Other prevention strategies include vector and reservoir avoidance and elimination, proper animal husbandry and food handling practices, and education of at-risk individuals about ways to prevent infection and curb the transmission of emerging viral diseases. Vector and reservoir abatement measures include use of chemical pest repellants, use of mosquito netting, elimination of vector and reservoir breeding sites, pesticide use, and avoidance of vector- and reservoir-inhabited areas. During the recent Zika virus epidemic in the Western Hemisphere, genetically altered male mosquitoes were introduced into regions where stable autochthonous transmission of Zika virus occurred in an effort to decrease the *Aedes aegypti* vector population. Data from earlier studies performed in Panama, where sterile male *A. aegypti* were released, showed a massive reduction in numbers, suggesting a possible means to curb the spread of Zika in Brazil [35]. The aim of improving animal husbandry and food handling practices is to prevent zoonotic- and food-borne transmission of viruses from food and companion animals to human. Animal biosecurity measures, including animal health surveillance and screening of sentinel animals, provides valuable information regarding the presence or absence of potentially pathogenic viruses in agriculturally relevant, companion, and wild animals [36]. Education of at-risk populations about the modes of disease transmission (e.g., sexual, airborne, etc.), methods of disease prevention (e.g., safe sex practices, safe animal and food handling practices, vector avoidance measures, etc.), symptom recognition, and treatment is also key to the prevention of infectious disease transmission.

Key to the prevention of emerging viral disease outbreaks is vigilant surveillance for known and novel agents among vector and potential reservoir species. Surveillance is useful for the detection and characterization of known viruses in endemic and nonendemic regions, and it offers insight into predicting where and when viruses might next emerge. It also permits determination of whether currently available diagnostics and prophylactics are able to detect viruses and prevent disease they cause, respectively, and it reveals information about the evolution and adaptability of these viruses. Surveillance also enables detection of novel agents that could pose health risks to human and/or animal populations. Together, prevention strategies are a front-line defense against threats posed by emerging viruses.

Atypical Presentations, Permanent Sequelae, and Complications of Emerging Viruses

While primarily known to cause acute febrile illnesses or hemorrhagic fevers, an increasing number of emerging viruses have been associated with congenital syndromes or perinatal complications. The emergence of ZIKV in the Western Hemisphere, first recognized in 2015, was accompanied by a dramatic spike in the incidence of stillbirth and babies born with microcephaly [37]. Postmortem examination of stillborn fetuses and miscarriage remains showed systemic presence of ZIKV [38], demonstrating its involvement in what is now termed congenital Zika syndrome. VEEV also causes a congenital syndrome featuring microcephaly, but the rate of occurrence and neuronal targets are poorly understood [39]. A recent report indicated poor neurocognitive development in children whose mothers were infected with CHIKV during pregnancy, suggesting that this rapidly emerging virus also potentially causes a congenital syndrome [40, 41].

Pregnancy is also a significant risk factor for enhanced mortality of both women and fetuses during Lassa fever. The pathophysiological mechanism leading to more severe disease is somewhat unclear, but the increase in blood volume in pregnancy causing enhanced viremia and LASV affinity for placental vasculature have been proposed [42, 43]. The intervention leading to substantially improved mortality in pregnant women is expulsion of the fetus by delivery, spontaneous abortion, or pregnancy termination [44]. The effect of ribavirin on maternal and fetal outcomes during pregnancy is unclear, likely because the potential teratogenic effects of ribavirin make it unsuitable for use during pregnancy [45]. The impact of infection with other arenaviruses (e.g., MACV, LUJV) on mortality during pregnancy is a question of clinical interest but has not yet been explored.

Multiple emerging viruses have been associated with permanent sequelae or ongoing, postinfectious symptoms. Permanent loss of hearing has been reported following recovery from Lassa fever [46], and loss of eyesight can result from Rift Valley fever [47]. Some patients experience chronic and debilitating joint pain following infection with RRV, CHIKV, MAYV, and OROV [48–51]. A significant proportion of patients who survive central nervous system (CNS) infection with NiV, POWV, EEEV, and numerous other viruses are left with severely debilitating neurological and cognitive damage. It is notable that the majority of infections caused by these and related viruses (e.g., SLEV, WEEV, WNV, POWV) result in subclinical or mild illnesses in the majority of exposed patients, but those experiencing CNS infection can have dramatic or fatal outcomes. In addition to decline in cognitive function, a proportion of Nipah virus-associated encephalitis patients also develop severe and permanent psychiatric symptoms [52, 53].

Factors Introducing Epidemiological Complexities

Outbreaks stemming from emerging viruses often evoke emergency response protocols based on prior observations of transmission dynamics, incubation period, and persistence of pathogen shedding. Risk assessment models for the scope and duration of outbreaks or epidemics are also calculated based on current understandings of these factors. As repeated outbreaks occur or animal models are developed for individual emerging viruses, more nuanced understandings can dramatically alter methods of prediction.

An unexpected finding of the West African Ebola virus epidemic of 2014 was the capacity of viable EBOV to persist in tears and semen long after patient recovery [54–57]. A subsequent study of Marburg virus disease using a macaque model demonstrated persistence of MARV in testicular tissue, indicating that the clinical observation reflects a previously unrecognized capacity of multiple filoviruses [58]. It is not yet clear if SUDV, BDBV, or TAFV are similarly capable of crossing the blood-testicle barrier and maintaining a reservoir in infected patients. Relapse of encephalitis has been reported in survivors

of Nipah virus disease months to years after acute disease and apparent recovery, suggesting that a reservoir of infectious NiV persists within the CNS [55, 59]. This observation is bolstered by a nonhuman primate model showing viable NiV in the brain of infected grivets surviving experimental exposure [60]. The unexpected persistence of these viruses in surviving patients raises the question of whether follow-up outbreaks can result from convalescent or relapsing patients, as human-to-human transmission has been clearly documented for EBOV, MARV, and NiV [61–63].

Disease risk assessment for ZIKV focused initially on the ranges of the competent transmission vectors *Aedes aegypti* and *Aedes albopictus* during the 2015 Western Hemisphere epidemic. A single report from 2011 had documented sexual transmission of ZIKV [64], necessitating the evaluation of this second modality of viral spread. Sexual transmission of ZIKV was thereafter confirmed to occur in the 2015 epidemic [65], and epidemiological models were then adapted to reflect these additional dynamics [66]. Viable filoviruses in semen historically suggested that sexual transmission is plausible for these viruses as well, and this was definitively confirmed for EBOV during the 2014 epidemic in West Africa [54]. Though sexual transmission has not been described, recent case reports document the detection of YFV, CHIKV, RVFV, LASV, ANDV, WNV, NiV, and SFTSV in the semen of convalescent patients [67–73]. Additionally, sexual transmission of EEEV and JEV following experimental infection or artificial insemination of livestock have been reported for avian and porcine systems [74–75], though neither virus has been reported in human semen. It is notable that the detection of these viruses in human semen has all been described within 3 years of this writing, indicating that persistence of emerging viruses in semen may be more common than previously appreciated. Evaluating the extent of their sexual transmission therefore become a matter of urgency.

Conclusions

The emergence of novel viral pathogens, previously unreported pathologies associated with known viral agents, and the re-emergence of previously well-controlled viruses, is a constant factor in human health. Greater recognition of this phenomenon and highly sensitive molecular diagnostic methods lead to broader and faster recognition of novel viral agents than in the past. This improved capacity is offset by greater density in the human population with its increased interconnectedness and rapid movement across the globe, against the backdrop of ecological flux due to climate change. Understanding the factors that drive disease emergence and pathogenic mechanisms of emerging viruses can help to predict or rapidly recognize these viruses and those that have yet to emerge.

Introduction

This chapter will attempt to summarize current information about, and working models for, the mechanisms of action of antimicrobial agents, which are in clinical use or in advanced stages of investigation, or which illustrate important points or are used in laboratory research. We shall provide references to more extensive information.

The antimicrobial agents presented here will be grouped into two major classes according to the target microbes, antibacterials and antimycobacterials, and then, where applicable, by mechanisms of action into five major categories:

- Inhibition of cell wall synthesis
- Interference with membrane integrity
- Inhibition of nucleic acid synthesis
- Inhibition of protein synthesis
- inhibition of synthesis of essential small molecules

A brief discussion of monoclonal antibacterial antitoxins appear at the end of this chapter.

Antibacterial Agents

Inhibition of Cell Wall Synthesis

The bacterial cell wall is a unique structure responsible for multiple functions: maintenance of cell shape, protection against osmotic pressure, or serving as a platform for bacterial appendages, such as flagella, fimbriae, and pili.

The main component of the bacterial cell wall is the peptidoglycan layer. In Gram-positive bacteria, cell walls are much thicker than those of Gram-negative bacteria (Figure 51.1). The Gram-negative cell wall is surrounded by an outer membrane, consisting of a phospholipid bilayer with incorporated protein molecules. Some of these proteins, the so-called porins, form aqueous channels through which hydrophilic molecules, including most antimicrobial agents, diffuse across the outer membrane to enter the periplasmic space, which lies between the outer membrane and inner (or cytoplasmic) membrane. The peptidoglycan lies in the periplasmic space, but it does not generally pose a physical barrier to penetration by most antimicrobials, since such small molecules easily pass through the cell wall. Interference with cell wall biosynthesis generally has bactericidal consequences, since cell wall lysis generally ensues. In some cases, the interference with cell wall synthesis leads to liberation of lipoteichoic acids, which normally regulate the activity of hydrolytic enzymes that play roles in the dynamic changes of the cell wall in cell growth and division. When such regulation is lifted by the loss of the lipoteichoic acids, these enzymes may actively hydrolyze the cell wall, leading to its disintegration.

Drugs That Inhibit Intracellular Cell Wall Biosynthetic Enzymes

Phosphonomycin (Fosfomycin)

Phosphonomycin (now more commonly known as fosfomycin) acts as an analog of phosphoenolpyruvate and binds covalently to a cysteinyl residue of MurA (the phosphoenolpyruvate, UDP-GlcNAc-3-enolpyruvyl transferase), inhibiting the enzyme and interfering with the formation of UDP-*N*-acetyl muramic acid (UDP-MurNAc), early in the synthesis of the bacterial cell wall (Figure 51.2).[1–4] Fosfomycin is rapidly bactericidal against a wide bacterial spectrum, including MRSA, vancomycin-resistant enterococci, and many Gram-negative bacteria, including *Pseudomonas aeruginosa* and ESBL-producing and other multidrug-resistant *Enterobacterales*. The activity of fosfomycin is dependent on two different transport systems for its uptake into the bacterial cell: the 1-α-glycero-phosphate transport system and the hexose monophosphate system, responsible for uptake of glucose-6-phosphate and other hexose monophosphates.[3]

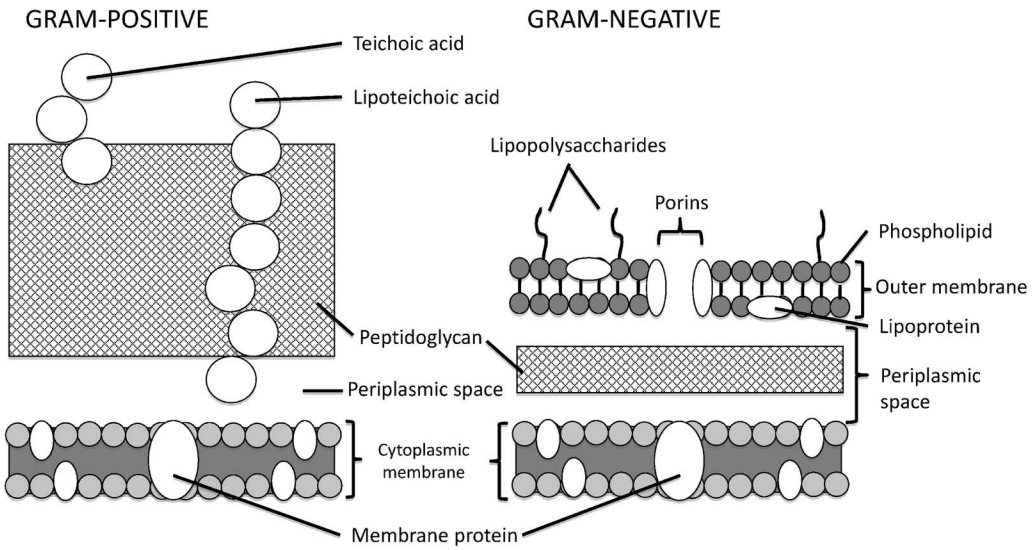

FIGURE 51.1 Cell envelopes of Gram-positive and Gram-negative bacteria.

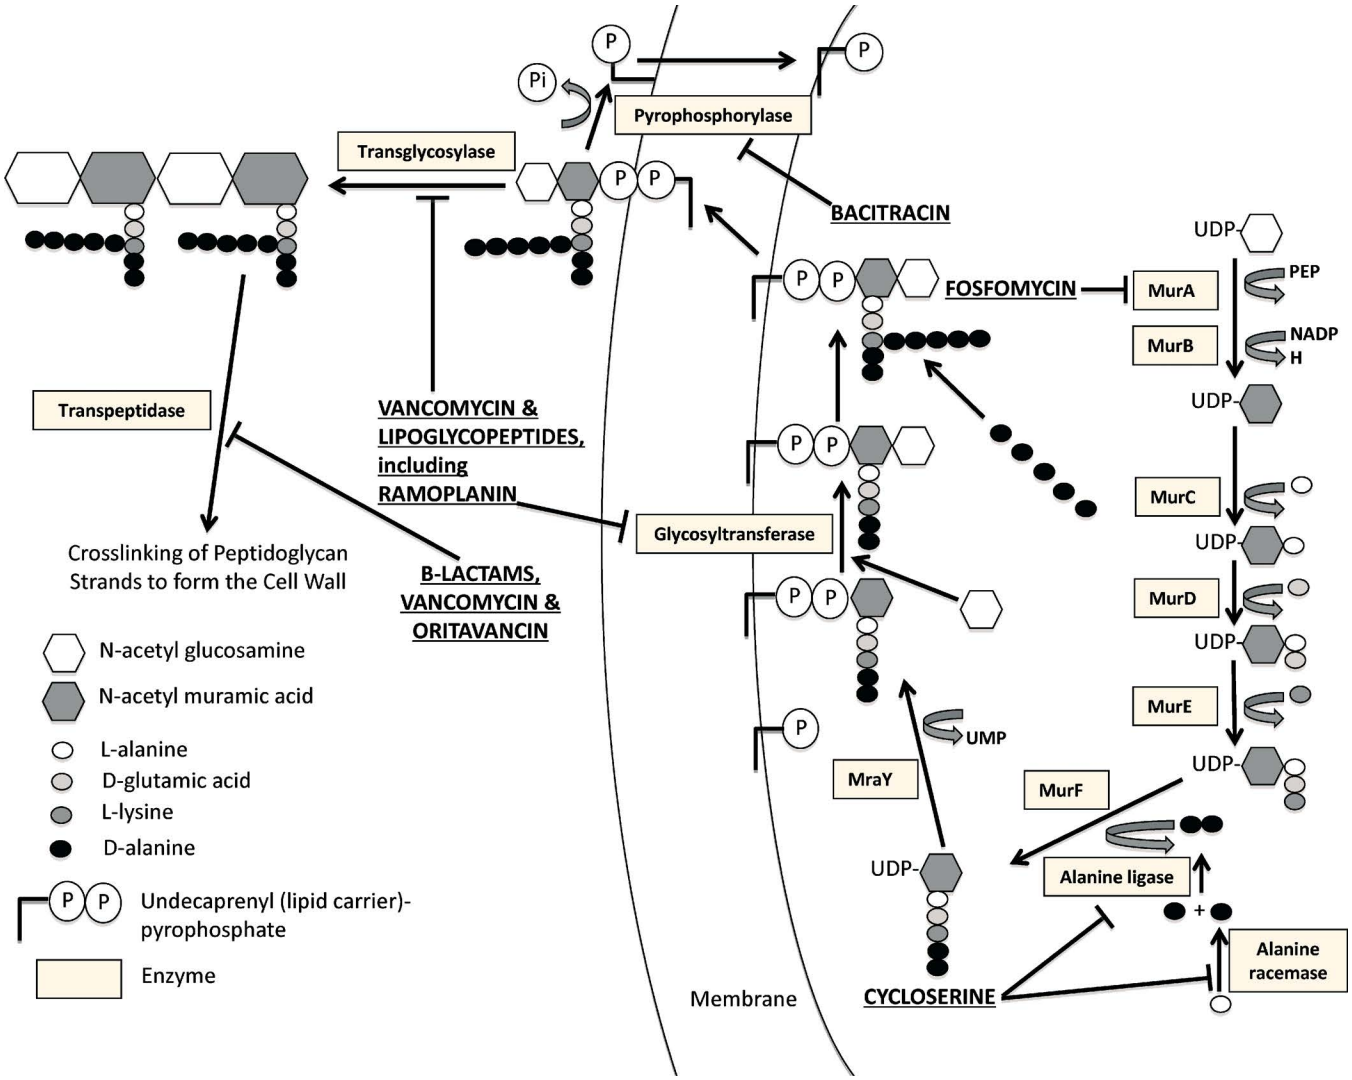

FIGURE 51.2 Cell Wall synthesis and antibacterial sites of action.

Cycloserine

Cycloserine is an inhibitor of cell wall peptidoglycan synthesis and is active against many Gram-positive and Gram-negative bacteria. Its intracellular targets are alanine racemase, which converts L-alanine to D-alanine, and D-alanine-D-alanine ligase, which links two D-alanine molecules to form the dipeptide (Figure 51.2). This dipeptide unit is then added to UDP-MurNAc-tripeptide to form the pentapeptide, which is essential for the eventual cross-linking to form the intact cell wall.[5] The principal use of cycloserine is as an antimycobacterial agent, so it is also discussed later in this chapter.

Drugs That Bind to Carrier Molecules

Bacitracin

Bacitracin is a mixture of at least 22 structurally related dodecapeptides produced by some strains of *Bacillus licheniformis* and *Bacillus subtilis*. Its basic structure consists of a cyclic peptide of seven amino acids plus a linear peptide side chain with five amino acids. At the N-terminus of the peptide, there is a thiazoline ring that is formed either by L-cysteine and L-isoleucine or L-cysteine and L-valine, as a result of substitutions of hydrophobic amino acids in the peptide sequence and from oxidative transformation of the thiazoline ring.[6]

More than four decades ago, it was observed that in the presence of divalent cations, bacitracin complexes with the membrane-bound pyrophosphate form of the undecaprenyl (C_{55}-isoprenyl) lipid carrier molecule that remains after the disaccharide-peptide unit (UDP-GlcNAC-[pentapeptide-MurNAC]) is transferred to the nascent peptidoglycan chain. This binding of bacitracin inhibits the enzymatic dephosphorylation of this lipid carrier to its monophosphate form, which is required for another round of transfer of the disaccharide-peptide unit to the growing peptidoglycan chain. Similar complex formation with intermediates of sterol biosynthesis in animal tissues (e.g., farnesyl pyrophosphate and mevalonic acid) may account in part for the toxicity of bacitracin in animal cells.[7–9]

There has also been discussion of alternative activity of bacitracin. It was reported to be a PDI inhibitor, but *in vitro* evidence for specificity of bacitracin for inhibiting PDI was scarce.[6] In fact, in 2010, Karala and Ruddock presented *in vitro* data

showing that bacitracin was not effective in PDI inhibition, failing to introduce or isomerize disulfide bonds in a folding protein, and unable to act effectively as a chaperone. What they did show was that bacitracin inhibited rhodanese aggregation in the non-catalyzed refolding of rhodanese. It inhibited chaperone activity of bacitracin-induced protein, and at the same time inhibited the reductive activity of PDI by competing with substrate binding.[10] But testing by Dickerhof et al. suggested that bacitracin, indeed, interacts with PDI in a robust, covalent manner. Their study reconciled with the work of Karala et al. by explaining that bacitracin targets not the catalytic domain, but the substrate-binding domain, of PDI. The thiazoline ring of bacitracin opens and interacts with free cysteines (Cys314 and 345) on PDI to form disulfide bonds, although it is non-specific to these amino acids.[6] This research reaffirms that bacitracin is a PDI inhibitor, but it is unclear whether or how this activity produces the antibacterial effect.

Drugs That Bind to Cell Wall Precursors

Glycopeptide: Vancomycin

Vancomycin is a glycopeptide antibiotic that interferes with bacterial cell wall synthesis. It is bactericidal and may even kill cell wall-deficient bacteria (L forms), suggesting secondary effects not limited to cell wall synthesis.

Vancomycin is a 1450-dalton tricyclic glycopeptide, in which are linked two chlorinated tyrosines, three substituted phenylglycines, glucose, vancosamine (a unique amino-sugar), *N*-methyl leucine, and aspartic acid amide. This structure can undergo hydrogen bonding to the D-alanyl-D-alanine terminus of the pentapeptide in various peptidoglycan precursors (e.g., UDP-MurNAc-pentapeptide, MurNAc-pentapeptide pyrophospholipid, and GlcNAc-MurNAc-pentapeptide pyrophospholipid). Binding of vancomycin occurs through a set of hydrogen bonds between the D-Ala-D-Ala dipeptide and the amides that line a cleft formed by the cross-linked heptapeptide of the vancomycin. The bound glycopeptide acts as a steric impediment, preventing the attack of the transglycosylase that links N-acetyl glucosamine with N-acetyl muramic acid-pentapeptide to form the repeating subunits of the peptidoglycan, and the subsequent attack of the transpeptidase that normally completes the peptidoglycan by cross-linking two peptidoglycan strands. The latter cross-linking normally occurs with binding of the transpeptidase to the penultimate D-Ala to the N-terminal amino acid of the species-specific cross-linking peptide (glycine in *Staphylococcus aureus*). Thus, the impairment of cross-linking by the transglycosylase of the disaccharide units to elongate the glycan strand and the impairment of transpeptidation that normally cross-links the strands via the peptides, lead to incomplete cell wall with poor integrity.[11–18]

The bactericidal activity of vancomycin is generally concentration-independent, although it carries out some (minimal) concentration-dependent killing, with a long postantibiotic effect that has been demonstrated *in vitro*.[16,19]

Because of the frequent use of vancomycin, certain drug-resistant Gram-positive bacterial pathogens have emerged, such as vancomycin-resistant *enterococci* (VRE), which continue to assemble peptidoglycan precursors because they are able to synthesize and place D-Lactate in the place of the terminal D-Alanine in the peptide chain of the nascent peptidoglycan. This drastically reduces the binding affinity of vancomycin, making it ineffective. Such resistance to vancomycin has stimulated efforts to examine the structure and activity of vancomycin derivatives in search of more effective drugs.[20,21]

Lipoglycopeptides: Telavancin, Teicoplanin, Ramoplanin, Dalbavancin, and Oritavancin

Telavancin is a semisynthetic derivative of vancomycin, featuring the same glycopeptide core as vancomycin, but with the addition of an extended lipophilic (decylaminoethyl) side chain to the vancosamine sugar and a hydrophilic side chain represented by the negatively charged phosphonomethyl aminomethyl moiety to the resorcinol-like 4'-position of amino acid 7. In contrast to vancomycin, which binds to the cell wall, telavancin binds predominantly to the cell membrane. Telavancin thus has a dual mode of action. First, the lipophilic moiety promotes interaction with the cell membrane and anchors the molecule to the cell surface, providing improved binding affinity of the glycopeptide core for D-alanyl-D-alanine-containing peptidoglycan, inhibiting peptidoglycan biosynthesis. Second, telavancin disrupts the barrier function of the cell membrane, producing a rapid bactericidal effect leading to both concentration- and time-dependent loss of membrane potential and increased membrane permeability, although most reports speak more of its concentration-dependent killing in both intra- and extracellular *S. aureus*.[22–24] This is a result of telavancin binding to lipid II, which places it in a good position to insert its lipophilic side chain into the membrane, thus disrupting the lipid bilayer.[25] Meanwhile, the hydrophilic substituent of the drug increases its distribution in the body and promotes rapid clearance, thus reducing the potential for nephrotoxicity. Global gene expression studies, which showed an increase in expression of the genes *vraS* and *vraR* (principal controllers of the cell wall stress regulon), and upregulation of cell-envelope genes *lytM*, *murZ*, *pbp2*, SAS1987, *murI*, *fmt*, *bacA*, and *llm/tarO*, among others, were supportive of inhibition of peptidoglycan synthesis as one mechanism of action. Furthermore, telavancin also causes upregulation of two important genes, *lrgA* and *lrgB*, which have been shown in the past to be induced by other known membrane depolarizers, daptomycin, and chitosan, supporting membrane depolarization as another mode of action. Lastly, this laboratory method also showed that telavancin administration led to a strong induction of *vraD* and *vraE* genes, which have been associated with detoxification and resistance (as in previous studies with bacitracin and nisin), and are, in turn, responses to membrane depolarization.[26–30]

Teicoplanin is a lipoglycopeptide antibiotic approved for human use outside the United States, and so its use has been mostly reported in European studies.[31–33] The activity profile of teicoplanin is similar to that of vancomycin.[16] Like vancomycin, teicoplanin acts by interacting and forming a complex with the substrate peptidoglycan units that have the pentapeptidyl tails terminating in D-Ala_4-D-Ala_5. This substrate sequestration effectively shuts down transpeptidation by making the D-Ala-D-Ala acceptor unavailable to the transpeptidases.[34,35] Teicoplanin has a long elimination half-life because of its high serum protein binding, and combined with good renal tubular resorption, this drug is able to reach high and prolonged serum concentrations.[36]

Ramoplanin is a novel lipoglycopeptide with a unique mechanism of action, causing alteration of cell wall peptidoglycan linkages and membrane permeability of Gram-positive bacteria, thereby disrupting the cell wall. Ramoplanin acts by inhibiting the late-stage assembly of the peptidoglycan monomer and its polymerization into mature peptidoglycan, by blocking two sequential enzymatic steps (Figure 51.2).[37] First, it inhibits the glycosyltransferase that links the N-acetyl-glucosamine (GlcNAC) unit with the N-acetyl-muramyl (MurNAC)-pentapeptide to form the recurring disaccharide-pentapeptide unit of the peptidoglycan chain.[28,38,39] Next, ramoplanin inhibits the transglycosylation step in peptidoglycan synthesis, joining the disaccharide peptide subunits into a peptidoglycan chain.[37]

Dalbavancin is a semisynthetic lipoglycopeptide structurally related to vancomycin and teicoplanin, with an unusually prolonged half-life of six to ten days. Dalbavancin interrupts Gram-positive bacterial cell wall biosynthesis by binding, like vancomycin, to the terminal D-alanyl-D-alanine of the pentapeptide-glycosyl cell wall intermediate, thus inhibiting transpeptidation and leading to cell death. A unique property of dalbavancin is the ability to dimerize and anchor itself into bacterial membranes, improving its interaction with, and binding affinity to, D-alanyl-D-alanine residues of nascent peptidoglycan precursors and producing more rapid and potent bactericidal activity against MRSA and coagulase-negative staphylococci, as compared with vancomycin and teicoplanin.[16,28,40,41]

Oritavancin is a novel semisynthetic lipoglycopeptide antibiotic with concentration-dependent bactericidal activity against Gram-positive cocci, including glycopeptide-resistant enterococci and *S. aureus* with intermediate susceptibility to glycopeptides. In comparison with vancomycin, it also displays a more prolonged post-antibiotic effect and elevated serum protein binding. The mechanism of action of oritavancin is similar to that of vancomycin (Figure 51.2), with some important differences that explain its activity against vancomycin-resistant pathogens. The mechanism of action of oritavancin has three steps: (1) inhibits the transglycosylation step of cell wall biosynthesis like vancomycin, (2) inhibits transpeptidation by binding to the peptidic cross-linking part (pentaglycine bridge in *S. aureus*, and Aspartate/Asparagine bridge in *E. faecium*), and (3) has certain cell membrane effects, particularly increased cell membrane anchoring and dimer formation (due to the presence of a hydrophobic side chain 4'-chlorobiphenylmethyl), which lead to concentration-dependent membrane depolarization, increased permeability, membrane disruption, and then cell death. The latter two actions allow oritavancin to remain active against vancomycin-resistant *S. aureus* and enterococci. Furthermore, it has been reported that oritavancin is able to sterilize biofilms of *S. aureus*, whether MSSA, MRSA, or VRSA.[28,42–45]

Drugs That Inhibit Enzymatic Polymerization and Attachment of New Peptidoglycan Units to the Nascent Cell Wall (β-Lactams)

All β-lactam antibiotics contain the highly reactive β-lactam ring that binds to, and inactivates, various penicillin-binding proteins (PBPs), a family of enzymes (transpeptidases and carboxypeptidases) in the cytoplasmic membrane that catalyze various steps in the biosynthesis and reshaping of the cell wall peptidoglycan. Notably, these target proteins are in the cytoplasmic membrane and accessible on the outside, which means that these antibiotics need not cross the membrane to act on them.[46]

Penicillins and Cephalosporins

Penicillins and cephalosporins interfere with the terminal step in the cross-linking of peptidoglycan chains (i.e., transpeptidation of the N-terminus of the amino acid or peptide bridge onto the penultimate D-alanine of the pentapeptide chain, with release of the terminal D-alanine). It has been suggested that penicillin is a structural analog of a transition state of the D-alanyl-D-alanine terminus of the peptidoglycan strand which is involved in transpeptidation. It thereby competes with the D-Ala-D-Ala bond in binding to the transpeptidase enzyme, compromising the formation of an acyl-enzyme intermediate with the penultimate D-alanine. The highly reactive CO-N bond of the β-lactam ring acylates the transpeptidase irreversibly, thereby inactivating it, so peptide cross-linking of peptidoglycan chains does not occur.[47] Bacteria display in their cytoplasmic membrane a variety of PBPs, which include other penicillin-sensitive enzymes besides the transpeptidases and D-alanine carboxypeptidases. The concept of multiple target sites for the actions of penicillins and cephalosporins is supported by the observations that various β-lactam antibiotics produce differential effects on the processes of cell division, elongation, and lysis. Specific β-lactam antibiotics bind different PBPs preferentially, and the differences in physiological and morphological effects of various β-lactams correlate with the affinity of their binding to different PBPs. The lytic and killing actions of penicillins and other β-lactams may not result directly from their inhibition of peptidoglycan synthesis, but may also involve the action of bacterial murein hydrolases. It has been observed that lipoteichoic acids, which inhibit these autolytic enzymes or autolysins, are released from some bacteria upon treatment with penicillin *in vitro*. It has thus been postulated that the release of these endogenous inhibitors of murein hydrolase enzymes interferes with the regulation of these enzymes in the cell, so the unregulated hydrolases destroy the integrity of the cell wall and contribute to cell lysis and death. Modifications of the side chains of some penicillins and cephalosporins have permitted improved penetration through the porins in cell envelope structures, resulting in an enhanced antibacterial spectrum.[48–52]

The β-lactam ring, which is the key to the success of this class of antibiotics, is hydrolyzed by β-lactamase enzymes that confer resistance to β-lactams and have evolved from penicillin-binding proteins by mutation and selective pressure. Fortunately, continued research has come up with ways to combat this resistance mechanism, such as combining β-lactamase inhibitors with a penicillin.[46] These inhibitors (such as clavulanate, and the penicillin sulfones, sulbactam, and tazobactam) inactivate serine-dependent β-lactamases, and when combined with a penicillin, the resulting drug combination has extended therapeutic effectiveness by inactivating many serine ß-lactamases and thereby protecting the associated penicillin from inactivation.[53]

The resistance conferred by ß-lactamases can also be overcome by modifying the side chain of penicillin, which may reduce the binding of the resulting penicillin to the ß-lactamase. Furthermore, cephalosporins and carbapenems (other classes of ß-lactams) may also bind poorly to existing ß-lactamases, and thereby retain activity against some ß-lactamase-containing bacteria.

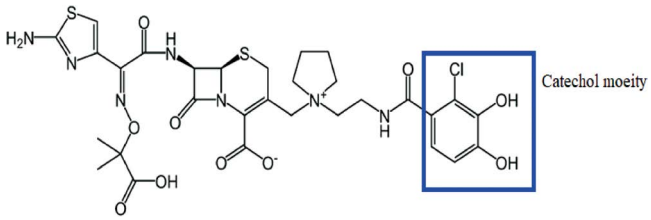

FIGURE 51.3 Chemical structure of cefiderocol.

New cephalosporins have been made by pairing the N-(α-oxyimino)acyl side chain of third-generation cephalosporins with structurally complex heterocycles at the C-3 position. Ceftaroline and ceftolozane have very good activity against methicillin-resistant *S. aureus* and against *P. aeruginosa*, respectively. The ability of ceftaroline to access the open cleft that leads to the PBP active site, particularly PBP 2a and PBP 2x in MRSA and *Streptococcus pneumoniae*, respectively, explains its improved activity against these organisms.[53–55]

Cefiderocol is a novel catechol-substituted siderophore cephalosporin that has potent activity against Gram-negative bacilli including multidrug-resistant Pseudomonas, multidrug-resistant *Acinetobacter*, and carbapenem-resistant *Enterobacterales* (Figure 51.3).[56] The presence of a halogenated catechol group at the C-3 position of cefiderocol enhances the *in vitro* potency against IMP-1, KPC-2, and OXA-producing strains of *P. aeruginosa*. Cefiderocol utilizes the bacterial iron transport systems and penetrates the outer membrane of the bacteria along with ferric iron.[56] It forms a chelating complex with free iron which is actively transported into the periplasm via iron transporters.[57] The iron transport systems as well as small molecules called siderophores are upregulated to sequester iron in an iron-depleted environment. It inhibits bacterial cell wall synthesis by binding mainly to PBP-3 of Gram-negative bacteria. There was increased intracellular accumulation of cefiderocol in *P. aeruginosa* cells incubated under iron-depleted conditions compared with those incubated under iron-sufficient conditions.[57] This transport of extracellular ferric iron was not enhanced when one of the hydroxyl groups of the catechol moiety of cefiderocol was replaced with a methoxy group.[57] It is unclear whether the molecule is stable by itself or only when bound to iron. The molecule has high stability against a range of ESBLs and carbapenemases.[57]

Ceftobiprole is a parenteral cephalosporin that is available in its prodrug form, ceftobiprole medocaril.[58] Like other β-lactams, it inhibits transpeptidation by binding to penicillin-binding proteins. It is an extended-spectrum antibiotic that is effective against both Gram-positive and Gram-negative bacteria, including MRSA, β-hemolytic streptococci, methicillin-resistant coagulase-negative staphylococci, *S. pneumoniae,* and *P. aeruginosa*.[58] Its activity against *P. aeruginosa* is an important distinguishing feature from ceftaroline. It is also active against AmpC-producing strains of *P. aeruginosa*, as ceftobiprole is a poor inducer and is hydrolyzed slowly by AmpC. Its activity for *P. aeruginosa* is attributed to its enhanced binding to PBP3. It has remarkably strong affinity of binding to PBP 2A, which is responsible for imparting resistance to β-lactam antibiotics in MRSA and methicillin-resistant CoNS.[58] In addition, ceftobiprole can also saturate PBPs 1, 3, and 4 in low concentrations, a property not shared by other β-lactams. It also has potent activity against penicillin- and ceftriaxone-resistant strains of *S. pneumoniae*.[58] It has activity against *E. faecalis*, but not against *E. faecium*. It has limited activity against *Acinetobacter* sp. and *Stenotrophomonas maltophilia*. Ceftobiprole is now approved for treatment in Europe of adults with hospital-acquired and community-acquired pneumonia.

Carbapenems: Imipenem, Meropenem, Ertapenem, Doripenem, Faropenem, Tebipenem, and Tomopenem

Carbapenems are β-lactams with the widest antibacterial spectrum, and the most potent agents versus Gram-positive and Gram-negative bacteria, although they are not active against MRSA. They have a 4:5 fused ring lactam, a double bond between C-2 and C-3, a sulfur (instead of a carbon at C-1), and a hydroxyethyl side chain, which is the key to their broad activity[59] and provides the mechanism of resistance to most β-lactamases.[60]

Carbapenems diffuse more readily through the outer membrane proteins (porins) of most Gram-negative bacteria, in part because of their zwitterionic characteristics. Furthermore, in *P. aeruginosa*, carbapenems enter more rapidly through pores formed by a specific porin, outer membrane protein D2, whose mutational loss or alteration produces carbapenem resistance by reducing entry into the cell. Once inside the periplasmic space, these drugs acylate multiple PBPs, inhibiting peptide crosslinking and peptidase action. This leads to peptidoglycan weakening and disruption of formation until the cell bursts from osmotic pressure.[59] Carbapenems are also generally less readily inactivated by bacterial β-lactamases than other β-lactams.[51,61,62]

The first carbapenem was thienamycin, which was unstable in aqueous solution, leading to the development of the more stable imipenem, which possesses a high affinity for PBPs.[63]

Imipenem inhibits bacterial cell wall synthesis by binding to and inactivating specific PBPs. In *Escherichia coli* imipenem inhibits the transpeptidase activities of PBPs-1A, -1B, and -2, and the D-alanine carboxypeptidase activities of PBP-4 and PBP-5. It also inhibits the transglycosylase activity of PBP-1A, and it is a weak inhibitor of the transpeptidase activity of PBP-3, in contrast to all other β-lactams and other carbapenems that preferentially bind to PBP-1 and –3. Imipenem induces sphere formation with subsequent cell rupture, and it does not inhibit septum formation by the cells, reducing the amount of lipopolysaccharide liberated during bacteriolysis. For human use, imipenem is administered in combination with cilastatin, an inhibitor of dehydropeptidase (DHP) I, an enzyme produced by the renal epithelial cells which hydrolyzes imipenem.[62,64] The inhibition of the renal dehydropeptidase preserves the activity of imipenem in urine, thereby permitting its use in treating urinary-tract infections.

Meropenem contains a C-methyl substituent at the 1-β position, and thus is not susceptible to hydrolysis by the renal DHP-I. Its bactericidal action is similar to that of imipenem, although various bacterial mechanisms of resistance may affect susceptibility to these two carbapenems differentially.[50,59]

Ertapenem binds most strongly to PBP-2 of *E. coli*, followed by PBP-3, and it also has good affinity for PBP-1A and -1B, achieving rapid bactericidal action without the prior filamentation that occurs with third-generation cephalosporins that bind primarily to PBP-3.[65,66] Although it has broad activity against *Enterobacterales*, it does not have activity against *P. aeruginosa*.

Doripenem, a 1b-methyl-carbapenem, is similar to meropenem in its stability to many β-lactamases and its resistance to inactivation by renal dehydropeptidases.[67]

Faropenem is an orally administered penem antibiotic which displays both bactericidal and β-lactamase inhibitor effects and is less susceptible to the renal dipeptidase enzyme DHP-1 as compared with imipenem. It has preferential affinity for PBP-2 but also affinity for PBP-1A, -1B, and -3. Faropenem exposure at concentrations below the minimum inhibitory concentration (MIC) for *S. aureus* affected septum formation with a decrease in the number of viable cells at increasing antibiotic concentrations; exposure to concentrations equivalent to the MIC and above produces cell lysis. A similar effect is observed in *E. coli*, with changes in cell shape at concentrations below the MIC and cell lysis at or above the MIC.[66,68]

Faropenem was approved for use in 2009 in Japan, where it has been used for dermatologic conditions, such as acne vulgaris (alone orally, or in combination with topical agents),[69,70] and even in clarithromycin-resistant cutaneous *Mycobacterium chelonae* infections.[71]

Tebipenem is another oral carbapenem that is being developed in Japan, but it lacks activity versus *P. aeruginosa* and MRSA.[59]

Tomopenem is another broader spectrum intravenous carbapenem with activity against both *P. aeruginosa* and MRSA. The presence of a basic group at position 6 is responsible for the activity against the latter.[67,72]

As with cephalosporins, new carbapenems continue to be developed by incorporating heterocycles at the C-2 position, resulting in even broader Gram-negative activity, such as razupenem and ME-1036.[53] Due its increased adverse effects, the development of razupenem in North America was terminated.[215]

Penicillins combined with β-Lactamase Inhibitors: Amoxicillin-clavulanate, Ampicillin-sulbactam, and Piperacillin-tazobactam

Amoxicillin and Clavulanic Acid. Amoxicillin is an orally administered penicillin that inhibits cell wall synthesis and has bactericidal activity. It works by binding to penicillin binding protein and thus inhibiting the transpeptidation reaction, which ultimately impairs cell wall synthesis and causes lysis of the cell wall. The major cause of bacterial resistance to amoxicillin is the presence of β-lactamase enzymes that hydrolyze the β-lactam structure of the antibiotic rendering it ineffective. An effective way to combat resistance conferred by β-lactamases is to use agents such as β-lactams, which bind the active site of the β-lactamase and inactivate it.[73] This could be achieved by either developing substrates that with high affinity to bind the enzyme (reversibly and/or irreversibly)form unfavorable steric interactions or by creating irreversible "suicide inhibitors."[73] Clavulanic acid belongs to the second category.[73] It functions by deactivating the β-lactamase enzyme permanently through secondary chemical reactions in the active site of the enzyme.[73] The reaction includes the development of a noncovalent complex between the enzyme and the inhibitor, which then leads to the formation of the acyl-enzyme intermediate by the nucleophilic attack by a serine residue of the enzyme.[74] This then develops into a catalytically inactive inhibitor-enzyme complex.[74] One problem that might arise by the use of these suicide inhibitors is that they themselves have β-lactam structure and are, therefore, liable to hydrolysis by β-lactamase enzyme, which could then lead to the regeneration of the enzyme.[74] Therefore, greater formation of permanently inactivated enzyme-inhibitor complex is required for the greater efficiency of suicide inhibitors.[74] Amoxicillin-clavulanate is a widely used parenteral β-lactam-β-lactamase-inhibitor combination. Clavulanic acid is the β-lactamase inhibitor and protects amoxicillin from hydrolysis by β-lactamase enzymes and, therefore, amplifies its antibacterial spectrum.

Ampicillin and Sulbactam. Ampicillin is a penicillin with an antibacterial spectrum of activity similar to that of amoxicillin, but it is generally administered intravenously. Ampicillin and sulbactam is the β-lactam-β-lactamase-inhibitor combination. Sulbactam, like clavulanic acid is a suicide inhibitor. Addition of sulbactam to ampicillin enhances antibacterial spectrum of ampicillin by protecting it from hydrolysis by certain β-lactamases. The spectrum of activity of ampicillin-sulbactam is similar to that of the orally administered amoxicillin-clavulanate.

Piperacillin and Tazobactam. Piperacillin-tazobactam is another β-lactam-β-lactamase-inhibitor combination. Piperacillin is a cell wall synthesis inhibitor and bactericidal in nature while tazobactam protects its partner from hydrolysis by certain β-lactamase enzymes. Piperacillin has a broader spectrum of activity against Gram-negative bacteria, including *P. aeruginosa*. Since sulbactam and tazobactam inhibit β-lactams in many gut anaerobes, these β-lactamase inactivators endow their respective combinations with penicillins with activity also against many gut anaerobes.

Newer β-Lactams combined with β-Lactamase Inhibitors: Ceftazidime-avibactam, Meropenem-vaborbactam, Ceftolozane-tazobactam, Imipenem-relebactam, and Cefepime-zidebactam

Resistance to the older inhibitors (clavulanic acid, sulbactam, and tazobactam) is now quite prevalent for several reasons. First, they only target the class A serine β-lactamases. Secondly, there are variants of class A β-lactamases that have acquired single amino acid substitutions, resulting in older inhibitors failing to inactivate these enzymes. Lastly, newer class A β-lactamases like KPC-2 were identified that can hydrolyze older β-lactamases. This led to the need to develop new β-lactam-β-lactamase inhibitor combinations discussed later.

Ceftazidime is a third-generation cephalosporin that is active against *P. aeruginosa* and other Gram-negative bacilli. The most common mechanism of resistance to β-lactams in Gram-negative bacteria is by production of β-lactamases that hydrolyze the β-lactam ring. Avibactam is a novel non-β-lactam β-lactamase inhibitor that is active against almost all members of class A and class C β-lactamase enzymes and some class D β-lactamase enzymes (Figure 51.4).[75] Inhibition of class C β-lactamase enzymes is the most important attribute of avibactam. Unlike other β-lactamase inhibitors, avibactam does not contain a β-lactam core in its structure. Furthermore, the mechanism of action through which avibactam resists hydrolysis and thus protects its associated ceftazidime differs from other β-lactamase inhibitors that are themselves β-lactams.[75]

The covalent inhibition of the catalytic serine occurs in a similar fashion via the opening of the avibactam ring, but the

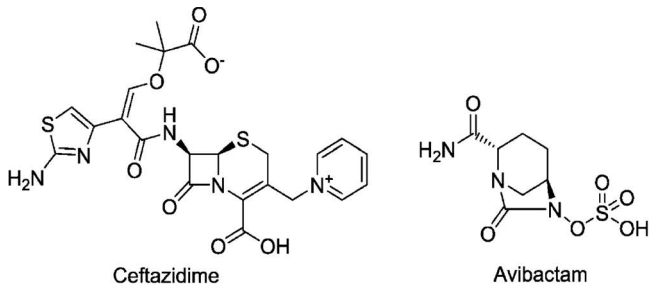

FIGURE 51.4 Chemical structure of ceftazidime and avibactam.

reaction is reversible. The deacylation of the opened avibactam ring leads to the regeneration of the original compound and therefore hydrolysis does not occur.[75] Therefore, reversible binding of avibactam to β-lactamases allowing for recyclization and inhibition of additional β-lactamase molecules is a unique feature of avibactam, compared to earlier generation inhibitors. The protection of ceftazidime by inactivation of a broad range of chromosomal and plasmidic β-lactamases including ESBLs, AmpCs, class D carbapenemases, and KPC-2 enzymes yields a broad spectrum of the combination of β-lactam-resistant Gram-negative bacterial pathogens.[76] *The key limitation of avibactam is that it is not active against class B metallo-β-lactamases*. Compared to meropenem-vaborbactam (discussed later), ceftazidime-avibactam is active against pan-β-lactam- and carbapenem- resistant *P. aeruginosa* and has a role for the same. Avibactam is active against OXA-48 enzymes, but vaborbactam and relebactam are not. In addition, avibactam has some intrinsic antibacterial activity because of its ability to bind to some PBPs like PBP2 of *E. coli* and *H. influenzae*, PBPs 2 and 3 of *P. aeruginos*a and *S. aureus,* and PBP3 of *S. pneumoniae*.[76] The combination can be used for treatment of infections caused by MDR *P. aeruginosa* and *Enterobacterales*. The combination has proven to be effective for the treatment of intra-abdominal and complicated urinary tract infection, and was shown to be noninferior to meropenem for the treatment of intra-abdominal infections.[76] Although its activity against anaerobic bacteria is restricted, studies in animal models suggest that avibactam is potent against BlaMab, which is a broad-spectrum β-lactamase produced by *Mycobacterium abscessus*. Resistance mechanisms against ceftazidime-avibactam involve efflux pumps and reduction of porins, resulting in reduced intracellular concentrations of ceftazidime-avibactam.[76]

Vaborbactam, a new β-lactamase inhibitor, is based on a cyclic boronic acid pharmacophore with high-affinity to serine β-lactamases.[77,78] The boron in vaborbactam is electrophilic, and mimics the carbonyl carbon of the β-lactam ring and forms a reversible covalent bond with the catalytic serine of some β-lactamases.[78] It is a potent broad-spectrum inhibitor of class A (e.g., KPC, CTX-M, SHV, TEM) and class C (e.g., P99, MIR, FOX) β-lactamases.[77] It even inhibits the newly discovered class A carbapenemases BKC-1 and FRI-1.[78] Vaborbactam achieves greatest reduction in MICs against KPC-producing strains when combined with carbapenems, compared to other β-lactams.[77] Vaborbactam, however, does not reduce the meropenem MIC of *A. baumannii, P. aeruginosa*, or *S. maltophilia*.[78] Vaborbactam also does not restore the activity of meropenem in the presence of OX-48 or MBLs. Inactivation of the porin protein OmpK36 in *K. pneumoniae* confers resistance to meropenem-vaborbactam (as well as imipenem-relebactam and ceftazidime-avibactam).[78] Pathogens that are resistant to meropenem-vaborbactam include *S. maltophilia, Elizabethkingia meningoseptica,* Aeromonas spp, *A. baumannii,* and class D β-lactamase-producing *K. pneumoniae*.[78] Furthermore, pathogens that are intrinsically resistant to carbapenems due to mechanisms other than β-lactamase production, are resistant to meropenem-vaborbactam, e.g., MRSA and VRE.[78] Meropenem-vaborbactam has a more potent *in vitro* activity against KPC producers and is less likely to acquire resistance, which may make it a preferred agent for KPC-producing CRE, compared to ceftazidime-avibactam.[79] Ceftazidime-avibactam, on the other hand, is the preferred agent for treatment of OXA-48 producing CRE.

Ceftolozane is a fifth-generation cephalosporin and it is available in combination with tazobactam (Figure 51.5).[80] Ceftolozane is structurally similar to late-generation cephalosporins, but has a bulkier side chain at the 3-position of the dihydrothiazine ring (R1 in Figure 51.5). This allows ceftolozane to be the most potent inhibitor of PBP1b and PBP3, which are among the PBPs essential for pseudomonal cell wall synthesis.[81,82] The ceftolozane molecule has a modified side chain at the 3-position of the cephem nucleus. This modification is responsible for its potent antipseudomonal activity, *which is the key feature of ceftolozane*. Ceftolozane is more stable against the Amp-C β-lactamase. Ceftolozane therefore then acts on PBPs, TEMs, SHVs, and AmpC and tazobactam targets class A serine β-lactamases and ESBLs. It is active against carbapenem-, piperacillin/tazobactam-, and ceftazidime-resistant isolates of *P. aeruginosa*. It can evade resistance mechanisms of efflux pumps, reduced uptake through porins, and modification of PBPs employed by Pseudomonas.[38] Ceftolozane has activity against Gram-negative bacilli including those that harbor classical β-lactamase inhibitors, e.g. TEM-1 and SHV-1. Ceftolozane is not active against strains with ESBLs and carbapenemases. Tazobactam, the

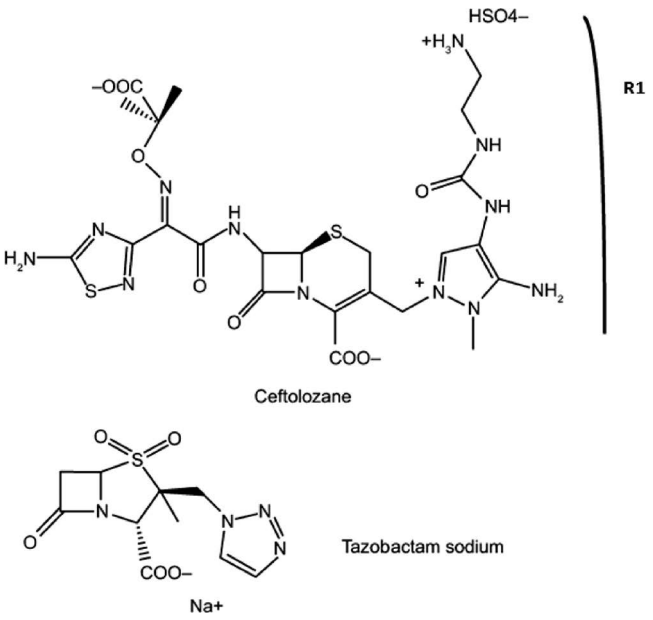

FIGURE 51.5 Chemical structures of ceftolozane and tazobactam.

β-lactamase inhibitor, extends the activity of ceftolozane to most ESBL producers and some anaerobes. Tazobactam inactivates most class A β-lactamases (including many ESBLs) and some class C β-lactamases (cephalosporinases), and ceftolozane is also more resistant to hydrolysis by Pseudomonas-derived cephalosporinase 1 (PDC-1) (a class C β-lactamase) as compared to the previous penicillin that was used in combination with tazobactam (piperacillin).[80] *P. aeruginosa* produces PDC-3, which robustly hydrolyzes early-generation cephalosporins, making it resistant to many β-lactam antibiotics.[80] The combination of ceftolozane and tazobactam is active against extended-spectrum β-lactamase (ESBL)-producing *Enterobacterales*, but it lacks useful activity against carbapenem-resistant strains. [81,82] A study showed that 94.4% of *Enterobacterales* were susceptible to ceftolozane-tazobactam.[83] Ceftolozane-tazobactam was more active than cefepime (90.2% susceptible), ceftazidime (87.3% susceptible), and piperacillin-tazobactam (91.7% susceptible) but less active than meropenem (98.0% susceptible) and amikacin (99.0% susceptible).[83]This study included 9.5% ESBL organisms that were non-CRE phenotype and 87.5% of those were susceptible to ceftolozane-tazobactam.[83] The combination is available for injection and has been approved for the treatment of complicated intra-abdominal and urinary tract infections. Resistance to this combination in *P. aeruginosa* is due to the mutations leading to expression of the AmpC gene and due to horizontally acquired β-lactamases.[82]

Relebactam is a non-β-lactam β-lactamase inhibitor.[84] Structurally, it differs from avibactam in that it contains a piperidine ring in the R1 side chain.[85] The presence of a highly strained bicyclic urea core and electron-withdrawing aminooxy sulfate moiety in its structure makes relebactam more reactive, which in turn makes it an effective inhibitor of β-lactamases.[84] Relebactam is effective against class A and C β-lactamases but not metallo-β-lactamases of class B (VIM, IMP, etc.) and β-lactamases of class D (e.g., OXA). Therefore, the organisms that produce class B (e.g., *S. maltophilia, E. meningoseptica*, *Aeromonas* spp.) and class D β-lactamases (e.g., *A. baumannii*) are resistant to the imipenem-cilastatin plus relebactam combination.[84]

Additionally, organisms in which resistance is not due to the presence of β-lactamases but of some other factor, for example, the presence of efflux pumps such as the MexA-MexB-OprM efflux system, or a mutated or altered PBP to which the binding of β-lactams is reduced, as observed in MRSA, remain unaffected by the combination.[84]

Cefepime is a fourth-generation cephalosporin and is effective against both Gram-positive (but not MRSA) and Gram-negative organisms like *E. coli*, *K. pneumoniae,* and *P. aeruginosa*. Zidebactam is a non-β-lactam bicyclo-acyl hydrazide β-lactamase inhibitor that also has some intrinsic antibacterial activity because of its ability to bind to PBP 2.[86] It inhibits class A, C, and D β-lactamases and also metallo-β-lactamases.[87]

The combination, cefepime, and zidebactam, also known as WCK 5222, is being developed for the treatment of serious infections caused by multidrug-resistant (MDR) and extensively drug-resistant (XDR) Gram-negative bacteria like *Enterobacterales*, and *P. aeruginosa*.

Cefepime-zidebactam was shown to be very active against *Enterobacterales,* producing CTX-M-15 (MIC90, 1 mg/L), SHV (MIC90, 0.25 mg/L), other ESBLs (MIC90, 1 mg/L), plasmidic AmpC (MIC90, ≤0.06 mg/L), derepressed AmpC (MIC90, 0.5 mg/L), KPC (MIC90, 1 mg/L) and metallo-β-lactamases (MIC90, 8 mg/L) in *in vitro* studies.[87] It also showed activity against *P. aeruginosa* with overexpression of AmpC (MIC90, 8 mg/L) and MBLs [MIC90, 8 mg/L].[87] Cefepime-zidebactam showed moderate activity against *A. baumannii* with OXA-23, -24, and -58 with MIC90 of 32 mg/L.[87] It has also been shown to have *in vitro* activity against strains of colistin-nonsusceptible mcr-1- and MBL-producing Gram-negative pathogens.[86]

Monobactam: Aztreonam

The binding of aztreonam to PBP-3 of Gram-negative aerobic organisms results in the formation of nonviable filamentous structures, resulting from the inhibition of cell wall synthesis, and ultimately, bacterial cell death. Its bactericidal activity is limited to aerobic Gram-negative bacteria, because it does not bind to PBPs in Gram-positive or anaerobic bacteria.[88–92] Aztreonam displays an intrinsic stability to metallo-β-lactamase-catalyzed hydrolysis.[93] Aztreonam is currently under development in combination with avibactam. Aztreonam, however, can be inactivated by ESBLs, which can frequently co-occur with MBLs. A current strategy to treat such strains is aztreonam with ceftazidime/avibactam.[79]

Interference with Cytoplasmic Membrane Integrity

Drugs That Disorganize the Cytoplasmic Membrane

Polymyxins: Polymyxin B, Colistin (Polymyxin E)

Polymyxins are cationic antimicrobial peptides, not synthesized by ribosomes, that bind to Lipid A found in the outer membrane of Gram-negative bacteria. Polymyxin is extremely bactericidal, which is related to its high lipopolysaccharide affinity. Positively charged amino acid residues in the drug form a ring and interact with the negatively charged residues in Lipid A, interacting electrostatically and competitively displacing covalent cations (calcium and magnesium) that normally stabilize the lipopolysaccharide molecules in the outer leaflet of the bacterial outer membrane. As a result of studies with liposome systems, it has been postulated that an ionic interaction occurs between the phospholipid phosphate and the ammonium group of polymyxin. Simultaneous proton transfers between these two groups and also between an ammonium group on the phospholipid and a γ-amino group on polymyxin result in neutralization of charge on the polar head of the phospholipid, which can alter the electrostatic and hydrophobic stabilizing forces of the membrane. Liposomes derived from methylated phospholipids are not sensitive to polymyxin; possible explanations are prevention of proper alignment of the phospholipid and antibiotic by the methyl groups, or an increase in the basicity of the phospholipid amino group, which would make proton transfer less favored. A unique and very beneficial property of colistin is its antiendotoxin activity, resulting from its ability to neutralize bacterial lipopolysaccharides (LPS).[94–99] In any case, the interaction also stimulates LPS to aggregate in a concentration-dependent fashion. In fact, it has been shown that at lower concentrations, polymyxins bind to membranes superficially, while at higher concentrations, they insert themselves deeper, as a result of the increase in the surface charge of LPS and the membrane. The drug and its hydrophobic

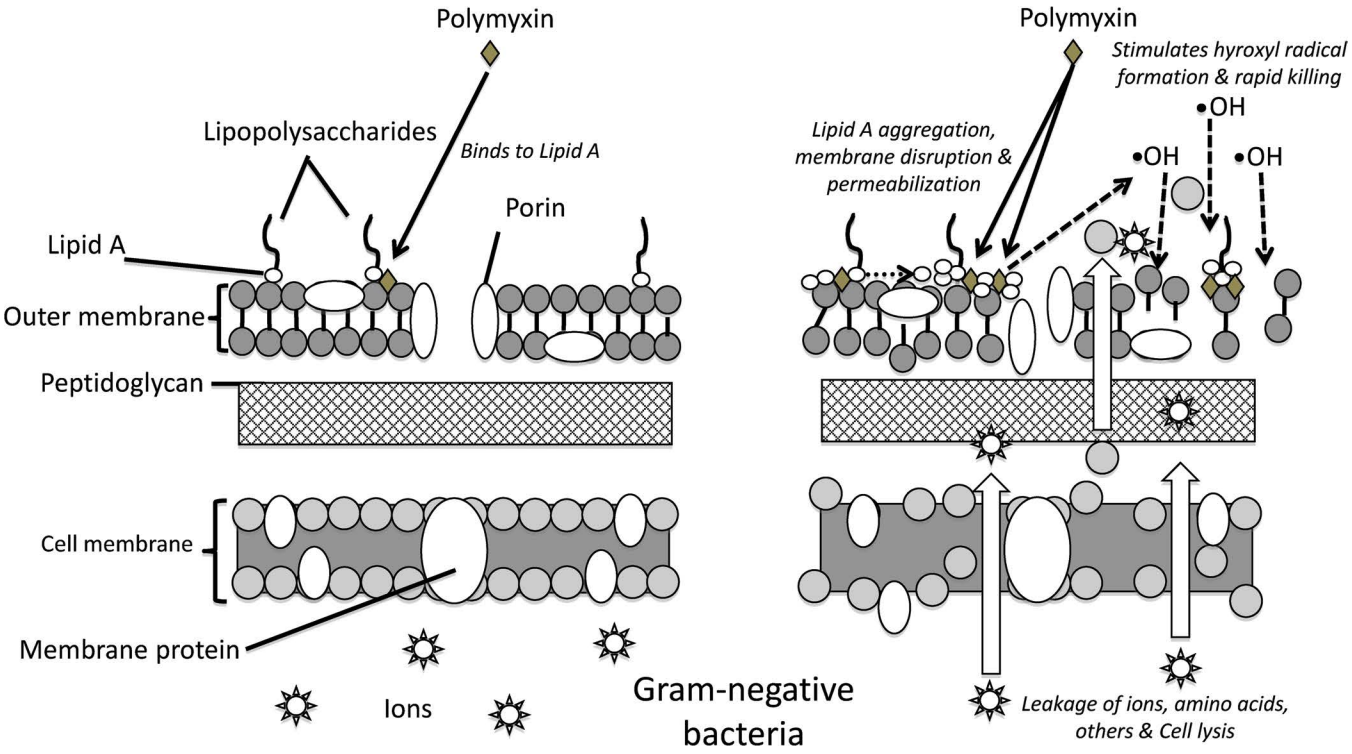

FIGURE 51.6 Mechanism of action of polymyxins.

amino acids then cause membrane permeabilization and disruptions, which result in the release of lipopolysaccharides, and the leakage of cytoplasmic components, including amino acids, uracil, and potassium. All this leads to death of the resulting bacterial cell (Figure 51.6).[100–103]

There is also evidence that polymyxins stimulate hydroxyl radical production which mediates rapid killing (Figure 51.6), holding true even in multidrug-resistant clinical isolates of *A. baumannii*, but not in colistin-resistant bacteria. Interestingly, the presence of significant intracellular iron increases the induction of hydroxyl radicals, whereas low levels of iron are associated with more resistance to oxidative killing.[101,102]

Polymyxin B is regarded as a model compound of polymyxins, which are polypeptides; colistin (polymyxin E) is believed to have an identical mechanism of action. There is evidence though that colistin may also have an added ability to inhibit cell division.[104]

Outer Membrane Protein-Targeting Antibiotic: Murepavadin

Murepavadin is a targeted drug for *P. aeruginosa* and has a novel and nonlytic mechanism of action (Figure 51.7).[105] Murepavadin is a first-in-class outer membrane protein-targeting antibiotic (OMPTA) currently under development for the treatment of hospital-acquired bacterial pneumonia (HABP) and ventilator-associated bacterial pneumonia (VABP).[105,106] The outer membrane (OM) of Gram-negatives is composed of lipopolysaccharides (LPS) on the outer surface and phospholipids on the inner surface.[19] The core-lipid A portion of LPS in *P. aeruginosa* is synthesized on the cytoplasmic side of the inner membrane (IM). It is then flipped to the outer surface of the IM by the ABC transporter MsbA, and more oligosaccharides are added there. Proteins LptD and LptE form a complex to transport LPS from periplasm to the OM. Murepavadin is bactericidal by binding to lipoprotein D (LptD).[105,107] Therefore, it interferes with the transport processes of LptD, leading to lethal modifications in lipopolysaccharides of the OM and cell death.[105] It is highly specific, and disturbances of the patient's natural bacterial flora are not expected.[105]

Drugs That Produce Pores in Membranes

Lipopeptides: Daptomycin

Lipopeptides are a class of antibiotics that are active against multidrug-resistant Gram-positive bacteria. Lipopeptides consist of a linear or cyclic peptide sequence, with either net positive or negative charge, to which a fatty acid moiety is covalently attached at its N-terminus.

Daptomycin is a cyclic lipopeptide with rapid bactericidal action that results from its binding to the cytoplasmic membrane in a calcium-dependent manner. The acyl chain of the daptomycin molecule partly inserts into the membrane. In the presence of Ca^{2+}, which binds to daptomycin, a conformational change occurs leading to membrane binding and oligomerization. This happens by bridging between the anionic daptomycin and the anionic headgroups of bacterial outer leaflet lipids, before the daptomycin molecule is anchored deeper into the membrane and forms aggregates. Daptomycin actually generates random patches on the cell membranes, and the drug-membrane "aggregates" that are formed affect cell division proteins that lead to severe alteration of the cell shapes and the cell membrane itself. These changes occur in multiple sites, producing local membrane

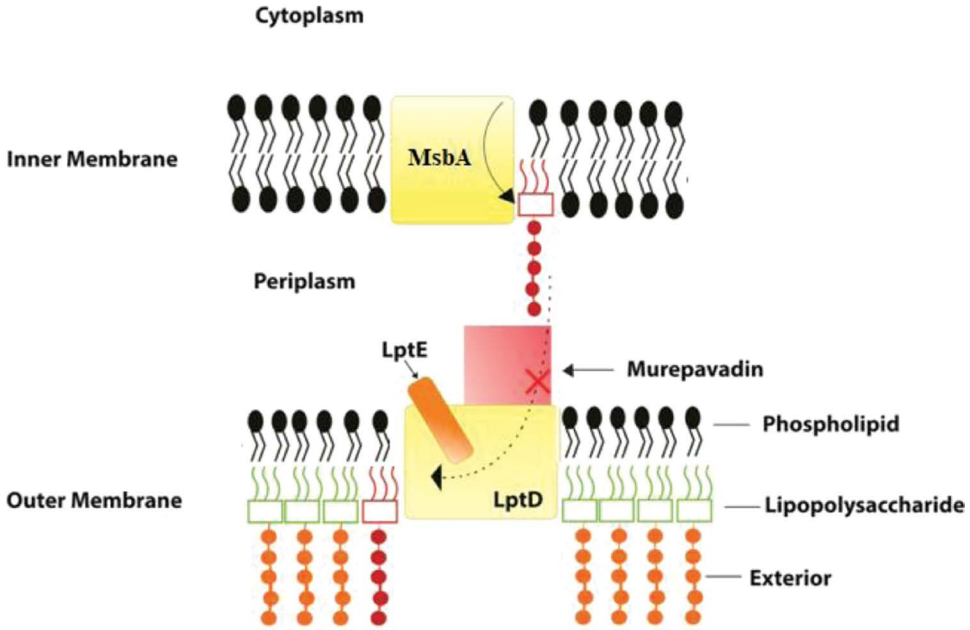

FIGURE 51.7 LPS transport in Pseudomonas aeruginosa. The arrow depicts LPS assembly in the cytoplasm and on the inner membrane and its subsequent transport to outer membrane.

activities, overwhelming the cells, which are unable to respond to the changes. These produce membrane discontinuities that cause leakage of ions and loss of membrane potential, with local dysregulation of cell division or cell wall synthesis. There is also activation of autolysis. Subsequently the bacterial membrane is depolarized and perforated, and cell death ensues (Figure 51.8). Daptomycin is rapidly bactericidal in a concentration-dependent fashion.[16,108–111]

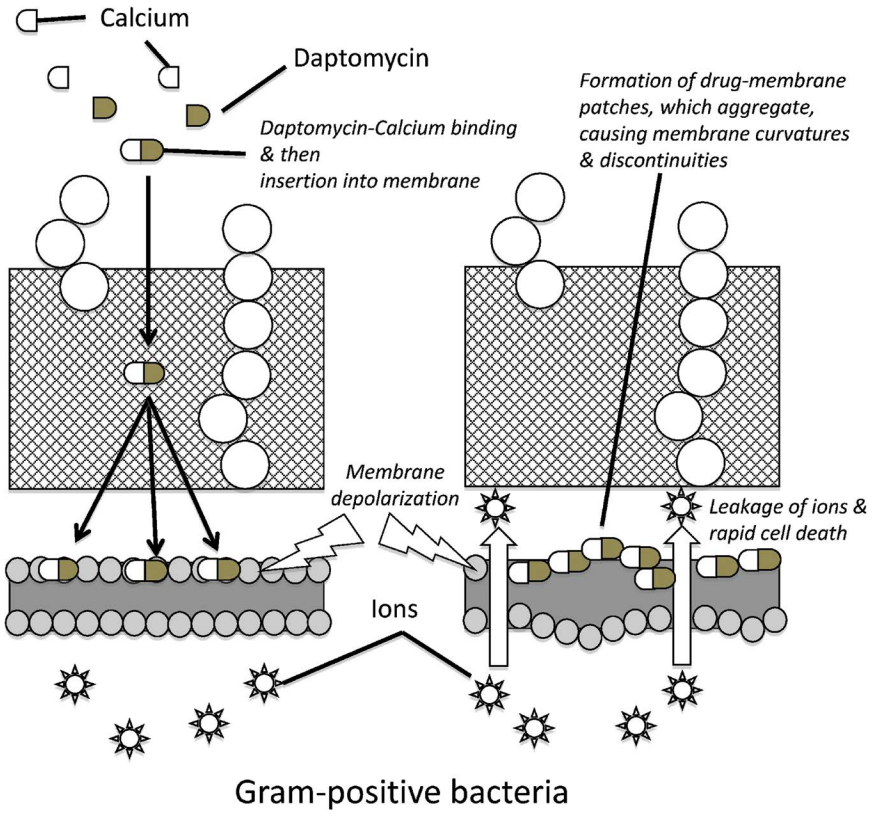

FIGURE 51.8 Mechanism of action of daptomycin.

Peptide Antibiotics: Gramicidin A, Gramicidin S

Gramicidin A is a linear pentadecapeptide with an alternating D- and L-amino acid structural sequence, which is active in a dimer form. In membranes, gramicidin A forms transient channels specific for monovalent cations.[112–116]

Gramicidin S is a cyclic decapeptide that interacts electrostatically with the membrane phospholipids, without incorporating into the lipid region of the membrane. It achieves its bactericidal action by promoting leakage of cytoplasmic solutes by disrupting the barrier properties of cell membranes. It may also cause uncoupling of oxidative phosphorylation as a secondary effect. The interaction of this peptide with the phospholipid bilayer is nonspecific, and in addition to the antimicrobial activity, it exhibits a highly hemolytic activity by interacting with the lipid bilayer of erythrocytes, limiting its use to topical preparations.[117–119]

These peptides kill bacteria by making the cell membranes permeable after interacting with the lipid bilayers. To date, the mechanism by which they do it is either through forming a peptide "carpet" on the membrane surface or by making a transmembrane pore. However, a different study suggests that gramicidin S does not form membrane pores.[216] Studies on the structural properties of Gramicidin S 14 gave some insight into the mechanism by which these peptides disrupt the membrane. Molecular models showed that since Gramicidin has a much shorter hydrophobic length compared to the hydrophobic lipid layers, each peptide displaced six to eight lipid molecules. Therefore, multiple peptides together, would form a "carpet" that would displace even more lipids, producing curvature strain at first, then disruption of the membrane. One of the latest structural studies also suggests that Gramicidin S self-assembles an oligomeric β-barrel pore that is stabilized by hydrogen bonding.[119,120]

Inhibition of Nucleic Acid Synthesis

Inhibitors of DNA Replication

Quinolones/Fluoroquinolones

The principal targets for the antibacterial activity of quinolones are DNA gyrase and topoisomerase IV, which are both bacterial type II topoisomerases.[121]

DNA gyrase is a tetramer enzyme with two GyrA and GyrB subunits (encoded by the *gyrA* and *gyrB* genes) that catalyzes the introduction of negative superhelical turns and elimination of positive supercoils at the replication fork into the double-stranded covalently closed circular bacterial DNA. DNA gyrase acts before the replicating fork, preventing replication-induced structural changes.[122]

Topoisomerase IV is also an enzyme composed of pairs of two subunits, named ParC and ParE (homologous to GyrA and B, but encoded by genes *parC/parE*) in *E. coli* and with GrlA and GrlB (encoded by genes *grlA/grlB*) in *S. aureus*. A *parF* locus has been identified in *Salmonella typhimurium* and is suggested to be involved in topoisomerase IV activity. Topoisomerase IV acts behind the replicating fork and catalyzes removal of supercoils and decatenation (unlinking) of interlocked daughter DNA molecules.[123]

Both DNA gyrase and topoisomerase IV appear to be targeted by all quinolones, regardless of bacterial species. However, the preferred drug target depends on the organisms and on the drug. For example, the preferred site of action for levofloxacin is topoisomerase IV, while the main target for moxifloxacin and gatifloxacin is DNA gyrase. In Gram-negative bacteria, DNA gyrase is generally bound more readily by quinolones. In Gram-positive bacteria, topoisomerase IV is generally preferred.[124,125]

To summarize (Figure 51.9), the first central step is the formation of the fluoroquinolone-enzyme-DNA complex. Next is

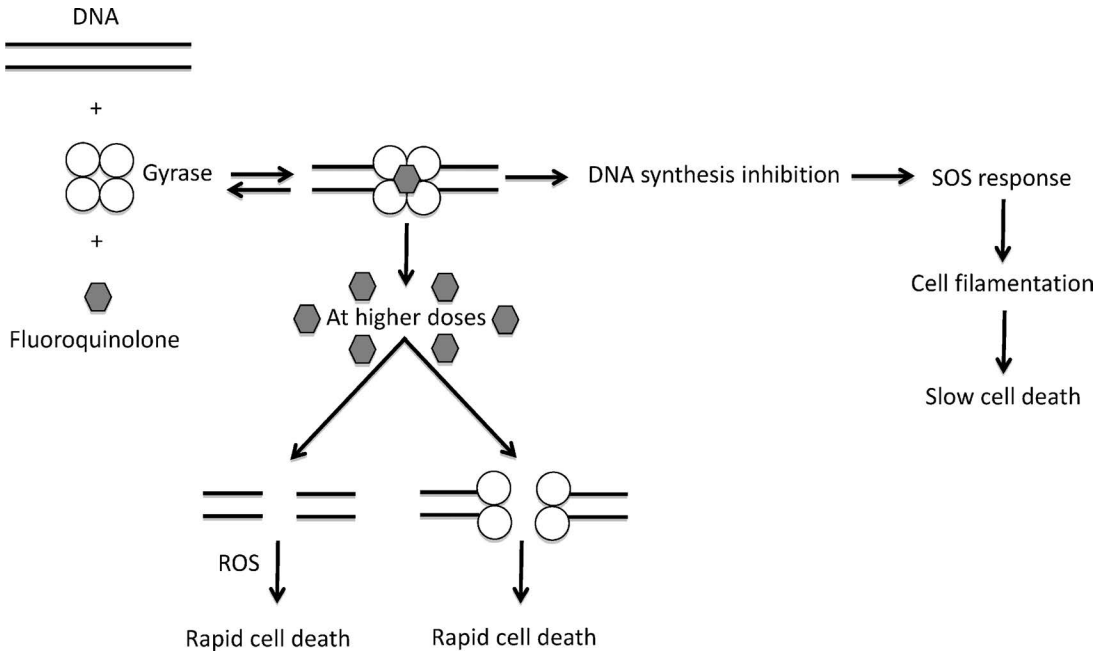

FIGURE 51.9 Mechanism of action of fluoroquinolones.

the bacteriostatic step, where there is formation of cleaved complexes. The quinolones turn these type II enzymes into toxins that keep the cleavage complexes in an open form by creating breaks in the chromosome.[121] This blocks bacterial DNA replication, stimulates the SOS response, and causes cell filamentation, and presumably slow cell death. With higher concentrations, DNA breaks occur via two pathways: the protein synthesis-dependent pathway, where the drug-gyrase complex is removed from the DNA and there is liberation of double-stranded DNA breaks; and the protein synthesis independent pathway, where the gyrase subunits dissociate and the DNA ends attached to them are released. These pathways result in stimulation of reactive oxygen species to act and cause irreversible oxidative DNA damage.[126]

Nalidixic acid, the first quinolone discovered and used in clinical practice, has a narrow spectrum of activity (active against Gram-negative bacteria).[126–128] But chemical structure changes at positions 1, 6, 7, and 8 resulted in more potent antibacterials.[129] The second-generation quinolones are "fluorinated" quinolones (hence the term "fluoroquinolones") and were discovered in the mid-1980s. They (e.g., norfloxacin, ciprofloxacin, enoxacin, ofloxacin, and pefloxacin) all have a fluorine atom at position 6, plus a piperidine at position 7, resulting in a much broader spectrum of activity that includes *P. aeruginosa* and some Gram-positive bacteria, such as *S. aureus*, and improved bioavailability. The third-generation fluoroquinolones (e.g., sparfloxacin, grepafloxacin, temafloxacin, and levofloxacin) have even better Gram-positive coverage, especially against pneumococci, and good potency versus anaerobes because of substitutions at positions 7 and 8. The fourth-generation fluoroquinolones (garenoxacin, gemifloxacin, gatifloxacin, moxifloxacin, and trovafloxacin) have even greater activity against pneumococci and anaerobes. Several fluoroquinolones, such as ciprofloxacin, levofloxacin, and moxifloxacin, have extensive usage in clinical practice for treatment of Gram-negative and some Gram-positive bacterial pathogens.[122,124–128,130–132]

Ozenoxacin is a novel topical, nonfluorinated quinolone antimicrobial.[133] It is used topically for the treatment of impetigo.[134] It binds with greater affinity than other established quinolones to both DNA gyrase and topoisomerase IV. It is active against Gram-positive organisms including MSSA, MRSA, methicillin-resistant Staphylococcus epidermidis, and Streptococcus pyogenes in vitro, and in clinical trials.[10,11] It also has activity against aerobic Gram-negative bacteria, but it is inferior to the activities of older quinolones. Resistance mechanisms are similar to those of other quinolones, including loss of binding affinity to its targets, efflux pumps, and modified bacterial porin channels.[11]

Delafloxacin is an anionic synthetic fluoroquinolone with broad-spectrum bactericidal activity against Gram-positive, Gram-negative, atypical (Legionella, Chlamydia, and Mycoplasma), and anaerobic bacteria in a concentration-dependent manner.[135,136] Other quinolones have binding affinity primarily for either DNA gyrase or topoisomerase IV, whereas delafloxacin is a dual-targeting fluoroquinolone that binds to both enzymes, leading to broader activity against Gram-positive and Gram-negative bacteria.[137] It forms cleavable complexes with topoisomerase IV or DNA gyrase.[27] It has similar affinity for both types of enzymes as other quinolones, however, due to mechanisms not completely understood, it has greater potency for Gram-positives.[27] It has been hypothesized that this improved affinity is due to structural features of the delafloxacin molecule, namely the presence of a heteroaromatic substituent at position 1, a weak polarity associated with the presence of a chlorine in position 8, and a lack of basic group in position 7 next to the fluorinated ring, which contributes to its weakly acidic properties.[135] This anionic structure of delafloxacin helps to enhance its potency in the acidic infectious or inflammatory environment, which is not seen with other quinolones.[137] It has activity against levofloxacin nonsusceptible (i.e., intermediate and resistant) strains of MRSA and MSSA, methicillin-susceptible and resistant coagulase-negative staphylococci, *S. pneumoniae*, β-hemolytic streptococci, viridans group streptococci, *P. aeruginosa*, and against isolates with documented mutations in the quinolone resistance-determining region.[136,137] It is active against *E. faecalis* but not against *E. faecium*.[137] *S. aureus* was eradicated in 98.4% of patients with acute bacterial skin and skin structure infections receiving delafloxacin, and the eradication rates were similar against levofloxacin-nonsusceptible and methicillin-resistant strains of *S. aureus*.[136] Mutations in both the gyrA and gyrB were required for resistance to delafloxacin in a mutant selection study.[17]

Triazaacenaphthylene: Gepotidacin

Gepotidacin is the first member of the class triazaacenaphthylene antibacterial and is a topoisomerase II inhibitor.[138] It has a unique mechanism of action that is currently not known for any other antibacterial agent. It arrests bacterial DNA replication, and consequently cell division, by acting on GyrA and ParC subunits of bacterial DNA gyrase and topoisomerase IV, respectively.[139] It is bactericidal against many drug-resistant Gram-positives, including MRSA, and Gram-negatives, including ESBL-producing strains of *E. coli*.[138] Its novel mode of action that is different from that of fluoroquinolones allows activity against fluoroquinolone-resistant strains, including fluoroquinolone-resistant *Neisseria gonorrhoeae*.[138] The novelty is that it has a binding site that is close to but distinct from that of quinolones and it does not form "cleavage complex". Gepotidacin binds to a distinct site and stabilizes the precleavage type II topoisomerase enzyme-DNA complex prior to DNA cleavage, generating single-strand breaks, instead of stabilizing DNA double-strand breaks as fluoroquinolones do. A study suggests that it is safe and effective for the treatment of Gram-positive acute bacterial skin and skin structure infections by both oral and intravenous routes.[139] Phase 2 trials of the use of gepotidacin as a single, oral dose for the treatment of uncomplicated urogenital gonorrhea due to *N. gonorrhoeae* was shown to be almost 95% effective for bacterial eradication.[140]

Spiropyrimidinetrione: Zoliflodacin

Zoliflodacin is an experimental spiropyrimidinetrione antibiotic that has completed phase II clinical trials for the treatment of gonorrhea. Its mode of action is to inhibit bacterial DNA gyrase/topoisomerase. It works by blocking re-ligation of the double-stranded cleaved DNA to form fused circular DNA.[141] It has shown *in vitro* activity against *Chlamydia trachomatis* and *Chlamydia pneumoniae,* and *Mycoplasma* and *Ureaplasma* species.[142,143] It also has potent *in vitro* activity against a number of Gram-positives (*S. aureus, S. epidermidis, S. pneumoniae, S. pyogenes, and Streptococcus agalactiae*), fastidious Gram-negatives (*Haemophilus influenzae* and

N. gonorrhoeae), atypical (*Legionella pneumophila*), and anaerobic (*Clostridioides difficile*) organisms, including those resistant to fluoroquinolones.[141]

Nitroimidazoles: Metronidazole and Secnidazole

Nitroimidazoles—with the class representative metronidazole—are cytotoxic to obligate anaerobes and facultative anaerobic bacteria through a four-step process: (1) entry into the bacterial cell by diffusion across the cell membrane; (2) reduction of the nitro group by the intracellular electron transport proteins; the nitro group of metronidazole acts as an electron recipient, capturing electrons that are usually transferred to hydrogen ions in the oxidative decarboxylation of pyruvate cycle; the concentration gradient created by this process promotes further uptake of metronidazole into the cell and formation of intermediate compounds and free radicals toxic to the cell; (3) interaction of cytotoxic byproducts with host cell DNA, resulting in DNA strand breakage, inhibited repair, and ultimately disrupted transcription and cell death; (4) the toxic intermediate compounds decay into inactive end-products.[144–147]

Aerobic bacteria are intrinsically resistant to metronidazole because these microbes lack electron-transport proteins with negative redox potential, making the drug inactive. It has activity versus some microaerophiles (e.g., *Helicobacter pylori*), although reoxidation can occur with exposure to oxygen, which will return it to its inactivated state.[148]

Secnidazole (a,2-Dimethyl-5-nitroimidazole-1-ethanol) is a 5-nitroimidazole and has a longer half-life than metronidazole. It is approved for the treatment of bacterial vaginosis (BV).[149] BV is characterized by a decrease in lactobacilli and an increase in other bacteria like *Gardnerella vaginalis, Atopobium vaginae*, and other anaerobes.[150] Secnidazole has activity against most bacteria implicated in BV and has limited activity against lactobacilli, the microbes that are important in maintaining vaginal health.[149] The MIC_{90} for secnidazole was similar to metronidazole and tinidazole for *Atopobium vaginae, Bacteroides* species, *Finegoldia magna, G. vaginalis, Mageeibacillus indolicus,* Megasphaera-like bacteria, *Mobiluncus curtisii* and *mulieris, Peptoniphilus lacrimalis* and *hare*, *Porphyromonas* species, *Prevotella bivia, Prevotella amnii,* and *Prevotella timonensis*.[151] The MIC_{90} of all lactobacilli tested was >128 mg/mL for secnidazole and metronidazole.[151] While not currently approved for such treatment in the United States, it is used for trichomoniasis, amebiasis, and giardiasis in other parts of the world.[151]

Inhibitors of RNA Polymerase: Rifamycins, Rifampin, and Rifaximin

Rifamycins, with rifampin as a class representative, specifically inhibit bacterial DNA-dependent RNA polymerases by blocking the RNA chain initiation step of bacterial DNA transcription to messenger RNA that is needed to synthesize bacterial proteins.[152] Rifampin is used as part of a combination regimen in the treatment of mycobacterial infections and some Gram-positive infections (e.g., *S. aureus, S. epidermidis*). Rifampin is bactericidal against Gram-positive bacteria, and in addition, diffuses well into biofilm where it continues to be bactericidal. It has the ability to disrupt biofilm, but one of the downsides of its use is that it may select fairly readily rifampin-resistant mutants. This is why rifampin should always be used in combination with other antibiotics. *In vitro* studies have shown that there is rapid synergy when rifampin is given with a β-lactam, and slower synergy with vancomycin.[152–154]

Rifamycins bind very tightly to the β-subunit of the RNA polymerase in a molar ratio of 1:1. They do not bind well to β-subunits of RNA polymerase isolated from rifamycin-resistant mutants, and mutations are found in the β-subunits of RNA polymerase in such mutants that reduce such binding of rifampin to ß-subunits of RNA polymerase. Mammalian enzymes are not affected by rifampin. Rifamycins also modify bacterial pathogenicity and may alter attachment and tissue toxicity.[155–157]

Rifaximin is a novel semisynthetic derivative of rifamycin, used for treatment of enteric infections because it is virtually nonabsorbable from the gastrointestinal tract and is active against enteric infections. Like other rifamycins, the mechanism of action involves binding of rifaximin to the β-subunit of the bacterial DNA-dependent RNA polymerase, inhibiting initiation of chain formation in RNA synthesis. In contrast to rifampin, rifaximin does not diffuse readily, is poorly absorbed, and so acts topically in the lumen of the gut. Another distinction from rifampin is that it is much less prone to select microbial resistance.[157,158]

Inhibition of Ribosome Function and Protein Synthesis

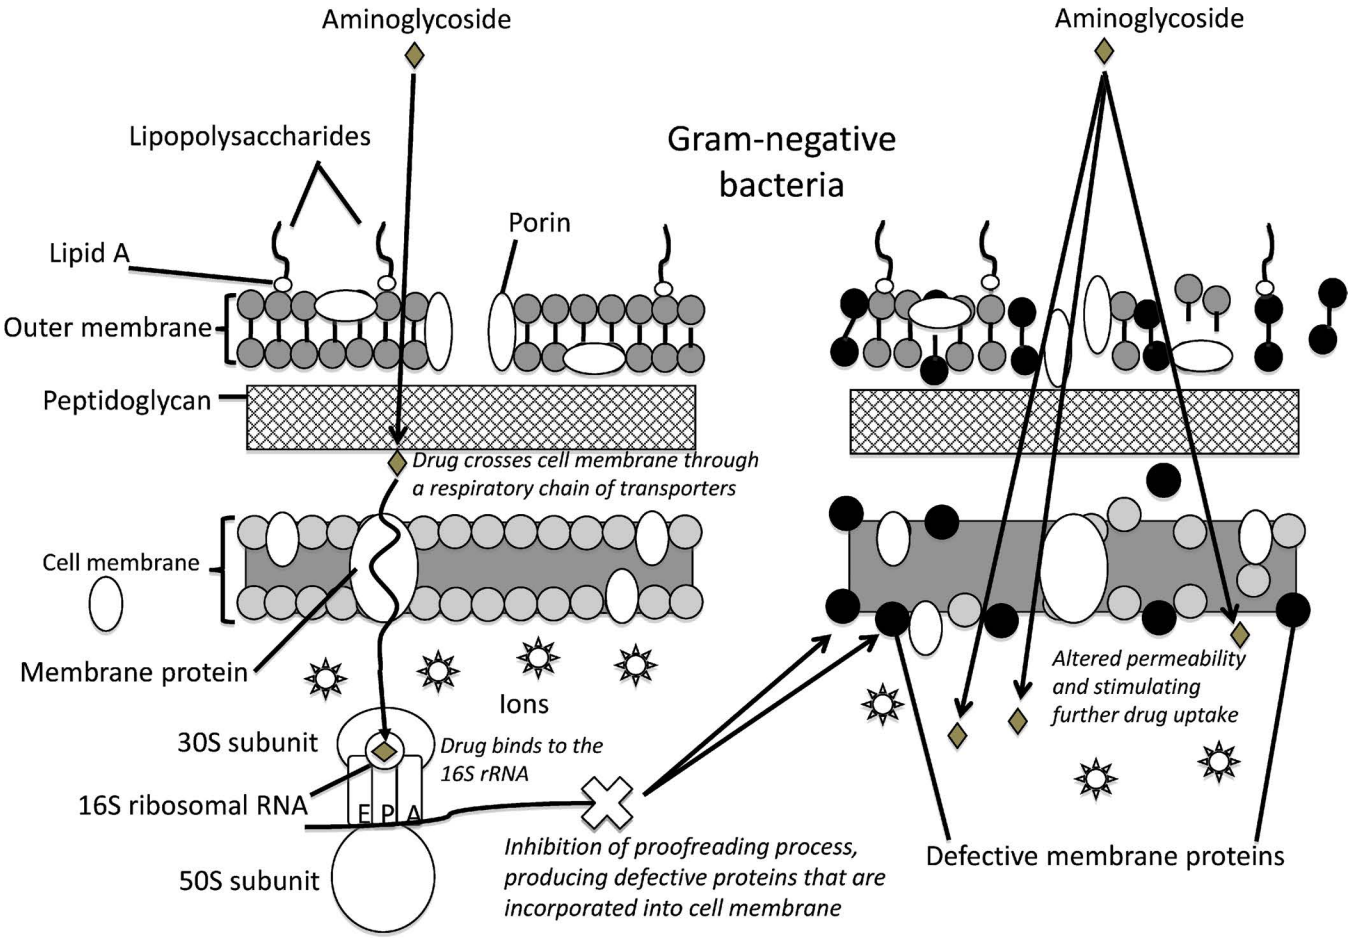
Inhibitors of 30S Ribosomal Subunits

Aminoglycosides

The aminoglycoside antibiotics (also known as aminocyclitols) are hydrophilic sugars with multiple amino groups, protonated at physiological pH to function as polycations. Two main categories of aminoglycosides are exemplified by the streptidine-containing class (primarily, streptomycin) and the 2-deoxystreptamine-containing aminoglycosides that include neomycin, kanamycin (with its derivative amikacin), gentamicin, and tobramycin.

Aminoglycosides are bactericidal antibiotics that target accessible regions of polyanionic 16S rRNA on the 30S ribosomal subunit, decreasing the accuracy of the translation of mRNA into protein by contributing to the misreading of codons in the mRNA. As a result of the tight binding of 2-deoxystreptamine aminoglycosides in the major groove of helix H44 of 16S rRNA, the A site in the 30S ribosomal subunit undergoes a conformational change. Incorporation of noncognate (or near-cognate) aminoacyl-tRNAs is allowed and the error rate of the ribosome is increased. Elongation is also retarded, but less drastically. As for the 2-deoxystreptamine aminoglycosides, the binding of streptomycin also allows the binding of near-cognate tRNAs to the mRNA, so mistranslation ensues. Studies with ribosomes from streptomycin-resistant mutants have shown that protein S12 of the 30S ribosomal subunit is altered; therefore, it plays a role in the binding of streptomycin to normal ribosomes and the resulting effects. Studies have shown that aminoglycosides also have a role in the inhibition of assembly of the 30S ribosomal subunit.[159–163]

The uptake of aminoglycosides into Gram-negative bacteria is energy-dependent, but is inhibited by divalent cations, hyperosmolarity, low pH, and anaerobiosis, explaining why this drug class is ineffective versus anaerobic bacteria, and is poor against



Abbreviation: rRNA – ribosomal ribonucleic acid

FIGURE 51.10 Mechanism of action of aminoglycosides.

localized infections with low pH and low pO_2, such as abscesses. The two phases of aminoglycoside uptake are: when small amounts of the drug cross the cell membrane by using a membrane-bound respiratory chain of electron transporters and when the drug binds to the 16S rRNA component of the 30S subunit of the bacterial ribosome. All this leads to the inhibition of the proofreading process in the rRNA, producing defective proteins that are incorporated in the cell membrane, causing increased permeability and stimulating further aminoglycoside uptake. This process will lead to bacterial cell death (Figure 51.10).[163,164]

Some aminoglycosides that are available in other countries include: Isepamicin, a derivative of gentamicin, is not degraded by the aminoglycoside-modifying enzyme (AME) called type I 6'-N-acetyltrasferase (AAC(6')-I), which acetylates, and this inactivates amikacin; and Arbekacin, a derivative of dibekacin, is another aminoglycoside that is also resistant to many AMEs, and it has been shown to have good activity against MRSA in *in vitro* studies. Arbekacin is licensed in Japan for systemic use while in United States, it is under developmental stages as an inhalation solution.[217] In addition, plazomicin, an aminoglycoside, was approved by the U.S. Food and Drug Administration (FDA) for treatment of cUTIs.[218] The drug is also resistant to inactivation by most AMEs and so may be a promising new agent for MDR bacteria.[164–166]

New laboratory research on aminoglycosides has come up with two new classes, pyranmycin, which is structurally related to neomycins, but with a 4,5-disubstituted 2-deoxystreptomycin core and a pyranose as the ring component; and amphiphilic neomycin (NEOF004). The former possesses the traditional mode of action already described, but with an additional antifungal activity, while the latter, a structurally modified neomycin, was shown to disrupt the bacterial cell wall. Another novel aminoglycoside, FG08, which is similar to kanamycin (except for a C-8 alkyl chain at the 4''-O position at ring III), acts as a broad-spectrum antifungal, but surprisingly has no antibacterial activity.[164,167]

Plazomicin is a novel semisynthetic aminoglycoside that is derived from sisomicin.[168] As with other aminoglycosides, it binds to the 30S ribosomal subunit of bacteria, thereby inhibiting protein synthesis. It is active against aerobic Gram-positive and Gram-negative bacteria, including organisms producing ESBLs, carbapenemases, and/or AMEs, and also organisms with site mutations conferring fluoroquinolone resistance.[168–170] Plazomicin was active against 99.3% of Enterobacterales (*E. coli*, *Klebsiella* spp., *Proteus* spp., and *Enterobacter* spp) isolates carrying AMEs, while amikacin, gentamicin, and tobramycin were active against 90.1%, 20.9%, and 18.3%, respectively.[25] CREs can be resistant to plazomicin due to production of 16S rRNA methyltransferases, which are often associated with New Delhi

metallo-ß-lactamase-1 (NDM-1), which is so far not yet common in the United States.[171] It has activity against colistin-resistant *Enterobacterales* as well, which are commonly resistant to older aminoglycosides.[168] A study showed that plazomicin inhibited 93.7% of colistin-resistant *Enterobacterales*.[168]

The mechanism of aminoglycoside resistance is generally by production of AMEs, which are encoded by genes on plasmids and can be present in various combinations in a given isolate.[171] Plazomicin is an aminoglycoside that is not inactivated by the vast majority of AMEs, such as acetyl-, phosphoryl- and nucleotidyltransferases.[172]

A study tested 110 CRE isolates for susceptibility to plazomicin and reference aminoglycosides and carbapenems. Of these, 97.3% and 100% were nonsusceptible to meropenem and imipenem, respectively. Similarly, many isolates were nonsusceptible to amikacin (76.4%), gentamicin (18.2%), kanamycin (91.8%), and tobramycin (96.4%). On the other hand, MIC50/MIC90 values for plazomicin were 0.5/1 mg/L for all 110 carbapenemase-producing isolates. Only one isolate, which was an NDM-1-producing *K. pneumoniae,* was resistant to plazomicin. Across the literature, plazomicin MICs against all tested isolates have been ≤4 µg/mL, except for a set of CRE isolates producing NDM-1 MBL because of associated 16S rRNA methyltransferases.[7] A large phase III clinical trial showed plazomicin to be noninferior to meropenem in the treatment of cUTI and it is FDA-approved for this indication.[26]

Tetracycline, Doxycycline, Minocycline, Omadacycline, Sarecycline, and Eravacycline

Tetracycline and the more recent members of the class, doxycycline and minocycline, exert their antibacterial effect by initially traversing the outer membrane of Gram-negative bacteria through the OmpF and OmpC porin channels as positively charged cation-tetracycline coordination complexes. The metal ion-tetracycline dissociates in the periplasm and tetracycline diffuses through the inner (cytoplasmic) membrane and binds to the acceptor A site on the 30S ribosomal subunit, subsequently preventing the binding of the incoming aminoacyl-tRNA (Figure 51.11). Since this interference is reversible, tetracyclines are bacteriostatic. A specific major binding site and a lower affinity binding site of tetracycline have been identified by determining the crystal structure of the 30S ribosomal subunit with the bound drug.[173–175]

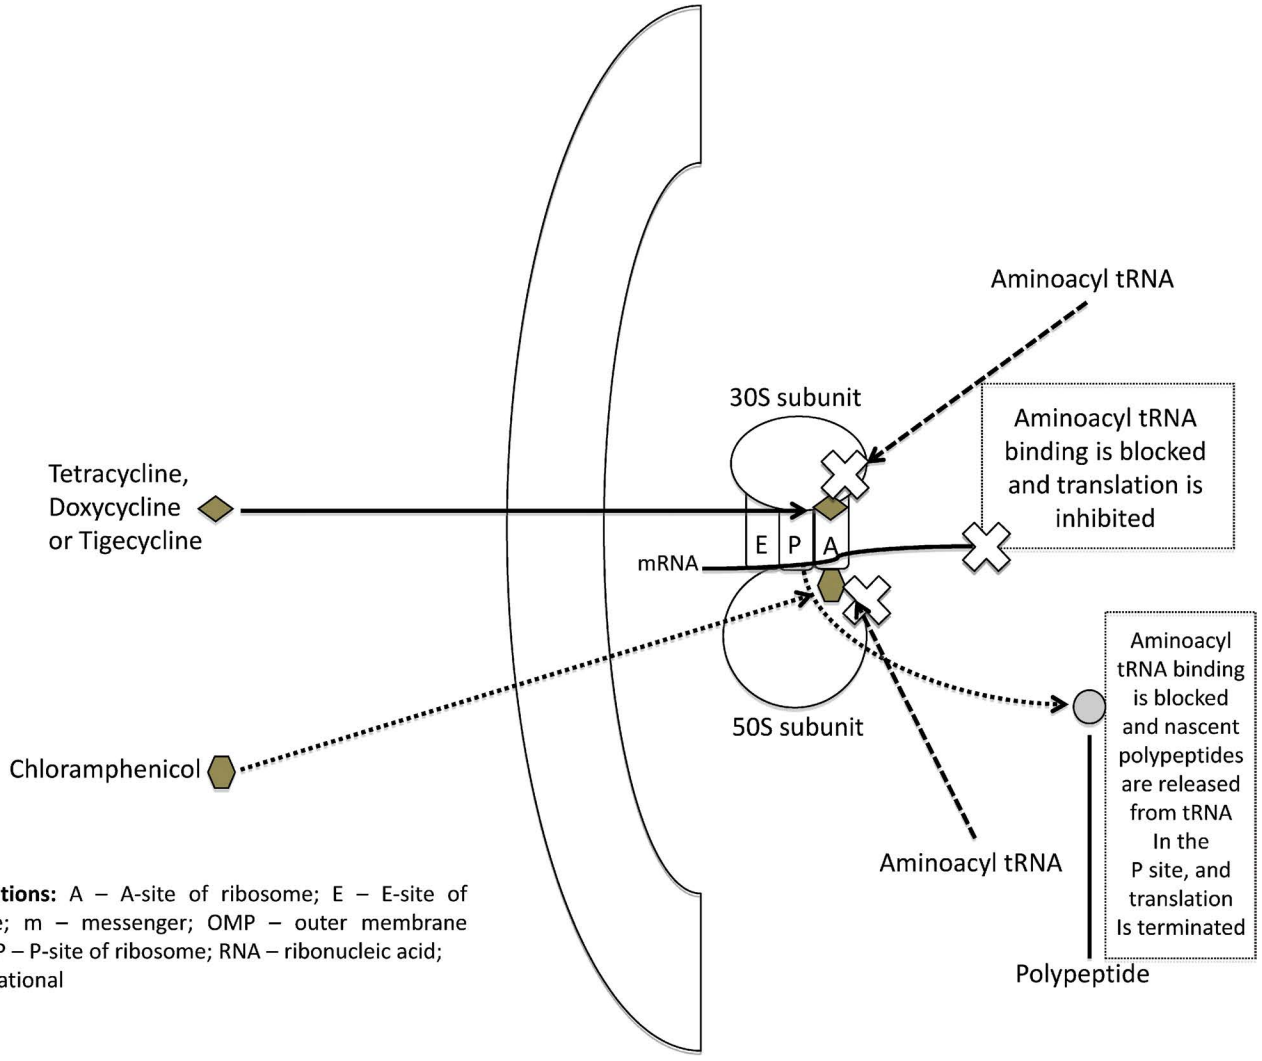


FIGURE 51.11 Mechanism of action of tetracycline, doxycycline, minocycline, tigecycline, and chloramphenicol.

Minocycline is more potent versus Staphylococcus (especially, CA-MRSA strains) than tetracycline or doxycycline, and *in vitro* data have shown that it may be active versus multidrug-resistant *Acinetobacter baumannii*.[176]

A novel semi-synthetic aminomethylcycline that is first in its class is omadacycline, a noteworthy approach to tetracycline resistance. It is derived from minocycline, and structural modifications include the presence of an aminoethyl group at the C9 position of the basic tetracycline structure.[182] As a result of this modification, omadacycline can evade bacterial resistance mechanisms, such as tetracycline efflux and ribosomal protection.[182] Omadacycline has potent activity versus skin and pneumonia pathogens, including CA-MRSA, β-hemolytic streptococci, penicillin-resistant *S. pneumoniae*, *H. influenzae,* and *Legionella*. It was approved by the FDA in 2018 for acute bacterial skin and skin structure infections (ABSSI) and community-acquired bacterial pneumonia (CABP).[219] Interestingly, it is not affected by the presence of either efflux (tet[K]) or ribosome protection (tet[M]) mechanisms that confer resistance to tetracycline. Omadacycline is active with or without Tet(O), unlike tetracycline, which is inhibited when the ribosomal protection protein, Tet(O), is present.[177]

In the tetracycline class, sarecycline is the first narrow-spectrum antibiotic for acne treatment. It has a stable modification at position C7–7-[methoxy(methyl)amino]methyl. This modification can potentially overcome a tetracycline resistance mechanism.[178] Sarecycline was also shown to have anti-inflammatory effects *in vitro*.[179] Unlike other tetracyclines, it has targeted activity against *Cutibacterium acnes* and is less active against aerobic Gram-negative bacilli and anaerobic bacteria that constitute normal gut microbiota.[178] Due to its targeted activity, it thus has fewer complications of diarrhea and fungal overgrowth.[178] This is especially important in patients undergoing treatment of acne, which requires longer duration of treatment. Sarecycline also has a low level of acquired resistance in *C. acnes* strains.[178]

Eravacycline is a fully synthetic fluorocycline in the tetracycline class that has activity against most Gram-negative and Gram-positive aerobic and facultative bacteria. Like other tetracyclines, it is a potent inhibitor of the bacterial ribosome. There are modifications at both the C-7 (fluorine) and C-9 [2-(pyrrolidin-1-yl) ethanamido] positions on the tetracyclic core.[180] It has activity against strains that are resistant to cephalosporins, β-lactam-β-lactamase inhibitors, carbapenems, and fluoroquinolones.[181] It is not active against *P. aeruginosa* and *Burkholderia cenocepacia*, but is active against *Acinetobacter baumannii*.[180] There are two main acquired tetracycline-specific resistance mechanisms that do not affect eravacycline activity: drug efflux and ribosomal protection. The activity of eravacycline was minimally affected by these resistance mechanisms.[180] Extended-spectrum β-lactamases are a common problem in healthcare settings, and eravacycline has *in vitro* activity against ESBL-producing *Enterobacterales*. It is also active against methicillin-resistant *S. aureus*, carbapenem-resistant *Enterobacterales*, and vancomycin-resistant enterococci.[180,181] Eravacycline was shown to be noninferior to ertapenem in complicated intra-abdominal infections requiring surgery or drainage and is FDA-approved for this indication.[181,182]

Tetracyclines have been found to have antimalarial activity by specifically blocking the expression of the apicoplast gene, leading to the distribution of nonfunctioning apicoplasts into merozoites, which is responsible for the slow but potent antimalarial activity.[183]

Glycylcycline: Tigecycline

Tigecycline is the 9-*t*-butylglycylamido derivative of minocycline. The central 4-ring carbocyclic skeleton and the addition of the large *N*-alkyl-glycylamido group provide the drug with a broad spectrum of activity (Gram-positive bacteria broadly, including MRSA, and Gram-negative bacteria [primarily *Enterobacterales*, not *P. aeruginosa*], anaerobes, and even many multidrug-resistant pathogens) and allow evasion from two major mechanisms of tetracycline resistance: tetracycline-specific efflux pump acquisition and ribosomal protection by production of a protein that sterically blocks the binding of tetracycline but not of tigecycline. Tigecycline exerts its effects by binding to the H34 helical region on the 30S ribosomal subunit of bacteria and blocking entry of amino-acyl transfer RNA into the A site of the ribosome. Studies have shown that protein S7 and 16S rRNA bases are essential to binding action, and that the ribosome-binding actually causes structural changes in the 16S rRNA. Compared with tetracyclines, tigecycline binds five times more efficiently to this ribosomal target site and subsequently amino acid residues are prevented from incorporation into elongating peptide chains and protein synthesis is inhibited. All these explain the bacteriostatic nature of tigecycline, which is the end-result of protein synthesis inhibition.[184–188]

Inhibitors of 50S Ribosomal Subunits

Chloramphenicol

Chloramphenicol inhibits peptide bond formation in bacterial ribosomes by binding to the 50S ribosomal subunit at low- and high- affinity sites. This inhibition is explained by the slow binding of chloramphenicol to the peptidyl transferase center of the 50S ribosomal subunit in the A-site, inhibiting that enzyme's activity, and subsequently blocking the interaction of the aminoacyl-tRNA with the A-site. Specifically, the entry of the 3'-terminus of the aminoacyl-tRNA is blocked from entering the ribosomal catalytic cavity. This results in translation termination and translation inaccuracies, producing nascent polypeptides that are released prematurely from the tRNA in the P site (Figure 51.7).[189–192]

Lincomycin and Clindamycin

Lincomycin and its chlorinated derivative, clindamycin, inhibit the peptidyl transferase function of the 50S ribosomal subunit, resulting in alteration of the P-site to produce an enhanced binding capacity for the fMet-tRNA. At lower concentrations, these antibiotics also interact with the process of peptide chain initiation in cell free systems. Both agents are protein synthesis inhibitors and are bacteriostatic. Clindamycin is more active than lincomycin in treating bacterial infections, especially those caused by staphylococci, streptococci, and anaerobes. An additional advantage of clindamycin is its ability to inhibit exotoxin production in toxic shock syndromes. Furthermore, it has been demonstrated that both drugs can act on peripheral ribosomes, causing selective inhibition of hemolysin and streptolysin S synthesis.[60,193–198]

Macrolides: Erythromycin, Azithromycin, Clarithromycin, and Fidaxomicin

Macrolides bind to the 50S ribosomal subunit of susceptible bacteria, inhibiting RNA-dependent protein synthesis. In addition, they appear to have anti-inflammatory activity as suggested by clinical trials in patients with chronic inflammatory lung diseases, in whom macrolides effect significant improvements in lung function, quality of life, and frequency of exacerbations.[60,199]

Erythromycin inhibits prokaryotic, but not eukaryotic, protein synthesis as a result of its binding to the 50S ribosomal subunit. Ribosomal protein L4 may be involved in this interaction since some erythromycin-resistant bacterial mutants have exhibited an altered L4 protein. It has been postulated that erythromycin inhibits translocation by preventing the positioning of peptidyl-tRNA in the donor site. Other studies have indicated that the peptidyl transferase reaction may also be involved.[195,200–203]

Azithromycin and clarithromycin bind to the same receptor on the bacterial 50S ribosomal subunit and inhibit RNA-dependent protein synthesis by the same mechanism as erythromycin. Azithromycin appears to penetrate better through the outer envelope of Gram-negative bacteria, such as *H. influenzae* and *Mycoplasma catarrhalis*.[203–205]

A new important macrolide antibiotic is fidaxomicin, which is the first medication for the treatment of *Clostridioides difficile*-associated diarrhea that has been approved (on May 27, 2011) by the FDA in over 20 years.[206] It is considered novel, and the first in a new class of macrocyclic antibiotics that is distinctly narrow-spectrum.[207] At present, fidaxomicin is the only other antibiotic (aside from vancomycin) that is approved by the FDA for treatment of *C. difficile*-associated diarrhea. Its active metabolite is OP-118, which is formed from fidaxomicin after hydrolysis of the isobutyl ester at the 4' position. Fidaxomicin and OP-1118 stop bacterial protein synthesis by inhibiting DNA transcription, specifically, inhibiting RNA polymerase at the σ subunit through inactivation of holoenzyme gene transcription.[206] Its absorption via the gut is minimal and it is considered specific in targeting *C. difficile*.[207] When compared with vancomycin, fidaxomicin use was shown to preserve the intestinal microbiome and, at the same time, it resulted in significantly less reappearance of toxin in stools, which is consistent with a decrease in recurrence of *C. difficile* infection.[208] Similarly, fidaxomicin and OP-1118 were found to be very effective in inhibiting *C. difficile* spore formation, even in strains with high sporulation efficiency. These compounds act even in the early stationary phase of growth, and their action is by potent inhibition of transcription of some, or even all, of the sporulation genes. All these contribute to fidaxomicin's clinical efficacy and ability to reduce recurrences and reduce pathogen shedding and transmission.[209,210]

Ketolides: Telithromycin, Solithromycin, Cethromycin, and Nafithromycin

Telithromycin was the first ketolide antibacterial to receive FDA approval. It is a derivative of erythromycin, and so has structural similarities to it and the other macrolides, except that ketolides have a keto group instead of an α-L-cladinose at the 3 position. This structural change has kept the drug active versus MLS_B (macrolide-lincomycin-streptogramin B)-resistant strains.[211]

The mechanism of action of telithromycin is essentially similar to that of erythromycin and other macrolides, by inhibiting bacterial protein synthesis via a close interaction with the peptidyl transferase site of the 50S ribosomal subunit, specifically binding to the 23S ribosomal RNA. Telithromycin has a higher binding affinity and mechanisms that may overcome the methylation of binding sites of the peptidyl transferase loop. At higher concentrations, telithromycin is also able to inhibit the formation of the 30S ribosomal subunit in addition to the inhibition of formation of the 50S ribosomal subunit. It is a bactericidal agent with a postantibiotic effect, able to suppress bacterial growth even after serum concentrations have fallen below the MIC.[203,211]

Solithromycin (CEM-101) is a "fluoroketolide," having a fluorine at the C-2 position of the 14-member macrocyclic lactone and an alkyl-aryl side chain, responsible for tighter ribosome-binding and enhanced antimicrobial activity, and it is less prone to resistance via post-translational methylation of the 23S rRNA in the 50S ribosomal subunit. It binds to the 50S subunit of the ribosome and inhibits protein biosynthesis, impairing ribosomal subunit function.[212,213] Solithromycin is active against *S. pneumoniae, H. influenzae, M. catarrhalis,* and *S. aureus*. It also has activity against macrolide-resistant strains of the above bacteria due to interaction with three ribosomal sites.[214] It is active against some resistant strains of *N. gonorrhoeae* and *Mycoplasma genitalium*.[214] *In vitro* studies also suggest antimalarial activity associated with solithromycin.[214] Like nafithromycin, it is under development for the treatment of CABP.

A new ketolide called cethromycin has the same mechanism of action as the other ketolides, but with greater potency than telithromycin, plus a superior safety profile. These differences may arise from its unique structural differences from the other ketolides, including (1) the macrolactone ring linkage via the 6(O)-position, and (2) the O-propyl allyl linkage instead of the aminopropyl linkage of telithromycin. These changes make the drug bind much more tightly to the ribosomes, preventing its efflux from the bacteria and allowing it to act on its target more efficiently.[215–218]

Nafithromycin is a lactone ketolide which works as a protein synthesis inhibitor. As described under telithromycin, ketolides are derivatives of the erythromycin A class that lack the L-cladinose sugar at position 3 and have a ketone in its place in the erythronolide ring (Figure 51.12). Ketolides interact at multiple positions on the ribosome, leading to activity against macrolide-resistant strains. *In vitro* studies suggest activity

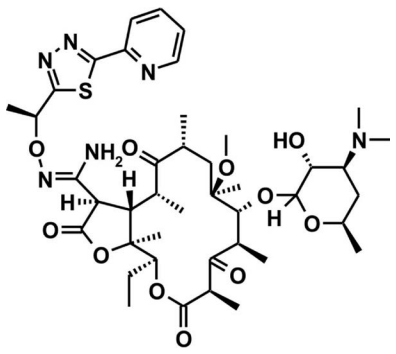

FIGURE 51.12 Chemical structure of nafithromycin.

against *S. aureus*, *H. influenzae*, *Moraxella catarrhalis*, atypicals (*Legionella*, *Mycoplasma*, *Chlamydophila*), and also macrolide-resistant and telithromycin-nonsusceptible strains of *S. pneumoniae*.[210] It is presently under development for the treatment of community-acquired bacterial pneumonia (CABP), which may be caused by multidrug-resistant Gram-positive bacteria.[210]

Pleuromutilin: Lefamulin

Pleuromutilins are natural antimicrobial substances obtained from *Pleurotus mutilus* (*Clitophilus scyphoides*), an edible mushroom.[219] Pleuromutilins are antibacterial agents that inhibit protein synthesis by binding to the 50S subunits of bacterial ribosomes. Lefamulin is a novel semisynthetic pleuromutilin antibiotic that works by inhibiting protein synthesis by binding to the 50S ribosomal subunit at the peptidyl transferase center (PTC), which leads to incorrect positioning of the CCA ends of tRNAs for peptide transfer in the A- and P-sites.[219] Lefamulin has a tricyclene mutilin core that interferes with 23S rRNA with high affinity and specificity.[220] A unique induced-fit mechanism is employed by lefamulin to close the binding pocket within the ribosome, leading to tight binding of lefamulin to its target.[220] This inhibits bacterial peptide chain elongation, leading to bacteriostatic activity of lefamulin. It is active against a number of aerobic Gram-positives (including MRSA, VISA, and vancomycin-resistant *Enterococcus faecium*), some anaerobic Gram-positives (e.g., *Cutibacterium acnes* and *Peptostreptococcus* sp.), and organisms related to community-acquired bacterial pneumonia (*S. pneumoniae, Chlamydia pneumoniae, Mycoplasma pneumoniae, L. pneumophila,* and *H. influenzae*).[220,221] It is not active against *E. faecalis*. *In vitro* studies show favorable results for the treatment of sexually transmitted infections caused by *Chlamydia trachomatis, Mycoplasma genitalium,* and *N. gonorrhoeae*.[222]

Streptogramins

Streptogramins are very potent against many highly resistant bacteria, and so are considered as last-resort treatment.[223] These drugs have a bacteriostatic effect individually, by binding to the 50S ribosomal subunit, which blocks translation. In combination, different streptogramins may demonstrate synergy of up to a hundred times more than as single agents, and in the process they become bactericidal. Their synergy arises after direct hydrophobic interaction between the streptogramins (e.g., quinupristin-dalfopristin) and a single 23S rRNA nucleotide, resulting in a stable ternary drug-ribosome complex that narrows the ribosomal exit tunnel, preventing nearly synthesized nascent peptide chains from extrusion from the peptide transferase site. These chains accumulate there, possibly blocking peptidyl-tRNA hydrolase activity, leading to a decrease in free tRNAs, and subsequently, bacterial death.[16,223,224] The conformational changes in the 50S subunit have been reported to be induced by the attachment of type A compounds.[225–227]

Type A streptogramins, such as dalfopristin and virginiamycin M, bind to a tight pocket in the peptidyl-transferase catalytic center, preventing attachment of the tRNA to both the acceptor (A) site and donor (D) site. This leads to inhibition of the early stages of protein synthesis, particularly peptide bond formation, and the inhibition of the elongation phase. Ribosomal initiation complexes are assembled in an apparently normal fashion but are functionally inactive.[225–227]

Type B streptogramins, such as quinupristin, inhibit late stages of protein synthesis by inhibiting the first two of the three elongation steps (AA-tRNA binding to the A site and peptidyl transfer from site P) and do not affect the third step (translocation from the A site to the P site). They act by binding to the 23S ribosomal RNA, thereby inhibiting peptide elongation after a few cycles of peptide bond formation. The nascent protein chain is prevented from extending, and the peptidyl tRNA is released from the ribosomes as incomplete peptides.[223,228]

Type A and B streptogramins exert a synergistic inhibitory activity due to the conformational changes in the 50S subunit induced by the attachment of type A compounds,[225–227] which enhances the binding of type B compounds.

Fusidic Acid

Fusidic acid is a steroidal antibiotic that inhibits protein synthesis in prokaryotic and eukaryotic subcellular systems. The antibiotic binds to the ternary complex of prokaryotic EF-G (or EF-2 in eukaryotes) and GDP with the ribosome, preventing release of the elongation factor for further rounds of translocation. This sequestration of EF-G may not explain the inhibitory action of fusidic acid *in vivo*, since growing cells appear to contain an excess of elongation factors; alternative explanations include interference with subsequent complex formation between the ribosome and aminoacyl-tRNA-EF-Tu-GTP and possible effects of fusidic acid on both ribosomal A and P sites.[229,230]

Oxazolidinones: Linezolid, Tedizolid, and Ranbezolid

Linezolid, the first oxazolidinone antibiotic approved for human use, inhibits bacterial growth by interfering with protein synthesis. The drug acts early in protein synthesis, binding to the 23S rRNA of the 50S ribosomal subunit, but not to the 30S ribosomal subunit.[231] Several ribosomal activities (such as formation of the initiation complex, synthesis of the first peptide bond, elongation factor G-dependent translocation, and termination of translation) may be inhibited by oxazolidinones. Linezolid acts early in protein synthesis, preventing binding to the 30S ribosome and formation of the 70S initiation complex. Some of these activities depend on the functions of the ribosomal peptidyl transferase center. Interaction of oxazolidinones with the mitochondrial ribosomes provides a structural basis for the inhibition of mitochondrial protein synthesis, which correlates with clinical side effects associated with oxazolidinone therapy. Molecular modeling has shown that oxazolidinones go "squarely" into the A site of the bacterial ribosome, specifically at the center of the phospholipase transferase center, in the site the aminoacyl-tRNA normally occupies, thereby preventing the latter from binding there.[232] This unique mechanism of action of linezolid explains the absence of cross-resistance with other antibiotics. Linezolid also exhibits antimycobacterial activity.[16,227,232,233]

Tedizolid is a novel oxazolidinone that inhibits protein synthesis. Tedizolid phosphate is a prodrug that is converted by serum phosphatases to the active form, tedizolid.[234] It binds to the 50S ribosomal subunit, thereby blocking the binding between the aminoacyl t-RNA and the A-site of the peptidyl transferase center. Its binding site is very similar to that of linezolid,

although tedizolid has an additional D-ring that also engages onto other ribosomal sites, and may explain its improved antimicrobial potency and the development of fewer target mutations and thus less resistance, when compared to linezolid.[235] Due to its increased affinity for the target site, tedizolid has more anti-Gram-positive activity than linezolid.[234] It is active against MRSA, *S. pneumoniae*, VRE, and some anaerobes, including some linezolid-resistant strains of these bacteria.[234]

Ranbezolid is a new investigational oxazolidinone that inhibits protein synthesis as well, by acting on the bacterial ribosome, at the same place where linezolid acts. In addition, it has been shown to inhibit both cell wall and lipid synthesis in a dose-dependent manner in *S. epidermidis*, where it has a bactericidal effect.[236]

Inhibition of Synthesis of Essential Small Molecules

Inhibitors of Dihydropteroate Synthetase

Sulfonamides

The sulfonamides are structural analogs of para-aminobenzoic acid (PABA) and compete with this natural substrate for dihydropteroate synthetases in the bacterial biosynthesis of dihydrofolate (Figure 51.13). In bacterial and mammalian cells, dihydrofolate is reduced by distinct reductases to tetrahydrofolate, which serves as a cofactor for one-carbon transfer in the biosynthesis of essential metabolites such as purines, thymidylate, glycine, and methionine. The susceptibility of bacterial dihydrofolate reductases to inhibition by trimethoprim thus permits sequential blockade of the biosynthesis of tetrahydrofolate in bacteria by the combination of a sulfonamide plus trimethoprim (Figure 51.13). Mammalian cells, which cannot synthesize dihydrofolate from PABA, derive preformed folates (folate, dihydrofolate, and also tetrahydrofolate) from the medium (or diet), whereas bacteria are unable to take up these compounds and are, thus, dependent on the endogenous synthesis of tetrahydrofolate. Sulfonamides are generally used clinically in combination with trimethoprim.[237,238] Like mammalian cells, enterococci are able to take up exogenous folates, and are likewise not inhibited by blockade of the synthesis of dihydro- and tetrahydrofolate.

Inhibitors of Dihydrofolate Reductase

Trimethoprim

Trimethoprim is a potent inhibitor of bacterial dihydrofolate reductases (Figure 51.13), which catalyze the reduction of dihydrofolate to the active tetrahydrofolate. Cofactors of tetrahydrofolate function as donors of one-carbon fragments in the synthesis of thymidylate and other essential compounds such as purines, methionine, panthotenate, glycine, other folate-dependent metabolites, and *N*-formyl methionyl-tRNA. The synthesis of thymidylate from uridylate involves not only C transfer, but also the oxidation of tetrahydrofolate to dihydrofolate (Figure 51.13), which must be reactivated to tetrahydrofolate by dihydrofolate reductase. The toxic effect of the limitation of tetrahydrofolate is primarily due to the deprivation of thymine, which results in

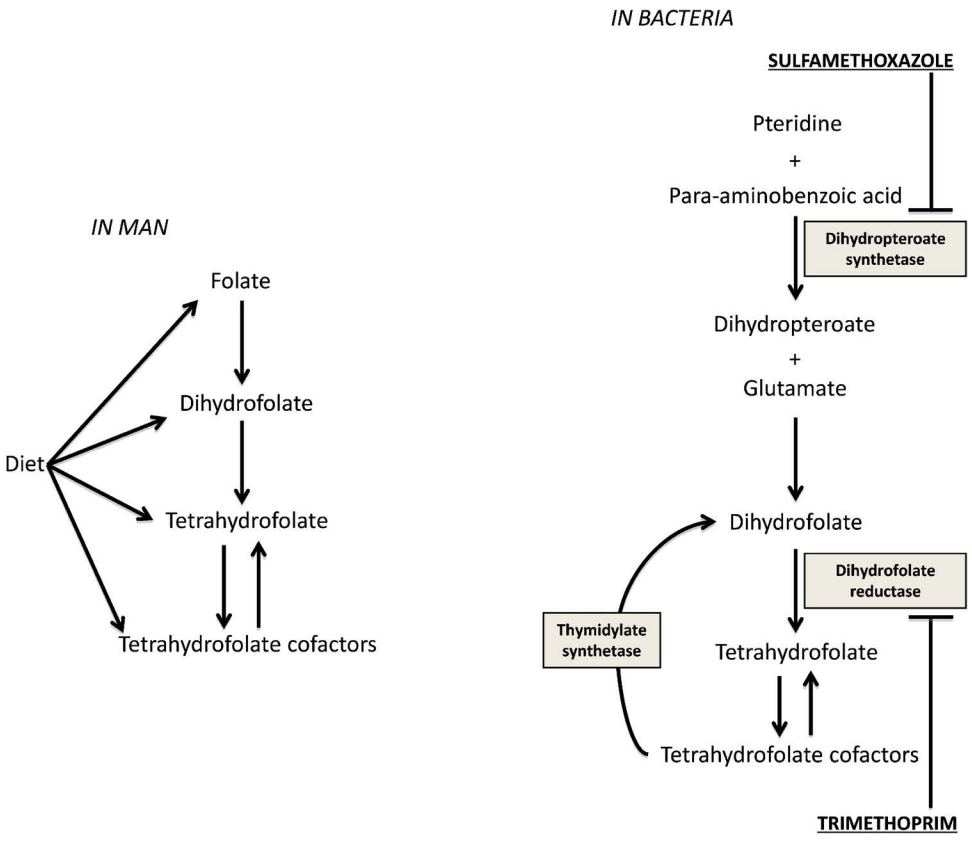

FIGURE 51.13 Folate metabolism in humans and in bacteria, and the sites of action of trimethoprim and sulfa drugs (sulfamethoxazole).

thymineless death because of the resulting "near complete cessation of DNA, RNA and protein synthesis." There is also a depletion of S-adenosyl methionine (SAM), which is an important methyl group donor, and this limits the synthesis of other essential cofactors, fatty acids, and polyamines, contributing to its action. It has been reported that treatment conditions, particularly the availability of folate-dependent metabolites, affect whether trimethoprim will be bacteriostatic or bactericidal. In general, mammalian cells are protected by the extraordinarily low affinity of their dihydrofolate reductase for trimethoprim. The inhibition of dihydrofolate reduction to tetrahydrofolate in bacteria and the resulting DNA damage areessential for the bactericidal effect of trimethoprim. This occurs at the start of the lag phase of treatment and the duration of which is dependent on mutations in the deoxyribose nucleotide salvage pathway and by the ability of cells to buffer themselves from the thymine starvation. It is the distribution of drug susceptibilities in the bacterial population that determines the rate of killing.[238–240]

Iclaprim

Dihydrofolate reductase (DHFR) is an enzyme required for the synthesis of tetrahydrofolate. It participates in the conversion of dihydrofolate to tetrahydrofolate. Like trimethoprim, iclaprim inhibits tetrahydrofolate synthesis by arresting the terminal step in this process, the conversion of dihydrofolateto tetrahydrofolateby acting on DHFR enzyme.[241] Iclaprim is active against many Gram-positive organisms, including methicillin-, vancomycin- and macrolide-resistant strains of *S. aureus*.[242,243] It is also active against some Gram-negatives, including *H. influenzae, M. catarrhalis, E. coli, and P. vulgaris*.[241] Iclaprim was modestly active against *K. pneumoniae* and *A. baumannii,* with MICs of 8 mg/L. It does not have activity against *P. aeruginosa*.

Iclaprim is one of the only two members of its class, the other one is trimethoprim.[241] Although both have the same mechanism of action, iclaprim is active against some trimethoprim-resistant strains because of increased hydrophobic interactions between iclaprim and the target enzyme.[241,242]

Iclaprim was synergistic when used with the sulfonamides, sulfamethoxazole, and sulfadiazine, and the combination has been studied as an alternative to TMP-SMX for treatment of *Pneumocystis jirovecii*.[244] Synergy between iclaprim and sulfamethoxazole was also observed for MSSA, MRSA, penicillin-susceptible and penicillin-resistant *S. pneumoniae, H. influenzae,* and *M. catarrhalis*. Synergy was not observed for *K. pneumoniae*.[243]

Antimycobacterial Agents

Inhibitors of Cell Wall Synthesis

Isoniazid (Isonicotinic Acid Hydrazide, INH)

Isoniazid (INH) is a bactericidal agent most active against *Mycobacterium tuberculosis*, *Mycobacterium bovis,* and *Mycobacterium kansasii*. INH enters the mycobacterial cell by passive diffusion. INH is not toxic to the bacterial cell, but acts as a prodrug. The primary target of action for INH is InhA.[245]

The *inhA* gene of *M. tuberculosis* encodes an NADH-specific enoyl-acyl carrier protein reductase, which was identified in 1994 as a putative target for both INH and the related drug, ethionamide.[246]

INH is activated by the mycobacterial enzyme KatG, a multifunctional catalase-peroxidase, leading to generation of reactive species that form adducts with NAD+ and NADP+, which in turn leads to inhibition of critical enzymes in the biosynthesis of cell wall lipid and nucleic acid.[247] These compounds are potent inhibitors of critical enzymes in the biosynthesis of cell wall lipid and nucleic acid. Some INH-derived reactive species, such as nitric oxide, have a direct role in inhibiting mycobacterial metabolic enzymes.[248]

Cycloserine

D-Cycloserine, a structural analog of D-alanine, is a broad-spectrum antibiotic with activity against mycobacteria including *M. tuberculosis* and strains of other organisms, such as *E. coli*, *S. aureus*, *Nocardia*, and *Chlamydia* species. At concentrations of 100–200 μg/mL, D-cycloserine inhibits the synthesis of bacterial cell wall peptidoglycan by competitively inhibiting L-alanine racemase and D-alanyl-D-alanine synthetase. This prevents the formation of D-alanine from L-alanine and the synthesis of the D-alanyl-D-alanine dipeptide prior to its addition to the UDP-MurNAc tripeptide. The rigidly planar D-cycloserine has greater affinity for alanine racemase than does either D- or L-alanine.[93,106] (Please see "Cycloserine" section and Figure 51.2 discussed previously in this chapter.)

Ethambutol (EMB)

The mechanism of action of ethambutol (EMB) is not completely understood. It appears to inhibit arabinosyl transferase enzymes that are involved in the biosynthesis of arabinoglycan and lipoarabinomannan, which are essential elements within the mycobacterial cell wall.[249]

EMB differentially affects a regulon (GC82) containing genes within the FAS-II (fatty acid synthase) pathway as well as a regulon (GC17) that contains genes implicated in fatty acid modification. This mechanistic divergence was confirmed by the observation that *M. tuberculosis* cells treated with EMB rapidly lost acid-fastness, while cells treated with the analogs did not.[250]

Pretomanid

Pretomanid is active against both rapidly replicating as well as hypoxic *M. tuberculosis*.[251] Activation of pretomanid is dependent on deazaflavin-dependent nitroreductase.[251] Pretomanid exhibits its antibacterial effects by the production of nitric oxide that results in nonspecific damage of intracellular macromolecules, including proteins and cell wall lipids.[251] This might explain its activity in anaerobic environment.[252] Its activity on replicating bacteria is explained in various studies that suggest that this drug affects mycolic acid synthesis through depletion and accumulation of ketomycolates and hydroxymycolates, respectively.[252]

It is now approved for treatment of multidrug-resistant and extensively drug-resistant tuberculosis in combination with linezolid and bedaquiline.

Interference with Cytoplasmic Membrane Function

Pyrazinamide (PZA)

Pyrazinamide (PZA), an analog of nicotinamide, is preferentially active against nonreplicating persistent mycobacteria with low metabolism at acid pH *in vitro*[253] or *in vivo* during active inflammation.[254] PZA is a prodrug that enters *M. tuberculosis* by passive diffusion, where it is converted into the active form, pyrazinoic acid, by bacterial nicotinamidase/pyrazinamidase.

The target of pyrazinoic acid is the ribosomal protein S1 (RpsA), a vital protein involved in protein translation and the ribosome-sparing process of trans-translation experienced by the bacteria under stress conditions. Inhibition of trans-translation may explain the ability of PZA to eradicate persisting organisms.[255] The remarkable *in vitro* sterilizing effect of PZA is also due to disruption of membrane energetics and inhibited membrane function in *M. tuberculosis.*[256]

Inhibition of Nucleic Acid Synthesis

Rifamycins: Rifampin, Rifabutin, and Rifapentine

The mechanism of action of rifamycins involves inhibition of DNA-dependent RNA synthesis caused by strong binding to the β-subunit of the DNA-dependent RNA polymerase of prokaryotes, with a binding constant in the range of 10^{-8} M. Eukaryotic enzymes are at least 10^2 to 10^4 times less sensitive to inhibition by rifampin. Rifabutin and rifapentine are semisynthetic derivatives of rifampin. Rifabutin is active against several rifampin-resistant clinical pathogens, and rifapentine has a long half-life of approximately 12 hours, allowing its administration in once-weekly regimens.[257–259] (Please see "Inhibitors of RNA Polymerase" section discussed previously in this chapter.)

Fluoroquinolones as Antimycobacterial Agents

Fluorinated quinolones have been studied and used as second-line antituberculous drugs. Some fluoroquinolones, such as levofloxacin and moxifloxacin, are bactericidal against *M. tuberculosis*, presumably by inhibition of its DNA gyrase at concentrations within achievable serum levels.[260–264]

Inhibitors of Ribosome Function and Protein Synthesis

Streptomycin and Amikacin

For streptomycin and amikacin, see previous section entitled "Aminoglycosides" in this chapter.

Capreomycin

Capreomycin is a polypeptide antibiotic with a poorly understood mechanism of action, even active on nonreplicating Mycobacteria. It is thought to inhibit protein synthesis by binding to the 50S ribosomal subunit of the 70S ribosome, leading to abnormal protein synthesis that is ultimately fatal to the bacteria. Microarray studies have suggested that capreomycin also affects biochemical and metabolic pathways.[265]

Inhibition of Mycobacterial ATP Synthase

Bedaquiline

Bedaquiline (formerly known as R207910 and TMC207) is a diarylquinoline compound with a unique spectrum specific to mycobacteria, including atypical Mycobacteria that are important in humans such as *Mycobacterium avium, Mycobacterium intracellulare complex, Mycobacterium kansasii*, and the fast growers, *Mycobacterium fortuitum* and *Mycobacterium abscessus.*

Due to its unique mechanism of action, bedaquiline is active not only on drug-sensitive *M. tuberculosis*, but also against isolates resistant to other TB agents: Isoniazid, rifampin, streptomycin, ethambutol, pyrazinamide, and moxifloxacin.[266,267] *In vitro*, it is also bactericidal against dormant, nonreplicating tubercle bacilli[266,268,269] and it has been shown to have synergistic activity against murine tuberculosis when combined with pyrazinamide.[270]

The target of bedaquiline in mycobacteria is the *atpE* gene product, the oligomeric subunit c of ATP synthase.[266–267]

Inhibition of the proton pump of ATP synthase may lead to ATP depletion and imbalance in ATP homeostasis, both contributing to decreased survival.[266,271,272]

Monoclonal Antibodies

Anthrax Antitoxin

Obiltoxaximab

Obiltoxaximab is a chimeric immunoglobulin G1 κ monoclonal antibody used for the prevention and treatment of inhalational anthrax due to *Bacillus anthracis* in combination with appropriate antibacterials.[273] The protective antigen (PA) of *B. anthracis* binds to host cell surface receptors and facilitates the transport of exotoxins, lethal factor (LF), and edema factor (EF) into the host cell.[273] The PA therefore plays a key role in *B. anthracis* pathogenesis.[273] Obiltoxaximab neutralizes the free PA and thereby prevents the cell entry of LF and EF, the two exotoxins that mediate the pathogenesis of anthrax.[273] It carries the risk of hypersensitivity and anaphylaxis, and therefore patients are premedicated with diphenhydramine.[273] It does not have direct antibacterial activity and does not cross the blood-brain barrier.[273]

Bezlotoxumab

Bezlotoxumab is a monoclonal antibody that binds to two separate sites in the N-terminal half of the combined repetitive oligopeptide (CROP) domain of toxin B produced by *Clostridioides difficile*.[274] Once it binds to toxin B, it prevents interaction of toxin B with the host receptor CSPG-4 (chondroitin sulfate proteoglycan 4) and resulting intoxication of the mammalian cells.[274] It can neutralize toxins from several strains of *C. difficile*, including the BI/NAP1/027 and BK/NAP7/078 strains.[274] A post-hoc analysis of pooled data revealed that patients with age >65, history of CDI, immunocompromise, or severe CDI had reduced risk of recurrent CDI, and 30-day readmission for CDI, and avoided fecal transplant if they received adjunctive treatment with a single-dose infusion of bezlotoxumab.[274] The risk of first

post-treatment relapse is nearly 40% lower with bezlotoxumab than that associated with standard treatment alone with oral vancomycin, metronidazole, or fidaxomicin.[275]

Introduction

There are currently only four structurally distinct antifungal classes available for the treatment of invasive fungal infections. As both fungal cells and mammalian cells are eukaryotic, anti-infective drug targets that are fungal specific are few. The most widely exploited strategy for antifungal therapy makes use of differences in sterol biosynthesis and targets either the ergosterol biosynthesis pathway or ergosterol itself, which is incorporated into the fungal cell membrane. Other strategies include inhibiting RNA and DNA synthesis by compounds that are selectively transported into the fungal cell and inhibition of the fungal cell wall. Mortality rates in neutropenic patients for yeast and mold infections are still unacceptably high and time to implementation of the optimal antifungal has a significant impact on patient outcomes (Garey, Rege et al. 2006).

Polyenes: Amphotericin B and Nystatin *Amphotericin B*

Amphotericin B

Amphotericin B is a polyene macrolide antifungal that was first isolated from *Streptomyces nodosus* in the 1950s. Over the past five decades, amphotericin B deoxycholate (Fungizone) has been the gold standard for the treatment of life-threatening fungal infections and generally remains refractory to resistance. Its primary fungicidal mechanism of action is the direct binding to ergosterol; the primary sterol found in the fungal cell membranes. Its dual complementary action of aggregating to form membrane-permeabilizing ion channels increases its potency but is not required for fungicidal activity (Gray, Palacios et al. 2012). Pharmacodynamic studies have demonstrated that fungicidal activity of amphotericin B can be enhanced by optimizing

the concentration-to-MIC ratio (also called the area under the concentration curve to MIC ratio [AUC:MIC]) (Klepser, Wolfe et al. 1997). Unfortunately, the clinical utility of amphotericin B deoxycholate is often times limited by its associated adverse effects such as nephrotoxicity and infusion-related reactions (Deray 2002). Because of these treatment-limiting adverse effects, newer lipid-associated formulations of amphotericin B (Ambisome, Abelcet, and Amphotec) have replaced conventional amphotericin B deoxycholate as therapy for treatment of life-threatening fungal infections, specifically if the causative organism is suspected to be non-*Candida* or a resistant organism.

Spectrum of Activity

Amphotericin B exhibits strong activity against most medically relevant fungal species as well as certain protozoa, including *Leishmania spp.* Species such as *Candida auris, C. lusitaniae*, *C. guilliermondii, Trichosporon spp.*, *Geotrichum spp.*, *Scedosporium apiospermum*, and the causative organisms of dermatomycoses are less susceptible to amphotericin B.

Adverse Effects

Although more specific for fungal ergosterol, amphotericin B can also bind mammalian cells causing toxic effects in patients. The most prominent treatment-limiting adverse effect is nephrotoxicity. Amphotericin B-induced nephrotoxicity is dose dependent and is primarily characterized by a decrease in glomerular filtration rate (GFR) by vasoconstriction, sodium, potassium, and magnesium wasting, as well as renal tubular acidosis (Sawaya, Briggs et al. 1995). The mechanism of this effect has been studied but has not been completely elucidated. There is evidence to show that the reduction in GFR may be mediated by the tubuloglomerular feedback system (TGF). Under normal conditions, the TGF system is triggered by the perceived loss of NaCl from the proximal tubule by macula densa cells located in the early distal tubule (Ito and Abe 1996). The TGF response triggers afferent arteriolar vasoconstriction to minimize excessive NaCl loss in the urine. Amphotericin B increases the permeability of the macula densa cells and inappropriately triggers the TGF response resulting in afferent arteriolar vasoconstriction and results in a decrease of GFR. Due to this proposed mechanism, the infusion of intravenous NaCl, known as "salt loading" has been utilized to prevent the effects of amphotericin B on GFR as volume expansion decreases the sensitivity of the TGF system (Gardner, Godley et al. 1990). In a human model, salt loading was shown to decrease the effects of amphotericin B on serum creatinine (SCr) level when compared to amphotericin B delivered in dextrose; however, the saline group required statistically significant K^+ supplementation and was observed to have decreased ability to acidify the urine (Llanos, Cieza et al. 1991).

Another common side effect of amphotericin B is infusion-related reactions such as nausea, vomiting, chills, rigors, and phlebitis (Grasela, Goodwin et al. 1990). Although the exact mechanism of infusion toxicity is not completely known, amphotericin B has been shown to stimulate the immune system via toll-like receptors resulting in an increased inflammatory cytokine production (Sau, Mambula et al. 2003). A wide variety of pretreatment medications, which commonly include a drug cocktail of diphenhydramine, acetaminophen and corticosteroids, are used to decrease these symptoms (Grasela, Goodwin et al. 1990).

Lipid Formulations

To decrease the nephrotoxic effects of amphotericin B deoxycholate, newer lipid formulations have been developed as a drug delivery system. Currently, there are three lipid-based amphotericin B products available, which have largely replaced the amphotericin B deoxycholate formulation as first-line therapy of life-threatening fungal infections. In 1995 and 1996, amphotericin B lipid complex, or ABLC (Abelcet; The Liposome Co.), and amphotericin B colloidal dispersion, or ABCD (Amphotec; Sequus Pharmaceuticals) became available, respectively. In 1997, the U.S. Food and Drug Administration (FDA) approved liposomal amphotericin B, or AmBisome (NeXstar Pharmaceuticals/Fujisawa). Although there are distinct differences between the formulations in regard to the lipid composition, particle size, and pharmacokinetics, the clinical significance of these variances is not yet known (Dupont 2002). All lipid formulations have been shown to be less nephrotoxic than amphotericin B deoxycholate formulation but vary in regard to infusion-related toxicity (Bowden, Cays et al. 1996; Leenders, Reiss et al. 1997; Prentice, Hann et al. 1997; Wingard, White et al. 2000).

Amphotericin B Resistance

Amphotericin B-resistant clinical fungal isolates are rare and resistance mechanisms are poorly understood. Mutations in genes involved in the ergosterol biosynthesis pathway, specifically *ERG3* and *ERG6*, have been identified in amphotericin B-resistant *C. albicans* isolates leading to decreased levels of ergosterol in the cell membrane (Kelly, Lamb et al. 1997). Decreased ergosterol content in the fungal cell membrane decreases the amphotericin B-ergosterol interaction and results in decreased polyene activity (Klepser 2001). Polyene resistant isolates of *Candida* and *Cryptococcus* have lower ergosterol content than in susceptible isolates (Espinel-Ingroff 2008). Isolates of *C. albicans*, the most common etiological agent of IFIs, have been documented to develop resistance to amphotericin B but this has only been observed in combination with resistance to azole antifungals (Kelly, Lamb et al. 1997; Nolte, Parkinson et al. 1997; Martel, Parker et al. 2010). Additionally, a large proportion of *C. auris* clinical isolates are found to have increased amphotericin B resistance at the time of isolation, and *C. lusitaniae* and *C. guilliermondii* can develop resistance secondarily during amphotericin B treatment.

Nystatin

Nystatin, also a polyene antifungal with the same mechanism of action of amphotericin B, is not formulated as an intravenous product. However, as it is not absorbed through mucocutaneous membranes, this agent can be applied either topically or orally to treat infections such as oropharyngeal candidiasis (OPC) with minimal risk.

Azole Antifungals

Members of the azole class are the most widely used of all antifungals. Their utility is mainly due to their activity against a broad spectrum of fungal pathogens and a mild spectrum of side effects, specifically lacking the treatment limiting nephrotoxicity experienced by patients undergoing treatment with amphotericin B. There are five azoles currently used for the treatment of invasive fungal infections. Although these agents are all of the same class, they vary individually with regard to spectrum of activity, pharmacokinetic and toxicity profiles. Appropriate utilization of these agents is based upon these unique characteristics.

The primary target of all azole antifungals is 14-α sterol-demethylase, which is the product of the *ERG11* gene (Yoshida 1988). Sterol demethylase is a member of the cytochrome P450 (CYP450) class of enzymes and is a critical enzyme in the biosynthesis of ergosterol. As ergosterol is not found in the mammalian cell membrane, inhibition of this pathway is a fungal specific mechanism of action for this class. Treatment with azoles results in decreased cellular ergosterol and leads to the accumulation of toxic methylated sterols (Ghannoum and Rice 1999). Azoles are considered fungistatic for *Candida* and other yeast species but some are fungicidal to *Aspergillus* species (Manavathu, Cutright et al. 1998).

Fluconazole (Diflucan, Pfizer)

Fluconazole is available in both an oral and intravenous formulations and has been widely studied in treating invasive fungal disease. When compared to amphotericin B, fluconazole is defined by a limited toxicity profile, but its spectrum of activity is limited to yeast. Species such as *C. krusei* display inherent resistance to this agent and *C. glabrata* has been observed to display inherent resistance and acquire resistance secondary to treatment (Orozco, Higginbotham et al. 1998; Pfaller 2012). Additionally, an approximate 90% of clinical isolates of the emerging fungal pathogen, *C. auris*, are found to have increased resistance to fluconazole (Chowdhary, Prakash et al. 2018). Fluconazole has excellent bioavailability independent of pH or concomitant meals and exhibits linear kinetics (Zimmermann, Yeates et al. 1994; Zimmermann, Yeates et al. 1994; Groll, Gea-Banacloche et al. 2003). This agent also exhibits limited protein binding (~10%), a high volume of distribution and achieves appreciable concentrations in the cerebrospinal fluid (CSF) (Brammer, Farrow et al. 1990; Thaler, Bernard et al. 1995). Fluconazole is primarily eliminated unchanged in the urine and requires dosage adjustment in renal insufficiency (Brammer, Coakley et al. 1991). As fluconazole is a moderate inhibitor of CYP450 enzymes 3A4, CYP2C9 and CYP2C19, it potentially interacts with the metabolism of a wide variety of drugs (Niwa, Shiraga et al. 2005). In addition, fluconazole also inhibits uridine diphosphate (UDP)-glucuronosyltransferase (UGTs), which mediates drug metabolism by glucuronidation (Uchaipichat, Winner et al. 2006). Like all azole antifungals, AUC:MIC is the best pharmacodynamic parameter that predicts azole antifungal activity (Klepser, Wolfe et al. 1997).

Itraconazole (Sporanox, Janssen Pharmaceuticals)

Itraconazole, voriconazole, posaconazole, and isavuconazole are all considered extended-spectrum azoles as they exhibit greater potency than fluconazole against most fungal species. Itraconazole is effective against most yeast however, *C. krusei* and *C. glabrata* may show cross resistance with fluconazole (Pfaller 2012). When compared to fluconazole, itraconazole gains activity against certain molds such as *Aspergillus* and dimorphic endemic fungi. Itraconazole is only available orally and is formulated as either a capsule or a solution. Oral bioavailability of itraconazole is significantly less than fluconazole (Zimmermann, Yeates et al. 1994). The oral solution exhibits better bioavailability than the capsule, and this improves under acidic fasting conditions (Zimmermann, Yeates et al. 1994). Itraconazole is highly protein bound and is metabolized in the liver by CYP3A4, which results in the formation of the pharmacologically active metabolite hydroxyitraconazole (Poirier and Cheymol 1998; Templeton, Thummel et al. 2008). Itraconazole is a strong inhibitor of CYP3A4 and has the potential for numerous drug-drug interactions (Isoherranen, Kunze et al. 2004).

Voriconazole (Vfend, Pfizer)

Voriconazole is also an extended spectrum azole that is structurally related to fluconazole. Voriconazole displays excellent activity against *Candida* spp. including *C. krusei* and is the drug of choice for treatment of invasive aspergillosis (Herbrecht, Denning et al. 2002). Voriconazole exhibits activity against endemic fungi but notably lacks activity against Zygomycetes. Voriconazole is formulated orally and intravenously with a cyclodextrin carrier. Like fluconazole, voriconazole is well-absorbed and displays high bioavailability upon oral administration (Johnson and Kauffman 2003). Voriconazole displays nonlinear kinetics and absorption is independent of pH and food administration. Voriconazole is moderately protein bound (~58%) and demonstrates CSF penetration (Lutsar, Roffey et al. 2003). Unlike itraconazole, voriconazole is primarily metabolized by CYP2C19. The argument has been made for therapeutic drug monitoring (TDM) of voriconazole levels due to inter-patient genetic differences in CYP2C19 activity (Desta, Zhao et al. 2002; Weiss, Ten Hoevel et al. 2009). Renal function should be monitored in patients receiving the intravenous formulation due to the sulfobutylether-beta-cyclodextrin carrier (Oude Lashof, Sobel et al. 2012).

Posaconazole (Noxafil, Schering Corporation)

Posaconazole is structurally related to itraconazole, and global surveillance studies have noted that posaconazole is more active than itraconazole and fluconazole, and as effective as voriconazole against a diverse population of clinically relevant *Candida* spp. (Pfaller, Messer et al. 2001; Pfaller, Messer et al. 2004). Posaconazole is now available in multiple formulations, including both those for oral and intravenous administration. Due to the lipophilicity of posaconazole, the original oral suspension formulation requires administered with a full meal or a nutritional supplement with high fat content (Courtney, Wexler et al. 2004). Absorption of posaconazole suspension is saturable so

the administration of this formulation in divided doses has been shown to increase the relative bioavailability when compared to a single dose (Ezzet, Wexler et al. 2005). Additionally, gastric pH also plays a role in posaconazole absorption so administration with an acidic beverage is recommended while coadministration with acid suppressing drugs may decrease absorption. (Courtney, Radwanski et al. 2004). The more recently introduced delayed release oral tablet formulation of posaconazole allows for once-daily administration following the initial loading dose, and is more minimally impacted by co-administration with high-fat-content food or agents altering gastric pH. Additionally, the intravenous formulation of posaconazole allows for administration to patients who are unable to take oral formulations (Cornely, Duarte et al. 2016; Cornely, Robertson et al. 2017). Posaconazole is highly protein bound and distributes widely to the tissues. Metabolism is largely mediated by UGT (glucuronosyltransferase), which allelic polymorphisms have been shown to alter pharmacokinetics (Ghosal, Hapangama et al. 2004). Excretion of posaconazole has also been shown to be mediated in part by P-glycoprotein and inducers of P-glycoprotein have been shown to increase clearance (Courtney 2004). Posaconazole is not metabolized significantly by CYP450 enzymes but remains an inhibitor of CYP isoenzyme 3A4 which can contribute to drug interactions (Krieter, Flannery et al. 2004).

Isavuconazole (Cresemba, Astellas)

Isavuconazole is the newest addition to the azole class and is indicated for the treatment of both invasive aspergillosis and invasive mucormycosis. Structurally similar to voriconazole, isavuconazole possesses a compact triazole pharmacophore as well as a lipophilic thiazolylbenzonitrile side chain. The spectrum of activity of isavuconazole is also most similar to that of voriconazole, but with improved activity against rare mold including both Mucoralean and endemic fungi (Rybak, Marx et al. 2015). Isavuconazole is however less active against *Fusarium* spp. than is voriconazole, and while demonstrating excellent *in vitro* activity against *Candida* spp., isavuconazole failed to meet the definition of noninferiority as compared to caspofungin in a Phase 3 clinical trial studying the treatment of invasive candidiasis, and multiple case of breakthrough *Candida* infections among patients receiving isavuconazole have been reported (Rausch, DiPippo et al. 2018; Kullberg, Viscoli et al. 2019).

Isavuconazole is available in both intravenous and oral capsule formulations, formulated as isavuconazonium sulfate, a prodrug that significantly improves water solubility and negates the need for the inclusion of cyclodextrin in the intravenous product. Upon intravenous administration, isavuconazonium sulfate is rapidly converted to the active isavuconazole by serum esterases. When administered orally, isavuconazonium sulfate is believed to be converted to the active isavuconazole by gut microbiota and only the active isavuconazole is detected in serum. Bioavailability of the oral formulation is excellent, approximating 98%, and absorption is not significantly affected by coadministration with food. Isavuconazole is extensively protein bound (~99%), and predominantly cleared via hepatic metabolism by CYP3A4 and CYP3A5 enzymes. Isavuconazole is generally well tolerated, exhibiting significantly less hepatobiliary toxicity and fewer drug metabolism interactions as compared with voriconazole (Rybak, Marx et al. 2015; Maertens, Raad et al. 2016).

Adverse Effects

Azoles are generally well tolerated, with the most common adverse effect being gastrointestinal symptoms such as nausea, vomiting, and diarrhea. Elevations in hepatic transaminases are associated with the use of all azoles, but cases of fulminant hepatotoxicity are rare. Cases of QT prolongation and torsades de pointes have also been associated with azoles; however, reports are usually in patients with comorbidities and on concomitant medications also associated with QT prolongation (Alkan, Haefeli et al. 2004; Philips, Marty et al. 2007). Voriconazole has been linked with a number of unique side effects, such as vision and neurologic changes, which are correlated with high voriconazole serum concentrations (Zonios, Gea-Banacloche et al. 2008).

Azole Resistance

Azole resistance in *Candida* spp. has been extensively studied and is commonly multifactorial in an azole resistant clinical isolate. The efficacy of azoles is decreased in clinical isolates of *Candida* spp. by the interplay of several mechanisms of resistance (Lopez-Ribot, McAtee et al. 1998; Perea, Lopez-Ribot et al. 2001; Morschhauser 2002). The mechanism of azole uptake into the fungal cell is unclear but recent kinetic data supports the hypothesis that its uptake is facilitated in *C. albicans* (Mansfield, Oltean et al. 2010). The constitutive overexpression of 14-α sterol demethylase requires higher concentrations of intracellular fluconazole for sufficient inhibition (Sanglard, Kuchler et al. 1995; Perea, Lopez-Ribot et al. 2001). Increased expression of *ERG11* from azole-resistant isolates can result from two documented methods. Gain-of-function (GOF) mutations in transcription factor *UPC2* results in increased expression of the gene encoding 14-α sterol demethylase, *ERG11*, and increased MICs to fluconazole (Flowers, Barker et al. 2012). Alternately, as *ERG11* resides on Chromosome 5, instances of aneuploidy, or specifically, increased chromosome 5 copy number can result in the increased expression of *ERG11* (Selmecki, Forche et al. 2006). Nonsynonymous mutations in 14-α sterol demethylase have also been shown to contribute to azole resistance (Sanglard, Ischer et al. 1998; Franz, Ruhnke et al. 1999). To date, over 30 amino acid substitutions have been described in 14-α sterol demethylase that have associated with fluconazole resistance, and the individual contribution of many of these mutations on azole susceptibility in *C. albicans* has been well described (Wang, Kong et al. 2009; Flowers, Colon et al. 2015).

Importantly, overexpression of efflux pumps is a common mechanism of resistance to drugs toxic to the fungal cell. In *C. albicans*, *CDR1, CDR2*, and *MDR1* are usually expressed in a low or nondetectable level, but expression is stimulated in response to azoles and other chemicals. In fluconazole-resistant strains of *C. albicans*, it is common to observe the constitutive overexpression of the *CDR1*, *CDR2*, and *MDR1* genes. In *C. glabrata*, efflux transporters *PDH1*, *CDR1*, and *SNQ2* mediate efflux of azoles (Cannon, Lamping et al. 2009; Whaley, Zhang et al. 2018). In *C. dubliniensis*, the Mdr1p transporter

is the primary mediator of fluconazole efflux however, CdCdr1 and CdCdr2 can contribute to azole resistance in some isolates (Pinjon, Jackson et al. 2005; Schubert, Rogers et al. 2008). In *C. auris*, increased expression of both *CDR1* and *MDR1* has been observed among fluconazole-resistant clinical isolates, and *CDR1* has been demonstrated to significantly contribute to clinical fluconazole resistance (Rybak, Doorley et al. 2019). These established mechanisms of resistance are all able to individually contribute to azole resistance but high-level resistance is mainly due to multiple mechanisms of resistance that accumulate over time.

In the opportunistic fungal pathogen *Cryptococcus neoformans*, azole resistance is acquired from similar mechanisms as *Candida* spp. Mutations in 14-α sterol demethylase in addition to overexpression of the *ERG11* gene by chromosomal aneuploidy can contribute to an azole-resistant phenotype (Shapiro, Robbins et al. 2011). Additionally, overexpression of drug efflux transporter *AFR1* contributes to azole resistance (Shapiro, Robbins et al. 2011).

While previously uncommon, azole resistance in *Aspergillus* species such as *A. fumigatus* is increasingly reported worldwide, and its emergence has been associated with increasing use of agricultural demethylase inhibitor antifungals (Ashu, Hagen et al. 2017; Rybak, Fortwendel et al. 2019; Sewell, Zhu et al. 2019). To date, this azole resistance has primarily been linked to mutations in the *cyp51A* gene, which encodes one of the two *A. fumigatus* 14-α sterol demethylase genes (Balashov, Gardiner et al. 2005). In fact, the vast majority of azole-resistant *A. fumigatus* isolates of both environmental and clinical origin are found to possess mutations in *cyp51A*. The two most encountered mutations, TR_{34}/L98H and TR_{46}/Y121F/T289A, encode both amino acid substitutions and promoter region alterations. The former of which decreases azole binding affinity for the mutant enzyme, and the latter of which has been shown to increase the expression *cyp51A* significantly (Snelders, Karawajczyk et al. 2011; Warrilow, Parker et al. 2015). More recently, however, mutations in the sterol sensing domain of the HMG-CoA reductase encoding gene, *hmg1*, have been found among a large number of azole-resistant clinical isolates and these mutations have been shown to directly contribute to greatly increased resistance to the entire azole class (Rybak, Ge et al. 2019). Additionally, studies have shown that overexpression of efflux transporters such as *abcC* and *mdr1* may also contribute to clinical azole resistance in *A. fumigatus* (Mellado, Garcia-Effron et al. 2007; Shapiro, Robbins et al. 2011; Fraczek, Bromley et al. 2013).

Allylamines: Terbinafine

Terbinafine is an allylamine antifungal that inhibits the first enzyme in the ergosterol biosynthesis pathway, squalene epoxidase, resulting in a decrease of cellular ergosterol (Ryder 1992). Unlike azoles, which target an alternate enzyme in the same pathway, terbinafine is fungicidal and is the drug of choice for dermatophytes. Terbinafine exhibits less activity against non-dermatophyte molds, which precludes its use in the treatment of invasive fungal disease (Trovato, Rapisarda et al. 2009). Oral terbinafine (Lamisil; Novartis) is primarily eliminated by the kidneys but is an inhibitor of CYP2D6. The toxicity profile of terbinafine is minimal with the most common adverse effects being nausea, diarrhea, and dermatologic events, such as rash and pruritus (Hall, Monka et al. 1997).

Resistance

Squalene epoxidase is encoded by ergosterol biosynthesis gene *ERG1*. Studies in *Saccharomyces cerevisiae* show specific mutations in *ERG1* result in amino acid substitutions in squalene epoxidase that result in terbinafine resistance (Leber, Fuchsbichler et al. 2003).

Echinocandins

Echinocandins are the newest class of antifungals to be introduced to the market. Current approved agents by the FDA are caspofungin (Cancidas, Merck and Co.), micafungin (Mycamine, Astellas Pharmaceuticals) and anidulafungin (Eraxis, Pfizer Pharmaceuticals). Echinocandins are now recommended as frontline therapy for treatment of invasive candidiasis based on results of three defining clinical trials in which caspofungin, micafungin, and anidulafungin were shown noninferior to amphotericin B, liposomal amphotericin B and fluconazole, respectively (Mora-Duarte, Betts et al. 2002; Kuse, Chetchotisakd et al. 2007; Reboli, Rotstein et al. 2007; Pappas, Kauffman et al. 2016). These agents are characterized by their broad spectrum of activity, low incidence of drug-drug interactions and a relative lack of adverse effects (Zaas and Alexander 2005). Echinocandins are lipopeptides that bind to 1,3-β-D glucan synthase, inhibiting production of β-1,3 glucan which, along with chitin, is responsible for integrity and shape of the fungal cell wall. 1,3-β-D glucan synthase is a multiunit enzyme that is made of a catalytic subunit Fksp, the target of echinocandins, and the regulatory unit Rho1p. All three echinocandin agents are fungicidal in a dose dependent fashion against the *Candida* species including those isolates resistant to azole antifungals (Ostrosky-Zeichner, Rex et al. 2003; Pfaller, Diekema et al. 2003; Pfaller, Boyken et al. 2005). Unlike the azole antifungal class, echinocandins are noted to retain activity against fungal biofilm and biofilm formation (Bachmann, VandeWalle et al. 2002; Soustre, Rodier et al. 2004).

Formulations

All agents in the echinocandin class are available only as a parenteral formulation. Caspofungin requires no dosage adjustment in patients with renal failure however this agent requires a dosage reduction in patients with moderate hepatic impairment (Childs-Pugh score of 7–9). Micafungin and anidulafungin require no dosage adjustment for hepatic or renal impairment. Echinocandins are generally well tolerated however, cases of hepatotoxicity and infusion related reactions are associated with this class (Sucher, Chahine et al. 2009).

Spectrum of Activity

Echinocandins are fungicidal in a dose dependent manner against *Candida* species and are clinically important because they retain activity against azole-resistant isolates. Although echinocandins are fungistatic against *Aspergillus* species, they

still retain excellent activity against *A. fumigatus*, *A. flavus*, *A. niger,* and *A. terreus*. Zygomycetes lack the 1,3-β-D glucan synthase component of the fungal cell wall, therefore, echinocandins show little activity for these species. Although the cell wall of *Cryptococcus neoformans* contains 1,3-β-D glucan synthase, these agents display little activity against this species.

The activity of the echinocandins against *Candida* species is divided into two broad groups. Echinocandins are particularly active against *C. albicans*, *C. glabrata*, *C. dubliniensis*, *C. tropicalis, C. auris*, and *C. krusei* (Pfaller, Boyken et al. 2008; Pfaller, Diekema et al. 2008; Berkow and Lockhart 2018; Chowdhary, Prakash et al. 2018). Though, as a class, echinocandins have reduced activity against *C. parapsilosis* and *C. guilliermondii* (Pfaller, Boyken et al. 2008; Pfaller, Diekema et al. 2008). However, while echinocandin MIC among clinical isolates of *C. parapsilosis* and *C. guilliermondii* are generally higher, 90–100% of isolates remain classified as echinocandin susceptible based on the MIC breakpoint of ≤ 2 mg/L (Pfaller, Boyken et al. 2008). Additionally, there is a lack of a clear relationship regarding echinocandin MIC to overall treatment response as even species with reduced susceptibilities can still be treated effectively with current echinocandin therapy (Mora-Duarte, Betts et al. 2002; Bennett 2006; Kartsonis, Killar et al. 2005). Thus, the clinical implications of the reduced susceptibility of certain *Candida* species to echinocandins remain unclear.

Data from the SENTRY Antimicrobial Surveillance Program (2008–2009) were recently published and compared the antifungal resistance patterns and species distributions from patients with community onset and nosocomial bloodstream infections (BSI) in 79 medical centers. For the 1,354 isolates examined, resistance to echinocandins was uncommon but was most prevalent among nosocomial bloodstream infection isolates of *C. glabrata* (Pfaller, Castanheira et al. 2010; Lewis, Wiederhold et al. 2013). Furthermore, previous prospective sentinel surveillance for the emergence of *in vitro* resistance to echinocandins comprised of 5,346 clinical *Candida* isolates from 91 medical centers from 2001 to 2006 showed no evidence of emerging echinocandin resistance among invasive isolates of *Candida* species (Pfaller, Boyken et al. 2008). However, reports of increasing echinocandin resistance among some institutions have been described. A recent review of echinocandin susceptibility among bloodstream isolates of *C. glabrata* over a 10-year period at a single academic medical center observed echinocandin resistance to rise from 5% to 12%. Notably, fluconazole resistance was also observed to rise from 18% to 30% over this same study period (Alexander, Johnson et al. 2013).

Echinocandin Resistance

Documentation of individual resistant *Candida* isolates is rare but as these agents are used more frequently, incidence of echinocandin resistance will assuredly increase. Unlike the azole antifungals, drug efflux transporters have not been documented to contribute to echinocandin resistance (Bachmann, Patterson et al. 2002; Niimi, Maki et al. 2006). Reduced susceptibility to echinocandins has been attributed to assorted alterations in 'hot spot' sequences within *FKS* genes; the target of the echinocandins and whose gene product is part of the β-1,3 glucan synthase complex (Park, Kelly et al. 2005; Laverdiere, Lalonde et al. 2006). The mechanism for echinocandin resistance was first documented in *C. albicans* by identifying mutations within the *FKS1* gene in isolates that were less susceptible to the drug (Park, Kelly et al. 2005). Mutations in *FKS1* generally map onto two locations and occur between amino acid positions 641-649 and 1345-1365 of Fks1p (Park, Kelly et al. 2005). As a consequence of these mutations, the Fks1p amino acid protein sequence is altered resulting in an enzyme with reduced catalytic activity (Garcia-Effron, Lee et al. 2009). For species such as *C. guilliermondii* and *C. glabrata*, mutations in the *CaFKS1* ortholog, *FKS2*, has also contributed to elevated echinocandin MICs and potential treatment failure (Katiyar, Pfaller et al. 2006, Garcia-Effron; Lee et al. 2009). Additionally, clinical isolates of *C. auris* with reduced susceptibility to echinocandins both possessing or lacking mutations in the homolog of *CaFKS1* have been described, and clinical isolates have been documented to acquire resistance while patients are receiving echinocandin therapy (Sharma, Kumar et al. 2016; Biagi, Wiederhold et al. 2019). Additionally, clinical isolates of *C. parapsilosis* and *C. guilliermondii* are commonly found to exhibit elevated echinocandin MIC attributable to naturally occurring polymorphisms within the *FKS1* gene. However, the clinical significance of these elevated MIC remains unclear (Katiyar, Pfaller et al. 2006; Garcia-Effron, Katiyar et al. 2008).

Some clinical isolates of *Candida* have shown a reproducible pattern of having reduced susceptibility to caspofungin at higher concentrations, allowing growth, while lower concentrations remaining effective at inhibiting growth (Stevens, Espiritu et al. 2004). This observation has been referred to as a paradoxical or "Eagle" effect, which is similar to that previously observed for other cell-wall active antimicrobial agents (Shah 1982; Stevens, Gibbons et al. 1988). Although the mechanisms responsible for this phenomenon have not been completely elucidated, investigations have shown that paradoxical growth is not associated with overexpression or mutations in the *FKS* gene. Some isolates capable of surviving in high concentrations of caspofungin have a documented increase in their cell wall chitin content. (Drakulovski, Dunyach et al. 2011; Stevens, Ichinomiya et al. 2006). Paradoxical attenuation of caspofungin activity may also be linked to calcineurin and PKC stress response pathways (Wiederhold, Kontoyiannis et al. 2005). Chamilos et al. showed that paradoxical growth was more frequent in caspofungin than with micafungin and anidulafungin and was completely absent in *C. glabrata* isolates (Chamilos, Lewis et al. 2007). Currently, the *in vivo* documentation of the paradoxical effect in *Candida* spp. is not significant and may not be relevant to patient treatment at this time.

Flucytosine

Flucytosine (5FC) is a pyrimidine analog that inhibits DNA replication and protein synthesis. Flucytosine is selectively transported into the fungal cell by cytosine permease and is then deaminated by cytosine deaminase to 5-fluorouracil. It is then converted to its active form, 5-fluorodeoxyuridylic acid to inhibit DNA synthesis (Vermes, Guchelaar et al. 2000). Due to the rapid development of resistance, 5FC is rarely used as monotherapy. In a murine model of disseminated candidiasis, time over MIC was the best pharmacodynamic parameter correlated with efficacy (Andes and

van Ogtrop 2000). Although the Clinical Practice Guidelines for the Management of Candidiasis recommend 5FC in combination with amphotericin B or fluconazole for a variety of infection types in the setting of refractory or resistant disease, concerns regarding toxicity such as bone marrow suppression and hepatic transaminase elevation often times prevent its use (Pappas, Kauffman et al. 2009). Its current utility is primarily limited to treatment of cryptococcal meningitis (Saag, Graybill et al. 2000).

Flucytosine Resistance

Intrinsic resistance to flucytosine is a result of mutations in purine-cytosine permease (Fcy2), which impairs cellular uptake of the drug (Kanafani and Perfect 2008). Secondary resistance often correlates with mutations in the enzyme uracil phosphoribosyltransferase (Fur1) or in cytosine deaminase (Fca1) thereby preventing conversion of 5-fluorouracil to its active form (Kanafani and Perfect 2008).

Introduction

Today, more than 50 compounds have been formally approved for the treatment of viral infections. They are formally licensed for clinical use in the treatment of several viral infections caused by several human viruses such as human immunodeficiency virus (HIV), herpes simplex viruses, varicella–zoster virus, respiratory syncytial virus, cytomegalovirus, hepatitis B virus, hepatitis C virus, or influenza A virus. The chapter first describes the mechanism of action of the main approved antiviral drugs, summarized in Table 53.1, and then discusses issues stemming from the broad use of the antiviral drugs that we have seen in the last decade.

Mechanism of Action of Antiviral Agents

A description of the mechanism of action of the various antiviral agents focused on the target they affect on the virus life cycle is presented. Figure 53.1 summarizes the steps of the viral life cycle that can be affected by the antiviral drugs. We will handle only drugs made by chemical synthesis approved for clinical use in western countries omitting the many antiviral drugs that are in the process of being approved. The following report neglects also an in-depth description of the mechanism of action of interferons that would deserve an extensive discussion, being an endogenous and a very potent mechanism of defense against viral diseases and have been the topic of several recent publications but are beyond the scope of this review (Scagnolari and Antonelli 2013; Antonelli et al. 2015).

Antiviral Agents Affecting Absorption and Entry (Entry Inhibitors)

The first stage of viral infection involves attachment of the virus to host cellular membranes. This phase is mediated by the interaction between viral surface molecules and cellular receptors. Following adsorption, virus entry into host cell occurs by different routes such as fusion or endocytosis.

Inhibitors that specifically target this first stage of the viral cycle have been approved for HIV infection treatment (Esté and Telenti 2007; Soriano et al. 2009; Tilton and Doms 2010) and in the prevention of RSV infection (Hu and Robinson 2010; Lanari et al. 2010; Welliver 2010).

HIV-1 entry is a multistep process. Binding of the HIV-1 envelope protein gp120 to the CD4 receptor on host cells is followed by engagement of specific chemokine receptors, either CCR5 or CXCR4, leading to rearrangements in the envelope transmembrane subunit that result in membrane fusion. An important step in the fusion process is a conformational change in the viral transmembrane glycoprotein gp41. HIV-1 entry inhibitors comprise three drugs: enfuvirtide, a fusion inhibitor, maraviroc, a CCR5 antagonist (Matthews et al. 2004; Perros 2007) and Ibalizumab, a genetically engineered IgG4 MAb which binds to CD4 T cell receptors (Burkly et al. 1992; Reimann et al. 1997; Iacob and Iacob 2017).

Enfuvirtide binds to a region of gp41 and disrupts the conformational changes associated with membrane fusion, thereby blocking virus entry. Maraviroc is an allosteric inhibitor of HIV-1 entry, binding to and altering the conformation of CCR5 such that it is no longer recognized by gp120 and membrane fusion

TABLE 53.1

Main Approved Antiviral Drugs and Their Mechanism of Action**

Anti-HIV	**Mechanism of Action (Main)**
Entry Inhibitors	
Enfuvirtide	It interferes with glycoprotein 41-dependent membrane fusion blocking virus entry.
Ibalizumab	It binds CD4 extracellular domain, preventing conformational changes in the CD4–gp120 complex essential for viral entry.
Maraviroc	Negative allosteric modulator of the CCR5 receptor that is an essential coreceptor for the entry process of HIV.
Reverse Transcriptase Inhibitors	
Nucleoside Analogs	Active as triphosphate derivates, which prematurely terminate DNA synthesis.
Abacavir	
Emtricitabine	
Lamivudine	
Stavudine	
Zidovudine	
Nucleotide analog	
Tenofovir	
Non-nucleoside inhibitors	They bind to a hydrophobic pocket of HIV-1 reverse transcriptase, blocking polymerization of viral DNA.
Doravirine	
Efavirenz	
Etravirine	
Nevirapine	
Rilpivirine	
Protease inhibitors	
Atazanavir	They bind to the active site of viral protease.
Fosamprenavir	
Lopinavir	
Darunavir	They bind strongly and selectively to the HIV-1 protease.
Tipranavir	
Pharmacodynamic enhancer	
Cobicistat	These drugs inhibit CYP3A4 leading to higher drug exposure.
Ritonavir	
Integrase inhibitor	
Dolutegravir	They bind viral integrase, inhibiting the strand transfer step of HIV-1 integration.
Bictegravir[a]	
Elvitegravi[a]	
Raltegravir	
Anti-Herpes viruses	
DNA Polymerase Inhibitors	
Nucleoside Analogs	
Aciclovir	Active as triphosphate derivates, which prematurely terminate DNA synthesis.
Brivudine[b]	
Famciclovir	
Ganciclovir	
Valaciclovir	
Valganciclovir	
Nucleotide Analog	
Cidofovir	
Pyrophosphate Analog	
Foscarnet	It selectively inhibits the pyrophosphate binding site on viral DNA polymerases.
DNA Maturation and Packaging Inhibitor	
Letermovir	It inhibits CMV replication by binding to components of the terminase complex.
Anti HBV	
Reverse Transcriptase Inhibitors	
Nucleoside Analogs	
Entecavir	Active as triphosphate derivates, which prematurely terminate viral DNA synthesis.
Telbivudine	
Lamivudine	
Nucleotide Analog	
Tenofovir	
Anti-HCV	
NS5B RNA Polymerase Inhibitor	
Non-Nucleoside Inhibitor	
Dasabuvir	It binds HCV NS5B polymerase and blocks viral RNA synthesis and replication.
Nucleotide Analog	
Sofosbuvir	Potent inhibitor of the NS5B polymerase. It blocks viral RNA synthesis and replication.
Nucleoside Analog	
Ribavirin	Active as triphosphate derivates, which prematurely terminate viral nucleic acid synthesis.[e]
NS5A Protein Inhibitor	
Elbasvir	They bind to the replication complex protein NS5A, disrupting HCV RNA replication and virion assembly.
Ledipasvir	
Ombitasvir	
Pibrentasvir	
Velpatasvir	
NS3/4A Protease Inhibitor	
Glecaprevir	They prevent viral replication by inhibiting the NS3/4A serine protease of HCV.
Grazoprevir	
Paritaprevir	
Voxilaprevir	
Anti-influenza Virus	
Uncoating Inhibitor	
Amantadine	Inhibitors of the viral M2 channel. The activity of channel is required for uncoating.
Rimantadine	
Neuraminidase Inhibitors	
Oseltamivir	Block influenza neuraminidase and prevent the cleavage of sialic acid residues, thus interfering with progeny virus release.
Peramivir	
Zanamivir	
Endonuclease Inhibitor	
Baloxavir marboxil	It inhibits cap-dependent endonuclease, a key enzyme involved in the initiation of influenza virus mRNA synthesis.

** See text for details.

[a] Used in fixed-dose combination formulations.

[b] Brivudine is approved in some European countries and in Central America.

TABLE 53.1 ***(Continued)***

Main Approved Antiviral Drugs and Their Mechanism of Action**

Anti-RSV		**Anti-SARS-CoV-2**	
Entry Inhibitors		*RNA Polymerase inhibitor*	
Palivizumab[c]	It Binds to RSV F protein, which plays a role in virus attachment and fusion.	Redmesivir[d]	It is a prodrug of a nucleotide analogue that is intracellularly metabolized to an analogue of adenosine triphosphate that inhibits a number of viral RNA polymerases
RNA Inhibitor			
Ribavirin	It interferes with viral RNA synthesis.[e]		
Anti-variola virus			
Maturation Inhibitor			
Tecovirimat[d]	It binds and inhibits P37 envelope protein, preventing the formation of egress-competent enveloped virions.		

[c] Palivizumab is indicated for the prevention of serious lower respiratory-tract disease caused by respiratory syncytial virus (RSV) in pediatric patients at high risk of RSV disease.

[d] Currently approved only by FDA-USA and Japan's authorities..

[e] Ribavirin has been reported also to inhibit inosine monophosphate dehydrogenase (IMPDH), thus reducing intracellular pools of GTP, and to induce mutagenesis, thus leading to lethal mutations. Furthermore, ribavirin has been used in the treatment of chronic hepatitis C in combination with IFN alpha (in this framework, some authors reported that it has immunomodulatory activity) and with the early DAAs before the introduction of the very effective new ones.

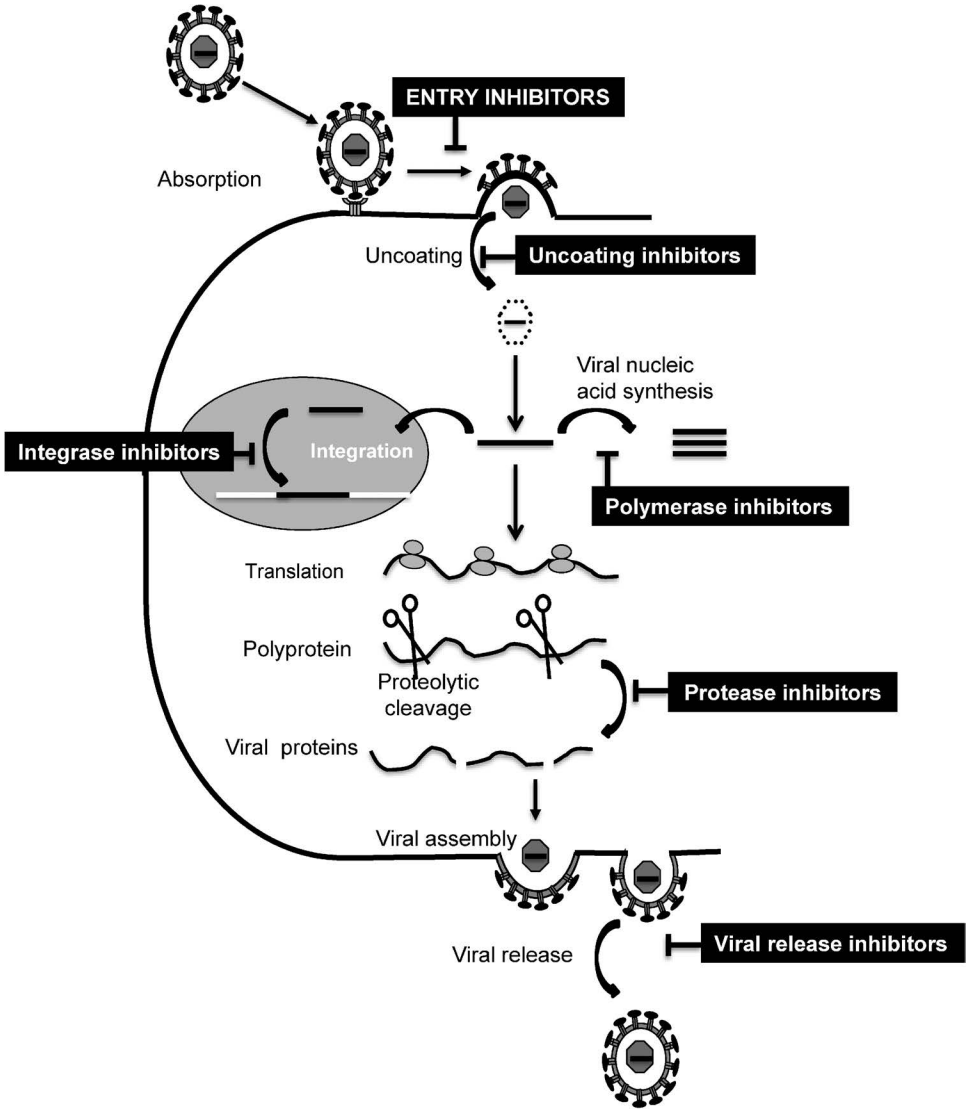

FIGURE 53.1 Entry inhibitors.

cannot proceed. Ibalizumab specifically leads to conformational changes of the CD4 T cell receptor–gp120 complex thus preventing HIV fusion and entry. Ibalizumab is the first monoclonal antibody for the treatment of multidrug resistant HIV-1 infection in combination with other forms of antiretroviral therapy in heavily treatment-experienced adults who are failing their current antiretroviral regimen (Beccari et al. 2019).

Fusion inhibitory activity is also displayed by palivizumab, a humanized monoclonal antibody directed to an epitope in the A antigenic site of the RSV fusion (F) protein (Scott and Lamb 1999). Palivizumab is a composite of primarily human antibody sequences (95%) and murine antibody sequences (5%) providing both neutralizing and fusion inhibitory activity against RSV, resulting in inhibition of RSV replication (see footnote to Table 53.1 for further details).

Antiviral Agents Affecting Uncoating (Uncoating Inhibitors)

Viral uncoating, an essential step in the viral replication occurring after penetration, leads to the removal of capsid from the viral structure. In most cases, it is a process of disaggregation that sometimes occurs with the aid of cellular enzymes. At the end of this process, only the nucleic acid or a nucleic acid-protein complex remains into the cytoplasm. Basically, the process enables viral genes to become available for transcription and translation.

Inhibitors targeting this phase have been identified against influenza virus (Davies et al. 1964). Specifically, following endocytosis and before hemagglutinin-mediated fusion between viral and endosomal membranes, the influenza virus M2 channels are activated by the low pH of the endosome and conduct protons to acidify the viral interior (Pinto et al. 1992). The acidification has been suggested to weaken the electrostatic interaction between matrix proteins and ribonucleoprotein complexes such that subsequent membrane fusion can release the uncoated ribonucleoproteins into the cytosol for transport into the nucleus (Martin and Helenius 1991). The tricyclic amines amantadine hydrochloride and rimantadine hydrochloride block replication of influenza A by inhibiting the function of its M2 protein. The adamantine derivatives are effective only against influenza A because influenza B does not have an M2 protein but has an NB protein that is not affected by amantadine (Hay et al. 1986).

Antiviral Agents Affecting Viral Nucleic Acid Synthesis (Polymerase Complex Inhibitor)

After uncoating, a series of complex key events occur that finally leads to the synthesis of viral proteins and genomes by the host synthesizing machinery. Irrespective of the structure, the size, the genome organization, and the replicative strategies, all the viruses must proceed to a synthesis of specific viral nucleic acids that are in some cases synthesized by a viral enzyme such as viral DNA polymerase, RNA polymerase, or reverse transcriptase. These polymerases are crucial in the viral life cycle and, as such, were and still are attractive drug targets for the treatment of many viral infections (Tsai et al. 2006).

Nucleoside analogs (NAs) represent the first polymerase inhibitors that showed clinical efficacy (Douglas et al. 1984; Straus et al. 1984; Fischl et al. 1987) and are nowadays broadly used to treat viral infections such as HBV, HSV-1, HSV-2, and HIV-1 infection (Coen and Schaffer 2003; Dienstag 2009; von Kleist et al. 2012). NAs are typically formulated as prodrugs, requiring intracellular phosphorylation to form an analog of (deoxy-)nucleoside triphosphate, which can be incorporated into nascent viral DNA by the viral polymerase. Most NAs are phosphorylated by cellular kinases, except the compounds used against herpetic infections in which the initial phosphorylation step is carried out by viral thymidine kinase and the two subsequent steps by cellular enzymes (Miller and Miller 1982; Elion 1993). After incorporation, NAs bring the polymerization machinery to a halt as they lack the 3-hydroxyl group on the deoxyribose moiety required to attach the next incoming nucleotide (Coen and Schaffer 2003; Painter et al. 2004). NAs such as adefovir and tenofovir show the same mode of action, but they need only two phosphorylation steps because they are already phosphorylated (De Clercq and Hol 2005). With regard to HIV infection, viral polymerase inhibitors are classified into three groups (Table 53.1): nucleoside reverse transcriptase inhibitors (NRTIs), such as zidovudine, lamivudine, and abacavir; nucleotide reverse transcriptase inhibitors (NtRTIs), of which tenofovir is the only one approved; and non-nucleoside reverse transcriptase inhibitors (NNRTIs) such as nevirapine and efavirenz (De Clercq 2009).

Since zidovudine was approved in 1987, another six NRTIs have been approved (see Table 53.1). Some of these, such as didanosine and zalcitabine are no longer used due the introduction in clinical practice of new drugs with a better pharmacological/toxicity profile.

NNRTIs have a completely different mode of action from NRTIs and NtRTIs. They are allosteric inhibitors of the HIV-1 reverse transcriptase. They bind to an allosteric pocket in the p66 subunit of the reverse transcriptase and inhibit DNA synthesis reactions by a noncompetitive mechanism of action (Kohlstaedt et al. 1992; de Béthune 2010). Five NNRTIs have currently been approved for the clinical treatment of acquired immune deficiency syndrome (AIDS) disease: nevirapine, doravirine, efavirenz, etravirine, and rilpivirine (Table 53.1). The rapid emergence of drug resistance mutations for the first-generation NNRTIs (nevirapine and efavirenz) dramatically reduced their use (de Béthune 2010). Alternatively, the second-generation NNRTIs, such as etravirine, rilpivirine, and the recently approved doravirine, possess a high genetic barrier and, thanks to their structurally intrinsic flexibility, are able to adapt their binding orientation and overcome common NNRTI resistance-associated mutations (Schiller and Youssef-Bessler 2009; Adams et al. 2010; Feng et al. 2016).

Ribavirin is a guanosine analog that has inhibitory activity against a broad spectrum of RNA viruses and is usually included among the different drugs able to affect viral nucleic acid synthesis. Although ribavirin is a NA, various mechanisms of action have been suggested to account for its antiviral activity (Hong and Cameron 2002), including (1) depletion of intracellular GTP pools by inhibition of the cellular inosine-5-monophosphate dehydrogenase by the 5-monophosphate metabolite of ribavirin, (2) inhibition of viral polymerase activity by the 5-triphosphate metabolite of ribavirin, (3) inhibition of viral capping by inhibition of (viral or

cellular) guanylyltransferase activity by ribavirin 5-triphosphate, and (4) induction of error catastrophe as a result of accumulation of mutations (some of them lethal) in the viral genome. In addition to its effect on viral replication, ribavirin is also thought to have immunomodulatory properties, including the regulation of macrophage- and T-helper cell-produced cytokines, modulation of the Th1/Th2 subset balance and enhancement of interferon stimulated gene expression (Stevenson et al. 2011).

The detailed characterization of the viral life cycle HCV of the different genotype of allowed the development of directly acting antiviral drugs (DAAs). Currently, NS5A phosphoprotein inhibitors and NS5B polymerase inhibitors are available for clinical use. Most of these drugs are administered as fixed-dose combinations of different DAAs (Bourlière and Pietri 2019). The combination of sofosbuvir and daclatasvir was the first pangenotypic combination achieving SVR rates over 90–95% in patients infected by genotypes 1–4 (Sulkowski et al. 2014; Alavian and Rezaee-Zavareh 2016). Since 2017, another two pangenotypic fixed-dose combinations, sofosbuvir/velpatasvir (Feld et al. 2015) and glecaprevir/pibrentasvir (Forns et al. 2017), were approved (see also the section entitled "Antiviral Agents Affecting Viral Proteases" later in this chapter).

In 2018, the first polymerase complex inhibitor, baloxavir marboxil, was approved for the treatment of uncomplicated influenza in the United States and in Japan. The polymerase complex of influenza viruses is a heterotrimer composed of three subunits: polymerase basic protein 1 (PB1), polymerase basic protein 2 (PB2), and polymerase acidic protein (PA). The PA protein of influenza A and B viruses possesses endonuclease activity that is necessary to cleave host mRNA caps in order to initiate viral transcription baloxavir marboxil is a prodrug that is metabolized into baloxavir marboxil acid, which directly inhibits the cap-dependent endonuclease activity of the PA protein of influenza, thereby inhibiting the cleavage of mRNA during the "cap-snatching" process (Mifsud et al. 2019).

At the time of writing, there are only few antiviral therapies of proven effectiveness in patients with coronavirus disease 2019 (COVID-19) caused by Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2). In vitro testing has shown that Remdesivir, an inhibitor which has broad-spectrum activity against members of several virus families, including filoviruses (e.g., Ebola) and coronaviruses (e.g., SARS-CoV and Middle East respiratory syndrome coronavirus [MERS-CoV]), has also activity against SARS-CoV-2 (Li G, De Clercq E, 2020) and has been authorized for potential COVID-19 treatment (US Food & Drug Administration, 2020).

Antiviral Agents Affecting Integration of Viral Genomes (Integrase Inhibitors)

Many viruses are able to insert their genetic material into host chromosomes. This process is called integration. For most of the members of *Retroviridae* family, such as HIV, the integration process is mandatory and results in a permanent insertion of the viral genome into the host chromosomal DNA. At this stage, the virus is referred as a provirus. It can remain latent and then be passively replicated along with the host genome and passed on to the cell's offspring. Changes of host's environmental condition, such as lymphocyte activation in the case of HIV, can reactivate the virus leading to a viral transcription, translation, and yield of new infectious viruses.

Inhibitors targeting this phase have been identified against HIV whose integrase is one of three essential enzymes encoded by the viral pol gene (Krishnan and Engelman 2012; Métifiot et al. 2013). Integrase is responsible for an essential step in HIV-1 replication involving integration of the viral genome into the host cell DNA. This viral enzyme catalyzes two reactions: 3' end processing of the viral DNA during which the terminal GpT dinucleotide is cleaved from the 3' end of each long terminal repeats, and strand transfer, which joins the viral genome to the host chromosomal DNA forming a functional integrated proviral DNA. Since integrase is indispensable for HIV replication, it has become a validated target for developing anti-HIV agents (Hazuda et al. 2000; Pommier et al. 2005) and inhibitors that specifically target integration have been approved for the treatment of HIV infection. One integrase inhibitor, raltegravir, was approved in late 2007 for the treatment of HIV-1 infection in patients with prior antiretroviral treatment experience and it was recently also approved for first-line therapy (Grinsztejn et al. 2007). Three other effective integrase inhibitors (elvitegravir, dolutegravir, and the recently approved bictegravir) are today available for the HIV infection treatment (Shimura and Kodama 2009; Fantauzzi et al. 2013; Stellbrink et al. 2019).

Antiviral Agents Affecting Viral Proteases (Protease Inhibitors)

Once viral genomes and proteins have been newly synthesized, they must be assembled into new virions. For many viruses, this phase occurs through a maturation of viral precursors that include proteolytic cleavage of capsid or envelope polyproteins/precursors. Specific viral proteases catalyze this process and their catalytic activity is required to produce new infectious virions.

For this reason, viral proteases represented an attractive target for the development of novel antiviral agents, and indeed, compounds that block these enzymes have been approved for HIV and HCV infection. The clinical relevance of viral protease inhibitors (PIs) was demonstrated with the successful application of HIV PIs (Eron 2000). Currently, 6 PIs, including ritonavir that is used as a pharmacokinetic booster, are available in clinical practice (Table 53.1). Indeed, over the past years other PIs were approved for HIV infection treatment, such as Nelfinavir, Amprenavir, and Indinavir, but their use was overcome with the introduction of more effective and safer drugs. Most HIV-1 PIs were designed as peptidomimetics of the viral peptide substrates with not cleavable structures in the scissile bond (Eron 2000). These compounds bind to the site where protein cutting occurs, thereby preventing the enzyme from releasing the individual core proteins so the new viral particles are unable to mature or become infectious. Two agents from a new chemical class of PI, namely tipranavir and darunavir, were approved by the U.S. Food and Drug Administration (FDA) in 2006. These two PIs are unique in their ability to remain active against the increasing number and combinations of PI mutations that render other PIs partially inactive (Luna and Townsend 2007; McCoy 2007).

HCV nonstructural (NS)3/NS4A protease inhibitors have been the target of intensive research for the past 20 years.

First generation of HCV PIs, telaprevir and boceprevir, had to be combined with interferons. These compounds were mainly specific for HCV genotype 1, showed a low genetic barrier to viral resistance and were associated with a plethora of side effects. Therefore, these drugs have been abandoned meanwhile. The scenario has been revolutionized by the introduction of new antiviral compounds, exhibiting excellent efficacy (80–100% sustained response) and improved safety profiles. In fact, new generation PIs, such as paritaprevir, grazoprevir, glecaprevir, and voxilaprevir, have increased intrinsic antiviral potency, wider coverage of viral genotypes, a high genetic barrier, and better pharmacokinetics (Bartenschlager et al. 2013). Specifically, third-generation pangenotypic NS3/4A protease inhibitors (mainly glecaprevir and voxilaprevir) show high antiviral activity and a genetic resistance barrier with cure rates of more than 95% when combined with an NS5A inhibitor, irrespective of baseline resistance associated variants being present. It is common opinion that, due to these new options, HCV will not represent a significant health issue in the future (Pawlotsky 2014). The World Health Organization (WHO) has already aimed for the elimination of hepatitis C as a public health threat by 2030 (defined as a 90% reduction in new infections and a 65% reduction in mortality) (WHO 2016).

Antiviral Agents Affecting Virus Maturation

In some viruses, a key step of maturation is the packaging of unit-length genomes into capsids. Taking human cytomegalovirus (HCMV), it is known that such a step occurs through the action of specific viral enzymes, so-called terminases. HCMV-terminase complex is a heterotrimer consisting of the ATPase pUL56, the nuclease pUL89 and a third component, pUL51 (Borst et al. 2013). Letermovir is a 3,4-dihydro-quinazoline-4-yl-acetic acid derivative that inhibits CMV replication by binding to components of the terminase complex (UL51, UL56, or both) (Goldner et al. 2011; Chou 2017). To date, Letermovir is registered and used to prevent illness caused by HCMV in adults having an allogeneic hematopoietic stem-cell transplant to replace their bone marrow.

Recently, the FDA has approved tecovirimat, the first drug with an indication for treatment of variola (smallpox) virus. Though the WHO declared smallpox, a contagious and sometimes fatal infectious disease, eradicated in 1980, there have been longstanding concerns that smallpox could be used as a bioweapon (Chan-Tack et al. 2019). Tecovirimat [4-trifluoromethyl-N-(3,3a,4,4a,5,5a,6,6a-octahydro-1,3-dioxo-4,6-ethenocycloprop[f] isoindol-2(1H)-yl)-benzamide] (TPOXX) is a small molecule that has been shown to impede the envelopment of virions and the egress of enveloped viruses from the infected cell. Specifically, this compound interferes with F13L, that is one of the pivotal proteins required for the production of enveloped virions, blocks its interaction with cellular Rab9 GTPase and TIP47, which prevents the formation of egress-competent enveloped virions necessary for cell-to-cell and long-range dissemination of virus Smith et al. 2009; Duraffour et al. 2015). The efficacy of TPOXX for the treatment of smallpox is based on studies in monkeys (cynomolgus macaques) and New Zealand White (NZW) rabbits. The primary efficacy endpoint was proportion of infected animals that survived to the prespecified end-of-study. It was not possible to conduct controlled clinical trials in humans with smallpox because of the ethical issue (Chan-Tack et al. 2019).

Antiviral Agents Affecting Viral Release (Release Inhibitors)

The release of the newly synthesized viral particles is the final stage of the virus' life cycle. In this stage, the naked viruses are released rapidly after maturation, in most cases when the cells undergo lysis while the enveloped virus pushes itself out of the host cell, taking with it part of the membrane of the cell. The newly synthesized viruses contain all the structures necessary to bind to a new cell and receptors and begin the process again.

In some cases, the released virions become infectious only after the intervention of a viral enzyme. Some drugs are able to inhibit this phase, acting on the viral protein involved in such a process, and have been approved for the treatment of influenza virus infection (Hayden et al. 1997; Gubareva et al. 2000). The hemagglutinin of influenza A and B viruses binds to neuraminic acid-containing receptors (Gubareva et al. 2000). The neuraminidase enzymatic activity promotes influenza virus disbursement within mucosal secretions of the respiratory tract and prevents progeny virions from self-aggregating by removing neuraminic (sialic) acids from oligosaccharide chains of receptors (Colman 1994). Neuraminidase inhibitors (NAIs) are designed to limit influenza virus infection by blocking the enzyme active site. Two NAIs, inhaled zanamivir and oral oseltamivir (prodrug), have been licensed for influenza treatment in several countries.

Interferons

As stated, interferon would deserve a special attention being an important mechanism of defense of the organism against viral infections.

Interferon (IFN) was discovered in 1957 (Isaacs and Lindenmann 1957) as a substance able to interfere with virus replication. It is now known that IFN was not only a protein but a group of proteins with parallel, but not analogous or identical, biochemical, and biological properties. It is now recognized that there are more than 20 nonallelic genes that codify proteins possessing properties comparable to those of IFN (i.e., direct antiviral activity, species specificity, relatively low molecular weights, and pleiotropic activity). All these genes can be divided into three main groups: IFN type I, which includes many different IFNs among which many IFN-alpha and IFN-beta; IFN type II, which includes IFN-gamma; and IFN type III, which includes IFN-lambda. In the last decades, interferons (IFNs) have been widely studied from the chemical and biochemical points of view. The mechanisms through which IFNs interact with the cell have been elucidated and many of their biological activities have been characterized. It is now known that IFNs, other than a direct antiviral effect elicited through the (over)expression of several cellular antiviral proteins, play a pivotal role in shaping innate and adaptive immune response to viral infections (Scagnolari and Antonelli 2013). Altogether, these acquisitions

led to the clinical use of different types of IFNs with an appreciable success in several viral diseases alone or in combination with other antiviral drugs (such as chronic hepatitis B and C, genital warts), marking a major advance in modern medicine.

Originally the commercial preparations of IFN-alpha currently available for clinical use were either of recombinant IFN (rIFN) alpha 2 obtained from transfected bacteria or were mixtures of many subtypes of IFN-alpha obtained from transformed cell cultures (lymphoblastoid IFN-alpha), or primary human blood leukocytes (leukocyte IFN-alpha), both stimulated by Sendai virus (Scagnolari and Antonelli 2013). The composition of the mixtures depended on the methods used for their production and purification. The short half-life of IFN-alpha has led to the development of IFN-alpha preparations that have a longer half-life. This was achieved by the attachment of a polyethylene glycol (PEG) molecule to the IFN-alpha molecule. This allows a once-weekly administration.

Recent, but consolidated, findings, prompted us to reconsider the application of the different type of IFNs (especially the most used type I IFNs) in therapy of infectious diseases (Antonelli et al. 2015).

As stated, it is well established that all IFNs have a strong and direct antiviral effect and that all type of IFNs are fundamental for host defense against virus infections. However, a better understanding of the IFN response is crucial to understand the natural course of viral infections. Indeed, it has been established that during viral infections (especially during chronic viral infections), definite levels of specific type of IFNs may be required at an early stage, to initiate cell-mediated immune responses but continuous production and high concentrations of the same type or other types of IFNs may lead to the induction of immunosuppressive molecules and then to immunosuppression and tissue damage. Then, IFN (especially type I)-induced negative regulatory pathways are emerging as pivotal determinants of chronic inflammation and progression of diseases in chronic viral infections, such as HIV or HCV (Snell et al. 2017; Scagnolari and Antonelli, 2018). More recently, type I IFNs have been shown to cause tissue damage in some acute viral infections, such as influenza or SARS virus infection (Galani et al. 2017).

It can be concluded that a precise and definite, but still unknown, balanced network of IFNs does exist during viral infection/disease to provide protection with minimum damage to the host and recovery from viral infections. It is our opinion that understanding in detail such a network, and its complex regulation, is essential for a future design of interferon-based therapies.

New Strategies in the Antiviral Chemotherapy Field

Although the primary goal of the chapter is to give basic knowledge and practical information on the mechanism action of the drugs currently used to treat viral infections, we believe it is worth to mention that the scenario of antiviral drugs is rapidly changing. Indeed, new classes of antiviral drugs directed not only to viral targets but also to host factors involved in virus replication, the immune response, or virus-cell interactions are starting to be considered. Some of the advances in this background will be briefly discussed later.

It is now clear that the life cycle of all viruses strictly depends on the participation of many cellular proteins that are largely unknown. However, some advances have been made in exactly identifying those cellular proteins participating to the replication of some viruses, such as HIV. Obviously, such proteins may provide an additional target for antiviral drugs that might, for definition, represent a potential target for broad-spectrum antiviral activity as many viruses may share a dependency on that host function.

The first example of the application of such a strategy is the CCR5 inhibitor (see earlier text), which can have a dramatic impact on HIV replication *in vivo* without considerably affecting essential cellular functions with the important exception of the immune response to West Nile virus and tick-borne encephalitis virus infections (Kindberg et al. 2008; Lim and Murphy 2011).

The entry inhibitor Myrcludex-B is a first-in-class virus entry inhibitor for patients with chronic hepatitis B or B/D infections. This compound inhibits the entry of HDV into hepatocytes by blocking its binding to the sodium taurocholate cotransporting polypeptide (NTCP), thereby depriving HDV of key functions provided by HBV (Bogomolov et al. 2016; Rizzetto 2018).

Another example of new target is provided by the observation indicating that two antifungal compounds, namely, ciclopirox and deferiprone, are able to *in vitro* cure HIV-1 infected cells through eradication of viral infection. Specifically, it appears that these drugs, inhibiting hydroxylation of cellular proteins essential for apoptosis, activate apoptosis, thus leading to the selective death of HIV-1-infected cells (Hanauske-Abel et al. 2013; Saxena et al. 2016). However other studies reported that ciclopirox inhibits HIV-1 replication through control of HIV-1 transcription. Recently it has also been demonstrated that ciclopirox may act as an anti-HBV agent by inhibiting normal HBV capsid assembly. However, minor effects of ciclopirox on HBV replication cannot be entirely excluded because it affects the regulation of several intracellular processes that account for most of the anticancer actions of ciclopirox.

Another example is Gleevec®, a drug approved for the treatment of cancer that may block the replication of some poxviruses and the Ebola virus because of its ability to inhibit the cellular tyrosine kinase (Reeves et al. 2005; Uebelhoer et al. 2014).

Host kinase inhibitors represent a category of compounds with a great potential to combat viral infections. Several kinase pathways are essential for virus cycle and thus represent attractive targets for broad-spectrum therapy. Recently, the repurposing of approved kinase inhibitors has been considered by some authors as a new cost- and time-effective strategy for the development of broad-spectrum antivirals (Schor and Einav, 2018).

Another known approach to block host factors involved in virus replication is represented by zinc-finger nucleases (ZFNs), transcription activator like effector nucleases (TALEN), and clustered regularly interspaced short palindromic repeats (CRISPR)-Cas9. Notably, first generation genome-editing technologies (i.e., ZFNs and TALENs) have been replaced by CRISPR/Cas9, which work with a short guide RNA (gRNA) to hybridize to a target DNA site and recruit the Cas9 endonuclease. All these technologies have been utilized to successfully disrupt the HIV-1 co-receptors CCR5 or CXCR4, thereby restricting HIV-1 infection (Tebas et al. 2014; Liu et al. 2017, Shi et al. 2017).

In recent years, lipidomics has gained importance in virology. Lipids play important roles in cellular signaling and regulatory

processes in both uninfected and infected cells. The study of modifications in lipid biosynthesis pathways and transport in infected cells is a promising research area because many viruses manipulate host membranes and lipid flows (Toledo and Benach 2015; Altan-Bonnet 2017).

Viruses generally unsettle lipid flows by three different mechanisms: the translocation and/or regulation of lipid biosynthesis enzymes, the interference with lipid-mediated signaling through the regulation of phosphatidylinositol (PI) kinases, and the regulation of lipid trafficking at membrane contact sites (MCSs) between adjacent organelles.

It has been observed that Dengue virus, Usutu virus and West Nile virus, are sensitive to the inhibitory effect of cerulenin a specific inhibitors of fatty acid synthase, the key multienzyme complex for fatty acid synthesis (Fernández-Oliva et al. 2019). Furthermore, it is known that viruses take advantage of cholesterol properties. Cholesterol is a critical membrane component that determines membrane fluidity, regulates the formation and function of membrane-bound complexes of proteins and lipids. Viruses exploit these properties to make specialized membrane platforms for RNA replication and virus assembly.

Lipid rafts have a key role in the life cycle of viruses, such as entry, RNA translation, virus progeny assembly, and egress (Kim et al. 2017; Verma et al. 2018; Chen et al. 2019). It is known that statins deplete cholesterol and disrupt lipid rafts. West Nile virus and Dengue virus are inhibited by lovastatin (Mackenzie et al. 2007; Soto−Acosta et al. 2017), and DENV and HIV-1 are inhibited by simvastatin (Bryan-Marrugo et al. 2016; DeLucia et al. 2018).

These findings confirm that host factors may positively modulate the replication of viruses thus indicating that their inhibition may eventually block viral replication. However, in some well-documented cases, host factors (i.e., APOBEC, TRIM, Tetherin, SAMDH1, etc.) have been developed by the cell machinery to affect viral replication (Huthoff and Towers 2008). Hence, it is tempting to speculate that another approach to achieve an effective antiviral strategy is to improve the action of these natural defense mechanisms, but only preliminary results are available.

Altogether these findings prompt speculation that the traditional paradigm "antiviral therapy must be directed only to the viral target" is being challenged. However, while this approach may represent an interesting and useful advance for acute infections, people are worried about their potential use in chronic infections due to the possibility of their interference with vital cellular functions.

A special and borderline situation is represented by the antiviral approaches through nucleic acids. Indeed, a number of nucleic acid-based antiviral therapies have been targeted to viral genes, including ribozymes (small, catalytically active RNA molecules, the most well studied being the hammerhead and the hairpin ribozymes), aptamers (nucleic acid sequences that bind to a specific target molecule and are synthesized by an amplification technique), antisense oligonucleotides and RNA interference (RNAi)-based therapeutic strategy (which utilizes short RNAs to mediate degradation of viral mRNA in a sequence-specific manner) (Ivacik et al. 2011; Zeller et al. 2011; Asha et al. 2018). Specifically, small interfering RNAs (siRNAs), the main effectors of RNAi, are now routinely used to assess gene function, both *in vitro* and *in vivo*, and many innovative screens have been reported on the use of RNAi to identify potential drug targets. Some of these approaches have demonstrated that siRNAs can effectively inhibit the replication of viruses despite different mechanisms they evolved to resist the pressure imposed by immune system and antiviral drugs (Levanova and Poranen 2018). However, the possibility of appearance of escape mutants, recently discovered inhibitors of RNAi in human viruses (Fabozzi et al. 2011; Qiu et al. 2018), and complex interactions between RNAi and interferon pathways (Seo et al. 2013; Maillard et al. 2016) must be taken into consideration when designing new antiviral siRNA molecules. Despite several technical advances, many challenges remain in determining the ideal design of nucleic acid-based antiviral therapy products, including pharmacokinetic and pharmacodynamic issues and competition with endogenous microRNAs. Although several clinical trials are ongoing (specifically against HIV, HCV, HBV, Ebola virus, Marburg virus, and influenza virus), translation of nucleic acid technology into the clinic depends on resolving these challenges.

Apart from targeting the host factors directly involved in virus replication, the drug market is also directed toward finding molecules able to modulate the host's inherent immune response. Here, we have not described any of these attempts because the discussion would deserve a description also of determinants of the immune response to viral infections, which is out of the scope of this chapter.

Forthcoming Issues on Antiviral Chemotherapy

Over the last two decades, beside the unceasing identification and development of new antiviral drugs above all against HIV and HCV, we have witnessed a concomitant and tremendous progress in understanding all the aspects of the modern medical virology: molecular steps of viral life cycle, pathogenesis, immune response, epidemiology, and diagnosis. From such concurrence, new and often unexpected issues in the antiviral chemotherapy field stemmed during the last few years. A detailed and exhaustive description of all these aspects is outside the scope of this chapter, but it is worth at least to discuss the main and most interesting one.

For instance, it became clear that one drug may be inadequate to control viral infections while combination therapy with several antiviral drugs may be therapeutically effective in controlling viral infections such as HIV, HCV, and HBV. Thus, the general strategy of antiviral therapy is changed drastically considering always as occurred in other diseases the use of a combination of different antiviral drugs targeting different steps of the viral life cycle.

At the same time, we have also learned that some viruses possess an extraordinary propensity to undergo continuous diversification of the viral population and this, other than making difficult to carry out the prevention strategies, raises issues related to the antiviral field because of the possibility to develop drug-resistant viral variants under antiviral drug pressure.

It is well known that administration of standard doses of most of the current antiviral drugs results in plasma drug concentrations that may differ significantly among different individuals. Obviously, this may influence the antiviral activity, the emergence of resistant variants and the incidence of drug-related

toxicities. In some viral infection, treatment compliance became one of the main aspects that may affect drug concentration and, consequently, the success of therapy. Optimal adherence to antiretroviral therapy is central to achieving suppression of the HIV viral load in plasma, slowing disease progression, and decreasing HIV transmission rates. In addition, low rates of adherence have also reduced the effectiveness of orally administered preexposure prophylaxis (PrEP). It's important to remember that PrEP is a prevention strategy of giving antiretroviral drugs to an uninfected individual at risk for HIV infection, which reduces the risk of acquiring infection by over 85% as indicated by some clinical trials (McCormack et al. 2016). Long-acting (LA) injectable antiretroviral formulations, that are under investigation, could improve success rates while also helping to prevent transmission (Stellbrink and Hoffmann 2018; Gulick and Flexner 2019). Currently, cabotegravir, an HIV integrase inhibitor, and rilpivirine are the compounds available as LA and under investigation as coformulation (Margolis et al. 2017; Murray et al. 2019).

Furthermore, it is now clear that antiviral therapy may have a role in preventing infection at individual and community levels by decreasing virus transmission. Indeed, in the case of HIV infection, it has been demonstrated that virus transmission in serodiscordant couples is reduced in those who achieved lower viral loads through an effective antiviral therapy, or that HIV suppression prevents virus transmission from infected women to their newborn babies (Grant et al. 2010; Anglemyer et al. 2013). More recently, "partner" studies demonstrated that the risk of HIV transmission in serodifferent heterosexual or gay couples through condomless sex is effectively zero when the HIV-positive partner was on virally suppressive ART (Rodger et al. 2016; Rodger et al. 2019).

Although treatment adherence is crucial to maintain the benefit of therapy, the high interindividual variability in drug concentrations are multifactorial and include differences in concomitant medications, underlying diseases, gender-related metabolism, and genetic factors (Turriziani and Antonelli 2004; Mahungu et al. 2009).

Another issue is represented by the genetic determinants, which include polymorphisms of genes encoding for drug-transporting proteins, receptors, and/or drug targets. To date, pharmacogenetic studies conducted with antiviral drugs have focused on metabolism-involved enzymes and transporter proteins on cell membranes. A few antiviral drugs used for the treatment of HIV infection can cause drug hypersensitivity reactions, which vary in severity, clinical manifestations, and frequency. In most cases, the pathogenesis of these manifestations is unknown, but there is increasing evidence that many are mediated by a combination of immunological and genetic factors through the major histocompatibility complex (MHC) (Chaponda and Pirmohamed 2011). One of the best-known cases is abacavir, which represents the gold standard example of the clinical utility of pharmacogenetic screening in HIV therapy. Indeed, there is a strong association between abacavir hypersensitivity reaction and HLA-B*5701 in racially diverse populations. Genotyping for HLA-B*5701 before prescribing an abacavir-containing regimen has been introduced into routine clinical practice as the standard of care for all patients (Chaponda and Pirmohamed 2011). The safety assessment of antiviral drugs is mandatory, especially in the case of life-long therapy. However, these considerations indicate the need for further research in this area to increase our understanding of the mechanisms underlying therapy-induced side effects and to try to develop predictive genetic biomarkers leading to better management of antiviral agents. Since genetic variations between human beings also account for the variability in the antiviral action of the drug, the same considerations apply to the pharmacokinetic and pharmacodynamic data of individual drugs. We now know that administration of drugs with a narrow therapeutic index may readily be associated with changes in pharmacokinetics and ultimately in variations in antiviral efficacy.

One of the possibilities to tackle the pharmacokinetics issue is therapeutic drug monitoring (TDM), which is widely used at least for those drugs whose plasma concentration is known to be directly correlated to the antiviral action (Wertheimer et al. 2006; Kredo et al. 2009). This approach has been extrapolated from well-known examples in other areas of medicine and again requires close collaboration between virologist, pharmacologist, and clinician for prompt decision making to improve individual patient management. Again, the possibility of TDM is available only for some antiviral drugs and this represents another issue that deserves attention and development in the future.

Finally, there are other challenges that affect the importance of the antiviral chemotherapy and lower, in some way, the extraordinary success obtained in the last decades on this topic: the low rate of viral diagnosis and the unavailability of effective drugs in developing countries; the difficulty in establishing the balance between benefits of treatment and keeping people chronically in care; the delay in development of safe and effective vaccine against some viral diseases. These challenges require additional research but, above all, policy and community discussions.

Introduction

Bacteriophages—specific kinds of viruses that can only replicate in bacteria—have been discussed in much detail in Chapter 48 (Introduction to Bacteriophages) of this book. The art of using these phages to kill pathogenic microorganisms was first developed early in the last century, but since chemical antibiotics became available in the 1940s, phage therapy has been little used in the West. Today, however, the growing incidence of bacteria that are resistant to most or all available antibiotics is leading to widespread renewed interest in the possibilities of phage therapy.[1–16]

In 2014, *Nature* published a news story entitled "Phage Therapy Gets Revitalized."[17] Particular emphasis there was placed on Phagoburn—"the first large, multicenter clinical trial of phage therapy for human infections, largely funded by the European Commission," which invested €3.8 million in the study. The phage

cocktails being used in this project had been developed by the French company Phagoburn, but the project also involved the French military, the patient advocacy group Phagospoir, the production company Clean Cells, and three major burn-care units in France, three in Belgium, and one in Switzerland. We will later discuss the outcome of this study. Collaborative approaches of this sort may well be required to rapidly harness phage to help fight the ever-growing serious antibiotic-resistance crisis. Progress there has been very slow, since phage therapy does not fit well into our standard corporate pharmaceutical model.

This overview is designed to put phage therapy into historical context and to bring the reader up to date with the current status of this approach. We will briefly explore some of the most interesting and extensive applications carried out in Eastern Europe, conducted primarily in a clinical rather than controlled-research mode, and we will look at the original decline and current renaissance of phage therapy work in the West. Ironically, this renaissance takes full advantage of the advances in molecular biology that were themselves made possible by the shift from therapeutic to molecular work with phages in the 1940s under the leadership of Max Delbrück. The rapidly increasing emergence of multiantibiotic-resistant pathogenic bacteria has rekindled the interest of the Western scientific community, industry, and the public in this century-old approach. This is highlighted by several new phage therapy-related publications in the Western peer-reviewed and popular literature and the formation of new biotechnology firms commercializing phage-based technology. Recent work also suggests potential for using phage lysins in accessible places such as nasal passages and in some systemic infections and biofilms as well.[18–21] Detailed discussions of phage ecology, engineering and interesting phage characteristics for human, agricultural and biocontrol applications can be found in the books by Kutter & Sulakvelidze[7] and by Borysowski et al.[21] However, in this review we will focus only on the use of natural, unmodified phages targeting human pathogens.

Biomedical technology today is very different from what it was in the early days of phage therapy research, and our understanding of the biological properties of phages and the basic mechanisms of phage-bacterial host interaction has improved dramatically. These advances can have a profound impact on the development of safe therapeutic phage preparations with optimal efficacy against their specific bacterial hosts and on designing science-based strategies for integrating phage therapy into our arsenal of tools for preventing and treating bacterial infections.

A major benchmark was reached in 2006 with the approval by the U.S. Food and Drug Administration (FDA) of an Intralytix phage cocktail targeting *Listeria monocytogenes* in packaged meats and other food applications. The FDA later also gave GRAS (generally regarded as safe) status to a similar product developed by the European branch of Exponential Biotherapies, EBI Food Safety (now named Micreos Food Safety). Intralytix also supplied the fully sequenced phages that were used in the first FDA-approved clinical trials in the United States, a physician-initiated study adding a cocktail containing two phages against *Staphylococcus aureus*, three against *Pseudomonas aeruginosa*, and one *Escherichia coli* phage to the standard treatment of leg ulcers. Randy Wolcott carried out that study using patients presenting for treatment in his Wound Care Center in Lubbock, Texas in 2006–2007. All safety criteria were met, but the population was too small and varied to establish efficacy.[22] In England, 2006 saw the advent of a clinical trial of phage against *P. aeruginosa* in human ear infections, led by James Soothill and building on a small successful trial in dog-ear infections.[23] In Poland, a phage therapy clinic approved under European Union experimental-therapies guidelines was set up by Andrzej Gorski, director of the Institute of Immunology and Experimental Therapy in Wroclaw, which had long been a center of phage therapy research, and it has been very successful in exploring a variety of phage applications,[24] as discussed in some detail later in this chapter.

Early History

In 1915 and 1917, respectively, Edward Twort and Felix d'Herelle independently reported isolating these filterable entities that could lyse bacterial cultures; they are jointly given credit for the discovery. It was d'Herelle, a Canadian working at the Paris Pasteur Institute, who gave them the name *bacteriophages*—using the suffix *phage* "not in its strict sense of *to eat*, but in that of *developing at the expense of*."[25] From the time he first discovered phages, d'Herelle was excited about their relationship to disease and their potential as therapeutic agents. Their discovery came while he was doing clinical work at the Pasteur Institute exploring why enteric bacteria are only sometimes pathogenic. He was called to investigate an outbreak of bacillary dysentery in a group of French soldiers and examined their filtered stool samples for signs of invisible viruses that might alter the pathogenicity of the bacteria from the dysentery patients. He observed clear, round spots in the confluent bacterial cultures covering his agar slants and determined that the responsible agent, which he called bacteriophage, multiplied indefinitely as long as appropriate living cells were present, and that cell lysis was required for multiplication. Importantly, the presence of the phage correlated with the recovery of sick soldiers.

Shortly after publishing his first paper describing bacteriophages, d'Herelle used specially selected phages to successfully treat avian typhoid in chickens and then human bacterial dysentery. The latter studies were conducted in 1919 with Victor Hutinel, chief of pediatrics at the Hôpital des Enfants-Malades in Paris.[6,7] A dose 100-fold higher than the chosen therapeutic dose was first ingested by d'Herelle, Hutinel, and several interns, and when none of the volunteers showed any side effects a day later, Hutinel approved the first known human therapeutic use of phage. The first patient, a 12-year-old boy with severe dysentery (10–12 bloody stools per day), was given 2 mL of phage orally after taking samples for microbiological analysis. The patient's condition rapidly improved after phage ingestion: he passed three more bloody stools that afternoon and one nonbloody stool during the night, and all symptoms disappeared by the next morning. Three brothers, aged 3, 7, and 10, were then treated the following month; they had been admitted in grave condition after their sister died of dysentery at home and were each given one dose of phage. All three started to recover within 24 hours.

Before attempting further clinical phage trials, d'Herelle turned to basic research, working out the details of phage infection of different bacterial hosts under a variety of environmental conditions. His 300-page 1922 book *The Bacteriophage*[25] includes excellent descriptions of plaque formation and composition,

infective centers, the lysis process, host specificity of adsorption and multiplication, the dependence of phage production on the precise state of the host, isolation of phages from sources of infectious bacteria, and the factors controlling stability of the free phage. He quickly became fascinated with the apparent role of phages in the natural control of microbial infections. He noted, for example, the frequent specificities of the phages isolated from recuperating patients for disease organisms infecting them and the rather rapid variations over time of the phage populations. However, others did not wait for a better understanding of phage biology before applying them clinically. The first known published report of successful phage therapy came from Bruynoghe & Maisin[26] who used phage to treat staphylococcal skin infections.

Throughout his life, d'Herelle worked to develop the therapeutic potential of properly selected phages against the most devastating health problems of the day. After travel to study epidemics in Latin America and a year at the Pasteur branch in Saigon, d'Herelle left the Pasteur Institute in 1922. He worked in Holland and then in Alexandria, Egypt as a health officer for the League of Nations, applying phage therapy and sanitation measures to deal with major outbreaks of infectious disease throughout the Middle East and India. In 1928, he was invited to Stanford to give the prestigious Lane lectures, which were published as the monograph, *The Bacteriophage and its Clinical Applications*.[27] He had accepted a regular faculty position at Yale, carrying on his phage work and helping inspire others to get involved in working with phage. However, he continued to spend summers in Paris working to strengthen the successful company he established there to produce high-quality therapeutic phage cocktails—a company which was run by his son-in-law. In 1933, he returned permanently to France, with excursions to Tbilisi, Georgia to help further establish phage therapy work there.

George Eliava, director of the Georgian Institute of Microbiology, had seen the bactericidal action of the water of the Koura river in Tbilisi, which he could not explain until he became familiar with d'Herelle's work while spending 1920–1921 at the Pasteur Institute.[7,25] The two developed the dream of founding an Institute of Bacteriophage Research in Tbilisi—to be a world center of phage therapy for infectious disease, including scientific and industrial facilities and supplied with its own experimental clinics. The dream quickly became a reality due to the support of Sergo Orjonikidze, the People's Commissar of Heavy Industry, despite KGB opposition to this "foreign project." A large campus on the river Mtkvari was allotted for the project in 1926 and d'Herelle sent supplies, equipment, and library materials.

In 1934 and 1935, d'Herelle visited Tbilisi for 6 months and wrote a book on *The Bacteriophage and the Phenomenon of Recovery*.[28] He intended to move to Georgia; a cottage built for his use still stands on the Eliava Institute's grounds. However, in 1937, Eliava was arrested as a "people's enemy" by Beria, then head of the KGB in Georgia and soon to direct the Soviet KGB. Eliava was executed, sharing the tragic fate of many Georgian and Russian progressive intellectuals of the time, and d'Herelle, disillusioned, never returned from France to Georgia. However, their Institute in Tbilisi survived, led by the people they had trained so well, and it is still functioning at its original site on the Mtkvari. In 1951, it was formally transferred to the Soviet All-Union Ministry of Health set of Institutes of Vaccine and Sera, taking on the leadership role in providing bacteriophages for therapy and bacterial typing throughout the Soviet Union. Under orders from the Ministry of Health, hundreds of thousands of samples of pathogenic bacteria were sent to the institute over the years from throughout the Soviet Union to isolate more effective phage strains and to better characterize their efficacy. The Institute's industrial branch eventually made up to two tons of phage products twice a week, 80% of it for the Soviet Army.[7,12,29] The challenges they faced following the break-up of the Soviet Union, including loss of their primary markets, forced privatization of the industrial arm, the Institute's more recent evolution into the Eliava Institute of Bacteriophage, Microbiology, and Virology, and their current activities are further discussed later in this chapter.

Early World-Wide Attempts at Commercialization

Since the 1930s, a major medically important commercial use of phages has been for so-called *phage typing*, using patterns of sensitivity to a specific battery of phages with particularly narrow host ranges to precisely characterize bacterial strains. This technique takes advantage of the fine specificity of many phages for their hosts and is still in common use around the world for epidemiological and diagnostic purposes, using various approved carefully defined sets of commercially prepared phages (see Chapter 8 in this book).

Therapeutic administration of phages was explored extensively in many parts of the world, with successes being reported for a variety of diseases, including dysentery, typhoid and paratyphoid fevers, pyogenic and urinary-tract infections, and cholera. Phages have been given orally, through colon infusion, as aerosols, and poured directly in lesions. They have also been given as injections: intradermal, intravascular, intramuscular, intraduodenal, intraperitoneal, and even (very rarely) into the lung, carotid artery, and pericardium. The early strong interest in phage therapy is reflected in some 800 papers published on the topic between 1917 and 1956, many of which have been reviewed by Ackermann & DuBow,[30] Kutter & Sulakvelidze,[7] Kutter et al.,[12] and Abedon et al.[14] The reported results were quite variable. Many of the early physicians and entrepreneurs who became so excited by the potential clinical implications jumped into applications with very little understanding of phages, microbiology, or basic scientific process. Thus, many of the studies were anecdotal and/or poorly controlled; many of the failures were predictable, and some of the reported successes did not make scientific sense.

Much of the understanding gained by d'Herelle was ignored in this early work, and inappropriate methods of preparation, supposed "preservatives" and storage procedures were often used. On one occasion, d'Herelle reported testing 20 preparations from various companies and finding that none of them contained active phages! On another occasion, a preparation was advertised as containing a number of different phages, but the technician responsible had decided it was easiest to grow them up in one large batch and one phage had out-competed all the others, so this was not, in fact, a polyvalent preparation. In general, there was little or no quality control except in a few research centers. It is not surprising that virtually all the published successful work in the United States in the 1920s–1940s involved phage preparations made in academic labs that were collaborating with clinical

researchers, not the phage produced by corporations. Large clinical studies were rare, and the results of those that were carried out were largely inaccessible outside of Eastern Europe until 1990, when Dr. Kutter spent 4 months in the Soviet Union on a U.S.-USSR Academies of Science exchange, including two visits to the Eliava Institute, establishing a collaborative partnership. Eliava scientists soon began participating in her biennial Evergreen International Phage Meetings. Accessibility to the classical Georgian phage therapy work further improved in 2012, when Nino Chanishvili published an extensive review[31] of the material in the library of the Eliava Institute, supported by the UK Global Partnership Program. Her book provides badly needed access to the extensive studies and clinical applications carried out in the early years in Georgia and, to some degree, in Russia.

Specific Problems of Early Phage Therapy Work

Many still believe (erroneously) that phage therapy was proven not to work during the explorations that began in the 1920s at the Pasteur Institute and went on until the 1940s in Europe and the United States; however, it simply was never adequately researched, having ended before most tools of microbiology and molecular biology became available, and the work that was done well is not widely enough known. It is thus important to carefully consider the reasons for the early problems and the questioning of efficacy. These included:

- Paucity of understanding of the heterogeneity and ecology of either the phages or the bacteria involved
- Lack of availability or reliability of bacterial laboratories for carefully identifying the pathogens involved (necessitated by the relative specificity of phage therapy)
- Frequent failure to select phages of high virulence against the target bacteria and to test them *in vitro* before using them in patients
- Use of single phages in infections, which involved mixtures of different bacterial species and strains
- Emergence of resistant bacterial strains, (especially problematic if only one phage strain is used against a particular bacterium); this can also happen by lysogenization if one uses temperate phages, discussed in the previous chapter.
- Failure to neutralize gastric pH prior to oral phage administration
- Inactivation of phages by both specific and nonspecific factors in bodily fluids, especially if phages were used intravenously

Key technical developments that helped to clarify the general nature and properties of bacteriophages included:

- The concentration and purification of some large phages by means of very high-speed centrifugation, developed in the early 1940s, and the demonstration that they were made up of approximately equal amounts of DNA and protein[32]
- Visualization of phages by means of the newly developed electron microscope (EM)[33,34]

A much better understanding of the interactions between lytic phages and bacteria began with the one-step growth curve experiments of Ellis and Delbrück[35] and the studies of Doermann.[36] These experiments demonstrated an eclipse period during which the DNA began replicating and there were no free phages in the cell; a period of accumulation of intracellular phages; and a lysis process that released the phage to go in search of new hosts, as discussed in Chapter 48 (Introduction to Bacteriophages). While this basic pattern had been described by d'Herelle,[25] few people were aware of the details of his work.

In 1943, an event happened that was to have a major impact on the orientation of phage research in the United States and much of western Europe, strongly shifting the emphasis from practical applications to basic science. Physicist-turned-phage biologist Max Delbrück met with Alfred Hershey and Salvador Luria and formed the "Phage Group," which rapidly expanded through the influence of the annual summer "Phage Course" and phage meetings at Cold Spring Harbor, Long Island that began in 1945. Their influence on the origins of molecular biology has been well documented.[37,38]

A major element of the successes of phage as model systems for working out fundamental biological principles was that Delbrück convinced most phage biologists in the United States to just focus on one bacterial host (*E. coli* B) and seven of its most lytic phages, which he renamed T(type)1–T7. As it turned out, T2, T4, and T6, originally isolated for potential therapeutic applications, were quite similar to each other, defining a family now called the "T-even phages." These phages were key in demonstrating that DNA is the genetic material, that viruses can encode enzymes, that gene expression is mediated through special copies in the form of "messenger RNA," that the genetic code is triplet in nature, and many other fundamental concepts. The negative side of this strong focus on a few phages growing under rich laboratory conditions, however, was that there was very little study or awareness of the ranges, roles, and properties of bacteriophages in the natural environment, or of potential therapeutic applications.

Early Studies of Phage Behavior in the Animal Body

A number of fairly early experiments involving the injection of phages into animals led to the widespread impression that phage therapy could not in fact succeed because the phage were too rapidly cleared by the immune system; the remarks in this regard by Gunter Stent[39] had a particularly strong impact on the phage community. For example, two early experiments involving rabbits showed rapid disappearance of the particular phages used from the blood and organs, but long-term survival in the spleen.[40,41] Subsequent experiments in rats and mice also showed rapid loss from the circulation. When Nungester & Watrous in 1934 injected 10^9 PFU of a staph phage intravenously into albino rats, a blood concentration of only 10^5 PFU/mL was seen after 5 minutes, and this dropped to 40 PFU/mL by 2 hours.[42,43]

The pessimistic conclusions broadly reached based on this research, however, had two serious flaws. First, the experiments were done in the absence of host bacteria in which the phage could multiply and find protection. Furthermore, they were carried out

by the very unnatural mode of intravenous injection, subjecting the phage almost immediately to the reticuloendothelial system. Many more recent results have made it clear that phage are often seen in the mammalian circulatory system; however, this generally occurs under conditions where they are entering the circulatory system from some sort of reservoir in other tissues and where the mammal is dealing with an infection by a bacterium that the phage can infect—precisely the sort of situation seen in phage therapy as currently practiced in Eastern Europe.

One of the best early sets of experiments was published in 1943 by the noted Harvard bacteriologist, René Dubos.[44] He injected white mice intracerebrally with a dose of a smooth *Shigella dysenteriae* strain that was sufficient to kill >95% of the mice in 2–5 days and then treated them by intraperitoneal injection of a phage mixture isolated from New York City sewage, grown in the same bacteria and purified only by sterile filtration. With no treatment, when treated with filtrates of uninfected bacterial cultures, or with heat-killed phage, only three of 84 (3.6%) survived, whereas 46 of 64 (72%) of those given 10^7–10^9 active phage survived. Dubos also carried out pharmacokinetic studies. When phage were given to uninfected mice, they appeared in the blood stream almost immediately, but the levels started to drop within hours and very few were seen in the brain. In contrast, brain levels in the infected animals quickly greatly exceeded blood levels; around 10^7–10^9 phage per gram were often seen between 8 and 110 hours, starting to drop anywhere between 75 and 140 hours. After the first 18 hours, the levels in the blood were far lower than in the brain, but still present at 10^4–10^5 PFU per mL in those cases where the brain levels were still over 10^9 per gram. Their data are shown graphically in the review by Kutter et al.[12] Dubos' studies clearly established that the phage themselves were responsible, not something in the lysate that just stimulated normal immune mechanisms; that phage could rapidly find and multiply in pockets of infection anywhere in the body; and that phage could be maintained in the circulation as long as there was a reservoir of infection where phage were continually being produced. Without providing data or pharmacokinetics, they mention that the mice were also rescued by subcutaneous or intravenous administration of the phage, but not by stomach tube or in drinking water.

Carefully controlled experiments carried out in 1943–1945 by Henry Morton's group at the University of Pennsylvania[45] supported those of Dubos. They further showed the lack of any protection when lysates of phage with inappropriate host specificities were used. A final review authorized by the Council on Pharmacy and Chemistry discussed the major advantages of phage, such as the ability to enter problem areas and multiple there if appropriate bacteria were present, thus treating localized infections that are relatively inaccessible via the circulatory system. Also, it emphasized that the high specificity of phage greatly aided in reducing later resistance problems and that almost all of the earlier research had been so poorly conceived and/or carried out that it offered no proof either for or against the promise of phage as antibiotics.

U.S. work with dysentery phages largely ended in 1944 when penicillin was made available to the general public. The military secrecy, the end of the war emergency funding, the rapid rise in antibiotic availability and their broad spectra, and Max Delbrück's success in convincing the phage community to shift its focus to basic mechanistic research involving a few model systems all contributed to the fact that there was little U.S. follow-up to these interesting and successful results, and few even knew about them—or about two successful subsequent human applications.

Penicillin only worked against some kinds of bacterial infections. Typhoid, for example, was not treatable, and some excellent phage work was carried out in the interim. It was known that the strains of *Salmonella typhi* that created the main pathogenicity problems were those carrying one particular antigen, named Vi (for "virulence"). In 1936, a pair of Canadians had identified phages specific against cells bearing the Vi antigen. In the early 1940s, Walter Ward, of the Los Angeles County Hospital, was trying to deal with repeated serious outbreaks of typhoid fever that were killing one in five of those afflicted.[46] He tested the Vi-specific phages against mouse typhoid, and found that the death rate fell to 6%, versus 93% in the controls. Some of his colleagues then used these phages to treat typhoid patients; only 3 of 56 of their treated patients died, versus the 20% mortality they were seeing with the other treatments available at the time.[47] Most impressively, the rest of the patients rapidly went from being largely comatose to full of vigor, with renewed appetite, in 24–48 hours. In 1948–1949, near Montreal, Desranleau treated nearly 100 dysentery patients with a cocktail of six Vi-specific phages, and the deaths dropped from 20% to 2%.[48] However, by 1947, chloramphenicol had been shown to work well against typhoid and it was much easier for pharmaceutical companies to deal with, so that seems to have been the (hopefully temporary) end of phage clinical trials in the Western Hemisphere.

Clinical Application: Phage Therapy Work in the Age of Antibiotics

The strong understanding of phage biology gained in recent years has the potential to facilitate far more rational thinking about the therapeutic process and the selection of therapeutic phages. During the evolution of molecular biology, there was little interaction between those who were so effectively developing the field using phage as tools to understand molecular mechanisms and structures and those working on phage ecology and therapeutic applications. As discussed extensively in the books by Kutter & Sulakvelidze,[7] Häusler,[11] McGrath & van Sinderen,[49] and Borysowski et al.,[21] the latter fields have grown greatly in recent years, spurred on by an increasing awareness of phage variety and roles in maintaining microbial balance in every ecosystem, and by concerns about the increasing incidence of nosocomial infections and of bacteria resistant against most or all known antibiotics, as well as by the fact that phages are far more effective than antibiotics in areas where the circulation is bad, and they do not disrupt normal flora. This strong sense of the potential importance of phage was seen particularly early on in Poland, France, Switzerland, and the former Soviet Union, where use of therapeutic phages never fully died out and where there has been some ongoing research and clinical experience. In France, Dr. Jean-François Vieu led the therapeutic phage efforts until his retirement in 1980. He worked in the *Service des Entirobactiries* of the Pasteur Institute in Paris and, for example, prepared *Pseudomonas* phages on a case-by-case basis for patients. The experience there is discussed in Vieu[50] and Vieu et al.[51] In Vevey, Switzerland, the small pharmaceutical firm *Saphal* made "Coliphagine," "Intestiphagine," "Pyophagine," and "Staphagine" in drinkable and injectable forms, salves, and

sprays into the 1960s.[11] The preparations were officially approved and were paid for by insurance there. However, in the Western world they soon were totally superseded by the explosive development and commercialization of modern antibiotics, with their broad host ranges.

Phage therapy continued to be extensively used in the Soviet Union. Much of the research and strong early therapeutic phage preparation and application came through the Eliava Institute in Tbilisi, Georgia, strongly stimulated and supported by Felix d'Herelle, as described in some detail later in this chapter. The Eliava Institute still plays a leading role in phage therapy education, exploration and application and its reintroduction to the rest of the world. By the 1980s, they had helped develop production centers in the Russian towns Ufa, Alma Ata, and Nizhniy Novgorod.[7] In recent years, these formed the kernel of Russian companies that are now again developing and marketing complex therapeutic phage preparations, led by the pharmaceutical giant Microgen and available in pharmacies throughout Russia as well as on line. They also held very interesting phage therapy conferences in 2016 in Moscow and 2018 in Nizhniy Novgorod, with significant international participation in addition to speakers actively involved in the field from all over Russia; Dr. Kutter, coauthor of this chapter, was keynote speaker at the latter.

Serious phage therapy research work in Wroclaw, Poland expanded markedly in the 1970s, and they hosted the 2018 Viruses of Microbes meeting, which drew more than 400 participants. In both Tbilisi and Wroclaw, the close interactions between research scientists and physicians played an important role in the high degree of success obtained—just as appears to have been the case for d'Herelle's early work and the many cases of successful phage therapy applications reported in the United States in the 1930s and 1940s.

Institute of Immunology and Experimental Medicine, Polish Academy of Sciences

The most detailed publications documenting successful early phage therapy have come from the group of Stefan Slopek, director for many years of the Institute of Immunology and Experimental Medicine, Polish Academy of Sciences, Wroclaw. They published a series of extensive papers describing work carried out from 1981 to 1986 with 550 patients.[52–54] This set of studies involved 10 Polish medical centers, including the Wroclaw Medical Academy Institute of Surgery Cardiosurgery Clinic, Children's Surgery Clinic and Orthopedic Clinic, the Institute of Internal Diseases Nephrology Clinic, and the Clinic of Pulmonary Diseases. The patients ranged in age from 1 week to 86 years. In 518 of the cases, phage use followed unsuccessful treatment with all available other antimicrobials. The major categories of infections treated were:

- long-persisting suppurative fistulas
- septicemia
- abscesses
- respiratory tract suppurative infections and bronchopneumonia
- purulent peritonitis
- furunculosis

In a final summary paper, the authors carefully analyzed the results with regard to such factors as nature and severity of the infection and monoinfection versus infection with multiple bacteria.[54] Rates of success ranged from 75% to 100% (92% overall), as measured by marked improvement, wound healing, and disappearance of titratable bacteria; 84% demonstrated full elimination of the suppurative process and healing of local wounds. Infants and children did particularly well. Not surprisingly, the poorest results came with the elderly and those in the final stages of extended serious illnesses, two groups with weakened immune systems and generally poor resistance.

The phages all came from the extensive collection of the Bacteriophage Laboratory of the Institute of Immunology and Experimental Therapy, Polish Academy of Sciences, Wroclaw. In the later studies, some of the specific phages they employed were identified. All were virulent, capable of completely lysing the bacteria being treated. In the first study alone, 259 different phages were tested (116 for S*taphylococcus*, 42 for *Klebsiella*, 11 for *Proteus*, 39 for *Escherichia*, 30 for *Shigella*, 20 for *Pseudomonas*, and one for *Salmonella*); 40% of them were selected to be used directly for therapy. All the treatments were carried out in a research mode, with the phage prepared at the institute by standard methods and tested for sterility. Treatment generally involved 10 mL of sterile phage lysate administered orally half an hour before each meal, with gastric juices neutralized by taking (basic) Vichy water, baking soda, or gelatum. In addition, phage-soaked compresses were often applied three times a day where dictated by localized infection. Treatment ran for 1.5–14 weeks, with an average of 5.3 weeks. For gastrointestinal problems, short treatment usually sufficed, while long-term use was necessary for such problems as pneumonia with pleural fistula and pyogenic arthritis. Bacterial levels and phage sensitivity were continually monitored, and the phage(s) were changed if the bacteria being targeted developed resistance to the particular phages, which was very common for gram-negative bacteria. Therapy was generally continued for 2 weeks beyond the last positive test for the bacteria.

Few side effects were observed; those that were seen seemed to be directly associated with the therapeutic process. On about days 3–5, pain in the liver area was often reported, lasting several hours. The authors suggested that this might be related to the extensive liberation of endotoxins as the phage are destroying the bacteria most effectively. In severe cases with sepsis, patients often ran a fever for 24 hours on about days 7 to 8.[52]

Various methods of administration were successfully used, including oral, aerosol, and infusion rectally or in surgical wounds. Intravenous administration was not recommended for fear of possible toxic shock from bacterial debris in the lysates.[52] However, it was clear that the phages readily entered the body from the digestive tract and multiplied internally wherever appropriate bacteria were present, as measured by the level of their occurrence in blood and urine as well as by therapeutic effects.[55] This interesting and rather unexpected finding has been replicated in many studies and systems,[56–59] while control studies in the absence of bacterial infection seldom show any phage in the urine.

Detailed notes were kept throughout on each patient. The final evaluating therapist also filled out a special inquiry form that was sent to the Polish Academy of Science research team along with

the notes. The Computer Center at Wroclaw Technical University carried out extensive analyses of the data. They used the categories established in the WHO (1977) International Classification of Diseases in assessing results. They also looked at the effects of age, severity of initial condition, type(s) of bacteria involved, length of treatment, and other concomitant treatments. The papers included many specific details on individual patients, which helped to give some insight into the ways phage therapy was used as well as an in-depth analysis of difficult cases.

After Slopek's retirement, Dr. Beatta Weber-Dabrowska carried on with the phage preparation and treatment work. She published a very interesting and useful summary in English of the results with the next 1,600 patients[60] and continues to play a very major role in the Institute's ongoing phage therapy work and the relevant training of excellent, dedicated young scientists. In 1998, immunologist A. Górski took over as Institute Director and helped her build up a very strong focus on their phage therapy work, with special emphasis on the immunological consequences of phage treatment.[10,15,21,61] He now has passed on the directorship of the Institute and focuses all of his energy on the Laboratory of Bacteriophages, which he still heads (http://www.iitd.pan.wroc.pl/en/Phages/). Under the experimental therapeutics rules of the European Union, to which Poland now belongs, they have opened their own small clinic at the Institute and are treating both Polish and occasional international patients there while collecting data in a carefully controlled fashion.[15,21,24,62]

Recent publications by this Polish group have focused on phage interactions with the immune system, ranging from studies on phage applications in allergy challenges and graft versus[63–77] host disease, to phage therapy in autoimmune liver disease and phage as an immune modulator. These important works give insight into the additional significant approaches and therapeutic properties phage can offer, including for example down regulation of inflammatory cascades, among others. They also have long worked closely with Dr. M. Lobocka's strong phage molecular biology group in Warsaw to sequence and further characterize their key therapeutic phages and explore a broad range of new candidates and targets, very effectively supporting their therapeutic work.[68]

Eliava Institute of Bacteriophage, Microbiology, and Virology, Tbilisi, Georgia

The most extensive work on phage therapy is still being carried out under the auspices of the Bacteriophage Institute in Tbilisi, in the former Soviet republic of Georgia, as discussed previously in this chapter; much more detail can be found in several reviews.[7,12–15] In Georgia, phage therapy was long part of the general standard of care, especially in pediatric, burn, and surgical hospital settings. Phage preparation was carried out on an industrial scale, employing 700 people in the factory and several hundred more in the research arm of the Institute just before the 1990 break-up of the Soviet Union, and many tons of various products were regularly shipped throughout the former Soviet Union, mainly for use by the military. They were also available both over the counter and through physicians. The largest use was in hospitals, to treat both primary and nosocomial infections, alone or in conjunction with other antibiotics and particularly when antibiotic-resistant organisms were found. The Georgian military was among the strongest supporters of phage therapy research and development because phage have proven so useful for wound and burn infections as well as for preventing debilitating gastrointestinal epidemics among the troops. The International Science and Technology Centers (ISTC) program, set up jointly by the United States, Europe, and Japan to give constructive opportunities to scientists formerly working with Soviet military projects, also became a strong supporter of basic and applied research in this area in Tbilisi in the 1990s, as did the Civilian Research and Defense Fund (CRDF) and the Science & Technology Center in Ukraine (STCU), with similar goals. National versions of the two very complex major therapeutic phage cocktails, Pyophage (for wounds) and Intestiphage, are still very widely sold in pharmacies in both Georgia and Russia.

From quite early on, the industrial arm of the Eliava was run on a self-supporting basis, making multiple tons weekly of the major phage cocktails, while its scientific branch was government-supported. The latter included the electron microscope facility, permanent strain collections, laboratories studying a variety of phages of the enterobacteria, staphylococci, and pseudomonads, constantly updating the commercial phage cocktails and formulating new ones. In addition, it had groups involved in immunology, vaccine production, *Lactobacillus* work, and other therapeutic approaches. It also carried out the very extensive studies of each new strain, addition to the therapeutic cocktail, host strain if any and means of delivery needed for approval by the Ministry of Health in Moscow. This careful study of the host ranges, lytic spectra, cross-resistance, and other fundamental properties of the phages being used was a major factor in the reported successes of the phage therapy work carried out through the institute, as was their ability to initially select particularly useful, highly virulent phages from among the myriads potentially available against any given host. All the phages used there for therapy are obligatorily lytic, avoiding the problems engendered by lysogeny. The problems of bacterial resistance were largely solved using well-chosen mixtures of phages with different receptor specificities against each target type of bacterium as well as of phages against the various bacteria likely to be causing the problem in multiple infections. The situation was further improved whenever the clinicians typed the pathogenic bacteria and monitored their phage sensitivity. Where necessary, they added additional phages to which the given bacteria were sensitive. Not infrequently, using a phage in conjunction with carefully chosen antibiotics was found to give better results than either the phage or the antibiotic alone.

A great deal of work went into developing and providing the documentation for Ministry of Health approval of specialized new cocktails and delivery systems, such as a spray for use in respiratory tract infections, in treating the incision area before surgery, and in sanitation of hospital problem areas such as operating rooms. An enteric-coated pill was also developed, using phage strains that could survive the drying process, and accounted for the bulk of the shipments to other parts of the former Soviet Union.

The depth and extent of the work involved are very impressive. For example, in 1983–85 alone, the Institute's Laboratory of Morphology and Biology of Bacteriophages carried out studies of growth, biochemical features, and phage sensitivity on 2,038 strains of *Staphylococcus*, 1,128 of *Streptococcus*, 328 of *Proteus*,

373 of *P. aeruginosa*, and 622 of *Clostridium* received from clinics and hospitals in towns across the former Soviet Union. New broader-acting phage strains were isolated using these and other Institute cultures and were included in a reformulation of their extensively used Pyophage and Intestiphage preparations. In the years since, both formulations have continued to be extensively improved based on further studies, and phages against *Klebsiella* and *Acinetobacter* have also been isolated and developed into therapeutic cocktails. The other major product, *Intestiphage*, was used very extensively by the military, the pediatric centers, and in regions with extensive diarrheal problems; it includes phages active against a range of enteric bacteria, which were often also prepared in tablet form.

Much of the focus in the last 50 years has been on combating nosocomial infections, where multidrug-resistant organisms have become a particularly lethal problem and where it is also easier to carry out proper long-term research. Special mixtures were developed for dealing with strains causing nosocomial infections in various hospitals, and they were very effectively used in sanitizing operating rooms and equipment, water taps and other sources of spread of the infections (most of them involving predominantly *Staphylococcus*). The number of sites testing positive for the problem bacteria decreased by orders of magnitude over the several months of the trial at each site. Clinical and prophylactic studies in collaboration with institutions such as the Leningrad (now St. Petersburg) Intensive Burn Therapy Center, the Academy of Military Medicine in Leningrad, the Karan Trauma Center, and the Kemerovo Maternity Hospital as well as in Tbilisi at the Pediatric Hospital, the Burn Center, the Center for Sepsis and the Institute for Surgery, were used to further develop treatment protocols and phage cocktails. During the 1991–1992 invasion by Russian troops, every soldier carried a special version of Pyophage formulated and constantly updated through a collaboration between the chief military surgeon Dr. Guram Gvasalia and the Eliava's Dr. Zemphira Alavidze to best target the major pathogens being encountered by the soldiers in the field. The soldiers could immediately use this in the field to treat any wounds received; this approach was highly successful. However, Western-style double-blind clinical trials are still needed before Intestiphage, Pyophage, and their other narrower-spectrum cocktails can be marketed in the rest of the world.

An exciting new product completed the Georgian approval process and was licensed in 2000 by the Georgian Ministry of Health. PhagoBioDerm™, developed by Dr. Alavidze in collaboration with chemist Ramaz Katsarava of Tbilisi's Technical University, is a biodegradable, nontoxic polymer composite that is impregnated with the Pyophage cocktail of phages, along with other antimicrobial agents.[69] Markoishvili et al.[70] reported the results of a study of PhagoBioDerm™ involving 107 patients with ulcers that had failed to respond to conventional therapy, including systemic antibiotics, antibiotic-containing ointments, and various phlebotonic and vascular-protecting agents. The patients were treated with PhagoBioDerm™ alone or in combination with other interventions during 1999 and 2000. The wounds or ulcers healed completely in 70% of the 96 patients for whom there was follow-up data. In the 22 cases for which complete microbiologic analyses were available, healing was associated with the concomitant elimination or very marked reduction of the pathogenic bacteria in the ulcers. Other versions of the product are now available in pharmacies or in the final developmental stages. Further studies investigating the immobilization of bacteriophage in nanostructure wound dressings are ongoing by both Portuguese and Georgian researchers.[71]

In 2005, Dr. Gvasalia, by then head surgeon at the central Georgian state medical school, started a Surgical Infections and Phage Therapy training program with support from the PhageBiotics Research Foundation to help prepare young Georgian surgeons for treating major wound infections and for carrying out research on phage therapy. Much of Dr. Gvasalia's expertise has been transferred to several of his former resident surgeons, but the main practical legacy is in the two phage-therapy clinics in Tbilisi. The Eliava Phage Therapy Center is a part of the Eliava Foundation suite of companies, treating both Georgian and international patients.

The older Tbilisi Phage Therapy Center was started in 2003 by the members of Dr. Alavidze's lab and the primary Bioderm co-developer, chemist Ramaz Katsarava, working with Dr. Gvasalia. In 2005, it became part of a new California-based American company, Phage International. In 2009, the Eliava Foundation was founded by the Eliava Institute group of senior scientists as a nongovernmental body to promote the development and marketing of Eliava products and services for human, animal, plant, and environmental applications (eliava-institute.org/eliava-foundation). It has spun off multiple small related companies, including under its umbrella the already established Diagnostics Center and Eliava BioPreparations, the phage cocktail production company. It has also formed new subsidiary enterprises such as an Eliava Media Production Center, the Eliava Authorized (Compounding) Pharmacy, the Eliava Phage Therapy Center, and the Eliava Management group. The purpose of the Foundation is to promote the development and marketing of Eliava products and services for human, animal, plant, and environmental applications, independently from the Institute's status under the Georgian Academy of Sciences (eliava-institute.org/eliava-foundation). A very important newly approved Eliava product soon joined their Intestiphage and Pyophage in most Georgian pharmacies.[72] This is a highly purified solution of their sequenced phage Sb1, which targets 99% of *S. aureus* strains.

Of particular importance, in 2010 the Eliava Foundation opened its own outpatient clinic on its grounds to treat both Georgians and foreign patients, and its own compounding pharmacy, whose services include isolating and preparing specific phages for patients when the commercial cocktails aren't efficacious.

Many Georgian pharmacies also market a variety of licensed phage cocktails produced by Biochimpharm. This is a privately-owned phage therapy company that was developed out of the commercial section of the old Eliava Institute, which was privatized in 1994 along with many other former Soviet companies. Biochimpharm also markets its phage cocktails online.

The extensive clinical observations in Georgia and Poland confirm that phages have many potential advantages:

- They are self-replicating but also self-limiting, since they multiply only as long as sensitive bacteria are present.
- They can be targeted far more specifically than most antibiotics to the problem bacteria, causing much less

damage to the normal microbial balance in the gut. Particular resultant problems of antibiotic treatment include *Pseudomonads*, which are especially difficult to treat, and *Clostridium difficile*, the cause of serious diarrhea and pseudomembranous colitis.[73]

- Phages can often be targeted to receptors on the bacterial surface that are involved in pathogenesis, so any resistant mutants are attenuated in virulence.
- Few side-effects have been observed, and none of them were serious.
- Phage therapy is particularly useful for people with allergies to antibiotics.
- Appropriately selected phages can easily be used prophylactically to help prevent bacterial disease at times of exposure or to sanitize hospitals and to help protect against hospital-acquired (nosocomial) infections.
- Especially for external applications, phages can be prepared fairly inexpensively and locally, facilitating their potential applications to underserved populations.
- Phages can be used either independently or in conjunction with antibiotics used intravenously and help reduce the development of bacterial resistance.

The Western World Rediscovers Phage Therapy: The 1980s and 1990s

Levin & Bull,[1] Barrow & Soothill,[3] and Kutter & Sulakvelidze[7] have extensively reviewed the animal research carried out in Britain and the United States after interest in the possibilities of phage therapy began resurfacing in the early 1980s. The results, in general, are in very good agreement with the clinical work described above in terms of efficacy, safety and importance of appropriate attention to the biology of the host–phage interactions, reinforcing trust in the reported extensive eastern European results.

In Britain, Smith & Huggins[56–59] carried out a series of excellent, well-controlled studies on the use of phages in systemic *E. coli* infections in mice and then in diarrheic disease in young calves and pigs. For example, they found that injecting 10^6 colony-forming units (CFU) of a particular pathogenic *E. coli* strain intramuscularly killed 10 out of 10 mice, but none died if they simultaneously injected 10^4 plaque-forming units of a phage selected against the K1 capsule antigen of that bacterial strain. A single treatment with this phage was far more effective than using such antibiotics as tetracycline, streptomycin, ampicillin, or trimethoprim/sulfafurazole, even when many doses of the antibiotics were used. Furthermore, the resistant bacteria that emerged had lost their capsule and were far less virulent. In calves, they also found very high and specific levels of protection. They had to isolate different phages for each of their pathogenic bacterial strains, since they were focusing on high specificity against the pathogens and did not succeed in isolating phages specific for more general pathogenicity-related surface receptors such as the K88 or K99 adhesive fimbriae, which play key roles in attachment to the small intestine. Still, the phage treatment was able to reduce the number of bacteria bound there by many orders of magnitude and to virtually stop fluid loss. The results were particularly effective if the phage were present before or at the time of bacterial infection, and if multiple phages with different attachment specificities were used. Furthermore, the phage could be transferred from animal to animal, supporting the possibility of prophylactic use in a herd. If the phage were given only after the development of diarrhea, the severity of the infection was still substantially reduced, and none of the animals died.[59]

Levin & Bull[1] conducted a detailed analysis of the population dynamics and tissue phage distribution of the 1982 Smith & Huggins[56] study, which can be helpful in assessing the parameters involved in successful phage therapy and its apparent superiority to antibiotics. They have gone on to do interesting animal studies of their own and conclude that phage therapy is at least well worth further study.[1]

Barrow & Soothill[3] carried out a series of studies preparatory to using phages for treating infections of burn patients. Using guinea pigs, they showed that skin graft rejection could be prevented by prior treatment with phages against *P. aeruginosa*. They also saw excellent protection of mice against systemic infections with both *Pseudomonas* and *Acinetobacter* when appropriate phages were used.[3] In the latter case, they reported that as few as 100 phages protected against infection with 10^8 bacteria—several times the LD_{50}.

Merrill et al.[74] carried out a series of experiments designed to better understand the interactions of phages with the human immune system and helped MD Richard Carlton start a company called Exponential Biotherapies to explore the possibilities of phage therapy. Their initial work was with lytic derivatives of the temperate phages λ and P22—very poor choices for therapeutic applications, as discussed in this chapter—but they gathered some very interesting data about factors affecting interactions between these phages and the innate immune system and patented a process for isolating longer-circulating mutants of phage lambda. They published successful animal studies with phages against Vancomycin-resistant *Enterococcus* and carried out a successful (but unpublished) small stage-one clinical safety trial with these phages, but focused more on work in the area of food safety, which required much less venture capital. In the spring of 2006, a spin-off Dutch branch, EBI food safety (now called Micreos food safety), became the first company to receive governmental approval of phage as a food additive. Their phage preparation to destroy *Listeria monocytogenes* on cheeses was also granted GRAS status by the United States Food and Drug Administration (FDA) that fall. Earlier in 2006, after taking 4 years for a very thorough review, the FDA had also approved a Listeria-phage cocktail made by Baltimore-based Intralytix for use on packaged meats.

Phage and Bacterial Pathogenicity

Most bacteria are not pathogenic; in fact, they play crucial roles in the ecological balance in the digestive system, mucous membranes, and all body surfaces. They often actually help to protect against pathogens. This is one reason why broad-spectrum antibiotics have such a large range of side-effects and why more narrowly targeted bactericidal agents would be highly advantageous. Interestingly, most of the serious pathogens are close relatives of nonpathogenic strains; there, antibiotics can't differentiate between pathogenic and nonpathogenic strains, but phages can be isolated that are appropriately selective.

Studies clarifying the mechanisms of pathogenesis at the molecular level have progressed remarkably in recent years, crowned by determination of the complete sequence of many bacteria and extensive cloning and sequencing of pathogenicity determinants. Generally, several genes are involved, and many of these are clustered in so-called "pathogenicity islands," or PAIS, which may be 50,000–200,000 base pairs long. They generally have some unique properties indicating that the bacterium itself probably acquired them as a sort of "infectious disease" at some time in the past, and then kept them because they helped the bacterium to infect new ecological niches where there was less competition. Many of these PAIS are carried on small extrachromosomal circles of DNA called *plasmids*, which can also be carriers of drug-resistance genes. Others reside in the chromosome where they are often found embedded in defective temperate prophages which have lost some key genes in the process and cannot be induced to form phage particles. However, they can sometimes recombine with related infecting phages. Therefore, it makes sense to avoid using temperate phages or their lytic derivatives for phage therapy to avoid any chance of picking up such pathogenicity islands.

For bacteria in the human gut, pathogenicity involves two main factors:

- The production of toxin molecules, such as Shiga toxin (from *Shigella* and some pathogenic *E. coli*) or cholera toxin; these toxins modify proteins in the target host cells and thereby cause the problem.
- The acquisition of cell-surface adhesins, which allow the bacterium to bind to specific receptor sites in the small intestine, rather than just moving on through to the colon.

Pathogenic bacteria also all contain the components of so-called type III secretion machinery, related to structures involved in the assembly of flagella (for motility) and of filamentous phages, and instrumental in many plant pathogens. For all of the pathogenic enteric bacteria, the infection process triggers changes in the neighboring intestinal cells. These include degeneration of the microvilli, formation of individual "pedestals" cupping each bacterium above the cell surface, and, in the case of *Salmonella* and *Shigella*, induction of cell-signaling molecules that trigger engulfment of the bacterium and its subsequent growth inside the cell.

For several years, *E. coli* O157:H7 has been the subject of much concern, with contamination of such products as hamburgers and unpasteurized fruit juices leading to very serious problems. Particularly in young children and the elderly, there is a high probability of death when O157 infections evolve into hemorrhagic colitis (bloody diarrhea) and hemolytic-uremic syndrome, where the kidneys are affected. Antibiotic therapy has shown no benefit; it is actually generally contraindicated because it leads to increased toxin release.[75] We have isolated phages that look promising for reducing the O157 load in livestock from sheep naturally *resistant* to inoculation with *E. coli* O157:H7, working with collaborators at the U.S. Department of Agriculture in College Station, Texas.[76–78] A major job there is to eliminate this human pathogen that is found in the normal flora of one-third of the cattle brought to slaughter in the United States, contaminating water sources and creating massive recalls for industries from meat packers to juices to packaged spinach. The first phage so isolated turns out to also be T4-related, and to infect virtually all tested O157 strains.[76] Studies are suggesting that this and additional phage we have isolated from sheep are good candidates for controlling O157 in the GI tracts of ruminants[78]; one of them, CBA120, is very highly specific for *E.coli* O157 and is closely related to *Salmonella typhi* phage ViI, used to treat typhoid fever in Los Angeles and Montreal in the 1940s.[47,79] Intralytix and Omnilytix have now both started marketing products that use anti-O157 phages for cleaning the hides of cattle prior to slaughter, and several commercial labs are making use of our CBA120 to explore further applications, such as detection of coli O157.

Phage Therapy with Well-Characterized, Professionally Lytic Phages

A substantial fraction of the phages in current various therapeutic mixes for gram-negative bacteria turn out to also be relatives of bacteriophage T4,[80] which has played such a key role in the development of molecular biology. This family is often called the T-even phages, an historical accident reflecting the fact that T2, T4 and T6 from the original collection of Delbrück's Phage Group all turned out to be related. T4-like phages are found infecting all of the enteric bacteria and their relatives.[81] Large sets have been isolated from all over the world: Long Island sewage treatment plants, animals in the Denver zoo, African lagoons and dysentery patients in eastern Europe (the latter using *Shigella* as host); pediatric diarrhea patients in Bangladesh.[80,82,83]

Most of the T4-like phages targeting enteric bacteria use 5-hydroxymethylcytosine (5-HMdC) instead of cytosine in their DNA, which protects them against most of the restriction enzymes that bacteria make to protect themselves against invaders; this gives the phage a much more effective host range. T4's DNA sequence was the first completed for a large phage, aided by its very extensive system of mutants and the general knowledge of its genome.[80,84,85] We know a great deal about its infection process in standard laboratory conditions and about the methods it uses to target bacteria so effectively.[85,86] We can potentially use this knowledge to develop more targeted approaches to phage therapy, particularly as more is learned about the similarities and differences in its extended family.[80,87] We now know the sequences of many T4-related phages and that certain ones of them use different outer membrane proteins and/or oligosaccharides as their receptors, and we understand the tail-fiber structures involved well enough to potentially predict which phages will work on given bacteria and to engineer phages with new specificities.[88,89]

There have still been far too few studies of T4 ecology and its behavior under conditions more closely approaching the natural environment and the circumstances it will encounter in phage therapy—often anaerobic and/or with frequent periods of starvation. The limited available information in that regard was summarized by Kutter et al.[86] A variety of studies are shedding light on the ability of these highly virulent phages infecting *E. coli* or *Pseudomonas* to coexist in balance with their hosts in nature.[90] For example, they can reproduce in the absence of oxygen as long as their *Pseudomonas* or *E. coli* bacterial host has

been growing anaerobically for several generations (Kutter and Brabban lab students, unpublished data, 2010-2015), or infect *E. coli K803* or *O157* several days into stationary phase. Most of the T4-related bacteriophages share a unique ability that contributes significantly to their widespread occurrence in nature and to their competitive advantage. They are able to control the timing of lysis in response to the relative availability of bacterial hosts in their environment. When *E. coli* are singly infected with T4, they lyse after 25–30 minutes at body temperature in rich media, releasing about 200–300 phage/cell. However, when additional T-even phages attack the cell more than 4 minutes after the initial infection, the cell does not lyse at the normal time. Instead, it continues to make phage for as long as 6 hours.[91,92] We have found that T4 can also survive for days in a hibernation-like state inside starved cells, allowing its host to readapt when appropriate nutrients are again supplied, and then very rapidly produce up to 40 phage per cell.[93] The precise patterns depend on the genetics of both the phage and the host, including on whether or not the host has a functional stationary-phase sigma factor and on the multiplicity of infection. This is particularly interesting and important since bacteria undergo many drastic changes to survive periods of starvation, which increase their resistance to a variety of environmental insults.[94]

Thus, for many reasons, the T4-like phages make excellent candidates for therapeutic and prophylactic use against enteric and other gram-negative bacteria, and widespread studies of their ecology and infection properties are now being carried out world-wide with these goals in mind. The most extensive clinical trial to date—the Nestlé study of phage targeting infant diarrhea in Bangladesh—provides the strongest safety studies available; in this case, the broad T4 family of phages. This trial grew out of Nestlé's efforts to address the serious developing world problem of infant diarrhea, 27% of which is due to coliform bacteria. Immunological-based treatments had worked for Nestlé against diarrheal viruses but were unsuccessful against these pathogenic *E. coli*, so Harald Brüssow decided to try phage. The Evergreen phage lab students had recently tested nearly 100 T4-related phages from around the world on the 72-member ECOR collection of *E. coli,* selected to represent as wide a variety as possible, and sent Brüssow those phages with the broadest host ranges. He found some that infected his Bangladesh strains, but not very efficiently, so he tried isolating phages from the stools of infant diarrheal patients at the pediatric diarrhea center in Dhaka. Initially, he used just two *E. coli* hosts for this isolation: lab strain K803 and a very widespread and well-studied enteropathogenic (EPEC) strain.

To their surprise, the phages Brüssow's lab isolated using the EPEC strain were all siphoviruses and none of them were able to infect more than a few of the Dhaka strains. All the useful broad-spectrum phages they obtained from the Dhaka patient samples were isolated using lab strain K12, and all of them were related to T4. Their broader host ranges presumably reflect the fact that the lab strains are missing the complex O-antigens that protect clinical coliform bacteria against the mammalian immune system; over 150 of these O-antigens have been identified for *E. coli*, and at most one of them is produced by each bacterial strain. Phages selected against lab strains that lack these O-antigens must either use one of the outer-membrane proteins or the highly conserved inner stretches of the lipopolysaccharide (LPS) that are still present in K12 and most other lab strains as their receptors. The versatile adhesin that T4 uses to bind to these primary receptors is located near the tip of its long tail fibers, which can penetrate the O-antigen forest on the clinical strains to reach those more conserved internal sites. During initial adsorption, these fibers bind the phage to the cell, bending in the process to bring the baseplate down close to the surface, at which point the short tail fibers are deployed to bind irreversibly to the secondary receptor, which is another very well-conserved internal component of the LPS. Eventually, Brüssow isolated and characterized nearly 100 of these T4-related phages, carrying out extensive studies of their genomics and their host ranges on broad sets of pathogenic enteric bacteria. He also explored the properties of several in a mouse-gut model.

After more than a decade of laying such groundwork, Brüssow was ready to initiate clinical trials in Dhaka. He prepared a cocktail using 15 of these phages that had a very broad spectrum on the set of Dhaka diarrheal strains. Metagenomic sequencing both of this phage cocktail and of a commercial Russian *E. coli/Proteus* phage cocktail that they used as an extra control established that there were no genes that could confer virulence to the host.[95,96] They complemented their molecular analyses with years of extensive safety studies of the phages in adults and older children in Bangladesh, following a range of physiological parameters. They then simply added either their phage cocktail, the Russian cocktail or a placebo to the routine rehydration fluid that was the standard treatment for these infants, with the amount each patient received thus depending on the amount of rehydration fluid they needed.

The Nestle study in Bangladesh was a long-awaited and carefully planned controlled clinical trial to look at the effects of *E.coli* T4-related phages on infant diarrhea.[97] The study results were inconclusive as to the effect of bacteriophage for several possible reasons. Initial research toward this study stretched over more than a 10-year period[98] and during this time development of techniques in microbiology and genetics significantly advanced.[96,98] Full genome sequencing after the trial provided a new perspective on the gut microbiota in acute infant diarrhea, which had not previously studied to any extent beyond determining the presence of *E. coli*. Sarker and Brüssow explain that while *E.coli* was isolated from stool cultures of all 120 children enrolled in the study, there were not high titers, especially compared to those of two *Streptococcal* bacteria, which were very high.[99] The ratio of the *Streptococcus* to *Bifidobacterium* titers was associated with disease progression and resolution. Symptoms of diarrhea were correlated with increased titers of *Streptococcus* with low *Bifidobacterium*, while improvement correlates more with an increase in *Bifidobacterium*. Sarker et al. noted, "Oral coliphages showed a safe gut transit in children but failed to achieve intestinal amplification and to improve diarrhea outcome, possibly due to insufficient phage coverage and too low E. coli pathogen titers requiring higher oral phage doses".[97] The authors noted the need to deepen our general understanding of the etiology of diarrhea and take into consideration the interaction within the fecal microbial community the best biomarker for their data group was *Bifidobacterium*.[97] A recent study from our Evergreen lab suggested another possible contributing factor. Stationary phase studies carried out on T4 indicated that phage require nutrient rich media to maintain efficient infection

ability,[93] the phage in the Nestle study were mixed with ORS, which could be another contributing factor to the lack of efficacy seen in the study. This very expensive trial has been extremely important as a safety study and for working through various sorts of procedures, regardless of the lack of demonstration of significant efficacy, many lessons were learned through this experience.

For gram-positive bacteria, the family of phages related to the genetically very well-characterized *B. subtilis* phage SBO1 appears to have similarly broad advantages to those of T4. The Listeria phages recently approved for food-safety use belong to this genus, as do virtually all of the staph phages therapeutically used in Poland and Georgia.[68,72] The best studied include staph phage K, isolated in Berlin in the 1930s and sequenced and extensively studied in Cork a decade ago,[100] the sequenced Eliava phage Sb1 used for their highly purified commercial staph phage preparation,[101] and the set of Polish staph phages sequenced and analyzed by Lobocka et al.[68] All of these staph phages that have been looked at in detail have far broader host ranges than any of the phages infecting gram-negative bacteria and give very good clinical results, with little development of resistance, making them excellent candidates for the modern clinical trials needed for FDA approval.

Other Modern Clinical Studies

For a variety of regulatory with financial and attitudinal reasons, disappointingly little progress has been made to date in moving forward with formal clinical trials of phage therapy.

In 2009, British company Biocontrol reported significant clinical efficacy of a phage treatment for intractable *Pseudomonas* ear infections, with no reported safety issues in a small phase I/IIa trial.[23] Biocontrol later joined with the American company Targeted Genetics (which had been involved in human gene-therapy work) and the Australian company Special Phage Services (SPS) to form AmpliPhi Biosciences. In 2019, they merged with the company C3J Therapeutics to form Armata Pharmaceuticals, which has both natural and synthetic phage preparations in its pipeline and purportedly plans to eventually proceed with clinical trials in both areas. SPS had focused mainly on aquaculture, agriculture and race-horse applications, but was also working toward human phage therapy. Their scientists had carried out a number of compassionate-use case studies in a local Sydney hospital using phage from Tbilisi and published one of them.[102]

A physician-initiated phase I trial of a phage cocktail designed to treat leg ulcer infections at the Wound Care Center in Lubbock, Texas received FDA approval. The formal trial built on earlier encouraging work at the Wound Care Center there, which had employed the commercial Pyophage cocktail from the Eliava Institute on a compassionate-use basis, but the FDA required that a set of fully sequenced phages be used for this formal study. Thus, they arranged with Intralytix to supply them with a cocktail of eight sequenced phages (five targeting *P. aeruginosa*, two targeting *S. aureus,* and one specific for *E. coli*). No safety concerns were observed,[103] but the conditions used were not such as to establish efficacy and no funding was available to proceed with a phase II trial. Randy Wolcott, the surgeon involved, has now primarily turned to other ways of treating the biofilms that make the wounds he treats so challenging.

Phagoburn Clinical Trial

The United States, Belgian, and French militaries have all shown an active interest in phage therapy. The Belgians have carried out a small clinical safety trial of phage therapy for the treatment of burns in their major military hospital using three phages—one targeting *S. aureus* and two against *P. aeruginosa*—that had been isolated in Georgia and Russia and were produced as a highly purified and fully defined cocktail in Belgium.[104] The trial used a second, similar burn site in the same patient, treated identically except for the phage, as the control in each case. No problems were reported.[12,105] This work helped lay the groundwork for the multisite clinical trial Phagoburn, mentioned at the start of this chapter. The trial used phage cocktails developed by Pherecydes that target either *P. aeruginosa* or *E. coli*. It was largely funded by grants from the European Union and the French military, with impressive levels of cooperation between public, private, military, and other governmental entities as part of the FP7 program of projects targeting solutions to fight antibiotic resistance. The needed GMP phages were produced, gradually the various logistic regulatory details worked out with all three governments, and the protocol registered at http://clinicaltrials.gov. Jault et al. in 2018 reported enrollment of 27 patients with a confirmed burn wound in the study, this group was randomly divided into two groups.[106] One group received topical application of a cocktail of 12 lytic bacteriophages against *P. aeruginosa* (PP1131, 1×10^6 plaque-forming units [PFU] per mL) while the other, the current standard of care 1% sulfadiazine silver emulsion cream once daily for 7 days with two weeks of follow up. The groups were divided as follows: 13 were designated in the phage treatment group and 14 were standard of care. In the standard of care group, one patient was not exposed to treatment, in the phage treatment group one patient was found to not have an infection, leaving the phage treated group $n = 12$ and the standard treatment group $n = 13$. However, very unusually and unexpectedly, the titer of the phage preparation decreased markedly during storage after manufacturing, so the patients' actual dosing was only 10^2 PFU/mL per daily dose).[106] The study was not continued because of the lack of efficacy at that concentration. This was a high-interest study, to proceed with such a low titer preparation predestined its failure. Pirnay notes that despite the study outcome, this study gave a good indication to regulators as to what kind of documentation requirements are necessary to guarantee a timely supply of phage product.[107]

Weastmead Clinical Trial: Safety of Bacteriophage in Severe Staphylococcal Infections

Petrovic Fabijan et al. in 2020 published work on safety of intravenous phage in severe Staphylococcal infection.[108] In a single-arm noncomparative trial, 13 patients were administered GMP-quality phage cocktail against *S. aureus* in patients with septic shock or infective prosthetic valve endocarditis as an adjunctive therapy to standard antibiotic treatment.[108] Patients were administered 50–100ml 10^9 phage every 12 hours for 14 days. Patient selection was determined based on clinical criteria (seriously ill patients were included but not those where imminent death (<48 hours) was expected. Some of the patient samples *in vitro* sensitivity to the phage preparation was determined prior to administration

while others were started on treatment empirically in parallel to testing—one patients' treatment was discontinued after showing resistance on initial testing. The primary endpoint of the study was safety and tolerability. Secondary outcomes were efficacy—specifically clinical improvement, inflammatory response, and mortality.[108] This study followed pharmacokinetics of the administered phage using qPCR. The levels of both phage and bacterial DNA were measured throughout treatment in addition to studying inflammatory markers overtime in patient samples. Inflammatory markers decreased in 11 of 13 patients soon after commencement of phage therapy.[108] The development of phage resistance was not noted during treatment. No adverse reactions including, fever, tachycardia, hypotension, diarrhea, or abdominal pain were observed. The authors concluded this preparation was safe for use in severe infections.[108] This study is an important stepping stone for a larger scale controlled clinical study.

Clinical Trial in Urology

A landmark clinical trial in urology took place at the Tsulukidze National Center of Urology, Tbilisi, Georgia in collaboration between the Eliava Institute and several Swiss institutions. This study was a double-blind placebo-controlled trial to treat urinary tract infections with bacteriophage in patients who were undergoing transurethral proctectomy.[109] The study had three arms, one group was to be treated with commercially available Pyophage adapted to the treated population, the second group was a placebo control, and the third received antibiotic therapy. A total of 81 patients were included in the study. While the results of the study have not yet been published, indications to positive results have been eluded to. Dr. Leitner, one of the authors of the study and physician at Neuro-Urology, Spinal Cord Injury Center & Research, University of Zürich, Balgrist University Hospital, Zürich, Switzerland recently published a review article discussing the potential of phage therapy to address the unmet need for chronic urinary tract infections in neuro-urologic conditions.[110]

Safety Issues

From a clinical standpoint, phages appear to be very safe, as discussed extensively in Chapter 14 of Kutter & Sulakvelidze[7] and chapters in Borysowski et al.[21] and by Kutter et al.,[12,15] Abedon et al.,[14] Chanishvili[31] and most other recent reviews. This is not surprising, given that humans are exposed to phages from birth. Bergh et al. reported in 1989 that nonpolluted water contains about 2×10^8 phages/mL.[111] They are normally found in the gastrointestinal tract, urine, mouth, and on the skin.[112–114] Phages also were shown to be unintentional contaminants of sera and thence of commercially available vaccines[115–118] that were allowed to be sold despite this discovery, due to the general consensus that phage are safe for humans.

Extensive preclinical animal testing was required for approving new phage formulations in the former Soviet Union, including Georgia, but few of these studies were published. Bogovazova et al.[119,120] evaluated the safety and efficacy of *Klebsiella* phages produced by the Russian company Immunopreparat. Pharmacokinetic and toxicological studies were carried out in mice and guinea pigs using intramuscular, intraperitoneal, or intravenous administration of phages. They found no signs of toxicity or gross histological changes, even using a dose/g 3,500-fold higher than the projected human dose. They then evaluated the safety and efficacy of the phages in treating 109 patients infected with *Klebsiella*. The phage preparation was reported to be nontoxic for humans and effective in treating *Klebsiella* infections, as manifested by marked clinical improvements and bacterial clearance in the phage-treated patients. Chanishvili[31] also provides very extensive data relevant to safety issues.

Side effects such as occasional liver pain and fever reported in the early days of Western phage therapy may well have been due to bacterial byproducts contaminating phage preparations used intravenously.[121–123] The Polish phage therapy group never administers their phage intravenously because of this concern. The same is true for almost all therapeutic work carried out in Tbilisi, including all that has been performed in the last 30 years, and helps explain their virtually total lack of significant problems.

Phage administration has never been reported to adversely affect the efficacy or safety of other drugs in the long history of work in Eastern Europe. No systematic studies have been carried out in this regard, but phages are so specific in their activity that it is hard to predict where such interactions might occur. On the other hand, at least some local antibiotics tend to interfere with phage treatment of infections in areas with poor circulation by killing off the most-accessible of the bacteria in which the phage need to multiply as they work their way deeper into the lesion. This would be a particular problem in cases where the phage can still attach and infect but cannot complete their replication cycle. (Many of the Georgian physicians feel that antibiotics should never be used topically for wounds with deep-seated infections, since the decrease in antibiotic concentration below the surface provides a strong selection for antibiotic resistance, while this problem does not occur with phages.)

Phage Interactions with Mammalian Systems: Modern Studies

Phage can never reproduce in mammalian cells due to different biosynthetic mechanisms between prokaryotic and eukaryotic cells. However, that does not mean that they cannot interact with or be taken up by mammalian cells. One of the most interesting and important areas of study is the exploration of direct phage interactions with the mammalian immune system, in ways that go beyond the production of antiphage antibodies.

The major studies relevant to this important question have been carried out at the Hirszfeld Institute in Poland, which has supported so much clinical phage work. These studies often take advantage of the extensive literature on bacteriophage T4 as well as the strong immunological focus of the whole Institute. Since phage can only replicate in their specific host bacteria, much of the rest of the world long discounted the work Gorski and his colleagues were doing on this topic.[124] However, the Polish studies and those of others now make it clear that some phages, including T4, have direct effects on mammalian cells. As Krystyna Dabrowska of the Hirszfeld Institute writes:

> Mammals have become 'an environment' for enterobacterial phage life cycles. Therefore, it could be expected that bacteriophage adapt to them. (T4's)

> gpHoc, not found in most related phages, seems to have significance neither for phage particle structure nor for phage antibacterial activity. …But the rules of evolution make it improbable that gpHoc really has no function … More interesting is the apparent eukaryotic origin of gpHoc: a strong resemblance to immunoglobulin-like proteins appears likely to reflect their evolutionary relation. Substantial differences in biological activity between T4 and a mutant that lacks gpHoc were observed in a mammalian system. Hoc protein seems to be one of the molecules predicted to interact with mammalian organisms and/or modulate these interactions.[125]

Further supporting this perspective is the fact that the Hoc protein binds in the center of each cluster of capsid proteins of all of the T4-like phages that infect *E. coli* and related animal pathogens, but not on other T4-related phages such as those infecting marine cyanobacteria.

Barr and colleagues[126] have identified a very interesting additional and potentially related role for this "nonessential" T4 Hoc protein. They showed that Hoc mediates interaction of the phage head with the mucus layer on various animal tissues, an interaction which leaves the phage tails sticking out, ready to interact with incoming bacteria. It appears that the phage help protect the underlying tissues from bacterial attack while benefiting from the rich source of bacterial hosts to be found in mucus layers.

A Possible Path Forward for Phage Therapy

> Phage therapy can be very effective in certain conditions and has some unique advantages over antibiotics. With the increasing incidence of antibiotic-resistant bacteria and a deficit in the development of new classes of antibiotics to counteract them, there is a need to investigate the use of phage in a range of infections.[3]

Clearly, the time has come to re-evaluate the potential of phage therapy, both by supporting new research and by evaluating the research already available.[5] Earlier research that deserves much more attention includes the extensive use of phage to very successfully treat typhoid fever over a number of years at a major hospital in Los Angeles in the 1940s[47] (which only came to light this century), as well as one in Montreal and in earlier extensive French and Polish work, and applications in the former Soviet Union.[6,7,12,14]

Many aspects of working therapeutically with phage are extensively discussed by both the Polish and Georgian groups and a number of others in the book *Phage Therapy: Current Research and Applications,* edited by J. Borysowski, R Miedzybrodzki, and A. Gorski.[127] Much more is being learned about various methods of phage delivery, interactions of phage in animal husbandry applications, and even applications involving intracellular pathogens.[128] The special complexities of the pharmacology of phage therapy are being more thoroughly explored.[129] Also, exciting new work is happening engineering phages for a variety of diagnostic and therapeutic applications.[130]

Phages are quite specific as to the bacteria they infect, and the stipulations of Ackermann & DuBow[30] are important here. The specificity of phages means that:

> Phages have to be tested against the patient's bacteria just as antibiotics [should be], and the indications have to be right, but this holds everywhere in medicine. However, phage therapy requires the creation of phage banks and a close collaboration between the clinician and the laboratory. Phages have at least one advantage.… While the concentration of antibiotics decreases from the moment of application, phage numbers increase whenever their targeted bacteria are present. Another advantage is that phages are able to spread and thus prevent disease. Nonetheless, much research remains to be done… on the stability of therapeutic preparations; clearance of phages from blood and tissues; their multiplication in the human body; inactivation by antibodies, serum or pus; and the release of bacterial endotoxins by lysis.[30]

Furthermore, compassionate use of appropriate phages seems warranted in cases where bacteria resistant against all available antibiotics cause life-threatening illness.[131] They are especially useful for treating recalcitrant nosocomial infections, where large numbers of vulnerable people are exposed to the same strains of bacteria in a closed hospital setting. In this case, the environment as well as the patients can be treated with phage. Multiple case studies published in recent years illustrate the widespread interest of physicians and researchers in using phage in a clinical setting, especially for patients who have failed antibiotic therapy.

One of the first publications on intravenous phage therapy for compassionate use is described by Belgian physicians at the Queen Astrid Military Hospital in Brussels. Jennes et al. reported the first contemporary intravenous use of bacteriophage monotherapy against multidrug resistant *P. aeruginosa* in septicemia.[132] This was a case of a hospitalized Belgian patient who, after a three-month complicated hospital course was transferred to the Queen Astrid Military Hospital to receive wound care for his infected pressure sores. During his stay, he developed a *P. aeruginosa* infection sensitive only to Colistin. Intravenous Colistin was started, but because of a rapid decline in kidney function, it was stopped after 10 days. The *P. aeruginosa* septicemia soon returned, and the patient went into a coma. At that time, the decision was made to use a purified bacteriophage preparation[93] to which the *Pseudomonas* strain had *in vitro* sensitivity. Daily six-hour IV infusions were performed over a 10-day period, and the same preparation was also applied to his wounds. During that time, the patient's body temperature and C-reactive protein levels normalized, and blood cultures came back sterile. The patient's kidney function was restored within a few days. Bacteriophage treatment was thus seen to be safe and effective in this case.[132] However, it should be noted that the infected wounds persisted significantly even after phage treatment in this case and there were several episodes of sepsis involving other bacteria, which were all treated with empirical antibiotic therapy since no appropriate phage were available. Unfortunately, four months later, the patient developed *Klebsiella* sepsis and died due to sudden cardiac arrest.[132]

Intravenous Bacteriophage for Prosthetic Valve Endocarditis

Gilbey and Ho et. al describe a case of a 65-year-old male patient with a staphylococcal prosthetic valve endocarditis.[133] The patient was given a 14-day course of intravenous phage therapy as an adjunct to antibiotic therapy. Shortly after commencement of phage therapy, the patient's blood cultures were negative. Within 24 hours, the patient's white blood cell count, body temperature and CRP were significantly reduced. No adverse reactions from the treatment were noted.[133]

Phage Against MDR Carbapenemase-Producing *Klebsiella Pneumoniae*

Physician-initiated advocacy for patients with antibiotic resistant infections is becoming more common. The Eliava Clinic was contacted regarding a 58-year-old woman with frequent hospitalization due to MDR carbapenemase-producing *Klebsiella pneumoniae* (Kp) by her physician, infectious disease specialist Dr. Mario Corbellino. The patient, a 58-year-old woman with Crohn's disease diagnosed at the age of 20, had a history of seven major surgical interventions, with clinical remission after Adalimumab therapy (2009–2015). From 2011 to 2017, she had 30 hospital admissions for recurrent bilateral renal calculosis, obstructive nephropathy and urinary tract infections complicated by massive fibrosis of the bladder (residual volume: 25 mL), with the creation of a left cutaneous ureterostomy and positioning of a ureteral stent. She also had multisite colonization of the gastrointestinal tract and urine and a ureteral stent of 1-month duration with an MDR *Kp* strain.[134]

The infecting strain was *Kp* Sequence Type ST307. It was resistant to all ß-lactams, including carbapenems and produced the KPC-3 carbapenemase, remaining department susceptible only to ceftazidime-avibactam (CZA), amikacin, fosfomycin, and tigecycline. The patient was admitted for sepsis; despite last resort antibiotic therapy, the proximal tip of the ureteral stent remained positive for Kp culture. Reappearance of the microorganism was observed in cultures of the urine, the ureteral stent, and the rectal swabs of the patient a few days after interruption of the antibiotic therapy. Patient samples had been sent to the Eliava Institute in the meantime and a custom phage preparation against Klebsiella was prepared. The phage is a 161,728 bp Myoviridae, which was sequenced in collaboration with the Medical and Molecular Microbiology, Faculty of Science and Medicine group at the University of Fribourg. They found no virulance or antibioitic resistance or integrase sequences in the genome of the phage using *in-silico* analysis.[134] A 10 mL dose of phage preparation *bid* (twice a day) was administered on an empty stomach, preceded by alkalinization of the gastric pH with the use of carbonated water. Intrarectal administration *via* suppository for the first 14 days was also carried out. The phage therapy did not result in any untoward effects. After the stent substitution and 14 days of phage treatment, both stent and rectal surveillance swabs were negative. Molecular screening for Carbapenemase genes since then were also negative (Cepheid Gene Xpert, carba R).[134] The patient has not had another case of Klebsiella infection in two years and was hospitalized only twice since for UTI involving other organisms, compared to more than 30 times prior to phage therapy (Hoyle, Aug. 2019, personal communication).

Phage Therapy in a Renal Transplant Patient

Dutch physicians reported a case study of a renal transplant patient with ESBL-*Klebsiella* UTI and epididymitis that was eradicated using a custom Eliava phage preparation of a lytic bacteriophage to which the patient's isolate was sensitive. Kuipers et al. reported that the patient underwent more than seven treatment courses of meropenem, fosfomycin, and intravesical amikacin without success. A combination of meropenem and 8 weeks of custom oral and intravesical application of anti-*Klebsiella* phage therapy successfully and permanently eradicated the infection.[135]

Refractory *Pseudomonas* UTI

Khawaldeh et al. discuss a successful case of treatment of a *P. aeruginosa* urinary tract infection, using combined phage-antibiotic therapy.[102] A 67-year-old woman developed a refractory UTI following a bilateral ureteric stent placement that was resistant to multiple courses of gentamicin, ceftazidime, ciprofloxacin, and meropenem. Several isolates of bacterial strains were screened against the bacteriophage library at the Eliava Institute in Tbilisi and six lytic bacteriophages were then combined into a filter-sterilized phage product. Two antibiotics—colistin and meropenem—were then used in combination with bacteriophage therapy. The therapy resulted in symptomatic relief as well as microbiological cure.[102] Importantly, a year posttreatment, the urine cultures were still negative.

Phage Therapy for Netherton's Syndrome

A very interesting and rare case was treated at the Eliava Phage Therapy Center and has been under continued periodic observation led by Dr. Pikria Zhvania since 2016.[136] Netherton's syndrome is a genetic disease that has a hallmark triad of ichthyosis, allergy, and chronic bacterial infections. The patient presented as a 16-year-old boy from France with a significant history of strong allergy to all groups of antibiotics and frequent hospitalizations due to *Staphylococcal* sepsis.[136] After initial phage treatment, the patient's skin began to restore, and most notably, the patient did not have any recurrences of sepsis for several years. He continues to use phage prophylactically both orally and topically, and periodically visits the clinic in Tbilisi for evaluation. As the patient has been taking phage steadily for several years, his serum was studied for antiphage antibodies. Neutralizing antibodies were found, but do not seem to interfere with the patient's continued clinical improvement, indicating phage efficacy continues despite antibody development (Hoyle, unpublished data). This phenomenon has also been confirmed by Lusiak-Szelachowska et al., who demonstrated that the level of antiphage antibodies does not correlate with a negative clinical outcome.[137]

Cystic Fibrosis and Bacteriophage Therapy

Cystic fibrosis has been an area of particular interest and continued research for phage therapy since the late 1990s, likely due

to the combination of frequent respiratory infections, need for constant chronic antibiotic use and impaired mucous clearance.

Numerous international as well as Georgian cystic fibrosis patients have been treated at the Eliava Institute and its Phage Therapy Center since it opened in 2011.[15,138] Some of the first patients treated there were from the National CF center, where eight patients ranging from infancy to adulthood were treated using inhaled phage in combination with antibiotics and other standard CF care.[13] The bacterial titers in sputum samples of these patients reduced significantly. This work was part of a collaboration with the Evergreen State College phage lab, which acquired a collection of 200 CF bacterial strains from the Seattle Children's Hospital in 1995. Through the years, undergraduate students have participated in phage research learning to isolate phage from sewage samples and further characterize these phages in the lab. The student-generated Pseudomonas phage collection against these isolates has grown to over 100 phages, which have interesting host range patterns against the CF collection. A set of six of these phages, representing all of the lytic Pseudomonas lytic phage types that have been described, were gradually tested against all 200 of the Children's Hospital strains, giving many different infectivity patterns, and have since been shared with a number of labs in various parts of the world. The most widely used are PEV2 and PEV40, which have for a number of years (and papers) been the most successful in a series of Australian pharmacology studies focused on optimizing phage type, dosage, and delivery system details for the treatment of cystic fibrosis and lung infections.[139]

Phage are also useful for a variety of lung infections. One particularly interesting case was of a 17-year-old girl with a multiantibiotic resistant *Achromobacter xylosoxidans* infection.[140] On presentation, the patient had dyspnea, cough, and generalized weakness. Well-characterized phage against *Achromobacter* were obtained from the Liebniz Institute DSMZ in Germany under a collaboration with the Eliava Institute and were prepared as a therapeutic preparation for the patient. The patient carried out phage therapy courses of treatment four times in one year, showing gradual improvement in both symptoms and lung function. Sputum cultures showed a two-fold reduction in bacterial titers over time.[140]

So far, most Western use of phage for treating CF and other lung patients has been as a rather last-minute endeavor when all else has failed. However, a group at the Yale School of Medicine have started treating CF patients with Pseudomonas infections with phage inhalation therapy. They have treated 13 patients with phage as a personalized medicine under the emergent indication mechanism at the FDA. Their largely successful research has been much discussed in a range of venues but has not been published in a scientific journal to date.[141]

Intravenous Phage Therapy in CF

Law et al. argue about the importance of bacteriophage therapy for multidrug-resistant *P. aeruginosa* infection in cystic fibrosis patients.[142] The researchers have successfully treated *P. aeruginosa* caused pneumonia in a 26-year-old patient awaiting lung transplantation surgery. Importantly, prior to receiving phage therapy, the patient had developed colistin-induced renal failure, further narrowing the possible therapeutic options. Intravenous administration of phage therapy was successful in resolving the bacterial infection and the patient has not had a recurrence of pseudomonal pneumonia and CF exacerbation within 100 days following the end of the bacteriophage therapy.

Novel Synthetic Bacteriophage Treatment Against *Mycobacteria abscessus*

We have refrained from including information about genetically engineered bacteriophages, as the topic area is significantly different from the use of natural bacteriophages traditionally used for therapeutic purposes. However, we must make an exception to note the groundbreaking case of a cystic fibrosis patient treated with phage against intracellular *Mycobacteria abscessus*, a nontuberculosis mycobacteria (NTM). *Mycobacteria* has been known to be a significant cause of morbidity and mortality.[143] A 15-year-old patient was the first patient to be treated with bacteriophage against a mycobacterial infection, and reflected the first use of genetically engineered phages, as described by Dedrick and colleagues.[144] The patient had a double lung transplant and was on immunosuppressive therapy. She had taken anti-NTM treatment for 8 years prior to transplant. One week after discontinuing postoperative antibiotic therapy, signs of the returning Mycobacterial infection were evident, including multiple skin lesions. The patient was sent home for palliative care after 7 months of treatment, with a diagnosis of disseminated mycobacterial infection. A three-phage cocktail was developed and was applied both topically and intravenously. The patient responded well to the therapy and had gradual improvement of both lung function and the skin lesions. No *Mycobacteria* were detected in serum or sputum after initiation of phage therapy.[144]

German CF Trial Expected

A clinical trial on the safety of phage preparations against *P. aeruginosa* in chronically infected CF and non-CF bronchiectasis patients by inhalation is to be conducted at the Charité University Hospital in Berlin (http://phage4cure.de/en/). The trial will also focus on the establishment of a GMP purification process for German phage production in the future.[145]

Many groups are interested in the idea of phage therapy for cystic fibrosis-associated infections as reflected by many review articles on the topic.[146–150] Further advancement in this area would greatly benefit the patient population.

Pharmacology and Delivery Technology

Much work and advancement in therapeutic phage pharmacology has occurred in recent years. Four major areas of focus are reflected in the literature: (1) high quality intravenous phage preparations, both phage cocktails and monophage; (2) Inhalation phage, both powder and liquid forms, spray; and (3) Encapsulation delivery. These modes of delivery are in addition to already well-used applications, such as oral, topical, and rectal, including wound care. During the development of a new pharmaceutical, attention would be paid to things like development of a delivery vehicle and optimization of delivery. As phage are a long-standing medicine, many studies are using the traditional formulas to conduct clinical studies. As we saw in the

Phagoburn study, adequate manufacturing process is critical in receiving a preparation that will sufficiently represent its therapeutic potential.[106] Malik et al. review the current work for phage as a pharmaceutical, highlighting encapsulation of phage into liposomes, which gives the phage preparation added stability, and allows for extended release and intracellular distribution.[151]

Preparatory work in terms of optimizing dosage and delivery has been extensively studied by Dr. Kim Chan's group at the University of Sydney. They have investigated stability and efficacy of spray dried inhalable phage powders using Kutter-lab Pseudomonas phages, particularly PEV2, a podophage.[139,152] Leung et al. also investigated structural effects of different Kutter-lab lytic-tailed phages after jet nebulization, noting that titer loss after nebulization was associated with phage-tail length.[153] Encapsulation methods for inhalation phage are also being investigated.[154]

The complexities of phage selection and designing appropriate phage cocktails are becoming better understood.[155] With the increasing availability and decreasing costs of genomic analysis, it is now generally expected that phage for therapeutic cocktails be sequenced, enabling the exclusion of temperate phages and/or phages likely to carry or acquire genes related to lysogeny, pathogenicity, or toxin production. This is now standard for therapeutic phages being developed in the West. The application of metagenomic analyses to longstanding complex therapeutic cocktails was illustrated above for the Russian phage cocktail being used as a control in the Nestlé study.[96] This awareness also is being applied to some of the Georgian phage cocktails through collaborations with scientists in a variety of countries as well as access to a new sequencing center at the Georgian Center for Disease Control. Metagenomic analyses of several of the key broad Georgian and Russian cocktails have found them to contain no potentially undesirable/harmful genes.[156–158] This is an important step in considering their importation for oral, topical, and surgical use in the Western world, taking advantage of the very extensive clinical experience with these phage preparations. The availability of a cocktail of eight sequenced Intralytix phages clearly played a role in the FDA's approval of the physician-initiated clinical trial of phage targeting bacteria in leg ulcers.[22] This was an important beginning in terms of phage being approved for safety studies, but this narrow cocktail was reportedly much less successful therapeutically than the complex cocktails obtained earlier from Tbilisi for extensive compassionate use applications there at the Wound Care Center in Lubbock, Texas.

Bacteriophage Therapy in Gastrointestinal Health

Many studies have been conducted in recent years on the microbiome. As we learned earlier from Brüssow's work discussed earlier, there is much to discover in terms of etiology and pathogenicity for various gastrointestinal disorders. Much of the progress that has been made in the study of the microbiome has come through metagenomics, which has provided much insight into the extent of diversity in the human gut. Phage scientists have started looking seriously at the virome of the distal GI tract, which, like all other phage ecology, reflects the diversity of the microbiome. Shkoporov and Hill review recent advances in the study of gut microbiota and note the importance of the phageome. There are estimated to be more than 10^{12} phage in the human gut.[159] Much of the viral taxonomy is unknown and the term "viral dark matter" has been coined to illustrate how much is left to be studied in this area.[160] Phages have been used for intestinal disorders virtually since their discovery, although understanding of some of the mechanisms for their efficacy is only now coming to light. Research in the areas of immunity and the role of the bacteria, viruses, and fungi is becoming better understood.[161–164] Fecal transplant quickly became an area of interest for physicians and phage enthusiasts, who were delighted at the work of Ott et al. demonstrating that sterile filtrated fecal transfer was effective in treating *Clostridia difficile* infection.[165] From this, it was determined that bacteriophages present in the filtrate were responsible for the inhibition of pathobionts.

Initial isolation of the needed phages to infect this *anaerobic* host was particularly challenging; virtually all the phage therapy-related work through the years has been carried out aerobically. The group at the University of Leicester lead by Dr. Martha Clokie has managed to isolate some potentially useful phages, largely from the environment, and has developed efficient *in vitro*[166] and *in vivo*[167] models for studying these infections in conditions similar to those in human infection. Movement toward a clinical trial in this area is much awaited, as it should have a significant impact on morbidity and mortality for those infected with *C. difficile*.

American Case Studies

A few American physicians and researchers are already employing phage therapy on a compassionate use basis. A very well-publicized case is that of an American UC San Diego professor who acquired a resistant *Acinetobacter* infection while on holiday in Egypt. The spell-binding book about their experiences by Strathdee and Patterson, called The Perfect Predator,[168] is on the 2019 best-seller lists—and Dr. Schooley et al.[169] describe how this 68-year-old patient of his presented over months with necrotizing pancreatitis and MDR *Acinetobacter* pseudocyst. Despite multiple courses of antibiotic therapy and drainage, his condition continued to worsen, and he was near death in a coma for several months before Strathdee came across a paper describing the strange idea of using bacteriophage to treat *Acinetobacter.* This reminded her of explorations with coliphage in a lab back in college, and she dove intensely into exploring this possible option. Virtually all of the phage therapy papers dealt with aerobic applications, but she fairly quickly found a few mentioning work with *Acinetobacter* and reached out to the researchers. Mobilizing all her many contacts, *Acinetobacter* phage isolates to which his strain was found to be sensitive were identified from two separate laboratories, some from a U.S. Navy project that had been precipitated by extensive *Acinetobacter* infections seen in soldiers fighting in Iraq, the other in Texas but originating from Intralytix in Australia. With Herculean efforts from many people, these phages were highly purified within days and administered both IV and percutaneously into the abscess cavity. Phage pharmacokinetics and antiphage bacterial mutants were studied in detail as the patient's condition quickly improved. The success of this case gave impetus to introduction of finding more common phages over the next 2 years to treat five organ-transplant

candidates who were fighting infections when an appropriate organ had been found. Its success led them to establish the first U.S. phage therapy research center there at UC San Diego—a very exciting step forward.

Phage Therapy of Aortic Graft

Yale University has also been involved in work to make phage therapy accessible for emergency cases in the United States, including both a variety of unusual surgical cases and treatment of CF patients presenting for lung transplant. For example, Chan et al. have published a case study of a 76-year old man who was treated for a major *P. aeruginosa* infection following aortic arch replacement surgery with a Dacron graft for an aortic aneurysm.[170] At presentation, the patient complained of increased serosanguinous drainage from his mediastinal fistula, which despite multiple antibiotic treatments, did not resolve. Initially, the team attempted to administer a combination of phage OMKO1 and ceftazidime by needle puncture into the perigraft collection. However, due to heavy scarring in this area, the combination was delivered into the mediastinal fistula, which was in continuity with the perigraft collection.[170] The patient has not had any evidence of recurrent infections, despite being off of antibiotic therapy. This study highlights the efficacy of the synergic use of antibiotics and bacteriophages, as well as the capability of phage therapy in resolving biofilm-associated infections.

Craniotomy Complicated by an MDR *Acinetobacter baumannii* Infection

LaVergne et al.[171] present a case study of a 77-year-old man who underwent craniotomy complicated by postoperative infection with cerebritis and a subdural and epidural empyema. Intraoperative cultures grew MDR *Acinetobacter baumannii*. Despite a combination therapy of Colistin, Azithromycin, and Rifampin, the patient's clinical condition did not improve. The phage cocktail was selected using a library with 104 *A. baumannii* bacteriophages, screened for activity against his *A. baumannii* strain cultured intraoperatively. The patient received 8 days of phage therapy, but due to the severity of his condition, the patient's family decided to withdraw care.[171] The researchers were not allowed to deliver phages via an intrathecal route, which would allow phages to enter the CSF. It can be argued that the phage titers were not high enough to have reached an effective therapeutic dose through IV delivery.

Scientists such as Brüssow[172] and Knoll Mylonakis[173] are very thoughtfully exploring what steps are most urgently needed for human phage therapy to become a reality in Western medicine. They argue persuasively that industry alone cannot carry out the studies necessary for approval under our current regulatory system, which is designed for nonbiologics, and suggest that a much broader partnership is required to evaluate and implement the promise of phage therapy. We strongly agree with Brüssow:[172]

> Organizations like the US or European CDC should establish phage collections for antibiotic-resistant pathogens which soon are likely to become untreatable in a sizable number of patients. The CDC should characterize, amplify and purify the relevant phages according to safety standards agreed with the FDA …. Until the value of PT is confirmed, it is also desirable that (such) international organizations supervise the controlled clinical trials … the first trials should target medical priorities. The lower economic prospects in treating these infections will necessitate that the first phase is paid by public money … It is only once the feasibility, regulatory, and legal parameters have been set that one might expect private companies to take the lead … for a variety of bacterial infections … we cannot simply wait another 10 years until non-coordinated PT approaches yield reliable answers…Even when it should turn out that PT does not work for a particular application, knowing this is better than cultivating the illusion that we have a secret weapon in our tool box against antibiotic-resistant infections …

Diabetic Foot Ulcers as an Early Target

Given the body of existing documentation, broad phage host range, and the small number of phage types involved, phage targeting *S. aureus* to treat diabetic ulcers and MRSA are among the most obvious candidates for this approach. (It should help that this would also be among the hardest applications to patent, with so much use of staph phage in the literature.)

Podiatrist Randy Fish[174] documents the use of the Eliava commercial staph phage cocktail to treat this series of eight patients with diabetic toe ulcers where all else had failed, including extensive IV antibiotics as well as local antibiotics, and the only other option was amputation. There had been no plan to publish this data—just to save these patients from amputation, which at least half the time leads to death within a few years. Dr. Fish had worked in the phage lab while an Evergreen student in 1975, tracked us down a few years earlier when he heard that the phage lab was still open and we had become interested in therapeutic applications of phage, and became a member of the Board of our nonprofit Phagebiotics Research Foundation, complementing well the other members of the board who included an medical doctor, veterinarian, and the head microbiologist of the Northwest Indian Fisheries Commission. A poster on the work was selected for top honors at both the 2014 Academy of Physicians and Wound Healing Scientific Conference in Philadelphia and the Desert Foot conference that year in Phoenix, Arizona, drawing much interest. This work is particularly significant in that it clearly recorded the regeneration of bone in the weeks after phage therapy and has long-term follow up showing no recurrence in treated patients. Further successful follow-up work was reported by Fish et al.[175,176] This is clearly an area that should be explored expeditiously as there is a large unmet need and could significantly reduce morbidity and mortality for diabetic patients.

It is clear that collaboration among governmental entities/health agencies, doctors and patients, and academia and industry is crucial to expeditiously bring phage therapy to fruition in the West. One major effort in that regard was the Phagoburn project (discussed previously in this chapter) that targeted *Pseudomonas* and *E. coli* in burn wounds. This effort has involved two companies, several other institutions, and burn units in seven hospitals in Belgium, France, and Switzerland. The French military, a very

active phage-oriented patient support group, and €3.8 million in funding from the EU also play important roles.

A Belgian/French/German nonprofit group called P.H.A.G.E. (Phages for Human Application Group Europe) has put in years of crucial educational and political advocacy work related to the regulatory challenges[177] and the experience of a related small-scale phase I clinical trial at the Queen Astrid Military Hospital in Brussels—one of the participants—all have helped the cause, but progress is still slow. Another key area is the education of doctors and potential patients about the possibilities of phage therapy, as started to happen more than two decades ago with BBC and CBS documentaries, but such exposure has bred frustration and dashed hopes when the only option to obtain phage therapy is medical tourism in Georgia or Poland. This has just further emphasized the importance of establishing clearer and faster paths forward for at least one or two clinical phage applications in the West.

Important gains were made in Belgium by the official approval of a magisterial product designation for bacteriophages, which allows phage to be prescribed by physicians after testing samples from the patient against an appropriate library of very well-characterized phages that is being, and then prepared for administration on an individual basis in a compounding pharmacy." In addition, nonauthorized ingredients may also be used in magistral preparations, providing that they are accompanied by a certificate of analysis issued by a Belgian Approved Laboratory. The so-called "Belgian Approved Laboratories" are quality control laboratories that are granted an accreditation by the Belgian regulatory authorities. This status allows them to perform the batch release testing of medicinal products.[178] The hurdle for this approach is to obtain an adequate phage bank that provides the active pharmaceutical ingredient (API) necessary to make the phage preparation.

To move the field of phage therapy forward as a viable international component of the war against antibiotic resistance, there is a pressing need for an unequivocal success leading to at least one approval by the FDA and/or the parallel EU regulatory body. For various reasons, phages targeting *S. aureus* in nosocomial hospital MRSA infections, wounds and/or diabetic ulcers offer the most clear-cut route to reaching this goal in timely fashion. This is most likely to be accomplished through collaborative public/private efforts leading to a product for external applications that will be widely available as a public good. First, phage therapy of staphylococcal infections is the application for which the most data is available based on work in various countries over the last 70 years. This also makes it one of the most difficult for which to get patent protection. At the same time, it is the application requiring the smallest number of individual phages due to the very broad host ranges of these particular phages and well-characterized, satisfactory phages are already available commercially or in the public domain. Some compassionate-care case studies are already being carried out in the United States using the DNA-sequenced, highly purified staph phage that is approved and commercially available in Tbilisi. It is simply added to standard treatments of, for example, diabetic foot ulcers that so often lead to amputation, but accomplishing that is challenging when the only way to access phage therapy is to travel to Poland or Georgia. Furthermore, staphylococcal phage therapy is straightforward enough that the requisite supportive infrastructure could easily be built. Learning to work effectively with these phages could help educate both the community and the medical community as to the potential benefits of phage therapy. Expanding this approach would help to deal with a major conundrum: much work is needed to raise the awareness of phage therapy among physicians and prospective patients and to determine the best conditions for definitive clinical trials. It could also lay the groundwork for developing the infrastructure for characterizing and treating more complex infections. Beyond the well-known targets, there is a wide range of possible new applications that would be more patentable. One already hears about phage targeting the etiological agents of periodontal disease, urinary tract infections, and prostatitis, the *Propionibacteria* that cause acne, and *C. difficile,* among others.

Support for phage therapy is evidenced by the active work from all corners of the world to utilize this treatment in patients via compassionate use, and in the multiple clinical trials being carried out that are necessary for broader access. Numerous reviews call for a closer look and highlight much of what we already know.[179–182] All in all, we need to somehow find our way through the regulatory labyrinth and the financial hurdles and further explore the possibilities of having phage help rescue us from the growing antibiotic resistance crisis and the health challenges resulting from excessive antibiotic use.

Introduction

Since the discovery of penicillin by Alexander Fleming in 1928, the world has been revolutionized by the further discovery and synthesis of antibiotics. This increased life expectancy, and reduced morbidity and mortality, which allowed for continued growth of the normal human lifespan well past its original bounds. Unfortunately, despite the rapid implementation of antibiotics into the healthcare field, there has been a continuous growth in the emergence of resistance in pathogenic organisms.[1] In Darwin-like fashion, continued use of suppressive agents has created a selective pressure for pathogens with the capabilities to survive most antibiotics, allowing them to continue to infect patients, which over a few years spread across different countries. The discovery of each new generation of antibiotic quickly followed the same trend (Figure 55.1). Several studies have demonstrated the association of antibiotic use with the emergence of resistance. In the past century, the majority of newly developed antibiotics have seen resistance within a few years of its initial introduction into the healthcare field.[2]

Antibiotic resistance and use have always been a consideration in clinical medicine, but it was not until 2013 that the impact of antibiotic resistance in patient health was thrust into the spotlight. In 2013, the Centers for Disease Control and Prevention (CDC) famously released a report detailing the escalating resistance threats in our healthcare system. By their estimates there were 2,049,442 illnesses and 23,000 deaths attributable to antibiotic resistance in that year.[3] Such a staggering number put the U.S. healthcare system on notice prompting a number of antimicrobial related initiatives. Some of these initiatives include Executive Order 13676, which established the Interagency Task Force for Combating Antibiotic-Resistant Bacteria and the Presidential Advisory Council on Combating Antibiotic-Resistant Bacteria (PACCARB).[4] These advocacy groups allowed for the creation of government incentives for developing new antibiotics and pushed for the increased utilization of formalized Antimicrobial Stewardship Programs (ASP) in hospitals.

Despite the massive amounts of media coverage that antibiotic stewardship is receiving now compared to the past, antimicrobial resistance remains a clinically relevant consideration today. According to the most recently available data from the CDC in conjuncture with the National Healthcare Safety Network (NHSN), national resistance rates to healthcare associated organisms remains high across the board. For example of common hospital pathogens methicillin-resistant *Staphylococcus aureus* (MRSA) and multidrug resistant (MDR) *Pseudomonas aeruginosa,* the most recently reported prevalence numbers were 45.1% and 14.2%, respectively.[5] When taking a deeper look at the prevalence of more resistant isolates, the percentage of carbapenem nonsusceptible *P. aeruginosa* was 19.3%, carbapenem nonsusceptible *Acinetobacter* spp. was 52.7%, and vancomycin-resistant *Enterococcus faecium* was 77.3%, respectively.[5] The high prevalence of resistance is a demonstration of continued antibiotic exposure and could very likely be associated with fewer available antibiotics to use in patients in individual patient cases and worse patient outcomes.[3,6,7]

In addition to negative clinical implications, there are several additional costs associated with antibiotic resistance. Antibiotic resistance can lead to increased morbidity, prolonged antibiotic treatment durations, and increased length of hospital stays, all of which are associated with additional costs to the healthcare

system and patient.[7,8] In terms of dollars, the CDC report from 2013 estimated that the overall economic burden of antibiotic resistance to the U.S. healthcare system ranges as high as $20 billion in excess medical costs with additional costs to society of up to $35 billion in lost productivity costs.[3] Resistance of individual organisms have varying cost burdens as well. For example, the additional excess cost of treatment of MRSA as compared to Methicillin-sensitive *Staphylococcus aureus* (MSSA) can range up to $29,030 annually, whereas the cost range for sensitive compared to resistant *P. aeruginosa* can be up to $45,256 annually.[8] Overall, the majority of cost associated with antibiotic resistance is more heavily weighted toward the hospital setting.

Managing antibiotic resistance in the healthcare system remains challenging, particularly in the hospital setting. We will continue to explore this concept throughout the rest of the chapter.

History of Antimicrobial Resistance in the Hospitals

One of the major threats to public health is the constant rise in the progression of resistance to antimicrobial drugs, which is a leading cause of development and relapse of infectious disease. The advent of penicillin has led to the reduction in the numbers of susceptible strains and the rise and propagation of more resistant strains.[9,10] The first signs of antibiotic resistance became apparent soon after the discovery of penicillin. In 1940, Abraham and Chain reported that an *E. coli* strain was able to inactivate penicillin by producing penicillinase. The spread of penicillin resistance was already documented by 1942, when four *S. aureus* strains were found to resist the action of penicillin in hospitalized patients and was found to have developed an ability to produce β-lactamase, which inactivates both natural penicillin and aminopenicillins making *S. aureus* resistant to antimicrobials.[11] During the next few years, the proportion of infections caused by penicillin-resistant *S. aureus* rapidly rose, spreading quickly from hospitals to communities. By the late 1960s, more than 80% of both community and hospital-acquired strains of *S. aureus* were penicillin-resistant.[22]. Initial sporadic appearance of penicillin resistance was observed in hospitals, however, with time it spread to the community. Emergence of penicillin resistant *S. aureus* fueled the development of second generation, β-lactamase-resistant, antimicrobial agents such as methicillin in 1960.[12] Soon after, the first case of MRSA appeared in the late 1960s, which spread to become endemic in hospitals during the 1980s, reaching 29% of hospitalized *S. aureus*-infected patients.[13–15] Earlier reports on parameters affecting this trend of emergence of resistance had indicated that the rate of increase in MRSA was proportional to the size of the hospital[14]; however, current trends show that rate of rise in methicillin resistance is similar irrespective of the hospital size.[15] Another such example is the emergence of resistance to vancomycin, which is the drug of choice to treat MRSA. In 1997,

initial reports of reduced vancomycin susceptibility in clinical isolates of *S. aureus* from Japan generated significant concern in the medical community, though, according to a report in 2004, the number of cases reporting reduced vancomycin susceptibility is low overall and hemodialysis patients are more prone to antibiotic resistance from vancomycin-intermediate *S. aureus* (VISA) and vancomycin-resistant *S. aureus* (VRSA).[16] Various mutations in VISA result in strains with impenetrable cell walls that make it difficult for vancomycin to enter the bacterial cell.[16,17] In 2003 a report by Fridkin et al. evaluated risk factors for appearance of Infections caused by *S. aureus* with reduced vancomycin susceptibility, and demonstrated that these include antecedent vancomycin use and prior oxacillin-resistant *S. aureus* infection 2–3 months before the current infection.[18] By 2015, only 14 reports of VRSA were reported in the United States, though a CDC report on antibiotic resistance threats in the United States published in 2013 considered VRSA to be a concerning threat.[19,20] Along with VRSA, other pathogenic microbes also started demonstrating vancomycin resistance, for example, vancomycin resistance in enterococci (VRE) emerged in 1988 in Europe and around the same time in United States.[21] By 1998, the prevalence of VRE increased by 20-fold in the intensive care setting in the United States. Flokas et al. reported an increased prevalence of VRE colonization among hospitalized children in hematology/oncology units. Additionally, the colonized children were reported to be nine times more likely to develop consequent VRE infections.[22] However, Kampmeier et al. published a study in 2018 that reported disassociation of surgical Intensive care units (ICU)from VRE colonization.[23]

In past few years, resistance related to Gram-negative bacteria has significantly increased, which has become a serious challenge for the healthcare community.[24] For example, a nine-year surveillance study in 2004, reported the appearance of multidrug-resistant (MDR) *P. aeruginosa* with a frequency of 1–16%, along with the appearance of MDR *Klebsiella* species with a frequency of 0.5–17%.[25] As per the NNIS database, *P. aeruginosa* samples from ICU patients in 2003 were found to have a rate of resistance of 20% to carbapenems and about 30% to third-generation cephalosporins as well as quinolones.[16] Another Gram-negative bacterium, *Acinetobacter baumannii,* is known for causing pneumonia in hospitalized patients. A rising number of cases related to MDR *A. Baumannii* have been reported in military field hospitals, tertiary care centers for treating military personnel in the United States and abroad, as well as U.S. Navy hospital ships.[26] It would be worthwhile to mention that *Clostridium difficile*-associated disease (CDAD) and antimicrobial-associated disease are amongst the most frequently occurring side effects due to antibiotic therapy. In the 1990s, a steady increase in antibiotic associated-CDAD was reported in NNIS hospitals.[27] Additionally, data from National Center for Health in 2001 suggested an alarming increase in the rate of *C. difficile* associated infections in U.S. hospitals.[28] An 11-year study conducted by Dallal et al. demonstrated that the incidence of *C. difficile* colitis accompanied by life threatening symptoms increased significantly in the hospitalized patients.[29] According to a report by the NHSN in 2009–2010, the infections associated with MRSA showed a slight dip, however, the same report showed an increase in MDR Gram-negative bacteria.[30] Furthermore, a report by CDC in 2013 stated that the fatalities related to antibiotic resistance are more prevalent in the healthcare settings as compared to community.[31]

Causative Mechanisms of Antimicrobial Resistance in the Hospitals

The cellular mechanism of acquisition of antibiotic resistance occurs through the interaction of antibiotics and bacteria in the environments. Certain resistance genes ward off destruction by giving rise to enzymes that degrade antibiotics or that chemically modify, and so inactivate, the drugs. Alternatively, some resistance genes cause bacteria to alter or replace molecules that are normally bound by an antibiotic, that is, changes that essentially eliminate the drug's targets in bacterial cells. Bacteria might also eliminate entry ports for the drugs by modifying the target receptor or their genes, or they may activate the synthesis protein pumps that export antibiotics before the medicines have a chance to find their intracellular targets.[32,33] Antibiotic resistant bacteria owe their drug insensitivity to resistance genes. For example, such genes might code for "efflux" pumps that eject antibiotics from cells, or the genes might give rise to enzymes that degrade the antibiotics or chemically alter and inactivate the drugs.

Bacteria can acquire resistance genes through a few routes. In some cases, they are obtained through vertical gene transmission. Other times, genetic mutations spontaneously occur and produce a new resistance trait or strengthen an existing one. Frequently, bacteria may also become resistant through horizontal gene transfer from other microorganisms in the environment. In these cases, genes located on plasmids or small pieces of chromosomal DNA from dead microorganisms must be integrated into the recipient bacteria. Resistance genes can also be transferred by viruses through transduction. Such integration occurs frequently, though, because resistance genes are often embedded in small units of DNA, called transposons that readily hop into other DNA molecules. Many bacteria play host to specialized transposons, termed integrons, that can consist of several different resistance genes that are passed to other bacteria as whole regiments of antibiotic-defying arsenals. Many bacteria possessed resistance genes even before commercial antibiotics came into use. Later, these protective genes found their way into other species, some of which were pathogenic. Bacteria acquire resistance genes from other bacterial cells in three main ways.[32] Often they receive whole plasmids bearing one or more such genes from a donor cell. Other times, a virus will pick up a resistance gene from one bacterium and inject it into a different bacterial cell. Alternatively, bacteria sometimes scavenge gene-bearing snippets of DNA from dead cells in their vicinity. Genes obtained through viruses or from dead cells persist in their new owner if they become incorporated stably into the recipient's chromosome or into a plasmid. See Table 55.1.

Regardless of how bacteria acquire resistance genes today, excessive and improper usage of commercial antibiotics can promote the survival and propagation of antibiotic-resistant strains. Excessive and unnecessary use of antibiotics favors rapid selection of antibiotic-resistant organisms in the microbial population. Exchange of genetic materials between different antibiotic resistant populations has also enabled emergence of multidrug-resistant strains. When antibiotics are given as a treatment for

TABLE 55.1

Summary of the Mechanism of Drug Resistance of Common Antibiotics

Antibiotic Class	Example(s)	Mode(s) of Resistance
P-lactams	Penicillins, cephalosporins, penems, monobactams	Hydrolysis, efflux, altered target
Aminoglycosides	Gentamicin, streptomycin, spectinomycin	Phosphorylation, acetylation, nucleotidylation, efflux, altered target
Glycopeptides	Vancomycin, teicoplanin	Reprogramming peptidoglycan biosynthesis
Tetracyclines	Minocycline, tigecycline	Monooxygenation, efflux, altered target
Macrolides	Erythromycin, azithromycin	Hydrolysis, glycosylation, phosphorylation, efflux, altered target
Lincosamides	Clindamycin	Nucleotidylation, efflux, altered target
Streptogramins	Synercid	Carbon-oxygen lyase, acetylation, efflux, altered target
Oxazolidinones	Linezolid	Efflux, altered target
Phenicols	Chloramphenicol	Acetylation, efflux, altered target
Quinolones	Ciprofloxacin	Acetylation, efflux, altered target
Pyrimidines	Trimethoprim	Efflux, altered target
Sulfonamides	Sulfamethoxazole	Efflux, altered target
Rifamycins	Rifampin	ADP-ribosylation, efflux, altered target
Lipopeptides	Daptomycin	Altered target
Cationic peptides	Colistin	Altered target, efflux

Source: Reproduced from Review on Antibiotic Resistance: Alarm Bells are Ringing, authored by Zaman et al. (2017).[1]

disease-causing bacteria, they also affect nonpathogenic bacteria in their vicinity. They eliminate these drug-susceptible bystanders that might otherwise limit the expansion of pathogens, and they simultaneously encourage the growth of resistant bystanders. Propagation of these resistant, nonpathogenic bacteria increases the reservoir of resistance traits in the bacterial population as a whole and raises the odds that such traits will spread to pathogens. There are two main biological routes of acquiring antibiotic resistance.[34] Microbes reproduce by dividing every few hours, allowing them to evolve rapidly and adapt quickly to new environmental conditions. With each replication, mutations arise, and some of these mutations may help an individual microbe survive exposure to an antimicrobial. Microbes may also acquire genes from each other through spontaneous genetic transfer, including genes that make the microbe drug resistant.

In addition, sometimes the growing populations of bystanders themselves become agents of disease. A significant example of this phenomenon is how the widespread use of cephalosporin antibiotics has promoted the proliferation of the once nonpathogenic intestinal bacterium *Enterococcus faecalis*, which is naturally resistant to those drugs. Subsequently, regular exposure to vancomycin persistently over the years has turned *E. faecalis* into a reservoir of vancomycin-resistance traits due to constant selection pressure. Since some strains of the pathogen *S. aureus* are multidrug-resistant, and are responsive only to vancomycin, public-health experts fear that it will soon deliver strong vancomycin resistance to those *S. aureus* strains, making them incurable.[35]

Human treatment accounts for roughly half the antibiotics consumed every year in the United States. Perhaps only half of that use is appropriate and meant to cure bacterial infections and administered correctly in ways that do not strongly encourage resistance. Reports from the CDC and other researchers have estimated that some 50 million of the 150 million outpatient prescriptions for antibiotics every year are unneeded.[36–38]

In the industrial world, most antibiotics are available only by prescription, but this restriction does not ensure proper use. People often fail to finish the full course of treatment. Patients then often store the leftover doses and medicate themselves, or their family and friends, in less than therapeutic amounts. In both circumstances, the improper dosing will fail to eliminate the disease agent completely and will, furthermore, encourage growth of the most resistant strains, which may later produce hard-to-treat disorders. Many studies have reported presence of resistance markers and resistance bacteria in the environment, which includes the presence of *vanA, mecA, AmpC,* and gentamicin resistance containing genetic material in hospital effluents and waste water, as well as presence of antibiotic resistant mutants of *P. aeruginosa, Acinetobacter* spp., *E. coli, Campylobacter* spp., *Pseudomonas* spp., *Enterococci* spp., etc.[39] In the developing world, antibiotic use is even less controlled. Many of the same drugs marketed in the industrial nations are available over the counter. Unfortunately, when resistance becomes a clinical problem, these countries, which often do not have access to expensive drugs, may have no substitutes available.

Antibiotics are used extensively to prevent or to treat microbial infections in human and veterinary medicine. Over-prescribing antibiotics for viral-caused conditions like the flu or common cold, against which antibiotics are useless, contributes to antibiotic resistance. Most of the compounds used in medicine are only partially metabolized by patients and are then discharged into the hospital sewage system or directly into municipal wastewater if used at home. Along with excreta, they flow with municipal wastewater to the sewage treatment plant. They may pass through the sewage system and end up in the environment, mainly in the water compartment. Antibacterial substances used for livestock enter the environment when manure is applied to fields. These antibiotics may either end up in soil or sediment or in ground water.[40–43] In addition, resistant bacteria themselves are excreted by humans and animals[44–46] and are emitted into sewage or manure and other environmental compartments.

Antibiotics affect the mixed population of resistant and nonresistant bacteria both in the individual being treated, and in that individual's environment. This is because the rise of resistant bacteria in treated individuals spread readily to the surrounding populations and to new hosts. Also, regular use of antimicrobials in such settings as hospitals, daycare centers, and even in the household (cleaning products, disinfectants, etc.), increases the levels of resistant bacteria in people and others who are not being treated, including in individuals who live near those epicenters of high consumption or who pass through the centers. So, these drugs also affect the kinds of bacteria in the environment

TABLE 55.2

Bacteria and Fungi Listed in the 2013 Antibiotic Resistant Threats Report

Urgent Threats	Serious Threats	Concerning Threats	Watch List
• Carbapenem-resistant *Acinetobacter* • *Candida auris* • *Clostridioides difficile* • Carbapenem-resistant *Enterobacteriaceae* • Drug-resistant *Neisseria gonorrhoeae*	• Drug-resistant *Campylobacter* • Drug-resistant *Candida* • ESBL-producing *Enterobacteriaceae* • Vancomycin-resistant *Enterococci* (VRE) • Multidrug-resistant *Pseudomonas aeruginosa* • Drug-resistant nontyphoidal *Salmonella* • Drug-resistant *Salmonella* serotype Typhi • Drug-resistant *Shigella* • Methicillin-resistant *Staphylococcus aureus* (MRSA) • Drug-resistant *Streptococcus pneumoniae* • Drug-resistant Tuberculosis	• Erythromycin-resistant Group A *Streptococcus* • Clindamycin-resistant Group B *Streptococcus*	• Azole-resistant *Aspergillus fumigatus* • Drug-resistant *Mycoplasma genitalium*

Source: Centers for Disease Control and Prevention Website.[3]

and people around the individual being treated, resulting in a widespread societal effect.[47] On a larger scale, antibiotic resistance that emerges in one place can often spread far and wide. The ever increasing volume of international travel has hastened transfer to the United States of multidrug-resistant tuberculosis from other countries.[37] And investigators have documented the migration of a strain of multidrug-resistant *Streptococcus pneumoniae* from Spain to the United Kingdom, the United States, South Africa, and elsewhere. This bacterium, also known as the pneumococcus, is a cause of pneumonia, meningitis, and other diseases. Antibiotic and other drug resistance is already a major issue in medicine, with significant health and economic impacts, as shown by the resurgence of tuberculosis and malaria, and multidrug resistance is easily developed.[48] What has not been appreciated is the potential of drugs as environmental pollutants to create new pools of resistance which, by genetic transfers across species, can accelerate the development of resistance in many disease organisms. If new forms of resistance start to come not only from human treatments and hospital settings, but by interspecies transfers from the environment, the growing ineffectiveness of present forms of treatment and a revival of major epidemics is a distinct possibility. Since the emergence of resistance renders that particular antibiotic unavailable to treat infections for a long time it means that the product's life cycle may be short. The result of this is that the costs of antibiotic research and development must be recouped quickly, raising the price of the drug.[49] If the current patterns of high levels of antibiotic utilization persist (while there remains a paucity of new antibiotics), then the availability of effective antibiotics will decline. It is unlikely that the rapidly growing problem of antibiotic resistance will be solved by new antibiotics in the near future, so in order to sustain the therapeutic functions of antibiotics, it is necessary to preserve the efficacy of those antibiotics that are currently available, at least for the next few decades.[50–54]

Antibiotic-Resistant Organisms in U.S. Hospitals

Out of the billions of microorganisms on this planet, only a smaller subset is known to be pathogenic to humans, and an even smaller subset still is known to be problematic in terms of hospital resistance. The CDC outlined a number of potentially problematic organisms in their 2013 report and organized them by level of threat level severity to the U.S. population.[3] The classification process describes three different levels: Urgent, serious, and concerning.[3] Of these organisms, we will focus on a select few based upon their prevalence in the hospital system. These organisms include: Carbapenem-resistant *Enterobacteriaceae* (CRE), *Clostridioides difficile*, multidrug-resistant *Acinetobacter* spp., multidrug-resistant *P. aeruginosa,* extended spectrum beta-lactamase (ESBL)-producing *Enterobacteriaceae*, and *S. aureus.* Information regarding other strains of resistant bacteria that have been identified as threats by the CDC can be found in the Drug Resistance Threat Report[3] published by CDC accessible in the CDC website. See Table 55.2.

Carbapenem-resistant *Enterobacteriaceae* (CRE)

Carbapenem-resistance *Enterobacteriaceae* are classified as an "Urgent" threat by the CDC 2013 report, meaning that it represents an immediate public-health threat that requires aggressive action.[3] They have estimated that of the 140,000 healthcare-associated *Enterobacteriaceae* infections in the United States in the last year, roughly 9,300 were due to CRE organisms.[3] Although CRE organisms have characteristically been identified in other countries around the world, increases in the use of broad-spectrum antibiotics and international travel have contributed to increased isolations of this organism. CRE organisms are Gram-negative aerobic bacilli (such as *E. coli, Klebsiella* spp., etc.) and are appropriately named for their resistance to the carbapenem medication class (such as meropenem, ertapenem, imipenem-cilastatin, and doripenem), one of the broadest and most effective class of antibiotics. In addition, CRE organisms often express additional mechanisms of resistance that confer nonsusceptibility to other nonbeta-lactam medication classes, such as sulfamethoxazole/trimethoprim, aminoglycosides, and fluoroquinolones.[55,56] This often leads to near-pan resistance among CRE organisms. This lack of available medication options has led to a high mortality (nearly 50%) of CRE bloodstream infections.[3,57] These organisms obtain resistance to the carbapenem class via production of carbapenemases, a subtype of beta-lactam hydrolyzing enzyme, which cleaves the structural integrity of the beta-lactam ring. These carbapenemases provide the organism with resistance to not only, carbapenems but also the majority of other

beta-lactams such as penicillins, cephalosporins, and monobactams.[56] Although the nomenclature and categorization have changed throughout the years, carbapenemases have been associated with both chromosomal and plasmid-mediated genes.[56] Genes associated with the production of carbapenemases include the molecular class A, B, and D classes, which include, but are not limited to, KPC, IMP, VIM, and OXA genes.[56,58,59]

The lack effectiveness of current agents has prompted the use of older or more last line antibiotics, such as colistin, polymyxin b, and tigecycline.[60] Colistin is a surface active agent that exerts its mechanism of action by disrupting the cell membrane of Gram-negative bacteria.[61] Although colistin retains activity against a majority of Gram-negative agents ($MIC_{90} \leq 0.5–1$ mg/L and resistance rates <0.1–1.5%), complicated pharmacokinetic dosing and renal toxicity severely limits its use in treatment.[61–63] Polymyxin B is in the same class as colistin (colistin is also known as polymyxin E) and works in the same fashion but does not exhibit the same type of complicated renal toxicity.[62–64] Tigecycline is another agent that also demonstrates activity against CRE. Unlike, polymyxin B and colistin, tigecycline is a glycylcycline that inhibits protein synthesis.[65] Although tigecycline was developed later, it is not used as frequently today due to postmarketing studies revealing an increased risk of mortality as compared to the standard of therapy.[65] Today, tigecycline is reserved for CRE infections.[63] Combination therapy has shown favorable outcomes when compared to monotherapy, often involving a combination of tigecycline, polymyxin b, colistin, and/or carbapenems if the MIC ≤8mcg/mL.[66–69]

Unfortunately, the trials involving treatment of CREs are scarce, and the data reported may not often be reliable, due to the small sample size, often performed retrospectively or observationally. The dearth of available antibiotics to treat CREs combined with the looming resistance growth in hospitals has prompted several initiatives for the development of new antibiotics. Many newly approved and pipeline antibiotics are being developed with the hope to treat CREs and will be discussed later in the chapter.

Antibiotic-Resistant *Clostridioides difficile* Infections

Clostridioides (formerly clostridium) difficile is classified as an "Urgent" threat by the CDC 2013 report, meaning that it represents an immediate public health threat that requires aggressive action not necessarily due to innate resistance and inability to treat the disease, but rather due to frequent recurrence of disease.[3] *C. difficile* is a Gram-positive, anaerobic, spore-forming, bacilli that most commonly manifests with clinical symptoms of diarrhea, abdominal pain, and in more serious cases, toxic megacolon, pseudomembranous colitis, septic shock, and death.[70] *C. difficile* can be both a pathogenic organism as well as a normal colonizer of the gastrointestinal tract. Infection is associated with overgrowth of *C. difficile* due to elimination of commensal gut flora from antibiotic exposure.[70,71] Although other risk factors have been associated with *C. difficile*-associated diarrhea (CDAD), antibiotic exposure (particularly exposure to erythromycin, penicillin, clindamycin, higher generation cephalosporins, and fluoroquinolones) remains the primary factor causing CDI to spread more widely in and out of the hospital and increase the resistance of the epidemic strains of *C. difficile* to those drugs.[72,73] Current treatments available for CDAD include oral vancomycin (intravenous vancomycin does not achieve adequate concentrations in the gastrointestinal lumen), fidaxomicin, and metronidazole (in rare cases).[73] Strain 027 is the most frequently observed drug-resistant *C. difficile* strain and shows a statistically high incidence in Europe and the United States. Several countries have reported the resistance of strain 027 to moxifloxacin and, more recently, to metronidazole and vancomycin.[70,74]

In recent years, an increase in CDI has been reported in different countries. China, Sweden, and several other countries as well as the United States have reported a CDI incidence rate of ~17.1 cases/10,000 admitted to a hospital.[70] Initial cure rates with fidaxomicin and oral vancomycin are relatively high, around 87% for both.[74] However, recurrence rates have been observed to be anywhere between 10–40%.[73,74] The high recurrence rate is due to the spores that are produced from the *C. difficile* organism. Spores are not eliminated by antibacterial therapy and can remain in the gut for a substantial amount of time before germinating and reinfecting the patient. With every concurrent recurrence, clinicians cannot use a therapy that has been used in previous episodes, effectively narrowing the available treatments.[73] Although other modalities of management such as fecal microbiota transplantation and bezlotoxumab have been developed, a large part of *C. difficile* management involves discontinuing insulting antibiotics and isolation precautions such as gowns, gloves, and handwashing.[73]

Multidrug-resistant *Acinetobacter* spp.

Multidrug-resistant *Acinetobacter* spp. is classified as a "Serious" threat by the CDC 2013 report, meaning that it represents a concern that requires prompt and sustained action to ensure that the problem does not grow.[3] A recent report by the CDC stated that carbapenem-resistant *Acinetobacter* spp. were responsible for an estimated 8,500 hospitalizations and 700 estimated deaths in 2017.[75] Like *P. aeruginosa*, *Acinetobacter* spp. (most commonly *Acinetobacter baumannii*) are Gram-negative, glucose nonfermenting bacteria. Although wild strains of *Acinetobacter* spp. have been associated with fresh water and soil environments, multidrug-resistant strains have been more widely associated with hospital infections such as ventilator-associated pneumonia (VAP), urinary tract infections, and bacteremia.[75] *Acinetobacter baumannii* has accumulated a number of different resistance mechanisms such as beta-lactamases, aminoglycoside-modifying enzymes, efflux pumps, porin channel degradation, and modification of antibiotic target sites. In terms of beta-lactamases, *Acinetobacter* spp. strains have exhibited all four molecular subgroups included prominent ESBL and CRE beta-lactamases.[76] Combined with the aforementioned resistance mechanisms, *Acinetobacter baumannii* represents a formidable problem in U.S. healthcare today.

Treatment of susceptible strains of Acinetobacter is consistent with treatment of susceptible *P. aeruginosa* strains. Antibiotics that tend to retain effectiveness against wild-type *Acinetobacter baumannii* strains include piperacillin/tazobactam, ceftazidime, cefepime, aztreonam, carbapenems (except ertapenem), aminoglycosides, and fluoroquinolones. There are a few medications that also have well-documented activity to *A. baumannii* but not *P. aeruginosa*. These antibiotics include ampicillin/sulbactam

(just the sulbactam component), minocycline, and tigecycline. Although sulbactam is primarily used in combination with ampicillin as a beta-lactamase inhibitor to protect the active antibiotic from Ambler class A beta-lactams, sulbactam has shown *in vitro* and *in vivo* activity against *A. baumannii* alone.[77] Since sulbactam is only available as a co-formulated product in the United States, ampicillin/sulbactam is a viable option whereas in Europe sulbactam is available as a single product. In addition, there are no evidence-based guideline recommendations for optimal therapy against multidrug resistant strains of *A. baumannii*. However, current practice generally involves the use of combination therapy of sulbactam, tigecycline, and colistin/polymyxin B as compared to monotherapy with any singular agent.[78] Of the new antibiotic agents, few have substantial evidence showing them to be effective against multidrug-resistant Acinetobacter, but eravacycline and omadacycline have shown promising *in vitro* activity and may be potential future options for treatment as resistance of *Acinetobacter* spp. grows.[79,80]

Multidrug-Resistant *Pseudomonas aeruginosa*

Multidrug-resistant *P. aeruginosa* is classified as a "Serious" threat by the CDC 2013 report, meaning that it represents a concern that requires prompt and sustained action to ensure that the problem does not grow.[3] It is estimated to be responsible for up to 6,700 infections per year (51,000 infections of non-MDR *P. aeruginosa*) and 440 deaths per year.[3] *P. aeruginosa* is an aerobic, glucose nonfermenting, Gram-negative bacillus that is commonly found in hospital fluid reservoirs.[81] *P. aeruginosa* represents one of the most common nosocomial pathogens in the U.S. healthcare systems today and display a high level of resistance (roughly 19.3% were found to have resistant or intermediate susceptibility to at least one carbapenem and approximately 14% of isolates are classified as multidrug-resistant).[5,82] These pathogens contain multiple resistance mechanisms combinations (such as beta-lactamase production, efflux pump overexpression, porin channel degradation, and target site alteration), which confer high levels of resistance to most commercially available antibiotics.[83–87] The high frequency of multiple resistance mechanisms expressed by *P. aeruginosa* infections make the organism unique compared to other gram negative pathogens.

Medications that have potential efficacy against *P. aeruginosa* include piperacillin/tazobactam, ceftazidime, cefepime, imipenem-cilastatin, meropenem, doripenem, aztreonam, ciprofloxacin, levofloxacin, the aminoglycosides, polymyxin b, and colistin.[88] Although these medications have the potential to treat *P. aeruginosa* infections, individual strains may be resistant to one, multiple, or all of these agents, which creates a clinically difficult management plan.[3] In combination with high virulence and mortality rates with insufficient treatment, some infectious disease guideline updates (such as the Hospital Acquired/Ventilator Associated Pneumonia Infectious Disease Society of America Guidelines) have suggested treatment regimens using two different antipseudomonal agents of different medication classes as a first-line option to ensure adequate coverage of the organism in the acute phase.[89] MDR *P. aeruginosa* infections are also an area of interest in the development of new Gram-negative antibiotics. Of the new agents mentioned above for CRE infections, almost all of them have *in vitro* and clinically relevant activity against wild-type *P. aeruginosa*, but only some have shown promising activity in MDR strains. Notably, meropenem/vaborbactam, plazomicin, and aztreonam/avibactam (currently in development) did not show additional activity against MDR *P. aeruginosa* isolates.[88] Of the newer agents, ceftazidime/avibactam, ceftolozane/tazobactam, imipenem-cilastatin/relebactam, and cefiderocol show promise against MDR *P. aeruginosa* isolates. Ceftazidime/avibactam shows clinical good *in vitro* activity against *P. aeruginosa* in general with susceptibility rates close to 90% in the United States.[90–92] The addition of avibactam to ceftazidime allows for additional stability against beta-lactamase produced by *P. aeruginosa* with roughly 80% of ceftazidime/avibactam susceptible isolates exhibiting resistance to ceftazidime alone.[91,92] Ceftolozane/tazobactam utilizes a novel cephalosporin with a historical beta-lactamase inhibitor. Ceftolozane is structurally similar to ceftazidime but is more stable against AmpC, allowing for better activity against AmpC derepressed strains of *P. aeruginosa*, and has a greater affinity for *P. aeruginosa* penicillin binding proteitns.[93,94] *In vitro* activity of ceftolozane/tazobactam to *P. aeruginosa* is high with susceptibility to 96.1% of isolates in general and 77% to ceftazidime.[95] Imipenem-cilastatin/relebactam is currently undergoing phase 3 trials, but utilizes a novel beta-lactamase inhibitor, relebactam, for additional Gram-negative coverage. *In vitro*, the addition of relebactam to imipenem-cilastatin has demonstrated increased susceptibility of *P. aeruginosa* from 70% to 94%.[96]

Extended Spectrum Beta-lactamase (ESBL)-Producing *Enterobaceriaceae*

Extended spectrum Beta-lactamase (ESBL)-producing *Enterobaceriaceae* are classified as "Serious" threats by the CDC 2013 report, meaning that it represents a concern that requires prompt and sustained action to ensure that the problem does not grow.[3] ESBLs were initially defined as beta-lactamases that could hydrolyze penicillins and third-generation cephalosporins, the latest generation of that time. Now ESBLs can be better defined as multiple plasma-mediated ambler class A beta-lactamases (most commonly mutations of the SHV, TEM, and CTX enzymes) that hydrolyze almost all beta-lactams except carbapenems, but remain susceptible to select beta-lactamase inhibitors.[97–99] In addition, the ESBL plasmids have also been found to contain other genes that code for resistance mechanisms of nonbeta lactam antibiotics, nullifying other empiric therapy options. Because ESBLs are plasma-mediated, the ability for resistance to transfer between pathogens (even different organisms entirely) creating infection prevention concerns as well.

Traditionally, carbapenems have been the treatment of choice for ESBL infections due to their resilience to hydrolysis and the aforementioned ineffectiveness of other beta-lactam and nonbeta-lactam antibiotics. This of course, only applies to empiric therapy, when susceptibilities of the particular infection strain are unknown. Once susceptibilities are available, other nonbeta-lactam antibiotic, such as sulfamethoxazole/trimethoprim and fluoroquinolones, may be used.[100] For a time, piperacillin/tazobactam was thought to be a potential carbapenem-sparring regimen due to the continued activity

of beta-lactamase inhibitors against ESBLs.[99] This practice was further supported by small clinical trials showing potential benefit in the using of carbapenem-sparring piperacillin/tazobactam, most notably in ESBL urinary tract infections.[101] However, these trials were generally observational studies or had low enrollment, lacking the ability to demonstrate effectiveness comparisons to a carbapenem-based regimen. A recent randomized controlled trail compared the efficacy of meropenem and piperacillin/tazobactam in ESBL bacteremia. The results of the trial showed that piperacillin/tazobactam failed to demonstrate noninferiority to meropenem in ESBL bacteremia.[102] Therefore, carbapenems remain the standard of therapy for ESBL infections. Luckily, the majority of newly approved antibiotics have activity against ESBLs.

Staphylococcus aureus

Methicillin-resistant *Staphylococcus aureus* (MRSA) is classified as a "Serious" threat by the CDC 2013 report, meaning that it represents a concern that requires prompt and sustained action to ensure that the problem does not grow.[3] A 2019 report by the CDC estimated that there were 323,700 cases and 10,600 deaths due to MRSA in the United States.[75] MRSA is the Gram-positive pathogen of greatest concern in hospital-related infections, often necessitating the addition of vancomycin to most empiric regimens. In addition to vancomycin, several other antibiotics have MRSA activity, such as ceftaroline, dalbavancin, oritavancin, doxycycline, tigecycline, sulfamethoxazole/trimethoprim, clindamycin, lefamulin, delafloxacin, linezolid, and tedizolid. In addition to hospital-acquired infections, community-acquired MRSA has been associated with intravenous drug users, confined living spaces, residence in nursing homes and assisted living facilities, hemodialysis, previous antimicrobial therapy, and previous hospitalization. However, more recent guidelines have begun to better define the risks for MRSA, elevating its previous isolation (via previous infection or colonization) as primary risk factors for MRSA infection.[89,103]

Although all the agents listed above may be used in MRSA infections, vancomycin remains the standard of therapy for the majority of hospitals in the United States. This is primarily due to the low cost, relatively high efficacy, and large amounts of experience and clinical data associated with vancomycin use for MRSA. However, vancomycin's adverse effect profile and a slowly increasing level of MRSA vancomycin resistance have prompted the use of alternative agents. Vancomycin is associated largely with nephrotoxicity and infusion related red man syndrome (a combination of symptoms including torso erythema, itching, and fever).[104] While the latter can be mitigated with antihistamine premedication and decreasing the rate of infusion, nephrotoxicity is dose related and can be difficult to avoid even with appropriate therapeutic drug monitoring. Recently a phenomenon, known as the "MIC creep," has been observed in MRSA isolates in which the MIC of MRSA isolates to vancomycin has started to rise, causing clinical failure despite MICs that remain below the CLSI breakpoint.[105,106] The decision to continue to treat with vancomycin or switch to an alternative agent is currently divisive amongst clinicians and requires more clinical data before a consensus can be made regarding optimal therapy.

The Clinician's Role in Combating Antimicrobial Resistance

Antimicrobial Stewardship Programs

The data from all the studies listed above, on incidence, causative factors, and mechanisms of action of antimicrobial resistance warrants a multifaceted approach to curb the effects of MDR that will include educating patients as well as physicians about the appropriate antimicrobial use. What this means is that the clinician's current antibiotic armamentarium is all they can expect in the foreseeable future. It also means that special care needs to be taken to optimally use currently available agents to ensure continued activity against the pathogens encountered in the hospital (and community) setting, now and in the future. Maximizing clinical outcomes, while minimizing the emergence and spread of antimicrobial resistance (and other adverse effects associated with suboptimal antimicrobial drug use), falls under the purview of antimicrobial stewardship.[107]

Early in the onset of many infections, the data needed to make a rational, informed decision about specific antibiotic therapy is usually unavailable. For many infections, therapy cannot be delayed waiting for microbiology or other findings, and broad-spectrum empiric therapy is begun based on educated guesses made from the patient's presentation and characteristics, and local or hospital antibiograms. In addition, for many serious infections, delay in antimicrobial therapy will increase patient morbidity and mortality.[108] Examining antibiotic usage at the hospital level, one notices that approximately 60% of adult patients admitted to U.S. hospitals receive at least one dose of an antibiotic agent during their stay (range: 44–74% for individual hospitals).[109,110] Similarly, at Wake Forest University Baptist Medical Center, approximately 75% of inpatients receive antimicrobials at some point during their hospitalization.[119] One recent example by Hecker and colleagues conducted in a 650-bed, university-affiliated U.S. hospital reported 30% of the total days of antibiotic therapy received by adult non-ICU inpatients was unnecessary.[111] The most common reasons for unnecessary use were administration for longer than recommended durations, administration for a noninfectious or nonbacterial syndrome, and treatment of colonizing or contaminating microorganisms. Unwanted consequences of antimicrobial therapy include increased morbidity and mortality, adverse drug reactions, increased length of hospital stay and hospitalization costs, predisposition to secondary infections, and emergence and selection of drug-resistant organisms.[112,113] Selection or induction of antimicrobial resistance and promotion of secondary infection with *C. difficile*, particularly with new, more toxigenic strains, are of particular concern in the current hospital environment.[113] These untoward consequences can be seen as a calculated risk of antibiotic therapy for any single-treated patient, or as an undesired outcome measure for excessive use at the level of the healthcare institution.

Antimicrobial stewardship programs in hospitals seek to optimize antimicrobial prescribing to improve individual patient care as well as reduce hospital costs and slow the spread of antimicrobial resistance. The various strategies used as part of these programs also help to reduce unwanted consequences

of antimicrobial overuse or misuse, including lowered efficacy, development of secondary infections, adverse drug reactions, increased length of hospital stay, and additional healthcare costs.[114,115] The role of an effective control of infections in achievement of optimized clinical outcomes and decreased potential pharmacotherapy-related damage is also very fundamental. Infection control is clearly necessary and often enough to reduce hospital-acquired infections (HAIs). However, a comprehensive infection-control program, combined with an effective antimicrobial stewardship agenda, synergistically limit the emergence and spread of antimicrobial-resistant bacteria, reduce HAIs, control resistance, and improve overall inpatient care.[114,116] With antimicrobial resistance on the rise worldwide and few new agents in development, antimicrobial stewardship programs are more important than ever in ensuring the continued efficacy of available antimicrobials.

The design of antimicrobial management programs should be based on the best current understanding of the relationship between antimicrobial use and resistance. Such programs should be administered by multidisciplinary teams composed of infectious diseases physicians, clinical pharmacists, clinical microbiologists, and infection control practitioners and should be actively supported by hospital administrators. Strategies for changing antimicrobial prescribing behavior include education of prescribers regarding proper antimicrobial usage, creation of an antimicrobial formulary with restricted prescribing of targeted agents, and review of antimicrobial prescribing with feedback to prescribers.[117] Clinical computer systems can aid in the implementation of each of these strategies, especially as expert systems able to provide patient-specific data and suggestions at the point of care. Antibiotic rotation strategies control the prescribing process by scheduled changes of antimicrobial classes used for empirical therapy. When instituting an antimicrobial stewardship program, a hospital should tailor its choice of strategies to its needs and available resources.

Recent guidelines established by the Infectious Diseases Society of America and Society for Healthcare Epidemiology of America (IDSA/SHEA) make specific recommendations for the development of institutional programs to enhance antimicrobial stewardship.[116,118] Optimally, such programs should be comprehensive, multidisciplinary, supported by hospital and medical staff leadership, and should employ evidence-based strategies that best fit local needs and resources.[114,115] Principal proactive strategies—with evidence supporting their consideration—include prospective audits, with intervention and feedback, formulary restriction, and preauthorization.[107,117] In addition, other strategies include persistent one-on-one and large group education, guidelines adapted to local needs; computer based informatics to support clinical decision making, using the antimicrobial stewardship program to adapt national guidelines to local antimicrobial use; microbiology, and resistance patterns[118,119]; and the use of rapid molecular diagnostic testing. All of these have also been shown to improve antimicrobial utilization at hospitals. A summarized list of potential strategies or elements of an antimicrobial stewardship program[107,117] is listed in Table 55.3.

The size and nature of the institution can make a big difference in determining what program to set up and what elements it should entail. The program components and effectiveness of each will differ for community hospitals compared to academic medical centers. A comprehensive program includes active monitoring, fostering of appropriate antimicrobial use, and collaboration with an effective infection control program as well as other hospital entities.[114] The role of a multidisciplinary team, with administrative support, is particularly underscored in the guidelines. According to the guidelines, core members of the multidisciplinary team should include an infectious diseases physician and a clinical pharmacist with infectious diseases training. It should also ideally include a clinical microbiologist, information system specialist, infection control professional, and hospital epidemiologist,[115,117] and all members understanding their responsibility for the successful implementation of the program and oversight of its implementation and daily functions.

Most community hospitals, if sufficiently resourced, should be able to implement a successful antimicrobial stewardship program. Evidence suggests that good antimicrobial stewardship can lead to less overall and inappropriate antimicrobial use, lower drug-related costs, reductions in antimicrobial use, improve patient outcomes, and have the potential to prevent or control the emergence of antimicrobial-resistant organisms.[120] For these programs to be successful, they must address the specific needs of individual institutions and be built on available resources, the limitations and advantages of each institution, and the available staffing and technological infrastructure.

Summary

The emergence of antibiotic-resistant organisms is a major public health concern that continues to increase and is acknowledged to be a major threat to the treatment of infectious diseases, particularly among patients in hospitals and other healthcare settings. Antibiotic-resistant organisms appear to be biologically fit and can cause serious, life-threatening infections that are difficult to manage because of limited treatment options. This increase in the prevalence of drug-resistant pathogens is occurring at a time when the discovery and development of new anti-infective agents is slowing down dramatically. Consequently, there is concern that in the not-too-distant future, we may be faced with a growing number of potentially untreatable infections. Over the years, with the development of antimicrobial agents, several antibiotic-resistant pathogens have been identified as causes of serious infections among patients in hospital. These organisms are typically resistant to multiple classes of antimicrobial agents and are, therefore, called multidrug-resistant organisms and may also be considered a nosocomial antibiotic-resistant organism because of their prevalence in hospital settings. Infections caused by antimicrobial-resistant organisms are almost always associated with increased attributable mortality, prolonged hospital stays and excess costs. Rates of emergence of antibiotic-resistant organisms will continue to increase unless aggressive control measures are implemented. These interventions must include enhanced surveillance of antibiotic resistance, attention to hand hygiene and other standard infection prevention and control measures, and antibiotic stewardship to ensure appropriate use of antimicrobial agents.

Overuse or misuse of antibiotics and other antimicrobials for hospital inpatients is relatively common and can be associated with several unintended negative consequences. Improving medical

TABLE 55.3

Summary of Strategies used in Antimicrobial Stewardship Programs[107,117]

Program Element	Strategy Procedure	Personnel	Advantages	Disadvantages
Guidelines and pathways	• Creation of guidelines for antimicrobial use • Best if local data and conditions are used to adapt guidelines to a specific institution	Antimicrobial committee to create guidelines	• May alter behavior patterns • Limits variation in therapy of infectious diseases • Best evidence-based • Assists in adherence with regulatory and third-party-payer stipulations	• Passive education likely ineffective • Often not utilized unless combined with other stewardship strategies or elements
Education and promotion of awareness in large group	• Group or individual education of clinicians by educators • Grand rounds or clinical staff meeting venues • Provides information to prescribers and thought-leader clinicians on justification for stewardship • Feedback antimicrobial susceptibility and use data to clinicians	Educators (physicians, pharmacists)	• Avoids loss of prescriber autonomy • Can reach many prescribers in a short period of time • Effective for communicating the need and rationale for subsequent stewardship interventions	• Not particularly effective in changing prescribing behavior without other interventions • Rapid extinction of gained knowledge
Formulary restriction or preauthorization	• Restrict dispensing of targeted antimicrobials to approved indications • "Front-end approach" • Formulary restriction or contact a stewardship team member to obtain authorization to prescribe a selected antimicrobial • Each intervention is a "mini-consult"	Antimicrobial committee to create guidelines	• Most direct control over antimicrobial use • Proven in clinical studies to reduce and modify antimicrobial consumption, improve selected clinical outcomes, and decrease antimicrobial expenditures • Together with infection control, effective in controlling outbreaks of resistant or secondary pathogens (such as *C. difficile*)	• Perceived loss of autonomy for prescribers • Less appealing to clinicians • Potential need for after-hours service • Time intensive • Potential for delay in antimicrobial administration
		Approval personnel (physician, infectious diseases fellow, clinical pharmacist)	• Individual educational opportunities	• Need for all-hours consultant availability
Prospective audit and feedback	• Daily review of targeted antimicrobials for appropriateness • "Back-end approach" • Identify and intervene on patients already started on antimicrobials • Interventions include changing, streamlining, de-escalation, pharmacodynamic/dose optimization, IV to PO switch, and limitation of duration of therapy	Antimicrobial committee to create guidelines	• Avoids loss of autonomy for prescribers	• Compliance with recommendations and adherence to stewardship interventions by the clinician is voluntary • Resource intensive • Requires a greater amount of team-member training and experience in anti-infective therapy
	• Contact prescribers with recommendations for alternative therapy	Review personnel (usually clinical pharmacist)	• Individual educational opportunities	
Computer assistance in physician order Entry and clinical Decision support	• Use of information technology to implement previous strategies • Often entails modification of existing or purchasing of additional informatics	Antimicrobial committee to create rules for computer systems	• Provides patient-specific data where most likely to impact (point of care) • Shown in limited clinical studies to reduce and modify antimicrobial consumption, improve selected clinical outcomes, and decrease antimicrobial expenditures • Once established, can greatly assist with implementation of guidelines and best-evidence therapy. • Reduces adverse events related to antimicrobials	• Significant time and resource investment to design and implement sophisticated systems • Expensive • Not readily available

TABLE 55.3 ***(Continued)***

Summary of Strategies used in Antimicrobial Stewardship Programs[107,117]

Program Element	Strategy Procedure	Personnel	Advantages	Disadvantages
	• Expert systems provide patient-specific recommendations at point of care (order entry)	Personnel for approval or review (physicians, pharmacists) Computer programmers	• Facilitates other strategies	
Antimicrobial cycling	• Scheduled rotation of antimicrobials used in hospital or unit (e.g., intensive care unit) • Changing antimicrobial protocols periodically in an attempt to reduce selection pressure for resistance	Antimicrobial committee to create cycling protocol	• Potential to decrease antimicrobial resistance for an institution or geographic unit by changing selective pressure	• Difficult and labor-intensive to ensure adherence to cycling protocol • Not consistently shown in clinical trials to improve clinical outcomes or decrease resistance • Often increases antimicrobial consumption
		Personnel to oversee adherence (pharmacist, physicians)		• Theoretical concerns about effectiveness
Microbiology interventions	• Includes cascade reporting to "hide" antimicrobial susceptibilities that might promote suboptimal therapy (e.g., fluoroquinolone susceptibility for invasive *S. aureus*) • Assistance with choices of automated susceptibility profile, communication of new or changes in testing protocols • Preauthorization of susceptibility testing for unconventional antibiotics	Clinical microbiologist	• Potential to improve antimicrobial use and anti-infective therapy for the individual patient	• Not well studied
Rapid diagnostics	• Includes PCR and antigen testing of clinical specimens or early culture growth with rapid turnaround of test results	Clinical microbiology and diagnostics laboratory personnel	• Provides opportunity for early targeted therapy • Assists with de-escalation • Shown in very limited studies to decrease antimicrobial consumption and improve clinical outcomes	• Not readily available • Expensive

care necessarily includes better use of antimicrobials to optimize outcomes and preserve the effectiveness of currently available agents. Further, an important additional consequence of effective antimicrobial stewardship and improved patient care is typically a lowering of overall healthcare costs. The recent 2007 IDSA/SHEA guidelines provide recommendations for developing an institutional program to enhance antimicrobial stewardship. However, individual institutions need to look closely at their own systems and patients to develop an antimicrobial stewardship program that best serves the needs of their hospital and the people it serves.

Introduction

The discovery of penicillin by Sir Alexander Fleming in 1928 marked the beginning of the modern era of antibiotics.[1] Following this discovery, the first penicillin resistance was reported in 1950.[2] Despite the availability of numerous antimicrobial agents available to treat microbial infections, sometimes these agents become ineffective against microorganisms such as bacteria, viruses, fungi, and protozoa. As a result infections persisted in the body increasing the risk of spread to others. Resistant microorganisms are emerging globally and are threatening our ability to fight common infections resulting in increased morbidity and mortality. Over time, changes occur naturally in the genetic composition of microbes due to overuse and misuse of antimicrobial agents which is one of the primary reasons for the emergence of antimicrobial resistance (AMR). Nearly two million Americans per year develop healthcare-associated infections (HAIs), resulting in 99,000 deaths. Most of the mortalities are due to antimicrobial-resistant pathogens. In 2006, two common HAIs, sepsis and pneumonia, were responsible for the deaths of nearly 50,000 Americans, costing the U.S. healthcare systems more than $8 billion. Estimates regarding the medical cost per patient with an antibiotic-resistant infection range from $18,588 to $29,069. The total economic burden placed on the U.S. economy is estimated to be as high as $20 billion in healthcare and $35 billion in lost

productivity because of AMR.[2] AMR has emerged in Europe and North America as well due to inappropriate use of antibiotics in humans and animals. Resistant pathogens such as methicillin-resistant *Staphylococcus aureus* (MRSA), penicillin nonsusceptible *Streptococcus pneumoniae* (PNSSP), vancomycin-resistant enterococci (VRE), and extended-spectrum β-lactamase (ESBL)-producing *Enterobacteriaceae* have emerged and spread into communities and hospitals.[3] In a recent study conducted at Children's hospital in China, it was found that there are five main pathogens responsible for multidrug-resistant infections. Extended spectrum β-lactamase (ESBL) was found in 1.9% cases making it the most common pathogen.[4] The second most common was MRSA, accounting for 1.51%.[4] The third, fourth, and fifth most common pathogens were Carbapenem-resistant *Enterobacteriaceae* (CRE) in 0.17% of the cases, Carbapenem-resistant *Acinetobacter baumannii* (CRAB) in 0.10% of the cases, and multidrug-resistant/pandrug-resistant *Pseudomonas aeruginosa* (MDR/PDR-PA) in 0.03% of the cases, respectively.[4]

AMR Mechanisms

Medical practice was transformed after discovery of antibiotics in early 20th century; however, antibiotic lethality is a complex system level process that is sensitive to the external environment.[5] Antibiotics inhibit cellular processes in microorganisms, retarding their growth and causing cell death. Microorganisms can develop resistance via resistance conferring mutation when they are exposed to concentrations of drugs below their minimum bactericidal concentration (MBC). Genetic mutations in these microorganisms arise from plasmids. These plasmids code for mutations or resistant genes in microbial chromosomes itself.[6]

Resistance Prevalence and Their Significance

The Infectious Diseases Society of America (IDSA) Emerging Infectious Network conducted a national survey in 2011 and found that more than 60% of participants had seen a pan-resistant, untreatable bacterial infection within a period of 1 year. In 2013, the Centers for Disease Control and Prevention (CDC) declared that the human race is now in the "post antibiotic era." CDC assesses antibiotic resistance based on the following factors: Clinical impact, economic impact, incidence, 10-year projection of incidence, transmissibility, availability of effective antibiotics, and barriers to prevention. Based on the impact, as assessed by CDC, Table 56.1 classifies the threat level of each bacteria as Urgent, Serious, Concerning, or to be put on the watch list.

In Europe, the combined resistance to fluoroquinolones, third-generation cephalosporins, and aminoglycosides increased between 2011 and 2014 in isolates of Gram-negative bacteria, including *Klebsiella pneumoniae* (from 16.7% to 19.6%) and *Escherichia coli* (from 3.8% to 4.8%).[7] Also, according to data published by CDC in 2002, foodborne diseases account for approximately 76 million illnesses, 325,000 hospitalizations, and 5,000 deaths each year in the United States alone.[52] Antimicrobial-resistant zoonotic foodborne bacterial pathogens are an undesired consequence of use of antimicrobials in animals, and subsequent transmission to humans as food causes foodborne diseases. In this regard, five pathogens account for more than 90% of estimated food-related deaths: Salmonella (31%), listeria (28%), toxoplasma (21%), Norwalk-like viruses (7%), *Campylobacter* (5%), and *E. coli* (3%).[29]

Causative Factors

Factors that contribute toward AMR are as following: Over use and misuse of antimicrobial agents, inappropriate prescribing methods, extensive agricultural use, availability of few new antibiotics, and regulatory barriers.[2] Level of education, low income, housing conditions, water, and sanitation are some of the other factors that are positively associated with AMR. In low- and middle-income countries, issues like housing, clean water and sanitation, lack of infrastructure, and access to vaccines leads to recurring infections and the use of antimicrobial agents, which also contributes to the emergence of resistance.[9] For example, before 1995 in countries like Taiwan, drugs were available in drug stores without prescriptions, which greatly contributed to AMR.[3] It is difficult and expensive to treat infections and harder to control epidemics when the effectiveness of antibiotics is declining. Of all the infections, bacterial infections contribute the most to human and animal diseases in developing countries and hence the emergence of antibiotic resistance. Also, unfortunately, not much has been accomplished in developing countries due to poverty and the lack of adequate resources when compared with developed countries.[12]

TABLE 56.1

Bacteria and Fungi Listed in the 2019 Antibiotic Resistance Threats Report

Urgent Threats	Serious Threats	Concerning Threats	Watch List
• Carbapenem-resistant *Acinetobacter* • *Candida auris* • *Clostridioides difficile* • Carbapenem-resistant *Enterobacteriaceae* • Drug-resistant *Neisseria gonorrhoeae*	• Drug-resistant *Campylobacter* • Drug-resistant *Candida* • ESBL-producing *Enterobacteriaceae* • Vancomycin-resistant *Enterococci* (VRE) • Multidrug-resistant *Pseudomonas aeruginosa* • Drug-resistant nontyphoidal *Salmonella* • Drug-resistant *Salmonella* serotype Typhi • Drug-resistant *Shigella* • Methicillin-resistant *Staphylococcus aureus* (MRSA) • Drug-resistant *Streptococcus pneumoniae* • Drug-resistant tuberculosis	• Erythromycin-resistant Group A *Streptococcus* • Clindamycin-resistant Group B *Streptococcus*	• Azole-resistant *Aspergillus fumigatus* • Drug-resistant *Mycoplasma genitalium*

Immune System Response and Duration of Antimicrobial Therapy

The correct length and timing of antimicrobial therapy are two important factors in effectively treating bacterial infections with minimal risk of the development of resistance. The immune system is effective in killing bacteria when bacterial load is below the minimal infecting dose and no infection develops in patient. Antimicrobial therapy of nine days reduces the bacterial load below that threshold and prevents the progression of infection. However, when the duration of therapy is less, for example six days, then bacterial load is not reduced below the threshold and bacterial infection persists. Such short therapies and early interruption of antibiotics are advantageous for resistant strains causing infections by these resistant bacteria to progress. Thus, it is important to develop optimal antibiotic regimens which can prevent the progression of infection with antibiotic-resistant strains. Delayed start of therapy is also one of the key factors that promotes a rapid rise in resistant strains.[16]

The quantity of antimicrobial drugs prescribed is overall highest in the community healthcare setting. Although the link between human antimicrobial use and resistance seems clear cut, this association is complex. The confounding factors influencing antimicrobial resistance in the community include pathogen-drug interactions, pathogen-host interactions, mutation rates of the pathogen, emergence of successful antimicrobial-resistant clones, the transmission rates of pathogens between human beings, animals, and the environment, cross-resistance, and selection of co-resistance to unrelated drugs. It is also proven by various studies that emergence in AMR can be the result of selective pressure exerted by antimicrobial use outside of human medicine. Use of antimicrobial agents in veterinary medicine, food-animal and fish production, and agriculture contributes towards AMR.[27]

Role of Environment

Antibacterial agents can enter the environment via several routes, namely sewage from communities or hospitals, as well as through manure and water bodies. The accumulation of antimicrobial agents in the environment makes it a gigantic reservoir for resistant microorganisms. A hotspot for horizontal gene transfer and coselection of genetic determinants is wastewater treatment plants, which provide organisms that are resistant to antibiotics, pollutants, heavy metals, biocides, disinfectants, or detergents. To address the risks of environmental exposure strategies should aim at improving industrial systems for sanitation and decontamination of hospital sewage water.[44]

Antibiotic Resistance and Epidemiological Trends

MRSA

S. aureus is the most commonly isolated human bacterial pathogen and an important cause of skin and soft-tissue infections (SSTIs), endovascular infections, pneumonia, septic arthritis, endocarditis, osteomyelitis, foreign-body infections, and sepsis.[94] MRSA isolates are resistant to all available penicillin and other β-lactam antimicrobial drugs. They were once confined largely to hospitals, other healthcare environments, and patients visiting these facilities. Since the mid-1990s, however, there has been an explosion in the number of MRSA infections reported for populations lacking risk factors for exposure to the healthcare system.[17] This increase has been associated with the recognition of new MRSA strains, often called community-associated MRSA (CA-MRSA) strains that have been responsible for a large proportion of the increased disease burden observed in the last decade. These CA-MRSA strains appear to have rapidly disseminated among the general population in most areas of the United States and affect patients with and without exposure to the healthcare environment.

The first case of MRSA was reported in the United Kingdom in 1962 and in the United States in 1968.[2] Since MRSA is resistant to penicillin and a number of similar β-lactam antibiotics, a number of other antibiotics including glycopeptides (e.g., vancomycin and teicoplanin), linezolid, tigecycline, daptomycin, and even some new β-lactams, such as ceftaroline and ceftobiprole are still active against MRSA, which shows tremendous versatility at emerging and spreading in different epidemiological settings over time (in hospitals, the community, and, more recently, in animals). Resistance to anti-MRSA agents usually occurs through bacterial mutation, but there have been reports of the horizontal transfer of resistance to linezolid and glycopeptide antibiotics, eliciting major concern. An earlier study conducted in Taiwan in 2002 reported that the prevalence of MRSA increased from 26.7% to 75% from 1980 to 1998 and reached to 84% in 2000. Also, 40% of out-patients reported incidence of MRSA in community settings.[3] But aggressive preventive hygiene measures in the community and hospitals have led to a decline in the incidence of MRSA infections between 2005 and 2011, where overall rates of invasive MRSA dropped 31%, while the largest declines (around 54%) were observed in healthcare–associated infections.[2] Data reported in a systematic review by Nellums et al. showed that prevalence of MRSA is 0.3–60% in Europe, 12–89% in Africa, and 10–53% in eastern Mediterranean countries.[7]

Resistance to first-line drugs used to treat infections caused by *S. aureus*, a common cause of severe infections in health facilities and the community, is widespread. People with MRSA are estimated to be 64% more likely to die than people with a nonresistant form of the infection per reports from WHO in 2018.[1] A recent shift in the epidemiological profile of MRSA has resulted not only in healthcare–associated infections, but now, it has recently been appreciated as a cause of community-associated infections. Some reports have also shown decreased susceptibility, and even resistance of these pathogens to vancomycin. The increasing prevalence of MRSA in hospitals has led to the increased use of vancomycin for treatment, leading to the emergence of decreased susceptibility and even resistance to vancomycin. There are now 14 isolates of vancomycin-intermediate *S. aureus* in the United States.[37] Vancomycin resistant *S. aureus* are susceptible to daptomycin, which is an antibacterial agent approved by the Food and Drug Administration (FDA) since 2006. MRSA infection in the community setting has been documented in patients without known risk factors for MRSA infection (e.g., recent hospitalization, recent surgery, residence in a long-term care facility, or injection drug use). The prevalence of community-associated MRSA (as a proportion of all MRSA infections) varies according to the geographic region of the United States (from 9% in

Maryland to 20% in Georgia) and according to race within the geographic regions (43% and 17% among African Americans and whites, respectively, in Georgia, and 12% and 5%, respectively, in Maryland.)[53,93] According to data collected during the U.S. influenza season from 2003 to 2004, 17 cases of community-acquired staphylococcal pneumonia were reported to the CDC, in which 15 of the cases were caused by MRSA.[95]

The emergence of MRSA in the community has an obvious effect on the choices of empirical treatment for skin and soft-tissue infections and community-acquired pneumonia. In regions where MRSA is prevalent in the community, clindamycin or trimethoprim-sulfamethoxazole has been proposed for the treatment of skin and soft-tissue infections. Sometimes this includes incision and drainage of purulent lesions where possible.[36] Cosgrove et al. evaluated two cohort studies that reported that methicillin resistance is also associated with significant increases in the median length of hospital stay after acquisition of infection and hospital charges after *S. aureus* bacteremia.[14]

Strains of *S. aureus* belonging to a few phage types that possessed an inducible penicillinase gradually spread throughout the world's hospitals in the 1950s and throughout communities everywhere in the 1960s.[40] In addition, 6 months after methicillin was marketed in October, 1960, three methicillin-resistant isolates were reported after the screening of 5,000 clinical isolates.[23,29] However, since methicillin resistance remained rare and was expressed only by the resistant organisms in conditions that seemed to be very different from those prevailing at the site of infections (such as at low temperatures and high salt concentrations), methicillin and its congeners were deemed successful as antistaphylococcal agents with long-term effectiveness. But, by 1967, the situation started to change and multidrug-resistant MRSA was reported from Switzerland, France, Denmark, England, Australia, and India. About 15% of all these *S. aureus* isolates were methicillin resistant with combined resistance to penicillin, streptomycin, tetracycline, and occasionally to erythromycin. Most of these isolates belonged to the same phage complex.[31] After the rapid dissemination of this clone, MRSA began to fall in Europe in the 1970s and early 1980s. There were renewed concerns in the early 1980s, when a rise in the frequency of gentamicin-resistant MRSA was reported from several countries, including the United States, Ireland, and the United Kingdom.[10,19,23,32]

Community-Acquired MRSA

The majority of documented MRSA infections are acquired nosocomially, with community acquired MRSA restricted to patients with frequent contact with health facilities, such as residents of long-term care facilities and intravenous drug users. In 1993, novel MRSA strains were reported from Western Australia, which seemed to be community acquired, since they had been isolated from Indigenous Australian patients who had not been previously exposed to the healthcare system. These strains were characteristically different from hospital-acquired MRSA in many ways. Firstly, they were more susceptible to antibiotic classes other than β-lactam antibiotics; secondly, their genotypes were not the same as isolates from local hospitals; thirdly, they harbored different methicillin-resistance cassettes; and finally, community isolates were more likely to encode a putative virulence factor called Panton-Valentine leukocidin.[20]

Community-acquired MRSA has been reported most often from indigenous populations,[22] homeless people,[23] men who have sex with men,[45] jailed inmates (Control and Prevention 2003), military recruits,[53] children in daycare centers,[47] and competitive athletes (Control and Prevention 2003). Common to all these groups is high intensity physical contact which might help with transmission. A publication from Texas, USA showed that more than 70% of community-acquired *S. aureus* infections in clinical settings were MRSA.[30] In 2002, MRSA with vancomycin resistance (VRSA) was isolated from two independent patients who were coinfected with vancomycin-resistant enterococci.[92] Although few publications have addressed this issue, heterogeneously expressed vancomycin resistance has proven to be associated with treatment failure, which is defined as persistent bacteremia and fever for longer than seven days. However, successful treatment with alternative agents (e.g., linezolid) has been documented after vancomycin treatment had failed.[28] MRSA is at present, the most commonly identified antibiotic-resistant pathogen in many parts of the world, including Europe, the Americas, north Africa, the middle east, and east Asia. Moreover, MRSA rates have been swiftly increasing worldwide over the past decades, as shown by data from continuing surveillance initiatives such as the National Nosocomial Infection Surveillance System and European Antimicrobial Resistance Surveillance Systems.[21,50,51] MRSA originates from the introduction of a large mobile genetic element called staphylococcal cassette chromosome mec (SCCmec) into a methicillin-susceptible *S. aureus* strain. Up to now, five types of SCCmec (SCCmec I to V) and several variants have been described according to the combination of the mec and ccr gene complexes they contain.[23]

Carbapenem-Resistant Enterobacteriaceae (CRE)

Out of 140,000 healthcare-associated *Enterobacteriaceae* infections occurring in the United States each year, 9,300 are caused by CRE, resulting in an average of 600 deaths. The two most common types of CRE causing these fatalities are carbapenem-resistant *Klebsiella* species and carbapenem resistant *E. coli*.[2]

Vancomycin-Resistant Enterococci (VRE)

The progression of vancomycin resistance amongst enterococci is increasing; however, vancomycin resistance in *Enterococcus faecium* is already at high levels. The first case of vancomycin resistance was reported in Europe in 1988. VRE on its own is not only an important reason of blood stream, wound, and urinary tract infection in immunocompromised and severely unwell patients, but also can serve as a supply of genetic determinants of vancomycin resistance genes, which can be transferred *in vivo* to MRSA in similar patients.[36] Enterococci mainly causes blood stream, surgical site infections, and urinary tract infections in hospital as well as other healthcare settings, making it a pathogen that poses a major therapeutic challenge. Every year, it is estimated that 66,000 HAI enterococci infections occur in the United States, of which approximately 20,000 (30%) are resistant to vancomycin. This leads to more than 1,300 deaths. The agents currently used to fight VRE are linezolid and quinupristin/dalfopristin since the roles of daptomycin and tigecycline are not very well-defined in the treatment of VRE infections. Novel

drugs like oritavancin might have bactericidal activity against VRE, however there is tremendous interest in developing others.[2] Vancomycin was being used for more than two decades before resistance was seen by a species of bacteria that were supposed to be susceptible. Not only was resistance-found on plasmids and transposons, but the resistance genes may have assembled an intricate, elaborate genetic construct.[40]

Multidrug-Resistant (MDR) Streptococcus pneumoniae

One of the major causes of bacterial pneumonia and meningitis, bloodstream, ear, and sinus infections is *S. pneumoniae*. The majority of morbidity and mortality occurs in adult patients above the age of 50, with the highest susceptibility in people 65 and above. Bacteria are fully resistant to one or more antibiotics in almost 30% of severe *S. pneumoniae* cases. Hence, in 2010, a new version of pneumococcal conjugate vaccine PCV13 was prepared against the most resistant pneumococcal strains. Thus, there is a decline in rates of resistant *S. pneumoniae* infections. PCV7, an earlier pneumococcal conjugate vaccine protected against only seven strains compared to PCV13, which protects against 13 strains. This vaccine not only protects against pneumococci, but also it reduces the spread of antibiotic resistance by blocking the transmission of resistant *S. pneumoniae* strains.[2] In Taiwan in 1999, the prevalence of MDR *S. pneumoniae* was 60%, which increased to 80% in 2000. Of these, 20–30% were penicillin-intermediate-resistant and 40–50% were penicillin-resistant strains. Of these penicillin-nonsusceptible *S. pneumoniae* (PSSNP), 60% also showed nonsusceptibility to extended spectrum cephalosporins and carbapenems, as well showing resistance to multiple antibiotics.[3] The problem of the emergence of AMR worsens due the ease of transmission and asymptomatic colonization in the upper respiratory tract of children. The most important determinant in the emergence of AMR in *S. pneumoniae* is selective pressure of the antimicrobial agents. The more the potent a drug, the less likely will be its selection for resistance.[18]

Mycobacterium Tuberculosis (TB) Drug Resistance

In 2012, 170,000 mortalities were reported from drug-resistant TB infections by WHO.[1] In 2011, 10,528 TB cases were reported in the United States, of which 1,042 (9.9%) cases were identified as antibiotic resistant. Incomplete, incorrect, or unavailability of treatment and lack of new drugs were identified as major causes.[2] WHO reported 480,000 cases of multidrug-resistant tuberculosis (MDR-TB) worldwide in 2014, of which only half of the MDR-TB cases were treated successfully. A form of TB that is resistant to at least four of the core anti-TB drugs is said to be extensively drug-resistant TB (XDR-TB). Prevalence of XDR-TB has been identified in 105 countries. It is also estimated that 9.7% people with MDR-TB have XDR-TB.[1]

Salmonella Drug Resistance

Human salmonellosis is one of the main causes of hospitalization and community outbreaks in developing countries. Despite an incidence of global morbidity, mortality is restricted to developing countries. A systematic review of the global morbidity and mortality of typhoid fever and paratyphoid fever found 13.5 million cases of typhoidal salmonella (TS) serotypes. Typhi, para typhi A and B have been reported especially in low- and middle-income countries in 2012.[11] However, nontyphoidal salmonella (NTS) infections are most notorious and represent 80% of infectious cases.[46] NTS is generally limited to gastroenteritis, but sometimes can get into the bloodstream and cause life-threatening bacteremia both in children and adults. Serotypes Typhimurium and Enteritidis are the most common agents of NTS outbreaks globally. Salmonellosis treatment is usually not required for straightforward gastroenteritis, but it is necessary for an invasive nontyphoidal salmonella (iNTS) infection. Drugs of choice for many years have been chloramphenicol, ampicillin, and Bactrim, but worldwide microbial resistance has been seen for these agents. Fluoroquinolones (such as ciprofloxacin and ofloxacin) and extended-spectrum cephalosporins (such as ceftriaxone and cefotaxime) have been preferred by the clinicians in the most recent years, although most iNTS have acquired resistance to these both antibiotics too.[41,49]

The situation has further deteriorated with the emergence of multidrug-resistant strains of salmonella, which are associated with long-term hospitalizations and increased risk of more severe outcomes (death). AMR to salmonella is a serious threat to public health in the United States. Enteritidis accounts for about half the incidence of ciprofloxacin nonsusceptible infections; Newport, Typhimurium, and Heidelberg for three-fourths of the incidence of infections with resistance to both ceftriaxone and ampicillin; and Typhimurium for more than half the incidence of infections with resistance to ampicillin only.[39,96] The main source of infection has been foods, such as beef, poultry, eggs, dairy products, etc. Most nontyphoidal salmonella infections that are AMR are caused by four out of five serotypes that are commonly isolated: Typhimurium, Enteritidis, Newport, and Heidelberg. They persist in food animals, are transmitted through food supplies, and cause illness in humans.[15,35,39,96] According to data reported by the National Antibiotic Resistance Monitoring System (NARMS) during the periods of 2004–2012, the percentage of Ceftriaxone-resistant infections increased from 9% to 22%. From 2004 through 2012, the 48 contiguous states reported 369,254 culture-confirmed salmonella infections to LEDS. During this period, NARMS tested 19,410 salmonella isolates from the 48 states for resistance. Overall resistance was detected in 2,320 (12%) isolates. Ampicillin-only resistance was the most common pattern, detected in 1,254 (6.5%) isolates, of which 60% were Typhimurium. Figure 56.1 summarizes the data of resistance of all the serotypes reported.[38,96]

Antimicrobial drug use in food-producing animals is a major driver of—although not the only contributor to—resistant salmonella infections. An example is the contribution of third-generation cephalosporin use in poultry to ceftriaxone resistance among Heidelberg infections of humans. The FDA is taking strict actions to prevent the spread of antimicrobial resistance and prolong the use of antimicrobial agents, which includes strategies for controlled use of agents under veterinary supervision.[38] In a retrospective case control study of sporadic NewportMDRAmpC infections in residents of New England by Gupta et al., it has been demonstrated that infections are domestically acquired and are associated with direct exposure to a dairy farm.[24] They found

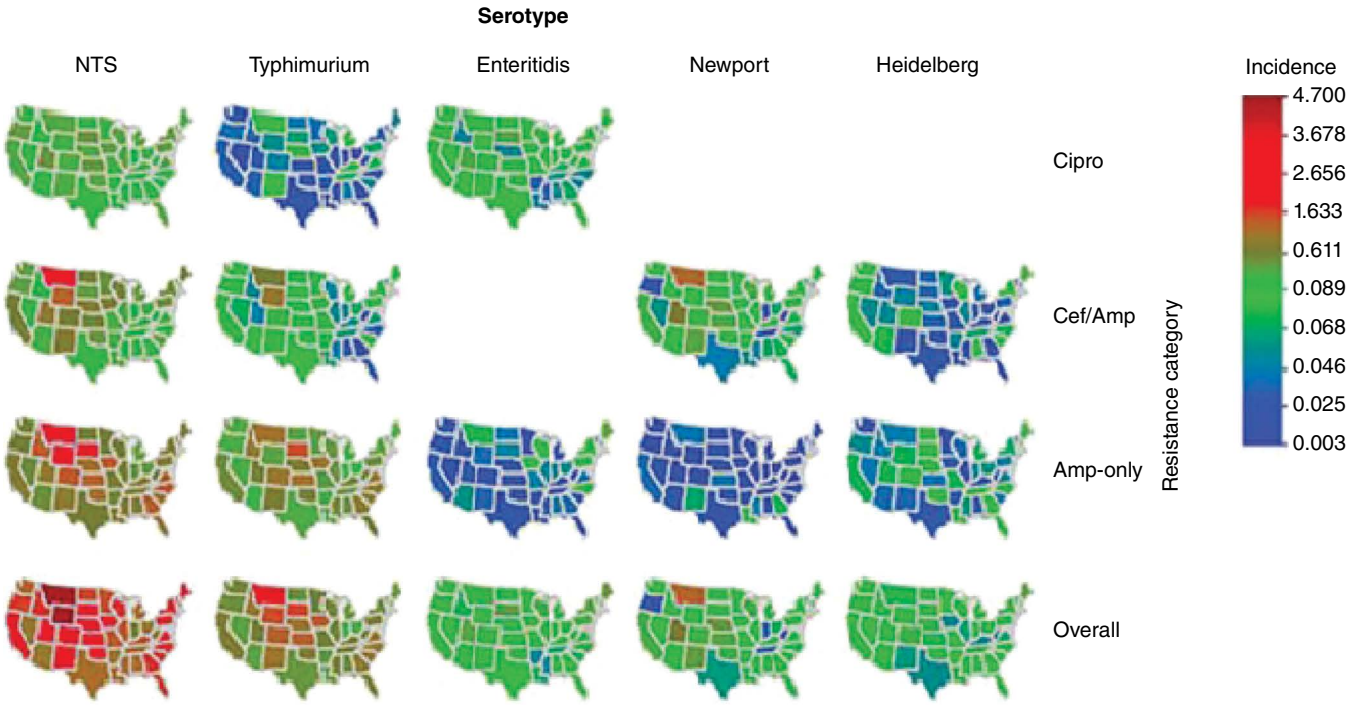

FIGURE 56.1 Estimated incidence of infection with all NTS and major serotypes with clinically important resistance (no. infections per 100,000 person-years), by state and resistance category, United States, 2004–2012. Estimates were derived by using Bayesian hierarchical models. All NTS includes the four major and other serotypes. Isolates in each category may have resistance to other agents. Data on Cipro among Newport (8 isolates), Cipro among Heidelberg (7), and Cef/Amp among Enteritidis (2) were too sparse to use in the Bayesian hierarchical models. Overall resistance was defined as Cipro, Cef/Amp, or Amp-only. Amp-only, resistant to ampicillin (MIC >32 μg/mL) but susceptible to ceftriaxone and ciprofloxacin; Cef/Amp, resistant to ceftriaxone (MIC >4 μg/mL) and ampicillin; Cipro, nonsusceptible to ciprofloxacin (MIC >0.12 μg /mL) but susceptible to ceftriaxone; NTS, nontyphoidal Salmonella. (Reproduced from Medalla et al. [2016], accessed from the Centers for Disease Control and Prevention website).[38]

that yogurt consumption is protective, which is intriguing, since some studies suggested that bacteria found in yogurt may prevent salmonellosis. Multistate outbreaks of MDR salmonella Newport caused by other, less resistant strains during the 1970s and 1980s were associated with the consumption of ground beef, particularly from dairy cattle. Subsequent to their investigation of sporadic cases of infection, multistate outbreaks of NewportMDRAmpC infection have been associated with foods, including cheese made from unpasteurized milk and ground beef produced at a large processing plant in the Mid-Atlantic that slaughters New England dairy cattle.

Prevention and control of Newport-MDRAmpC infection in humans and cattle requires an understanding of how this strain is introduced onto farms and disseminated among cattle. The management practices that promote its spread are not known but could include the use of therapeutic or prophylactic antimicrobial agents on farms, as has been suggested elsewhere. Ceftiofur, an expanded-spectrum cephalosporin, is commonly used therapeutically in dairy cattle, whereas tetracycline and neomycin are used prophylactically in calf milk replacers. Approximately 55% of dairy farms surveyed in 21 major dairy states during 2002 reported using calf milk replacer that contained medication; oxytetracycline and neomycin were the most commonly used. On the farms visited by the authors, they documented the therapeutic use of ceftiofur in ill cattle and the use of tetracycline- and neomycin-supplemented calf-milk replacers. Use of these or other antimicrobial agents on farms, especially if used frequently, create a selective pressure that is likely to promote transmission and dissemination of Newport-MDRAmpC. This study confirmed that Newport-MDRAmpC isolates contains genes of the blaCMY family, which produce AmpC-type β-lactamases.[24]

Clinically important resistance is strongly linked to specific serotypes. A study conducted in Brazil in 2018 described the serotype distribution and AMR of NTS isolated from enteric and nonenteric human samples and also investigated the AMR patterns.[42] The results of the study showed that salmonellosis frequency was higher in adults above the age of 45. Also, serotypes Typhimurium and Enteritidis were dominant in the study samples collected. This study showed that most sporadic cases of salmonella isolates were from hospitalized patients and that Typhimurium was the most frequently isolated serotypes. Resistance to more than three antibiotics was showed by most Typhimurium isolates whereas Enteritidis showed resistance to two antibiotics. All the other remaining serotypes were susceptible to antibiotics.[42] Earlier, another study conducted by Chen, Zhao et al. in 2004 characterized multiple-antimicrobial-resistant salmonella serovars isolates from retail meats in United States and the People's Republic of China.[13] Molecular genetic techniques were used to characterize antimicrobial-resistant salmonellae, especially *Salmonella enterica* serovar Typhimurium DT104. A total of 133 salmonella isolates were recovered from retail meats purchased in the United States and the People's Republic of China. These were assayed for antimicrobial susceptibility, the presence of integrons and antimicrobial resistance

genes, and horizontal transfer of characterized antimicrobial resistance determinants via conjugation. Their findings showed that 73 (82%) of the total salmonella isolates were resistant to at least one antimicrobial agent. Resistance to the following antibiotics was common among the U.S. isolates: Tetracycline (68% of the isolates were resistant), streptomycin (61%), sulfamethoxazole (42%), and ampicillin (29%). Eight salmonella isolates (6%) were resistant to ceftriaxone. Fourteen isolates (11%) from the People's Republic of China were resistant to nalidixic acid and displayed decreased susceptibility to ciprofloxacin. A total of 19 different antimicrobial resistance genes were identified in 30 multidrug-resistant salmonella isolates. The study concluded that salmonella isolates in retail meats are commonly resistant to multiple antimicrobials, including tetracycline, sulfamethoxazole, and streptomycin. Resistance to ceftriaxone is a concern because of the importance of this agent for treatment of salmonellosis in children.[13]

In the United States, antimicrobial-resistant Salmonella strains have emerged in the last two decades, causing increased morbidity and hospitalization especially in children. A multidrug-resistant (MDR) strain of Salmonella serotype Typhimurium definitive type 104(DT104) (resistant to ampicillin, chloramphenicol, streptomycin, sulfamethoxazole, and tetracycline) emerged across the United States during the 1990s. Alarmingly, between 1998 and 2001 alone, Newport-MDRAmpC (resistant) strains of Salmonella have rapidly emerged throughout the United States increasing from 1–25% in prevalence. These strains are resistant to nine antimicrobials, have either decreased susceptibility to or resistance to extended-spectrum cephalosporins, such as ceftriaxone, and are sometimes resistant to trimethoprim-sulfamethoxazole.[24]

E. coli Drug Resistance

E. coli is the most prominent enteropathogenic bacterial cause of infectious diseases that span from the gastrointestinal tract to extraintestinal sites such as urinary-tract infection, septicemia, and neonatal meningitis.[56,57] The emergence and spread of antibiotic resistance in *E. coli* is an increasing public-health concern across the world. An important example of antibiotic resistance is multidrug-resistant (MDR) and ESBL-producing *E. coli*, which can cause life-threatening infections. In 1982, *E. coli* was suspected in two epidemics of hemorrhagic colitis that were associated with consumption of undercooked ground beef. There have been more than 200 *E. coli* serotypes that have been identified and isolated from animals, food, and other resources since then. Sixty of these serotypes are associated with human diseases. In 2002, it was reported that 73,000 illnesses were caused by *E. coli* and 61 deaths were reported in the United States.[52] In the recent estimates of global antibiotic resistance published by the WHO in 2014, *E. coli* was named as one of the biggest concerns associated with hospital- and community-acquired infections.[54,55] In Europe, antimicrobial resistance in Gram-negative bacteria, particularly in *E. coli* continues to increase, which constitutes a majority of invasive Gram-negative isolates in European countries.[58] The emergence and diffusion of multidrug-resistant strains of *E. coli* is complicating the treatment of several serious infections. *Enterobacteriaceae*, particularly *E. coli*, are the most frequent cause of hospital- and community-acquired infections.[60–62] A recent annual surveillance report of the European Centre for Disease Prevention and Control showed the presence of isolates resistant to third-generation cephalosporins, fluoroquinolones, and aminoglycosides as well as isolates with resistance to all three antimicrobial classes. This was observed in all EU member states and Norway, Iceland, and Liechtenstein, but only 0.04% of 59,326 isolates of *E. coli* studied were found to be resistant to carbapenems ([63]).

Multidrug-resistant *E. coli* strains are also commonly isolated from animals and food.[64–70] The use of antibiotics in animals contributed to the emergence and spread of the number of antibiotic-resistant strains, including *E. coli*, which can also infect humans through either direct contact with animals or through consumption of contaminated food. *E. coli* is able to survive and adapt in various extra-intestinal habitats and to spread resistances between humans, animals, their products and the environment through several transmission pathways.[59]

The environment plays a key role in the spread of antimicrobial resistance serving as an unlimited reservoir of antimicrobial resistance genes.[71] Therefore, *E. coli* may acquire other drug resistance traits from environmental bacteria, and conversely, can spread its resistance genes to potential pathogens in different habitats.[72] A source of multidrug-resistant *E. coli* could be hospital effluents. Several studies have reported the presence of multidrug-resistant strains in hospital effluents contributing to the spread of their antibiotic resistance genes in the municipal sewage systems and in the environment.[73]

A very recent meta-analysis assessed the prevalence of antibiotic resistance in *E. coli* strains simultaneously isolated from human, animal, food, and environmental samples from 2000 to 2018 worldwide, and provided a comprehensive systematic review on the prevalence of antimicrobial resistance in *E. coli* from different sources.[74] The data reported on the comparison of MDR *E. coli* strains isolated from different sources. It showed higher prevalence in animal and environmental sources than humans, prevalence of drug resistance in different sources, and documented increases in *E. coli* drug resistance. Overall, the results showed that antibiotic resistance in American and European countries is lower than other regions of the world. Subgroup analysis from 2000 to 2018 also indicated a significant increase in ciprofloxacin resistance. Moreover, the results also showed that the prevalence of ESBL antibiotic resistance and MDR *E. coli* strains in animal isolates was higher than in human isolates. According to their findings, systematic surveillance of hospital-associated infections, proper monitoring of disposal processes in hospitals, monitoring the use of antibiotics in animals, monitoring and evaluation of antibiotic-sensitivity patterns, and preparation of reliable antibiotic strategies may ease more corrective actions for the inhibition and control of *E. coli* infections in different parts of the world.[74]

Neisseria gonorrhea Drug Resistance

Annually, more than 800,000 cases of gonorrhea are estimated by CDC, which makes it the second most frequently reported infectious disease in the United States. It is projected over 10 years that an additional 75,000 cases of pelvic inflammatory disease, 15,000 cases of epididymitis and 222 additional human immunodeficiency virus infections will be caused by drug resistant

N. gonorrhoeae, making it more widespread.[2] The WHO has recently updated the treatment guidelines to address the issue of emerging resistance in *N. gonorrhea*. As per the new guideline, quinolones are no longer recommended for the treatment of gonorrhea due to the high levels of resistance.[1]

Malaria Drug Resistance

Resistant strains of malaria can spread from their origins in Cambodia, Myanmar, Thailand, and Vietnam to other parts of the world and become a major challenge to public health, threatening the recent gains in malaria control.[1] In 1955, the WHO launched the "Global Malaria Eradication Program" and chloroquine chemotherapy was implemented to complement the initial vector control measures leading to eradication of malaria from 27 countries.[97]

Unfortunately, elimination of malaria could not be achieved in most underdeveloped countries, resulting in the current predominant distribution of malaria to subtropical and tropical regions.[1] Among the reasons for the eventual halt to the eradication effort were widespread resistance to available insecticides and the emergence of chloroquine-resistant malaria in southeast Asia and South America around 1960.[98] The subsequent spread of chloroquine-resistant *P. falciparum* to Africa and the lack of an effective and affordable alternative ultimately led to a two-to-three-fold increase in malaria-related deaths in the 1980s.[99] The only viable alternative to chloroquine at that time was sulfadoxine-pyrimethamine, however, it also encountered drug-resistant parasites about a year after implementation.[100] Several other antimalarial drugs have since been deployed to combat parasites resistant to chloroquine and sulfadoxine-pyrimethamine, including mefloquine, amodiaquine, and quinine. The historic usage of these replacement drugs in monotherapy has now similarly resulted in the selection of resistant parasites, at least in some parts of the world.

Despite causing an estimated 72–80 million malaria infections yearly, *P. vivax* has not received as much public and scientific attention as *P. falciparum*.[101] One of the main reasons for this is that *P. vivax* usually produces less severe symptoms. Nevertheless, *P. vivax* leads to a disabling disease that can be fatal, and exacts a similar economic burden as falciparum malaria. Additionally, it has been recently noted that the severity of the disease caused by *P. vivax* is increasing in some parts of the world and the development of drug resistance could result in an expansion of this debilitating and sometimes deadly infection.[102] To assess drug resistance in *P. vivax* in the field, results from clinical studies and a limited number of laboratory studies using modified drug susceptibility assays, which are recommended by the WHO for *P. falciparum*, have been used.[103]

Human Immunodeficiency Virus (HIV) Drug Resistance

HIV drug resistance is reported in 7% of people by WHO, even before they start their treatment. Similar figures are reported to be 15–20% in developing countries. Levels above 15% have been reported by some countries amongst those starting HIV treatments and up to 40% in those restarting the treatment.[1]

Other Drug-Resistant Infections

ESBL-Producing Enterobacteriaceae

26,000 HAIs and 1,700 deaths per year are caused by ESBL-producing *Enterobacteriaceae*.[2] A study conducted by Sun, Liu et al. in 2019 at Children's Hospital in China showed that 52.21% of all the MDR infections are caused by ESBL.[4] When pathogens are isolated from all types of clinical specimens, species of the family *Enterobacteriaceae* are very commonly identified. *E.coli* was the third most prevalent bacterial species out of the 15 found in intensive care unit (ICU) patients of 25 European hospitals in 1997–1998. Among the bloodstream isolates, *E. coli* ranked third, *Enterobacter* species ranked sixth, *Klebsiella pneumonia* ranked eighth with *Proteus mirabilis* ranking the tenth most frequently isolated pathogens. The highest rates of carbapenem resistance were found in *K. pneumonia*. Greece has the highest proportion of this phenotype with 46% of tested isolates in 2007 that were nonsusceptible to carbapenems among the 33 European countries.[48] ESBLs have been identified in 70–90% of *Enterobacteriaceae* in India in recent surveys. These statistics suggest a serious problem, making it necessary to use reserved antibiotics like carbapenems. *Enterobacteriaceae* with NDM-1 carbapenemases show high resistance to a lot of antibiotics and potentially indicate that treatment with β-lactams, fluoroquinolones, and aminoglycosides, which are the main classes of antibiotics used for treatment of Gram-negative infections, may soon end. Owing to the loss of resistant genes, a few isolates remain sensitive to individual aminoglycosides and aztreonam. Susceptibility to colistin and tigecycline is still present in most isolates. Since there are only few new anti-Gram-negative antibiotics in the pipeline and none are active against NDM-1 producers, treatment options in the future are of utmost concern.

On the advice of the Health Protection Agency, the Department of Health in the United Kingdom had prompted the release of a National Resistance Alert 3 notice due to introduction of NDM-1 in the United Kingdom. It is not surprising that the United Kingdom is the first Western country to register the widespread presence of NDM-1 positive bacteria due to its historical link to India.[33] After birth, neonates are rapidly colonized by *Enterobacteriaceae* irrespective of whether they are breast fed. In a cohort study on breast-fed babies in India, it was noted that 14.3% 1-day olds harbored *Enterobacteriaceae* that contained enzymes that could inactivate β-lactam drugs (ESBL). By day 60, this increased to 41.5% of babies. To establish a normal healthy gut microflora environment, drinking water and food are the most important means. In an ecosystem free from external antimicrobial selection pressure, antimicrobial-resistant and nonresistant species coexist in a stable balance. Human microbiota is exposed to unprecedented high concentrations of antimicrobials due to their use in clinical settings. Within the human body, the *in vivo* development of *de novo* resistance to antimicrobial agents has been recorded during the course of treatment, which also includes carbapenems.

MDR *Pseudomonas aeruginosa*

Each year in the United States, 51,000 healthcare-associated *P. aeruginosa* infections are reported, of which more than

6,000 (13%) are MDR, causing roughly 400 deaths.[2] They are one of the causative pathogens of nosocomial infections in the immunocompromised and the immunocompetent host associated with invasive devices, mechanical ventilation, burn wounds, or surgery is *P. aeruginosa*. Between 1997 and 2002, the prevalence of *P. aeruginosa* in bloodstream infections increased slightly from 5.5–6.8% in Europe according to the SENTRY Antimicrobial Surveillance Program. Thirteen medical centers from 15 European countries participated in the survey. *P. aeruginosa* resistance to carbapenems appeared to be higher all over Europe in 2007. As per that date, carbapenem resistance above 25% was seen in Croatia, Turkey, Germany, Italy, Czech Republic, and Greece, whereas carbapenem resistance was below 10% in Denmark, the Netherlands, Switzerland, Sweden, and Finland.[48] The emergence of MDR *P. aeruginosa* was seen in a tertiary care center in the United States between 1994 and 2002 with a prevalence of 1–16%. This was seen along with the emergence of MDR *Klebsiella* species with prevalence of 0.5–17%.

MDR Actinobacteria

Each year in the United States, approximately 12,000 healthcare-acquired *Acinetobacter* infections occur. Of those, 7,300 (63%) are resistant to at least three different classes of antibiotics, causing 500 deaths.[2]

Campylobacter

Another indistinguishable form of acute diarrheal disease is *Campylobacterial* gastroenteritis. It is similar to those caused by *Salmonella* spp. and *Shigella* spp. More than 95% of *Campylobacter enteritis* associated with diarrheal illness is caused by *C. Jejuni* and *C. coli,* which are clinically indistinguishable. Fecal *C. jejuni* or *C. coli* are regarded as a commensal organism in cattle, poultry, and swine. It is routinely recovered from retail chicken and poultry products. As per a study in 1986 by Washington State, 57% of poultry processing-plant samples and 23% of retail chicken carried *C. jejuni*. However, no reports of ciprofloxacin-resistant human *Campylobacter* strains are reported in isolates prior to 1992. Countries in which use of antimicrobials is not restricted have fluoroquinolone-resistant *Campylobacter* as a threat. In Spain, 88% of *Campylobacter* isolates displayed fluoroquinolone resistance. Due to high levels of fluoroquinolone-resistance in *Campylobacter,* the FDA and the Center for Veterinary Medicine (CVM) in 2000 had proposed to withdraw the approval of the new animal drug application for use of the fluoroquinolones in poultry. There was a temporal relation that was cited between the approval of these drugs for use in poultry in the United States and the increase in resistance to fluoroquinolones in *Campylobacter* species associated with human infections.[8]

Listeria monocytogenes

Several large foodborne epidemics of listeriosis have been reported in several nations, which include England, Germany, Sweden, New Zealand, Switzerland, Australia, France, and the United States. It is predicted that there are 2,500 cases of listeriosis in the United States every 12 months, resulting in 500 deaths. Most manifestations of listeriosis are treated with ampicillin, rifampin, or penicillin plus gentamycin. Co-trimoxazole is considered as a second-choice therapy. If a pregnant woman is diagnosed with listeriosis or if bacteremia is present in a patient, then Vancomycin and erythromycin are used for treatment. The first strains of *L. monocytogenes* that were antibiotic resistant were reported in 1988. Since then, resistance of *L. monocytogenes* to antibiotics has emerged. Studies have shown that this pathogen acquires its antibiotic resistance genes from foreign sources through mobile genetic elements, such as plasmids and transposons. Enterococci and streptococci have appeared to be a common source of resistant genes for *L. monocytogenes.*[8]

Yersinia

Out of the 11 species of *Yersinia* that are recognized presently, only three species are medically important. *Y. pestis* is a pathogen that causes bubonic and pneumonic plague whereas *Y. enterocolitica* and *Y. pseudotuberculosis* both can induce severe gastroenteritis. The susceptibility pattern of *Y. enterocolitica* to antibiotics is biogroup dependent. Strains of biogroup 1B are generally susceptible to ampicillin but resistant to carbenicillin, ticarcillin, and cephalothin. Biogroup 1A and biogroup 3 strains are resistant to amoxicillin/clavulanic acid and cefoxitin. However, biogroup 3 strains are reported to be susceptible to carbenicillin and ticarcillin. Nonetheless, *Yersinia* remain susceptible to tetracycline and quinolones in contrast to the above susceptibility and resistant patterns.[8]

Clinical and Economic Burden of Antimicrobial Effectiveness

A systematic review by Nellums, Thompson et al. in Europe, showed that there is an increased risk of antibiotic resistance in migrant groups.[7] This could be because of poor sanitation, overcrowded living conditions, barriers to accessing health services including antibiotics or vaccinations, disruptions in treatment during migration and on arrival in host countries, high prevalence rates of AMR in the countries of origin or transit. The risk of bacterial resistance increases with insufficient health infrastructure, antibiotic stewardship, infection prevention and control, vaccine coverage, or surveillance. Return travel to the countries of origin and contact with healthcare services in those settings can also pose a threat. The prevalence of AMR carriage and infection is elevated in refugees and asylum seekers and in high-migrant community settings. AMR organisms are acquired by immigrants during migration or in the host country from local populations or between migrants.[7]

AMR is not only a medical problem, but also an economic problem. There is enormous potential in finding new antimicrobials in virgin tropical forests with plant resources in developing countries. These may provide solutions to a lot of current resistance problems. However, their exploitation requires a great financial investment. The risk factors for antimicrobial resistance are poverty and inadequate resources, natural calamities, human population growth, healthcare-provider-related factors, health service provision centers, user related factors, policy and regulatory issues, and use of antimicrobial drugs in food animal production.[12]

The steady increase in resistance is seen to quinolones, carbapenems, and third-generation cephalosporins in community settings. Identification, assessment, and communication of the threats of current and emerging antimicrobial resistance are a crucial task for CDC. The updating of local prescribing guidelines, active reporting on antibiotic prescribing and consumption, or enforcement of local surveillance programs on antibiotic resistance are some measures that can be implemented. However, substantial legislative action and increased funding is needed to implement these measures. This requires a strong commitment from policy makers at the national and international levels. Appropriate use of antibiotics is important in low-income countries since there are additional factors that contribute to the emergence of resistance. These include, (a) less potent activity of some antibacterial agents (including counterfeit drugs), (b) over-the-counter availability, with insufficient dosages, (c) lack of diagnostic laboratories, and (d) poor level of sanitation. This leads to familial and community spread of resistance.

Global food commercialization and international travel also needs special attention.[44] A review of the available data on the relationship between antimicrobial resistance and patient outcomes by Cosgrove et al. describes the most sensitive patient outcomes and factors affected by AMR. These include decreased functional status, loss of work and fewer antimicrobial agent options available for therapy for the patient, and societal issues such as increase of total healthcare costs, as well as loss of antimicrobial classes usable for treatment.[4]

Resolution of AMR

In spite of the challenges faced by developing countries, it is imperative that they use antimicrobial agents responsibly. AMR is greatly influenced by poverty-associated factors, particularly because there are more important problems like providing basic healthcare or sanitation in developing countries. Hence, developing countries have to depend upon partnerships with developed nations and global organizations to formulate and implement mechanisms that will allow their healthcare providers, policy makers, and users to understand the problems and the consequences of lack of control in AMR[12] (Table 56.2).

Uncertainty in diagnosis and laboratory detection of microbial infections is one of the key drivers for drug misuse and overuse. To reduce the antimicrobial selection pressure, diagnosis of microbial infections can be improved by incorporation of new biological markers such as procalcitonin, soluble triggering receptors expressed on myeloid cells, use of newer molecular diagnostic techniques, amplification technology with DNA microarray, etc. These improvements in diagnostic techniques not only improve accuracy in results but increase the speed of testing. Diagnostic tools that can rapidly distinguish between bacterial and viral infections should be made available especially in hospitals. Table 56.3 gives a list of countries, many of which are industrialized, where either the number of antimicrobial agent prescriptions or the volume of antimicrobial use has decreased over the last 20 years, especially in the ambulatory setting[26]. Greater antimicrobial drug use and the spread of resistant microbes increase due to an increase in immunocompromised patients, the growing life-expectancy, and the susceptibility of older persons to infections. Increased use of medical devices, gene therapy, and better management of conditions like diabetes and cancer are key trends in clinical care and greatly influence AMR. Prescribing of antimicrobial drugs can be affected by global threats such as the influenza pandemic or the current coronavirus outbreak, by reversing the decreasing trend of

TABLE 56.2

Potential Determinants Influencing Future Dissemination and Control of Antimicrobial Resistance

Dimension	Determinant	Potential Control Measures and Interventions
Pathogen and microbial ecology	Evolution Survival fitness Virulence Commensal flora Laboratory detection and identification	Evolutionary engineering Inhibition of microbial gene expression Antibodies, antipathogenic drugs, biologic response modifiers Probiotics Improved rapid diagnostic tests
Physician's prescribing practice	Antimicrobial drug usage pattern Diversity of antimicrobial drug prescribing Training and knowledge	Multimodal interventions Decision support tools Academic detailing and educational campaigns
Population characteristics	Migration, travel, and globalization Case mix and host susceptibility to infections Antimicrobial demand and health beliefs Transmission and infection rates	Screening and improved surveillance Immunization; better control of chronic diseases Public information campaigns Hand hygiene and barrier precautions
Politics and healthcare policy	Healthcare policy Promotional activities by industry Technologic development	Change in reimbursement patterns Regulation New prevention and treatment approaches

antimicrobial drug consumption. A decrease in transmission rates and the impact of AMR can be improved by developing new vaccines in near future.[19]

It is not only important to optimize antimicrobial drug use, but it is also important to understand how to minimize the selection of antimicrobial resistance. Defining optimum duration and dosage of a therapy needs detailed analysis especially in specific patient populations (infants, pregnant women, undernourished, obese, and coinfected patients). Secondly, rapid diagnosis of infections has to be enabled to improve targeting. Due to technical and financial barriers and issues around the adoption of innovative techniques, implementation of the methods is slow despite them being widely advocated. Thirdly, research needs to be focused on improving the quality of current antimicrobials along with the discovery of new drugs.[27]

Nanomedical Approach

Recently, nanoparticles (NPs) have emerged as new tools that can be used to combat deadly bacterial infections. Nanoparticle-based strategies can overcome the barriers faced by traditional antimicrobials, including antibiotic resistance. The various strategies by which nanoparticles can overcome this resistance, include the following: Nitric oxide-releasing nanoparticles (NO NPs), chitosan-containing nanoparticles (chitosan NPs), and metal-containing nanoparticles—all of which use multiple mechanisms simultaneously to combat microbes. This makes the development of resistance to these nanoparticles unlikely. These strategies have been studied in an oral/dental setting in ongoing clinical trials (NCT03588351),[75] which compare *in vivo* susceptibility of root canal bacteria to chitosan, chitosan nanoparticles, and chlorhexidine gluconate as intracanal medicaments in necrotic primary molars. Other approaches include ongoing clinical trials (NCT03666195)[76] studying the antimicrobial effect of titanium dioxide nanoparticles in complete dentures made for edentulous patients to control oral biofilm formation. Another area where antimicrobial properties of nanomaterials and their use in treatment of antibiotic resistance are tested is chronic wound/ulcer infections. One such study reports that a Carbopol® 934-based nanogold formulation prevents microbial adhesion, reducing fungal infections and accelerates the wound healing potential of the WfAuNPs.[77] Antibacterial activities of carbon nanotubes coated with different concentrations of iron oxide NPs on cultures of Gram-negative and Gram-positive bacteria are being examined in animal models by Khashan et al. and show good healing properties.[78] It is possible to package multiple antimicrobial agents within the same.[79,85] Development of resistance to the multiple antimicrobial agents within these nanoparticles is, again, unlikely,[86] possibly because it would require multiple simultaneous gene mutations in the same microbial cell. Nanoparticles can also overcome drug-resistance mechanisms of microbes, including decreased uptake and increased efflux of drug from the microbial cell,[85,83,87] biofilm formation[83,88] and intracellular bacteria.[81,83,87] Finally, nanoparticles have been used to target antimicrobial agents to the site of infection, so that higher doses of drug can be given at the infected site, thereby overcoming resistance with fewer adverse effects upon the patient.[89]

The use of multiple simultaneous mechanisms of antimicrobial action makes the development of resistance to these nanoparticles unlikely, because multiple simultaneous gene mutations in the same microbial cell would be required for that resistance to develop.[79–84]

Needs

Due to global nature of antimicrobial resistance and the failure to control the emergence of resistant organisms, a global surveillance program involving both developed and developing countries had to been implemented. To address this problem, CDC initiated the International Network for the Study and Prevention of Emerging Antimicrobial Resistance (INSPEAR). INSPEAR serves as an early warning system for emergence of drug-resistant pathogens, as outlined in Table 56.4 and serves to facilitate rapid distribution of information about emerging multidrug-resistant pathogens to hospitals and public health authorities worldwide. It serves as a model for the development and implementation of infection control interventions.[43]

Resolution

There is a need for better ways of dosing and sequencing antibiotics to prevent resistance, since there are a limited number of

TABLE 56.4

Important Types of Antimicrobial Resistance of Public Health Importance

Microorganism	Resistance
Early warning system: Local and regional sentinel events	
Staphylococcus aureus	Methicillin, intermediate susceptibility to glycopeptides
Enterococcus spp.	Vancomycin
Enterobacteriaceae	Extended-spectrum β-lactamase-mediated resistance, carbapenems, fluoroquinolones
Acinetobacter baumannii	Carbapenem
Any bacteria	All antimicrobials available at the regional and local settings
Early warning system: Global sentinel events	
Streptococcus spp.	Penicillinase, gentamicin, glycopeptides, fluoroquinolones
S. pneumoniae	Vancomycin, third-generation cephalosporins, new fluoroquinolones (gemifloxacin, grepafloxacin, levofloxacin, trovafloxacin)
Staphylococcus spp.	Glycopeptides (high level)
Enterobacteriaceae	Carbapenemase
Neisseria meningitidis	Penicillinase, chloramphenicol, cephalosporins, fluoroquinolones
Acinetobacter baumannii	Carbapenemase
Salmonella typhi	Third-generation cephalosporins, fluoroquinolones
Haemophilus influenzae	Cephalosporins
Brucella spp.	Tetracycline, rifampin, streptomycin
Clostridium difficile	Glycopeptides
Clostridium perfringens	Penicillinase

antibiotics available. Alternating between antimicrobial agents is one way to improve dosing. Maximizing collateral sensitivity and minimizing cross resistance is the key goal of alternating drug therapy. Sometimes the efficacy of synergistic antibiotics is more than sum of individual efficacies. However, if a single-drug regimen is used, then proper dosing has to be followed. Immune system clearance of antimicrobial resistant infections also plays an important role.[6] Conflicting recommendations are often being made to reduce antimicrobial resistance. For instance, to reduce the burden of resistance in hospitals, strategies incorporate reduced the use of all antimicrobial classes, increased use of prophylactic antimicrobials, rotation of different antibiotic classes in temporal sequence, and simultaneous use of different antibiotics for different patients. There is conflicting evidence about the relationship between antibiotic treatment and resistance patterns. It is difficult to show that antibiotic treatment cuts a patient's risk of acquiring resistant organisms. However, the cumulative effect of using antibiotics has shown to increase the prevalence of AMR in the population as a whole.[34] Some of the ways in which MRSA can be controlled in hospital settings are screening of patients, screening of staff, isolation and barrier nursing, hand hygiene, environmental cleaning, ionization therapy, and multifaceted MRSA control programs.[23]

Summary

Higher awareness of the prevalence of antimicrobial resistance is needed among the medical community and the general public. With the emergence of drug resistance, it is of critical importance to implement antidrug-resistance policies to contain, and hopefully curtail, the emergence and spread of resistance. Failure to do so would lead to a tragic setback in the current efforts to eliminate the diseases that are being spread due to drug resistance and the achieved reductions in disease-related morbidity and mortality. Coordinated action is needed by all countries to minimize the emergence and spread of antimicrobial resistance. Knowledge of the effect of antimicrobial resistance on patient outcomes can have several benefits. Healthcare providers can initiate and support infection control programs and antimicrobial-agent management programs if patient outcomes are a priority. Influencing healthcare providers to follow guidelines about isolation and making rational decisions with regards to use of antimicrobial agents can stimulate their interest in developing new antimicrobial agents and therapies. Knowledge of the implications of resistance on patient outcomes, which include decreased functional status, loss of work, fewer antimicrobial agent options available for therapy for the patient, and societal issues (such as increase of total healthcare costs)—as well as loss of antimicrobial classes usable for treatment—is needed to overcome these effects.

Introduction

Perhaps we can say that microbiology began in the late 17th century through the curiosity of Antony van Leeuwenhoek, who was the first to describe accurately the creatures of the "invisible world" we now recognize as bacteria and eukaryotic microbes. In the earlier era of the study of microbes, the growth of bacteria and their study were predicated on the concept that bacteria are free-living, planktonic cells. This view dominated the study of bacteria for decades [1–3]. But by the 1970s, the concept of biofilms, which have multiple definitions, became known. They generally refer to communities of microbes (prokaryotic and eukaryotic) that adhere to a surface to form a slimy coat and are enclosed in an extracellular polysaccharide matrix [3–5]. A structured community of bacterial cells that attach to surfaces aggregates in a hydrated polymeric matrix of their own synthesis to form biofilms. Biofilms constitute a protected mode of growth that allows survival in a hostile environment leading to their inherent resistance to antimicrobial agents and host immune responses, which are at the root of many persistent and chronic bacterial infections [6]. In both the healthcare and the food industry, the number of bacterial infections and noninfectious complications are rising due to the bacterial biofilms formation and the subsequent failure of many medical devices [7].

Microscopy, especially light microscopy [8, 9], and transmission and scanning electron microscopy [8, 10, 11] played a pivotal role in the realization of the biofilm concept. Through the application of transmission electron microscopy, morphological evidence was found for an attachment of *Escherichia coli* to the intestines of newborn calves. Subsequently, it was shown that biofilms form in aquatic ecosystems under high-shear conditions [12]. Application of scanning confocal laser microscopy to the study of biofilms showed that morphologically a biofilm is an open system of cells, exopolymeric material, and extracellular spaces. The spatial arrangement of the cells, the extracellular polymeric substances (EPS), and the spaces may be referred to as the architecture of the biofilm [13, 14]. Major advantages of this technology are that the samples are living and hydrated. Consequently, it was discovered that there is a complex organization to biofilms with mushroom-like and tower-like structures enclosed in a matrix with intervening water channels [15, 16]. Biofilm is also composed of rigid bacteria (analogous to colloids), soft viscoelastic extracellular matrix, and small molecules that may provide signaling or generate forces for spreading and survival have been observed [17, 18].

The process of biofilm formation starts with colonization by microorganisms. They do so by adhering to living or inert surfaces, followed by multiplication and forming a self-produced polymeric matrix, which may trap both organic and inorganic debris and numerous microbial species [19]. Biofilms, therefore, may be made up of monocultures, multiple species, or combinations of phenotypes of different species [20]. Attached bacteria grow as a multicellular community, forming microcolonies in which they proliferate and mature. This microbial organization results in the development of a mature biofilm and eventually serves as a bacterial reservoir, from which bacterial cells are transmitted back to the environment through biofilm dispersal and then colonize new surfaces [17].

It has been established that biofilm formation and survival is not restricted to specific species of bacteria, rather, under adequate environmental conditions, many microbes will develop biofilms [21]. Bacteria form biofilm when the environment becomes stressful. These stressful environmental factors include a change in pH or temperature, and adhesive properties, nutrient availability, composition of the microbial community, hydrodynamics, quorum sensing, and cellular transport [22]. Biofilm formation in response to stress is much faster in pace when compared to planktonic cells, which occurs to overcome the adverse effects of the stress agent to avoid the complete extinction of the microbial community.

The arrangement of bacterial biofilm can be extremely variable and complex. For instance, intracellular bacterial communities (IBCs) including uropathogenic *E. coli* (UPEC) and *Klebsiella pneumoniae* bacteria can attach directly to their host or form bare or immersed biofilms on either biotic or abiotic surfaces and under static or shear-flow conditions [23]. Biofilm communities may also demonstrate differences in response to incoming signals such as nutritional availability and may play a role in bacterial biofilm formation [10]. For example, it has been demonstrated that D-amino acids act individually or synergistically to elicit dispersion of biofilms and inhibit Bacillus subtilis and other species pellicle formation [24]. Similarly, cyclic diguanylate monophosphate (c-di-GMP) concentration affects matrix and structural component production, motility, cell attachment, and eventually biofilm formation in a number of bacterial species [25, 26].

Numerous investigations have shown that biofilms have properties, probably derived from their organization, that are of both biological and clinical importance. It has been found consistently that biofilms are far more resistant to static and cidal agents than planktonic cells [27–29]. This applies to a broad spectrum of pathogens, including *Legionella, Listeria, Mycobacteria, Pseudomonas*, and *Vibrio.* There can be as much as a 100–1000 times greater resistance of the biofilms compared to their planktonic counterparts [27, 30, 31]. Treating biofilms of *P. aeruginosa* is of medical importance because of its pathogenesis in cystic fibrosis patients, and this has proved a difficult task [29–32]. The increased resistance of biofilms to antimicrobials is not the result of mutation or horizontal gene transfer because, upon removal of the cells from biofilms, and their subsequent growth as planktonic cells, the sensitivity to the agents re-emerges [3, 27, 32].

The resistance phenomenon also applies to fungal biofilms and has been documented with *Candida albicans* [33–35]. *Candida* is cited as being the fourth most-common cause of bloodstream infections [36], and is also a major clinical problem because of its ability to form biofilms on indwelling medical devices [33].

Multiple explanations have been advanced for the high resistance of biofilms to antimicrobials [27]. These include (1) depletion of the antimicrobial agent through its interaction and neutralization by the biofilm; (2) slow penetration of the antimicrobial into the biofilm [29]; (3) the presence of slow-growing and/or nongrowing cells (e.g., due to oxygen, pH, or nutrient gradients in the biofilm) [15, 37]; (4) stress responses, induced or constitutive; and more controversially, (5) persister cells. Bacterial populations produce persisters—cells that neither grow nor die in the presence of bactericidal agents—and, thus, exhibit multidrug tolerance. Research done by Spoering and Lewis showed that persisters are largely responsible for the recalcitrance of infections caused by bacterial

biofilms. The persister cells, if they exist, constitute only a small percentage of the population, but represent a cell state that is tolerant to antimicrobial assault [38].

Due to the ability of microbial cells to adhere to surfaces, both biotic and abiotic, a major problem has developed in medicine with the colonization of indwelling medical devices and nosocomial infections. As the technology of medicine has advanced, and concomitantly the population of the aged is increasing, there has been increased utilization of indwelling medical devices. One major reason for this is that there has been a reduction in the length of hospital stays and a subsequent reliance on ambulatory care. For people of all ages, there are catheters to deliver medications or fluids. In addition, there are devices for those with heart defects and prostheses for joint replacements, particularly hips and knees [31, 39].

A negative consequence of these advances is that biofilms, whether bacterial or fungal, can form on these indwelling medical devices [40, 41]. These biofilms are difficult to treat and can lead to infection, which leads to a serious economic impact. For example, millions of intravascular catheters are commonly used in today's medicine in the United States. However, there are a huge number of bloodstream infections that arise from this use, which result in raising costs of treatment billions of dollars per annum [40, 42]. Often, the only recourse is to remove the device and replace it.

An understanding of the above-mentioned features of bacterial biofilms is utterly imperative in the discovery of novel means of controlling and preventing their resistance. This brief introduction gives a taste of the importance of biofilms, and why methods are needed to assess their formation as well as to test their response to antimicrobials.

Methods to Assess Biofilm Formation in Lab Conditions

There are various strategies used to study biofilm formation. Many of these generally employ stationary phase cells. These modes of study used static systems, which are better for the study of early events in biofilm formation, and continuous flow or chemostat systems, which are preferable for the examination of mature biofilms [43].

Microtiter Plate Biofilm Assay

A popular static method that has the advantage of high throughput is the microtiter plate biofilm assay. This method is based on its development and modification by Christensen et al. [44], Mack et al. [45], and O'Toole and Kolter [46].

Procedure

1. The bacterial strain is grown in batch culture overnight at the desired temperature to stationary phase in the desired medium, such as minimal medium or Luria-Bertani medium. A 10 mL culture or less will suffice.
2. Dilute the cells 1:100 with the desired growth medium into the wells of a 96-well polystyrene microtiter plate. It is recommended that each strain be assayed in quadruplicate. Some wells should be filled with sterile water, and the plate should be covered with a lid and/or parafilm to prevent dehydration.
3. Incubate the cells in the plate at the appropriate temperature, 25–37°C is typically used [43], and the length of the incubation should be between 2 and 48 hours, depending on the strain, the medium, and the growth temperature.
4. After the incubation, the planktonic bacteria should be separated from those cells that have formed the biofilm. First, invert the plate and shake firmly over a wastewater tray. Alternatively, the cells can be washed using a water bottle that gently delivers the liquid. The wells should then be washed three more times, either by immersing them into water washes or gently applying water. Finally, invert the plates and tap them to remove any remaining water.
5. Air-dry the wells for a few minutes at room temperature, and then add 0.1% crystal violet solution, 20–200 uL, to each well. Allow the staining to proceed for 10–20 minutes at room temperature.
6. Wash the wells with water to remove crystal violet that has not adhered to the cells. Repeat three more times and air-dry the microtiter plate at room temperature.
7. Add 200 uL of 95% ethanol to each well, and incubate for 10–15 minutes at room temperature to solubilize the crystal violet. Mix with a pipette. Other solvents, such as dimethyl sulfoxide, have been used instead of ethanol [47].
8. Transfer 100–150 uL of crystal violet solution to corresponding wells of an optically clear, flat-bottom 96-well plate, and measure the absorbance at 500–600 nm with a plate reader.
9. Alternatively, the crystal violet stain can be quantified by another means [46]:
   a. Add 200 uL of 95% ethanol twice to each microtiter plate well and mix.
   b. Transfer the ethanol to a 1.5-mL microcentrifuge tube.
   c. Bring the volume to 1 mL with deionized water.
   d. Transfer to a cuvette and read spectrophotometrically at 540 nm.

An *In Vitro* Cell Culture Method for Assessing Biofilm Formation [48]

Batch culture is commonly used in studying biofilms because it is easy to grow the cells in a variety of media and vessels, and the cost is low [8]. In this method, the biofilm is grown on a coverslip that has been inserted into the culture medium.

Procedure

1. Cells are grown overnight in the appropriate medium. The bacteria can be grown aerobically or anaerobically, depending on the organism and the objective of the study.

2. Add 2.5 mL medium to individual sterile culture dishes.
3. To each dish, add a sterile 18 mm-diameter glass microscope coverslip and cover the dish.
4. Add the requisite amount of overnight culture to the dish and incubate overnight.
5. Remove the coverslips and rinse briefly with water. These can be viewed by phase-contrast microscopy.
6. For fluorescence microscopy, use the following approach:
   a. Remove the coverslip from the culture and transfer to a dry dish.
   b. Add 20 uL monoclonal antibody solution and incubate 30 minutes at room temperature [49].
   c. Add 5 uL fluorescein-conjugated goat secondary antibody and incubate at room temperature for 10 minutes.
   d. Briefly rinse the coverslips with water to remove unbound antibodies and cells, and then use immediately for microscopy to demonstrate biofilm development.

A Static Method for Assessment of *Staphylococcus* Biofilms

It has been well established that indwelling medical devices provide excellent surfaces for biofilm formation [33]. *Staphylococcus* spp.—in particular *Staphylococcus aureus* and *Staphylococcus epidermidis* as well as other coagulase-negative staphylococci—can produce a mucoid exopolysaccharide (referred to as slime) that allows them to form biofilms on the surfaces of these devices [50–52]. It is these staphylococci that are frequently involved in troublesome infections because of the difficulty in treating biofilms with antibiotics [27, 30, 31]. Biofilm formation can be assessed by a microtiter plate method [53] similar to that described above [44, 46]. Also, it was found that adding 1% glucose to trypticase soy broth or 2% sucrose to brain-heart infusion broth markedly increased the number of species that formed biofilms [53].

As an alternative, a method that requires simpler equipment and detects the slime production is the tube method [52, 53]. This is considered a qualitative method, but Mathur et al. [53] have shown that it is equivalent to the plate method, at least for strong biofilm formers.

Tube Method

Procedure

1. Grow staphylococcus on culture plate overnight.
2. Inoculate 10 mL TSB containing 1% glucose with a loopful of cells from the culture plate and incubate statically for 18–24 hours at 37°C in a glass or polystyrene test tube.
3. Decant the tube and wash with phosphate buffered saline (pH 7.3).
4. Air dry up to 10 minutes.
5. Stain with 0.1% crystal violet for 5–10 minutes at room temperature.
6. Wash with deionized water to remove the excess stain.
7. Invert the tube and allow it to air dry.
8. A positive result is a visible film that lines the wall and the bottom of the tube [52, 53]. In assessing the results, the formation of a ring at the liquid interface is not considered a positive result.

Flow Cell Method

Microscopic studies have been an important tool in the study of biofilm development. An effective protocol for the microscopic examination of developing biofilms is via the flow cell technique. This method was developed to allow direct, online observation of biofilm structure by light microscopy and scanning confocal laser microscopy [8, 54, 55]. Initially, light microscopy can be used; but as the biofilm thickens, scanning confocal laser microscopy (SCLM) is required to obtain interpretable images.

The scanning consists of five units. A container of medium is connected to a flow pump that is connected to a bubble trap; the medium then flows into a flow cell (chamber), and the effluent then goes to a waste bottle [54, 55]. The flow cell has four parallel flow channels (for details of its construction, see Wolfaardt et al. [54] or Christensen et al. [55]). The bubble chamber is present to prevent air bubbles from reaching the biofilm and disrupting its structure. The tubing between the bubble chamber and the flow cell must be of sufficient length to allow the flow cell to be mounted on a microscope. A critical component of the apparatus is a microscope glass coverslip that serves as a substratum for biofilm development as well as for microscopic observation. According to Christensen et al. [55], the coverslip is turned upward to prevent the sedimentation of flocs detached from other parts of the biofilm.

Procedure [55]

1. Sterilize flow cell with 0.5% (vol/vol) hypochlorite overnight, and then rinse with distilled water.
2. Using a syringe, 250 uL of an overnight culture diluted to an A_{450} of 0.05 is injected into the flow cell while the pump is turned off.
3. The flow cell is turned upside down.
4. The influent line is clamped to prevent back-growth.
5. After 1 hour, the flow chamber is righted and medium is pumped through the system at a rate of 0.2 mm/second.
6. The development of the biofilm can be followed by microscopy.

The Modified Robbins Device

A motivation for the development of the Robbins device derived from the problem of biofouling in industry [56–58]. This instrument, to a large degree, has been supplanted by the modified Robbins device [8, 30]. With the modified device, materials such as catheter surfaces can be employed to monitor the growth of biofilms [30]. Consequently, depending on the material chosen, the device can be used for industrial purposes, or for clinical or laboratory investigations [8, 30, 59]. It has also been used for

the determination of the cidal effects of antibiotics on biofilms [30]. A key aspect in the design of this instrument is that the sampling ports have disks of the test surface attached at the bottom and in contact with the medium, but the flow of the medium does not disturb the biofilm. Because this is a multiport system, samples can be removed at various times or in multiples. The biofilms that grow can be examined by microscopy, or cells can be scraped off the surface of the disk material for enumeration [30]. The modified Robbins device can be used with continuous cultures systems as well as with batch culture [60].

Procedure

The experimental design is that of Nickel et al. [30], which is the seminal publication with respect to the modified Robbins device. In this work, a batch culture was used. The disks attached to the sampling ports were derived from a urinary catheter, and the system was organized with a flask that contained the medium fitted with a line containing a valve going to a peristaltic pump. From the pump, medium flowed through tubing into the modified Robbins device and the effluent was collected in an appropriate vessel.

1. The entire experimental apparatus was sterilized using ethylene oxide.
2. Cells *(Pseudomonas aeruginosa)* were added to the medium so that they would be in log phase for the duration of the experiment.
3. The pump rate was 60 mL per hour.
4. During the course of the experiment, up to 8 hours, the disks were aseptically removed and examined by scanning electron microscopy, or cells were scraped off the disks into medium for enumeration.

Microscopy

Microscopy has been an invaluable tool in studying the development of biofilms [3, 8–11]. Two major modes of microscopy used are scanning electron microscopy (SEM) and scanning confocal laser microscopy (SCLM). The major advantage of SEM is its high resolution; but because of fixation and dehydration of the samples in the preparative phases, it gives a distorted image of biofilm structure. In contrast, SCLM yields a lower resolution; but because the samples are more representative of their natural state, the image obtained is more accurate and has allowed for a much-improved understanding of biofilm structure [3].

Scanning Electron Microscopy (SEM)

Preparation of Samples for SEM [61–65]

1. Place the sample in 2.5 to 5% glutaraldehyde in 0.05 to 0.1 M cacodylate buffer (pH 6.2–7.0) for 1–24 hours at 20°C. The mixture often contains 0.15% ruthenium red to stain the exopolysaccharide matrix.
2. If desired, the sample can be washed two to three times with the buffer for 1 hour each.
3. Treat the sample with 1% osmium tetroxide [66, 67].
4. Dehydrate in an ethanol series from 25% to 100%. Each ethanol wash is for 10 minutes at room temperature.
5. The samples are critical-point dried.
6. The samples are coated with gold or platinum-palladium.

A variation on this procedure, which was used for the study of *Acinetobacter baumannii,* was published more recently by Tomaras et al. [65]. In this study, the bacteria were grown in Petri dishes without shaking.

1. After the appropriate time period, the dishes were flooded with 2.5% glutaraldehyde in 0.05 M cacodylate buffer.
2. This was incubated at room temperature for 2 hours.
3. The glutaraldehyde was removed and the cells were washed with distilled water.
4. Samples of 1 cm × 1 cm were cut from the Petri dish and rinsed gently with distilled water.
5. The preparation was treated with an ethanol series of washes as above.
6. The samples were then CO_2-critical-point dried for 60–120 minutes.
7. The samples were then gold-coated.

Scanning Confocal Laser Microscopy (SCLM)

Sample Preparation and Analysis for SCLM [68–72]

With SCLM it is possible to view live samples that have not been distorted by fixation. This has allowed for a much better understanding of the three-dimensional organization of biofilms. In addition, SCLM has been an effective experimental tool in conjunction with *in situ* hybridization [73, 74].

Treatment of the sample in order to view it using SCLM depends on the type of instrument used:

1. Upright microscope: With this type of microscope, the samples are mounted with a material such as acid-free silicone glue.
   a. Grow biofilm overnight in the appropriate medium on a 35 mm, collagen-coated, glass coverslip that is sealed to the bottom of a culture dish [72]. An alternative is to use a poly-L-lysine-coated coverslip [71] glued to an appropriate vessel.
   b. Remove the medium and wash once with water or 0.85% saline.
   c. Mount the coverslip.
2. Inverted microscope:
   a. Grow biofilm on an appropriate substratum. Flat surfaces are better because they are easily mounted and stained. Flow cells and the disks of the modified Robbins device are well suited for this.
   b. Wash the biofilm in 0.85% saline or the medium of growth.
   c. The use of an inverted microscope dictates that the growth chamber is mounted upside down using a

coverslip (sealed around with nail polish) at the bottom [58]. This way, the laser light penetrates the coverslip from the bottom of the biofilm to the top, producing an inverted image [72].

3. Staining:
   a. There are a variety of fluors for nucleic acids. Positive stains include SYTO dyes, acridine orange, and the DAPI stain and propidium iodide [68]. Fluorescein can be used for either negative or positive staining, depending on the pH [54]. Depending on the experimental system, the amount of fluor added must be empirically determined.
   b. When more than one fluor stain is used, factors such as relative intensity emission characteristics, photostability, interference, additive effects, and quenching effects must be considered [68].
4. The mountant: The primary purposes served by the mountant are to preserve the sample and prevent photobleaching. Dimethyl sulfoxide (DMSO) is often used with bacterial samples and mixed with the fluor before its addition to the sample.
   a. The mountant should have a pH that is compatible with the optimum pH for the fluor.
   b. The mountant must have an additive such as DMSO to prevent photobleaching.
   c. The refractive index of the mountant should be as close to that of the sample as possible. For bacteria, this is 1.517 [69].
5. Magnification: This is much less than with SEM and is 40× or 100× with an oil immersion lens. Another option is a 63× water immersion objective lens [72]. The sample (with the fluor) is then excited with light of appropriate wavelength, causing it to emit light (fluorescence).
6. Imaging:
   a. After locating suitable fields (usually with phase contrast or epifluorescence), the appropriate excitation and emission filters are set before scanning the sample.
   b. Either a single thin section (x-y plane) is scanned or a series of x-y optically thin sections through the biofilm are scanned. This is called a z series or section. It is also referred to as sagittal imaging [54]. The distance between the z sections depends on the thickness of the biofilm. For example, if the biofilm is approximately 30–40 u thick, then z slices are obtained every 2 u [72]. Another option is to collect a single or a series of x-z vertical sections through the specimen [68].
   c. These two-dimensional (2D) cross-sectional images are stacked using the SCLM software (provided by the manufacturer) to get 3D information. With the quantitative extraction of information contained in each image, a three-dimensional reconstruction of the principal biological events can be achieved [70].
7. Image processing and analysis:
   a. The SCLM images may require basic processing and enhancement before analysis. These include histogram analysis, gray-level transformation, normalization, contrast enhancement, application of median or lowpass filters or image addition, or multiplication. These are done using specialized digital image processing and analysis software. The processing applied also depends on the information desired. For example, when two different fluors are used (e.g., green and red), images of the biofilms can be converted to Adobe Photoshop files [70]. A region near the center of the biofilm is selected, a histogram of the region obtained, and the mean intensity value of the green pixels is divided by the mean intensity of the red pixels to obtain a semiquantitative measure of the accumulation of the fluorophore in the biofilm. Ratios of green/red intensity values obtained for the same region at different time points can be used to calculate the rate of fluorophore transport.
   b. Alternatively, images can be generated interactively by calling appropriate command-line scripts using the dialog and menu facilities of the SCLM software (provided by the manufacturer). Then digital image processing and analysis are performed with analytical packages such as the QUANTIMET 570 (Leica) computer system, which enhances images, discards unwanted details, and accelerates gray-scale processing [68].
   c. Computerized image analysis comprises a sequence of operations that depend on the specimen being studied. Before the automated image processing is activated, pixel calibration is done through the QUANTIMET program. The size and position of the area of interest for measurement are specified, and the computer is then programmed to perform a sequence of automated operations, such as image acquisition, gray image analysis, detection, measurements of signal intensity, volume integration, and data recording and display [68, 70].
   d. Deconvolution can also be applied to SCLM images to sharpen the image by mathematical removal of "out-of-focus" information. All these functions help in smoothing the image, reducing the noise, and sharpening the image, thus defining the objects more accurately.
8. Image output: After obtaining the images, they are stored as TIFF, GIFF, PICT, or JPEG, depending on the degree of image fidelity and the degree of image compression required.

Atomic Force Microscopy

An atomic force microscope has a nanoprobe or tip fixed on a sensitive cantilever, which can handle the micrometer scale. Atomic force microscopy (AFM) is an advanced technology for observing the force interactions between the tip or probe and

the surface of the sample under observation [75, 76]. When the probe is very close to the sample, the top surface of the probe on the cantilever will bend from the original location. A photo detector receives the tiny signal from a laser beam deflected from the cantilever, and transfers/converts it into images viewed in a computer. In AFM, the force between the sample and the tip is used to sense the proximity of the tip to the sample. AFM offers considerable advantages in many scientific areas, including mapping of biological samples such as bacterial biofilms. Chemical modification of the AFM tip by using functional groups such as hydrophilic, hydrophobic, alkyl, or carboxyl groups can detect microbial surface functional groups, such as surface hydrophobicity or surface charge [77–79].

Recently, electrochemical experimental techniques have been used to monitor the growth of bacteria in the process of biofilm growth. Factors such as biofilm age, cell density, and pH as well as macromolecules in the EPS, such as polysaccharides, protein, humic substances and nucleic acids, as discussed later in this chapter) were studied. Biofilms on the electrode surface have been studied using cyclic voltammetry (CV) [80], impedance spectroscopy [81], and infrared reflection spectroscopy [82]. Electrochemistry has been used to control biofilm growth, such as stimulation on positively charged solid surfaces and inhibition on negatively charged surfaces [83, 84]. Some studies have shown that the negatively charged bacterial biofilms are more likely to grow faster on positively charged electrode surfaces; whereas, negatively charged surfaces inhibit bacterial growth [85]. Other research has shown that static electric fields play a major role in the adhesion of bacterial biofilms to solid surfaces [76, 86, 87].

The combination of AFM and electrochemistry is a new approach to track and observe the growth of live bacterial biofilms in their natural complex environment with high resolution. Advanced techniques such as AFM and electrochemical methods have been used to carry out investigations of the adhesion mechanisms of biofilms on various substrates, e.g., mica, glass, and pure and self-assembled monolayer (SAM) gold AU (111) surfaces (parentheses indicate the most stable isotope of gold). A SAM, an organized molecular assembly of amphiphilic molecules, is formed by adsorption onto a solid surface from a homogeneous solution [88]. This organization is achieved due to the affinity of the head group for the surface, and from the slow two-dimensional orientations of the hydrophobic tail groups.

Preparation of the Sample and the AFM Tip

Immobilization of Cells

AFM requires the sample to be attached to a solid substrate, which can be a glass slides, mica, or metal surface. Glass is composed of silicon dioxide and is not atomically flat; whereas mica can provide atomically flat surfaces that are ideal as a supporting substrate for AFM studies. Biosamples can be immobilized on a solid surface by physical adsorption or chemical adsorption. For physical adsorption, a drop of sample solution is put on a surface and dried in air. For chemical adsorption, a functional chemical is used to immobilize the target sample on a surface through formation of chemical bonds. L-lysine, fibronectin, and agglutinin are examples of linkers for chemical adsorption or electrostatic adsorption. Along this line, a surface modified by a chemical can change its original physical or chemical properties and increase the adhesion of cells. Denaturation of biological samples is an essential problem for any immobilization method. Much effort has been put into seeking an approach with high AFM resolution and little denaturation. Mechanical fixation of individual cells in a polymer membrane is among the most successful developments. Some approaches with modified surfaces, like SAMs on AU (111) or the change of molecular charge on a surface, offer a promise to improve bacterial adhesion [89]. Some modes of attachment on a solid surface use extracellular polymeric substance or agar gel or a porous membrane to immobilize the cells mechanically. In the latter, spherical cells are trapped in a polycarbonate membrane with a pore size similar to that of the cells, to obtain high-resolution images without cell attachment or cell damage [90]. This approach has two advantages: (1), it is simple and does not involve drying, coating or chemical fixation; and (2), it can be used for AFM observations *in situ*, which is close to the natural environment during bacterial growth.

Chemically Modified Tips

A chemically modified tip is a prerequisite for a reliable, quantitative surface force measurement. The surfaces of commercial tips have defined surface coatings, such as silicon nitride, or gold-coated films, which are easily contaminated. Functional tips with SAMs of alkanethiols give high-resolution images due to their chemical sensitivity. The procedure is described in the experimental section (subsection describing preparation of hydrophobic tips and surfaces under the procedures section). Alkanethiols with different terminal functional groups: -OH, -CH3, -COOH, -NH2, can be used to detect the physical and chemical properties (hydrophobicity, charge) of biological surfaces [79].

Biologically Modified Tips

Some biomolecules are used to modify tips with the purpose of measuring intermolecular forces between individual ligand-receptor contacts, the adhesion of the biofilms, or the receptor protein location on single cell surfaces [91]. The binding of the biomolecules to the tips should be much stronger than the intermolecular force.

Cell-Modified Probes

A method has been developed to attach cells directly onto an AFM cantilever. This approach can probe cell-solid and cell-cell interactions. This method preserves the native ultrastructure of the cells during measuring. First, cells were immobilized by using glutaraldehyde treatment to create covalent crosslinking between the bacterial layer and the polyethylene glycol, polyethyleneimine (PEG-PEI)-coated tip, or by attaching a single yeast cell with a small amount of glue [92]. Lower and coworkers [93] adsorbed bacteria onto poly-L-lysine-coated glass beads, and subsequently attached a cell-coated bead to a cantilever by using a small amount of epoxy resin. Another approach is to attach individual cells to an AFM cantilever via lectins, such as wheat germ agglutinin [94]. However, these treatments are likely to affect the structure and properties of the cell surface.

General Procedure [94–96]

Cleaning

All glassware and the cells for both electrochemistry and AFM are boiled in 15% nitric acid, and washed thoroughly with ultrapure deionized water. The glassware and the cells are then placed in an ultrasound bath for at least 20 minutes, and washed again to ensure that all impurities have been removed. Both the electrochemical cell and the AFM cell were kept in a beaker filled with ultrapure deionized water, and sealed with Parafilm after cleaning.

Procedure for Cleaning Gold Surfaces

All gold electrodes were annealed in an oven at 860°C overnight. Prior to use, the surfaces were flame-annealed in a hydrogen flame, and quenched in ultrapure deionized water saturated with hydrogen gas. Gold surfaces that had been in contact with metal ions were electropolished in 3M sulfuric acid before the annealing procedures. The electro-oxidation produces a thin crust of gold oxide containing possible surface impurities, which are subsequently removed by dissolution in concentrated (36–38%) hydrochloric acid.

Self-Assembled Monolayers (SAM)

Self-assembled monolayers on Au (111) surfaces were prepared by immersion of the freshly annealed metal surfaces into a 1–2 mM solution of the monolayer-forming compound for 24 hours. The solvent was either ultrapure deionized water or ethanol as required. The surfaces were thoroughly rinsed in both solvent and ultrapure deionized water before further use.

Procedure

1. Biofilm growth:
   a. Mica is used for growing biofilms. 2.0 × 1.0 cm mica sheets were cut and freshly cleaved by tape on both sides. Prior to use, the sheets were sterilized by immersion into sodium hypochlorite solution (0.5%) for 2 hours.
   b. The mica slices were then washed three times with sterilized ultrapure deionized water, autoclaved at 121°C and 15 psi for 30 minutes, and then immersed into a Petri dish containing 10 mL of nutrient medium. Typically, bacteria are cultivated on mica in Trypticase Soy Broth (TSB) for 4 or 24 hours.
   c. Overnight cultures grown in appropriate medium are diluted to $OD_{600} = 0.05$ into fresh TSB medium, added over the mica, sealed by Parafilm, and incubated for given lengths of time at 37°C. The mica was then washed three times with ultrapure deionized water, and put into a new Petri dish to dehydrate naturally for one day.
2. Preparation of hydrophobic tips and surfaces. Gold-coated surfaces are obtained as follow:
   a. Silicon wafers are coated with electron beam thermal evaporation with a 5 nm thick chromium layer followed by a 30 nm thick gold [Au (111)] layer.
   b. The Au (111) substrate is coated with a SAM of octadecanethiol. The gold-coated surfaces and gold-coated AFM tips are cleaned for 15 minutes by UV and ozone treatment, rinsed with ethanol, dried with a gentle nitrogen flow, and immersed overnight in a 1 mM solution of octadecanethiol in ethanol, and then rinsed in ethanol.
3. AFM measurements and image acquisition:
   a. AFM measurements in ultrapure deionized water are performed using a Nanoscope 111a AFM and oxide-sharpened microfabricated silicon nitride cantilevers. To probe the microbes in their native state by AFM, the biofilm bacteria are immobilized by mechanical trapping into the mica surface. The mounted sample is transferred into the AFM liquid cell while avoiding dewetting, which can occur at a solid-liquid or liquid-liquid interface. Generally, dewetting describes the rupture of a thin liquid film on the substrate (either a liquid itself or a solid) and the formation of droplets. The imaging force is kept as low as possible (=250 pN) to minimize sample damage.
   b. To study adhesion properties of biofilms, both topographical and deflection images were recorded as they yield complementary information. Topographical images provide quantitative information on sample surface topography (surface roughness and height measurements). Deflection images often exhibit a higher contrast of the morphological details, and are especially useful for rough surfaces. Real time images were collected at time intervals, for example every 15 minutes.
   c. To study biofilm structure and dynamics in a natural aqueous medium, and other aspects of the chemical as well as cell surface properties important in biofilm formation and growth, a dualscope microscope equipped with a C-21 controller can be used. The tapping mode is used to record all images. A second instrument that can be employed is a PicoScan 5500 with a 100 um scanner and cantilevers (NP-S). This instrument is used in the contact mode.

AFM-Electrochemistry

The AFM-electrochemical approach is used to study electrostatic interactions between the bacteria and both the electrode surface and electroactive probe molecules [95, 96].

1. Cultivation of biofilms on solid surfaces:
   a. Biofilms were cultivated on either bare or SAM-modified Au (111) in Brain-heart infusion (BHI) medium for 24 hours. Thereafter, the cells were diluted to $OD_{600} = 0.05$ and regrown in fresh BHI medium. The development of the biofilm was sampled by AFM after suitable time periods (four hours and 24 hours).
   b. The clean gold sample is added, sealed with Parafilm, and incubated for given lengths of time

at 37°C. The Au (111) sample is then washed three times with Millipore-grade water.

c. The gold (biofilm) sample was then placed in a clean Petri dish to dehydrate naturally for 1 day before being imaged by AFM, but used directly without drying for cyclic voltammetry and linear sweep voltammetry. Bare Au (111) or SAM-modified Au (111) surfaces without bacteria are used as a reference.

2. AFM sample preparation and image recording: An atomic force microscope with a 100 um scanner and cantilevers (NP-S) in the contact mode is used. Twelve mm diameter Au (111) discs are used for AFM observations.
3. Electrochemistry:
   a. Cyclic voltammetry is carried out using an Autolab system. The electrochemical cell is kept in a Faraday cage. The hanging meniscus method is used.
   b. A freshly prepared reversible hydrogen electrode is used as a reference electrode and checked against a saturated calomel electrode (SCE) after each measurement. A clean, coiled, platinum wire serves as a counter electrode. Purified argon is used to deoxygenate all solutions and an argon stream is maintained over the solutions.
   c. Phosphate buffered saline, pH 7.4, is the supporting electrolyte solution. Potassium ferrocyanide or potassium hexachloroiridate (negatively charged molecular probes), or ruthenium ammonium chloride or cobalt terpy perchlorate (terpy = 2, 2', 2''-terpyridine), which are positively charged molecular probes, are added independently (as needed) to the buffer.

Methods for Examining the Effect of Antibiotics or Biocides on Biofilms

It is now accepted that bacterial growth in natural settings is most commonly in the form of biofilms. From a clinical perspective, this presents a problem because biofilms grow on indwelling medical devices, particularly central venous catheters [40], and may be involved in the persistence of chronic infections [31]. A common experience is that the biofilms are considerably more resistant to antibiotics and biocides than planktonic cells [30, 97, 98]. Consequently, methods have been developed to examine the inhibition or killing of biofilms by antimicrobials, which have led to the term minimal biofilm eradication concentrations (MBECs) [97, 98]. These include the use of the modified Robbins device, the Calgary Biofilm Device, and simpler methods.

The Modified Robbins Device [30, 99]

As detailed previously, the modified Robbins device was designed primarily to measure biofilm formation. However, it can be used to determine the ability of antibiotics to inhibit the growth or kill cells in a biofilm [30, 99].

Procedure

Grow cells in the modified Robbins device to form a biofilm as described previously.

1. After the biofilm has formed, open the valve of a parallel reservoir containing antibiotic in the same medium.
2. After the appropriate period of antibiotic exposure, aseptically scrape the cells on a disk (urinary catheter) from a specimen plug into a tube containing sterile phosphate-buffered saline.
3. Subject the cells along with the disk to low-output sonication to disperse the cells.
4. Dilute the cells as needed and plate on nutrient agar for plate counting.

The Calgary Biofilm Device [8, 97–100]

Although the modified Robbins device could be used to determine the susceptibility of biofilms to antibiotics, it was deemed less than optimal for rapid antibiotic susceptibility testing for clinical purposes [97]. The Calgary biofilm device is relatively simple in that it consists of two parts that are composed of plastic. One is the bottom, which contains 96 troughs (channels) for bacterial growth, and the other is a lid into which pegs are placed to fit into the troughs. The biofilms grow on the pegs. The pegs will also fit into standard 96-well polystyrene microtiter plates [98]. Ceri et al. [97, 98] demonstrated that the device can produce 96 equivalent biofilms and is highly reproducible. Advantages of this system are that it requires no pumps or tubing, thereby reducing problems of contamination; allows for multiple testing; has a platform that uses standard 96-well plates; and is considerably faster than the modified Robbins device [99, 100]. This system is also referred to as the MBEC Assay System, and can be obtained from MBEC Biofilms Technologies Limited, Calgary, Alberta, Canada.

Procedure

1. Establish biofilm conditions:
   a. Add a standardized inoculum to the channels in the bottom plate using TSB as the growth medium.
   b. Attach the lid and place on a rocking table. The rocking action creates shear forces that promote biofilm formation. For aerobic cultures, the temperature is usually 35°C with 95% relative humidity.
   c. At selected times, remove duplicate pegs, place in 200 uL sterile buffer, and sonicate for five minutes using a sonic cleaning system.
   d. Plate on an appropriate medium to determine viable counts.
2. Susceptibility testing:
   a. After generating a standardized biofilm, then its susceptibility to antibiotics or biocides can be tested.
   b. Prepare working solutions of antibiotics in cation-adjusted Mueller-Hinton broth (CAMHB) to a concentration of 1024 ug mL^{-1}.

c. Serially dilute the antibiotics in CAMHB and add to the wells of a 96-well plate.
d. Wash the pegs (in the lid) on which biofilms have grown in a wash tray containing sterile buffer.
e. Place the lid (with the pegs) over the wells to expose the pegs with the biofilms to the antibiotics. The assembly is usually incubated overnight.
f. Determine the MBEC value (the minimal concentration of antibiotic that prevents growth of the biofilm).

3. Take the lid with the pegs and wash as previously discussed. Then place the lid over a 96-well plate in which the wells contain recovery medium.
4. Sonicate as above to disperse the cells into the recovery medium.
5. Determine the viable cell number by plating onto the medium of choice.
6. Alternatively, measure the turbidity in the wells using a 96-well plate reader.

Other Methods for Assessing the Effects of Antibiotics or Biocides on Biofilm Viability [32, 101–103]

Method 1

Stone et al. [101] examined the effect of tetracycline on biofilms of uropathogenic *E. coli* grown in Plexiglas flow cells.

1. For enumeration, first aseptically scrape the biofilm into 400 uL of 0.1M phosphate buffer at pH 7.0.
2. Vigorously vortex the cells.
3. Serially dilute the suspensions and plate on LB agar for enumeration.

Method 2

Anderl et al. [102] examined the effect of ampicillin and ciprofloxacin on *Klebsiella pneumoniae*. In this study, the biofilms were propagated on polycarbonate filters.

1. To enumerate the biofilm, first immerse the membrane in 9 mL phosphate-buffered water.
2. Vigorously vortex the membrane to suspend the cells.
3. Plate serial dilutions on R2A agar by the drop plating method [103].

Method 3

Elkins et al. [32] studied the killing of planktonic cells and biofilms of *Pseudomonas aeruginosa* by hydrogen peroxide. The biofilms were generated using a drip-flow reactor with stainless steel slides as the substratum.

1. To enumerate the biofilms, remove the slides and scrape aseptically into 50 mL phosphate-buffered saline (pH 7.2) containing 0.2% sodium thiosulfate to neutralize the hydrogen peroxide.
2. To suspend the cells, homogenize the above mixture in a PT 10/35 Brinkman homogenizer for 15 seconds at setting 4.
3. Appropriately dilute the homogenate and plate on R2A agar medium.

Molecular Genetic Methods

Polymerase Chain Reaction (PCR)

Based on PCR, various analytical techniques can be used to identify biofilm organisms without prior cultivation [104–107] in order to study the composition of the biofilm.

1. DNA fragments have to be extracted from the sample. It may be suitable to disrupt the organisms within the biofilm, (for example, by ultrasonic treatment), then they are concentrated by membrane filtration and lysed afterward again, e.g., by using organic solvents like chloroform, methanol, or detergents like Triton etc. (biofilms require mechanical lysis followed by chemical lysis to disrupt the membranes for complete extraction of DNA). It is also possible to lyse the cells directly in the sample, and obtain the DNA by high-speed centrifugation. The use of polyvinylpolypyrrolidone is recommended to remove humic substances if these are present in the sample, as they can interfere with the PCR reaction [104, 105].
2. After amplification of the 16S rRNA genes from the extracted genomic DNA by PCR, a mixture of the amplified products is obtained, which has to be separated by molecular biological techniques (like gel electrophoresis) and subsequently cloned [106] into vectors to get the corresponding rDNA.
3. Restriction analysis of the cloned rDNA fragments is performed, and the pattern of the fragment analysis can be compared to that of the culturable organisms of the population. In this way, it is possible to obtain genetic fingerprints of bacteria, protozoa, and fungi possibly present in the sample. An efficient analysis of the microorganisms by means of PCR fingerprinting can be supported by using DNA sequencing, capillary electrophoresis, and databases with reference patterns for the identification of unknown isolates [107]. Facultative bacteria can also be identified by polymerase chain reaction amplification and sequencing of the 16S rRNA gene [115].

Real-Time Quantitative Reverse-transcription-PCR (qRT-PCR)

In biofilms, the use of this method allows the investigator to identify efficiently the presence of specific genetic sequences related to individual bacterial species. Traditional PCR as such, is not suitable for quantitative studies of biofilms. Another difficulty is that PCR amplifies the DNA of both viable and dead cells. Thus PCR cannot be used accurately for the enumeration of living cells in a biofilm. To overcome these problems, qRT-PCR has been adopted. While in traditional PCR analysis, results are collected

at the end of the reaction, during qRT-PCR, the fluorescent signal is measured in real time at each amplification cycle, and is directly proportional to the number of amplicons generated. Moreover, PCR amplifies all DNA present in the sample, whereas qRT-PCR detects the bacterial mRNA, with its short half-life. Detection of the mRNA is a promising indicator of cell viability [108]; therefore qRT-PCR has been applied not only to detect but also to quantify a specific microorganism in a biofilm [109–111].

Fluorescence *In Situ* Hybridization (FISH)

Fluorescence *in situ* hybridization (FISH) technique is a genetic approach using oligonucleotide probes labelled with fluorescent dyes. With the use of rDNA directed and fluorescence labeled oligonucleotide probes, it is possible to detect and localize microorganisms in a biofilm that may not be culturable and identify them phylogenetically. More than one oligonucleotide probe can be applied in order to label more than one kind of organism. Combining the FISH technique with SCLM facilitates the identification and topographical visualization of different species in a multispecies biofilm. This method provides not only information about the species present in the undisturbed sample, but also reveals their position in relation to each other, using the potential of SCLM to demonstrate three dimensional structures. This approach makes it particularly suitable to investigate the functional architecture of a biofilm, and the intensity of the signal depends on the ribosome content and thus reflects the physiological status [112–114].

Though the gene probe (FISH) strategy has brought significant progress to biofilm research, a drawback is that, in order to apply the probes, the cells must be permeabilized. The procedure required for this purpose may kill them, and therefore the possibility of affecting the architecture of the biofilm cannot be completely excluded.

Immunological Methods

Detection and identification of biofilm population members can also be performed by immunological coupling reactions between fluorescent labeled antibodies that are specific to certain organisms. This method requires cultivation of the target organisms, and the availability of antibodies that can detect suitable epitopes in a thin biofilm. In multilayered biofilms, the EPS matrix acts as a diffusion barrier for large molecules and the antibodies will be impeded in reaching the antigenic sites of the target organisms [114, 116]. The advantage in the use of mono- or polyclonal antibodies is that the cells are not killed by this method, and thus cellular processes in the biofilm still can be observed. Also, the combination with other nondestructive fluorescence staining methods is possible, e.g., using the tetrazolium salt 5-cyano-2,3-ditolyltetrazolium chloride [117].

Methods to Study Biofilms in Clinical Conditions

There is a great deal of literature dealing with how to cultivate and quantify biofilms, however, there is no real standard method. This is partly due to the differences in bacterial response to internal and environmental triggers before and during biofilm production and genetic variability in the community [118].

Vortexing-sonication-vortexing Method

The approach detailed in this section is a combination of conventional quantitative methods to optimize biofilm growth and quantification, particularly on curved surfaces, (catheter) to mimic the lumen of the urethra. The methods involve vortexing, sonication, and vortexing. It has been established that when biofilm cells are vortexed before sonication it aids in dislodging any loosely attached layers of biofilm and boosts the effect of sonication on deep-seated layers that might be sturdily attached to catheter surfaces. Furthermore, when the cells are vortexed after limited sonication, it helps in breaking down the bacterial communities into individual cells, which improves bacterial isolation. This facilitates a more accurate and uniform quantification without excessively destroying bacterial cells [119].

Although this method has advantages over others, it is not without limitations. First, the extent of sonication may affect the cell structure and/or the metabolism of bacteria. It has been reported that sonication more than 5 minutes can be detrimental to cell viability [120]. In addition, destructive techniques can have negative effects on biofilm-forming bacteria by producing viable but nonculturable bacteria. It is worthy to note that Gram-negative bacteria are more sensitive to sonication than are Gram-positive bacteria [121].

Another factor that needs to be considered is the intensity of the sonicator. For example, it is important to note that the intensity of cavitation in a water bath sonicator is low and the effect can be uneven [122] when compared to a probe-based ultrasonic processor. This difference in output can considerably affect the outcome.

Imaging is a prominent nondestructive method used to study biofilms. Thus, the use of microscopy with phase contrast or bacteria-specific staining is commonly used. One of the advantages of microscopy is the high-resolution images that can be directly used in publications or even quantified using imaging software. Another major advantage of microscopy is that it is able to be used to quantitatively analyze biofilms without the harvesting or disrupting and resuspension the biofilms. This permits the natural structures to be preserved [123].

The methods listed have been modified to cover other bacteria that can cause urinary-tract infections.

1. Growing bacterial biofilm on a urinary catheter segment *in vitro:*
   a. Obtain a single bacterial colony and inoculate in 10 mL of LB broth.
   b. Incubate the cells overnight at 37°C in static condition.
   c. Dilute the overnight culture to ~5×10^5 CFU/mL and subculture again overnight.

   Two static serial passages have been shown to be essential for ideal type 1-pilus expression, which plays a critical role in attachment of cells to catheter surface [124–125].

d. Immerse Foley catheter segments (1 cm long) in a tube with 5 mL culture and provide sufficient aeration.
e. Allow the biofilm to develop on samples by incubating at 37°C (nonshaking) for 7 days using the fed batch culture method, by replacing the growth medium with fresh medium every 24 hours [126].

2. Biofilm growth *in vivo:*
   a. Collect catheter samples from mice with associated urinary-tract infections (CAUTI) after 10–14 days of bacterial inoculation as described previously by Kadurugamuwa et al. [127].
   b. Collect full-length indwelling catheters from female micropigs after 25 days of catheter placement, as described [119, 128].
   c. Collect full-length indwelling urinary catheters from human patients and treat them as (b) above.
3. Extraction of biofilms:
   a. Wash the loosely attached planktonic bacterial cells from catheter segments.
      i. Cut full length catheters from micropigs and humans into segments of 0.5 cm and 1 cm, respectively, for ease of extraction and calculation.
      ii. Gently dip samples and wash once in 5 mL sterile 1x PBS.
      iii. Gently tap the Foley catheter on a sterile absorbent to remove remaining liquid from the lumen.
   b. Extract the biofilm using vortexing-sonication-vortexing method.
      i. Transfer samples to 10 mL 1x PBS in a 50 mL tube.
      ii. Execute a continuous vortex for 1 minute at full speed.
      iii. Using Ultrasonic Cell Disruptor XL-2000 probe P-1 (with a tip diameter of 3.2 mm), perform sonication at 10 W (RMS) for 50–60 seconds.
         – Enhance the strength and timing for different sonicators.
         – Keep the PBS with segments on ice to prevent heating due to sonication.
         – Clean the probe with 70% ethanol and ddH_2O between each sample.
      iv. Conduct another round of continuous vortex for one minute at full.
   c. Verify nearly complete removal of biofilm.
      i. Dip-wash samples once in sterile PBS and then transfer to 5 mL sterile LB broth.
      ii. Incubate the samples in LB broth at 37°C with shaking at 200 rpm for the log phase period determined.
         – Incubation period depends on the doubling time for the bacteria.
      iii. Serial dilute the culture and plate on nutrient agar.
4. Plating:
   a. Concentrate the sonicate by centrifuging at 3,100 g for 10 minutes.
      i. Carefully discard 9 mL of supernatant
      ii. Resuspend the pellet in the remaining 1 mL PBS.
   b. Prepare ten-fold serial dilutions of the sonication supernatant.
      i. Plate serial dilutions including undiluted sonicate on LB Agar plate by 20 µL drop (Miles and Misra) method in triplicate [129]
      ii. Use CLED agar for all porcine samples to prevent swarming of *P. mirabilis.*
      iii. Streak and plate 20 µL sonicate of human samples on CHROMagarTM to identify other organisms.
      iv. At least triplicate samples all serial dilutions and plate.
   c. Invert the agar plates and incubate at 37°C (nonshaking) for 14–18 hours.
5. Quantification of bacteria:
   a. Count the number of colonies per 20 µL drop and note the dilution for each drop.
   b. Calculate the average number of colonies.
      i. Count between 5 and 50 colonies per drop.
   c. CFU per cm of a segment can be calculated as final quantification using the formula: CFU/cm = Average number of colonies for a dilution × 50 × dilution factor.
      i. The formula is adjusted per the length of the catheter segment.

Scanning Electron Microscopy (SEM) of Clinical Biofilm Samples

To qualitatively assess the biofilms from clinical samples, SEM should be performed as published elsewhere [130] with some modifications.

1. Fix the samples in 2.5% glutaraldehyde in PBS at 4°C overnight.
2. Wash the samples with PBS three times, then fix the samples once again with 1% OsO_4 reagent for 1–2 hours.
3. Dehydrate the samples in a stepwise manner in increasing percentages of ethanol from 25% up to 100%.
4. Dry the dehydrated samples with CO_2 in a critical point drier.
5. Mount the dried samples on stubs and sputter coat with a thin layer of gold.
6. Visualize the coated samples using a field emission scanning electron microscope.

Introduction

Antibiotics have revolutionized the treatment of infections, saving millions of lives in the process. Antibiotic resistance occurs when microorganisms acquire the ability to resist the effects of an antimicrobial agent. As bacteria develop new ways to resist antibiotic effects, researchers have been driven to develop more sophisticated antibiotics. There are many mechanisms by which microorganisms become resistant to antibiotics, one of which being formation of a biofilm. These three-dimensional formations of bacteria can form on as varied surfaces as human teeth, lungs, intravenous catheters, and surgical implants.

Biofilms are colonies of bacteria, or more rarely fungi, existing within a hydrated extracellular matrix of polymeric substances (EPS) produced by the organisms.[1,2] The microorganisms within the biofilm adhere strongly to each other, as well as any surrounding surfaces. Biofilms form on organic or artificial surfaces within the human body. This process becomes problematic for healthcare providers, as formation of biofilms renders bacteria more resistant to antimicrobials, less susceptible to host immune responses, and allows the bacteria to survive harsh conditions. Once bacteria have formed a biofilm, the microbes are exceedingly difficult to eradicate. Biofilms provide microorganisms protection from environmental toxins and antibiotics via two general mechanisms: genetically inherited antibiotic resistance and phenotypes that confer drug resistance.[3–7] These biofilms can seed further bacterial expansion into other protected areas of the human body and potentiate relapse of infectious processes. Biofilm-related disease is associated with significant morbidity and mortality.[2] Understanding the nature of biofilm-related disease, the locations commonly implicated in biofilm formation, typical causative organisms, and how to treat and eradicate biofilms once they form is critical to reducing the risk of infection relapse and improving patient outcomes.

Pathophysiology

Bacterial biofilms are usually pathogenic in nature and can cause persistent and chronic bacterial infections as well as nosocomial infections. The National Institutes of Health (NIH) revealed that among all microbial and chronic infections; 65% and 80%, respectively, are associated with biofilm formation, which includes both device-related and nondevice-related infections. These numbers become cause for greater concern since most bacterial biofilms show resistance against the human immune system, as well as against antibiotics, increasing the potential of biofilms to cause infections and reduce the ability to treat them.[1] During biofilm formation, an organized aggregate of microorganisms adhere to one another and to a static surface (living or nonliving) by producing a matrix composed extracellular polymeric substances (EPS), which provides strength to the interaction of the microorganisms in the biofilm.[8] This attachment leads to formation of a micro-colony, giving rise to three-dimensional structures and ending up, after maturation, with detachment caused by producing saccharolytic enzymes that help to release the surface of the microbes into a new area for colonization. During the formation of a biofilm, bacteria communicate within and between species, using quorum sensing through small secreted autoinducer signal molecules.[9,10] This activates certain genes responsible to produce virulence factors. To some extent, microbe structure within a biofilm will appear different from the planktonic forms of the same microbial organisms.[11] Since bacteria that adhere to implanted medical devices or damaged tissue are able to encase themselves in a hydrated matrix of polysaccharide and protein, they are highly resistant to antimicrobial agents due to delay in penetration. This antibiotic resistance of bacteria in the biofilm mode of growth contributes to the chronicity of infections. The mechanism of resistance depends on multicellular strategies.

Biofilm-associated microorganisms have been shown to be associated with several human diseases, such as native valve endocarditis and cystic fibrosis; and to colonize a wide variety of medical devices. Though epidemiologic evidence points to biofilms as a source of several infectious diseases, the exact mechanisms by which biofilm-associated microorganisms elicit disease are poorly understood. Detachment of cells or cell aggregates, production of endotoxin, increased resistance to the host immune system, and provision of a niche for the generation of resistant organisms are all biofilm processes which can initiate the disease process.[12] Mechanisms responsible for resistance may be one or more of the following: (i) delayed penetration of the antimicrobial agent through the biofilm matrix, (ii) altered growth rate of biofilm organisms, and (iii) other physiological changes due to the biofilm mode of growth. Several pathogens associated with chronic infections include *Pseudomonas aeruginosa* in cystic fibrosis pneumonia, *Haemophilus influenzae* and *Streptococcus pneumoniae* in chronic otitis media, *Staphylococcus aureus* in chronic rhinosinusitis, and enteropathogenic *Escherichia coli* in recurrent urinary-tract infections, are linked to biofilm formation.[13]

Biofilm infections are important clinically because bacteria in biofilms exhibit recalcitrance to antimicrobial compounds and persistence despite sustained host defenses. Nutrient-depleted zones can result in a stationary phase-like dormancy within the biofilm, which may be responsible for the general resistance of biofilms to antibiotics.[14,15] Therefore, limited penetration of nutrients, rather than restricted antibiotic diffusion, may contribute to a generalized resistance or tolerance to antibiotics.[16] Although the matrix may not inhibit the penetration of antibiotics into the biofilm altogether, it may retard the rate of penetration long enough to induce the expression of genes within the biofilm that mediate resistance.

Typical Locations

In the medical setting, bacterial biofilms lead to high levels of antibiotic tolerance on medical devices. Biofilms are also responsible for the pathophysiology of the chronic infections many healthcare-associated infections (see Table 58.1).

TABLE 58.1

Infections Caused by Biofilms

Device-Related Infections	Tissue-Related Infections
Ventricular derivations	Chronic otitis media, chronic sinusitis
Contact lenses	Chronic tonsillitis, dental plaque, chronic laryngitis
Voice prosthesis	Periodontitis
Endotracheal tubes	Endocarditis
Central vascular catheters	Lung infection in cystic fibrosis
Prosthetic cardiac valves, pacemakers, and vascular grafts	Chronic obstructive pulmonary disease (COPD) and diffuse panbronchiolitis (DPB)
Tissue fillers, breast implants	Intestinal and gallbladder Infections
Peripheral vascular catheters	Kidney stones
Urinary catheters	Biliary tract infections
Orthopedic implants and prosthetic joints	Urinary tract infections
Peritoneal dialysis catheters	Osteomyelitis
Ventilator-associated pneumonia	Chronic wounds
Surgical meshes	Chronic bacterial prostatitis
Intrauterine devices	Vaginosis

Source: Adapted from selected articles.[1,12,13,17,18]

Device-Related Biofilm Infections

Biofilms usually occur on or within indwelling medical devices, such as contact lenses, central venous catheters, mechanical heart valves, peritoneal dialysis catheters, prosthetic joints, pacemakers, urinary catheters, and voice prostheses.[19,20] Biofilms may be composed of only a single species or may also include several species. This will depend on the devices and their duration of action.[9]

Contact lenses are categorized as soft and hard, and microorganisms can adhere to both. Their classification is based on construction materials, frequency of disposal, wear schedule, and design. The type of microorganisms attached to contact lenses are mainly *E. coli, P. aeruginosa, Staphylococcus aureus, Staphylococcus epidermidis*, species of *Candida, Serratia and Proteus*. The most important factor in infection, the degree of adherence to the lenses, depends on the water content, substrate nature, electrolyte concentration, type of microbial strain involved, and lastly the composition of the polymer. Under scanning electron microscopy biofilms have been observed on contact lenses of a patient diagnosed with keratitis, produced by *P. aeruginosa*. Biofilms can also form more frequently on contact lenses that are usually kept in lens storage cases. The lens storage cases, therefore, have been declared as a source of lens contamination.[12]

Formation of biofilm is universal on central venous catheters, but the location and extent of biofilm formation depends upon the duration of catheterization. For example, short-term (<10 days) catheters have more biofilm formation on the external surface, whereas long-term catheters (30 days) have greater biofilm formation in the catheter lumen. The growth of microbes may be affected by the nature of the fluid which is administered through the central venous catheter. For example, Gram-positive bacteria, such as *S. epidermidis* and *S. aureus*, do not grow well in intravenous fluids, whereas Gram-negative aquatic bacteria, such as *P. aeruginosa*, *Enterobacter* species and *Klebsiella* species sustain growth in such fluids.[21,22]

Microbial cells attach and produce biofilms on mechanical heart valves and surrounding tissues, a condition known as prosthetic valve endocarditis. The types of bacteria responsible for this unpleasant condition are *Streptococcus* species, *S. aureus, S. epidermidis,* Gram-negative *Bacillus*, *Enterococcus,* and *Candida* spp. The origin of these microorganisms may be from the skin or from other indwelling devices like central venous catheters or dental work.[23] At the time of surgical implantation of prosthetic heart valves, tissue damage may occur as a result of the accumulation of platelets and fibrin at the location of suture and on the devices. Microbial cells have better ability to colonize at these locations.[12]

Urinary catheters are usually made of silicon or latex and are normally used during surgical operations to measure the urine

generation and excretion. Urinary catheters are administered through the urethra into the urinary bladder. They may be closed or open systems. In an open catheter system, urine is drained into an open collector. This type of system increases the chances of contamination and this may lead to urinary tract infections (UTI) within days. In closed catheter systems, urine accumulates in a plastic bag, and this type of system results in a smaller incidence of UTIs.[24] Microbial cells that commonly contaminate and form biofilms on these devices are *E. coli, Enterococcus faecalis, S. epidermidis, P. aeruginosa, Proteus mirabilis, Klebsiella pneumoniae*, and other Gram-negative bacteria.[25]

Nondevice-Related Biofilm Infections

Periodontitis is an infection of the gums. In this infection damaging of soft tissues, as well as that of bones supporting the teeth occurs. Normally, it is caused by poor oral hygiene. Tooth loss is also possible.[26] *P. aerobicus* and *Fusobacterium nucleatum* are among the causative agents of periodontitis. These microbes also have the ability to form biofilms on a variety of surfaces, including mucosal surfaces in the oral cavity.[27] Microbial colonization of teeth surfaces may allow microorganisms to invade mucosal cells and alter the flow of calcium in the epithelial cells. The microorganisms can also release toxins. A plaque can then develop within 2–3 weeks. The plaque may mineralize with calcium and phosphate ions, forming the so-called tartar or calculus.[28]

Osteomyelitis is a disease of bones, which may be caused by bacterial cells or fungi. Bacteria enter the bones through the bloodstream, trauma, or through previous infections.[29] When microbes enter through the bloodstream and infect the metaphysis of the bone, this leads to the recruitment of white blood cells (WBCs) at the site. These WBCs attempt to phagocytose or lyse the pathogens by secreting enzymes, which may lyse the bone. This can result in the formation of pus, and spread infection through the bone blood vessels, thus stopping the proper flow of blood and causing tissue damage and deterioration of the function of the affected bone areas.[30]

Typical Organisms

A diverse population of microbes colonizes wounds, which can cause a delay in wound healing. However, microbial composition and diversity will vary depending upon the type of wound and may vary from wound to wound.[31] Major pathogens frequently isolated from acute and chronic wounds that can be grown in biofilms under lab conditions are *Staphylococcus aureus* and *Pseudomonas aeruginosa*.[32–35] One study described how *Staphylococcus* can be found on the surface whereas *Pseudomonas* can be detected in deeper tissues. Most chronic wounds contain at least one or more bacterial species and may cause synergistic virulence activity between the species. Other organisms such as *Escherichia coli*, *Enterococcus faecalis* and various species of *Klebsiella, Peptoniphilus, Enterobacter, Stenotrophomonas, Finegoldia, Serratia*, *Proteus*, *Moraxella,* and *Staphylococci* can be also be detected in clinical wounds using molecular techniques.[36,37] Polymicrobial species consisting of bacteria, fungus, and anaerobic bacteria can be identified in chronic nonhealing wounds. Some chronic wounds may be devoid of an oxygen supply and this may permit anaerobic bacteria to form microcolonies. A diverse microbial population makes treatment challenging in chronic wounds and particularly when there are antibiotic resistant strains within biofilms. Few studies have indicated that biofilm forming potential of microbes isolated from wounds are greater than that found in skin.

Etiology

Breaks in the skin expose the subcutaneous tissue and provide microbes an opportunity to colonize open wounds due to suitable pH, moisture, nutrient, temperature, and other growth conditions. The subsequent formation of a biofilm requires multiple virulence factors such as flagella, pili, self-synthesized exopolysaccharides (such as alginate), lipopolysaccharides, specific membrane proteins, receptors, and toxins among others.[38] Initially pili, flagella, and other surface appendages assist microbes in making reversible attachments to each other or to a surface. This is followed by EPS-mediated irreversible attachment. The third step is cell proliferation leading to the formation of an aggregate or microcolony. The fourth step is growth and differentiation leading to establishment of a mature three-dimensional biofilm with structural features such as towers and channels. Quorum sensing is also required for biofilm formation with many wound pathogens such as *Pseudomonas aeruginosa* and *Staphylococcus aureus.*[39–41] Biofilm formation in wounds requires quorum sensing mediated diffusible signals termed autoinducers (AI) secreted in response to population density. Formation of a microcolony or aggregate of bacteria is dependent upon the presence and concentration of AI. In case of *Pseudomonas,* secretion of alginate protects the organism from immune defenses, which leads to the persistence of bacteria in wounds.

Treatment

Biofilm-associated infections can cause chronic illness, despite antibiotic therapy and innate and adaptive immune responses of the infected individual.[42] One of the reasons that bacteria protected by biofilms are so difficult to eradicate is the varied metabolic activity of cells inside the matrix. Biofilm clusters contain persister cells, which are neither growing nor dying.[43] These unique cells, which are metabolically inactive, are resistant to antibiotics that may rely on cellular activity to exert their bactericidal effects. Exposure of these persister cells to antibiotics leads to rapid development of antibiotic resistance.[44] Biofilms have been implicated in many different infectious processes, and treatments vary based on the causative pathogen and the location of the suspected biofilm. Whenever possible, surgical or non-surgical removal of the biofilm-infected object (implant, prosthetic, catheter etc.) should be performed to make the underlying bacterial load more susceptible to targeted antimicrobial therapy.[45]

It is important that clinicians consider the goals of therapy when treating patients with known or suspected biofilms.[46] Typically, when using antibiotics for patients with infections, clinicians are aiming for a cure and eradication of the pathogen.

This may be different for patients with biofilm formation. For example, for patients with cystic fibrosis and colonization with *Pseudomonas aeruginosa*, the goal of therapy may be first to eradicate the active infection. If the same patient develops a *Pseudomonas* biofilm in their lung tissue, the goal of antibiotic therapy may instead to target suppression of bacterial growth and maintenance of lung function. Wound-associated biofilms are particularly problematic because they not only permit antibiotic tolerance, but they also may sequester the source of infection from host immune responses. An exciting development in treatment of wound-associated biofilms is the use of biofilm-disrupting topical therapies.[47] A study by Miller et al. found that surfactants dissolved a *Pseudomonas aeruginosa* biofilm and associated bacteria in as little as one day after application of the surfactant. Another study by Wolcott et al. demonstrated that a biofilm-disrupting gel showed a robust wound-volume reduction within four weeks.[48] This wound-volume reduction was even more pronounced when the biofilm-disrupting gel was combined with topical antimicrobial agents. Authors noted that wound-associated biofilms should be treated with debridement in addition to these topical antibiofilm and antimicrobial agents. They also note that wound volume reduction is a surrogate marker of efficacy and does not take into account the full picture of wound improvement. A panel of wound management experts convened in 2017, echoed these recommendations. They also noted that there is positive data on use of high-osmolarity surfactant solution to assist in the disruption of the EPS and the prevention of biofilm formation after debridement.[49]

A combination of antimicrobials that target the causative pathogen with biofilm controllers can be used to treat and disperse biofilms. Most biofilm-controlling agents do not eradicate bacteria, so this combination could be promising for future research and development.[50] Some antimicrobials that can penetrate a biofilm matrix include tetracyclines, rifampin, daptomycin, amikacin, and ciprofloxacin. Although rifampin is commonly used in practice for biofilm-related disease, there is little clinical data to support this. Most rifampin studies are limited to *in vitro* and *in vivo* studies or retrospective observations.[51]

Biofilms remain some of the most difficult infectious processes for clinicians to treat effectively. This continues to be an area for ongoing *in vitro* and *in vivo* research. Clinicians should consider the source of biofilm formation, and seriously consider if this source can be safely removed from the patient. If not, they might consider a combination of antibiotics that are shown to have efficacy in penetrating biofilms. Clinicians may not be able to realistically achieve bacterial eradication, so their goal of therapy may need to be bacterial suppression and maintenance of biologic function.

Introduction

This chapter was introduced in the previous edition of this book to help assist businesspeople requiring an understanding of the microbiology and underlying technologies associated with the companies they were considering supporting. This was important because microorganisms and infectious disease can oftentimes form a main portion of the intellectual property (IP) or the strategic basis of many start-up companies in the healthcare industry. This updated chapter is meant to provide businesspeople with a few basic insights into the industry regarding the various commercialization opportunities. A secondary goal of this chapter is to again introduce academic scientists to some of the factors that businesspeople consider when deciding on making an investment in a company, a technology, or a product. Academic scientists that are considering commercializing their research should find this information useful.

Scope of the Industry

With the advent of the cloning techniques developed in the mid-1970s that allowed scientists to insert the genes coding for proteins into the plasmids of bacteria, the scope of microbiology rapidly shifted from one of identifying and eliminating the causes of disease, to one in which microorganisms could be used as reagents and raw materials in the synthesis of medicines. Microbiology-based companies expanded from the healthcare industry, into industries ranging from bioremediation to agriculture to the energy industry. While this book will provide useful information to businesspeople interested in those areas, this chapter will confine itself to the industry of diagnosing the causes of infectious disease.

There are myriad opportunities for commercialization in the infectious disease diagnostics space from traditional culture, microscopy, and biochemical detection to novel technologies such as molecular detection methods, mass spectrometry, and genetic sequencing. The opportunities continue to grow as the need for fast, accurate diagnostic information will only become more important in the era of emerging diseases and new pandemic outbreaks. This challenge has been quite evident during the ongoing COVID-19 pandemic in which the scarcity of robust diagnostic tests and immunological assays led the FDA to quickly clear several new tests under their emergency use authorization (EUA).[1] Companies with open architecture on their molecular diagnostics platforms and those that had early prototype designs were able to move fast to meet the critical issue, but this experience highlights

the need for robust pipelines and ongoing development to try to preempt the detection of emerging infections.

Genetic sequencing has become increasingly effective for research applications, but the development of useful bioinformatics tools has allowed this technology to penetrate deeper into clinical diagnostics microbiology.[2] Bioinformatics will ultimately help clinicians translate the wealth of data that is gained from sequencing applications into targeted useful information that can affect therapeutic decision making. Molecular detection methods are becoming more widely used and are replacing traditional methodologies for those clinical conditions that require either a rapid result (e.g. hours vs days) or more accurate ones (infections associated with healthcare workers, sexually transmitted diseases, etc.). In addition, molecular detection methods are ideal when the clinician is interested in a screening for a specific target or gene. The newest molecular detection methods consist of highly multiplexed assays and arrays that can detect many different analytes in a single sample. These multiplex assays are gaining rapid clinical acceptance in U.S. hospitals. One example is in screening for the cause of complex respiratory pathogens.[3] This "syndromic" approach to molecular diagnostics is particularly important when patients have conditions with similar clinical presentation. For instance, there are many pathogens that are the etiology of "flu like" illnesses. With the advent of these highly multiplexed molecular detection methods, clinicians can order a test for upwards of 20+ pathogens, collecting a single sample and providing a broad range of pathogen information based on patient symptoms.[4]

Although the development of innovative technologies in microbiology continues at a rapid pace, there are still many opportunities to commercialize traditional methodologies. Organism cultivation, isolation, and phenotypical differentiation for antibiotic resistance characteristics, for example, are still commonly used and in some instances are a critical requirement in making therapeutic decisions or tracking organisms from an epidemiological perspective. If a new method can produce an accurate result, is reasonably fast (most growth-based methods require at least 24-hour incubation) and is inexpensive to use, many laboratories will implement it for the cost effectiveness alone. Most newer technologies are not inexpensive, however, and in instances when a result is not urgent, laboratorians may be willing to accept a longer turnaround time as a tradeoff to a more cost-effective approach. Ultimately, the cost benefit analysis would be conducted by the laboratory leadership in conjunction with medical staff to determine the best clinical approach that is also cost effective and implementable in the facility. In many instances, hospitals will utilize several technologies and take a front-line approach, then cascade to other methods if the most likely pathogen is determined to be negative. When commercializing novel technologies, it is important that the marketing on these devices encompasses a clear positioning around the quantifiable economic and clinical outcome benefits that will be gained to offset the increased cost of the device. These benefits could be reduction in readmissions, more efficient bed utilization, reduction in healthcare-associated infections or better, more cost-effective antibiotic usage. There will always be a need to bring in a diagnostic test that offers the same accuracy, but may be able to provide a result better, faster, or cheaper. In recent years, declining reimbursement rates for diagnostic tests have put a downward pressure on laboratory operational costs. Even in an era in which new technologies are entering the market at rapid pace, traditional methodologies, such as culture and microscopy, are widely considered the "gold standard" for reference methods in clinical trial and FDA 510K submissions for diagnostic tests.

History of Microbiology Technologies

Perhaps the most important aspect of any microbiology company's IP is its technology. In the 135 years since Koch first developed his postulates to identify the microorganisms that caused cholera and tuberculosis, the technologies used to identify microorganisms has been evolving. This evolution initially began at a slow pace, but much like other mainstream innovations, it has accelerated rapidly in the past 60 years. Unlike biological evolution, however, none of the ancestral forms of technology used to identify microorganisms, have gone extinct. The reason for this is that while technologies have evolved to meet ever changing marketing demands, the expanse of the field still provides plenty of niches that allow for the survival of older technologies. It is important that an investor in a company have a clear view of the market conditions, target opportunities, and the benefits of the technology to the ultimate user. In many cases, new, better technologies have not replaced the traditional methods. Clinical microbiology has historically been somewhat more subjective with microbiologists relying on observation of morphology through microscopic and growth-based methodologies to categorize the cause of an infection. Because of the qualitative and subjective nature of clinical microbiology, there will continue to be a place for traditional methods in the market for the foreseeable future. Despite rapid innovation, clinical microbiologists can oftentimes be resistant to change, at times preferring the tried and true techniques of growth-based observation for diagnosing pathogens. Despite this tendency, molecular methodologies have become widely available and prevalent in even the most ardent traditionalist microbiology laboratories. The key element in adoption of these molecular methods in some of the more traditional culture-oriented microbiology laboratories is full sample to result integration and ease of use.

As shown in Figure 59.1 at the outset of the study of microbiology, the only technologies available were microscopy. It was almost 200 years before the techniques of culture and biochemical testing were added to identify microorganisms. The combination of these three technologies remained at the cutting edge of microbial identification for decades. Due to their low cost and relative ease to perform, they still account for a large share of the microbiology testing that is done today. Even the widespread introduction of antibiotics in the mid-to-late 1940s did not really alter the use of microscopy, culture, and biochemical testing in identifying microorganisms or in ascertaining which antibiotics would be effective in treating a patient infection.

In the 1970s, the API strip introduced an age of miniaturization of biochemical testing (United States Patent 3,936,356 Janin February 3, 1976).[5] The API strip transformed biochemical testing from a cumbersome procedure that required the inoculation of 20 or more test tubes and the use of large incubators, to one in which all of the biochemical tests could be performed on a small plastic strip. While this was a great improvement for the

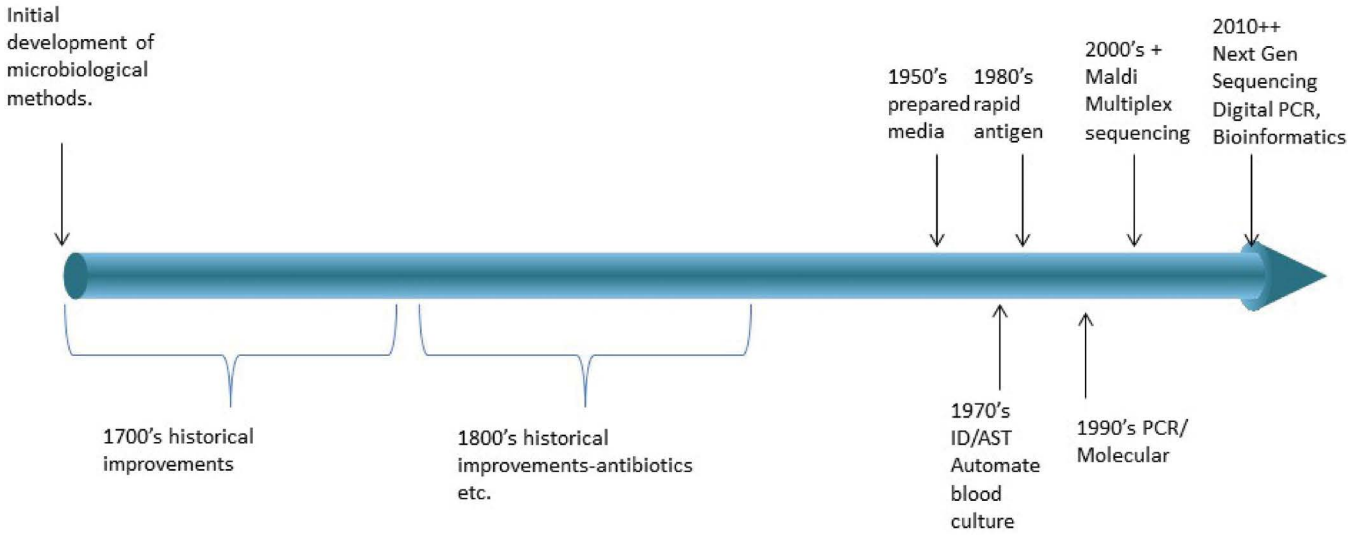

FIGURE 59.1 Timeline of innovations in the microbiology field.

identification of microorganisms, it still used the same microscopy, culturing, and biochemical technologies.

The first major shift in technology in identifying microorganisms came as this field was nearing the end of its first century, in the early 1960s, with the advent of antibody-based tests. These tests were based on the use of antibody molecules that were specific for certain organisms. First, was the introduction of the radioimmunoassays, which was followed by enzyme immunoassays in the 1970s.[6,7]

The ability to bind antibodies to inert particles such as latex, charcoal, or fixed red blood cells, led to the widespread use of easy to perform agglutination tests. The problem with these antibody-based technologies was that while they were fast and easy to perform, they were limited to only identifying a single pathogen. Thus, if the patient did not have the suspected infection, no additional useful information was provided. Immunoassays were further improved in the 1980s and 1990s with the development of lateral flow and membrane filtration immunoassays that would capture organism antigen on a filter and bind antigens directly on the membrane for detection of a specific microorganism.

The next major change came in the late 1970s and early 1980s and was driven by the revolution in isolating specific nucleic acid sequences that could be used to identify small numbers of microorganisms in samples, as detailed in Chapter 10 (Diagnostic Medical Microbiology), since this time many variations of these techniques have been developed. These include simple DNA probe tests and amplification methods such as polymerase chain reaction. While these Nucleic Acid based tests were originally developed to identify microorganisms, recently they have also been applied to determining antibiotic susceptibility patterns.[8] Today's molecular methods with multiplexing capability will not only identify pathogen strains with a single sample input, but also identify novel or otherwise well-understood resistance markers to provide additional clinical benefit to the diagnostic tool.

Reagents and test methods were not the only new technologies to enter the field at this time. By the late 1980s, many companies in the diagnostics industry had introduced completely automated testing units, capable of processing dozens of samples at one time. These instruments combined technologies such as spectrophotometry, video image processing, infrared detection, fluorescent detection, and computer software to develop instruments that required nothing more than that a technician prepare a sample and put it in the machine.

Marketing Forces in Diagnostic Microbiology

Several marketing forces in this industry have been at work at different times during the past 160 years. In most instances, the marketing forces have driven the technology rather than the other way around.

Microorganism Identification

Since the dawn of the human race, people have been getting sick and dying of infectious diseases. There has been a basic concomitant human need to determine the cause of these diseases and thus save the lives of loved ones. Long before the discovery that microorganisms were the causative agent of disease, people ascribed the causes to many things. Malaria, still a major worldwide killer, derives its name from the contraction of the Italian words *mala* (bad) and *aria* (air), since this was believed to be its cause.[9] Influenza derives its name from the Italian *influenza* (influence) since it was thought that the disease was caused by the influence of the stars.[10]

In the 1850s while attempting to determine why grapes were producing vinegar instead of the fine wines of France, Pasteur demonstrated that microbes, which had been known to exist since the 1660s, could affect their environment. It was soon realized that they were also capable of causing disease. Thus, the impetus of medical microbiology since that time has been to identify which microorganisms caused which diseases, and this became a primary marketing force. Today, the emergence of many new, primarily viral pathogens, and bacteria that are resistant to antibiotics, are creating new challenges to develop infectious disease diagnostics.

Population Centers

The late 18th and early 19th centuries witnessed the start of the Industrial Revolution. Over the next several decades, this led to more and more people leaving the farms and moving to population centers where the factories were located. Population centers continued to grow and expand, which eventually led to the large metropolitan areas that exist today.[11] This also led to an increase in the number of people that had to be treated in a small area, which then gave rise to the large hospitals. For example, today, Northwell Health System in New York has more than 1,000 beds and performs hundreds of tests each day.[12] Many hospitals are coming together to form major health systems and many smaller community hospitals are either disappearing or being absorbed into these systems, which will certainly continue to have an impact on diagnostic testing requirements and where this testing occurs.

Population centers have been responsible for several marketing forces. As populations centers grew and the number of laboratory tests grew, the amount of space required for multiple racks of tubes in biochemical identification procedures increased as well. The need to streamline these identification procedures became necessary due to the sheer volume of chambers required to incubate standard tests. When API strips were developed, they were not only easy to perform and interpret, but they also offered the benefit of providing a drastic reduction in the amount of incubator space needed to perform a microbial identification. This is probably one of the reasons why the test was, and after more than half a century, still is so popular. In addition to space constraints, as volume in testing grew, the need to develop tests that could be batched (e.g. tests in which many patient samples are tested at the same time) grew as well. This led to more automation of some of the highest volume samples in the microbiology lab, such as blood cultures.

As laboratory volume grew, there was also a need to develop systems that were easier to use, more efficient, and automated. This led to the development of automated identification and susceptibility systems, such as the Microscan Walkaway®, the BD Phoenix™ and Vitek® systems. Many of these systems could now perform biochemical testing to identify bacterial isolates in hours or overnight. In addition, these systems now provided the ability to conduct susceptibility testing more quickly and accurately using the minimum inhibitory concentration (MIC) determinations versus the less accurate antibiotic disc diffusion testing that was subject to overnight incubation, space constraints, and manual interpretation by the microbiologist. New developments continue to emerge in MIC testing as microfluidics now allows for growth-based detection of a bacterial response to an antibiotic more quickly.[13] There are several new technologies entering the market that promise "rapid" MIC detection. These technologies may be combined with resistant marker detection using molecular methodologies that will allow for demonstration of a resistance factor. In some instances, the gene for a resistance factor may be present, but not active. MIC detection in a growth-based system allows for laboratorians to determine if there is gene expression with the particular pathogen.

As a result of having large treatment facilities, large quantities of patient data were generated. These fully automated systems eventually included sophisticated database systems that allowed databases that could not only collect and store data, but could also be used to help interpret this data, thus, minimizing error through manual interpretation. The use of these databases also offered a more efficient electronic method of updating changing MIC values and endpoints for antibiotic resistance routinely issued by the Clinical Laboratory Standards Institute (CLSI). Electronic updates also ensured that the personnel in the microbiology lab were using the latest guidelines.

Hospital-based testing remains somewhat less urgent than point-of-care or emergency room-based testing and has not resulted in significant pressure to develop rapid tests. Oftentimes, patients with chronic or longer-term conditions may not need a result very quickly or the therapeutic intervention based on the result may be limited. This is evident in cases of infection monitoring such as transplant infections and viral load assessments. When a patient is in a more acute condition (i.e. emergency room) and a therapeutic intervention can be made, there is a greater need for a rapid, even syndromic approach to testing. It is important to note that while there is a general desire to have the results of tests on patient samples provided quickly, when weighing the speed of obtaining a result against the costs of obtaining that speed; tradeoffs may result in a hospital adopting a slower test, particularly for a less urgent sample or a less acute patient condition. In addition, hospitals currently deal with several delays that are built into their systems. For instance, samples are collected and brought down to a central lab for testing, which oftentimes can take hours. Since tests must fit into a hospital routine, rapid test (less than 30 minutes) are actually something that is not desired. Generally, tests that can be completed in less than 30 minutes will ideally be CLIA waivable (discussed later) and can be performed in point-of-care settings such as doctors' offices and urgent care settings. Again, these diagnostics should also allow the ability to change a therapy or add a therapy while the patient is still onsite.

Epidemics and Bioterrorism

Today's population is much more mobile than the previous generations. As a result, diseases that may have once taken days or months to spread can now be spread in a matter of hours across the world. Additionally, diseases are now expanding beyond their traditional endemic areas. Globalization and a more mobile population have now forced laboratories, primarily those in large cities, to be prepared for a wider range of pathogens and drug-resistance factors. In the current pandemic, the CDC has issued guidance documents for airline employees on how to deal with possible COVID-19 infections.[14] In addition to epidemics, as was discovered in 2001 with the anthrax attacks in the United States, large segments of the population may be vulnerable to microbial terrorist attacks. Both factors have contributed to a marketing force that is driving the development of very rapid, accurate, and specific tests. This same force is also being seen in the doctor's office, where a test that can provide a result in a short enough amount of time to allow the doctor to begin treatment has great value.

Fewer and Less-Skilled Technicians

In recent years, there has been a shortage in the clinical laboratory workforce. This has been due to retirement of the aging workforce, an increase in demand for laboratory services, changes in the field, and vacancy rates that exceed the number

of graduates.[15] This is partially due to the fact that students who might have originally considered this profession with a bachelor's degree are now opting to spend an extra year or two in school to become a Physician's Assistant (PA), which has a significantly higher starting salary. In addition, the implementation of more stringent educational requirements by some states has also led to a migration to PA programs.

With fewer and younger people entering this profession, laboratory tests need to become automated and simplified. This is particularly important in the microbiology lab because it has traditionally been the most labor intensive of the diagnostic laboratory areas. These issues, coupled with the ever-increasing cost of healthcare, have resulted in laboratories trying to replace more expensive staff with less expensive staff. As a result, this has led to a force that is driving to the development of tests that do not require a lot of expertise to run or that are automated.

In 1988, the Clinical Laboratory Improvement Amendments (CLIA) set the standards that apply to all clinical laboratory testing performed on humans in the United States. Tests were assigned to one of three categories, based on the simplicity of performing the test and of the amount of harm that might be caused to a patient if a test produced an erroneous result.

- **Category 1, CLIA Waived:** These tests are the simplest to perform and interpret. They generally require a limited number of steps and if they produce an erroneous result, it will result in very little harm to the patient. CLIA Waived tests can be performed in a doctor's office by staff with less technical training. These include pregnancy tests, dipstick urine analysis tests, and some tests for influenza or strep throat diagnosis.
- **Category 2, Moderate Complexity:** These tests include automated tests for *S. aureus*, MRSA, *C. difficile*, or various other infectious agents. They require a greater degree of technical intervention, but interpretation is relatively straightforward.
- **Category 3, High Complexity:** These tests include automated tests for antibiotic susceptibility testing that require the greatest amount of technical interpretation or intervention and processing. To run testing of this designation, laboratory directors must have doctoral degrees in chemical, physical, biological, or clinical laboratory science from an accredited institution and be certified, and continue to be certified, by a board-approved by the U.S. Department of Health and Human Services.[16]

Since manufacturing a test that falls into the Waived Category means that a laboratory running it has fewer constraints and can hire lesser trained technicians to perform it, the impetus on the companies has been to develop tests that are much less complex to run. Waived tests also find use in the less-developed areas of the world, where fully trained laboratory technicians are scarce.

FDA guidance documents can be accessed at: http://www.fda.gov/medicaldevices/deviceregulationandguidance/guidancedocuments/ucm079632.htm#1 (Accessed October 23, 2020)

Hospital Cost Cutting

While this section has focused on marketing forces that are confined to the microbiology laboratory, this is not the only place where an effective test can save the institution money. There is great pressure to have people released from the hospital as soon as possible. Managing admissions and readmissions are important metrics that are being considered by today's hospital administrators. This means that even though a specific test might cost more than its immediate competitor in the microbiology laboratory, if using it results in a patient getting out of the hospital a day sooner or reduces the likelihood that that patient will return with the same condition, hospitals will be interested in considering that test. The overall savings to hospitals can be upward of hundreds of thousands of dollars in reducing readmissions alone. Companies will need to invest in outcomes studies and healthcare economics analysis to demonstrate and quantify the value of the specific diagnostic.

Developing Countries

As described above, many of the newer technologies are being used in the developed world. Billions of people, however, live in undeveloped countries and this has led to the survival of the older technologies as well as the development of easy-to-use technologies that do not require a great deal of technical expertise to run. Unlike the 1800s in which treatment options were limited, today, identifying a pathogen means that a physician can prescribe an antimicrobial. Developing markets need inexpensive accurate diagnostic tests to influence treatment and patient management. These tests need to be rapid since oftentimes patients may spend half a day walking to a clinic for testing and treatment. In addition, many of these clinicians need portable technology that they can take with them since they are often taking diagnostics and treatment directly to the patient in remote areas.

Today, antigen testing provides a good opportunity to pursue these markets, but as molecular diagnostics are developed, that dynamic is changing fast. There are more molecular diagnostics companies in the market than ever before, and they are beginning to offer technologies to developing markets to pursue this vast potential. As more of these molecular-based companies commercialize and develop their technologies, costs will continue to come down quickly for molecular diagnostics. As these costs decrease, these markets are becoming increasingly realistic growth opportunities. To fully unlock the potential in the developing markets, a fast, accurate diagnostic that can be purchased for a few dollars will be required. Portable molecular diagnostic systems for diseases such as HIV, TB, malaria and dengue fever are great opportunities to establish growth in developing markets.[17,18]

Future Marketing Forces

Government-Mandated Health Insurance

Healthcare in the United States is changing rapidly. There are many aspects of these changes that create both challenges and opportunities for people considering investments in companies that focus on the diagnosis of infectious diseases. Some challenges will arise as pools of money shrink and the number of

insured patients increases. These two factors will create significant price pressures on diagnostic manufacturers to lower costs, maintain profit margins, and allow for the price reductions that hospital, hospital systems, and purchasing coalitions are requiring. With the additional patients being covered under mandatory insurance programs, it is possible that specific test markets, once deemed too small for investors to consider, may now have enough consumers to provide lucrative opportunities.

Government-required cost reductions may also provide an opportunity to tap into the downstream cost savings that hospitals and integrated delivery networks are going to need to stay viable in the new healthcare environment. Diagnostic tests that can show the economic benefits of a reduced length of hospital stay, a reduction in readmissions, and a reduction in costly drug therapies will have an opportunity to differentiate themselves from their competition. This data will need to be supported by peer-reviewed white papers and clinical evidence that demonstrates these quantifiable benefits. Producing this material can be costly for a small, startup company, but will be a critical component of any market strategy in the new environment.

Consolidation

Hospital consolidation is happening on a global level. In the United States as more hospitals lose funding, it becomes more and more challenging to stay in business. Larger integrated delivery networks, some with global locations, are actively pursuing doctors' practices, urgent-care centers, and community hospitals to gain access to markets they haven't been supplying previously. This could eventually lead to organizations with the ability to purchase tests not only for local networks, but for global ones as well.[19]

Reimbursement

Changing reimbursement in the United States will have an impact on diagnostic tests in the future. Congress passed the Protecting Access to Medicare Act (PAMA) in 2014 to help safeguard Medicare beneficiaries' access to needed health services, including laboratory tests. According to the American Clinical Laboratory Association (ACLA) laboratory testing cuts in 2018 amounted to close to $670 million in reduction of reimbursement for diagnostic testing in which most laboratory test reimbursement was reduced by close to 10%.[20] This will create additional price pressures on novel diagnostic technologies and the ability to bring new solutions to market. Selling tests using these technologies will require the additional associated costs of new product development, scale up to manufacturing-sized lots, and market introduction and acceptance. In the case of novel technologies where the consumer has multiple options and where there is limited differentiation from competitors, vendors will be forced to drastically lower pricing.[21]

Product Research and Development

Historically, companies that developed diagnostic test kits did this using research generated internally. Most diagnostic companies continue to have large research and development structures within their organizations, but starting in the late 1980s, a trend began in which these larger companies acquired technologies and product pipelines from smaller, independent companies. This led to entrepreneurs and innovators financing beginning diagnostic start-up companies. Unfortunately, most of these small companies were at a very early stage of development, where the risk of being successful was small. Companies of this size could only take a diagnostic tool so far given expansive resource required for development, clinical evaluation, and regulatory clearance. As the number of these start-up companies grew, so too did the competition to get a corporate buyer or sponsor. As a result, big companies now demand that technologies are much further along in development. Today, while there are still plenty of opportunities for entrepreneurs to invest in diagnostic startups, the investment is much larger, and the chance of actually being able to sell the technology is much smaller. There remain some pathways that include licensure, third-party development, or pursuing several rounds of investment—all of which are capital and time intensive. A clear exit strategy needs to be considered for these endeavors and the assumption that the "big guys" will come along and scoop up a good idea or novel technology may not be realistic.

Factors That Investors Need to Consider

When large, established diagnostic manufacturers begin a product development process, the strategic marketing team in conjunction with business development will assess opportunities and propose these technologies for development or acquisition. The first step in this market assessment requires a great deal of research into the market need, the clinical disease considerations, and significant competition analysis. Many companies will assemble a target product profile (TPP). This is a master document outlining the proposed development. This document will answer many questions concerning whether to undertake a product development project for a specific diagnostic test. Critical for the success of a TPP or any similar methodology that may be employed, is ensuring that all key details are included in the opportunity assessment. Factors such as the total available market and the potential available market are important. The total available market is the total amount of revenue that is available to a product assuming that there are no competitors. Potential available market is that portion of the revenue that the product might possibly capture. Many times, startup companies will mistakenly assume that both the total and the potential available market for a product are the same. The market numbers should also consider the annual expected rate of growth of the market.

Market size is a very important factor that investors need to consider when assessing an opportunity, but it is only the first step. While the company with the technology must also have conducted research, it is always important for the investor to independently verify the opportunity. A potential investor should also perform an assessment of the attributes of the product that will provide a point of differentiation that hospitals and laboratories will embrace. Oftentimes it is this step that requires some more significant scientific and medical consultation to determine that key point of differentiation. It should be reviewed by key opinion leaders (KOLs) with significant expertise in the specific disease area. In many cases, laboratory directors or KOLs will have broad knowledge and experience across a multitude of disciplines that will allow for some efficiency in looking at technologies.

Current and potential competitors in the field are also another area that must be considered. What are the advantages that a product will offer that are not offered by the competitor? How will competitors react when the new product is introduced? Are there future improvements in the design of the product being considered that may help give it an advantage over competitors? Are there other future competitors on the horizon?

If one looks at a list of the current pathogens in the news today, you soon realize that at least some of them were almost unknown as few as 10 years ago and some are new strains of otherwise known pathogens. Emerging pathogens are a reality in this field, and investors should also consider how adaptable a product or a technology may be. This is particularly important when pursuing diagnostic test kits in respiratory disease and healthcare-associated infections. Pathogens in these spaces change and emerge quickly. Bird Flu (H7N9), SARS, MERS, and COVID-19 are very good current examples of how a pathogen can emerge and result in the almost immediate need for a diagnostic test.

Emerging antibiotic resistance is another area that evolves very quickly. While methicillin-resistant *Staphylococcus aureus* (MRSA) was known as a leading cause of nosocomial infection, as early as the 1980s, it wasn't until more than 10 years later that it was realized that this organism was now out in the community.[22] Rapidly identifying MRSA remains a huge opportunity to commercialize a variety of methods and procedures even beyond simply diagnosing the infection. It is important to continually scan the horizon for the next emerging antibiotic resistances since tracking and identifying these dangerous pathogens early is an area of great concern.

Technology

What innovation is being considered for commercialization? Is it a completely new technology that may present unique challenges during its development, or is it an adaptation of an existing technology? New technology can be a very exciting commercial opportunity, but truly novel technology often has challenges in adoption in the clinical lab. This is due partly to the regulatory nature of the medical-device industry and to the lack of innovators and early adopters in the microbiology lab. There are also cost considerations. New technologies tend to be very expensive and unless the differentiation and value are clear and quantifiable, market uptake can be slow in a price-focused hospital environment. An example of this is MALDI-TOF MS (matrix-assisted laser desorption/ionization time of flight mass spectrometry) technology for the rapid identification of microbiological organisms. This novel technology has gained significant traction in Europe with fewer regulatory restrictions, but has been slower to develop in the United States.

There are still many opportunities to commercialize upon existing technologies. An example of this is in the area of chromogenic growth media. Several manufacturers have now entered the market with a number of new products. Chromogenic media are being used to detect antibiotic resistance for organisms such as MRSA, VRE, and Gram-negative antibiotic resistance.[23] Hospitals are very cost conscious and if they can get an accurate result and time is not critical, these methodologies have proven to be very useful to the lab and hospital.

Estimated Life Cycle for Product

As is true of all products, diagnostic tests have a defined life cycle. Due to several factors mentioned above, however, these cycles can last from just a few years to more than four decades in this industry for a product such as the API 20E.

Government Regulations

The diagnostics industry comes under the control of the FDA using the regulations described under the Code of Federal Regulations Title 21 (CFR 21, available at http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfcfr/cfrsearch.cfm. Accessed October 23, 2020). Links from this website will also direct an investor to databases concerning device classification, product life cycle, and tests approved by the 510(k) route.

Time to Get to Market: Window of Opportunity

These are three critical components when considering an investment opportunity. Questions that need to be considered are:

1. The research and development plan. Is it realistic? What obstacles need to be overcome?
2. Product manufacturing. Is this a product that can be produced on a laboratory scale, but may have limitations when produced in manufacturing sized lots?
3. The time required for all clinical trials and government approvals.

These items are critical in today's environment because new opportunities appeal to a great number of small entrepreneurial start-up companies; and a project that arrives late may find a marketplace already crowded with competitors.

How Will the Product Penetrate the Market?

Consumers of diagnostic tests are supplied either by a company's direct sales supply chain or through a distributor. Hospitals and buying groups negotiate contracts with most of the major distributors and oftentimes choose a single distributor for their facility or system. Partnering with a distributor may allow a company quicker market penetration for its product, but there are tradeoffs in using this supply channel. There are distributors ranging in size from multibillion-dollar organizations, such as Cardinal Health and Fisher Scientific with large national contracts and group purchasing agreements, to smaller, local and regional partners who may have contracts with regional medical centers and laboratories.

In either case, some of the key negotiating points in distributing a product, regardless of the supply chain used, revolve around a company's revenue and gross profit goals. Distributors will require a margin to carry and distribute the product and this must be considered when assessing the gross profit of the product. If the product is highly complex or the positioning and value proposition is highly technical, the distribution sales teams may not have the correct skills to adequately inform the clinical staff, doctors, or laboratory personnel. On the other hand, distributors of almost all sizes will give significantly more market access

than going through a direct channel with a direct sales force. In a distributor model, the company providing the technology to the distributor will need field-based associates who can train their distribution partners on the important aspects of the technical and economic value proposition so they can articulate it to the end user. In addition, if a company decides to use a distributor to sell its products, it should place restrictions on the distributor to prevent or limit it from also selling other products that directly compete.

Even in today's challenging healthcare economics environment, hospitals will continue to purchase products directly from a company. This is particularly true if the product is a very specific, valued niche technology. If this is the case, a direct sales channel may be a good direction to take, particularly in the early stages of market adoption. While there is more control over profitability and value proposition in the direct model, hospital invoicing and collections can be challenging. A strong gross-profit position loses significant value when payments are delayed beyond 120 days. Another factor to consider in looking at the direct-chain path is that most hospitals and laboratories buy tests from a single supplier since vendor consolidation is a benefit for them. If a company has a great test for identifying *Streptococcus pyogenes*, but the hospital or even doctor's office is buying all of their other tests from someone else, even if a test is better, the laboratories may not buy it directly unless the company is partnered with an incumbent and established distributor.

In short, there is a great deal of variables to consider when approaching an investment in the business of microbiology. There is far more detail than can be communicated through a single chapter. The goal of this chapter was to provide some overview of key areas to investigate and be aware of when pursuing opportunities in microbiology. It is important to note that this chapter only scratches the surfaces of the opportunities; there continues to be significant growth in industrial, food, brewing, and a significant number of other microbiology disciplines outside of the infectious disease diagnostics.

Launching a Microbiology-Based Company

Leonard Osser

In preparation for writing this chapter, I read and then reread the chapter on the Business of Microbiology written by Lorrence H. Green and Michael C. Nugent in the *Practical Handbook of Microbiology*, third edition.[1] While it was a scholarly chapter written with a strong focus on microbiology, many of the points made would apply to any industry. Having a background in many diverse industries only some of which involve microbiology, this chapter will focus on the aspects of what I have learned when starting out on the quest to begin a business.

My first observation: If you believe the adage, "if you build a better mouse trap, the world will beat a path to your door," you are mistaken. There are many examples of companies that have had better technologies, but have not succeeded. We invested in such a technology more than 20 years ago that dealt with a common problem: fear of going to the dentist. Studies indicated that one in seven Americans are dental phobic.[2] One of the main reasons for this is the fear of the hypodermic syringe.[3] Our technology not only delivered a drug without pain, but avoided the problem of causing collateral numbness. If this product were marketed directly to the patient, one would have predicted that it would have been readily and happily accepted.

The cost of the small computer was under $3,000, and the disposable cost was approximately $3. Studies indicate that there are over 300 million dental injections in the United States per year, with a potential market of approaching $1 billion.[4] As such, one would have expected sales of this instrument to have been significant. Why then is it only a $9 million business? The reason quite possibly is that while it was the patient that most benefited from the product, it was the dentist that was actually the customer. In the case of dental injections, the current standard of use is the hypodermic, which was introduced in 1885.[5] The barrier is not technology, funding, regulation, or the cost of a product that does not deliver; it is overcoming market inertia. To be successful, you must make certain that the market needs, wants, and must have your product.

In pursuing a career as someone who both starts and develops companies, I have not only read business books, but I have read the works of Marcus Aurelius. While getting an MBA will help, getting actual experience will be invaluable. In addition, I have found these four books to be almost required reading for any business person: *The Art of Worldly Wisdom,* by Baltasar Gracian; *The Prince,* by Nicolo Machiavelli; *The Art of War,* by Sun Tzu; and *Why Smart People Do Dumb Things,* by John Tarrant and Mortimer Feinberg. These books have taught me that this career path is one in which you will make mistakes, many mistakes. When this happens, you must fix them immediately. Do not wait. Sometimes you may find yourself making mistakes until you get it right. In the companies that I have been involved with, I have found that the biggest mistake that CEOs made was keeping the wrong people for too long. Another thing these books taught me is to always tell the truth—even when you find that no one believes you. If nothing else, it easier to remember. Also, spend time just thinking. Finally, if people think that you are wasting time, then you are probably succeeding.

When starting a new business or investigating an opportunity, whether it be a general company or one that specifically involves microbiology, one should work backward. What is the need? What is the need that is perceived by the market? What is the value of this need to the buyer? Is the buyer the one who can write the check? In the case of the dental instrument, is it the buyer that will actually be driving the market?

Another observation is that while the people reading this chapter might think that the microbiology industry is not like any other, that is not true. All businesses are the same. I have been involved in several health-related companies, and I am by no means a microbiologist. This means that I must hire the right experts, people who can explain the science to me and to other investors in a way that we will understand. I have found that the best people for this are the creative people in large companies. While working in stable positions, they usually tire of large companies due to the wasted time dealing with bureaucracy and politics. Get the best possible people, then watch them and learn from them. Let them fulfill your agreed-upon goals. Enable them, and don't get in their way.

Before starting your company, figure out how much time and money will be required to make the company self-sustaining. Once you have figured out what that number is, then double it. Many great and useful ideas do not come to fruition because the entrepreneur simply runs out of capital. Always try to get capital from people that have it, not from people that must raise it. This is less complicated and almost always less costly in the long run, to say nothing of much less risk and time spent. Do not raise money from relatives or friends.

In the arena of funding options, we have rather large groups of sources. All the following funding options come with their unique risks: Venture capitalists, vulture capitalists, venture funds, family funds, tertiary market, bankers, crowd funding, angel investors, etc. These people fully understand your financial situation. They also know that you will not perform on time. They know that you will need more money than you have planned for.

Do not, however, mistake their helicopter for your umbrella. If you manage to attract a true angel long-term investor who will be supportive and ethical, you have achieved nirvana. There are such people, but not many. To varying degrees, the other investors will set up arrangements that anticipate that you will not reach your goals on time. Depending on their level of mendacity, they will acquire more and more of the company each time you do not meet a goal. Their models anticipate this happening. If you have a public offering too soon for too little net money, the same will occur to a lesser degree.

If you engage someone to help you find funding (called a finder), interview all of their clients going back at least five years. Pay on performance only—do not pay any upfront money when raising capital. If they want upfront money, that is their profit center. This means that even if the company does not succeed, they will.

Do not be impressed by opulent offices or firm names. Many excellent investors work from offices no bigger than closets. It is the person that you work with who is key, not their firms. This is also true for attorneys, advisers, and bankers. When interviewing, get the names of all their past deals, not just the specific references they supply. While hearing success stories is important, most companies do not succeed. You will also learn about your investors by finding out about their failures. While you're raising money, you're not running your business—this means that you need to raise sufficient money before you need it. When people want to give you too much money, take it, you'll probably need it.

Form a board of people who are willing to invest. Pay them in stock, not money. Get people who know more than you do. A top name in the field always helps. Investigate them. A public underwriting will be impossible should anyone on your team have regulatory issues, such as a bankruptcy. Board members are not there to agree with you, they are there to support the company by expressing their views. Once a decision is made, the board is there to support it. Again, they do not have to be your friends, they must, however, be able to function well together.

When you plan the amount of time it will take until the company is self-sufficient, triple it. Nothing goes as planned you will require much more time and money than you envision. You have to be prepared for numerous setbacks prior to reaching your goal, and you must have enough time and money to deal with them. If you then do not have access to either of the multiples of time and money, do not start the business. This can be difficult given other obligations that you may have in life, but I have found maintaining a positive mental attitude to be very helpful.

While the science and technology are important to any company, what is more important are investors. You must develop a plan that shows success along the way so investors can feel positive about what they are doing. Investors must see that goals are being achieved. This will enhance the opportunity to raise more capital. Raise much more money before you need it, even if you are certain you will not need it. If you don't, it will cost you much more of the company when you do need it. Make sure that your backers have significantly greater resources than they are investing.

I have found especially in trying to bring new healthcare products to the market that the biggest enemy I encounter is obstinance. To get the market to accept a new product, I have to deal with potential users who, for a good part of their lives, have trained and used the products that you want to replace. They are experts on the old technology, and if you challenge them, you will not be well received. Even if what they have been doing is problematic, even if your solution is obviously superior, they will find reasons not to change, including worries of your product being too slow, too expensive, too difficult to learn, etc. However, after you address all these issues, they probably will still not buy your product because they are being challenged. I have found that the solution is to make certain that you show them that you are enhancing their abilities and making them more valuable, rather than challenging their abilities.

To get new products or technologies accepted you will probably have to partner with or at least convince those opinion leaders that can force the issue. These may include hospitals, insurance companies, regulatory agencies, etc. Have successful experts evaluate your projects. Meet with the decision makers, end users, buyers, salespeople, and owners of distribution companies. Do they all want your product? What do they envision the barriers will be? Will they buy it for the price that will make your venture successful?

Of course, with any new product you must always have top patent attorneys first review your ideas. Without proper patent protection, it will be far more difficult to raise money. This is not an inexpensive proposition. You will also need excellent attorneys to help you with fundraising. Before selecting one, interview many. Focus on those that have securities and fundraising backgrounds. Remember in your search that the best attorney and the best surgeon are not necessarily the one that you like the best. Their ability, not their bedside manner, is what you're looking for. Their fees, although they may tell you are carved in stone, in fact they are negotiable like everything else. Estimates are exactly that; get a firm commitment on the high end. Interview others for whom they have raised money.

Everything that you do will depend on people—investors, staff, attorneys, accountants, auditors, regulators, etc.—so you must hire the best. To do otherwise will not serve you well. Be 100% loyal to your partners and staff. If not, you will never have their loyalty. Also, remember that no one, including you, is indispensable. Your shareholders want you in the business for the money, not ego gratification. The investors want a return. If you are reading this, then you are probably thinking of being an entrepreneur for the first time. All those that you encounter will, in their area of expertise, have more knowledge and experience than you. You may think that you're smarter, and in fact you may be, but the odds are on their side. The larger and more established organizations are almost always favored.

Something that may not be obvious is that while having the best test kit in a market might be important, it is not necessarily sufficient. Sometimes, the finances might cause a distributor, for instance, to accept a product for sale that isn't the best in the marketplace because it offers them the best financial return. Sometimes they may accept an inferior product and even put up a very small amount of money for it, if they can be assured that they will get the product as soon as it is available. There are many examples of companies that have had inferior technologies but have succeeded for other reasons.

I have found that a very good indicator of how well-accepted a product may ultimately be is seeing if a distributor will invest

any of their own money at the beginning or give you an irrevocable order. While many will be kind and encouraging, an investment no matter how small, will tell you what they really think of your product.

Having the product completed, functioning perfectly, approved by regulators, and patented is not the end of the process, it is just the beginning. It has to sell at a profit and it must continue to sell. Once you are in this position you then must start thinking about what the next generation of your product is going to look like. Competitors are always examining each other's products in great detail to see what they can learn. In the case of our painless injection device mentioned at the beginning of this chapter, I once had a meeting with the marketing people from one of the potential competitors in which we were shown *their* new needle. They were certain it would significantly reduce pain because it was sharper than the needle of their competitors. However, needle sharpness is almost irrelevant regarding pain. Pain is controlled by the pressure and flow rate of the drug entering the body. In order to show how much better their sharper needle could penetrate tissue, they produced a small device to be used as a demonstration for potential customers. They were able to show that their needle penetrated more easily. Unfortunately, it did not reduce pain when used. They were thinking in a small, irrelevant box. You need to develop the next generation before one of your competitors does.

While this might appear counterintuitive, to be successful in developing new companies or promoting new technologies—whether they are microbiologically based or not—the most successful people are not going to be the smartest, they are going to be the ones who can escape the confines or their own subjectivity and do things others do not think are possible. Perhaps Einstein said it best:

> Imagination is more important than knowledge. For knowledge is limited, whereas imagination embraces the entire world, stimulating progress, giving birth to evolution.[6]

History and Role of the Dental Hygienist

The first dental hygienist on record was in 1906 and the first dental hygiene courses began in 1913 in Bridgeport, Connecticut. In those early days, full academic courses ran for a duration of one year with dental hygiene students only permitted to remove "lime deposits, accretions, and stain" on teeth above the gumline.[1] Fast forward to today, and the roles of the dental hygienist have vastly improved. Graduates can now earn associate, baccalaureate, and master's degrees in dental hygiene with emphasis not only on removing said accretions from the teeth above and below the gumline, but to now having a full understanding of how the body reacts to such accretions and the necessary measures for disease prevention for both the patient and the clinician.[1]

Currently, the dental hygienist's role is one that is collaborative amongst dentists, physicians, chiropractors, nutritionists, nurses, and other healthcare professionals. This intra and interprofessional collaboration is partly what makes their role so valuable in maintaining optimal health. For example, by collecting all necessary medical history data from a patient, the dental hygienist may need to confer with pacemaker companies, physicians, such as cardiologists, gastroenterologists, chiropractors, and other healthcare professionals to ascertain if modified treatment is required. Dental hygienists provide educational, clinical, and consultative services to individuals and populations of all ages in a variety of settings and capacities, including private dental practices, community hospitals, university dental clinics, prison facilities, long-term care facilities, and schools.[2]

The following are many responsibilities of current hygienists.[2,3]

- Patient screening procedures, such as assessment of oral health conditions, review of the health history, oral cancer screening, head and neck inspection, skin inspection, dental charting and taking blood pressure and pulse

- Taking and developing dental radiographs (x-rays)
- Assessing, diagnosing, planning, implementing, evaluating, and documenting treatment for prevention, intervention, and control of oral diseases
- Removing calculus and oral biofilm/dental plaque (hard and soft deposits) from all surfaces above and below the teeth
- Applying preventive materials to the teeth (e.g., sealants and fluorides)
- Teaching patients appropriate oral hygiene strategies to maintain oral health; (e.g., tooth brushing, flossing, and nutritional counseling)
- Counseling patients about good nutrition and its impact on oral health
- Making impressions of patient teeth for study casts (models of teeth used by dentists to evaluate patient treatment needs)
- Performing documentation and office management activities
- Practicing proper disinfection and sterilization techniques

Dental Hygienists' Educational Role in Disease Prevention

Studies consistently support the correlation between poor oral health and several systemic diseases, such as periodontal disease, cardiovascular and cerebrovascular disease, respiratory disease, certain cancers, diabetes, low birth-weight babies, and possibly dementia.[4,5] Dental hygienists use evidence-based research to inform patients of such connections. The dental professional's role in prevention is through thorough oral education and assisting patients in devising specific home-care regimens to reduce and prevent oral inflammation in hopes of preventing many systemic diseases.[4]

Oral-Pathogens and Dental Hygiene Exposure

The oral cavity plays a central role in the process of infection.[6] More than 700 bacterial species inhabit the oral cavity, as well as species of several other types of microorganisms. Many of these can cause both local and systemic disease. Specific microorganisms and diseases that dental healthcare professionals and patients are at risk for include but are not limited to staphylococci, streptococci, *Mycobacterium tuberculosis*, hepatitis B and hepatitis C viruses, herpes simplex virus type 1 and type 2, human immunodeficiency virus, mumps, influenza, rubella, pneumonia, tuberculosis, influenza, Legionnaire's disease and severe acute respiratory syndrome (SARS).[9]

The majority of dental procedures allow such microorganisms to become airborne in the form of aerosols and stay suspended contaminating the air within treatment areas.[7] According to Aas et al., "Aerosols can originate from a variety of patient sources including plaque, calculus, dental materials, blood, saliva, nasopharynx, and inadequately disinfected dental unit waterlines".[7] These aerosols place dental healthcare professionals and patients at risk for illness due to the exposure of many infectious agents, including bacteria, viruses, and fungi.[8] The teeth also serve as a reservoir for respiratory pathogen colonization and subsequent nosocomial pneumonia.

Influenza and Pneumonia

The influenza virus is the cause of the majority of acute respiratory illnesses annually.[10] The virus is transmitted from person to person through close contact, which is something that dental professionals cannot avoid. Transmission can occur as a result of droplet exposure from coughing or sneezing, contact with a contaminated surface and then self-inoculation onto mucosal areas, such as the mouth, nose or eyes, or through aerosols. This can be spread from one clinician to another, from clinician to patient, from patient to patient, or patient to clinician.[10] As soon as a person opens their mouth, aerosols are spread into the air. Additional aerosols are spread via use of ultrasonic prophylactic devices and dental instruments, which can cause aerosols to remain in the air for up to 2 hours.[9] Dental professionals can take the following precautions to limit the transmission of the influenza virus: Educating staff members about symptoms and prevention, following appropriate infection control protocols, such as wearing a (NIOSH)-certified particulate-filter respirator (e.g., N95, N99, or N100), and donning other proper personal protective equipment (PPE), practicing proper hand hygiene and sterilization methods, avoiding persons if they have been diagnosed with the virus, actively screening patients who enter the waiting area before treatment is performed, and employing the use of air purifiers.[8–11]

The same precautions can be taken by dental professionals to prevent the spread of pneumonia within a dental setting amongst each other and patients. Since dental hygienists are also permitted to perform prophylactic procedures in long term-care facilities, it is vital that aspiration pneumonia/ventilator-associated pneumonia be prevented. By performing thorough and routine oral care to remove oral biofilm, the number of oral bacteria can be reduced, possibly inhibiting the development and mortality rates of pneumonia.[12]

Tuberculosis

Mycobacterium tuberculosis (*M. tuberculosis*) is the pathogen responsible for causing tuberculosis (TB). The infection is spread through inhalation when an individual with active pulmonary TB coughs, sneezes, or even sings, causing droplet nuclei.[13,14] A clinician or patient can transmit the disease in less than an hour in some cases. The risk of developing TB is higher in those born outside the United States, residents and employees who work in high-risk facilities such as correctional facilities, long-term care facilities and homeless shelters, and in healthcare professionals who care for those who are at high risk. Although the risk of transmission is low amongst dental professionals, contraction is still possible since they can legally care for patients in correctional institutions and long-term care facilities. There are even documented cases of transmission within the dental setting.[11] The Centers for Disease Control and Prevention (CDC) updated their guidelines in 2005 for preventing transmission of

M. tuberculosis in healthcare settings.[13] All dental settings need to follow a TB infection control program based on three levels of controls. The most important component of this program is the use of administrative measures to reduce the risk of exposure to potentially infectious persons. Environmental controls reduce the spread and concentration of infectious droplet nuclei in the air. And the use respiratory protection and respiratory hygiene to reduce the risk of exposure to infectious droplet nuclei that may be expelled into the air.[14]

Although the CDC does not recommend routine immunization of United States healthcare workers against TB, it does recommend all persons in the dental office who have the potential for exposure to *M. tuberculosis* through air space shared with persons with infectious tuberculosis disease (which essentially means all personnel) be tested for infection. This can be done by a two-step baseline tuberculin skin test at the beginning of employment. The CDC recommends annual TB education for all healthcare workers, which is to include information about TB exposure risk.[14]

Hepatitis B Virus (HBV)

The hepatitis virus causes liver disease, which left untreated may develop into chronic diseases, such as cirrhosis, liver cancer, liver failure, and even death.[15] In 2016, 3,218 cases of acute hepatitis B (HBV) infection were reported in the United States. And between 847,000 to 2.2 million people in the United States are estimated to be infected with chronic HBV infection. The HBV can be transmitted through direct and indirect contact with the virus. Direct contact includes a percutaneous injury (such as a needlestick or cut with a sharp object), contact with mucous membranes, nonintact skin with HBV-positive blood, or other bodily fluids. Indirect contact includes operatory equipment or contact with airborne contaminants (blood and saliva) present in aerosols and respiratory fluid.[15,16] The use of ultrasonic scalers increases the amount of aerosols produced, allowing the virus to become more easily airborne.[16] Although blood is the most efficient mode of transmission, the virus has been found in other body fluids, such as bile, nasopharyngeal secretions, saliva, and sweat. The risk of infection after a needlestick with HBV-positive blood ranges from 23% to 62% depending on the individual's immunity. Although percutaneous injuries are the most common mode of transmission, the majority of HBV infections among dental practitioners occur from infected blood or body fluids coming in contact with mucosa or existing breaks in the surface of the skin.[15]

Dental practitioners need to follow proper infection control protocols to avoid direct contact with blood and saliva during dental procedures, as well as receive the HBV vaccine. In the past, dental practitioners had a three- to four-fold higher risk of HBV infection than the general population, but vaccines and precautionary methods have contributed to a decrease in risk.[15]

Hepatitis C Virus (HCV)

Although hepatitis C (HCV) is a short-term illness, it is still deadly. In 2016, 18,153 people died from the hepatitis C virus and the death toll continues to rise annually.[15] The virus can be transmitted through a percutaneous injury (such as a needlestick or cut with a sharp object) or contact between mucous membranes or nonintact skin with blood, tissue, or other bodily fluids. After a needlestick exposure to HCV-positive blood, the risk of HCV infection is approximately 1.8%. HCV has been detected in saliva, but as of yet, no undisputed case of HCV salivary transmission has been documented. However, this may change, therefore, dental professionals should take the same infection control precautions as all other infectious diseases. Unlike HBV infection, there is no effective vaccine or postexposure prophylaxis available for HCV infection.[15]

Cytomegalovirus (CMV)

Cytomegalovirus (CMV) is a virus that belongs to the *Herpesviridae* family.[17] It is frequently excreted in saliva, particularly in children and individuals who suffer from significant immune suppression. However, 11–33.5% of the healthy population can also excrete this virus. Therefore, dental practitioners may be at higher risk of developing the CMV infection due to frequent contact with saliva of infected persons.[17]

Epstein-Barr Virus (EBV)

The Epstein-Barr virus (EBV) also belongs to the *Herpesviridae* family.[18] More than 90% of the adult population is infected with EBV and it is associated with the nasopharyngeal carcinoma, oral hairy leukoplakia, and lymphoma.[19–21] Transmission occurs mainly by exchange of saliva.[20] The infection is asymptomatic or mild in children, but it causes infectious mononucleosis in adolescents and young adults. Once established, the virus often remains dormant and individuals become lifelong carriers. The virus persists in epithelial cells of the oropharynx and possibly also in salivary glands. The primary site of EBV infection is the oropharynx. It has been noted that at any point in time, as many as 20–30% of healthy adults who are previously infected with EBV shed the virus in low concentrations in their oral secretions.[18]

The EBV has also been implicated in the pathogenesis of advanced types of periodontal disease.[20] EBV DNA is detected in 60–80% of aggressive periodontitis lesions and in 15–20% of gingivitis lesions or normal periodontal sites. EBV and cytomegalovirus often co-exist in marginal and apical periodontitis.[20] Dental practitioners should look for signs of periodontal disease and oral cancer during routine examinations.

Herpetic Whitlow

Herpetic whitlow is an acute viral infection of the hand caused by the herpes simplex virus (herpes simplex virus 1 or 2). Its characteristic findings are significant pain and localized erythema followed by development of small nonpurulent vesicles.[22] This infection can be found in any age group. However, it is most common in children who suck their thumbs and in healthcare providers (medical or dental) who are exposed to patients' oral mucosa while not wearing gloves. The infection is most common in dental hygienists and respiratory therapists. Its incidence has been reported at 2.4 cases per 100,000 people per year.[23] Prevention includes donning proper PPE and practicing proper hand hygiene.

Legionnaires' Disease

Legionnaires' disease is a type of pneumonia.[24] Patients and dental healthcare workers may contract a *Legionella* infection through inhalation of potentially contaminated aerosols produced by ultrasonic dental instruments and through exposure from contaminated dental unit water lines. Those at greatest risk for developing the infection are individuals who are current or previous smokers, are older than 50, and/or are immune-compromised.[24] Ensuring that dental unit water lines are properly cared for can help prevent contraction of this infection in the dental office.

Human Papillomavirus (HPV)

The human papillomavirus (HPV) is the most common sexually transmitted disease in America and is known to cause very serious health issues, including oropharyngeal cancer. Human papilloma cancers are associated with 72% of cancers in the back of the throat, base of tongue and tonsils in men alone. Reports show that 79 million individuals are infected with some strain on HPV.[25] While dental practitioners already screen for oral cancer, their prevention efforts can expand to education and recommendations regarding additional prevention efforts, such as the HPV vaccines.

Human Immunodeficiency Virus (HIV)

The human immunodeficiency virus (HIV) continues to be a worldwide health issue affecting 36.7 million people globally.[26] HIV infection may result in destruction in the oral mucosal tissues. It is possible that immunological changes following HIV infection compromise the integrity of physical barrier in the oral cavity and contributes to chronic inflammation.[26]

Blood has the greatest amount of infectious viral particles but all bodily fluids, secretions, and excretions other than sweat may contain transmissible infectious agents. Avoiding exposure to blood and bodily fluids is the primary key to prevent transmission of the virus in dental care settings.[27] During dental procedures, the risk of HIV transmission is increased because saliva tends to become contaminated with blood. Standard precautions should be followed with all patients, whether or not they have been diagnosed with HIV and dental personnel should don PPE and utilize appropriate barriers (e.g., gloves, masks, protective eyewear, and barrier tape and covers) whenever there is potential for contact with body fluids, nonintact skin, or mucous membranes. Though the occupational source of greatest risk of HIV transmission is percutaneous injuries, needlestick exposures with HIV-infected blood has a low transmission rate of approximately 0.3% in dental settings.[27]

Periodontal Organisms Associated with Systemic Disease

Porphyromonas gingivalis

Human subgingival plaque harbors more than 700 bacterial species and considerable research has shown that *Porphyromonas gingivalis (P. gingivalis)*, a Gram-negative anaerobic bacterium that resides subgingivally, is the major contributing etiologic agent causing chronic periodontitis, as well as several systemic diseases.[4,28] *P. gingivalis* causes direct and indirect destruction of the periodontium by evoking an inflammation response by producing a myriad of virulence factors.[28]

P. gingivalis has also been found in the brain plaques of Alzheimer's patients and has been shown to impair cognitive functions.[29] Recent animal models demonstrated that inflammation that results from *P. gingivalis* causes alterations in neurovascular functions, resulting in an increase in the blood-brain barrier permeability, reduction of nutrient supplements, and aggregation of toxins. Elevated levels of proinflammatory mediators in the blood can lead to their direct or indirect transport to the brain, which could accelerate brain impairment.[30]

P. gingivalis has also been implicated as the main pathogen in several cancers, including pancreatic cancer, oral squamous cell carcinoma, head and neck cancer, and precancerous gastric and colon lesions.[31]

Aggregatibacter actinomycetemcomitans

Epidemiological studies have a proven association between the periodontal pathogens *Aggregatibacter actinomycetemcomitans* (formerly *Actinobacillus actinomycetemcomitans*) and *P. gingivalis*, and coronary artery disease (atherosclerosis) and cerebrovascular disease (stroke).[32] Both species have been shown to increase proinflammatory cytokines causing local and systemic inflammation and contributing to atherosclerotic plaques in the coronary arteries and cerebrovascular arteries. Endarterectomy studies show that more than 40% of atheromatous plaques in the carotid arteries presented with antigens from periodontal pathogens.[4,32] Individuals with active periodontal disease are twice as likely to suffer from heart attacks and at least three times as likely to suffer a stroke.[33,34]

Several oral bacterial species have been investigated for their role in inflammation and the link between chronic periodontitis and diabetes. *A. actinomycetemcomitans* and *P. gingivalis* have both been implicated in such a link through their ability to interfere with the immune response.[35]

Methods of Disease Prevention

Not only do dental hygienists/dental professionals need to take precautions to prevent oral disease for their patient's through education and devising effective home care regimens and treatments, but they must also take necessary precautions to prevent infectious disease from spreading from patient to patient, clinician to patient, patient to clinician, clinician to clinician, and clinician to other workers. Dental professionals should follow the CDC current recommendations that are outlined in the *Guidelines for Infection Control in Dental Health-Care Settings* and *The Summary of Infection Prevention Practices in Dental Settings: Basic Expectations for Safe Care*.[9,36] These guidelines highlight the existing CDC recommendations, state basic infection prevention principles and recommendations for dental professionals, and reiterate standard precautions as the foundation for preventing transmission of infectious agents.

Prevention of Aerosols

Dental patients and professionals are constantly exposed to tens of thousands of aerosols per cubic meter and the potential to breathe contaminated air during procedures is almost unavoidable.[37] Aerosols are extremely small particles (>50 µm) that can stay suspended in air for up to two hours after completion of dental procedures and inhalation can be deadly.[7] As previously noted, aerosols consist of water, saliva, blood, microorganisms (bacteria, fungi, viruses, protozoa), and other toxins and can originate from several patient sources, such as oral biofilm, calculus, and improperly disinfected dental unit water lines. The use of a dental turbine handpieces, air-polishers, air/water syringes, hand instrumentation, laser or electrosurgery units, prophy angles, and ultrasonic scaling devices have been reported to increase bioaerosol levels dramatically.[6,7] Inhalation of aerosols by patients and clinicians produced during dental procedures have the potential to cause adverse respiratory health effects.[37] Dental professionals should to be cognizant of the dangers of aerosols within treatment areas and need to assume the responsibility of preventing the risk of transmission before, during, and after patient care.

Many procedures that dental professionals can incorporate into daily practice to reduce aerosol production include utilizing high-velocity air evacuation, preprocedural antimicrobial mouth rinses, flushing water lines at the beginning of the workday and between each patient, donning PPE, and employing air purifications systems.[7,36]

High-Volume Evacuation

The use of a high-volume evacuator/high-velocity air evacuation device is commonly used in dental settings to help reduce the transmission of aerosols. Its suction capability and wide opening draw a large volume of air into it, diminishing aerosol emission by 100 cubic feet per minute and reducing the amount of bioaerosols created during patient treatment by as much as 90%.[38]

Preprocedural Rinse

Providing patients with preprocedural antimicrobial rinses for 60 seconds, such as chlorhexidine gluconate, essential oils, or povidone-iodine, has shown to decrease the level of oral microorganisms in aerosols generated during routine dental procedures, as well as reduce the amount of microorganisms that may be introduced into the patient's bloodstream during certain invasive dental procedures.[9]

Air Purification

Control of aerosols in confined, poorly ventilated spaces presents a challenge and can spread microorganisms from patient to patient.[39] The aerosols in dental treatment areas can be purified through the use of air cleaning systems, i.e., high efficiency particulate air (HEPA) filters, gas filter cartridges, and electrostatic filters. HEPA filters continuously trap aerosols and retain particles as small as 0.3 µm while electrostatically charged post-filters help to purify air by minimizing dust, particulates, and vapors.[6]

Dental Unit Water Quality

Dental hygienists use both air and water devices, such as dental handpieces, air/water syringes, and ultrasonic/sonic scalers that are attached to the dental unit for use during routine treatments. Several species of bacteria, fungi, and protozoa have been cultivated from these dental unit waterlines and thus are a potential source of infection.[9,40] The specific bacteria known to cause adverse health conditions include species of *Staphylococcus, Streptococcus*, *Legionella*, *Pseudomonas*, *Propionibacterium, Stenotrophomonas,* and *Mycobacterium tuberculosis*.[41,42] To ensure the delivery of quality water, the dental hygienist should follow the manufacturer instructions for proper disinfection to avoid cross-infection during treatment. The CDC recommends air and water be discharged for a minimum of 20–30 seconds after every patient. This should be completed for all devices that connect to a water line and enters the patient's mouth. Some manufacturers require purging water lines at the beginning of the workday as well as between patients for two minutes. Monitoring water quality can be completed through laboratory or in-office testing kits. Independent reservoirs, chemical treatment, filtration, sterile water delivery system, or combinations of technologies are modalities of improving/maintaining water quality.[9]

Disposable Items

Single-use devices, otherwise known as disposable devices, are meant for use on one patient during a single procedure. Such items are not meant to be cleaned, disinfected, or sterilized and used on additional patients. Disposable devices/items eliminate the risk of patient-to-patient contamination because the item is disposed of and not reused, therefore, such items should be used when applicable.[9] Examples of common single-use items/devices employed by dental hygienists include but are not limited to: High- and low-speed volume evacuation devices, such as saliva ejectors and high-speed evacuation tips, air/water syringe tips, barrier wrap, masks, gloves, paper drapes, paper bibs and paper bib holders, bracket table paper, single-use needles, prophylaxis cups and brushes, prophylaxis angles, plastic impression trays, retraction devices, cotton rolls, gauze, and irrigating syringes.[43]

Personal Protective Equipment

As noted by the CDC, personal protective equipment is a means of protecting skin and mucous membranes (eyes, nose, and mouth) from transmission of pathogens found in blood and other potentially infectious material. Donning PPE, such as proper fitting gloves and surgical masks, protective eyewear with solid side shields or face shield, and protective clothing/disposable arm length gowns are necessary measures.[9] Intact skin is the primary defense against disease; lotions and petroleum based lubricants can breakdown the integrity of gloves, and therefore, are only recommended for use at the end of the day and not during patient care. The dental professional should don PPE whenever there is a potential to encounter splatter during patient care and also during disinfecting treatment areas because bioaerosols stay suspended in the atmosphere after commencement of patient care. Providing protective eye wear for patients is a necessary prophylactic measure meant to reduce the risk of

infection if splatter is generated during procedures. Masks and gloves should be changed between every patient. Additionally, PPE should be changed if torn, wet, or visibly soiled.[9] The CDC and the National Institute for Occupational Safety and Health (NIOSH) recommends that healthcare workers wear a NIOSH-certified N95 or improved respirator (N99 or N100) if providing care for patients with known infectious diseases, such as influenza and other infectious diseases.[44] To reduce disease transmission, it is imperative to remove all PPE and wash hands prior to exiting the treatment area.[9]

Sterilization Methods and Testing

Cleaning, disinfecting, and sterilization methods are necessary precautions for the prevention of disease in a dental setting and dental hygienists must be trained to properly follow these precautions.[36] According to the CDC's sterilizing practices guide[45]:

> Ensuring consistency of sterilization practices requires a comprehensive program that ensures operator competence and proper methods of cleaning and wrapping instruments, loading the sterilizer, operating the sterilizer, and monitoring of the entire process. Such procedures should take place in a central processing area to minimize disease transmission.

Sterilization monitoring is done through biological, mechanical, and chemical indicators. Biological indicators, aka spore tests, are the most accepted means of monitoring sterilization because they assess the sterilization process directly by killing highly resistant microorganisms. Spore tests are only performed weekly, therefore, mechanical and chemical monitoring should also be employed.[45,46]

Conclusion

Any healthcare profession that involves contact with mucosa, blood, or blood contaminated with body fluids should be compliant and follow standard precautions and other methods to minimize infection risks amongst themselves and patients, such as training on bloodborne pathogens as outlined by the Occupational Safety and Health Administration (OSHA).[16,47] According to the CDC's recommended infection control practices for dentistry:[48]

> Dental personnel may be exposed to a wide variety of microorganisms in the blood and saliva of patients they treat in the dental operatory. Infections may be transmitted in dental practice by blood or saliva through direct contact, droplets, or aerosols. Patients and dental health-care workers have the potential of transmitting infections to each other.

To minimize transmission potential, precautions include following proper hand-hygiene protocol (washing hands before and after wearing gloves and prior to touching potentially contaminated surfaces), changing gloves when torn or soiled, utilizing proper PPE and barrier techniques during treatment, properly disinfecting and sterilizing dental instruments and operatory surfaces, using disposable items when possible, instituting the use of high-volume evacuation systems, maintaining dental unit water quality, providing patients with preprocedural mouth rinses, and employing air purification systems to help reduce aerosols.[6,9,27,36–40,45] By practicing a combination of these protective measures, the risk of infection from patient to patient and dental professional to patient can be greatly reduced.

Our Middle School Program

Introduction

> Many of tomorrow's jobs… don't exist today. These jobs will most certainly require a workforce of highly educated workers, utilizing skills that have not yet been identified in fields and operations that, at the moment, are only being discussed in theory.
>
> Hearing on Careers for the 21st century, 2004[1]

While meeting the national/state standards is foremost in our minds, educating students is so much more than how they perform on high-stakes tests at the end of the year. Embedded in each assignment we give them are the intangible skills that students learn that aren't measured on a test. Some of these skills are:

- Working in a group. Students must learn how to function as a group. This also teaches them that if work does not get done, the entire group fails.
- Communication. Students must learn how to get the rest of the group to listen to them, and how to listen to others.
- Materials and methods. How are the parts put together to work? The directions are very specific (on purpose).
- Creativity. What if we try this? Are there alternate but viable solutions to a testable question that I haven't even thought of yet?

Attracting Students to Our Program

As classroom teachers, we all know the dreaded email from the principal that starts with "Thank you so much for volunteering…." For us, this year's volunteering opportunity was to develop an engaging hands-on science experience for our Open House Meeting whose purpose was to recruit students to our medical magnet middle/high school. Open House at our school is a family affair. Parents, siblings, and extended family all attend. We had to design an activity that would appeal to all. We chose to do a project involving microbiology. What's more engaging that viewing drops of water teeming with microorganisms? We recruited students that we taught last year to be lab assistants. With a sample of pond water, our students interacted with the student visitors to help them make and view their slides in our classroom microscopes. Parents were impressed as their children looked up from their microscopes and exclaimed, "Mom you have got to see this!" There was minimal set up and clean up. Our former students were excited to assist potential students. We overheard more than one visitor state, "This is the school I want to attend."

First Day of School

In secondary schools across the nation, the first day of school is where students are sitting class after class listening to classroom/school rules and procedures. This year, we switched the lesson plan to include learning stations. Around the classroom we designed short self-directed lessons that a group of two to four students finished in 15 minutes. They rotated through each

station in a clockwise rotation. Of course, there was a station that included classroom expectations, as well as one that included an ice breaker to meet your new classmates.

We wanted stations that would give students a hint of what concepts we would study this year. Microscopes were set up with prepared plant and animal slides, and students were asked to look into the microscopes and decide whether what they were observing on the slides were plants or animals. This exercise also served as a preassessment for later exercises that meet one of our elementary benchmarks: having students identify structures in plant versus animal cells. (Today's public-school educators are given a curriculum that is written to meet the science benchmarks that the State Board of Education has determined that will be taught. National benchmarks are described in Appendix 1.)

The Microbiology Unit

Many of the microbiology investigations that are assigned in our middle school classrooms are common to middle schools across the nation. The excitement for us as educators is when a student looks up from their microscope declaring, "Is there a job that includes microscopes?" Although not a specific benchmark, students need to learn how to operate a microscope to have a successful experience. Learning the specific parts and how to focus a microscope is accomplished through the "d lab." Using a wet mount technique, students make their own slides using a typed letter d and drops of water. Students learn that the microscope reverses and inverts the image when they observe that the "letter d" becomes the "letter p" when viewed under the microscope. To address the benchmarks that compare animal and plant cells, students will prepare their own slides using onion cells. This "tried and true" investigation allows students to make their own slides learning proper technique for making wet mounts.

Making animal-cell slides is a little more difficult, because for several years, our district has banned the traditional cheek cell lab due to possible pathogen transmittal. Looking for a creative way to examine epithelial cells, we have students rub clear tape on their inner arms. Following this, the tape is then pressed onto a clean slide. Using methylene blue, the transferred epithelial cells are stained and then observed.

One of our benchmarks is learning the levels of taxonomy from species up to domains. Knowing the different kingdoms is essential to mastering these benchmarks. Middle school students are familiar with Kingdom Plantae and Kingdom Animalia, but Kingdom Protista, Kingdom Fungi and Kingdom Monera are a mystery.

Students are thrilled to look at prepared slides of paramecium, euglena, and volvox. But what is even more exciting is investigating life in a drop of pond water. Aside from freshwater that is available near school, a filter from a classroom fish tank is an interesting source for Protista.

Last Days of School

The end of the school year is always hectic. Our students must turn in their textbooks, clean out their lockers, and, of course, complete the exams that will be important in determining their final grades. Here again, microbiology is an important part of the process. Every school has a collection of prepared microscope slides that can be organized into stations. As students rotate through the stations, there are task cards at each station that direct the students to observe a specific part of the slide. Students are engaged and learning new content.

Our High School Program

Introduction

One of our goals as teachers of high school environmental science is to instill in our students a sense of stewardship for our planet's natural resources. It is not enough that the students leave the school year knowing more about the soil, the groundwater, or the atmosphere. Rather, we want them to be able to act on that knowledge as environmentally aware citizens, either in a science-related profession or in everyday decisions. Therefore, the content must be meaningful. It must have purposeful and meaningful utility in their daily lives. That is especially true when it comes to the intersection of environmental science and microbiology.

To explicitly work on this goal, we try and make microbiology a thread within our course. While we do not have a particular unit that covers microbiology itself, we do have a clear reoccurrence of microorganisms in various topics. In the past, we did not connect these micro-moments; rather, we would leave them as isolated comments within lessons and labs. However, drawing a curricular thread among these lessons can be very useful. That way, students walk away with a clearer understanding of the roles the microorganisms play in the environment.

Microbial Misconception

The main misconception that our students have regarding microbiology is that they think that there is no biodiversity within microbes. The understanding typically brought to the table is that all microbes are a homogenous group. While they may have a tentative grasp of photosynthetic versus heterotrophic microbes, there typically is no further discernment within these two groups. To many of our students, microorganisms are simply little living things in the soil that do everything and nothing at the same time. Students may be familiar with the different shapes, sizes, colors, and structures of microorganisms from looking at collections of prepared slides, but they see those differences more as varieties within a species rather than distinct species themselves. While they can clearly discuss the different ecological niches of a hummingbird and a pelican, they lack that discernment when it comes to microbes. It is as if the hummingbird might at any point dive into the ocean and catch a fish with its beak.

This misconception is counterproductive to strong learning within environmental science, as it limits the students' understanding of many Earth systems and the anthropogenic effects on them (e.g., high-input agriculture's effects on the nitrogen cycle).

To address important misconceptions, we often use the conceptual change model.[2] This pedagogical strategy provides a framework for constructing learning experiences within the course. In a nutshell, the conceptual change model has four distinct stages that work to replace a student's misconception with more scientifically correct concepts.

- *Dissatisfaction:* In this first stage, the student sees the limitations of their current understanding. This is where teachers can use discrepant events or inquiry to explicitly point out why the current understanding is incorrect. The goal here is to disrupt with cognitive dissonance.
- *Intelligibility:* The students can then understand and explain the new (and more scientifically correct) understanding. In our classes, this is achieved via more traditional, teacher-centered explanations. The goal here is to clearly explain the new idea.
- *Plausibility:* The student then needs to see that this new understanding fits within their current ideas about the world. The goal here is for students to see the new concept as true.
- *Fruitfulness:* In the final stage, the student needs to be able to use this new understanding in a novel context. The goal is for the teacher to provide experiences in which the student can see that their new understanding is meaningful.

We use these cognitive stages as simple reminders about how to orchestrate learning experiences with our students. It shapes the lectures that are given, the classroom discussions that we have, and the laboratory investigations we work through. If this model is used successfully, the students will abandon their initial misconception about a homogeneous group of microorganisms, and ideally replace that misconception with the idea that there are myriad different species of microorganisms; each with a unique niche, and a fruitful role in the discipline of environmental science.

Here is an example of a lesson sequence that uses the conceptual change model:

Discuss the resource Nutrient Cycling in the Serengeti

- Dissatisfaction: Point out that different things need to happen in order for nutrients to cycle (i.e., different microbes need to do different things); because if they were all the same, the cycle would not work.
- Intelligibility: Define/explain the different microorganisms and their niches.
- Plausibility: Do the inquiry activity where students work through the nutrient cycling in the Serengeti, seeing that microbes play a central role in allowing plants to have access to limiting nutrients.
- Fruitfulness: Use the new-tank-syndrome as the new context; allow students to work through a novel situation, using the different roles microorganisms play in the nitrogen cycle; OR discuss the issue of over-irrigation and denitrification during agriculture.

Exploring Fruitfulness

This last phase, fruitfulness, is the one we would like to expand upon a bit more. If a student has a robust understanding of the vast biodiversity of microbes on the planet, then they are more likely to appreciate the role certain microorganisms play in environmental issues. It is a powerful moment when a student realizes that the ecological niche of *Rhizobium* is vastly different from that of *Alcanivorax*. *Rhizobium*'s nitrogen fixation in the soil is dramatically distinct from *Alcanivorax*'s oil-degrading in the ocean. Two very different organisms with very little niche overlap. To mitigate the effects of high-input, industrialized agriculture or the effects of an oil spill, we need to understand the roles these microorganisms play. In fact, once we understand their roles in nature, we can use those roles to improve our lives and the environment. Thus, students in environmental science find meaningfulness and fruitfulness with their microbe knowledge.

Looking across our environmental science courses, there are many moments in which microbes play meaningful roles. For example, take the simple idea of decomposition, both terrestrial and aquatic. If students understand the roles microorganisms play in the decomposition of organic matter, they are more likely to be able to understand things such as wastewater treatment plants, biogas digesters, or sanitary landfills.

Here in Florida, algal blooms are an environmental menace. It is important for our students to see how nutrient pollution and microorganisms all play in an algal bloom event. Connecting fertilizer runoff, failing septic tanks, and decomposing microorganisms gives students more agency in addressing this environmental issue.

Constructing Systems Models

Once a student's misconceptions about microorganisms are challenged and replaced and the new ideas are seen as meaningful and fruitful, they can strengthen the fruitfulness of their ideas using systems models.

Students are now ready to construct, revise, and use systems models to understand how anthropogenic factors can affect natural processes that will result in measurable changes. An example is: Understanding Global Change (https://cleanet.org/clean/literacy/tools/UGC/index.html Accessed April 19, 2020).

Other useful resources are listed in Appendix 2.

APPENDIX 1: NATIONAL BENCHMARKS

MS-LS1-1. Conduct an investigation to provide evidence that living things are made of cells; either one cell or many different numbers and types of cells. (Clarification Statement: Emphasis is on developing evidence that living things are made of cells, distinguishing between living and nonliving things, and understanding that living things may be made of one cell or many and varied cells.)

MS-LS1-2. Develop and use a model to describe the function of a cell as a whole and ways the parts of cells contribute to the function. (Clarification Statement: Emphasis is on the cell functioning as a whole system and the primary role of identified parts of the cell, specifically the nucleus, chloroplasts, mitochondria, cell membrane, and cell wall.) (Assessment Boundary: Assessment of organelle structure/function relationships is limited to the cell wall and cell membrane. Assessment of the function of the other organelles is limited to their relationship to the whole cell. Assessment does not include the biochemical function of cells or cell parts.)

MS-LS1-3. Use argument supported by evidence for how the body is a system of interacting subsystems composed of groups of cells. (Clarification Statement: Emphasis is on the conceptual understanding that cells form tissues and tissues form organs specialized for particular body functions. Examples could include the interaction of subsystems within a system and the normal functioning of those systems.) (Assessment Boundary: Assessment does not include the mechanism of one body system independent of others. Assessment is limited to the circulatory, excretory, digestive, respiratory, muscular, and nervous systems.)

MS-LS1-4. Use argument based on empirical evidence and scientific reasoning to support an explanation for how characteristic animal behaviors and specialized plant structures affect the probability of successful reproduction of animals and plants respectively. (Clarification Statement: Examples of behaviors that affect the probability of animal reproduction could include nest building to protect young from cold, herding of animals to protect young from predators, and vocalization of animals and colorful plumage to attract mates for breeding. Examples of animal behaviors that affect the probability of plant reproduction could include transferring pollen or seeds and creating conditions for seed germination and growth. Examples of plant structures could include bright flowers attracting butterflies that transfer pollen, flower nectar and odors that attract insects that transfer pollen, and hard shells on nuts that squirrels bury.)

MS-LS1-5. Construct a scientific explanation based on evidence for how environmental and genetic factors influence the growth of organisms. (Clarification Statement: Examples of local environmental conditions could include availability of food, light, space, and water. Examples of genetic factors could include large breed cattle and species of grass affecting growth of organisms. Examples of evidence could include drought decreasing plant growth, fertilizer increasing plant growth, different varieties of plant seeds growing at different rates in different conditions, and fish growing larger in large ponds than they do in small ponds.) (Assessment Boundary: Assessment does not include genetic mechanisms, gene regulation, or biochemical processes.)

Disciplinary Core Ideas

LS1.A: Structure and Function

- All living things are made up of cells, which is the smallest unit that can be said to be alive. An organism may consist of one single cell (unicellular) or many different numbers and types of cells (multicellular). (MS-LS1-1).
- Within cells, special structures are responsible for particular functions, and the cell membrane forms the boundary that controls what enters and leaves the cell. (MS-LS1-2)
- In multicellular organisms, the body is a system of multiple interacting subsystems. These subsystems are groups of cells that work together to form tissues and organs that are specialized for particular body functions (MS-LS1-3)

LS1.C: Organization for Matter and Energy Flow in Organisms

- Plants, algae (including phytoplankton), and many microorganisms use the energy from light to make sugars (food) from carbon dioxide from the atmosphere and water through the process of photosynthesis, which also releases oxygen. These sugars can be used immediately or stored for growth or later use. (MS-LS1-6)
- Within individual organisms, food moves through a series of chemical reactions in which it is broken down and rearranged to form new molecules, to support growth, or to release energy. (MS-LS1-7)

High School

HS-LS1: From Molecules to Organisms: Structures and Processes. Students who demonstrate understanding can:

- *HS-LS1-1*. Construct an explanation based on evidence for how the structure of DNA determines the structure of proteins which carry out the essential functions of life through systems of specialized cells. (Assessment Boundary: Assessment does not include identification of specific cell or tissue ty pes, whole body systems, specific protein structures and functions, or the biochemistry of protein synthesis.)
- *HS-LS1-2*. Develop and use a model to illustrate the hierarchical organization of interacting systems that provide specific functions within multicellular organisms. (Clarification Statement: Emphasis is on functions at the organism system level, such as nutrient uptake, water delivery, and organism movement in response to neural stimuli. An example of an interacting system could be an artery depending on the proper function of elastic tissue and smooth muscle to regulate and deliver the proper amount of blood within the circulatory system.) (Assessment Boundary: Assessment does not include interactions and functions at the molecular or chemical reaction level.)
- *HS-LS1-3*. Plan and conduct an investigation to provide evidence that feedback mechanisms maintain homeostasis. (Clarification Statement: Examples of investigations could include heart rate response to exercise, stomate response to moisture and temperature, and root development in response to water levels.) (Assessment Boundary: Assessment does not include the cellular processes involved in the feedback mechanism.)
- *HS-LS1-4*. Use a model to illustrate the role of cellular division (mitosis) and differentiation in producing and

maintaining complex organisms. (Assessment Boundary: Assessment does not include specific gene control mechanisms or rote memorization of the steps of mitosis.)

- *HS-LS1-5.* Use a model to illustrate how photosynthesis transforms light energy into stored chemical energy. (Clarification Statement: Emphasis is on illustrating inputs and outputs of matter and the transfer and transformation of energy in photosynthesis by plants and other photosynthesizing organisms. Examples of models could include diagrams, chemical equations, and conceptual models. Assessment Boundary: Assessment does not include specific biochemical steps.)
- *HS-LS1-6.* Construct and revise an explanation based on evidence for how carbon, hydrogen, and oxygen from sugar molecules may combine with other elements to form amino acids and/or other large carbon-based molecules. (Clarification Statement: Emphasis is on using evidence from models and simulations to support explanations.) (Assessment Boundary: Assessment does not include the details of the specific chemical reactions or identification of macromolecules.)
- *HS-LS1-7.* Use a model to illustrate that cellular respiration is a chemical process whereby the bonds of food molecules and oxygen molecules are broken and the bonds in new compounds are formed resulting in a net transfer of energy. (Clarification Statement: Emphasis is on the conceptual understanding of the inputs and outputs of the process of cellular respiration.) (Assessment Boundary: Assessment should not include identification of the steps or specific processes involved in cellular respiration.)

APPENDIX 2: SECONDARY SCIENCE PROFESSIONAL ORGANIZATIONS

- **(National Science Teachers Association www.nsta.org).** From peer-reviewed journals to national conferences, this educational organization has something for every level and content area of secondary science. Although membership is needed for full access, podcasts, resources, and conference materials are free.
- **(National Biology Teachers Association www.nabt.org).** Established in 1938, this association offers invaluable material for biology teachers in microbiology. Links to a wide assortment of instructional materials that could be adapted to any classroom.
- **(National Education Association www.nea.org).** The Microbe Passport link has virtual slides that allow students to view microbes online. Free lesson plans are also available on this site.
- **(American Society for Microbiology www.asm.org).** The secondary science teacher can find free lesson plans that are ready for classroom use.
- **(CPALMS www.cpalms.org).** This website contains lesson plans, student video tutorials, and articles that are classroom-ready and fully editable. There 63 lessons for microbiology in middle school. For high school biology, there are 265 lessons that align to cellular biology.

Microbiology for Home Inspectors

William E. Herrmann

CONTENTS

Inspecting the Attic 905
Infections Caused by Pets 905
Water Testing 906
Mold 906
Off-Gassing 906

As a home inspector, I have dealt with many different types of microorganisms: Bacteria parasites, nematodes, protozoa, fungi, algae, and viruses. As it turned out, it was not that safe. I retired recently after chest pains led to a 7-hour heart procedure. The doctors also found asbestos in my lung, which contributed to breathing problems developed over the past few years. One of my strengths is putting complex subjects into simple practical terms, and I'm happy for the opportunity to relate microbiology to real-world application in my career as a Home Inspector.

When we walk into an unfamiliar home, we never know what is inside that may harm us. Our job is to evaluate almost everything inside and outside of the home. While we are worried about the health, safety, and welfare of our clients, we are exposed to many things that we need to worry about for ourselves. By industry standards and most state regulations, Home Inspectors evaluate heat, plumbing, insulation, foundation, electric, roof, windows, doors, etc. (As an example, New York State regulations may be found at https://www.dos.ny.gov/licensing/homeinspect/hinspector.html. Accessed April 1, 2020). These items are primarily mechanical things. Water, septic, radon levels, and air quality testing are ancillary services that are usually not covered within the scope of a formal Home Inspection. High school and college science courses have greatly helped my understanding of the challenges that I face—the research to understand, explain to the client, and recommend or oversee solutions becomes easier because of a firm science-based approach.

I have performed many initial investigations into "sick homes." This can be tricky because sometimes the diagnosis is straight forward—mold, back-drafting fuel burning appliances (exhaust byproducts including carbon monoxide), sewer gases, etc.—and sometimes it isn't. I have vacuumed carpets and looked through the debris for anything of interest to the challenge at hand. Insect fragments, unidentifiable strange dusts, dander, and mouse or insect droppings have all helped contribute to causing sick homes. Sometimes an industrial engineer is needed. Knowing my limits when I have reached them, I unapologetically recommend the next level of expertise.

Inspecting the Attic

The importance of wearing a dust mask cannot be overemphasized, because of what can be encountered when testing an attic. Bat, bird, squirrel, and raccoon droppings can introduce not only ectoparasites (organisms that live on the skin, such as fleas and lice), but also microorganisms that can cause diseases. These include leptospirosis and histoplasmosis, which are respiratory diseases; candidiasis, which are yeast infections spread by pigeons; cryptococcosis, which is a yeast found in the intestinal tract of pigeons; St. Louis encephalitis (inflammation of the nervous system); salmonellosis, caused by the salmonella bacteria; *Escherichia. coli*, also a bacteria; rabies, bubonic plague, West Nile encephalitis, and Legionnaires' disease.

Diseases passed from animals to humans are called zoonoses and we encounter many of them. Among these are bubonic plague, which is spread by rodents; Q fever, which is spread by barnyard animals; *Campylobacter* infection, which is spread by animal feces; hantavirus, which is spread by mice; lymphocytic choriomeningitis, which is spread by house mice; tularemia, which is spread by rabbits; raccoon roundworm; and Giardia.

Infections Caused by Pets

Cats allowed to roam outdoors and then return home, often pick up a parasite known as *Toxoplasma gondii*. Toxoplasmosis is of particular danger to small children, people with damaged immune systems, people undergoing cancer treatment, and pregnant women. Cats are also a vector for *Bartonella henselae*, which causes cat scratch fever. Dogs can come into contact with rats, mice, cows, pigs, or other dogs and then spread infection when they greet you. They can expose the Home Inspector to leptospirosis, which can lead to liver and kidney damage and even death. In addition, rabies is another occupational hazard that can be encountered.

Water Testing

Water testing includes testing for both organic and inorganic compounds. One must specify what is to be tested as there are specific lab procedures for each test agent. Almost all wells are routinely tested for total coliform and *E. coli* bacteria. Total coliforms are a group of closely related, mostly harmless bacteria that live in soil and water as well as the gut of animals (including humans). Total coliforms are currently controlled by drinking water regulations (i.e., Total Coliform Rule which can be found at https://www.epa.gov/dwreginfo/revised-total-coliform-rule-and-total-coliform-rule. Accessed April 1, 2020). Their presence above the standard indicates problems in water treatment or in the distribution system. If total coliforms are found, then the water system sample is further analyzed to determine if specific types of coliforms (i.e., fecal coliforms or *E. coli*) are present. *E. coli* are fecal coliforms commonly found in the intestines of animals and humans. The presence of E. coli in water is a strong indication of recent sewage or animal waste contamination of the drinking water. It is also an indicator for the presence of other disease-causing organisms.

If we turn the water on and smell "rotten eggs," it means that hydrogen sulfide (H_2S) is present. It comes from the sulfur bacteria that occur naturally from the decay and chemical reactions within soil and rocks. Although this is normally a nuisance and not a real concern, in extremely high concentrations it can be both poisonous and flammable.

It is important to understand the proper operation of septic systems. Aerobic bacteria require oxygen to live while anaerobic bacteria do not. A very important function of the septic tank is to allow bacteria to convert organic material into energy that the bacteria then use for their life functions. This conversion is what causes the breakdown of organic solids in the wastewater into simpler solids and gas, making the wastewater leaving the septic tank comparatively cleaner than what enters. However, since most septic tanks do not contain oxygen, an anaerobic environment, the aerobic bacteria quickly die off, leaving the job of breaking down waste to the anaerobic bacteria. There are alternative systems to the traditional, which may cost an additional $20,000–$30,000, that have pumps in the tank to encourage the aerobic activity. (I have one of these in my home in the Georgia mountains. They are required by the local codes because of the poor soil types. In addition, instead of discharging through traditional 4-inch perforated PVC, it is distributed below the soil at a shallower depth through small diameter drip irrigation tubes.) When performing a rudimentary septic dye test, a nontoxic fluorescent dye is put into the tank and water is introduced for a while to put pressure on the leach field. If the color (yellow, blue, green, red) comes to the surface or if standing water by the leach field or the river stream lake close by turns color, you have a problem. Dye in the toilet ending up on the surface of the lawn means an inadequate septic system.

Water may also spread Legionnaires' disease. This form of pneumonia caused by a bacterium, spreads mostly as a mist leaking from air conditioning, but can come from a shower, hot tubs, etc. It causes disease through aspiration.

Mold

Mold is common and in fact, in my years of mold testing, I have discovered it is uncommon to find a zero level of mold in a home. It is everywhere and there are many types. Some are more toxic and dangerous than others. It is not the mold itself that is toxic, but the toxins the mold produces that are the concern. All molds produce toxins (called mycotoxins). They are the organism's natural defense system. Some are worse than others. They can cause toxicity. These mycotoxins, depending on exposure levels, create various symptoms: brain fog, fatigue, asthmas, muscle cramps, weakness, cognitive problems, headaches, numbness, sinus problems, shortness of breath, eye problems, infections, toxic reactions, flu-like symptoms, and skin infections. Aflatoxins, produced by *Aspergillus*, are among the most poisonous; ochratoxin produced by *Aspergillus* and *Penicillium*; patulin produced from *Aspergillus, Penicillium,* and *Byssochlamys* are other toxins that are encountered.

The mold spores are an irritant to the respiratory system. We look at air-quality test results in comparative terms. The most common molds we find (in alphabetical not in order of pathogenicity) are Alternaria (respiratory response), *Aspergillus* (lung), *Cladosporium* (asthma), *Penicillium* (allergy and asthma), and *Stachybotrys. Stachybotrys*, aka black mold, is probably the most serious as it causes serious health problems including bleeding of the lungs.

Off-Gassing

Finally, we are concerned with the off-gassing of construction materials. Off-gassing is the release of chemicals, such as volatile organic chemicals (VOCs) or airborne particles. It is correlated with congestion, coughing, lymphomas, cognitive issues, skin irritation, asthma, leukemia, and fatigue. It can be caused by carpeting (five plus years of off-gassing), cabinetry, furniture (plywood and particleboard off-gas for two years), paint, nail polish remover, dryer sheets, household cleaners, and other household goods. Gasses can include benzene, ammonia, ozone (electronics), toluene, and the carcinogen formaldehyde. Many of these can induce the same symptoms, which makes identifying a specific compound difficult. It is estimated that there have been about 80,000 chemicals introduced into our environment in the past 50 years and the current building science instructs us to make houses "tight" to avoid heat loss. The problem is that this limits air exchange with the outside unless this was addressed in the design, which is often doubtful since it requires expensive systems. This is why some people believe the old drafty houses were healthier.

Every day, while processing the many thousands of mechanical elements it takes to build a home, I am always extremely mindful of the health-related issues, most of which are microbiologically based. These elements have mostly been created or introduced after the initial home construction. Higher temperatures and humidity make most things off-gas more quickly. These can be slowed by using a dehumidifier to keep the humidity levels at about 45%. Since mold will grow above 60%, the dehumidifier will prevent both off-gassing and as well as mold growth. Solid wood furniture is better than particleboard. If you remove wall to wall carpeting to get rid of VOCs you will also have the added benefit of getting rid of mold and dust mites.

Writing this chapter has made me consider all the things that I have come across in the past 29 years, and all the mental gymnastics I executed daily. It has been an interesting, challenging, and rewarding career, in which I have helped a lot of people make what might be the largest purchase in their life. My experience has taught me that this can be a dangerous career and the Home Inspectors need to make sure that they adequately protect themselves.

Survey of Selected Clinical, Commercial, and Research-Model Eubacterial Species

Emanuel Goldman

Organism	Growth	Staining	Habitat	Pathogenesis (in Humans)	Comments
Acetobacter spp.	aerobic	gram⁻ rod	plants and soil	nonpathogenic	converts ethanol to acetic acid
Acidithiobacillus ferrooxidans	aerobic	gram⁻ rod	soil, water	nonpathogenic	thermo- & acidophilic; mine waste recovery
Acinetobacter spp.	aerobic	gram⁻ rod	soil and other environments	lung, blood, wound infections	nosocomial in debilitated patients
Actinomyces israelii	anaerobic[1]	gram⁺ rod	normal mouth/ intestine flora	lung, abdomen, cervicofacial abscess	opportunistic pathogen, sulfur-like granules
Actinomyces naeslundii	facultative anaerobe	gram⁺ rod	normal mouth flora	periodontal disease, dental caries	networked filaments, sulfur-like granules
Aeromonas spp.	facultative	gram⁻ rod	fresh & slightly salted water	gastroenteritis, wound infections	systemic disease in immunocompromised
Agrobacterium tumefaciens	facultative	gram⁻ rod	plants	rarely pathogenic (catheters)	plant tumors; plant genetic engineering
Alcaligenes spp.	aerobic	gram⁻ rod	soil and water	lung infections in cystic fibrosis	used to produce non-standard amino acids
Anabaena spp.	facultative aerobe	gram⁻ oval	water, soil, plankton	nonpathogenic but some make toxin	heterocysts; photosynthetic & N_2-fixing
Anaplasma spp.	intracellular	gram⁻ rod	ticks, animals	pathogenic primarily in animals	transmission by insect vectors
Arthrobacter spp.	aerobic	gram⁺ variable[2]	soil	nonpathogenic	cleans some environmental pollutants
Bacillus spp.	facultative and aerobes	gram⁺ rod	soil	nonpathogenic	forms spores (all *Bacillus*)
Bacillus anthracis	facultative aerobe	gram⁺ rod	soil	anthrax	found on animal skins
Bacillus cereus	facultative aerobe	gram⁺ rod	soil	gastroenteritis	food-poisoning both by intoxication & growth
Bacillus megaterium	facultative aerobe	gram⁺ rod	soil	nonpathogenic	large organism; soil inoculant & biotech uses
Bacillus subtilis	facultative aerobe	gram⁺ rod	soil	nonpathogenic	model organism for research
Bacillus thuringiensis	facultative aerobe	gram⁺ rod	soil	nonpathogenic	produces insecticide, agricultural use
Bacteroides fragilis	anaerobic	gram⁻ rod	normal intestinal flora	peritonitis, abdominal & other sites	causes disease in inappropriate sites
Bartonella spp.	intracellular	gram⁻ rod	ticks, insects, animals	cat scratch disease, trench fever, carditis	transmission to humans by insect vectors
Bdellovibrio bacteriovorus	aerobic	gram⁻ rod	fresh water and soil	nonpathogenic	kills other gram neg bacteria, in periplasm
Beggiatoa spp.	facultative anaerobe	gram⁻ rod	fresh water	nonpathogenic	filaments; sulfur granules; pollution indicator
Beijerinckia spp.	aerobic	gram⁻ rod	soil	nonpathogenic	nitrogen-fixing
Bifidobacterium spp.	anaerobic	gram⁺ rod	normal intestinal flora	nonpathogenic	symbiotic to humans; used as a probiotic
Bordetella pertussis	aerobic	gram⁻ coccobacilli	humans	whooping cough	effective vaccine has reduced incidence

(*Continued*)

Organism	Growth	Staining	Habitat	Pathogenesis (in Humans)	Comments
Borrelia burgdorferi	microaerophile	gram⁻ spirochete	animals, insects	Lyme disease	transmission to humans by ticks
Brucella melitensis	facultative aerobe	gram⁻ rod	animals	brucellosis	zoonotic disease in humans
Burkholderia spp.	aerobic	gram⁻ rod	soil, water, animals	melioidosis; lung in cystic fibrosis	degrades polychlorinated biphenyls
Campylobacter jejuni	microaerophile	gram⁻ rod	animals, chickens	gastroenteritis	widespread cause of food-poisoning
Caulobacter spp.	aerobic	gram⁻ rod	fresh water	nonpathogenic	asymmetric division; stalks; research model
Chlamydia pneumoniae	intracellular	gram⁻ rod	animals, insects, protozoa	pneumonia	elementary and reticulate body forms
Chlamydia trachomatis	intracellular	gram⁻ rod	humans	chlamydia	STD[3] that can cause infertility
Chlorobium spp.	facultative anaerobe	gram⁻ coccobacilli	warm water	nonpathogenic	photosynthetic
Citrobacter spp.	facultative	gram⁻ rod	normal intestinal flora, soil	rarely pathogenic; some UTIs[4]	uses citrate as sole carbon source
Clostridium botulinum	anaerobic	gram⁺ rod	soil	botulism (food-poisoning)	forms spores; toxin used cosmetically
Clostridium difficile	anaerobic	gram⁺ rod	endogenous intestinal flora	pseudomembranous colitis	forms spores; antibiotic-induced disease
Clostridium perfringens	anaerobic	gram⁺ rod	soil and other environments	gas gangrene; food-poisoning	forms spores; also normal intestinal flora
Clostridium tetani	anaerobic	gram⁺ rod	soil	tetanus	spores; wound infection; effective vaccine
Corynebacterium diphtheriae	facultative anaerobe	gram⁺ rod	mammals	diphtheria (upper respiratory disease)	pathogenicity due to phage; effective vaccine
Corynebacterium glutamicum	facultative anaerobe	gram+ rod	soil	non-pathogenic	industrial production of amino acids
Corynebacterium spp.	facultative anaerobe	gram⁺ rod	normal skin flora	most are non-pathogenic	can cause disease in debilitated patients
Coxiella burnetii	intracellular	gram⁻ rod-like	animals	Q-fever	forms spores; transmitted by inhalation
Cyanobacteria genera & spp.	facultative	gram⁻ mixed	water and soil	a few species produce toxins	"blue-green algae"; some in food; "bio-concrete"
Cytophaga spp.	aerobic	gram⁻ rod	water and soil	nonpathogenic	gliders; degrade cellulose; make antibiotics
Desulfovibrio spp.	anaerobic	gram⁻ rod	water and soil	nonpathogenic	sulfate-reducing; pollution control
Ehrlichia spp.	intracellular	gram⁻ coccus	ticks, animals	ehrlichiosis; blood disease	transmission by insect vectors; dog pathogen
Enterobacter spp.	facultative	gram⁻ rod	normal intestinal flora	skin and tissue	opportunistic; nosocomial; debilitated patient
Enterococcus faecalis	facultative	gram⁺ coccus	normal intestinal flora	UTIs[4], endocarditis	causes disease in inappropriate sites
Enterococcus faecium	facultative	gram⁺ coccus	normal intestinal flora	UTIs[4], endocarditis	causes disease in inappropriate sites
Erwinia spp.	facultative	gram⁻ rod	soil, water, insects, plants	nonpathogenic	plant pathogen affects fruits & vegetables
Erysipelothrix rhusiopathiae	facultative anaerobe	gram⁺ rod	animals, soil	skin infections	primarily an animal pathogen
Escherichia coli	facultative	gram⁻ rod	normal intestinal flora	gastroenteritis, UTI[4], septicemia	fast grower; diseases at inappropriate sites
Escherichia coli O157:H7	facultative	gram⁻ rod	cattle	HUS[5], hemorrhagic colitis	food-poisoning: beef, manure runoff in water
Eubacterium spp.	anaerobic	gram⁺ rod	endogenous mouth flora	periodontal disease	historically genus of convenience; diverse
Flavobacterium spp.	aerobic	gram⁻ rod	fresh water, soil	nonpathogenic	serious pathogen of fish
Francisella tularensis	aerobic	gram⁻ coccobacilli	animals; rodents, rabbits	tularemia	transmitted by insects, animals, food, air

Organism	Growth	Staining	Habitat	Pathogenesis (in Humans)	Comments
Frankia spp.	microaerophile	gram$^+$ rod	soil, plant roots	nonpathogenic	N_2-fixing filamentous plant symbiont; spores
Fusobacterium spp.	anaerobic	gram$^-$ rod	endogenous mouth flora	periodontal disease, part of ANUG[6]	biofilms; can cause disease at other sites
Gallionella ferruginea	aerobic	no peptidoglycan	fresh and salt water	nonpathogenic	chemolithotrophic; iron-fixing; biofilms
Gardnerella vaginalis	facultative anaerobe	gram variable rod	endogenous vaginal flora	vaginosis	not exclusively an STD[3]
Haemophilus ducreyi	facultative aerobe	gram$^-$ coccobacilli	humans	chancroid (genital lesions)	STD[3] facilitates HIV transmission
Haemophilus influenzae	facultative aerobe	gram$^-$ coccobacilli	normal nasopharynx flora	lung, ear, eye, meningitis in children	effective vaccine for children
Haemophilus parainfluenzae	facultative aerobe	gram$^-$ coccobacilli	normal oral flora	endocarditis, meningitis, lung	infrequent disease, secondary to trauma
Helicobacter pylori	microaerophile	gram$^-$ helical	stomach and duodenum	gastric ulcers	survives in high acidity; carcinogen
Klebsiella granulomatis[7]	aerobic	gram$^-$ rod	humans, tropical/ subtropical	granuloma inguinale	STD[3] forms intracellular Donovan bodies
Klebsiella pneumoniae	facultative	gram$^-$ rod	normal gut flora; water, soil	pneumonia, UTIs[4], septicemia	often nosocomial; model research organism
Lactobacillus acidophilus	facultative anaerobe	gram$^+$ rod	normal flora gut, vagina etc.	nonpathogenic	probiotic, control of yeast infections
Lactobacillus spp.	facultative anaerobe	gram$^+$ rod	flora of humans & animals	dental caries	used in production of various foods
Lactococcus lactis	facultative	gram$^+$ coccus	plants, human gut flora	nonpathogenic	probiotic used in dairy food production
Legionella pneumophila	facultative aerobe	gram$^-$ rod	fresh water; in amoeba	Legionnaire's disease (pneumonia)	transmitted by inhalation of aerosols
Leptospirillum ferrooxidans	aerobic	gram$^-$ spiral	fresh water, acidic	nonpathogenic	chemolithotrophic; iron-fixing; industrial use
Leptospira spp.	aerobic	gram$^-$ spirochete	animals, water	leptospirosis	transmitted by contaminated water or food
Listeria monocytogenes	facultative aerobe	gram$^+$ rod	soil, animals	listeriosis; food-poisoning, meningitis	danger to pregnancy; grows in cold temperature
Magnetospirillum magneticum	microaerophilic	gram$^-$ rod	fresh water, sediments	nonpathogenic	magnetic organelles have commercial potential
Methylococcus capsulatus	aerobic	gram$^-$ coccus	soil, animals	nonpathogenic	methanotroph may help control pollution
Methylomonas spp.	aerobic	gram$^-$ rod	soil, water	nonpathogenic	methane primary carbon and energy source
Micrococcus spp.	aerobic	gram$^+$ coccus	normal skin flora, soil, water	rarely pathogenic	pathogen in immunocompromised hosts
Moraxella catarrhalis	aerobic	gram$^-$ coccus	endogenous to nasopharynx	respiratory tract infections	other *Moraxella* spp. are gram$^-$ rods
Morganella morganii	facultative	gram$^-$ rod	human gut, animals, water	UTIs[4] and other infections	nosocomial, opportunist
Mycobacterium avium	aerobic	gm$^+$ acid fast rod	soil, water, animals, birds	disseminated disease (wasting, etc.)	immunocompromised patients at risk
Mycobacterium bovis	aerobic	gm$^+$ acid fast rod	cattle	tuberculosis (infrequent)	source of the BCG vaccination; TB in cattle
Mycobacterium intracellulare	aerobic	gm$^+$ acid fast rod	soil, water, animals, birds	lung & disseminated disease	in the *Mycobacterium avium* complex, MAC
Mycobacterium leprae	aerobic	gm$^+$ acid fast rod	soil, humans, animals	leprosy (Hansen's disease)	intracellular infection of many tissues
Mycobacterium marinum	aerobic	gm$^+$ acid fast rod	fresh and salt water	wound infections	swimming/fish tank granuloma; fish pathogen

(*Continued*)

Organism	Growth	Staining	Habitat	Pathogenesis (in Humans)	Comments
Mycobacterium smegmatis	aerobic	gm$^+$ acid fast rod	water, soil, plants, biofilms	nonpathogenic	fast growth enables research model for genus
Mycobacterium tuberculosis	aerobic	gm$^+$ acid fast rod	humans	tuberculosis ("TB")	slow growth; drug-resistance a problem
Mycoplasma capricolum	aerobic	no cell wall, round	goats	nonpathogenic	goat pathogen; needs cholesterol for growth
Mycoplasma pneumoniae	aerobic	no cell wall, rod	humans	atypical pneumonia	small; common cell culture contaminant
Myxococcus xanthus	aerobic	gram$^-$ rod[8]	soil, plants, fresh water	nonpathogenic	developmental cycle, fruiting bodies, spores
Neisseria gonorrhoeae	aerobic	gram$^-$ coccus	humans	gonorrhea	STD[3]; intracellular; antigenic variation
Neisseria meningitides	aerobic	gram$^-$ coccus	humans	meningitis	entry to blood via nasopharyngeal mucosa
Nitrobacter spp.	facultative	gram$^-$ rod	soil, fresh water	nonpathogenic	nitrite-oxidizing; wastewater treatment
Nitrosomonas spp.	aerobic	gram$^-$ rod	soil, water	nonpathogenic	oxidizes ammonia to nitrite; treat wastewater
Nitrosomonas eutropha	facultative	gram$^-$ coccobacilli	soil, water	nonpathogenic	used as skin cleanser in place of soap
Nocardia asteroids	aerobic	gm$^+$ acid fast rod	soil, water	lung infection	infection by inhalation, not person-to-person
Pantoea spp.	facultative	gram$^-$ rod	plants, water, animal guts	skin, blood, endocarditis	plant pathogen, opportunistic in humans
Pasteurella multocida	facultative anaerobe	gram$^-$ coccobacilli	animals	inflammation, possible systemic	zoonotic disease
Peptostreptococcus spp.	anaerobic	gram$^+$ coccus	endogenous mouth, gut flora	multiple sites: skin, mouth, blood etc.	also contributes to caries
Photobacterium spp.	facultative	gram$^-$ rod	salt water, marine organisms	mostly nonpathogenic	luminescent fish symbiont, some pathogenic
Porphyromonas gingivalis	anaerobic	gram$^-$ rod	endogenous mouth flora	periodontal disease, gingivitis	biofilms; black pigment from iron
Prevotella spp.	anaerobic	gram$^-$ rod	mouth flora, cattle	periodontal disease, caries	used to treat acidosis in cattle
Propionibacterium acnes	anaerobic	gram$^+$ rod	skin, gut	acne and other infections	as the name implies, produces propionic acid
Proteus mirabilis	facultative	gram$^-$ rod	soil, water, humans	kidney stones, UTIs[4]	swarming motility, biofilms; urease
Proteus vulgaris	facultative	gram$^-$ rod	normal intestinal flora	UTIs[4], wound infections	swarming motility, putrefies meat
Providencia stuartii	facultative	gram$^-$ rod	Soil, water, sewage	UTIs[4] from catheters, burn wounds	source for restriction endonuclease PstI
Providencia spp.	facultative	gram$^-$ rod	humans, animals, water	UTIs[4] from catheters, burn wounds	opportunist can also cause gastroenteritis
Pseudomonas aeruginosa	facultative[9] aerobe	gram$^-$ rod	soil, water, humans, plants	lung and many other sites	opportunist harmful for cystic fibrosis, others
Pseudomonas syringae	facultative aerobe	gram$^-$ rod	plants, water	nonpathogenic	crop spoilage; promotes ice nucleation
Rhizobium spp.	facultative aerobe	gram$^-$ rod	soil, plant nodules	nonpathogenic	major terrestrial N_2-fixing plant symbiont
Rhodopseudomonas spp.	facultative aerobe	gram$^-$ rod	water, soil	nonpathogenic	photosynthetic; clean environmental waste
Rhodospirillum spp.	facultative	gram$^-$ spiral	marine environments, soil	non-pathogenic	photosynthetic; N_2-fixing
Rickettsia prowazekii	intracellular	gram$^-$ rod	lice, humans	epidemic typhus	Brill-Zinsser disease a relapse long afterward
Rickettsia rickettsii	intracellular	gram$^-$ rod	ticks, humans	rocky mountain spotted fever	zoonotic disease (applies to all *Rickettsia*)
Rickettsia typhi	intracellular	gram$^-$ rod	fleas, rodents, cats	murine (endemic) typhus	obligate intracellular parasite (all *Rickettsia*)

Organism	Growth	Staining	Habitat	Pathogenesis (in Humans)	Comments
Roseburia spp.	anaerobic	gram$^+$ rod	normal intestinal flora	nonpathogenic	breakdown polysaccharides, produce butyrate
Salmonella enterica	facultative	gram$^-$ rod	animals, birds, water	mostly gastrointestinal diseases	>2,000 subspecies including 5 serovars below
Salmonella choleraesuis[10]	facultative	gram$^-$ rod	swine	Septicemia	mycotic aneurysm a dangerous complication
Salmonella enteritidis	facultative	gram$^-$ rod	animals, birds, water	gastroenteritis	ovarian transmission from chicken to eggs
Salmonella paratyphi	facultative	gram$^-$ rod	animals, birds, water	paratyphoid enteric fever	fecal-oral transmission (all *Salmonella*)
Salmonella typhi	facultative	gram$^-$ rod	animals, birds, water	typhoid fever	asymptomatic carriers in gall bladder
Salmonella typhimurium	facultative	gram$^-$ rod	animals, birds, water	gastroenteritis	grows fast (all *Salmonella*); research-model
Sarcina spp.	anaerobic	gram$^+$ coccus	soil, water, humans	dental caries, periodontal disease	ferment carbohydrates; one sp. in stomach
Serratia marcescens	facultative	gram$^-$ rod	soil, water, humans	UTIs[4], wound infections, other sites	nosocomial; red pigment
Shigella boydii	facultative	gram$^-$ rod	humans, primates, water	dysentery, shigellosis	fecal-oral transmission (all *Shigella*)
Shigella dysenteriae	facultative	gram$^-$ rod	humans, primates, water	dysentery, shigellosis, HUS[5]	makes Shiga toxin, inhibits protein synthesis
Shigella flexneri	facultative	gram$^-$ rod	humans, primates, water	dysentery, shigellosis	Reiter's syndrome sequel to primary disease
Shigella sonnei	facultative	gram$^-$ rod	humans, primates, water	dysentery, shigellosis	10 cells enough to cause disease (all *Shigella*)
Sphaerotilus natans	aerobic	gram$^-$ rod	flowing and waste water	nonpathogenic	filamentous; sheathed; pipe-clogging
Spirillum volutans	microaerophile	gram$^-$ helical	stagnant water	nonpathogenic	use in motility assay due to active flagella
Spiroplasma spp.	intracellular	no cell wall, helical	insects, plants	nonpathogenic[11]	insect and plant pathogen
Spirulina spp.	facultative aerobe	gram$^-$ spiral	water, soil, plankton	nonpathogenic	food supplement with reputed health benefits
Staphylococcus aureus	facultative	gram$^+$ coccus	endogenous human flora	skin infection, food-poisoning, TSS[12]	+ other diseases; MRSA[13] a major problem
Staphylococcus epidermidis	facultative	gram$^+$ coccus	normal skin flora	septicemia, endocarditis	nosocomial from catheters & implants
Staphylococcus saprophyticus	facultative	gram$^+$ coccus	animals, human urinary tract	UTIs[4]	primarily affects females
Streptobacillus moniliformis	facultative	gram$^-$ rod	rodents	rat-bite fever, Haverhill fever	also transmitted by food; develops L-forms[14]
Streptococcus agalactiae	facultative	gram$^+$ coccus	gut & urogenital flora	neonatal meningitis	CAMP[15] hemolysis test for identification
Streptococcus bovis	facultative	gram$^+$ coccus	human gut, cows, sheep	endocarditis	bacteremia associated with colon cancer
Streptococcus gordonii	facultative	gram$^+$ coccus	human mouth flora	dental plaque; endocarditis	member of the *S. viridans* group of spp.
Streptococcus mutans	facultative	gram$^+$ coccus	human mouth flora	dental caries	member of the *S. viridans* group of spp.
Streptococcus pneumoniae	facultative	gram$^+$ coccus	human nasopharynx flora	pneumonia, meningitis, others	phage lysin has potential to eradicate species
Streptococcus pyogenes	facultative	gram$^+$ coccus	endogenous human flora	strep throat; toxic shock; flesh-eating	rheumatic fever & glomerulonephritis sequelae
Streptococcus thermophilus[16]	facultative	gram$^+$ coccus	dairy, cow mammary glands	nonpathogenic	manufacture of yogurt and some cheeses
Streptococcus viridans (spp.)	facultative	gram$^+$ coccus	normal human flora	generally nonpathogenic	large group mostly α-hemolytic *Streptococci*
Streptomyces spp.	aerobic	gram$^+$ rod	soil, water	nonpathogenic (a few exceptions)	fungi-like filaments, mycelium, spores

(*Continued*)

Organism	Growth	Staining	Habitat	Pathogenesis (in Humans)	Comments
Streptomyces avermitilis	aerobic	gram$^+$ rod	Soil	nonpathogenic	producer of anti-parasitic agent avermectin
Streptomyces coelicolor	aerobic	gram$^+$ rod	soil, water	nonpathogenic	major producer of antibiotics (all *Streptomyces*)
Streptomyces somaliensis	aerobic	gram$^+$ rod	soil	bacterial mycetoma (Madura foot)	other bacterial & fungal causes of this disease
Streptomyces verticillus	aerobic	gram$^+$ rod	soil	nonpathogenic	produces anticancer drug bleomycin
Thiobacillus denitrificans	facultative anaerobe	gram$^-$ rod	water, soil	nonpathogenic	autotrophic denitrification; sulfur oxidation
Thiothrix spp.	aerobic	gram$^-$ rod	water	nonpathogenic	filaments; oxidize sulfur; wastewater problem
Treponema denticola	anaerobic	gram$^-$ spirochete	endogenous mouth flora	periodontal disease, part of ANUG[6]	forms biofilms with other organisms
Treponema pallidum	microaerophile	gram$^-$ spirochete	humans	syphilis	slow growth; obligate intracellular parasite
Ureaplasma spp.	facultative	no cell wall, oval	human urogenital tract	urethritis, neonatal illness, others	hydrolyze urea; opportunist; debilitated hosts
Veillonella spp.	anaerobic	gram$^-$ coccus	mouth, gut, vagina flora	oral, bone & other infections	dental plaque biofilm; infrequent pathogen
Vibrio cholera	facultative	gram$^-$ rod	salt water	cholera	transmission by seafood & oral-fecal
Vibrio fischeri	facultative	gram$^-$ rod	salt water, marine animals	nonpathogenic	bioluminescent; symbiotic with fish
Vibrio harveyi	facultative	gram$^-$ rod	salt water	nonpathogenic	bioluminescent; research-model organism
Vibrio parahaemolyticus	facultative	gram$^-$ rod	salt water	gastroenteritis	from undercooked seafood, shellfish
Vibrio vulnificus	facultative	gram$^-$ rod	salt water	gastroenteritis, wounds, septicemia	contaminated seafood; debilitated patients
Xanthomonas spp.	facultative aerobe	gram$^-$ rod	plants	nonpathogenic	plant pathogen; agricultural crop spoilage
Yersinia enterocolitica	facultative anaerobe	gram$^-$ coccobacilli	rodents, animals, water, soil	gastroenteritis	poisoning from contaminated animal foods
Yersinia pestis	facultative	gram$^-$ coccobacilli	rodents, animals, insects	bubonic/pneumonic plague	transmitted from rodents via fleas
Yersinia pseudotuberculosis	facultative	gram$^-$ coccobacilli	rodents, animals	disseminated disease from the gut	fecal-oral transmission; intracellular in host
Zoogloea spp.	aerobic	gram$^-$ rod	wastewater	nonpathogenic	form flocs (gels); sewage & water treatment
Zymomonas mobilis	facultative anaerobe	gram$^-$ rod	plant and tree saps	nonpathogen; protects against sepsis	industrial use for ethanol production

[1] Some research papers describe *Actinomyces israelii* as a facultative anaerobe
[2] Rods in log phase, cocci in stationary phase
[3] STD, sexually transmitted disease
[4] UTI, urinary-tract infection
[5] HUS, hemolytic uremic syndrome
[6] ANUG, acute necrotizing ulcerative gingivitis
[7] Formerly named *Calymmatobacterium granulomatis*
[8] The rod shape of *Myxococcus xanthus* refers to the vegetative form. The "coccus" in the species name refers to the shape of the myxospore.
[9] Usually described as an obligate aerobe, *Pseudomonas aeruginosa* can also grow anaerobically, but does not have the ability to conduct fermentation.
[10] *S. choleraesuis* is the former species name now replaced with *S. enterica*. However, there also remains a subspecies serovar named *S. choleraesuis.*
[11] Some controversy as there is evidence from some workers that *Spiroplasma* spp. can cause transmissible spongiform encephalopathies
[12] TSS, toxic shock syndrome
[13] MRSA, methicillin-resistant *Staphylococcus aureus*
[14] L-forms are cell-wall deficient derivatives that render the bacteria resistant to penicillin.
[15] CAMP, acronym for Christie, Atkins and Munch-Petersen, who discovered the basis for this test in 1944.
[16] Despite its name, *S. thermophilus* does not appear to be particularly thermophilic, with optimal growth from 35°C to 42°C.

Virginiamycin M, 765
Viridans streptococci, 571–572
Vir-repressed genes, 281
Virulence and pathogenesis, 520
Virulence factors, *Bordetella pertussis*
  acellular vaccines, included
    FHA, 286
    Fim, 286
    Prn, 286
    Ptx, 285–286
  acellular vaccines, not included
    adenylate cyclase-hemolysin, 286
    BrkA, 286
    DNT, 286
    LPS, 286
    TCT, 286
Virulence factor synthesis, 552
Virus
  antiviral drugs, 713
  assembly, 709
  definition, 704
  DNA viruses
    adenoviruses, 714
    herpesviruses, 714
    papillomaviruses, 713–714
    parvoviruses, 713
    polyomaviruses, 714
    poxviruses, 714–715
  epidemiology
    geography and season, 712
    individual at risk, 712
    transmission, 711–712
  host protective responses, 709–710
  pathogenesis and disease
    immunopathogenesis, 711
    laboratory detection, 711
    viral pathogenesis, 710–711
  prions, 719
  release, 709
  replication and consequences
    genome replication, 708
    recognition, attachment, and entry, 706–707
    viral mRNA and protein synthesis, 707–708
    virus assembly, 709
    virus release, 709
  RNA viruses
    arenaviruses, 717
    bornaviruses, 716
    bunyaviruses, 717
    caliciviruses and hepeviridae, 715
    coronaviruses, 715
    filoviruses, 716
    flaviviruses, 717
    hepatitis B virus (HBV), 718–719
    hepatitis D virus (HDV), 719

orthomyxoviruses, 716
paramyxoviruses, 715–716
picornaviruses, 715
reoviruses, 717
retroviruses, 717–718
rhabdoviruses, 716
togaviruses, 717
structure, 704–706
vaccines, 712–713
Virus emergence
antiviral medications, 740
clinical presentations associated with, **725–726**
Crimean-Congo hemorrhagic fever virus activity and vector distribution, *732*
cultivation-based detection, 740
diagnostic codes and synonyms, **729–730**
disease names and clinical interventions, **726–727**
febrile thrombocytopenia, *732*
hantaviruses, global distribution, *731*
hemorrhagic fever viruses in Africa, *730*
hemorrhagic fever viruses in Americas, *731*
histopathological analyses, 740
majora competent vectors for, **728**
non-neuroinvasive La Crosse virus infections, 740
notable, **724–725**
notable re-emerging, **733**
nucleic acid amplification tests, 740
polymerase chain reaction (PCR), 740
principles and drivers, 723–733
real-time PCR, 740
ribavirin, 740
viral antigens and nucleic acids, 740
viral culture, 740
virus-specific immunohistochemical, 740
Visceral leishmaniasis, 676
VITEK 2, 571–572
VITEK II system, 574
VNTR, *see* Variable number of tandem repeats
Voges-Proskauer reaction and sensitivity, 581
Voges-Proskauer (VP) test, 64–65
Voriconazole, 779
Vortexing, 867
Vortexing-sonication-vortexing method, 867–868
VP test, *see* Voges-Proskauer
Vulture capitalists, 887–888

W

Waddliaceae, 312, 315, 321
Waddlia chondrophila, 321
Waddlia malaysiensis, 321
Wall teichoic acids (WTA), 546, 548–549, *550*
Warthin-Starry silver impregnation stain, 621
Wassermann antibody, 537
Wasserman test, 535
Water-borne *P. syringae,* 499
Water-soluble monomer, 546
WCK 5222, 755
Weissella cryptocerci, 171
Western blacklegged tick, 534
Western Equine encephalitis virus, **725**
Western equine encephalomyelitis, **727**
Western immunoblots, 623
West Nile encephalitis, **727**
West Nile fever, **727**
West Nile virus, **725**
WGS, *see* Whole genome sequencing
Wheatley procedure, 48
Wheatley trichrome stain, 48
Whipworm, 675
Whole genome sequencing (WGS), 162–163, 252, 544
Actinobacteria phylum
annotation, 223
assembly, 223
basecalling, 223
debarcoding, 223
DNA preparation, 222
library preparation, 222–223
sequencing run, 223
Enterobacteriaceae, 353
Woesearchaeota, 240, 242
Wolbachia, 514, 619–620
Wolbachia endosymbionts and parasites, 514
Wood-Ljungdahl pathway, 327
World Federation for Culture Collections, 135
Woronin body, 634, 642
Wound volume reduction, 876
Wright-Giemsa combination stains, 50
Wuchereria, 49
Wuchereria bancrofti, 674, 678

X

Xanthomonas, 164
Xanthomonas campestris, 39
Xanthomonas maltophilia, 164
XDR, *see* Extreme drug resistance
Xenopsylla cheopis, 521
Xenorhabdus, 353

Y

Yeast growth form, fungi, 635
Yellow fever, **727**
Yellow fever virus, **725**
Yersinia, 63, 65–66, 849
cellular morphology, 589
culture, 589
diagnosis, treatment, and prevention, 591–592
diseases
plague, 590–591
Yersinia enterocolitica infections, 591
Yersinia pseudotuberculosis infections, 591
enteritis, 359
epidemiology, 588
human-pathogenic identification, **590**
isolates, identification of, 589–590
laboratory safety, 590
pathogenic species, 359–360
plague, 359
taxonomy, 587–588
Yersinia pestis, 359–360
Yersinia pseudotuberculosis, 359–360
Yop virulon, 360
Yersinia bercovieri, 359
Yersinia enterocolitica, 39, 64–65, 359–360, 588
Yersinia enterocolitica infections, 591
Yersinia entomophaga, 358–359
Yersinia frederiksenii, 359
Yersinia frederiksensii, 359
Yersinia intermedia, 359
Yersinia kristensenii, 359
Yersinia mollaretti, 359
Yersinia paleartica, 359

Yersinia pestis, 60, 66, 80, 82, 147, 359–360, 587–588, *589*
Yersinia pseudotuberculosis, 359–360, 588
Yersinia pseudotuberculosis infections, 591
Yersinia rohdei, 359
Yersinia ruckeri, 358
Yersinia similis, 588
Yersinia wautersii, 358, 588
Yop virulon, 360

Z

Zaire ebolavirus, **725**
Zestosphaera tikiterensis, 241
Zidebactam, 755
Zidovudine, 792
Ziehl-Neelsen staining
  procedure, 44
  reagents, 44
Zika congenital syndrome, **727**
Zika virus disease, **725**, **727**, 741
Zinc-dependent metalloprotease domain, 546
Zinc-finger nucleases (ZFNs), 795
Zinc floatation, 679
Zoliflodacin, 759–760
Zoonoses, 905
Zoonotic bacteria, 619
Zoonotic disease, 675–676
Zoonotic pathogens
  anaplasma, 619–620
  Bartonella, 621–622
  Borrelia, 622–623
  Brucella, 623–624
  Coxiella, 624–625
  Francisella, 625–626
  Pasteurella, 626–627
Zoopagomycota, 632
Zoosporangium, 637–638
Zoospores, 636–637
Zygomycosis, 642
Zygomycota, 632, 639, 641
Zygophores, 639–640
Zygosporangium, 640
Zygospore, 640
Zymogen, 546
