coli* cell harboring the phagemid and superinfected with helper phage will produce large amounts of a smaller version of the phage carrying phagemid DNA and displaying the heterologous proteins. Such particles are then used in, for example, affinity-selection experiments.

An often-used version of the M13 helper phage is the interference resistant M13K07 [18] available from New England Biolabs. It is an M13 derivative that carries the mutation Met40Ile in gII, with the origin of replication from P15A and the kanamycin resistance gene from Tn903 both inserted within the M13 origin of replication [18]. Other types of M13 helper phage are R408 and VCSM13 (Stratagene).

One may opt to alternate between different helpers throughout a selection campaign, which is usually based on multiple rounds of target selection and amplification of eluted phages (see discussed later in this chapter). For instance, it can be very useful to alternate between low valence and high valence display on pIII or pIX. This has been made possible by the use of special helper phages that lack functional expression of relevant capsids and thus mimicking the pure 3 and 9 genomic systems [57, 58].

Considerations for Successful Phage-Display Experiments

While many applications of phage display have been reported, most phage-display experiments fall into the following three categories based on the type of protein immobilized on the phage:

1. Preparation and screening of a random peptide library, with the goal of identifying a peptide capable of binding to a given protein under study
2. Cloning of a naturally occurring repertoire of gene segments based on a distinct protein scaffold, such as antibody variable genes, which have been diversified by endogenous mechanisms of the chosen donor, followed by selection, with the goal of finding a variant of the protein possessing a desired property, typically a binding specificity to another molecule
3. Cloning of a protein, followed by randomization and selection, with the goal of finding a variant (mutant) of the protein possessing a desired property, typically a binding specificity to another molecule

Peptide Library

The first question to ask is whether an existing peptide library will be adequate for the particular experiment. Throughout the years, a comprehensive list of random peptide libraries have been reported [31]. In addition, New England Biolabs (www.neb.com) supplies the Ph.D. phage display system and several types of libraries, in which 7 or 12 amino acid random or disulfide-linked peptides are displayed on the phage. The diversity of these libraries is in the range of $1–3 \times 10^9$ different peptides.

There is a focus now on how to optimize the library generation protocols to improve the speed of the process as well as to increase library diversity and functionality. Thus, using current protocols one can manufacture peptide libraries in a swift and streamlined manner that reaches end diversities of more than 10^{10} to 10^{11} different peptides [59–61].

If the decision is made to construct a new peptide library by cloning a random or partially random nucleic acid sequence within the pIII or pVIII gene, the desired length of the peptide needs to be determined as well as the choice of cloning vector, cloning site, and signal sequence. The majority of peptide libraries constructed are of type 3 (Figure 9.4) and the gene insert is placed downstream of the signal sequence in front of gene III, often in a derivative of phage M13; this is a recommended (default) approach. It is more difficult to recommend the peptide length because, while longer peptides provide a higher level of sequence heterogeneity (proportional to the peptide length) and more possibilities for formation of secondary/tertiary protein structures, these longer peptides might be more rapidly degraded proteolytically and the library more difficult to handle. Interpretation of the results might be more difficult as well. However, recent improvements in library generation protocols and the very recent introduction of next generation sequencing as a phage selection screening tool has greatly improved the ability to delineate also highly diverse and complex selection protocols.

Display of Proteins

Many different proteins have been displayed on the phage [3, 31], ranging from enzymes (alkaline phosphatase, trypsin, lysozyme, β-lactamase, glutathione transferase), hormones (human growth hormone, angiotensin), inhibitors (bovine pancreatic trypsin inhibitor, cystatin, tendamistan), toxins (ricin B chain), receptors (α subunit of IgE receptor, T cell receptor, B domain of protein A), ligands (substance P, neurokinin A), and cytokines (IL3, IL-4), two different forms of antibodies (scFv, Fab), and T cell receptors (scTCR and dsTCR). The size of the protein, up to around 60,000 daltons per subunit (e.g., alkaline phosphatase), does not seem to be of major concern (except on pVIII), nor is the existence of a protein in a dimeric form, since a dimeric protein as large as alkaline phosphatase has been successfully displayed on the phage [46]. Similarly, a successful phage display experiment does not depend on whether or not the protein is secreted in its native form, since many intracellular proteins have been displayed on the phage (glutathione S-transferase, cytochrome b_{562}, FK506 binding protein, and others). The typical approach involves use of the 3 + 3 system (with an alternative being the single vector 3 system), with the gene cloned for expression on the amino terminus of pIII.

Antibody Libraries

Special attention needs to be given to the display of antibodies on filamentous phage due to its popularity and wide number of possible applications on the one hand, but common difficulties encountered with such libraries on the other. Antibodies are disulfide-linked heterodimers composed of light and heavy chains, with their total molecular weight often exceeding 150,000 Da. The complexity of the antibody molecule in its native state renders it prohibitively difficult to display on the phage, which is why approaches have been developed to display a truncated single-chain version of the antibody molecule. The single chain Fv (scFv) antibody consists of the variable regions of the heavy and light chains, comprising the full Fv antigen binding site of the parent antibody, connected with a short and flexible peptide linker (Figure 9.5, Panel A). Thus, the antigen-binding region of the antibody is preserved; however, functionalities associated with the remainder of both heavy and light chains, such as

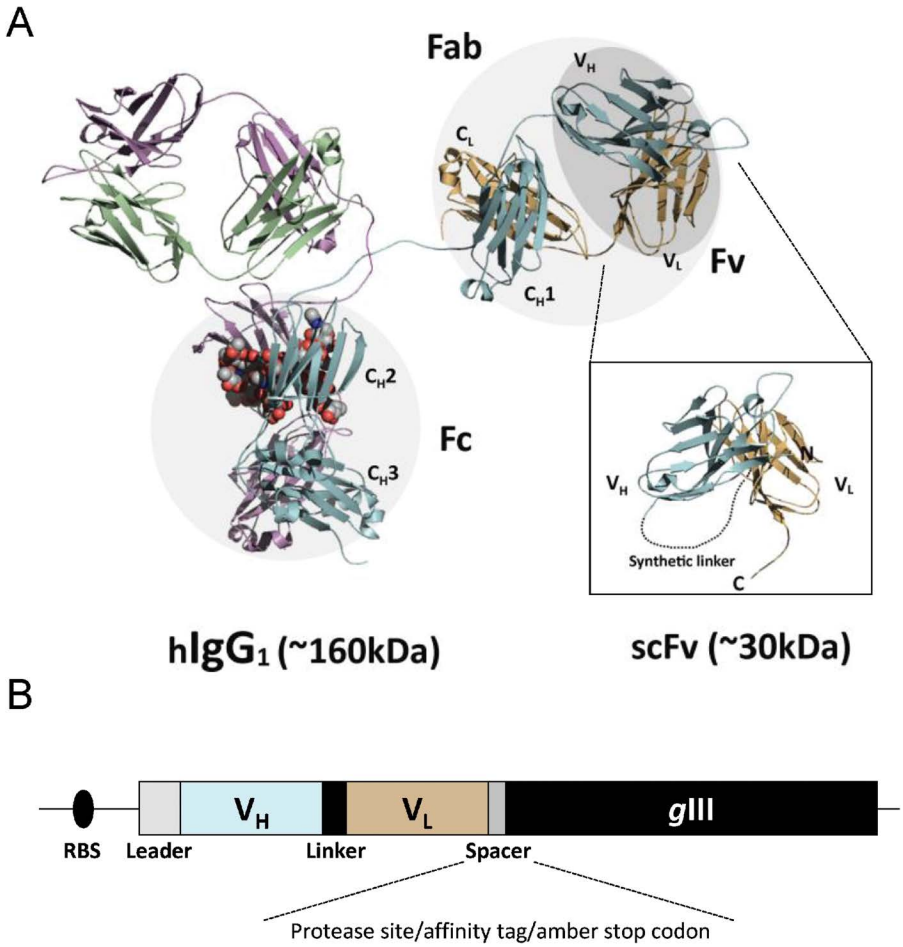

FIGURE 9.5 Antibody structure and recombinant forms used for phage display. Panel A: The single chain Fv (scFv) contains the antigen binding V_H and V_L domains from, for example, immunoglobulin G (IgG) and can be displayed on phage. In the case of the Fab and the diabody, one of the chains is secreted as a pIII fusion and the other is secreted as native nonfusion protein. The figure was prepared using PyMOL based on PDB: 1HZH. Panel B: Schematic illustration of a typical scFv-pIII fusion protein expression cassette used for antibody phage display. The scFv is directly fused to pIII by use of a spacer sequence typically containing tags for detection and purification of the soluble version. The latter can easily be made, for example, by incorporating an amber stop codon in the spacer, which comes into effect dependent on the *E. coli* host used for expression.

binding to various cell receptors and complement proteins, are removed upon the conversion to the single-chain form. Another popular format is to display the full fragment antigen binding (Fab). Throughout the years, several engineered antibody formats have been developed [62], many of which have been displayed [63], significantly contributing to the strong position of phage display as a combinatorial platform [9].

The construction of scFv libraries, which is still the most common type, typically involves the joining of PCR amplified gene fragments corresponding to the F_v regions of the heavy and light chains through a glycine-rich linker, placing the signal sequence in front of the construct and followed by cloning between a suitable ribosome binding site/signal sequence and the 5'-terminal region of pIII (Figure 9.5, Panel B). Often, both mAb-tag, his-tag, and an amber stop codon are introduced into the construct as well.

Construction of the Phage Library

After a phage vector system is chosen for library construction, a cloning strategy needs to be identified. A typical approach for inserting a peptide-encoding randomized sequence into a vector relies on the cloning of synthetic DNA. An example is presented in Figure 9.6, and the experiment is described in detail by Ravera et al. [64].

The pCANTAB5E phage vector (GE Healthcare) was chosen for cloning, and its two unique restriction sites, *Sfi*I and *Not*I, were selected as the insertion sites for randomized DNA. As a result, the randomized peptide was expressed fused to the pIII protein and had on its amino terminus the FLAG peptide. The random insert sequence was of the type $(NNK)_m$ where N = A, C, G, or T; K = T or G; and m is the number of codons in the random sequence. In the example quoted, m = 40; however, m can vary greatly depending on the experimental design but it typically ranges from 8 to 30 codons. The purpose of the NNK codon design is to avoid two out of three stop codons. The third stop codon (TAG) can be suppressed if the phage is prepared in an *E. coli* suppressor strain, such as TG1, [F' *traD*36 *lacI*^{q} *lac*ZM15 *proA*$^+$*B*$^+$/*supE* Δ(*hsdM-mcrB*)5(rk$^-$mk$^-$ *mcrB*$^-$) *thi,* Δ(*lac-proAB*)], leading to incorporation of glutamine into the polypeptide chain in response to TAG codons. Despite this limitation, which effectively can be alleviated by the use of oligos based on defined triblock codon synthesis [65], all amino acid residues could thus be incorporated into the polypeptide due to redundancy in the genetic code. In this example, the random sequence resided on a synthetic oligonucleotide, 145 nt long, which was converted to double-stranded DNA in a PCR reaction, digested with *Sfi*I and *Not*I, ligated into the pCANTAB5E vector, and electroporated into *E. coli*.

There are many methods to clone DNA into phage vectors. Other than the PCR-based cloning outlined previously, approaches often used to clone randomized cDNAs that encode larger proteins include Kunkel mutagenesis [35, 60], a variety of oligonucleotide-based mutagenesis methods, random mutagenesis, combinatorial infection and recombination, and DNA shuffling [30].

Library Diversity

The potential library diversity D goes up very rapidly with the number of randomized positions m, according to the formula $D = 20^m$ (assuming all 20 amino acids can be incorporated). For m = 8, the potential diversity exceeds 2×10^{10}, which is already larger than the number of independent clones in a typical phage library, and if based on NNK randomization, this number increased to above 10^{12} due to the degenerate use of 32 codons. This means that libraries in which more than 8 positions are fully randomized will actually not contain a representation of all possible sequences—a reflection of the enormous diversity of protein sequences. It is reassuring for those who work with phage peptide libraries that binders to many (if not most) proteins are obtainable from such libraries despite a striking contrast between the number of clones in the phage library and the number of allowable sequences. The selection of the binder can be represented as a search for function in a multidimensional protein sequence space [31, 66].

Achieving a library diversity of more than 10^{10} independent clones has traditionally not been easy. While electroporation efficiency can be more than 10^{10} clones per 1 mL of electrocompetent cells and the amount of DNA is typically not an issue, one needs to remember that the electroporation efficiency quoted applies to ideal conditions (i.e., native double-stranded supercoiled DNA), while the *in vitro* constructed DNAs typically transform with significantly lower efficiency. In the example quoted previously [64], the peptide library of 1.5×10^{10} clones was constructed by combining five sublibraries, each of which was obtained from about 100 electroporations. As of today, it is only the improved Kunkel-based protocols that have been able to alleviate this bottle neck, by using the improved preparation of high-density ultracompetent SS320 *E. coli* [60, 61], which now may be purchased from, for example, Lucigen (www.lucigen.com).

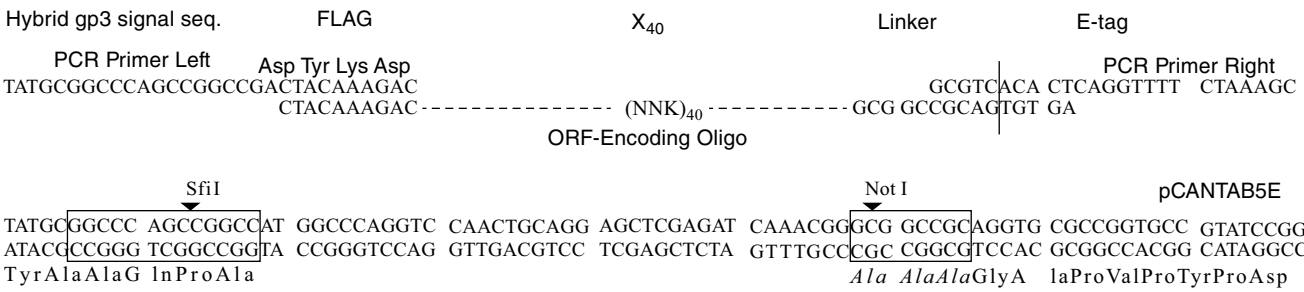

FIGURE 9.6 Cloning of a DNA insert carrying a randomized sequence into the pCANTAB5E phagemid. (See Figure 1, p. 1994 in Ref. [64].)

Selection (Biopanning) Experiment

The principle of phage selection (Figure 9.7) relies on exposing the target proteins immobilized on solid phase to the phage library, allowing peptides carried on phage to bind specifically to the target proteins and be retained on solid phase, and removing of the excess phage by washing. Since this biopanning step will always result in an undesired retention of nonspecifically bound phage, the step is repeated with the eluted and amplified phage. The total number of biopanning steps can vary from two to four or more, depending on the experimental strategy and conditions. The final product of the phage enrichment procedure is a group of phage clones that are considered potential binders to the target protein. Typically, the target-binding properties of the phage clone are confirmed in a phage ELISA assay, and the phage DNA is subjected to DNA sequencing, which identifies peptide sequences capable of binding to the target of interest. The biopanning cycle is schematically represented in Figure 9.8, and a comprehensive selection of biopanning protocols is presented in Refs. [29] and [28].

A great deal of variation is allowed in biopanning procedures ranging from solid phase inorganic materials to selection on live cells [10]. Classically, different solid phase materials have been used for target immobilization, such as polystyrene, nitrocellulose, or streptavidin-coats on beads or plates. The binding

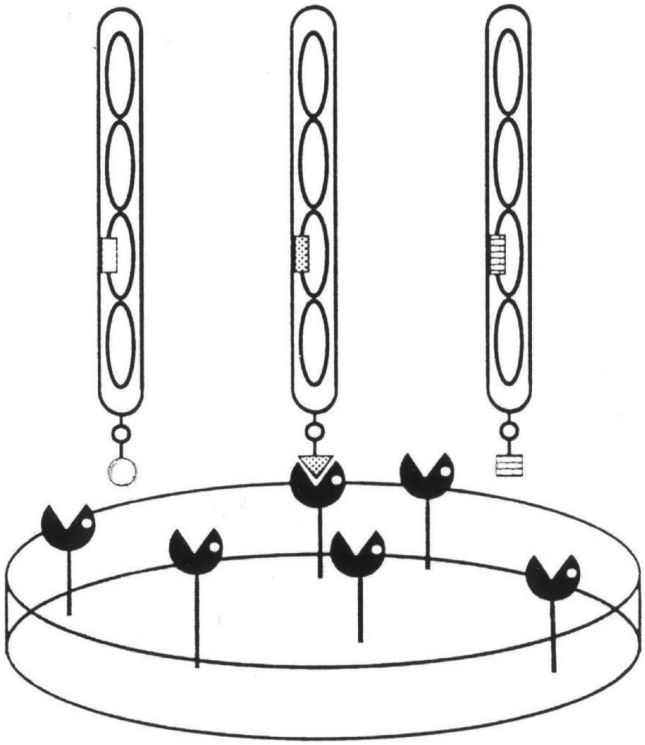

FIGURE 9.7 Phage display principle. Schematic diagram of a display library being "panned" on a petri dish to which an open-jawed receptor has been tethered. Phage displaying peptides that bind the receptor are captured on the dish, while the other phage are washed away; the captured phage are eluted, cloned, and propagated by infecting fresh host cells, and the relevant part of their DNA sequenced to identify the peptide responsible for specific binding. (With permission from GP Smith [*Gene* 128, 1-2] and the publisher [© 1993 Elsevier].)

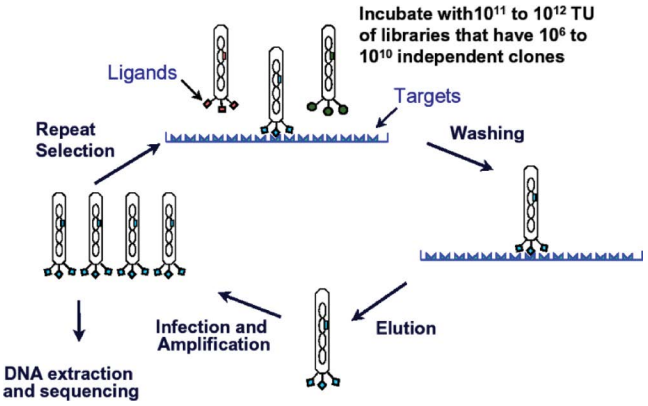

FIGURE 9.8 A schematic for the biopanning cycle.

reaction can take place in solution; in this case, the target protein is biotinylated and the phage-target complex is harvested by binding it to, for example, streptavidin-coated microtiter plates [67]. The biopanning stringency can be varied as well by adjusting the binding/elution buffer composition, time, temperature, etc. A general rule for protein targets known to bind to short linear epitopes (e.g., antibodies recognizing such epitopes) is to use more stringent conditions and fewer biopanning rounds, while target proteins that bind to more complex structures often require an optimization of the biopanning approach.

The analysis of phage clones after biopanning may take several case-specific directions, but traditionally begins with a phage capture ELISA. The prototypic ELISA screen involves immobilizing the target and relevant controls as coat, followed by phage clone capture, where the same phage samples are tested in parallel. Successful phage capture is then detected by anti-phage antibodies directed toward the pVIII, which offers very high sensitivity to the assay as this capsid is found in thousands of copies per phage.

In the next analysis step, several (often as many as 100 or more) ELISA-positive clones are subjected to DNA sequencing over the randomized region of the heterologous gene or cloned insert. The obtained DNA sequences are translated and the amino acid sequence of the peptide or the randomized region is defined. Often, a short linear region of homology can be readily spotted amongst the sequences and a consensus sequence can be derived.

Typical results from a simple biopanning experiment [68] are presented in Figure 9.9. In Panel A, biopanning of a peptide library against an HCV monoclonal antibody (mAb) led to a simple linear sequence of six amino acid residues, RGRRQP, as a consensus. In Panel B, with the target being an anti-HBsAg mAb, the consensus is still a short linear sequence, C*TC, where * is any amino acid residue. However, the presence of two cysteine residues strongly suggests that the binding form of the peptide adopts a looped conformation that is anchored by a disulfide bond formed by two cysteine residues. Nonetheless, the confirmation of such a secondary structure as a binding motif requires additional experimentation.

In view of the phage display complexities that can develop due to the high number of different molecules (over 10^{10}) involved and largely unknown binding properties, it may be of help to seek guidance by theoretical models and simulations of phage

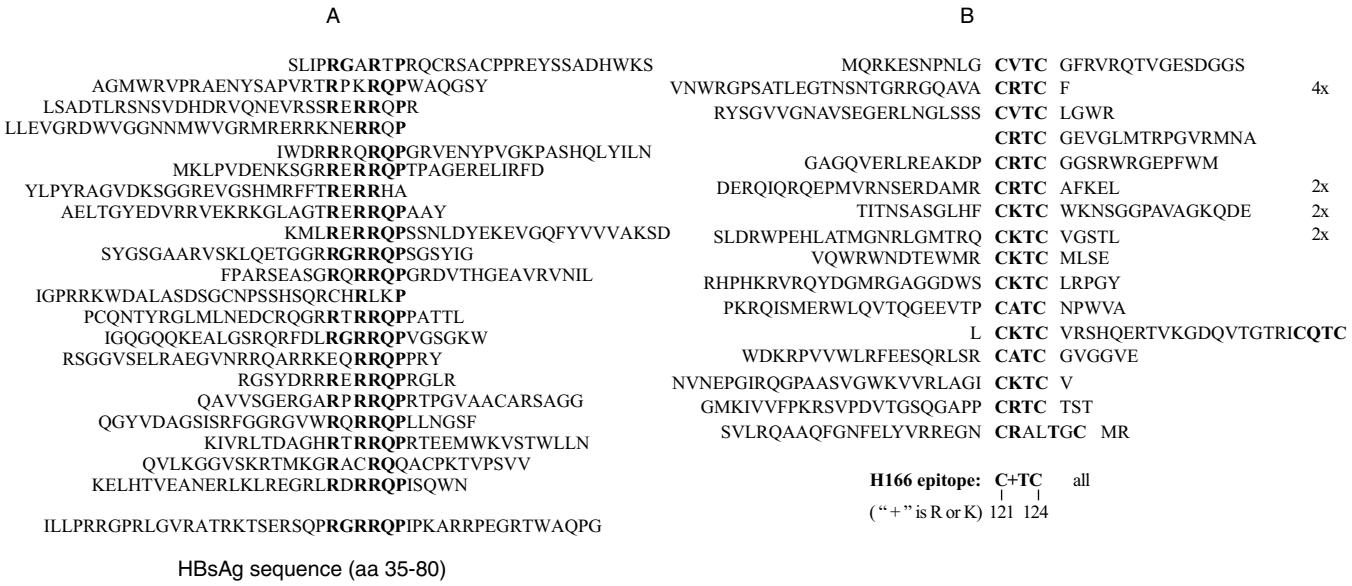

FIGURE 9.9 Examples of biopanning results: Consensus sequences obtained from biopanning against two mAbs, against the HCV core protein (Panel A) and HBV surface antigen (Panel B). ([A] From Figure 5, p. 192 in Ref. [88]; [B] from Figure 1A, p. 1999 in Ref. [68].)

display [19, 20, 22]. Complexities arise because randomized proteins displayed on the phage in the library have vastly differing binding affinities to the target. Depending on the target, the binding clones may or may not be abundant, and depending on the biopanning procedure, particularly its stringency and number of washes, different groups of clones can be retained or lost at varying rates, which can lead to uncertainties in obtaining a desired type of binder. Theoretical analyses as in Ref. [19] provide insight regarding the number of biopanning rounds and washes per round needed while also helping to track the quantitative increase of the number of desired binding clones. Models can help one to understand how the affinity distributions of phage populations change during panning. Though such initial considerations are recommended during planning of a selection campaign, it will nonetheless often be necessary to empirically adjust many of the parameters in the lab. This may range from specific blocking and elution condition to the choice of target immobilization strategy, which have major impact on the number and type of binders retrieved during the actual selection [69, 70].

Expression of Identified Protein or Synthesis of Peptide

Obtaining consensus sequences can sometimes provide an important clue as to the significance of a particular region within a protein sequence, particularly when there is a match between the two sequences. But more often than not, further characterization of the binding clones is needed, and toward that goal, the protein displayed on the phage needs to be made in appropriate quantity and then purified and analyzed. Several approaches to this are possible.

First, certain phagemid vectors, such as those presented in Figure 9.5, have an amber stop codon (TAG) between the gene encoding the displayed protein and p*III*. A transfer of the phagemid to a nonsuppressor strain of *E. coli* can allow for expression of the protein as an entity not fused to pIII. Moreover, the vector may provide the his-tag or an antibody-tag, which is retained on the expressed protein in the nonsuppressor strain; such a tag may facilitate protein purification and subsequent characterization by ELISA.

Second, the gene encoding the protein can be recloned into an expression system. Many expression systems are available, and a good choice to start with is the system typically used to make the native protein in quantity.

Third, for random peptide libraries on phage, peptide synthesis is a very good method to obtain the peptide in quantity (see, e.g., Ref. [71]). Alternatively, the short genes encoding those peptides can be fused to a well-characterized affinity protein, such as maltose binding protein (MBP), and studies of the fusion protein can confirm the properties of the peptide from phage display. Alternatively, the candidate peptides may be indirectly coupled to carriers that allow for further characterization of the complexes by immobilizing biotinylated versions of the peptides to streptavidin [72, 73].

Common Difficulties and the Source of Repertoire Bias

While phage display is a powerful tool to select for a peptide or protein that binds specifically to a ligand, certain problems might arise due to the complexity of the approach. First, the custom library quality is difficult to judge, and in particular, the number of independent clones in the library and the valency of display (the actual number of displayed peptides/proteins). Second, certain clones could be under- or over-represented due to expression inefficiencies or toxicity. Third, procedural difficulties with selection (often, over-selection) may lead to elimination of clones otherwise expected to be identified.

In recent years, the ability to tap into a more representative portion of the enormous diversity found in phage display libraries has been made possible due to the introduction of next generation sequencing. Several studies have illuminated the intrinsic bias introduced during selection, but also identified experimental means to counteract the effects [26, 27, 74–76]. Combined with tools, such as the SAROTUP database (http://i.uestc.edu.cn/sarotup3), researcher today has powerful tools to successfully identify truly target-specific clones by selection [23].

However, in some circumstances, the sequence encoding the displayed peptide cannot be readily identified by sequencing. In our hands, screening a phage display random peptide library for binders to specific targets resulted in some instances with as many as 50% of all selected clones not having an obvious open reading frame, nevertheless the peptide had to have been synthesized or the phage would not have bound to the target ligand [71].

In a series of experiments, we pursued the explanation for this anomaly for one specific clone and its derivatives by fusing the peptide-encoding sequence to a β-galactosidase reporter and expressing it in *E. coli* [77–79]. Ultimately, our experiments indicated that an unexpected translational reinitiation phenomenon was responsible for the anomalous expression [79], however, other unexpected translational events are also possible in such cases [80].

Conclusions

Phage display provides a wealth of approaches to identify protein ligands. In skilled hands, the procedures are quite rapid (a few days), and the results provide a wealth of information about the protein ligands and the target protein itself, as well as their interactions [81]. Despite the emergence in recent years of alternatives to filamentous phage display, such as aptamers, ribosome display, yeast two-hybrid system, bacterial display, other phage systems (T4, T7 and lambda) (see [35] for references), the filamentous phage display nonetheless offers a very reliable set of tools and tested procedures and has been improved over many years by a large number of investigators. Undoubtedly, the merger of phage display library screening by deep sequencing will further fuel this development [82], as may the possibility of alternative display avenues such as offered by pVII and pIX display [7]. Thus, phage display remains an excellent starting point for the identification and activation of protein ligands.

Introduction

Microbiologists have been identifying organisms since Louis Pasteur in the 1800s first realized that, in addition to producing the fine wines of France, microorganisms also caused disease. Since that time, it appears is if the chief goal of diagnostic microbiology, has been to come up with the one test that would separate the helpful organisms from the harmful ones. Unfortunately, it seems that every time someone developed this ultimate test, eventually someone else would discover that there was overlap. The purpose of this chapter is to describe the major methods being used to identify microorganisms in the laboratory during the 19th and 20th centuries. Diagnostic methods in use in the 21st century will be reviewed in Chapter 11.

Culture

This is the oldest technique used in the laboratory today and has a very simple premise. Organisms are grown on media, and then identified using biochemical tests. Despite the advances in the laboratory since this technique was first used by Pasteur and Koch over 145 years ago, it is still the number one method used in clinical laboratories today (personal observation). Many sources and formulations for media exist and a description

of them can be found in the Difco™ & BBL™ *Manual of Microbiological Culture Media*, available at: http://www.bd.com/ds/technicalCenter/misc/difcobblmanual_2nded_preview.pdf (Accessed April 1, 2020).

Selecting the appropriate media seems like a daunting task, but it can be made much easier if one realizes that all media can be categorized into one of three groups: General, selective, or differential. In determining which medium is best-suited for a particular application, the technician should first determine which of the three groups best suits the needs of the research.

Media Types

General media. These have been developed to allow the widest variety of microorganisms to grow. Typically, they are used in applications in which the sample contains a mixture of microorganisms, and the specific one responsible for causing a particular medical or environmental effect is not known. As a result, a medium that will support the growth of all organisms in a sample is needed. One of the most widely used general media is trypticase soy blood agar. These are usually prepared with 5% defibrinated sheep blood in a nutrient agar base.

Selective media. These have been developed to allow only certain microorganisms to grow. Typically, they are used in applications in which the organism of interest comprises only a small percentage of the organisms contained in a sample. They are used when one wants to isolate specific pathogens in samples with an extensive normal flora. An example of a selective medium is Thayer Martin Agar that is used in the isolation of *Neisseria*.

Differential media. These are a subset of selective media that have been developed to not only select organisms, but also help to identify them. Not only will the organisms of interest grow on the plate, but they will also produce characteristically colored colonies. An example of a differential medium is MacConkey agar, which is used to differentiate lactose fermenting *Enterobacteriacae* from nonlactose fermenters. While both types of colonies will grow on the media, only the lactose fermenting organisms will produce purple colonies. Recently, there has been a trend toward the use of differential media for the screening of antibiotic resistant microorganisms.[1] Examples of this are chromID OXA-48, which screens for carbapenem resistant *Enterobacteriaceae*[2] BBL CHROMagar MRSA II[3] and Oxoid Brilliance™ MRSA, which screen for methicillin-resistant *Staphylococcus aureus* (MRSA).[4]

Two other factors that should be considered when choosing a growth medium are whether the medium is defined or undefined. A defined medium is one in which all components are chemically defined. They are rarely encountered in the microbiology laboratory. Most media are undefined. Undefined media are usually prepared from digests of animal or plant proteins, and as such do not have a defined chemical formula. These media are usually tested for growth with a small specific battery of microorganisms, prior to release for sale by the manufacturer. This can sometimes result in lot to lot variations in growth patterns for organisms that are not found on the manufacturer's quality control testing battery of microorganisms. If a researcher is using an organism not being tested by the manufacturer, it is always a good idea to test any new lots of media with their own battery to determine if that lot is suitable.

Colonial Morphology

Different species of organisms will usually produce colonies that have characteristic appearances following incubation on solid media. Some common characteristics used to describe colonies are:

1. Size, measured in mm: Can vary from very small (punctiform, pinpoint) to very large
2. General shape or form of the colony: Round, irregular, filamentous
3. Edge or margin of the colony: Rounded (entire), irregular, lobed
4. Chromogenesis: Some microorganisms may produce pigments as they grow. The pigment can either remain in the colony or diffuse into the surrounding media.
5. Colony texture: Rough, smooth, wrinkled, mucoid butyrous, viscid, brittle
6. Opacity: Transparent, translucent, opaque, iridescent
7. Colony elevation when viewed in cross section: Flat, domed, convex.[5–7]

Gram Stain

After streaking microorganisms on a solid media so that individual colonies are obtained, the first test routinely performed is the Gram stain. A standard method is described in Chapter 4. After staining, the organisms are examined under a microscope and characterized by reaction (+ = purple, − = pink) and by morphology (cocci = spheres, bacilli = rods, spirochete = helix). While these morphologies represent the basic patterns, variations in shape exist.

Biochemical Tests

Once the Gram stain reaction has been ascertained, conventional biochemical testing is then performed. Organisms are suspended, usually in physiological saline, and then inoculated into test tubes containing chemicals and indicators, and incubated. The choice of chemicals will depend upon the results of the Gram stain. Other chapters in this book will describe the chemicals used to identify specific microorganisms. Following incubation, results are read and the identification of the organism is determined. These tests can consist of solutions of simple carbohydrates, which contain a dye that changes color with a change in pH; solutions of chromogenic substrates that change color when they are cleaved; or antibody tests that will specifically react to one organism. Tests can also consist of the extraction and identification of cellular components by chromatography.

Most laboratories no longer routinely perform conventional testing, but rely instead on commercial biochemical test systems. The trend over the past few years has been to use single biochemical tests in instances where a clinician already suspects the identity of the microorganism. While historically these tests used chromogenic or fluorogenic compounds such as the Oxoid™ O.B.I.S. PYR test for *Streptococcus pyogenes*, today, many of these one-step tests are immunologically based and will be discussed later.

Note: All websites accessed April 1, 2020.

Most of the time, the clinician will use one of several multitest commercial kits. These kits are all similar in that they contain many biochemical tests packaged together. The tests are inoculated with a suspension of a single microorganism, and incubated. Following incubation, the results of the tests are read and the identity of the organism is determined. For example, the API 20E strip (bioMerieux, Inc.) is used for identifying Gram-negative bacilli. After incubation, positive and negative results are obtained for each chemical test and are used to generate a seven-digit code number. The company's database then uses this number to determine the microorganism. Table 10.1 lists several of commercially available kits, as well as websites for the companies that supply them.

While commercial manual tests are easier than conventional tests, they are still labor intensive and cumbersome in high-volume laboratories. Since the mid-1980s, instruments have been introduced to perform as much of the work as possible. Instruments can perform the inoculation, incubation, reading, and determination of steps automatically. Table 10.1 also lists some of the commercially available systems. Ohara has written an excellent in-depth review of many of these systems.[8]

In addition to bacteria and fungi, viruses can also be identified using culture techniques. This is usually performed by inoculating samples of suspected virus into cultures containing specific cell lines instead of into tubes of specific chemicals. Following incubation, the culture will then be examined for the presence of a distortion of the cell morphology called a cytopathic effect (CPE), which can be diagnostic for certain viruses. Alternatively, as described next in this chapter, the inoculated cells can be stained using specific antiviral immunofluorescent reagents and observed under the microscope. Specific cell cultures can be obtained from sources listed in Chapter 14.

Immunology-Based Assays

Agglutination Assays

Antibodies or antigens, depending upon the test, are attached to a solid support. The support can consist of latex, polymers (such as styrene), red blood cells, bacteria (coagglutination), charcoal, liposomes, or colloidal gold. The sample is added, and, if present, the analyte binds to the corresponding molecule on the support. The support molecules then form a lattice, which is visible as a clump. The tests can be direct or indirect. A direct test is one in which the clinician is attempting to detect a pathogen in the sample. An indirect test is one in which the clinician is looking for the body's response to a pathogen (e.g. an antibody). In a direct test, an antibody is bound to the support. In an indirect test, an antigen (or an antibody) is bound to the support.

Figure 10.1 shows an example of a direct and an indirect test. Tests for identifying common pathogens are available from many commercial suppliers. There are also several suppliers for latex particles for researchers that wish to develop their own tests. Practical information for binding molecules to inert particles can be found at the website of Bangs Laboratories (www.bangslabs.com, accessed April 1, 2020).

Antibody Labeling Techniques

An antibody is labeled with a tag. This tag can be an enzyme, a fluorescent molecule, a radioactive element, or even a colored particle such as latex or gold. As stated previously, tests can be direct or indirect. Figure 10.2 shows an example of an enzyme immunoassays (EIA). This test is carried out on a solid matrix; the most frequently used is the plastic microtiter tray. The analyte is specifically trapped on the matrix by using either an antibody (direct test) or an antigen (indirect test). The matrix is then washed and the labeled antibody is added. Following another washing step, the label is then detected. In EIA or enzyme-linked immunosorbent assays (ELISA), the label is detected by adding a substrate and observing the formation of a color. In fluorescent immunoassays (FIA), the label is detected using a fluorimeter. In radio immunoassays (RIA), the label is detected using a Geiger or scintillation counter.

Enzyme Immunoassay Generations

Diseases such as AIDS and hepatitis C have prompted the need for rapid, easy-to-use tests to identify people that are unknowingly infected before they inadvertently spread the disease. Several generations of tests have been developed over time as technology and information about the diseases improved. In the

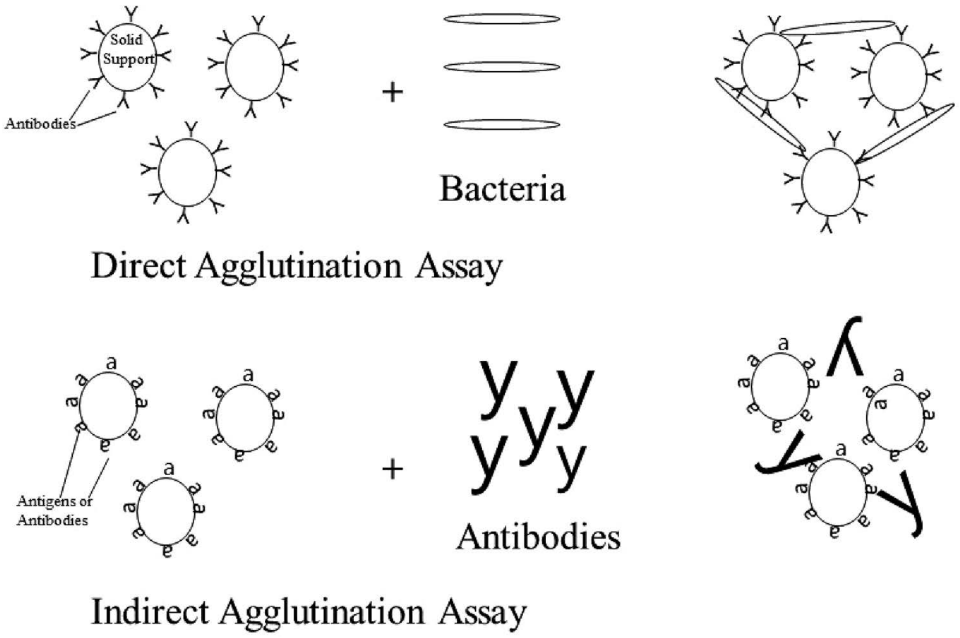

FIGURE 10.1 Agglutination assay.

case of AIDS, the first generation of test looked only for IgG molecules generated in response to infection by the HIV-1 virus. AIDS was later found to be caused by both HIV-1 and HIV-2, and as a result, second-generation tests looked for IgG molecules generated in response to both viruses. Since detectable levels of IgG antibodies might not appear for weeks after the initial infection, the third generation of AIDS tests detected both IgG and IgM molecules generated as a result of infection by both HIV-1 and HIV-2. Fourth-generation tests followed, which not only tested for the antibodies, but also had the sensitivity to simultaneously test for the HIV p24 antigen as well.[9,10] Recently a fifth-generation test was introduced, which not only tested for antibodies and the HIV p24 antigen, but reported separate results for both HIV-1 and HIV-2 antibodies and antigens.[11] Fourth-generation tests are

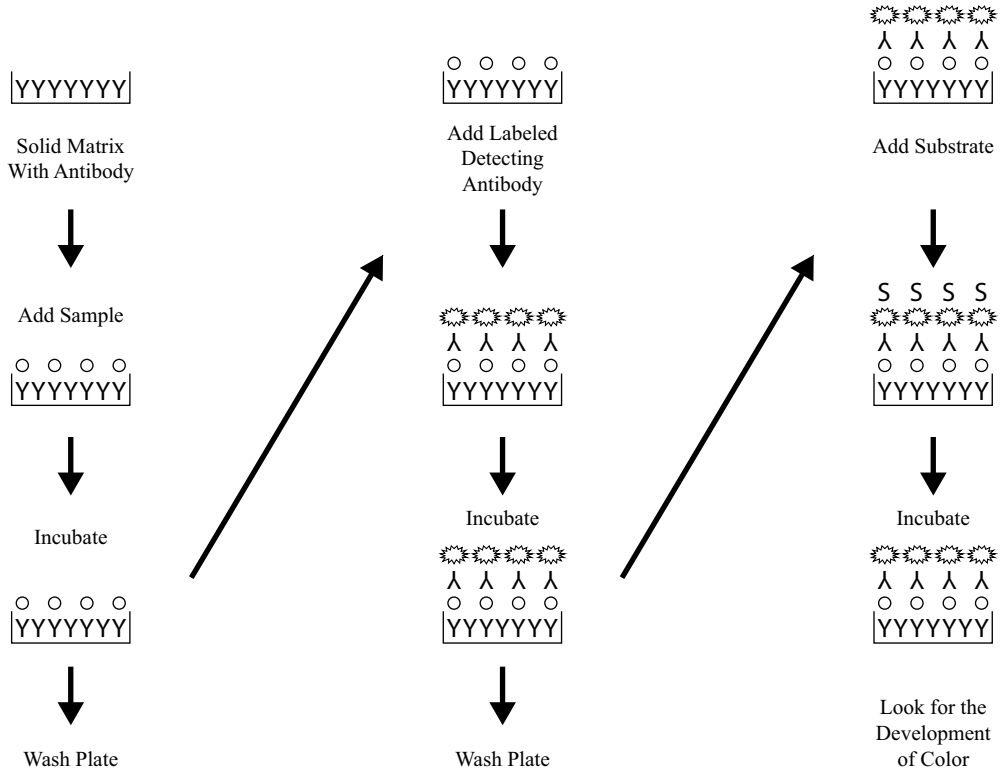

FIGURE 10.2 Steps of an enzyme immunoassay.

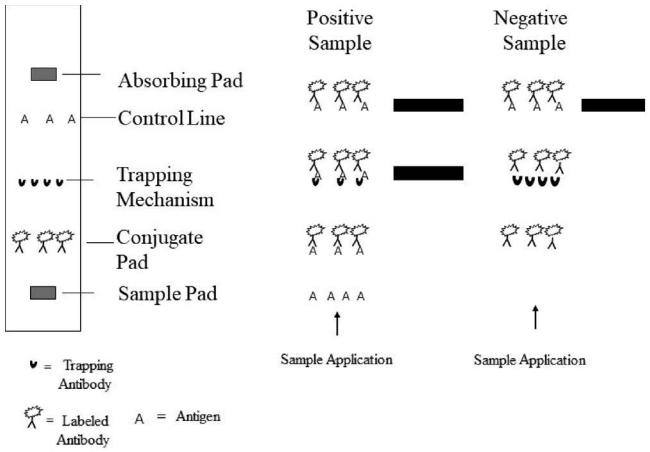

FIGURE 10.3 Lateral flow assay.

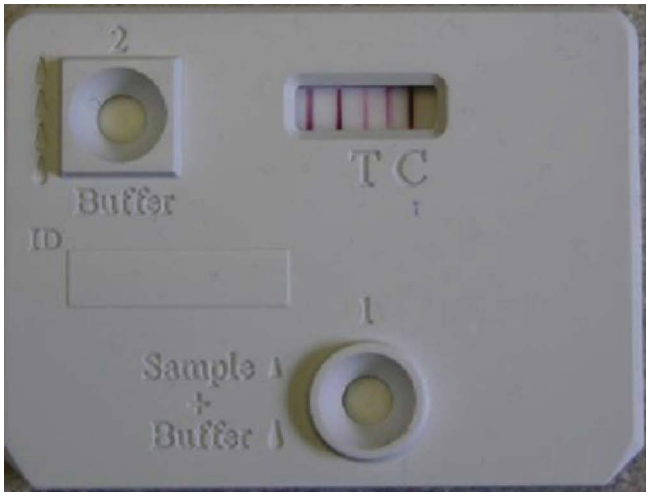

FIGURE 10.4 Dual Path Platform.

also available for hepatitis C virus detection.[12,13] In recent years, labeled antibody assays have been improved with the introduction of lateral flow assays (see Posthuma-Trumpie et al.[14] for a review).

As shown in Figure 10.3, the lateral flow test consists of a strip with several components printed on it. First, there is the conjugate pad, which contains the labeled antibody. There is also a line of trapping antibody and, finally, a control line containing the analyte being assayed. The sample is added and moved through the conjugate pad by capillary action. If the sample contains the analyte, it will bind to the labeled antibody conjugate and pull it forward as it migrates down the strip. When this labeled complex encounters the trapping antibody, if the analyte is present, the complex will bind, forming a colored line. To allow for a positive control, these tests are designed to have an excess of labeled antibody. As the front continues to flow, this excess labeled antibody will bind to the analyte in the control line. If the analyte is present, two lines will be visualized; if the analyte is absent, only the control line will be observed. There are two major ways of visualizing the lines. In one type of test, the antibody is labeled with an enzyme and the line is visualized after a substrate is added. In another type of test, the antibody is labeled with colored markers (such as latex or gold particles) and can be viewed without any additional steps.

A variation of the lateral flow assay is the Dual Path Platform (DPP™). As shown in Figure 10.4, the sample and conjugate have independent flow paths, which allows for greater sensitivity and the ability to identify multiple analytes in a single sample (see www.chembio.com, accessed April 1, 2020, for full description of the technology.)

Antibody Technique Variations

Second antibody. This procedure is used to increase sensitivity, and to minimize the number of labeled antibodies that the lab must maintain. The steps are as described in Figure 10.2, except that the "detecting" antibody is unlabeled. After this antibody has bound to the analyte, it is detected by using a generic labeled second antibody prepared in a different species. For example, individual unlabeled antibodies to separate microorganisms can be prepared in a rabbit. These rabbit antibodies can be used to bind the pathogen in the plate as in Figure 10.2. If one now adds a labeled antirabbit immunoglobulin antibody prepared in another animal, such as a goat, this will bind to the rabbit antibodies and be detected. Since there are many more sites to bind, this will also increase the sensitivity of the assay.

Another advantage of this technique is that this single reagent can be used to detect any antibodies produced in a rabbit. As a result, a laboratory can produce rabbit antibodies to an entire array of pathogens, but only need produce the single labeled antirabbit immunoglobulin antibody to detect them.

Enhanced EIA. This is used to increase sensitivity. The steps are as described in Figure 10.2, except that the first antibody does not produce a colored end product, it produces a substrate for a second antibody. This second antibody now reacts with an increased amount of substrate and produces the colored end-product.

Biotin avidin. Biotin is a vitamin that can be bound to an antibody and which also has a strong affinity for the glycoprotein avidin. After the antibody has bound to the analyte, it is detected by adding an avidin molecule that has been labeled with an enzyme. Upon adding the substrate, a colored end-product is produced.[15] This variation is used to increase sensitivity and provide a system where multiple analytes can be detected using only a single labeled reagent.

Magnetic beads. Antibodies to analytes of interest are bound to magnetic beads. These are placed into a suspension of the sample. After the antibody has bound to the analyte, the beads can be extracted by use of a magnet and the extracted analyte can then be tested. Some researchers have reported being able to treat the beads so that they can be reused; saving both antibodies and costs.[16] This technique has also been used to isolate specific microorganisms from complex mixtures that can then be tested using antibody assays or PCR.[17,18]

Neutralization. This is a technique that is usually used to detect low levels of antibody in a patient's serum. A known amount of antigen is bound to a solid support. A labeled antibody is then added, and the amount of the end-product is recorded. Following this, the procedure is repeated, but increasing amounts of the patient sample are mixed with the labeled antibody. If the patient

sample contains an antibody to the antigen, it will compete with the labeled antibody and reduce (neutralize) the amount of end-product detected. The clinician can calculate the level of antibody in the patient's blood by noting the quantities of patient sample and the decrease in end-product.

Slide tests. Labeled antibodies can also be used to specifically stain pathogens on a slide. One type of very sensitive assay is the direct fluoroimmunoassay. In this procedure, the sample is fixed to a slide and then the slide is incubated with a fluorescently labeled antibody. Following a washing step, the slide is viewed under a fluorescent microscope. If the analyte is present, fluorescence will be observed. This test can be used to detect viruses growing in cell culture.

Many of the companies listed in Table 10.1 also supply antibody-based tests. Suppliers of specific antibodies as well as contracting services can be found at the website www.antibodyresource.com (accessed April 1, 2020).

Nucleic Acid Probes

A labeled DNA probe that is complementary to a specific sequence in the organism of interest is synthesized. This probe is added to the sample and allowed to anneal. Following a washing step, the sample is assayed for the presence of the label. As with antibodies, the label can be a radioactive molecule, an enzyme, biotin/avidin, or a fluorescent molecule. Labeled probes have also been used to identify species on the bases of their ribosomal RNA sequences. Figure 10.5 shows an example of the use of a DNA probe.

A disadvantage of this technique is that many DNA sequences used to identify an organism may only occur once in the genome. As a result, there are usually only limited molecules to detect.

Sample Amplification Methods

Polymerase Chain Reaction

To begin, a specific region of DNA is copied exponentially. The DNA is amplified by supplying primers flanking the region of interest, nucleotides, and DNA polymerase, and allowing them to undergo many rounds of replication. Usually, the polymerase that is used is the one derived from the thermophilic bacterium *Thermus aquaticus* (Taq polymerase). Since the enzyme is heat-resistant, this allows multiple cycles of the replication to take place without having to constantly add fresh polymerase. Figure 10.6 shows the basic steps. After the first round, there will be four strands. In addition to the original two strands, there will be one strand which will be missing the bases at the 5' end, and one missing them at the 3' end. After the second round of replication, strands that contain only the area of interest will have been produced. In subsequent rounds, these strands will be produced exponentially. Cycle times of 15 minutes are now possible, meaning that in 8 hours, the region of interest can be multiplied millions of times.[19] Once the DNA has been amplified, specific probes can now be used to detect the pathogen. While the steps are fairly standard, different types of DNA may necessitate variations in the temperatures and in the times of incubation. In many instances these parameters must be determined by the investigator. Protocols for performing PCR can be found at http://www.protocol-online.org/prot/Molecular_Biology/PCR/index.html (accessed April 1, 2020).

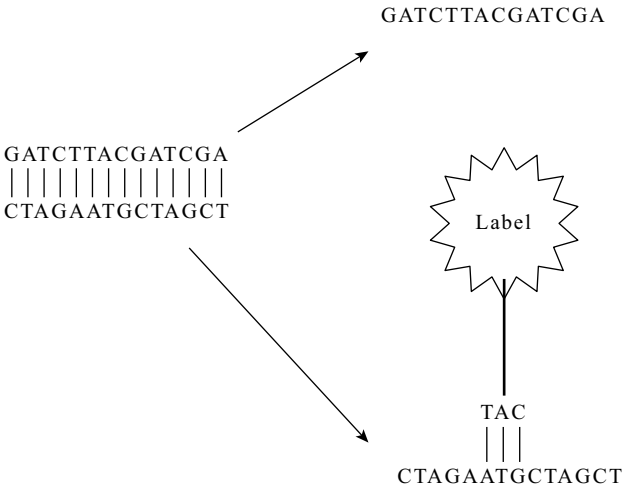

FIGURE 10.5 DNA probe.

Real-Time PCR

In recent years, the trend has been to detect the nucleic acid sequence, as it is replicated in real time. Two examples of commercial systems are the Light Cycler® and Taqman®.

Taqman

Similar to conventional PCR, but in addition, a small probe is annealed to the amplicon. This probe has a fluorescent molecule at one end, and a fluorescent quencher at the other. As replication takes place, the Taq polymerase, in addition to adding bases to the primer, also uses its nuclease activity to destroy the probe. When the probe is destroyed, the fluorescent molecule is freed from the quencher, which results in fluorescence that can be measured.

LightCycler

In addition to the primers that are used in the standard PCR protocol, two additional fluorescent probes are also included with LightCycler. Each fluorescent probe hybridizes to the same strand of DNA being copied, but contains a different fluorescent molecule. Both fluorescent probes are incorporated as the amplicon is synthesized. To detect them, light is directed at the sample at a wavelength that excites the first fluorescent molecule. When the first molecule is excited by this wavelength, it fluoresces at a second wavelength. This wavelength will only excite the second molecule if it is on the same strand of the copy. When the second molecule is excited, it fluoresces at a third wavelength. The instrument then detects the third wavelength. Light at the third wavelength will only be detected if the amplicon contains both probes.

Information about Taqman can be found at: www.lifetechnologies.com (accessed April 1, 2020)

Information about LightCycler can be found at: www.roche-applied-science.com (accessed April 1, 2020)

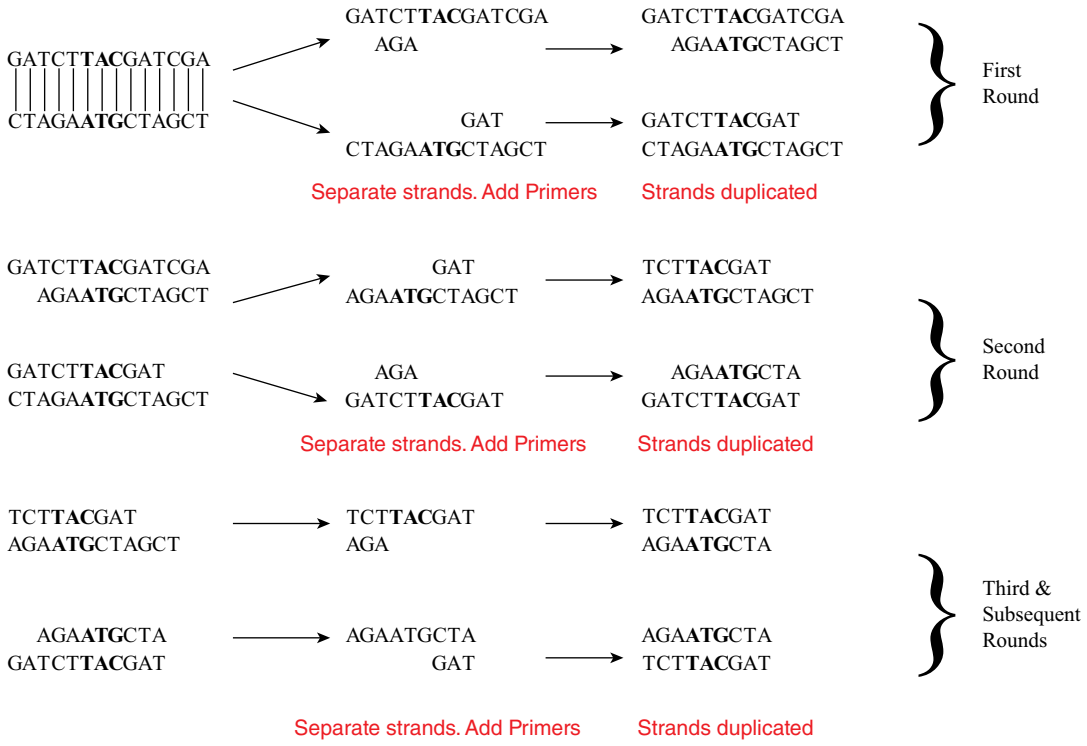

FIGURE 10.6 Polymerase chain reaction.

Variations of PCR

Nested PCR. Amplification occurs in two steps using two different primer pairs. This can increase the sensitivity and specificity of the PCR reaction.[20,21]

Hot start PCR. The PCR mixture, except for one ingredient, is kept at temperatures above the nonspecific binding threshold. The missing component is then added and cycling begins at an elevated temperature. This reduces nonspecific binding.[22]

Multiplex PCR. Several probes are used at one time. This technique can be used to distinguish multiple organisms in a single sample. This helps overcome the expense of having to test a single sample, such as a sputum, with assays for several different microorganisms that might be present.[23]

Random amplified polymorphic DNA. Random primers are used for PCR in a sample. Following replication, the amplified products are separated by size using gel electrophoresis. Patterns obtained from different samples are compared. This can be used to identify similar organism biotypes.[24]

Fluorescent amplified-fragment length polymorphism. Genomic DNA is specifically cut in a limited number of locations, using restriction endonucleases. These fragments are then ligated to double-stranded oligonucleotides. Fluorescene-labeled primers are then added, and several cycles of PCR are run. The labeled fragments are separated on a gel, by size. Different strains of an organism will give different patterns of fluorescent bands, which can be used as a fingerprint.[25]

Ligase Chain Reaction

The steps in ligase chain reaction (LCR) are similar to PCR. Oligonucleotide primers are constructed, but in LCR, the four primers actually flank the gene on both sides of each strand. The sample is heated to denature the DNA and then cooled to allow the probes to anneal to their complementary strand. Ligase is added and fills in the gaps between the two primers, but only if they are aligned. As the reaction proceeds, the newly formed ligated primers, as well as the initial DNA, can now be used as templates. This leads to an exponential replication of the DNA region of interest.[26]

Nanoparticle-assisted PCR. An innovative technique in which nanoparticles are used in the PCR reaction. Their presence reduces the time required to reach the target temperature and thus lowers the time per PCR cycle.[27]

Reverse transcription PCR. In this variation, the enzyme reverse transcriptase is used to make cDNA copies from RNA. This DNA is then amplified using PCR. This technique is useful for identifying RNA viruses, and also for identifying regions of the genome being transcribed.[28]

Other Sample Amplification Methods

Amplicor™. A specific DNA primer is first annealed to a target RNA molecule. An enzyme with both DNA polymerase and reverse transcriptase activity is then used to complete the complementary DNA copy, using this cDNA as a template. PCR is then carried out, using biotinylated primers. The biotinylated amplicon is then bound to a specific probe coated microwell. The amplicon is detected using an avidin-HRP conjugate, which yields a colorimetric result.[29,30] Commercially developed by Roche Molecular Systems.

Reverse hybridization. A series of probes are placed on an inert support. The organism DNA is labeled and hybridized to

the support. The label will be visible in areas where there is homology between the organism and the probe and this information is used to identify the organism. Reverse hybridization is especially useful in epidemiological studies in which one is trying to identify organism biotypes. Reverse hybridization and PCR are frequently combined to produce tests to identify species or even strains of microorganisms.[31]

One of the disadvantages of PCR and technologies that employ it is that it requires expensive thermocycling equipment to amplify nucleic acids. The newer techniques described next are all isothermal.

Transcription-mediated amplification (TMA). In TMA, RNA polymerase and reverse transcriptase are used to amplify RNA to produce a DNA copy. A double-stranded DNA molecule is then synthesized and used for transcription to produce new RNA copies of the original sequence. The most recent version of TMA can also amplify DNA. Commercially developed by Hologic (see www.hologic.com, accessed April 9, 2020).

Nucleic acid sequence-based amplification (NASBA). The process uses reverse transcriptase, RNA polymerase, and RNase H to amplify RNA molecules.[32] It is also isothermal. Molecular beacons are now being used to perform real time NASBA.[33] Commercially developed by Biomerieux Organon/Technika.

Strand displacement. This is a technology that involves using a restriction endonuclease to create a nick in a DNA molecule. Polymerases and primers are subsequently used to continuously produce new strands downstream from the site of the nick. As each new strand is started, it replaces the one that had been previously been created.[34]

Other methods of sample nucleic acid amplification include reverse transcription loop-mediated isothermal amplification (RT-LAMP)[35]; rolling circle replication (RCR),[36] and helicase-dependent amplification (HDA).[37]

Signal Amplification Methods

Branched-Chain DNA

Unlike the technologies discussed earlier in this chapter, this technology increases assay sensitivity by amplifying the signal molecules in a reaction. As described in Figure 10.7, a trapping sequence is immobilized on the bottom of a microtiter tray. The sample is added and hybridizes to it. An extender sequence, which is complementary to the sample and to an arm of the amplification molecule, is then added and allowed to hybridize to the sample. An amplification molecule with many branches on it is then added and hybridizes to the other side of the extender sequence. In the next step, enzyme-labeled sequences that are complementary to the chains of the branch are added. Multiple numbers of these will hybridize with the amplification molecule and, in the final step, the label is detected. These assays are frequently used to estimate viral load in HIV and HCV infection.[38]

Hybrid Capture

This technique was originally developed to test for the presence of DNA from papilloma virus in cases of cervical dysplasia.[39] In this technique, RNA probes for the pathogen are added to the sample. If the pathogen is present, an RNA-DNA duplex is formed, which is then added to a microtiter plate with a trapping mechanism that captures RNA-DNA hybrids. Following this, a chemiluminescently labeled antibody specific for RNA-DNA duplexes is added. Following the washing steps, the chemiluminescent reagent is added and the duplex is detected. Commercial systems are available from Quiagen, Inc. (www.qiagen.com, accessed April 1, 2020).

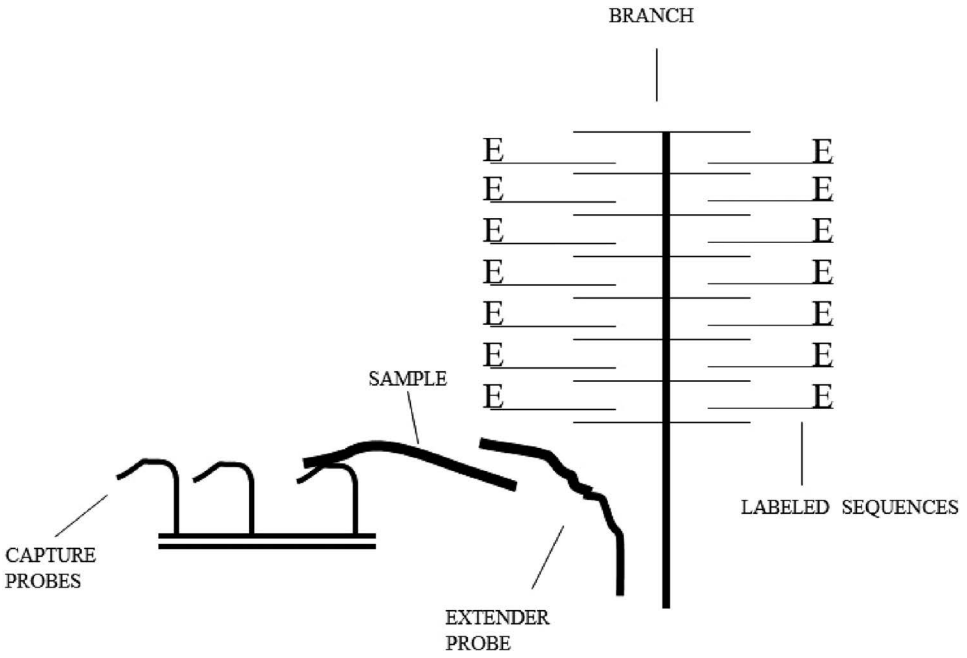

FIGURE 10.7 Branched-chain reaction.

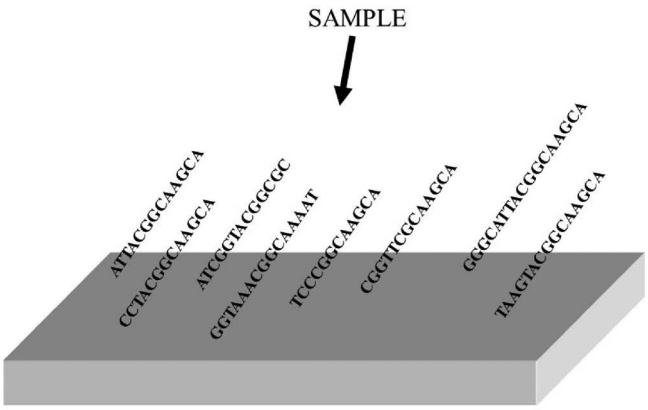

FIGURE 10.8 DNA microarray technology.

DNA Microarray Technology

DNA microarray technology refers to a technique in which hundreds or thousands of oligonucleotides are attached to a solid support (Figure 10.8). The sample DNA or RNA is then hybridized to the support. Following this, sites of binding are detected. Information can be found at http://www.genome.gov/10000533 (accessed April 1, 2020). This technology has been used in detecting genetic variations among a single species of microorganisms[40] and in trying to identify multiple pathogens from a single isolate.[41] Currently labeled nucleic acids are used to identify points of hybridization. However, newer techniques using biosensors may eliminate the need for labels.[42,43]

The advantages and disadvantages of this technology have been reviewed by Lupo et al.[44]

Electrophoresis

This is a method based on separating proteins or nucleic acids from microorganisms based upon their charge (Figure 10.9). A support matrix, usually a gel (acrylamide or agarose) or acetate strip, is prepared and the sample, prepared in an appropriate buffer, is placed in or on the support. When a current is applied, charged molecules in the sample will migrate at a speed relative to their charge. There are variations of this technique that create a chemical environment in which the molecules can also be separated by size or isoelectric point. Following electrophoresis, the support is stained and specific molecules can then be identified based on how far they have migrated. Alternatively, the molecules can be removed from the support by blotting onto an absorbing media and used for further analysis.[45]

Polyacrylamide Gel Electrophoresis (PAGE)

Microorganism proteins are run in the support and stained. Coomassie blue and methyl green are commonly used. Specific protein bands are identified.

Two-Dimensional Gels

The support matrix is subjected to an electric field, and then rotated 90° and run again. This provides much greater resolution.

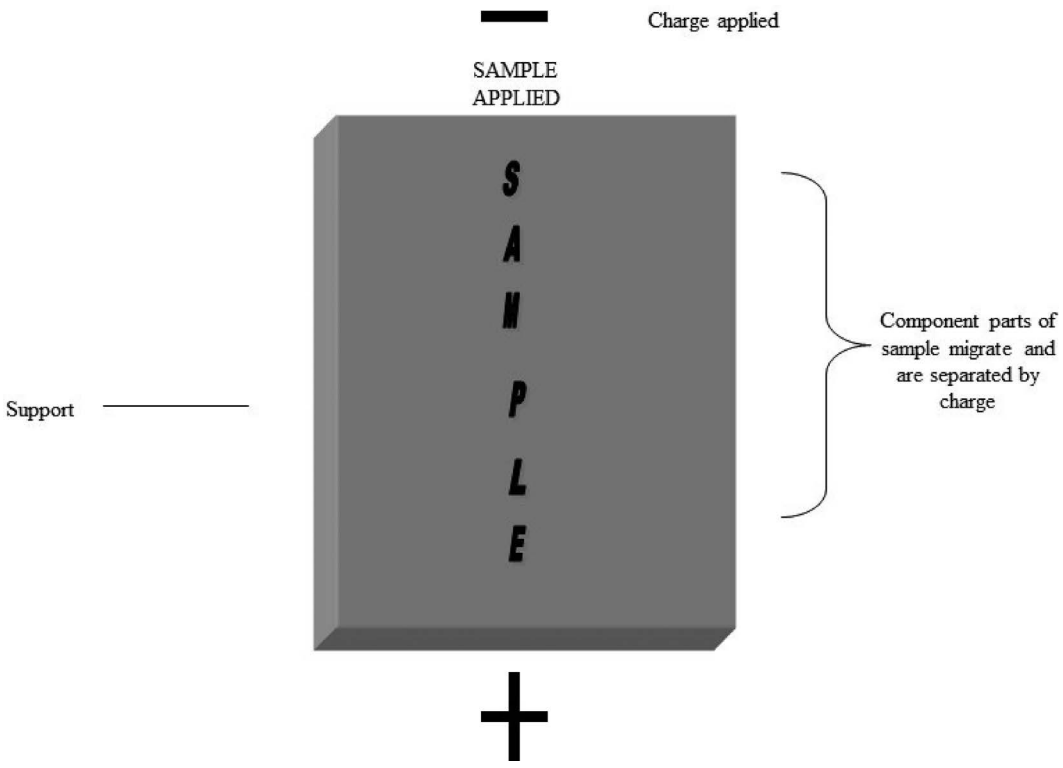

FIGURE 10.9 Electrophoresis.

Pulse Field Gels

The support matrix is alternately exposed to electric fields in varying directions. The advantage of this technique is that it can be used for very large molecules. It is useful in identifying the sources of hospital-acquired infections.

Southern Blots

Microorganism DNA is digested using restriction endonucleases and is then run in the support. Following this, the material in the gel is transferred to either a nitrocellulose or nylon sheet. Staining the sheet with a DNA-specific stain or by hybridizing a labeled specific DNA probe, can then identify bands.

Northern Blots

Similar to Southern blot, except that the sample that is run is RNA. Bands can be identified by staining or by using labeled DNA probes.

Western Blots

Proteins are run and bands are stained using labeled antibodies. This is a confirmatory test in HIV testing.

The previous chapter summarized many of the now classic technologies and methods being used to identify microorganisms in the laboratory today. Some of these can trace their lineage as far back as the 19th century. They allowed a very simplistic approach to identifying microorganisms, and more specifically those that caused disease. Koch's postulates, espoused in the 1870s, held that diseases were caused by a single species of microorganism, which could be isolated, grown, and then be used to infect an animal and cause the same disease.[1] With the advent of molecular biology in the 1980s and 1990s, newer methods started finding their way into the clinical laboratories and began challenging that concept. The challenge was brought about because technologies used to identify microorganisms changed from those that used phenotypic markers, such as the presence or absence of an enzyme or specific antigen, to those that used genotypic markers, such as the use of specific nucleic acid sequences.

The advent of 21st-century technologies, such as next-generation sequencing and metagenomics, has challenged that concept even further. The result has been that our understanding of what constitutes a bacterial species, as well as their role in causing disease or affecting the environment, has changed dramatically in just the past few years. The suspected organism identified by Koch's postulates may represent only one of hundreds of genomes that may be present. Disease may not simply be caused by the actions of one organism but may depend upon many complex interdependent interactions in a microbiome. As this book goes to press the world is dealing with a coronavirus pandemic. While the situation is still developing, researchers using modern technologies have found that there are thousands of different genomic combinations associated with the disease.[2] Future research may find that this explains the different outcomes that have been reported.

Matrix-Assisted Laser Desorption Ionization-Time-of-Flight Mass Spectrometry (MALDI-TOF MS)

The application of mass spectrometry to microbial identification has led to the development of instruments that can identify microorganisms directly from a patient sample in a short amount of time. The technique requires 10^4 to 10^6 CFU, so current attention has been focused on samples that are likely to have these numbers, such as positive blood culture bottles and urine samples. The technology also allows for the rapid identification of organisms grown on culture plates.

In the first step of the protocol, the sample is extracted to remove extraneous materials and then is placed on a target plate. Next, a matrix solution composed of a small organic molecule such as 2,5-dihydroxybenzoic acid or ferulic acid is added and allowed to dry.[3] The sample is then exposed to short pulses of high-intensity laser beams. The net effect of this exposure is to ionize the proteins in the sample. Ionized ribosomal proteins appear to provide the best source of information for organism identification. These ionized proteins are then subjected to an electromagnetic field that separates them based on their size and charge. Each microorganism produces its own unique pattern of ionized proteins. When an unknown sample is placed into the test instrument, the pattern that is generated can be compared to a library of patterns produced by known organisms.

Studies have found that the accuracy rate in identifying common organisms using MALDI-TOF was comparable to that obtained using automated instruments based on biochemical tests. The rate was even better for less common isolates.[4]

Since identification using MALDI-TOF does not require that the organism either grow or metabolize many biochemicals, it is much faster, less labor intensive, and less expensive than identification systems based on biochemical testing.[5]

Currently, there are two commercial MALDI-TOF instruments in the clinical microbiology market: the VITEK® MS Biomerieux and the Bruker Microflex, both of which were given FDA approval in 2013.

Next-Generation Sequencing

Perhaps the greatest advances in the microbiology laboratory in the past 10 years have been in the field of DNA sequencing. In 1977, Sanger developed a method of sequencing DNA.[6] The first step of the process used enzymes to cut the sample DNA

into fragments. The strands of these fragments were then separated and used as templates for DNA replication using DNA polymerase and nucleotides. Four polymerization chambers were used and a specific dideoxynucleotide analog of either G, C, T, or A was added to each chamber. These analogs inhibited polymerization. Polymerization would proceed until the analog was added. As a result fragments of different lengths were generated in each chamber. These fragments were then run on gels and separated by size. By noting the different fragment lengths generated in each of the chambers, one could determine the sequence of the original fragment. This method worked well for DNA fragments up to as many as 900 bases. By using different restriction endonucleases, overlapping fragments would be generated and the genome sequenced. While very useful, this method was time consuming, required specialized equipment, and required large numbers of DNA strands in the original sample. In addition, the steps of polymerization and detection were two different processes.

Next-generation sequencing (NGS) of bacterial genomes emerged with the whole genome of *Mycoplasma genitalium*, which was sequenced by 454 pyrosequencing in one run in 2005[7] and a human genome[8] relatively soon after. Other techniques soon followed. Among these are Illumina (Solexa) and Ion Torrent:Proton/PGM sequencing. These second-generation methods differed from the Sanger technique in that they combined both the polymerization and detection steps.[9] They do, however, all have the same basic steps. After cutting the DNA into fragments, one strand of the fragment is bound to a support. DNA polymerase and labeled nucleotides are then added to the sample. As a nucleotide is incorporated during polymerization a signal is observed. In this way sequencing is done quickly in real time. The techniques differ in how they are immobilized, and how nucleotide addition is detected.

The demand for high throughput, and low cost per base, has meant that the sample DNA must be cut into short fragments. These are usually 150 bases or fewer.[10] Using fragments of this length means that it is difficult to try and match overlapping fragments. This problem has been partially solved by using huge computing power and innovative software development. Thus, the prediction that sequencing the human genome can be done for $1,000[11,12] will also entail performing a $100,000 analysis. This analysis will be required even in the field of smaller and simpler prokaryotic genomes.[13]

An in-depth tutorial of second-generation sequencing can be found at: https://www.ebi.ac.uk/training/online/course/ebi-next-generation-sequencing-practical-course/what-you-will-learn/what-next-generation-dna- (accessed October 23, 2020).

Sequencing, which can produce long-read, usually single molecules, and often real-time sequencing, has the potential to overcome many of the problems of short-read sequences and add new analytical strategies. Referred to as both long-read and third-generation sequencing, these technologies initially came with the downsides of lower throughput, higher cost, and much higher error rates. Equally, many of the bioinformatic tools for data analysis developed for short-read sequencing were inappropriate for long-read, high-error sequence data.

PacBio, the most mature technology,[14] is based on picoliter-sized wells, each containing a single polymerase. The sequence of a single DNA molecule is detected, in real time through the transparent well bottom (zero-mode waveguide) by fluorescence, and induced as each fluorescent-labeled base is incorporated. Initially, PacBio came as a very large sequencer with read lengths around 1–2 kb, and an error rate about 13–14%.[15] Currently, Wenger et al. achieved ~2 Gb per SMRT cell using an accurate circular consensus (CCS) long-read sequencing protocol, which achieved an average read length >13.5 kb with 99.8% accuracy.[16] CCS in which hairpin adapters are ligated to both ends of double-stranded DNA and the circularized DNA molecule is sequenced multiple times, sacrifices read length for multiple rounds of sequencing across a single fragment, and typically gives ten copies of 2 kb fragments, limited by the processivity of the sequencing DNA polymerase.[17] Wenger et al. noted increasing read lengths >100 kb and exploited this to achieve much longer reads.[16] However, the impact on prokaryotic sequencing is revealed by the increasing number of complete bacterial genomes based on combined PacBio and Illumina sequencing in the databases.

Another long-read technology, nanopore sequencing, is based on a completely different paradigm, both in size, sequencing technology and commercial introduction. In nanopore sequencing, single-strand DNA is driven through a membrane-embedded open pore with a transmembrane voltage; the flow of ions through the pore is measured as ionic current by a pico-current amplifier. The ion current trace (known as a squiggle) is then translated to base sequence.[18]

The initial experience with this technique was somewhat underwhelming. Mikheyev and Tin found 5 kb average read length and about 150 Mb data on the $1,000 MinION from the MinION Access Program, and cited less than 50% read identity, 16× coverage resequencing the 48 kb lambda phage standard DNA.[19] However, over the last 5 years, the development of the MinION has followed the trajectory of third-generation sequencing with dramatic gains. Currently, library preparation from high-quality, high-molecular-weight DNA can be achieved in a few minutes, with transpososome adapter, and barcode attachment. Yields of 20–30 Gb are expected (but not always achieved) from a single-flow cell, at least using the longer ligation-based library preparation. The current record for sequence length of a single read is almost a million bases[20] or longer, 2 Mb,[21] with bases translocated through the pore at speeds of 450 bases/second. Direct sequencing of RNA is underway and direct determination of methylated bases is possible.[22] With sufficient coverage and postanalysis nanopolishing of the signal-level reads in the whole genome assembly of *Escherichia coli*, Loman et al. resequenced the full genome *de novo* with 99.5% identity to the reference.[23]

Metagenomics

The ability to perform rapid nucleic acid sequencing, combined with the fields of genomics and microbiology, has led to the birth of metagenomics. It is both a technique and a field of study.[24] In a very simplified description, total DNA is extracted from all of the organisms in an environment (i.e., Rondon et al. described performing a metagenomics study on a soil sample).[25] The DNA is then processed and cut into fragments using a restriction endonuclease.[26] Fragments are then placed into a plasmid, which as

the bacterial artificial chromosome (BAC) might be specially constructed.[27,28]. Following transformation, isolates containing the fragments are cultured and screened for various markers. These might be specific enzymes, or more commonly, the DNA coding for 16S RNA. The fragments are purified and then amplified using PCR, after which they are sequenced. At this point, very intricate software programs are used to establish total organism genomes. This is a daunting task, as samples might have millions of different DNA fragments from thousands of different species.[25]

Metagenomics has allowed scientists to identify microorganisms in a sample that cannot be cultured. Estimates are that in soil samples up to 99% of species may not be culturable.[24] This number is probably equally as high in clinical samples.[29] In addition, it has given scientists the ability to not only study specific genomes, but also see how those genomes might interact with each other in a biome. For a full review of metagenomics see Breitwieser et al.[30]

Metagenomics in the Clinical Laboratory

Traditionally, after a sample arrives in the clinical microbiology laboratory, it is incubated in various media and under different conditions, depending upon the sample source. Following isolation, organisms are identified by looking for phenotypic traits, such as the presence of specific enzymes or other molecular markers. This allows them to then be classified by genus and species. Since these traits are one level removed from DNA, this system is actually classifying microorganisms in a very gross fashion. As a result, organisms are always being renamed and moved from one taxa to another. (See Chapter 17 for a full description)

The introduction of metagenomics into the clinical microbiology laboratory has been a mixed blessing. While it has allowed clinicians to very rapidly identify a pathogenic microorganism in a patient sample without the need to either culture or do traditional biochemical tests, it has also added a great deal of expense, and with routine samples, has not provided much additional information that can be used in treatment. As described previously, clinical microbiology is still very much guided by Koch's postulates. A sample is taken, processed in the standard manner, and a genus and species are determined. This information is then used to treat the patient. This system, which has worked well for more than a century, is based on the premise that the concept of a defined species is valid for bacteria. Metagenomic studies are demonstrating that this may not be true. Assigning a genus and species name to *E. coli* may not be as valid as *Felis catus* is for the cat or *Canus lupus familiaris* is for the dog. In the case of a routine clinical sample, urine for example, the patient is best served by being told that they have an *E. coli* infection and receiving appropriate treatment. Being told that their infection might be caused by multiple subvariants of *E.coli*, some of which might no longer be considered to be *E. coli*, does little to affect treatment, but adds greatly to the cost.[31]

All samples that come into the laboratory are not routine, however. Metagenomic studies are finding that the simple paradigm espoused by Koch does not apply to instances in which many interacting organisms in the biome may ultimately be responsible for causing pathogenesis. Ruppe et al. examined 24 samples of severe bone and joint infections. Metagenomic sequencing was especially useful in those instances in which the samples were polymicrobial and contained organisms that could not be cultured by conventional means. Furthermore, the information was used to infer the correct antibiotic susceptibility patterns in 94.1% of the monomicrobial samples and in 76.5% of the polymicrobial samples. This is clearly a technology still in its infancy, but one that will probably revolutionize treatment.[32]

Several commercial metagenomics instruments and services for the clinical laboratory are in development and a few are now commercially available (see Table 11.1).

Basic Principles of Antimicrobial Susceptibility Testing (AST)

The purpose of performing antimicrobial susceptibility testing (AST) is to provide *in vitro* data to help ensure that appropriate and adequate antimicrobial therapy is used to optimize treatment outcomes. In addition, the AST data generated daily can be statistically analyzed on an annual basis to generate an antibiogram that reflects the antimicrobial susceptibility and resistance patterns of important pathogens that prevail in a particular hospital. These hospital-specific AST epidemiologic data provide valuable guidance to the clinicians for the appropriate selection of empiric therapy, prior to the availability of culture and susceptibility results that often takes 2–3 days. The purpose of the AST of the culture pathogen is to help clinicians correct and/or modify empiric therapy as soon as the results become available.

Two basic methods of AST are available to laboratories: (1) qualitative and (2) quantitative. Qualitative methods, such as disk diffusion and abbreviated breakpoint dilution systems, are acceptable options for the testing of isolates from "healthy" patients with intact immune defenses and for less serious infections such as uncomplicated urinary tract infections. Both disk diffusion and breakpoint agar or broth dilution systems are considered satisfactory for predicting treatment outcome in these cases (Craig 1993). Quantitative systems that provide a minimal inhibitory concentration (MIC) value are more important in the treatment of serious infections such as endocarditis or osteomyelitis, and for infections in high-risk patient groups such as immunocompromised patients (e.g., transplant patients) and those who are critically ill.

Depending on the size of the workloads, personnel resources available, and issues of convenience, many clinical laboratories prefer to use one or more automated systems for AST regardless of whether results obtained are qualitative or quantitative. These systems handle the majority of the higher volume specimens, such as urines, and are usually supplemented with manual methods, such as disk diffusion and other MIC tests, to handle the limitations of automation as well as provide MIC results for different clinical situations (Jorgensen and Ferraro 1998). Clinical laboratories should continue to develop and improve their AST algorithms to include different types of test systems in order to provide meaningful and accurate data depending on the type of patient, source of specimen, organism species, and anticipated problems in detecting various types of resistance mechanisms.

Disk Diffusion

The principle behind the disk diffusion method, or "Kirby Bauer" test, is the use of a paper disk with a defined amount of antibiotic to generate a dynamically changing gradient of antibiotic concentrations in the agar in the vicinity of the disk (Bauer et al. 1966). The disk is applied to the surface of an agar plate inoculated with the test organism; and while the antibiotic diffuses out of the disk to form the gradient, the test organism starts to divide and grow and progresses toward a critical mass of cells. The so-called inhibition zone edge is formed at the critical time, where a particular concentration of the antibiotic is just able to inhibit the organism before it reaches an overwhelming cell mass or critical mass (Acar and Goldstein 1996). At the zone demarcation point, the density of cells on the growth side is sufficiently large to absorb antibiotic in the immediate vicinity, thus maintaining

the concentration at a subinhibitory level and enabling the test organism to grow. The critical times for the demarcation of the inhibition zone edge for most rapidly growing aerobic and facultative anaerobic bacteria vary between 3 and 6 hours, while critical times of fastidious organisms and anaerobic bacteria can vary from 6 to 12 hours or longer.

A density of approximately 10^8 CFU mL^{-1} (CFU = colony-forming unit) of the test organism in the inoculum suspension is used to obtain semiconfluent growth on the agar. The inoculum is prepared by suspending enough well-isolated colonies from an 18- to 24-hour agar plate in broth or physiologic saline (0.85%) to achieve a turbidity matching a 0.5 McFarland Standard. The Prompt™ (BD Diagnostic Systems, Sparks, MD) inoculum preparation system, which consists of a sampling wand and inoculum solution in a plastic bottle, can also be used to optimize workflow because the organisms are maintained at the same density for up to 6 hours. However, this system is not suitable for mucoid strains or fastidious organisms because the amount of cell mass absorbed onto the tip of the sampling wand may be insufficient to give the appropriate inoculum density. Furthermore, the inoculum solution contains Tween, a surfactant that can have potential antimicrobial effects on certain organism groups and can interfere with the antimicrobial activity of some classes of antibiotics. Colony counts of the inoculum suspension should be regularly performed to verify that the inoculum density is correct in terms of CFU mL^{-1}.

Because the disk diffusion is based on the use of a dynamically changing gradient, inoculum density variations can directly affect the critical times and influence the inhibition zone sizes, regardless of the susceptibility of the test organism. A heavy inoculum will shorten the critical time and lead to falsely smaller inhibition zone sizes, resulting in potentially false resistant results, while a light inoculum will cause the reverse effect and generate potentially false susceptible results.

The inoculum suspension should be used within 15 minutes of preparation. This is particularly important for fastidious organisms that lose their viability rapidly. A sterile cotton swab is dipped into the suspension and pressed firmly on the inside of the tube to remove excess liquid. The dried surface of the appropriate agar plate is inoculated by streaking the entire surface and then repeating this twice, rotating the plate 60° each time. This will result in an even distribution of the inoculum. The inoculated plate is then allowed to dry with the lid left ajar for no more than 15 minutes. Once the agar plate is completely dry, the different antibiotic disks are applied either manually or with a dispensing apparatus. In general, no more than 12 disks should be placed on a 150-mm agar plate or five disks on a 90-mm plate. Fewer disks are used when anticipating highly susceptible organisms.

Optimally, disks should be positioned at a distance of 30 mm apart and no closer than 24 mm apart when measured center to center, to minimize the overlap of inhibition zones. Most dispenser devices are self-tamping (disks are tapped or pressed onto the agar surface). If applied manually, the disk must be pressed down to make immediate and complete contact with the agar surface. Once in contact with the agar, the disk cannot be moved because of instantaneous diffusion of antibiotics from the disk to the agar.

Agar plates are incubated in an inverted position (agar side up) under conditions appropriate for the test organism. Plates should not be stacked more than five high to ensure that the plate in the middle reaches incubator temperature within the same time frame as the other plates. After 16–18 hours of incubation at 35°C for rapidly growing aerobic bacteria, or longer where appropriate for fastidious organisms or specific resistance detection conditions, the agar plate is examined to determine if a semiconfluent and even lawn of growth has been obtained before reading the plate. If individual colonies are seen, the inoculum is too light and the test should be repeated because zone sizes may be falsely larger. The same holds true for excessively heavy inoculum, where zone edges may be very hazy and difficult to read and zone sizes may be falsely small.

If the lawn of growth is satisfactory, the zone diameter is read to the nearest millimeter using a ruler or sliding calipers. For Mueller Hinton agar (without blood supplements), zone diameters are read from the back of the plate. For blood-containing agar, zone diameters are read from the surface of the agar. The zone margin, unless otherwise specified, is identified as the area in which no obvious visible growth is seen by the naked eye. Faint growth or microcolonies detectable only with a magnifying glass or by tilting the plate should be ignored in disk diffusion tests.

Reading of zone sizes can be simplified using automated zone readers that use a camera-based image analysis system such as the BIOMIC (Giles Scientific, New York, NY); Aura (Oxoid, Basingstoke, UK); Protozone (Microbiology International, Frederick, MD); or SirScan (i2a., France) (Korgenski and Daly 1998). The agar plate is placed into the zone reader instrument that is connected to a computer system. The system then reads the different zone sizes directly from the agar plate and converts the result to a susceptibility category interpretation using various zone-MIC interpretive guidelines in the software. Although zone sizes are automatically read, the user can intervene and adjust results. The BIOMIC system also converts zone sizes to MIC equivalents using a database of regression analyses based on the assumption of a linear correlation between the zone size and the MIC value. This may not always be the case, however, particularly for fastidious, slow-growing organisms.

The main advantages of disk diffusion testing are the simplicity, lack of need for expensive equipment, and the cost-effective and flexible choice of antibiotics for testing. The main disadvantage of the disk diffusion method is that the information is qualitative, providing only susceptibility category results. It cannot be used to compare the potential efficacy of different agents or to fine-tune the therapy by making dosage adjustments. The other disadvantage is the amount of technologist time required for setting up the test and for manually reading the zone sizes and then consulting the interpretive standards prior to the interpretation of results. Certain antibiotics can be problematic to test with the disk diffusion method due to specific physicochemical properties of the molecule. Glycopeptides such as vancomycin have a high molecular weight (1450) and diffuse very slowly in agar. The slow diffusion results in a poorly resolved concentration gradient around the vancomycin disk, and an inhibition zone size that differs by only a few millimeters between susceptible and resistant strains (CDC 1997; Walsh et al. 2001).

Quantitative Testing (Minimum Inhibitory Concentration)

In critical infections such as endocarditis, meningitis, osteomyelitis, or in the immunocompromised host, accurate quantitative

determination of the exact minimum inhibitory concentration (MIC) value of the infecting organism is crucial to guide choices of optimal therapy. In these situations, an MIC value of 0.016 μg mL^{-1} has significantly different therapeutic implications than does an MIC of 1 μg mL^{-1} in influencing the antibiotic choice and dose relative to factors such as body weight, potential drug toxicity, and drug concentrations at the site of infection (Craig 1993).

Broth Macrodilution, Microdilution, or Agar Dilution

Broth macrodilution and agar dilution methods are infrequently performed today. These techniques are predominantly performed in reference or research laboratories because they are not easily automated and require that the laboratory acquire and prepare stock solutions, perform dilutions accurately, and dispense the aliquots either into tubes with broth or agar medium. Quality control of the broth and agar dilution plates also needs to be performed to verify the quality of the reagents before they can be used for testing the clinical isolates. The limited stability of many antibiotic agents in broth and/or agar also necessitates the preparation of fresh reagents, which makes these methods very cumbersome and time consuming. The setup and reading of these methods also require significant experience.

Semiautomated or automated broth microdilution provided by commercial manufacturers is most commonly used in clinical laboratories. The various systems and instruments currently available include Phoenix (Becton Dickinson, Sparks, MD); Vitek and Vitek 2 (bioMerieux, St. Louis, MO); Microscan (Dade Behring, Sacramento, CA); and Sensititre (Trek Diagnostic Systems, Westlake, OH). The advantage of these instrument-based systems includes automation in reading and interpretation. Some of these systems even include automated setup and inoculation. Most systems have both a species identification and AST function. In addition, they include computerized systems for the interpretation of results, and a database "expert" system to help look for inconsistencies between the organism identification and the anticipated susceptibility patterns against multiple antibiotics. Predetermined panels with different types of antibiotics, and to some extent preferred dilution ranges, are selected depending on the requirements of the particular hospital. Most of these systems work well for rapidly growing routine organisms that form the bulk of organisms that are routinely tested (Evangelista et al. 2002).

Limitations may exist, however, that are associated with the resistance mechanisms. These include inducible and/or heteroresistances, testing of mucoid organisms, and slower growing and/or fastidious organisms. The primary underlying reason for these potential limitations is the combination of the use of a relatively small amount of the inoculum of the test organism and the shortened incubation time in the rapid same-day reading systems. The Vitek or Vitek 2 system is promoted as a rapid system with results available in as little as 4–6 hours for identification and slightly longer for susceptibility results. Inducible β-lactamases produced by Gram-negative aerobes such as *Enterobacter*, *Serratia*, and *Citrobacter* species can be difficult to detect, while resistance to cephalosporins may be falsely reported as susceptible in these automated systems. The Sensititre and MicroScan systems both use an "overnight" broth microtiter format. Results are read either automatically or manually after 18–24 hours of incubation. Both the Vitek and the Phoenix can only be read by the instrument. Sensititre can only be used for susceptibility testing and not for organism identification. It can be customized to provide specific panels for individual needs, however, particularly for small volume use.

Etest®

Etest is an agar-based predefined gradient method specifically developed for the determination of exact MIC values and is used to complement other routinely used AST methods. The product was approved by the U.S. Food and Drug Administration (FDA) in 1991 and is currently cleared for clinical testing of Gram-positive and -negative aerobes, anaerobes, pneumococci, streptococci, haemophilus, gonococci, and yeasts (*Candida* species) with a wide variety of antimicrobial agents. Etest is a gradient technique that combines the principles of both the disk diffusion and agar dilution methods. A preformed and predefined gradient of antibiotic concentrations that spans across 15 dilutions of the reference MIC method is immobilized in a dry format onto the surface of a plastic strip. When applied to the surface of an inoculated agar plate, the antibiotic on the plastic strip is instantaneously transferred to the agar in the form of a stable, continuous gradient directly beneath and in the immediate vicinity of the strip. The stability of the gradient is maintained for up to 18–20 hours, depending on the antibiotic. This covers the critical times of a wide range of pathogens, from rapid-growing aerobic bacteria to slow-growing fastidious organisms such as anaerobes and fungi as well as mucoid organisms. The predefined and stable gradient in Etest, unlike the unstable and dynamic gradient around a disk, provides inoculum tolerance. This means that a 100-fold variation in colony-forming units per milliliter (CFU mL^{-1}) has minimal effect on the results of homogeneously susceptible strains (Sanchez and Jones 1992).

A unique feature exclusive to Etest is the ability to use the method in a macro format through the use of a heavier inoculum. This helps optimize the detection of low-level resistance, inducible resistance, and heteroresistance and resistant subpopulations that may occur in varying frequencies. Important examples of heterogeneous resistance are oxacillin resistance in *Staphylococcus aureus* and heterovancomycin intermediate *S. aureus* (hVISA), both of which are well detected by Etest and the latter by the macro method format (Hubert et al. 1999).

After incubation, a parabola-shaped inhibition zone centered alongside the test strip is seen. The MIC is read at the point where the growth/inhibition margin of the organism intersects the edge of the MIC calibrated strip. This can easily be seen with the naked eye for the majority of organisms. Tilting the plate or using a magnifying glass can be helpful to visualize microcolonies, hazes, or other colonies within the ellipse of inhibition when reading the endpoints for bactericidal drugs and for detecting different resistance phenomena such as heteroresistance to oxacillin in *S. aureus*.

More recently, the company Liofilchem® began producing gradient diffusion testing and in 2017 received U.S. FDA approval of their MIC Test Strip (MTS™). These gradient diffusion test strips are similar in principle of methodology to Etest strips. MTS™ are made of special high quality paper impregnated with a predefined concentration gradient of antibiotic, across 15 twofold dilutions like those of a conventional MIC method. When

the MTS™ is applied onto an inoculated agar surface, the preformed exponential gradient of antimicrobial agent diffuses into the agar for more than an hour. After incubation, a symmetrical inhibition ellipse centered along the strip is formed. The MIC is read directly from the scale in terms of µg/mL at the point where the edge of the inhibition ellipse intersects the strip MTS™ (Liofilchem Inc., Waltham, MA).

AST of Fastidious Organisms

Most fastidious organisms do not grow well enough in routine antimicrobial testing systems and require some type of supplementation—for example, blood. Disk diffusion was initially developed for susceptibility testing of rapidly growing aerobic bacteria, including enterococci, staphylococci, Enterobacteriaceae, and *Pseudomonas aeruginosa*. Modifications have been described by the CLSI (Clinical Laboratory Standards Institute, formerly NCCLS, United States) for certain fastidious organisms, including *Haemophilus influenzae*, *Neisseria gonorrhoeae*, *Streptococcus pneumoniae*, and *Streptococcus* species (CLSI 2020). Modifications for broth microdilution can also be used for testing fastidious organisms, although panels must be read manually and not by automated instruments. The MicroScan MicroStrep panel (Dade Behring, Sacramento, CA) is a freeze-dried panel containing Mueller Hinton broth with lysed horse blood for testing of *S. pneumoniae* and other *Streptococcus* species. Similar panels are available on Sensititre (Trek Diagnostics). Vitek 2 (bioMerieux) also has a card specifically designed for susceptibility testing of *Streptococcus* species. Etest, being an agar-based system that can be easily adapted to various growth media, can be used for testing of fastidious organisms, including *Streptococcus*, *Haemophilus*, and *Neisseria* as well as many other fastidious and very slow-growing organisms.

The CLSI developed a document with guidelines for testing and interpretation of several groups of fastidious organisms such as *Corynebacterium*, *Listeria*, and *Bacillus* species (CLSI 2016b).Other unusual and/or rarely encountered opportunistic pathogens for which no CLSI guidelines are available can also be tested by an MIC method if the system supports good growth of these organisms and only the MIC value is reported without an interpretation. Scientific references can be used to guide the choice of appropriate media, incubation conditions, and antibiotics to test for these unusual organisms.

AST of Anaerobes

Antimicrobial resistance among many clinically important species of anaerobes has increased, which has made empiric therapy choices unpredictable. Few antimicrobials remain where these pathogens are expected to be uniformly susceptible (Hecht 2002, 2006). Although rare, metronidazole resistance has been found in *Bacteroides* species as well as other anaerobes. Equally important is the need to recognize inherent resistance to metronidazole in anaerobes such as *Propionibacterium*. In 2004, the CLSI published a document describing agar dilution as the reference method for anaerobic susceptibility testing. Shortly afterward, a broth microdilution method for rapidly growing anaerobes (*Bacteroides* species only) was included in the reference standard; however, the method is only described for a limited number of antimicrobials and the panels are not commercially available (CLSI 2018a). Anaerobic susceptibility testing is indicated for the management of patients with serious infections who may require long-term therapy and for the guidance of appropriate therapy for organisms that are not predictably susceptible. The CLSI also recommends that clinical laboratories save significant anaerobes and perform AST at the end of the year in a batch format in order to create an anaerobic antibiogram to help guide empiric therapy. The media recommended by the CLSI is Brucella agar or broth supplemented with vitamin K and hemin. After inoculation in agar or broth, results can be read after 24–48 hours of incubation in an anaerobic environment.

AST of Fungi

In 1997, the CLSI published a standard method for antifungal susceptibility testing of yeasts, and later for filamentous fungi (molds) (2002) (CLSI 2016c, 2012). Although no MIC interpretive breakpoints exist for molds with any of the currently available antifungal agents, reproducible results have been achieved with the CLSI as well as alternative methods as documented in the literature. The CLSI reference methods for fungi include disk diffusion (yeast only), as well as broth macro and microdilution (CLSI 2017). A commercially available broth microdilution method (Yeast One, Trek Diagnostics, Cleveland, OH), as well as an automated method (Vitek) and Etest, is FDA-cleared for antifungal testing for a limited set of organism and antifungal agent combinations. The recommended medium is RPMI 1640 buffered with MOPS in either a broth or agar format, the latter of which requires supplementation with 2% glucose for Etest. After incubating for 24–48 hours, the MIC results for *Candida* species can be read. Endpoints are determined based on the class of antifungal agent with fungicidal agents such as amphotericin being read at 100% inhibition and fungistatic agents such as the azoles read at 80% inhibition; or the first dilution showing a significant decrease in turbidity or growth. MIC breakpoints are published by the CLSI for fluconazole, itraconazole, voriconazole, and flucytosine for some *Candida* species as well as anidulafungin, caspofungin, and micafungin (CLSI 2017; Pfaller et al. 2011).

For *Candida* species with no current breakpoints or for Cryptococcus and mold isolates, epidemiological cutoff values (ECVs) can be used. The ECV cutoff is based on the susceptibility of a wild type population of the isolate. Available values can be found in CLSI M59 (CLSI, 2016a). When testing echinocandins, reading of the endpoints is recommended to be performed based on the minimal effective concentration (MEC). The MEC refers to the lowest concentration of an antifungal agent, which results with the growth of small, rounded, compact hyphal forms when compared to the hyphal growth seen in the control well (Pfaller et al. 2010; Pfaller, Boyken, et al. 2011)

AST of Mycobacteria

The reference method for AST of slow-growing mycobacteria, in particular *Mycobacterium tuberculosis*, is the agar proportion method. This technique uses a single critical concentration of the antimycobacterial agent to define susceptibility/resistance. A standardized inoculum of the organisms is added to a Middlebrook 7H11 agar plate. The agent is then added to a single

quadrant. Drugs tested include isoniazid, rifampin, ethambutol, and streptomycin. Colonies are counted after 3 weeks of incubation, and the number on the drug-containing quadrant is compared to the control quadrant, which does not contain any drug. Organisms are considered resistant to the drug if the number of colonies on the drug-containing quadrant of resistant colonies is greater than 1% of the control population (CLSI 2018b).

To provide more timely results, clinical laboratories use an automated or semiautomated broth-based system for the detection of growth of *M. tuberculosis* in the presence of a defined critical concentration of the drug in broth as described by the CLSI. Due to the hazards of radiometric testing, nonradiometric automated systems for susceptibility testing of *M. tuberculosis* have been developed and cleared by the FDA. These systems include VersaTREK (ThermoScientific) and Mycobacteria Growth Indicator Tube (MGIT, Becton Dickinson, Sparks, MD) (Woods et al. 2011). Both systems have been FDA-cleared for susceptibility testing of rifampin, isoniazid, ethambutol, pyrazinamide, and streptomycin. The MGIT system consists of a florescent indicator tube, which will emit an orange glow for positive cultures that are inoculated with the prepared specimen and incubated and read daily. The VersaTREK system detects mycobacterial growth by monitoring the rate of oxygen consumption in the culture bottle every 24 minutes automatically or can be read manually.

Susceptibility testing of rapidly growing mycobacteria can be performed by either broth microdilution (CLSI 2018b) or by Etest. Broth dilution can be prepared by the laboratory, or Sensititre™ 96-well plates can be purchased commercially through ThermoFisher Scientific. The laboratory can purchase a plate with antibiotics for susceptibility testing for rapidly growing mycobacteria or other nontuberculous mycobacteria as well.

Susceptibility testing of nontuberculous mycobacteria (NTM) should only be considered for clinically significant isolates, especially those isolated from sterile body fluids. Microbroth dilution is the recommended method for susceptibility testing. In addition, for the *Mycobacterium avium/intracellulare* complex, CLSI and the American Thoracic Society (ATS) recommend susceptibility testing for patients who have been treated with a macrolide and/or those who develop bacteremia while on macrolide prophylaxis or from patients who relapse while on macrolide therapy. Testing is also recommended on initial isolates from blood, tissue, or significant respiratory samples (CLSI) 2018b; Griffith et al. 2007). Additionally, some mycobacteria species have been shown to carry the *erm* gene, which can result in inducible resistance to macrolides. To detect inducible macrolide resistance, the CLSI recommends that a final reading for clarithromycin should be at least after 14 days, unless the isolate has an MIC of ≥8 μg/mL in which case it can be finalized as being resistant (CLSI 2018b).

Susceptibility Interpretation

Information on drug levels, the site of infection, and MIC distributions of biological populations of bacteria and clinical outcome data from clinical trials are used to select MIC cutoffs or breakpoints to predict whether a pathogen with a certain zone-MIC correlate would respond to therapy with standard dosages. These breakpoints are published in the CLSI AST documents and are updated on a yearly basis as needed. The FDA also approves specific MIC breakpoints for antimicrobial agents when the drug is approved for clinical use, and these breakpoints are published in the package insert for the drug. Most clinical laboratories in the United States use the CLSI breakpoints; however, commercially available systems are required to use FDA breakpoints in their interpretive software. For several new agents, only FDA breakpoints may be available; and for some agents, FDA and CLSI breakpoints may be different, causing confusion for laboratorians.

Currently four categories of interpretation are used for reporting of AST results:

1. *Susceptible.* An infection caused by the organism will most probably respond to treatment with a standard dosage of the antibiotic as indicated for use for that infection
2. *Susceptible-dose dependent*. This category defines the likely susceptibility of an organism that is dependent on the dosing regimen used in the patient. Higher exposure in a maximum approved dosage regimen will give the highest probability of adequate coverage. The SDD category is assigned when doses well above those used to calculate the susceptible breakpoint are approved and used clinically (CLSI 2020).
3. *Intermediate.* These results are usually regarded as indicative of nonuseful therapeutic options similar to the resistant category for treatment purposes. It also serves as a buffer zone to help prevent major categorical errors caused by slight changes in the zone sizes due to the influence of technical variables. However, infections at sites where the antibiotic is likely to be highly concentrated, such as β-lactams in the urinary tract, may respond to therapy.
4. *Resistant.* The infection is not likely to respond to therapy.

Agar Screen Methods

Agar-based methods are available for screening of certain resistance mechanisms (Swenson et al. 2007). The agar screen method uses a certain cutoff concentration of the antibiotic that is expected to inhibit the growth of normal susceptible strains and allow resistant phenotypes to grow. The test is performed by inoculating a defined volume of a suspension of the test strain from a pure culture onto the agar, followed by incubation for 18–24 hours. Examples of these agar screen methods include the use of Mueller Hinton agar supplemented with 4% NaCl and 6 μg mL^{-1} oxacillin to detect oxacillin resistance in *S. aureus* (MRSA screen plate). The agar screen plate is inoculated with a 1-μL loop dipped into a bacterial suspension with a turbidity equivalent to 0.5 McFarland standard. After 24 hours of incubation at 35°C, the appearance of more than one colony is reported as MRSA screen positive and requires the laboratory to perform a confirmatory test to verify the resistance.

Brain heart infusion (BHI) agar supplemented with 6 μg mL^{-1} of vancomycin is used as a screen for vancomycin resistance

in *S. aureus* (VISA) or *Enterococcus* (VRE). The same procedure and interpretation as for the MRSA screen agar plates are used for these tests. Additional screening agars are available for detecting high-level aminoglycoside resistance (HLAR) in enterococci using BHI agar supplemented with 500 μg mL^{-1} of gentamicin and 2000 μg mL^{-1} of streptomycin. A positive HLAR screen result indicates that a synergistic effect will not be seen when the aminoglycoside is combined with either ampicillin, penicillin, or vancomycin. These screen agar plates are commercially available from several manufacturers.

Latex agglutination methods are also available as a direct method for detecting oxacillin resistance in *S. aureus*. A suspension of pure colonies of the test organism is added to latex beads bound to antibody against the PBP2a antigen (marker for MRSA), and the presence of agglutination is interpreted as a positive MRSA result (Cavassini et al. 1999). Due to the expense of this assay and the recent availability of molecular methods for detection of oxacillin resistance, these assays are not often used in clinical laboratories.

Various companies manufacture media that can differentiate various drug-resistant organisms based on a chromogenic medium with the supplementation of the inhibitory antibiotic. For example, the first chromogenic media, CHROMagar™ MRSA, inhibited methicillin-sensitive strains with the addition of methicillin and oxacillin (Merlino et al. 2000). Later, cefoxitin was demonstrated as superior for the selection of MRSA from other staphylococci (Perry et al. 2004). Since then, other companies have marketed chromogenic agar for MRSA, including CHROMID® (bioMérieux), MRSASelect™ (Bio-Rad), Brilliance™ MRSA Agar (Oxoid), and Spectra™ MRSA Medium (Thermo Fisher Scientific).

The first medium for the isolation of vancomycin-resistant enterococci, CHROMID® VRE (bioMérieux), can identify vancomycin resistant enterococci and will also differentiate between *Enterococcus faecium* and *Enterococcus faecalis* (Ledeboer et al. 2007). Other media available include CHROMID VRE (bioMérieux) and Brilliance™ VRE Agar (Oxoid) CHROMagar™ VRE, Spectra™ VRE(Thermo Fisher Scientific), and VRESelect Medium (Bio-Rad).

The same commercial companies listed above have produced media for extended spectrum beta lactamase detection. Typically, these media contain a combination of chromogenic substrates that detect a β-galactosidase or β-glucuronidase. For carbapenemase-producing Enterobacteriaceae, various products can detect isolates that contain genes responsible for the majority of resistance, including IMP, NDM, and VIM metalloenzymes, *Klebsiella pneumoniae* carbapenemase, and OXA-48. These are reviewed by J.D. Perry (2017). The modified Hodge test, MHT, was previously used to test for suspected carbapenemase production in Enterobacteriaceae. The MHT was performed by using a carbapenem disk placed on a lawn of a carbapenem susceptible *Escherichia coli* strain with the clinical isolate streaked in a line away from the disk. If the carbapenem susceptible isolate grew near the streak line and produced a cloverleaf appearance, the isolate was thought to decrease the local concentration of the carbapenem antibiotic (Tamma and Simner 2018). Due to poor specificity and sensitivity, this test was deemed suboptimal and was removed from the 2018 CLSI M100.

Molecular Methods

Molecular-based methods are becoming more common as adjuncts for specific testing needs in the clinical microbiology laboratory (Rasheed et al. 2007). Several molecular tests are now packaged in an easy-to-use kit format where the amplification reaction takes place in a closed environment. This obviates the need for a separate room to perform the testing. Although most of the assays are more expensive than culture methods, the turnaround time of same-day results, theoretically available in several hours, is a major advantage for patient care and can contribute to cost savings to the hospital. Another advantage of these assays is that they do not rely on viable organisms for detection. The most commonly used molecular test for antimicrobial resistance detection is the polymerase chain reaction (PCR) method for the mecA gene to detect oxacillin resistance in *S. aureus* (MRSA). Molecular assays that require a pure culture of the test organism are being replaced by newer assays that directly detect the presence of MRSA in patient specimens. These assays are currently approved by the FDA for use on nasal swabs, skin, and soft tissue, as well as positive blood cultures (Paule et al. 2007; Kelley et al. 2011).

Multiplex assays performed directly on positive blood-culture bottles are now available that can detect the most common organisms found in blood cultures and the most common resistance mechanisms. Results can be read within 2–3 hours, require little hands on time and are closed systems that can be performed in routine microbiology laboratories (Beal et al. 2013). These assays have been shown to shorten the time to administration of appropriate antibiotics to patients when combined with an antibiotic stewardship program. Major companies that are FDA approved include the VERIGENE® (Luminex Corporation), Biofire® Diagnostics FilmArray®, and GenMarkDx ePlex® blood culture identification panels.

Use of molecular testing on colonies can be used as an adjunct to routine susceptibility testing to specify the mechanism of resistance in multidrug resistant Gram-negative bacilli. This can be very useful for treatment selection and also for epidemiology to define the particular resistant mechanisms in individual hospitals. One recently FDA-cleared example is the NG-Test® (Takissian et al. 2019).

Molecular assays have become commonplace; however, antimicrobial resistance is complex and requires critical thinking when comparing genotypic results with phenotypic results. In some instances, the antibiotic susceptibility testing will result in a different phenotypic pattern than what is predicted with molecular testing. The presence of a resistance marker may not predict the failure of the antimicrobial agent and the absence of a genetic marker does not necessarily indicate susceptibility. The CLSI has published guidelines to follow to ensure provision of relevant clinical guidance as these methods evolve (CLSI 2020).

For example, poor growth of the organisms may mask higher MICs, while some resistance markers may be truncated and not cause the expected resistance. Recently, a letter was published regarding an isolate of *E. coli* and *K. pneumoniae* both of which were found to have a truncated carbapenemase that was detected by the molecular testing; however, when susceptibilities were completed, the carbapenem was within a susceptible range (Salimnia et al. 2020).

Another method is matrix-assisted laser desorption-time-of-flight (MALDI-TOF) mass spectroscopy (MS) for rapid AST. A direct-on-target microdroplet growth assay (DOT-MGA) was developed to be used directly from positive blood cultures. In this assay, a bacterial isolate was inoculated into various concentrations of an antibiotic and spotted onto the target for analysis. A score of ≥1.7 was considered a nonsusceptible result, while a score of ≤1.7 was defined as susceptible (Idelevich et al. 2018).

A newer method by ACCELERATE Diagnostics™, the ACCELERATE Pheno™ system uses fluorescent *in situ* hybridization (FISH) probes for organism identification in positive blood cultures and morphokinetic cell analysis for AST. This system evaluates cell morphology and light intensity of a growing clone over time in the presence of each test antibiotic. Three panels exist, one for Gram-positive bacteria, one for Gram-negatives, and one for yeast. Identification is carried out by using a multiplexed FISH, which is a rapid hybridization of monolabeled DNA oligonucleotides that target ribosomal RNA and use a nucleic acid stain for organism detection. The isolate identification is confirmed by comparing the signal from a target probe with a signal from universal bacterial and eukaryotic probes. This technology also allows for polymicrobial identification, AST is carried out by analyzing the ratio of individual cells by recording division and growth patterns compared to a growth control. The instrument will generate a profile that includes growth probability and time and can identify a susceptible versus resistant cell (Marschal et al. 2017). ACCELERATE Pheno™ provides rapid and accurate identification and antimicrobial susceptibility results for organisms routinely found in blood cultures. The system reduces hands on time and enables clinically actionable results to be obtained earlier than with other systems currently available (Pancholi et al. 2018; Charnot-Katsikas et al. 2018).

Quality Control

The CLSI-recommended media for AST is cation-adjusted Mueller Hinton broth for broth methods or the standard Mueller Hinton agar for agar-based methods. The CLSI provides guidelines for the selection of quality control (QC) strains and the frequency with which QC should be performed for both disk diffusion and MIC methods. QC strains chosen for MIC testing should be such that the expected MIC value for the strain falls in the middle of the concentration range being tested for that antibiotic. However, this is seldom the case in MIC test systems that use abbreviated or limited dilution ranges of the drug. QC strains can be purchased in dehydrated form either as Culti-loops® (Remel), pellets, swabs (KWIK-STIK, Hardy Diagnostics), or lyophilized in multiple unit containers (LYFO-DISK, MicroBioLogics, St. Cloud, MN). After processing according to the manufacturer's instructions, organisms should be maintained on an agar slant, stored at 2–8°C, and subcultured weekly for up to 1 month, after which a new QC stock organism should be used. QC organisms can be stored for prolonged periods of time at –70°C in broth (such as brain heart infusion or *Brucella*) or skim milk. Stock organisms should be subcultured at least twice when processed from the freezer storage before being used for quality control testing. Testing of QC strains should be done either on each day of clinical testing for infrequently performed tests or weekly after qualifying an initial 30-day QC validation. The CLSI provides flow diagrams for frequency of QC testing, troubleshooting, and corrective action for out-of-control results.

Antibiotic disks are available from several manufacturers (e.g., Becton Dickinson, Remel, and Hardy Diagnostics). They should be handled and stored according to the manufacturer's instructions. Disks can be stored at 4°C in disk dispensers containing desiccant for day-to-day use for up to 1 week for short-term purposes. Long-term storage of unopened cartridges should be at –20°C. Packages should be allowed to reach room temperature prior to opening to prevent moisture condensing on the outer surface from penetrating into the cartridge and deteriorating the antibiotic.

The CLSI also provides recommendations for detecting unusual AST results and suggests that laboratories modify the list of agents to test based on the prevalence of resistance mechanisms in their institutions. Unusual or questionable results include carbapenem (imipenem, meropenem, ertapenem) resistance in strains belonging to the family Enterobacteriaceae that are susceptible to extended-spectrum cephalosporins (cefotaxime, ceftriaxone, or cefepime). Labile compounds such as imipenem may give unexpected resistant results due to degradation of the compound even with proper storage (CLSI 2020).

Introduction

While bacterial cell lysis is a relatively straight-forward process, there are significant variations in its practice. The type of lysis is often dependent upon what subcellular component is to be purified; such as the isolation of DNA versus protein, the scale of the project; miniprep versus industrial-scale, and the type of microbe; Gram-negative versus Gram-positive. Generally, microbial lysis methods can be broken down into three categories based on the relative harshness/intensity of the method: gentle, moderate, or vigorous (Table 13.1).[1] Many of these methods give comparable results and only personal preference plays a role in selection. Others are better suited to specific tasks and should be looked on with preference.

The methods of lysis have been categorized by type of subcellular component to be isolated. The most common components isolated are: nucleic acids, DNA (either genomic or plasmid) and RNA, proteins (either endogenous or recombinant), cell membranes (ghosts), and cell wall (liposaccharide). For both nucleic acids and proteins, there is also discussion of the scale of the project with attention paid to the requirements of large-scale lysis. Differences in lysis between Gram-positive and Gram-negative bacteria as well as Archaea are pointed out where appropriate.

Nucleic Acid Lysis

The two primary types of DNA (genomic and plasmid) extracted from bacteria require differing lysis methods. The extraction of RNA requires additional care due to the fragility of the RNA molecule. For either type, a gentle method is best as to prevent damage to the DNA in the form of cleavage or denaturation or degradation of the RNA.

Plasmid DNA

During the preparation of plasmid DNA, lysis should allow for the plasmids to exit the cell without releasing any of the genomic DNA. This is commonly accomplished via alkaline/sodium dodecyl sulfate (SDS) lysis. During this procedure, the bacteria are exposed to a mild (0.2N) sodium hydroxide (NaOH) solution in the presence of 1% SDS. Exposure to these chemicals is kept relatively short, usually around 5 minutes, and it is often done on ice to further slow the reaction. The reason is to prevent complete loss of the cell membrane due to solubilization by the SDS. The SDS also begins to denature proteins. In the NaOH both proteins and DNA are denatured and RNA is degraded. The genomic DNA is often sheared during the lysis process and, upon denaturation, complementary strands may drift away from each other. The plasmid DNA is also denatured, but because it is relatively small and circular the complementary strands will be joined like links on a chain. When reannealing occurs, the strands will base-pair properly reconstituting the double-stranded DNA plasmids. The genomic DNA strands will not be near their complement and will reanneal into a large mass of intertwined DNA. This reannealing occurs due to neutralization by addition of acidic potassium or sodium acetate. The addition of these salts also causes proteins and SDS to precipitate. This precipitation traps the larger genomic DNA fragments. The preparation is cleared by centrifugation leaving plasmid DNA, some RNA, and a few

TABLE 13.1

Various Lysis Methods Categorized by Their Intensity

Gentle	Moderate	Vigorous
Alkaline lysis	Mortar/Pestle	French press
Triton X-100	Blender	Manton-Gaulin Homogenizer
Phenol		Bead mill
Boiling		Sonication
Proteinase K		
Freeze/Thaw		
Lysozyme/EDTA		

proteins in the supernatant. RNase treatment followed by extraction with organic solvents leaves a solution of nearly pure plasmid DNA, which can be precipitated with alcohol.[2,3] The alkaline lysis method has become the method of choice for the preparation of plasmid DNA and is the method found in the commercial plasmid DNA kits listed in Table 13.2.

A second common method of lysis uses heat (boiling) instead of high pH and a nonionic detergent such as Triton X-100 or Tween-20 instead of SDS. Though these detergents are not as disruptive as SDS, the heat completely denatures both the

[a] The suppliers shown are the most common, but are by no means the only suppliers.
The kits listed are representative of the supplier's product line and do not constitute their entire catalog.
[b] Plasmid DNA kits are often available for varying yields of DNA; mini up to 20 µg, midi up to 100 µg, maxi up to 500 µg, mega up to 2500 µg, and giga up to 10,000 µg.

proteins and the DNA. Upon cooling, coagulated proteins trap genomic DNA and both precipitate out of solution. The boiling method does contain more RNA as it is not destroyed by the heat as it is by high pH. This method is often augmented by the addition of lysozyme (activity explained later in this chapter).[4,5]

Prior to the lysis steps outlined previously, there is usually the requirement of concentrating the bacterial cells via centrifugation and resuspension in a smaller volume. Typically, the buffered solution used to resuspend contains a chelating agent, typically, ethylenediaminetetraacetic acid (EDTA), and an osmotic regulator such as glucose. EDTA is a chelator of divalent cations and helps to inactivate DNases by removing Mg^{2+}. It also aids in disrupting the outer envelope of Gram-negative bacteria by removing Mg^{2+} from the lipopolysaccharide (LPS) layer. The osmotic regulator is important to prevent the bacterial cells from bursting in the hypotonic solution which would defeat the purpose of the controlled lysis procedures.

Genomic DNA

Unlike a plasmid DNA preparation, a genomic or chromosomal DNA preparation requires the complete degradation of the cell's peptidoglycan layer and cell membrane. Gram-negative bacteria also need their LPS layer disrupted. Digestion with the enzyme lysozyme is required for gram-positive bacteria and is useful, but not required for Gram-negative bacteria. Lysozyme hydrolyzes β(1-4)-linkages between N-acetylmuramic acid and N-acetyl-D-glucosamine residues in peptidoglycans.[6] Other enzymes (Table 13.3) may also prove useful for specific bacterial types that may be resistant to lysozyme. The cells are then subjected to extended incubation (>15 minutes) in 1% SDS at elevated temperature (37–45°C). This is either followed or accompanied by proteolytic enzyme treatment to further remove proteins. Proteinase K is the enzyme of choice since it actually works better in the presence of SDS. Treatment with DNase-free RNase is also required to remove RNA contamination.

TABLE 13.3

Enzymes Used During Bacterial Lysis

Enzyme	Mode of Action	Sensitive Microbe
Achromopeptidase	A lysyl endopeptidase	Gram-positive bacteria resistant to lysozyme
Labiase	Contains β-N-acetyl-D-glucosaminidase and lysozyme activity	Gram-positive bacteria such as *Lactobacillus*, *Aerococcus*, and *Streptococcus*
Lysostaphin	Cleaves polyglycine cross-links in peptidoglycan	*Staphylococcus* species
Lysozyme	Cleaves between N-acetylmuramic acid and N-acetyl-D-glucosamine residues in peptidoglycans	Gram-positive cells with Gram-negative cells being less susceptible
Mutanolysin	Cleaves N-acetylmuramyl-β(1-4)-N-acetylglucosamine linkages	Lyses *Listeria* and other Gram-positive bacteria such as *Lactobacillus* and *Lactococcus*

As with plasmid preparations chelation of divalent cations such as Mg^{2+} with EDTA is important for lysis and for maintaining the integrity of the chromosomal DNA.[7] Finally, it is critical to treat the lysate gently to prevent shearing of the chromosomal DNA. The purification of genomic DNA, like plasmid DNA, has been reduced to a commercial kit. A list of suppliers is found in Table 13.2.

Mechanical disruption has been found to increase DNA yields when used in conjunction with enzymatic lysis. This is of particular concern when trying to increase the sensitivity of PCR reactions.[8] Some commercial kits rely on mechanical, concussive disruption in the form of bead beating (see Table 13.2), which breaks up bacterial cell wall mechanically by vibrating bacteria with microbeads at high speed.[9] This method can be used with any bacterial strain and is particularly usefully for pathogenic bacteria as there are virtually no unlysed cells, a possibility with enzymatic disruption due to uneven mixing or inactivated enzyme.

RNA

During RNA isolation, the most important issue is stabilization of the RNA. RNases, unlike DNases, are very stable and are found throughout the lab. In addition, because bacterial mRNAs lack a 5' cap and 3' poly(A) tail they are more unstable than their eukaryotic counterparts, with an average half-life of approximately 3 minutes.[10] Traditionally chaotropic (chaos producing) agents, such as guanidinium isothiocyanate or guanidinium hydrochloride, are used to inactivate RNases and preserve RNA. However, there are proprietary reagents such as RNAprotect® by Qiagen Inc. (www.qiagen.com), which can be added to a bacterial culture prior to lysis to protect RNA and reduce artifactual changes in expression that may occur during lysis. In addition to treating the culture, all solutions, glassware, and plasticware must be RNase-free. Solutions except those containing Tris must be treated with 0.1% diethyl pyrocarbonate (DEPC) to inactivate RNases. Autoclaving of solutions after DEPC treatment destroys the DEPC. Tris solutions cannot be treated because Tris reacts with DEPC to inactivate it. Instead, Tris solutions are made using DEPC-treated water. Glassware must be baked at 300°C for at least 4 hours (autoclaving does not inactivate all RNases).[5] Plasticware should be bought already RNase-free. Alternatively, plasticware and equipment may be cleaned with RNase *Zap*™.

The actual lysis can be done either enzymatically or mechanically. Gram-negative bacteria may be lysed with lysozyme alone or in combination with Proteinase K. Gram-positive bacteria should be lysed with both lysozyme and Proteinase K. Certain difficult-to-lyse Gram-positive bacteria may require mechanical disruption with bead beating or a tissue homogenizer in addition to enzymatic lysis. A tissue homogenizer, sold under various brand names, is a rapidly turning rotor that draws liquid-suspended cells into a core region. The cells are repeatedly cycled through narrow slits, which mechanically shears them. Mechanical lysis on its own is suitable for a wide range of bacteria and is rapid, but overall, RNA yields are generally lower than when used in conjunction with enzymatic methods.[11] Depending on the purification method, RNase-free DNase may be required to remove any contaminating DNA.

Large-Scale Lysis

Most bacterial lysis for plasmid DNA is done in the laboratory with yields varying in size from 20 µg (miniprep) to 10 mg (gigaprep). The advent of applications such as gene therapy and DNA vaccines will require multigram to kilogram amounts of purified plasmid DNA to be produced in a cost-effective manner. Traditional protocols such as alkaline lysis do not scale up well due to complex mixing requirements that can leave local regions of extremely high pH, which can irreversibly damage plasmids. Use of lysozyme is also problematic due to costs. Large-scale lysis of bacterial filter cakes via fragilization followed by heat has been shown to be viable.[12]

Protein Lysis

Lysis for protein extraction either endogenous or recombinant proteins requires mechanical or chemical (enzymatic and mild detergent) disruption since protocols such as alkaline lysis deliberately destroy proteins. The addition of serine protease inhibitors, such as phenylmethylsulfonyl fluoride (PMSF), or aprotinin are also strongly encouraged to improve yield. Lysis also needs to be carried out either on ice or at 4°C to protect the proteins from denaturing heat.

These methods are primarily for the recovery of exogenous, recombinant proteins, but they are also useful for the recovery of endogenous bacterial proteins.

Mechanical Lysis

Traditionally, bacteria are lysed through liquid homogenization. In this method, cells are sheared by forcing them through a small opening. With bacteria, this is often done with a handheld tissue homogenizer or the larger French press. A French press consists of a piston that applies high pressure to a sample, forcing it through a tiny hole in the press. Only two passes are required for efficient lysis due to the high pressures used with this process. The equipment is expensive, but the French press is often the method of choice for breaking bacterial cells mechanically. Typical sample volumes range from 40 mL to 250 mL. Sonication or the use of high frequency sound waves is commonly used for samples <100 mL. A vibrating probe is immersed in a liquid cell suspension and energy from the probe creates shock waves that reverberate through the sample. The primary disadvantage of mechanical disruption besides a requirement of expensive specialized equipment is the potential for sample overheating. Either generalized sample heating or localized regions of overheating within a sample can denature proteins, lowering final yield. Lysis must not only be performed at low temperature, but particularly with sonication, the lysis needs to be done in short bursts with enough time in between to allow the sample to cool again.

Because mechanical lysis breaks cells completely all intracellular components, including nucleic acids are released. These can increase viscosity of the lysate and complicate downstream processing. To resolve this, DNase and RNase are added to the sample or Benzonase® (registered trademark of Merck KGaA,

Darmstadt, Germany) alone. Benzonase® is an endonuclease that degrades all forms of DNA and RNA (single-stranded, double-stranded, linear, and circular). One final method, freeze/thaw, can also be used to lyse bacterial cells for the release of recombinant proteins.[13] This technique involves repeated cycles of freezing a cell suspension and then thawing to room temperature or 37°C. Ice crystals that form during the freezing process cause the cells to swell and ultimately burst. The problem is the process can consume a lot of time and is effective only on relatively small samples.

Chemical Lysis

For small-scale lysis, chemical methods are effective and economical. Many companies sell protein lysis kits based on this method (Table 13.4). These kits contain a nonionic detergent-based lysis buffer, lysozyme, and DNase/RNase or Benzonase®. Nonionic detergents are considered more gentle than SDS and less likely to denature proteins.[14] However, most purification schemes will require the extra step of removal of the detergent.

The major disadvantages of these methods are their relative expense due primarily to the enzymes involved.

Large-Scale Lysis

In commercial or very large-scale laboratory settings, it is common to require lysis from tens of liters to thousands of liters of cells. As stated earlier, chemical means are not viable at large-scale due to expense, so mechanical lysis is the most common method of large-scale lysis. Of the methods discussed, neither French press nor sonication is amenable to large-scale protein production. The most common methods are bead beating with a mechanical ball mill or Manton-Gaulin Homogenizer. These are effective at lysing large volumes of cells; continuously operating ball mills have the capability of lysing up to 40 L per hour. Due to the tremendous heat generated by the process, ball mills are jacket-cooled, some employing liquid nitrogen to prevent overheating of samples.[15]

Bacterial Ghosts

Bacterial ghosts are empty cells with intact nondenatured envelopes.[16] They have potential uses as drug carriers and vaccine adjuvants.[16–18] They retain all the functional and antigenic determinants found in the living bacteria. Bacterial ghosts are generated through controlled expression of the PhiX174 gene *E* in Gram-negative bacteria. PhiX174 gene *E* encodes a membrane protein that fuses the inner and outer membranes, creating a tunnel through which the cytoplasmic contents of the bacteria are expelled. Except for the tunnel generated by the *E* gene product, the morphology and cell surface structures are unaffected by the lysis. The lumen of the ghost may be filled with vaccine[17] or drugs.[16] In addition to the greater carrying capacity as compared to other delivery systems, ghosts also have the potential to target tissues such as the mucosal surfaces of the gastrointestinal and respiratory tract, and their uptake by phagocytes and M cells.[16]

LPS Lysis

While not technically lysis, the liposaccharide cell envelope of Gram-positive bacteria can be removed and purified via extraction. The most common method uses phenol and hot water.[19] Alternatives include butanol and water as well as detergent.[20]

Archaea

Because the cell walls of Archaea differ from those of eubacteria, enzymatic lysis is not the optimal method of disruption. Archaeal cell walls are composed of the polysaccharide pseudomurein and contain no peptidoglycan.[21] This precludes the use of lysozyme. However, most mechanical methods of lysis, such as the French press or bead beating, are effective and allow archaea to be treated the same as bacteria.

Conclusions

The lysis methods discussed in this chapter are the most popular, but not necessarily the sole methods of lysis. Other methods may be more suitable depending on your cell type, volume, or final application.

Major Culture Collections and Sources

Lorrence H. Green

Since the publication of the previous edition of this book, one of the major changes that has taken place in the area of culture collections has been the efforts to standardize how repositories function. To this end, the United States Culture Collection Network was founded in 2012 [1]. The network's mission is to:

> facilitate the safe and responsible utilization of microbial resources for research, education, industry, medicine, and agriculture for the betterment of humankind by providing opportunities for US culture collection workers to engage with each other and with the broader culture collection community

Their main focus has been to ensure standardization of infrastructure items such as access to strains, robust taxonomy, quality control, stock preservation, and collection succession, among others. As methods for identifying microorganisms have come to rely more and more on methods such as DNA sequencing and metagenomics, instead of the traditional enzyme activity tests; the need for absolute consistency in standard strains has become of paramount importance. More information about the network can be found at http://www.usccn.org/Pages/default.aspx (accessed October 23, 2020).

Many sources exist for obtaining microbiological species in pure culture, which can be used as references. Foremost among these is the American Type Culture Collection (ATCC) (Manassas, VA, USA) (www.ATCC.org, accessed October 23, 2020). Several commercial companies such as Microbiologics (www.microbiologics.com, accessed October 23, 2020) and Remel (www.remel.com/About.aspx, accessed October 23, 2020) also supply ATCC microorganisms.

The World Federation for Culture Collections (www.wfcc.info/index.php/collections/display, accessed October 23, 2020) lists 789 culture collections in 77 countries and regions in the world. Among these are:

Japan Collection of Microorganisms (jcm.brc.riken.jp/en/, accessed October 23, 2020).

HAMBI Culture Collection (Finland) (www.helsinki.fi/en/infrastructures/biodiversity-collections/infrastructures/microbial-domain-biological-resource-centre-hambi#section-63074, accessed October 23, 2020).

Biotech Culture Collection Laboratory (Thailand) (www.biotec.or.th/bcc/, accessed October 23, 2020).

Culture Collection of Switzerland (CCOS) (www.ccos.ch/material/ccos_strains, accessed October 23, 2020).

Microbial Culture Collection (India) (https://mtccindia.res.in/, accessed October 23, 2020).

The Chinese General Culture Collection Center (www.cgmcc.net/english/, accessed October 23, 2020).

Amazon Bacteria Collection (Brazil) (http://cbam.fiocruz.br/, accessed October 23, 2020)

The National Collection of Industrial, Marine and Food Bacteria (Scotland) (www.ncimb.com, accessed October 23, 2020).

Another change since the last edition of this book has been the increasing number of collections that specialize in specific organisms. For instance:

Coli Genetic Stock Center (https://cgsc.biology.yale.edu/, accessed October 23, 2020): a collection that contains non-pathogenic strains of *Escherichia coli*: predominantly K-12 derivatives, but a few B strains.

UC Davis Viticulture and Enology (https://wineserver.ucdavis.edu/industry-info/enology/culture-collection, accessed October 23, 2020): a collection that specializes in wine yeast and bacteria from around the world.

Culture Collection of Cryophilic Algae (http://cccryo.fraunhofer.de, accessed 3/9/2020): a collection that specializes in extremophiles.

Introduction

Epidemiological methods in microbiology include laboratory and analytical tools that are used to study the microbial distributions and determinants of infectious disease in host populations. The scope of this chapter is limited to a discussion of the tools that are used to study the molecular and genomic epidemiology of bacterial infectious disease, but these tools have broader application for studying diseases caused by fungi, parasites, and viruses. Natural populations of named bacterial species can accumulate immense levels of genetic variation, and the now widespread use of whole genome sequencing has enabled this variation to be detected at the base-pair level across nearly complete genomes. Analysis of this genetic variation provides the basis for making epidemiological and evolutionary inferences about short-term bacterial transmission, longer-term bacterial evolution, and dispersal, and for identifying the precise bacterial determinants of disease. In this chapter, we discuss the criteria that are used to evaluate different bacterial strain typing tools, the concepts that are used to interpret the genetic variation that is revealed by these tools, and the epidemiological applications for which these tools are deployed.

Overview of Strain Typing

Some Definitions and Assumptions

Although the fundamental concept of bacterial species is still subject to debate, some intraspecies taxonomic units of epidemiological relevance have been defined [1–3]. An isolate has been defined as a group of bacterial cells that represent a pure culture obtained from a single colony grown on a solid medium [4, 5]. Isolates are collected from sources such as clinical specimens, fomites, and environmental samples. A strain has been defined as a group of isolates that are genotypically or phenotypically identical to each other and distinct from other such isolates [4, 5]. A clone has been defined as a group of isolates that are genotypically identical to each other due to common ancestry. It has been emphasized that multiple genotypic markers must be examined in order to classify isolates into a clone [4, 5]. Strain typing tools are the laboratory techniques that are used to assess variation in the phenotypes and genotypes of bacterial isolates. With the increased resolution to distinguish between isolates, which has been made possible in recent years by advances in whole genome sequencing technologies, it has become apparent that substantial

genetic variation exists among groups of isolates previously designated as strains and clones [6–8]. Consequently, in recent years, there has been less focus on developing new strain typing tools and more focus on using sequence data to estimate the degree of genetic relatedness between isolates that is most epidemiologically relevant [9].

Isolates that are part of the same chain of transmission are defined as epidemiologically related. A fundamental assumption that underlies the epidemiological use of strain typing is that epidemiologically related isolates are also genetically closely related isolates [10, 11]. This assumption is based on the reasoning that if isolates share a recent common ancestor, they are also likely to share a common set of biological attributes, including virulence factors that enable bacteria to damage their host and cause disease. It is reasoned that a common set of virulence factors will result in a common disease pathophysiology.

Criteria of Strain Typing Tools

Numerous strain typing tools are available to distinguish between isolates of a bacterial species. However, the selection of a strain typing tool should be tailored to the particular epidemiological problem that is presented [5, 12, 13]. Not all epidemiological problems require the use of high-resolution strain typing tools such as whole genome sequencing. For example, a crowded, inadequately ventilated environment may be linked to an outbreak of pneumococcal pneumonia and an intervention may be devised with little knowledge of the genetic relatedness of the isolates collected from the outbreak; knowledge of the capsular serotype and the antibiotic susceptibility of the isolates may be sufficient to devise an intervention [14]. On the other hand, preventing the spread of an epidemic methicillin-resistant *Staphylococcus aureus* (MRSA) strain in a nosocomial environment may require a genotyping tool in order to distinguish cases from those infected with endemic MRSA strains [15, 16]. For bacterial populations with relatively low genetic diversity, which includes some circulating strains of *Mycobacterium tuberculosis*, the higher resolution provided by whole genome sequencing may be required to make epidemiologically meaningful inferences about clustering or transmission [6, 17].

Strain typing should be viewed as complimentary to an epidemiological investigation [13, 18–21]. Strain typing does not replace the examination of space, time, and other risk factors associated with an infectious disease; rather, the results of strain typing are evaluated in the context of these other factors. Finally, it has been emphasized that strain typing should be done to achieve the public health goal of epidemiology to prevent infectious disease [18]. Strain typing is not exclusively within the domain of epidemiology. The need to distinguish among bacterial isolates also arises in systematics and taxonomy, population genetics, phylogenetics, and other basic endeavors.

Several considerations must be made in order to select an appropriate strain typing tool for a particular epidemiological application [5, 12, 13]. Not all biological variation provides a valid target for strain typing. The validity of a strain typing tool is based on its ability to distinguish between epidemiologically related and unrelated isolates, which defines the sensitivity and specificity of the tool, respectively [10]. A strain typing tool should be validated for a particular epidemiological application, which means that it should be able to confirm established epidemiological findings. No "gold standard" exists that can be used for validation. Validation of a strain typing tool is done empirically by comparison of the tool with previously validated tools and by demonstration that epidemiologically related and unrelated isolates can be distinguished [10]. Lastly, the choice of appropriate tool should be considered along with the sampling strategy for collecting isolates, the statistical framework used for hypothesis testing, and the analytical methods used to estimate relatedness between isolates [22].

Three basic performance criteria, which include discriminatory ability, reproducibility, and typeability, have been used to evaluate strain typing tools [5, 20, 23]. Discriminatory ability is defined as the ability of a strain typing tool to detect differences between isolates. Simpson's index of diversity is widely used to quantify discriminatory ability and it takes into account both the richness and abundance of types in a sample of isolates [24]. Simpson's index estimates the probability that two isolates randomly selected from a sample will have different types. Confidence intervals can be calculated for Simpson's index, which enables statistical comparisons of the discriminatory ability of different strain typing tools applied to the same sample of isolates and statistical comparisons of different samples of isolates (e.g., from cases and controls) characterized with the same typing tools [25]. Reproducibility is defined as the ability of a strain typing tool to yield the same results for the same isolates upon repeated testing. Both within- and between-laboratory reproducibility are evaluated. Typeability is defined as the ability of a strain typing tool to score a positive result for each isolate. Nontypeable isolates produce either null or ambiguous results. All three performance criteria are affected by experimental variation in laboratory techniques and by biological variation in the isolates [5, 20, 23].

Numerous convenience criteria also have been used to evaluate strain typing tools [5]. These criteria include the ease of performance (technical simplicity), the speed of performance (rapidity), the applicability to a broad taxonomic range of species (versatility), and cost. Additional criteria, such as concordance, stability, and ease of interpretation [5, 23], also have been used to evaluate strain typing tools. Epidemiological concordance is analogous to validity, as defined above. On the other hand, strain typing concordance describes the relative agreement of different strain typing tools in classifying isolates as "same" or "different." The Rand and Wallace indices have been used to quantify concordance [26]. Adjusted versions of these indices are available that provide chance-corrected estimates of concordance, and confidence intervals for these indices can be calculated to enable statistical comparisons of concordance [26–28].

Description of Strain Typing Tools

Subgenomic Tools

Classical Strain Typing

Strain typing tools are commonly classified according to whether they assess phenotypes or genotypes. Historically, strain typing tools were based on phenotypes, but these tools have been largely replaced with genetic methods. Phenotyping tools have been used

to assess variation in metabolic characteristics (biotyping), susceptibility to lytic bacteriophage (phage typing), susceptibility to antibiotics (resistotyping), immunological reactivity to antibodies (serotyping), and other characteristics. While phenotypic characteristics can be highly correlated with epidemiological relationships, they are generally poor indicators of genetic relationships [29, 30]. The expression of phenotypes can be strongly influenced by environment (e.g., temperature, nutrients, oxygen availability), so a shared phenotype might reflect a shared environmental variable rather than a shared ancestry in a sample of isolates [29, 30].

Several classical strain typing tools, previously in widespread use, are important to describe. Multilocus enzyme electrophoresis (MLEE) is a phenotyping tool that was pivotal to the development of the field of bacterial population genetics [31, 32]. MLEE indirectly assesses variation in gene sequences based on differences in the electrostatic charge of different alleles at expressed enzyme loci [33]. MLEE was the forerunner of a genotyping tool called multilocus sequence typing (MLST) that directly assesses variation in gene sequence from fragments of enzyme loci and other loci that encode products with cellular housekeeping functions [34].

Another category of classical strain typing tools called band-based, or molecular fingerprinting, tools produce data in the form of electrophoretic banding patterns. These tools were the basis for early advancements in molecular epidemiology in the 1980s and 1990s [35, 36]. Among these tools, restriction fragment length polymorphism (RFLP), pulsed-field gel electrophoresis (PFGE), and variable number of tandem repeats (VNTR), remain the most relevant. RFLP refers to variation that is revealed through the digestion of DNA templates with restriction endonucleases [20, 37]. These enzymes recognize short nucleotide sequences (~4–6 bp) called restriction sites with varying levels of specificity depending on the enzyme. If the restriction sites occur within a DNA template, then the enzymes will precisely cut the template at these sites resulting in pieces of a template called restriction fragments. These fragments can be separated by agarose gel electrophoresis. The number and location of the restriction sites can differ among isolates. Banding patterns from RFLP analysis can be made less complex by Southern blotting and hybridization with probes of rRNA genes (ribotyping), insertion sequences (IS typing), and other sequences [20, 37, 38]. PFGE analysis uses restriction endonucleases that recognize relatively few restriction sites in a chromosome, resulting in a small number (~10–30) of large fragments (~10–800 kb) [4, 20]. These large restriction fragments are separated by special electrophoresis equipment that alternates the direction of current. Lastly, VNTR analysis employs PCR amplification of various kinds repetitive sequences including microsatellites (~1–10 bp) and minisatellites (~10–100 bp) [39, 40]. Arrays of these repeats can differ between isolates in length and in sequence, and the length variation can be distinguished by electrophoresis. Due to relatively high discriminatory ability, band-based genotyping tools have been very useful for local outbreak investigations [41]. On the other hand, reproducibility has been low for many of these tools.

Sequence-Based Genotyping

Sequence-based genotyping tools assess variation directly from the nucleotide sequences of either a single locus or multiple loci. These tools provide a fundamental view of genetic variation [34]. The Sanger method of sequencing has been used widely for epidemiological and evolutionary applications. PCR templates are linearly replicated using a reaction mixture that includes fluorescently-labeled dideoxynucleotides and other reagents. Incorporation of dideoxynucleotides interrupts replication, leading to a ladder of amplicons each with their 3' terminus marked by a fluorescent label that can be detected by an automated sequencer. Single locus sequence typing (SLST) has often targeted highly variable sequences, such as VNTR sequences [42]. In contrast, MLST has often targeted relatively conserved sequences, such as the sort of housekeeping loci used for phenotyping by MLEE [43]. The MLST technique utilizes partial nucleotide sequences (~500 bp) from a set of housekeeping loci (~7), which are selected for a given species to be present in all tested isolates, physically distant from each other on the chromosome, and not subject to strong diversifying selection. Unique nucleotide sequences at each locus define alleles, and unique combinations of alleles across loci define sequence types (STs). MLST databases of alleles and STs are publicly accessible via the internet for dozens of microbial species, most of which are bacterial species [44].

Sequence-based genotyping tools achieve high reproducibility. MLST has become one of the most important tools for elucidating bacterial population genetic structure at a coarse scale [45, 46]. Public health networks have used SLST and MLST for international surveillance of bacterial pathogens [44, 47, 48]. Moreover, some SLST schemes have exhibited high enough discriminatory ability to be used for outbreak investigations [49, 50]. The discriminatory ability of VNTR sequences can be greatly improved when characterized by sequencing rather than by electrophoresis [51]. Convenience criteria, such as high time requirement and cost, are the principal weaknesses of sequence-based genotyping tools.

Binary-Based Genotyping

Binary-based genotyping tools assess the presence or absence of specific genetic markers. These tools are generally based on hybridization of labeled genomic DNA to an array of sequences that are fixed onto a surface, such as a membrane or glass slide (microarray or gene-chip) [52]. The reverse of this technique can also be performed, whereby labeled sequences are hybridized to an array of genomic DNA preparations that are fixed onto a surface (library on a slide) [53]. The sequences can consist of parts of a chromosome, such as virulence factors, or they can be more representative of the entire contents of a reference strain's genome using arrayed amplicons or oligonucleotides as is done with comparative genomic hybridization (CGH) [54–57]. CGH studies provided early estimates of gene content variation between strains of a species [52, 54, 55]. Binary-based genotyping tools can exhibit high discriminatory ability, but they can also present problems with reproducibility and they can be time-consuming and costly to use. These tools have most often been applied to studies of the association between virulence factors and infectious disease.

Genotyping of single nucleotide polymorphisms (SNPs) can be viewed as a binary-based genotyping tool. A wide variety of different techniques can be used to distinguish between alleles

at polymorphic nucleotide sites in a cost-efficient manner [58]. These techniques make use of allele-specific hybridization, amplification, extension, and ligation reactions, and various characteristics of DNA (e.g., melting temperature) that differ in an allele-specific fashion. Some of these techniques allow the discovery of new SNPs, whereas others are only used to genotype known SNPs. The SNP discovery process needs to be carefully considered in order to reduce biases in subsequent population genetic and phylogenetic analyses [59]. SNPs have been used to provide information about antimicrobial resistance mechanisms [60], and bacterial population genetic structure at the coarse scale of MLST [61, 62] and at a more granular scale [63, 64]. SNP genotyping protocols can be standardized and can provide high reproducibility and discriminatory ability [65].

Genome Sequencing

Second-generation sequencing platforms provide nearly complete, draft-quality genome sequences of bacteria. While these platforms use different underlying technologies that have different strengths and weaknesses [66, 67], they share several characteristics that distinguish them from first-generation Sanger sequencing: (1) libraries of fragmented DNA are produced and platform-specific adapters are ligated to the ends of the fragments; (2) PCR amplification of the library is performed; (3) sequencing is done in parallel, generating millions of relatively short (~50–500 bp) sequence reads. By ligating unique sequences, or barcodes, to each isolate's library, multiple isolates can be sequenced at the same time and the data from each isolate can be separated during downstream analysis. This multiplexing capability decreases the cost per isolate and can make second-generation sequencing competitive in cost with other genotyping tools. Of course, there is a trade-off between the cost per isolate and the number of reads per isolate, which impacts the quality of the resulting genome sequence. Therefore, the goals of the study and the desired quality of the genome sequences need to be carefully considered.

The sequence reads can be assembled into a genome sequence by two basic analysis techniques. With the read-mapping technique, the reads are aligned to a reference sequence, which is often chosen to be a complete genome sequence from a closely related isolate. This technique is useful for discovering SNPs and short insertions and deletions [16, 68, 69]. Several read-mapping quality metrics, such as base depth, quality, and "heterozygosity," should be evaluated [70]. With the *de novo* assembly technique, the reads are aligned to each other to build as complete a genome sequence for an isolate as possible. This technique is useful for assessing gene content [68]. Assembly quality metrics, such as the number and size distribution of contiguous sequences (contigs), should be evaluated [70]. Read mapping also can be used to assess gene content; for example, reads can be mapped onto a customized reference sequence of known virulence factors [71]. Likewise, *de novo* assemblies from multiple isolates can be subsequently aligned to discover SNPs, insertions, and deletions [69]. A large portion (>90%) of a bacterial genome can be assembled with reads from second-generation platforms [66], but repetitive sequences are difficult to sequence and assemble from these platforms.

So-called third- and fourth-generation sequencing platforms, single-molecule real-time (SMRT) sequencing and nanopore-based platforms, respectively, are increasingly used to improve the sequencing of regions where second-generation sequencing is difficult or unreliable [72, 73]. In brief, the core process underlying SMRT sequencing records the sequential addition of individual fluorophore-bound nucleotides to a circular DNA template [72]. This process is parallelized over tens of thousands of specialized reaction cells, which have internal dimensions that are small with respect to the wavelength of light being used. The fluorescence wavelengths measured after each round of a long series of light pulses records the elongating nucleotide sequence in each cell. The DNA template used in SMRT is circular, such that multiple passes over the template are possible during a single sequencing run, allowing for relatively high sequencing depth [72]. In addition, variations in the kinetics of fluorescence emission following each nucleotide addition can be used to detect base-pair modifications such as DNA methylation.

Nanopore-based sequencing uses specialized protein structures (nanopores) that allow for the passage of single nucleotide strands [73]. As each nucleotide of the strand passes through the nanopore, it introduces a distinct disturbance in an electrical field applied across an array of nanopores, which is recorded and used to infer the nucleotide sequence of the strand. This technology is highly compact and portable, allowing for its use in contexts where other sequencers are impractical. Use of nanopore sequencing in infectious disease epidemiology is limited in some situations by this platform's relatively high sequencing error rate [73]. This is most problematic for bacterial species with low genetic diversity where the error rate of nanopore sequencing can potentially exceed the basal mutation rate of the species, but ongoing substantial improvements in this technology and related computational approaches for variant calling from nanopore data may help to address this issue.

Like other sequence-based strain typing tools, genome sequencing should have a high reproducibility. However, it should be recognized that *all* current sequencing platforms have limitations [66, 67, 72, 73]. Standardized or "best practices" protocols are needed for both the sequencing and analysis steps, as with other genotyping tools, to maximize reproducibility. The importance of the reproducibility criterion becomes apparent when considering that a single SNP may be relevant to hypotheses of transmission among outbreak isolates, such as some isolates from the 2011 *Escherichia coli* O104:H4 outbreak in Europe [74]. In contrast, the high discriminatory ability of genome sequencing has been demonstrated repeatedly. Isolates that are indistinguishable by other genotyping tools, even using highly discriminatory markers such as VNTRs, can often be distinguished by genome sequencing [68, 75].

Whole genome sequencing can also resolve between otherwise indistinguishable isolates from the same host and, consequently, has become an important tool for studying within-host evolution of different bacterial species [76–78]. Likewise, whole genome sequencing has become a central tool for identifying the constituents of entire microbial communities isolated from hosts, fomites, and the environment—a field known as metagenomics. Although metagenomic analysis techniques for species-level identification are well-established, additional work is needed to develop and validate tools for strain typing from these complex

data [79, 80]. It is difficult to overstate the impact that genome sequencing has on the epidemiology of bacterial infectious disease [81, 82]. Clearly, the challenge has moved from developing high-throughput, high-coverage genotyping tools that satisfy various performance and convenience criteria, to the daunting task of interpreting the data.

Interpretation of Strain Typing Data

Some Considerations

The interpretation of strain typing data can be complicated even if the performance of the selected strain typing tool is well-characterized. In some cases, the fundamental assumption underlying the epidemiological use of strain typing is violated; epidemiologically related isolates will not always be genetically closely related isolates. For example, contamination of food and water with sewage can result in diarrheal outbreaks due to multiple bacterial species [12]. Furthermore, horizontal gene transfer, recombination, and convergent evolution, can spread a common set of virulence factors or drug-resistance mutations to multiple bacterial strains [83]. In other cases, genetically closely related isolates will not always be epidemiologically related in a discernable fashion; this situation can occur with low-incidence infections or those with long latency periods such as tuberculosis. The selected strain typing tool may not have high enough resolution to identify the epidemiologically relevant variation. For example, undetected virulence factors that are imported on mobile genetic elements or point mutations that slightly alter virulence gene expression, may cause isolates that appear to be identical based on subgenomic typing tools to behave with distinct epidemiological patterns [84, 85]. To reinforce the notion that subgenomic typing tools do not detect all of the variation that occurs within a bacterial genome, it has been emphasized that genotypically identical isolates be referred to as "indistinguishable" rather than "identical" [4, 20]. Finally, it is important to remember that infectious disease is a particular outcome of an interaction that is influenced both by bacterial virulence factors and by host risk factors. Strain typing provides information about the bacterial determinants of infectious disease but, especially for bacterial pathogens that sometimes harmlessly colonize hosts and sometimes cause disease (facultative pathogens), the host's risk factors can decisively influence the outcome of the bacteria-host interaction [10].

Strain typing data is more straightforward to interpret when isolates are shown to be either indistinguishable or completely different. The major difficulty in interpretation arises when isolates are shown to be similar with some differences, because the level of similarity that is epidemiologically relevant must be established [5, 11, 20, 86, 87]. Interpretive criteria have been proposed, but these criteria are specific for particular strain typing tools and particular epidemiological applications. For example, PFGE data are interpreted in local outbreak investigations according to the number of banding pattern differences that can arise per genetic event [4, 20]. The loss of a restriction site due to a single point mutation can result in a three-band difference. Thus, to allow for some variation to accumulate in a strain during the course of an outbreak, isolates that differ by two to three bands are interpreted as probably part of the same outbreak. Sequence-based strain typing tools allow genetic events to be more precisely and comprehensively discerned, but judgement calls regarding the epidemiological relevance of bacterial genetic variation are made with all strain typing tools. In the context of whole genome sequence data, the number of SNPs between isolates is often used to estimate their degree of genetic relatedness [88]. However, the number of SNPs can be influenced by species biology (mutation rate), density with which isolates are sampled from a given transmission network, and technical details related to the sequencing and analysis protocols. In addition, polyclonal infection and within-host heterogeneity can confound inference of epidemiological relationships between hosts. Thus, the importance of properly validating particular strain typing tools for particular epidemiological applications should be underscored. Interpretive criteria are dependent on how rapidly bacteria evolve and the elapsed time since the isolates shared a common ancestor [11, 87]. For most strain typing tools, these two parameters are not known. However, these two parameters can be estimated from sequence data [19].

Insights from Population Genetics and Phylogenetics

Origin and Fate of Genetic Variation

To interpret the results of strain typing tools, the stability of the markers should be taken into account. Stability is defined as the constancy of the markers over time. Stability is best considered within a population genetics framework, which focuses study on the origin and fate of genetic variation [46, 87, 89]. Bacteria are haploid, which means that they contain a single copy of their chromosome(s). Bacteria also reproduce asexually, which means that two identical daughter cells, or clones, are produced from a single parent cell. Mutations refer to the heritable genetic variations that occur within DNA. These variations include nucleotide substitutions, insertions, and deletions. The movements of mobile genetic elements (e.g., transposons, lysogenic phage, integrative conjugative elements) also produce heritable changes in a genome. When the bacterial DNA mismatch-repair machinery undergoes mutations that impair its function, clones can experience a high rate of mutation [90].

Horizontal gene transfer and recombination between clones can occur if the clones have both a mechanism (genetic factors) and opportunity (ecological factors) to exchange genes. Parasexual processes, such as conjugation, transduction, and transformation, enable clones to horizontally transfer genetic material [91]. Recombination between clones can reduce genetic variation if it occurs frequently within a population. In this sense, recombination is a homogenizing force that can speed the replacement of less favorable mutations. Recombination between clones can preserve genetic variation if it occurs frequently between different populations. In this sense, recombination can allow rare alleles to escape extinction. Recombination between clones can also increase genetic variation by combining mutations, thereby creating new alleles. In population genetics parlance, a unique position on a chromosome is called a locus, and a unique combination of mutations at a locus is called an allele. The consequences of recombination between clones are profound for bacterial population genetic structure and infectious disease epidemiology since

it causes virulence factors to embark on independent chains of transmission. If recombination occurs frequently enough, clones can become too ephemeral to be epidemiologically relevant taxonomic units [31].

The frequency of alleles in a population can be altered through stochastic processes (genetic drift) and deterministic processes (natural selection) [59]. Some alleles can increase the fitness of a clone in a particular environment, and thus its frequency, while other alleles have no effect on fitness or are deleterious and are slowly replaced. In other words, natural selection can promote (positive selection) or prevent (negative selection) the accumulation of variation at a locus. So-called neutral alleles, which are considered neither advantageous nor deleterious, are thought to vary in frequency primarily under the influence of genetic drift, although many such alleles may be linked to others that are under positive or negative selection. Demographic processes, such as population subdivisions, growth, and bottlenecks, also alter the frequency of alleles in profound ways. Both neutral demography and natural selection can contribute to the evolution of bacteria [59]. These processes combine to cause bacteria to naturally form a clonal population genetic structure [46, 87, 88].

Criteria of Clonality

Two basic criteria have been used to assess the role of recombination in disrupting clonal population genetic structure [92]. These criteria include the repeated isolation of a spatially and temporally stable clone and the nonrandom association of alleles at different loci. It has been emphasized that a clone should occur more frequently than a random assortment of alleles would produce [31]. The repeated isolation of a clone in a bacterial population that experienced frequent recombination would occur only if natural selection favored a unique combination of alleles across loci. Such selection would be unlikely if the study examined genetic variation in multiple loci that encode products of unrelated physiological function. In this case, the simplest explanation is that recombination is rare and that periodic selection is influencing genetic variation in a relatively clonal population [32].

As clones propagate and accumulate variation, clonal lineages are developed. Because the chromosomes within a clonal lineage share a common ancestry, the alleles that occur at one locus will be statistically associated with the alleles that occur at other loci. This nonrandom occurrence of genetic variation is called linkage disequilibrium (LD) [92]. However, processes other than clonal population growth can cause LD. For example, bacterial populations that consist of genetically isolated subpopulations, where recombination occurs frequently within but not between subpopulations, can produce apparent LD if the strain typing data of the subpopulations are analyzed together. In this case, the LD that is detected is due to fixed mutations that distinguish the subpopulations. Such bacterial subpopulations have been called cryptic species [31]. Additionally, the spread of highly fit clones can produce temporary LD even if recombination occurs frequently within the bacterial population. These highly fit clones can achieve broad geographic distributions, but their genetic identity will eventually be eroded by recombination with other clones. This situation describes an epidemic population genetic structure and, interestingly, may have been first recognized by epidemiologists [31, 93]. In summary, bacteria display a spectrum of population genetic structures, ranging from the extremes of clonal to freely recombining (panmictic) [31, 45]. Even within the boundaries of a named bacterial species, there can be differences in the relative influence of recombination versus mutation on population genetic structure [83, 94].

Evolutionary Epidemiology

Provided that recombination between clones is relatively rare compared to mutation, the analysis of genetic relatedness can be greatly facilitated by phylogenetic clustering techniques. These techniques enable the tree-like (bifurcating) structures of clonal lineages to be reconstructed from strain typing data, primarily sequence data, and they enable the statistical support for these structures to be quantified [95]. On the other hand, when recombination is relatively common compared to mutation, different loci will have different histories and a single phylogenetic tree will not provide an adequate description of the clone's history. In population genetics terminology, if two isolates share the same allele at a given locus, they are considered *identical by state* at that locus, but this shared allele is only considered *identical by descent* if both isolates inherited it from the same shared ancestor. Thus, in populations with high rates of recombination, the presence of sites that are identical by state, but not by descent can confound efforts to infer the genetic relatedness of isolates. In this case, population genetics techniques can be used to assign isolates to "populations," while accounting for recombination between populations (admixture) [59, 62, 96] and identity by descent can estimated directly as a measurement of relatedness between isolate pairs. Both phylogenetic clustering and population genetics assignment techniques provide a means to classify the variation that is detected through strain typing into biological groups that might have some epidemiological relevance.

Much information about the transmission history of a clone can be extracted from a phylogenetic tree. Not only can the rates of evolution and dates of origin of clonal lineages be estimated, patterns of spatial spread can be studied quantitatively [7, 69, 97, 98]. The powerful insights that arise from phylogenetic analysis of genome sequences raise ethical considerations [21], since the precise role of individuals in the chain of transmission might be revealed [16]. Additional insights about the dynamics of bacterial infectious disease, including estimates of some parameters from standard epidemiological models, may be extractable from population genetics analysis [99]. These advances highlight the potential for strain typing to complement epidemiological investigations. Some advantages of more closely integrating epidemiology and evolution have been noted [46, 75, 100].

Epidemiological Applications of Strain Typing

Local Epidemiology

Local epidemiology refers to the investigation of chains of transmission that unfold over limited spatial and temporal scales. Strain typing in this context has been referred to as comparative typing [86]. Applications include the testing of prior epidemiological hypotheses that have identified a source as a possible cause of an outbreak of infectious disease. Strain typing is essentially

confirmatory for this application because it is expected that the epidemiologically related isolates will also be genetically closely related; infection control decisions may be made without the strain typing data [12]. Strain typing can also be applied to identify unsuspected sources in a spatial or temporal cluster of infectious disease. With this application, strain typing can point to a need for an epidemiological investigation or it can prevent a superfluous investigation [10, 12]. Finally, strain typing can be applied to distinguish between reinfection of a person with a new strain versus reactivation of a chronic infection caused by a persistently-colonizing strain (e.g., tuberculosis) [101–103].

Strain typing tools with high discriminatory ability are needed for local epidemiology because the putative outbreak isolates need to be distinguished from potentially closely related sporadic isolates that constitute the endemic bacterial population [16]. VNTR analysis, SLST, and genome sequencing, are examples of tools that can be used for local epidemiology [41, 50, 75] and multiple approaches have been developed to characterize transmission patterns from these data. These tools allow closely related isolates to be identified, and their routes of transmission and reservoirs to be studied. This information can contribute to the development of infection control practices within an institution or within a community [12, 41, 86].

Global Epidemiology

Global epidemiology refers to the investigation of chains of transmission that unfold over broad spatial and temporal scales. Strain typing in this context has been referred to as library typing [86]. Applications include monitoring the global circulation and distribution of strains in different host populations. These data allow the emergence or re-emergence of strains to be detected, and they can distinguish between the spread of strains versus the independent spread of virulence factors [11, 104].

Strain typing tools that exhibit high reproducibility and assess relatively stable markers are needed for global epidemiology. In addition, these tools should be high-throughput, should have standardized protocols, and should provide a nomenclature that facilitates between-laboratory communication about the strains [86]. PFGE, MLST, and genome sequencing are examples of strain typing tools that can be used for global epidemiology [44, 47, 105]. These tools allow distantly related isolates to be clustered into clonal lineages, and their patterns of spread and virulence trends to be studied [106, 107]. This information can contribute to the development of public health strategies at national and international levels [87, 102].

Association Mapping

Association mapping refers to the use of strain typing tools to identify the precise bacterial determinants (virulence factors) of infectious disease [108]. Association mapping can be used to identify virulence factors even when it is not clear whether strains differ in their virulence potential [109–111]. The virulence of a strain is often determined by its gene content, with more virulent strains differing from less virulent strains by the presence of conspicuous genetic elements. The loss of genes from commensal ancestors can also lead to increased virulence [112]. Association mapping studies resemble epidemiological case-control studies, whereby isolates that are sampled from persons with infectious disease (cases) are compared for gene content and other sequence variations with isolates that are sampled from persons without infectious disease (controls). Principles of sound epidemiological study design should be considered [12]. Moreover, since bacterial chromosomes can exhibit strong LD, it is necessary to subsequently assess whether the putative virulence factors that are identified have a causal association with infectious disease or are merely genetically linked to the authentic virulence factors [108, 113, 114]. Experimental studies are needed for these subsequent steps.

Association mapping provides an observational approach to virulence factor discovery that is based on discerning bacterial exposures in human populations. In contrast, the experimental approach to virulence factor discovery that is often used in microbiology is based on assigning bacterial exposures in a laboratory microcosm. The observational approach allows multiple bacterial exposures to be simultaneously evaluated in their natural setting, but its results can be confounded by imperfect study design. By comparison, the experimental approach addresses the biological plausibility of causation between bacterial exposures and infectious disease, but its results are often restricted to the simultaneous evaluation of a single bacterial exposure in a model of infectious disease that imperfectly represents the natural setting. Thus, the observational and experimental approaches to virulence factor discovery should be viewed as complimentary to each other.

Concluding Remarks

Recent major advances in the laboratory techniques available for bacterial strain typing, in particular the advances in whole genome sequencing technologies, have led to substantial progress in understanding the bacterial-specific determinants of infectious disease. These technological advances have led to the unraveling of the sometimes cryptic epidemiology of important old threats to human health, while also raising a host of important new questions. Knowledge of the characteristics of different strain typing tools, the population genetic structure of different bacterial species, and the peculiarities of different epidemiological applications still need to be integrated within an overarching conceptual framework. These will remain essential knowledge areas as whole genome sequencing becomes more routinely used to address epidemiological problems.

Introduction

History of CRISPR-Cas Biology

The clustered regularly interspaced short palindromic repeat (CRISPR)/CRISPR-associated (Cas) protein system is an adaptive immune system in prokaryotic organisms. It defends against invading bacteriophages and conjugative plasmids.[1] Besides the genes that encode Cas proteins, CRISPR loci harbor short repeats (usually 20–50 bp) separated by nonrepeating spacers (21–72 bp) derived from the invading DNA (Figure 16.1). New spacers are acquired over time and when expressed, guide the Cas effector protein(s) to cleave the invading DNA thus providing immunity against reinfection. Diverse CRISPR-Cas systems have been identified from many bacteria and are now divided into two classes (1 and 2) and further subdivided into six types (I–VI).[2] Class 1 includes type I, III, and IV CRISPR-Cas systems that use multisubunit effector complexes to degrade foreign nucleic acids. Class 2 includes type II, V, and VI and uses a single large Cas protein for the same purposes. Distinct signature Cas proteins are classified in different types, for example, Cas3 in type I, Cas9 in type II, and Cas10 in type III. Understanding the molecular mechanisms of these CRISPR-Cas systems launched the birth of a diversity of novel, programmable CRISPR-based tools for genome editing,[3–5] transcriptional control,[6] nucleic acid detection,[7,8] as well as DNA cloning and imaging.[9,10] Here we summarize the history of CRISPR-Cas biology including major discoveries that led to our mechanistic understanding of these systems and their subsequent translational applications (Figure 16.2).

The CRISPR sequence was fortuitously found in *Escherichia coli* in 1987;[11] however, it was not until 1993 when it was first characterized by Mojica who described the pattern of palindromic repeated sequences separated by short DNA spacers in salt-tolerant *Haloferax mediterranei*.[12] Soon, various types of CRISPR loci were found in many microbes, such as *Mycobacterium tuberculosis* and *Yersinia pestis*. The discovery of other features, such as the presence of specific CRISPR-associated (*cas*) genes in the immediate vicinity and the identification of the protospacer

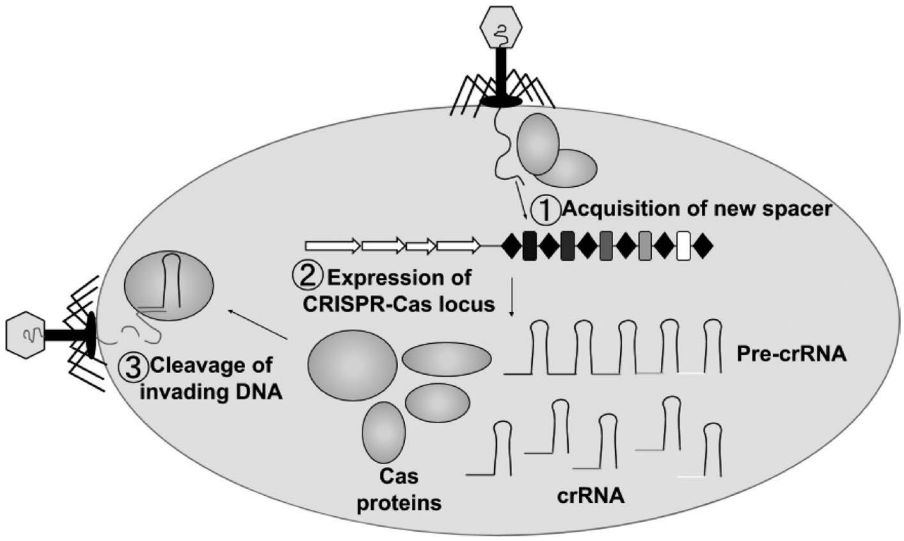

FIGURE 16.1 General mechanism of CRISPR-Cas system in bacterial immunity. (1) A new spacer is added to the CRISPR-Cas locus from an invading phage or conjugal plasmid. (2) Expression of the CRISPR-Cas locus and processing of crRNA. (3) Detection and degradation of foreign genetic material via a crRNA and Cas effector complex.

adjacent motif (PAM), soon followed.[13,14] In 2005, Mojica and other researchers hypothesized that CRISPR was an adaptive immune system based on the sequence of the spacers homologous to bacteriophages, prophages, and plasmids.[15,16] Barrangou et al. proved this hypothesis in 2007 by isolating phage-resistant *Streptococcus thermophilus* that were originally phage-sensitive, where they found the resistant strains had acquired phage-derived sequences in the CRISPR loci and the insertion of multiple spacers correlated with increased phage resistance.[17] They also experimentally identified the role of type II CRISPR *cas9* in phage resistance and *cas7* in generating new spacers and repeats to gain resistance.

The early mechanistic understanding of the CRISPR-Cas system can be ascribed to four major discoveries. First, in 2008 Brouns et al. showed that the CRISPR spacer sequences in *E. coli* produced small RNAs, termed CRISPR RNAs (crRNAs) that were programmable and guided type I CRISPR Cas proteins to target essential genes of lambda phage.[18] Second, Marraffini and Sontheimer reconstituted the type III-A CRISPR system of *Staphylococcus epidermidis in vitro* and demonstrated that it acted on DNA instead of RNA.[19] Third, Moineau et al. demonstrated that CRISPR-Cas9 in conjunction with crRNAs created double-stranded breaks in target DNA at precise positions, 3-nt upstream of the PAM,[20] and Cas9 was the only protein of the CRISPR-Cas9 system required for cleavage. Fourth, by using small RNA sequencing of *Streptococcus pyogenes* with a Cas9-containing CRISPR-Cas system, Deltcheva et al. discovered the trans-activating CRISPR RNA (tracrRNA) in 2011,[21] which forms a duplex with crRNA to guide Cas9 to bind a target. These components (Cas nuclease, crRNA, and tracrRNA) are

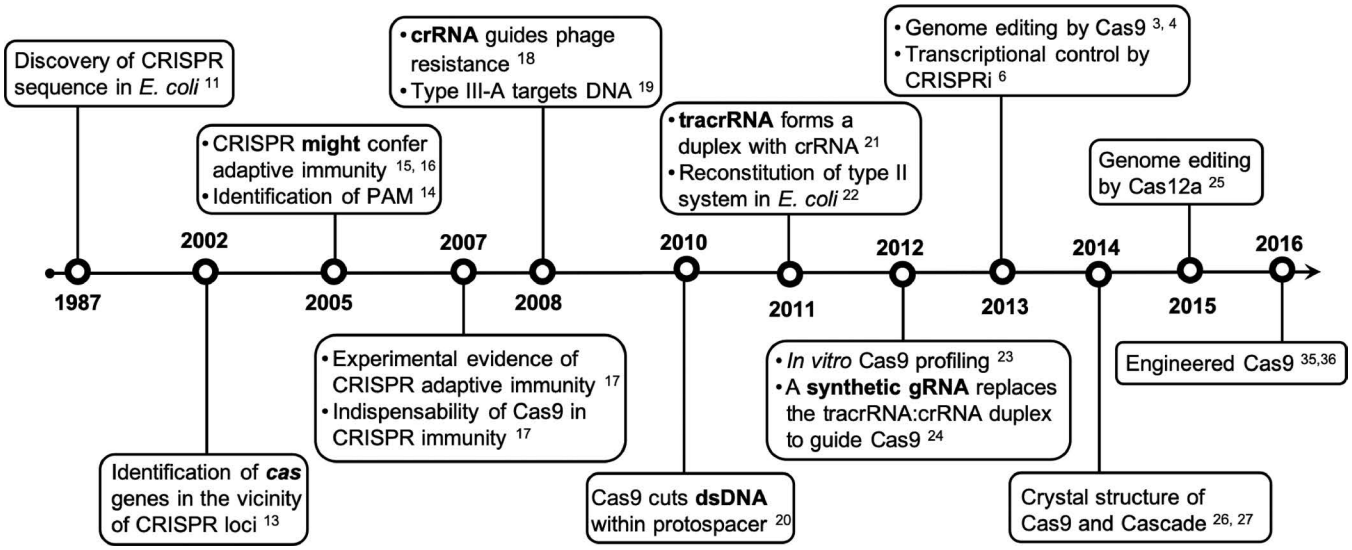

FIGURE 16.2 Major discoveries in the history of CRISPR-Cas biology that lead to CRISPR-Cas technologies.

characterized as major components for immunity in different types of CRISPR-Cas systems.

Further biochemical studies of the CRISPR-Cas components elucidated the detailed molecular mechanisms of action. In 2011, Sapranauskas et al. demonstrated that heterologous expression of a type II CRISPR-Cas system in *E. coli* gained plasmid resistance found in *S. thermophilus*.[22] They biochemically characterized *S. thermophilus* Cas9, including the cleavage site, the requirement for the PAM, and the role of RuvC and HNH domains in cleaving DNA.[23] More importantly, they successfully reprogrammed Cas9 to target a specific site by customizing the 20-nt sequence of the crRNA. At almost the same time, Charpentier and Doudna reported that a single, synthetic guide RNA (gRNA) could replace the tracrRNA:crRNA duplex to guide Cas9 to a target site.[24]

In 2013, multiple research groups repurposed the CRISPR-Cas system for sequence-specific genome editing and transcriptional regulation in both prokaryotes and eukaryotes. Zhang's team first adapted Cas9 for genome editing in eukaryotic cells.[4] Marraffini's group established a two-plasmid based CRISPR-Cas9 system to efficiently counter-select edited genomes in *Streptococcus pneumoniae* and *E. coli* by customizing the crRNA array.[3] Qi et al. employed a catalytically dead Cas9 (dCas9) lacking endonuclease activity to repress expression of targeted genes in *E. coli*, which is also called CRISPR interference (CRISPRi).[6] These exciting reports strongly inspired later studies in many other organisms for a broad range of applied and fundamental research purposes. The continued discovery and dissection of novel CRISPR-Cas systems dramatically expands our understanding of bacterial defense systems and yields novel nucleotide detection and editing tools. For example, the core nuclease of the type V system, Cas12a (also known as Cpf1), presents distinct molecular and biochemical characteristics from Cas9 and has also been applied to edit genomes.[25] Studies on the crystal structure of Cas proteins, such as Cas9,[26,27] Cas12a,[28] Cas module-repeat-associated mysterious proteins (Cmr complex),[29] and Cascade proteins, provides unprecedented insights into how these nucleases work at the molecular level. Extensive studies on Cas9 protein engineering, gRNA modification, optimization of gRNA design and screening tools, have evolved the dominant Cas9 genome editing tool to be a reliable, versatile, and robust system with an exceptional editing efficiency and accuracy.

Cas Nucleases, the Core of CRISPR-Cas Systems

Immunization and immunity are two steps of the CRISPR-Cas mechanism by which prokaryotes become resistant to foreign nucleic acids (Figure 16.1).[30] During the immunization process, exogenous DNA is recognized by a Cas complex and integrated into the CRISPR locus. During the immunity process, the CRISPR locus is transcribed and processed to mature crRNA for interacting with Cas nucleases to form enzymatically active effector complexes. Notably, the effector complexes from different bacteria generally differ in their signature Cas nucleases that are directly responsible for target cleavage and also other accompanying molecular features (e.g., RNA structure, PAM sequence, and PAM position) that the gRNA and target sites must contain for Cas nucleases to work properly. For instance, Cas9 orthologs have distinct preferences for the PAM sequence. Many Cas nucleases have been characterized biochemically, however, here we will focus on two representatives, Cas9 (type II) and Cas12a (type V), both of which have been well studied and widely used for genome editing. A side-by-side comparison of their mechanistic characteristics is shown in Table 16.1.

Cas9 (formerly known as Csn1 or Csx12) is the major component of type II CRISPR-Cas systems and can cleave double-stranded DNA (dsDNA) in a sequence-specific manner. *S. pyogenes* Cas9 (SpCas9) is the most well-known Cas9 that has been widely used in genome editing. It is a large multidomain protein with two nuclease domains, a RuvC-like nuclease domain near the amino terminus and an HNH nuclease domain in the middle.[24] Its cleavage activity is guided by an incorporated tracrRNA:crRNA duplex or a single-stranded chimeric gRNA. The 20-nt sequence preceding the 83-nt conserved gRNA scaffold can be customized to target different DNA sites. The endonuclease activity of SpCas9 creates blunt dsDNA breaks located 3-bp upstream of the 3'-terminal complementarity region formed between the gRNA recognition sequence and the genomic protospacer. Mutagenesis of either of the catalytic sites in the RuvC or HNH motifs abolishes the ability to create DSBs, leaving only nickase activity. Mutations in these active sites did not alter the affinity of protospacer binding. Importantly, a PAM consensus sequence, a short conserved nucleotide stretch next to the protospacer, is required for Cas9 binding and cleavage; however, Cas9 orthologs may require different PAM sequences, for example, *S. pyogenes* (5'-NGG-3'), *N. meningitidis* (5'-NNNNGATT-3'),[31] *Streptococcus thermophilus* CRISPR1 (5'-NNAGAA-3'),[32] *Treponema denticola* (5'-NAAAAN-3').[33] Therefore, the target site of SpCas9 is a 20-bp protospacer sequence followed by the PAM consensus, NGG. Structure-guided protein engineering of SpCas9 developed an "enhanced specificity" SpCas9 with three amino acids mutated (K848A/K1003A/R1060A),[34] which reduced off-target effects without sacrificing its robust on-target cleavage. Engineered Cas9 variants, such as spCas9-NG and xCas9, dramatically expand our targeting space with relaxed PAMs required for targeting.[35,36]

Some Cas9 enzymes from both subtypes II-A and II-C CRISPR systems are able to recognize and cleave single-stranded RNA (ssRNA) with no requirement of a PAM. *Staphylococcus aureus* Cas9 (SauCas9) and *Campylobacter jejuni* Cas9 (CjeCas9) demonstrated RNA targeting capability when provided with both guide RNAs and divalent metal ions.[37] Apart from the programmable and site-specific characteristics, this RNA-guided RNA cleavage is capable of reducing infection by ssRNA phage *in vivo*. The catalytically inactive SauCas9 enables direct PAM-independent repression of gene expression in *E. coli*, which dramatically expands target accessibility. However, structured or occluded RNA regions will block SauCas9 binding and thereby prevent cleavage or repression activity.

Cas12a is a single RNA-guided DNA nuclease type V CRISPR-Cas system in bacteria such as *Prevotella* and *Francisella*.[25] Cas12a typically contains a RuvC-like endonuclease domain but lacks the second HNH endonuclease domain found in Cas9. The RuvC-like domain of *Francisella novicida* Cas12a (FnCas12a) cleaves both strands of the target DNA, perhaps in a dimeric configuration.[25] Instead of requiring both crRNA and tracrRNA like Cas9, FnCas12a only requires crRNA for sufficient DNA cleavage; a minimum of 18 nt of guide sequence in the crRNA will achieve efficient DNA cleavage *in vitro*. The PAM for FnCas12a,

TABLE 16.1

Model of Representative CRISPR-Cas Systems

	Type II Cas9 Nuclease	**Type V Cas12a Nuclease**
Effector complex		Mechanism	Guided by the RNA duplex, SpCas9 cleaves both strands of DNA with two distinct domains, RuvC and HNH, at the position of 3-bp preceding the PAM site.	Guided by the crRNA, FnCas12a makes staggered cut away from the PAM site. The 5-nt or 8-nt overhang depends on the crRNA length.
Guide RNA	tracrRNA:crRNA duplex or a single-strand chimeric RNA	A single-strand crRNA
Substrate	Double-stranded DNA	Double-stranded DNA
Target site (5'– >3')	5'–20 nt protospacer + 3 nt NGG PAM-3' for SpCas9	5'–3 nt TTN PAM + 18–24 nt protospacer-3' for FnCas12a
Seed region	10-mer gRNA sequence in the vicinity of PAM	8-mer gRNA sequence in the vicinity of PAM
Cleavage type	Blunt cut	Staggered cut
Application	Cas9-NHEJ genome editing; Cas9-HDR genome editing; Cas9 nickase-HDR genome editing; Cas9-ssDNA recombineering; Cas9-deaminase base editing; dCas9-based transcriptional repression and activation	Cas12a-NHEJ genome editing; Cas12a-HDR genome editing; DNase-dead Cas12a-based transcriptional repression

which is 5'-TTN-3', is located upstream of the 5' end of the displaced strand of the protospacer. The PAM-proximal seed region that drastically determines target binding is the first 5-nt on the 5' end of the spacer sequence. Two Cas12a enzymes from *Acidaminococcus* and *Lachnospiraceae* have demonstrated efficient genome-editing activity in human cells.[25,38] FnCas12a has been adapted to edit the genome of *Corynebacterium glutamicum*, an anaerobic Gram-positive bacterium for amino acid production.[39] The most efficient *C. glutamicum* crRNA contained a 5'-NYTV-3' PAM and a 21 bp target sequence.

Comparison of Targeted Genetic Engineering Tools

A variety of targeted genetic engineering tools have been developed to modify DNA sequences based on DNA or RNA homology (Table 16.2). TargeTron is based on the group IIA intron Ll.LtrB from *Lactococcus lactis*. As a type of retrotransposon, group II introns achieve site-specific DNA integration through base-pairing of intron RNA with specific DNA sequences assisted by an intron-encoded multifunctional reverse transcriptase. By modifying the intron RNA sequence according to the desired DNA targets, group II intron can

TABLE 16.2

Comparison of Mainstream Targeted Genetic Engineering Tools

Method	**Targeting Steps**	**Factors for Targeting Specificity**	**Efficiency**	**Multiplex Targets**	**Feasible to Study Essential Genes**	**Targeting Spectrum**	**Off-Target Effect**	**Application**
CRISPR-Cas	1	guide RNA	high, but varies in organisms	Yes	Yes	everywhere	low	deletion, insertion, point mutation, transcriptional repression, and activation
TargeTron	1 or 2	intron RNA	varies, depends on the insertion sites and species	No	No	limited, biased near the replication origin	high	gene disruption

be programmed to disrupt a target gene by intron insertion. This technique has been intensively used in microbes with a low DNA repair capacity and transformation efficiency such as solventogenic *Clostridium*;[40,41] however, it might be challenging to find target sites in small genes. Double crossover recombination is based on homologous recombination and requires a suitable counterselectable marker. It involves single crossover integration of the whole plasmid at the target site and then recombination to excise the plasmid backbone to yield a scarless mutant. Recombineering is also a homologous recombination-based method, which is usually assisted by coliphage λ Red systems or the RecET system from Rac prophage. Linear DNA molecules, either double stranded PCR products or single-stranded synthetic oligonucleotides, serve as homologous substrates. Seamless mutants can be generated by two rounds of targeting, recombination, and counterselection.[42] RNA interference is an RNA-dependent gene silencing process to knockdown gene expression. In bacteria, the antisense RNA expressed from a vector will bind to messenger RNA to form an RNA duplex, which will not only promote RNA degradation but also slow down translation to reduce the production of functional proteins. Compared to these mainstream nucleotide-directed targeted genetic engineering tools for genome editing and gene regulation in bacteria, the major advantage of CRISPR-Cas system is the simplicity of the design and the potential of application in multiplexed editing and genome-scale mutagenesis.

CRISPR-Cas Tools for Genome Editing

CRISPR-Cas genome editing tools, irrespective of which Cas nucleases are employed, rely on DNA repair systems to introduce modifications at the target site; involved Cas nucleases either destroy unmutated genomes or create DNA damage to boost DNA repair.[43] Nonhomologous end-joining (NHEJ) and homology-directed repair (HDR) are two major repair systems that are involved with CRISPR-Cas genome editing in both eukaryotes and prokaryotes.[44] Beyond that, irreversible DNA base conversion by cytidine deaminases and introduction of phage recombination machineries have also been implemented during genome editing.[3,45,46] Here we describe four well-established CRISPR-Cas9 editing strategies (Figure 16.3), Cas9-NHEJ, Cas9-HDR, Cas9-deaminase, and Cas9-ssDNA recombineering.

NHEJ-Based Editing

In NHEJ, DSBs are repaired without a homologous template. The Ku protein directly binds and stabilizes the DSB ends, then recruits other NHEJ factors for DNA ligation.[47] NHEJ often generates undefined insertions/deletions (indels) at the target site when the ends of DSBs are remodeled by nucleases and polymerases before DNA ligation (Figure 16.3).[48] NHEJ is mainly found in three bacterial genera, *Bacillus*, *Mycobacteria* and *Pseudomonas*[48,49]; however, the majority of other bacteria lack homologous proteins of Ku and LigD. There are few cases of Cas9-based gene editing in

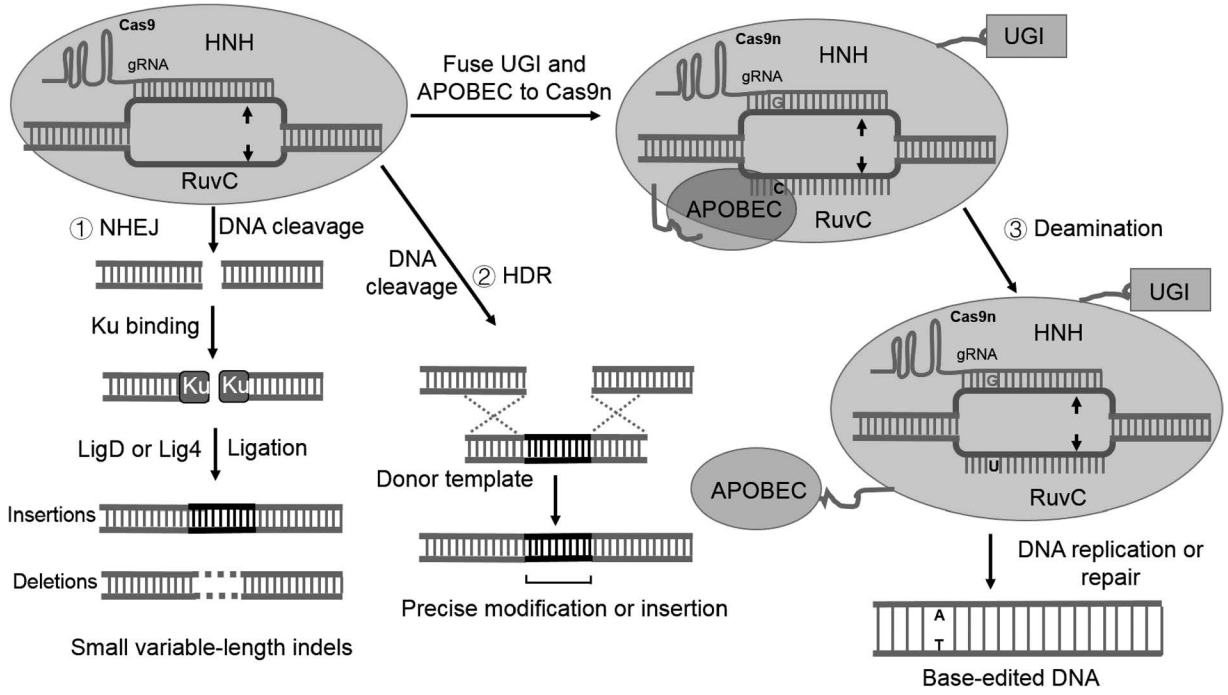

FIGURE 16.3 Cas9-based genome editing. Double-stranded breaks (DSBs) induced by Cas9 can be repaired by NHEJ (①) or HDR (②). NHEJ is Ku-dependent and ends of DSB are repaired without a template and sealed by DNA ligase (Lig4 in Eukarya and LigD in bacteria). As it is error-prone, NHEJ usually introduces small insertion/deletion mutations of various lengths by which the translational frame can be altered. Compared to NHEJ, HDR requires a homologous template sequence to repair the DSB. By recombination, HDR can introduce desired modifications including insertions, deletions, or substitutions. Additionally, Cas9 nickase (Cas9n) can be fused with a cytidine deaminase (APOBEC) and uracil glycosylase inhibitor (UGI) to generate a "base editor" (BE) for direct and irreversible conversion of one target DNA base to another (③). After targeting, the APOBEC will convert cytosine (C) to uracil (U) and then the G:U heteroduplex will be permanently altered to A:T during DNA replication and repair.

prokaryotes using the endogenous NHEJ pathway for DSB repair. For instance, Tong et al. inactivated two genes in *Streptomyces coelicolor* using the Cas9-NHEJ editing strategy.[50] Large chromosomal DNA fragments were deleted efficiently in *E. coli* based on the CRISPR-Cas9 system with a heterologously expressed NHEJ system.[51] The Cas9-NHEJ editing strategy is a powerful tool for bacterial genome reduction and accelerating genome evolution.[51] As NHEJ is a favored DNA repair pathway for DSB repair in most filamentous fungi, particularly in oomycetes,[52,53] the Cas9-NHEJ editing strategy can efficiently introduce indels causing frameshifts or premature stop codons to inactivate gene functions in the absence of homologous templates.

Homologous Recombination-Based Editing

HDR requires an intact copy of the broken chromosomal site to serve as a template for DNA repair.[48,54] It is a faithful and nonmutagenic process[55,56]; its primary function in bacteria is to rescue a stalled or collapsed replication fork. The RecA protein plays a critical role in HDR and is present in all sequenced bacterial species.[55] Cas9 (or its variants) mediated target cleavage is often coupled with HDR for precise genome engineering in bacteria. This Cas9-HDR editing strategy has been successfully applied in many bacteria, including *E. coli*,[57] *Streptococcus*,[3] *Streptomyces*,[58,59] *Tatumella*[57] and *Clostridium*.[5,60] To do so, three components, including *cas9* gene, a target specific gRNA, and a user-designed homologous DNA template, need to be delivered into bacterial cells typically by a single "all-in-one" plasmid or two separate plasmids. Combined with massively parallel oligomer synthesis, Cas9-HDR has enabled genome-wide trackable editing for protein engineering and reconstruction of adaptive laboratory evolution experiments in *E. coli*.[61] While efficient in most bacteria, HDR-based genome engineering is inefficient in most yeasts. Deletion of *ku70* and/or *ku80* genes interestingly promoted HDR events.[52,53] The presence of large homologous donor templates improved Cas9-based editing efficiency in fungi,[62] such as in *Trichoderma reesei*, *Myceliophthora thermophila*, and *Myceliophthora heterothallica*.[63,64] Compared with Cas9-NHEJ editing, Cas9-HDR editing can provide precise editing at intended genomic loci, especially for DNA deletion, insertion, or codon change via substitution.[5,54]

Deaminase-Assisted Base Editing

In addition to insertions, deletions, and substitutions, the CRISPR-Cas9 system has been applied for editing a target base (G:C to A:T conversion), which has been named "base editor" (BE).[46,65] The system consists of two components: (i) a catalytically dead Cas9 (dCas9) or a Cas9 nickase (Cas9n) for targeted DNA binding; (ii) a deaminase tethered to dCas9 for converting cytosine to uracil (Figure 16.3). The original G:C base pair is temporarily converted to a G:U heteroduplex by the deaminase; the G:U will be permanently converted to A:T during DNA replication and repair. This base editing system advances both the scope and efficiency of generating point mutations.[46] Liu et al developed a third generation BE system (BE3) in *E. coli*, which uses Cas9n instead of dCas9 and contains a uracil glycosylase inhibitor at the C terminus of Cas9n. BE3 was able to carry out G:C to A:T conversions precisely and more efficiently than the previous base editing systems.[66] In addition to the G:C to A:T conversion, another new class of base editors, named adenine base editors (ABEs), converts A:T to G:C in *E. coli* and human genomic DNA.[45] The BE3 deaminase is replaced by an evolved tRNA adenosine deaminase in ABE, which is able to deaminate adenine to inosine (I). The inosine can be read as guanosine by the polymerase enzyme and finally the I:T heteroduplex is converted to G:C. Taken together, the application of BE and ABE systems enables precise base editing for all transitions (C↔T and A↔G) in DNA. A major advantage to these base editing systems is that they do not require a donor template, greatly simplifying the entire editing process. They may provide new insights into evolutionary studies of bacteria, especially for studying single nucleotide polymorphisms (SNPs), by improving the construction of this type of mutant.

Cas9-Assisted ssDNA Recombineering

Recombineering (homologous recombination-mediated genetic engineering) is a useful *in vivo* method for genetic engineering, primarily used in *E. coli*.[42,67–70] Based on homologous recombination, it can circumvent the need for the restriction enzyme sites of *in vitro* cloning techniques, and can precisely insert, delete or alter any sequence by homologous recombination of linear DNA including dsDNA from PCR products or ssDNA from synthetic oligonucleotides.[69,71] The λ Red system is now the most commonly used system for recombineering, and contains three phage recombination proteins, Gam, Exo and Beta.[42] Gam prevents the degradation of linear DNA fragments by the RecBCD nuclease in *E. coli*.[72,73] Exo is a 5' to 3' dsDNA exonuclease,[74,75] which generates 3'-overhangs of linear DNA. Beta binds to ssDNA and promotes the annealing of two complementary DNA molecules.[76–78] Using these enzymes, the transformed linear DNA will guide the generation of genetic recombinants.[68,79] As recombineering itself has a low efficiency in promoting homologous recombination, there is little chance of directly selecting the desired mutations without selection pressure.[3,42] Relying on the toxicity of DSBs as a result of inefficient DSB repair in *E. coli*, Wenyan et al. combined Cas9 DNA cleavage with ssDNA recombineering to kill nonmutated cells, thus increasing the targeted editing efficiency.[3] This Cas9-recombineering editing strategy has been applied in other bacteria, such as *Lactobacillus reuteri*,[80] *Corynebacterium glutamicum*[81] and *Pseudomonas putida*.[82]

CRISPR-Cas Tools for Gene Regulation

The ability to precisely control gene regulation is a powerful tool that allows for the interrogation of gene function and aids in improving our understanding of cellular pathways. In addition to gene editing, CRISPR-Cas systems have been repurposed to suppress or activate gene expression. This has presented biologists with an unprecedented ability to reprogram cells, investigate gene function including essential genes, and build new genetic pathways.

Transcriptional Suppression

The first use of CRISPR-Cas tools to suppress gene expression was achieved by engineering a catalytically dead Cas9 (dCas9), named CRISPRi. This was accomplished by altering an amino acid in both the RuvC (D10A) and the HNH (H840A) endonuclease domains

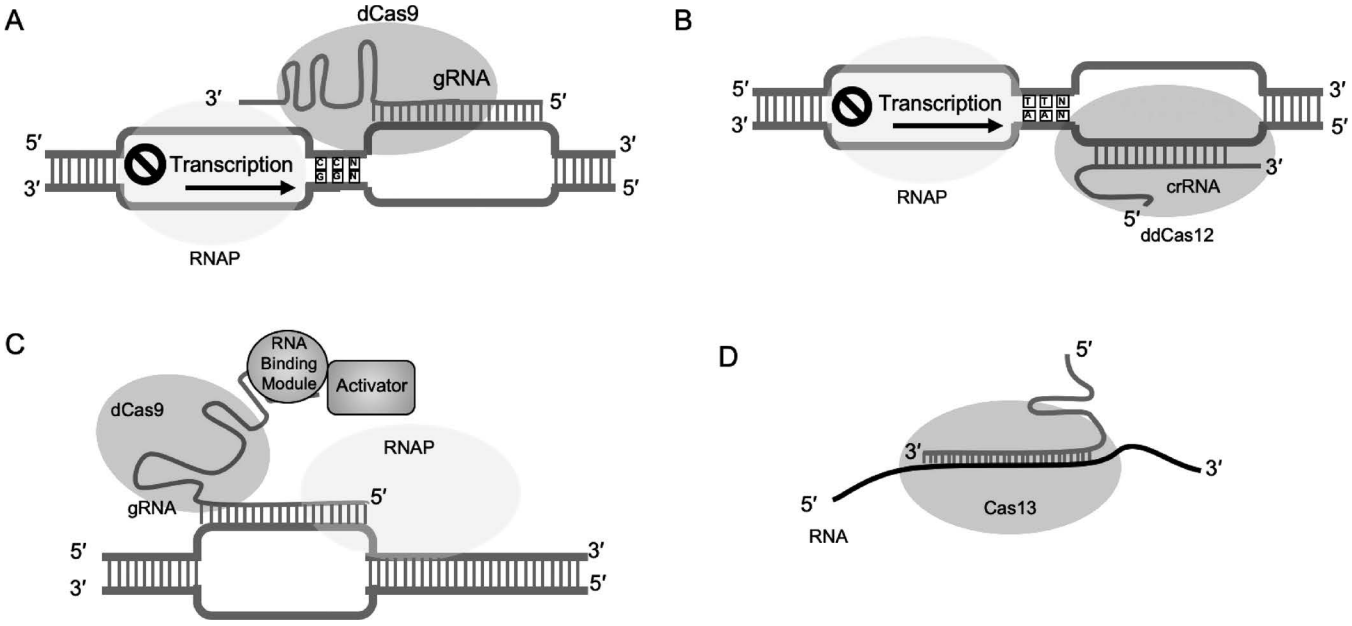

FIGURE 16.4 CRISPR-Cas transcriptional control methods. (A and B) Transcriptional suppression via CRISPRi is achieved by using a catalytically inactive form of either (A) Cas9 or (B) Cas12 to sterically block RNAP from transcribing a gene. (C) Transcriptional activation via CRISPRa is achieved through recruitment of RNAP to the promoter site of a gene. This can be achieved by fusing an activator to either a catalytically inactive form of a Cas protein or to an RNA binding module that interacts with the gRNA. (D) Cas13 directly targets RNA transcripts which can lead to transcriptional suppression of a gene.

(Figure 16.4A).[3,6,23,24,83] Expression of dCas9 along with a gRNA designed to target a gene of interest can precisely and reversibly modify transcription without changing the target sequence. CRISPRi relies on steric hindrance of the RNA polymerase (RNAP) by the catalytically inactive Cas nuclease-gRNA complex (Figure 16.4A and B).[6] The level of silencing can be precisely controlled by moving the target region for the gRNA, altering the length of the gRNA, targeting the same gene with two or more gRNAs, or by using inducible promoters which can be finely tuned to drive the expression of the gRNA and dCas9. Moreover, multiple target genes can be silenced simultaneously just by the expression of additional gRNAs allowing for suppression of an entire operon, pathway, or signaling network.[6] CRISPRi can also be used to interrogate promoter elements and the activity of transcriptional factors by using gRNAs designed to sterically block cognate binding motifs.

Although dCas9 is the most widely used form of CRISPRi, an additional transcriptional suppression system was recently designed using a DNase dead Cas12a (ddCas12a, originally named ddCpf1) from *Acidaminococcus* sp. Cpf1 (Figure 16.4B).[84] Since Cas12a lacks an HNH domain, a single mutation in the RuvC domain (E993A) results in the loss of DNA cleavage. Unlike Cas9, Cas12a possesses its own RNase activity which allows for the processing of the necessary crRNA without tracrRNA or RNase III. This ability offers an advantage over the dCas9 system for multiplexed gene targeting. The dCas9 system requires that each gRNA be expressed separately. However, since ddCpf1 retains its RNase activity, a single CRISPR array can be designed to target multiple genes, greatly simplifying multiplexed gene repression studies.[84]

Transcriptional Activation

The catalytically inactive dCas9 has also been repurposed to activate gene expression, termed CRISPR activation (CRISPRa). However, compared to CRISPRi, targeted gene activation systems in bacteria have lagged behind. While CRISPRi depends on steric hindrance, CRISPRa is inherently more complicated as it requires transcriptional activators that recruit RNAP to the promoter site of a target gene (Figure 16.4C). While the availability of many broadly applicable gene activators in eukaryotes has led to numerous applications of CRISPRa, a paucity of reports in bacteria has stemmed from the lack of usable, well-characterized transcriptional activation domains. The first report of a successful CRISPRa system in *E. coli* utilized the ω subunit (*rpoZ*) of RNA polymerase, which was fused to dCas9 and with the co-expression of a gRNA was able to achieve induction of target gene expression.[85,86] However, this system has not been widely adopted suggesting that it may not be easily adaptable to other types of promoters or other bacteria.

Another group sought to expand CRISPRa by using modified gRNAs, named scaffold RNAs (scRNA), that were designed to contain an RNA hairpin to recruit RNA binding proteins.[87] These RNA binding proteins were then coupled to potential transcriptional activators and used to screen the efficacy of a variety of activation domains. The most prominent induction was produced using the *E. coli* regulator SoxS and was substantially stronger than the RpoZ-based system. Additionally, simultaneous activation of one gene and suppression of a second gene was achieved by expressing both a scRNA and a gRNA in the same system, which allows for unprecedented control over cellular pathways. Fine-tuning of the system can be achieved by using inducible promoters to control the expression of the scRNA, gRNA, and dCas9.

The initial CRISPRa systems all relied on σ^{70} promoters in *E. coli* limiting their applicability and flexibility. Recently, a CRISPRa system was developed that can achieve high activation (over 1,000-fold when all components were induced) from σ^{54} dependent promoters.[88] The activity of σ^{54} is quite different from σ^{70} and, when bound with RNAP to the promoter, forms a stable

closed complex by a way that requires ATP-dependent activation.[89,90] These activators are referred to as bacterial enhancer binding proteins (bEBPs), bind upstream activating domains, and are similar to RNAP II activation in eukaryotes. An engineered activator was constructed by fusing the activation domain of an *E. coli* bEBP PspF (PspFΔHTH) to an RNA-binding peptide ƛN22plus. The gRNA was designed to contain two BoxB aptamer domains, which recruits ƛN22plus peptide containing proteins. This system was able to activate expression from several σ^{54} dependent promoters in *E. coli* and in a nonmodel bacteria *Klebsiella oxytoca* and greatly expands the applicability and flexibility of CRISPRa tools.[88]

Direct RNA Cleavage by Cas Proteins

While the majority of CRISPR-Cas systems are known to target dsDNA, the ability to target RNA has recently been established for Cas9 homologs from *S. pyogenes*, *C. jejuni*, *S. aureus*, and *Neisseria meningitidis*.[37] Initial studies showed that if SpCas9 was supplied with a DNA oligo that contained the PAM sequence (referred to as a PAMmer), it was able to bind and cut ssRNA and, in the absence of a PAMmer, repress translation.[91–94] As mentioned above, SauCas9 was able to protect *E. coli* against an infecting RNA phage.[37] Whether or not this ability exists in nature remains to be seen but was an integral step in confirming the ability of a Cas9 to target RNA *in vivo*. Additionally, SauCas9, along with a gRNA, was able to suppress translation of a GFP reporter sequence chromosomally inserted into *E. coli* as long as the targeted RNA was accessible (unstructured). While it is speculated that repression was caused by occluding the RBS, further investigation will be required to confirm the mechanism of RNA targeting by SauCas9.[37] A programmable, RNA targeted Cas9 greatly expands the application of CRISPR-Cas tools and provides researchers with another level of control over gene expression. Additionally, since SauCas9 can bind ssRNA, this provides the potential to couple this activity to other effector proteins to test their ability to alter translational activity.

Recent efforts to discover novel CRISPR-Cas systems identified a Cas protein (Cas13) that contained an endoRNAse domain suggesting its native activity was to target RNA.[95,96] Cas13 was shown to be able to protect *E. coli* against invading RNA phage infections (Figure 16.4D). However, despite the ability of programmable RNA targeting, Cas13 will indiscriminately cleave surrounding RNA transcripts, which has limited its use in bacteria. This activity does not seem to occur in eukaryotic cells and thus the Cas13 system has been engineered for RNA knockdown, RNA base editing, and live cell imaging.[97]

Other Applications

Nucleotide Acid Detection

Cas nucleases, such as Cas12a and Cas13a, have been used for nucleic acid detection, with the advantages of low cost, high sensitivity, and high specificity. Cas12a and Cas13a are guided by crRNAs; however, Cas12a cleaves dsDNA whereas Cas13a acts on ssRNA. Notably, after target cleavage by these two nucleases, their activated Cas-crRNA complexes present a "collateral" cleavage activity on any nearby nontargeted sequences. Based on the robust collateral cleavage of Cas12a against nonspecific ssDNA, researchers developed a DNA Endonuclease Targeted CRISPR Trans Reporter method (DETECTR),[8] which couples a Cas12a-based DNA reporter with isothermal preamplification. It has been successfully applied for rapid and accurate qualitative detection of carcinoma-associated human papillomavirus (HPV) types from clinical specimens with 1 attomolar detection limit. Similarly, the specific high-sensitivity enzymatic reporter unlocking method (SHERLOCK),[98] employs the collateral cleavage activity of *Leptotrichia wadei* Cas13a to cleave and activate a quenched fluorescent reporter RNA by which the presence of the target sequence of interest is determined. SHERLOCK also demonstrated a remarkable sensitivity detecting target RNA on an attomolar scale, which is more sensitive than currently reported PCR-based methods that have a detection limit on a femtomolar scale. In addition, it has a strong specificity able to distinguish virus strains and pathogenic bacterial strains with low cross-reactivity. Additionally, the SHERLOCK system was upgraded to simultaneously incorporate three Cas13a orthologs and Cas12a,[7] enabling the detection of three ssRNA targets and one dsDNA target in a single reaction in less than 90 minutes.

In Situ DNA Imaging

Fluorescence in situ hybridization (FISH) with oligonucleotide probes plays an important role in studying the composition and distribution of microorganisms in phylogenetic, ecological, diagnostic, and environmental studies. Cas9-mediated fluorescence in situ hybridization (CASFISH) uses a fluorescently labeled dCas9 protein assembled with various gRNAs to rapidly label genomic loci in fixed cells,[9] even at repetitive DNA elements in a G-rich context. This method does not require global DNA denaturation. The experimental duration for detection takes less than an hour, instead of the hours to days that traditional DNA FISH usually takes. Since the dCas9/gRNA complexes bind target DNA with high affinity and stability, it allows for sequential or simultaneous probing of multiple targets and multicolor labeling of target loci in cells if differently colored dCas9/gRNA complexes are applied. This rapid, robust, less disruptive, and cost-effective technology is a valuable tool for basic research and genetic diagnosis.

DNA Cloning

In light of the programmable sequence-specific cleavage by Cas9, researchers have applied it to perform targeted cloning of large gene clusters that are usually expensive to synthesize or difficult to clone using traditional PCR or restriction enzyme-based methods. The Cas9-Assisted Targeting of CHromosome segments (CATCH) method liberates 150 kb DNA from a bacterial chromosome by in-gel Cas9-based cleavage on both sides of the target DNA, followed by *in vitro* Gibson assembly to ligate with a BAC vector.[10] In contrast, the transformation-associated recombination (TAR)-CRISPR method integrates Cas9-based DNA liberation with intracellular homologous recombination in yeast cells to accomplish DNA ligation.[99] TAR uses homology of up to a few hundred bp for homologous recombination, instead of the ~20 bp of homology required in Gibson assembly. These methods overcome the longstanding challenge of heterologously

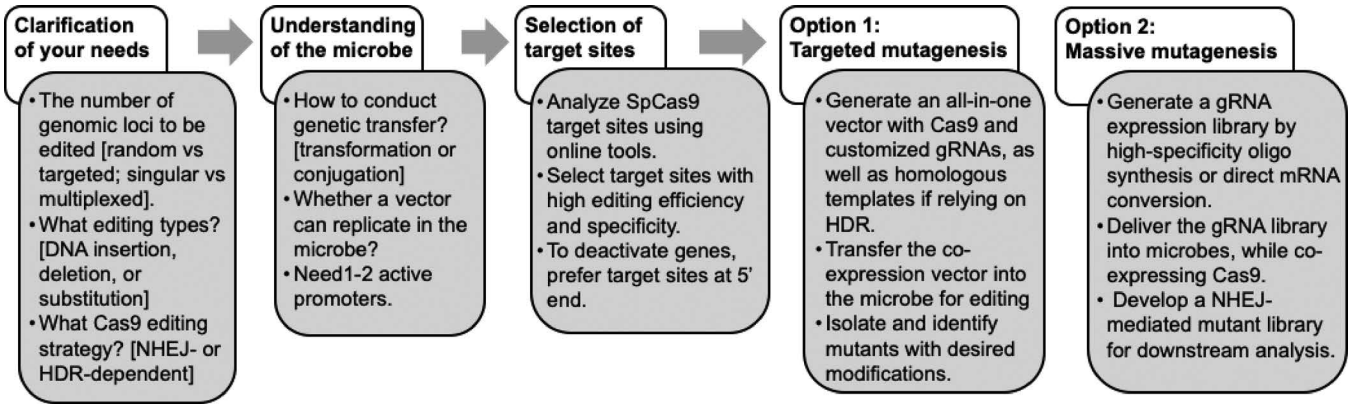

FIGURE 16.5 A guideline for the development of Cas9-based genetic engineering for microbes of interest.

studying large DNA fragments and hopefully promote the engineering of microorganisms to study microbial biosynthetic gene clusters that potentially produce valuable biomolecules, such as pharmaceuticals and biofuels.

Harnessing Cas9 for Your Editing Interest

As the prominent advantages of CRISPR-Cas genome editing tools have been proven in all three domains of life, here we describe a general guideline for users to harness the well-characterized SpCas9 to edit bacterial genomes of interest. We aim to clarify the overall feasibility, preparatory work, and experimental implementation of SpCas9 adaptation (Figure 16.5).

Knowing Your Purpose

The user should specify what DNA sequences or genes will be targeted and by what editing types (e.g. deletion, insertion, and substitution). The SpCas9 genome editing tool provides strong flexibility, allowing for singular and multiplexed editing, as well as the generation of genome wide random mutant libraries. The targeting capability is determined by whether the gRNA is singular or multiplexed in a cell, or if many singular gRNAs are pooled for editing in a large cell population. To achieve a precise modification at the target site, a homologous DNA template that carries the desired modification should be provided along with the SpCas9-gRNA co-expression system in order to guide the endogenous HDR system to fix the DNA break made by SpCas9 cleavage. If no homologous sequence is present, the error-prone NHEJ system will repair the cut and introduce unpredictable indels at the joint site. As unpredictable, these indels may cause a frameshift mutation but this does not guarantee the creation of a loss-of-function mutant. As most bacteria lack functional NHEJ, the toxicity of the SpCas9-induced dsDNA breaks can often lead to failure of successful genome editing.[5]

Preparation of Basic Genetic Toolkit

The Cas9 nuclease and its corresponding gRNA are two essential components that need to be co-expressed in host cells. The user should have prior knowledge of whether the microbe of interest is genetically tractable in terms of genetic transfer (e.g., transduction or transformation) and basic genetic toolkit (e.g., shuttle vectors and functional elements, like promoters, for gene expression). More specifically, the user should determine the antibiotic resistance of the microbe of interest, a suitable vector backbone, a genetic transfer protocol, as well as one or two active promoters to drive the expression of SpCas9 and gRNA.

Selection of Your Target Sites

Cas9 nucleases may require distinct characteristics at the target sites. SpCas9 recognizes a ~20 bp protospacer ending with a 5'-NGG-3' PAM site. Extensive studies have shown that the GC content, secondary structure, and nucleotide preference in the protospacer, as well as the location of mismatches between the target site and gRNA, are all important for editing efficiency and accuracy.[100–103] A few computational programs or online tools, such as CRISPOR (http://crispor.org),[104] CHOPCHOP (https://chopchop.cbu.uib.no),[105] and CRISPR library designer (http://www.e-crisp.org/E-CRISP/index.html),[106] provide user-friendly interfaces to search for qualified target sites in bacterial genes or genomes. Qualified target sites closer to the 5' end of a gene are preferred to avoid the potential for a truncated product that could result from a target site toward the end of a gene.

Plasmid Construction and Mutagenesis

Homologous template-dependent genome editing by Cas9 or Cas9n can circumvent the toxicity of DNA breaks, allowing for predictable, precise, and efficient editing. To do so, the user needs to clone three components into a host-applicable vector, including a Cas9n cassette, a customized gRNA cassette, and a homologous DNA template. The vector backbone with a suitable selection marker gene can be modified to an intermediate plasmid containing just the Cas9n expression cassette. It is worthwhile to determine if the microbial host has a biased codon usage, which may require a codon optimized Cas9 for efficient translation. The intermediate plasmid will be further devised to target a specific gene by incorporating a customized gRNA expression cassette and corresponding homologous donor template. The all-in-one plasmid can be constructed in a single step using Gibson assembly. Multiplexed targeting is also feasible by integrating more than one gRNA and their corresponding donor templates into a single plasmid.

Once the plasmid is transferred into the host cells, antibiotic-resistant recipient cells will express Cas9n and the gRNA to form catalytic effector complexes to create a nick at the target site, which triggers the HDR system to introduce a faithful modification based on the homologous donor template. It is encouraged to check the expression of SpCas9 nickase and gRNAs by real-time PCR. Targeted editing sites are identifiable by PCR amplification of the region harboring the modification and Sanger sequencing of PCR amplicons. Passaging the antibiotic-resistant cells in a selective liquid medium is an efficient way to enrich edited cells for isolation. If the plasmid has a temperature-sensitive replication origin, elevating the growth temperature will cure the plasmid to get plasmid-free cells with desired genetic modifications. Plasmid curing is necessary to iterate editing using the same plasmid backbone.

Massive Mutagenesis

To generate a genome-wide mutant library using Cas9-NHEJ or Cas9n-NHEJ strategies, high-quality gRNAs for all genes should be computationally designed and then chemically synthesized; however, it may be costly to synthesize a large gRNA pool. Alternatively, a method that converts mRNA into a gRNA library for random editing has been established,[107] such that neither chemically synthesized gRNAs nor prior knowledge of target DNA sequences is required. Its major limitation is the potential off-targeting of some resulting gRNAs in the pool. For genome-wide transcriptional repression with the CRISPRi technology, the user should use dCas9, instead of Cas9.

Conclusion and Future Outlook

CRISPR-Cas technologies have revolutionized our ability to edit genomes, finely tune gene expression, and image genomic loci. Major advantages of these tools are their efficiency, cost-effectiveness, simplicity, and applicability to a wide range of cell types. Engineering and directed evolution have already greatly expanded the application of the most widely used Cas9 system by increasing its targeting ability while decreasing off-targeting effects. The diversity of CRISPR-Cas systems continues to grow as new systems are being identified at a rapid pace. As researchers adapt these technologies to fit their specific needs, innovative applications continue to emerge. These tools will continue to transform all areas of biological research for years to come.

Introduction

The ability of humans to interact and communicate effectively with one another is dependent upon a language system that places similar objects together in distinct categories that are easily recognizable by the general population. Items such as saws, screwdrivers, and hammers are grouped together under the general term "tools," while meat, bread, and milk are collectively referred to as "foods."

The field of microbiology is no different than those examples. Bacteria recovered from a variety of sources, such as soil, water, aquatic and terrestrial ecosystems, and vertebrates need to be "labeled" such that they can be associated with various functions, including industrial processes, bioremediation, and plant growth. In no area of the microbial world are these labels more important than in the arena of medical and diagnostic microbiology, infectious diseases, and related disciplines. Here, the ability to communicate locally, nationally, or internationally regarding infection, disease outbreak investigations, epidemics, and pandemics is critical in the detection, identification, epidemiologic monitoring, and control of infectious diseases of bacterial etiology. For these subdisciplines, labels must be created that can be effectively communicated worldwide. To achieve these goals, a defined set of rules and guidelines have been developed that cover these labels better known as bacterial taxonomy.

History of Bacterial Taxonomy

The history of bacterial taxonomy began when Antony van Leeuwenhoek through his mastery of developing lenses and construction of more than 500 microscopes in his lifetime, described "tiny animacules" for the first time.[1] Visualization of bacteria, protozoa, and molds from lakes, human saliva, and tooth scrapings by Leeuwenhoek between 1673 and 1674 ushered in a new era. However, initial attempts at naming and classifying these bacteria did not occur until the late 19th century.[2] Almost 200 years later, the field of bacteriology had advanced significantly, such that by the mid- to late-19th-century scientists had created various media, some biochemical tests, and stains to culture, identify, and describe many bacteria associated with various processes including life-threatening human infections. Examples of cardinal achievements produced during this era include the description/isolation of *Shigella dysenteriae* type 1 by Kiyoshi Shiga, *Salmonella* Typhi by Eberth and Gaffky, and the development of Endo agar to help differentiate typhoid bacilli from *Escherichia coli*.[3–5]

Along with the multitude of scientific discoveries during the "golden era" of bacteriology came a litany of names associated with disease-causing bacteria or those associated with commensal processes. Most of these bacteria were given scientific names (genus and species) although acronyms or scientific jargon were also used such as "Shiga's bacillus." Despite these achievements, several problematic issues arose. Since there was a very limited number of phenotypic tests available at the time, bacteria that were isolated were often poorly characterized. It was also difficult to determine quickly whether two independent researchers were working on identical, similar, or different bacterial species. Various bacteriologists described *Bacillus coli commune* (1885), *Bacillus coli* (1895), and *Bacterium coli* (1895), which were actually synonyms of *E. coli*, while *Micrococcus pneumoniae* (1884) and *Diplococcus pneumoniae* (1886) hold the same taxonomic status in relation to *Streptococcus pneumoniae*. The multiplicity of names for a single bacterial species during the infancy of bacteriology led to uncertainty, taxonomic confusion, and numerous issues regarding isolation and identification.

Today's bacterial taxonomy that is used worldwide to effectively communicate between clinicians, scientists, and investigators is a continuum of three ongoing major processes, namely (1) the attempt to put stability and order to bacterial systematics regarding the naming and description of new species; (2) the evolution from biochemical (phenetic analysis) to molecular and phylogenetic

tests (cladistic analysis) with which to assess the uniqueness or relatedness of one taxon to another, and; (3) the current rules regarding the identification, naming, and description of new taxa.

Bacterial Systematics

By the 1930s, bacterial taxonomy had already become quite complex with more than 2,700 species recognized in the fourth edition of *Bergey's Manual of Systematic Bacteriology* (note: most of these species no longer exist).[2] Numbers of new species and genera continued to be described as more metabolic, phenotypic, and structural data became available.[6] Where bacteria should be classified was highly speculative with many scientists believing they should be grouped with plants— even the seventh edition of *Bergey's* in 1957 still classified them with plants.[6]

During the mid-to-late 1930s, however, a movement began that culminated in a proposal by Stanier and van Niel in 1962 to accept a clear division between bacteria (prokaryotes) and animals and plants (eukaryotes).[6] This separation was also reflected in the 1974 eighth edition of *Bergey's Manual*. Concurrent to these changes was a drive to codify the nomenclature of prokaryotes.[7] The first edition of the *International Code of Nomenclature of Prokaryotes* was published in 1957 with the goal for those who use scientific names of microorganisms "to use correct names and to use them correctly."[8] However, reclassification of bacteria and establishment of *The Code* did not alleviate the myriad problems associated with the existing taxonomy, including duplication of names, lack of type cultures, and poorly characterized or described taxa. To rectify this situation, the Judicial Commission of the International Committee on Systematic Bacteriology authorized a review of all taxa and to only retain those names that were adequately described, and if cultivatable, with a type or neotype strain.[9] That list was published in 1980 as the Approved Lists of Bacterial Names and consisted of 1,792 species and 290 genera.[9] If the species name did not appear on that list it had no standing in nomenclature. Essentially, this 1980 list set the bacterial taxonomy time clock at zero, providing us with a fresh start.

Evolution of Methodologies in the Description of Prokaryotic Species

Figure 17.1 represents a graphic depiction of the transition in methodologies used to describe and propose new prokaryotic species between 1960 and 2010.[2,6,10] Prior to 1960, description and classification of bacterial species was almost totally reliant on cellular morphology, metabolic requirements, and in some instances, pathogenicity.[6] By the early 1960s, phenotypic characterization of bacteria had taken a major step forward with the introduction of numerical taxonomy (NT) into bacterial systematics. NT of bacteria, pioneered by Sokal and Sneath, involves determining the overall similarity of groups to each other based upon the analysis of many weighted or unweighted phenotypic features or characters.[11].

Results were originally coded into a computer to generate matching coefficients such that groups were linked together based upon highest similarity. Matching similarity (S_{sm}) indicating essentially identical groups at the species level required threshold values around 85% using NT methods.[12] Coupled to the use of NT was the mol% G+C content of bacteria. Strains belonging to the same species should not exhibit more than a 2–3% variation in G+C content.[13,14]

NT had faded from playing a principle role in the identification and description of new taxa by the 1980s and was largely replaced by DNA-DNA hybridization (DDH). DDH started to be introduced in the field of bacterial systematics in the early 1970s and was immediately used to describe many new species of fermentative as well as nonfermentative bacteria of clinical importance. Instead of phenotypic markers, DDH was an overall assessment of the genetic similarity or relatedness between two DNA genomes. The phylogenetic definition for a species using DDH was subsequently determined to be 70% or more relatedness with a ΔT_m (stability of the heteroduplex) of 5°C or less.[15] This method was highly successful and has remained the "gold standard" for many years in determining the uniqueness of a newly proposed taxon and the relatedness of existing species. Traditional DDH, however, suffers from several drawbacks being expensive to perform, technically challenging, labor-intensive and restricted to only a few major research laboratories worldwide. Chemotaxonomy, which was commonly used in describing new species by studying the composition of cell walls, isoprenoid quinones, and bacterial cytochromes, was primarily utilized in this aspect between 1960 and 1980.[6]

In the mid-1990s, an additional molecular platform became available commercially with the introduction of 16S rDNA gene sequencing.[16] The technology allows for the sequencing of the 16S housekeeping genes, which occur in multiple copies within the bacterial chromosome and codes for rRNA. Commercial products contained database matrices that could be compared to variable regions (or full reads) within the 16S gene of test strains sequenced by users. Strains exhibiting <98.7% sequence similarity to established taxa strongly suggested a new species.[12,16] However, the converse statement of ≥98.7% sequence similarity did not necessarily imply species identity to the top match as many studies have indicated that for many groups rRNA sequence similarities are highly conserved with little variation detected among species of a given genus and in some instances a family.[16] Higher sequence similarity values require other techniques, such as DDH, to determine true relatedness.

A novel molecular-phenotypic technique, MALDI-TOF or matrix-assisted laser desorption/ionization-time of flight mass spectrometry had made its way from the research laboratories of the 1980s into diagnostic laboratories by 2010. The technique, based upon the spectral analysis of surface proteins (phenotypic), determines a spectrum for each strain analyzed.[17] The technique has been commercialized with a standard database matrix similar to 16S rDNA sequencing. However, unlike 16S, final results for a possible identification can be rapid (minutes). Like 16S, it has limitations, such as it cannot accurately detect certain groups at the species level. While it is not a standalone technology, such as DDH or 16S, with defined thresholds to determine species relatedness, it has been used in conjunction with sequence analysis (polyphasic approach) to screen for novel species. The term "taxonogenomics" has been coined by Fournier and Drancourt to describe such an application.[18]

The replacement of Sanger sequencing by the advent of high-throughput technologies, often referred to as whole genome

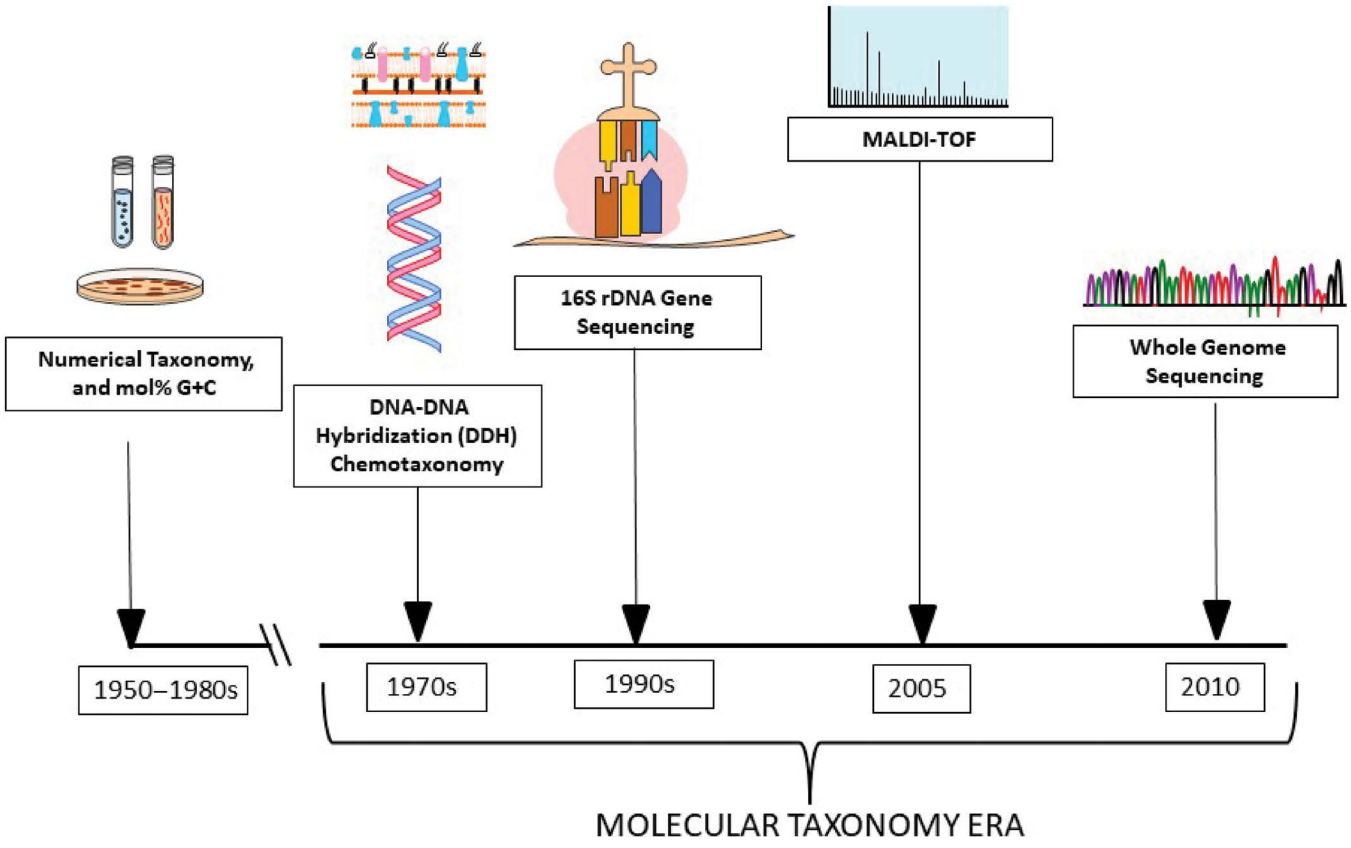

FIGURE 17.1 Molecular taxonomy era.

sequencing (WGS) or next-generation sequencing, has revolutionized our ability to redefine bacterial species and phylogenies on a molecular basis since 2010. Now, the availability of WGS to many laboratories allows for the side-by-side comparison of complete genetic sequences of both genomes. A numeric value, called the average nucleotide identity or ANI, provides for a similarity comparison between two chromosomes. It has been determined that an ANI of 95% is similar to DDH relatedness values of 70% in defining a genomospecies.[6,19] Many other potential applications of WGS are available that are not discussed here. These include routine species identification, outbreak investigations, and epidemiologic disease monitoring.

The Taxonomic Revolution: Domains, Divisions, and Diversifications

The collective impact of the emergence of molecular technologies to delineate bacterial taxonomy and phylogeny has been enormous and cannot be underestimated. It has led to major scientific discoveries of immense importance regarding prokaryotes and their biology, ecology, and disease spectrum. Only a few will be mentioned here.[20] Probably the single greatest achievement in modern microbial systematics was the discovery by Carl Woese of a third "domain" of life. Comparing 16S and 18S sequence catalogues of prokaryotes and eukaryotes revealed to Woese that two types of prokaryotes existed, one called "Bacteria" and the other called "Archaea."[21] These two domains, despite being prokaryotes, are only distantly related to each other. The third domain is "Eucarya."[22] This discovery by Woese has revolutionized our concept of the tree of life with researchers trying to discover an ancestral form from which some or all of these domains originated.

Molecular methodologies have led to many other discoveries regarding prokaryotes. DDH supported by WGS has determined that all *Shigella* species and *E. coli* constitute a single species at the DNA level.[23,24] Separate names are retained because of the immense clinical and public health importance of *Shigella*. Similarly, *Salmonella* serotypes, previously thought to each represent a different species (at one time more than 2,000 species existed), have been determined to fall within a single species designated *Salmonella enterica*.[25] Thus, such common foodborne pathogens like *S.* Typhimurium, *S.* Enteritidis, and *S.* Newport all belong to a single subspecies (there are five) of *S. enterica*. The outcome of these taxonomic investigations has been a complete revision of *Salmonella* nomenclature.[26]

The availability of less expensive high-throughput WGS has led to the development of new fields of endeavor involving bacterial taxonomy. Metagenomics and culturomics have the ability to characterize and study microbial populations composed of noncultivable and well as culturable bacteria.[27] These technologies are being used to study the NIH-funded Human Microbiome Project (HMP), that is, the resident microbial flora of humans. One aspect of the HMP is to determine the microbial composition of the gastrointestinal tract, what constitutes homeostasis, and how this population changes in disease states.[28] Disease states

that such data might have a profound influence on include ulcerative colitis and Crohn's disease.

Bacterial Taxonomy: Nomenclature, Classification, and Rules for the Road

Bacterial taxonomy is composed of two distinct yet related entities, nomenclature and classification. Nomenclature involves the naming and description of new taxa, principally at the species level. It also involves to a lesser extent the correct naming of various groups within taxonomic rank such as genus, family, order, and higher levels. Classification, on the other hand, involves the appropriate placement of related groups or clades next to each other based upon phylogenetic analyses. Taxa, such as species, are placed next to their "nearest neighbors" using one or more bioinformatic methods (such as maximum likelihood) to create trees. Together, nomenclature and classification create dendritic trees or trees of life for the domain, Bacteria.

Bacterial nomenclature is codified, that is, it is governed by an international set of rules and guidelines that are required to be followed for the valid publication of a new taxon such as a bacterial species (only taxonomic rank with defined criteria). Valid publication requires the proposed species to be formally published in the *International Journal of Systematic and Evolutionary Microbiology* (IJSEM) or be published elsewhere, meet all the requirements for valid publication, and subsequently appear in a Validation List in IJSEM. Some of the rules for valid publication include deposition of the nomenclature type strain in at least two recognized culture collections, the proposed name must be clearly indicated, the etymology of the new name must be stated, and the properties of the taxon described.[29,30] A set of minimal standards for the use of genome data regarding the taxonomy of prokaryotes has also been proposed.[20] A complete set of rules can be found in the latest edition of the *International Code of Nomenclature of Prokaryotes*.[8] The ultimate goal or aim of bacterial nomenclature is to maintain stability of names.

In contrast to bacterial nomenclature, there is no official classification system for bacteria. No rules or codes exist. Bacterial classification is currently applied using an operational-based model.[6] This model uses a defined set of criteria with thresholds or limits to identify groups or clades that share phylogenetic similarities.[6] A polyphasic approach to this type of analysis includes phenotypic (biochemical, chemotaxonomic, MALDI-TOF) as well as genetic (G+C, 16S, WGS) data. Unlike bacterial nomenclature, classification is always in a state of flux, constantly evolving, as new techniques and methods generate different approaches, theories, and proposals as to where taxa should be placed or linked on phylogenetic trees. Acceptance of a classification scheme is primarily based upon general acceptance and broad-based use by the medical and scientific communities. A perfect example of this is the species *Pseudomonas maltophilia* (1961), which has been reclassified as *Xanthomonas maltophilia* (1980), and then *Stenotrophomonas maltophilia* (1983) where it resides today. Same taxon (species) but found by phylogenetic investigations not to be a pseudomonad nor a member of the genus *Xanthomonas*.

Bacterial nomenclature and classification are currently intertwined in the proposal, description, and creation of new taxa and taxonomic ranks, although what involves nomenclature versus classification can be confusing to the average microbiologist. As an example, the major taxonomic changes occurring in the genus *Aeromonas* from its proposal in 1943 through 1988 are depicted in Table 17.1. The genus has undergone multiple transformations including reclassification into three separate families (*Pseudomonadaceae* → *Vibrionaceae* → *Aeromonadaceae*) and creation of several new species based initially on phenotypic methods and later using DDH. Today, the genus is composed of more than 30 validly published species (http://www.bacterio.net/aeromonas.html) with several species containing multiple subspecies. The dramatic increase in the number of *Aeromonas* species since 1988 is a testimony to the general availability of a number of techniques besides DDH such as 16S gene sequencing, MALDI-TOF, and the phylogenetic analysis of housekeeping genes including *rpoD, gyrB, dnaJ,* and *recA*.

Bacterial Taxonomy Issues

The complexity of bacterial systematics is not without its issues. These issues fall into two main categories, namely **practical issues** and **theoretical issues**. Practical issues for bacterial taxonomy are those matters that affect everyday scientific communications in the literature to laboratory reports identifying infectious agents. Theoretical issues involve conceptual topics concerning the status of taxonomic ranks, their definition and description, and real and virtual methods of such descriptions encompassing each rank.

Practical Issues

In the practical arena, there are important concerns regarding the proliferation and description of new species. Due to the emergence of WGS, more than 1,000 new bacterial species are proposed each year in major systematic journals.[40] As of 2017, there are more than 15,448 validly published species. To add to this logarithmic explosion of taxa are two simple facts, that the vast majority (>90%) of newly proposed species are described on the basis of a single type strain and that most of these species originate from environmental rather than clinical sources.

Such trends have a profound effect on both the medical and scientific community. Companies producing commercial identification/susceptibility panels will undoubtably be unable to keep up with the increasing number of proposed taxa. This is due to several factors including the gross number of species described, the fact that most new taxa cannot be identified by phenotypic methods, and finally the clinical/medical significance of these single-strain species is unknown. Even updating in-house MALDI-TOF systems will be problematic as the cost of acquiring each type strain from a recognized culture collection could be prohibitive. For international culture collections the increasing number of new taxa may overwhelm their capabilities.

What can be done? The publication of single isolates as new species has been questioned as early as 2001.[2,41] A leading systematic publication, *Antonie van Leeuwenhoek*, has recently changed its editorial policy such that the "one species, one paper" concept will only be considered for publication for studies where the authors can demonstrate novel biology and features of interest such as ecological insights relevant to sources of isolation.[42] A theoretical proposal to establish plural taxonomies for cultured

TABLE 17.1

Taxonomic Evolution of the Genus *Aeromonas* 1943–1988

Date	Family	Genus	Species	Bacterial Taxonomy	Taxonomic Application	Comments	Ref
1943	*Pseudomonadaceae*	*Aeromonas*	*hydrophila*	Nomenclature & Classification	Phenetic	Previously known as: *P. hydrophilus*, (*Aerobacter liquefaciens*)	31
1953	*Pseudomonadaceae*	*Aeromonas*	*salmonicida*	Nomenclature & Classification	Phenetic	*Bacterium salmonicida* Fish pathogen	32
1965	*Vibrionaceae*	*Aeromonas*	All species	Classification	NT	Transfer to new family	33
1976	*Vibrionaceae*	*Aeromonas*	*sobria*	Nomenclature	NT	New species	34
1980	*Vibrionaceae*	*Aeromonas*	*hydrophila punctata salmonicida*	Nomenclature & Classification	Previous data	Approved List	9
1983	*Vibrionaceae*	*Aeromonas*	*media*	Nomenclature	NT	New species	35
1984	*Vibrionaceae*	*Aeromonas*	*caviae*	Nomenclature	Previous data	Revived name, Validation List 15	36
1986	*Aeromonadaceae*	*Aeromonas*	All species	Classification	16S, 5S, rRNA/DNA hybridization	Transfer to a new family	37
1987	*Aeromonadaceae*	*Aeromonas*	*veronii*	Nomenclature	DDH	New species	38
1988	*Aeromonadaceae*	*Aeromonas*	*schubertii*	Nomenclature	DDH	New species	39

Abbreviations: DDH = DNA-DNA hybridization; NT = numerical taxonomy.

and uncultured bacteria could be expanded.[43] Such a concept could have separate tracts for bacterial taxonomy involving taxa of clinical, public health, and medical importance versus environmental species. With a minimum estimate of at least 10 million microbial species on the planet, the vast majority of unnamed taxa described in the future will originate from soil, water, vegetation, invertebrates, and vertebrate species other than humans.

Theoretical Issues

There has always been some controversy regarding what constitutes a useful and workable modern bacterial taxonomy, particularly since the advent of the molecular era. The cornerstone or foundation for all bacterial taxonomy is the definition of a bacterial species, which is the only taxonomic rank that, at present, is clearly defined based on DNA relatedness, 16S rDNA sequence similarities, and ANI. However, what constitutes a bacterial species or the "species concept" in general continues to be a major topic of discussion and contention.[44] The species definition has always been evaluated and re-evaluated as technology and methods change.[45] Many taxonomists believe the present definition of a bacterial species should be completely revised[2,6,46–48] while others suggest that it be entirely rebuilt from scratch.[49] One of the current proposed revisions is the designation of DNA sequence information in lieu of a type culture for uncultured bacteria.[50]

While taxonomic updates are required to address emerging definitions, concepts, and theories on bacterial taxonomy, such changes are not without potential consequences, particularly for the medical community, including clinical microbiologists. Some of these severe implications have been recently addressed in a multiauthored international commentary.[51] Whether a universal approach to bacterial taxonomy can ever be achieved is highly debatable as pure taxonomists and those that use scientific names daily (physicians, nurses, laboratorians) have entirely different perspectives on the topic. Above all, taxonomy for those in clinical practices needs to be understandable, useful, and workable on a day-to-day basis. Communication is important as we deal with infections, outbreaks, and epidemics from a human perspective.

Introduction and Summary

The exterior structure of the unicellular microorganism contains and protects its intracellular structure, while regulating solute ingress and egress. This exterior structure is called the *cell envelope*. Within the domain of the archaea the structure of the cell envelope is a proteinaceous surface layer.[1–3] Within the domain of the bacteria, different cell envelope structures are found.[4–7] A key difference is whether the bacterium has a single membrane (is monoderm) or has two membranes (is diderm).[8] A key similarity for most monoderm and diderm bacteria is the presence of a structural *peptidoglycan* polymer that surrounds the entire bacterium.[9–14] This polymer is also called the bacterial *cell wall*. Although the terms cell envelope and cell wall often are used interchangeably, the terms are distinct. The cell envelope is the multilayer barrier that separates and protects the cytoplasm of the bacterium from its external environment. It includes the peptidoglycan cell wall, the membrane(s), the periplasmic space between the two membranes of the diderm bacteria, and the macromolecules that are associated with all of these structures. The location of the cell wall within the cell envelope is a fundamental distinction. The cell wall is the exoskeleton of the Gram-positive bacteria, albeit with extensive integration of a second glycopolymer, the teichoic acids[15–17] as well as capsular polysaccharides.[18] This peptidoglycan cell surface overlays an interstitial space, itself above the single bilayered, cytoplasmic membrane.[19] The cell wall of Gram-negative bacteria is an endoskeleton that is located within the *periplasm*, an interstitial space that separates the cytoplasmic membrane from the outer membrane on the surface of the bacterium. Both of its membranes are bilayered.[20] The dominant structural entity of the surface layer of the Gram-negative bacterium is the lipopolysaccharide.[4,21] The nonmotile, strictly aerobic, nonfermenter Gram-negative pathogen *Acinetobacter baumannii* is an excellent example, from the dual perspectives of structure and pathogenicity, of the overall organization of the Gram-negative cell envelope.[22] The peptidoglycan cell wall of the *mycobacteria* is likewise an endoskeleton that is located above the cytoplasmic membrane.[23–27] The mycobacterial peptidoglycan is extensively modified on its outward face by a galactofuran polysaccharide outer surface, to which in turn are attached oligoarabinofuran strands that themselves have mycolic acid lipids. In numerous cartoon representations of the mycobacterial cell envelope, these mycolic lipids are represented as the inner leaflet of a second membrane (mycomembrane), with the exterior surface of the mycobacterium cell envelope a structurally heterogeneous (lipid, protein) "capsule."[28] These three envelopes are represented in cartoon form in Figure 18.1A. Bacteria further diversify their cell envelopes. The cell wall is absent in the phylogenically Gram-positive *Mycoplasma* (within the class *Mollicutes*),[11,29,30] and appears in cryptic structural form in the "cell-wall-less" and obligate intracellular pathogens of the class *Chlamydiae*.[31–33] Figure 18.1B shows in cartoon form the proteinaceous Z-ring that initiates septal peptidoglycan synthesis in Gram-negative bacteria, Gram-positive bacteria, and mycobacteria in contrast with the peptidoglycan ring of the cell-wall-less *Chlamydiae*. Other unusual adaptations with respect to the peptidoglycan cell wall are encountered. The symbiotic relationship between the mealybug and its *Moranella* bacterial symbiont derives from the horizontal transfer of genes for peptidoglycan biosynthesis from the genome of the bacterium to the genome of the insect.[34,35]

Peptidoglycan is a synonym for the cell wall. The term peptidoglycan is encountered especially when the molecular structure of the cell wall is emphasized, while a second synonym *murein* (Latin, wall) emphasizes its etymology. In the mature

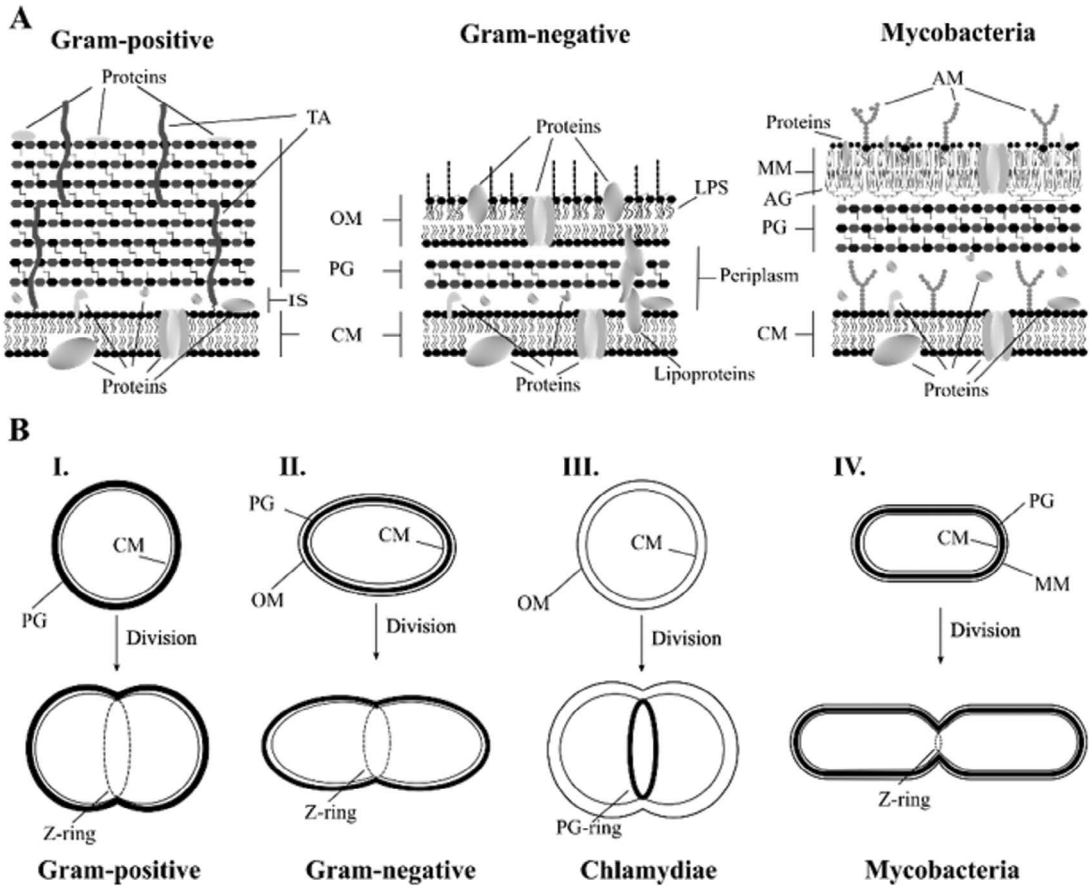

FIGURE 18.1 Panel A. A schematic comparison of the cell wall of the three major eukaryotic pathogens (I.) Gram-positive, (II.) Gram-negative, and (III.) mycobacteria. The notable differences are the presence of one or two membranes, the thickness of the peptidoglycan layer, and the modifications made to the membranes. Panel B. Representation of the peptidoglycan localization in bacteria: in (I.) Gram-positive, (II.) Gram-negative, and (IV.) mycobacteria, peptidoglycan is present throughout the whole cell-cycle (including in cell division). In the Gram-negative *Chlamydiae* (III.) peptidoglycan is synthesized at the septum during cell division, and recruits the division proteins.[31,36–38] (*Abbreviations:* CM: cytoplasmic membrane, PG: peptidoglycan, OM: outer membrane.)

bacterium the peptidoglycan (the cell wall) is a polymer—a single molecule—called the *sacculus*. In this final form it surrounds the three-dimensional bacterium and both imparts, and captures, the shape of the bacterium.[39–44] As its name implies, the molecular structure of the peptidoglycan has both saccharide and peptide components. The bacterium biosynthesizes glycan strands that have, on alternate saccharides, a peptide stem. The structure of the glycan strands is a repeating β-(1,4)-linked disaccharide. This disaccharide, [(*N*-acetylglucosamine)-(*N*-acetylmuramic acid)]$_n$, is often referred to by the acronym "NAG-NAM." This disaccharide is highly conserved among the Gram-positive bacteria, Gram-negative bacteria, and the mycobacteria. Depending on the bacterium, the NAG-NAM glycan is further structurally modified. For example, *O*-acetylation of the saccharide is a common resistance mechanism that protects the cell wall from degradation by the [NAM-NAG]$_n$-cleaving hydrolase lysozyme. *O*-Acetylation also regulates autolysin-dependent transformation of the peptidoglycan during cell division.[45–48] Spore-forming Gram-positive bacteria extensively transform their peptidoglycan during spore formation and germination, notably involving the formation of an intramolecular δ-lactam moiety in the NAG saccharide during spore formation.[49–52] The oligopeptide stem distinguishes the NAM saccharide from the NAG saccharide. The polymeric cell wall is made by the covalent crosslinking of the stem peptide of one glycan strand, with the stem peptide of an adjacent glycan strand. The result is a polymeric mesh of cross-linked glycan strands surrounding the bacterium. Although Gram-positive bacteria, Gram-negative bacteria, and mycobacteria show common structural features with respect to the oligopeptide structure of the stem, the precise stem structure is characteristic of the particular bacterium. Stem structure is particularly varied among the Gram-positive bacteria (as discussed later). An elegant scientific history of the peptidoglycan, written from the perspective of the numerous methods used for the imaging of this polymer, is available.[53]

The functions of the cell wall—whether exposed to the environment (as is the case for the Gram-positive bacteria) or protected from the environment (as is the case for the Gram-negative bacteria and mycobacteria)—are the preservation of the integrity of the bacterium through both cell growth and cell division, the creation of cell shape, and the creation of a scaffold for the attachment of macromolecular complexes. Examples of these complexes include the porin proteins used for solute ingress and egress, and complexes used for adhesion, environmental sensing, molecular transport and secretion, and propulsion (the pili and the flagella). The peptidoglycan segregates the bacterium from its

environment while containing the turgor pressure of the bacterial cytoplasm. This polymeric barrier is not static. Not only does the peptidoglycan undergo continuous remodeling as the bacterium grows, cell division requires the creation of a cell-wall septum that ultimately fractures as the cells divide. At all stages of bacterial growth, structural integrity of the cell wall is paramount. The ability of the cell wall to simultaneously possess structural strength, integrity, and malleability; to contain the turgor pressure and to impart cell shape; to embed numerous complexes; and to accommodate the complex restructuring demanded by cell growth and division is truly remarkable. Moreover, all of these tasks must coordinate with the bacterial cell cycle.[54–61]

As a consequence of the essentiality of the cell wall to bacterial viability, and the relative accessibility of many of the enzymes involved in cell-wall synthesis and remodeling, these enzymes are important targets for antimicrobial agents.[62–66] The search for new targets for new antimicrobials, for structural improvements of existing antimicrobials, and for the identification of new synergistic antimicrobial combinations, are moving forces for research on the cell wall.

Gram-Positive and Gram-Negative Bacteria

In 1884, the Danish bacteriologist Hans Christian Gram developed a staining process that categorized most prokaryotes as either stain-retaining (positive) or stain-negative. Gram-staining involves the gentle drying of a bacterial suspension on the microscopy slide, the addition of a solution of crystal violet (or methylene blue), the rinsing with an iodine solution, the decolorizing with ethanol, and the final addition of safranin as a counterstain. Bacteria that retain the crystal violet-iodine complex, and thus appear purple-brown colored under microscope, are designated as Gram-positive. Those bacteria that do not retain the crystal violet stain appear red-colored and are designated as Gram-negative.[67–69] Numerous bacteria (such as the mycobacteria), however, do not stain decisively. Although it was intuitively clear the staining differentiated between structurally different cell envelopes, it took more than half a century to confirm this hypothesis.[70] Developments in transmission electron microscopy (TEM) in the 1950s gave the first images of bacterial cell envelopes. These images revealed the two membranes of the Gram-negative bacteria. The 5–7 nm-thick (in the Gram-negative bacterium *Escherichia coli*) cell wall is located in the periplasmic space between the inner and the outer membranes.[14] Imaging places the cell wall centrally located within the periplasm and close (if not adjacent) to the inner leaflet of the outer membrane where the peptidoglycan anchors cell envelope-penetrating structures such as the flagellum and secretion systems.[71–74] The exterior surface of Gram-negative bacteria—that is, the outer leaflet of the outer-membrane bilayer—consists primarily of specialized glycolipids (the lipopolysaccharides, LPS) and proteins. The approximately 20 nm-thick cell wall of the Gram-positive bacteria is located above their single membrane.[75–79] This peptidoglycan is extensively modified by the addition of teichoic lipopolysaccharides, capsular polysaccharides, and proteins. A superbly illustrated review presents the current molecular-level understanding of the key structural complexes of the Gram-positive bacterium using *Streptococcus pneumoniae* as the teaching example.[80] The absence of an outer membrane, and the greater thickness of the Gram-positive cell wall compared to Gram-negative bacteria, result in better retention of the iodine-dye complex and thus preservation of the characteristic color of the stain.[81] Gram-staining facilitates mass-spectral identification of bacteria in blood culture.[82] Efforts toward alternative bacterial "staining" methods include modification of the crystal violet with fluorophores, gold nanoparticles, and magnetic nanoparticles[83]; the development of fluorescent stains that are selective for Gram-negative bacteria[84] or for Gram-positive bacteria[85]; and fluorophores that are incorporated metabolically into the peptidoglycan to facilitate imaging.[86,87] The development of imaging modalities that might have diagnostic value—especially with respect to distinguishing resistance mechanisms—is an active area of research.[88–90] For example, the incorporation of 11C-radiolabeled methionine into the peptidoglycan has promise for PET diagnosis of bacterial infection in whole animals.[91,92]

Chemical Structure of the Peptidoglycan

The nuance of peptidoglycan structure for Gram-positive bacteria is more diverse than that for Gram-negative bacteria, reflecting (for example) the growth circumstance.[93] The glycan strand component of the peptidoglycan for most eubacteria peptidoglycan is a repeating β-1,4-linked disaccharide.[94] The structure of the repeating disaccharide is *N*-acetylglucosamine (abbreviated NAG or GlcNAc) linked to an *N*-acetylmuramic acid (NAM or MurNAc) saccharide (Figure 18.2). The NAG-NAM disaccharide

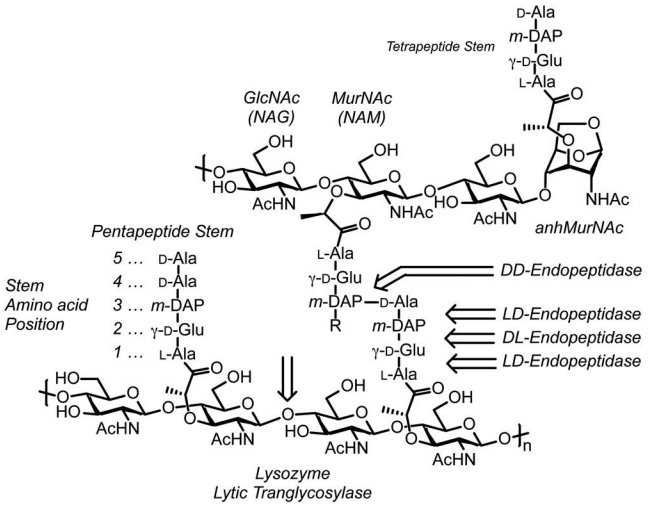

FIGURE 18.2 Structure of two Gram-negative peptidoglycan strands interconnected by a 4,3-crosslink. The glycan structure of the strands is the repeating $(GlcNAc\text{-}\beta\text{-}1,4\text{-}MurNAc)_n$ disaccharide. The left MurNAc of the lower strand has a full-length pentapeptide stem terminating with the customary D-Ala-D-Ala as the amino acids 4 and 5. The left MurNAc of the upper strand is crosslinked, using the ε-amine of the m-DAP amino acid at position 3, to the D-Ala at position 4 of the right MurNAc of the lower strand. The upper strand shows an anhydroMurNAc (anhMurNAc) terminus created by a lytic glycosylase (the structure of the glycan strand terminus in Gram-positive bacteria is not proven). The arrows indicate the position and generic identity of the enzymes that cleave the peptide and the glycan of the peptidoglycan.

core is identical for most Gram-positive bacteria, Gram-negative bacteria, and mycobacteria. An exception is the Gram-positive methanogenic Archaebacteria, that have a pseudomurein peptidoglycan structure having a β-D-*N*-acetylglucosamine (NAG) β-1,3-linked to α-L-*N*-acetyltalosaminuronic acid (NAT) as the repeating disaccharide.[3,29,95] The length of the $(NAG\text{-}NAM)_n$ strands can be analyzed by exhaustive amidase degradation of the peptide stem of the NAM saccharide, followed by chromatography with mass-spectrometry analysis. However, this analysis is uncommon due to the lack of availability of the specific amidases required to degrade the specific peptidoglycan of the bacterium.[96] This analysis has been done for a number of common bacteria. A key basis for this analysis is recognition that the terminating step in glycan strand biosynthesis is the nonhydrolytic, enzyme-catalyzed cleavage of the NAM-NAG disaccharide. The cleavage reaction is an intramolecular transacetalization at the NAM saccharide, cleaving the glycosidic bond, to create an anhydromuramic (anhNAM) glycan strand terminus.[97,98] This reaction is catalyzed by members of a family of lysozyme-like enzymes, called the lytic transglycosylases.[99,100] Glycan strand lengths, in the few bacteria where this length has been measured, indicate a distribution of lengths. The average glycan strand length for the Gram-negative, rod-shaped bacterium *E. coli* is 54 saccharides corresponding to the $[NAG\text{-}NAM]_{27}$ structure. The average length value for the Gram-negative, curve-shaped bacterium *Vibrio cholerae* is $[NAG\text{-}NAM]_{12}$.[101,102] A concise perspective on the intimate relationship among the bacterial cytoskeleton, peptidoglycan biosynthesis and structure, and cell shape is given in a complementary review.[103] The average glycan length in the PAO1 laboratory strain of *P. aeruginosa* is $[NAG\text{-}NAM]_{60}$ (measured by the terminal anhNAM content of the muropeptides) with 42% cross-linking.[104] The distribution of the length of most glycan strands in the Gram-positive *Staphylococcus aureus* ranges from $[NAG\text{-}NAM]_3$ to $[NAG\text{-}NAM]_{10}$ with a maximum of $[NAG\text{-}NAM]_{26}$ disaccharide units per strand.[105]

Unlike the repeating disaccharide backbone, the amino acids comprising the NAM stem demonstrate variability, especially among the Gram-positive bacteria. The most common peptide stem structure is the (full-length) pentapeptide attached to the D-lactyl moiety of the muramic (NAM) saccharide. The customary pentapeptide sequence is L-Ala (the first amino acid, position-1), γ-D-Glu (amino acid-2), *meso*-diaminopimelate (abbreviated *m*-A_2pm or *m*-DAP, and customary to Gram-negative bacteria and some Gram-positive bacteria such as *B. subtilis*) or L-Lys (customary to Gram-positive bacteria) as amino acid-3, and D-Ala in positions four and five. In many Gram-positive bacteria additional amino acids (usually a mono-, di-, tri-, tetra-, or pentapeptide) are added to the ε-amine of the position-3 L-Lys. These additional amino acids are referred to as the bridging oligopeptide of the peptidoglycan stem. Peptidoglycan polymerization involves the crosslinking of the stem found on one glycan chain to the stem found on a neighboring glycan strand. Cross-linking occurs in either of two ways. The predominant way is DD-4,3-crosslinking (sometimes written as DD-3,4-crosslinking). Figure 18.2 shows the structural schematic for two DD-4,3-crosslinked Gram-negative glycan strands. This crosslink is synthesized by a penicillin-binding protein (PBP) DD-transpeptidase enzyme. As suggested by the historical appellation penicillin-binding protein, PBPs are inactivated by members of the β-lactam antibiotic family (penicillins, cephalosporins, carbapenems, monobactams, and monosulfactams). This inactivation predisposes the bacterium to the bactericidal effect of the β-lactam. In DD-transpeptidase catalysis, the first step is the transfer of the acyl moiety of the position-4 D-Ala to an active-site serine of the transpeptidase, with loss of the position-5 D-Ala as a leaving group. This first step is the acylation half-reaction. In Gram-negative bacteria, the second step is transfer of this acyl moiety to the ε-amine of the D-stereocenter of the position-3 *m*-A_2pm amino acid of a neighboring strand. In Gram-positive bacteria, acyl transfer is made to the ε-amine of the L-Lys, or to the terminal amine of the bridging oligopeptide attached to the ε-amine of the L-Lys. This step is the acyltransfer, or deacylation, half-reaction. β-Lactam antibiotics are structural surrogates for the -D-Ala-D-Ala dipeptide terminus of the full-length stem. The β-lactam antibiotics readily acylate the active-site serine of the PBPs (with opening of the β-lactam ring), but then cannot transfer the resulting acyl-moiety. The PBP is inactivated as the acyl-enzyme.[106] All bacteria contain multiple PBPs. The pattern for PBP inactivation by β-lactams is absolutely dependent on β-lactam structure. Some PBPs are essential, and some less essential. Accordingly, the selection of a β-lactam with high affinity for an essential PBP has clinical importance. PBP profiles for many of the clinically used β-lactams are available for the Gram-positive bacterium *Streptococcus pneumoniae*,[107] and the Gram-negative bacteria *E. coli* and *Klebsiella pneumoniae*.[108,109]

The second way of crosslinking is LD-3,3-crosslinking. Here, the acyl-donor moiety is the α-L-stereocenter of the position-3 amino acid, with the position-4 D-Ala as the leaving group. The acyl-acceptor used to accomplish crosslinking is (as is also the case in DD-4,3-crosslinking) the terminal amine of the position-3 amino acid. LD-3,3-Crosslinking is catalyzed by cysteine-dependent LD-transpeptidases (Ldts). The Ldt transpeptidases are inactivated by some carbapenem β-lactams.[110–115] The widely used penicillin and cephalosporin β-lactam antibiotics do not inactivate the Ldt transpeptidases. Ldt transpeptidases are found in mycobacteria, Gram-positive bacteria, and Gram-negative bacteria. Indeed, LD-3,3-crosslinking is the dominant crosslinking pattern in stationary-phase mycobacteria.[116,117] In *E. coli* LD-3,3-crosslinking accounts for 2–10% of the peptidoglycan crosslinks in exponential growth, and up to 16% at stationary growth.[118] Microbiological interest in LD-3,3-crosslinking has followed recognition of its abundance in mycobacteria, of its possible role as an emerging mechanism for resistance of the Gram-negative bacteria to clinically used β-lactams,[119,120] and of the importance of LD-carboxypeptidase activity to the creation of the helical shape of *Helicobacter pylori* (and other "bent" bacteria).[44,121,122]

Stem peptide structure is the basis for a semisystematic nomenclature that is used to describe the peptidoglycan.[123,124] In this three-fold alphanumeric nomenclature, a first letter "A" denotes a DD-4,3-crosslink, a second number denotes the type of bridge peptide structure, and the third Greek letter denotes the amino acid at position-3 of the peptide stem. The common crosslink of *E. coli* (a DD-4,3-crosslink, *m*-A_2pm at position-3 with no bridging amino acid, and thus a "direct" link) is designated as "A1γ". The common crosslink of *S. aureus* (a DD-4,3-crosslink, L-Lys at position-3 with a pentaglycine crossbridge) has "A3α"

designation. Although this nomenclature is cumbersome and imprecise, it is still used. Thus the peptidoglycan of the Gram-positive, rod-shaped, nonmotile, catalase-negative bacterium *Weissella cryptocerci* (isolated from the gut of an insect) is described as an "A4α" type (DD-4,3-crosslink, L-Lys at position-3 with a -Gly-D-Glu dipeptide bridge).[125] Common stem crosslinking patterns are shown in Figure 18.3.

The presence of D-amino acids in the stem (and in some bridge) peptides is widely understood to prevent their degradation by ordinary peptidases and proteases. This objective is further abetted by the D-Glu position-2 amino acid, linked through its γ-carboxyl rather than through its α-carboxyl. The differing amino acids found in the bridge, and the differing oligopeptide lengths of the bridge, are understood to provide the basis for recognition by the PBPs (and other cell-wall enzymes) involved in peptidoglycan synthesis, remodeling, and degradation. The pentaglycine bridge structure that is found in methicillin-resistant *S. aureus* (MRSA) is notable.[127,128] MRSA uses a PBP (termed PBP2a) that is intrinsically resistant to irreversible acylation by the β-lactams as the key basis for its β-lactam resistance.[129] In the presence of β-lactams, PBP2a is synthesized and functions as a transpeptidase where the other PBP transpeptidases of *S. aureus* are impaired. The *fem* factor genes—encoding factors essential for methicillin resistance—facilitate the transpeptidase function of PBP2a.[130,131] The most notable of the Fem proteins are three acyl transferases that assemble the Gly_5 bridge using glycyl-tRNA as the glycyl donor. FemX adds the first Gly, FemA adds the second and third Gly, and FemB adds sequentially the fourth and fifth Gly residues. The pentaglycine bridge is essential to the cell integrity of the MRSA bacterium.[132] The extent of the peptidoglycan crosslinking reaction is variable. In *E. coli* the degree of crosslinking varies from 30% to 60%,[101,133] while the extent of crosslinking for *S. aureus* is higher (74–92%).[105]

The stem peptide is also an attachment point in Gram-positive bacteria for macromolecules, including polysaccharides and proteins. These attached proteins function in cell-wall remodeling, adhesion (adhesins and pili), resistance, and virulence.[1,134–138] The catalysts for protein attachment are the membrane-bound sortases. The best-studied sortase system is that of *S. aureus*.[139] Attachment of the wall teichoic acids to the peptidoglycan contributes significantly to the viability of the Gram-positive bacterium,[15,140,141] and attachment of the pili and adhesins contributes to virulence.[142–146] Sortase inhibition is advantageous to antibacterial chemotherapy.[147–151] Sortases recognize an LPXTG motif in the leader sequence of proteins. As this leader sequence emerges on the periplasmic side from the Sec transport pathway, the threonine acyl moiety is transferred to the active-site cysteine of the sortase as the threonine-glycine bond of the LPXTG motif is cleaved.[152–155] The sortase catalyzes transfer of this acyl moiety to the stem peptide of the key biosynthetic intermediate in peptidoglycan biosynthesis, Lipid II.[138] This modified Lipid II serves as the substrate for transglycosylase-catalyzed synthesis of the glycan strands of the peptidoglycan, which are subsequently cross-linked by transpeptidase catalysis.

Sacculus degradation is a robust method for evaluating peptidoglycan structure. Chemical dissolution of the bacterium (accomplished by boiling the bacterium in SDS detergent, or alternatively with hot brine)[156] recovers the polymeric sacculus in the form of an insoluble shell that preserves the shape of the bacterium—a ghost of the bacterial shape stripped of proteins and membranes. Exhaustive hydrolytic degradation of the sacculus, using lysozymes tolerant of NAG-NAM structural variation, transforms the insoluble sacculus polymer into an array of soluble *muropeptides*.[157] The muropeptides are separated by chromatography[96,156,158–160] or by electrophoresis.[161] Muropeptide characterization is done using mass spectrometry.[162,163] The muropeptide array includes both uncrosslinked NAM-NAG disaccharide derivatives, crosslinked (two NAM-NAG disaccharides, connected through the stem), and small amounts of anhNAM structures arising from lytic transglycosylase termination of glycan strand biosynthesis. Mass spectrometry gives the mass of the muropeptide, including the crosslink position and functional group modifications (such as amidation)[164] to the stem peptide. The presumably distinct muropeptide (peptidoglycan) domains within the sacculus—for example, in a rod-shaped bacterium the different peptidoglycan composition of its poles compared to its sidewalls—are not differentiated. The different methodologies for muropeptide analysis of Gram-negative, Gram-positive, and acid-fast bacteria are reviewed elsewhere.[165] The application of this methodology is exemplified. The peptidoglycan structures of both *Staphylococcus carnosus* and *Deinococcus indicus* reflect metabolic influence.[93,166] Muropeptide analysis identified the role of the *msaABCR* operon in the control of the balance between cell-wall synthesis and cell-wall hydrolysis in *S. aureus*.[167] Significant change in the peptidoglycan structure of *Streptomyces coelicolor* accompanies the transition from mycelial growth to spores, with identification of a role for specific muropeptide structures in spore development.[168] *Enterococcus faecium* releases a peptidoglycan hydrolase (SagA) to the gut for the purpose of cleaving crosslinked muropeptides derived from its peptidoglycan, to give structures that are better recognized by the NOD-dependent innate immunity pathway. As a result the intestinal barrier function is enhanced and host immunity toward competitive pathogens is improved.[169] Muropeptide analysis clarified the subtle structural differences with respect to muropeptide-dependent pathogenicity of *Neisseria* species,[170] guided the identification of a membrane-spanning complex for helical shape formation in *H. pylori*,[122] and demonstrated that the *Campylobacter jejuni* helical to coccoid transition correlated to specific alteration of peptidoglycan structure and diminished the ability of the muropeptides to effect NOD1-dependent and NOD2-dependent activation of innate immunity.[171] The peptidoglycan is different between the body and the stalk of *Caulobacter crescentus*.[172] Muropeptide analysis identified a new peptidoglycan hydrolase (TagX) that is essential for the biogenesis of the type VI secretion system of *A. baumannii*.[173] The peptidoglycan of the spirochete *Borrelia burgdorferi* is atypical, with an L-ornithine-glycine dipeptide replacing the much more common *meso*-diaminopimelic acid of other Gram-negative bacteria at the third position of the stem. The resulting muropeptides are persistent antigens in Lyme arthritis.[174] The use of the sacculus as a substrate allowed characterization of the entire family of the eleven lytic transglycosylases of *Pseudomonas aeruginosa*.[175] Last, in response to outer membrane lipopolysaccharide stress, *E. coli* compensates by activation of an LD-transpeptidase to accomplish 3,3-crosslinking transpeptidation (to replace the more common DD-4,3-crosslinking).[118] The distinction between LD-3,3-crosslinked peptidoglycan and DD-4,3-crosslinked

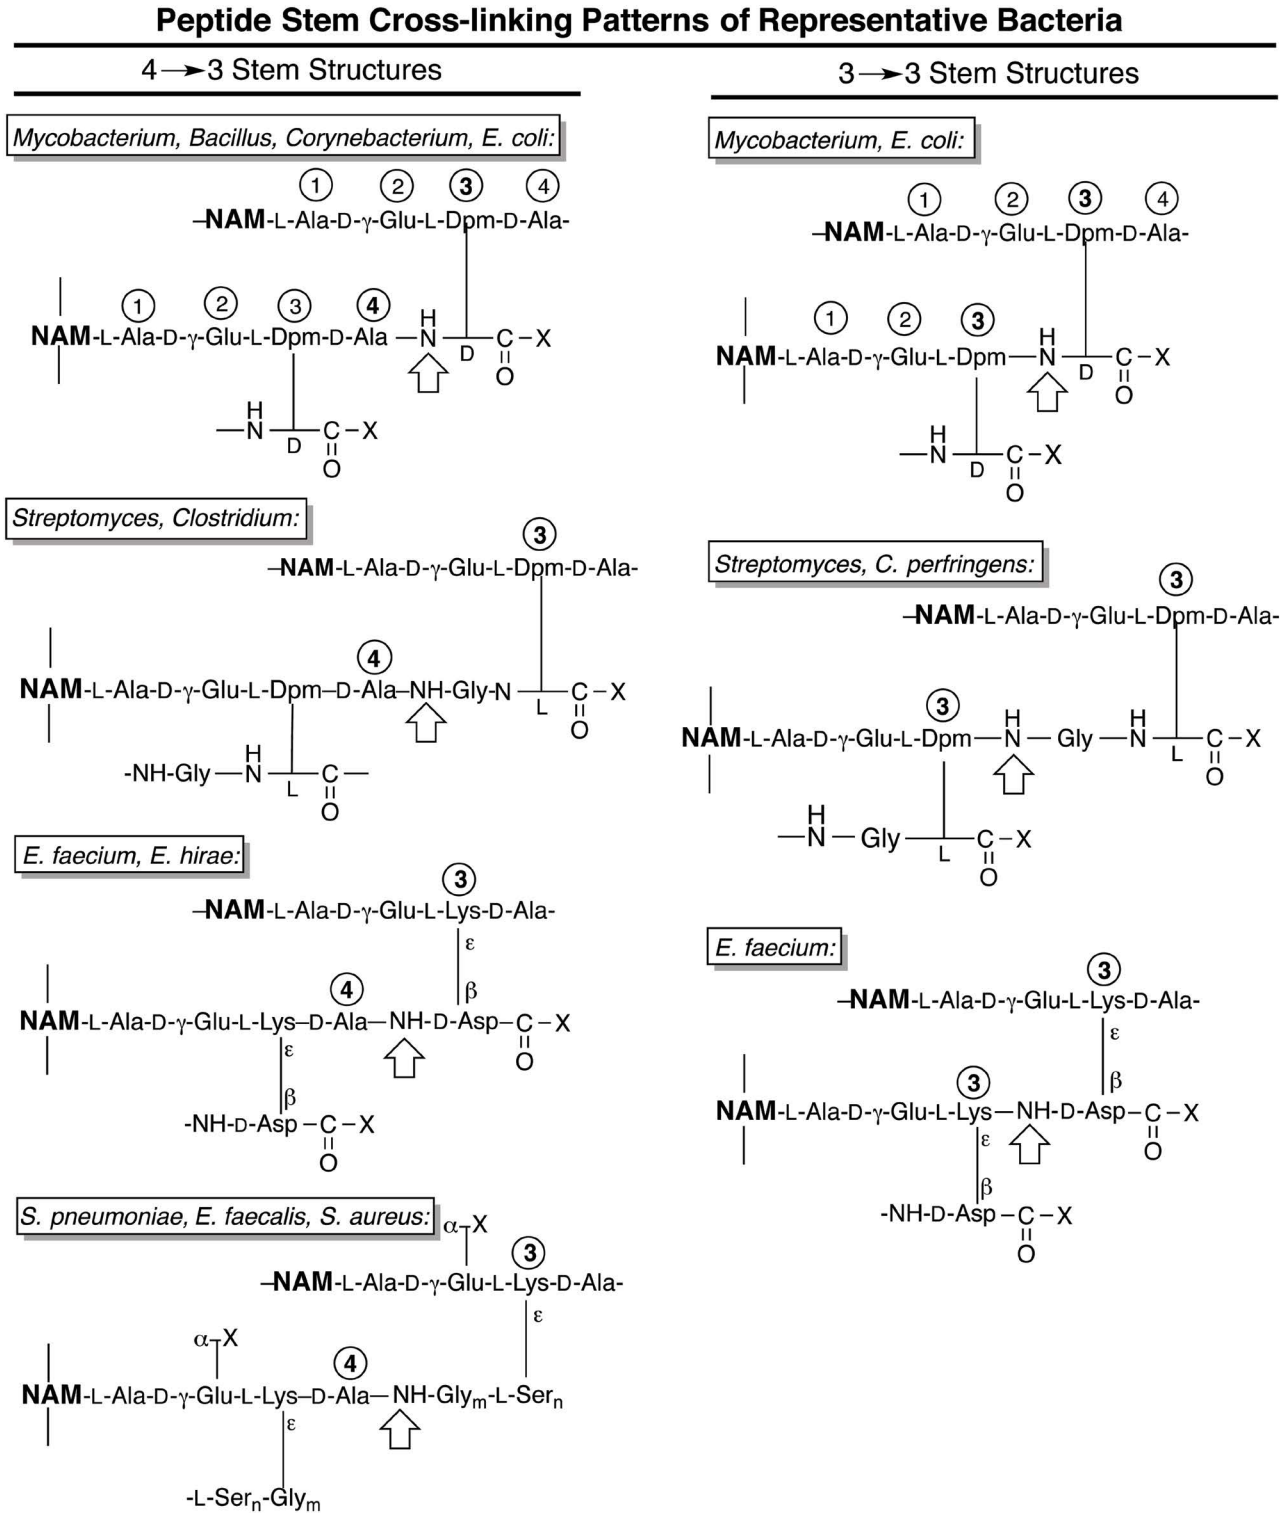

FIGURE 18.3 Stem cross-linking patterns found in different bacteria.[126] The left column exemplifies 4,3-peptidoglycan cross-linking, and the right column 3,3-cross-linking. For each exemplification, the acyl-donor stem of the cross-link is the lower NAM-stem structure, and the acyl-acceptor stem is the upper NAM-stem structure. The nitrogen atom that accepts the acyl moiety, mediated by PBP catalysis, is identified with an arrow. The diamino-containing amino acids found at position 3 of the stems are *meso*-diaminopimelic acid (L,D-Dpm), L,L-aminopimelic acid (L,L-Dpm), or L-lysine. The distal amine of these diamino acid residues is the acyl acceptor in *Mycobacterium*, *Corynebacterium*, *Bacillus* spp., and *E. coli*. Mycobacteria use both 4,3 and 3,3 cross-linking and the extent of 3,3 cross-linking is a resistance mechanism in Gram-positive bacteria. The stem may be substituted by the presence of one or more bridging amino acids. For example, in some *S. aureus* strains the 4,3 stem has a two L-serine and three glycine residue bridge where the terminal glycine serves as the acyl acceptor (right column, bottom entry: $m = 2$, $n = 3$), while in most *S. aureus* strains the stem has a pentaglycine ($m = 0$, $n = 5$) bridge. In *S. pneumoniae* and *S. aureus* the α-carboxylate of the γ-D-glutamate residue at position 2 of the stem is amidated (X = NH_2). This same amidation, as well as extensive other modifications to the peptidoglycan, is also found for *E. faecium*.

peptidoglycan is an emerging focus with respect to bacterial resistance to the β-lactam antibiotics.[176,177] A concluding observation is that muropeptide analysis of the *core* peptidoglycans of laboratory and clinical strains of the Gram-negative rod-shaped bacterium *P. aeruginosa* are nearly indistinguishable.[102,178,179] However, comprehensive analysis of a more complete set of 160 muropeptides identified a subset of less abundant muropeptides, that are termed adaptive muropeptides (contrasting planktonic and biofilm growth states). A notable discovery was the presence of NAG de-*N*-acetyl muropeptides (six identified, total relative abundance of 0.5%) among the core planktonic muropeptides that diminished significantly in abundance compared to the biofilm-derived muropeptides.[179] These observations attest to the importance of the preservation of the core peptidoglycan, and the likelihood that specific peptidoglycan structure correlates—in ways yet to be discovered—with bacterial shape, nutrient availability, and growth condition.

Overall muropeptide structure varies as a function of the stage of the bacterium, its growth phase, its shape, the growth medium, the presence of resistance determinants relating to the cell wall, and the presence of antibiotics. The ability of certain D-amino acids (such as D-Cys) to incorporate into the peptidoglycan was a critical methodology in early studies on peptidoglycan growth and to the visualization within the sacculus of new peptidoglycan domains.[180,181] This methodology is still used to analyze the patterns of peptidoglycan growth, as exemplified by analysis of glycine incorporation into the stem peptide (at the fifth position, a position normally occupied by the terminal D-Ala) in growing *C. crescentus*.[182] Muropeptide analysis shows incorporation of other D-amino acids during the stationary phase transition of *Bacillus subtilis* (Gram-positive) and *V. cholerae* (Gram-negative), and the possible correlation with stationary phase cell-wall remodeling and with biofilm dispersal.[183–185] The use of fluorescent D-amino acids has matured into a robust method for the study of peptidoglycan biosynthesis by fluorescent microscopy.[86,186–191] Detailed protocols for the preparation and incorporation of these amino acids in cell culture,[192] and in high-throughput assay for the discovery of inhibitors of peptidoglycan biosynthesis,[193] are available. Alternatively, *N*-acetyl muramic acid derivatives may be used.[194] Fluorescent microscopy has validated the treadmilling by FtsZ filaments as a driving force for peptidoglycan biosynthesis in Gram-negative bacteria,[195,196] the role of penicillin-binding protein 4 (PBP4) in extraseptal peptidoglycan crosslinking in *S. aureus*,[197,198] the evaluation of the spatiotemporal dynamics of peptidoglycan synthesis in both *S. aureus*[199] and the mycobacteria,[200,201] establishing that the biosynthesis of peptidoglycan and the incorporation of wall teichoic acid are directly coordinated in *S. pneumoniae*,[202] and demonstrating the presence of functional peptidoglycan in Chlamydia species.[31] The complementary use of fluorescent antibiotics that inhibit peptidoglycan biosynthesis, or fluorescent indicators of bacterial structure, is a powerful method for the cytological profiling of antibiotic mechanism (differentiating the cell wall, ribosome, DNA, RNA and lipids as the bacterial target).[203–205] Further applications of fluorescence for the study of the peptidoglycan are exemplified by the validation of Lipid II binding as the antibacterial mechanism of ribosomally synthesized post-translationally modified peptides,[206] the study of peptidoglycan remodeling during *B. subtilis* sporulation[207] and *S. coelicolor* spore wall synthesis,[208] the selection of β-lactam structures that optimally synergize with vancomycin and daptomycin against *S. aureus*,[209] imaging peptidoglycan biosynthesis in *B. subtilis*,[210] and imaging bacterial infection.[211,212]

The Peptidoglycan-Binding Proteins of the Cell Envelope

The peptidoglycan is attached, by both covalent and noncovalent interactions, to both the inner and outer membranes of the Gram-negative bacterium. Three protein-peptidoglycan interactions dominate: covalent attachment to the Braun Lpp lipoprotein, and the noncovalent attachment of the peptidoglycan to the outer membrane porins and to the Pal (peptidoglycan-associated lipoprotein) protein of the Tol-Pal protein system that structurally bridges the inner and outer membranes. These three systems are important (if not essential) to the viability of the Gram-negative bacterium.

The Braun lipoprotein (Lpp) is the most abundant protein of *E. coli* (1×10^6 copies per cell).[213–216] Lpp is a 58-residue (*E. coli*, mature protein) α-helical peptide, approximately 76 Å in length that assembles as a coiled-coil homotrimer.[217,218] It is encountered primarily as a lipoprotein, covalently attached through the sulfur atom of its N-terminal cysteine to a lipid of the inner leaflet of the outer membrane. A lysine at the other end of the Lpp homotrimer is covalently attached to the L-center of the *meso*-diaminopimelic acid residue at position 3 of the peptide stem of the peptidoglycan. This connection is catalyzed by one of the three (in *E. coli)* L,D-tranpspeptidases of the periplasm.[219] These two covalent linking events stabilize the outer membrane structure.[220,221] Manipulation of the length of the Lpp helix effectively alters the size of the periplasm, and consequently compromises the ability of *E. coli* to sense envelope defects and to respond to stress signals[222] and to assemble its flagellum.[223] Lpp is found to a lesser extent as an integral outer-membrane protein—its "free" form, not bound covalently to peptidoglycan—wherein its C-terminus lysine is exposed on the cell surface (growing *E.* coli, approximately 33% of the Lpp copies).[213,214] The free form of Lpp is involved in the recognition of some cationic antimicrobial peptides[224] but not others.[225] The beneficial, and presumably structural, function of the free Lpp protein in the outer leaflet of the outer membrane is not known.

The OmpA porin is an abundant protein (*E. coli*, 2×10^5 copies per cell) of the outer membrane.[226] Deletion of the OmpA porin in *E. coli* gives a viable, but fragile, phenotype. Although its function as a porin demands that the protein is integral to the outer membrane, OmpA of *E. coli* (and other porins of other bacteria)[227,228] has a peptidoglycan-interacting domain.[229,230] The fragility of the bacterium in the absence of OmpA results from the loss of the cooperative binding by OmpA (in the outer membrane) with the peptidoglycan, concurrent with noncovalent binding of OmpA with the TolR stator protein of the Tol-Pal complex[231] located in the inner membrane.[232] Moreover, a protein-protein interaction between Lpp and OmpA facilitates the noncovalent binding of peptidoglycan by OmpA.[233,234] Structures of several peptidoglycan-OmpA complexes have

been determined.[227,235] The inability of OmpA to diffuse in the outer membrane of *E. coli* is not caused by the peptidoglycan binding.[236] Peptidoglycan binding may facilitate recovery of the Omp structure following its reversible deformation in response to mechanical stress.[237]

The third peptidoglycan-associated protein complex in Gram-negative bacteria is the Tol-Pal system. The Pal lipoprotein has an N-terminal lipoprotein domain that localizes the protein to the inner leaflet of the outer membrane, and a C-terminal peptidoglycan-binding domain that is similar in structure to that of OmpA.[238,239] The Tol-Pal system comprises four additional proteins, thus forming a five-protein complex that interconnects the outer membrane, the peptidoglycan, and the inner membrane across the periplasm[240] and that interacts additionally with the outer-membrane porins.[241] The essential functions of the Tol-Pal system are the proton-motive force-dependent maintenance of the cell-envelope integrity (especially with respect to membrane invagination during cell division),[242–246] the transport of macromolecules across the periplasm,[247,248] and the polar localization of proteins and chemoreceptors.[245,249] The Tol-Pal system contributes to the function of the outer membrane as a permeability barrier, whereas Lpp does not.[250] The mechanism of the bacterial colicin toxins is compromise of Tol-Pal function.[251–254] The structure of the *Haemophilus influenzae* Pal-peptidoglycan complex shows Pal recognition of the peptide stem of the peptidoglycan, centered at an uncrosslinked diaminopimelate residue of the stem.[255]

These three systems are the most abundant but emphatically are not all of the important protein-peptidoglycan interactions. Peptidoglycan recognition is important to the structural integration of numerous bacterial machines and systems.[256] The stator proteins of the bacterial flagellum[257–259] have the dual function of ion transport (either H^+ or Na^+) and anchoring the flagellar protein assembly to the peptidoglycan.[260–265] Peptidoglycan binding and ion channel competence are coupled events.[266,267] A functional identity between the *E. coli* Pal and MotB stator peptidoglycan-binding domains was proven by replacement of the MotB domain with that of the Pal domain with retention of function.[268] Excavation of the peptidoglycan to enable insertion of secretion systems uses both hydrolytic excision (amidases)[269–271] and nonhydrolytic excision (lytic transglycosylases)[272–274] of the peptidoglycan. In addition to the OmpA-like peptidoglycan-binding motifs, the LysM carbohydrate-recognition motif is encountered in innumerable peptidoglycan-binding proteins.[275–277]

A compilation of peptidoglycan-binding proteins would be remiss without mention of the lysozymes, the catalysts of peptidoglycan hydrolytic degradation by cleavage of the NAM-NAG glycosidic bond.[278,279] The lysozymes encompass three different protein motifs, isolated from phages, bacteria, plants, and eukaryotes. Their purposes are antibacterial defense, bacterial digestion, bacterial penetration, and bacterial transformation. Peptidoglycan-recognition proteins (PGRPs) are multisubstrate recognition proteins[280] of the innate immune systems.[281] As peptidoglycan-binding proteins they are a primary component of the immune response of insects.[282] The structures of several PGRPs in complex with peptidoglycan fragments are known.[283] PGRP binding to the peptidoglycan results in steric interference with peptidoglycan remodeling and amidase-dependent peptidoglycan remodeling, culminating in the induction of a reactive-oxygen stress response that is ultimately bactericidal.[284]

Peptidoglycan Biosynthesis

Bacteria display an astonishing breadth of shape and morphological differences as exemplified by the spherical (coccus) shape of the Gram-positive *S. aureus*, the rod shape of the Gram-negative *E. coli*, the spiral shape of the Gram-negative *H. pylori*. Peptidoglycan biosynthesis is fundamentally similar (especially in its early stages) in the Gram-positive bacteria, the Gram-negative bacteria, and the mycobacteria.[10,13,61,285] While the nearly identical molecular structures of the Gram-negative and Gram-positive peptidoglycans are consistent with biosynthetic similarity, the variety of bacterial shapes indicates structural complexity. The basis of this complexity—such as how variation in peptidoglycan structure and interconnectivity controls the shape of the bacterium—is not known. Our imperfect understanding is exemplified by the dimorphic life cycle of the Gram-negative alphaproteobacterium *C. crescentus*. Under conditions of phosphate limitation, it divides asymmetrically to give a motile, swarmer cell and an adherent, stalked cell.[286] The peptidoglycan of the two cells is substantially different: that of the motile cell is dominated by 4,3-DD-transpeptidation, while that of the adherent cell is dominated by 3,3-LD-transpeptidation.[172] Presumably, the two represent different spatial interconnection of otherwise structurally similar glycan strands. Peptidoglycan biosynthesis is customarily studied with respect to the 4,3-DD-transpeptidation in the Gram-positive bacteria *B. subtilis* (rod-shaped), *S. pneumoniae* (coccus), and *S. aureus* (coccus); and in the Gram-negative bacterium *E. coli* (rod-shaped). In rod-shaped bacteria there is presumptive difference between the new peptidoglycan integrated into the old peptidoglycan of the sidewall, and the wholly new peptidoglycan of the septum.[287] The following summary has as its focus the 4,3-DD-transpeptidation event of Gram-negative peptidoglycan biosynthesis. A complementary perspective on peptidoglycan biosynthesis in Gram-positive bacteria is available.[164,288]

The first cytoplasmic step is the Glm-catalyzed conversion of fructose-6-phosphate to UDP-*N*-acetylglucosamine (Figure 18.4). Sequential addition of the stem peptide amino-acid residues is catalyzed by the enzymes of the Mur pathway, to give UDP-MurNAc-pentapeptide.[291–293] Transfer of the MurNAc-pentapeptide-*O*-phosphate to the phosphate group of the membrane-embedded C_{55}-isoprenoid alcohol (undecaprenol) phosphate[294] is catalyzed by the MraY enzyme[295] with the glycolipid *Lipid I* as product.[296,297] The MurNAc-pentapeptide moiety of Lipid I rests as a head group protruding from the inner leaflet of the cytoplasmic membrane.[298] The ensuing reactions of cell-wall biosynthesis, through the release of the new, stem-crosslinked glycan strand in the periplasm, involve membrane-bound intermediates. The MurG enzyme adds *N*-acetylglucosamine to the C-4 position of the NAM (MurNAc) to give the *Lipid II* disaccharide.[299] MurG additionally provides a scaffold for the cytoplasmic organization of the Mur enzymes (as observed in both *S. pneumoniae* and the Gram-negative coccobacillus *Bordetella pertussis*).[300,301]

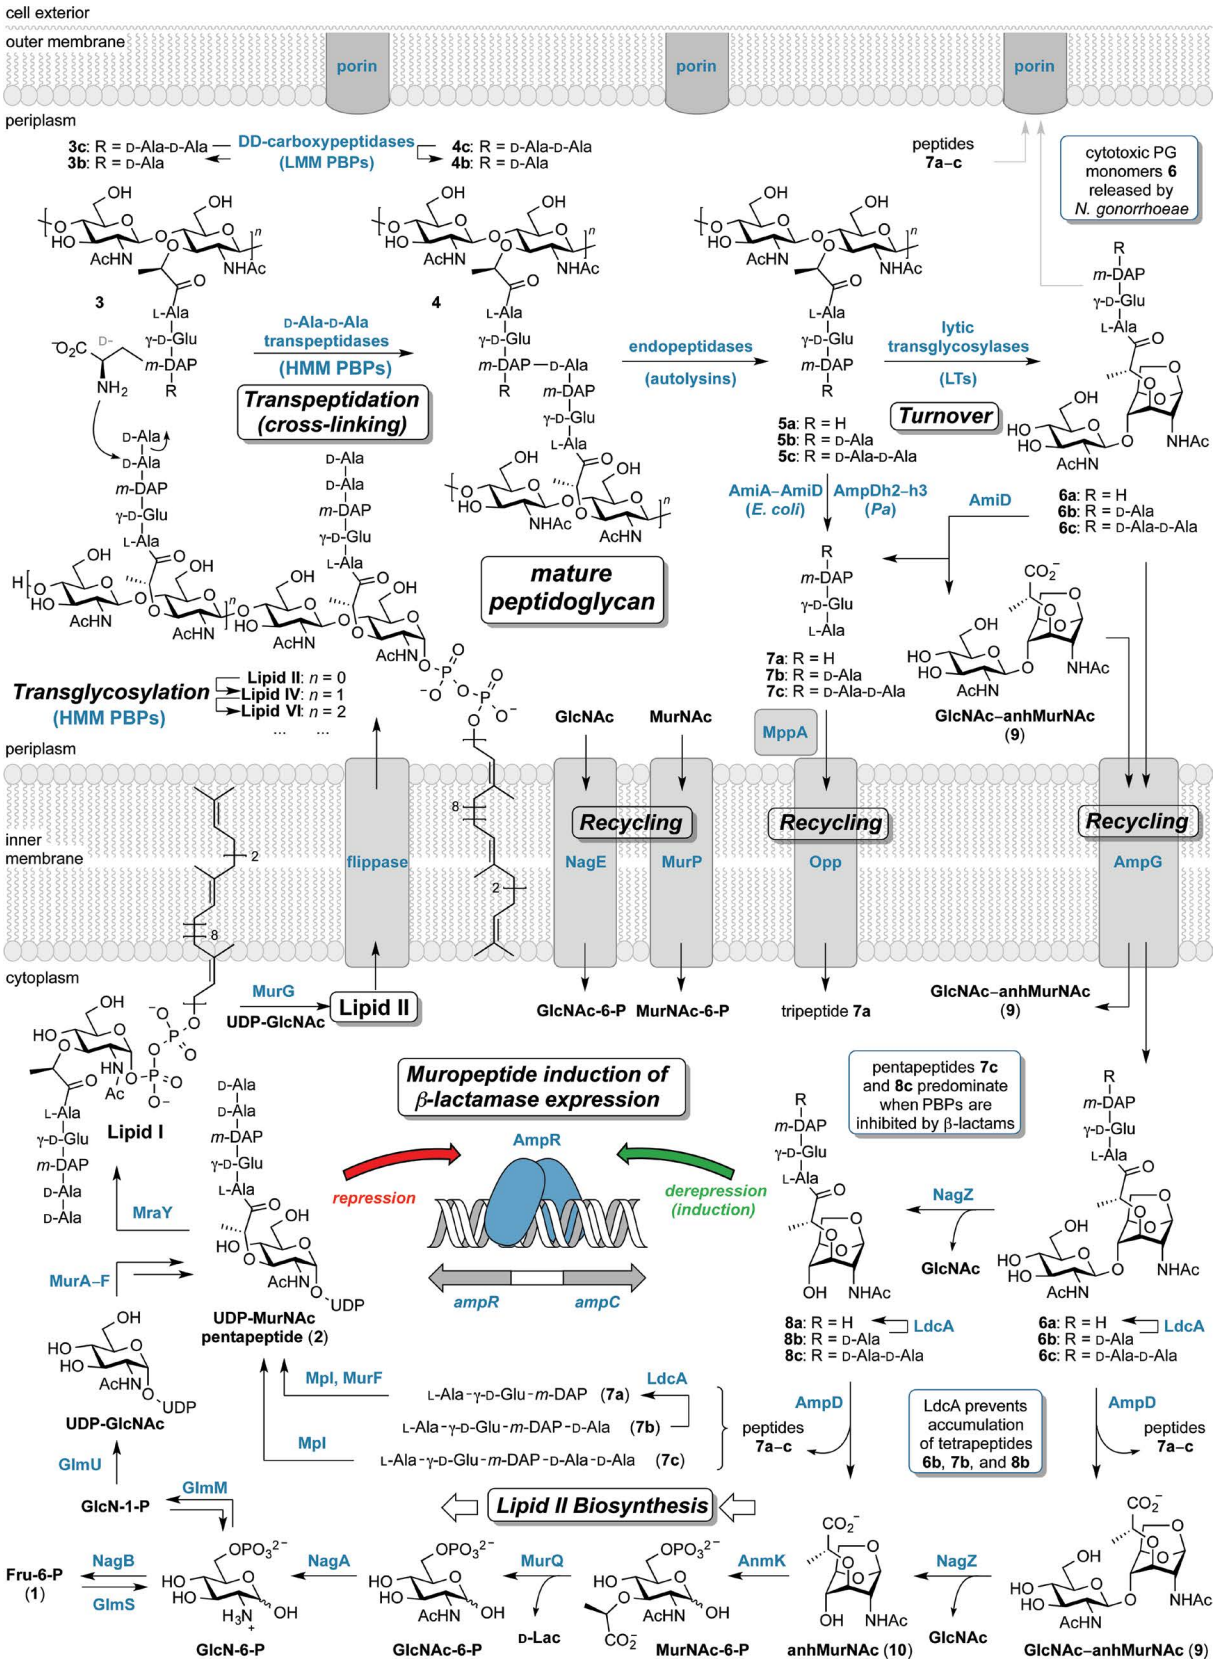

FIGURE 18.4 Overview of the primary events in the biosynthesis, turnover, and recycling of the cell wall of a Gram-negative Enterobacteriaceae bacterium. Lipid II biosynthesis commences with the synthesis of glucosamine-6-phosphate from fructose-6-phosphate (extreme lower left), catalyzed by the GlmS enzyme. GlcNAc-6-P is also a product of peptidoglycan recycling. It is transformed through the Mur pathway, and finally by MraY and MurG, to Lipid II. Lipid II is translocated to the periplasm by the MurJ flippase. The SEDS transglycosylases, the PBP transpeptidases, the PBP bifunctional transglycosylases/transpeptidases, and PBP carboxypeptidases/endopeptidases of the periplasm catalyze the glycan strand assembling, peptide stem crosslinking, and stem structure refinement to give the "mature" peptidoglycan polymer. In many Gram-negative pathogens the inactivation of a low-molecular mass PBP carboxypeptidase by a β-lactam antibiotic alters the pool of recycling muropeptide structures, resulting in the derepression of the gene encoding the AmpC β-lactamase resistance enzyme through the AmpR transcription factor (lower center, in the cytoplasm). In contrast cytoplasmic recycling of muropeptides in *P. aeruginosa* does not use the MurQ etherase pathway as is shown here for *E. coli*.[289,290]

The final event in the cytoplasmic biosynthesis of the peptidoglycan is the membrane-potential requiring translocation of the NAG-NAM disaccharide of Lipid II, as a head group of the glycolipid, from the cytoplasmic side of the membrane to the periplasmic side of the membrane.[302] In the rod-shaped *E. coli* bacterium, peptidoglycan biosynthesis occurs initially in the sidewall, and finally to form a septum. The former (elongasome-dependent synthesis) involves coordination with and insertion into existing peptidoglycan, whereas the latter (divisome-dependent synthesis) does not. Elongasome-dependent synthesis is not connected *intimately* with the cell cycle, whereas divisome-dependent synthesis connects directly and is coordinated by the bacterial cytoskeletal system. Nonetheless, the two systems must coordinate to preserve the cell diameter and for midcell septum localization, and a critical aspect of this coordination occurs when the two intersect in a transition zone of peptidoglycan synthesis from the sidewall to the septum. Each is a multiprotein and multienzyme system centered around penicillin-binding proteins (and are discussed further in the following paragraphs). The PBPs are membrane-bound enzymes, with active sites projecting into the periplasm. They fall into three primary protein classes. Two classes are the high-molecular-mass PBPs (HMM PBPs). Class A HMM PBPs (aPBPs) are bifunctional, with a peptidoglycan glycosyltransferase (PGT) active site close to the outer leaflet of the cytoplasmic membrane and a transpeptidase crosslinking site at the apex of the protein coinciding with the middle of the periplasm. The second class (bPBPs) has comparable mass, but lacks the glycan active site and acts as a monofunctional enzyme through its single transpeptidase active site. The substrate for both the aPBPs and bPBPs is Lipid II. The low-molecular-mass PBPs (cPBPs) are smaller monofunctional enzymes with either (and in some cases, both) DD-carboxypeptidase or DD-endopeptidase activity. The substructure recognized by all PBPs is the -D-Ala-D-Ala terminus of the peptidoglycan stem. All bacteria have at least one PBP of each of the three classes. *E. coli* has three aPBPs (PBP1a, *ponA*; PBP1b, *ponB*; PBP1c, *pbpC*), two bPBPs (PBP2, *pbpA*; PBP3, *ftsI)*, and seven cPBPs (PBP4, *dacB*; PBP5, *dacA*; PBP6, *dacC*; PBP6b, *dacD*; PBP7, *pbpG*; PBP4b, *yefW*; AmpH, *ampH*).[303] In *E. coli* both bPBPs are essential, with PBP2 functional in the elongasome and PBP3 functional in the divisome. PBP1a and PBP1b are semiredundant (i.e., the catalytic activity of one can compensate for the loss of activity of the other, under most but not all growth circumstances).[304] Hence, a functional PBP1a or PBP1b is essential. PBP1a is associated primarily, but not exclusively, with PBP2 in the elongasome. PBP1b is associated primarily, but not exclusively, with the divisome.[305] The cPBPs control the degree of cross-linking of the peptidoglycan by hydrolysis of the D-Ala-D-Ala bond of the stem peptides, participate in murein degradation and recycling by hydrolytic cleavage of the peptide cross-bridges, and facilitate (by an unknown mechanism) the bacterial cytoskeleton-dependent organization of cell-wall biosynthesis and ultimately bacterial shape.[306–308] Functional redundancy within the cPBPs ensures both the shape and the integrity of the bacterium.[42] The cPBPs further provide to the bacterium—as a result of their abundance as PBPs and (for some) an ability to hydrolytically turnover β-lactam antibiotics—intrinsic β-lactam resistance.[309,310] Remarkably, a single mutation in the Ω-like loop of the active site of *E. coli* PBP5 abolishes both the intrinsic resistance as well as the ability of this enzyme to maintain the cell shape.[311]

Recognition of two separate systems for peptidoglycan biosynthesis in the rod-shaped bacteria—sidewall biosynthesis by the elongasome proteins and enzymes, and septal biosynthesis by the divisome proteins and enzymes—has been known for some time. Three significant, and complementary, advances characterize the past decade.[189,312] The first is the core (as distinct from the complete) identities of the proteins and enzymes in each system. The second is the recognition that peptidoglycan glycan strand synthesis, in both complexes, involves explicit coordination of a SEDS (shape, elongation, division, sporulation) membrane enzyme with a PBP enzyme.[304,313,314] A further notable advance is recognition that the membrane protein MurJ functions as the translocase to the periplasmic leaflet side of the membrane of the Lipid II molecules (whose biosynthesis is completed at the inner leaflet of the cytoplasmic membrane by MraY as the penultimate catalyst and MurG as the ultimate catalyst) for both complexes.[315–317] A mechanism for the membrane potential-dependent[302] Lipid II translocation is suggested from crystallographic studies of MurJ.[318–321] The third advance is that the dynamics of peptidoglycan biosynthesis at the elongasome and at the divisome are fundamentally different. Each of these three advances are summarized further.

Both the elongasome and the divisome organize under the guidance of protein oligomers that assemble as filaments against the inner leaflet of the cytoplasmic membrane.[322] The actin-like protein component that generates the filament used by the elongasome is the MreB protein.[323,324] MreB polymerizes as an antiparallel double filament that localizes to the sidewall of the rod-shaped bacterium aligned with the curvature of the sidewall.[325–327] MreB is excluded from the pole of the bacterium by its incompatibility with the cardiolipin-rich membrane required by the pole curvature.[328,329] The enzyme catalysts of the elongasome are the binary complex of RodA (the SEDS glycosyltransferase)[330] and PBP2 (the transpeptidase). This binary complex alone is non-catalytic. Recruitment of additional elongasome proteins (notably but not exclusively the membrane protein MreC) effects a conformational change.[331] On the periplasmic side of the membrane, the MreC·RodA·PBP2 complex acquires catalytic competence. With this competence, MreB is recruited to the complex on its cytoplasmic face. This event initiates the recruitment of the remaining proteins of the elongasome.[332] This recruitment presumptively includes the Mur components—the Mur enzymes of *S. pneumoniae* assemble as a multiprotein complex[301]—of Lipid II biosynthesis.[333] Lipid II-dependent peptidoglycan biosynthesis ensues.[334] During elongation growth the MreB filament rotates around the short axis of the cell thus giving direction to the new glycan strands. Movement of the MreB filaments is a response to sidewall peptidoglycan synthesis. β-Lactam inactivation of PBP2, for example, stops the motion.[335,336] A dynamic balance between RodZ and MreB is one basis for the preservation of the rod shape by patch-wise peptidoglycan insertion.[337] Key questions remain unanswered. The complete list of elongasome proteins is not known. Sidewall growth requires integration of new peptidoglycan into old peptidoglycan under a presumptive

make-before-break mechanism (so as to preserve cell integrity). A concept for the operation of such a mechanism, incorporating the experimental observation of extensive peptidoglycan release of muropeptides for recycling concurrent with new peptidoglycan synthesis, is discussed.[304,338] The molecular mechanism for sequential synthesis, attachment, and excision of peptidoglycan to achieve net growth is unknown.

The filament that guides the divisome is composed of the tubulin-like protein FtsZ. As the divisome has universal bacterial relevance (encompassing both the Gram-positive coccus and the Gram-negative rod) it is better understood than the elongasome.[339] Peptidoglycan biosynthesis is studied in *E. coli* and in *B. subtilis* with complementary observations.[340,341] Regulation of the divisome in Gram-positive bacteria is, however, different.[342–347] In rod-shaped bacteria the FtsZ filaments assemble circumferentially at precisely the midcell prior to cell division, by a GTP-dependent mechanism. The filament is tethered to the inner leaflet of the cytoplasmic membrane through engagement of anchor proteins (FtsA, ZipA) and is oriented to align with the curvature of the membrane surface by the EzrA regulatory protein.[348] An ensemble of similarly oriented filaments anneal together through lateral interaction to form a ring—the Z-ring—around the diameter of the bacterial membrane at the mid-cell. Recruitment of the remaining 20–30 proteins of the divisome follows. These proteins include the structural and regulatory FtsBLQ sub-complex; the peptidoglycan-synthesizing enzymes FtsW, PBP3, and PBP1b; and the key regulatory protein FtsN. FtsW is the SEDS glycotransferase and PBP3 is the transpeptidase that cross-links the emerging glycan strands from FtsW.[349] The organization of the divisome is suggested to resemble three interconnected layers. The proteins and enzymes of peptidoglycan synthesis (including FtsQ, FtsL, PBP3, and FtsN) comprise as the outer layer; the proto-ring proteins FtsA, FtsZ, and FtsL comprise the middle ring; and the regulatory proteins ZapB and MatP comprise the inner ring.[350,351] Upon recruitment of the Lipid II–synthesizing MraY/Mur complex, Lipid II is synthesized on the cytoplasmic side of the membrane. Its synthesis recruits to the divisome, as possibly the final step of divisome assembly, MurJ. The Lipid II molecule is translocated to the periplasm, and the assembly of the septal peptidoglycan commences. The FtsZ filaments migrate at the expense of GTP hydrolysis by a treadmilling mechanism, carrying forward the divisome.[195,196] One end of the FtsZ filament shortens by FtsZ monomer dissociation, as the other end grows by FtsZ monomer accretion. The septal peptidoglycan is made by growth in increasingly smaller concentric rings.

These terse summaries of the elongasome and divisome necessarily are oversimplifications and do not address key questions. As septal peptidoglycan synthesis nears completion, FtsZ dissociates[352] and the divisome disassembles. How disassembly reconciles with completion of the intact septum by final peptidoglycan polymerization is not known. Septum synthesis is energy intensive beyond the cost of the chemical synthesis of Lipid II and its polymerization. Whereas sidewall peptidoglycan synthesis is driven by Lipid II polymerization, septal peptidoglycan biosynthesis requires FtsZ-catalyzed GTP hydrolysis. The mechanism for how GTP hydrolysis drives FtsZ-filament treadmilling and divisome motion is not known. Figure 18.5 gives a cartoon

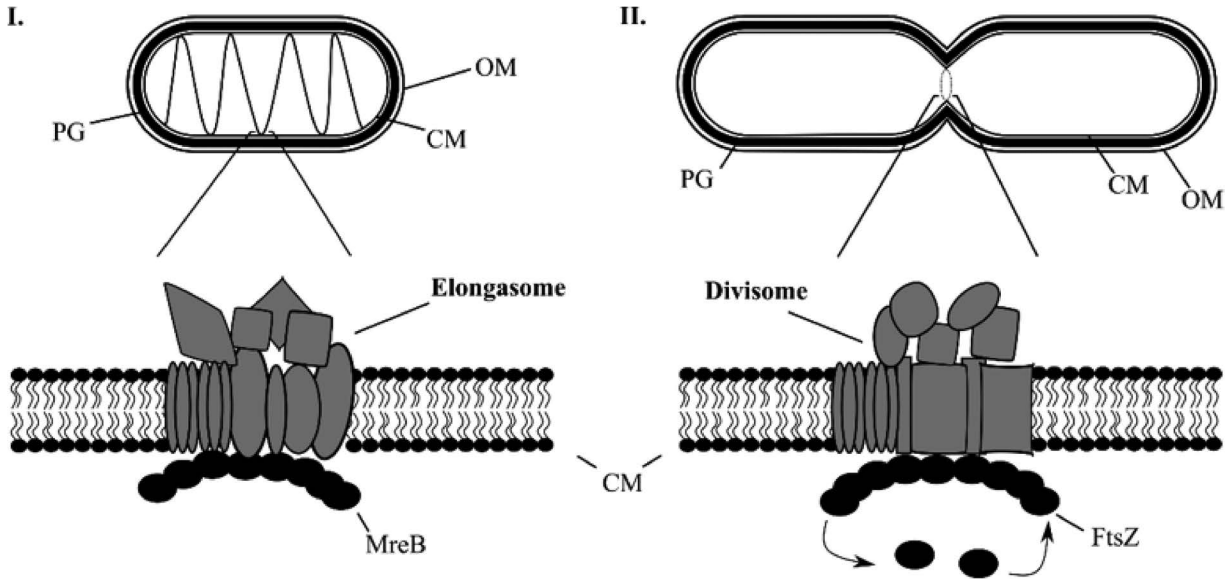

FIGURE 18.5 Schematic representation of the (I.) elongasome and the (II.) divisome machineries of Gram-negative bacteria. Part of both machineries are the cytoplasmic Mur enzymes which synthesize the ultimate peptidoglycan precursor Lipid II; the transmembrane MraY (attachment of the soluble Lipid I to the membrane) and MurJ, the flippase that transfers the Lipid II in the periplasm; and the transpeptidase PBP2 and carboxypeptidase PBP5 in the periplasm. Notable proteins of the elongasome are the cytoplasmic MreB and RodZ, the transmembrane RodA and MreC, and the periplasmic PBP1a. Notable proteins of the divisome are FtsZ (cytoplasm), FtsW (transmembrane), and the bifunctional PBP1b and the transpeptidase PBP3 in the periplasm. The protein stoichiometry of the core of the divisome is suggested by Egan and Vollmer to correspond to two molecules of PBP3, two of PBP1b, two of LpoB, four of FtsN, two of FtsW, two of FtsQ, two of FtsL, two of FtsB, three of FtsK, and eight of FtsA.338 CM: cytoplasmic membrane, PG: peptidoglycan, OM: outer membrane.

summary of the difference between the translocation motions of the elongasome and the divisome. Moreover, the motion of the divisome must align with the concurrent force, exerted in a different spatial direction, that is necessary to constrict the membrane.[246,353] As complicated as they are individually, conceptualizing the elongasome and divisome as independent entities for peptidoglycan synthesis is wrong. They both function in partnership with respect to the events of the cell cycle; in coordination with the assembly of the lipids, saccharides, and proteins of the entire cell envelope; and in the regulation of the cell shape and size.[56,354,355] Moreover, it should be evident that the elongasome and divisome are not independent of each other. A critical event in peptidoglycan biosynthesis in the rod-shaped bacterium is the decision at midcell to initiate synthesis of a septum. This initiation—the creation of preseptal peptidoglycan as a transition from sidewall to septal peptidoglycan—requires colocalization of both systems.[14,356] Successful Z-ring formation requires sequential division-site localization of the membrane protein RodZ followed by MreB.[357] RodZ has the important task of aligning MreB with the membrane curvature and for the engagement of PBP2 with MreB.[325,337] Preseptal peptidoglycan requires FtsZ, the ZipA anchor protein for FtsZ,[358] and the recruitment by ZipA of either PBP1a or PBP1b.[359] PBP2 and PBP3 are present (or proximal) but both activities are suppressed. While the surface dimension of the preseptal peptidoglycan in *E. coli* is small (not the case for other bacteria)[359] circumstantial evidence indicates that its structural integrity is less than either the sidewall or the septal peptidoglycan. This evidence includes the separation of the pole peptidoglycan during the isolation of the sacculus (loss of the pole peptidoglycan as a result of the rupture of the preseptal peptidoglycan under mechanical stress), and the appearance of "bulges" at the presumptive location of the preseptal peptidoglycan under conditions of antibiotic-induced loss of function of PBPs[360,361] or of lytic transglycosylases.[362,363] The assumption that the bactericidal mechanism of the β-lactam antibiotics was the loss of PBP function has given way to recognition of PBP loss of function as the initiation (and not the culmination) of bactericidal pathway(s). SEDS-dependent glycan synthesis in the absence of PBP crosslinking, or disruption in the clearance and recycling of uncross-linked peptidoglycan, weakens the peptidoglycan polymer and predispose it to catastrophic failure.[364] In Gram-positive bacteria the loss of ordered peptidoglycan synthesis, as a result of cell-wall-targeting antibiotics, disrupts the balance between lipid-anchored teichoic acids and wall-anchored teichoic acids and thus dysregulates autolysin activity as a direct contributing cause to the antibiotic mechanism.[365,366]

This section of peptidoglycan synthesis concludes with consideration of the extraordinary complexity of PBP function as exemplified by the *E. coli* class A bifunctional PBP1b enzyme.[367,368] PBP1b assembles as a homodimer.[369,370] PBP1b is the biosynthetic catalyst of the PBP3-independent, but ZipA-FtsZ-dependent, synthesis of the transitional peptidoglycan between the sidewall and the septum.[358] It locates at this peptidoglycan interface by protein-protein interaction with PBP3, FtsW, FtsBLQ, FtsN, CpoB, MipA, PgpB, and ZipA.[314,359,371,372] PBP1b additionally complexes *in vitro* with the lytic transglycosylase MltA and Slt70.[373–375] Its activity is regulated concurrently by the protein components of the divisome,[371] by the CpoB-Tol system for membrane invagination,[353] and by complexation with the LpoB lipoprotein.[376–379] Upregulation of PBP1b and LpoB compensates for the loss of PBP2 as a result of specific inactivation of PBP2 by the β-lactam mecillinam (amidinocillin).[380] Both the glycosyltransferase and transpeptidase activities of PBP1b contribute (albeit differently) to the multi-generational recovery of the natural rod shape of *E. coli* from spheroplasts.[381–383] Overproduction of inactive PBP1b variants in *E. coli* results in cell lysis.[384] Cell lysis also occurs in a ΔPBP1b *E. coli* strain under conditions of impaired undecaprenyl phosphate recycling.[385] A subinhibitory concentration of a β-lactam that specifically inhibits PBP1b (or genetic deletion of PBP1b) sensitizes *E. coli* to other β-lactams.[386] PBP1b contributes directly to the motility and biofilm-capability of *E. coli*, and to its stationary phase-competitive survival.[387,388] For these reasons, conceptualizing this PBP (and indeed, all PBPs) as single task-specific catalysts is not possible. The breadth of properties of PBP1b emphasizes the extraordinary complexity of these enzymes in peptidoglycan synthesis.

Polymeric Structure of the Peptidoglycan

The spatial relationships and dimensions of the components of the cell envelope have been analyzed by different imaging methods. Cryotransmission electron microscopy of cross-sectioned, vitreously frozen bacteria show the peptidoglycan of the Gram-negative bacterium *E. coli* underneath the outer membrane.[71] Subsequent studies with Gram-negative bacteria place the peptidoglycan near to the center of the periplasm in *C. crescentus*,[389] a *Prochlorococcus* cyanobacterium,[390] and the *Treponema pallidum* spirochete.[391] An exception may occur where peptidoglycan-protein complexation is critical to strengthening membrane-penetrating structures. For example, the tight binding by the stator proteins of its flagellum of *T. pallidum* to the peptidoglycan occurs adjacent to the inner leaflet of the outer membrane.[79] The outer membrane of the Gram-negative bacterium shares with the peptidoglycan the load-bearing task of the cell envelope.[392] The peptidoglycan that is found at the midsection of the *E. coli* bacterium has a uniform thickness of 6.4 nm, consistent with values from atomic force microscopy (AFM).[393] The thickness of the midsection peptidoglycan of the related Gram-negative bacterium *P. aeruginosa* is less (2.4 nm). In contrast, the thickness of the *E. coli* and *P. aeruginosa* cell envelopes are comparable as assessed by their outer membranes (approximately 7 nm), cytoplasmic membrane (approximately 6 nm), and periplasmic space (approximately 22 nm).[71] Cryoelectron tomography microscopy[72,77] of *E. coli* suggests similar dimensions for the cell envelope at the midsection and at the pole.[394,395] Although the exterior surface of Gram-negative bacteria is lipopolysaccharide, AFM detects the perturbation of their membrane surface, in the form of blebbing, as a result of β-lactam inactivation of peptidoglycan synthesis.[396] Cryo-EM also visualized the capsular layer of mycobacteria.[397]

In contrast to the mycobacterium and the Gram-negative bacterium, the exterior of the Gram-positive bacterium is composed of peptidoglycan, teichoic acids, and capsular saccharides.[164] AFM is useful for the imaging of this exterior.[398] The peptidoglycan of *B. subtilis* appears with AFM imaging as long (>1,000 NAG-NAM units) glycan strands, suggested to coincide with 50 nm-wide coiled "cables" running parallel to the short

axis of the cell.[399] Subsequent AFM study of *B. subtilis* also found peptidoglycan cables and further demonstrated that the cables underwent remodeling during growth.[400] This observation is consistent with the observations that the peptidoglycan composition at the *B. subtilis* cell-division site is structurally distinctive (pentapeptide-rich),[401] and that the septal peptidoglycan of *S. pneumoniae* is extensively remodeled as its synthesis is completed.[402,403] Complementary observations with the cell shape dynamics of *S. aureus*,[404] and the D-amino acid remodeling of *S. aureus* during its infection of *Caenorhabditis elegans*, further emphasize the dynamic character of the bacterial peptidoglycan.[405] Swarming in two Gram-negative bacteria (*Proteus mirabilis* and *Vibrio parahaemolyticus*) coincides with reduced cell stiffness. This reduction in turn coincides with peptidoglycan that has shorter glycan strands (from approximately $[NAG\text{-}NAM]_{30}$ to $[NAG\text{-}NAM]_{20}$ and is thinner (from 1.5 nm to 1.0 nm), and with increased sensitivity of the bacteria to β-lactams.[406]

AFM study of *S. aureus* as a Gram-positive cocci is hampered by the orthogonal ribs of thickened septal peptidoglycan that mark past division planes.[407,408] AFM analysis of the wild-type ovococcoid bacterium *Lactococcus lactis* showed a featureless surface as a result of a uniform coat of exopolysaccharides.[78] Upon genetic deletion of wall-polysaccharide biosynthesis, the peptidoglycan was imaged as 25 nm-wide concentric bands perpendicular to the long axis of the cell. A detailed AFM analysis of polymeric Gram-negative peptidoglycan, in the form of isolated sacculus, confirms a mesh-like character comprising long (200 nm), circumferentially ordered glycan cables. This character is disrupted by inhibitors of MreB polymerization.[409] Exceptionally detailed deep-etch electron microscopy of *B. subtilis* shows distinction in appearance between the sidewall and septal surface. The former surface shows 13 nm circumferential peptidoglycan filaments that transition abruptly to the concentric 11 nm filaments of the septum. Visualization of the effect of lysozyme and β-lactams supports the structural assignment of these filaments as peptidoglycan.[410]

Solid-state NMR spectra of the sacculus support a defined three-dimensional structure for the peptidoglycan.[411,412] Nonetheless, the molecular-level structure (as a function of cell growth, shape, and subcellular location; and in response to stressors) is not known.[413] An important constraint is the total NAG-NAM mass in the bacterium. Wientjes *et al.* measured [^{3}H]-labeled *meso*-diaminopimelic acid (*m*-Dap) incorporation into the *E. coli* cell wall.[414] As *m*-Dap acid is exclusive to the peptidoglycan, the number of *m*-Dap molecules equals the number of NAG-NAM disaccharide segments. The value of 3.5×10^6 *m*-Dap molecules gives a mass for the *E. coli* sacculus of 2.3×10^9 Da. Using a value for the surface area of the *E. coli* bacterium of 10×10^6 nm^2, a thin (mostly single-layered with some triple-layered) peptidoglycan was calculated.[415] The alternative "scaffold model" (wherein the glycan strands are orthogonal to the membrane surface)[416] is less satisfactory.[133] Extensive NMR studies using isotopic labeling of the peptidoglycan of intact *S. aureus* implicate tightly packed glycan strands having both near-parallel and near-perpendicular stems as a repeating structural motif.[417,418] Structural models for the peptidoglycan polymer are discussed elsewhere.[101,419,420]

Cell wall-associated proteins have domains tasked with recognition of specific peptidoglycan sub-structure. Amidase-dependent removal of the stem peptide at the septal peptidoglycan recruits to this "denuded" peptidoglycan the small number of bacterial proteins (in *E. coli*: FtsN, DamX, DedD, RlpA) that possess a sporulation-related repeat (SPOR domain).[287,421,422] SPOR-domain proteins are found in both Gram-negative and Gram-positive bacteria. Additional notable peptidoglycan-binding domains found in proteins are the SH3 anchor domains proteins of *S. aureus* that recognize the pentaglycine bridge motif of its peptidoglycan[423,424] and the ubiquitous LysM domain that recognizes the [GlcNAc–X–GlcNAc] substructure of chitin and the peptidoglycan. While there is an understanding of the substructure bound by these domains, the place and circumstance where this recognition occurs remains largely unknown.

The structure of the glycan strand of the peptidoglycan in solution is also important. This structure is encountered by the enzymes of peptidoglycan biosynthesis and the recognition proteins of innate immunity. In solution the solitary glycan strand shows a tertiary structure that is a right-handed helix.[425] This identical conformation is seen in the complex between a synthetic peptidoglycan strand and a human peptidoglycan-recognition protein[426] and numerous other peptidoglycan-binding proteins.

The Enzymes of Cell-Wall Biosynthesis as Targets for Antibiotics

The cell wall is the target of numerous antibiotics.[62–64] Exhaustive efforts to discover antibiotics defined the Golden Age of antibacterial discovery in the middle decades of the 20th century.[427–429] Many of the best antibiotics then discovered are still used in the clinic. Many of these structures target the enzymes of peptidoglycan biosynthesis.[430] While the discussion in this chapter has emphasized the β-lactam inhibitors of the PBP catalysts of peptidoglycan transpeptidation, other notable peptidoglycan-targeting antibiotics include fosfomycin, moenomycin, the glycopeptides (exemplified by vancomycin), and structures that inhibit peptidoglycan biosynthesis by complexing Lipid II. Current perspectives for each of these antibiotics are given.

Fosfomycin and moenomycin have (like the β-lactams) specific molecular targets. Fosfomycin is an oral, nontoxic, broad-spectrum, and bactericidal inhibitor of MurA, the first committed enzyme of peptidoglycan synthesis.[431–435] Although fosfomycin resistance develops easily *in vitro*, the *in vivo* development of resistance is much less frequent. As a consequence of this peculiar characteristic, fosfomycin continues in use worldwide (although less so in the United States) for the treatment of bacterial urinary tract infection. The identification of antibiotics that are synergistic when combined with fosfomycin has attracted considerable interest.[436–438] Moenomycin is an inhibitor of the glycan-synthesizing enzymes, including the high-mass PBPs, of peptidoglycan biosynthesis.[439] The gene cluster for its biosynthesis is known[440] and a presumed biosynthetic intermediate has antibiotic activity.[441] The structure of moenomycin bound to the transglycosylase domain of PBPs is known.[298,368,442,443] Moenomycin has validated assays to screen for new structures with a similar biological activity.[444–446] Given this understanding, and recognizing that initial studies assessing resistance mutation in *S. aureus* gave a low viability phenotype,[447] moenomycin presents opportunity for structure-based optimization.[448,449]

The glycopeptides and the Lipid II-binding antibiotics do not easily focus to a specific target. Vancomycin is the preeminent glycopeptide.[450,451] Its primary molecular mechanism as an antibiotic—based on its self-resistance mechanism and its Gram-positive activity—is steric interference with peptidoglycan biosynthesis as a result of its ability to non-covalently complex the -D-Ala-D-Ala terminus of the peptidoglycan stem.[452–454] Although vancomycin-resistant enterococci did not emerge as a clinically pervasive superbug,[455] the continuing erosion of the antibiotic efficacy of vancomycin[456,457] has stimulated continuing study of its mechanism, and continued structure-activity study. There is now evidence that the ability of vancomycin to block the incorporation of D-Ala into the teichoic acids of the cell wall is an important component of its mechansim.[458] A derivative of a glycopeptide structurally related to vancomycin, oritavancin, has the same ability.[459] The realization that the structure-activity landscape of the glycopeptides was underdeveloped has led to a resurgence of interest in this antibiotic class,[460–464] including the possibility of extending glycopeptide activity to Gram-negative bacteria.[465,466] Indeed, it is possible that notwithstanding the closeness of their structures, both teicoplanin[467–469] and oritavancin[470,471] each may have unique structure-activity character. Bacitracin is a mixture of structurally modified nonribosomal peptides produced by various *Bacillus* species, and used extensively as a topical antibiotic and as prophylaxis and therapy in food animals. The core structure of bacitracin is a cyclic dodecapeptide that contains both L- and D-amino acids. Bacitracin is active against many Gram-positive bacteria, but is inactive against MRSA. The complex of bacitracin with a divalent metal (most commonly zinc) tightly binds to the undecaprenol diphosphate lipid of the cytoplasmic membrane.[472,473] This complexation prevents the conversion of the undecaprenol diphosphate to undecaprenol phosphate, a transformation that is critical to undecaprenol recycling. Undecaprenol diphosphate is the lipid carrier of the structural bacterial glycosides. Its efficient recycling is critical to peptidoglycan biosynthesis (and in Gram-negative bacteria, also to lipopolysaccharide biosynthesis).[385,474] The determination of the crystal structure of a bacitracin-undecaprenol diphosphate mimic[475] opens the structure of this antibiotic to redesign so as to ameliorate its poor oral availability and toxicity. Resistance to bacitracin is seen in different bacterial species. It is caused either by ABC transporter (BcrAB) efflux pump or by a phosphatase that dephosphorylates the pyrophosphate to phosphate, reducing the concentration of the target molecule.[476–478] In this era of difficulty with respect to the discovery of new antibiotics, a resource is the natural products produced by the 99% of bacterial species that cannot be cultivated in laboratories.[479] The use of an "iChip" led to the isolation of *Eleftheria terrae*, a previously uncultivated Gram-negative bacterium. This bacterium produced the new antibiotic, teixobactin.[480] Teixobactin is a depsipeptide composed of 7 L-amino acids and 4 D-amino acids. Its unusual L-*allo*-enduracididine amino acid is part of the tetrapeptide lactone formed by an ester bond between D-Thr-8 and L-Ile-11. The lactone, but not the L-*allo*-enduracididine, is essential to its mechanism.[481,482] Teixobactin binds to the pyrophosphate moiety of Lipid II and Lipid III, precursors of peptidoglycan and teichoic acid biosynthesis, respectively, causing cell-wall damage and autolysin delocalization.[480,483,484] Teixobactin is active against Gram-positive bacteria (MRSA, VISA, *C. difficile*) and mycobacteria. Its lack of activity against Gram-negative bacteria is due to its exclusion from access to its lipid targets in the periplasm, by the outer membrane. Indeed, teixobactin is active against an outer membrane-deficient *E. coli* strain, and when an outer membrane-disruptive antibiotic (such as colistin) is used in combination.[480,481] Lipid II is a new focus for antibiotic discovery and design.[206,485–487]

An emerging theme in antibiotic discovery is the use of genomics and proteomics for structure and for target identification.[488] For example, antibiotics that target the assembly of the cytoskeleton of *S. aureus*,[489–491] or interfere with teichoic-acid assembly,[492–494] are synergistic with β-lactam antibiotics. An inhibitor of the MurG enzyme of Lipid II biosynthesis is synergistic with the β-lactam antibiotics against *S. aureus* as a consequence of failed localization of PBP2 to the division septum when MurG is inhibited.[495] The possible necessity of combination antibiotic chemotherapy (as exemplified by the pairing of β-lactams with β-lactamases) is at the forefront of antibiotic research.[496–499]

Peptidoglycan Remodeling and Recycling

The processes of cell growth, division, and (in some bacteria) sporulation require not just the synthesis of new peptidoglycan, but the concurrent remodeling of existing cell wall. The presence of peptidoglycan-cleaving amidases affixed to the exterior of the Gram-positive cell wall is widely understood to reflect the necessity of enabling the outer diameter peptidoglycan to relax and expand as it is driven outward by the new peptidoglycan assembled at the membrane.[500] As the peptidoglycan of the Gram-negative is much thinner, the need for such a process is lower (or even, unnecessary). Accordingly, the discovery that *E. coli* remodels approximately 50% of its peptidoglycan per generation was a surprise.[501,502] The prescient suggestion that new peptidoglycan growth required excision of old peptidoglycan, to allow old peptidoglycan to act as a template for incorporation of new peptidoglycan, has the same credibility today decades after the suggestion was made.[9] How this task might be done at the molecular level is still unknown. Murein remodeling requires specific enzymes, called autolysins. This group of enzymes includes the nonhydrolytic lytic transglycosylases, and the hydrolytic DD-endopeptidase, carboxypeptidase, *N*-acetylmuramidase (lysozyme), acetylglucosaminidase, and *N*-acetylmuramyl-L-alanine amidase enzymes.[503,504] The estimate of 18 murein hydrolases in *E. coli* has expanded as a result of genetic and biochemical study,[505] as exemplified by the identification in *E. coli* of three redundantly essential hydrolases that cleave D-Ala-*m*-A_2pm crosslinks as an obligatory event in peptidoglycan growth[506] and the discovery of a quality control periplasmic enzyme (having both uncertain substrate and mechanism) that ensures peptidoglycan having a L-Ala as the position-1 amino acid of the peptidoglycan stem, and not either glycine or L-Ser.[507] Peptidoglycan with position-1 glycine or L-Ser is defective. Hyperstructures such as the flagellum and the secretion systems have dedicated peptidoglycan autolysins. The type VI secretion system (T6SS)[508] of *E. coli* requires adaptation of its peptidoglycan by the MltE lytic transglycosylase,[273] while the T6SS of *A. baumannii* requires adaptation of its peptidoglycan by the TagX L,D-endopeptidase. The redundancies

in function among the breadth of enzymes has made the identification of their mechanistic role(s) exceedingly difficult. It is entirely possible that coordination of both the MltE and TagX enzymes is required. Extensive peptidoglycan remodeling occurs during spore formation, and subsequent spore resuscitation (germination) by the Gram-positive bacteria of the *Bacillales* and *Clostridiales* orders.[49,50,509,510] A structural sub-class of the cephalosporins, the cephamycins, inhibit specifically the sporulation PBPs of *Clostridioides difficile*. The most potent of the cephamycins, cefotetan, may represent chemotherapy for the prevention of recurrent *C. difficile* intestinal colonization.[511] Muropeptides stimulate growth resumption from stationary phase *E. coli*.[512]

Significant progress has been made, however, toward answers with respect to the biochemical pathways for peptidoglycan recycling. Under laboratory growth conditions peptidoglycan recycling by *E. coli* is not essential. Nonetheless, the efficiency with which *E. coli* accomplishes this recycling—90% of the released peptidoglycan is recovered and reused—can only be interpreted in terms of a competitive advantage to being able to do so.[513] Recycling in Gram-positive bacteria was once thought as insignificant (on the basis that peptidoglycan segments accumulated in the medium), but is now recognized to exist especially under conditions of limited nutrients, such as is necessary for stationary-phase survival.[514,515] Unique pathways are encountered for peptidoglycan recycling when different bacteria are examined.[516] This diversity may reflect an additional mechanism for competitive advantage. The direct relationship between peptidoglycan recycling and the expression of the AmpC β-lactamase by pathogenic Gram-negative *Enterobacteriales*, as a resistance response to the penicillins and cephalosporins, has generated intense interest. Figure 18.4 includes the pathways for peptidoglycan synthesis and peptidoglycan recycling partitioned among the cytoplasm, the cytoplasmic membrane, and the periplasm. At its center is the AmpR transcription factor that controls expression of the *ampC* gene. In the absence of a β-lactam antibiotic an "unperturbed" pool of recycled muropeptides enters the cytoplasm by transport through the PMF-dependent AmpG permease. In the absence of a β-lactam threat, the muropeptide structures (in partnership with key intermediates in peptidoglycan biosynthesis) that are bound to AmpR enforce repression of the synthesis of the AmpC β-lactamase. In the presence of β-lactams, the composition of the muropeptide pool is perturbed. The resulting different muropeptides displace the muropeptides bound to AmpR, leading to a conformational change in the AmpR-DNA complex that is now permissive for AmpC synthesis.[517–519] Understanding the molecular basis for the perturbation is central to preserving the clinical value of the cephalosporin β-lactams that are AmpC substrates.[520–523] The best-studied bacterium is *P. aeruginosa*.[104,524] Indeed, the potential therapeutic benefit of altering the peptidoglycan recycling so as to minimize the muropeptide perturbation (and prevent AmpC synthesis) is validated in a murine model of *P. aeruginosa* infection.[525,526] The relationship among muropeptide recycling, potential targets within the recycling pathway, and the breadth of AmpR regulation (beyond AmpC) are reviewed.[527–529] Although key aspects of the *P. aeruginosa* pathway hold for all AmpC-expressing *Enterobacteriaceae*, variation in this pathway is evident when these bacteria are compared.[289,290] In *Pseudomonas* the central enzyme defining the perturbation of the pool of recycling muropeptides is the low-molecular-mass PBP4, acting as both a DD-carboxypeptidase with respect to the stem peptide and DD-endopeptidase with respect to the crosslinked stem of the peptidoglycan.[530–533] When this PBP4 is inactivated by a β-lactam, its catalytic activity is lost and the resulting replete stem structures, as distinct from the truncated stem structures, lead to derepression of AmpC synthesis.

Sensing and Preserving Peptidoglycan Integrity

Bacteria sense compromise in the structural integrity of their envelope. Not surprisingly, our understanding of how this sensing is done, and how it is responded to, derives largely from exposure of bacteria to cell envelope-targeting antibiotics. A notable example is the sophisticated monitoring of peptidoglycan recycling as a means to regulate production of the AmpC β-lactamase enzyme as a critical resistance mechanism in the *Enterobacteriaceae*, as just discussed. A second notable example is the adaptation of the self-resistance mechanism that enables vancomycin biosynthesis[534,535] by the *Enterococci* as a vancomycin resistance mechansim. Noncovalent engagement by vancomycin of the acyl-D-Ala-D-Ala stem terminus of the peptidoglycan by hydrogen bond formation is central to its mechanism. By alteration of the peptidoglycan biosynthetic pathway to use a acyl-D-Ala-D-Lac stem terminus, an energetically important hydrogen bond to the vancomycin interaction is lost, and with this loss its antibiotic activity. Although the use of this resistance mechanism by the *Enterococci* has not as led to pervasive infection caused by vancomycin-resistant *Enterococci* (VRE), persistent VRE infection remains clinically important.[536,537] Here it may be noted that intestinal commensals secrete a nisin-type, peptidoglycan-targeting lantibiotic in order to suppress VRE growth.[538,539] This observation emphasizes the broader perspective that the antibiotics should be understood to function as a means for ecological competitiveness within ceaseless internecine bacterial competition.[540,541]

The operation of these networks used by bacteria to detect and respond to cell-wall stress is complex. The SOS response is found in varying capacities among the bacteria (it is considered to be a robust response in *E. coli*, *P. aeruginosa*, and *B. subtilis*; and as less robust in *S. aureus*). As the SOS response is primarily a response to DNA damage, the ability of β-lactams to induce the SOS response is perhaps surprising. In *S. aureus*, β-lactams induce the LexA/RecA proteins, trigger prophage induction, and effect high-frequency horizontal transfer of pathogenicity islands.[542,543] Direct cell-wall damage in *S. aureus* is monitored by the VraSR two-component system, resulting in VraS auto-phosphorylation with subsequent VraR phosphorylation and dimerization.[544,545] The molecular identity stimulus effecting the autophosphorylation is not known. The effect of VraR dimerization is increased expression levels of genes relating to peptidoglycan and teichoic acid synthesis. In the mycobacteria and the Gram-positive Firmicutes and Actinobacteria, PASTA (for "penicillin-binding protein and serine-threonine kinase associated" domain)-containing proteins act as sensors. The PASTA domain interacts directly with the peptidoglycan,[546] and the PASTA domain-containing eukaryotic-type kinases interact directly with key PBPs and with complementary two-component

systems.[547,548] While the importance of PASTA kinase activity to the Gram-positive bacteria with these activities is proven,[549] here also the molecular mechanisms of activation are not well understood. PASTA kinases are a particular focus as control points of the mycobacteria. Peptidoglycan fragments (muropeptides) resuscitate mycobacteria from host-evading dormancy[550,551] and resuscitate nonculturable mycobacteria.[552,553] In the example of the *M. tuberculosis* PknB kinase, a comprehensive evaluation of muropeptide structure implicated the co-presence of glycan strand length, a tetrapeptide stem, and a 1,6-anhydroMurNAc terminus as optimal for binding affinity.[554] The compromise of the peptidoglycan structure of one bacterium, as a result of the deliberate action of another, is exemplified by the synergy of the effectors injected into bacteria by the type VI secretion system of the Gram-negative bacterium *P. aeruginosa*.[555–557] One of the six effectors (Tse3) is a peptidoglycan-degrading enzyme that synergizes with loss of the proton motive force effected by the Tse4 effector.[558]

As bacterial regulation of their peptidoglycan is sophisticated, bacterial co-culture is a potentially valuable mechanism for unlocking cryptic antibiotic biosynthetic pathways. Notwithstanding the challenge of translating this conception to experiment, this approach led to the discovery of teixobactin, a Lipid II-binding antibiotic,[559] and darobactin, an inhibitor of the essential BamA chaperone of outer membrane protein insertion.[560] While the likelihood that these new antibiotics will have the practicality, efficacy, and safety required for clinical use is uncertain, there is no doubt that this approach defines an important path for new antibiotic discovery.[561–564]

Innate Immunity Detection of the Peptidoglycan

Muropeptide recognition is an essential component of the innate-immune system.[565,566] Deliberate muropeptide release to subvert the innate-immune system is a virulence mechanism of certain bacterial pathogens (notably the Gram-negative *Neisseria*).[567,568] The molecular basis for peptidoglycan recognition by the innate immunity-recognition proteins NOD1 (classic ligand is γ-D-glutamyl-*meso*-diaminopimelic acid, derived from degradation of the peptide stem of the peptidoglycan) and NOD2 (classic ligand is *N*-acetylmuramyl-L-Ala-D-isoglutamine, known as MDP, derived from the glycan strand of the peptidoglycan)[569,570] is summarized in a recent review.[571] The development of the chemistry for the synthesis of peptidoglycan structure has allowed evaluation of the structural basis for the long-recognized immunostimulatory capability of MDP.[572–575] The relevance of NOD2 to host defense and inflammation, and in the etiology of Crohn's disease (and other diseases), is reviewed.[576,577] The relationship of peptidoglycan structure to the immune response continues to be explored broadly. Five recent examples give a sense of the breadth of this exploration. Peptidoglycan photoaffinity reporters differentiate between the active and inactive states of NOD1 and NOD2 in the immune response pathway.[574] As noted previously, *B. burgdorferi* peptidoglycan is a persistent antigen in patients with Lyme disease.[174] Antibody neutralization of circulating peptidoglycan suppresses development of autoimmune arthritis and encephalomyelitis in murine pharmacological models.[578] The structurally different peptidoglycan of stationary-phase *S. aureus* elicits a less robust immune response than that of exponential growth *S. aureus*.[579] The immune-stimulating property of the peptidoglycan is not limited to bacterial infection. A conjugate of MDP with docetaxel, a taxol derivative, is more active than docetaxel alone in the growth suppression of implanted tumors in mice.[580]

A notable recent development with respect to peptidoglycan and innate immunity is recognition of the ability of (many, if not all) cell-wall containing Gram-positive and Gram-negative bacteria to transform, in the presence of cell-wall-targeting antibiotics and other stressors, into a cell-wall-deficient "L-form" state.[581,582] In the L-form bacteria dispense with their peptidoglycan cell wall and use a membrane-only cell envelope. This change gives survival advantages. Without a cell wall the cell-wall-targeting antibiotic is impotent. Without a cell wall the L-form bacterium evades innate immunity. Thirdly, the metabolic alteration (from respiration to glycolysis) that accompanies the L-form transition is less stressful to the bacterium.[583] A closer relationship is observed between antibiotic lethality and the bacterial metabolic state, as opposed to the bacterial growth rate.[584] Compelling data are suggestive of the infection circumstances where L-form conversion confers a survival advantage.[585] These observations complement studies that correlate the suppression of peptidoglycan synthesis by cell-wall acting antibiotics[586] as an important tolerance resistance mechanism.[587–589]

Conclusion

The peptidoglycan is an essential structural polymer component of virtually all bacterial cell envelopes. It is not a static structure. Rather, it exists in perpetual states of remodeling, recycling, and regeneration with each process connected intimately to the bacterial cell cycle. The enzyme catalysts involved in this dynamic are the target of medical-critical antibiotics. Research vistas for the peptidoglycan include its pivotal role in the cohesion of the bacterial cell envelope; as a locus for signal transduction within the bacterium and by the host during bacterial infection; and as a frontier for new antibiotic discovery and the subversion of bacterial resistance.

Introduction

Microbes, used collectively to describe bacteria, fungi, archaea, other unicellular organisms, and viruses, are everywhere. We are increasingly aware of their critical importance to human health: it is estimated that in the human body bacteria alone are as numerous as human cells (Sender et al. 2016), and in terms of gene content and function we are vastly outnumbered (Qin et al. 2010). Microbes contribute to the breakdown of food into accessible nutrients (Hooper et al. 2002; Smith et al. 2013), outcompete invading pathogens in the gut, on the skin and in the urogenital tract (Smits et al. 2016; Grice & Segre 2011; Hickey et al. 2012; Roubaud-Baudron et al. 2019), and affect our mood and behavior through metabolite signaling in the gut (Johnson & Foster 2018). Studying the human microbiome is not only of basic biological interest, but particularly important as we begin to identify associations between changes in composition and most metabolic and autoimmune disorders, including diabetes, obesity, asthma and allergies (Blaser & Falkow 2009). Correlative studies show that the human gut microbiome diversity is lower in populations in developed countries compared to those of hunter-gatherers and inhabitants of rural communities, with the loss suggested to be caused by consumption of less complex and more processed food, increased hygiene, and use of antibiotics (Clemente et al. 2015; Schnorr et al. 2014; Yatsunenko et al. 2012). Cause, effect, and mechanisms are studied *in vivo* in mouse models, and *in vitro* in cell cultures such as organoids, complemented by an increasing number of large-scale observational studies in human patients and the first randomized trials, as discussed later.

Advances in sequencing technologies have revolutionized our study, and understanding, of microbial communities. Circumventing culture-based approaches enables identification and quantitation of microbes that we are as of yet not able to grow in culture. The analysis is split between the lab bench, with, e.g., extraction of DNA, PCR amplification, and high-throughput sequencing, and the subsequent computational analysis by classifying sequences and comparing distributions between samples. Here, we aim to provide an introduction to this rapidly developing field of research, including core concepts, considerations, and pitfalls in the methodology and interpretation of data related to human health.

Methods in Microbiome Sampling and Analysis

Sample Collection and DNA Extraction

For collection of samples, timing and location should be considered in the study design to address biological variation. Microbiome composition differs vastly between body sites (Bouslimani et al. 2015), even between different section of the gut and fecal samples (Durbán et al. 2011; Gu et al. 2013), and vary with the time of day and season (Davenport et al. 2014; Zarrinpar et al. 2014). Technical variation may be introduced by sample storage conditions (Choo et al. 2015; Blekhman et al. 2016), and the complexity of the sample needs to be taken into account when extracting DNA; different kits and disruption methods favor different microbes so care should be taken in this step to minimize bias (Yuan et al. 2012). A step in which the sample is treated by bead-beating can facilitate both disruption of, e.g., tissues to dislodge microbes, and the release of DNA from cells. Specific filtration and extraction techniques can be employed to target DNA viruses (Minot et al. 2013; Kumar et al. 2017).

During extraction, and in the subsequent steps, it is critical to take precautions to avoid contamination and include negative controls, particularly when analyzing samples with a low abundance of microbes (Eisenhofer et al. 2019). Equipment and reagents contain traces of microbial DNA, colloquially referred to as the "kitome" (Salter et al. 2014). When including negative controls, the sequences retrieved can be subtracted from those obtained from the samples, as background noise (Segal et al. 2013; Goffau et al. 2019). An additional concern for samples with low levels of microbial DNA is whether it was present simply as that, i.e. a trace of dead cells, or from living organisms. As such, studies proclaiming characterization of microbiomes from organs usually believed to not contain living microbes, e.g., the placenta or brain, are increasingly met with skepticism (Eisenhofer et al. 2019).

Sequencing Platforms and Analysis Approaches

The development of high throughput sequencing technology is fast-paced, with competition on read length, error rate and type, run time, and cost. For a comparison of past and current technologies see Kchouk et al. (2017). The best choice will be determined by the research aims and the price available to the scientist. The short-read sequencing-by-synthesis approach of Illumina, with a low error rate, is used extensively for microbiome analysis. Single molecule, real-time (SMRT) sequencing by SMRT Pacific Biosciences (PacBio) and Oxford Nanopore Technologies (ONT) produce very long reads with a higher error rate. For whole genome assembly, technologies can be used in complement by using long reads to build scaffolds that are proof-read by short reads with high accuracy (Koren et al. 2012). Another approach, from 10X Genomics, is to partition long fragments in droplets for short read barcoded sequencing, where the barcodes are used to guide the assembly of contigs of the short reads (Bishara et al. 2018).

Estimating Diversity Using a Marker Gene

When targeting a specific genomic region for analysis, the DNA is amplified by PCR following extraction. Samples can be multiplexed in the sequencing step by adding short oligonucleotide barcodes to the primers, unique for each sample (Hamady et al. 2008). That allows for pooling of PCR products from multiple samples for sequencing, and separating the reads contributed from each sample in the analysis. Increasing the number of samples comes at the cost of the sequencing depth for each individual sample. PCR amplification intrinsically introduces bias, as some sequence variants are amplified at a higher rate than others. Such bias can be estimated, and computationally corrected for, by sequencing PCR products amplified at different cycle numbers (Silverman et al. 2019). Overall, one approach is to keep cycle number as low as possible. Another way to estimate technical bias is to include a mock community in analyses, with a known species composition, which also allows for comparisons between runs (Schloss et al. 2011).

Studies on the human microbiome usually focus on bacteria, which are considered the most important in terms of both biomass and function. The diversity of a bacterial community can be profiled by sequencing marker genes such as that for 16S rRNA. Ribosomal genes were early recognized as being ideal for this purpose, as they are sufficiently similar between species to amplify and align, yet enough different to confidently distinguish between organisms at least at the genus level and commonly considered to the species level. The 16S rRNA gene is on average 1525 bp long, and comprises variable and conserved regions. Primers targeting conserved regions ensure broad specificity, for amplification of hypervariable regions to estimate diversity. The majority of studies focus on a subset of the gene, such as the V3-V4 region, due to length limitations in read length in the sequencing step (Kumar et al. 2011, Yang et al. 2016, Rintala et al. 2017). Using the whole ribosomal RNA operon gives better taxonomic resolution to the strain level (de Oliveira Martins et al. 2020). High throughput sequencing of the full length 16S gene is possible with SMRT sequencing by constructing circular sequences; these are read multiple times and using the consensus output sequence compensates for the higher error rate of this technology (Callahan et al. 2019). Differences in copy-number of the 16S rRNA gene between species, and allele variation within genomes (Klappenbach et al. 2001), can skew the analyses of community composition. Alternatives to 16S are being explored, such as the single-copy highly conserved gene *rpoB*, which shows promise in terms of specificity and sensitivity in detecting diversity (Ogier et al. 2019). Eukaryotes can be targeted with 18S sequencing and the fungi in the mycobiome may be specifically targeted by sequencing of the Internal Transcribed Spacer (ITS) region (Nash et al. 2017). No general target region is available to analyze the virome, given the high diversity and frequently small genome size of viruses, so identification of DNA viruses requires a metagenomic approach.

Identifying Organisms in Data from Targeted Amplicon Sequencing

Analysis of the reads from high throughput sequencing aims to correctly identify unique biological variants, while limiting the noise introduced by sequencing errors. For 16S sequencing the clustering of sequences based on 97% similarity as operational taxonomic units (OTUs) has been the most widely

used approach, using a database of reference sequences to group reads, or with *de novo* identification of OTUs. The most popular pipelines for this and subsequent steps are QIIME (Caporaso et al. 2010; Bolyen et al. 2019) and mothur (Westcott & Schloss, 2015), which are being continually improved. Here, the likelihood of missing potential strain level diversity is weighed against the error rate of the input. With the advent of more accurate sequencing, the use of Amplicon Sequence Variants (ASVs) may be replacing OTUs. Computational approaches such as DADA2 for identifying ASVs have the benefit of achieving a finer resolution of diversity, to single-nucleotide differences, and facilitate comparison across studies as they are not dependent on the other sequences in the dataset as is analysis of OTUs (Callahan et al. 2016, 2017). Following clustering of sequences, they are classified to the highest level possible, by comparison to a database (Balvocuite & Hudson 2017). This approach potentially permits resolution to the bacterial strain level.

Comparing Relative Abundances of Organisms

Amplicon-based diversity studies estimate the relative abundance of different organisms in a sample and should ideally be combined with an estimation of the absolute prevalence. Using only compositional data limits the choice of statistical tools and biases the impression of the similarity between samples: we would expect that microbiomes with the same diversity but a tenfold difference in actual numbers impact the host in different ways (Figure 19.1A; Morton et al. 2019). The actual abundance of microorganisms in a sample can be estimated by quantitative PCR targeting a region of a conserved indicator gene, e.g., the 16S rRNA gene (Nadkarni et al. 2002). A caveat, just as for 16S amplicon sequencing, is that different organisms have different copy-number of the 16S rRNA gene in their genome. An alternative approach is to stain bacteria with, e.g., a fluorescent nucleic dye or a probe with a broad specificity, and count the bacteria by flow cytometry (Props et al. 2017; Vandeputte et al. 2017). If an estimation of the absolute microbial prevalence is not feasible, Morton et al. (2019) suggest a computational approach to identify direction of community changes based on the differential ranking of microbes across samples.

Predicting Interactions from Relative Abundance Data

Comparing relative abundance data from multiple samples is used to predict interactions based on co-occurrence. The underlying hypothesis is that if a specific pattern in distribution is repeatedly observed, e.g., a positive or negative correlation between a consortium of species, this may be caused by interactions between those organisms (Faust & Raes 2012). Network analysis can identify pairwise and more complex correlations between organisms. Caution is advised when interpreting such results. Biologically, a positive correlation could arise if two organisms respond to availability of a specific food source, and network analysis may wrongly label such a competitive or neutral association as beneficial. Likewise, a strong negative correlation between the prevalence of organisms could represent the ability to use different resources, or be entirely spurious, rather than direct competition (Faust & Raes 2012). Computationally, there are limitations to comparing compositional data across samples. The measured abundances of organisms are inherently interdependent (Figure 19.1B), and this dependence is substantially more impactful in less-diverse communities, where, e.g., the importance of rare organisms, and their absence in some samples, may be inflated (Kurtz et al. 2015). This can be addressed in the choice of analytical approach, such as where the SPIEC-EASI method uses center-log transformation and assumes a sparse ecological network to decrease compositional bias (Kurtz et al. 2015).

Beyond 16S—Describing Lower Level Variation and Microbiome Function

While species composition and indices of diversity based on 16S rRNA gene sequencing are used to describe and compare communities, the overarching aim is to understand how composition reflects function. The PICRUSt software exploits the correlation between phylogeny and functional profile to extrapolate from 16S diversity to metabolic capabilities (Langille et al. 2013). This method maps 16S sequences to their closest relatives that have full genomes available and predicts whole genome level function based on that of related organisms. Even when 16S sequencing allows for identification of the correct species, an

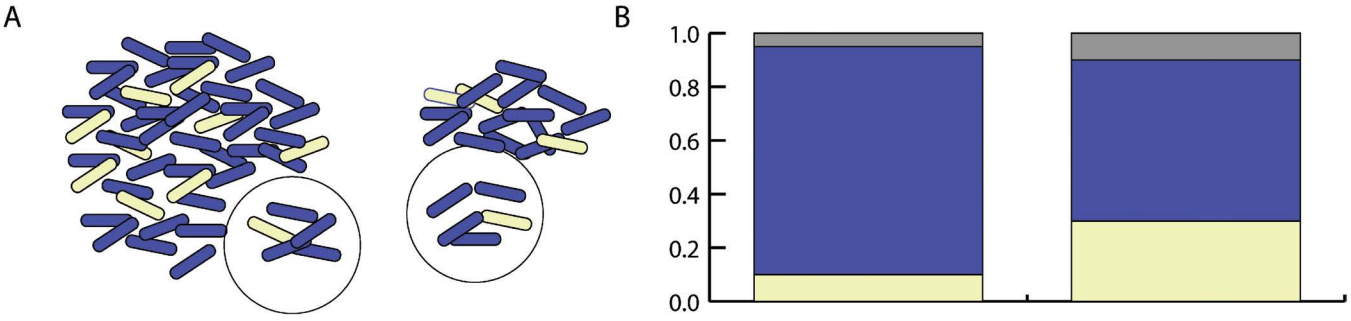

FIGURE 19.1 Challenges of using compositional data. A: An unbiased analysis of the diversity of the two microbiomes will show that the yellow bacteria comprise 20% in both, suggesting that the constituent populations are highly similar. However, quantifying the biomass will reveal a difference in the absolute number of bacteria that potentially can affect the host. B: The relative abundance of a species in a sample is dependent on the prevalence of other species as the sum is always 1. For two identical samples, in which extraction of DNA from the blue bacteria was more efficient in the first sample compared to the second, different measures of diversity are observed despite the proportion of DNA from the yellow bacteria being exactly the same in both samples.

obvious limitation of this approach is the inability to detect variation below the phylotype or species level, and the accuracy of microbiome function reconstruction is greatly restricted by the incompleteness of the database of genomes used. Metabolic profiles and production of exoproducts can vary extensively between strains and evolve over time within a microbiome (Zhang & Zhao 2016). Mutations such as single nucleotide polymorphisms (SNPs), and inserts and deletions can cause loss of function, while new traits can be acquired by recent or past horizontal transfer of genomic DNA or plasmids. Thus, functional analysis based on 16S is only a very crude approximation, but provides a well-established and cost-effective first-view into the biochemical attributes of a sample.

Metagenomics and metatranscriptomics with sequencing of DNA or cDNA associated with all organisms in a community, without prior PCR enrichment of a specific genomic region, provide more direct approaches to estimate function but are also both more expensive and computationally demanding. Depending on the study objective, sequences can be grouped by organisms or function. The reference database-based methods compare sequences to a library, and when a threshold is met, they are assigned to a corresponding organism or function (Franzosa et al. 2018; Segata et al. 2012; Wood & Salzberg, 2014). Here, the incompleteness of current libraries is an even greater challenge than for 16S sequencing. Alternatively, full genome *de novo* assembly can be considered, where sequences are stitched together based on overlapping patterns. It is challenging to assemble full genomes from a mixed community, but sequences can be "binned" based on patterns in oligonucleotide use, similarity to related genomes, and read prevalence. This approach is based on the assumption that different regions of a genome will have similar sequencing depth, so that contigs of sequences originating from the same organism are likely to have similar prevalence (Albertsen et al. 2013; Venter et al. 2004). The long reads of SMRT sequencing are particularly useful for such assembly, e.g., in resolving placement of repetitive elements, and this approach also identifies methylation patterns, which can be used to group sequences as they may be strain-specific (Zhu et al. 2018; Beaulaurier et al. 2019). The identification of functional pathways from genomic data can be done with or without full genome assembly and reveals the metabolic potential of a microbiome. Combining metagenomics and transcriptomics (the analysis of which genes are expressed by sequencing cDNA made from RNA) allows for inference of which members of the microbiome contribute to specific pathways and their relative importance (Liu et al. 2020).

Data Sharing

With the publication of research on sequencing data it should be, and is for most journals, a requirement to upload raw data to appropriate repositories. Care should be taken to include metadata for reproducibility, and so that data can be used for other studies (Navas-Molina et al. 2017). In addition to raw data, publication of the code used for analyses, including choice of parameters and tables with, e.g., OTUs or ASVs, will facilitate cross-study comparisons of the biological findings and the methodology used for sequencing and analysis. Sequencing data publication, however, also raises new questions about protection of privacy, as the microbiome is sufficiently unique to be used to identify individuals, and guidelines will surely need to be continuously developed (Franzosa et al. 2015; Wagner et al. 2016).

Interpreting Results

What Is a Healthy Microbiome?

A goal of human microbiome analyses is the identification of organisms that are associated with, and potentially contributing to, a specific host state, such as disease, geographic origin, diet, and medical treatment. Massive efforts such as the European Metagenomics of the Human Intestinal Tract project (MetaHIT) and the NIH Human Microbiome Project (HMP) have made great strides in developing computational methods and characterizing the microbiomes at different body sites (Qin et al. 2010; Peterson et al. 2009), and a wealth of metadata facilitates the finding of correlations between organisms and health factors. A major result is that there is no obvious composition of a core healthy microbiome, as taxonomic composition varies greatly with, e.g., diet and geographical location. However, as different species can overlap in their metabolic range, substantial variation may mask functional similarities (Bäckhed et al. 2012). Although such studies have shifted the focus from attempts to identify "good" and "bad" bacteria, there continue to be substantial efforts in this direction. In contrast, most research points to the importance of stability in composition and overall diversity, and that the loss of microbial diversity frequently is associated with poor outcomes.

The term dysbiosis has been used extensively to describe an unhealthy and unbalanced microbiome. However, the lack of a clear classification of what constitutes a healthy microbiome obviously poses a challenge to define what comprises a deviation from this, in particular if no "healthy" samples of a subject are available for comparison (Hooks & O'Malley 2017). Olesen & Alm (2016) argue that the way dysbiosis is used, without distinguishing whether an altered microbiome is the cause or effect of disease (or its treatment), is holding the field back from identifying the areas in which microbiome research can improve health. We do not need gut microbiome analyses to tell us that obese and healthy controls differ, so to be useful we would have to gain information on why they differ and how we can change it (Olesen & Alm 2016).

The Ecology and Evolution of Host-Microbiome Interactions

From a discovery-based research commencement, with the screening of many individuals, the microbiome field is entering a hypothesis-driven phase (Tripathi et al. 2018). Central to address questions such as why diversity is important and how it can be maintained or reconstituted, is the implementation of ecological and evolutionary theory. Ecological theory and experimental studies have dealt with how the diversity of an ecosystem affects function, resistance to change in the face of disturbance (Figure 19.2A), and resilience, as the likelihood to return to the starting point following perturbation (Figure 19.2B; Oliver et al 2015). Studies of aquatic systems have shown that the colonization success of a species is affected by arrival time through

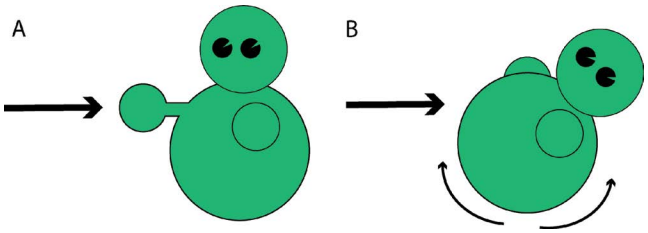

FIGURE 19.2 Characteristics of a stable ecosystem. Stable ecosystems can be characterized as both resistant and resilient in the face of a challenge. A: A resistant system will not be perturbed by a disturbance. An example is the resistance of a diverse gut microbiome to *Clostridium difficile* infection in which invaders are outcompeted. B: A resilient ecosystem bounces back to its initial state, like a roly-poly toy, following a disturbance. An example is the composition of the fecal microbiome of healthy volunteers treated with antibiotics for a short duration, in which diversity is largely restored after some time.

priority effects (Alford & Wilbur 1985; Shulman et al. 1983). The same dynamics matter for the human microbiome, where a perturbation can come in the form of dietary change or antibiotic treatment, and diversity affects the likelihood of pathogen invasion (Lozupone et al. 2012).

Evolutionary theory helps us consider the potential for host microbe-interaction (Foster et al. 2017). As we consider how an organism affects our health, it is easy to expect that beneficial traits were selected through co-evolution. The timescale that matters to a microbe with a short multiplication time, however, is if it can outcompete its neighbor, not whether it benefits the host. Can the host control microbiome composition, and if so, how? The most frequent interactions between microbes are expected to be competitive and weak, and those types of interactions, perhaps counter-intuitively, result in a more stable community (Coyte et al. 2015). The host may select for organisms with beneficial properties by providing resources that select for specific properties (Schluter & Foster 2012). In addition, the host may recognize groups of bacteria based on surface markers and can potentially remove or enhance them selectively (Foster et al. 2017).

With regard to the question of whether humans have co-evolved with our microbes, the term phylosymbiosis is used to describe congruency between host and symbiont phylogenies (Moran & Sloan 2015). There are obvious examples of this in obligate, vertically inherited, symbionts co-speciating with their host over time, such as many insects and their symbionts that provide essential nutrients (Douglas 2011). Yet such strict conditions do not have to be fulfilled to create patterns of matching phylogenies, which could arise also when related species acquire related microbes from shared or similar environmental niches. Groussin et al. 2017 teased apart the role of these mechanisms, and the effect of diet, in shaping mammalian microbiomes. A range of phylogenetically older microorganisms were positively correlated with diet, while showing a weaker association with host phylogeny. In contrast, other "younger" bacteria showed strong signals of host specificity and co-speciation.

Overinterpreting Results?

With a substantial decrease in sequencing prices, and ease of analyses facilitated by well-supported open-source bioinformatics tools, the number of microbiome studies has naturally increased. Careful studies have greatly increased our knowledge of the human microbiome, in addition to those of other organisms, and various environmental sites. With increased funding to the field (Proctor 2019), also comes the risk of overinterpreting results ("hype"). This may be in the form of equating correlation with causation, and explicitly translating patterns observed in mouse experiments to humans. Reduction of scientific findings to click-bait headlines by the press further exacerbates this issue. Critique of a study claiming to show a causative effect of microbiome composition on the development of autism (Sharon et al. 2019), highlight the challenges in this field of small sample sizes, translating mouse experiments to human conditions, selective collection of samples and analyses, and conflicting financial interests (Lowe 2019). As the field matures, such issues must be addressed.

How Close Are We to Direct Consumer Benefits?

A veritable industry has blossomed around direct-to-consumer microbiome sequencing. Several companies offer analyses of fecal samples, collected by the customer at home, for identification of "good and bad" microbes, and prediction of the optimal customized diet despite limited evidence to support their claims. The most promising results for designing dietary intervention come from using microbiome data as a component of a wider profiling of metabolic markers (Zeevi et al. 2015). In addition, there is a large consumer market for pre- and probiotics. The assumption has been that while perhaps not beneficial, probiotics would at least not be harmful. However, this may have been naive. Studies show that probiotics taken following a course of antibiotics can negatively affect the return to a pretreatment community (Suez et al. 2018), and probiotics given to ICU patients may lead to an increased rate of developing sepsis (Yelin et al. 2019). The problem is worsened by the multiplicity of "probiotic" products and the lack of transparency about actual compositions, or even their viability.

Clinical Applications of Microbiome Manipulation

Alleviating Malnourishment

Targeting gut microbiome function is showing potential in addressing the long-term consequences of early childhood malnutrition, where development is impaired despite subsequent increased caloric intake. In the first years of life, a healthy human gut microbiome changes in composition and shows an increase in complexity as it matures (Yatsunenko et al. 2012; Bokulich et al. 2016; Raman et al. 2019). Malnourished children were found to have immature microbiomes compared to healthy age-matched controls, possibly missing specific species (Subramanian et al. 2014; Blanton et al. 2016; Raman et al. 2019). Longitudinal sampling of fecal microbiomes and blood metabolites from malnourished children treated with a standard diet identified markers of incomplete recovery (Gehrig et al. 2019). Experiments with mice and piglets "humanized" by fecal transplants identified supplementary diet ingredients that benefitted microbiome maturation

and host metabolite profile. The positive results were supported by a smaller-scale clinical study of malnourished Bangladeshi children (Gehrig et al. 2019), and shows that a supplementary diet targeting microbiome function, and not solely host nutrition, may be a constructive approach.

Outcompeting Pathogens by Fecal Microbiota Transplantation

Fecal microbiota transplantation (FMT) to treat recurrent infection with the bacterium *Clostridium difficile* represents a major success story in microbiome manipulation with clinical consequences (Smits et al. 2016; van Nood et al. 2013). *C. difficile* is a spore-forming, toxin-producing opportunistic pathogen that can establish infection in immunocompromised patients with low gut microbiome diversity. This increasingly common nosocomial infection causes severe, and potentially fatal, diarrhea and colitis, and unsuccessful treatment with antibiotics further diminishes competition in the gut and exacerbates problems with resistance (Leffler & Lamont, 2015). As a last resort, experimental treatment with a transplant of a healthy gut microbiome has proven highly effective (van Nood et al. 2013). Oral or rectal introduction of fecal material from a healthy donor contributes to establish a diverse microbiome capable of outcompeting *C. difficile*. It is still to be shown whether specific species, or the overall diversity, is most important to achieve this result, and even bacteria-free materials show beneficial effects, suggesting a role of metabolites (Ott et al. 2017). FMT has proven much less successful in the treatment of other conditions such as inflammatory bowel disease (Colman & Rubin 2014), and fatal outcomes following transplant of antibiotic resistant strains from a healthy donor highlights the importance of pretransplant screening, in particular as FMT recipients usually are immunosuppressed (DeFilipp et al. 2019). Development of a culture-based inoculum with a controlled composition may increase safety (Blaser 2019), and a clinical trial of autologous FMT, using material from the recipient acquired prior to antibiotic treatment shows promise for immunocompromised cancer patients (Taur et al. 2018).

Avoiding Side Effects of Drug Metabolism

Gut microbiome profiling can contribute to the development of personalized medicine. The effect of most drugs depends on how they are metabolized and the microbiome, with a wider array of biochemical pathways available than human cells, can play a significant role here. Large-scale screening of drug-microbe interactions revealed a broad range of drug modification by common gut microbes (Zimmermann et al. 2019a), and many widely used drugs have off-target effects on particular members of the gut microbiome (Maier et al. 2018). A mouse study aimed to disentangle the role of the host and microbes by comparing germ-free individuals with introduced microbiomes differing only in the ability of specific strains to metabolize two drugs (Zimmermann et al. 2019b). By modelling measured serum and blood metabolite concentrations, the host and microbial contributions to drug pharmacokinetics was accurately predicted. For the drug irinotecan used against colorectal cancer, members of the gut microbiome can cause serious adverse reactions to treatment, by reactivating excreted metabolites (Wallace et al. 2010). Screening for strains with this enzymatic repertoire can identify patients that are better served with a different treatment (Guthrie et al. 2017).

Improving Response to Cancer Immunotherapy

Microbiome composition also influences the efficacy of cancer immunotherapy (CI). One of the most advanced CI strategies is to use immune checkpoint inhibitors such as anti-PD-1 blockade, which unleash the immune system to target cancer cells directly. However, fewer than 20% of CI patients show partial or complete response to treatment clinically (Carretero-González et al. 2018; Haslam & Prasad 2019). Recent studies demonstrated the microbiome may play a role in modulating CI efficacy and response. The baseline gut microbiome of CI responders is substantially different from CI nonresponders; and transferring of fecal samples from those patients to germ free mice recapitulated the phenotypes, suggesting the microbiome is sufficient to drive these different response (Gopalakrishnan et al. 2018; Matson et al. 2018; Routy et al. 2018). A consortium of 11 bacteria isolated from the human gut microbiota was shown to increase the population of CD8 T cells, which are crucial effector cells in CI, and increase the efficacy of immune checkpoint inhibitors (Tanoue et al. 2019). These studies suggest the potential for using microbiome screening to identify patients that will respond well to a specific treatment, or where manipulation of the gut microbiome prior to treatment can facilitate a better outcome, if the results can be recapitulated in clinical trials.

Bacteriophage Therapy to Eliminate Antibiotic Resistant Infections

While understudied, the human virome appears to be dynamic and dominated by viruses that target bacteria (bacteriophages) in a healthy host, which likely affect bacterial community composition (Minot et al. 2013). A study of IBD patients showed that both the bacterial and viral portions of the microbiomes differed from that of healthy controls (Clooney et al. 2019). Problems with antibiotic resistance has led to renewed interest in treatment with bacteriophages, which has been used particularly in parts of Eastern Europe and Russia (Chanishvili 2012; Chapter 54 in this volume). A high degree of host specialization of bacteriophages imply that they can be used for targeted treatment of specific pathogens, with limited collateral damage to the host microbiome, and may represent a last resort when antibiotic resistance rules out this first line of defense. A cystic fibrosis patient with an antibiotic resistant *Mycobacterium abscessus* infection was recently successfully treated with an engineered cocktail of bacteriophages (Dedrick et al. 2019), and a mouse study showed improvement of liver disease by targeting *Enterococcus faecalis* with bacteriophages (Duan et al. 2019). More research is required to inform us on the role of bacteriophages in healthy microbiomes, and how they can be used therapeutically.

Looking to the Future

As the above examples demonstrate, it is an exciting time to be working on the human microbiome. Technological advances expand the possibilities for studying host-microbe interactions on an ever-finer scale, and facilitate ways to experimentally test the selective pressures that have shaped them. Longitudinal sampling of individual patients or across a population can provide retrospective or near real-time tracking of natural community dynamics, or responses to treatment, and randomized controlled trials can test the promising findings of mouse studies in humans. With input from eco-evolutionary approaches, we should see the continued development of new strategies for ways to manipulate (to "harness") the microbiome for health benefits.

Introduction

The *Actinobacteria* are a major phylum in the bacterial domain. Many large-scale tools for visualizing taxonomic and phylogenetic relationships are emerging (de Vienne, 2016; Jovanovic and Mikheyev, 2019; Zhang et al. 2012) with a brilliant interactive visualization at http://lifemap-ncbi.univ-lyon1.fr/ (accessed February 2019) showing the relationship of this major clade to the Terrabacteria group, Bacteria, and the rest of the tree of life. Their origin seems significantly more recent than the divergence of the Bacteria from Archaea and Eukaryota and has been linked to the colonization of the land (Battistuzzi et al., 2004).

The phylum encompasses a number of significant genera and species, including major human pathogens such as: *Mycobacterium tuberculosis* (Chai et al., 2018) and other members of the Mtb group; *Mycobacterium leprae* (Walker and Lockwood, 2006); and a number of other opportunistic pathogens, such as *M. avium, M. intracellulare, M. scrofulaceum, M. kansasii, M. xenopi, M. malmoense*, *M. fortuitum, M. marinum*,

M. ulcerans, and *M. abscessus* (Cowman et al., 2016). The genus *Corynebacterium* (Oliveira et al., 2017) includes human and animal pathogens (Bernard, 2012; Soares et al., 2013) and is a workhorse of industrial biotechnological production of biochemicals (Becker et al., 2018). The members of the genus *Bifidobacterium* are a major component of the gut microflora of adults and infants and crucial in immune development and immunomodulatory activity in a healthy gut (Ruiz et al., 2017).

Many actinobacteria are environmental including soil, rhizosphere, and endophytic organisms for example the genus *Frankia* responsible for symbiotic nitrogen fixation in nonleguminous plants (Nguyen et al., 2019; Ventura et al., 2007). Other actinobacteria species are cultured as endophytes from plants, especially *Streptomyces* but also *Microbispora*, *Micromonospora*, *Nocardioides*, *Nocardia*, and *Streptosporangium* are common (Dinesh et al., 2017); however, their role, for example, as symbiotic or commensal, is often less clear than in the case of *Frankia*. In the case of endophytic *Micromonospora* in nitrogen-fixing plants, plants with rhizobial nodules infected by *Micromonospora* do seem to show improved growth (Trujillo et al., 2015), though the basis for that improvement is unclear. In the soil, they play a role in degradation of biomass and in recycling, including recalcitrant molecules and pollutants (Alvarez et al., 2017). In activated sludge, as well as contributing to biodegradation (e.g., playing a positive role in enhanced biological phosphorus removal), filamentous Actinobacteria play a role in normal floc formation, as well as being major players in bulking and foaming, both significant problems in waste water treatment (Seviour et al., 2008).

Marine actinobacteria, once seen as terrestrial wash-in, are a rich source of novel diversity (Ward and Bora, 2006) and have come to prominence in search and discovery for bioactive metabolites, for example, *Salinispora* (Jensen et al., 2015). Both marine and terrestrial actinobacteria have been and continue to be the major source of bioactive natural products (Newman and Cragg, 2016), as have actinomycetes from diverse ecological niches (Bull et al., 2000), such as endophytes (Newman and Cragg, 2020).

The phylum *Actinobacteria* (Goodfellow, 2012) currently (List of Prokaryotic names with Standing in Nomenclature [LPSN], https://www.bacterio.net/ accessed February 2020) contains six classes with some deep-rooted clades (Table 20.1a). The major clades of diversity map roughly to the 31 orders (Table 20.1a and 20.1b). Understanding the diversity of organisms, their identity in the membership of functional biomes, and the ability to communicate that information is essential for our ability to interact with, manage, and exploit our relationships with the microbial world. That role should be played by systematics, the discovery, description, classification, and naming of organisms, enabling their identification. That reference classification consists of type

		Thermomonosporaceae			*Actinomadura*

species organized into a hierarchical set of nested groups—from strains, to species, genera, families, orders, classes, phyla, and domains.

Isolation and description of organisms now recognized as *Actinobacteria*, such as *Mycobacterium tuberculosis* (Koch, 1882; Taylor et al., 2003), *Streptomyces albus* (Rossi-Doria, 1891; Pridham and Lyons, 1961), and *Bifidobacterium bifidum* (Lee and O'sullivan, 2010; Tissier, 1899), have a long history. Descriptions and classifications were based on morphology, staining, growth, and physiology. Later, chemotaxonomic methods were added to the arsenal of techniques, as described in the first edition of the *CRC Practical Handbook of Microbiology* (Lechevalier and Lechevalier, 1989), just as molecular systematics—especially 16S gene sequencing—changed the field. Prior to 16S, taxonomy was explicitly an attempt to classify organisms into groups by similarity—not phylogeny—though evolutionary speculation was common (Stanier and van Niel, 1962). Subsequently, 16S revolutionized the field and 40 years of research have resulted in, probably, ~80,000–100,000 actinobacterial 16S sequences longer than 1,000 bp (the lower figure after removal of duplicate sequences) published in public databases. The integration of molecular systematics, chemotaxonomy, and phenotypic data in a polyphasic taxonomy did result in big changes in prokaryotic taxonomy (Zhulin, 2016). The chapter on actinobacteria in the second and third editions of the aforementioned handbook (Ward and Bora, 2008, 2015) was based upon 16S phylogeny. It has not taken 40 years for the next revolution, next generation, and third-generation sequencing (van Dijk et al., 2018); a revolution in biology has unfolded at tremendous speed, and the impact on the taxonomy and phylogeny of prokaryotes is illustrated by the contentious proposal (Bisgaard et al., 2019) to allow genome sequence data as type material for species descriptions (Whitman, 2015), as well as more than 20,000 actinobacterial genomes (though more than 6,700 genomes are for *Mycobacterium tuberculosis* strains) in the Genbank Genome database (https://www.ncbi.nlm.nih.gov/genome/—accessed February 2020). It is clear that genome phylogeny is the way forward, not only because of the sheer volume of phylogenetically relevant data, for inferring both phylogeny and taxonomic relationships, but also its integration with the further functional analysis for which phylogenetic analysis provides a framework. The Ad Hoc Committee on Reconciliation of Approaches to Bacterial Systematics (Wayne et al., 1987) agreed the complete DNA sequence should be the reference standard to determine phylogeny and that phylogeny should determine taxonomy.

Genomics

The advent of Sanger sequencing (Sanger et al., 1977) revolutionized biology over 25 years, evolving into a fast, accurate, low-cost, and high-throughput technology, in particular providing the backbone for the current prokaryotic and actinobacterial taxonomy from 16S sequencing. It culminated in the dramatic sequencing of the human genome (Lander et al., 2001; Venter et al., 2001)—taking 13 years and costing of the order of $3 billion. Sequencing a human genome drove the development of next-generation sequencing (Schloss, 2008)—454 (Margulies et al., 2005), Ion Torrent (Merriman and Rothberg, 2012), and Solexa (Davies, 2010). Massively parallel, high-throughput, accurate, short-read sequencing increased speed and minimized cost (van Dijk et al., 2014), but massive coverage cannot overcome the fundamental limitations of short reads (Salzberg and Yorke, 2005). Many of the actinobacterial genomes in the databases are highly fragmented with a few to thousands of contigs.

Third-generation, single-molecule, real-time, long-read sequencing followed rapidly (van Dijk et al., 2018) with PacBio (Eid et al., 2009) and Nanopore (Jain et al., 2015) sequencing. Long-read sequencing overcomes many of the limitations of short-read sequencing, but is significantly error prone (85–90% accuracy), though accuracy can be measured in different ways.

PacBio errors seem to be random and probably correctible by coverage (Chaisson et al., 2015), but computationally intensive. However, circular consensus sequencing (CCS), in which multiple rounds of sequencing around a single circularized fragment, removes the errors arising from mismapping of individual long reads. CCS initially came at the price of shorter long reads (<2 Kb), but recent developments (Wenger et al., 2019) promise long (average 13.5 Kb) accurate (96–99.9% depending how you measure) at the cost of sample preparation. The aim is a single sequencing technology to give comprehensive high-accuracy sequencing for human genomic DNA (with the complexity of large plant genomes an additional challenge). Although some actinobacterial genomes are relatively large (e.g., 10–14 Mb), they are simple compared to these eukaryotic genomes but nevertheless benefit from the sequencing technology developments.

Nanopore sequencing errors may contain a nonrandom element, though mostly correctible with coverage (Jain et al., 2018). However, to match PacBio CCS required polishing with short-read sequence data (Illumina Solexa). On-going software and hardware developments, such as neural network based Medaka (https://nanoporetech.github.io/medaka/) continue to improve accuracy.

Currently, combined long-read, PacBio sequencing with short-read Solexa data can be seen as state of the art (Gomez-Escribano et al., 2015). Initially, the PacBio RS II was a large floor-standing machine (though current Sequel II are still >300 kg) with complex sample preparation and data collection suited to generation of sequence data through a sequence provider, similar to Solexa data from MiSeq and HiSeq machines.

The nanopore Minion Mk1B sequencer is 90 g (3.3 cm × 10.5 cm × 2.3 cm) and much more directed to personal use.

Actinobacterial Genomics

There are 22,661 actinobacterial genomes in the Genbank Genome browser (17,893 in the validly described taxa listed in Table 20.1; see https://www.ncbi.nlm.nih.gov/genome/browse#!/prokaryotes/Actinobacteria—accessed February 2020). A majority of higher taxonomic levels are single species in a genus, which is the only member of a family and order (Figure 20.1). In Table 20.1, genera that constitute useful representatives of the major clades are highlighted. Genome sequencing is driven by research in the whole of biology but provides the data for comparing strains, organizing relationships and estimating phylogeny across diversity. There are about 4,479 actinobacterial species listed in validly described genera in the LPSN (Parte, 2018) (accessed February 2020), but the distribution of genomes across that reference set of type strains is not even (e.g., 6,710 genomes for *Mycobacterium tuberculosis*) and about 10% (1,860) are whole genomes (complete or single scaffold). The incentive for a whole genome phylogeny is the limited resolution of the 16S gene at the species level, as a single gene potentially influenced by lateral gene transfer, multiple copy number, and variable rates of evolution. Examples include strains with identical 16S sequences but significantly different genomic similarity (Stach et al., 2003); a study of 287 *Streptomyces* strains (Chevrette et al., 2019) with 100% 16S identity showed a genomic average nucleotide identity (ANI) as low as 84.4%. A limited number of examples are known in which multiple different 16S sequences occur in the same strain (Antony-Babu et al., 2017; Conville and Witebsky, 2007). Chevrette et al. (2019) show incongruence when 16S identity is plotted against genomic ANI, but 16S identity is not the optimum metric to determine phylogenetic relationships. Many studies show a good, if not exact, phylogenetic congruity between 16S phylogenetic trees and genome phylogenies (Hu et al., 2018; Jade et al., 2016; Ward and Allenby, 2018). Genomes are complex and determining metrics that best represent similarity between genomes is more of a challenge than for single-gene phylogenies. The first option is the ability to perform more single-gene phylogenies, for example, 23S rRNA. There are significant differences between multiple single-gene phylogenies so improvement on the single-gene 16S phylogeny depends upon generating a consensus from multiple single-gene phylogenies. However, being able to perform a multilocus sequence typing (MLST) analysis, but without the problems of finding conserved primer sites for polymerase chain reaction (PCR) amplification (Larsen et al., 2012; Miro et al., 2020), by alignment of concatenated gene sequences from whole genomes, is a better option. Classical MLST is linked to clinical identification and epidemiology of strains within a single pathogenic species, but has been extended to taxonomy (Rong and Huang, 2010; https://pubmlst.org/databases/). The equivalent phylogenomic procedure requires whole genome sequence data and has the aim of comparing organisms across the tree of life. It depends on the identification of single-copy number genes conserved across all the taxa to be analyzed, and the alignment, concatenation, and building of a tree, for example, with phylosift (Darling et al., 2014), though the 40 conserved genes for *Bacteria* are dominated by ribosomal proteins. These methods only use a fraction of the information encoded in the whole genome and exclude the pan-genome. Alignment of whole genomes for

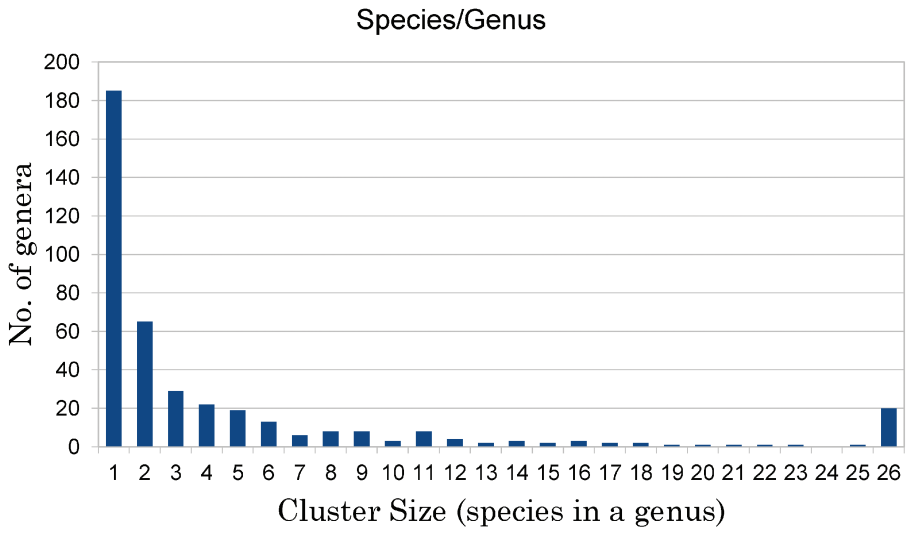

FIGURE 20.1 Numbers of species in genera.

comparative genomics is routine using software, including, for example, ProgessiveMauve (Darling et al., 2010), but multiple genome alignment at the scales needed for the current numbers of whole genomes is still challenging (Armstrong et al., 2019; Dewey, 2019) and an ongoing area of research, Dewey (2019) cites 40 whole genome alignment methods. New, large-scale phylogenomic trees use increasing numbers of marker genes—there are 381 marker genes in the phylogenomic tree of bacteria and archaea (Zhu et al., 2019)—requiring extensive analysis and massive computational resources. Alignment-free methods, such as CVTree3 (Zuo and Hao, 2015), use the whole genome and count K-peptides (peptide k-mers) in protein coding regions to measure genome similarity. Gene content phylogenies also use the whole genome, but need identification of homologous genes (Gupta and Sharma, 2015; Snel et al., 1999) as do gene order phylogenies (Zhou et al., 2017). DNA:DNA similarity was introduced in the 1970s and has been the fundamental basis for species identification in the era of 16S-based bacterial taxonomy (Wayne et al., 1987). The calculation of the ANI from genome sequences (Goris et al., 2007; Meier-Kolthoff et al., 2013) correlates well with DNA:DNA similarity. For large-scale phylogeny, the high-throughput version of the Genome BLAST Distance algorithm (Meier-Kolthoff et al., 2014) can be used to calculate genomic similarities.

Phylogenomic Studies in *Actinobacteria*

Studies of taxa in the *Actinobacteria* using phylogenomic methods provide models of the strategies and software to analyze genomic data, frequently illustrating the integration of both the phylogenomic analysis and addressing broader biological questions.

Acidimicrobiia

Phylogenomic studies have been done for *Acidimicrobiia* (Hu et al., 2018), a deep-rooted class with few cultivated members that are mostly isolated from extreme acidic environments, mine waste, and geothermal sites and able to oxidize ferrous ion (Jones and Johnson, 2015). However, they are abundant in marine and freshwater metagenomic studies and other uncultivatable members in the *Acidimicrobiia* are not acidophiles, for example *Candidatus Microthrix parvicella* from activated sludge and a related clade in the deep chlorophyll maximum (DCM) of the Sargasso Sea (Treusch et al., 2009). *Acidimicrobiia* were a major clade from the deep sea along the Southwest Indian Ridge (Chen et al., 2016), and four nearly complete genomes were assembled from samples from the Mediterranean DCM (Mizuno et al., 2015), including one encoding a novel actinorhodopsin (acidirhodopsin). The "acIV lineage" one of four major lineages detected in freshwater (Warnecke et al., 2004) is related to *Acidimicrobiales*.

Coriobacteriia

Coriobacterium glomerans was isolated from the gut of the red soldier bug (Haas and König, 1988) but is prevalent in the human distal gut. They metabolize drugs and bile acids, biotransform plant polyphenols to phytoestrogens, and have been associated with bacteremia, type 2 diabetes, cardiovascular disease, and rheumatoid arthritis. Bisanz et al. (2018) sequenced and annotated strains from 14 genera and performed genome-wide alignments with public sequences previously analyzed (Gupta et al., 2013).

Nitriliruptoria

The five members of the four genera in this class all have genomes, and although they are halophiles or halotolerant they have been isolated from other distinct ecological sites. Chen et al. (2020) have performed comparative genomics.

Thermoleophilia

Hu et al. (2019) performed a phylogenomic analysis of twelve genomes, six sequenced species, and six reconstructed genomes from metagenomic data. The genome from the one species in the order *Gaiellales, Gaiella occulta* F2-233, places it between *Thermoleophilia* and *Rubrobacteria* as indicated by 16S analysis. Members of the genus *Thermoleophilium*, the only genus in the order *Thermoleophilales*, are heat and oil loving, grow on n-alkanes, and are found largely in hot springs, while *Solirubrobacterales* contains species found in soil and grows on more diverse substrates, for example, part of the paddy soil microbiome (Li et al., 2018).

Bifidobacteriaceae

Members of the genus *Bifidobacterium* are facultatively anaerobic chemoorganotrophs found in the gut of humans, animals, and bees with diverse carbohydrate utilization abilities (Milani et al., 2016). They are linked to probiotics and development of the infant gut (Turroni et al., 2014. The other genera are more often present in the oral cavity and associated with organisms responsible for dental caries. Phylogenomic analysis was performed by Zhang et al. (2016) of the members of the genera *Bifidobacterium* and *Gardnerella*. Lugli et al. (2017) sequenced the members of the additional genera in *Bifidobacteriaceae* and identified acquisition of glycosyl hydrolase-encoding genes to enhance the utilization of carbohydrates, with the relative number of acquisitions linked to the diet of the host. *Gardnerella* was confirmed as more closely related to bifidobacteria rather than the other genera.

Corynebacteriales

Rhodococcus

The genus *Rhodococcus* contains *Rhodococcus equi*, an opportunistic pathogen for humans and animals, specifically foals; *R. fascians*, a pathogen forming leafy galls in dicotyledonous plants; and *R. erythropolis* used for industrial bioconversions. The genetic heterogeneity of the genus *Rhodococcus* is clear from 16S studies (Gürtler et al., 2004) and the analysis of some genomes (Creason et al., 2014). A more comprehensive phylogenomic study of more than 100 strains reveals the diverse groups, which they conclude are as similar to other *corynebacteria* as to one another (Sangal et al., 2016).

Rhodococcus equi

The phylogenomic analysis of 29 *R. equi* strains (Anastasi et al., 2016) confirmed that evolution of *R. equi* is by gene gain/loss in

a clonal clade, while the lack of a phosphoenolpyruvate:carbohydrate transport system is shared only with the closely related *Rhodococcus defluvii*. The genomic relationships indicated that *R. equi* occupies a position within the *Rhodococcus* clade.

Tsukamurella

In describing *Tsukamurella hongkongensis*, Teng et al. (2015) observed high similarity in 16S across all described *Tsukamurella* species and anomalous similarity between pairs of validly described species (*Tsukamurella pulmonis/Tsukamurella spongiae*, *Tsukamurella tyrosinosolvens/Tsukamurella carboxydivorans*, and *Tsukamurella pseudospumae/Tsukamurella sunchonensis*). Resequencing of 16S revealed that these pairs had identical 16S sequences. Teng et al. (2016) performed a full phylogenomic and phenotypic analysis to reclassify these pairs of strains as the same species.

Geodermatophilales

Geodermatophilaceae

The family *Geodermatophilaceae* is distant from other actinobacterial clades and found in metagenomic studies of arid and hyperarid habitats. Initially problematic to study because of how difficult they are to cultivate, there are now many more isolates. They are clustered together by 16S because they are so different from their nearest neighbors. The phylogenomic analysis by Montero-Calasanz et al. (2017) clarifies the taxonomy and proposes a new genus *Klenkia*.

Micromonosporales

Micromonospora

Micromonospora have been isolated from soil, freshwater, and marine habitats, but also from insects, sponges, and as endophytes from plants. They are prolific producers of bioactive secondary metabolites, including antibiotics, antitumor, and biocontrol agents. A genome-based classification has been performed (Carro et al., 2018).

Salinispora

The three species of *Salinispora* are a well-studied clade of marine producers of bioactive metabolites. The three species are not definable as separate species by 16S, but are well-established species. They provide one of the best models for the integration of ecology, speciation, and the ecological role and search and discovery of bioactive metabolites (Patin et al., 2016). Millán-Aguiñaga et al. (2017) analyzed the genomes of 119 *Salinispora* genomes from diverse marine sediments and identified three major clades corresponding to the three identified species. They identified the core/pan-genomes and detected genes with evidence of recombination. Phylogenetic analysis was performed based on all core genes, core genes without evidence of recombination, and core genes with evidence of recombination. Phylogenies based on concatenation and coalescence of these individual gene trees all gave congruent phylogenies. The threshold to define species is not inherent in these tree distances. An ANI analysis concluded that the data may encompass ten clusters that exhibit ANI similarity to less than the 95% species threshold. The paper provides a model for a wide-ranging theoretical and practical phylogenetic and systematic analysis of members of an actinobacterial clade.

Pseudonocardiales

Pseudonocardia

Pseudonocardia are famously associated with the leaf-cutter ant *Escovopsis-Pseudonocardia* assembly (Mueller et al., 2010). Caldera et al. (2019) analyzed the genomes of 29 ant-associated *Pseudonocardia* as well as their biosynthetic gene clusters (BGC) and identified significant variation of BGCs against a background of low diversity in the core genomes. They found elevated *Escovopsis* inhibition by *Pseudonocardia* from sites in the Panama Canal Zone compared to Costa Rica, That inhibition was locally adapted to the strains present at one site, but not the other two sites, in Panama. However, this pattern of inhibition was not correlated with the presence/absence of single BGCs. They assess these results against the geographic mosaic theory of coevolution.

Amycolatopsis

The genus *Amycolatopsis* is well-known for the prolific production of bioactive metabolites (Chen et al., 2016) including vancomycin and rifamycin. Adamek et al. (2018) sequenced two *Amycolatopsis* genomes and downloaded 41 others to analyze, generating a phylogenetic tree based upon an MLST analysis of gene sequences from the genomes, and mapped the BGCs identified by antiSMASH (Blin et al., 2019) onto the phylogenomic clades.

Streptomycetales

Streptomyces

The genus *Streptomyces* is the largest bacterial genus, the result of its predominance as a prolific producer of bioactive metabolites. The genus is extremely diverse and found across almost all ecological sites, the result perhaps of aerobic growth and profuse spore formation. *Streptomyces albidoflavus* is perhaps the most ubiquitous, with many independent genomes (30) defining a single species, and is found in diverse habitats (from air and soil to ants and marine cone snails) with a largely common set of BGCs (Ward and Allenby, 2018), though perhaps differentially expressed.

The phylogeny of the genus has been studied with 16S for all valid species (Labeda et al., 2012) and by MLST (Labeda et al., 2017). Whole genome phylogenies have been published (Alam et al., 2010; Chaves et al., 2018) but only including three and twenty-six genomes, respectively, at the time of writing there were 244 complete whole genomes and 1,891 genomes in total for the genus in Genbank.

Streptosporangiales

Nocardiopsis

Nocardiopsis has *N. dassonvillei* as the type strain of the genus. Both *N. dassonvillei* and *N. synnemataformans* are opportunistic

pathogens and may cause mycetoma and abscesses. Otherwise, members of the genus are common in soil, though also found in marine and hyper-saline environments associated with sponges, coral, sea anemone, mollusks, pufferfish, earthworms, and mosquitos, and produce diverse bioactive metabolites. Li et al. (2013) analyzed 17 genomes and defined the core and pan-genomes.

Actinobacteria

Several studies have used whole genomes to look at the whole phylum. The first application of the analysis of whole genomes to the whole phylum (Sen et al., 2014) used 100 completely sequenced genomes representing 35 families and 17 orders. They evaluated eight different hypotheses for their phylogeny, including one based on a concatenation of 54 conserved proteins. They made proposals regarding a number of taxa, but recognized that formal proposals required more whole genomes. *Frankiales* and *Micrococcales* were recognized as Orders needing revision.

Salam et al. (2019) created a full 16S phylogenetic tree and resolved inconsistencies using gene sequences from whole genome data. A full phylogenomic analysis (Nouioui et al., 2018) was based upon 1,142 downloaded genomes and analyzed with the high-throughput version of the Genome BLAST Distance Phylogeny (Meier-Kolthoff et al., 2014) and presented as a multipage phylogenetic tree and detailed taxonomic scrutiny, most of which is incorporated in the LPSN (Parte, 2018). Gupta (2019) provides a commentary on the analysis by Nouioui et al. (2018)..

Hands-on Whole Genome Sequencing and Analysis

The increasing number of publicly available actinobacterial whole genomes means that the sequencing of a lab strain under study is potentially leveraged by related strains already sequenced. If the project is based around a single strain, it probably makes sense to sequence with sequence providers for PacBio and Illumina MiSeq or HiSeq (Gomez-Escribano et al., 2015). Depending on the study objectives, the sequence data will still need extensive analysis and will involve significant bioinformatic analysis. Submitting the genome to the databases means that data can potentially be utilized to leverage other studies.

However, if the study objectives involve sequencing the genomes of multiple strains, the advances in sequencing make "in house" sequencing more accessible than ever. The portable nanopore sequencing device produced by Oxford Nanopore (https://nanoporetech.com/) is the most personal of personal sequencers producing significant data, perhaps 20 Gb sequenced bases per flow cell, as long reads (the record long read is about 2 Mb; hundreds of Kb are easily achieved and typically at least >7 Kb), though with relatively high error. Illumina has now produced the iSEQ (https://emea.illumina.com/systems/sequencing-platforms/iseq.html) as an inexpensive system with simple sample preparation producing 1.2 Gb or more of accurate short-read data. Alternatively, the error correcting short-read data can be provided by a low cost, relatively low coverage short read run from a service provider. Improved flow cells and base calling software continue to improve long read only assemblies.

The wet lab side is very accessible though DNA quality and preparation is much more important for long-read sequencing and beneficial for short-read sequencing too. The massive amounts of data generated are challenging. Barcoded samples can be run on both nanopore flow cells 12- and 24-barcode kits and the iSEQ 12-barcode kit, making sequencing costs per genome accessible, though not guaranteeing enough data for a complete genome for every sample in one run.

A $1,000 starter kit comes with the Oxford Nanopore MinION sequencer, two flow cells, and a library preparation kit. You will need a high-end computer with at least a core i7 processor, 16 Gb RAM, a 1 TB solid state drive, and USB 3.0 high-speed data connection to run the software to collect the data from a MinION run over 1 days.

DNA Preparation for Long-Read Sequencing

DNA preparation will depend on the organisms and sample, but long-read sequencing needs high molecular weight, high quality DNA that is completely free of contaminants, such as protein, polysaccharides, RNA, salt, phenol, chloroform, and SDS; it is essential to optimize this and minimize actions that shear the DNA. Growth of actinobacteria in an optimal medium supplemented with sucrose and glycine may aid lysis, though the concentrations may need to be optimized to prevent inhibition and premature lysis. Extraction of high-molecular-weight DNA using the salting out method (Hopwood et al., 2000) followed by a magnetic bead purification (Agencourt AMPure XP beads), or using the Qiagen Puregene Yeast/Bacteria kit or the MagAttract HMW DNA Kit has worked in our hands. Classic phenol:chloroform methods can work well, but it is essential that all traces of chloroform and phenol are removed. Size selection using magnetic beads can be used to deplete low-molecular-weight fragments, though short fragments can be utilized for error correction. Detailed protocols are on the Oxford Nanopore website (accessible after purchase of a starter kit). The same precautions apply for both nanopore sequencing and DNA preparation for PacBio sequencing—detailed guidelines are freely available online (https://www.pacb.com/wp-content/uploads/Technical-Note-Preparing-DNA-for-PacBio-HiFi-Sequencing-Extraction-and-Quality-Control.pdf—accessed September 2020). Although 260/280 nm and 260/230 nm values of 1.8–2.0 and 2.0–2.2 should be achieved, and can be determined by Nanodrop spectrophotometry, Nanodrop is not suitable for quantification (it typically overestimates DNA, perhaps twofold) and DNA quantification is essential and should be done fluorimetrically (Qubit or PicoGreen). Molecular weight should be checked by gel and TapeStation—running a gel is potentially diagnostic for other problems, such as the presence of RNA, phenol, or sheared DNA. Pipetting of high MW DNA needs wide-bore tips and avoidance of vortexing. More DNA is better, though low-input protocols are available (0.1–1 µg) HMW DNA is needed as input to the library preparation protocols.

Library Preparation

Single-molecule sequencing, PacBio (Wenger et al., 2019), and nanopore 2D sequencing revealed the extent of DNA damage, nicks, and abasic sites occurring in DNA preparations so that

end-repair before attaching sequencing adapters and barcodes, followed by FFPE repair (e.g., NEB FFPE Repair Kit #M6630) improve DNA quality for long reads. Adding these steps, followed by DNA cleanup by magnetic beads, loses DNA at each step. The transposasome rapid sequencing kit is a fast, one-step library preparation method in which a transposasome adds the barcode and sequencing adapter in a brief 1-minute reaction. The ligation adapter kit adds adapter and barcode by ligation and is a multistep protocol (nominally 2–3 hours, but we allow longer). However, the ligation protocol tends to generate more data and longer average read length. Flow cells, kits, protocols, and software are all subject to updating.

Sequencing Run

Connect the sequencer to a USB port, insert the flow cell, and start the software as directed in the protocols. Next, run the QC check for the flow cell. Make up the priming buffer and transfer the priming buffer into the flow cell, then add the library preparation. In the protocol cited later, the priming buffer and library were pipetted directly into the flow cell port but later, flow cells use spot-on loading in which samples are added by dropping the sample onto the port where it is drawn in by capillary action, preventing bubbles entering the sequencing chamber. The sequencing can be followed on the software as single molecules attach to pores, transport through driven by the motor protein, and change the ion current flowing through the pore as the DNA bases translocate. The ion current traces (squiggles) are written to HDF5 files (https://www.hdfgroup.org/solutions/hdf5/) in nanopore fast5 format. They can be visualized with BulkVis (https://github.com/LooseLab/bulkvis).

A good overview of the steps, now slightly out of date, can be found in the protocol for ultra-long reads (Gong et al., 2019).

Basecalling

The next step, converting the raw signal data into FastQ base sequences, is the most demanding single step. The latest generation of basecallers are installed locally and run artificial neural networks. The Oxford Nanopore-supplied program, Guppy, comes in two formats: GuppyCPU and GuppyGPU. The neural network basecalling is computationally intensive and the Nvidia GPU-enabled Guppy requires a high-end GPU with a compute value >6.1—as in a high-end gaming computer. Basecalling the output from a single run can take several days, basecalling with the CPU version of Guppy is significantly slower.

Debarcoding

The Guppy software can debarcode the FastQ data relatively quickly and save the reads for each barcoded dataset into separate folders. Each folder then contains the reads as FastQ files, corresponding to the genome for the sample with that barcode.

Assembly

Assembling long reads with high errors is a different computational problem from assembling accurate short reads—different assemblers and assembly pipelines are needed (Wick and Holt, 2019). It make sense to assemble error-prone long reads with more than one assembler, but an initial assembly with Unicycler (Wick et al., 2017) means the same assembler can be used to assemble long read only, short read only, and do a hybrid assembly with both long and short reads. Then, other assemblers like Canu (Koren et al., 2017) and Flye (Kolmogorov et al., 2019) can be used to identify potential assembly mismatches.

Annotation

The NCBI's Prokaryote Genome Annotation Pipeline (PGAP—Haft et al., 2018) has been released as a standalone version (https://github.com/ncbi/pgap/wiki) with an ignore-all-errors parameter that will annotate draft assemblies. In particular, it will identify, count, and mark frameshifts and unexpected stop codons, which are hallmarks of the indel errors present in long-read assemblies

Conclusion

Whole genome sequencing has revolutionized biology and will undoubtedly change our understanding of the taxonomy and phylogeny of major clades, such as the *Actinobacteria*. But more particularly, it will integrate with broader research objectives, such as understanding evolution and identifying how pathogens function and can be targeted. The application of phylogenomics to the systematics of the actinobacteria is still in its infancy, but the research cited here not only provides more information about the relationships within the *Actinobacteria* studied, but also provides models for data analysis of both the organisms and how they function. These examples are important because we are in an era of big data, and massive data analysis with a plethora of software solutions.

The hands-on approach to genome sequencing identifies some major hurdles to the democratization of genome sequencing. Addressing these hurdles in the age of big data is going to be key for more than just genome sequencing or phylogenomics.

Introduction

Just about half a century ago, all prokaryotes, i.e., cells without nucleus, were classified within one kingdom: *Monera*. However, in the late 1970s, scientists were starting to recognize that this classification system, based predominantly on morphological and metabolic traits, underestimated the vast diversity of prokaryotic life. Around the same time, the pioneering work of Carl Woese and George Fox led to the discovery that prokaryotes were, in fact, composed of two fundamentally different domains of life—the *Bacteria* and the *Archaea* (originally referred to as "Eubacteria" and "Archaebacteria," respectively) [1]. Woese and coworkers used the RNA components of the ribosome to reconstruct the first phylogenetic tree of life based on molecular data [2], which divided cellular organisms into three separate domains of life

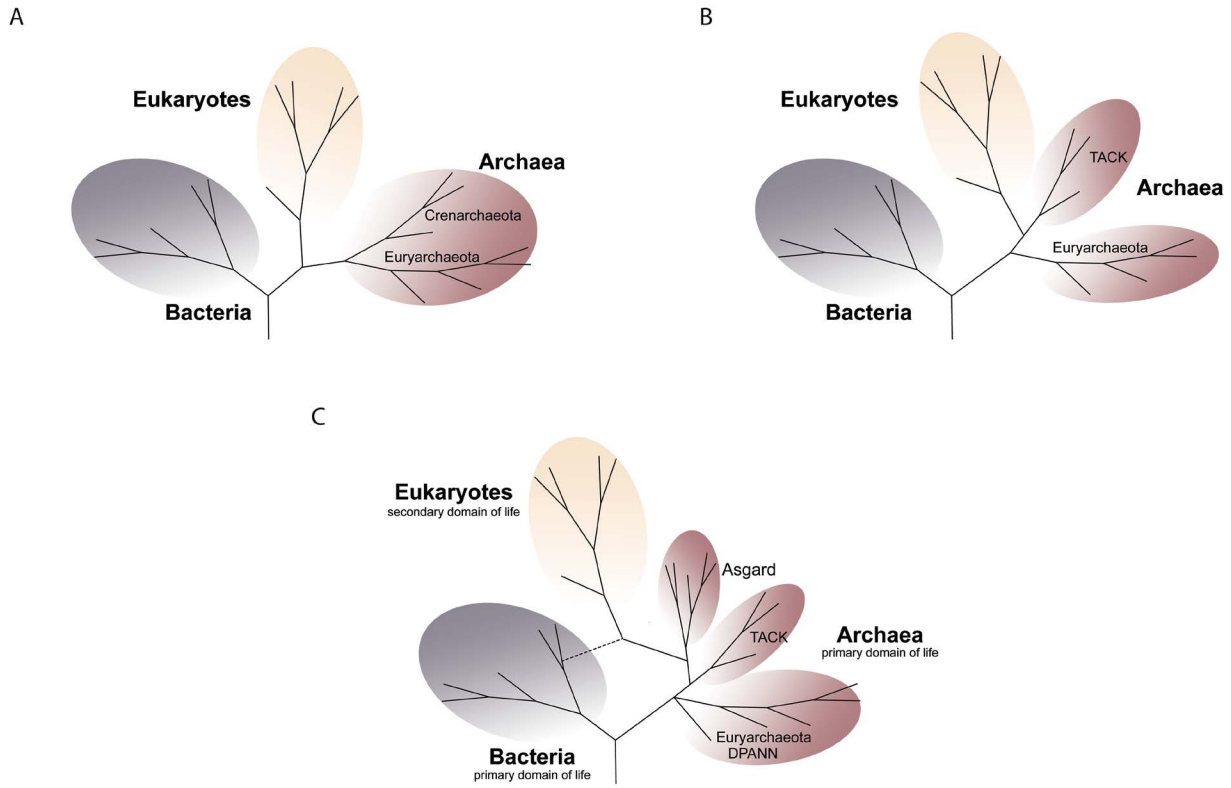

FIGURE 21.1 Schematic depictions of the relationship of *Archaea* with *Bacteria* and eukaryotes in the tree of life. A: Upon the discovery of *Archaea* as a separate domain, the tree of life was divided into three major domains. B: However, phylogenetic analyses of core informational proteins suggested later that eukaryotes may have evolved from within the *Archaea*, challenging the three-domain topology. C: Recent research, among others enabled by the discovery of the Asgard archaea, has shed further support on the branching of eukaryotes from within the *Archaea* (in terms of universal marker proteins). In turn, it has been suggested that the tree of life has two primary domains of life—the *Archaea* and *Bacteria*—and one secondary domain of life, which evolved from the former (see text for more details).

(Figure 21.1A)—the *Bacteria*, *Archaea*, and *Eukarya*, the latter of which comprised all organisms with a true nucleus [2]. At that time, it was suggested that *Archaea*, in spite of their superficial similarity to *Bacteria*, may be more closely related to eukaryotes than *Bacteria*. In fact, they seemed to harbor simplified versions of eukaryotic informational processing machineries (replication, transcription, translation, and cell division), in addition to unique characteristics such as ether-bound isoprenoids rather than ester-bound fatty acid-based lipids (Table 21.1). Subsequent research on *Archaea*, accompanied by extensive methodological developments in environmental microbiology, sequencing technologies, physiology, cell biology, and phylogenetics, has further changed our view on the diversity of life, the tree topology, as well as the ecological and evolutionary importance of *Archaea*. In particular, the use of cultivation-independent techniques, such as metagenomics and single-cell genomics, which allow us to obtain genomes of uncultivated organisms directly from environmental samples [3, 4], have been a key element leading to our changed perception of archaeal diversity and distribution. While *Archaea* have originally been viewed as comprising predominantly "extremophilic" organisms inhabiting environments with high temperature, salinity, and high or low pH, they are now known to be ubiquitous in all environments on Earth, including marine waters and freshwater lakes, sediments, soils (including plant roots), aquifers, and the human microbiome to name a few [5–7]. With their widespread ecological distribution and important metabolic capabilities, *Archaea* are recognized as key players in a wide variety of biogeochemical processes, including the sulfur, nitrogen, and carbon cycles [8]. For instance, *Archaea* include the only known organisms able to conserve energy through the anaerobic production or consumption of methane in processes referred to as methanogenesis and anaerobic methane oxidation, respectively. Since methane is an extremely potent greenhouse gas, with a global-warming potential about 25 times greater than carbon dioxide, these *Archaea* have an essential role in the global carbon budget and consequently climate change [9]. Finally, the study of archaeal phylogenetic diversity and evolution has fundamentally changed our understanding of the eukaryotic cell (see below) [10].

Archaea and the Tree of Life

Since the discovery of the *Archaea* as a separate domain of life (Figure 21.1A), their relationship to *Bacteria* and eukaryotes has been a matter of debate and is regarded to be of fundamental importance for our understanding of the origin of eukaryotes. Eukaryotic cells are highly compartmentalized and it has long been recognized that eukaryotic compartments, such as mitochondria (the site of ATP generation via oxidative phosphorylation) and chloroplasts (the organelles in which photosynthesis occurs in plants), evolved as a result of endosymbiosis, i.e., mitochondria and chloroplasts seem to be derived from Alphaproteobacteria

TABLE 21.1

Comparison of Selected Characteristics of the Major Domains of Life

Characteristic	Bacteria	Archaea	Eukarya
Membrane-enclosed nucleus	No	No	Yes
Chromosomal structure	Circular	Circular	Linear
Peptidoglycan in cell wall	Yes	No	No
Membrane lipids	Ester-linked	Ether-linked	Ester-linked
Glycerol	Glycerol-3-phosphate	Glycerol-1-phosphate	Glycerol-3-phosphate
Ribosomes (mass)	70S	70S	80S
Initiator tRNA	formylmethionine	methionine	methionine
Introns	No	No	Yes
Operons	Yes	Yes	No
RNA polymerase	One (4 subunits)	One (8–12 subunits)	Three (12–14 subunits)
Transcription factors required	No	Yes	Yes
TATA box in promoter	No	Yes	Yes

and Cyanobacteria, respectively (e.g., reviewed in [11]). In contrast, the nature of the host cell taking up the progenitors of these compartments was unknown until recently; while some hypotheses suggested that this cell was a proto-eukaryote that already resembled extant eukaryotic cells, others point out that the host was an archaeon or even bacterium [11–13]. For a long time, the prevailing view was that *Archaea* and eukaryotes represent two independent sister lineages in the tree of life [2, 14], and it was unclear how the shared ancestor of *Archaea* and eukaryotes looked like. However, while certain phylogenetic analyses have supported this model, others have suggested alternative scenarios, in which eukaryotes evolved from within the *Archaea* ([15] and reference therein).

The use of cultivation-independent genomic approaches combined with improved phylogenetic methods and more realistic evolutionary models have recently led new insights into the evolutionary history of the Archaea, their placement in the tree of life and eukaryogenesis. In particular, these analyses have provided increasing support for eukaryotes branching from within the *Archaea* [10, 15] instead of as a sister lineage as originally assumed (Figure 21.1 B–C). Though eukaryotes initially appeared to branch close to the TACK superphylum (discussed later in this chapter) [16] (Figure 21.1B), it was challenging to pinpoint a specific archaeal lineage as being more closely related to eukaryotes than the others. The position of eukaryotes among *Archaea* became clearer with the recent discovery the Asgard archaea—a novel archaeal superphylum [17, 18] (discussed later in this chapter). Phylogenomic analyses revealed that Asgard archaea form a sister group of eukaryotes (Figure 21.1C) and harbor an extended set of proteins that were previously assumed to be specific to eukaryotes [17, 18] (discussed later in this chapter). Together, these findings indicate that eukaryotes may have evolved from a symbiosis between an archaeal host cell and a bacterial endosymbiont, and also provide greater evidence in support of a two-domain tree of life [19–22], with *Archaea* and *Bacteria* representing two primary domains and eukaryotes being a secondary domain [15, 23]. Although the exact placement of eukaryotes with respect to the different members of the Asgard archaea remains to be elucidated, continued exploration of Asgard archaeal diversity will allow to further refine the position of Archaea and eukaryotes in the tree of life.

Archaeal Cell Biology and Eukaryotic Signature Proteins (ESPs)

In agreement with their close relationship to eukaryotes, *Archaea* encode informational processing machineries that closely resemble those of eukaryotic representatives. Although *Archaea* harbor a single circular chromosome like *Bacteria*, their replication machinery includes various components homologous (i.e., shared by common ancestry) to those of eukaryotes, while most functionally equivalent complexes in *Bacteria* are unrelated [24, 25]. For instance, *Archaea* and eukaryotes share homologous subunits comprising the origin of replication complex (ORC), a replicative helicase unit referred to as the CMG (Cdc45, MCM, GINS) complex, and the active replisome, which includes a two-subunit primase, a DNA polymerase sliding clamp and clamp loader, and DNA polymerases [24]. Yet, some *Archaea* also encode components that are absent from both eukaryotes and *Bacteria* and others that are shared with *Bacteria*. For example the two-subunit DNA polymerase D [24, 26] is unique to *Archaea* while the NAD+-dependent DNA ligase, the DNA gyrase, and the DNA primase DnaG are homologous to bacterial enzymes [25]. In many cases, archaeal complexes seem to represent a simplified version of their counterparts in eukaryotes [25], the latter of which often encode additional paralogous enzymes (i.e., those that evolved by gene duplication), whose evolution involved subfunctionalization [24]. For instance, while *Archaea* collectively encode three families of polymerase B, eukaryotes harbor the four polymerase B family enzymes referred to as Pol alpha, beta, gamma and delta [24, 26]. Notably, all of these eukaryotic enzymes seem to have evolved from two distinct archaeal polymerase B family homologs [18, 26]. Another interesting example represents the nucleosome: *Archaea* harbor histone-like proteins, which form a homodimeric histone complex in part homologous to the heterodimeric nucleosome of eukaryotes [27, 28].

Archaeal transcription also shares several features in common with eukaryotes. While many archaeal genomes encode gene clusters reminiscent of bacterial operons, the archaeal transcription machinery represents a simplified version of their eukaryotic counterparts [29]. For instance, the archaeal DNA-dependent RNA polymerase (RNAP) consists of 12-13 subunits, which are homologous to the subunits of the three eukaryotic RNA polymerases (RNAP I-III) [29]. In contrast, RNAP of Bacteria consists of only five subunits, two of which are distantly related to archaeal RNAP subunits 1 and 2 (i.e., RpoA and RpoB). Transcription initiation, which is based on the same molecular mechanisms across the domains, also involves homologous transcription factors in *Archaea* and eukaryotes [29].

Similarities in the translational machinery between *Archaea* and eukaryotes are also evident. Archaeal ribosomes are of

comparable size to bacterial ribosomes (70S), but share various ribosomal subunits uniquely with eukaryotes [30]. Additionally, translation in *Archaea* is initiated by an initiator tRNA carrying methionine and several translation initiation factors, as is seen in eukaryotic organisms but contrasts with the use of formylmethionine by bacteria. Further, a 22nd amino acid, pyrrolysine, has been identified uniquely in certain members of the *Archaea*, in particular methanogens [31].

Notably, *Archaea* not only share homologous replication, transcription, and translation machineries with eukaryotes, but have also been found to encode various so-called eukaryotic signature proteins (ESPs) [32], i.e., proteins that are generally absent from bacterial genomes while being central to the integrity and functioning of eukaryotic cells. These proteins include, for instance, components of the eukaryotic cytoskeleton (such as actin and tubulins), cell division and vesicle trafficking machineries, endosomal sorting complexes required for transport (ESCRT), as well as the proteasome and ubiquitin system [10].

In particular, members of the TACK archaea (discussed later in this chapter) including among others the *Cren-*, *Aig-* and *Thaumarchaeota* have early on been found to encode certain ESPs that were absent from *Euryarchaeota* [15, 16, 33–35]. For instance, while *Euryarchaeota* use FtsZ as major cell division protein, many *Cren-* and *Thaumarchaeota* harbor a cell division system (also referred to as cdvABC system) that includes homologs of eukaryotic ESCRT-III and an ATPase related to vacuolar protein sorting-associated protein 4 (Vps4) [36–39]. Furthermore, archaeal actin homologs referred to as crenactin, which are distantly related to eukaryotic actins, have been discovered in *Thermoproteales*, as well as in *Korarchaeota* [40]. Yutin and coworkers identified distant homologs of eukaryotic tubulins—the artubulins—in the genomes of two species of *Thaumarchaeota*, "*Candidatus Nitrosoarchaeum limnia*" and "*Candidatus Nitrosoarchaeum koreensis*" [41], and an analysis of the "*Candidatus Caldiarchaeaum subterraneum*" composite genome revealed the presence of a presumably fully functional ubiquitin-like protein modifier system [42].

The discovery of the Asgard archaea [17, 18], the currently most closely related archaeal sister lineage of eukaryotes, has recently revealed a variety of additional ESPs in *Archaea*. For instance, Asgard archaea not only encode additional homologs of eukaryotic informational processing machineries but also harbor simplified versions of the eukaryotic oligosaccharyl-transferase-complex and ubiquitin modifier system. Furthermore, they encode an extended set of small GTPases [17, 18], which are key regulators in eukaryotic cells with a central role in vesicle trafficking machineries [43]. Additional central components homologous to eukaryotic vesicle transport and tethering were identified in the genomes of the *Thorarchaeota* [18]. Further, Asgard archaea harbor protein domains homologous to the key domains of the three major eukaryotic ESCRT machinery complexes (ESCRT I-III) and a diversity of cytoskeleton-related proteins that are much more similar to their eukaryotic counterparts than those previously identified in *Archaea*. These include the lokiactins found across the Asgard representatives, as well as *bona fide* tubulins in *Odinarchaeota* [10, 17, 18]. Notably, Asgard archaea also encode actin-regulating proteins, such as the profilins [18], which were recently shown to be functionally equivalent to those of eukaryotes [44].

Altogether, archaeal information processing machineries as well as an extended set of ESPs in members of the TACK and in particular the Asgard archaea, further testify to the archaeal origin of the eukaryotic cell. Importantly, the study of these complexes in *Archaea* can help to provide a better understanding of eukaryotic cell biology and provide insight into the relative timing of the evolution of cellular complexity.

Archaeal Cell Membranes and Cells Walls

The composition of archaeal cell membranes differs fundamentally from those of *Bacteria* and eukaryotes [45]. For instance, the glycerol used to make archaeal phospholipids is a stereoisomer of the glycerol used to build bacterial and eukaryotic membranes, i.e., while *Archaea* use glycerol-1-phosphate, eukaryotes and bacteria have glycerol-3-phosphate. Furthermore, *Archaea* harbor isoprenoid side chains instead of the fatty acid side chains found in Bacteria and eukaryotes. These isoprenoids are bound to the glycerol backbone by ether linkages contrasting with the ester linkages formed between the bacterial and eukaryotic glycerol and fatty acid moieties. Archaeal isoprenoid side chains in the two monolayers of the lipid bilayer can be linked, thereby giving rise to transmembrane phospholipids. The isoprenes can also form five-carbon ring structures, which may function in the stabilization of the membranes of archaeal species that live in high temperature environments. More than 100 different ether-type polar lipids, such as phospholipids and glycolipids, have been identified in *Archaea* [46].

Different archaeal representatives differ with regard to their cell walls. In contrast to *Bacteria*, *Archaea* lack peptidoglycan and are thus naturally resistant to antibiotics that impair the synthesis of peptidoglycan, such as penicillins. Some species of methanogenic *Archaea* contain cell walls of pseudopeptidoglycan (pseudomurein) that superficially resemble bacterial peptidoglycan but contain different components (e.g., N-acetyltalosaminuronic acid instead of and N-acetylmuramic acid) and have β-1,3 instead of β-1,4-glycosidic bonds. Yet, most archaeal species lack pseudomurein and instead harbor cell walls made of proteins, glycoproteins, or polysaccharides [47]. For instance, a common cell wall structure found in *Archaea* is composed of a paracrystalline surface layer, termed S-layer, consisting of protein or glycoprotein moieties arranged in hexagonal patterns. Finally, some *Archaea*, such as certain members of the order *Thermoplasmatales*, lack cell walls altogether.

Taxonomic Diversity of *Archaea*

The *Archaea* were originally divided into two major phyla, termed *Crenarchaeota* and *Euryarchaeota* [2]. However, recent advances in culture-independent, high-throughput sequencing techniques have uncovered a large diversity of novel archaeal lineages, most of which remain uncultivated [5]. Many of these newly discovered archaeal lineages are only distantly related to established lineages within the *Cren-* and *Euryarchaeota*, which has led to the proposal of many additional archaeal phyla and superphyla during the past years [7]. Figure 21.2 summarizes the

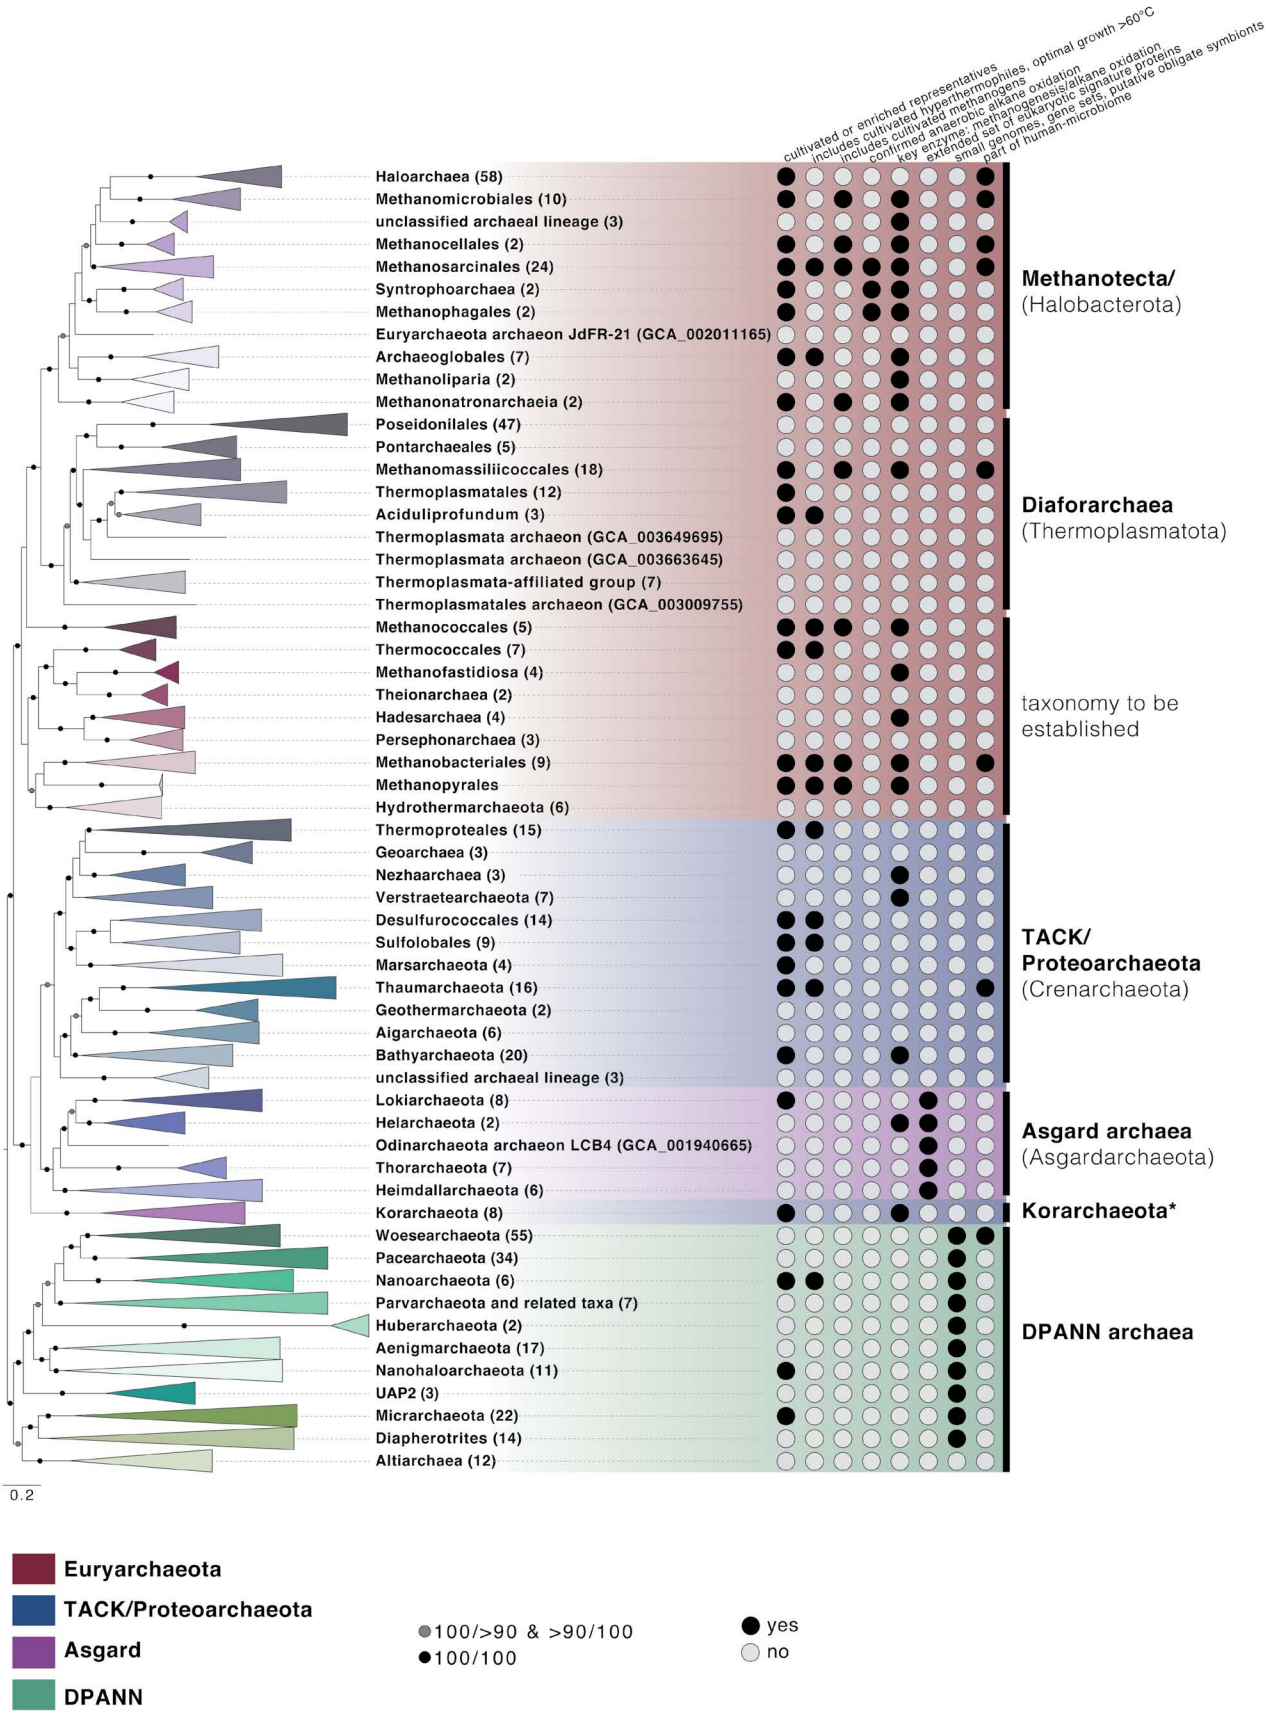

FIGURE 21.2 Depiction of the phylogenetic diversity of the *Archaea* and the presence/absence of key features. The unrooted phylogenetic tree was inferred with maximum likelihood using the IQ-tree software (with the C20+LG+F+R mixture model) and was based on an alignment of 11399 positions from a representative set of 569 archaeal taxa. Highly supported clusters (assessed by ultrafast bootstraps [220] and SH-like approximate-likelihood ratio test [221]) are indicated with gray or black dots based on their branch support values (see figure inlet). Taxa were predominantly named according to Adam et al. [7] (bold face), but alternative names suggested by GTDB (https://gtdb.ecogenomic.org/) are indicated in parenthesis when available. Numbers in brackets indicate the number of genomes/taxa per cluster. The presence and absence of certain features are shown with black and gray circles for each major taxonomic lineage (see figure inlet). Please note that the last column only reports those archaeal taxa that have been confirmed to be part of the human archaeome.

current understanding of the archaeal phylogeny, including established and proposed phyla, classes, and orders, as well as their general physiological grouping and certain features discussed below. However, please note that there is currently no consensus on how to best classify archaeal lineages. Therefore, a widely accepted taxonomy of the *Archaea* remains to be established [5]. In particular, there are currently two main classification schemes used: the classification suggested by Adam and coworkers that is implemented in NCBI [7] and the system introduced by the developers of the Genome Taxonomy Database (GTDB) (https://gtdb.ecogenomic.org/). The latter of these was suggested to provide a standardized and rank-normalized genome-based classification system, which was recently used to revise the bacterial taxonomy [48].

Euryarchaeota

The *Euryarchaeota* (Figure 21.2) comprise various cultivated and well-characterized archaeal species including the globally important methanogens (i.e., methane producers) as well as anaerobic methane-oxidizing Euryarchaeota (ANME) [49, 50]. Methanogens and ANME play a key role in the carbon cycle by anaerobically producing or consuming the potent climate gas, methane [8, 9, 50–52]. However, research during the past years has shown that the *Euryarchaeota* are a phylogenetically and physiologically much more diverse radiation than originally thought [5, 7]. Indeed, it remains to be elucidated whether *Euryarchaeota* comprise a monophyletic group or phylogenetically distinct divisions, some of which may be more closely related to the TACK and Asgard archaea [7, 53, 54]. In the following, we provide an overview of the major lineages comprising canonical and recently discovered lineages affiliating with the *Euryarchaeota*.

Methanotecta

The *Methanotecta* (Figure 21.2), a recently proposed superclass [7], comprise the so-called class II methanogens (*Methanosarcinales*, *Methanomicrobiales*, *Methanocellales*), several phylogenetically distinct ANME archaeal lineages, the *Haloarchaeota*, *Archaeoglobales*, as well as the more recently described archaeal orders referred to as *Methanonatronarchaeia*, *Syntrophoarchaeales*, *Methanoliparales*, and *Methanophagales*. We present major features of these different lineages below.

Methanomicrobiales

The order *Methanomicrobiales* comprises several families, such as the *Methanocalculaceae*, *Methanoregulaceae*, *Methanospirillaceae*, *Methanomicrobiaceae*, and *Methanocorpusculaceae* (e.g., reviewed in [55]), and can be found in a variety of anoxic habitats, including wetlands, soil, oceans and freshwater, landfills, rice paddies, as well as associated with animals [50]. Members of the *Methanomicrobiales* have diverse cell shapes, ranging from rods to cocci to plates, including motile and nonmotile species, and grow between 0°C and 60°C [55]. Cells are often surrounded by glycoprotein-containing S-layers. Many *Methanomicrobiales* use hydrogen and carbon dioxide to form methane and all species are obligate anaerobes. They can use formate and alcohol but not acetate and methylated C1-compounds as substrates for methanogenesis, distinguishing them from the *Methanosarcinales* [9, 55].

Methanosarcinales

The *Methanosarcinales* are closely related to the *Methanomicrobiales* and include families such as the *Methanosarcinaceae*, *Methanotrichaceae* (formerly *Methanosaetaceae*), and *Methermicoccaceae* (Table 21.1), as well as the *Methanoperedenaceae* (ANME-2d). While this order comprises diverse methanogenic organisms, it also includes representatives of the anaerobic methane-oxidizing *Euryarchaeota* ANME-2 and -3 lineages [50, 52, 56]. Similar to the *Methanomicrobiales*, representatives of the *Methanosarcinales* are found in a range of anoxic habitats [50]. Yet, in contrast to other methanogenic orders, the *Methanosarcinales* are known for their much wider substrate range for methanogenesis, i.e., members of this group not only use hydrogen and formate as substrates but also a variety of methylated compounds and acetate [8, 9]. Considering that methanogenesis based on acetate may contribute up to two-thirds of methane released to the atmosphere, members of this group have important roles in the global carbon cycle [8, 51]. Representatives of the ANME-2 and -3 lineages use the reverse methanogenesis pathway to anaerobically oxidize methane [52]. While some ANME-2 members can grow independently using nitrate, nitrite, or Fe(III) as electron acceptors [57–59], other ANME-2 grow in syntrophic consortia with bacterial partners (especially sulfate reducers) that serve as external electron sinks [52, 60]. Members of these groups are particularly abundant in the sulfate-methane transition zone in marine sediments and play an important role in the global carbon cycle by reoxidizing a large fraction of the methane produced in marine sediments before it can enter the atmosphere [52, 61].

Methanophagales (ANME-1)

The *Methanophagales* comprise another lineage of anaerobic methane-oxidizing archaea, also known as the ANME-1 lineage. While originally thought to affiliate with the *Methanosarcinales*, they were recently shown to represent a sister lineage of the *Syntrophoarchaeales* [7] (Figure 21.2 and later in this chapter). Similar to the ANME-2 and -3 lineages that belong to the *Methanosarcinales*, members of this group occur in diverse marine, terrestrial, and freshwater environments [62], are particularly abundant in the sulfur-methane transition zone [61], and use the reverse methanogenesis pathway for the anaerobic oxidation of methane (AOM) [63]. While ANME-1 has not been cultivated thus far, various lines of research have suggested that members are able to oxidize methane in syntrophy with sulfate-reducing bacteria (SRB) through direct electron transfer [52, 60, 64].

Methanocellales

Methanocellales represents a more recently described order of hydrogenotrophic methanogens that were originally referred to as Rice Cluster I (RC-I) [65] due to their initial discovery in rice paddy fields, where they are important producers of methane [66]. The first representative of this order, *Methanocella paludicola*, was isolated from an anaerobic,

propionate-containing enrichment culture [65] and represents a nonmotile anaerobe with rod-shaped cells thriving at temperatures between 25°C and 40°C [65]. While the isolate performs methanogenesis using hydrogen, carbon dioxide, and formate, it uses acetate as a carbon source. Hydrogen is provided by its syntrophic partner, the bacterium *Syntrophobacter fumaroxidans* [67]. Similar metabolic features were found in other representatives of this order, including *M. arvoryzae* [68] and *M. conradii* [69].

Syntrophoarchaeales

Syntrophoarchaeales (sometimes assigned to the *Methanosarcinales*; Table 21.1) represent a recently discovered group of anaerobic, alkane-oxidizing archaea usually found in hydrocarbon-rich sediments [70, 71]. For example, the first two representatives of this lineage, *Syntrophoarchaeum butanivorans* and *Syntrophoarchaeum caldarius*, were originally isolated from hydrothermal- and hydrocarbon-rich marine sediments of the Guaymas Basin [71, 72]. Notably, *Syntrophoarchaeales* grow by the anaerobic oxidation of butane as well as propane, which are thought to be metabolized using the reverse methanogenesis pathway also operating in ANME archaea [73]. In particular, they encode subunits homologous to the Methyl-Coenzyme M Reductase (MCR) complex, which represents the key enzyme of methanogens catalyzing the demethylation of CH_3-S-CoM to methane [51]. In *Syntrophoarchaeales*, MCR is thought to be used in reverse and to mediate the first step of the breakdown of short-chain alkanes eventually yielding carbon dioxide as an end product [71]. As indicated by the names of members of this group, studied representatives grow syntrophically with the sulfate-reducing bacterium *Candidatus* Desulfofervidus auxilii.

Archaeoglobales

The *Archaeaoglobales* comprises species belonging to the genera *Archaeoglobus*, *Ferroglobus*, and *Geoglobus* [74]. The *Archaeoglobus* sp. is believed to be predominantly composed of strictly anaerobic and hyperthermophilic members, growing optimally at 80°C and neutral pH. The best studied representatives are autotrophs and/or organotrophs and can reduce sulfate or sulfite during respiration [75]. Species of *Ferroglobus* grow by oxidation of $Fe(II)S^{2-}$ and H_2 [75], whereas *Geoglobus* grows anaerobically in the presence of acetate and ferric iron [74]. Recently, genomes of so far uncultivated members of the *Archaeoglobi* were reconstructed from environmental samples and shown to encode MCR-like protein complexes similar to those of methanogens and ANME archaea [76, 77]. Based on genomic inferences, it was suggested that the respective organisms may be able to grow by the oxidation of methane or alternative short-chain alkanes.

Methanoliparales

Methanoliparales is an uncultivated lineage within the *Methanotecta* that phylogenetically places between *Archaeoglobales* and a cluster comprising *Syntrophoarchaeales* and *Methanophagales*. *Methanoliparales* were first discovered in two metagenomes from a petroleum-enrichment culture and an oil seep and are represented by two metagenome-assembled genomes: *Candidatus Methanoliparum thermophilum* NM1a and *Candidatus Methanolliviera hydrocarbonicum* NM1b [78]. Genomic analyses suggest that *Methanolipirales* are methanogens that encode the Wood-Ljungdahl carbon fixation pathway and are capable of beta-oxidation. Interestingly, both genomes code for two distinct MCR complexes, which may be involved in methanogenesis and the oxidation of alkanes, respectively.

Haloarchaeota

Halobacteria, herein referred to as *Haloarchaea*, are a diverse group of *Archaea*, most of which are adapted to high salinity. Salt requirements of these species range from 1.5 to 5.2 M NaCl, although most strains grow best between 3.5 and 4.5 M NaCl, at or near the saturation point of salt (36% w/v salts). In order to maintain osmolarity of their cells in high-salt environments, haloarchaeal members accumulate up to 5 M intracellular levels of KCl to counterbalance high extracellular salt concentration. As a result, the entire intracellular machinery, including enzymes and structural proteins, must be adapted to high salt levels. The proteins of all haloarchaeal species have a very low isoelectric point and the genomes contain high GC contents that are well above 60% [79].

Some species of *Haloarchaea* are motile by means of tufts of flagella, although many species are nonmotile [75]. *Haloarchaea* comprise various aerobic or facultative anaerobes and show diverse morphologies and shapes, including rods, cocci, and a multitude of pleomorphic forms [75, 80]. The lack of turgor pressure within haloarchaeal cells enables the cells to tolerate the formation of corners, and as such, some species are even triangular or square-shaped [75, 80]. Cell envelopes of coccoid *Haloarchaea* are stable in the absence of salt, while, noncoccoid species maintain their integrity only in the presence of high concentrations of NaCl or KCl [75]. Non-coccoid species have a proteinaceous cell envelope with glycoprotein subunits forming a hexagonal pattern [75]. Species of *Haloarchaea* are abundant in salt lakes, inland seas, and evaporating ponds of seawater, such as the Dead Sea and solar salterns. *Haloarchaea* often tint the water column and sediments in bright colors due to the presence of retinal-based pigments. Some of these pigments are capable of the light-mediated translocation of ions across cell membranes. The best known halobacterial pigment is bacteriorhodopsin, which is an outwardly directed proton pump. Bacteriorhodopsin is involved in energy conservation and is the only nonchlorophyll-mediated light energy transducing system known to date [79]. Other retinal-based pigments found in *Haloarchaea* include halorhodopsin, which is an inward chloride pump involved in osmotic homeostasis, as well as sensory rhodopsin I and II (SRI and SRII, respectively). SRI and SRII can mediate positive and/or negative phototaxis [79].

Methanonatronarchaeota

Another lineage of halophilic archaea are the *Methanonatronarchaeota*, which were first recovered from hypersaline anoxic lake sediments [81] and are currently represented by isolates from two distinct subgroups: the soda lake isolate *Methanonatronarchaeum thermophilum* AMET and the salt lake isolate *Candidatus Methanohalarchaeum thermophilum*

HMET [82]. *Cand. M. thermophilum* has motile, coccoid cells that are around 0.4 µM in diameter and are surrounded by an S-layer. These anaerobic organisms tolerate a range of pH (between 6.5 and 8 [HMET] and 9.5 and 9.8 [AMET]) and grow optimally at a temperature of 50°C and salt concentrations of 4 M by accumulating high concentrations of potassium inside their cells for osmotic balance ("salt-in strategy") [81, 82]. *Cand. M. thermophilum* is a heterotrophic methanogen that grows with C1-methylated compounds as electron acceptors, such as methanol or trimethylamine, and formate or hydrogen as electron donors [81]. The 16S rRNA gene analyses indicate that *Methanonatronarchaeota* are the first cultured representatives of the SA1 group, which is commonly found in hypersaline environments [81, 83]. Yet, the exact placement of *Methanonatronarchaeota* in the archaeal tree of life is still debated. While initial phylogenetic analyses placed this lineage sister to *Haloarchaea* [81], recent analyses have suggested that the *Methanonatronarchaeota* form an early diverging lineage of the *Methanotecta* [84].

Diaforarchaea

The *Diaforarchaea* comprise a recently suggested superclass [7] that includes the *Thermoplasmata* and related lineages, such as the diverse and abundant Marine Group II and III archaea [85, 86], now also known as the *Poseidoniales* and *Pontarchaeales*, respectively, as well as a recently discovered new order of methanogens, the *Methanomassiliicoccales* [87].

Thermoplasmatales

The *Thermoplasmatales* comprise the genera *Acidiplasma, Thermoplasma, Picrophilus, Cuniculiplasma,* and *Ferroplasma*. *Cunicuplasma, Thermoplasma,* and *Ferroplasma* are the only cultivated archaeal representatives that lack cell walls [75, 88]. Species of *Thermoplasma* are facultative anaerobes and obligate heterotrophs, using elemental sulfur for respiration. Most members of this group are thermoacidophiles and grow optimally at 60°C and pH 2 [75]. For instance, representatives may be found in self-heating coal refuse piles and in acidic solfatara fields [75].

Members of the *Picrophilus* are the most acidophilic organisms known so far [89]. They form irregular cocci that are 1–1.5 µm in diameter and contain S-layer cell walls [75]. *Picrophilus* are thermophilic and hyperacidophilic and grow at temperatures between 47°C and 60°C and pH ranges of 0–3.5 [75]. Their ability to grow at pH values near 0 and at high temperatures has shifted the physicochemical boundaries at which life was considered to exist.

In contrast to other members of the *Thermoplasmatales*, *Ferroplasma* are not thermophilic and can grow autotrophically using ferrous iron as energy and inorganic carbon as a carbon source. Representatives can be found in a variety of acidic environments with stable chemical conditions, such as ore deposits, mines, and acid mine drainage systems (natural or man-made), as well as in areas with geothermal activity [90, 91]. Representatives of this family are cell wall-lacking extreme and obligate acidophiles that are able to grow at pH values around 0. Together with members of *Picrophilum*, they comprise a group of the most extreme acidophilic organisms known, members of which tolerate high concentrations of iron, copper, zinc, and other metals [91].

Aciduliprofundales

Aciduliprofundales, formerly named the "deep-sea hydrothermal vent euryarchaeota 2" (DHVE2) lineage, is currently represented by the cultivated *Aciduliprofundum boonei* [92, 93]. As the original name suggests, *Aciduliprofundales* are predominantly found across hydrothermal vents, where they can represent up to 15% of the archaeal community [92–94]. *A. boonei* is an anaerobic heterotroph that ferments peptides and is able to reduce elemental sulfur or ferric iron at a pH between 3.3 and 5.8 (optimum pH 4.6) and an optimal growth temperature of 70°C [92]. This organism is motile with a single flagellum and has pleomorphic cells of about 0.6–1 µM in diameter that are surrounded by a single S-layer.

Methanomassiliicoccales

The order *Methanomassiliicoccales* represents the first lineage of the *Thermoplasmata* known to comprise methanogenic members [87], several of which have been isolated, such as *Methanomassiliicoccus luminyensis* [95, 96], *Candidatus Methanomethylophilus alvus* [97], and *Candidatus Methanoplasma termitum* [98]. *Methanomassiliicoccales* are widely distributed in wetlands and sediments as well as the gastrointestinal tracts of animals including those of humans and cows [87, 99, 100]. Members of this group comprise H_2-dependent methylotrophic methanogens, which are able to use methylated amines [100] including mono-, di-, and trimethylamines for methanogenesis. Considering that the latter compounds have been implicated in human disease, gut-associated members of the *Methanomassiliicoccales* may play an important role in human health [100].

Poseidoniales

The *Poseidoniales* [101], formerly Marine Group II (MG II), lack any cultured representatives and are mainly known from 16S rRNA gene diversity assays and genomic analyses. *Poseidoniales* are often found in the photic zone of marine waters and can present up to 15% of archaeal cells in the Atlantic ocean [102–104]. They are further divided into *Candidatus Poseidonaceae* (MGIIa) and *Candidatus Thalassarchaeacea* (MGIIb), whose abundances seasonally fluctuate, i.e., members of MGIIa and MGIIb are more abundant in the summer and winter, respectively [105]. Members of this group comprise aerobic heterotrophs with the potential to utilize a range of substrates such as proteins, peptides, amino acids, fatty acids, carbohydrates, xenobiotics, and agar [101, 106–110]. In addition, some representatives of the class *Ca. Poseidoniia*, found in the photic zone, encode proteorhodopsin indicative of a photoheterotrophic lifestyle [101, 107, 110].

Pontarchaeales

The order *Pontarchaeales*, or Marine Group III, are often found in the deep ocean, while being less abundant in the photic zone [102, 111]. Based on genomic data, it was inferred that deep-sea *Pontarchaeales* likely represent motile heterotrophs that might degrade proteins, carbohydrates, and lipids [112]. In contrast, surface dwelling members of the *Pontarchaeales* seem to encode photolyase and rhodopsin genes and in turn may be photoheterotrophs [111]. Notably, both the *Pontarchaeales* and the *Poseidoniales* lack the key archaeal lipid biosynthesis gene encoding glycerol-1 phosphate dehydrogenase, such that it is currently unclear whether members of these orders encode

canonical archaeal lipids [45]. In particular, the presence of genes for glycerol-3 phosphate dehydrogenase, which is essential in the synthesis of bacterial lipids, has led to the suggestion that these *Archaea* may have mixed membranes [45, 101].

Other Euryarchaeota

The following section provides an overview of additional lineages affiliating with the *Euryarchaeota*, including methanogenic lineages that have been extensively studied in the past. However, some analyses indicate that at least some of these orders may be more closely related to the TACK and Asgard archaea [7, 53, 54].

Methanococcales

As the name implies, the *Methanococcales* include representatives with coccoid shapes and proteinous cell walls [75]. All members of this lineage are thought to be strict anaerobes that obtain energy by the reduction of CO_2 to methane [9] and comprise mesophilic (e.g., *Methanococcus*) to thermophilic (e.g., *Methanothermococcus*) to hyperthermophilic (e.g., *Methanocaldococcus*) taxa [75].

Thermococcales

Members of the *Thermococcales* represent anaerobic heterotrophs that utilize a wide range of organic compounds, including amino acids, a variety of sugars, and organic acids such as pyruvate. When available, they can use elemental sulfur as the terminal electron acceptor. Extensive research has been carried out on the metabolism of cultivated representatives and led to the discovery of unique enzymes and pathways [113]. Certain members of the *Thermococcales* represent important model organisms. For example, the hyperthermophilic *Pyrococcus furiosus*, which grows anaerobically at temperatures near 100°C using carbohydrates and peptides as carbon and energy sources [75], has been extensively used to study thermostable enzymes and adaptations to high-temperature environments [114].

Methanobacteriales

The *Methanobacteriales* comprise another lineage of methanogenic archaea that reduce CO_2 or methyl compounds with H_2, formate, or secondary alcohols as electron donors. They include rod-shaped, lancet-shaped, or coccoid members, which contain cell walls made of pseudopeptidoglycan. *Methanobacteriales* are widely distributed in nature and are found in anaerobic habitats such as aquatic sediments, soil, anaerobic sewage digesters, and the gastrointestinal tracts of animals to name a few [50, 75].

Methanopyrales

The *Methanopyrales* consists of a single genus, *Methanopyrus*, comprising rod-shaped members with cell walls made of pseudopeptidoglycan [75]. Known *Methanopyrus* are hyperthermophilic, and grow between 84°C and 110°C, with optimal growth at 98°C. Similar to other methanogenic lineages, members of this group have a chemolitoautotrophic lifestyle converting CO_2 and H_2 to methane [9, 75]. While it has proven difficult to resolve the exact phylogenetic placement of the *Methanopyrales* relative to other archaea, it has recently been suggested that this lineage forms a monophyletic clade together with the *Methanobacteriales* and the *Methanococcales* referred to as *Methanomada* [7]. However, it remains to be determined whether these so-called group 1 methanogens [9] are indeed closely related phylogenetically (Figure 21.2).

Methanofastidiosales

Methanofastidiosales represent a recently discovered and thus far uncultivated archaeal lineage (also known as WSA2 or Arc I), whose members are present in diverse environments including sediments, groundwater, and bioreactors [115–117]. Metagenomic approaches have enabled the reconstruction of genomes of representatives of the *Methanofastidiosales* from wastewater-treatment bioreactors [117]. While members of this group encode key genes for methanogenesis, they lack genes related to carbon-fixation pathways and were suggested to solely use methylated thiols as substrates for methanogenesis [117].

Theionarchaeota

Theionarchaea (formerly Z7ME43) represents another clade of uncultivated archaea, which forms a sister lineage of the *Hadesarchaea* (see next) and was originally discovered in water-filled limestone sinkholes in northeastern Mexico [118]. This clade is currently represented by two genomes that were recovered from the White Oak River Estuary in North Carolina [119]. Genomic analyses indicated that *Theionarchaea* might conserve energy by peptide fermentation.

Hadesarchaea

The *Hadesarchaea*, which were originally referred to as the South-African Gold Mine Miscellaneous Euryarchaeal Group (SAGMEG), are distributed in a variety of anoxic environments, including the terrestrial subsurface as well as marine sediments, which cover a wide span of temperatures [120–123]. The first genomes of members of this clade were reconstructed from the water column of the White Oak River estuary [123] as well as Yellowstone National Park (YNP) hot spring sediments and indicated the capability of anaerobic CO oxidation potentially coupled to nitrite or H_2O reduction [123]. Notably, another genome of a member of the *Hadesarchaea* was recently obtained from a hot spring metagenome and shown to encode a *mcr*-like operon. Based on phylogenetic analyses of MCR subunits as well as genomic analyses, it was suggested that these *Hadesarchaea* may represent alkane-oxidizing archaea similar to members of the *Syntrophoarchaeales* [124] and perhaps some representatives of the *Bathyarchaeota* [50].

Persephonarchaea

The Mediterranean Sea Brine Lakes 1 (MSBL1) clade, now referred to as the *Persephonarchaea* [7], is another lineage of uncultivated archaea that is closely related to the *Hadesarchaea*. The *Persephonarchaea* are commonly found in marine hypersaline environments [125, 126] and comprise potential anaerobic mixotrophs that may conserve energy through sugar fermentation but may also be able to fix inorganic carbon [127]. Genomic inferences suggest that MSBL1 archaea synthesize trehalose as putative osmolyte to encounter the high salt conditions in their environment [127].

Hydrothermarchaeota

The *Hydrothermarchaeota* [7], also known as the Marine Benthic Group-E (MBG-E), were originally discovered in marine deep-sea

sediments [128] and represent an uncultivated archaeal lineage widely distributed in deep subseafloor environments. Genomes from members of this group have been reconstructed from metagenomes of the Juan de Fuca Ridge flank, Guaymas Basin hydrothermal sediments, and the Mid-Atlantic Ridge of the South Atlantic Ocean [129–131]. Genomic analyses have indicated that *Hydrothermarchaea* are metabolically versatile [131] and include putative anaerobic chemolithoautotrophs that use carbon monoxide and/or hydrogen as electron donors as well as a variety of electron acceptors including nitrate and sulfate [132, 133].

The TACK Superphylum

The TACK superphylum was originally introduced to describe the *Crenarchaeota* and the related phyla referred to as the *Thaumarchaeota, Aigarchaeota*, and *Korarchaeota* [16]. During the past years, many additional lineages affiliating with the TACK archaea have been discovered through metagenomics and single cell genomics approaches and the TACK lineage has therefore been suggested to be referred to as the *Proteoarchaeota* [134]. However, a consensus has yet to be reached regarding both the naming as well as the validity of using a superphylum as a taxonomic level. In the following sections, we introduce canonical and recently discovered clades belonging to the TACK archaea.

Crenarchaeota

The *Crenarchaeota* includes a diversity of (hyper-) thermophilic archaeal species, many of which have been discovered through cultivation-based approaches before the onset of the genomics era in microbiology and now represent important model organisms. This taxon is composed of a single class, the *Thermoprotei*, which is subdivided into three to five subclades, the *Thermoproteales, Sulfolobales, Desulfurcoccales* as well as the *Fervidicoccales* and *Acidilobales*. However, the latter two may in fact belong to the *Desulfurococcales* (Figure 21.2). Cultured crenarchaeal species are morphologically diverse, and include rods, cocci, filamentous, and disk-shaped cells. Almost all cultured species are obligate (hyper-) thermophiles, with optimal growth temperatures ranging from 70°C to 113°C and many members are also acidophiles and capable of metabolizing sulfur. Representatives of the *Crenarchaeota* thrive in environments such as hot solfataras, volcanic areas, as well as hydrothermal vents at the bottom of the ocean. A variety of metabolic capabilities have been described in the different members of the *Crenarchaeota*. For instance, some *Thermoproteales* are chemolithoautotrophs, using carbon dioxide as a carbon source and conserving energy by the conversion of hydrogen and elemental sulfur to hydrogen sulfide. Others respire various organic substrates using oxygen, sulfur, nitrate, or nitrite as electron acceptors [75]. Many members of the *Desulfurococcales* are strict anaerobes and neutrophiles to weak acidophiles, growing optimally at pH 5.5–7.5 [135]. Representatives of the *Sulfolobales* are acidophilic hyperthermophiles, which can grow lithoautotrophically by oxidizing sulfur or chemoheterotrophically on simple reduced carbon compounds using sulfur derivatives as electron acceptors. Notably, the *Crenarchaeota* include several members that have been shown to be hosts of the small-celled *Nanoarchaeota* [136–140] (see later in this chapter). In particular, the biocoenosis between *Ignicoccus hospitalis*, a member of the *Desulfurococcales*, and its nanoarchaeal ectosymbiont, *Nanoarchaeum equitans*, has been extensively studied and provides important insights into archaeal cell biology and cell-cell communication [141]. For instance, investigation of *I. hospitalis* has revealed remarkable cellular features including the presence of two outer membranes surrounding a large periplasmic space as well as an endomembrane system reminiscent of eukaryotic cells [142].

Thaumarchaeota

Environmental 16S rRNA-based surveys in the early 1990s have led to the discovery of uncultivated archaeal lineages distantly related to the *Crenarchaeota* in moderate marine and terrestrial ecosystems. The subsequent cultivation of the first representatives of these so-called mesophilic *Crenarchaeota* (also MG1) from marine and terrestrial environments [143] and the study of the first genomes of members of this group [144, 145], revealed that they form a separate phylum within the *Archaea* referred to as the *Thaumarchaeota* that distantly affiliates with the *Crenarchaeota*. Most cultivated *Thaumarchaeota* are chemolithoautotrophic ammonia-oxidizing archaea (AOA), which play an important role in the nitrogen and carbon cycles in both aquatic and terrestrial environments [146]. However, the reconstruction of genomes of deep-branching *Thaumarchaeota* has recently led to the suggestion that not all members of this group are AOA but instead represent chemoorganotrophs that may reduce oxygen, nitrate, or sulfur [147]. This notion was recently confirmed with the isolation of the thermoacidophilic, sulfur- and iron-reducing organoheterotrophic *Conexivisphaera calidus*, a potentially early diverging member of the *Thaumarchaeota* [148].

Aigarchaeota

The *Aigarchaeota* represent another proposed candidate phylum that comprises species of the Hot Water Crenarchaeotic Group I (HWCGI), members of which have not been cultivated so far. Genomic analyses of the first representatives of this group have suggested that the *Aigarchaeota* comprise both facultative and obligate anaerobes, which may respire a variety of organic substrates and perhaps also hydrogen and carbon monoxide using oxygen or oxidized sulfur or nitrogen compounds as electron acceptors [42, 149–152]. Furthermore, several representatives seem to have the ability to fix inorganic carbon. *Aigarchaeota* seem to predominantly inhabit thermally heated terrestrial and marine ecosystems, including hot springs, subsurface aquifers, and mine fracture waters [150, 152].

Korarchaeota

The *Korarchaeota* comprises a group of uncultivated *Archaea* that had already been discovered in the late 1990s in terrestrial and marine thermal environments [153]. The first member of this clade, referred to as "*Ca. Korarchaeum cryptofilum*," was shown to comprise ultra-thin, needle-shaped cells measuring up to 100 µm in length. Genomic analyses indicated that this organism represents a peptide fermenter with a unique set of informational processing genes, which early on indicated that it comprises the first member of a distinct archaeal phylum [154]. Recently, genomes of additional members of the *Korarchaeota* have been recovered from

deep-sea hydrothermal vent sediments [130] and hot spring environments [18, 124, 155] providing novel insights into the metabolic features of this clade. Notably, genomic analyses revealed that certain members of the *Korarchaeota* harbor the key genes for methanogenesis, [155] which may for instance enable methanogenesis from methanol and hydrogen or the coupling of the anaerobic oxidation of methane with sulfite reduction [155].

Bathyarchaeota

Bathyarchaeota were originally discovered through 16S rRNA gene surveys in hot springs [153] and were referred to as Miscellaneous Crenarchaeota Group (MCG) [156] due to their distant affiliation with cultivated *Crenarchaeota*. This extremely diverse phylum is now subdivided into at least 25 subgroups, which are defined at family and order level [157]. Notably, members of this putative phylum-level lineage can be found in a diversity of anoxic marine, terrestrial, and hydrothermal environments including marine sediments and often represent the most abundant archaeal community members [157–159]. Based on genomic analyses, it is inferred that many *Bathyarchaeota* are heterotrophs with a wide substrate range including acetate, proteins, and aromatic compounds such as lignin [157, 160]. However, the *Bathyarchaeota* also includes putative acetogenic species [161] as well as organisms with *mcr* genes [162], which are closely related to those of *Syntrophoarchaea* [71]. In turn, it has been suggested that some members of the *Bathyarchaeota* may be able to mediate the anaerobic oxidation of short-chain alkanes [50].

Geoarchaeota

Geoarchaeota, also Novel Archaeal Group 1 (NAG1), are often found in hypoxic to oxic, hot, acidic, iron-rich springs [163–165] and represent a lineage of thus far uncultivated archaea which seem to be closely related to or part of the Crenarchaeota [164, 166]. Based on genomic inferences, it has been suggested that the *Geoarchaeota* are likely motile and might conserve energy through the oxidation of carbon monoxide, peptides, and/or carbohydrates using oxygen as a terminal electron acceptor [149, 164].

Verstraetearchaeota

Verstraetearchaeota were originally discovered in deep South-African Gold mine microbial communities through 16S rRNA gene surveys and were referred to as Terrestrial Miscellaneous Crenarchaeota Group (TMCG) [120]. Members of this group seem to be widely distributed and are also found in hydrocarbon-rich environments, sediments, soil, and wetlands [167]. First insights into the metabolic features of members of this group were derived from genomes assembled from anoxic digesters, named *Methanomethylicus sp.* and *Methanosuratus sp.* [167]. Subsequently, additional representatives were discovered and referred to as *Methanohydrogenales* and *Methanomediales* [168]. Notably, the *Verstraetearchaeota* comprise members with *mcr*-gene operons most similar to those found in methanogenic *Euryarchaeota*. In turn, based on genomic inferences, it was suggested that the *Verstraetearchaeota* likely include anaerobic methylotrophic as well as hydrogenotrophic methanogens [167–169].

Nezhaarchaeota

Nezhaarchaeota are a recent addition to the TACK superphylum represented solely by uncultivated members, whose genomes were assembled from hot spring metagenomes and hydrothermal sediments [77]. Notably, the *Nezhaarchaeota* encode a MCR protein cluster and are potential hydrogenotrophic methanogens [77].

Marsarchaeota

The *Marsarchaeota*, or "Novel Archaeal Group 2" (NAG2), are typically found in geothermal, iron oxide-rich mats [163]. The first genomes of members of this lineage were recently recovered from thermal (50–80°C) and acidic (pH 2.5–2.5) microbial mats from Yellowstone National Park [170] and led to the suggestions that the *Marsarchaeota* are aerobic chemoorganotrophs that degrade lipids, peptides, and carbohydrates and may be able to reduce ferric oxide.

Geothermarchaeota

The *Geothermarchaeota* represents one of the most recent additions to the *Archaea* and is thus far only represented by uncultivated members, whose genomes have been reconstructed from metagenomes from the Juan de Fuca Ridge subseafloor [129] and hydrothermal vent sediments in the Guaymas Basin [130]. Little is yet known about the lifestyle and ecological roles of *Geothermarchaeota*, and in-depth genomic analyses will be necessary to infer their metabolic potential.

The Asgard Superphylum

The Asgard superphylum is a recently described archaeal radiation, which comprises several different archaeal clades of high taxonomic rank (likely phylum-level) [17, 18]. Notably, phylogenetic and comparative genomic analyses have indicated that this archaeal clade includes the closest archaeal sister lineage of eukaryotes (discussed previously in this chapter). Members of this superphylum have originally been discovered in sediments all around the world, in which they can comprise a significant fraction of the microbial diversity. In the following, we briefly introduce the major metabolic features of the currently known members of the Asgard archaea, i.e., the *Loki-*, *Thor-*, *Odin-*, *Hel-*, and *Heimdallarchaeota*.

Lokiarchaeota

The *Lokiarchaeota* represents an archaeal lineage originally referred to as the Deep Sea Archaeal Group (DSAG) or Marine Benthic Group B (MBGB) archaea, which are abundant in diverse marine sediments [94, 171]. For example, the *Lokiarchaeota* comprise up to 10% of the microbial community in cold sediments near Loki's Castle hydrothermal vent field from which the first metagenomes were obtained [17, 18]. Members of the *Lokiarchaeota* might be autotrophs using the Wood-Ljungdahl pathway for carbon fixation [172]. However, genomic analyses also revealed the potential for the use of a variety of organic carbon substrates, suggesting that representatives of the *Lokiarchaeota* may predominantly rely on fermentative growth [20]. In fact, the successful cultivation of the first *Lokiarchaeote*, *Candidatus*

Prometheoarchaeum syntrophicum, revealed that this organism ferments amino acids enabled through a syntrophic interaction with hydrogen- or formate-consuming partner organisms [22].

Thorarchaeota

The *Thorarchaeota* share many metabolic features with the *Lokiarchaeota* [20, 173, 174]. Currently known representatives harbor a variety of genes likely encoding proteins involved in the usage of organic substrates. Furthermore, they encode the Wood-Ljungdahl pathway, which could be used for carbon fixation or serve as an electron sink during growth on organics. In contrast to currently known *Lokiarchaeota*, members of this group also harbor a putative NADH dehydrogenase that may enable respiratory growth in addition to fermentation [20]. Based on current environmental survey data, the *Thorarchaeota* seem less abundant than the *Lokiarchaeota* but occur in a wide variety of anoxic environments [18].

Heimdallarchaeota

Thus far known representatives of the *Heimdallarchaeota* are metabolically diverse and differ from other Asgard lineages [20]. While genomic analyses indicate that they are able to utilize a large variety of organic substrates similar to other members of the Asgards, they do not seem to be fermentative organisms and current members lack the Wood-Ljungdahl pathway. Instead, they encode a membrane-bound electron chain, which allows growth using oxygen and nitrite as electron acceptors [20, 21]. *Heimdallarchaeota* are currently thought to comprise the archaeal lineage most closely related to the archaeal ancestor of eukaryotes. However, though found in a variety of environmental samples including anoxic sediments and oxygenated waters, they are generally less abundant than the *Loki-* and *Thorarchaeota*.

Odinarchaeota

Odinarchaeota are currently represented by a single genome, which was obtained from a hot spring metagenome [18]. Similar to other members of the Asgard superphylum, *Odinarchaeum* encodes the ability to use organic compounds as growth substrates [20]. Yet, it lacks the key enzyme of the Wood-Ljungdahl pathway and instead encodes membrane-bound hydrogenases, which suggests that the thermophilic *Odinarchaeum* may conserve energy through fermentation of organic substrates to hydrogen, acetate, and carbon dioxide. Members of the *Odinarchaeota* are thought to predominantly inhabit thermal environments such as hot spring sediments and hydrothermal vents [18].

Helarchaeota

The *Helarchaeota* represent the most recently discovered clade within the Asgard archaea [175]. While they harbor similar gene sets as the *Loki-* and *Thorarchaeota*, currently known representatives of this lineage also contain *mcr*-gene clusters. Phylogenetic analyses of the encoded proteins revealed their close relationship with proteins of *Syntrophoarchaea* opening the possibility that certain members of the Asgard archaea have the potential to anaerobically oxidize short-chain alkanes, perhaps in syntrophy with microbial partners [175]. However, the environmental distribution of the *Helarchaeota* and the functional importance of this potential alkane metabolism in Asgard archaea remain to be determined.

The DPANN Superphylum

The DPANN superphylum is the fourth major radiation in the *Archaea*, besides the *Euryarchaeota*, TACK, and Asgard archaea [149, 176, 177]. Currently, this radiation is assumed to comprise a large diversity of distinct archaeal clades most of which seem to predominantly include members with extremely small genomes and cell sizes that are thought to depend on partner organisms for growth and survival [177]. While first defined in reference to the *Diapherotrites, Parvarchaeota, Aenigmarchaeota, Nanoarchaeota,* and *Nanohaloarchaeota* (DPANN) [149], additional lineages such as the *Micrarchaeota, Pacearchaeota, Woesearchaeota*, and *Huberarchaeota* are now also considered members of this group [177, 178]. Furthermore, the *Altiarchaeota* [179], representatives of which do not have reduced genomes, are sometimes considered to belong to the DPANN [177, 180]. However, the boundaries between certain clades of DPANN and other archaea (in particular the *Euryarchaeota*) are not well defined and it remains to be established which lineages indeed belong to a monophyletic (i.e., sharing a common ancestor) DPANN clade [180].

Nanoarchaeota

The first representative lineage of the DPANN archaea was already discovered in 2002, i.e., long before the DPANN radiation was known. In particular, Huber and coworkers discovered a small-celled organism in cultures of the crenarchaeaum, *I. hospitalis,* which they referred to as *N. equitans* [136]. Initially, it was suggested that this organism is the first representative of a novel phylum called *Nanoarchaeota* or may represent a highly derived member of the *Euryarchaeota* [136, 181]. However, upon the genomics-based discovery of additional archaeal lineages represented by organisms with small genomes, which affiliated with *Nanoarchaeota*, it was proposed that the *Nanoarchaeota* belong to the DPANN radiation [149].

Notably, the nanosized hyperthermophilic *N. equitans* is obligately host-dependent and grows as an ectoparasite on the surface of *I. hospitalis* [182, 183]. It lacks genes for many major metabolic pathways and in turn depends on its host for the acquisition of diverse metabolites likely including lipids, amino acids, and ATP. In line with this, the genome of *N. equitans* represents one of the smallest known genomes of any extracellular organism (480 kb) [184]. However, compared to the genomes of many bacterial endosymbionts, the genome of *N. equitans* does not show evidence of pseudogenes and contains a full complement of tightly packed genes encoding informational processing machineries [184]. Similar trends have recently been seen in other representatives of the DPANN radiation [177]. Members of the *Nanoarchaeota* have been found in a variety of thermal environments ranging from hydrothermal vents to hot springs and are now assumed to infect a variety of different crenarchaeal hosts. For instance, additional *Nanoarchaeaota*, such as *Candidatus Nanobsidianus stetteri*, *Candidatus Nanopusillus acidilobi*, and *Candidatus Nanoclepta minutus* have recently been successfully co-cultivated with their crenarchaeal hosts referred to as

Acidolobus sp., Acidilobus sp. 7A, and *Zestosphaera tikiterensis*, respectively [138, 185, 186].

Overview of Other Putative DPANN Clades

Most of the other DPANN clades are represented by genomes reconstructed through metagenomics or single-cell genomics approaches. However, recent cultivation efforts have led to the enrichment of the first co-culture of a member of the *Nanohaloarchaeota* with its haloarchaeal host, i.e., *Ca. Nanohaloarchaeum antarcticus* and *Halorubrum lacusprofundi* [187], and of members of the *Micraarchaeota* members with their putative archaeal partners belonging to the *Thermoplasmatales* [188, 189]. Even though *Ca. N. antarcticus* has a larger genome and metabolic gene repertoire than *N. equitans*, it seems to obligately depend on its host for growth and survival [187].

Additional insights into the diversity and metabolic potential of members of the various DPANN clades predominantly derive from genomic inferences [6, 177, 180]. For instance, the *Woese-* and *Pacearchaeota* seemingly represent extremely diverse DPANN lineages whose members differ in the extent of genome reduction and metabolic capabilities. However, all representatives lack major and essential metabolic pathways indicating obligate host dependency. Few representatives of the DPANN, such as members of the *Diapherotrites* [190], may be able to conserve energy through fermentation. But the lack of some biosynthetic pathways indicates that they still depend on the external acquisition of certain amino acids, vitamins and/or cofactors [177, 180].

While much has to be learned about the DPANN archaea, the discovery of this large diversity of putative archaeal symbionts and the occurrence of certain representatives in almost all environments on Earth indicates that the future investigation of this radiation will be crucial for our understanding of both the evolution and ecology of *Archaea* and their impact on global nutrient cycles.

Altiarchaeota and its Symbiont—A Member of the Huberarchaeota

The *Altiarchaeota* represent a lineage variably affiliating either with the DPANN archaea or *Euryarchaeota* [6, 135, 177, 179, 180, 191] in phylogenetic analyses depending on the type of analysis (e.g., with regard to model choice) and data used. *Altiarchaeota* (formerly also referred to as SM1 *Euryarchaeota*) were originally discovered in a cold (~10°C), sulfurous Moor in Germany [135] but can also be found in sulfidic springs [192, 193], marine sediments, hot springs, and aquifers [191]. Notably, some members of the *Altiarchaeota* are found in microbial consortia that display a unique morphology described as a "string-of-pearls," which is several millimeters in length and consists of tiny white pearls (0.5–3 mm diameter) connected by thin threads [135]. The outer part of the pearl is composed of bacteria, such as the *Gammaproteobacterium Thiotrix uunzi* [194] or the *Epsilonproteobacterium* IMB1 [195], while the inside is dominated by *Altiarchaeota* [135]. The large size of the consortium allows for the effective enrichment of *Altiarchaeota* on polyethylene nets that can consist of ~98% of archaeal cells and ~2% bacteria [196]. Other representatives of the *Altiarchaeota* occur in almost single-member biofilms (~5% bacteria, ~95% *Altiarchaeota*) in sulfidic springs [192, 193].

Notably, *Altiarchaeota* have not only been found in symbiosis with bacteria but represent the hosts of members of the *Huberarchaeota*, a recent addition to the DPANN superphylum [178, 197]. Similar to other DPANN archaea, known members of the *Huberarchaeota* have reduced genomes and lack proteins related to energy metabolism, regeneration of redox equivalents and nucleotide biosynthesis indicating that they depend on a variety of compounds from their hosts.

The first insights into the metabolism of the Altiarchaeota came from the metagenome-assembled genome (MAG) of *Candidatus* Altiarchaeum hamiconexum, which was reconstructed from a cold, sulfidic spring in Germany [179]. Genomic analyses suggested this representative is an anaerobic autotroph, potentially capable of growth on carbon dioxide and possibly acetate, formate, and carbon monoxide [179]. *Ca.* A. hamiconexum is a biofilm-forming, nonmotile organism with coccoid cells (0.4–0.7 µM in diameter) and a double membrane [179]. Cells can be surrounded by up to 100 hair-like proteinaceous appendages of 2–3 µM length, so-called hami, which mediate adhesion to various surfaces [198]. However, representatives of the *Altiarchaeota* from sediments lack genes encoding proteins involved in hami formation and show specific adaptations to their respective environments [191].

Archaea as Part of the Human Microbiome

For a long time, it was thought that *Archaea* played minor roles in the microbiomes of humans and other mammals and true archaeal pathogens remain to be discovered. The first archaeon associated with humans was described in 1982, the methanogenic *Methanobrevibacter smithii*, which was isolated from human feces [199] suggesting that the methane exhaled by a certain proportion of humans may be produced by methanogens residing in the gastrointestinal tract [200]. Since then, several archaeal species have been identified to be associated with the intestinal, oral, gut, nasal, vaginal, lung, and skin microbiota of both humans and other animals [201–203]. However, their roles in human health and disease remain poorly understood [201–205]. In the following, we summarize current knowledge regarding the diversity and function of human-associated archaea.

Oral Archaeome

Methanogenic archaea are part of the oral archaeome with *Methanobrevibacter oralis* being the most frequently detected species [205, 206]. Notably, *M. oralis* seems to be correlated with periodontitis severity, supporting a potential pathogenic role of methanogenic archaea [206–208]. While no direct experimental evidence has demonstrated the virulence pattern of *M. oralis* and other oral archaeal species, the unique metabolism of methanogenic archaea provides insight into possible drivers of oral disease. For instance, methanogens in periodontal pockets may serve as an H_2 sink, which would favor the proliferation of syntrophic pathogenic microbes [206–209]. Recent investigation into microbial communities in the oral cavity has shown significant positive correlations between the abundance of methanogens with that of *Prevotella intermedia*, a known bacterial pathogen involved in periodontal infections such as periodontitis, gingivitis, and necrotizing ulcerative gingivitis [208].

The relationship between these two groups in periodontal pockets is still unknown, but indirect and direct associations between the methanogens and the local environment may be driving the proliferation of *P. intermedia* through a series of possible syntrophic interactions [208]. A current key research interest is to further determine the immediate role of archaea in the pathogenesis of periodontal infections [206, 210]

Gut Archaeome

To date, three species of methanogenic archaea have been cultivated and isolated from gut-derived samples, i.e., from human stool: *M. smithii*, *Methanosphaera stadtmanae*, and *Methanomassiliicoccus luminyensis* [95, 199, 211]. With the help of molecular tools, two candidate-species, *Candidatus Methanomassiliicoccus intestinalis* and *Candidatus Methanomethylophilus alvus*, in addition to several unknown members of the orders *Methanosarcinales*, *Methanobacteriales*, *Methanococcales*, *Methanomicrobiales*, and *Methanopyrales*, have been shown to inhabit the human gastrointestinal tract [202]. Further, the presence of methanogens in biopsy samples suggests that they may be associated with the mucosal lining in addition to their presumed presence in the lumen [202]. *M. smithii* is the major archaeal component in the human gut, while *M. stadtmanae* and *M. luminyensis* are less frequently detected species [201, 202] and appear to play an important role as H_2-consumers in the complex microbial ecosystem of the gut [201, 205, 209]. Fermentative microorganisms produce short-chain fatty acids and H_2, the former being consumed by the host and the latter being scavenged and consumed by the archaea. This removal of H_2 from the system by methanogens makes the fermentative processes kinetically more favorable and continuously drives this cyclical syntrophy [201, 202, 205]. Furthermore, there is evidence that methanogens may be involved in inflammatory bowel disease, irritable bowel syndrome, colorectal cancer, diverticulosis, and obesity [201, 205]. However, it is unclear whether methanogens directly or indirectly contribute to the development of gastrointestinal disorders and without doubt, more research is needed to unravel the role of archaea in intestinal disorders [204, 212]. For instance, it has also been suggested that some human-associated archaea may be mutualistic, providing health benefits and influencing host metabolism [202, 213].

Not all gut-associated archaea are methanogens however [202]. For instance, a halophilic archaeon belonging to the halobacteria, *Haloferax massiliensis*, was recently isolated from a human stool sample, reigniting the debate over whether halophiles may colonize the gut [214, 215]. Other studies have revealed a diversity of halobacteria-related sequences in fecal samples collected from healthy Korean people, with analyzed sequences representing *Halorubrum alimentarium* and *Halorubrum koreense*. Interestingly, both *H. alimentarium* and *H. koreense* had previously been isolated from salt-fermented sea foods suggesting native cuisine and eating habits may contribute to the propensity of these organisms in the gut environment [201, 216].

Global Human Archaeome

Technological advancements in high-throughput sequencing have further improved insights into the human microbiome and revealed unexpected diversity of representatives from archaeal phyla that had not previously been detected in human habitats, including members of the DPANN archaea. In particular, members of the *Woesearchaeota* appear to be present in the human lung, and while it is speculated that they may exhibit parasitic/symbiotic lifestyles, their environmental role remains unclear [202]. Analytical exploration into the distribution of archaeal signatures in the human body has revealed site-specific patterns that shape a preliminary biogeographical view of the human archaeome: (1) *Thaumarchaeota* on the skin, (2) methanogenic *Euryarchaeota* in the gut, (3) mixed skin-gut nasal archaeal communities, and (4) *Woesearchaeota* inhabiting the lungs [202].

While *M. smithii*, *M. oralis*, *M. stadtmanae*, *M. luminyensis*, and *H. massiliensis* are the only archaeal species that have been successfully isolated and cultivated from human habitats, efforts are underway to culture more archaeal species associated with humans in order to better understand their roles as potential pathogens or commensal members with potentially positive physiological impacts. For instance, a major step toward a better understanding of the function and dynamics of human-associated archaea may be gained through the Human Microbiome Project [209, 217].

Concurrent with efforts to culture archaeal species infecting humans and elucidate their potential roles in human pathogenesis, there are several initiatives aiming to identify antimicrobial agents that are effective against *Archaea*. Research shows that archaea are resistant to antibiotics used to treat bacterial infections, in part due to morphological and physiological features that impede the action of many bacterial-targeting antimicrobial agents. *In vivo* and *in vitro* experiments have indicated susceptibility of several archaeal groups to certain protein synthesis inhibitors, including fusidic acid and imidazole derivatives [218]. Nonetheless, antibiotic-resistant archaea may become indirectly susceptible to antimicrobial treatments when relying on chemically susceptible bacterial partners within their complex communities. To date, there are a limited number of antimicrobials that target archaea directly. Greater exploration into archaea as causative agents of human disease would also require further investigation into antiarchaeal compounds and treatments [210, 218].

Summary

Thought to be of limited ecological relevance originally, *Archaea* are now known to inhabit a wide range of ecosystems and to play a key role in major biogeochemical cycles [8]. Furthermore, *Archaea* have proven to be of fundamental importance for our understanding of the evolution of complex eukaryotic cells [10] and have emerged as important model systems. Notably, representatives of the *Archaea* are now known to form a stable part of the human microbiome and may even be involved in disease. Unique metabolic and cellular features of *Archaea* are being utilized in a variety of biotechnological applications as well as the development of novel adjuvants in the use of vaccines utilizing the unique membrane lipids of archaeal membranes [219]. Considering that a large fraction of *Archaea* of high-taxonomic rank likely still awaits discovery [5], the coming years will certainly witness further insights into the role of *Archaea* in ecological food webs, the evolution of life and human biology.

Introduction

The genus *Bacillus* comprises an expansive and diverse set of bacteria distinguished by a common feature: the ability to make dormant endospores aerobically when challenged with unfavorable growth conditions. A photograph of sporulating cells of *B. subtilis* is shown in Figure 22.1A. In 1989, Ruth Gordon authored a chapter for the *Practical Handbook of Microbiology* (CRC Press) that reviewed the systematics of the genus *Bacillus* (Gordon 1989). The various species of *Bacillus* were divided into three groups based on the morphologies of the sporangium (swollen or nonswollen) and the mature spore (spherical, cylindrical, or ellipsoidal) along with physiological and biochemical test results (such as catalase production and starch hydrolysis) and growth requirements (such as salinity, temperature, and pH). The species within these groups were highly heterogeneous. Since that time, however, there have been several major reclassifications of species within *Bacillus*, a reassessment necessitated by the introduction of more sophisticated analytical methods that rely on comparison at the genome level and by the constant influx of novel species isolated from unusual environments. *Bacillus* now represents just a small part of a larger taxonomical consortium of endospore-producing bacteria referred to as *Bacillus sensu lato*. Consequently, it is no longer possible in a review such as this one to describe each *Bacillus* species. On the contrary, the goal of this work is to provide the reader with an over-arching summary of *Bacillus sensu lato*, describing in broad brushstrokes the common characteristics of its current members. However, the review will also attempt to focus on those key species, especially *B. subtilis*, which play an increasingly important role in industry, medicine, and basic science. This two-tiered approach should provide the investigator with a greater appreciation of a fascinating and useful group of bacteria.

The Systematics of *Bacillus sensu lato*

Bacillus Systematics: The Classical Paradigm

The bacterial genus *Bacillus* has a long and rich history in the annals of microbiology. During the 1870s, Ferdinand Cohn, working at the University of Breslau, isolated a small, motile, aerobic bacterium from boiled hay infusions. He named it *Bacillus subtilis*, meaning "thin rod." Cohn provided the first accurate description of the *Bacillus* life cycle, demonstrating the formation, heat resistance, germination, and outgrowth of endospores (Cohn 1872). When Robert Koch established that a phenotypically similar organism, *B. anthracis*, was the causative agent of anthrax (Koch 1876), the scientific importance of this novel group of organisms became obvious. For the next 50 years, many new endospore-forming bacteria were identified. Due to limitations in the available tools, however, classification of these bacterial species was often a confusing and disorderly process.

The formidable challenge of bringing order to *Bacillus* taxonomy was met with admirable dedication by Nathan R. Smith,

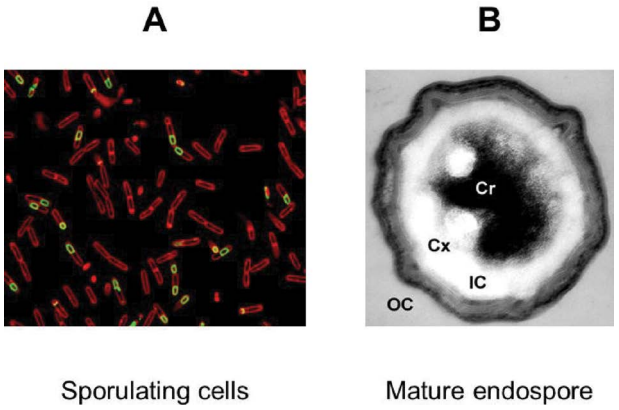

FIGURE 22.1 Formation of endospores in representative *Bacillus* strains. (A) Fluorescence micrograph of *Bacillus subtilis* sporangia. The engulfment membrane (green) is visualized with the fluorescent protein fused to a sporulation protein that surrounds the growing spore (forespore). The cytoplasmic membrane is stained with the vital stain FM 4-64. (B) Cross-section showing the structure of a mature endospore of a wild-type derivative of *B. subtilis* 168. The endospore is approximately 1.2 µm in diameter and is composed of a thick spore coat that lies just underneath a small exosporium (not labeled). The spore coat contains up to 70 proteins, which are cross-linked to form two layers, a thick outer coat (OC) and a less dense layered inner coat (IC). The number and thickness of layers vary from spore to spore (Driks 2004). The spore coat encases the spore cortex (Cx) that consists of a large peptidoglycan layer with dipicolinic acid (DPA); this structure is thought to keep the interior of the endospore dehydrated, protecting the nucleoid from heat and radiation. The interior of the endospore, called the core (Cr), contains the ribosomes and the spore nucleoid. The highly condensed nucleoid is wrapped with small, acid-soluble spore proteins (SASPs) into a strongly protective structure not observed in growing cells. ([A] Micrograph taken by E. Angert and K. Price, Harvard University. Reprinted with permission of Prof. Richard Losick, Harvard University, and the American Society for Microbiology; [B] electron micrograph reproduced from Silvaggi et al., 2004 with permission from the American Society for Microbiology.)

Francis E. Clark, and Ruth E. Gordon in the 1930s and 1940s. They adopted a clear working definition of the genus as comprising "rod-shaped bacteria capable of aerobically forming refractile endospores that are more resistant than vegetative cells to heat, drying, and other destructive agencies" (Gordon, Haynes et al. 1973). Smith assembled a collection of 1,134 mesophilic *Bacillus* strains bearing 158 different species names. With his colleagues, he began to gather a meticulous set of morphological and physiological data on each strain. After analyzing the data—with a deliberate bias towards "lumping" rather than "splitting"—they assigned each isolate to one of 19 rigorously defined species (Smith, Gordon et al. 1946). Soon afterwards, Gordon and Smith repeated the process with a collection of 206 thermophilic *Bacillus* isolates, assigning them to only two additional species (Gordon and Smith 1949).

In the now classic 1973 monograph *The Genus Bacillus* (Gordon, Haynes et al. 1973), Gordon and her colleagues provided precise, detailed descriptions for 18 *Bacillus* species, together with a battery of 33 morphological and physiological tests and an identification key that could unambiguously assign most known isolates to one of those species. *Bacillus* taxonomy had grown into a logical, orderly, and lucid science. With this landmark publication, what one could call the classical period of *Bacillus* systematics, which largely succeeded in bringing order out of chaos, was drawing to a close.

Bacillus Systematics: The Molecular Paradigm

In the 1970s and early 1980s, Woese and his colleagues ushered in a dynamic new era of systematics, which led to the reordering of all known organisms into three domains of life, two of them prokaryotic (Fox, Pechman et al. 1977, Woese and Fox 1977). The core technology that underpinned this revolution was sequencing of the 16S ribosomal RNA. When the new tools of molecular taxonomy were applied to the genus *Bacillus*, the resulting data challenged the existing paradigm that the genus comprised a small number of rigorously defined species identifiable by certain key phenotypic characteristics. Ash utilized this new technology to scrutinize most of the known species of *Bacillus* and concluded that they fell into five distinct 16S sequence similarity groups, which they suggested could logically correspond to five novel genera (Ash, Farrow et al. 1991). *B. subtilis*, *B. licheniformis*, *B. amyloliquefaciens*, *B. megaterium*, *B. cereus*, *B. anthracis*, *Bacillus thuringiensis*, and many of the other best known and earliest studied species were placed in Group 1. This group can be termed *Bacillus sensu stricto*, since members of this group are considered to have the classic characteristics known for aerobic Gram-positive endospore-forming bacilli. It is important to note that additional species that were phenotypically similar to members of these five groups, yet were nonetheless sequence outliers, were thought to "represent the nuclei of other hitherto unrecognized genera."

An Overview of *Bacillus sensu lato*

This prediction was soon realized by a new generation of taxonomists who began mining the rich biodiversity of the earth's ecosystem in search for novel microorganisms. It is no exaggeration to say that virtually everywhere they have looked, microbiologists have uncovered Gram-positive endospore-formers closely related to the classical genus *Bacillus*. Such novel species have been recovered from ocean sediments thousands of meters below sea level (Rüger, Fritze et al. 2000, Lu, Nogi et al. 2001, Bae, Lee et al. 2005, Xu, Yu et al. 2019) and from stratospheric air samplers tens of kilometers above it (Shivaji, Chaturvedi et al. 2006). Other *Bacillus* species have been isolated from acidic geothermal pools and peat bogs (Simbahan, Drijber et al. 2004, Albert, Archambault et al. 2005) and from highly alkaline groundwater (Tiago, Chung et al. 2004). Several *Bacillus* species have been found in hypersaline terminal lakes, some contaminated with heavy metals (Switzer Blum, Burns Bindi et al. 1998, Arahal, Márquez et al. 1999, Vargas, Delgado et al. 2005, Lim, Jeon et al. 2006). Others have been discovered in human-created niches both ancient and modern, from Mexican shaft tombs and deteriorating Roman wall paintings (Heyrman, Balcaen et al. 2003, Gatson, Benz et al. 2006) to ultra-clean rooms in spacecraft assembly facilities (Venkateswaran, Kempf et al. 2003, La Duc, Satomi et al. 2004, Satomi, La Duc et al. 2006, Seuylemezian, Ott et al. 2019). With increasing frequency, novel *Bacillus* species have being isolated from the human gut (Tidjani Alou, Rathored et al. 2015, Tidjiani Alou, Rathored et al. 2015, Senghor, Seck et al. 2017). Plants continue to be a rich source of novel *Bacillus* species, some endophytic and others rhizosphere-associated (Reva, Smirnov et al. 2002, Olivera, Siñeriz et al. 2005). A wide diversity of *Bacillus* and related bacteria have even been detected by molecular methods in the subglacial Antarctic lake, Lake Vostok, buried under 3.7 km of ice (Shtarkman, Kocer et al. 2013).

As a result of these efforts, the systematics of the old genus *Bacillus* has been radically transformed. With the exponential influx of valid described endospore-forming species since the 1990s, the five *Bacillus* groups developed by Ash (Ash, Farrow et al. 1991) and later refined by Priest (1993) have not only been assigned novel genus names but have been subdivided into many additional genera, while the outliers from the original similarity groups have been assigned to novel genera as well. At the time of writing, there have been valid descriptions published for at least 1,070 *Bacillus*-like species comprising 102 genera (see the "List of Prokaryotic Names with Standing in Nomenclature," http://bacterio.net). This enlarged category of endospore formers is termed *Bacillus sensu lato* ("in the broad sense"), with the many of the original *Bacillus* species still defined as *Bacillus sensu stricto* ("in the narrow sense"). Moreover, during the decade from since 2004, novel species of *Bacillus sensu lato* have been described at an average rate of almost one per week. This trend shows no signs of abating. The interested reader is directed to several authoritative books and reviews that describe these new genera and their genotypic and phenotypic basis (Goto, Omura et al. 2000, Logan and Turnbull 2003, Fritze 2004, Logan and Rodriguez-Diaz 2006, Maughan and Van der Auwera 2011).

The oldest isolate—and therefore the nomenclatural type species for the genus *Bacillus*—is *B. subtilis* (Figure 22.1A). Descriptive studies have characterized *B. subtilis* as a mesophile, though a hardy one, growing at temperatures as low as 5–20°C and as high as 45–55°C and in salinities as great as 7% NaCl (w/v). Cells are moderate sized rods, about 0.7–0.8 µM by 2.0–3.0 µM, typically with many long peritrichous flagella and strong motility. Endospores are ellipsoidal and located near the end of the mother cell. The mature endospore, shown in Figure 22.1B, is released upon mother cell lysis. *B. subtilis* is one of the most thoroughly studied of all bacteria, both as an industrial powerhouse (see section entitled Industrial Applications of *Bacillus* later in this chapter) and a model system for cell development (see section entitled Cell Physiology and Development later in this chapter). A cluster of closely related species, labeled in Figure 22.2, is often referred to as the "*Bacillus subtilis* group." One of these species,

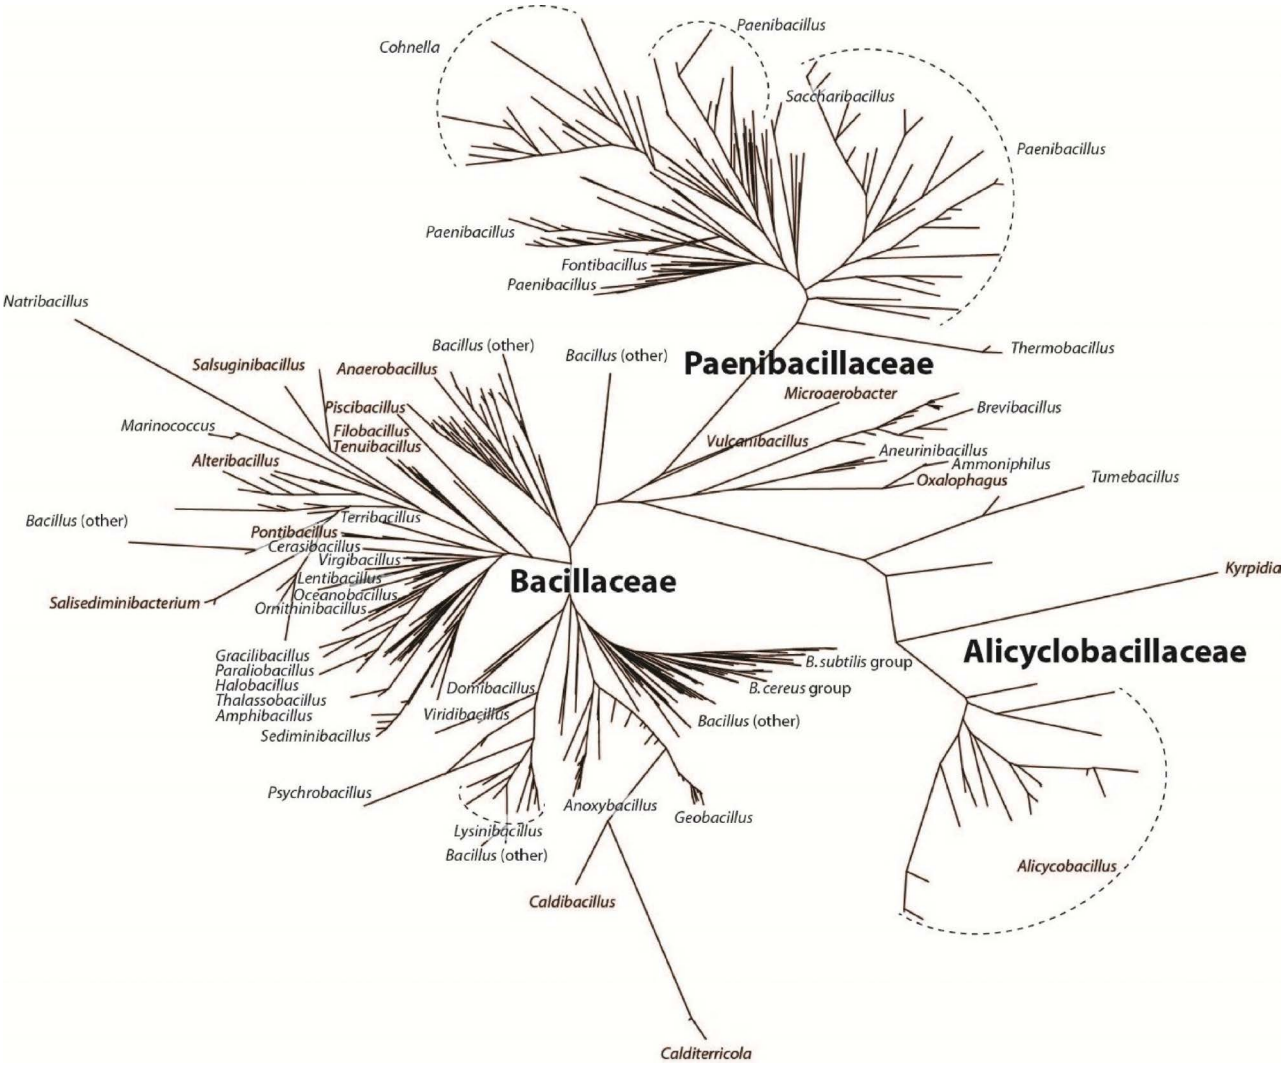

FIGURE 22.2 Phylogeny of *Bacillus sensu lato* from 16S rRNA gene sequences. GenBank DNA sequences for species type strains were aligned with ClustalW (Higgins, Thompson et al. 1994). An unrooted phylogenetic tree was constructed from the ClustalW distance matrix with the PHYLIP Neighbour application (Felsenstein 1989) and visualized with PhyloDraw. Dashed lines group sequences that have been assigned to the same taxon. A few species mentioned frequently in the text are indicated. The *"B. subtilis* group" consists of 14 species, including *B. licheniformis*, that are closely related to *B. subtilis.* The *"B. cereus* group" consists of six species, including *B. anthracis* and *B. thuringiensis*, which are closely related to *B. cereus.*

B. licheniformis, is also an important industrial microorganism. The species is named for its lichen-like appearance when grown on solid media, where it typically forms rough, dry, irregular colonies that adhere stubbornly to the agar surface (Gibson 1944).

Another very commonly studied cluster of species is known as the "*Bacillus cereus* group" (Figure 22.2). Descriptive studies of these species show that their cells are somewhat larger than those of *B. subtilis,* with widths of 1.0–1.2 µM and lengths of 3.0–5.0 µM. Most members of the group form colonies with a distinctive "ice crystal" surface texture, although strains of *B. mycoides* usually form complex rhizoid colonies. The *B. cereus* group of species is perhaps best known for its pathogenic members. *B. thuringiensis* forms large parasporal crystals composed of protoxins targeting specific invertebrate organisms, notably insect larvae (discussed later in this chapter). *B. anthracis* and certain strains of *B. cereus* are causative agents for human diseases (discussed later in this chapter). Some strains from the *B. cereus* group are known to produce spores with caps, spikes, filaments, and other bizarre appendages (Rampersad, Khan et al. 2003) (see Figure 22.3A and B). Unusual spore morphologies and complex developmental structures can also be found in isolates throughout the *Bacillus sensu lato* (Ajithkumar, Ajithkumar et al. 2001) (see Figure 22.3C).

Although these commonly studied species are illustrative of *Bacillus*, they are by no means fully representative of its diversity. It is now realized that the defining characteristic of the classical genus *Bacillus*—endospore formation—is an ancient trait that probably appeared a single time near the base of the bacterial phylum Firmicutes (Galperin, Mekhedov et al. 2012, Abecasis, Serrano et al. 2013, Traag, Pugliese et al. 2013). As a result, this characteristic circumscribes an extremely diverse set

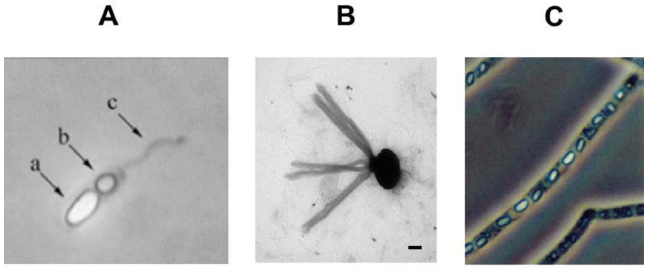

FIGURE 22.3 Diversity of *Bacillus* endospores. (A) Phase contrast micrograph of a *B. thuringiensis* Bt2-56 cell, which produces a complex endospore assembly consisting of the spore, a spherical parasporal body, and a long filament, which upon germination remains attached to the cell wall of the outgrowing bacterium. This filament structure is unique and is not observed with other commonly known *B. thuringiensis* strains. (B) Electron micrograph of *B. thuringiensis* Bt1-88 spores with multiple filaments. This species is related to *B. thuringiensis* Bt2-56, but produces multiple filaments as opposed to singlets. Bar represents 500 nm. (C) Phase contrast micrograph of *Bacillus* spp. NAF001 filaments with endospores. Cells are also able to produce spore-like resting cells (SLRCs), which are heat resistant and can bud to form short filaments. ([A] The photograph is reprinted from Rampersad, Khan et al. 2003 with permission from Springer-Verlag New York Inc.; [B] the micrograph is reproduced with permission from Dra. Luz Irene Rojas Avelizapa, Departamento de Microbiología, Escuela National de Ciencias Biológicas, México; [C] the photograph is reprinted from Ajithkumar, Ajithkumar et al. (2001), with permission from the Society for General Microbiology.)

of bacteria that have adapted to life under a broad array of environmental conditions. Currently, these species have been grouped into three taxonomic families (*Bacillaceae, Paenibacillaceae, and Alicyclobacillaceae*), joining seven other non-*Bacillus* families in the order *Bacillales*. Many of these novel genera of *Bacillus sensu lato* contain organisms adapted to extreme conditions, bacteria largely unknown to the classical taxonomists of the 1930s and 1940s. Thermophiles, psychrophiles, acidophiles, alkaliphiles, and halophiles, as well as isolates that are neither rod-shaped nor spore-forming, all have a place within these newly described genera.

If we repeat the analysis of Ash, Farrow et al. (1991) and construct a phylogram from the 16S rRNA gene sequences of type strains within *Bacillus sensu lato*, some patterns begin to emerge (Figure 22.2). First, there is a reassuring—though by no means totally consistent—congruity between certain broad phenotypic traits and position on the phylogenetic tree. For example, two thermophilic genera, the aerobic *Geobacillus* and the anaerobic *Anoxybacillus,* cluster together on the phylogram. Several moderately alkalophilic and halophilic genera also tend to cluster together in another branch of the tree. There is some degree of convergence between classical phenotypic approaches and modern genotypic approaches to bacterial systematics after all. Secondly, species classified as *Bacillus sensu stricto* are nevertheless scattered in distantly related clusters all over the tree. Despite being subdivided multiple times, the genus is still phylogenetically incoherent. A similar situation exists for the genus *Paenibacillus.* It has recently been proposed that the genus *Bacillus* should be reserved only for those species clustering either with the *B. subtilis* or *B. cereus* groups in molecular sequence phylogenies, and that all other species should eventually be transferred to other genera (Bhandari, Ahmod et al. 2013). Very recently, six such genera have been proposed, based on comparative genomic approaches (Patel and Gupta 2019). There remains much work to be done, then, in reorganizing the taxonomy of these bacteria, even without taking into consideration the novel species that continue to be described. Careful systematic studies of *Bacillus* are still absolutely necessary if their taxonomy is to retain any significance and usefulness. A newly constituted Subcommittee on the Taxonomy of Order Bacillales under the oversight of the International Committee on Systematics of Prokaryotes has been charged with pursuing these goals (http://www.the-icsp.org/).

Characterization and Classification of Novel *Bacillus* Isolates

In today's era, what should a researcher do to characterize a *Bacillus* isolate adequately and to perhaps assign it to a novel species or even genus? In recent years, it has become increasingly practical simply to obtain a whole genome sequence (WGS) using one of the next generation (NextGen) sequencing technologies, a development that is rapidly changing nearly every aspect of microbiology (Loman, Constantinidou et al. 2012). Indeed, the existence of a publicly available genome sequence is a requirement for description of a novel species in most microbiology journals, and common standards have been widely adopted (Chun, Oren et al. 2018). Although further improvements in high throughput sequencing may render most other biochemical and molecular taxonomic methods obsolete in the near future, at this writing, some conventional methods can still provide an adequate

level of characterization more rapidly and less expensively than genome sequencing. For example, a clinical microbiologist may need to determine quickly whether a certain *B. cereus* isolate from a patient with emetic food poisoning is identical with a previous isolate or represents a novel pathogenic strain. In that case—or in any number of applications where closely related members of the same species must be compared—a molecular fingerprinting technique using nucleic acid, peptide, or fatty acid profiles could still be an efficient approach. Several examples of these methods, together with references that illustrate their practical application to *Bacillus sensu lato*, are given in Table 22.1. In asking epidemiological questions that go deeper than mere strain

TABLE 22.1

Common Methods for Identifying and Characterizing Novel *Bacillus* Isolates

Method, with Selected Examples	**Useful Range**[a]	**Application to** *Bacillus Sensu Lato*
Physiological and morphological tests		
Microscopy and 26-test battery	species	Gordon, Haynes et al. 1973
Microscopy and 26-test battery	species	Priest and Alexander 1988
Microscopy and 20-test battery	species	Reva, Sorokulova et al. 2001
Carbohydrate utilization (commercial kit)	species	Logan and Berkeley 1984
DNA fingerprinting		
Restriction Fragment Length Polymorphism (RFLP)		
rRNA operons	subspecies-strain	Joung and Cote 2001; Coelho, von der Weid et al. 2003; Yi, Wu et al. 2012
amplified *secY* genes	genus-species	Palmisano, Nakamura et al. 2001
amplified *gyrB* genes	genus-species	Manzano, Cocolin et al. 2003
Pulsed Field Gel Electrophoresis (PFGE)	subspecies-strain	Gaviria Rivera and Priest 2003a
Conventional DNA sequencing		
Single locus sequence analysis		
16S rRNA	domain-genus	Ash, Farrow et al. 1991; Bavykin, Lysov et al. 2004; Zeigler 2005
23S rRNA	domain-genus	Bavykin, Lysov et al. 2004
groEL	species-subspecies	Chang, Shangkuan et al. 2003
gyrB	species-subspecies	Goto, Mochida et al. 2003; Bavykin, Lysov et al. 2004
recN	species-subspecies	Zeigler 2005
rpoB	species-subspecies	Palmisano, Nakamura et al. 2001
hag	subspecies	Xu and Cote 2006
panC	species-subspecies	Guinebretiere, Thompson et al. 2008
Multilocus Sequence Typing (MLST)		
adk, ccpA, ftsA, glpT, pyrE, recF, sucC	genus-subspecies	Helgason, Tourasse et al. 2004

rpoB, gyrB, pycA, mdh, mbl, mutS, plcR	genus-subspecies	Ko, Kim et al. 2004
rpoB, purH, gyrA, groEL, polC, 16S rRNA	genus-subspecies	Kubo, Rooney et al. 2011
adk, ccpA, pycA, glyA, glcK, glpF	genus-subspecies	Ge, Hu et al. 2011
Repetitive DNA PCR fingerprinting	subspecies-strain	Satomi, La Duc et al. 2006
Random Amplified Polymorphic DNA (RAPD)	subspecies-strain	Gaviria Rivera and Priest 2003b
Oligonucleotide microarray fingerprinting	subspecies-strain	Chandler, Alferov et al. 2006
Multilocus variable number tandem repeat (MLVA)	subspecies-strain	Durmaz, Doganay et al. 2012; Dhakal, Chauhan et al. 2013
Conserved signature indels in protein sequences	genus-species	Bhandari, Ahmod et al. 2013; Patel and Gupta 2019
Core genome sequence comparison		
Core genome protein sequence comparison	genus-subspecies	Patel and Gupta 2019
Core genome DNA sequence comparison	genus-subspecies	Bazinet 2017, Fan, Blom et al. 2017; Kim, Koh et al. 2017
Other molecular methods		
Fatty Acid profiling	species-subspecies	Kämpfer 1994; Schraft, Steele et al. 1996; Palmisano, Nakamura et al. 2001
MALDI-TOF Mass Spectroscopy	species-subspecies	Dickinson, La Duc et al. 2004; Farfour, Leto et al. 2012; Fernández-No, Böhme et al. 2013
Multilocus Enzyme Electrophoresis (MLEE)	subspecies-strain	Zahner, Momen et al. 1989; Zahner, Rabinovitch et al. 1994; Helgason, Økstad et al. 2000; Coelho, von der Weid et al. 2003

[a] Approximate range of taxonomic levels over which the method has maximum utility for both distinguishing and grouping related bacterial isolates.

identification, however, WGS analysis can provide characterization in unprecedented detail. A powerful example can be found in the forensic investigation into the "Amerithrax" incident in 2001, when comparative genomics combined with conventional analysis methodologies to reveal strain-specific differences in *B. anthracis* isolates (Rasko, Worsham et al. 2011).

When the aim is to address basic questions in environmental, evolutionary, or systematic microbiology, a broader analysis is generally required. Often, the very first information that a researcher will acquire is the 16S rRNA gene sequence of the isolate. While those data may be sufficient to place an isolate in a given genus—or perhaps to demonstrate that it is rather unlike any known genus—they may not be adequate for a reliable assignment at the species level or below. The 16S sequence is a powerful tool for tracing deeper phylogenies, but may show too little variability to differentiate among closely related species (Zeigler 2005). In fact, there are known examples where two *Bacillus* isolates may be clearly distinguishable by whole genome comparison techniques yet share essentially identical 16S rRNA genes (Fox, Wisotzkey et al. 1992). For this reason, a 16S sequence alone is not considered sufficient grounds to propose that a bacterial isolate belongs to a novel species. Unless a WGS is obtained, a 16S sequence should be supplemented with experiments to estimate whole genome relatedness between related organisms (Stackebrandt and Goebel 1994). Highly conserved protein-encoding genes may offer greater resolution when comparing bacteria at the species or subspecies level (Zeigler 2003). Comparing the concatenated set of gene sequences, a strategy known as multilocus sequence typing, has been a powerful tool for characterizing members of the *B. cereus* group, for example (Didelot, Barker et al. 2009). DNA-DNA cross-hybridization, together with %G + C genome content comparison, was once considered the "gold standard" in defining new species (Wayne, Brenner et al. 1987, Stackebrandt, Frederiksen et al. 2002), although a variety of other methods have also been useful (Gürtler and Mayall 2001). With the advent of low-cost DNA sequencing, however, WGS analysis is emerging as the new standard (Loman, Constantinidou et al. 2012). In any event, the ideal approach for systematics includes a polyphasic analysis, in which data gathered from complementary techniques are compared in order to draw a consensus conclusion (Brenner, Staley et al. 2001). Physiological and morphological phenotypic testing, together with 16S rRNA gene sequence comparison and comparative genomics using tools such as the Genome-to-Genome Distance Calculator (Meier-Kolthoff, Auch et al. 2013) and Average Nucleotide Identity (Yoon, Ha et al. 2017), provide a solid foundation for bacterial taxonomy (Ludwig and Klenk 2001, Maughan and Van der Auwera 2011, Chun, Oren et al. 2018). Table 22.1 also lists a variety of methods that have found application in *Bacillus* systematics.

Although these methods have increased our understanding of aerobic endospore former in *Bacillus sensu lato*, still only a handful of these species have been intensely studied for academic and commercial use. Nevertheless, as described in the following section, this small group of bacteria has led the way in various fields of science and industry, which has made a profound impact on our society.

Industrial Applications of *Bacillus*

Developing *Bacillus* Strains for Industry

Bacillus species have played a crucial role in establishing a wide range of sustainable industrial fermentation processes, which in some cases (e.g., riboflavin production) have supplanted older, less efficient chemical processes. Commercial products produced by *Bacillus* sp. range from specialty chemicals, surfactants, and antibiotics to vitamins and food enzymes (Hohmann and Stahmann 2010, Eggersdorfer, Laudert et al. 2012, Hohmann, van Dijl et al. 2017, Singh, Patil et al. 2019). Table 22.2 lists the key industrial fermentation processes that use *Bacillus* species.

In large part, many of these processes were established or improved using a combination of classical genetic methods and recombinant DNA technology and more recently using synthetic biology. Implementation of these latter techniques has been facilitated by the excellent natural competence and DNA recombination mechanisms exhibited by many of these species (Dubnau 1991, Hamoen, Venema et al. 2003). The process-development toolbox for *Bacillus* includes numerous plasmid cloning vectors (Errington 1988, Janniere, Bruand et al. 1990, Bruckner 1992, Kobayashi and Kawamura 1992, Vary 1992, Wang 1992, Choi, Wang et al. 2002), transposon mutagenesis systems (Youngman, Perkins et al. 1983, Perkins and Youngman 1986, Steinmetz and Richter 1994, Le Breton, Mohapatra et al. 2006), conjugative mobile elements (Lee, Thomas et al. 2012), antibiotic resistance markers to select for transformed cells (Horinouchi and Weisblum 1982, Perkins and Youngman 1983, Itaya, Kondo et al. 1989, Itaya, Yamaguchi et al. 1990, Dale, Langen et al. 1995, Guérout-Fleury, Shazand et al. 1995), constitutive and regulated promoters (Lee and Pero 1981, Udaka and Yamagata 1993–1994, Goldstein and Doi 1995, Nguyen, Nguyen et al. 2005, Terpe 2006), and single and multicopy gene expression cassettes, including those with promoter and signal sequence combinations to secrete high valued proteins and enzymes (see below). Introduction of genetic material into the cell can occur by natural competence, protoplast fusion, and electroporation transformation methods and in some instances by conjugation (Jensen, Andrup et al. 1996, Aquino de Muro and Priest 2000, Poluektova, Fedorina et al. 2004). Although most of these tools were first developed in *B. subtilis*, many have been adapted for use in related *Bacillus* species, facilitating the rapid development of new industrial processes. Moreover, the utility of these tools have been amplified by the availability of the complete genome sequences of *B. subtilis* and related species and the subsequent application of powerful omics technologies. The importance of genomics is addressed later in this review. So in many ways the development and ease of use of modern recombinant genetic tools in *Bacillus* rivals that of the other well-known production hosts, such as *E. coli* and *S. cerevisiae*. Extensive description of the key genetic modification and recombinant cloning techniques used for *Bacillus* has been well reviewed (Harwood and Cutting 1990, Meima, van Dijl et al. 2004, Perkins, Wyss et al. 2009, Dong and Zhang 2014, Gu, Xu et al. 2018, Liu, Yang et al. 2019).

TABLE 22.2

Industrial Fermentation Products Produced by *Bacillus* Species

Product	*Bacillus* Species	Industrial Application
Fine Chemicals		
Riboflavin	*B. subtilis*	Food and Pharma
Purine Nucleosides	*B. subtilis*	Food
Poly-γ-glutamic acid	*B. subtilis*	Food, Animal, and Pharma
D-ribose	*B. subtilis, B. pumilus*	Food, Animal, Cosmetics, and Pharma
Thaumatin	*B. subtilis*	Food and Pharma
Streptavidin	*B. subtilis*	Microarrays
2-actyl-1-pyrroline	*B. cereus*	Food
L-malate	*B. subtilis*	Food and Pharma
Biofuels and Bio-Based Chemicals		
Isobutanol	*B. subtilis*	Biofuel/Chemical
2-methyl-1-propanol	*B. subtilis*	Biofuel/Chemical
BDO	*B. subtilis*	Polymers
Acetoin	*B. subtilis*	Food and Beverage
H_2	*B. cereus, B. coagulans, B. licheniformis, B. megaterium, B. pumilus, B. sphaericus, B. subtilis, B. thuringiensis*	Biofuel
Polyhydroxybutyrate	*B. megaterium, B. cereus, B. licheniformis, B. mycoides*	Polymers
Surfactant	*B. subtilis*	Personal care, Detergents, Lubricants
Enzymes		
α-Amylase	*B. licheniformis, B. amyloliquefaciens, B. circulans, B. subtilis, G. stearothermophilus*[a]	Food, Paper, Starch, Textile, and Brewing
β-Amylase	*P. polymyxa*[b], *B. cereus, B. megaterium*	Textile
Alkaline phosphatase	*B. licheniformis*	Detergent
Cyclodextran Glucanotransferase	*P. macerans*[c], *B. megaterium, Bacillus* sp.	
β-Galactosidase	*G. stearothermophilus*[a], *B. circulans*	Food
β-Glucanase	*B. subtilis, B. circulans, B. amyloliquefaciens*	Beverage
β-Glucosidase	*Bacillus* sp.	
Glucose isomerase	*B. coagulans, B. acidipullulyticus, B. deramificans*	Starch
Glucosyl transferase	*B. megaterium*	
Glutaminase	*B. subtilis*	
Galactomannase	*B. subtilis*	
β-Lactamase	*B. licheniformis*	
Lipases	*Bacillus* sp.	Detergent
Neutral (metallo-) rotease	*B. lentus, P. polymyxa, B. subtilis, B. thermoproteolyticus, B. amyloliquefaciens*	
Penicillin acylase	*Bacillus* sp.	
Pullulanase	*Bacillus* sp., *B. acidopullulans*	Starch
Alkaline (serine-) protease	*B. amyloliquefaciens, B. amylosaccharicus, B. licheniformis, B. subtilis*	Detergent
Urease	*Bacillus* sp.	
Xylanases	*Bacillus* sp.	
Lignocellulolytic enzymes	*B. subtilis*	Food and biofuel
L-Asparaginase	*B. subtilis*	Food
Fibrinolytic enzymes	*Bacillus* sp.	Food and Pharma
Fermentation	*B. natto*	Food
Insect Pathogen	*B. thuringiensis, B. sphaericus, P. popilliae*[d] *P. lentimorbus*[e]	Agriculture
Plant Probiotic (Endophyte)	*B. subtilis, B. amyloliquefaciens, B. licheniformis, B. pasteurii, B. cereus, B. pumilus, B. mycoides, and B. sphaericus*	Agriculture

(*Continued*)

TABLE 22.2 *(Continued)*

Industrial Fermentation Products Produced by *Bacillus* Species

Product	*Bacillus* Species	Industrial Application
Animal Probiotic	*B. licheniformis, B. subtilis, B. cereus* var *toyoi, B. clausii*[f], *B. cereus*[f]	Animal feed
Aqua Probiotic	*B. subtilis, B. megaterium, B. licheniformis, P. polymyxa*[e], *Bacillus* sp.	Aquaculture feed
MEOR	*B. subtilis*	Enhanced oil recovery

Note: This table presents a condensed description of industrial products produced by *Bacillus* species. This table is by no means comprehensive since new products are continually being introduced into the market.

Sources: The data are compiled from previously published lists (enzymes from Meima et al. 2004 with permission from Horizon Scientific Press/Horizon Bioscience, UK; fine chemicals, insect pathogens, and fermentation from Schallmey et al. 2004, with permission from NRC Research Press, Canada and Gu et al. 2018; probiotics from Hong et al. 2005 with permission from Blackwell Publishing, UK) (Meima, van Dijl et al. 2004, Schallmey, Singh et al. 2004, Hong et al. 2005), and individual publications: β-galactosidase from (Kyoji 2011); L-malate from (Mu and Wen 2013); cellulosic enzymes from (Maki, Leung et al. 2009, Anderson, Robson et al. 2011, You, Zhang et al. 2012); proteases from (Contesini, de Melo et al. 2018); fibrinolytic enzymes from (Yogesh and Halami 2017); biofuels and chemicals from (Kumar, Patel et al. 2013 [isobutanol and H2]; Biswas, Yamaoka et al. 2012 [BDO]; Blombach and Eikmanns 2011[isobutanol]; Wang, Fu et al. 2012 and Zhang, Zhang et al. 2013 [acetoin]; and Li, Jia et al. 2012 [isobutanol]); plant endophytes from (Mongkolthanaruk 2012); and MEOR from (Gudiña, Pereira et al. 2013).

[a] Formerly *B. stearothermophilus*; [b]formerly *B. polymyxa*; [c]formerly *B. macerans*; [d]formerly *B. popilliae*; [e]formerly *B. lentimorbus*; [f]not approved for use in the EU.

Enzymes

By far the largest product group produced by *Bacillus* species is bulk and specialty enzymes, making up about 50% of the total market size. Applications include household detergents, starch hydrolysis, textile, baking, and beverages. Many of these enzymes have unique properties, such as tolerance to high temperatures (thermostability) or alkaline conditions, broad pH ranges, or inhibitory levels of by-products which make them the enzymes of choice in many industrial processes and household products (Meima, van Dijl et al. 2004). Moreover, with the availability of classical and recombinant methods, protein-engineered variants with novel or improved catalytic properties have been developed to expand their use into new commercial applications (Schmidt-Dannert, Pleiss et al. 1988, Takagi 1993, Nielsen and Borchert 2000, Olempska-Beer, Merker et al. 2006). Due to their propensity to secrete proteins into the extracellular medium, *Bacillus* species are also good hosts for the production of heterologous proteins; this product class will be addressed in later sections. Numerous plasmid-borne or chromosomal integration expression cassettes have been reported that combine transcriptional and translation controlling signals with secretion signal sequences that allow transport of the candidate proteins into the culture medium for subsequent isolation (Song, Nikoloff et al. 2015, Ozturk, Ergun et al. 2017, Cui, Han et al. 2018, Cai, Rao et al. 2019). In addition, a variety of protease-deficient mutants have been constructed to prevent degradation of the heterologous protein; strains with up to eight major and minor protease-encode genes have been constructed (Pero and Sloma 1993, Wu, Yeung et al. 2002).

More recently, the display of proteins on the surface of cells (rather than secretion and release from the cell) has shown great potential for use in the medical and agricultural fields. Such protein displays have been demonstrated for *B. subtilis* and *B. thuringiensis* using a variety of anchoring protein motifs found on the vegetative cell wall, such as *B. subtilis* LytE, (Chen, Wu et al. 2008). Anchoring is also possible using proteins involved in the process of sporulation, e.g., SpoIIIJ (Ding, Guan et al. 2019), or even on the spore surface itself via the *B. subtilis* spore coat proteins CotB (Isticato, Cangiano et al. 2001, Duc le, Hong et al. 2007, Hinc, Isticato et al. 2010), CotC (Ricca and Cutting 2003, Mauriello, Duc le et al. 2004, Hinc, Isticato et al. 2010), CotE (Hwang, Pan et al. 2013), CotG (Kim, Lee et al. 2005, Hinc, Isticato et al. 2010, Hwang, Pan et al. 2013, Liu, Liu et al. 2019), and CotA (Park, Kim et al. 2019), and on the *B. subtilis* inner-coat enzyme oxalate decarboxylase, OxdD (Potot, Serra et al. 2010). A full up-to-date accounting on spore-specific anchors and their displayed proteins can be found in research by Guoyan, Yingfang et al. (2019). In *B. thuringiensis*, proteins can be anchored to both surfaces via the spore cortex-lytic enzyme SceA (Shao, Ni et al. 2012). However, the success rate of displaying a functional enzyme is mixed (Potot, Serra et al. 2010). Future work is aimed to improve the technique to make success more predictable (Nguyen and Schumann 2014, Huang, Gosschalk et al. 2018).

Vitamins and Fine Chemicals

Another commercial area in which several *Bacillus* species play an important role as a fermentation host is the production of vitamins and fine chemicals. Commercialized processes include those for purine nucleotides, riboflavin, and poly-γ-glutamic acid (Ashiuchi, Shimanouchi et al. 2006), surfactants, D-ribose, and an array of minor products such as thaumatin, a low-calorie sugar substitute, polyhydroxybutyrate, streptavidin, and 2-acetyl-1-pyrroline. All but PHB (from *B. cereus*) utilize *B. subtilis* as the production host. *B. subtilis*-based processes for other vitamins, including biotin, pantothenate, thiamin and folic acid, and fine chemicals have as been reported, but none have been commercialized (Perkins, Wyss et al. 2009, Gu, Xu et al. 2018).

Products produced by these *Bacillus* species have a long history of safe use and as such have gained "generally regarded as safe" (GRAS) status in the United States (Silano and Silano 2008). GRAS status is based either on a recognized history of safe use in foods prior to 1958 or on scientific procedures similar to those required for a food additive regulation. An important criterion in determining GRAS status is the lack of pathogenicity of the production microorganism. In this regard, these *Bacillus* species are found not to be harmful to humans or animals.

A status similar to GRAS, called qualified presumption of safety (QPS), has been implemented by EU regulatory authorities. As of March 2019, the following *Bacillus* species have

been granted QPS status: *Bacillus amyloliquefaciens, Bacillus atrophaeus, Bacillus clausii, Bacillus coagulans, Bacillus flexus, Bacillus fusiformis, Bacillus lentus, Bacillus licheniformis, Bacillus megaterium, Bacillus mojavensis, Bacillus pumilus, Bacillus smithii, Bacillus subtilis, Bacillus vallismortis*, and *Geobacillus stearothermophilus* (Koutsoumanis, Allende et al. 2019).

Another regulatory issue that affects the use of *Bacillus* in industrial processes that utilize GMO-derived strains is the physical containment of the engineered bacteria (EU Council Directive 90/219/EEC of April 23, 1990 on the contained use of genetically modified microorganisms). Since spores can persist in the environment for years due their unique resistance to heat, chemicals, and UV radiation, commercial strains are required to contain one or more mutations that arrest this terminal developmental stage. Consequently, most commercialized production strains contain a mutation that prevents the formation of a mature, resistant spore.

Biofuels and Bio-Based Chemicals

Replacing oil-based production of fuels and chemicals with sustainable production systems that use renewable (cellulosic) feedstocks is one of the major trends of the new millennium. In particular, many microbial metabolic pathways are currently being exploited to generate energy and produced valuable chemicals. The genus *Bacillus* plays a key role in this commercial endeavor due its wide use as an industrial fermentation host and the ease of metabolic engineering of its biosynthetic pathways as mentioned earlier. Examples include the production of biofuels, e.g., isobutanol and H_2 (Blombach and Eikmanns 2011, Li, Jia et al. 2012, Kumar, Patel et al. 2013), as well as the production of bio-based chemicals, e.g., BDO and PHA, that can be used in the formation of new polymer materials (Biswas, Yamaoka et al. 2012, Wang, Fu et al. 2012, Kumar, Patel et al. 2013, Zhang, Zhang et al. 2013, Rebecchi, Pinelli et al. 2018). Thermophilic members of *Bacillus sensu lato*, namely *Geobacillus* species, already serve as a production platform in the emerging second-generation biofuels industry (Taylor, Eley et al. 2009). In addition, more novel applications of *Bacillus*, such as in the production of biocement, biobricks, and other bio-based building materials, have been developed (Raut, Sarode et al. 2014, Wong 2015, Pungrasmi, Intarasoontron et al. 2019, Royne, Phua et al. 2019). The future goal will be to convert these lab-scale results to viable commercial processes.

A primary obstacle to fermentative production of bio-based fuels and chemicals is the high cost of degrading the cellulosic biomass into fermentable sugars, which is caused by the high recalcitrance of the plant biomass. However, production costs could be dramatically lowered if the biofuel or chemical production host could also synthesize cellulosic enzymes that solubilize the plant cell wall into fermentable sugars. This approach, referred to as consolidated bioprocessing (CBP), has been investigated in a number of naturally occurring cellulolytic microorganisms, such as *Clostridium thermocellum* (Maki, Leung et al. 2009, Singh, Mathur et al. 2018, Tian, Conway et al. 2019). However, since *C. thermocellum* is not easily engineered for biofuel production, an alternative approach has been to engineer microbes for both recombinant-product-forming and cellulose-utilizing abilities. *Bacillus* and its relatives are another group of bacteria that has been successfully altered for CBP. Cellulolytic strains of *B. subtilis* have been engineered to display cellulase enzymes (e.g., *C. thermocellum* Cel8A endoglucanase) covalently anchored to the peptidoglycan cell wall (Anderson, Robson et al. 2011). A trifunctional cellulosome has also been displayed on the surface of *B. subtilis* using a cell-wall-binding module of LytE (You, Zhang et al. 2012). Cellulolytic activity can also occur if the minicellulosome is freely secreted into the medium and not attached to the cell surface. Recently, *Geobacillus* has been demonstrated to perform CBP for the production of ethanol on wheat straw (Bashir, Sheng et al. 2019). Future studies are aimed at generating better CBP strains by varying the cellulosic enzyme combination and improving cellulose hydrolysis by increasing cellulase synthesis and specific activity.

Conversely, *Bacillus* isolates (individually or in consortia) also play a role in the petroleum industry, as they are used in tertiary recovery of oil from mature wells (Malik and Ahmed 2012, Gudiña, Pereira et al. 2013). Microbial enhanced oil recovery (MEOR) is used to recover additional oil from older wells after primary and secondary methods have been used. Due to its high viscosity, up to two-thirds or the petroleum in a reservoir can be refractile to recovery by conventional methods. *Bacillus* species appear to be well suited for MEOR since they produce biosurfactants and oil-degrading enzymes that reduce viscosity, promoting oil flow and eventual recovery and thus extending the life of the existing oil reservoir. In recent years, sophisticated screens based on cyclic lipopeptide fingerprinting have been used to isolate new *Bacillus* isolates with improved oil-recovery properties (Farias, Hissa et al. 2018). In addition, application of classical mutagenesis has been used to obtain mutants with improved biosurfactant production (Bouassida, Ghazala et al. 2018).

Agriculture

Bacillus is an important commercial product in the agricultural sector. *B. thuringiensis*, *Lysinibacillus sphaericus*, *Paenibacillus popilliae*, and *P. lentimorbus* have long been recognized as natural biopesticides effective against a wide range of insect pests (Schnepf, Crickmore et al. 1998, Schallmey, Singh et al. 2004, el-Bendary 2006). By far, the most widely used is *B. thuringiensis*, which accumulates delta-endotoxin pesticides, or Cry proteins, in large, highly visible crystals during the process of sporulation. The species is equipped with a potent arsenal of highly specific pesticides that vary widely in target specificity from strain to strain. Cry proteins are classified according to their amino acid sequence, but the classifications frequently correspond to the insect order that the toxin is effective against. For example, Cry1 proteins of *B. thuringiensis* serovar. *kurstaki* are toxic mainly to *Lepidoptera* species, Cry3 proteins of *B. thuringiensis* biovar. *tenebrionis* are toxic to certain Coleoptera, and Cry4 and Cry10 proteins of *B. thuringiensis* serovar. *israelensis* are highly toxic against mosquitoes and black flies (Schnepf et al. 1998). As of 2019, there were 26 *B. thuringiensis*-based active ingredients and eight labeled products registered by the United States Environmental Protection Agency (EPA) (https://www.epa.gov/ingredients-used-pesticide-products/biopesticide-active-ingredients; https://iaspub.epa.gov/apex/pesticides/f?p=PPLS:1). Interestingly, an almost equal number of pesticide

ingredients (18) and labeled products (nine) from other *Bacillus* species (e.g., *B. subtilis, B. firmus, B. amyloliquefaciens, B. mycoides, B. pumilus, Paenibacillus popilliae, B. cereus,* and *Lysinibacillus sphaericus*) have been registered by the EPA.

Moreover, with the advent of recombinant genetic techniques, the toxicity of these insecticides has been improved and the killing spectrum widened (Sanchis, Agaisse et al. 1996, Ghribj, Zouari et al. 2004, Liu and Dean 2006). The genes that encode these highly diverse toxins are now expressed directly into a variety of agricultural plants, such as corn, tobacco, and soybean, which further extends the usefulness of these *Bacillus* species in agriculture (Mehlo, Gahakwa et al. 2005, Christou, Capell et al. 2006). Between 1995 and 2018, 27 Bt *cry* genes have been approved for production in plants (i.e., plant incorporated protection, PIP): 12 for corn, 9 for cotton, 5 for soybean and 1 for potato (https://www.epa.gov/ingredients-used-pesticide-products/current-and-previously-registered-section-3-plant-incorporated).

The use of *Bacillus* for plant growth promotion (PGP) is an area with great potential for agriculture (Radhakrishnan, Hashem et al. 2017). Many species of *Bacillus* are found to be associated with plants as rhizosphere bacteria or endophytes (Mongkolthanaruk 2012). These species include *B. subtilis, B. amyloliquefaciens, B. licheniformis, B. pasteurii, B. cereus, B. pumilus, B. mycoides,* and *L. sphaericus*, *B. insolitus, B. velezensis, B. megaterium,* and *B. mojavensis*. Application of *B. subtilis* on plant seeds has been shown to greatly enhance the survival and robustness of the seedlings (Cavaglieri, Orlando et al. 2005, Ugoji, Laing et al. 2005). *Bacillus sensu lato* species, such as *Paenibacillus polymyxa*, *B. cereus*, and *B. subtilis*, are also used to facilitate the establishment and durability of sport turf grass. The mechanisms by which *Bacillus* promotes plant growth are still being investigated, but include the synthesis of plant growth hormones and antimicrobial agents (Mongkolthanaruk 2012) and the production of enzymes, such as phytase (Tye, Siu et al. 2002), that increase nutrient availability (Gange and Hagley 2004). Interaction of beneficial bacteria may also induce plant stress genes, protecting the host from both pathogenic attach and abiotic stress, such as drought (Timmusk, Grantcharova et al. 2005). Finally, the ability of many *Bacillus* PGP strains to form biofilms on plant surfaces suggests that niche exclusion may be a key mechanism for controlling plant pathogens (Haggag and Timmusk 2008, Timmusk, van West et al. 2009, Beauregard, Chai et al. 2013, Chen, Yan et al. 2013).

Medical Applications of *Bacillus*

The importance of *Bacillus* in the field of medicine was established in the late 1800s by the identification of *B. anthracis* by Pasteur and Koch as the causative agent of anthrax. However, the genus as a whole is considered relatively benign in terms of human and animal disease when compared to other Gram-positive genera, like *Staphylococcus* and *Streptococcus*. *B. cereus* and the highly related species *B. weihenstephanensis* can be responsible for gastrointestinal illnesses caused by contaminated food or dairy products. Pathogenesis requires a common set of enterotoxin genes (Phelps and McKillip 2002). On rare occasions *B. cereus* can be an opportunistic human pathogen in immunocompromised patients (Kotiranta, Lounatmaa et al. 2000, Schoeni and Wong 2005). The general public's awareness of *Bacillus* has been heightened by the use of *B. anthracis* in acts and threats of bioterrorism (Schneider, Parish et al. 2004).

Despite this heightened awareness, what is not nearly so well-known are the numerous beneficial medical-related products produce by this genus (Table 22.3). By far, the most predominant product class is antibiotics. Most of these are peptide antibiotics that are synthesized either by nonribosomal enzymatic processes or by ribosomal synthesis of linear peptides that then undergo post-translational modification and proteolytic processing (Stein 2005, Ortiz and Sansinenea 2019). Another important product class is the synthesis of human proteins and vaccines, processes which take advantage of *Bacillus'* natural ability to produce and secrete enzymes as previously described for industrial and food enzymes. Almost all of these processes have been developed using *B. subtilis*, *B. megaterium,* and *Brevibacillus brevis* (Udaka and Yamagata 1993–1994, Vary 1994, Meima, van Dijl et al. 2004, Westers, Westers et al. 2004, Ferreira, Ferreira et al. 2005, Terpe 2006, Karauzum, Updegrove et al. 2018). The advantage of *B. brevis* is that extracellular protease production is low and heterologous protein expression is high. Although the number of implemented processes is not as extensive as for other better known protein production host such as *E. coli* or yeast, there are nevertheless several successful examples, such as the use of *B. megaterium* to produce HIV proteins for commercial diagnostic tests (Vary 1994). More recently, *B. subtilis* has been developed as a needle-free delivery vehicle of immunogens for intranasal, sublingual, and oral immunization by utilizing recombinant forms that display the antigen of the surface of the spore (Amuguni and Tzipori 2012, McKenney, Driks et al. 2013).

As mentioned in the preceding section, products produced by *B. subtilis* and related species have GRAS status. Moreover, the microorganisms themselves can also be of medical use as a probiotic. Two major human applications are as prophylactics and as health food supplements. Key species found in these preparations are *B. subtilis, B. licheniformis, B. coagulans, B. pumilus*, *B. clausii*, nonpathogenic *B. cereus* strains and other spore formers from *Bacillus sensu lato*. In Europe (excluding the UK), *Bacillus* probiotics are used prophylactically against gastrointestinal ailments. In southeast Asia, they are used as an adjunct to antibiotic treatment (Sanders, Morelli et al. 2003, Hong, Duc et al. 2005, Cutting 2011). Use in Western societies, especially in the United States, have increased over the last several years, perhaps due to use in developing countries as discussed above and with the realization that strains closely related to *B. subtilis* 168 are already consumed in *nattō*, a traditional Japanese fermented soy bean delicacy (Ueda 1989, Hosoi and Kiuchi 2004, Elshaghabee, Rokana et al. 2017, Jezewska-Frackowiak, Seroczynska et al. 2018).

B. cereus, *B. subtilis*, and *B. licheniformis* have also been shown to be a very potent animal probiotics, especially in the pig and poultry sectors and in aquaculture (Alexopoulos, Georgoulakis et al. 2004, Barbosa, Serra et al. 2004, Cartman and La Ragione 2004, Farzanfar 2006, Tam, Uyen et al. 2006, Mingmongkolchai and Panbangred 2018, Kuebutornye, Abarike et al. 2019). The effectiveness of these *Bacillus* species is thought to lie in their ability to be retained in the gut of the animal by undergoing repeated rounds of vegetative growth, sporulation, and germination, during which time the production of

TABLE 22.3

Medical and Human Health Products Produced by *Bacillus* Species

Product	*Bacillus* Species
Antibiotics	
Bacitracin	*B. licheniformis*
Gramicidin	*Brevibacillus brevis*
Tyrocidines	*B. brevis*
Subtilin	*B. subtilis*
Polymyxins	*B. polymyxa*
Edeines	*B. brevis*
Butirosins	*B. circulans*
Diagnostic test	
AIDS coat proteins	*B. megaterium*
Antigens for vaccines	
PA (*B. anthracis*)	*B. subtilis*
Pneumolysin (*Streptococcus pneumonia*)	*B. subtilis*
P1 (*Neisseria meningitides*)	*B. subtilis*
OmpP2 (*Haemophilus influenzae*)	*B. subtilis*
PT subunits (*Bordetella pertussis*)	*B. subtilis*
Omps and Hsp60 (*Chlamydia pneumonis*)	*B. subtilis*
Tetanus toxin fragment C (TTFC),	*B. subtilis*
Adjuvant	*B. subtilis*
Human proteins	
Growth hormone	*B. subtilis*
Interferon	*B. subtilis*
Proinsulin	*B. subtilis*
Tissue plasminogen activator	*B. subtilis*
scFv	*B. subtilis*
Insulin-like growth factor 1 (IGF-1)	*B. subtilis*
Human Probiotic	*B. subtilis, B. licheniformis, B. cereus, B. pumilus, B. polyfermenticus SCD, B. clausii, B. laterosporus, B. coagulans, B. polymyxa, B. bifidum*
Bioactive fine chemicals	
Hyaluronic acid	*B. subtilis*
Glucosamine	*B. subtilis*
Amorphadiene	*B. subtilis*
scyllo-inositol	*B. subtilis*
Heparosan	*B. subtilis*

Note: This table presents a condensed description of products produced by *Bacillus* species. This table is by no means comprehensive since new products are continually introduced into the market.

Sources: The data are compiled from previously published lists: antigens for vaccines from (Ferreira, Ferreira et al. 2005) with permission from Anais da Academia Brasileira de Ciências, Brazil and (Amuguni and Tzipori 2012); antibiotic and human proteins from (Schallmey, Singh et al. 2004), with permission from, NRC Research Press, Canada; probiotics from (Hong, Duc et al. 2005) with permission from Blackwell Publishing, UK (Schallmey, Singh et al. 2004, Ferreira, Ferreira et al. 2005, Hong, Duc et al. 2005), and individual publications (hyaluronic acid from (Jia, Zhu et al. 2013), glucosamine from (Liu, Liu et al. 2013), amorphadiene from (Zhou, Zou et al. 2013), vaccine adjuvant and delivery (Amuguni and Tzipori 2012), *scyllo*-Inositol and Heparosan from (Gu, Xu et al. 2018), and IGF-1 from (Wang, Yu et al. 2017).

bacteriocins, antibiotics, or other antimicrobial agents effectively prevents the establishment of pathogenic bacteria in the gut (Cutting 2011). Moreover, use of probiotics in combination with its complementary prebiotic (i.e., synbiotic) can further enhance the health benefit (Hamasalim 2016).

B. subtilis is also used to identify and validate novel antibacterial targets. *In silico* genome analysis and functional testing have been used to identify potential targets for new antimicrobial agents. Possible targets include proteases, biosynthetic enzymes for amino acids and vitamins (Gerdes, Scholle et al. 2002, Kobayashi, Ehrlich et al. 2003, Perkins, Goese et al. 2004, Yocum and Patterson 2005), and regulatory elements such as riboswitches (Blount and Breaker 2007). Due to its well-developed tools for genetics and recombinant engineering, *B. subtilis* has also been used as a screening host to identify new antimicrobial agents (Bunyapaiboonsri, Ramstroem et al. 2003, Lacriola, Falk et al. 2013).

Cell Physiology and Development

By virtue of its ability to make endospores through a primitive yet intricate developmental process, the genus *Bacillus* has been intensively studied in the academic arena. *B. subtilis* has received most of this attention (and research funding) due its nonpathogenicity and its user-friendly genetic system. Practically all *B. subtilis* strains used in academic research are derived from strain 168, a tryptophan-requiring derivative of wild-type *B. subtilis* Marburg isolated after x-ray mutagenesis (Burkholder and Giles 1947). It was with this strain that DNA transformation was first demonstrated for this species (Spizizen 1958). *B. subtilis* 168 has become a paradigm for Gram-positive molecular and developmental biology, second only to *E. coli* as a bacterial model organism.

The genetic analysis of sporulation mutations in *B. subtilis* 168 (Hoch 1971) was the first step in the ongoing endeavor to identify the proteins required for sporulation, to elucidate how these proteins function together to create a spore, and to understand how the cell regulates their expression in response to the environmental conditions that trigger the process. Figure 22.4 shows the well-defined developmental stages that lead from a vegetative cell to a mature spore. At least 239 genes are required for completing the intricate developmental program that converts the growing cell into two asymmetric compartments, into which are assembled the macromolecular structures that constitute the spore (Piggot and Losick 2001, Higgins and Dworkin 2012, Watabe 2013). To help explain the choreography of this process, concepts such as sigma-factor cascades (Losick and Pero 1981, Stragier and Losick 1996), multicomponent phosphorelays (Burbulys, Trach et al. 1991, Hoch 1993), inter-compartmental cross-talk (Bassler and Losick 2006), and cell cannibalism and fratricide (Gonzalez-Pastor, Hobbs et al. 2003, Ellermeier, Hobbs et al. 2006) have been introduced. More importantly these concepts can be applied to understand other more complex developmental processes, such as fruiting body formation in *Myxococcus* and swarmer-stalked cell differentiation in *Caulobacter* (Shapiro and Losick 2000, Ryan and Shapiro 2003).

Since sporulation is an energy-intensive process and requires a variety of molecular building blocks, substantial work has been

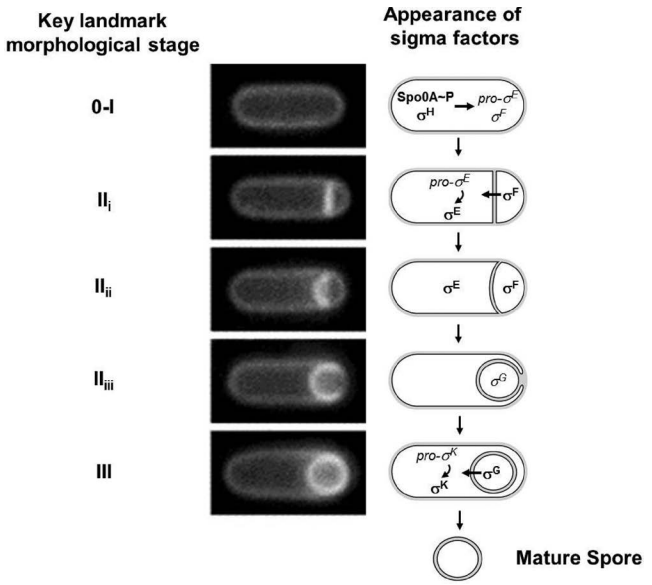

FIGURE 22.4 Key landmark morphological stages in sporulation. Sporulating cells of *B. subtilis* stained with the membrane dye TMA-DPH is depicted in the middle panel. The sequence from top to bottom shows a cell at the predivisional stage (0-I) progressing though stages of polar division (II) to engulfment (III); stages (IV–VI) from spore maturation to final release of the mature spore from the mother cell are not shown. The right panel shows a schematic representation of the landmark morphological events and cascade-like appearance of sporulation-specific sigma factors. Activate and inactivate factors are highlighted in bold and italics, respectively. Spo0A~P and sigma H (σ^H) are first activated in the predivisional cell (stage 0) by external environmental signals (Piggot and Losick 2001). During this stage, terminal DNA replication of the genome takes place. Spo0A~P and σ^H direct the transcription of early sporulation genes, includes those involved in formation of the asymmetric septum and the synthesis of inactive sigma F (σ^F) and pro-σ^E (stage I). Formation of the sporulation septum triggers the activation of σ^F (stage II). This regulatory factor directs the transcription of forespore-specific genes, include those involved in eliciting an interdepartmental signal, which emanates from the forespore to the mother cell and activate sigma E (σ^E) through processing of inactive proprotein precursor (pro-σ^E). Translocation of the genome into the preforespore compartment occurs during this time. Inactive sigma G (σ^G), whose transcription is initiated by σ^F, is then synthesized during engulfment (stages II$_{i\text{-}iii}$), or shortly thereafter, but requires engulfment completion (stage III) for activation. Again, interdepartmental signal transduction, controlled by σ^G, is required to activate sigma K (σ^K) via processing of the inactive proprotein form (pro-σ^K). Final stages involve maturation of the spore cortex, including depositing of the spore-coat proteins, and eventual release of the mature spore from the mother cell. (Illustration reprinted from *Developmental Cell*, vol. 1, Rudner, D. Z., and Losick, R., "Morphological coupling in development: lessons from Prokaryotes," pp. 733–742. Copyright 2001, with permission from Elsevier.)

undertaken to elucidate central carbon metabolism, the pentose phosphate pathway, nitrogen and phosphate assimilation, and the biosynthesis of amino acids, vitamins, nucleotides, and macromolecules. Special emphasis has been placed on understanding carbon, nitrogen, and phosphate metabolism, since a limitation in any of these compounds induces sporulation (Hulett 1996, Fisher 1999, Sonenshein 2001).

Importantly, sporulation represents just one of several possible outcomes of late stationary growth phase. Considerable attention has been given to other phenomena that occur during this period such as antibiotic production and genetic competence (Szurmant and Ordal 2004). Moreover, current thinking now places sporulation and these other cellular behaviors as part of an overarching developmental scheme that encompasses the bacterial population as a whole. This concept is referred to as bimodality (also referred to as bistability), a phenomenon in which a population of genetically identical cells can reversibly switch into different physiological states or cell types, such as one type that is geared to sporulate and a second that is not. The outcome of bimodality is to maximize the population's freedom of action to confront and overcome present and future adverse environmental conditions (Dubnau and Losick 2006), which has been referred to as bet-hedging. Within a stationary phase culture (or colony), cell types include individual motile and nonmotile cells, long-chained sessile cells, K-cells, and sporulating cells. The nonmotile cells secrete massive quantities of antibiotics and degradative enzymes (e.g., proteases, nucleases, and amylases), whereas some of the sessile cells release an extracellular matrix that is used to enable cells to adhere to a surface or to each other to form a biofilm (discussed next). These two cell types provide additional nutrients and protection to the cell population as it proceeds into late stationary growth phase. These cells can also induce cellular death and lysis and make the ultimate sacrifice to provide nutrients to the remainder of the cell population. The K-cells are arrested in cell growth and septum formation, but are active in DNA uptake and chromosomal integration, allowing these cells to potentially acquiring new functions to survive an increasingly nutrient-deficient environment. However, if nutrients are completely depleted, K-cells can transition into sporulation (Zeigler and Nicholson 2017).

Differentiation into multiple cell types is the first step to develop multicellular communities such as biofilms and fruiting bodies. It was originally thought that *B. subtilis* lacked this ability. However, studies of natural isolates (e.g., NCBI 3610) clearly show that this species can form such architecturally complex structures, in which sporulation, competence, and swimming are tightly interwoven (Branda, Gonzalez-Pastor et al. 2001, Branda, Gonzalez-Pastor et al. 2004, Shank and Kolter 2011, Vlamakis, Chai et al. 2013). Moreover, comparison of these natural isolates to domesticated counterparts, which have lost multicellularity, has led to the identification of master regulatory genes that control these processes (Kearns, Chu et al. 2005). Other controlling elements include extracellular peptides ("pheromones") that maintain cell-to-cell communication via quorum sensing and facilitate recruitment of cells for specific developmental roles. So far, peptide pheromones have been identified for sporulation, competence, and cell cannibalism/fratricide (Gonzalez-Pastor, Hobbs et al. 2003, Cormella and Grossman 2005).

To regulate the expression of genes necessary to carry out these developmental processes, several regulatory mechanisms are used in *B. subtilis*. One stratagem involves the deployment of alternate sigma subunits to temporally and spatially control the expression of specific groups of genes by altering the specificity of the RNA polymerase to recognize particular sets of promoters. *B. subtilis* contains 17 such sigma factors (Goldstein and Doi 1995, Haldenwang 1995, Missiakas and Raina 1998, Helman and Moran 2001, Helmann 2002). In most cases, the genes encoding these factors are themselves under control of a sigma subunit that is expressed at an earlier time in cell growth or in a preceding

step in a developmental process. During sporulation, five sigma factors are expressed in a cascade-like manner to link the expression of specific gene sets to the landmark stages (see Figure 22.4). As an added layer of regulation, the activity of the sigma factors themselves are modulated through protein processing or by inhibition via antisigma factors (Hughes and Mathee 1998).

The two-component regulatory mechanism found in *E. coli* and other bacteria also play a major regulatory role in *B. subtilis* cell development, as described above, by permitting it to detect environmental signals and then to convert these stimuli into an actionable response at the cellular level. *B. subtilis* has 34 identified two-component systems that control key developmental activities, including competence, sporulation, protein secretion, and cell growth. Combination of several two-component systems result in formation of a gene regulatory network (GRN), which has the ability to dramatically shift gene expression profiles within a cell resulting in different cell type states. How is this switch-like behavior achieved? For the three-gene regulatory network, *sinI, sinR,* and *slrR,* that controls alternation between single motile cells and long connected chains of sessile cells, double feed-back loops are used (Piggot 2010). Microfluidic technology has been used to dissect the stochastic decision between formation of these two cell forms, indicating that that the motile state is "memory-less," exhibiting no autonomous control of the time spent in this state, whereas sessile cell chaining is strictly timed. (Norman, Lord et al. 2013). For the KinA-Spo0F-Spo0B-Spo0A phosphorelay, which is used to activate the onset of sporulation, a multi-layered feedback regulatory network is used, involving not only these four phospho-activated regulators, but an array of other kinases, phosphatases, and other stationary phase regulators (KinB, KinC, RapA, AbrB, etc.). Recent microfluidic studies of individual cells have shown that the process to enter sporulation is heterogeneous, stochastic, and memory-less. Moreover, the build-up of Spo0A~P, the ultimate regulatory protein that initiates sporulation, does not occur in a progressively higher oscillating manner, as initially thought (Narula, Fujita et al. 2016), but is activated abruptly within a single cell cycle, just before asymmetric division. It is postulated that the stochastic behavior of Spo0A activation is due to "noise" generated by the intrinsic structure of the phosphorelay itself (Russell, Cabeen et al. 2017). For biofilm formation, which is also controlled by Spo0A, intermediate levels of Spo0A~P result in biofilm matrix gene expression whereas higher levels induce sporulation genes. Although Spo0A~P does not accumulate in an oscillating manner, as mentioned above, biofilm formation does (Martinez-Corral, Liu et al. 2018). This is likely due to nitrogen (limitation) codependency in which cells in the biofilm periphery is driven by glutamate consumption and cells in the interior by ammonium production (Liu, Prindle et al. 2015).

A third regulatory mechanism used in *B. subtilis* is called the riboswitch. This mechanism involves the direct binding of metabolites to nascent mRNA molecules to regulate their expression. Depending on the secondary structure of the 5' leader, binding leads to termination of the nascent RNA transcript (or in Gram-negative bacteria the prevention of translation by blocking access of the ribosome binding site). In the case of regulation of the riboflavin biosynthetic genes, the riboswitch repressor has been identified as FMN. Riboswitch elements have also been detected to regulated gene expression involved in SAM, lysine, thiamine, purine, pyrimidine, and other metabolic pathways (Mandal and Breaker 2004, Vitreschak, Rodionov et al. 2004, Sudarsan, Hammond et al. 2006). Other riboswitches involving uncharged tRNA molecules have also been identified for amino acid metabolism genes (Henkin 1994, Henkin and Yanofsky 2002). Interestingly, it has been proposed that this mechanism is a vestige of an ancient RNA world, when living organisms used RNA as their main heredity material and source of enzymes (ribozymes).

A final regulatory mechanism has recently been described, by which *B. subtilis* can respond to physiological cues to regulate gene expression and hence development. This mechanism relies not on protein or RNA sensors, but on codon frequencies. High levels of serine in the growth medium suppress biofilm formation. In mRNA molecules, serine can be encoded either by any of six codons. Interestingly, the frequency of TCN serine codons is overrepresented in the *sinR* gene, which encodes the major repressor of biofilm formation genes, relative to the rest of the *B. subtilis* genome. Under serine starvation conditions, the rate of *sinR* transcription is therefore significantly reduced; this reduction is alleviated if the TCN codons are mutated to AGC or AGU, which also code for serine. Apparently the TCN codons act as a serine-sensing mechanism, bringing information on the nutritional state of the cell to bear on the decision to form biofilms during stationary growth phase (Subramaniam, Deloughery et al. 2013).

All the metabolic and developmental processes described so far occur during aerobic growth. Although originally thought to be a strict aerobe, *B. subtilis* is also capable of either anaerobic growth using nitrate or fumarate as the final electron accepter, or fermentative growth from glucose and pyruvate resulting in various end products such as ethanol, acetate, lactate, acetoin, and 2,3-butanediol (Nakano, Dailly et al. 1997, Nakano and Zuber 1998, Hartig and Jahn 2012). Other species able to grow or at least respire under anaerobic condition include *B. licheniformis* (Bulthuis, Rommens et al. 1991, Clements, Miller et al. 2002), *B. megaterium* (Freedman, Peet et al. 2018), *B. cereus*, and *B. mojavensis*. Extensive studies of *B. subtilis* have identified and characterized the two component regulatory mechanism (*resDE*) controlling the expression of a set of genes that permit growth under anaerobic conditions (Nakano, Yang et al. 1995, Nakano, Zuber et al. 1996, Sun, Sharkova et al. 1996, Hartig and Jahn 2012). Along with Fnr (the key regulator of genes involved with nitrate respiration), reduced oxygen tension is directly sensed by the membrane-bound ResDE. The ResDE response, in turn, is modified by nitric oxide and the NsrR repressor. Recently the genome-wide analysis of ResD, NsrR, and Fur regulation in *B. subtilis* has been elucidated during anaerobic fermentative growth, showing a complex arrangement of overlapping regulatory sites control genes within this regulon (Chumsakul, Anantsri et al. 2017). This regulatory mechanism is also conserved among *Bacillus* species that are facultative anaerobes. It will be interesting to see how this anaerobic behavior fits with the extensive repertoire of aerobic cell development displayed by *B. subtilis* in the overall ecology of this bacterium.

Future Technology and Applications

The authors have been involved in preparation of this chapter two times; first, 10 years ago for the second edition of *Practical Handbook of Microbiology*, and the update 4 years later for

the third edition. Both times, we speculated on what the future held for the genus *Bacillus* in terms of the development of new technologies to further understand the genetics, physiology, and developmental biology of these species, and the application of this knowledge for new industrial and medical applications. We saw genomics and other "-omics" technologies as having a vital impact on *Bacillus* basic and applied research. This impact still applies today. We first noted that the determination of the *B. subtilis* genome sequence in 1997 (Kunst, Ogasawara et al. 1997) quickly led to the establishment of gene knock-out libraries (Schumann, Ehrlich et al. 2001, Kobayashi, Ehrlich et al. 2003), whole genome microarrays (Caldwell, Sapolsky et al. 2001, Lee, Zhang et al. 2001, Jürgen, Tobisch et al. 2005), regulatory element databases (Makita, Nakao et al. 2004), proteomic libraries (Bernhardt, Buttner et al. 1999, Hecker and Volker 2004), global mRNA half-life determinations (Hambraeus, von Wachenfeldt et al. 2003), minimal genome determinations (Westers, Dorenbos et al. 2003), and extensive metabolic flux determination (Fischer and Sauer 2005, Sauer and Elkmanns 2005). These approaches provided invaluable insights into *B. subtilis* as a developmental system and as an industrially important platform strain. In 2013, the *B. subtilis* genome sequence was updated to include toxin/antitoxin and small RNA genes, and a more complete metabolic network has been described (Belda, Sekowska et al. 2013). In addition, a more comprehensive inventory of proteins encoded by the *B. subtilis* genome was developed. More recent, the genome sequences of lab strains of *Bacillus subtilis* subsp. *subtilis* 168 and subspecies (e.g., *Bacillus subtilis* subsp. *spizizenii* strain W23; *Bacillus subtilis* subsp. *subtilis* KT3135, *Bacillus subtilis* "natto"), have been determined and used to elucidate the history of specific genetic lesions and ultimately the origin of 168 and W23 legacy strains (Zeigler, Pragai et al. 2008, Zeigler 2011, Kamada, Hase et al. 2014, Smith, Goldberg et al. 2014, Ahn, Jun et al. 2018). Finally, the introduction of microfluidics has taken place to analyze individual cells (Cabeen and Losick 2018), since it has been known for some time that average data obtained from microbial population-based studies may not be representative of the behavior, state, or phenotype of single cells. The ability to study single cells will make possible a more nuanced understanding of microbial development and physiology.

During this period, further improvements in the existing "-omics" platforms have also kept pace, such as metabolic flux (i.e., fluxome) and mathematical modeling (Dettwiler, Heinzle et al. 1993, Lee, Goel et al. 1997, Dasika, Gupta et al. 2004, Sauer 2006), identification of new global regulatory elements, such as sRNA (Silvaggi, Perkins et al. 2005, Silvaggi, Perkins et al. 2006), cataloging of global protein-protein interactions (Noirot and Noirot-Gros 2004), and establishment of metabolite compound libraries (i.e., metabolomics; Soga, Ohashi et al. 2003, Koek, Muilwijk et al. 2006). More recently, -omics platforms have expanded to include a two genome-scale deletion library (Koo, Kritikos et al. 2017), and attempts to combine -omics technology (i.e., mixomics) in single experiments to answer specific metabolic engineering questions such as riboflavin production (Hu, Lei et al. 2017).

Moreover, these data have been consolidated and organized into increasingly user-friendly "wiki"-style databases, facilitating the access and analysis of information on the genes, proteins, and regulatory elements of *B. subtilis*. Examples include *Subti*Wiki 1.0 and 2.0 (Michna, Zhu et al. 2016), *Subti*Pathway (Lammers, Florez et al. 2010), BacillOndex (Misirli, Wipat et al. 2013), and SporeWeb (Eijlander, de Jong et al. 2014).

More importantly, the establishment of these databases can be seen as part of a larger movement to dramatically improve the genetic toolbox of *B. subtilis* by the development of synthetic biology methodologies. This shift from traditional genetic engineering to synthetic biology-based technologies allows for faster, larger scale genetic changes. Over the last 10 years, development of such synthetic biology tools and methods have exploded by the development of newer gene expression systems based on the BioBrick concept, more efficient scar-less transformation systems and directed evolution platforms, counter-selection selection markers, marker-free knock-out and mutation delivery methods, large DNA cloning methods, cell-free and improved heterologous protein secretion, and genome size reduction to optimize *B. subtilis* as a production host (Itaya and Kaneko 2010, Toymentseva, Schrecke et al. 2012, Liu, Liu et al. 2013, Radeck, Kraft et al. 2013, Shi, Wang et al. 2013, Dong and Zhang 2014, Jeong, Park et al. 2015, Ogawa, Iwata et al. 2015, Tsuge, Sato et al. 2015, Ozturk, Ergun et al. 2017, Popp, Dotzler et al. 2017, Itaya, Sato et al. 2018, Liu, Zhang et al. 2019, Liu, Liu et al. 2019). More recently, the introduction of CRISPR-based tools has allowed faster and more precise alteration of the *B. subtilis* chromosome. These alterations include single base pair changes, insertions and deletions, including large DNA segments (So, Park et al. 2017). CRISPR/Cas systems that have been demonstrated to function in *Bacillus subtilis* are those from *Streptococcus pneumoniae* (Jiang, Bikard et al. 2013, Westbrook, Moo-Young et al. 2016, Burby and Simmons 2017a, Burby and Simmons 2017b) and *Streptococcus pyogenes* (Altenbuchner 2016, Zhang, Duan et al. 2016). Moreover, CRISPR/CasA gene editing has also been demonstrated in non-*Bacillus* model strains or for undomesticated strains with natural transformability: *B. licheniformis* and natural *Bacillus* spp. isolates found in the plant rhizosphere (Li, Cai et al. 2018, Yi, Li et al. 2018).

These new techniques have already borne fruit. For example, *B. subtilis* strains have been modified to contain the glyoxylate shunt, a pathway that allows for use of overflow metabolites as carbon source (Kabisch, Pratzka et al. 2013). These techniques have likewise facilitated the introduction of heterologous biosynthetic pathways for the production of commercially important compounds, such as amorphadiene (Zhou, Zou et al. 2013) and L-malate (Mu and Wen 2013). Finally, the first steps in construct a true chassis for SynBio engineering have taken place, such as reducing the genome to 2.68 Mb with 1,605 gene deletions, reducing carbon catabolite repression to simultaneously utilize of multiple carbon source from hydrolyzed biomass, engineering of the membrane to improve excretion of molecular compounds, and protecting the chassis against bacteriophage destruction (Tanaka, Henry et al. 2013, Ofir, Melamed et al. 2018, Liu, Liu et al. 2019).

Another trend we previously noted was the dramatically lowering cost of genomic (re)sequencing, allowing for the rapid determination of genetic differences between related species or industrial strain lineages (Albert, Dailidiene et al. 2005, Bennett, Barnes et al. 2005, Margulies, Egholm et al. 2005). These technologies include 454 pyrosequencing (Gharizadeh, Akhras et al. 2006), Illumina/Solexa, (Bentley, Balasubramanian et al. 2008)

SOLiD (Schuster 2008), and single molecule real time (SMRT) sequencing (Ardui, Ameur et al. 2018). Application of these sequencing technologies to improved strains recovered from classical mutagenesis programs can rapidly identify those critical mutations that result in higher metabolic function or enzyme overproduction. Moreover, this technology is being applied to rapidly sequence natural isolates of *B. subtilis* as a way to better understand genomic diversity (Earl, Losick et al. 2007, Zeigler, Pragai et al. 2008). Based on 2017 data, the number of sequenced *Bacillus* species and isolates has reached more than 13,000, an order of magnitude increase since our last review (https://gold.jgi-psf.org/; Reddy, Thomas et al. 2015, Mukherjee, Stamatis et al. 2017).

Of course, this wealth of genome sequence data opens the door to bring powerful -omics technologies to bear on the physiology and molecular biology of these species, perhaps uncovering novel developmental behaviors or industrial applications along the way. But in a broader sense, such studies also have a significant impact on how we perceive evolutionary changes at the genomic level. For example, based the high percentage of conserved genes among *Bacillus* species, one can consider genomes from highly related species to be actually composed of two components: a "core genome" shared by all members of the group, and a much larger "dispensable genome" consisting of partially shared or strain-specific genes. The core and dispensable genomes together comprise the group's "pangenome" (Tettelin, Masignani et al. 2005). An important implication of this concept is that bacteria are not completely clonal; that is, they do not inherit their genetic material (and therefore phenotypic traits) solely from a parental line, with a gradual accumulation of random mutations fixed by chance or natural selection. Instead, much of their genetic content is acquired through horizontal gene transfer (HGT) from nonrelated bacterial sources. One reasonable estimate, based on variations in G+C content in the DNA sequence, is that 552 of the roughly 4,112 protein-encoding genes in the *B. subtilis* chromosome entered the genome via HGT from non-*Bacillus* sources (Garcia-Vallve, Guzman et al. 2003). *B. cereus*, *B. thuringiensis*, and *B. anthracis* are known to share an extensive core genome while differing primarily in plasmid-borne pathogenicity genes (Rasko, Altherr et al. 2005). As the cost of DNA sequencing decreases through the introduction of new technologies (e.g., single-strand sequencing (Eid, Fehr et al. 2009), nanoball sequencing (Porreca 2010), and nanopore sequencing (Stoddart, Heron et al. 2009), genomes of a vast number of novel endospore-forming isolates will be determined, which future studies in *Bacillus* systematics will have to grapple with. Such approaches have already borne fruit. Using high-throughput sequencing technology, Kim et al. (2017) have identified core and strain-specific genes in 238 strains of five different *Bacillus* species from various food microbiomes; without resorting to culture-based whole genome sequencing, they were also able to reconstruct an unexpectedly large portion of the core genes, 98.22% of core genes in *B. amyloliquefaciens* and 97.77% of *B. subtilis*. Similar studies have already identified the number of harmful *Bacillus* species from food commodities procured from small and large retail outlets in a U.S. metropolitan area (Higgins, Pal et al. 2018), raw and pasteurized milk (Porcellato, Aspholm et al. 2019), and even in contaminated illegal drugs (Kalinowski, Ahrens et al. 2018). Alternative, we see similar approaches being used to identify novel beneficial *Bacillus* probiotic strains from various microbiome sources (i.e., gastrointestinal tracts (GITs) and feces) of chickens, pigs, ruminants, and aquatic animals (Mingmongkolchai and Panbangred 2018).

As we have asked in the past, what next is in store for *Bacillus* in terms of new technologies and applications? We see a continuing trend of coupling synthetic biology and sequencing technology with miniaturization, allowing single cells to be studied on a molecular level. As mentioned above, single-cell analysis has been used to dissect the expression patterns of key regulatory genes during sporulation (e.g., Spo0A) and biofilm development, gaining a fuller understanding of these complex developmental processes. Microfluidics has also been used to decipher other *Bacillus* regulation circuits, such as germination (Zabrocka, Langer et al. 2015), the stress response controlled by sigma B (Cabeen, Russell et al. 2017), and more recently the *Bacillus subtilis* cell cycle (Lee, Wu et al. 2019). In the continuing years, we see this technology as the gold standard in studies of *Bacillus* developmental biology. Together with deep DNA sequencing, we see microfluidics and cell sorting also being applied to more commercial applications of *Bacillus*; to allow the isolation of commercially-important strains that would otherwise be hidden within a larger population or at least minimize the emergence of nonproducers (Rugbjerg and Sommer 2019). For example, Walser et al. were able to develop a high-throughput colony screening method using nanoliter-reactors. By use of alginate beads, this technique allowed single cells in 35 nl reaction compartments to be assessed for biological process properties (Walser, Pellaux et al. 2009). Use of cell sorters to isolate individual cells with favorable properties could potentially establish strains producing important metabolites. This "molecular" assessment can also be visualized by live single-cell imaging techniques allowing for the study of an entire lineage or history starting from a single common ancestor (de Jong, Beilharz et al. 2011). Overlaying this technology with mixomics (e.g., integrating ^{13}C metabolic flux analysis, metabolomics, and transcriptomics as described by Hu, Lei et al. 2017) should result in a powerful technology platform to improve protein and small molecule production in *Bacillus* species. In summary, further refinement of these technologies should foster new and exciting insights into the biology of *Bacillus* so that both our understanding of this intriguing endospore-forming taxon and our ability to harness its biotechnological potential will continue to grow.

Acknowledgements

We thank Richard Losick for critical reading of the manuscript.

Introduction and History

The members of the genus *Bordetella* are small non-spore-forming Gram-negative aerobic coccobacilli. There are now 16 named species. Among them are the more notable and familiar mammalian pathogens *Bordetella pertussis* and *B. parapertussis*$_{hu}$, which cause whooping cough in humans; *B. parapertussis*$_{ov}$, which causes a respiratory disease in sheep; and *B. bronchiseptica,* which causes respiratory diseases in numerous mammals.[1–7]

B. pertussis was the first *Bordetella* identified in the early 1900s by Jules Bordet at the Pasteur Institute.[8] It was originally named *Haemophilus pertussis*, based on some phenotypic similarities to members of the *Haemophilus* genus, but subsequent biochemical and genetic studies showed little similarity with *Haemophilus*. In 1952, the distinct genus *Bordetella* was named in honor of Bordet's foundational work.[9,10]

B. holmesii, *B. trematum*, and *B. hinzii* have also been associated with human infection. Although *B. hinzii* is more commonly isolated from the respiratory tracts of birds, all three species have caused bloodborne infections in immunocompromised individuals.[11–13] *B. holmesii* is also responsible for causing respiratory disease in humans,[14–19] whereas *B. trematum* more typically causes wound infections.[20,21] Recent additions to the genus *Bordetella* include three organisms recovered from the respiratory tract of cystic fibrosis patients: *B. bronchialis*, *B. flabilis*, *and B. sputigena*.[22] *B. pseudohinzii* has been isolated from the respiratory system of mice.[23] *B. muralis*, *B. tumbae*, and *B. tumulicola* join *B. petrii* as organisms recovered in environmental samples.[24–27] *Bordetella avium*, more distantly related to the *B. bronchiseptica* cluster, is found in the respiratory tract of birds[28] and is a respiratory pathogen of poultry.[29] An overview of characteristics of the *Bordetella* can be found in Table 23.1.

Phylogenetic Relationships and Physiology

Genetic data suggest that four pathogenic species: *B. pertussis*, *B. parapertussis*$_{hu}$, B. *parapertussis*$_{ov}$, and *B. bronchiseptica* are related enough to actually be subspecies of a single ancestor of *B. bronchiseptica* and are sometimes referred to as the *B. bronchiseptica* cluster[2,3,30–32] An interesting aspect to note is that these organisms are capable of presenting markedly different antigenic profiles, depending on how they are grown. This is particularly important to be aware of if expression of desired proteins, such as those associated with virulence, is being sought for isolation or characterization.[1,33–40]

[*] We thank T. H. Stenson & M. S. Peppler for their contribution to this chapter in the second edition.

The regulation of virulence-associated antigens in the *Bordetella bronchiseptica* cluster is controlled by the *bvg* regulon.[1,33,41,42] "Bvg" is short for *Bordetella vir* (virulence) genes.[1,43] The Bvg regulon encodes three key gene products (BvgA, BvgS, and BvgR). BvgS and BvgA make up a classic two-component regulatory system involving a sensor and an activator, respectively. However, the BvgS sensor has more complexity than most common two-component sensors, including another phosphorylation site in what is known as the (cytoplasmic) linker dom ain.[1,38,39,44] The linker region and associated phosphorylation site add complexity to the signaling system that allows it to act more as a "rheostat switch" rather than an "on-off" signaler.[45–47] Evidence indicates that this allows the signaling system to control a more highly defined and complex phenotypic control than some other two-component global gene regulation systems. BvgS is a cytoplasmic membrane protein that senses environmental signals such as temperature, certain anions such as sulfate, and special molecules such as nicotinic acid.[44] At body temperatures and at *in vivo* conditions, BvgS is phosphorylated through a cascade relay system and transfers the phosphate group to the cytoplasmic protein BvgA. Phosphorylated BvgA can then bind to gene sequences that allow for transcription ("activation") of the virulence genes downstream from the promoter sites where BvgA binds.[48] The shorthand for genes that are transcribed this way is "*vags*," which stands for *vir*-activated genes. (Strictly speaking, these should be called "*bvg*"-activated genes" but the old name for the bvg locus was "*vir*" and the term *vags* was coined at that time).[48] Organisms expressing *vags* are said to be in the Bvg+ state. This is the fully virulent state of the organism as it is typically isolated from infected individuals.

One of the genes activated by BvgA is called BvgR, which is a repressor of a second family of genes called "*vrg*s" or *vir*-repressed genes.[40,49,50] When *vags* are highly expressed, *vrg* expression is repressed, and vice versa.[51] There are, however, a group of genes that can be expressed when environmental conditions result in an intermediate of BvgS and BvgA phosphorylation, and these are known as *bvg*-intermediate genes or "*vigs*."[52–56] The amount of phosphorylated BvgA has been shown to directly affect the positive or negative regulation of these *vigs*, independent of the BvgR repressor protein.[53,54,57] In sum, depending on the environment in which the organisms find themselves, certain gene products can be expressed or not, and this regulation is referred to as phenotypic modulation (or sometimes antigenic modulation).[34,35,46,54,58]

Environmental conditions are one way the organisms can change their phenotypes. Another mechanism is through mutation. In particular, a string of cytosines in the *bvgS* gene of *B. pertussis* is vulnerable to modification, causing *bvgS* to go out of frame and to not be expressed.[59] This results in a phenotype in which only *vrgs* are expressed and is therefore phenotypically Bvg–. These mutations are relatively rare (e.g., 1 in 10^6 colonies per subculture), depending on the strain, and are reversible.[38,59] The process has been called phase variation and importantly, in the pre-antibiotic era has been observed during the course of disease in *B. pertussis* human disease isolates.[60] When growing *Bordetella* organisms, one needs to keep in mind the potential for such alteration of phenotype, both spontaneous phase variation and the influence of media composition on antigenic modulation. Furthermore, despite relatively limited genetic variability, *B. pertussis* is recognized as having the ability to alter its genomic structure through accumulation of various mutations, including point mutations, gene deletions, and chromosomal inversions that are facilitated by insertion elements in its genome.[61–63] A gene-array study demonstrated alteration of gene expression in loci after as few as 12 culture passages.[64] When cultivating *B. pertussis*, it is of great importance to make a reserve stock culture of isolated strains and take care not to over-passage.

The remainder of this chapter will highlight the most important features of each species, with emphasis on *B. pertussis*.

Bordetella pertussis

Background

As discussed previously, *B. pertussis* was the first member of the *Bordetella* genus to be isolated and characterized. This priority reflects the negative impact the organism has had on human health as the agent of whooping cough in children. According to the Centers for Disease Control (CDC), prior to routine immunization in the United States in the 1940s, nearly 200,000 cases were recorded annually with approximately 9,000 fatalities.[65] Most affected were children under the age of 5 years, although whooping cough can occur at any age.[1,66,67] The incidence of pertussis in the United States for 2018 was reported to be 15,609 with five deaths.[68] This is substantially lower than the 2012 statistics mentioned in the previous edition, which was 48,277 with 20 deaths.[69]

Looking at the impact of pertussis disease globally is more challenging. Estimates of pertussis disease reported by the World Health Organization (WHO) in 1999 were 30.6 million cases and 390,000 deaths from pertussis in children younger than 5 years. In 2008, approximately 16 million cases of worldwide pertussis were estimated with 95% occurring in developing countries, resulting in approximately 195,000 child fatalities.[70] A more recent modeling study for 2014 estimated 24.1 million pertussis cases and 160,700 deaths in children younger than 5 years.[71]

Disease

B. pertussis is most often recognized for its role as the causative agent of whooping cough and the disease will be described in more detail in this section. As molecular detection of the organism has become more readily available, its possible implication in other respiratory disease such as community acquired pneumonia and asthma is being proposed and investigated.[72,73]

Whooping cough, also known as "pertussis," begins on average 7–10 days[74] after organisms are transferred from an infected individual to a susceptible person usually by aerosols generated through coughing or by direct contact with contaminated unwashed hands. *B. pertussis* was thought not to have any known environmental or animal reservoir nor was it traditionally thought to have a classical carriage state in people where it might be harbored in between outbreaks.[1,7,75–77] A recent systematic review of the literature, however, found that multiple studies have identified the presence of laboratory confirmed *B. pertussis* in asymptomatic household contacts and several studies provided evidence of asymptomatic transmission.[77]

Classic whooping cough, occurring primarily in unvaccinated children, will usually present with symptoms in a well-known pattern.[75] The first symptoms of classic pertussis disease will

usually appear within 5–10 days of exposure and are much like those of a common cold, including runny nose, sneezing, and in some, a slight fever. This is known as the catarrhal stage. The second or paroxysmal stage, which begins during the second week of illness is named for the most dramatic and hallmark symptoms of the disease, the bouts of severe coughing fits, or paroxysms that occur. In a typical case, the patient coughs repeatedly and forcefully, multiple times in rapid succession. In a concentrated attempt to draw in air, the glottis is often narrowed, and the inspiration produces a whoop or crowing sound that gives the disease its name. Coughing is commonly so forceful that vomiting occurs. Episodes of paroxysmal coughing increase during this stage and tend to be most common at night. The lack of oxygen caused by the cough sequence is one of the main dangers of the disease and can lead to brain damage or even death. Coughing can also result in broken blood vessels in the conjunctivae, hernia, and prolapsed rectum. As the individual's immune defenses gain the upper hand in 1–4 weeks, the severity and frequency of the paroxysmal coughs subside slowly, taking up to 6 months to completely disappear. Even then, subsequent respiratory infections or irritations can trigger a cough reminiscent of the paroxysmal stage. The recovery period is called the convalescent stage; and if the individual has not experienced the more severe consequences of the paroxysmal stage, there usually are no other permanent side effects. Individuals who have recovered from pertussis can get the disease again.[1,78]

Infants demonstrate the highest mortality, presenting often only with initial symptoms of apnea and cyanosis.[70] Seizures in this age group are not uncommon. Infant fatalities are often a result of severe pulmonary hypertension leading to cardiac arrest.[1] Adults and adolescents can have a range of symptoms from persistent cough to those consistent with classic pertussis described above.[70] Infection in these age groups can occur in those that have had either a prior pertussis infection or the full series of immunization as immune response does not appear to offer long lasting protection.

Treatment

Susceptibility testing of *B. pertussis* is not routinely performed. Susceptibility to a wide range of antibiotics with the exception of the oral cephalosporins have been shown *in vitro*.[74] Antibiotic treatment for *B. pertussis* as recommended by the CDC (http://www.cdc.gov/pertussis/clinical/treatment.html) include the macrolides with trimethoprim sulfamethoxazole as an alternative for patients over 1-year old. Rare erythromycin resistance has been demonstrated and shown to be a result of a mutation in the macrolide binding site of tSe 23s rRNA.[79]

Treatment should be administered prior to the onset of the paroxysmal stage to have the benefit of a shorter symptomatic period and clearing of organism from the upper respiratory tract. This leads to a shorter period of possible transmission to other susceptible individuals lasting only 5 days versus 3 weeks for an untreated patient.[80] If treatment is not administered until after the paroxysmal symptoms start, clinical benefit is questionable. This is thought to be consistent with the pathogenesis of disease that is mediated through toxin production. Once the protein toxins are bound and internalized into their target human cells, the damage is done. Killing the infecting bacteria will prevent any further toxin production, but has no effect on the toxins already doing their job.[1,81,82]

Vaccination

The first vaccine for pertussis was implemented in 1943 in Canada and in 1944 in the United States. Most commonly, this consisted of formalin-treated, whole killed bacteria. The whole-cell pertussis vaccine is administered with diphtheria and tetanus toxoids in a single intramuscular injection and is known as DPT or DTP. A form of this vaccine is still used in developing countries and typically follows a three- to five-dose regimen starting at 2 or 3 months of age, with boosters at 2-month intervals for the first three doses, and subsequent boosters at different intervals depending on the jurisdiction administering the vaccine.[83]

In developing countries as the number of whooping cough cases declined, in large part due to vaccination, public concern was voiced over the side effects of the whole-cell vaccine. Concern peaked in the late 1970s and early 1980s when purported vaccine-associated encephalopathy and deaths occurred. Several countries suspended use of the vaccine. While no scientific study had ever established a clear cause-and-effect relationship between vaccination and brain damage or death, the scientific community responded by pursuing systematic studies of the molecular basis of disease and of protective components in the vaccine.[84–86] In 1981, Japan produced the first "acellular" vaccines, which were made from components released into broth during growth.[87] The Japanese vaccines were used with good effect in Japan; but in North America and Europe, further purification and quantification of individual antigens followed by extensive clinical trials, resulted in the first acellular vaccines approved for use in the United States in the late 1990s.[88] Because of the increased costs associated with production of the acellular vaccines, many countries continue to vaccinate with the whole-cell pertussis vacinne.[89] There are currently several combination vaccines offering an acellular pertussis component along with diphtheria and tetanus protections in use in the United States.

DTaP is recommended to be administered at 2, 4, 6, and 15–18 months with a fifth dose between 4 and 6 years of age. Additional recommendations include administering a dose of Tdap to adolescents and adults to help reduce the number of infections in these age groups. To improve protection of the most vulnerable in the population, the newborn, the CDC recommendations include vaccinating pregnant women between weeks 27 and 36 of each pregnancy as that should allow maternal antibodies to protect the infants until they begin to receive their own immunizations.[90] Research supports this with evidence of improved infant protection and by demonstrating newborns have statistically significant higher antibody titers against pertussis when mothers were vaccinated.[91–95] Despite this benefit, there is also some evidence that high maternal antibody titers could actually interfere with development of an infant's own immunity.[96,97] Additional protective strategy for newborns involves cocooning—urging all family members and potential close contacts of the infant to be up-to-date on their pertussis immunization.[98]

In the years that followed the administration of the acellular vaccines, there had been increased incidents of pertussis reported by the CDC with numbers reaching close to 50,000 cases in the United States in 2012.[99] Outbreaks had been documented in many states in the United States at that time, calling into question the effectiveness of the attenuated vaccines in preventing pertussis illness and brought attention to the apparent

waning immunity.[98,100,101] In 2014, the pertussis vaccination was reportedly at 86% globally, but concern over increasing pertussis numbers existed.[102] This prompted the WHO to conduct a review of data from 19 countries. They concluded a global resurgence of the illness had not occurred, rather the dramatic increases in pertussis illness were limited to five countries: the United States, United Kingdom, Australia, Chile, and Portugal. The WHO further stated that several factors were contributing to the increase of pertussis in these countries, such as improvements in awareness, surveillance, and diagnosis in addition to the naturally occurring cycles of increased pertussis that happen every 2–5 years.[103] While these factors do, in fact, play an important role in the recent pertussis situation, it has been proposed that the real key to understanding the resurgence of pertussis disease lies in understanding the differences in immune response between the vaccine types, in particular the inability of the attenuated vaccine to provoke a mucosal immune response and prevent colonization with the organism, which appears to happen with the whole-cell vaccine or natural infection.[104–105]

To combat pertussis, work continues to develop and test new formulations of vaccine in hopes of achieving a more lasting protection. Researchers are investigating the use of live, attenuated intranasal or oral vaccines as an alternative to those currently in use.[106–112]

Clinical and Laboratory Diagnosis

Diagnosis of whooping cough can be accomplished by defined clinical criteria but is clearly strengthened by laboratory confirmation. Differing clinical definitions of whooping cough have resulted in different interpretations of vaccine efficacy and therefore need to be clearly stated and applied for meaningful results.[87] The ability to choose the most advantageous method of laboratory diagnosis for pertussis is greatly influenced by variability of several factors including: disease stage, vaccination and patient age. A recommendation for navigating these complexities is available in schematic form in the literature.[113]

Isolation and Growth

Isolation of the organism has been an important element in understanding infectious pertussis disease and is vital for future study. The "gold standard" for diagnosis of whooping cough is still the traditional isolation of the causative agent by growth on appropriate culture media. Isolation of living bacteria also provides a resource from which epidemiological studies of changes in genetic and antigenic structure can be monitored over time. Cultivation of living organisms from active cases continues to present a challenge. Culture is most successful within the first 2 weeks of the onset of cough.[114] Traditionally, collection of a sample involved using the cough plate technique: a Bordet-Gengou (BG) agar plate held in front of the patient during a coughing episode, to recover organism.[115]

Samples are typically taken by one of two means: a nasopharyngeal (NP) swab or an NP aspirate. *B. pertussis* can be found in ciliated epithelial cells which explains why the NP and not the throat, are acceptable for culture. The NP swab consists of a long (14 cm) flexible wire with a small swab. Dacron, calcium alginate, or nylon are acceptable materials for the swab, which is designed to be inserted through the nose to reach the back of the nasopharynx where the organisms reside. To increase the success of isolation, separate samples are often taken from each side of the nose. These are then either directly plated onto appropriate agar medium such as Regan-Lowe (RL), containing 40 g mL^{-1} cephalexin to suppress the growth of other intranasal bacteria, or are placed in a suitable transport medium (i.e., Stainer-Scholte broth (SSB) or RL transport medium) for delivery to a laboratory for further subculture. Likewise, the thin canula attached to a syringe containing a buffered wash solution is used to collect an NP aspirate from the same area.[116]

In successful culture attempts, white colonies about 1 mm in diameter appear within 3–7 days (may be up to 12 days) of incubation in a humidified environment at 36°C.[67] Recommended CO_2 level is less than 4%. Automated bacterial identification systems are not reliable for identification of *B. pertussis*. Biochemicals such as catalase, oxidase, urease, citrate, and nitrate were traditionally performed. *B. pertussis* is typically described as being nonmotile, but recent observations of motile strains from both laboratory-derived and clinical sources have been described.[117] More modern methods of identification are recommended over traditional biochemicals and include PCR and MALDI-TOF.[74]

Once viable organisms are recovered, they can be either lyophilized or frozen at –70°C for long-term storage. A Dacron swab is used to remove the pure growth from an entire 9-cm plate, and suspended in a suitable cryoprotective medium, such as 20% (w/v) skim milk.[118] For research purposes, growth of organisms from stock on BG medium containing 15% defibrinated sheep blood is recommended.[119] This is so the phenotype of the *Bordetella* organisms can be observed and sub-cultured faithfully. For example, wild-type (Bvg+) clinical isolates of *B. pertussis* grow as small (1–2 mm diameter) domed colonies with notable hemolysis on BG agar. Bvg– phase variants, in contrast, form larger (3–4 mm) flat, nonhemolytic colonies see Figure 23.1.[119] BG agar does not have the same shelf life as R-L agar but the charcoal base of R-L agar prevents the observation of hemolysis. For growth in broth, the preferred medium is SSB or modified SSB, which is aerated through shaking or by having a large surface-to-volume ratio for static liquid culture.[119,120] SSB is a synthetic medium developed for the commercial production of pertussis vaccine and has a good

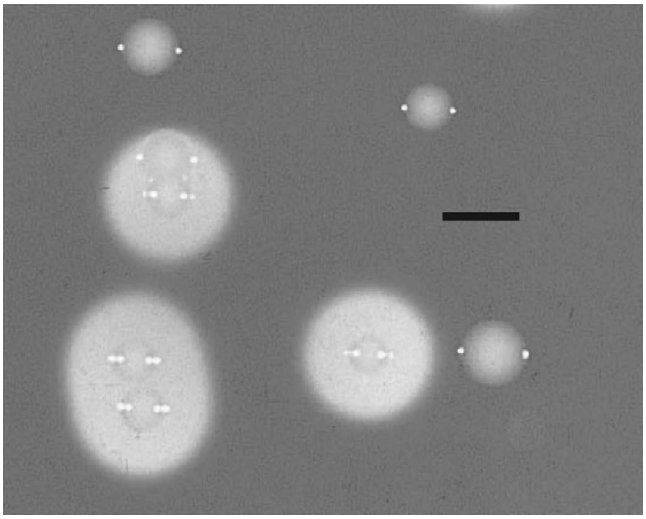

FIGURE 23.1 Colonies of *B. pertussis* phase variants on Bordet–Gengou agar (BGA). Bvg+ (domed, hemolytic) and Bvg– (flat, non-hemolytic). Bar = 3 mm.

track record. A drawback is that it must be made *de novo* in the laboratory because there is no commercial supplier. Other broth media have been used but the defined composition of SSB is a distinct advantage when it comes to reproducibility.

Non-culture Identification of Bordetella pertussis

Polymerase Chain Reaction (PCR). One of the great advances in the diagnosis of whooping cough has been the introduction of PCR and its evolution from earlier conventional PCR to real-time PCR (RT-PCR), to its incorporation into multiplex respiratory panels. Many clinical labs in the United States have adopted these modern methodologies over traditional culture, and it has had a real impact on the number of reported cases.[121] PCR is an acceptable test method during the first 4 weeks of cough.[114] The technique is highly specific and is sensitive enough to detect very low numbers of organism. Unfortunately, the presence of nonviable DNA in a sample is also detectable, so care is needed to prevent contaminating DNA from giving a false positive and causing a pseudooutbreak.[122] Healthcare providers are cautioned to be aware of the ability of pertussis DNA, found in some vaccines, to contaminate patient samples. Best practices mandate that to prevent such false positives from occurring, specimen collection for pertussis testing should not take place in the same area as pertussis vaccination.[123] While both NP aspirate and NP swab are suitable for PCR analysis, an NP aspirate is preferred because the swab is easier to contaminate.[74,123,124] Due to the numerous commercially available or in-house developed PCR tests for pertussis testing, clinicians should consult the protocol issued by the testing laboratory for specifics about specimen collection and transport.

Several different targets are utilized in PCR testing of the *Bordetella*. Several insertion sequences (IS) were identified and used in early PCR testing but cross-reactivity had led to some diagnostic problems. IS*481* present in *B. pertussis*, has cross reactivity with both *B. holmesii* and less often *B. bronchiseptica*. IS*1002* is present in both *B. pertussis* and *B. parapertussis* and IS*1001* is found with *B. parapertussis* and *B. bronchiseptica*.[75,125]

One assay has been developed that targets all three in an effort to better identify the species of *Bordetella* present.[126] The pertussis toxin promotor (*ptxP*) gene has also been used to enhance detection of *B. pertussis*.[127–130] The IS*1001*-like (*IS1001Bhii)* target can be used to enhance discrimination of *B. holmesii*.[131] An additional target for *B. holmesii* is *recA*, an identified housekeeping gene.[132] A PCR test has been developed to detect Erythromycin resistant *B. pertussis* directly in nasal-pharyngeal swabs.[133]

Advances in technology have resulted in the automation of PCR assays that can be completed in a matter of hours. Such technology exists for assays designed strictly to identify *Bordetella* or for those multiplex assays that test for a host of additional potential viral and bacterial respiratory pathogens.[134] The latter are commercially available and serve as useful tools for clinical laboratories that lack a fully functional molecular laboratory.[113] The former can be commercially available or may be developed in house by a particular laboratory. Validation of all laboratory developed assays should be performed. This will assure quality. and guidelines for performing validations can be found in the literature.[113]

It is important to be aware of the limitations and variability of PCR result reporting from the many assays available for use in laboratory testing. PCR with a single-copy target may result in a false negative result due to gene loss as evidenced by the fluidity of the *Bordetella* genomes.[113] Diagnostic algorithms to aid in interpretation of molecular analysis for pertussis disease have been proposed and discussed in the literature.[135] It is predicted that the inclusion of *B. pertussis* in routine multiplex PCR used to diagnose respiratory disease may further implicate the organism in additional respiratory disease such as community acquired pneumonia.[72]

Fluorescence Microscopy. Fluorescently labeled monoclonal antibody is commercially available to detect and distinguish between *B. pertussis* and *B. parapertussis*. The specificity is adequate, but it is no longer recommended by the CDC for clinical case definitions.[136,137] In settings where PCR equipment is not available, the monoclonal direct fluorescent antibody can be an adjunct to culture.[74]

Serological Diagnostics. Problems with diagnosis of pertussis through serology exist and include: cross-reactivity, vaccine interference, and previous *Bordetella* infections. Despite these, it remains an important method of diagnosis while patients are in the latter stages of pertussis disease. The CDC recommends serology as a diagnostic tool to be used beginning 2 weeks after cough begins through week 12.

A number of studies have demonstrated the feasibility of using isolated antigens from *B. pertussis* as the foundation of antibody-based diagnosis by enzyme-linked immunosorbent assays (ELISAs).[113] Issues for standardization surround the number of serum samples and the number of antigens needed for reliability of the results.[138,139] Serologic tests are often used to retrospectively diagnose pertussis illness in adults, adolescents, and in older children.[75] This method should not be used, however, within a year of vaccination with acellular pertussis vaccine.[74] The CDC classifies a clinical case with only serological evidence of pertussis as a probable case.[137]

Epidemiology

Pertussis has changed from a disease of principally nonimmunized infants, aged newborn to 6 months, to a disease that includes a large proportion of cases in adolescents and adults.[140] Increased recognition and diagnosis of pertussis in older children, adolescents, and adults has been a result of several factors including: the clarification of case definitions, increased emphasis on reporting, and the availability of new molecular diagnostic technologies.[140]

CDC data on pertussis in the United States dates back to the 1920s. Passive reporting was done between 1922 and 1949 and cases were in the hundreds of thousands annually. After the introduction of the whole-cell vaccine in the 1940s, the number of pertussis cases trended downward to less than 10,000 by the mid-1960s. They remained about this level until the change to the attenuated pertussis vaccine was implemented. Since the change, the number of pertussis cases has gradually risen to greater than 15,000 annually with several years spiking much higher. The latest data shows a downward trend has once again been achieved in 2018.[68]

The early use of PCR for diagnosing pertussis was not without controversy as it contributed to misidentification of other members of the *Bordetella*, including *B. parapertussis* and *B. holmesii*, as *B. pertussis.* This is believed to be responsible for causing inaccuracies in reports of pertussis numbers resulting in false elevation. Another potential source of false positive diagnosis of pertussis has been shown to be the contamination of PCR specimens with DNA from pertussis vaccines. Vaccine DNA remains on environmental surfaces or the hands of workers in clinics

where vaccines are administered and can contaminate specimens and lead to false reporting.[122]

It is also believed that the increasing numbers of unvaccinated children is a contributing factor to pertussis like illness in the United States.[142] Waning immunity helps to create vulnerable populations.[143,144]

In addition to the theories that have been proposed as contributing factors to the recent increase of pertussis infection seen in the United States between 2012 and 2014, emergence of vaccine resistant strains should be mentioned. Data suggests that evolutionary changes have led to the emergence of and persistence of clinical pertussis strains that differ from the vaccine strain. This difference appears to have emerged as a persisting evolutionary change in gene order.[145] It is important that the emergence and persistence of vaccine resistant strains should continue to be investigated.[146] Specifics of some of these changes are highlighted in the next few sections.

Pertactin Negative Pertussis

As the investigation into the biological cause of increasing numbers of pertussis disease began, documented clinical strains showing antigenic differences from vaccine components strains were found.[147,148] Pertactin is a major component in acellular vaccines and reports of pertactin negative strains of pertussis have been demonstrated in France,[149] Finland,[150] Japan,[151] Australia,[152] and the United States[153] prompting the attention of the CDC. The resulting CDC investigation of the genomic diversity of clinical isolates recovered in the United States between 2000 and 2013 demonstrated that pertactin-deficient strains increased markedly in number from 2010 to 2013.[154,155] Reports from Australian outbreaks that occurred between 2013 to 2017 indicate that pertactin-negative strains continued to persist.[152] Contrastingly, analysis of pertussis in Argentina, where vaccination with wP remains, showed low prevalence of pertactin-negative strains.[156] Monitoring of pertactin-negative strains is important for understanding changing pertussis disease and should continue.

Pertussis Toxin Production

The emergence of pertussis strains that produce higher levels of pertussis toxin associated with the *ptxP3* allele were first identified in the 1980s but continue to persist throughout the world.[148] Nearly 96% of isolates analyzed from a recent U.S. outbreak were *ptxP3* strains and produced higher levels of pertussis toxin.[155] Australia also saw an increase of *ptxP3* in its most recently described outbreak.[152] One European study looked at isolates from nine European countries between 2012 and 2015 and nearly 96% of the strains tested were found to carry the *ptxP3* allele.[157]

Research Methods

The characterization of different isolates of *B. pertussis* is an important adjunct in monitoring changing trends in pertussis disease.[1,81,158] An elaborate scheme for characterizing *B. pertussis* isolates by agglutination with adsorbed polyclonal antisera was developed by Eldering in the 1960s.[159,160] As antigens associated with virulence were characterized genetically and biochemically, assays had been developed to replace the traditional serological method with molecular techniques. These new methods provide much more sensitive and sophisticated tools for observing subtle changes among isolates.[161–163] Molecular analysis continues to be advanced and is applied by researchers to understand global pertussis patterns.[164,165]

Genomic Polymorphisms

Pulsed-field gel electrophoresis (PFGE) has provided a reliable means by which to fingerprint *B. pertussis* isolates.[166–170] This is a particularly useful tool for confirming the identity of known research strains, akin to karyotyping of tissue culture cells. For epidemiology of disease isolates, PFGE provides an entry point for comparisons. Other genomic techniques have been proposed for strain monitoring, but none has been uniformly adopted worldwide.[170,171]

Allelic Polymorphisms

Changes in gene sequences have been used to determine the genetic relatedness of individual strains of *B. pertussis* and for tracking changes in specific genes. Of special interest are genes associated with virulence that would amount to antigenic drift over time in disease isolates. Changes based on PCR and sequencing or single-strand polymorphisms have demonstrated insertions and deletions in pertussis toxin, pertactin, and fimbria genes that support a shift to new allelic types over time.[170,171,173–175]

Pathogenesis and Virulence

Overview

Because *B. pertussis* is only found in humans, the use of an animal model is necessary to study the definitive stepwise process of infection and disease. A commonly used animal model is the mouse aerosol challenge model. While mice provide insights into the disease process, it is important to note that the aerosol challenge causes a pneumonia and mice do not experience paroxysmal coughing.[176–178] The following scenario is pieced together from various animal sources and from human clinical data, but there are gaps that remain.

Once *B. pertussis* is inoculated into the human nose by aerosol or by hands contaminated with infected secretions, the organism colonizes the nasopharynx using adhesins, most likely fimbriae or filamentous hemagglutinin (FHA).[1,179,180] Organisms also colonize the bronchi where they adhere to the cilia of the respiratory epithelium by means of FHA, and likely other adhesins, and begin to grow. As part of their growth, several toxins are secreted that cause the cilia to stop beating and also affect the respiratory epithelium to cause an accumulation of mucus and trigger the paroxysmal cough.[1,74,181]

Organisms appear to be sequestered in the respiratory tree and are not found in the bloodstream, even in immunocompromised patients. Thus, *B. pertussis* does its damage in the extracellular compartment where in nonlethal cases it is eventually cleared by the host immune response and the respiratory epithelium returns to normal.[1,70] Post mortem examination of infant respiratory tissue samples showed histopathology characterized with necrotizing bronchiolitis, bronchopneumonia, pulmonary hemorrhage, pulmonary edema, and angiolymphatic leukocytosis.[182] Severe leukocytosis has been examined as an outcome predictor of severe infant disease.[183]

An impressive body of work has been devoted to the study of the molecular basis of pathogenesis in whooping cough. The goal of much of this work was to establish which proteins should be included in acellular vaccines to give the most complete immunity to *B. pertussis*. Not all the molecules known to contribute to virulence are found in an acellular vaccine, nor are all acellular vaccines composed of the same number of proteins. The following list will therefore be grouped based on whether the molecules

are found in the acellular vaccine or not, and on the basis of how commonly they are found in the vaccine.

Virulence Factors of Bordetella pertussis

Virulence Factors Included in Acellular Vaccines.

1. **Pertussis toxin (Ptx)**: The one protein found in all acellular vaccines is pertussis toxin. It has been shown to be necessary to produce disease in most animal models and has been attributed to many biological activities. This is due to its ability to enter cells and modify the inhibitory GTP binding protein of the mammalian cell adenylate cyclase system by covalently adding ADP-ribose derived from intracellular nicotinamide adenine dinucleotide (NAD). The consequence to the target cell is deregulation of normal cellular processes and, depending on the cell affected, can result in altered function that ultimately assists *B. pertussis* in its ability to infect in the lung. The crystal structure of Ptx has been determined; it is a unique A-B type toxin with an A (enzymatically active) subunit called S1 and a heteropentameric B (binding) subunit composed of one S2, one S3, two S4, and one S5 subunit.[164] Despite the clear association of Ptx with virulence, there is no definitive correlation between serum anti-Ptx levels and protection in humans. Ptx, along with cholera toxin, has also been widely used to study the cellular physiology of the 16 mammalian adenylate cyclase systems and other regulatory systems for which GTP-binding proteins play a key role in cellular homeostasis.[1,74,180,181] Worldwide emergence and persistence of various strains of *B. pertussis* that are found to contain the ptxP3 allele, which is associated with increased toxin production has been documented.[152,155] It is still unclear what exact role this emergence might play in recent increases in infection.[185]
2. **Filamentous hemagglutinin (FHA):** FHA is a unique adhesin with a rod-like structure and an affinity for sulfated glycolipids and cholesterol. It is presumed that antibody to FHA provides protection from colonization with virulent *B. pertussis*.[1,179,180]
3. **Pertactin (Prn):** Pertactin is an outer-membrane protein that has adhesive characteristics.[1,179,186,187] Its importance as a vaccine component was strongly supported by results of the early Japanese acellular vaccines that showed the presence of Prn in the most protective vaccines.[187] However the emergence of pertactin-negative strains along with pertactin polymorphism is a cause for concern and its impact on acellular vaccine protectiveness is unclear.[151] Research indicates that the majority of strains isolated in the United States during recent outbreaks were in fact, Prn negative.[188,189]
4. **Fimbriae (Fim):** Two major antigenic types of fimbriae recognized in *B. pertussis* are Fim2 and Fim3. Each is thought to play a role in the attachment of *B. pertussis* to respiratory epithelium. Subunits of each type have also been identified.[190,191] Epidemiological evidence supported the importance of having both Fim types in whole cell vaccines, and this observation was applied to the production of some of the licensed acellular vaccines.[1,180,187,192]

Virulence Factors Not Included in Acellular Vaccines.

1. **Adenylate cyclase-hemolysin or adenylate cyclase toxin (CyaA):** Early work by Alison Weiss showed that *cya* mutants were as avirulent in mice as mutants in pertussis toxin,[193,194] but the cloning and characterization of this complex molecule lagged behind that of the other virulence factors. It was never included in any of the acellular vaccines that are currently licensed. CyaA is responsible for the hemolysis produced by Bvg+ organisms on BGA and is also one of the most actively catalytic adenylate cyclases known in the bacterial world.[1,180,195,196] For this reason, it has been successfully used as a reporter molecule for bacterial two-hybrid systems.[197] In addition, the adenylate cyclase portion of this bifunctional protein is known to impede phagocytosis of *B. pertussis* by human neutrophils through its enzymatic activity on these host cells.[198–201]
2. **BrkA:** This protein is another *vag* product and gets its name from its ability to confer to *Bordetella* resistance to killing by serum.[1,202,203] The protein is a member of the autotransporter family of proteins and can mediate its own assembly into the outer membrane of *B. pertussis*.[1,204–206]
3. **Lipopolysaccharide (LPS):** The lipopolysaccharide of *B. pertussis* has the same endotoxic characteristics as other typical gram-negative bacteria but interestingly does not produce O side chains. On SDS-PAGE and oxidative silver staining, the great majority of clinical isolates produce two distinct bands.[37] The composition of these two species of short LPS is known, as are all of the genes responsible for its production.[207–209] Due to its endotoxicity, LPS was targeted as one of the components that should be absent from any acellular pertussis vaccine.[87]
4. **Tracheal cytotoxin (TCT):** TCT is a breakdown product of peptidoglycan synthesis in most *Bordetellae*, regardless of phase or phenotypic state. It has a profound effect on causing cilia to stop beating and is thought to be important in the pathogenesis of *Bordetella* disease. However, it is poorly immunogenic and has not been included in any acellular vaccine.[1,180,192,210]
5. **Dermonecrotic toxin (DNT)**: DNT, a product of a *vag*, is another true toxin that is sensitive to denaturation by heat and is poorly immunogenic. It causes cell death in low concentrations and is thought to contribute to pertussis pathogenesis in humans although its precise role is still unknown.[1,180,192,211]

Bordetella parapertussis

B. parapertussis exists in two distinct lineages. One, designated *B. parapertussis*$_{hu}$, is a pathogen of humans and causes a milder form of whooping cough. The other lineage is designated *B. parapertussis*$_{ov}$ and is principally a respiratory pathogen of sheep, although human infections have been reported.[30] Each lineage is impressively homogeneous genetically with minor differences among strains, especially *B. parapertussis*$_{hu}$.[3]

One of the most intriguing aspects of *B. parapertussis*$_{hu}$ is its ability to cause a disease very similar to whooping cough without

producing pertussis toxin. Whether or not *B. parapertussis*$_{hu}$ has caused true outbreaks of whooping cough on its own in the past remains open for debate.[212,213]

An interesting difference worth noting between *B. parapertussis*$_{hu}$ and *B. pertussis* includes the presence of a complete O antigen on *B. parapertussis*$_{hu}$. It has been demonstrated that the O antigen plays a role in the inhibition of binding of *B. pertussis*-induced antibodies allowing the survival of *B. parapertussis* in immune hosts.[213]

B. parapertussis$_{hu}$ grows more rapidly than *B. pertussis* and is able to grow on blood-free media (such as nutrient agar), where it typically produces a pronounced browning of the medium due to the expression of an enzyme that cleaves tyrosine.[9] Colonies on RL appear larger and are not as shiny as *B. pertussis*. One routine biochemical difference between *B. pertussis* and *B. parapertussis* is the oxidase reaction, with *B. parapertussis* testing negative. Like *B. pertussis*, attempts at identification on commercial gram-negative identification systems are not recommended, while MALDI-TOF and molecular methods are. Molecular testing indicates the presence of *B. parapertussis* when positive results are reported for assays that target both IS1001 and IS1002.[125]

An important question that has been raised in the past is whether *B. parapertussis* might have had a resurgence with the advent of acellular pertussis vaccines. There is some evidence that whole-cell pertussis vaccines provided some cross-protection to *B. parapertussis*$_{hu}$.[214] In contrast, the composition of even the five-component vaccines would not necessarily have enough similarity to antigens in *B. parapertussis*$_{hu}$ to have the same beneficial effect. Animal models show that there appears to be an enhancement of *B. parapertussis* infection following vaccination with aP vaccine allowing the development of more favorable hosts.[215] Reports on this question have come to conflicting conclusions.[216,217] Recent work, in the mouse model, with a new protein candidate for inclusion in pertussis vaccine, AfuA, indicated immune protection against both *B. pertussis* and *B. parapertussis* was achieved.[218]

Not nearly as much research has been focused on understanding the mechanisms of *B. parapertussis* pathogenesis. However, in the rat model of whooping cough, *B. pertussis* was able to cause rats to cough and *B. parapertussis*$_{hu}$ was not.[177] Infections with *B. parapertussis* outside of the respiratory tract are rare but have been reported.[217]

Bordetella bronchiseptica

B. bronchiseptica possesses genetic diversity. This makes some intuitive sense when one appreciates it has the second largest genome (only *B. ansorpii* is larger) and a broad host range. It has even been shown to survive in lake water.[219] *B. bronchiseptica* produce flagella as the product of a *vrg*. Its growth rate rivals that of *Escherichia coli* and it has full O side chains that are nearly identical to those of *B. parapertussis*$_{hu}$.[207]

The regulation of virulence in *B. bronchiseptica* has been studied in detail; and because the Bvg locus is interchangeable with that of *B. pertussis*, *B. bronchiseptica* has been used as a model for virulence regulation in the *Bordetellae*. Rodents are part of the natural host range of *B. bronchiseptica*, so infection models are numerous and relevant. Its faster growth rate makes it an attractive organism to study. *B. bronchiseptica* has been shown to invade eukaryotic cells and has even been isolated from human blood.[220–222]

B. bronchiseptica is found in the respiratory tract of domestic mammals including dogs, cats, guinea pigs, and rabbits. It is the cause of kennel cough or tracheobronchitis in dogs.[223] Transmission occurs by close contact with animals or exposure of immunocompromised hosts to infectious materials.[224] The species can also be found as a commensal microbe of the upper respiratory tract of humans.

B. bronchiseptica is motile via peritrichous flagella and can be grown on routine culture media, such as 5% sheep blood agar (SBA) as small, convex colonies and on MacConkey as non-lactose fermenting rods[174] (Table 23.1) It has also been recovered from thioglycolate broth when incubated in 5% CO_2.[224] Identification of *B. bronchiseptica* was traditionally dependent on staining characteristics and biochemical reactions. The use of routine biochemical identification systems in clinical laboratories appears better than with *B. pertussis* and *B. parapertussis*. Supplemental testing through MALDI-TOF or molecular methods is recommended.

For all its capabilities, it is somewhat surprising that *B. bronchiseptica* does not cause more than rare zoonotic disease in humans, although these are becoming more common with the increased number of immunocompromised individuals.[225] *B. bronchiseptica*, along with *B. holmesii* and *B. hinzii*, can cause pertussis-like symptoms in immunocompromised hosts and those with underlying conditions, including HIV and cystic fibrosis.[74] Vaccines are available for veterinary use only and mainly for dogs and swine.

Other *Bordetella*

The other named *Bordetella* species will be discussed in this section. Most are easily recovered, within 1–3 days, on routine media such as sheep blood agar or trypticase soy agar. Most are considered strict aerobic organisms unless otherwise mentioned. These less common *Bordetella* species may become more commonplace in the future as more thorough identification methods are put into practice and increasing awareness of their potential role in illness is realized.

Bordetella avium

Of the classically studied *Bordetellae*, *B. avium* is genetically the least related to *B. pertussis* and yet it shares similar pathogenic mechanisms and some of the same virulence factors.[226,227] As a pathogen of poultry and other domestic birds, *B. avium* has an affinity for young turkeys and is therefore of economic consequence to the poultry industry.[29,74] *B. avium* most resembles *B. bronchiseptica*. Like *B. bronchiseptica*, *B. avium* produces flagella and can be recovered from sheep blood agar and MacConkey under aerobic conditions (see Table 23.1). Sequence data shows many differences in surface structures that likely contribute to the unique host range for *B. avium*.[226]

Both live attenuated and killed bacteria (bacterin) vaccines have been tested, but vaccination of turkeys is not generally practiced and, instead, good hygiene and biosafety practices are usually employed.[29] Fluorescent antibody and PCR tests are available for distinguishing isolates from *B. bronchiseptica* and *B. hinzii*.[29]

B. avium has demonstrated similar virulence factors to *B. pertussis* however, it is mainly a pathogen of poultry and other domestic

birds.[74,227] This isolate has rarely caused human infections but is emerging as a potential pathogen of the respiratory tract.[228]

Bordetella holmesii

B. holmesii is an interesting member of the genus. In part, this is due to its similarity to *B. pertussis* in terms of its ability to cause human respiratory infection. *B. holmesii* causes a pertussis-like illness and should be differentiated from *B. pertussis* and *B. parapertussis*.[229,230] Misidentification occurred in the past through problems with the specificity of primers for RT-PCR contributing.[75,229] In the midst of pertussis outbreaks between 2010 and 2012 in both Japan and France, patients with pertussis-like illness were given an initial diagnosis of pertussis, when in fact *B. holmesii* was later found to be the causative agent.[231,232] In recent years, many other countries have reported the same after retrospective testing.

Because *B. holmesii* can be recovered from nasopharyngeal specimens and shares the insertion sequence IS481, testing for additional targets is important to avoid misdiagnosis of pertussis. Newer molecular assays have been developed with this in mind.[131,132]

Another case describes how bronchitis, presumptively thought to be caused by *Mycoplasma pneumonia*, was determined to be caused by *B. holmesii* through nucleic acid testing, reemphasizing the need for accurate diagnosis of this organism.[233]

In addition to the nasopharynx, *B. holmesii* has also been recovered in cases of bacteremia, endocarditis, pericarditis, and meningitis, highlighting its ability to cause invasive infections in the immunocompromised and otherwise healthy people.[234,235] It is possible for those with compromising disease or underlying conditions to be at greater risk of invasive disease if exposed. There is evidence of a prevalence of *B. holmesii* bacteremia among asplenic patients during increased pertussis cases in some regions of the United States.[236] Studies conducted to investigate possible development of immunity toward *B. holmesii* after a case of whooping cough, or vaccination with either wP or aP vaccine, determined protection against *B. holmesii* was inadequate.[237] *B. holmesii*, although causing similar respiratory disease, demonstrates a lack of the virulence factors of *B. pertussis* that causes more invasive disease contributing to this lack of protective immunity.

Susceptibility testing interpretations for the *Bordetella* species are not standardized and if necessary, an MIC method should be performed.[68]

B. hinzii, B. trematum, B. petrii, and B. ansorpii

The pathogenic potential of *B. hinzii* for humans has been more recently appreciated and its virulence properties continue to be assessed.[238] It remains an important concern in the avian population, especially in turkeys, where it is important to differentiate from *B. avium*. A specific PCR has been developed for *B. hinzii* identification, which targets the *ompA* gene as a result.[239] *B. trematum* has been isolated from a variety of human sources including an ear culture and various wound sources.[20,21] It has also been linked to chronic leg ulcers.[240] *B. trematum* has also been shown to progress from a soft-tissue infection into sepsis.[241] *B. petrii*, is a free-living environmental microorganism that grows under aerobic as well as anaerobic conditions.[26] It has been recovered from a case of chronic suppurative mastoiditis, and from the respiratory tract.[24,25,242] *B. ansorpii* is predominantly an environmental organism, but possesses some of the virulence factors of other *Bordetella*, namely filamentous hemagglutinin and BvgAS virulence regulator. It lacks, however, the toxins known to this genus.[243] *B. ansorpii* has been isolated from an epidermal cyst and blood in addition to its environmental source.[74,244,245]

Newest Members of the *Bordetella*

B. bronchialis, B. sputigena, B. flabilis, B. pseudohinzii, B. muralis, B. tumbae and B. tumulicola

Of the recently named *Bordetella* species, *B. bronchialis*, *B. sputigena*, and *B. flabilis* were recovered from respiratory samples of cystic fibrosis patients and *B. pseudohinzii* was recovered from a cystic fibrosis mouse model.[246–248]

B. muralis, *B. tumbae*, and *B. tumulicola* have been found in environmental samples, such as plaster and murals, that date to more than 1,000 years old.[249] These species were not recovered from the stone that encased the art, however. It is proposed that these species may have some biodegradable capabilities as a result, but this is still being studied. Additional unnamed species have also been recovered from soil, rocks found in caves, plants, and a wide variety of bodies of water.[248] Some characteristics of the newer named species associated with human and animals are included in Table 23.1.

Taxonomic History of Campylobacters

Spiral campylobacter-like organisms were first observed microscopically from the stool of children by Escherich in 1886. Between 1909 and 1944, there were a growing number of reports of similar "vibrio-like" organisms isolated from bovine and ovine sources, but they were not isolated from humans until 1938, in association with a milk-borne outbreak of gastroenteritis where blood cultures were positive for organisms resembling "*Vibrio jejuni*."[1] The microaerobic vibrios were assigned to the new genus *Campylobacter* in 1963,[2] and included just two species: *Campylobacter fetus* and *Campylobacter bubulus* (now *Campylobacter sputorum*). Campylobacters were first successfully isolated from stool in the late 1960s using a filtration technique.[1] Later, the development of selective media brought the routine isolation of *Campylobacter* into the clinical microbiology setting and *Campylobacter* spp. rapidly became recognized as a common cause of bacterial gastroenteritis. The taxonomic structure of *Campylobacter* has changed substantially since its inception in 1963, first with a comprehensive study of the taxonomy of the genus in 1973.[3] By the late 1980s, there was a rapid increase in classification at the species level, and 14 species had been described (see review by Penner).[4]

* Disclaimer: Use of trade names is for identification only and does not imply endorsement by the Public Health Service or by the U.S. Department of Health and Human Services.

Advances in DNA technology, particularly 16S rRNA sequence analysis and DNA-DNA hybridization,[5] clarified the systematics of campylobacters and resulted in the extensive restructuring of the genus and assignment of campylobacters to the phylogenetic group rRNA superfamily VI.[6] The proposal that the genera *Campylobacter* and *Arcobacter* should be included in a separate family, the *Campylobacteraceae*, was also made in 1991 by Vandamme and Levy.[7] A detailed review of the taxonomy of *Campylobacteraceae* was published in 2008.[8] Thirty-one *Campylobacter* species are currently described within the family *Campylobacteraceae*. (Table 24.1). The disease spectrum of this genus ranges from well-established for *C. jejuni*, to emerging for

TABLE 24.1

Currently Described *Campylobacter* Species

Campylobacter Species	Known Sources	Human Disease Associated
C. jejuni subsp. *jejuni*	Poultry, cattle, sheep, wild birds, pigs	Gastroenteritis, meningitis, septicemia, Guillain-Barré syndrome
C. jejuni subsp. *doylei*	Humans	Gastroenteritis, septicemia
C. coli	Pigs, poultry, sheep Wild birds, cattle	Gastroenteritis Septicemia, meningitis
C. lari subsp. *lari*	Wild birds, poultry, dogs Cats	Gastroenteritis Septicemia
C. lari subsp. *concheus*	Shellfish	Gastroenteritis
C. fetus subsp. *fetus*	Cattle, sheep, reptiles	Gastroenteritis, septicemia
C. fetus subsp. *testudinum*	Humans, reptiles	Septicemia, chronic kidney disease
C. fetus subsp. *venerealis*	Cattle, sheep	Septicemia
C. upsaliensis	Dogs, cats	Gastroenteritis Septicemia
C. helveticus	Cats, dogs	Gastroenteritis
C. insulaenigrae	Marine mammals	Gastroenteritis
C. peloridis	Shellfish	Gastroenteritis
C. hyointestinalis subsp. *hyointestinalis*	Pigs, cattle	Gastroenteritis
C. hyointestinalis subsp. *lawsonii*	Pigs	None at present
C. lanienae	Cattle, pigs	Gastroenteritis
C. sputorum bv. *sputorum*	Cattle, pigs	Abscesses, gastroenteritis
C. sputorum bv. *faecalis*	Sheep, bulls	None at present
C. sputorum bv. *paraureolyticus*	Cattle	Gastroenteritis
C. concisus	Humans, domestic pets	Gastroenteritis, periodontal disease, abscesses
C. curvus	Humans	Periodontal disease, gastroenteritis
C. rectus	Humans	Periodontal disease, abscesses
C. showae	Humans	Periodontal disease, abscesses
C. ureolyticus	Humans	Gastroenteritis, septicemia, soft tissue abscesses
C. gracilis	Humans	Periodontal disease, abscesses
C. hominis	Humans	None at present
C. mucosalis	Pigs	None at present
C. avium	Poultry	None at present
C. canadensis	Whooping cranes	None at present
C. cuniculorum	Rabbits	None at present
C. subantarcticus	Gray-headed albatrosses, black-browed albatrosses, gentoo penguins	None at present
C. volucris	Black-headed gulls	None at present
C. blaseri	Common seals	None at present
C. corcagiensis	Lion-tailed macaques	None at present
C. geochelonis	Hermann's tortoise	None at present
C. hepaticus	Chickens	None at present
C. iguaniorum	Reptiles	None at present
C. ornithocola	Wild birds	None at present
C. pinnipediorum subsp. *pinnipediorum*	Common seals, gray seals	None at present
C. pinnipediorum subsp. *caledonicus*	Common seals, gray seals	None at present

species such as *C. fetus* ssp. *fetus*, to speculative for species such as *C. concisus*. Since the last edition of this handbook, seven new *Campylobacter* species and one new subspecies have been described including *C. blaseri* from seals,[9] *C. corcagiensis* from lion-tailed macaques,[10] *C. geochelonis* from tortoises,[11] *C. hepaticus* from chickens,[12] *C. iguaniorum* from reptiles,[13] *C. ornithocola* from wild birds,[14] *C. pinnipediorum* from pinniped seals,[15] and *C. fetus* subsp. *testudinum* from humans and reptiles.[16]

The family *Campylobacteraceae* also contains 25 *Arcobacter* species and seven *Sulfurospirillum* species. Species belonging to the genus *Sulfurospirillum* have no known pathogenicity for humans or animals, and are considered environmental organisms.[17]

The most commonly recognized *Campylobacter* species, *C. jejuni*, is the leading cause of *Campylobacter* enteritis cases in humans; a number of other *Campylobacter* species, including *C. coli, C. upsaliensis, C. lari,* and *C. fetus,* have also been linked with enteritis (see Table 24.1). The true proportion of illness attributable to each of these species is not clear because campylobacters are difficult to differentiate, and many clinical laboratories do not identify *Campylobacter* isolates to the species level. *C. jejuni* is divided into two subspecies: *C. jejuni* ssp. *jejuni* (referred to as *C. jejuni* and the main focus of the chapter) and *C. jejuni* ssp. *doylei* (seldom found as the cause of human disease). *C. jejuni, C. coli, C. lari*, *C. upsaliensis,* and *C. helveticus* form a genetically close group as shown by 16S rRNA analysis[18] and are known as the thermotolerant or thermophilic campylobacters because they all grow optimally at 42°C.

Another group that is closely related genetically is the hydrogen-requiring species *Campylobacter sputorum, C. concisus, C. curvus, C. showae, C. rectus, C. gracilis*, and *C. hominis*. Most of these species have been associated with periodontal disease, although *C. hominis* has been isolated only from healthy human feces[19] and *C. sputorum* is also found in the reproductive and gastrointestinal tracts of various production animals. The taxonomic history of *C. sputorum* is complex and was revised in 1998 to include three biovars[20]: bv. *sputorum*, bv. *faecalis,* and bv. *paraureolyticus* based on the ability of a given strain to produce catalase or urease. Strains previously described as *C. bubulus* were reclassified as bv. *sputorum* as the tests that had been used to differentiate these two taxa were not reproducible.[21]

Campylobacter mucosalis and *C. sputorum* are closely related based on DNA-DNA hybridization studies, and they share a common source (porcine).[18] Because *C. mucosalis* strains require a hydrogen-enriched microaerobic atmosphere in order to grow, they will not be detected using culture methods used in most clinical laboratories, so their clinical significance is unknown. There are three *C. fetus* subspecies; C. *fetus* subsp. *fetus* is associated with both ovine/bovine reproductive disorders as well as human infections, *C. fetus* subsp. *testudinum* is associated with infections in both humans and reptiles[16] and *C. fetus* subsp. *venerealis* causes bovine-associated abortion and infertility.[3,22] This species is most similar phenotypically and genetically to the two *C. hyointestinalis* subspecies: *C. hyointestinalis* ssp. *hyointestinalis* and *C. hyointestinalis* ssp. *lawsonii*. Extensive 16S rRNA diversity has been reported for *C. hyointestinalis* strains.[23] *C. gracilis* was originally described as a *Bacteroides* species associated with periodontal disease but formally assigned to the genus *Campylobacter* in 1995.[24] *C. gracilis* is often not recognized as being a *Campylobacter* because of its unusual morphology and metabolic characteristics; *C. gracilis* has an anaerobic growth requirement, a straight rod-shaped morphology, and is oxidase-negative.

General Characteristics

Campylobacter species are Gram-negative, nonspore forming rods. *Campylobacter* cells are typically curved, S-shaped, or spiral rods that are 0.2–0.9 μm wide and 0.5–5 μm long. Some species, such as *C. hominis* and *C. gracilis,* form straight rods. Organisms are usually motile by means of a single, polar, unsheathed flagellum at one or both ends. Cells of some species are nonmotile (*C. gracilis*) or have multiple flagella (*C. showae*). Most species require a microaerobic atmosphere for optimal growth; however, some species grow aerobically or anaerobically. An atmosphere containing increased hydrogen appears to be a growth requirement for other species such as *C. sputorum, C. concisus, C. mucosalis, C. curvus, C. showae, C. rectus, C. gracilis*, and *C. hominis*.[25]

Epidemiology

Campylobacters are a leading cause of bacterial enteritis worldwide and cause approximately 1.3 million illnesses annually in the United States.[26] Campylobacters can be transmitted directly from animal to person, through ingestion of fecally contaminated water, food, or by direct contact with animal feces or contaminated environmental surfaces. *Campylobacter* species are primarily zoonotic, with a variety of animals implicated as reservoirs of infection, including a diverse range of domestic and wild animals and birds.[1,27] In addition, water and the environment play a significant but poorly understood role in the epidemiology of campylobacteriosis.[28]

In the United States, requirements for reporting incidence of culture-confirmed infections vary by state. The Foodborne Diseases Active Surveillance network, FoodNet (Accessed August 5, 2019) provides uniform reporting from 10 sentinel sites, giving an accurate incidence of diagnosed infections. The reported incidence of *Campylobacter* infections in the United States in 2017 was 19.2 per 100,000 population, which represents a 10% increase from the 2014–2016 baseline.[29]

Most *Campylobacter* infections are acquired domestically, but *Campylobacter* is also a major cause of traveler's diarrhea.[30] While sporadic infections with *Campylobacter* are extremely common, *Campylobacter* outbreaks, defined as two or more persons epidemiologically linked by time and exposure, are relatively rare compared with other enteric pathogens. Outbreaks in the United States have been linked to a variety of foods, including poultry and other meats, and produce as well as contact with dogs obtained through the commercial dog industry. However, the most common single food implicated in *Campylobacter* outbreaks is unpasteurized milk.[31] Outbreaks have also been caused by contamination of untreated or poorly disinfected water supplies, and by drinking water from unprotected sources

such as lakes or streams.[32,33] In contrast to other enteric pathogens, person-to-person transmission is unusual for outbreaks of campylobacteriosis despite the low infectious dose of *C. jejuni*. Handling or consumption of contaminated poultry meat is a major risk factor for human infection with *C. jejuni* and is thought to be responsible for making an important contribution to the number of sporadic *Campylobacter* infections seen annually.[34,35] While poultry is a principal source of campylobacteriosis, the contribution of other reservoirs to the overall burden of sporadic human disease has not been established.

In a typical case of diagnosed *Campylobacter* infection, illness lasts 5–7 days[36]; the infection resolves without antimicrobial treatment in the great majority of cases. Symptoms of infection typically begin 2–5 days after ingesting *C. jejuni* bacteria and include diarrhea with cramping abdominal pain, often with fever and some nausea. Extraintestinal *Campylobacter* infections are rare for people in good health, but are more likely to occur if the person is immunocompromised, elderly, or pregnant. Other complications of *Campylobacter* illness include bacteremia, Guillain-Barré syndrome (GBS), reactive arthritis, and irritable bowel syndrome.[37]

Isolation and Identification of *Campylobacter* spp.

Diagnosis of *Campylobacter* infection is usually made by isolating the organism from stool, blood, or other clinical specimens. Fastidious growth requirements can make isolation of *Campylobacter* from clinical specimens difficult. However, once isolated, presumptive identification of the genus *Campylobacter* is easily made based on morphology and darting motility. Further differentiation to species level is difficult because of the complex and rapidly evolving taxonomy and biochemical inertness of these bacteria. These problems have resulted in a proliferation of phenotypic and genotypic methods for identifying members of this group.

Direct Examination of Specimens

Microscopy

Presumptive diagnosis of a *Campylobacter* infection can be made directly by microscopic detection of the organism in a fresh stool specimen from patients with acute enteritis. Dark-field microscopy reveals the characteristic morphology and darting motility of campylobacters. Gram-stain analysis of stool specimens looking for organisms with typical *Campylobacter* morphology is also a highly sensitive and specific test that can be performed for rapid preliminary diagnosis of *Campylobacter* infection[38] and is currently underutilized.

Culture Independent Diagnostic Tests (CIDTs)

Culture independent methods for the direct detection of *Campylobacter* in stool specimens allow the detection of this fastidious organism without the specialized media and equipment that is needed for *Campylobacter* culture. Both immunologic and nucleic acid amplification tests (NAATs) are now commercially available. CIDTs are rapid, and provide same day results, however, they do not yield an isolate for epidemiologic studies or antibiotic susceptibility testing.

Antigen Detection

Currently there are four immunoassays cleared by the U.S. Food and Drug Administration (FDA) for use in the United States that allow for the direct detection of Campylobacter antigen in stool specimens (ProSpecT™ Campylobacter Microplate Assay, Remel, Lenexa, KS; Premier™ CAMPY, Meridian Bioscience, Cincinnati, OH; ImmunoCard STAT! CAMPY®, Meridian Bioscience, Cincinnati, OH; and *Campylobacter* Quik Chek™, TechLab, Blacksburg, VA). These immunoassays detect both *C. jejuni* and *C. coli* in stool specimens, but cannot differentiate between them; the ProSpecT, Premier CAMPY and ImmunoCard STAT! tests have also been reported to cross react with *C. upsaliensis;* to date, a review or comparison of the performance of the *Campylobacter* Quik Chek has not been reported.[39,40] These methods have provided an attractive alternative to culture-based methods allowing rapid detection of *Campylobacter* within 2 hours.[41] However, inconsistent conclusions as to their sensitivity, specificity and false positivity rates have been reported[42,43] and cost is in excess of culture.

Nucleic Acid Detection

Many NAAT assays have been described to directly detect *Campylobacter* in stool specimens.[44] Currently there are six NAAT assays that detect *Campylobacter* and other gastrointestinal pathogens, FDA cleared for use in the United States. All of these tests detect a variety of gastrointestinal pathogens, including *Campylobacter.* The Prodesse Progastro SSCS (*Salmonella*, *Shigella*, *Campylobacter* and STEC) assay and BD MAX Enteric Bacterial Panel can detect the DNA from *C. jejuni* and *C. coli* but not differentiate between the species. The xTAG® GPP (gastrointestinal pathogen panel) and Verigene Enteric Pathogens assay can detect *C. jejuni, C. coli*, and *C. lari*, also without differentiating between the species. The BioFire Film Array and the Savyon GIP (gastrointestinal panel) both detects DNA from *C. jejuni*, *C. coli*, and *C. upsaliensis* but, again, does not differentiate between species. Advantages of using a nucleic acid detection approach include same-day detection and identification of *Campylobacter* to the species level and identification of the less-common *Campylobacter* species that are often missed by conventional culture.[45] However, this approach is more expensive than culture and does not provide an isolate for further characterization.

Transport Media

For the clinical microbiology laboratory whose main goal is to detect *Campylobacter* in the stool of patients with diarrhea, fresh stool (less than 2 hours old) is the ideal specimen. If a delay is anticipated, the specimen should be put in transport media such as modified Cary-Blair and kept at 4°C, not frozen. Transport media should also be used for rectal swab specimens. *Campylobacter* can be isolated from routine blood culture systems or wound specimens, so blood cultures should be done if the clinical features of the patient suggest campylobacteriosis.

Isolation from Human Specimens

Selective Media for Isolation

Diagnosis of *Campylobacter* gastroenteritis is commonly based on direct plating of stool onto selective media. No single medium will isolate all *Campylobacter* species. *C. jejuni* and *C. coli* can be isolated from stool samples by plating the stool on selective media and incubation in a microaerobic atmosphere at 42°C for 72 hours. A variety of media with different formulations, including both blood-based and charcoal-based selective media, are currently used for the isolation of these two species, most of which are commercially available. The history of the development of selective media for isolation of campylobacters was reviewed by Corry et al.[46] All the selective media contain a basal medium, either blood or other agents such as charcoal, to quench oxygen toxicity and a cocktail of antimicrobial agents to inhibit the normal flora associated with fecal specimens.

The use of antimicrobial-containing selective media and 42°C as the incubation temperature can inhibit the growth of the more fastidious emerging *Campylobacter* spp.[47] For example, the antimicrobial agent cephalothin that is present in some selective media formulations such as Campy-blood agar plates (BAPs) is inhibitory to *C. fetus* ssp. *fetus*. *C. jejuni* ssp. *doylei*, *C. upsaliensis*, and *C. concisus*. Therefore, these species generally do not grow on cephalothin-containing media. For primary isolation of *Campylobacter* from fecal samples, the use of cefoperazone-containing media instead of cephalothin-containing formulations is recommended.[25]

Enrichment Culture

A number of enrichment broths have been formulated to enhance the recovery of *Campylobacter* from stool samples.[46] Inclusion of an enrichment step may be beneficial in instances where low numbers of organisms are expected due to delayed transport to the laboratory, or after the acute stage of disease when the concentration of organisms may be low, such as in the investigation of GBS following acute *Campylobacter* infection.[25] Enrichment culture also is used to enhance the culture sensitivity of potentially environmentally stressed organisms. After selective enrichment, suspect *Campylobacter* colonies are subcultured onto *Campylobacter*-selective media such as mCCDA (modified charcoal cefoperazone deoxycholate agar).

Filtration Method for Isolation

A passive filtration technique that uses a nonselective medium developed by Steele and McDermott[48] is an effective approach to isolate campylobacters, particularly *Campylobacter* species that are susceptible to the antibiotics in selective agar isolation procedures.[49,50] The method is based on the principle that campylobacters can pass through membrane filters (0.45–0.65 µm) with relative ease (because of their small size and motility), while other stool flora are retained during the short processing time. Complete details of the procedure can be found in the *Manual of Clinical Microbiology*.[51] Incubation of nonselective media at 37°C under microaerobic conditions, preferably with an atmosphere containing increased hydrogen (for the hydrogen-requiring species) will allow isolation of the non-*C. jejuni*/*C. coli* species. When this method is used, a variety of other *Campylobacter* taxa can be identified in diarrheic stool, although their pathogenic potential remains to be clarified.[52] Stool samples containing ~10^5 colony forming units (CFU) mL^{-1} *Campylobacter* will be detected with this method, and thus the filtration method is not as sensitive as primary culture with selective media.

Incubation Variables

Atmosphere

Most *Campylobacter* species require a microaerobic atmosphere containing approximately 5% O_2, 10% CO_2, and 85% N_2 for optimal recovery. There are a number of ways to generate microaerobic conditions; several manufacturers produce commercial microaerobic gas packs that are suitable for routine use in conjunction with an anaerobic jar, the evacuation-replacement method in conjunction with the approximate gas mixture, a tri-gas incubator, or the Anoxomat system (www.anoxomat.com. Accessed August 5, 2019) can also be used for routine cultures.[25] Some species of *Campylobacter*, such as *C. sputorum*, *C. concisus*, *C. mucosalis*, *C. curvus*, *C. rectus*, and *C. hyointestinalis* require an increased hydrogen concentration for isolation and growth. Typically, these species will not be recovered using commercial gas packs because the amount of hydrogen generated in properly used, commercial gas packs is less than 2%. A gas mixture containing at least 6% H_2 is sufficient for isolating hydrogen-requiring species.

Temperature and Length of Incubation

Species within the genus *Campylobacter* have different optimal temperatures for growth. Therefore, the choice of incubation temperature for routine stool cultures is critical in determining the spectrum of species that will be recovered.[25] It is common practice for most laboratories to use 42°C as the primary incubation temperature for *Campylobacter*, as this temperature allows growth of *C. jejuni* and *C. coli* on selective media. The nonthermophilic species will not grow at 42°C. In contrast, most *Campylobacter* species grow well at 37°C. Many of the selective media containing blood, such as Skirrow medium, were devised for use at 42°C and have poor selective properties at 37°C, whereas mCCDA and Karmali show good selective properties at 37°C.[46] Growth of *C. jejuni* and *C. coli* on selective media is typically visible within 24–48 hours. However, several studies report increased isolation rates when the incubation time is extended to 72 hours. Plates should be incubated a minimum of 72 hours before reporting as negative for *Campylobacter*.

Isolation of Campylobacters from Non-human Sources

Protocols for the isolation of *Campylobacter* species from food and water are available in the FDA's *Bacteriological Analytical Manual*[51] (https://www.fda.gov/food/laboratory-methods-food/bacteriological-analytical-manual-bam. Accessed August 5, 2019) and have recently been updated.[53] An international standard procedure for the detection of thermotolerant *Campylobacter* in food and animal foodstuff was first made by the ISO (International Organization for Standardization) in 1995.[54]

This method was updated in 2006 (ISO10272-1:2006),[55] in 2009[55], and more recently in 2017.[56] The recent validations of current methodologies to isolate *Campylobacter* spp. from foods were published.[57] Standard methods for the isolation of campylobacters from live animals are available from the World Organization of Animal Health (OIE) (www.oie.int. Accessed August 5, 2019).

Isolation of campylobacters from water can be difficult because campylobacters can be present in low numbers and may be stressed as a consequence of low temperature, osmotic stress, nutrient depletion, and/or competition from other organisms. For this reason, recovery of *Campylobacter* from water samples from contaminated surface and ground water sources implicated in *Campylobacter* outbreaks worldwide has not always been successful using conventional culture techniques.[58,59] ISO 17995 describes a standardized procedure for the isolation of *Campylobacter* from water.[60]

Identification

Identification of *Campylobacter* to the species level can be difficult because campylobacters are biochemically inert; few phenotypic tests are available to identify them to the species level. A presumptive identification of *Campylobacter* spp. can be made if oxidase-positive colonies exhibiting a characteristic Gram-stain appearance (curved Gram-negative rods) grow on selective media incubated at 42°C under microaerobic conditions. All *Campylobacter* species except *C. gracilis* are typically oxidase-positive. Campylobacters neither oxidize nor ferment glucose. Isolates that are hippurate-positive can be further identified as *C. jejuni* because it is the only *Campylobacter* sp. isolated from humans that produces the enzyme hippuricase. However, isolates of *C. jejuni* that are hippuricase-negative have been reported.[61] Hippuricase-negative *C. jejuni* strains cannot be differentiated from *C. coli* by phenotypic testing (see Figures 24.1A and B). Detection of species-specific sequences via PCR can be helpful in these instances to differentiate between these two closely related species.[62,63] The number of available PCR assays for species-specific identification of *C. jejuni* and *C. coli* continues to grow. Published evaluations of some of these assays highlight the importance of validating their sensitivity and specificity[62,63] and the continued need to revalidate protocols and certify their accuracy as new species are described.[64] Figure 24.2 shows a flowchart for identification of *C. jejuni* and *C. coli*. Additional tests are needed to determine the species of hippurate-negative, indoxyl acetate-negative isolates.[25]

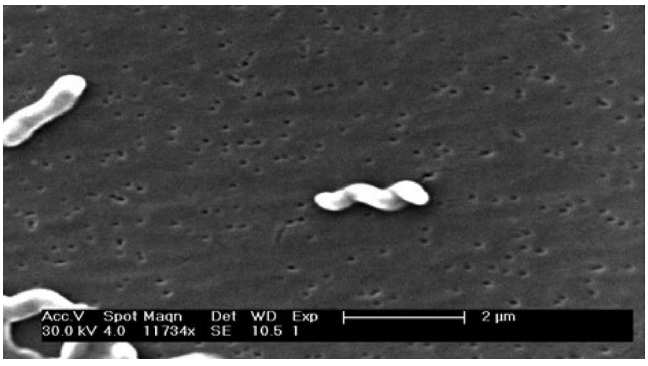

FIGURE 24.1A Electron micrograph of *Campylobacter jejuni*. (Courtesy of Public Health Image Library.)

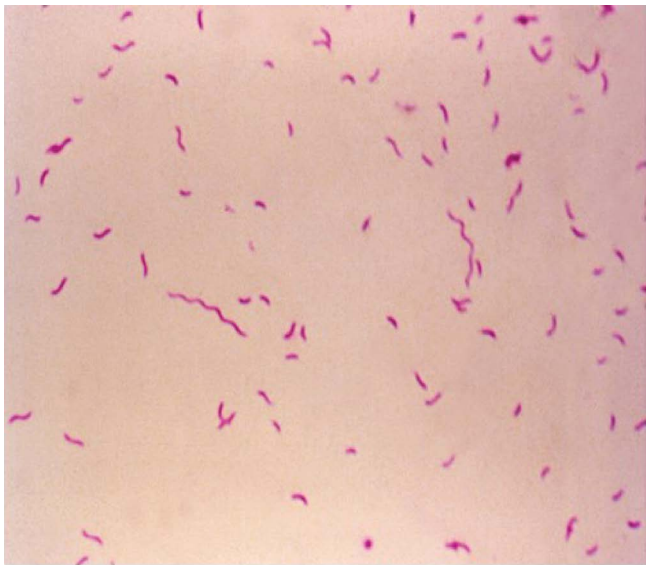

FIGURE 24.1B Gram stain image showing spiral morphology of *Campylobacter fetus* subsp.

Nalidixic acid and cephalothin susceptibility testing have been used in species identification in the past.[65] A presumptive *Campylobacter* strain that was hippurate-positive, sensitive to nalidixic acid, and resistant to cephalothin was identified as a *C. jejuni*. However, fluoroquinolone resistant and cross-resistant to nalidixic acid *Campylobacter* species have become increasingly common, with rates reported to be as high as 80%.[66] Therefore, antimicrobial susceptibility tests can no longer be relied upon for the phenotypic identification of *Campylobacter* isolates.

The use of matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometry has more recently been shown to be an accurate, sensitive and rapid method for identification of *Campylobacter* spp.[67] and is becoming increasingly used in the routine clinical microbiology setting.[68]

Whole genome sequence (WGS) is an emerging technology that shows great potential for the identification of bacterial pathogens, including *Campylobacter,* in the clinical setting. WGS is already widely used in public health for subtyping and surveillance and by academia for research; however, there are challenges to the full implementation of WGS in the clinical setting.[69,70]

Antimicrobial Susceptibility Testing

The unique growth requirements of *Campylobacter* species present challenges for antimicrobial susceptibility determination. The Clinical and Laboratory Standards Institute (CLSI, formerly the National Committee for Clinical Laboratory Standards, NCCLS) and the European Committee for Antimicrobial Susceptibility Testing (EUCAST) are two widely used resources for standardized susceptibility testing methods,[71,72] and both committees provide specific guidance for *Campylobacter* testing. Before 2005, the CLSI described *Campylobacter* agar

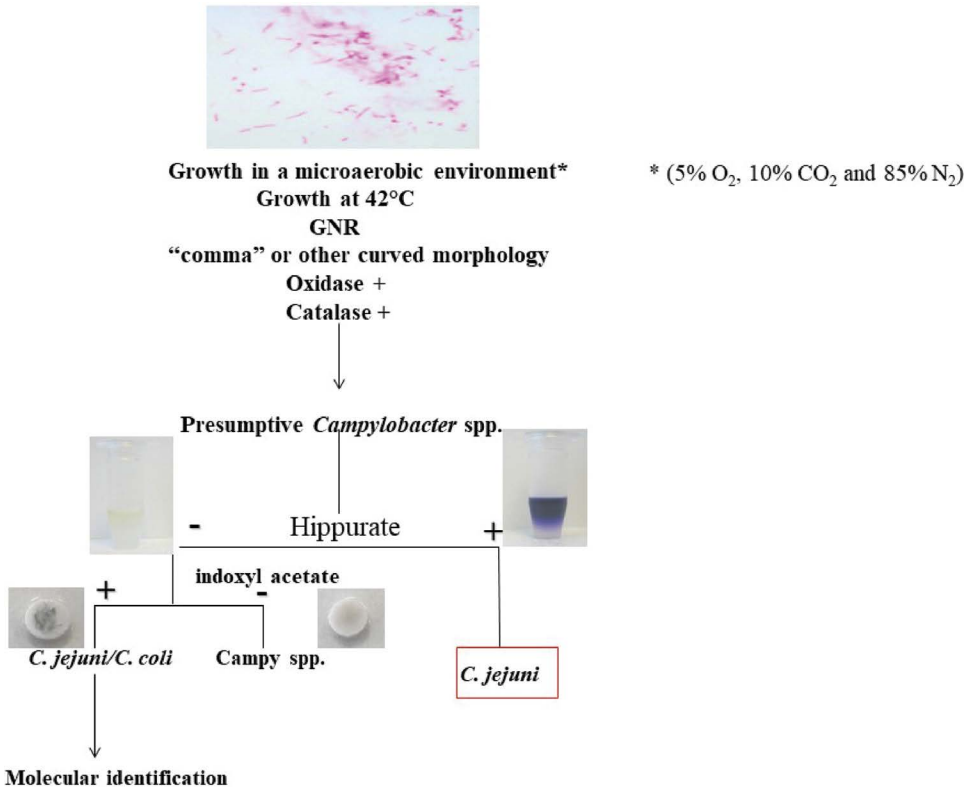

FIGURE 24.2 Identification of hippurate negative.

dilution testing as a standardized method for in *vitro* antimicrobial susceptibility testing of *Campylobacter* spp.[73] Given that agar dilution is cumbersome and can be costly to perform, broth microdilution and diffusion methods have also been used.[74–76] In 2004, broth microdilution minimum inhibitory concentration (MIC) was developed with quality control (QC) ranges for five antimicrobials: ciprofloxacin, doxycycline, gentamycin, erythromycin, and meropenem using *C. jejuni* ATCC 33560.[77] Methods for performing broth microdilution were also provided along with methodology for a variation of the standard disk diffusion method, allowing *Campylobacter* isolates to be screened for erythromycin and ciprofloxacin resistance. This approach uses growth up to the edge of a 6-mm disk (i.e., no zone of inhibition) as an indicator of acquired resistance (CLSI, M45AE). The CLSI agar dilution and disk diffusion methods require media supplemented with 5% sheep blood, whereas the CLSI broth microdilution tests require supplementation with 2.5–5% lysed horse blood. The tests can either be incubated at 36°C for 48 hours or at 42°C for 24 hours under microaerobic conditions. In the United States, if a laboratory chooses to apply EUCAST breakpoints, it is imperative that the FDA-cleared disk used contains the disk content assigned by EUCAST, and vice versa. Similarly, the disk quality control ranges are based on the disk content, and laboratories must ensure they are using the correct quality control range for the disk content employed. In 2017, CLSI and EUCAST formed a joint disk-diffusion working group endeavored to harmonize disk contents for new antimicrobial agents going forward.

Recently, EUCAST developed a standardized disk diffusion method for *Campylobacter* and used it to establish epidemiological cut off values (ECOFFs) for *C. jejuni* and *C. coli* with the same erythromycin and ciprofloxacin disk contents as those used by CLSI, as well as tetracycline (30 µg disk).[78] Compared to the CLSI method, EUCAST uses a different test medium (Mueller-Hinton agar with 5% mechanically defibrinated horse blood and 20 mg/L β-NAD). Based on the proposed ECOFFs, clinical breakpoints for disk diffusion were proposed beginning on January 1, 2013.[79]

Along with the disk diffusion guidelines, EUCAST also published ECOFFs and clinical breakpoints for MIC methods (http://www.eucast.org/mic_distributions_and_ecoffs/). Effective January 1, 2019, an updated correlation between MIC and zone distribution for ciprofloxacin, erythromycin, and tetracycline are available (http://www.eucast.org/ast_of_bacteria/calibration_and_validation/). As test medium for broth microdilution EUCAST recommends cation-adjusted Mueller-Hinton broth with 5% lysed horse blood and 20 mg/L β-NAD. The recommended incubation conditions for both disk diffusion and broth microdilution are 41 ± 1°C for 24 hours in a microaerobic environment.

Antimicrobial Resistance among Campylobacter

Antibiotic resistance in *Campylobacter* spp is an increasing concern, as it is in many other microorganisms. *Campylobacter* has evolved various mechanisms of resistance. These mechanisms include (i) restricting the access of antibiotics to their targets, which evolves reducing membrane permeability and increasing extrusion of antibiotics by efflux pumps; (ii) modification or protection of antibiotic targets; and (iii) modification or inactivation of antibiotics.[80] These emerging mechanisms threaten the usefulness of clinically important antibiotics used

for treating human campylobacteriosis. As a foodborne pathogen, *Campylobacter* is constantly exposed to antimicrobials used for food production and has shown an amazing ability to adapt to antibiotic selection pressure.[81] The over-use of antibiotics in the human population and in animal husbandry has led to an increase in *Campylobacter* antibiotic-resistant infections, particularly with fluoroquinolones. Of greatest clinical concern would be the emergence of widespread macrolide resistance, since this class is the current treatment of choice of choice for campylobacteriosis. Also, the contribution of efflux pumps to antibiotic resistance warrants further studies, since this mechanism acts synergistically with other mechanisms of antibiotic resistance to confer high-level resistance in many instances.[81–83]

Antimicrobial resistance among *Campylobacter* varies by species, perhaps because *Campylobacter* species can be associated with different animal reservoirs. Resistance rates can vary between *C. jejuni* and *C. coli* because *C. jejuni* is more common in poultry and cattle while *C. coli* predominates in pigs[84] and antimicrobial use patterns vary by food animal species. The differences between *C. jejuni* and *C. coli* resistance are most notable in the case of the macrolides.

Macrolide Resistance

The increasing incidence of fluoroquinolone (FQ) resistance in *Campylobacter* has rendered macrolides such as erythromycin and azithromycin the drugs of choice for human campylobacteriosis.[85] Macrolide resistance among *Campylobacter jejuni* and *C. coli* was reviewed by Gibreel and Taylor.[86] This antimicrobial class includes erythromycin, azithromycin, and tylosin (a veterinary pharmaceutical), and resistance is attributed to chromosomal point mutations in the 23S rDNA that result in an altered ribosome binding site. These alterations most likely affect binding of the macrolide to the ribosome and are nontransmissible. The contribution of the CmeABC efflux systems to macrolide resistance in *Campylobacter* has been described in several recent studies.[87,88] The multidrug efflux pump CmeABC functions synergistically with 23S rRNA mutations to effect high-level macrolide resistance.[87–91] Almost all studies report higher macrolide resistance among *C. coli* than among *C. jejuni*. Because *C. coli* are associated with a swine reservoir, this raises questions about macrolide-selective pressure in those production settings.[66,92] The use of macrolides for growth promotion in animals was banned by the European Union in 1999 but they may still be used therapeutically.[93] In the United States, macrolide resistance was observed in 1.7% of *C. jejuni* and 2.7% of *C. coli* in 2011.[94]

Fluoroquinolone (FQ) Resistance

The fluoroquinolones such ciprofloxacin, enrofloxacin, and levofloxacin, are one of the drugs of choice to treat campylobacteriosis in humans as well as other bacterial diseases in both animals and humans.[81,95] In *Campylobacter*, the main resistance mechanism to FQ is mediated par points of mutations in the quinolone resistance determining region (QRDR) of *gyrA*.[96,97] One unique feature of FQ resistance in *Campylobacter* is that acquisition of high-level resistance does not stepwise accumulation of point of mutations in *gyrA*. Instead, a single mutation in *gyrA* can lead to clinically relevant levels of resistance in FQ antimicrobials.[98,99] In addition to mutations in *gyrA*, the functional multidrug efflux pump, CmeABC, is also required for fluoroquinolone resistance in *Campylobacter*.[99,100] It is widely accepted that poultry is a common source of *C. jejuni* infections in humans, and fluoroquinolone-resistant *C. jejuni* has been isolated from retail poultry products.[101,102] Effective September 2005, enrofloxacin was withdrawn from use in U.S. poultry farms.[103]. However, it is not yet clear if the elevated rates of FQ resistance will decline after FQ restriction. Studies in several countries have shown that FQ resistance persists in poultry populations after the withdrawal of FQ, suggesting that there is a little/no fitness cost to FQ resistance in *Campylobacter*.[104,105]

Tetracycline Resistance

To date, resistance to tetracyclines in *Campylobacter* is conferred by a soluble protein factor called *tet*(O) and efflux pumps (CmeABC and *cme*G).[106] A recent study indicated that several critical residues located in the three loops of *tet*(O) disrupt the binding of tetracycline to the ribosome complex.[107] The *tet*(O) gene, which is widely present in *C. jejuni* and *C. coli*, can be located either in the chromosomal DNA or on a plasmid (e.g., pTet and pCC31).[108] Although high-level resistance to tetracyclines can be mediated by *tet*(O) alone, CmeABC and *cmeG* multidrug efflux pumps contribute to both intrinsic and acquired resistance to tetracycline in *Campylobacter,* and function synergistically with *tet*(O) to confer high-level resistance to tetracycline.[109]

Aminoglycoside Resistance

Aminoglycosides are bactericidal antibiotics that bind to ribosomes and inhibit protein synthesis.[110] Aminoglycoside resistance was first detected in *C. coli* and was mediated by a 3'-aminoglycoside phosphotransferase (encoded by aphA-3) that has been previously described as conferring kanamycin resistance in *Streptococcus* and *Staphylococcus*.[83] Other *Campylobacter* strains harbor mosaic plasmids that contain various aminoglycoside resistance and insertion or transposon sequences from Gram-negative and Gram-positive bacteria, along with *tet(O)* genes[111–113] Other genes which confer kanamycin resistance include *aphA-1* and aphA-7, which were detected on plasmids in *C. jejuni*. Unlike *aphA-3* and *aphA-1*, which are thought have been horizontally acquired, *aph-7* has a similar G-C content to *C. jejuni* chromosomal DNA, suggesting it is intrinsic in *Campylobacter*.[112,113]

The gene conferring resistance to gentamycin in *Campylobacter* was initially annotated as *aac(6')-le/aph(2")-la* (also *aacA/aphD*), but it was found to encode the phosphotransferase only and thus was renamed *aph(2")-lf_*.[114] Very recently, several variants of 2"-phosphotransferase accounting for gentamycin resistance were identified in *Campylobacter* in the United States.[114,115] The contribution of efflux to aminoglycoside resistance in *Campylobacter* is not completely clear but it is likely to be less important than the plasmid-borne drug-modifying enzymes.[83]

Antimicrobial Resistance in Other Campylobacter Species

There is very little information available on the epidemiology of antimicrobial resistance among *Campylobacter* species other

than *C. jejuni* and *C. coli*. Thwaites and Frost[116] reported susceptibility results for 25 isolates of *C. lari*. Resistance was observed for ampicillin (36%), kanamycin (60%), and tetracycline (12%); none were erythromycin-resistant. All the isolates were resistant to nalidixic acid, due to the long-recognized intrinsic resistance. They were also resistant to ciprofloxacin. In a study of 104 human isolates of *C. fetus* ssp. *fetus*, nonsusceptibility (intermediate or resistant) was found for cefotaxime (13%), erythromycin (71%), ciprofloxacin (5%), and tetracycline (34%).[117] In a 2006 study of 994 *C. fetus* isolated from cattle feces in Alberta, Canada, 39% were resistant to doxycycline and tetracycline, and 97% were resistant to nalidixic acid.[118] However, ciprofloxacin resistance was not found among the nalidixic acid-resistant *C. fetus* isolates, a phenotype typical for *C. fetus*. Ciprofloxacin resistance has been seen in *C. fetus* due to a *gyrA* mutation that has also been found in a ciprofloxacin-resistant *C. coli* strain.[119] Vandenberg et al.[50] found 100% nalidixic acid resistance among the eleven *C. fetus* strains isolated from humans in Belgium, but no resistance to the other five drugs tested, including ciprofloxacin. Of the 85 *C. upsaliensis* included in this study, 12% were nalidixic acid-resistant, 6% were ciprofloxacin-resistant, and 13% were erythromycin-resistant. Of 20 *C. concisus* isolates tested, 80% were nalidixic acid-resistant but only one isolate was ciprofloxacin-resistant.[81–83]

Epidemiologic Subtyping of *C. jejuni*

The ability to discriminate or subtype campylobacters below the level of species has been successfully applied to aid the epidemiological investigation of outbreaks of campylobacteriosis.[120] Subtyping provides information to recognize outbreaks of infection, match cases with potential vehicles of infection, and discriminate these from unrelated strains. In addition, these methods are important to identify potential reservoirs of strains that cause disease in humans, identify routes of transmission, and improve our understanding of *Campylobacter* epidemiology.[121]

A number of criteria are used to evaluate subtyping methods, including typability, reproducibility, discriminatory power, ease of use, ease of interpretation, and cost. The subtyping methods available to subtype *C. jejuni* vary considerably using these criteria, depending on the method used. The subtyping method of choice is ultimately determined by consideration of the basic microbiology of the organism in question, the nature of the microbiological question being asked, and, importantly, the ability of the typing method to detect significant epidemiological differences. Traditionally, phenotypic subtyping methods have been widely used to differentiate *C. jejuni* strains. There are two generally accepted, well-evaluated serotyping schemes that were developed in the 1980s for epidemiological characterization of *Campylobacter* isolates; the Penner scheme is based on heat-stable (HS) antigens using a passive hemagglutination technique,[122] and the Lior scheme is based on heat-labile (HL) antigens and a bacterial agglutination method.[123] The application of these techniques to *C. jejuni* isolates from human, farm animal, and environmental specimens has proven useful in outbreak investigations and for identification of potential reservoirs for human infection. However, the maintenance of a large panel of antisera that is not commercially available has prevented its routine application for strain characterization and not all isolates are typable.[124]

The limitations associated with phenotypic subtyping methods and the rapid growth of molecular biology techniques led to the development of a wide range of molecular subtyping methods. A review of various molecular subtyping methods, including pulsed field gel electrophoresis (PFGE), and seven-gene multilocus sequence typing (MLST), used for characterization of *Campylobacter* isolates is described in Refs. [125, 126]. These methods demonstrated large genetic diversity among human *C. jejuni* isolates, indicative of the sporadic nature of human campylobacteriosis and the variety of different sources for *Campylobacter* infection. The implementation of standard PFGE protocols and data sharing through the PulseNet network provided additional ability to compare and exchange data and determine if the same *C. jejuni* strains are circulating in different places.[127–129]

Advances in DNA sequencing technology have provided a means to investigate genetic diversity at the nucleotide level. DNA sequence analysis is accurate, highly reproducible, does not rely on the interpretation of gel patterns and allows the inference of genetic relatedness between closely related strains. MLST characterizes bacterial isolates by indexing the variation present in short (400–550 nucleotide base pairs) gene fragments from seven housekeeping genes. MLST is not more discriminatory than PFGE, but also enables investigation of the population structure of the organism. In addition, MLST data generated is electronically portable and amenable to storage in web-accessible databases.[130] MLST schemes have been developed and databases are available for several *Campylobacter* species, including *C. jejuni,* at the pubMLST website (http://pubmlst.org/campylobacter). MLST studies have established the population structure for *C. jejuni*; strains have been confirmed to be genetically diverse, exhibit a high degree of plasticity, and have a weakly clonal population structure.[131] Subsequent studies have also begun to demonstrate associations of *C. jejuni* genotypes with particular animal hosts,[132–135] which greatly advanced the understanding of the molecular epidemiology of *C. jejuni*.

MLST data have been successfully applied in microbial subtype-based source attribution studies to understand the relative contribution of different sources to the burden of *C. jejuni* infections. These studies provided a mounting body of evidence that a large proportion of sporadic human infections originate from poultry sources, which stimulated and informed the implementation of intervention strategies that have led to sustained decline in the number of *Campylobacter* infections in New Zealand.[136,137]

The advent of next generation sequencing technology, accompanied by the rapidly expansion of sequencing platforms, has significantly increased the cost-effectiveness and throughput for WGS.[138] The sequencing of the first complete genome of a *C. jejuni* strain (NCTC11168) in 2000[139] and the subsequent sequencing of many more *Campylobacter* genomes since, has resulted in a new range of approaches to understand the genetic nature of pathogenicity, host association, environmental adaptation and evolution.[140] The vastly increased availability of full genome sequence data has paved the way for the emerging discipline of genomic epidemiology. The utility of WGS data to provide routine surveillance of *Campylobacter* infections has been shown in a real-time clinical setting to provide improved resolution among very closely related isolates and allowed the

detection of single-strain clusters.[141,142] To facilitate this, web-accessible analysis tools and algorithms have been developed to compare various subsets of genetic loci, including MLST, core genome MLST (cgMLST), and whole genome MLST (wgMLST), without the need for a reference genome in a computationally nonintensive fashion.[143] Within PulseNet laboratories, foodborne outbreak clusters are detected using cgMLST. If further discrimination of isolates is needed, wgMLST or high-quality single-nucleotide polymorphism (hqSNP) analysis can be performed using the assembled sequences.[144–146]

The application of these powerful new molecular tools for comparative genomic studies of *C. jejuni* will facilitate the identification of phenotypic and molecular markers that may contribute to virulence, different disease outcomes, and host and ecological niche specificities. This, in turn, will greatly enhance source attribution studies to determine the fraction of *Campylobacter* infections attributable to different food sources, which will aid greatly the design of targeted control strategies to eliminate *C. jejuni* from the food chain so that food safety and public health risks are reduced.

Introduction

The first CRC series chapter on Chlamydia was written by Leslie A. Page and published in 1989. Since then, significant advances in Chlamydiae diagnostics, genomics, pharmacotherapeutics, classification of new species, and bioinformatics have come to light. This chapter provides a review of our current understanding of Chlamydiia, while addressing how its classification has evolved to date.

With the advent of electron microscopy in the 1960s (Nunes and Gomes 2014), Chlamydiae were classified as bacteria, essentially because they possess DNA, RNA, ribosomes, and have a cell wall similar to that of Gram-negative bacteria (Nunes and Gomes 2014; Moulder 1966; Nunes et al. 2010). In 1966, Dr. Page first published evidence for the Chlamydiales order, the *Chlamydiaceae* family, and the *Chlamydia* genus (Page 1966). The classification system described at the time was based on a *Chlamydia*-specific developmental cycle that, ultimately,

separated the *Chlamydiae* from the *Rickettsiae* species (Ward 1983)—both obligate intracellular parasites. The identification of *C. trachomatis* and *C. psittaci* species were subsequently possible after the American Society of Microbiology adopted stricter numerical—plus and minus—taxonomic criteria for bacterial classification (Everett and Andersen 2001; Ward 1983). These numerical criteria were organized into matrices and only included phenotypic characteristics of bacteriological "morphology, biochemistry, culture composition, physiology, nutritional requirements, antigenic composition, and phage sensitivity" (Ward 1983). However, relying on phenotypic characteristics and numerical matrices is considered problematic because divergent organisms sharing the same environment typically have similar phenotypes, without evidence of evolutionary relatedness. Thus, phenotypic criteria may not necessarily imply relatedness, rather evolutionary convergence.

Chlamydiae's unique intracellular, biphasic developmental cycle has led to their historic taxonomic misclassification as protozoa or viruses (Nunes and Gomes 2014). The misnomer "*Chlamydia*," from the Greek word "Chlamys/Khlamus" to mean mantle or cloak, stemmed from a misconception dating back to 1907, when Halberstaedter and von Prowazek noted what they thought were bacteria with intracytoplasmic inclusions that appeared "draped/cloaked" around infected cell nuclei from humans with active trachoma (Longbottom and Coulter 2003; Budai 2007). Intracytoplasmic bodies or vacuoles were also noted in active human cases of urethritis, cervicitis, pneumonia (Nunes and Gomes 2014), conjunctivitis scrapings, as well as inoculated orangutans from trachoma cases (Longbottom and Coulter 2003). Yet, despite the high phenotypic homology, tissue tropism and host preference noted in the *Chlamydia* genus (Sachse et al. 2015), low homology by DNA-DNA hybridization was described across species (Nunes and Gomes 2014; Budai 2007; Sachse et al. 2015). In 1999, less than 70% hybridization homology was a common cutoff for the establishment of new species (Everett, Bush, and Andersen 1999), though homology by DNA-DNA hybridization within the phylum Chlamydiae, was 95% and was suggestive of a common origin (Nunes and Gomes 2014; Budai 2007).

In 1999, a controversial proposal was made to divide the *Chlamydiaceae* family into two genera and nine species (Clarke 2011; Everett, Bush, and Andersen 1999). In order to definitively establish the number and type of *Chlamydiae* species, researchers at the United States Department of Agriculture (USDA) National Animal Disease Center set about developing a DNA-based classification system based on 16S and 23S ribosomal RNA genes and the major outer membrane protein (MOMP)/ompA gene (Everett, Bush, and Andersen 1999). Based on gene analysis, the order Chlamydiales was redefined—the original family of *Chlamydiaceae* was analyzed by gene sequencing, which led to the establishment of four families, instead of one. The species that retained a >90% 16S rRNA sequence identity remained within the family *Chlamydiaceae*; whereas species with 80–90% sequence identity were separated into one of three new families—*Parachlamydiaceae*, *Simkaniaceae*, and *Waddliaceae* (Everett, Bush, and Andersen 1999).

Within this newly defined *Chlamydiaceae* family, the genus *Chlamydia* was expanded to include not just *C. trachomatis*, but also *C. suis*, and *C. muridarum* (Everett, Bush, and Andersen 1999). The species *C. psittaci* and its associated species, *C. pecorum* and *C. pneumoniae,* were moved to a new genus *Chlamydophila* in 1999. Three new species, *Chlamydophila felis*, *Chlamydophila caviae*, and *Chlamydophila abortus,* were added to *Chlamydophila* (Everett, Bush, and Andersen 1999). As of 2015, in light of newly identified species and more complete genomic sequence data, the taxonomy of *Chlamydia* species has undergone a second significant revision. The class of Chlamydiia was split into two orders: the retained, original order of Chlamydiales and a new order, Parachlamydiales (Gupta et al. 2015). The original four families classified in the original Chlamydiales order were subsequently further divided, while five additional *Candidatus* families were created (Gupta et al. 2015). Four of the five new candidate families were included under the Parachlamydiales order and the new candidate family, *Candidatus* Clavichlamydiaceae was retained within the original Chlamydiales order. The novel order of Parachlamydiales retained the *Parachlamydiaecae*, *Simkaniaceae,* and *Waddliaceae* families, with the added novel *Candidatus:* Criblamydiceae, Parailichlamydiceae, Piscichlamydiceae, and Rhabdochlamydiceae families (Gupta et al. 2015).

To date, the current Chlamydiia class taxonomy has been further diversified from one order with four families, to two orders (Chlamydiales and Parachlamydiales), with nine families—however, approval of the *Candidatus* families by the Subcommittee on Taxonomy of Chlamydiae of the International Committee on Systemics of Prokaryotes (ICSP) remains to be formalized as of 2019 (Borel and Greub 2019).

Significant controversy has existed within the *Chlamydiaceae* family as a result of inconsistencies in sequence-identity cut-off criteria in taxonomic classification. The 16S rRNA gene sequence identity threshold for the two genera (*Chlamydia* and *Chlamydophila*) proposed for *Chlamydiaceae* in 1999 was 95% (Everett, Bush, and Andersen 1999), however in 2008, more standardized and consistent evolutionary lineage criteria were recommended for boundary thresholds in prokaryotes (Sachse et al. 2015). The All-Species Living Tree Project, a collaborative of microbial taxonomists, created more consistent criteria for evolutionary lineage relationships (Yarza et al. 2008). To meet a standardized boundary threshold for a prokaryotic genus, a 94.5% sequence identity of 16S rRNA gene cut-off was instead recommended (Sachse et al. 2015). Newer analyses of 16S rRNA sequences generally showed higher sequence identities than the thresholds of 94.5–95%, which at the time, suggested that *Chlamydia* and *Chlamydophila* genera in separate phylogenetic branches were actually more similar to each other than were members of different genera in other bacterial groups (Stephens et al. 2009). Comparative pairwise protein sequencing has provided confirmation for emending two genres to a single genus (Stephens et al. 2009). In an analysis of 97 bacterial and archaeal genera, it was determined that a 50% threshold for the percentage of conserved proteins (POCP) was consistent with current levels of genus classification (Sachse et al. 2015), where *Chlamydia trachomatis* and *Chlamydophila psittaci* generated a POCP value of 82% (Sachse et al. 2015; Sachse and Laroucau 2015). In this review, we will be reverting to a single genus for all species.

Finally, a number of new species have been identified bringing the number of species from 9 to 13, and three additional *Candidatus* species (Cheong et al. 2019). Originally, the species

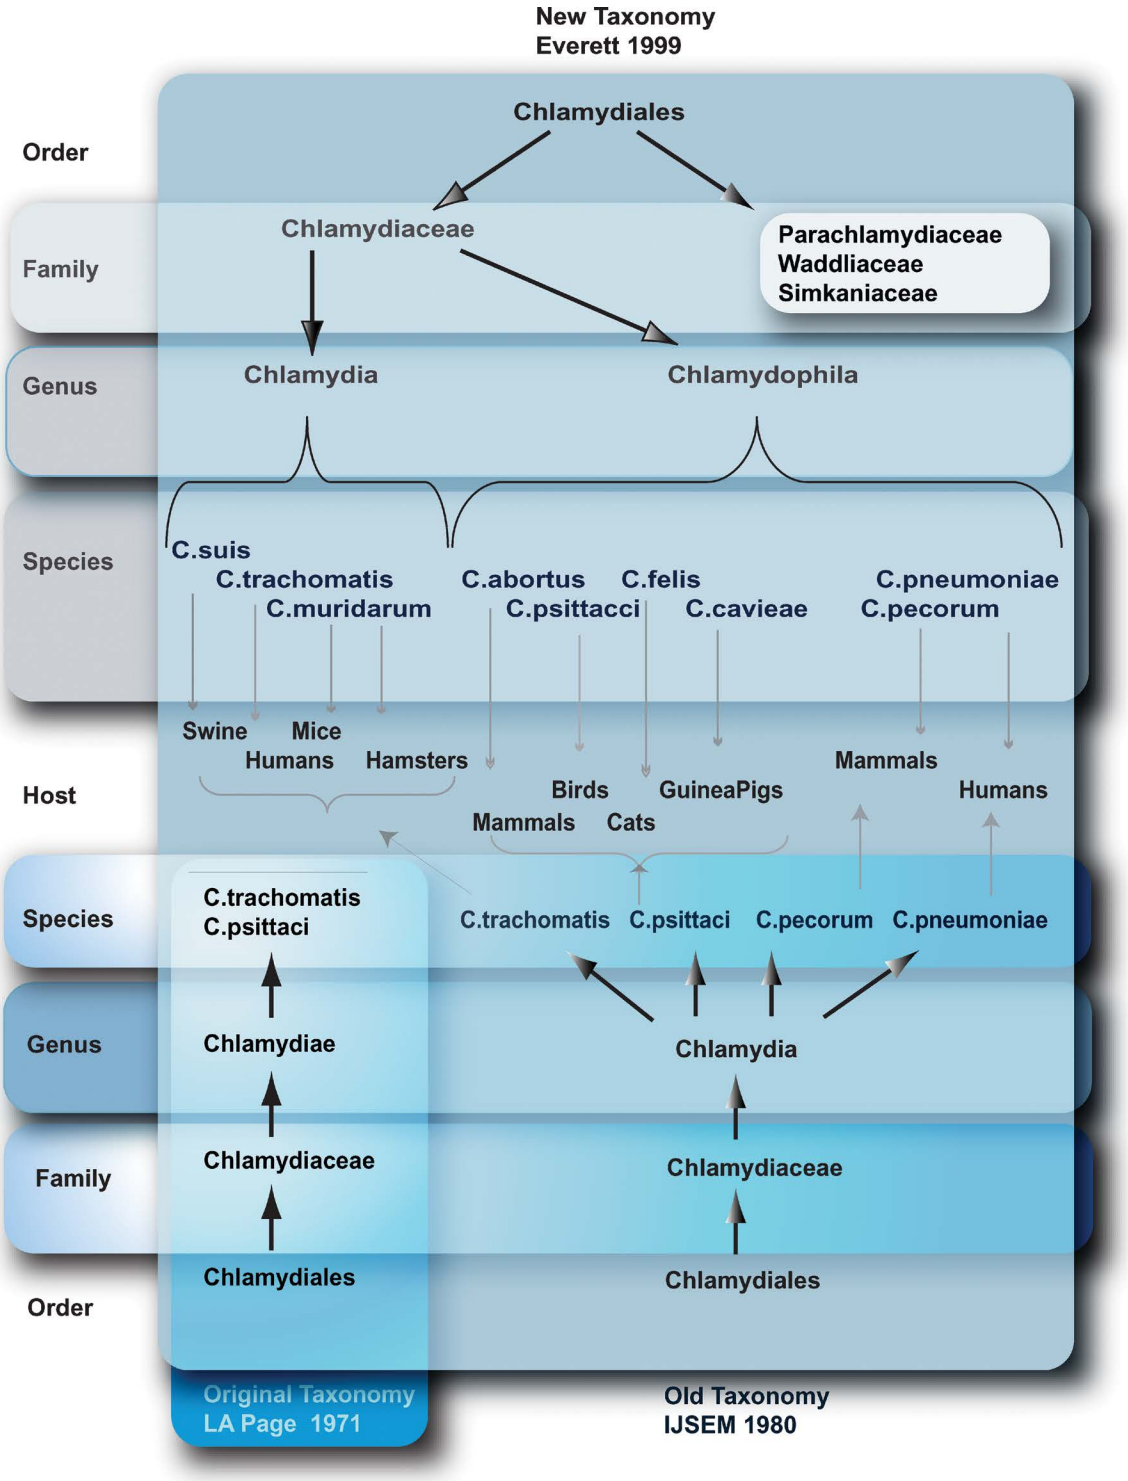

FIGURE 25.1A Historical taxonomy overview.

C. psittaci was thought to be the only avian species. However, two new avian species were subsequently identified in pigeons and poultry—*Chlamydia avium* and *Chlamydia gallinacea*—which were *Chlamydiaceae*-positive species, but *Chlamydia-psittaci*-negative avian species (Cheong et al. 2019; Sachse et al. 2014). The species *Candidatus* Chlamydia ibidis has so far only been identified in feral populations of sacred ibis, wading birds (Sachse et al. 2015). The rest of the new species, *Chlamydia serpentis*, *Chlamydia poikilothermis*, as well as the candidate species *Candidatus* Chlamydia corallus and *Candidatus* Chlamydia sanzinia, have all been found in captive snakes (Cheong et al. 2019; Sachse et al. 2014) (see Figures 25.1A and B).

As phylogenetically isolated, intracellular microbes, Chlamydiales are believed to have evolved differently than other

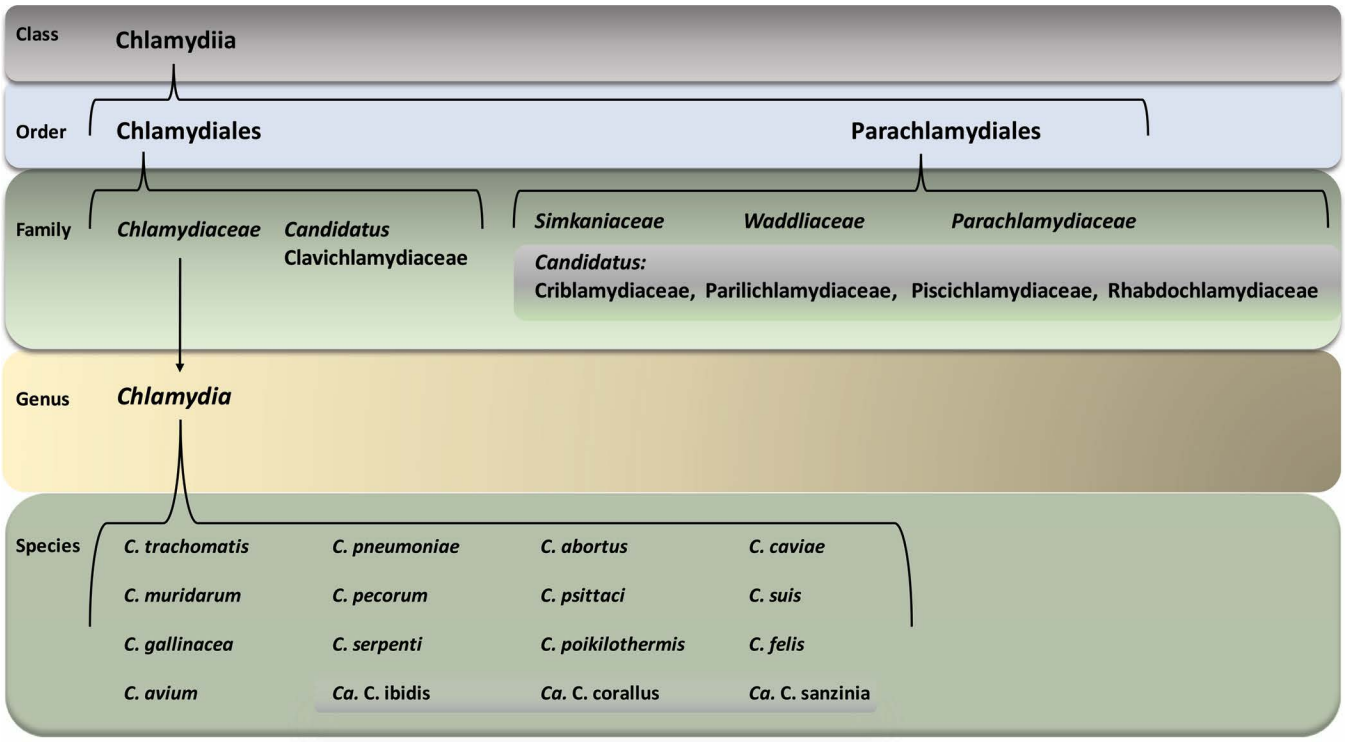

FIGURE 25.1B Current taxonomic lineage.

well-characterized facultative and obligate intracellular eubacteria (Nunes et al. 2010). *Chlamydiae* species differ in host range, tissue tropism and pathogenicity (Nunes et al. 2010). Their interaction with multiple hosts can be elucidated from primate DNA analyses and from the isolation of plant-like genes; both suggest a divergence from a common ancestor approximately 700 million years ago (Clarke 2011) and an ancestral evolutionary relationship with cyanobacteria (Nunes et al. 2010). Understanding the mechanisms of genomic variation will enable us to identify potential genetic causes of pathogenicity (Nunes et al. 2010). Moreover, the suggestion that the species' pathogenicity could be partially mediated by an enhanced activation of the hosts' innate immune response could point to unique mechanisms underlying persistent infection (Rusconi and Greub 2011), and potentially lead to the development of innovative prophylactic and therapeutic treatments (Nunes et al. 2010).

Life Cycle

Chlamydiae are obligate intracellular bacteria that exist in two morphologically distinct forms and are characterized by a biphasic life cycle under cell culture conditions (Vandahl, Birkelund, and Christiansen 2004; Hogan et al. 2004). The bacteria alternate between a small infectious (300–400 nm) extracellular form—the elementary body (EB)—and a larger noninfectious (800–1000 nm) intracellular replicating form—the reticulate body (RB) (Murray 1998; Vandahl, Birkelund, and Christiansen 2004). Resistant to environmental factors, EB are spore-like and infectious, albeit unable to replicate outside of a host. EB are made up of DNA wrapped around histone-like proteins and enveloped by an outer membrane of cross-linked proteins with disulfide bonds between cysteine residues for osmotic stability (Vandahl, Birkelund, and Christiansen 2004).

The EB life cycle begins when they attach to and stimulate phagocytosis by host cells (Figure 25.2). Within the phagosome, named an inclusion, the EB differentiate into metabolically active RB that later undergo multiple cycles of binary fission leading to their secondary differentiation back to an EB form (Hogan et al. 2004; Abdelrahman and Belland 2005). Lysis of the host cell releases a new generation of infectious EB that propagates

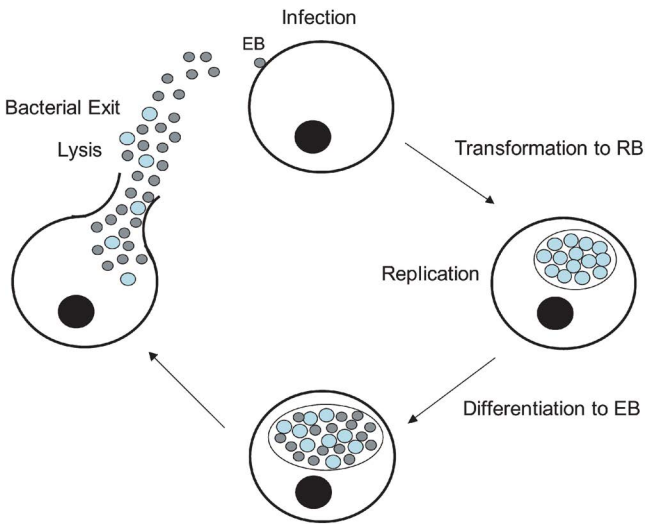

FIGURE 25.2 Chlamydiae life cycle.

among neighboring cells (Abdelrahman and Belland 2005). This life cycle often lasts 2–3 days, with some *Chlamydia*-like strains taking up to 14 days. The conditions under which this propagation occurs can lead to aberrant RB and can determine whether the host will continue to express infective EB forms with each bacterial cell division (Abdelrahman and Belland 2005). Propagation is linked to host immune responses *in vivo*, therefore pro-inflammatory chemokines, cytokines, nutrient availability and antibiotics are among some of the environmental factors that can disrupt the EB life cycle (Stephens 2003).

Characterization of *in vitro* persistent phase of infection and *in vivo* models suggest that Chlamydiae can persist in an altered form (Hogan et al. 2004). This form is now known as an aberrant body (AB) (Bayramova, Jacquier, and Greub 2018). These are persistent, viable nondividing, noninfectious forms. They are characterized as enlarged RBs due to continuous DNA replication without division, and their formation seems to be in response to stress with multiple stimuli (Bayramova, Jacquier, and Greub 2018). Antibiotics such as penicillin, clavulanic acid, and phosphomycin; depletion of nutrients such as iron, glucose, or amino acids; treatment with interferon; and coinfection with herpes, can all induce AB formation (Bayramova, Jacquier, and Greub 2018). These changes are reversible and continuation to the RB stage can occur upon removal of stressors, however, recurrent chlamydial infection may result from aberrant body formation (Hogan et al. 2004; Stephens 2003).

Identification

Phenotypic Markers

The genus *Chlamydia* is marked by the presence of intracellular glycogen, unfortunately those formally of the genus *Chlamydophila* are marked by neither the presence nor the absence of glycogen since some species show transient levels of glycogen during their life cycle. Originally, chlamydial species were distinguished by resistance to sulfadiazine, but this turned out to be highly variable.

Microimmunofluorescence, based on the immunoreactivity of the chlamydial major outer membrane protein (MOMP) and dominant antigen, is reported to be the first widely used methodology to discern differences in the molecular epidemiology between strains (Nunes et al. 2010). Initially, it employed polyclonal antibodies, later replaced by more specific and sensitive monoclonal antibodies (Nunes et al. 2010).

The *Chlamydiaceae* family is marked by detection with monoclonal antibodies to the group-specific lipopolysaccharide epitope: αKdo-(2→8)-αKdo-(2→4)-αKdo (originally: the genus-specific epitope) (Everett 1999). *Chlamydophilae* were originally differentiated from *Chlamydiae* by antibodies that recognize epitopes (NPTI, TLNPTI, LNPTIA, LNPTI) in the variable region - of the *Chlamydiae* MOMP, but not *Chlamydophilae*. Because these mAbs are routinely used to serotype human *C. trachomatis* isolates, cross-reaction may lead to errors in species identification (Everett 2000). It is worth noting that the classification of antibiotic resistance among species prior to 1999 is unreliable, since a DNA-typing, taxonomic classification system of species had not yet been adopted—e.g., data on antibiotic sensitivity and resistance for *C. trachomatis* prior to 1999 may have inadvertently included *C. trachomatis* and *C. suis* strains.

DNA Markers

Since phenotypic markers cannot reliably differentiate between Chlamydial species, DNA typing and sequencing is the best manner of identifying them. This makes sense since the various species were established via DNA sequence analysis in the first place. Real-time polymerase chain reaction (PCR) primers are available to amplify ompA (that encodes MOMP), 16S rRNA, and 23S rRNA genes (Nunes et al.; Everett 2000). The ompA primers are specific for all *Chlamydiaceae,* while the 16S and 23S primers are specific for all Chlamydiales (Everett 2000). Multilocus sequence typing using 400–500 base pair fragments of seven housekeeping genes (enoA, fumC, gatA, gidA, hemN, hlfX, oppa) have identified population genetic structure and diversity within *C. trachomatis* (Pannekoek et al. 2008) and *C. psittaci* (Pannekoek et al. 2010).

DNA Microarray technology is increasingly being deployed as a diagnostic technique capable of overcoming the limitations of PCR by increasing the number of targeted genomic loci used to identify an organism. This allows for rapid discrimination between species, strains, genotypes, serotypes, and resistance types. Validated protocols for 20 *Chlamydia* species are now available (Sachse and Ruettger 2015). Genomic sequence data is available for at least 20 *Chlamydiae* species within the phylum. These genomes are useful in developing phylogenetic trees and for identifying sequences valuable for typing of Chlamydiae during infection (Gupta et al. 2015). Conserved signature insertions/deletions (CSIs) which are insertions or deletions within protein sequences that are unique to a related group of organisms and conserved signature proteins (CSPs), which are proteins specific to certain lineages and found only in related groups (Gupta et al. 2015).

Thirty two CSIs have been identified that are specific to the phylum Chlamydiae with 17 CSIs being specific to the family *Chlamydiaceae* with three others being specific to the grouping of families *Candidatus* Criblamydiaceae, *Parachlamydiaceae*, *Simkaniaceae*, and *Waddliaceae*. In regard to the CSPs, 98 are specific to *Chlamydiaceae* and 15 are specific to the grouping of families *Candidatus* Criblamydiaceae, *Parachlamydiaceae*, *Simkaniaceae*, and *Waddliaceae*. Based on this finding, along with additional 16s rRNA gene sequence data, it was proposed that the class Chlamydiia be split into two orders. Chlamydiales would contain the family *Chlamydiaceae* and the *Candidatus* family Clavichlamydiacae. A novel order of Parachlamydiales was established to contain the families *Parachlamydiaceae*, *Simkaniaceae*, and *Waddliaceae* as well as the *Candidatus* families of Criblamydiaceae, Parilichlamydiaceae, Piscichlamydiaceae, and Rhabdochlamydiaceae (Gupta et al. 2015).

Pathogenicity of Chlamydiae

Chlamydiae were believed to exclusively cause infection and disease in humans and other animals (Everett 2000); however, as new and old species are genetically identified and classified, the epidemiology of Chlamydiae in a vast number of microbial, eukaryote hosts have come to light. There is also evidence of

Chlamydia-like strains found in soil, as well as *Chlamydia*-infected amoeba in marine water and anoxic, deep-marine sediment, without evidence of a host (Dharamshi et al. 2020). These recent findings may be of importance in understanding the comparative evolution and plausible tropism between *Chlamydia* species and specific hosts; as well as the potential mechanisms that may lead to their transmissibility to humans and other animals, some with greater pathogenicity than others (Fritsche et al. 2000; Everett 2000).

Many *Chlamydia* species carry a 7.5-kb plasmid containing reading frames not considered to be critical for its growth *in vitro;* however, it is demonstrated to play a role in species pathogenicity in certain species; e.g., *C. muridarum* (Zhong 2017). *Chlamydia* plasmids generally described encode eight open reading frames conventionally called plasmid glycoproteins 1–8 or pGP1–8, which are thought to promote species adaptation to various animal tissues and enable our further understanding of their pathogenicity (Zhong 2017).

Although host multitropism of some pathogens has rendered their manipulation possible in animal models, the human-restricted tropism of numerous viruses, bacteria, fungi, and parasites has seriously hampered our understanding of these pathogens. Uncovering the genetic basis underlying the narrow tropism of such pathogens is critical for understanding their mechanisms of infection and pathogenesis. Moreover, such genetic dissection is essential for the generation of permissive animal models that can serve as critical tools for the development of therapeutics or vaccines against challenging human pathogens. In this review, we describe different experimental approaches utilized to uncover the genetic foundation regulating pathogen host tropism as well as their relevance for studying the tropism of several important human pathogens (Douam et al. 2015).

Chlamydiales

The order Chlamydiales contains the *Chlamydiaceae* (Everett et al. 1999) and the *Candidatus* Clavichlamydiaceae families. Based on phylogenomic analyses of the phylum Chlamydiae by Gupta et al. (2015), members of this order can be distinguished from the Parachlamydiales by their branching in phylogenetic trees and distinguished from all other *Chlamydiae* species by Clade 1-specific CSIs; and typically showing >89% 16S rRNA gene sequence identity with each other (Gupta et al. 2015).

Chlamydiaceae

Chlamydiaceae, the original family described in previous editions of this book chapter, was formerly divided into two genera: *Chlamydia* and *Chlamydophila*. These are currently emended to one genus, *Chlamydia,* and now includes 13 phylogenetically classified species and three additional candidate species (Stephens et al. 2009). All are Gram-negative and express the family-specific lipopolysaccharide epitope αKdo-(2→8)-αKdo-(2→4)-αKdo. The extracellular osmotic stability of the *Chlamydiaceae* EBs is maintained by a complex of disulfide-cross-linked envelope proteins that include the 40 kDa major outer membrane protein, a hydrophilic cysteine-rich 60 kDa protein, and a low-molecular-mass cysteine-rich lipoprotein (Ward 1983). Phenotypic variability, host specificity and other molecular factors involved in chlamydial pathogenicity are thought to be the result of cumulative single nucleotide polymorphisms (SNPs) and small indels, as the species coevolves with their hosts (Nunes et al. 2010).

Chlamydia trachomatis

C. trachomatis comprises three geno-groups (formerly known as biovars) that are transmitted by sexual or other contact (Pannekoek et al. 2008; Stephens et al. 1998; Carlson et al. 2005). Their complete gene sequences have been identified (A/HAR-13 and D/UW-3/CX) (Stephens et al. 1998; Carlson et al. 2005) and these exhibit a genomic conservation of >98% (Nunes et al. 2010).

The *C. trachomatis* genome, under the influence of selective environmental factors and coexisting flora, gives the species an advantage in specific ecological niches (Nunes and Gomes 2014). *C. trachomatis* has only been isolated from humans. More recently however, Chlamydia-like microorganisms were detected in the gut microbiota of chimpanzees (Clarke 2011; Ochman et al. 2010). Whole genome sequence dissimilarities and phenotypic consequences of each colonizing species are believed to be under the direct influence of their host's innate immune response—their pattern-recognition receptors, signal molecules such as cytokines, and reactive oxygen species (Nunes and Gomes 2014; Rusconi and Greub 2011; Seth-Smith et al. 2013). Understanding the mechanisms underlying the coevolution of Chlamydiae and each host's innate immune response will enable the development of innovative treatment strategies, including effective vaccines (Rusconi and Greub 2011).

C. trachomatis is of global importance as the most common bacterial sexually transmitted infection and the leading cause of infectious blindness worldwide, according to the World Health Organization (Prevalence and Incidence of Sexually Transmitted Infections 2011; Rusconi and Greub 2011; Seth-Smith et al. 2013). *C. trachomatis* requires tissue culture for *in vitro* growth, a technically challenging and time-consuming technique (Seth-Smith et al. 2013).

Immunoreactivity of antibodies against epitopes on the *C. trachomatis* MOMP has enabled the identification of 19 distinct serovars, divided into three geno-groups—B class (serovars B, D, Da, E, L1, L2, L2a); C class (A, C, H, I, Ia, J, Ja, K, L3); and Intermediate class (F, G, Ga) (Everett, Bush, and Andersen 1999; Gomes et al. 2006; Pannekoek et al. 2008). Specifically, A, B, Ba, and C are implicated in chronic eye infections (trachoma) and serovars D, Da, E, F, G, Ga, H, I, Ia, J, and K in urogenital infections (Gomes et al. 2006). The lymphogranuloma venereum (LGV) serovars L1, L2, L2a, and L3 can cause more invasive urogenital disease, including painful buboes and proctatitis (Gomes et al. 2006; Manavi 2006). *C. trachomatis* has also been implicated in some forms of arthritis, neonatal conjunctivitis, and pneumonia (Everett, Bush, and Andersen 1999).

Although clinicians consider Chlamydiae culture methods to be the gold standard for identification of chlamydial infection, it has low specificity and it is laboratory expertise-dependent (Manavi 2006). Serotyping using direct fluorescent staining with monoclonal antibodies (DFA) is highly specific, but time and labor intensive (Manavi 2006). *C. trachomatis* routinely

cross-reacts with *C. suis* epitopes with DFA serotyping, leading to errors in species identification (Everett 2000). Conversely, PCR has a sensitivity of 90% and specificity of 99% (Manavi 2006). Treatment of choice against *C. trachomatis* includes macrolides (azithromycin, erythromycin), tetracyclines, quinolones (ciprofloxacin, ofloxacin), and penicillins (amoxicillin) (Manavi 2006). Most *C. trachomatis* strains have extrachromosomal plasmids and, in general, therapeutic failure is uncommon (Nunes and Gomes 2014).

Chlamydia muridarum

Isolated from mice and hamsters, the two strains of *C. muridarum*—MoPn (Nigg) and SFPD (Weiss) had originally belonged to the *C. trachomatis* mouse pneumonitis biovar, due to their high relatedness (Cheong et al. 2019; Nunes and Gomes 2014; Everett, Bush, and Andersen 1999). SFPD is not known to cause disease, while MoPn may produce pneumonia in mice or cause an asymptomatic infection. The MoPn genome has been sequenced and the isolate used contained an extrachromosomal plasmid (Read et al. 2000). MoPn is sensitive to sulfadiazine.

Chlamydia suis

C. suis strains were originally referred to as *C. trachomatis* due to DNA sequence homology in the MOMP gene (*ompA*) (Everett 2000). *C. suis* had only been isolated from swine, where they caused conjunctivitis, enteritis, pneumonia, and asymptomatic infections (Everett 2000). *C. suis* DNA has also been more recently reported in conjunctival swabs of Nepalese trachoma patients and Belgian slaughterhouse workers by PCR and microarray, suggesting potential zoonotic transmission from pigs to humans (Borel, Polkinghorne, and Pospischil 2018). In the wild, *Chlamydiae* are commonly found in the intestine of pigs, in mostly endemic subclinical cases (Borel, Polkinghorne, and Pospischil 2018). However, *C. suis* might be opportunistic in nature; with variations in ocular, respiratory, and intestinal virulence influenced by the age, host immune status and/or the presence of a *C. suis* strain extrachromosomal plasmid (Borel, Polkinghorne, and Pospischil 2018).

Some strains of *C. suis* are resistant to sulfadiazine and/or tetracycline (Everett 2000); however, *C. suis* is the only chlamydial species known to have naturally acquired genes encoding for tetracycline resistance (Borel, Polkinghorne, and Pospischil 2018). Fears of horizontal transfer of the tetracycline resistant Tet(C) gene into human chlamydial pathogens is a growing fear (Bommana and Polkinghorne 2019).

Chlamydia abortus

C. abortus, formerly *Chlamydophila abortus*, was originally classified under *C. psittaci,* but is in fact its own species (Everett, Bush, and Andersen 1999). Associated primarily with cases of abortion and poor prognosis in neonate animals, *C. abortus* infections affect the placenta and has been reported to be endemic in ruminants—rabbits, guinea pigs, as well as pigs and horses (Borel, Polkinghorne, and Pospischil 2018). After aborting, most mammals have been reported to acquire immunity and rebreed successfully (Vretou et al. 2007). The potential to cause serious economic impacts to livestock have made research into *C. abortus* a priority (Bommana and Polkinghorne 2019).

In humans, upper respiratory infection due to *C. abortus* in a laboratory worker responsible for experimental, intranasal infections of sheep has also been reported as probable causative organism of human atypical pneumonia (Borel, Polkinghorne, and Pospischil 2018), which should compel public health officials to inform laboratory personnel of the potential for zoonotic chronic pulmonary infection by *C. abortus* via aerosol inhalation (Borel, Polkinghorne, and Pospischil 2018).

Documented cases of zoonotic abortion in women due to *C. abortus* are suspected to have resulted from close contact with sheep infected tissue (Everett 2000; Cheong et al. 2019). The complete genome has been sequenced; however, no strain of *C. abortus* has been identified to contain an extrachromosomal plasmid (Thomson et al. 2005). Chlamydiosis is a zoonosis that places pregnant women at a particularly high risk of abortion (Borel, Polkinghorne, and Pospischil 2018), with complicated cases of *C. abortus* septicemia also reported, carrying a fetal mortality of 94% and maternal mortality of 6.3% (Walder et al. 2005). Early treatment with erythromycin should be considered in suspected zoonotic exposure to *C. abortus*—especially since fetal abortions may be preventable with early administration of macrolides or tetracyclines (Walder et al. 2005).

Chlamydia caviae

C. caviae species, was taxonomically separated from *C. psittaci* in 1999 (Borel, Polkinghorne, and Pospischil 2018). *C. caviae*, formerly *Chlamydophila caviae*, has been exclusively isolated from conjunctivae of infected guinea pigs (Everett 2000), although it has also been identified in cats, dogs, rabbits, and horses as primary hosts with conjunctivitis and urogenital tract infections (Cheong et al. 2019). *C. caviae* can be transmitted sexually in humans, with clinical manifestations resembling active *C. trachomatis* disease (Cheong et al. 2019).

Guinea pig inclusion conjunctivitis has been reported in cytological smears stained with Giemsa, where intracytoplasmic inclusion bodies were evaluated from swabbed conjunctival epithelial cells confirmed to be *C. caviae* by PCR (Borel, Polkinghorne, and Pospischil 2018). The genome of *C. caviae* has been sequenced and it contains an extrachromosomal plasmid (Read et al. 2003) carrying virulence-associated chromosomal genes (Nunes and Gomes 2014).

Chlamydia felis

Formerly *Chlamydophila felis* it is endemic among domestic cats and dogs, its primary hosts (Cheong et al. 2019). *C. felis* primarily causes conjunctivitis, rhinitis, chronic salpingitis, and respiratory pathology in its primary host. Zoonotic infection of humans has also been reported, as a possible cause of conjunctivitis (Cheong et al. 2019). Strains differ in their pathogenesis, though the causes of these pathogenic differences are not clearly understood (Everett 2000). The genome of strain Fe/C-56, as well as that of other strains, have been sequenced (Azuma et al. 2006) and some have been identified to have an extrachromosomal plasmid, which may suggest evolutionary tropism (Douam et al. 2015; Zhong 2017).

Seroprevalence of *C. felis* amongst domestic cats is relatively high with rates among strays being >10% and among house cats at >3% in some countries. While cats are the primary host, dogs are now seen to be a significant reservoir of the bacterium, thus increasing the likelihood of zoonotic infection (Cheong et al. 2019). Chlamydial infection from a domestic cat with signs of conjunctivitis and rhinitis to a human-owner who developed acute follicular conjunctivitis was first demonstrated by Schachter et al. in 1969 (Paolillo et al. 2019). While direct evidence linking *C. felis* to human disease is ambiguous, a seroepidemiological study in Japan found a prevalence of 1.7% in the general population and 8.8% amongst small animal veterinarians (Cheong et al. 2019).

Zoonotic chlamydial infection is rare and it may be underestimated secondary to faulty isolation and detection practices (Di Francesco et al. 2004). Seroepidemiological data on *C. felis* reported sera tested for anti-*C. felis* antibodies by microimmunofluorescence test (MIF), using purified elementary bodies and fluorescein-conjugated goat anti-cat immunoglobulin G sera (Euroclone) (Di Francesco et al. 2004). However, sera positive for *C. felis* was also positive for *C. pneumoniae* and *C. psittaci,* demonstrating significant cross-reactivity between the species (Di Francesco et al. 2004). Given the higher seroprevalence of *C. pneumoniae* among humans, cross-reactivity is expected (Di Francesco et al. 2004), thus molecular classification techniques should be used in order to improve accuracy of evidence for zoonotic infection of *C. felis* (Longbottom and Livingstone 2006). Recently, *Parachlamydiaceae* have been identified in cats with neutrophilic and eosinophilic conjunctivitis (Sykes 2005) and the treatment of choice was found to be doxycycline, with azithromycin affording less efficacy (Sykes 2005).

Chlamydia pecorum

C. pecorum, formerly *Chlamydophila pecorum*, has been isolated only from mammals and is serologically and pathogenically diverse (Everett 2000). *C. pecorum*, was initially named *C. psittaci*, is reported to be more virulent in the koala than *C. pneumoniae* (Borel, Polkinghorne, and Pospischil 2018). Many animals, such as sheep, goats, pigs, and cattle, as well as wild ruminants, wild boars, and marsupials, such as koalas, can develop active clinical diseases (Borel, Polkinghorne, and Pospischil 2018). These include conjunctivitis, encephalomyelitis, enteritis, pneumonia, polyarthritis, infertility, and abortion, all of which have contributed to substantial population declines (Everett 2000).

C. pecorum infections in koalas have been associated with keratoconjunctivitis and aspermia with *C. pecorum* and *C. pneumoniae* (Borel, Polkinghorne, and Pospischil 2018). *C. pecorum* has been reported to have a prevalence of up to 100% in eastern states of Australia (Borel, Polkinghorne, and Pospischil 2018). Chlamydial inclusions were demonstrated in testis, Sertoli cells by IHC and TEM; and chlamydial DNA was also detected by PCR (Borel, Polkinghorne, and Pospischil 2018).

Chlamydia pneumoniae

Formerly *Chlamydophila pneumoniae* was previously synonymous with TWAR (a human biovar). *C. pneumoniae* primary hosts have included humans and a wide range of nonhuman animals, including mammals and reptiles (Cheong et al. 2019); however, zoonotic transmission has been linked to the discovery of nonhuman genotypes of *C. pneumoniae* in humans (Cheong et al. 2019). Pathology has been described in its primary host—respiratory disease not only in humans, but also in koalas, bandicoots, and horses, as well as a wide range of reptiles, such as snakes, iguanas, chameleons, frogs, turtles (Everett, Bush, and Andersen 1999; Cheong et al. 2019). Animal isolates have been shown to contain an extrachromosomal plasmid similar to that found in *C. trachomatis* and *C. muridarum*, but absent from human isolates (Everett, Bush, and Andersen 1999). Complete gene sequence of four strains, AR39, CWL029, J138, and TW183 have been cited in the literature (Read et al. 2000; Kalman et al. 1999; Shirai et al. 2000). The potential economic impact of *C. pneumoniae* transmission and the implication of pathogenic-association of disease onset and progression in asthma, primary biliary cirrhosis, atherosclerosis, and lung cancer have made research into *C. pneumoniae* a priority (Cheong et al. 2019).

The human *C. pneumoniae* strain TWAR is primarily a pathogen of the respiratory tract capable of causing acute or chronic bronchitis and pneumonia (Everett, Bush, and Andersen 1999). *C. pneumoniae* has been identified in asymptomatic and coinfected individuals (Cevenini, Donati, and Sambri 2002). It has been implicated in obstructive pulmonary disease, cystic fibrosis, Alzheimer's disease, asthma, erythema nodosum, reactive airway disease, Reiter's syndrome, and sarcoidosis (Everett, Bush, and Andersen 1999). There is evidence that *C. pneumoniae* may be involved in atherosclerosis and the acceleration of atherosclerotic-lesion development in humans and mice (de Kruif et al. 2005). Although *C. pneumoniae* primarily infects humans, mice have been found to be susceptible via intranasal inoculations, making them a useful animal model for the study of pneumonitis (Yang, Kuo, and Grayston 1993). The atherogenic properties of *C. pneumoniae* were not influenced by antibiotic therapy, unless the antibiotics were administered in the early, acute state of infection (de Kruif et al. 2005). Immunization against *C. pneumoniae* is the focus of current research (de Kruif et al. 2005; Longbottom and Livingstone 2006). At current, the most reliable assay for the detection of *C. pneumoniae* is real-time PCR; however, no well-standardized assay has been approved by the U.S. Food and Drug Administration (Kumar and Hammerschlag 2007).

Chlamydia psittaci

The eight formerly *Chlamydophila psittaci* serovars (A-F, M56, WC), and the three more recently described genotypes, have been identified in a wide range of bird groups, as its primary hosts (Heddema et al. 2006). *C. psittaci* strains (A-F) have been described as transmissible to birds, but have also been described as transmissible to mammals (WC and M56), as well as humans through possible inhalation (Cheong et al. 2019; Everett 2000) of feather dust or aerosolized fecal material (Vogler et al. 2019). Infection is often systemic, with or without apparent symptoms, including fever, headache, myalgia, and/or intermittent shedding (Cheong et al. 2019). *C. pneumoniae* has been reported to be passed through eggs and to chicks via regurgitation causing chronic Chlamydiosis (Cheong et al. 2019). Stress often triggers onset of severe symptoms, resulting in rapid deterioration and death. Serovar A is found among psittacine birds. Serovar B

however, is described as endemic to pigeons; Serovar C among ducks and geese; Serovar D among turkeys; Serovar E among pigeons and other birds; and Serovar F, among parakeets and turkeys (Cheong et al. 2019). Genotyping of the *C. psittaci* ompA gene has revealed additional genotypes, including E/B, I, and J; with several strains containing an extrachromosomal plasmid (Everett 2000).

Infection by *C. psittaci* causes psittacosis (Heddema et al. 2006). In 1895, the term psittacosis derived from the Greek for parrot was first used to describe this disease, however a Gram-negative bacterium from parrots dying of psittacosis (*Bacillus psittacosis*) was instead identified belonging to the genus, *Salmonella* (Borel, Polkinghorne, and Pospischil 2018). Inconsistencies reported in classification of bacteriological isolates prompted the suspicion of a viral etiology of psittacosis, though in the late 1970s, *C. trachomatis* and *C. psittaci* were distinguished as separate species on the basis of sulfonamide susceptibility and glycogen accumulation by iodine staining (Borel, Polkinghorne, and Pospischil 2018).

C. psittaci has been particularly prevalent among bird slaughterhouse workers and owners of pet birds—with samples mainly of serovar A in psittacine birds and patients with psittacosis (Heddema et al. 2006; Longbottom et al. 2001; Everett, Bush, and Andersen 1999). Zoonotic infection is described as occurring horizontally by diseased or subclinically infected birds through contaminated aerosols and droppings (Chahota et al. 2006). Avian *C. psittaci* infections are often systemic, with bacteria infecting blood monocytes/macrophages leading to clinically unapparent manifestations of disease; although case reports of mucosal epithelial cells in the gastrointestinal tract, and other organs, leading to myocarditis, endocarditis, hepatitis, encephalitis, and meningitis have also been identified (Knittler and Sachse 2015; Longbottom and Livingstone 2006). Due to its airborne transmission, *C. psittaci* is classified as a Category B Crucial Biological agent as it could easily be misused as a biological warfare agent (Cheong et al. 2019). Currently, no vaccines have been developed against *C. psittaci* (Longbottom and Livingstone 2006). Innate immunity plays a key role in primary recognition of chlamydial infections; with adaptive immune response by lymphocytes, dendritic cells, antigen-presenting cells, enhanced major histocompatibility complex expression, and autophagic degradation aiding the elimination of the offending bacteria (Knittler and Sachse 2015).

Human cases of psittacosis are effectively treated using orally administered doxycycline and tetracycline hydrochloride for a period of 10–14 days in patients for whom tetracycline is contra-indicated (Bommana and Polkinghorne 2019). Availability of an effective treatment is reported as a main contributor for the general decline in psittacosis cases worldwide, particularly those with fatal outcome, in the past decades (Bommana and Polkinghorne 2019). Use of quinolones to treat chlamydia infection in humans has resulted in reports of treatment failure (Bommana and Polkinghorne 2019).

Treatment options for *C. psittaci* include bacteriostatic antibiotics effective against other *Chlamydiaceae*. In veterinary medicine, *C. psittaci* infections are treated with doxycycline or other tetracyclines and the fluoroquinolone, enrofloxacin, administered orally (feed/drinking water) or parenterally (intramuscular or subcutaneous routes) (Bommana and Polkinghorne 2019). Unfortunately, the widespread use of tetracycline in feed and/drinking water and long periods of treatment (21–25 days) in the poultry/bird industry is implicated in chronically subtherapeutic drug plasma levels that promote the emergence of drug-resistant *C. psittaci* strains (Bommana and Polkinghorne 2019). Despite available and effective antimicrobial treatments, vaccination remains at the forefront of best approaches to reduce chlamydial infections and prevalence in the population (Knittler and Sachse 2015). Antichlamydial T-cell vaccines induce cellular immune responses, which activate antigen-presenting cells effect long-lived T-cell memory and offer protective immunity against Chlamydiae (Knittler and Sachse 2015).

Chlamydia avium

C. avium, *Chlamydia gallinaceae*, and *Candidatus* Chlamydia ibidis are newly described avian species (Cheong et al. 2019). To date, *C. avium* has been identified in pigeons and psittacine birds, whereas *C. gallinaceae* is endemic in domestic poultry, such as chickens, ducks, turkeys, and guinea fowls (Sachse and Laroucau 2015; Sachse et al. 2014). Factors affecting infection rates of wild/captive and farmed fowl include the number of animals per farm, density of animals per stable, expanded feed, good on-farm hygiene management with hygienic storage of bedding material, and health monitoring of the animals (Borel, Polkinghorne, and Pospischil 2018). *C. avium* and *C. gallinacea* may be able to cause respiratory disease in psittacine birds and pigeons; neither species is known to be pathogenic in humans, but it has been suggested that *C. gallinacea* may be implicated in several cases of atypical pneumoniae in slaughterhouse workers (Cheong et al. 2019).

A complete genome of a *C. avium* strain from a feral pigeon in Italy was recently published (Floriano et al. 2020), describing significant variation in alignment and length of plasmid sequences that could shed light on the possible evolution of *C. avium* and differences in virulence of avian species (Floriano et al. 2020). To date, the only known hosts reported for *C. avium* are European feral pigeons and captive psittacine birds worldwide (Cheong et al. 2019), pointing to the potential *C. avium* spread in the wild by captive parakeet pets and other exotic pet birds. In light of more common reintroduction programs of captive birds into the wild worldwide, increased human contact (more commonly by people who feed birds, an evolving threat to sanitation and human health) warrants further investigation (Cheong et al. 2019).

Chlamydia gallinacea

The species had been previously described as "atypical chicken chlamydia," later named *Chlamydia gallinacea;* with reports of suspected non-*C. psittaci* pneumonia in poultry slaughterhouse workers. It was first identified in cloacal swabs and feces from clinically healthy chickens and turkeys from various European countries, and is not considered endemic in chickens (Vogler et al. 2019). Reports of bird-to-human transmission could not be demonstrated in recent studies by farmers caring for *C. gallinacea*-positive chicken flocks (Vogler et al. 2019). A review of zoonotic Chlamydiae described experimentally infected chickens that remained without overt clinical disease, except their

showing signs of significant loss of body weight, with an isolated type strains of *C. gallinacea* containing a plasmid, suspected to be responsible for its virulence (Borel, Polkinghorne, and Pospischil 2018). Phylogenetic plasmids as well as polymorphic *ompA* sequences, have been typed in *C. gallinacea* genetic variant isolates from diverse geographic locations, with DNA detected in healthy dairy and beef cattle specimens from China, where both *C. gallinacea* and *C. psittaci* were detected in whole blood, milk, feces and vaginal swabs (Borel, Polkinghorne, and Pospischil 2018).

Chlamydia serpentis

The four newly identified species, *C. serpentis*, *C. poikilothermis*, *Ca*. C. corallus, and *Ca*. C. sanzinia, were all identified in captive snakes and little is understood of their pathogenicity or host range (Cheong et al. 2019). *C. serpentis* strains have also been reported in asymptomatic corn snakes, green bush vipers and other captive snakes, whose pathogenicity was believed to have been influenced and exacerbated by stress from their capture, transportation, high-density farming, or their hibernation state (Staub et al. 2018).

Comparative phylogenetic analyses of *Candidatus* C. sanzinia reported *C. pneumoniae* and *C. pecorum* forming a clade distinct from former "*Chlamydophila*" species (Bommana and Polkinghorne 2019). Culture-independent, full sequencing of genomic DNA obtained from the choana of a captive, healthy Madagascar tree boa found the novel *Candidatus* Chlamydia sanzinia, and similarly found from the choana of a captive Amazon basin emerald tree boa (Bommana and Polkinghorne 2019). Lack of suited *in vitro* culture systems remain a challenge to further the characterization of novel chlamydial strains (Staub et al. 2018). Molecular and phylogenetic characterization of free-living and captive turtle (semi-aquatic animal), as well as tortoise species (land animal) could help confirm these animals as *C. poikilothermis* host reservoirs (Staub et al. 2018). Implications of the increased occurrence of *Chlamydiaceae* in poikilothermic animals often found in captivity and recreational areas, such as zoos, parks, and lakes, as well as the zoonotic implications of reptiles should be further investigated (Staub et al. 2018).

Recent studies describing antibiotic sensitivity to tetracycline and moxifloxacin and phenotypic resistance to azithromycin in the newly described chlamydial species infecting snakes, *C. serpentis* and *C. poikilothermis* (Staub et al. 2018), demonstrate the potential for considerable variability in the antibiotic resistance profile of bacteria in the genus *Chlamydia*. As new chlamydial species continue to emerge in animals, the demonstration or prediction of antibiotic resistance to inform clinical treatment of these infections will become increasingly important (Bommana and Polkinghorne 2019).

Chlamydia poikilothermis

C. poikilothermis are reported in animals whose internal temperature can vary considerably; samples isolated from choanal and cloacal swabs from a captive corn snake were reported within the snake family *Colubridae*, although it is believed to also be present in other families of captive and free-ranging snakes (Staub et al. 2018). *C. poikilothermis* is reported susceptible to tetracycline and moxifloxacin, but with intermediate resistance potential to azithromycin (Staub et al. 2018).

Candidatus Chlamydia ibidis

C. avium, *C. gallinacea*, and *Ca*. C. ibidis are three newly described avian chlamydial species; and like others of the family *Chlamydiaceae*, *Ca*. C. ibidis can be grown in cell culture and in embryonated chicken eggs (Vorimore et al. 2013). Morphology of this candidate species, as revealed by electron microscopy, demonstrated features typical of *Chlamydia* genus (Vorimore et al. 2013). *Ca*. C. ibidis has been described in cloacal swabs of healthy, feral African sacred ibis birds described as living along the west coast of France (Borel, Polkinghorne, and Pospischil 2018; Cheong et al. 2019), although its pathogenicity to avian species or other animals, is currently unknown (Borel, Polkinghorne, and Pospischil 2018). *Ca*. C. ibidis has also been described in the previously thought extinct crested ibis. In contrast to the African sacred ibis, the crested ibis is described as an endangered bird living in Sado Island, Japan after being introduced from China; however a few crested ibis were rediscovered in China in 1981 (Li et al. 2020) and harbored *C. psittaci* and *Ca*. C. ibidis (Li et al. 2020), suggestive of plausible evolution of *Chlamydiaceae* as potential threat to the endangered bird, which could warrant future protection practices (Li et al. 2020).

The genetic diversity in *Ca*. C. ibidis is suspected to have resulted from diverse host species not yet identified, as well as the geographic origin of the organisms (Li et al. 2020). To date, *Ca*. C. ibidis pathogenicity has not been confirmed in either feral African sacred ibises or crested ibises; for this reason, prevalence, transmission and pathogenicity of this *Candidatus* species have not been concluded (Li et al. 2020).

Candidatus Chlamydia sanzinia

Novel *Ca*. Chlamydia sanzinia was identified from culture-independent, full sequencing of genomic DNA obtained from the choana of a captive, healthy Madagascar tree boa in Switzerland (Bommana and Polkinghorne 2019).

Candidatus Chlamydia corallus

Novel *Ca*. Chlamydia corallus was identified from culture-independent, full sequencing of genomic DNA obtained from the choana of a captive, healthy Amazon basin emerald tree boa (Bommana and Polkinghorne 2019).

Chlamydiales-like Family Candidate

Candidatus Clavichlamydiaceae

The taxonomic family-level lineage *Candidatus* Clavichlamydiaceae was determined by phylogenetic relationships and genetic distance to be the closest relative to the original *Chlamydiaceae* (Greub 2013). This newest candidate family was originally reported as *Clavochlamydia* and was then renamed *Clavichlamydia* (Greub 2013). Chlamydiosis due to *Candidatus* Clavichlamydiaceae has been implicated in the bacterial

pathology of marine and fresh water fish skin and gills (Borel, Polkinghorne, and Pospischil 2018).

Parachlamydiales

The Parachlamydiales order contains the *Parachlamydiaceae* family (Everett 1999), the *Simkaniaceae*, *Waddliaceae*, and four *Candidatus* families: Criblamydiaceae, Parilichlamydiaceae, Piscichlamydiaceae and Rhabdochlamydiaceae (Gupta et al. 2015). Based on phylogenomic analyses of the phylum Chlamydiae by Gupta et. al. (2015), Parachlamydiales can be distinguished from Chlamydiales by their branching in phylogenetic trees and three CSI variants in DNA topoisomerase I, TC_0635 and Phenylalanyl-tRNA synthetase beta subunit; they typically show >84% 16S rRNA gene sequence identity with each other (Gupta et al. 2015).

By immunohistochemistry using monoclonal antibody targeting of chlamydial lipopolysaccharides within the *Chlamydiaceae* family, antibodies directed against the group-specific LPS epitope αKdo-(2→8)-αKdo-(2→4)-αKdo, do not recognize members of the more recently classified *Parachlamydiaceae*, *Simkaniaceae*, or *Waddiaceae* families (Everett, Bush, and Andersen 1999; Corsaro and Greub 2006).

Parachlamydiaceae

Originally described as *Candidatus* Parachlamydia acanthamoebae, *Parachlamydiaceae* have been declared a new family (Everett, Bush, and Andersen 1999). Isolated from amoebae, the *Parachlamydiaceae* can also infect *Dictyostelium* and can be grown in cultures of African Green Monkey Kidney (Vero) cells (Everett, Bush, and Andersen 1999). Two genera have been isolated, *Parachlamydia* and *Neochlamydia* with other isolates being considered (Everett 2000). Among case reports, at least one of these isolates has been found to increase the cytotoxicity of the amoeba they infect and was isolated from humans during an outbreak of humidifier fever in Vermont, USA ("Hall's coccus") (Everett, Bush, and Andersen 1999). Other members of this family have been detected in cats, Australian marsupials, reptiles, and fishes (Corsaro and Greub 2006).

Simikaniaceae

The *Simikaniaceae* family originally contained only one strain: *Simikania negevensis*. First identified as a bacterial contaminant in cell cultures, the strain is associated with pneumonia in humans. The strain lacks any extrachromosomal plasmids and has a longer than normal developmental cycle in Vero cells (2 weeks versus the normal 2–3 days) (Everett 2000). Newly discovered members of this family, *Fritschea bemisiae* and *Fritschea eriococci*, have been found to infect invertebrates (Corsaro and Greub 2006).

Waddliaceae

The defining strain of this family, *Waddlia chondrophila* was identified in 1986 as an agent of bovine abortion. Serological studies have shown that titers of anti-*Waddlia* antibodies are statistically associated with cows that have aborted (Everett 2000). A second family member, *Waddlia malaysiensis* was identified in urine samples from Malaysian fruit bats (Corsaro and Greub 2006).

Parachlamydiales-like Family Candidates

Candidatus Parilichlamydiaceae, Rhabdochlamydiaceae, Criblamydiaceae and Piscichlamydiaceae

Currently, of these four candidate families, *Candidatus* Piscichlamydiaceae has been implicated in skin and gill pathology of diverse marine and fresh water fish (Borel, Polkinghorne, and Pospischil 2018). The reported pathology is described as local to multifocal epithelial hyperplasia with an interlamellar filling that can lead to fusion of the lamellae and cellular hypertrophy, with cyst-like inclusions within the affected gill epithelial cells (Borel, Polkinghorne, and Pospischil 2018; Stride et al. 2013). Histopathologically, these epithelial cysts have been reported to have intracytoplasmic inclusions that are sometimes basophilic and are referred to as epitheliocystis (Borel, Polkinghorne, and Pospischil 2018). Epitheliocystis in fish was first described in carp in 1920 and named in the 1960s in reference to gill cysts described in bluegill (Pawlikowska-Warych and Deptula 2016). Other histopathologic analyses of gill samples taken from striped trumpeter in Tasmania, Australia have identified epitheliocystis-like basophilic inclusions from distinct species of Chlamydiales as well as Parachlamydiales in yellowtail kingfish (Stride et al. 2013).

Highly diverse Chlamydiae have been described in >20 fish species (Borel, Polkinghorne, and Pospischil 2018); however, further phylogenetic differentiation will need to be supported by PCR and *in situ* hybridization (Borel, Polkinghorne, and Pospischil 2018). Common lesions observed in the form of epitheliocystis from infection of many of these *Candidatus* families, have been described in farmed fish, including barramundi, white sturgeon, silver perch, Atlantic salmon, red seabream, carp, and yellowtail amberjack (Pawlikowska-Warych and Deptula 2016). Common clinical signs that have been implicated include fish growth inhibition, spread to other tissues of fish, respiratory disorders and death of fish with high mortality rates (even up to 100%) (Pawlikowska-Warych and Deptula 2016).

Experimentally, epithelial cells in fish are also sensitive to infection and an immune response. (Pawlikowska-Warych and Deptula 2016). A common characteristic observed among Chlamydiales is their reported immune response by macrophage infiltrations, as well as their fastidious *in vitro* growth (Pawlikowska-Warych and Deptula 2016).

Conclusion

Due to being obligate pathogens coupled with their inability to be genetically manipulated like other bacteria, Chlamydiae are notoriously difficult to study (Subtil and Dautry-Varsat 2004). Yet the Chlamydiales has undergone tremendous reorganization in the last few years due to the application of whole genome

sequencing and DNA-sequence comparison. These techniques continue to allow for greater understanding of the Chlamydia life cycle and its pathogenicity. The most recent taxonomy, as outlined here, is the subject of debate among Chlamydialogists, but is in line with a great number of taxonomic studies (Olsen, Woese, and Overbeek 1994; Everett and Andersen 2001). Continued genomic and proteomic studies will expand our understanding of the Chlamydiales order (Vandahl, Birkelund, and Christiansen 2004), leading to better treatment options that could potentially benefit both human and animal health.

Acknowledgments

Much appreciation to my husband, whose brilliance, endless support, and clear direction motivates me to challenge myself in ways unimaginable, and to our son, who is evidence that dreams do come true. We are grateful to our coeditor, Lorrence Green, for his saintly patience, virtuous guidance, and mentorship over the years.

Introduction

Clostridium is one of the largest bacterial genera, including more than 160 validly described species. Among these are several with enormous biotechnological potential (e.g., for production of biofuels, bulk chemicals, and important enzymes as well as for usage in cancer treatment) and also a few well-known pathogens. However, some of their toxins proved to be valuable in medical and cosmetic applications. Clostridia, thus, belong to the avant-garde of industrially useful microbes. Members of this genus stain, in general, Gram-positive, are more or less strictly anaerobic bacteria, employ an impressive number of varying fermentation routes, and are able to degrade numerous natural and artificial substances. Due to required precautions for excluding oxygen during handling, clostridia were, for a long time, virtually inaccessible at the genetic level. This situation has completely changed. Gene cloning, DNA transfer, gene expression modulation, and gene knock-out and knock-in systems have been successfully established. Thus, the road is paved for further elucidation and commercial exploitation of the enormous metabolic potential of the clostridia.

In the past three decades, six books have been published, completely devoted to clostridia (Minton and Clarke, 1989; Woods, 1993; Rood et al., 1997; Bahl and Dürre, 2001; Dürre, 2005, Dürre, 2014). Due to the limited space of this chapter, the interested reader is referred to these references for additional and more detailed information.

Historical Background

Hippocrates (460–377 B.C.), a physician living on the Greek island of Kos, was probably the first who reported clostridia-effected diseases. His documentation describes gas gangrene (Sussman, 1958), caused by *C. histolyticum*, and lockjaw (also called opisthotonus or tetanus) (Kiple, 1993), caused by *C. tetani*. Until the Middle Ages, indigo dyeing in Europe was based on the woad plant. It contains two indigo precursors, isatan B (indoxyl-5-ketogluconate) and indican (indoxyl-β-D-glucoside), which are converted in a two-step process to indigo. Scientific research in the 1990s revealed that the responsible bacteria are *Enterobacter agglomerans* for the initial aerobic process and *C. isatidis* for the successive fermentation (Ewerdwalbesloh and Meyer, 1995; Padden et al., 1998; Padden et al., 1999). Similarly, it is now clear that flax and hemp retting, in use for thousands of years for clothing fabrication, are essentially dependent on clostridia (Bahl and Dürre, 1993; Tamburini et al., 2003). Microbiological investigations on these bacteria only started in 1861, when the famous French microbiologist Louis Pasteur discovered that microbes exist that can grow without oxygen (Pasteur, 1861). This represented a revolutionary finding at that time. It is usually concluded that the term "*Clostridium*" stems from Prazmowski (1880). However, before him, Trécul had already used this expression (compare Dürre, 2001). It is based on a Greek root, later became Latinized, and means "small spindle." Originally, it was used exclusively to describe the bacterial morphology, not any metabolic properties (Dürre, 2001). The first pure culture obtained was *C. butyricum* (Prazmowski, 1880), which now represents the type species of the genus *Clostridium*. Without a doubt, one of the world's most famous bacteria is *C. acetobutylicum*. It had both, enormous biotechnological as well as political impact. The acetone-butanol fermentation ranks second in size to ethanol production and was thus one of the largest bioprocesses ever performed. Until about 1950, two-thirds of the world's butanol production was obtained by fermentation, and the solvent was an important bulk chemical for industry (Jones and Woods, 1986; Dürre and Bahl, 1996). Originally, however, acetone was the desired product. Weizmann isolated the organism during World War I in the United Kingdom (Weizmann, 1915), when this chemical was in demand for production of ammunition. Despite

his important contribution, he refused any honors, but made clear that he was in favor of a Jewish homeland in Palestine. There is no doubt that the Balfour Declaration of 1917 on this very subject was affected by Weizmann's achievements, who later became the first president of the State of Israel.

Metabolism

Clostridia in the public opinion are associated with production of a bad smell. In most cases, this is caused by butyric acid, one of the major fermentation products. Butyrate is produced by saccharolytic as well as proteolytic pathways (Table 26.1). For the former, the uptake of glucose (and other sugars) is performed by a phosphoenolpyruvate:phosphotransferase system. Glycolytic reactions then lead to pyruvate, which is split into acetyl-CoA, CO_2, and reduced ferredoxin by pyruvate:ferredoxin oxidoreductase. Ferredoxin is a small iron-sulfur protein with a very negative redox potential (~ –400 mV). This is of considerable advantage for the anaerobic clostridia, as they can "blow off" reducing equivalents as hydrogen (employing an additional hydrogenase) and do not need to sacrifice carbon compounds as acceptor molecules. Acetyl-CoA is the starting point for production of acetate (via phosphotransacetylase and acetate kinase, thereby also yielding ATP), ethanol (via acetaldehyde and alcohol dehydrogenases, thereby consuming reducing equivalents), and C_4 compounds such as butyrate and butanol. The latter step is accomplished by fusion of two acetyl-CoA to acetoacetyl-CoA and free coenzyme A. Acetoacetyl-CoA is reduced to butyryl-CoA, which is transformed into butyrate or butanol by reactions analogous to those of the C_2 compounds. The ATP-yielding reaction might either be catalyzed by a butyrate kinase or by transfer of the CoA moiety to acetate and then conversion of acetyl-CoA via acetyl phosphate to acetate by acetate kinase. For caproate formation in case of *C. kluyveri*, a third molecule of acetyl-CoA is fused to butyryl-CoA. Except for the substrate combination ethanol/acetate, this organism can also grow on ethanol/succinate, thereby forming acetate and butyrate (in this case, directly from a C_4 compound). Acetone is made from acetoacetate after transfer of the CoA moiety to either acetate or butyrate, and isopropanol (e.g., by *C. beijerinckii*) by further reduction of acetone.

A landmark discovery in energy metabolism of anaerobes was the flavin-based and ferredoxin-dependent electron bifurcation that can be coupled to proton or Na^+ gradient generation and thus to ATP formation (Herrmann et al., 2008; Buckel and Thauer, 2018). The first such reaction found in clostridia was the reduction of crotonyl-CoA to butyryl-CoA in *C. kluyveri*, catalyzed by the butyryl-CoA dehydrogenase/EtfBC complex (Li et al., 2008). Etf stands for electron-transferring flavoprotein. This NADH-coupled reduction is highly exergonic, so that one electron of NADH is transferred to the more positive acceptor butyryl-CoA dehydrogenase and the second electron to the more negative acceptor ferredoxin. This bifurcation mechanism is repeated with a second NADH molecule. The total reaction sequence thus is:

$$\text{crotonyl-CoA} + 2\ \text{NADH} + \text{oxidized ferredoxin } (Fd_{ox}) \rightarrow \text{butyryl-CoA} + 2\ NAD^+ + \text{reduced ferredoxin } (Fd^{2-})$$

TABLE 26.1

Clostridial Fermentations

Fermentation Type	Typical Fermentation Balance	Example for Respective Species
Saccharolytic		
butyrate	glucose → 0.8 butyrate + 0.4 acetate + 2 CO_2 + 2.1 H_2	*C. butyricum*
butanol	glucose → 0.6 butanol + 0.2 acetone + 2.2 CO_2 + 1.4 H_2 + 0.04 butyrate + 0.14 acetate + 0.07 ethanol	*C. acetobutylicum*
homoacetate	fructose → 3 acetate	*C. aceticum*
Acidotrophic		
propionate	lactate → 0.66 propionate + 0.33 acetate + 0.33 CO_2	*C. propionicum*
propionate, Na^+-dependent	succinate → propionate + CO_2	probably *C. mayombei*
Alcoholotrophic	2 ethanol + acetate → butyrate + 0.33 caproate + 0.66 H_2	*C. kluyveri*
Autotrophic	2 CO_2 + 4 H_2 → acetate	*C. aceticum*
	10 CO → acetate + ethanol + 6 CO_2	*C. ljungdahlii*
	4 CO + 6 H_2 → acetate + ethanol	*C. ljungdahlii*
Proteolytic		
pairs of amino acids		
Stickland reaction	alanine + 2 glycine → 3 acetate + CO_2 + 3 NH_4^+	*C. sporogenes*
single amino acids		
2-, 3-elimination	threonine → 0.66 propionate + 0.33 butyrate + 0.66 CO_2 + NH_4^+	*C. propionicum*
B_{12}-dependent	glutamate → acetate + 0.5 butyrate + CO_2 + NH_4^+	*C. tetanomorphum*
SAM-dependent	lysine → butyrate + acetate + 2 NH_4^+	*C. subterminale*
Se-dependent	glycine → 0.75 acetate + 0.5 CO_2 + NH_4^+	*C. purinilyticum*
Heteroaromaticotrophic		
purine	adenine → acetate + formate + 2 CO_2 + 5 NH_4^+	*C. purinilyticum*
pyrimidine	orotic acid → aspartate + CO_2 + NH_4^+	*C. oroticum*

Note: H_2O is not indicated in fermentation reactions.

Abbreviation: SAM = S-adenosylmethionine.

TABLE 26.2

Flavin-Based and Ferredoxin (Flavodoxin)-Dependent Electron Bifurcation Enzyme Complexes

Enzyme Complex	Reaction Catalyzed	Organism
Butyryl-CoA dehydrogenase/electron-transfer flavoproteins (Bcd/Etf)	crotonyl-CoA + 2 NADH + Fd_{ox} → butyryl-CoA + 2 NAD^+ + Fd^{2-}	*C. kluyveri*
NAD^+-specific [FeFe]-hydrogenase (HydABC)	3 H^+ + NADH + Fd^{2-} ⇌ 2 H_2 + NAD^+ + Fd_{ox}	*Thermotoga maritima* *Acetobacterium woodii* *Moorella thermoacetica*
Ferredoxin:$NADP^+$ reductase (NfnAB)	2 $NADP^+$ + NADH + Fd^{2-} + H^+ ⇌ 2 NADPH + NAD^+ + Fd_{ox}	*C. kluyveri* *M. thermoacetica*
Heterodisulfide reductase (MvhADG-HdrABC)	CoM-S-S-CoB + 2 H_2 + Fd_{ox} → CoM-SH + CoB-SH + Fd^{2-} + 2 H^+	methanogenic Archaea
Caffeyl-CoA reductase (CarCDE)	caffeyl-CoA + 2 NADH + Fd_{ox} → dihydrocaffeyl-CoA + 2 NAD^+ + 2 H^+ + Fd^{2-}	*A. woodii*
Formate dehydrogenase (FdhF2-HylABC)	2 formate + NAD^+ + Fd_{ox} ⇌ 2 CO_2 + NADH + H^+ + Fd^{2-}	*C. acidurici*
$NADP^+$-specific [FeFe]-hydrogenase (HytA-E)	$NADP^+$ + Fd_{ox} + 2 H_2 ⇌ NADPH + Fd^{2-} + 3 H^+	*C. autoethanogenum*
Methylene-tetrahydrofolate reductase (MetF-HdrABCMvhD)	2 NADH + methylene-THF + Fd_{ox}(?) ⇌ 2 NAD^+ + methyl-THF + Fd^{2-} (?)	*M. thermoacetica*
Lactate dehydrogenase (LctBCD)	lactate + 2 NAD^+ + Fd^{2-} ⇌ pyruvate + 2 NADH + Fd_{ox}	*A. woodii*
F_{420}-specific heterodisulfide reductase (HdrA2B2C2)	CoM-S-S-CoB + 2 $F_{420}H_2$ + Fd_{ox} → CoM-SH + CoB-SH + Fd^{2-} + 2 F_{420} + 2 H^+	*Methanosarcina acetivorans*
NAD^+-specific ubiquinol reductase (FixABCX)	2 NADH + Q + Fld_{sq} → 2 NAD^+ + QH_2 + Fld_{hq}^{2-}	*Azotobacter vinelandii*

Abbreviations: CoM-SH, coenzyme M = 2-mercaptoethanesulfonate; CoB-SH, coenzyme B = 7-mercaptoheptanoylthreoninephosphate; F_{420}, factor 420 = deazaflavin adenine dinucleotide; Q = quinone; Fld_{sq} = flavodoxin semiquinone; Fld_{hq} = flavodoxin hydroquinone

Source: Data are taken from Buckel and Thauer (2018).

Reduced ferredoxin can be reoxidized at the membrane-bound Rnf complex (Rnf stems from *Rhodobacter* nitrogen fixation, in which organism this protein complex was discovered first), with concomitant NAD^+ reduction to NADH. This exergonic step is used by the Rnf complex to pump ions across the cytoplasmic membrane. This way, either a H^+ or a Na^+ gradient is formed, which can then be used for ATP formation by respective ATPases. So far, 11 flavin-based electron-bifurcating enzyme complexes have been discovered (Table 26.2), of which four are present in clostridia (Li et al., 2008). However, this might only be the tip of the iceberg, as several other reactions might be candidates for such a mechanism.

Proteolytic production of butyrate follows either the pathways described above starting with acetyl-CoA, or it is made directly from the C_4 compound threonine by a 2-,3-elimination reaction of the amino group (Table 26.1) (Buckel, 1990). For utilization of amino acids, fermentation in parallel oxidative and reductive branches is very common. Examples are the so-called Stickland reaction, in which pairs of amino acids are degraded, or the selenium-dependent glycine fermentation, in which one glycine is completely oxidized to CO_2 and the reducing equivalents are used to reduce three glycines to acetate via the selenoenzyme glycine reductase and producing ATP from acetyl-phosphate via acetate kinase (Dürre and Andreesen, 1982). In many cases, amino acids are transformed into the respective 2-oxo compounds, removing the amino group by 2-,3-elimination as already mentioned, oxidation, or transamination (Buckel, 1990). The 2-oxo acid can then be converted into a saturated fatty acid by a number of reduction, CoA activation, and dehydration steps. Other pathways employ B_{12}-dependent C-C or S-adenosylmethionine-dependent C-N rearrangements.

Another important route in some saccharolytic clostridia is homoacetate fermentation. By reutilization of the CO_2 formed in pyruvate degradation, three acetates are formed per hexose. Species such as *C. aceticum* are also able to grow autotrophically by converting CO_2 and H_2 into acetate. This metabolic route is called Wood-Ljungdahl pathway and depicted in Figure 26.1. It also allows the utilization of carbon monoxide as the sole carbon and energy source, e.g., by *C. ljungdahlii*. Energy conservation during autotrophic growth occurs by different mechanisms. The one molecule of ATP required for formyl-THF formation is compensated for by the ATP formed in the acetate kinase reaction. *C. ljungdahlii* builds up a proton gradient from reduced ferredoxin by action of the Rnf complex, with concomitant utilization of the produced NADH in formation of reduced THF-derivatives and formation of ethanol from acetyl-CoA (Köpke et al., 2010; Tremblay et al., 2012). A variation of this route is found in another anaerobe, *Acetobacterium woodii*, which contains a Na^+-pumping Rnf complex (Biegel and Müller, 2010). The situation is clearly different in acetogens such as *Moorella thermoacetica* (formerly *Clostridium thermoaceticum*) and *Thermoanaerobacter kivui* that employ an energy-conserving hydrogenase (Ech) for proton gradient formation (Schuchmann and Müller, 2014). An additional proton gradient might be generated in cytochrome- and quinone-harboring acetogens by a yet unknown electron transport chain. A possible model has been suggested by Das and Ljungdahl (2003).

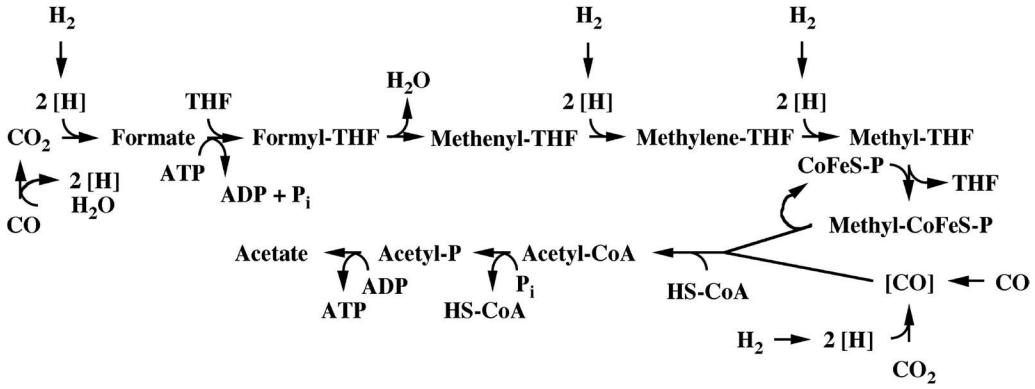

FIGURE 26.1 Wood-Ljungdahl pathway employed by clostridial acetogens. (*Abbreviations:* CoFeS-P, corrinoid iron-sulfur protein; Pi, inorganic phosphate; THF, tetrahydrofolate.)

A variety of organic acids, alcohols, polymers, aromatics, and halogenated substances can also be used as substrates by clostridia. For a detailed description, see Bahl and Dürre (1993). Several typical examples are listed in Table 26.1. Also, some clostridia such as *C. pasteurianum* are able to fix molecular nitrogen, thereby producing NH_4^+ and H_2.

Lactate is metabolized by several clostridia. *C. propionicum* converts this organic acid to propionate and acetate by branched pathways. 2 Lactate are activated with coenzyme A and dehydrated to yield acrylyl-CoA, which then is reduced to propionyl-CoA. Transfer of the CoA moiety to lactate leads to propionate formation. The reducing equivalents stem from oxidation of a third lactate to acetate and CO_2. The acetate kinase reaction of this branch generates the only ATP of this fermentation. It is thus clearly less efficient than the methylmalonyl-CoA pathway employed by *Propionibacterium*. Succinate decarboylation is another possibility to produce propionate from an organic acid. This way is employed by *Propionigenium modestum* and based on a membrane-located decarboxylation of methylmalonyl-CoA, which generates a Na^+-gradient. This gradient can be directly used for ATP generation by a Na^+-dependent F_1F_O-ATPase (as in *P. modestum*) or indirectly after conversion into a H^+-gradient by action of a Na^+/H^+ antiporter. The other decarboxylation product propionyl-CoA is used to activate succinate, and succinyl-CoA is converted into methylmalonyl-CoA. Thus, only three enzymes are required for this pathway. Within the clostridia, probably *C. mayombei* degrades succinate by Na^+-dependent decarboxylation (Bahl and Dürre, 1993). A dangerous organism for the cheese industry is *C. tyrobutyricum*, which forms butyrate from lactate. The so-called late blowing ruins structure and taste of contaminated cheese.

Heteroaromates stemming from the degradation of nucleic acids can also be used for growth by clostridia. *C. acidurici*, *C. cylindrosporum*, and *C. purinilyticum* are almost completely specialized on fermenting purines (*C. purinilyticum* grows also well on glycine). The pyrimidine moiety is split first, degraded to CO_2 and NH_4^+, and then the imidazole moiety is hydrolytically cleaved, yielding finally acetate (via glycine reductase and acetate kinase), formate, CO_2, and NH_4^+ (Dürre and Andreesen, 1983). Pyrimidine fermentation is accomplished by *C. glycolicum* and *C. oroticum* and is based on similar reactions (Vogels and van der Drift, 1976).

Clostridia belong to those bacteria, which can form endospores. These are the most resistant biological survival forms known and protect the genome against environmental danger such as desiccation, heat, radiation, and hazardous compounds. Retrieval of *C. aceticum*, a species considered to be lost from culture collections during World War II, provided evidence for successful germination even after four decades (Braun et al., 1981). Clostridia thus belong to the few prokaryotes able to perform cell differentiation. The sporulation process resembles very much that of *Bacillus* (Dürre and Hollergschwandner 2004), which is well understood. Initiation is achieved via a number of phosphate transfers from sensor kinases to the response regulator Spo0A, the so-called phosphorelay (Hoch 1993). Such a chain of transfer components is obviously not present in clostridia, as shown by the numerous genome sequencing projects, but the master regulator Spo0A is conserved and fulfills the same functions. In cooperation with the sporulation-specific sigma factor σ^H, Spo0A~P induces transcription of further forespore- and mother cell-specific sporulation sigma factors. In both compartments, pairs of these proteins become active successively, to guarantee a sequential number of steps, required for mature spore synthesis. In the forespore, σ^F and σ^G are responsible for this task and are regulated via anti- and anti-anti-sigma factors. In the mother cell, their companions are σ^E and σ^K, which are proteolytically activated. While most endospore-forming bacteria produce just one such compartment per cell, there are a few notable exceptions. *Anaerobacter polyendosporus* and *Metabacterium polyspora*, phylogenetically close relatives of *Clostridium*, produce up to five endospores in a single mother cell (Angert et al., 1996; Siunov et al., 1999). An evolutionary link to production of already living offspring might be represented by *Epulopiscium fishelsoni*. This is not only one of world's largest bacteria, surpassing many eukaryotic microorganisms in size, but also belongs phylogenetically to the clostridia and gives birth to several internal daughter cells (Angert et al., 1993).

An important task in food preservation is to prevent contamination with spores of pathogenic clostridia. For this purpose, preservatives can be added such as nitrite, which converts important redox-active iron-sulfur clusters (e.g., in ferredoxin) into inactive iron-nitric oxide complexes (Reddy et al., 1983; Carpenter et al., 1987), benzoic acid, sodium chloride, and sorbate. Acidification, desiccation, heating, ionizing radiation,

and refrigeration are other methods to achieve extended shelf life (Lund and Peck, 2000). Hygienic conditions during preparation are of utmost importance, as failure in this respect might even affect vacuum-packed materials (production of gas and/or sulfides). In the future, high pressure treatment might become an important additional means to prevent clostridial spoilage of foods.

Phylogeny and Taxonomy

Phylogenetically, the clostridia belong to the low G + C Gram-positive phylum. This classification is based on 16 S rRNA gene sequence analysis. It reflects ordering of the species according to common ancestry, disregarding physiological and morphological features. Relatedness is usually displayed as a dendrogram. Historically, however, members of the genus *Clostridium* had been defined as performing an anaerobic life style, having a Gram-positive-type cell wall, producing endospores, and being unable of dissimilatory sulfate reduction. Thus, the genus represents a problem to taxonomists, and many bacteria, originally described as a *Clostridium*, have been reclassified. Taxonomy follows the scheme: order *Firmicutes*, class *Clostridia*, order *Clostridiales*, family *Clostridiaceae*, genus *Clostridium*. Compilations of validly described clostridia (currently more than 160 species, making *Clostridium* one of the largest bacterial genera) can be found in the internet (http://www.bacterio.net/clostridium.html, LPSN: List of Prokaryotic Names with Standing in Nomenclature—Genus Clostridium; http://www.taxonomicoutline.org/content/7/7/, Taxonomic Outline of the Bacteria and Archaea, Release 2007.07, Part 7—The Bacteria: Phylum Firmicutes, Class "*Clostridia*," by G. M. Garrity, T. G. Lilburn, J. R. Cole, S. H. Harrison, J. Euzéby, B. J. Tindall). There, and also in catalogs of culture collections such as ATCC (American Type Culture Collection) and DSMZ (Deutsche Sammlung von Mikroorganismen und Zellkulturen), are numerous indications of new genera with which former clostridia are now affiliated. These genera are *Caloramator, Dendrosporobacter, Eubacterium, Filifactor, Fusobacterium, Moorella, Oxalophagus, Oxobacter, Paenibacillus, Thermoanaerobacter, Thermoanaerobacterium, Sedimentibacter, Sporohalobacter,* and *Syntrophospora* (Stackebrandt, 2004; Wiegel et al., 2006). A further complication is that not all taxonomically validly described *Clostridium* species form phylogenetically coherent clusters. 16 S rDNA analyses of the *Bacillus/Clostridium* subphylum of the Gram-positives allowed identification of 20 clusters, designated I through XX. Clostridia are found in Clusters I (with a number of subdivisions and regarded as genus *Clostridium* sensu stricto [Stackebrandt and Hippe, 2001; Wiegel et al. 2006]), III, IV, XIa, XIb, XII, XIVa, XIVb, XVI, XVIII, and XIX. Cluster I contains the type species of the genus, *C. butyricum*. Different classifications of single species can be found (e.g., *C. limosum* in Cluster II; Stackebrandt and Hippe, 2001 or Cluster I; Wiegel et al., 2006). A compilation of genomes classified as *Clostridium* and *Clostrioides* revealed taxonomic inconsistencies even in Cluster I, arguably the authentic *Clostridium* genus (Cruz-Morales et al., 2019). Thus, the phylum *Firmicutes* will probably still remain the "greatest challenge for taxonomists" (Stackebrandt, 2004) for quite some time.

Pathogenicity

Despite the bad public reputation of clostridia caused by well-known species such as *C. botulinum* and *C. tetani*, only few members of this genus (less than 10%) form dangerous toxins. Some species contain more than one (outstanding is *C. perfringens* with 14 toxins), altogether 58 clostridial toxins have been identified thus far (Popoff and Stiles 2005). This number is slightly less than a fifth of all bacterial toxins. The clostridial toxins are proteins and can be classified as either pore-forming, zinc-dependent metalloproteases, glycosyltransferases, ADP-ribosyltransferases, or phospholipases (Table 26.3).

One of the most intensively studied representatives is the *C. perfringens* enterotoxin (CPE) (McClane, 2005). It is a common cause of foodborne disease. However, it should be kept in mind that the vast majority of strains of this species do not carry a *cpe* gene. While *in vitro* studies revealed that CPE can form pores in artificial lipid membranes, the *in vivo* effect relies on recruiting a number of host proteins to trigger massive changes in membrane permeability. Members of the claudin family are most probably the primary target and serve as receptors of CPE. With the help of additional membrane proteins, first a small complex of approximately 90 kDa and then large complexes of approximately 135, 155, and 200 kDa are formed. Interaction of a large complex with tight junction proteins leads to massive damage of the latter. CPE is one of the clostridial toxins, whose synthesis is tightly linked to sporulation. The protein is not secreted, but only set free upon lysis of the mother cell, together with the mature endospore.

The prototype of thiol-activated pore-forming toxins is perfringolysin O (Popoff and Stiles, 2005), which shows highest activity in the presence of reducing compounds. Elucidation of the structure revealed an elongated, rod-shaped molecule. Upon binding to its membrane target cholesterol, oligomerization of 40–50 molecules results in large pore formation. *C. septicum* α-toxin is secreted as a nontoxic precursor and becomes active by proteolysis. *C. perfringens* β-toxin does not destroy erythrocyte membranes, but rather forms cation-specific membrane pores. It is a major cause of necrotic enteritis in domesticated livestock and humans.

Most public attention achieves the clostridial neurotoxins (Johnson, 2005). Botulinum toxin is the most poisonous substance of biological origin known to date (for human beings a concentration of approximately 0.1 ng kg^{-1} has been calculated to be lethal) (Arnon, 1997). There are three forms of botulism: (1) infant (probably the most common with up to 100 cases per year in the United States, honey feeding before approximately 6 months of age is a risk factor); (2) foodborne (classical, ingestion of toxin); and (3) wound (very rare, bacterial spores infect a tissue with damaged blood and, thus, oxygen supply, germinate, and subsequently produce toxin). Botulinum toxin (BoNT) is on the list of bioterrorist agents, because of its extreme toxicity. In 1995, the Japanese Aum Shinrikyo sect wanted to use this compound to attack passengers on the Tokyo subway. Due to problems with aerosolization, they ultimately decided to use sarin gas. Also, following the first Gulf War in 1990 and during United Nations weapons inspections, Iraq conceded the production of botulinum toxin. About half of the total amount of 19,000 L had already been used for preparation of SCUD missile warheads and

TABLE 26.3

Clostridial Toxins

Class of Toxins	Type	Typical Representative	Pathogenic Species
Pore-forming	Enterotoxin	CPE	*C. perfringens*
	Thiol-activated	Perfringolysin O (Θ-toxin)	*C. perfringens*
	Aerolysin-like	α-toxin	*C. septicum*
	Hemolysin-like	β-toxin	*C. perfringens*
Zinc-dependent metalloprotease	Neurotoxin	Botulinum toxin	*C. botulinum A-F* *C. baratii* *C. argentinense*
		Tetanus toxin	*C. tetani*
	Collagenase	ColG, ColH	*C. histolyticum*
		ColA	*C. perfringens*
Glycosyltransferase	UDP-glucose-dependent (large clostridial toxins)	ToxA, ToxB	*C. difficile*
		Lethal toxin (LT)	*C. sordellii*
		Hemorrhagic toxin (HT)	*C. sordellii*
	UDP-N-acetyl-glucosamine-dependent	α-toxin	*C. novyi*
ADP-ribosyltransferase	Actin ADP-ribosylating (Binary toxins)	C2 toxin	*C. botulinum C, D*
		Iota toxin	*C. perfringens*
		Spiroforme toxin	*C. spiroforme*
		CDT	*C. difficile*
	Rho ADP-ribosylating	C3	*C. botulinum C, D*
		C3	*C. limosum*
Phospholipase	Phosphatidylcholine-, sphingomyelin-degrading	α-toxin	*C. perfringens*
		PLC	*C. absonum*
		PLC	*C. bifermentans*
		γ-toxin	*C. novyi*
		PLC	*C. haemolyticum*
	Additionally phosphatidylserine-degrading	α-toxin	*C. perfringens*
		γ-toxin	*C. novyi*
	Additionally phosphatidylethanol-amine-, phosphatidylinositol-degrading	γ-toxin	*C. novyi*

artillery shells (Arnon et al., 2001). However, even this extremely dangerous compound is now extensively used in medical therapy and cosmetic applications. Blepharospasm (unvoluntary eye lid contractions), cervical dystonia (involuntary contraction of neck and shoulder muscles), and strabismus (crossed eyes) are uncontrolled muscle spasms that can be treated by injecting sublethal doses of toxin. Economically even more important are cosmetic applications. Commercial preparations of botulinum toxin ("Botox", "Dysport") are used in treatment of face ageing (relaxation of muscle contractions leading to frown lines and wrinkles) as well as hyperhidrosis and hypersalivation (Keller and Vann, 2004). The injected toxin (in very diluted concentration) is active for only a few months, then injection must be repeated. Seven serotypes of botulinum toxin are known. The proteolytic group I of *C. botulinum* produces serotypes A, B, and F (whose genes are all located on the chromosome); the nonproteolytic group II produces B, E, and F (also from chromosomally located genes); and group III produces C and D (encoded by bacteriophages). Group IV is actually *C. argentinense* and produces serotype G (from a plasmid-located gene). In addition, strains of *C. barati* can produce F and strains of *C. butyricum* can produce E (both from chromosomally located genes). The molecular action starts by lysis of bacterial cells, release of the progenitor toxin, and cleavage of the large precursor protein into a heavy and a light chain (approximately 100 and 50 kDa, respectively). The light chain carries the metalloprotease domain. Linkage of the chains is achieved by a disulfide bond. The heavy chain binds then to receptors at the nerve terminal and the complex of heavy and light chain is internalized as an endosomal vesicle. Acidification of the endosome leads to a conformational change of the heavy chain and subsequent translocation of the light chain into the cytosol. There, several SNARE (soluble N-ethylmaleimide sensitive factor attachment protein receptor) protein family members are proteolytically inactivated. Substrate specificity depends on the serotype of botulinum toxin. Serotypes A, C, and E cleave SNAP-25; C cleaves syntaxin; and B, D, F, and G cleave VAMP (vesicle-associated membrane protein). Due to the large number of serotypes, vaccination is a problem. Only a pentavalent toxoid (A-E) is available. Current treatment is injection of equine antiserum for absorbing circulating toxin. Medical countermeasure for infant botulism is an antitoxin-based therapy with a novel immune globulin.

With tetanus toxin, the situation is different. The genome of the causative agent, *C. tetani*, has been sequenced (discussed later in this chapter), and the gene encoding the toxin (*tetX*) is located on the 74-kb plasmid pE88. Thus, only one serotype is known and

vaccination is the preferred medical countermeasure. It is performed with a toxoid originating from formaldehyde-inactivated 150-kDa toxin. Tetanus toxin (TeTx) is less toxic than BoNT. The human lethal dose is estimated at about 1 ng kg^{-1}. The disease is a spastic paralysis and almost exclusively caused by infections of deep wounds. Thereby, blood vessels are disrupted and the tissue becomes hypoxic, allowing the endospores to germinate and the arising vegetative cells to produce toxin. The mode of action is similar to that of BoNT, except that TeTx does not act on the peripheral, but rather on the central nervous system. TeTx also is cleaved into a light and a heavy chain, which are then linked by a disulfide bond. The complex binds to the neuromuscular junction of motorneurons. After internalization, it is transported to the spinal cord and migrates into inhibitory interneuron terminals. There, the catalytic activity of the light chain blocks release of inhibitory neurotransmitters by cleaving VAMP (also designated synaptobrevin).

Collagenases also belong to the class of zinc-dependent proteases. The causative agent of gas gangrene and myonecrosis, *C. histolyticum*, produces six such enzymes, which are now used in medical therapies (see following paragraph). They have molecular masses of 68–125 kDa, are also called α-clostripain, and specifically cleave collagen and gelatin at the glycine residue of a PXGP motif. *C. perfringens* also produces a collagenase (ColA), which resembles ColG of *C. histolyticum*.

The paradigm of a glycosyltransferase producer is *C. difficile*, a major contributor to healthcare-associated illnesses. Due to their molecular mass of up to 308 kDa, these proteins are also designated as large clostridial cytotoxins (Barth and Aktories, 2005). *C. difficile* produces ToxA and ToxB, which use UDP-glucose as a cofactor and glycosylate G-proteins such as Rho, Rac, Cdc42, Rap, and Ral. Similar enzymes are synthesized by *C. novyi* (α-toxin uses UDP-N-acetyl-glucosamine as a cofactor) and *C. sordellii* (hemorrhagic and lethal toxins, the latter ones act additionally on Ras, but not on Rho). The toxins are bound by a receptor of the host cell and taken up by endocytosis. After processing (the location of this process still awaits elucidation), acidification of the endosome leads to secretion of the enzyme domain into the cytosol of the host cell, where it modifies its target proteins. Glycosylated G-proteins become inactive, and signal chains important for proliferation, cell differentiation, organization of actin cytoskeleton, enzyme activation, and transcription are blocked. *C. difficile* is remarkable in another aspect: bacterial pathogens are generally considered to grow only under heterotrophic conditions. However, *C. difficile* has been shown to represent the first pathogen able of autotrophy, possibly adding to the persistence of this bacterium in the infected human intestinal tract (Köpke et al., 2013).

ADP-ribosyltransferases target either actin or Rho (Barth and Aktories, 2005). The best studied example of the first group is the C2 toxin of *C. botulinum*. It comprises two proteins, and the group is therefore referred to as binary toxins. In addition to type C and D *C. botulinum*, such proteins are produced by *C. difficile* (CDT), *C. perfringens* (iota toxin), and *C. spiroforme* (spiroforme toxin). In order to become cytotoxic, the binding component of C2 (C2II) is cleaved at its N terminus (removal of an app. 20-kDa peptide) to create C2IIa. This component oligomerizes into heptamers, binds to a receptor, and attaches to the host cell membrane. The other component, C2I, docks to this complex, which is then translocated into the host cell by endocytosis. Acidification of the endosome leads to a conformational change of C2IIa, its insertion into the membrane, and finally the release of C2I into the cytosol of the host cell, where it ADP-ribosylates G-actin monomers and thus prevents their polymerization.

The paradigm of the second group is C3 toxin of *C. botulinum*. It lacks a cell binding and transport domain. It ADP-ribosylates Rho GTPases, thereby inactivating them. A similar toxin is found in *C. limosum*. Since free toxin is poorly taken up by eukaryotic cells, invasion of pathogen into the host and subsequent release of toxin is a prerequisite for cytotoxic action.

Phospholipases produced by clostridia all belong to class C (Titball and Tweten, 2005). Such enzymes have been detected in *C. absonum*, *C. barati*, *C. bifermentans*, *C. haemolyticum*, *C. novyi*, *C. perfringens*, and *C. sordellii*. As yet to be characterized, all cleave phosphatidylcholine and sphingomyelin. Diseases caused by these toxins are gas gangrene and necrotic enteritis. The latter occurs in farmed fowl and increased significantly during the past decade.

Biotechnology

An outstanding historical application of biotechnology employing clostridia was the acetone-butanol fermentation by *C. acetobutylicum* (discussed earlier in this chapter). Plant sizes were enormous, the largest facilities in the United States were located in Terre Haute, Indiana (52 fermenters) and Peoria, Illinois (96 fermenters with a capacity of 189,250-liters each) (Gabriel, 1928). South Africa operated a plant until 1982 in Germiston, consisting of 12 production fermenters with a working volume of 90,000-liters each (Jones, 2001). Facilities were also located in Australia, Brazil, Canada, China, Egypt, India, Japan, the former Soviet Union, and the United Kingdom (Jones and Woods, 1986). Production in China was only stopped in 2004 (Chiao and Sun, 2007), but soon after restarted and later stopped again. In addition to acetone and 1-butanol, 2-propanol (or isopropanol) is another solvent produced by clostridia, namely *C. aurantibutyricum*, *C. beijerinckii*, *C. puniceum*, and *C. roseum* (Dürre and Bahl, 1996; Poehlein et al., 2017). Due to increasing crude oil prices, the fermentative production of butanol is again able to compete economically with the petrochemical process. Consequently, BP and DuPont formed a joint venture, Butamax Advanced Biofuels, aiming at producing biobutanol. A number of other companies are also actively pursuing the biotechnological production, especially focusing on substrates that do not compete for human nutrition (e. g., lignocellulosic hydrolysates) (Schiel-Bengelsdorf et al., 2013). In addition to its being an important bulk chemical for industrial purposes, butanol can also serve as a biofuel (Dürre, 2005; 2007b). Mixtures with gasoline are superior to those with ethanol, as butanol has a lower vapor pressure and a higher energy content, can be blended at higher concentrations than ethanol, and does not require specific adjustments of vehicle and engine technologies.

The clostridial metabolic pathways leading to solvent production are tightly coupled to regulation of endospore formation (Paredes et al., 2005, Dürre, 2005). This makes sense, as formation of acids during exponential growth leads to acidification of the surrounding environment. Anaerobic bacteria are unable to keep their internal pH constant, so it will drop in parallel with

the external one, but being more alkaline by about 1 pH unit (Dürre et al., 1988). Reaching an external pH of about 4, undissociated acid from the outside will diffuse into the cytoplasm and will dissociate there. As a consequence, the proton gradient over the membrane will collapse, and the cell will die. Converting acids into neutral products will avoid this lethal effect, and thus respective species have an ecological advantage. However, since butanol in higher concentrations is also toxic, sporulation must be initiated at the same time as solvent formation to guarantee long-time survival. Overall, the cells thus manage to stay metabolically active for a longer period and to postpone entering a dormant stage.

Enzymes required for solventogenesis are coenzyme A transferase, butyraldehyde and butanol dehydrogenases for butanol formation, as well as coenzyme A transferase and acetoacetate decarboxylase for acetone production (an additional alcohol dehydrogenase allows 2-propanol synthesis from acetone in *C. beijerinckii*). In *C. acetobutylicum*, four dehydrogenases are known. Butanol dehydrogenases A and B are encoded by chromosomal genes, forming a monocistronic operon each (Walter et al., 1992). BdhA seems to function as an electron sink, removing excess reducing equivalents by alcohol formation, while BdhB plays a major role in massive butanol production (Sauer and Dürre, 1995). Initiation of solventogenesis is mediated by AdhE, a bifunctional butyraldehyde/butanol dehydrogenase, whose gene is located on a large plasmid (pSOL1, 192 kbp) and forms a common operon (*sol*) with two genes encoding the subunits of coenzyme A transferase. Directly downstream, but with convergent direction of transcription, lies a monocistronic operon encoding the gene for acetoacetate decarboxylase (*adc*). This arrangement is unique, as in other solventogenic species such as *C. beijerinckii*, *C. saccharobutylicum*, and *C. saccharoperbutylacetonicum* the *sol* operon consists of genes encoding butyraldehyde dehydrogenase, coenzyme A transferase, and acetoacetate decarboxylase (Dürre, 2005; Schiel-Bengelsdorf et al., 2013; Poehlein et al., 2017). Another *adhE* gene (*adhE2*) is also located on plasmid pSOL1. The signal(s) responsible for inducing solventogenesis (and also sporulation) have not been unequivocally identified, although pH, concentration of undissociated acids, metabolic intermediates, cofactors, and salts, as well as DNA supercoiling all play a role (Dürre, 1998; Girbal and Soucaille, 1998). The master regulator of sporulation, Spo0A, which in contrast to *Bacillus* species is directly phosphorylated and not by a phosphorelay (Steiner et al., 2011), also acts as a transcription factor during onset of solventogenesis. In addition to other regulatory proteins, RNA processing, a small noncoding regulatory RNA, and protein modification represent further levels of regulation (Dürre, 2005; 2011). The use of DNA microarrays allowed a new approach for studying this complex regulatory network (Tummala et al., 2005; Grimmler et al., 2011) and, consequently, construction of production strains with superior properties (Dürre, 2005; Tomas et al., 2005).

The emerging field of systems biology offers another possibility of improving performance of the acetone-butanol fermentation. Modelling of the metabolism of *C. acetobutylicum* can be based on enzymatic, transcriptome, proteome, and metabolome data or combinations thereof. Characterization of the quantitative dynamics of metabolic processes and regulatory networks within a cell will allow predictions of behavior under altered conditions and thus improvement of productivity of butanol. Several such models have meanwhile been reported (Shinto et al., 2007; Senger and Papoutsakis, 2008a; 2008b; Jabbari et al., 2013; Millat et al., 2013a), but none does yet fully incorporate all important parameters such as pH-dependency of the shift and the whole repertoire of controlling mechanisms. An interesting aspect is the influence of population dynamics, which might result in a switch of an acidogenic to an solventogenic subpopulation (Millat et al., 2013b).

As already mentioned, industrial fermentation processes leading to large-value and low-price bulk chemicals are hampered, when using substrates that compete with human nutrition (e.g., sugar-or starch-containing materials). This raised the so-called food-versus-fuel debate. One way of avoiding this problem is the use of lignocellulosic hydrolysates. However, such hydrolysates require collection of biomass and costly pretreatments and may thus not always be applicable. Therefore, a very promising approach is the use of autotrophic clostridia that capture greenhouse gases such as CO or $CO_2 + H_2$ and use them as sole carbon and energy source, thus combining use of an abundant and cheap substrate with climate protection. Synthesis gas (Syngas) is a mixture of mostly CO and H_2 and often a waste product from the chemical industry or steel mills. It can also be easily generated from biomass. Syngas is already a major feedstock in the chemical industry, thus, its handling represents no problem. *C. autoethanogenum* or *C. ljungdahlii* form acetate and/or ethanol from syngas. Gas fermentation to ethanol has passed the pilot and demonstration scale (Köpke et al., 2011a) and the Chicago (U.S.)-based company LanzaTech has built a commercial size production plant (46,000 t/a) in China, which started operation in 2018. Instead of hydrogen, reducing power could also be provided by electricity. When electrons stem from photovoltaics, this could be even considered a new form of photosynthesis (Nevin et al., 2010). In addition to acetate and ethanol, 2,3-butanediol is also formed naturally by these acetogens (Köpke et al., 2011b). Recombinant strain construction allowed to expand the product repertoire, with *C. ljungdahlii* becoming a butanol producer (Köpke et al., 2010), *C. aceticum* an acetone producer (Schiel-Bengelsdorf and Dürre, 2012), and *C. autoethanogenum* and others an acetone and/or isopropanol producer (Chen et al., 2012).

Because some clostridia can degrade halogenated and hazardous compounds partially or completely, they may also be used in bioremediation processes. Examples are lindane (hexachlorocyclohexane, used as an insecticide), which is completely dechlorinated by *C. butyricum*; PCBs (polychlorinated biphenyls, used in insulating fluids), which is metabolized by *C. hydroxybenzoicum*, and TNT (trinitrotoluene, used as an explosive), which is reduced to triaminotoluene (Bahl and Dürre, 1993, Ahmad et al., 2005).

A medical application of a clostridial enzyme is wound debridement (Brett, 2005). Chronic, nonhealing wounds require removal of necrotic tissue, which is anchored by collagen to the wound surface, to achieve successful curing. Such treatment might become necessary in case of severe burns or dermal ulcer. One of the agents used for this goal is collagenase from *C. histolyticum*, of which six different such proteins are known. They cleave interstitial collagens into small peptides, mostly tripeptides. Collagen accounts for approximately 75% of the skin tissue (dry weight), and the enzymes act at physiological

pH and temperature. Commercial preparations of collagenase (e.g., "Santyl," "Iruxol," or "Novuxol") are therefore particularly useful in the removal of detritus and contribute toward the formation of granulation tissue and subsequent epithelization. Collagen in healthy tissue or in newly formed granulation tissue is not attacked.

Oncolysis caused by clostridia can be used for treatment of solid cancers (Minton, 2003). It has been successfully tested at the laboratory stage with animals and is about to enter clinical trials (Brown and Liu, 2004). As clostridia perform an anaerobic lifestyle, their spores will only germinate in an anaerobic or at least hypoxic environment. This is a situation normally not occurring in mammals. Consequently, injected clostridial spores are cleared from blood within a few days (Brown and Liu, 2004). However, the environment of solid tumors in a mammal is hypoxic, thus allowing spores reaching such an area to germinate (only in this place, which is a very specific targeting) and to produce vegetative cells, which are able to multiply in that region. The bacteria proliferate at the expense of only necrotic tissue, as healthy, oxygenated tissue does not allow colonization. Recombinant spores will give rise to recombinant clostridia, which are able to produce specific proteins at the tumor. Examples are cytosine deaminase, carboxypeptidase G2, and nitroreductase that are all able to convert a harmless prodrug, injected into and delivered by the bloodstream, into an effective anticancer agent, which is generated only at the tumor and causes oncolysis (Minton, 2003). Another possibility is the transformation and expression of genes, which encode cytotoxic proteins. After secretion, the gene products will then be able to exert antitumor activity. Currently investigated are tumor necrosis factor α (TNFα) (van Mellaert et al., 2005) and, especially for treatment of pancreatic cancer, *C. perfringens* enterotoxin (CPE) (Dürre, 2007a). The direct use of *C. novyi*-NT (nontoxic) spores in combination with radiation therapy or as bacteriolytic therapy is another promising approach (Bettegowda et al., 2003; Maletzki et al., 2010).

Handling and Molecular Biology Techniques

Due to the large number of species in the genus *Clostridium*, almost the entire range of microbial metabolic properties is represented (Bahl and Dürre, 1993, Dürre, 2007a). Clostridia are found within acidophiles, neutrophiles, and alkaliphiles (thus covering the pH range from 4 to 10.5) as well as in psychrophiles, mesophiles, and thermophiles (thus covering most of the temperature range). Although in general being obligate anaerobes, some species are able to detoxify oxygen (to varying extent) by employing superoxide reductase, peroxidases, and/or superoxide dismutase (Dürre, 2001). In addition to using specific substrates already mentioned, clostridia can be grown in complex media commercially available (e.g., CMC, chopped meat-carbohydrate; PYG, peptone-yeast extract-glucose). Detailed media compositions are provided by culture collections distributing the species and in species-specific original publications.

The technique originally invented by Robert Hungate allows easy handling of clostridia by using anaerobic and prereduced media with help of titanium(III) citrate, a mixture of sodium sulfide and cysteine-HCl, or sodium thioglycolate (Breznak and Costilow, 1994). Media are boiled to remove oxygen and cooled under a constant flow of nitrogen. After addition of the reducing agents and a redox indicator (such as resorufin) for visual detection of potential oxygen contamination, the liquid is poured into tubes or bottles, and then a butyl rubber stopper is secured in place. After sterilization, inoculation or sampling can easily be performed with sterile syringes and needles. Solid media can be poured and streaked in an anaerobic chamber.

Many clostridial genomes have meanwhile been completely sequenced, many more are in various stages of completion. Mining of this information is in progress, one of the first general conclusions that can be drawn is that initiation of endospore formation is not triggered by a phosphorelay as in bacilli (Dürre and Hollergschwandner, 2004). Plasmids are quite common in clostridia, with about a third of the investigated species containing extrachromosomal elements (Lee et al., 1987). A number of shuttle vectors have been constructed, in general making use of erythromycin and chloramphenicol resistance genes (Tummala et al., 2001; Davis et al., 2005; Heap et al., 2009). However, in practice, these two antibiotics can be inactivated by clostridia so that clarithromycin (a pH-stable derivative of erythromycin) and thiamphenicol (a chloramphenicol derivative without the reducible nitro group) are employed. Transformation of free DNA into clostridia can be achieved by electroporation, and conjugation (direct cell contact with a donor cell) is also possible (Davis et al., 2005). Shelter against host restriction endonucleases can be artificially provided by a *Bacillus* phage methylase expressed in the intermediate host *E. coli* (Mermelstein and Papoutsakis, 1993).

Random mutagenesis has been tried with *C. acetobutylicum* and *C. tetani* using conjugative transposons from streptococci such as Tn*916*, Tn*925*, and Tn*1545* (for a review, see Dürre, 1993). Several mutants have been obtained, but because these elements prefer AT-rich regions found especially in promoters, structural gene inactivations are not frequent. However, based on the *mariner* transposon, an effective system for *in vivo* random mutagenesis of *C. difficile* has been developed (Cartman and Minton, 2010), which also might be transferable to other clostridia. Natural transposons are also found in clostridia. A conjugative element of 20.7 kb (Tn*5397*) is present in *C. difficile*, integrative mobilizable elements of 6.3 kb (Tn*4451* and Tn*4453*) have been detected in *C. perfringens* and *C. difficile*, a transmobilizable element of 9.6 kb (Tn*5398*) was found in *C. difficile*, and a compound transposon of 6.3 kb (Tn*5565*) has been described for *C. perfringens* (Lyras and Rood, 2005). Chemical mutagenesis by nitrite is not possible, as this compound destroys essential iron-sulfur centers, as mentioned before. However, a targeted gene knock-out system with a high success rate has been developed, which is based on the use of a mobile group II intron from *Lactococcus lactis* ("ClosTron," Heap et al., 2010; Kuehne and Minton, 2012). The system can also be used for cargo DNA delivery (Kuehne et al., 2011). Integration of DNA into clostridial chromosomes could also be achieved without a counter-selection marker (Heap et al., 2012). Modulation of gene expression is possible by means of antisense RNA constructs (Tummala et al., 2005). In *C. saccharobutylicum*, a naturally expressed asRNA participates in regulation of nitrogen assimilation. The 43-bp transcript is complementary to a region at the start of the *glnA* gene (encoding glutamine synthetase) and thus inhibits translation during nitrogen rich conditions (Fierro-Monti et al., 1992). The toolbox for genetic manipulation of clostridia also contains

several well-suited reporter gene systems. Successful use of *catP* (encoding chloramphenicol acetyltransferase), *eglA* (encoding β-1,4-endoglucanase), *gusA* (encoding β-glucuronidase), *lacZ* (encoding β-galactosidase), and *luxAB* or *lucB* (encoding luciferase) has been reported (Tummala et al., 2001; Feustel et al., 2004). The latter one is especially well suited, as no interfering metabolic equivalent is known from clostridia. In summary, all technologies required for genetic analysis and manipulation of members of this large bacterial genus are at hand.

General Features

Corynebacterium was originally defined in 1896 by Lehmann and Neumann to accommodate nonmotile parasitic and pathogenic bacteria including diphtheroid bacilli [1]. "Diphther" is the Greek word for membrane and describes the fact that these latter bacteria typically can be isolated from a false membrane in the pharynx developed due to the necrotic action of the toxin made by *Corynebacterium diphtheriae*. Before the establishment of modern systematics the taxon *Corynebacterium* accommodated a number of heterogeneous bacteria. However, based on the extended use of chemotaxonomic markers, mainly in the last third of the last century, like cell wall chemistry and lipid composition, the taxon *Corynebacterium* was brought into a sharper focus and it was also recognized that it is a member of the so called CMN-group of bacteria, including besides *Corynebacterium* also bacteria like *Mycobacterium* and *Nocardia*. Based on 16S rRNA/rDNA sequence patterns and in particular whole genome sequences, it is now clear that *Corynebacterium* forms a robust and well-defined monophyletic group, which together with *Gordonia, Mycobacterium, Nocardia, Rhodococcus, Tsukamurella*, and *Dietzia* forms the order *Corynebacteriales* belonging to the large clade of *Actinobacteria* [2, 3]. Recent reviews and monographs covering several aspects of pathogenic and nonpathogenic *Corynebacterium* species are available [4–8].

The current number of validated *Corynebacterium* species in 2019 exceeds 132 [9]. A phylogenetic tree using a maximum likelihood analysis, based on approx. 2,500 sequences and evaluated among others by maximum parsimony and distance procedures is given in Figure 27.1. In addition, two type strains for the closely related species *Dietzia* and *Tsukamurella* are included as a reference. It can be seen, for instance, that the amino acid producing *Corynebacterium* species *C. glutamicum, C. efficiens,* and *C. callunae* cluster closely together.

Corynebacterium species can be isolated from a number of sources. Nonpathogenic species are found in a broad variety of habitats such as dairy products, animal fodder, rotting plant material, and also in soil as is the case with the biotechnologically important *C. glutamicum*. Pathogenic species are isolated from human or animal specimens, where they occur either as true pathogens or as cutaneous or mucocutaneous contaminants. Corynebacteria are part of the regular microbiome of the skin, as is the case with *C. xerosis*, which however in immunocompromised hosts may cause infections, such as endocarditis, pneumonia, empyema, wound infection, and peritonitis. Although there is no selective medium or enrichment procedure known specifically suited for *Corynebacterium* species, a number of rapid identification and differentiation methods are commercially available that are based on physiological traits. These include the API CORYNE (bioMerieux), API ZYM (bioMerieux), BIOLOG (Biolog), MINITEK (Becton Dickinson), and RapID CB Plus (Remel) identification systems. They are possibly biased toward the identification of clinically relevant species.

For the in-depth identification of *Corynebacterium* species and the study of their phylogenetic relationship, DNA and 16S rRNA analysis is used. Besides total DNA characterization by either thermal denaturation, or hybridization, most informative and convenient is 16S rDNA sequence analysis. For this purpose, a large fragment of the 16S rRNA gene is amplified via PCR, using the universal primers pA 5′-AGAGTTTGATCCTGGCTCAG (positions 8 to 27 of the *Escherichia coli* sequence) and pH* 5′-AAGGAGGTGATCCAGCCGCA (positions 1,541 to 1,522). These bind near the 5' and 3' ends of the rRNA gene and the PCR product is subsequently sequenced and analyzed by comparison with known 16S rDNA sequences [10], as has been done for the *Corynebacterium* species compiled in Figure 27.1.

Corynebacterium cells appear rod-shaped with a somewhat irregular ("coryneform") morphology. Two cells may be arranged in V-formation as a consequence of cell division ("snapping mode"). Also packages of several cells in parallel arrangement ("pallisades") occur. Cells are nonmotile, and mycelia, capsules, and spores are absent. Some species show piliation, like *C. diphtheriae*. Corynebacteria are catalase-positive,

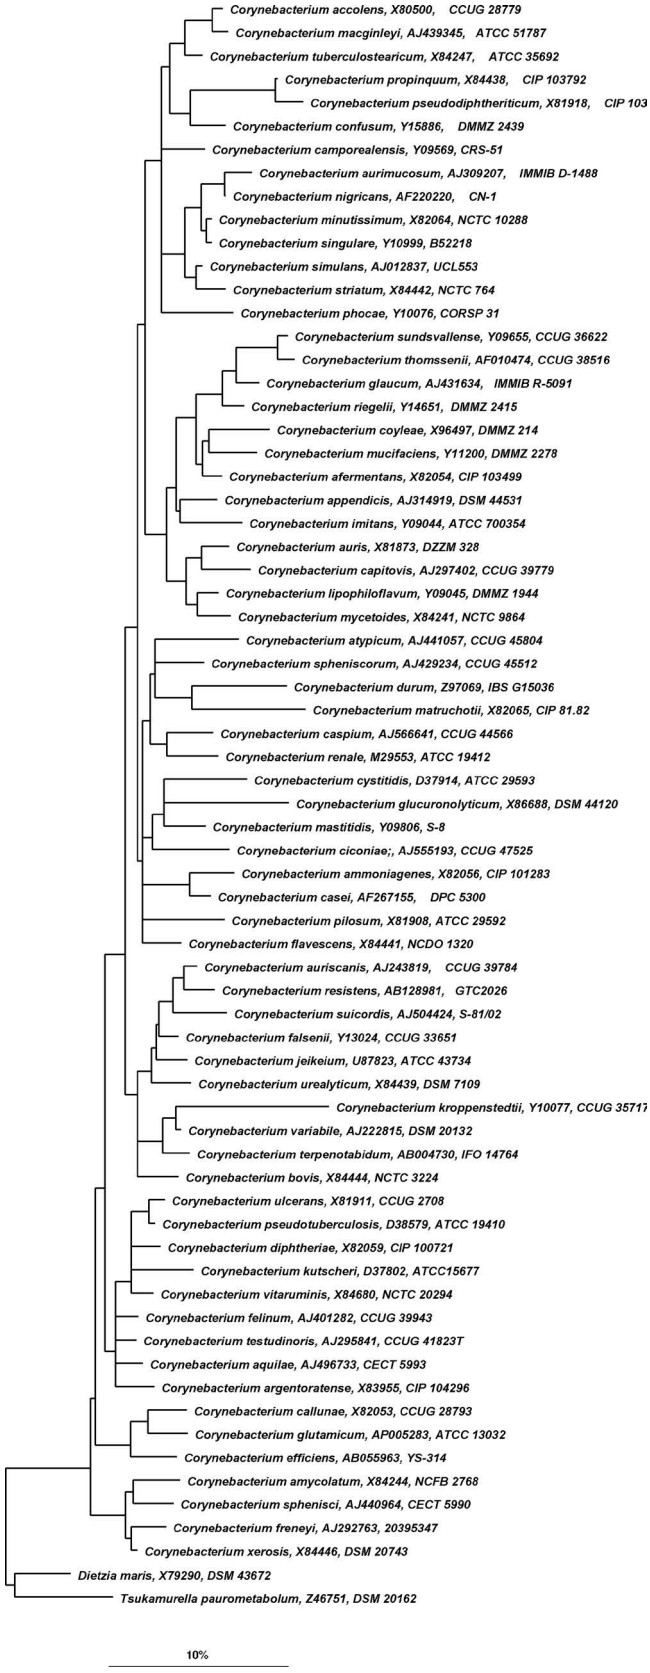

FIGURE 27.1 Clustering of *Corynebacterium* species. The scale bar indicates 10% estimated sequence divergence. (Figure kindly provided by Dr. W. Ludwig, Technical University Munich.)

aerobic or facultatively anaerobic bacteria. They grow in the range of 15–45°C.

Cell Wall

Interestingly, in some properties, the architecture and function of the cell wall of the Gram-positive *Corynebacterium* and related genera like *Mycobacterium* resembles those of the Gram-negative cell envelope, although the molecular details are strikingly different. *Corynebacterium* possesses an outer lipid bilayer membrane [11]. However, this is made up of α-branched, β-hydroxylated fatty acids (mycolic acids, see below) instead of linear fatty acids [12]. In addition *Corynebacterium* possesses unusual sugar polymers like arabinogalactan (AG), which contains D-arabinose, which rarely occurs in nature as the "D" enantiomer [13]. The major macromolecular cell wall components are AG, peptidoglycan, lipomannan, and lipoarabinomannan. Whereas the peptidoglycan is similar to that found in other bacteria, like *E. coli* for instance [14], the sugar polymers and liposugar Alderw polymers deserve closer attention since they are common to *Corynebacterium* and other members of the order *Corynebacteriales* within the *Actinobacteria*, giving them their unique position.

The sugar polymers are of relevance since they might come in direct contact with the environment, respectively, the host, and therefore decide on immunological properties and persistence of the bacterium [15]. Much progress has been made in recent years on the enzymology and structure of these polymers. AG is covalently linked via its galactan part to peptidoglycan via a unique α-L-rhamnopyranose–(1→3)-α-D-GlcNAc-(1→P) linker unit. To the arabinose part of AG mycolic acids are bound. Thus AG is part of a large mycolyl-AG-peptidoglycan (mAGP) complex. It can be considered as the major scaffold within the cell wall, whose absence or disorder causes serve growth defects [16–18], and existing antibiotics, like ethambutol, have AG as target as might have future antibiotics hoped for. For isolation of the mAGP complex cells are suspended in phosphate-buffered saline containing 2% Triton X-100 (pH 7.2), disrupted by sonication and centrifuged. The pelleted material is then extracted with 2% SDS in phosphate-buffered saline at 95°C to remove associated proteins, successively washed with water, 80% (v/v) acetone in water, and acetone, and finally lyophilized to yield a highly purified cell wall preparation [19].

Access to the glycosyl composition of AG is by the further analysis of the isolated cell wall preparation. This is hydrolyzed with 2 M trifluoroacetic acid (TFA) and reduced with $NaBH_4$ to result in alditols, which are per-*O*-acetylated and examined by gas chromatography [20–22]. An example for such a cell wall analysis for *C. glutamicum* is shown in Figure 27.2, left panel. A recent comparison of *C. glutamicum, C. diphtheriae, C. xerosis*, and *C. amycolatum* by such methodology confirmed that all species have as expected primarily arabinose (Ara) and galactose (Gal) in their arabinogalactan. In addition, there are small but significant amounts of glucose linked to AG of *C. xerosis* and *C. amycolatum*, whereas AG of *C. diphtheriae* contains additionally mannose [28] and AG of *C. glutamicum* rhamnose [23].

Besides the total composition of AG, further information concerning the structure of this sugar polymer comes from a linkage

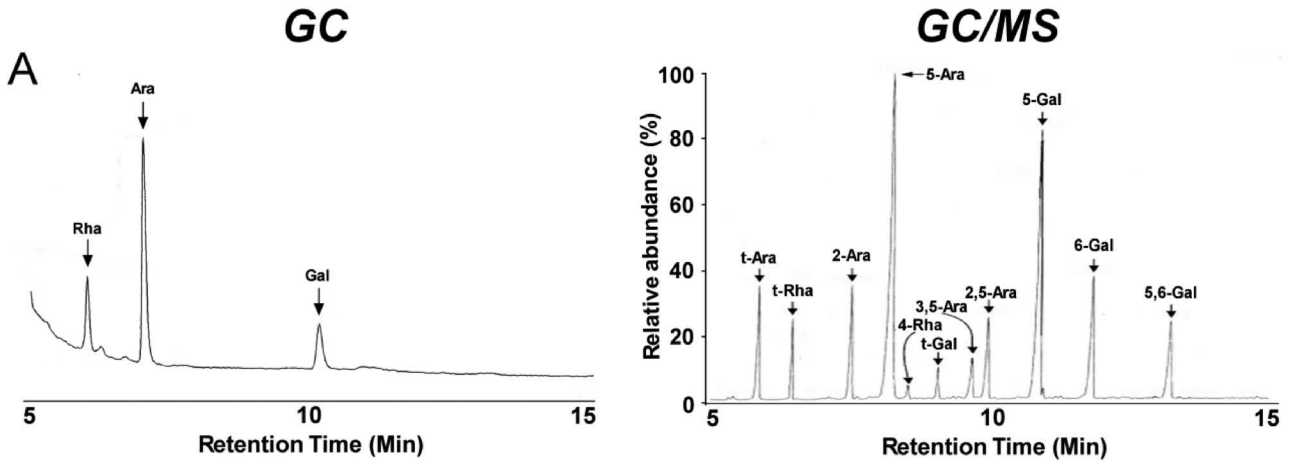

FIGURE 27.2 On the left is shown a GC analysis of arabinogalactan of *C. glutamicum* showing the basic building blocks arabinose, galactose, and rhamnose of this heterosugarpolymer, whereas on the right, the individually linked sugars are shown as analyzed by GC/MS.

analysis of the sugars. This is done by per-*O*-methylation of cell wall preparations using dimethyl sulfinyl carbanion [19, 22, 24], followed by hydrolysis using 2 M TFA and reduction with $NaBH_4$. Subsequently, the free hydroxyl groups of per-*O*-methylated sugar derivatives are per-*O*-acetylated and examined by gas chromatography/mass spectrometry. Such an analysis for *C. glutamicum* is shown in Figure 27.2, right panel. It reveals that 5-Gal*f*, 6-Gal*f* and 5,6-Gal*f* residues are present. They form a linear chain of alternating β(1→6) linked β(1→5) Gal*f* residues [25, 26]. To this backbone, arabinose chains are attached at the 8th, 10th, and 12th β(1→6) Gal*f* residue [24]. Thus the latter Gal*f* residue with arabinose attached has three linkages, and results in the 5,6-Gal*f* residue (for convention the 1 position is not given). The arabinan domain is made up of α(1→5), α(1→3), and β(1→2) arabinofuranosyl linkages to form a branched polymer of approximately 25 residues in size [19].

To the *t*-Ara*f* and 2-Ara*f* residues mycolic acids are bound representing the unique lipophilic components of the cell envelopes of *Corynebacterium*. In *Corynebacterium,* the mycolic acids are of rather simple structure and consist of two condensed linear fatty acid chains, whereas in *Mycobacterium,* the basic structure is retained, but one of the two fatty acids is much more elaborated. Interestingly, there are a few atypical *Corynebacterium* species not possessing mycolic acids. These are *C. amycolatum*, *C. kroppenstedtii*, and *C. atypicum*. The mycolic acids in *Corynebacterium* species are collectively called corynomycolic acids and consist of up to 38 carbon atoms. The most prominent mycolic acid in *C. glutamicum* has the formula 34:1 followed by 32:0 [21, 27], the latter apparently the result of a condensation of two palmitic acid molecules, and the former of one palmitic plus one oleic acid molecule. The mycolic acids formed may depend on the culture conditions. Thus addition of oleic acid to *C. glutamicum* results in a dominant content of more than 90% of the mycolic acid of the type 36:2.

In addition to the mycolic acids bound to arabinogalactan mycolic acids exist bound to trehalose to form trehalose mono- and dimycolates, respectively. These latter mycolic acid conjugates are solvent extractable [12]. Together with the mycolic acids bound to AG, they form the outer lipid bilayer of *Corynebacterium*, which is clearly visible by electronmicroscopic techniques in addition to the cytoplasmic membrane [11, 28]. The existence of an outer lipid layer is entirely consistent with the presence of a range of pore-forming proteins, porins, within the cell walls of these Gram-positive bacteria [29].

The condensation of two linear fatty acids to the mycolic acids requires the activity of a specific enzyme complex as evident from a genetic analysis of *C. glutamicum*. Whereas the carboxylase α-subunit D1 is a component of the ubiquitous acetyl-CoA carboxylase required for linear fatty acid synthesis, the paralogous carboxylase α-subunits D2 and D3 present in all *Corynebacterium* species are essential for the mycolic acid-forming enzyme complex [21, 30, 31]. The acetyl-CoA carboxylase consists of the carboxylase α-subunit D1, the biotin-carrying β-subunit and an additional ε-subunit. It carboxylates acetyl-CoA in *Corynebacterium* to provide malonyl CoA necessary for linear fatty acid synthesis, as is similar the case in Gram-negative bacteria and other organisms. However, the carboxylase involved in mycolic acid synthesis is apparently a specific evolutionary incidence, involving gene duplications, to derive an enzyme complex structurally and mechanistically related to the acetyl-CoA carboxylase. The acyl carboxylase consists of the carboxylase α-subunits D2 and D3 forming a complex together with the same β- and ε-subunit as required for acetyl-CoA carboxylase complex formation. Although the details are not yet fully understood, it is clear that one linear fatty acid is carboxylated forming an intermediate during condensation of the two linear fatty acid chains by the single polyketide synthase present in *Corynebacterium* [21, 31, 32]. Due to the importance of pathogenic *Corynebacterium* species like *C. diphtheriae* or *C. jeikeium* and the related *Mycobacterium* species, which also possess mycolic acids, considerable efforts are currently made to understand the biochemical details of mycolic acid synthesis. Structural information on one of the carboxylase α-subunits involved is available [32, 33]. In this respect, the ease of handling *C. glutamicum* and its rather small genome structure just containing the genes required for core reactions of cell wall synthesis, and not overloaded with paralogous genes as is the case in *Mycobacterium*, offers a great advantage to understand the basic principles of mycolic acid synthesis.

Genomes

At present, approximately 60 genome sequences of different *Corynebacterium* species are deposited. Many of them are at the level of contigs or scaffolds. The majority of the sequences are derived from pathogenic species. Of the facultative intracellular pathogen *C. pseudotuberculosis,* 15 isolates from different hosts and countries were sequenced and their genomes compared [34, 35]. Analysis of pathogenic islands enabled differentiation of *C. pseudotuberculosis* biovar *ovis* from *C. pseudotuberculosis* biovar *equi*. In the biovar *ovis* strains, a high similarity of the pilus genes is present, whereas these genes show great variability in the biovar *equi* strains. This may be responsible for the ability of the biovar *ovis* strains to spread throughout host tissues and penetrate cells to live intracellularly, in contrast to biovar *equi* strains, which rarely attack visceral organs. Similarly, the genomes of 13 different *C. diphtheriae* isolates were compared to identify a core genome consisting of 1,632 conserved genes. With each newly sequenced strain, an average 65 unique new genes are found. From genome comparisons, it appears that variation in the genome is due to horizontal gene transfer between species and that this is a strategy of *C. diphtheriae* to establish differences in host-pathogen interactions [36].

Nonpathogenic *Corynebacterium* species from which genome sequences are available include, among others, that of *C. glutamicum*. Indeed, the *C. glutamicum* sequence was the first *Corynebacterium* sequence published due to the importance of *C. glutamicum* in industry. Mutants of this bacterium have been used for amino acid production since more than 50 years. Currently, L-glutamate and L-lysine are produced annually in amounts exceeding 3.5 million and 2.5 million tons, respectively. This is done in fermenters of about 500 m^3 in size with mutants of *C. glutamicum* [4, 37]. It is, therefore, not surprising that even two sequences of the type strain *C. glutamicum* ATCC 13032 were released at almost the same time, reflecting the commercial interest in this organism [38, 39]. They are not perfectly identical, but differ roughly by 27 kb, which is mainly due to additional copies of insertion elements and an additional prophage region present in the larger genome. The prophage regions can be deleted leading to a 6% reduced genome, which does not influence growth [40]. There is a publically available genome sequence of an L-lysine-producing *C. glutamicum* mutant, which was isolated from the type strain *C. glutamicum* ATCC13032 by a new selection procedure [41]. This mutant is characterized by 268 single nucleotide polymorphisms with the mutation *murE*-G81E identified as a causative mutation leading to increased L-lysine synthesis [42]. Other nonpathogenic *Corynebacterium* species for which whole genome sequences are available include *C. ammoniagenes*, *C. flavescens*, and *C. variabile;* all are involved in smear-ripening of cheeses where they contribute to the specific flavor and textural properties of the cheese [43]. The genome sequence is also known for *C. halotolerans* [44], which tolerates salt concentrations up to 25%, a trait that could be of industrial interest. The GC content of 68.4% is exceptionally high for a *Corynebacterium* species. Also *C. efficiens* has a high GC content (63.4%), which is attributed to its high growth temperature of up to 45°C [45]. This trait is of also interest for the large-scale production of amino acids, since cooling costs in fermentations are reduced [4].

Not unexpectedly, the overall genome sequence organization of the *Corynebacterium* species shows that genes are largely syntenic. The comparison of *C. glutamicum* versus *C. diphtheriae* is shown in Figure 27.3, left panel. It reveals one insertion in *C. glutamicum* compared to *C. diphtheriae*, in the range from 1,775,332 to 1,973,456 bp. Nothing in that ~200 kb range of the *C. glutamicum* genome is found in *C. diphtheriae*. In contrast, the comparison of *C. diphtheriae* versus *C. jeikeium* or *C. glutamicum* versus *C. jeikeium* (Figure 27.3, middle and right panels) reveals one major large inversion in *C. jeikeium*, which is interestingly symmetric about the origin of replication creating an "X" pattern (or the beginning of one). Such features of genome structures are known for moderately related bacteria and were also shown to occur in *E. coli* and *Salmonella typhimurium* under laboratory conditions [38]. In *C. jeikeium,* there are also some smaller breakpoints of synteny present, indicating that this species is the most distant of the three analyzed. *C. jeikeium* is characterized by a restricted carbohydrate utilization pattern as compared to the other *Corynebacterium* species, and it lacks phosphoenolpyruvate:carbohydrate phosphotransferase systems (PTSs), which might be one reason for the smaller genome and might also reflect an adaptation of

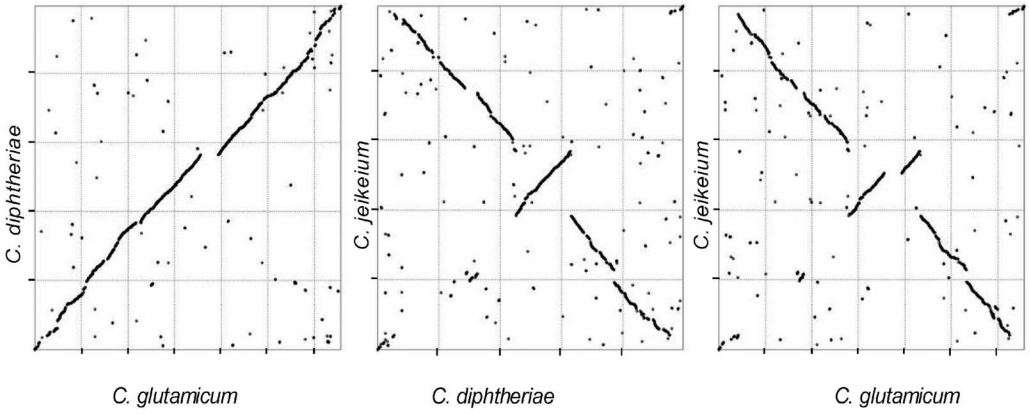

FIGURE 27.3 Synteny between the genomes of *C. glutamicum* ATCC 13032, *C. jeikeium* K411, and *C. diphtheriae* NCTC 13129. The diagram shows scatterplots of the conserved protein sequences between each pair of species, forming syntenic regions between the corynebacterial genomes. The x and y axes are scaled in 0.5 Mbp. C. jeikeium to the availability of nutrients in the predominantly colonized areas of the human skin.

Transcriptional Regulators

There are structural and functional types of transcription factors (TRs). Most of them present in *Corynebacterium* consist of one protein, as is also the case in other bacteria [46]. These one-component systems directly bind to DNA, typically in the promoter region, to induce or repress downstream genes. In contrast, two-component systems consist of one protein that is usually membrane-bound with kinase activity and a second protein that functions in response to phosphorylation by the kinase as transcriptional regulator [47]. This particular setting enables transmission of extracytoplasmic signals to the genome. A third type of TRs is the sigma factors, which are bound to the core RNA polymerase to initiate transcription of genes. The transcriptional regulatory repertoire is similar between the closely related nonpathogenic *Corynebacterium* species, but differs remarkable when comparing the nonpathogenic species with their pathogenic relatives [43]. This is related with the complexity and size of the genomes, a trend that has been observed in many other microbial families and can be interpreted with the necessity to integrate the additional genetic information into the regulatory network of the cell [48].

Genome comparisons enabled to define the core set of TRs in *Corynebacterium* [49, 50]. It includes 22 DNA-binding TRs, two two-component systems, and six sigma factors (Table 27.1). The high degree of conservation indicates that the respective TRs fulfill important functions in *Corynebacterium*. Among the core TRs is DtxR, which was first identified in *Corynebacterium diphtheria* as a repressor of the diphtheria toxin gene *tox,* located on the corynebacteriophage ß [51]. It is now clear that DtxR has a much broader function [52, 53], as revealed by DNA microarray analysis and proteome analysis with *C. glutamicum* [54] and other species [19, 55]. It is involved in iron homeostasis and represses in *C. glutamicum* more than 50 genes under iron excess, including those of three other transcriptional regulators, RipA, HrrA, and the ArsR-type regulator GlyR. The AraC-type regulator RipA was shown to repress a set of prominent iron proteins under iron limitation, e.g. aconitase, succinate dehydrogenase, nitrate reductase, isopropylmalate dehydratase, and others [56]. The anticipated function of RipA is therefore to reduce the cell's iron demand under iron-limiting conditions. HrrA mediates heme-dependent gene regulation when hemin is used as an iron source [57]. DtxR is not only a repressor, but presumably also an activator of about a dozen genes that encode the iron storage proteins ferritin and Dps and proteins required for the assembly of iron-sulfur clusters in proteins. Another TR belonging to the core set of regulators is ClgR (Table 27.1), which is involved in proteolysis and DNA repair [58]. The TRs RamA and RamB of *C. glutamicum* are involved in carbon flux control [59–62], with RamA belonging to the core set of regulators. Among the two-component systems, MtrAB is retained in all *Corynebacterium* species studied so far (Table 27.1). It is involved in osmoregulation and cell wall homeostasis [63]. Also, PhoSR and CgtSR4 are highly conserved two-component systems, with the former involved in phosphate homeostasis [64] and the latter with unknown function, but probably essential for growth [47].

In *C. glutamicum,* a minimum of 159 TRs can be regarded as the regulatory repertoire required to coordinate the expression of about 3,000 predicted protein-coding genes under varying environmental conditions [49, 50, 65]. These are organized in a hierarchical and modular transcriptional regulatory network of global, master, or local regulators [66]. Most prominent is GlxR as global regulator, which is a cAMP-sensing TR. In *C. glutamicum*, it represses or activates 25 regulators and thereby controls either directly or indirectly by hierarchical cross-regulations the expression of a large number of genes. Almost 200 genes are directly regulated by GlxR. It can be regarded as a major regulatory hub to adapt *C. glutamicum* to fluctuations in the environment influencing the growth conditions and in particular to

the availability of alternative carbon and energy sources. Since GlxR belongs to the core set of regulators (Table 27.2), it might exert a similar global function in all corynebacteria. The TRs SigH, SigB, DtxR, LexA, PhoR, and McbR operate at a lower hierarchical level (Table 27.2). They control, at least in *C. glutamicum*, the expression of a number of functionally related genes, including TRs. In contrast to the extended regulons of these global TRs, local TRs act on a single or a few transcription units and tend to be encoded next to the regulated gene(s). A typical example is the first TR identified in *C. glutamicum*, which is LysG, controlling the transcription of the adjacent *lysE* gene encoding the basic amino acid exporter LysE, which has made possible the industrial use of *C. glutamicum* for L-lysine production [4, 69, 70].

Posttranscriptional Regulation

The genomes of *C. glutamicum*, *C. efficiens*, *C. diphtheriae*, and *C. jeikeium* contain four or five (*C. jeikeium*) genes for serine/threonine protein kinases. Those common to all are designated PknA, PknB, PknL, and PknG, the one specific for *C. jeikeium* has been named PknJ (*jk1732*). In addition, a gene for a phosphoserine/phosphothreonine-specific phosphoprotein phosphatase (*ppp*) is present in these four species. The genes for PknA, PknB, and Ppp are part of a gene cluster that is highly conserved in the order *Corynebacteriales* and implicated in cell division. Whereas PknA, PknB, PknL, and PknJ are predicted to contain a single transmembrane helix, and thus are

membrane-integral proteins, PknG appears to be a cytosolic protein. Recent proteome studies with *C. glutamicum* led to the identification of the first target of PknG, a 15-kDa protein with a forkhead-associated domain that was designated OdhI [71]. In its unphosphorylated state, OdhI binds to the E1 subunit OdhA of the 2-oxoglutarate dehydrogenase complex and inhibits the activity of this enzyme complex [72, 73], which catalyzes the oxidative decarboxylation of 2-oxoglutarate to succinyl-CoA in the citric acid cycle. Phosphorylation of OdhI at threonine residue 14 by PknG relieves the inhibitory function of OdhI, and thus, allows for a high activity of 2-oxoglutarate dehydrogenase. This happens for example when glutamine is used as carbon source, which is catabolized via glutamate and 2-oxoglutarate. However, there might be many other stimuli that affect the phosphorylation status of OdhI. Most interestingly, not only PknG, but also one or several of the other serine/threonine protein kinases can phosphorylate OdhI, as even in a *pknG* mutant part of OdhI is present in a phosphorylated state [74]. Thus, OdhI might be able to integrate diverse stimuli to optimally control the flux at the 2-oxoglutarate node of metabolism. This novel control mechanism for 2-oxoglutarate dehydrogenase via PknG and OdhI, probably operating in many corynebacteria and mycobacteria, is of prime importance for glutamate production [75, 76], as a reduced 2-oxoglutarate dehydrogenase activity was shown to be the key factor in the metabolic network leading to glutamate. A *C. glutamicum* mutant lacking *odhI* was severely inhibited (90–100%) in its ability to secrete glutamate under different conditions. On the other hand, a mutant lacking *pknG* showed significantly improved glutamate production under certain conditions [75]. It is now clear that the ability of *C. glutamicum* to excrete L-glutamate under specific conditions, which led to its isolation, is dependent on the mechanosensitive channel MscCG [77]. Regulation of the activity of MscCG is a topic of current studies.

Plasmids and Transposon Use

Based on the strong demand to improve the amino acid production properties of *C. glutamicum,* a broad set of vectors has been developed. They include shuttle vectors, shuttle expression vectors, vectors for integration into the chromosome, promoter- and terminator-probe vectors, vectors for site specific integration, and vectors for self-cloning. They are compiled in the *Handbook of Corynebacterium glutamicum*, which is also a comprehensive source for additional information on *Corynebacterium* [4]. The plasmids are mostly based on the two different replicons pBL1 and pCG1 and their close relatives occurring in *Corynebacterium*, each of these plasmids replicating by a rolling circle mechanism. For more details on the plasmids of amino acid-producing coryneform bacteria, excellent reviews are available [76–80]. It has already been demonstrated that derivatives of pBL1 and pCG1 also replicate in other *Corynebacterium* species, including pathogenic ones, thus presuming that they might be useful for molecular work in probably all *Corynebacterium* strains. There are also a few examples on vectors originally developed for use in other species than *C. glutamicum* and shown to replicate in *C. glutamicum* (Table 27.3). To these vectors belongs pNG2, the archetype of vectors like pCG1, and originally isolated from *C. diphtheriae*. The smallest plasmid isolated to date from *Corynebacterium* is the cryptic plasmid pCR1 isolated from *C. renale,* which has a size of 1,488 bp and was shown to replicate also in *C. glutamicum*, *C. lilium*, and *C. acetoacidophilum* [88]. These data corroborate the belief that the molecular tools developed for *C. glutamicum* are of broader use.

It is important to realize that the developed vectors might be present in different copy numbers in the host. This is of particular relevance in case they encode proteins that, due to structure or localization, are deleterious to the cells, as can be the case for membrane proteins or for deregulated biosynthesis enzymes. For representative examples, their relative copy numbers can be compared in Figure 27.4. The lowest copy numbers in *C. glutamicum* have pWK0 [89] and pBHK18 [90], both using the replicon of pNG2 [87], and pKW0 using the replicon of pGA1 [84]. Based on homoserine dehydrogenase and threonine dehydratase genes cloned in pWK0 and enzyme activity determinations, pWK0 is present in three to four copies in *C. glutamicum* [89]. Plasmid pEKEx2 might be of intermediate copy number, whereas the highest copy numbers are present for pJC1 and pECT18mob2. An assessment of the band intensities from the gels and transformations with aliquots of plasmids isolated from *C. glutamicum* suggests that the copy numbers of pJC1 and pECT18mob2 are at least ten-fold increased relative to pKW0. As can be seen from Figure 27.4, the copy numbers in *E. coli* are very much different. As a control, pUC18 was isolated in an identical manner as the other vectors from *E. coli* and shown on the far right. Plasmid pKW0 is also present in *E. coli* at a low copy number, but since replication of this vector relies in *E. coli* on *repA*, which is under control of the temperature sensitive repressor cI^{857} [91], a shift to higher cultivation temperatures allows "run-away replication" and, therefore, easy preparation of sufficient vector for further use in recombinant work.

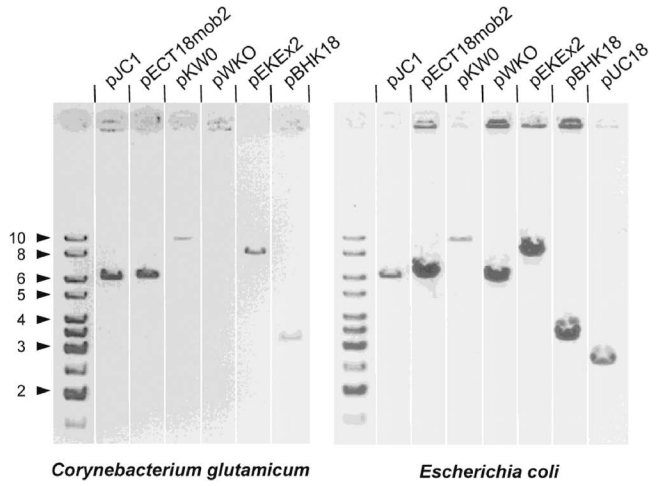

FIGURE 27.4 Comparison of relative copy numbers. Plasmids were isolated from recombinant strains of 100 mL LB cultures and isolated via the QIAfilter Plasmid Midi Kit according to the protocol of the supplier (QIAGEN, Hilden, Germany). 2.5 µl plasmid preparation digested with EcoRI was applied in each lane for plasmids isolated from *C. glutamicum,* and 0.5 µl plasmid preparation digested with EcoRI was applied for plasmids isolated from *E. coli*. With plasmid pWKO isolated from *C. glutamicum,* no band is visible in the reproduction, but is on the original gel.

For transformation of *Corynebacterium*, various methods have been developed and used over time. The most efficient protocol is also characterized by its simplicity. It uses brain-heart infusion medium containing 91 g sorbitol/L (BHIS) for cultivation of cells up to a low optical density at 578 nm (OD_{578}) of 1.75 [82]. Cells are carefully washed and transformed via electroporation. Applying the same protocol to *C. diphtheriae,* a very high transformation efficiency of up to 5.6×10^5 colony forming units per µg DNA is obtained when DNA directly prepared from *E. coli* is used. Such high transformation efficiency is particular of relevance when vectors are integrated into the chromosome of the recipient, since additional host-specific recombination processes reduce the chance of plasmid, once it is present in the cytosol, to be integrated in the chromosome. Also for *C. pseudotuberculosis,* similar transformation protocols have been described [92–94].

For a genome-scale analysis, application of transposon mutagenesis is a valuable tool. It is established and used in a number of applications for *C. glutamicum* with Tn*5531* [95–97]. This transposon is composed of *aph3* conferring kanamycin resistance flanked by two IS*1207* sequences encoding the transposase. Since Tn*5531* relies on the IS*1207* sequences, only strains without IS*1207* present in the chromosome are appropriate hosts to generate mutants. Whereas the type strain *C. glutamicum* ATCC 13032 contains seven copies of highly similar sequences related to IS*1207*, hosts like *C. glutamicum* ATCC 14752, *C. efficiens* YS-314, and *Corynebacterium* sp. 2262 are appropriate. Another transposon operating in *C. glutamicum* is based on IS*6100,* which is present on plasmid pTET3 isolated from strain *C. glutamicum* LP-6. The transposon is useful to isolate mutants from the type strain ATCC 13032 [98]. Also, other transposons were isolated and shown to operate in *C. glutamicum* [99, 100]. There is little information on the application of these transposon delivery vectors in other *Corynebacterium* species. However, a transposon derivative based on Tn*4001* and originally developed for *Streptococcus pyogenes* was profitably used in *C. pseudotuberculosis* to identify genes encoding extracytosolic genes, like fimbriae or transporter subunits [101]. A number of techniques for genome-scale deletions and analysis were developed for *C. glutamicum* R, which are compiled in a recent review [102].

Whereas the *in vivo* systems described depend on nonreplicative delivery vectors, a recent *in vitro* system has been developed [103], which might represent an attractive alternative in particular due to its ease of handling, its general applicability, and its commercial availability (Epicentre Biotechnologies, Madison, WI, USA). It involves the *in vitro* formation of released Tn5 transposition complexes, called transposomes, followed by introduction of the complexes into the target cell of choice by electroporation. This simple technology has been used for construction and characterization of transposon insertion mutations in *C. diphtheriae* and the isolation of mutations that affect expression of the diphtheria toxin repressor (DtxR) [104]. It has similarly been used in *C. diphtheriae* to isolate a gene involved in adherence to epithelial cells [105], and to identify iron-regulated promoters [106]. The transposome technology was also successfully applied to *C. matruchotii*, leading to the identification of an integral membrane transporter probably linked to corynomycolic acid synthesis [107], and leading to mutants that synthesize unnatural hybrid fatty acids that functionally replace corynomycolic acid. Application of the transposome system to *C. glutamicum* R enabled to construct a library of 2,300 different mutants covering 75% of the genes in that strain [108]. The transposome-mediated insertions in selected *Corynebacterium* species, and their established function in a wide range of organisms, including *Acinetobacter*, *Mycobacterium*, *Proteus*, and even *Saccharomyces*, and *Trypanosoma*, reveals that this molecular device will be instrumental for the analysis of other *Corynebacterium* species, too.

A recent tool introduced for *Corynebacteriales* like *C. glutamicum* or *Mycobacterium smegmatis* uses the CRISPR/Cas system [109, 110]. Simplicity and programmability of this system has enabled its straightforward application to specifically target any genomic location. In *C. glutamicum* the cleavage activity of the nuclease Cas12a was directed by its crRNA to a sensitive region in the γ-glutamyl kinase, which together with single-stranded DNA (ssDNA) recombineering, enabled to relieve allosteric feedback inhibition of the γ-glutamyl kinase by L-proline, thus converting the wild type of *C. glutamicum* to an L-proline producer [109]. Similarly, the system was used to perform codon saturation mutagenesis at critical positions in the mechanosensitive channel MscCG to identify new gain-of-function mutations leading to enhanced L-glutamate export of *C. glutamicum* [111].

Conclusion

Nonpathogenic *Corynebacterium* species find many applications, like amino acid production with *C. glutamicum*, *C. efficiens,* and *C. callunae* [4, 50], or nucleotide production with *C. ammoniagenes* [112]. This strong industrial interest explains the interest of companies and associated research groups to

understand *Corynebacterium* at the physiological, molecular, and genomic level. A recent vision is to use the ability of *C. glutamicum* to make, besides the "bulk" products already mentioned, additional metabolites that are cell inherent or whose synthesis capacity is artificially expanded, summarized under the term "white biotechnology" [113, 114]. Fortunately, the fast development of standard techniques, such as genome sequencing and RNA-Seq, has also generated the basic blueprint information for a number of pathogenic *Corynebacterium* species. The fact that *Corynebacterium* species share basic molecular features helps to deepen the knowledge on pathogenic *Corynebacterium* species, with *C. diphtheriae* probably representing the most important species with respect to its epidemiological properties [115, 116]. However, *C. xerosis*, *C. urealyticum*, *C. ulcerans, C. pseudotuberculosis, C. striatum*, and further species pose severe problems as nosocomial pathogens, for instance, where a molecular understanding on physiology and antibiotic resistance mechanisms might assist to have control on these bacteria.

Introduction

There is no single family in the δ class of the phylum Proteobacteria that has had a greater impact on medicine and public health, molecular genetics and phylogeny, pathogenesis, gene structure, regulation, and function, or microbial ecology than the *Enterobacteriaceae*. The family currently consists of more than 65 validated genera including over 350 species (http://www.bacterio.net). About 25% of current genera consist of a single species (e.g., *Plesiomonas*) while other genera contain more than 20 species (e.g., *Erwinia*, *Xenorhabdus*). The metamorphosis of the family over the past few decades and the logarithmic explosion in the number of recognized taxa is due to pioneering studies conducted by the Centers for Disease Control and Prevention and the Pasteur Institute (French: Institut Pasteur) and the upsurge in phylogenetic investigations employing molecular chronometers such as digital DNA-DNA hybridization, 16S rDNA and *rpoB* gene sequencing, matrix-assisted laser desorption/ionization time of flight mass spectrometry (MALDI-TOF), amino acid sequence identity, multilocus sequence analysis (MLST), average nucleotide identity, and genome-to-genome distance calculator.[1] These investigations have led to dramatic classification changes within some important members of the family with some genera, such as *Enterobacter*, experiencing marked attrition in the number of valid species within the taxon. The latest proposed additions to the family *Enterobacteriaceae* include the genera *Metakosakonia*, *Pluralibacter*,[2] and *Mixta*.[3]

In contrast to the common misconception that enterobacteria are solely inhabitants of the gastrointestinal tract of vertebrates, the family *Enterobacteriaceae* is widely dispersed in nature and many species exist in free-living states in diverse niches in the biosphere. These ecosystems can be broadly broken down into four major groups, namely strains (1) principally associated in commensal or saprophytic states in the alimentary tract of humans and other vertebrates or at extraintestinal sites; (2) intimately associated as epi- or endophytic symbionts with plants or plant-associated diseases; (3) chiefly found in water, soil, invertebrate species, and industrial processes; and (4) obligate endosymbionts or commensals of insects.[4] Some species have developed such stable symbiotic relationships with their hosts that no genomic rearrangements or gene acquisitions have occurred over the past 50 million years.[4]

Due to the "molecular taxonomy" revolution, the classic biochemical features that previously defined membership in this family are no longer used routinely, but instead rely almost exclusively on genetic relatedness (Table 28.1). Biochemical traits are still valid for the identification of most common genera and species in clinical laboratory settings but rare species or new genera and species most recently proposed for inclusion in the family defy traditional phenotypic identification. For bacteria that cannot be grown on routine media or that lack the required gene arrays to be cultured *in vitro*, inclusion in the family *Enterobacteriaceae* is based on a genetic rather than phenetic definition. Accurate biochemical identification of less commonly encountered groups of bacteria in this family requires reliance on a large battery of phenotypic tests, many of which are not readily available on commercial panels. Current clinical laboratory alternatives include 16S rDNA gene sequencing and MALDI-TOF although even proprietary databases associated with these commercial products may not achieve the discriminatory level needed without in-house matrix supplementation. Whole genome sequencing (WGS) may be relevant in particular settings. Although traditionally most members of this family have been susceptible to a wide variety of antimicrobial agents, including extended-spectrum cephalosporins, the exceptionally high usage of these drugs in hospital settings has led to the development of resistance to many β-lactam antibiotics via extended-spectrum β-lactamases (ESBLs) and carbapenemases.[5] Of particular concern is the recent emergence of carbapenemases

TABLE 28.1

Defining Phenotypic Traits of the Family *Enterobacteriaceae*

Character	Marker for Family	Notable Exceptions
Metabolism		
Facultatively anaerobic rods	+	*Alterococcus agarolyticus*
Morphology		
Gram reaction	–	
Structure		
Possession of ECA	+	*Dickeya chrysanthemi*
Spore formation	–	*Serratia marcescens (rare)*
Biochemical		
Oxidase	–	*Plesiomonas*
Catalase	+	*Shigella dysenteriae 1, Xenorhabdus*
Nitrate reductase	+	*Erwinia, Lonsdalea, Yersinia (some)*
D-glucose	+	
D-xylose	+	*Cedecea (some), Cosenzea, Edwardsiella, Lonsdalea, Morganella*

Note: ECA, enterobacterial common antigen.

and colistin resistance in *Klebsiella pneumoniae* (KPC, NDM-1, MRC), *Enterobacter cloacae* (KPC, VIM, OXA-48), and *Escherichia coli* (KPC, NDM-1, OXA-48, MRC), which are a major concern in healthcare settings.[5] Carbapenems-resistant *Enterobacteriaceae* are commonly found in wildlife, pets, and livestock presenting a significant public health risk to the general population.[6]

Many species in the family *Enterobacteriaceae* serve as prototypes or models for studying global processes thought to play important roles in microbial communities, cell-to-cell communication, and gene expression with regard to virulence. *E. coli* has long been an established vector system to clone and express genes and their gene products. Other high-profile processes that enterobacteria are thought to be intimately involved in include quorum sensing (*E. coli*, *Salmonella*) and biofilm formation (*E. coli*, *Klebsiella*, *Salmonella*).[7]

Klebsiella and *Enterobacter*

Klebsiella

Members of the genus *Klebsiella* are widely distributed in nature and are ubiquitous in forest environments, soil, vegetation, and water.[4] They can exist in a free-living state in the environment for prolonged periods of time. Klebsiellae are also found as normal commensals in the gastrointestinal tract of many vertebrates and mammals, including birds, reptiles, and even insects. As animal pathogens they cause diseases such as mastitis and septicemia in bovine and porcine species respectively.

It is presently difficult attempting to define biochemical characteristics for inclusion in the genus *Klebsiella* because the genus continues to undergo major taxonomic revisions. Most traditional klebsiellae are nonmotile, Voges-Proskauer (VP) positive (acetylmethylcarbinol production), and indole-negative; however, there are exceptions to each of these traits. Other common traits that are associated with many *Klebsiella* species include urea hydrolysis and fermentation of *m*-inositol, a carbohydrate-like compound that is not commonly utilized by many other enterobacteria. With the revised taxonomy within the genus, many isolates are difficult or impossible to identify to species without the use of PCR, MALDI-TOF, or specific gene sequencing.[8] Many klebsiellae isolates, particularly those of *K. pneumoniae,* can produce copious capsular material (K antigen) that can often be observed on primary plating of isolates recovered from clinical specimens.

With current revisions the genus *Klebsiella* is composed of 13 species. Several former species have been transferred to the genus, *Raoultella*,[9] while others relegated to subspecies status within *K. pneumoniae* (ssp. *ozaenae* and ssp. *rhinoscleromatis*). The species names *Enterobacter aerogenes* and *Klebsiella mobilis* are homotypic synonyms and share the same type strain ATCC 13048^T. The type strain is clearly a klebsiellae. Based upon rules of nomenclature the proposal has been made to use the name *Klebsiella aerogenes* to resolve this taxonomic quagmire.[10]

Klebsiella, and in particular *K. pneumoniae* and *Klebsiella oxytoca*, are extremely important human pathogens in the healthcare setting. These species are often responsible for devastating healthcare-associated illnesses such as septicemia and endocarditis, pneumonia, infections of the face (orbital cellulitis and endophthalmitis), bones (osteomyelitis), and urinary tract.[4] Of particular concern with regard to the treatment of such infections is the rapid emergence of ESBLs in these species and the difficulty in eradicating such systemic infections with the currently available arsenal of drugs.[5,11] Furthermore, hypervirulent *K. pneumoniae* infections, originally reported from Asia, are now being seen globally. These strains can cause pyogenic liver and lung abscesses with possible secondary complications such as endophthalmitis and meningitis. Infections are primarily caused by *K. pneumoniae* strains carrying the K1 or K2 capsular antigens plus specific other virulence determinants.[12,13] Persons with underlying conditions such as diabetes, or who are of Asian ancestry, appear to be especially prone to developing such infections. Hypervirulent *K. pneumoniae* are also being reported as significant causes of monomicrobial necrotizing fasciitis[14] and a call for consensus definition and international collaboration has been made.[15] Outbreaks associated with high neonatal mortality rates have also been recently linked to hypervirulent *K.* variicola.[16] Another evolving human infection associated with klebsiellae concerns *Klebsiella oxytoca* antibiotic-associated hemorrhagic colitis.[17] This hospital-acquired infection is most often observed in patients receiving penicillin or nonsteroidal anti-inflammatory drugs and is uniquely associated with certain cytotoxin-producing *Klebsiella oxytoca* isolates.[17,18]

Enterobacter

Most of the statements previously made regarding the genus *Klebsiella* equally apply to the genus *Enterobacter.* This includes their ubiquitous environmental distribution (trees, plants, crops, soil, water, foods), an incredibly complicated taxonomy, a lack of definitive phenotypic traits to characterize the genus, enhanced drug resistance mediated via ESBLs, and their overall importance as healthcare-associated pathogens.[4,19,20]

This genus has numerous complex taxonomic issues. From a peak of more than 30 validated species within this genus, less than 20 are now considered true members (http://www.bacterio.net/enterobacter.html). Former members of this genus have been transferred to newly created genera including *Lelliottia*, *Kosakonia,* and *Pluralibacter*, while two prominent species, *Enterobacter sakazakii and Enterobacter agglomerans*, have been transferred to the genera *Cronobacter* and *Pantoea*, respectively. *E. cloacae*, the preeminent pathogen of this genus, as currently defined, is genetically heterogeneous, being composed of from 5 to 12 distinct genomic groups within the complex that cannot be unambiguously separated from one another on a biochemical basis.[4,21,22] The second most common species in the genus, *E. aerogenes,* belongs in the genus *Klebsiella* (as discussed previously). Most members of the genus are VP and ornithine decarboxylase-positive, utilize citrate, and ferment L-arabinose, L-rhamnose, raffinose, and D-xylose; exceptions to each of these characteristics exist.[4,21] Some species such as *Enterobacter sakazakii* (now *Cronobacter sakazakii*) often produce yellow-pigmented colonies upon subculture.

E. cloacae causes many serious, life-threatening medical complications associated with hospitalization, among which are pediatric and adult bacteremia, central nervous system (CNS) disease and meningitis, and respiratory and urinary tract infections.[4,19,20] A less common but equally devastating pathogen is *Cronobacter* (*Enterobacter*) *sakazakii,* which causes serious invasive disease (meningitis, brain abscess) in infants and is linked to contaminated powered infant formula.[22,23] *E. cloacae* and *Enterobacter asburiae* produce saxitoxins in the rumina of cattle associated with bovine paraplegic syndrome and can cause coliform mastitis in dairy cows.[4]

Proteus, Morganella, and *Providencia*

In the 1980s, these three genera were grouped together in the tribe Proteeae, based on similar phenotypic and morphologic features. In many ways these associations still remain valid. Phylogenetically, these genera appear at the periphery of the *Enterobacteriaceae* based on 16S rDNA gene sequencing, and they are only 20% or less related to core members of this family (such as *E. coli, Salmonella, Enterobacter*, and *Citrobacter*).

A number of biochemical features are almost exclusively associated with these three genera in the family *Enterobacteriaceae* and include production of phenylalanine deaminase, elaboration of a reddish-brown pigment on media containing DL-tryptophan, and the ability to degrade L-tryosine crystals via a tyrosine phenol-lyase. The most remarkable distinguishing feature within this tribe is the ability of many *Proteus* strains belonging to the species *Proteus mirabilis* and *Proteus vulgaris* to form concentric rings of outgrowth on solid media such as MacConkey agar.[4,24] This swarming phenomenon is due to conversion of swimmer cells in broth to swarmer cells in agar and is associated with cellular elongation and increased flagellin synthesis. Other features that help separate these three genera from one another include formation of H_2S on Triple Sugar Iron (TSI) agar slants and degradation of gelatin by *Proteus* and the fermentation of mannose by both *Morganella* and *Providencia*.

The singular disease principally associated with *Proteus, Morganella,* and *Providencia* is urinary tract infections (UTIs), and the preeminent pathogen of this group is *P. mirabilis* (up to 5% of all UTIs).[4,24,25] *P. mirabilis* typically produces uncomplicated UTIs in healthy women and less frequently in young children. Less often, *P. mirabilis* can cause complicated UTIs in persons with structural, physiologic, or neurologic disorders of the urinary tract necessitating catheterization.[24] The virulence factors thought to be operative in *P. mirabilis* UTIs have been extensively studied and include MR/P fimbriae, a urease, cytotoxins, an IgA degrading protease, an hemolysin, and flagella.[24] Proteeae are also common causes of bacteremia[26] and a variety of other less frequently encountered clinical conditions including CNS disease, wound infections, and rheumatoid arthritis.[4] *Providencia alcalifaciens* and related species are associated with travelers' diarrhea and foodborne outbreaks of gastroenteritis in Japan and Kenya.[27,28] Recent studies suggest that *Proteus* spp. may play a role in various gastrointestinal disturbances including gastroenteritis and Crohn's disease.[29]

Members of the Proteeae are often isolated from homeothermic and poikilothermic species, including dogs, cows, birds, snakes, and fish.[4] Some studies have found clonal relatedness between strains recovered from humans and their companion animals.[30] *Morganella morganii*, a copious histamine producer, is associated with the spoilage of fish and the clinical condition known as scombroid poisoning.[31] A number of infections in animals have been attributed to these groups, including equine abortions, hoof canker, stomatitis, neonatal diarrhea in calves, and a large variety of additional systemic infections.

Salmonella

The genus *Salmonella* has two species, *S. bongori* (previously subspecies V) and *S. enterica*, with the latter species subdivided into six subspecies (I, II, IIIA, IIIB, IV, and VI).[32] All of the commonly encountered serotypes belong in subspecies I of *S. enterica* (subsp. *enterica*) while organisms previously known as *Arizona* fall within subspecies IIIA and IIIB. *S. bongori* and serotypes from all six *S. enterica* subspecies have been isolated from humans although *S. bongori* and *S. enterica* subspecies VI isolates are rare.[33] *Salmonella* is part of the intestinal microbiome of many reptiles, which serve as the most common source for human infections caused by subspecies II, IIIA, IIIB, and IV.[34,35] As the practice of maintaining reptiles as pets has increased, so has the risk of *Salmonella* transmission to humans and other animals.[35] Several serotypes are host-adapted (but can cause disease in other hosts, e.g., Dublin in cattle) or host-restricted (Gallinarum in poultry, Typhi in humans) but most serotypes cause disease in both warm- and cold-blooded animals. The gastrointestinal tract is the natural habitat for salmonellae but unlike *E. coli* it can survive for weeks to years in water and soil. Any food contaminated by fecal matter, including fresh fruits, vegetables, and shellfish, may serve as a source of salmonella infection; however, meats, raw milk, and eggs are the most frequently involved causes.[4] Poultry farms can have high prevalence of low-virulence *Salmonella* serotypes, which has important public health implications because horizontal gene transmission has been documented in this genus,

as has antibiotic resistance.[35] Infections may be acquired by direct transmission from both domesticated and wild animals and birds, although infrequently.

Nontyphoidal salmonellae (NTS) are a major cause of diarrheal disease in both industrialized and developing countries. In the United States in 2015, the annual incidence rate was estimated to be 15.7 cases/100,000 population.[36] *Salmonella* Enteritidis can be found in the egg yolks from seemingly healthy chickens. This serotype traveled, with the transport of infected chickens, down the east coast in the late 1980s and is now the most common serotype of *Salmonella* associated with gastroenteritis in the United States.[37] In 2015, it made up 19.2% of serotypes isolated, followed by Newport (11.4%), and Typhimurium (10.4%). The emergence of multidrug-resistant strains have raised the importance of more precise source tracking methods, using molecular tools such as WGS.[38] Multidrug-resistant strains related to *Salmonella* Enteritidis and another subspecies *enterica* serotype, *S.* Typhimurium, have been associated with outbreaks worldwide. Drug-resistance is a major public health concern and *Salmonella* have demonstrated resistance to multiple classes of antimicrobials, including penicillin, sulfonamides, tetracyclines, fluoroquinolones, aminoglycosides, and cephalosporins.[35] For typhoid fever (caused by *Salmonella enterica* serotype Typhi) there are more than 20 million new cases per year.[39] Highest incidence rates occur in sub-Saharan Africa (>700 cases/100,000 population), and, of particular concern, multidrug-resistant (MDR) strains are on the rise. There have even been cases of extensively drug-resistant (XDR) strains, which demonstrate resistance to cephalosporins and can result in treatment failure.[40] The next highest incidence rates occur in other areas of Asia, Africa, Latin America, the Caribbean, and Oceania (exclusive of Australia and New Zealand) with rates of 15 to >400.[41] The typhoid vaccine is an important public health control measure in areas with high incidence rates and antimicrobial resistance. In industrialized countries (Europe, North America, etc.), the rate is less than <1 per 100,000 population.[33] Mortality rates are difficult to determine for typhoid fever. Current estimates suggest a 1% overall case fatality rate.[4,41] Gastrointestinal illness, the most common infection caused by NTS, is characterized by abdominal pain and watery diarrhea (mild to cholera-like) with mucus and, in some cases, blood (occult or visible). Patients with NTS may develop a temporary carrier state usually lasting 1–2 months (occasionally up to a year with infants). Permanent carriers are rare (1%) with NTS infection; however, 2–5% of typhoid patients will become chronic carriers, shedding high levels of *S.* Typhi while outwardly asymptomatic; 25% of typhoid carriers have no history of disease.[4] NTS cause a variety of extraintestinal illnesses, the most common and/or severe of which include sepsis, UTI, meningitis, and osteomyelitis. Enteric fever is caused by serotypes Typhi and Paratyphi A and C, all of which are host-adapted to humans, and tartrate-negative strains of serotype Paratyphi B. Untreated typhoid fever has three stages and persists approximately 3–4 weeks.[42] During the first week, symptoms are consistent with gastroenteritis, and stool cultures will be transiently positive while blood is usually negative. The second stage includes bacteremia and other extraintestinal symptoms, and cultures from blood, stool, bone marrow, and rose spots (if present) are generally positive. If complications arise, they usually occur in the third week; otherwise, the patient begins convalescence; cultures are not usually positive at this time, with the possible exception of stool.

Both NTS and serotypes causing enteric fever are easily isolated from stool in the acute phase of disease on traditional enteric isolation media such as MacConkey (MAC), xylose-lysine-desoxycholate (XLD), Hektoen (HE), and/or Salmonella-Shigella (SS) agars. Other media specific for salmonellae are also available (bismuth sulfite, brilliant green) as are a variety of chromogenic agars. To detect carriers, preincubation in enrichment broth is recommended. Selenite F with cystine and Hajna's Gram-negative broth are generally used; tetrathionate does not recover serotype Typhi and should not be used for human specimens. Most standard blood culture methods are satisfactory for recovery of both NTS and agents of typhoid fever; however, for the latter group, use of 10% Oxgall in distilled water in lieu of tryptic soy broth and using a 1:10 dilution of blood (5 mL) to medium (25 mL), or culture of bone marrow, will increase the chance of recovery of these agents.[43,44] Serological assays are not useful for diagnosis. However, PCR is sensitive and specific and the faster turnaround time may be a useful complement to culture. All commercial systems approved for clinical diagnostic use in the United States identify *Salmonella* satisfactorily for phenotypically typical strains;[4] however, they fail to identify lactose-, sucrose-, or indol-positive strains of salmonellae. Strains of serotype Typhi are anaerogenic, produce little or no H_2S, and give negative reactions for citrate and ornithine. All subspecies of NTS, including serotype Typhi, are easily identified with a minimal number of conventional media, including lactose- and sucrose-positive strains that are not correctly identified using commercial systems. Most subgroup I strains of NTS are indol- and *o*-nitrophenyl-β-D-galactopyranoside (ONPG)-negative and H_2S-, LDC-, and citrate-positive and ferment dulcitol, a combination distinctive for salmonellae. Subgroup III strains are ONPG- and malonate-positive and dulcitol-negative. DNA- and protein-based methods of identification are increasingly common in clinical laboratories, in particular WGS and MALDI-TOF MS.[45]

For epidemiological purposes, salmonellae have classically been characterized to serotype using the Kauffmann-White schema.[46] Cell surface (somatic) antigens place the organism within a group while the type is determined by a particular combination of flagellar antigens. There are more than 2,000 serotypes of salmonellae distributed in more than 40 groups, although approximately 95% of salmonellae isolated from humans belong to groups A, B, C_1, C_2, D, and E. Typhi strains have a Vi (virulence) capsule that masks the somatic antigen; full identification of these strains requires biochemical and serological testing, including testing for Vi antigen. There are commercial molecular serotyping kits available as a high-throughput alternative to traditional serotyping.[47] Because of their frequent involvement in outbreaks, salmonellae are often subjected to additional genetic characterization. Whereas pulsed-field gel electrophoresis used to be the method of choice, WGS is now preferred, offering additional data on antimicrobial resistance genes and other virulence factors.

As with most enteric pathogens, salmonellae virulence is multifactorial, and both chromosomal and plasmid determinants are involved. Twelve pathogenicity islands (PIs) have been identified in salmonellae, two of which (*Salmonella* PI-1 and PI-2) contain

type III secretion systems that are involved in invasion and intracellular multiplication.[48] A number of other chromosomal genes are involved in adhesion and colonization of the bacterium to the intestine and resistance to gastric acidity. Determinants on virulence plasmids mediate colonization, resistance to complement-mediated lysis, and enhance the ability of strains to multiply in extraintestinal tissue. Biofilm formation, which is enhanced in *Salmonella* using a quorum sensing mechanism, is an important virulence factor. Biofilms allow *Salmonella*, subspecies *enterica* in particular, to persist in the environment and throughout the food processing chain.

Shigella and *Escherichia Coli*

The genera *Shigella* and *Escherichia* genetically reside in a single genus by DNA hybridization, although the genus name, *Shigella,* is presently retained because of the immense medical importance of shigellae in comparison to the commensal nature of most *E.* coli.[49] Pathogenic *E. coli* can be subdivided into two major groups, intestinal pathogenic *E. coli* (IPEC) and extraintestinal pathogenic *E. coli* or ExPEC (see Table 28.2 for groupings and acronyms).[50] ExPEC strains primarily affect humans and the poultry industry (APEC). Hybrids of both groups containing both IPEC and ExPEC virulence genes exist and appear to be increasing.[50] *E. coli* can be serotyped, and specific types are associated with each of the above groups, the most notable of which is *E. coli* O157:H7 with the STEC group. Shigellae are broken down into four groups based on their cell surface (somatic) antigens and are designated as A (*Shigella dysenteriae*), B (*Shigella flexneri*), C (*Shigella boydii*), and D (*Shigella sonnei*).[51] Three groups (A, B, and C) are divided into types and *S. flexneri* types are further subdivided into subtypes. Currently subgroup A (*S. dysenteriae*) contains 17 serotypes, subgroup B (*S. flexneri*) 14 serotypes, and subgroup C (*S. boydii*) 19 serotypes.[51] *S. boydii* 13 has been reclassified as *Escherichia albertii*.

E. coli makes their way into the food chain via fecal contamination of animal carcasses during slaughter, with subsequent improper handling (storage and/or cooking) of the product or by fecal adulteration of agricultural crops in the field or packing sheds. A study of retail foods at 10 commercial markets in the Minneapolis-St. Paul area sampled between 2001 and 2003 found 24% of the 1,648 food items contaminated with *E. coli*.[52] Of these food items, poultry (92%) and meats (69%) predominated with only 9% of produce and other nonmeat items culture-positive.[52] Shigellae are host-adapted to the human intestine and, outside of humans, have only rarely been found to infect dogs or primates; isolations of shigellae from food and water only occur following contamination with human feces.[4]

E. coli can cause a variety of extraintestinal infections, and has been isolated from virtually every organ and anatomical site. In 2000, in the United States alone, the estimate of mortality from *E. coli* bloodstream infections was 40,000 deaths, with $1.1 to $2.8 billion in healthcare costs.[53] Similar values for *E. coli* UTIs included 6–8 million cases of uncomplicated cystitis, 250,000 cases of pyelonephritis, and a quarter- to half-million cases of catheter-associated UTI.[53] The World Health Organization and CDC estimate that there are between 80 and 165 million cases of shigella per year on a worldwide basis with >90% occurring in developing countries.[51] In comparison, the CDC estimates that approximately 500,000 cases of shigellosis with 38 deaths occur in the United States yearly.[51,54,55] The mortality rate in developing countries exceeds 1 million, and 61% of deaths occur in children under 5 years of age. In industrialized nations, the estimate of infections is 1.5 million per year with a 0.2% mortality rate. The predominant two species causing shigellosis are *S. flexneri* and *Shigella sonnei*. *Shigella sonnei* appears to be replacing *S. flexneri* as the predominant species in developing countries and in regions undergoing transitional environments.[55]

Cases of *E. coli* sepsis usually arise following UTI and occur more frequently in women than in men. Approximately 85–95% of patients who develop *E. coli* sepsis have underlying conditions with liver disease, hematologic malignancies, and solid tumors or other cancers being the most common.[4] *E. coli* meningitis can occur in any age group; neonates primarily acquire infection by vertical transmission from colonized mothers during or immediately following delivery and less frequently via the nosocomial route.[56] Approximately 90% of these strains carry a K1 capsule (which is identical to the type B polysaccharide of *Neisseria meningitidis*) and an increasing number of strains carry the CTX-M type or TEM-type extended spectrum β-lactamase.[4,56]

TABLE 28.2

Pathogenic Groups of *Escherichia*

	Group Designation	Disease, Site of Infection	Pathogenic Mechanism
Diarrheagenic	Enteropathogenic (EPEC)	Watery diarrhea, small intestine	Adherence
	Enteroinvasive (EIEC)	Watery diarrhea followed by bloody diarrhea, colon	Invasion
	Enterotoxigenic (ETEC)	Watery diarrhea, small intestine	Heat-stable and/or heat-labile toxin
	Shiga-toxin producing (STEC) Also known as: Enterohemorrhagic (EHEC) Verotoxigenic (VTEC)	Watery diarrhea, sometimes bloody, especially for O157:H7, colon	Shiga toxins, type 1 and/or type 2
	Enteroadherent (EAEC)	Watery diarrhea, small intestine and colon	Adherence
	Diffuse adhering (DAEC)	Watery diarrhea, small intestine	Adherence
Extraintestinal (ExPEC)	Uropathogenic *E. coli* (UPEC)	Urinary tract, bloodstream, meninges	Adherence, toxins, biofilm formation, siderophore
	Neonatal Meningitis *E. coli* (NMEC)	Meninges, cerebrospinal fluid, blood	Cell invasion, complement inhibition, meningitis-associated fimbriae

E. coli cystitis is characterized by acute dysuria and lower back pain, while pyelonephritis involves the upper urinary tract (kidneys and/or pelvis) and may be of a mild nature or cause vomiting and nausea with concomitant sepsis.[57] Gastrointestinal symptoms for the diarrheagenic groups of *E. coli* are given in Table 28.2. *Shigella* infections are typically characterized by generalized symptoms of fever, fatigue, anorexia, and malaise at onset, followed by watery diarrhea and abdominal pain.[58] Blood and mucus are present in approximately 40% and 50% of stools, respectively, with bloody stools occurring more commonly in children than in adults.[4] Although such isolations are infrequent, shigella can be isolated from sources other than stool, including urine, blood, wounds, sputum, gallbladder, and ears. *Shigella* bacteremia is rare, occurring primarily in developing countries in malnourished children with decreased serum bactericidal activity.[4] Both STEC and shigellae, especially *S. dysenteriae* type 1, can cause hemolytic uremic syndrome (HUS), a disease characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure.[59] *Shigella*- and *E. coli*-associated HUS is linked to the production of Shiga-toxin (Stx) by these organisms. In the United States, the most common serotype associated with HUS is O157:H7; however, other serotypes of STEC and shigellae are capable of causing the disease. Recently two clusters of *Shigella sonnei* producing Stx1 have caused more than 50 illnesses in California.[60] Although no cases of HUS were detected, 71% of the case-patients presented with bloody diarrhea.

E. coli can be easily isolated from blood by routine blood culture methods, but if a single bottle is used, aerobic incubation recovers more isolates than anaerobic (nonvented) incubation.[4] Chromogenic agars are equal or superior to routine media (blood or MacConkey agars) used for UTI isolation in terms of numbers recovered, and have the added advantage that *E. coli* can be readily distinguished by their colony appearance and easily confirmed by a spot indole test.[4] Isolation of *E. coli* strains involved in diarrheal disease is a much more difficult task because most are biochemically indistinguishable from commensal strains.[61] *E. coli* O157:H7 strains, which are delayed D-sorbitol fermenters, are the exception to this rule, and this trait is exploited in media used for their isolation. Sorbitol MacConkey (SMAC) agar contains D-sorbitol as a substitute for lactose and is the primary isolation medium for O157 strains that present as colorless colonies.[47] Other formulations exist, such as SMAC and CT-SMAC with cefixime and tellurite incorporated to increase selectivity. A variety of chromogenic agars have been developed that detect both O157:H7 STEC as well as non-O157 STEC strains.[62,63] Immunomagnetic separation is a sensitive isolation technique for O157 and for a limited number of other serotypes of STEC, in which somatic antibody is coated on magnetic beads. Enzyme immunoassays (EIAs), which are commercially available and FDA approved, can be used to detect the somatic O157 antigen or Shiga toxin (Meridian Bioscience, Cincinnati, OH; Remel, Lenexa, KS). Stx can be detected directly from stool as well as from an isolate of STEC, but there is a 3-log difference between EIA Stx detection from stool and the more sensitive tissue culture technique using Vero cells. An Oxoid latex agglutination assay for Stx (E. coli Latex Test) is also commercially available (ThermoFisher Scientific, Waltham MA). Both the latex assay and the EIA detect the presence of Stx but unlike the Vero cell assay with neutralizing antibody to type 1 and 2, neither can detect which toxin type(s), 1 or 2, are present. Multiplex PCR assays are now widely available and FDA-approved, which detect a variety of syndromic diseases including gastroenteritis. Almost all such platforms include both STEC and *Shigella* targets on them such as Luminex GPP panel (Austin TX), Verigene EP (Luminex Corporation), and BioFire GIP (Salt Lake City, UT).[64] Panels detect from 9 to 22 bacterial, viral, and parasitic targets simultaneously.[64] Isolates of *E. coli* from other types of diarrheal diseases not included on syndromic panels or with hybrid characteristics are detected by determining the presence of the virulence factor(s) causing the infection. As with most specialized assays, these tests are available in a limited number of laboratories. Direct plating of stool is the method of choice for the isolation of shigellae for public health reasons; if culture is not performed within 2–4 hours of taking the stool, a transport medium must be used because shigellae are extremely sensitive to metabolic end products of other bacteria, phages, etc. present in stool. MAC, XLD, and HE agars work well for isolation of shigella, as does SS agar, but the latter may be too inhibitory for some strains; colonies of shigella will be colorless on these media (colonies on HE may appear green because of the color of the medium). *Shigella sonnei* is easily recognizable on plating media as it throws off large, rough colonies as well as smaller convex, smooth colonies; laboratories should select the smooth colonies for further testing.

Biochemically, typical strains of *E. coli* present no challenge to commercial identification systems.[4] However, *E. coli* are phenotypically diverse organisms and may be biochemically inactive (indol-, lysine- or ornithine decarboxylase-, and ONPG-negative) or conversely can give positive reactions for tests (H_2S, urea) that are usually negative; such strains are not accurately identified by commercial kits.[4] Shigellae do not fare as well as *E. coli* in commercial identification systems. In data derived from various studies, of 198 strains tested collectively, 14 different systems correctly identified only 162 *Shigella*.[4] There is considerable biochemical variation between species and types within species; distinctive traits include lack of mannitol fermentation for *S. dysenteriae* strains, ODC- and ONPG-positive reactions for *Shigella sonnei*, and gas-production from D-glucose for some strains of *S. flexneri* type 6 and *S. boydii* type 14.

Virulence characteristics are specific for each of the diarrheagenic *E. coli* groups and for strains of ExPEC. Numerous genes, located on both the chromosome and on plasmids, are involved for each group but the primary virulence mechanism is given in Table 28.2. Shigellae are invasive pathogens; a 220-kb plasmid encodes the genes involved in invasion but genes that regulate plasmid-borne virulence factors are located on the chromosome along with other virulence genes.

Yersinia

The genus *Yersinia* presently consists of 18 validly published species, although the legitimacy of *Yersinia wautersii* ("Korean strains") has been questioned. The disease spectrum and pathogenicity of taxa within the genus ranges from humans (*Y. pestis*) to fish (*Yersinia ruckeri*) to insects (*Yersinia entomophaga*). Many of the more recently described environmental species have

only been rarely isolated, and then from samples such as soil, vegetation, and water.

Fourteen of the 18 *Yersinia* species have been recovered from clinical samples, which includes the recent isolation of *Y. entomophaga* from the urine of an 85-year-old man.[65] The preeminent human pathogens of the genus are *Yersinia pestis* (bubonic plague), *Yersinia enterocolitica* (enterocolitis, mesenteric lymphadenitis), and *Yersinia pseudotuberculosis* (mesenteric lymphadenitis, septicemia). Environmentally, *Y. ruckeri* is an increasingly important pathogen of fish, causing enteric redmouth disease in salmonids.[66]

While most strains of *Y. pestis* and *Y. pseudotuberculosis* are virulent, only certain *Y. enterocolitica* strains with specific serotype/biotype combinations are thought to cause disease. Currently there are two subspecies of *Y. enterocolitica*: subspecies *enterocolitica* and *paleartica*.[67] In general, bioserotypes of subspecies *enterocolitica* are considered to be more virulent with the exception of subspecies *paleartica* serotype O:3 biotype 4, which is the dominant bioserotype worldwide.[68] Since these subspecies can only be identified by molecular techniques such as 16S rDNA gene sequencing or MLST, the subspecies designations aren't currently used.[69] *Y. pestis* is a zoonotic organism causing epidemic plague in a number of rodents as well as humans.[70] Rats (*Rattus rattus* and *R. norvegicus*) play a major role in the spread of plague but are not significant in maintaining *Y. pestis* in the wild; enzootic rodents highly resistant to the organism (carriers) are believed to be one reservoir as well as soil.[70] Unlike domesticated dogs, ferrets, coyotes, skunks, and raccoons that are highly resistant to infection, cats can develop clinical plague.[71] Lagomorphs, birds, boars, and pigs, and rodents and aquatic environments are major reservoirs for *Y. pseudotuberculosis* and *Y. enterocolitica,* respectively, although both can be isolated from a wide variety of sources.[4] In rare cases, inpatients with underlying disorders may present with infections caused by *Yersinia frederiksensii, Yersinia kristensenii, Yersinia intermedia, Yersinia bercovieri, Yersinia mollaretii, or Yersinia rohdei.*

Plague (*Y. pestis*) is a vector-borne (flea) zoonotic infection that can occur in one of three forms (bubonic, septicemic, pneumonic).[72] The organism migrates via the bloodstream to the lymphatic system, causing inflammation of the lymph nodes (buboes) in the groin, axilla, or neck[71] with an incubation period of 2–8 days following the fleabite. Plague is characterized by fever, chills, headache, and weakness, and, if present, gastrointestinal symptoms of abdominal pain, nausea, vomiting, and diarrhea. Secondary pneumonic plaque follows spread from the bloodstream to the respiratory tract and is distinguished by bronchopneumonia, cavitation, or consolidation with bloody or purulent sputum.[71] Patients with secondary pneumonic plague can infect close contacts with primary pneumonic plague in 1–3 days; these cases will be fatal if not treated within 1 day. In primary septicemic plague, which occurs in 25% of cases, symptoms resemble those of any Gram-negative infection (there are no buboes) but the mortality rate is 30–50%. Plague now primarily occurs as sporadic cases associated with rodent contact[70]; however, outbreaks do occur, most notably in Madagascar in 2017 where over 2,000 suspected cases of pneumonic plague were reported.[72] In endemic areas, plague may occur as a mild or unapparent disease, detected primarily in seroprevalence studies.[71] In the United States, squirrels, rabbits, and prairie dogs are the most common vectors involved in plague cases but sources cannot be identified for a third of all infections. Infected cats have transmitted plague to humans by scratches (bubonic) and aerosolized droplets (pneumonic).

Y. pseudotuberculosis is a relatively uncommon zoonotic pathogen and infections are more often seen in Europe where a variety of animals including voles, hares, fowl, and pigs harbor these microbes as pathogens or commensals. While *Y. pseudotuberculosis* is most often acquired by consumption of contaminated foods, the chief clinical manifestations are often not enteric (diarrhea) per se but rather as mesenteric lymphadenitis (mimicking appendicitis), granulomatous disease, or upon dissemination as septicemia. As with *Y. enterocolitica, Y. pseudotuberculosis* occurs in patients with underlying medical complications such as iron overload conditions.[4] Most infections occur in older children and young adults, especially in males.

Enteritis is the most frequently encountered gastrointestinal illness associated with *Y. enterocolitica* but it can also cause mesenteric lymphadenitis and terminal ileitis, conditions that mimic appendicitis. *Y. enterocolitica* is also a major cause of transfusion-related sepsis.[73] *Y. enterocolitica* serogroups of biotype 1A are regarded as nonpathogenic because they lack the virulence characteristics of pathogenic strains. However recent studies suggest some or many biotype 1A strains may cause disease.[74] Patients who carry the HLA-B27 allele are at increased risk of developing reactive arthritis (RA) following gastrointestinal illness; approximately 10% of patients with yersinia-associated RA develop chronic arthritis.[4]

Y. pestis present in blood, bubo aspirates, sputum, or cerebrospinal fluid exhibit a characteristic bipolar appearance when stained with Wayson's or Giemsa stain. Colonies on blood agar are opaque with a fried egg appearance appearing within 48 hours; however, plates should be held 7 days. *Y. pseudotuberculosis* is most often isolated from blood, and routine blood culture techniques are satisfactory. Like, *Y. enterocolitica*, *Y. pseudotuberculosis* can be isolated from MAC or SS agars although recovery on these media is variable for both organisms and colonies are often small (<1 mm) or pinpoint. On Cefsulodin-Irgasan-Novobiocin (CIN), a selective media designed specifically for isolation of *Y. enterocolitica*, colonies have a bull's-eye appearance with a red center and colorless apron. Both *Aeromonas* and *Plesiomonas shigelloides* also grow on CIN, appearing as bull's-eyes and colorless colonies, respectively, which allow this medium to be used to isolate pathogens other than yersinia. CIN, as prepared for *Y. enterocolitica*, could be inhibitory for strains of *Y. pestis.*

With respect to the identification of yersinia, the performance of commercial identification systems, overall, is mediocre, with *Y. pseudotuberculosis* faring the worst (correctly identified only 83% of the time).[4] Only three systems (API 20E, MicroScan Walk/Away, and VITEK) licensed for clinical use in the United States include *Y. pestis* in their database (Tier 1 Select Agent). All isolates of this organism should be sent to an appropriate public health reference laboratory immediately if the isolate is suspicious for plague. Most kits identify *Y. enterocolitica* as "*Y. enterocolitica* group," a designation that includes *Yersinia frederiksenii*, *Y. intermedia*, and *Y. kristensenii*, species generally considered nonpathogenic; systems that identify *Y. enterocolitica* as a species (API 20E and RapID) do not distinguish between virulent and nonvirulent biotypes. Using conventional

media, *Y. pestis* and *Y. pseudotuberculosis* are nonmotile at 35°C, do not ferment sucrose, and are LDC-, ODC-, and ADH-negative; unlike *Y. pestis*, *Y. pseudotuberculosis* is urea-positive and L-rhamnose-negative. *Y. enterocolitica* hydrolyzes urea, ferments sucrose but not L-rhamnose, and is ODC-positive.

All three pathogenic species have a type III secretion system, also called the Yop virulon, located on a 70-kb plasmid. The Yop virulon is composed of a Ysc secretion apparatus (protein pump), Yop effector (causes pore formation in the host cell), and Yop translocator (blocks the host cell's ability to respond to infection) proteins.[72,75] Furthermore, a chromosomal high-pathogenicity island, containing genes encoding for a siderophore with a high affinity for iron, occurs in *Y. enterocolitica* pathogenic serogroup IB, *Y. pseudotuberculosis* serogroups I and III, and *Y. pestis*.[76]

Additional Members of the Family *Enterobacteriaceae*

There are many other genera and species in the family *Enterobacteriaceae* that cause serious diseases or illnesses in humans, animals, plants, and other living creatures. Many of these diseases are not specific to a single entity; that is, many different species can cause bloodborne disease in humans to varying degrees. However, a number of syndromes are either species-specific or are intimately linked to the genus and/or species, and some of these are presented in Table 28.3.

The genus *Citrobacter* consists of a large number of species ($n = 15$), most of which are lysine decarboxylase-negative (LDC-negative) and citrate-positive. Members of the *Citrobacter freundii* complex are also H_2S-positive on TSI. The most common species involved in human disease belong to the *Citrobacter freundii* complex, where they primarily cause bacteremia and UTIs.[4] A less frequently isolated indole-positive species, *Citrobacter koseri* causes a variety of CNS diseases (ventriculitis, meningitis, brain abscesses) in neonates less than 2 months of age. Risk factors for developing CNS disease caused by *Citrobacter koseri* include a gestation age of less than 37 weeks and low birth weight.[77] *Citrobacter rodentium*, a citrobacter species that does not cause disease in humans, can cause massive outbreaks of morbidity and mortality in mouse and gerbil colonies.[78]

Several other enterobacteria typically cause diarrhea as their most common clinical presentation. *Edwardsiella tarda*, an H_2S-, indole-, and LDC-positive species, causes watery to bloody diarrhea, particularly in subtropical regions of the world.[79] Infection is often associated with close contact with reptiles. *P. shigelloides*, the only oxidase-positive member of the family, causes enteritis and is associated with consumption of seafood or shellfish or contaminated water.[80]

At least six genera are considered phytopathogens. Not all isolates of these individual species cause disease under all circumstances, and many exist as commensals or part of the microbial rhizosphere. Many of these strains exhibit varying degrees of pigmentation (e.g., yellow) upon subculture in the laboratory. Specific tests have been designed to measure pathogenicity, such as the onion maceration test.

TABLE 28.3

Selected Examples of Major Diseases Associated with Other Members of the Family *Enterobacteriaceae*

Category	Disease	Agent(s)
Humans	Gastroenteritis	*Edwardsiella tarda, Plesiomonas shigelloides*
	Neonatal meningitis, brain abscess	*Citrobacter koseri Cronobacter sakazakii*
Animals	Murine colonic hyperplasia	*Citrobacter rodentium*
	Amber disease (grub)	*Serratia entomophila*
	Insect sepsis	*Photorhabdus*
	Sepsis in tilapia, ducks, and egrets	*Edwardsiella* spp.
	Sepsis in penguins	*Plesiomonas shigelloides*
Plants	Bark cankers	*Brenneria species*
	Stem canker, fire blight	*Erwinia species*
	Black spot necrosis, pink disease, seed and boil rot, onion rot, brown apical necrosis of walnut, leaf blight and vascular wilt of maize	*Pantoea species*
	Soft rot, black leg disease	*Dickeya species Pectobacterium carotovorum*
	Bark necrosis	*Samsonia*
