Book: Microbiology (Boundless)

Boundless

This text is disseminated via the Open Education Resource (OER) LibreTexts Project (https://LibreTexts.org) and like the hundreds of other texts available within this powerful platform, it is freely available for reading, printing and "consuming." Most, but not all, pages in the library have licenses that may allow individuals to make changes, save, and print this book. Carefully consult the applicable license(s) before pursuing such effects.

Instructors can adopt existing LibreTexts texts or Remix them to quickly build course-specific resources to meet the needs of their students. Unlike traditional textbooks, LibreTexts' web based origins allow powerful integration of advanced features and new technologies to support learning.

The LibreTexts mission is to unite students, faculty and scholars in a cooperative effort to develop an easy-to-use online platform for the construction, customization, and dissemination of OER content to reduce the burdens of unreasonable textbook costs to our students and society. The LibreTexts project is a multi-institutional collaborative venture to develop the next generation of open-access texts to improve postsecondary education at all levels of higher learning by developing an Open Access Resource environment. The project currently consists of 14 independently operating and interconnected libraries that are constantly being optimized by students, faculty, and outside experts to supplant conventional paper-based books. These free textbook alternatives are organized within a central environment that is both vertically (from advance to basic level) and horizontally (across different fields) integrated.

The LibreTexts libraries are Powered by MindTouch® and are supported by the Department of Education Open Textbook Pilot Project, the UC Davis Office of the Provost, the UC Davis Library, the California State University Affordable Learning Solutions Program, and Merlot. This material is based upon work supported by the National Science Foundation under Grant No. 1246120, 1525057, and 1413739. Unless otherwise noted, LibreTexts content is licensed by CC BY-NC-SA 3.0.

Any opinions, findings, and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the National Science Foundation nor the US Department of Education.

Have questions or comments? For information about adoptions or adaptions contact info@LibreTexts.org. More information on our activities can be found via Facebook (https://facebook.com/Libretexts), Twitter (https://twitter.com/libretexts), or our blog (http://Blog.Libretexts.org).

This text was compiled on 08/18/2022

TABLE OF CONTENTS

1: Introduction to Microbiology

1.1: Introduction to Microbiology

1.1A: Defining Microbes

1.1B: History of Microbiology - Hooke, van Leeuwenhoek, and Cohn

1.1C: Pasteur and Spontaneous Generation

1.1D: Koch and Pure Culture

1.2: Microbes and the World

1.2A Types of Microorganisms

1.2B: Classification of Microorganisms

1.2C: Microbes and the Origin of Life on Earth

1.2D: Environmental Diversity of Microbes

1.3: The Science of Microbiology

1.3A: Basic Microbiology

1.3B Applied Microbiology

1.3C: Immunization, Antiseptics, and Antibiotics

1.3D: Modern Microbiology

10: Epidemiology

10.1: Principles of Epidemiology

10.1A: History of Epidemiology

10.1B: The Science of Epidemiology

10.1C: The Vocabulary Epidemiology

10.1D: Koch’s Postulates

10.1E: Exceptions to Koch’s Postulates

10.2: Pathogen Identification

10.2A: Occurrence of a Disease

10.2B: Disease Severity and Duration

10.2C: Extent of Host Involvement

10.2D: Identification of Microbes Based on Molecular Genetics

10.3: Disease Patterns

10.3A: Predisposing Factors

10.3B: Disease Development

10.3C: Disease Reservoirs and Epidemics

10.3D: Infectious Disease Transmission

10.3E: Ecology, Epidemiology, and Evolution of Pathogens

10.3F: Safety in the Microbiology Laboratory

10.3G: Finding Patient Zero and Tracking Diseases

10.4: Nosocomial Infections

10.4A: Microorganisms in the Hospital

10.4B: Compromised Host

10.4C: Chain of Transmission

10.4D: Control of Nosocomial Infections

10.5: Epidemiology and Public Health
10.5A: Descriptive Epidemiology
10.5B: Analytical Epidemiology
10.5C: Experimental Epidemiology
10.5D: Public Health Measures for Disease Control
10.5E: Global Health
10.5F: Emerging and Reemerging Infectious Diseases
10.5G: Biological Weapons
10.5H: Technology and New Infectious Agents
10.5I: Current Epidemics

11: Immunology
11.1: Overview of Immunity
11.1A: Cells and Organs of the Immune System
11.1B: Overview of Human-Microbial Reactions
11.1C: Overview of the Immune System
11.2: The Innate Immune Response
11.3A: Natural Killer Cells
11.3B: Physical and Chemical Barriers
11.3C: The Complement System
11.3D: Pathogen Recognition
11.3: Phagocytes
11.4A: Phagocyte Migration and Phagocytosis
11.4B: Antigen-presenting Cells - B and T cells
11.4: Innate Defenders
11.4A: The Complement System
11.4B: Interferons
11.4C: Natural Killer Cells
11.4D: Toll-Like Receptors
11.4E: Iron-Binding Proteins
11.4F: Antimicrobial Peptides
11.4G: The Complement System and Heart Disease
11.5: The Adaptive Immune Response
11.5A: Humoral Immune Response
11.5B: Development of the Dual Lymphocyte System
11.6: Antigens and Antibodies
11.6A: Immunodeficiency
11.6B: Antibody Functions
11.7: Antibodies
11.7A: Antibody Proteins and Antigen Binding
11.7B: Antibody Genes and Diversity
11.7C: Clonal Selection of Antibody-Producing Cells
11.7D: Isotype Class Switching
11.7E: Making Memory B Cells
11.7F: Primary and Secondary Antibody Responses

11.8: T Cells and Cellular Immunity
11.8A: Cytotoxic T Lymphocytes and Mucosal Surfaces
11.8B: Classes of T Cells
11.8C: Cell-Mediated Immunity
11.8D: Regulatory T Cells
11.8E: T Cell Receptors
11.8F: Adaptive Immunity and the Immunoglobulin Superfamily
11.9: Antigen-Presenting Cells
11.9A: Dendritic Cells
11.9B: Macrophages
11.10: Immunity and Molecular Signals
11.10A: Clonal Selection and Tolerance
11.10B: Cytokines and Chemokines
11.10C: Superantigens
11.10D: The Complement System
11.11: The Major Histocompatibility Complex (MHC)
11.11A: MHC Polymorphism and Antigen Binding
11.12: Classifying Immunities
11.12A: Natural Active Immunity
11.12B: Natural Passive Immunity
11.12C: Artificial Immunity

12: Immunology Applications
12.1: Immunization
12.1A: Passive Immunization
12.1B: Vaccination
12.1C: Development of New Vaccines
12.1D: Vaccine Safety
12.2: Immunoassays for Disease
12.2A: Immunoassays for Disease
12.2B: Antibody Functions
12.2C: Serology
12.2D: Precipitation Reactions
12.2E: Agglutination Reactions
12.2F: Neutralization Reaction
12.2G: Complement Fixation
12.2H: Fluorescent Antibodies
12.2I: Enzyme-Linked Immunosorbent Assay (ELISA)
12.2J: Immunoblot Procedures
12.2K: Tests That Differentiate Between T Cells and B cells
12.2L: In Vivo Testing
12.2M: The Future of Diagnostic Immunology
12.3: Preparations for Diagnosing Infection
12.3A: Specimen Collection
12.3B: Immediate Direct Examination of Specimen

12.3C: Cultivation of Specimen
12.3D: DNA Analysis Using Genetic Probes and PCR
12.3E: Nucleic Acid Sequencing and rRNA Analysis
12.4: Immunity Disorders: Hypersensitivity
12.4A: Type I (Anaphylactic) Reactions
12.4B: Diagnosis and Treatment of Allergy
12.4C: Type II (Cytotoxic) Reactions
12.4D: Type III (Immune Complex) Reactions
12.4E: Type IV (Delayed Cell-Mediated) Reactions
12.5: Immunity Disorders: Autoimmune Diseases
12.5A: Immunodeficiency
12.5B: The Roles of Genetics and Gender in Autoimmune Disease
12.5C: Cytotoxic Autoimmune Reactions
12.5D: Immune Complex Autoimmune Reactions
12.5E: Cell-Mediated Autoimmune Reactions
12.6: Immunity Disorders: Immunodeficiencies
12.6A: Primary Immunodeficiency Diseases
12.6B: Secondary Immunodeficiency Diseases
12.6C: Immunotherapy for Cancer

13: Antimicrobial Drugs
13.1: Overview of Antimicrobial Therapy
13.1A: Origins of Antimicrobial Drugs
13.1B: Antibiotic Discovery
13.1C: Antibiotics and Selective Toxicity
13.1D: Spectrum of Antimicrobial Activity
13.1E: Antibiotic Classifications
13.2: Functions of Antimicrobial Drugs
13.2A: Inhibiting Cell Wall Synthesis
13.2B: Injuring the Plasma Membrane
13.2C: Inhibiting Nucleic Acid Synthesis
13.2D: Inhibiting Protein Synthesis
13.2E: Inhibiting Essential Metabolite Synthesis
13.3: Commonly Used Antimicrobial Drugs
13.3A: Synthetic Antimicrobial Drugs
13.3B: Naturally Occurring Antimicrobial Drugs: Antibiotics
13.3C: Beta-Lactam Antibiotics: Penicillins and Cephalosporins
13.3D: Antibiotics from Prokaryotes
13.3E: Antimycobacterial Antibiotics
13.4: Interactions Between Drug and Host
13.4A: Organ Toxicity
13.4B: Allergic Responses to Drugs
13.4C: Suppression and Alteration of Microbiota by Antimicrobials
13.4D: Effects of Drug Combinations
13.5: Measuring Drug Susceptibility

13.5A: Minimal Inhibitory Concentration (MIC)
13.5B: Kirby-Bauer Disk Susceptibility Test
13.6: Drug Resistance
13.6A: Mechanisms of Resistance
13.6B: Antibiotic Misuse
13.6C: Cost and Prevention of Resistance
13.6D: Biofilms, Persisters, and Antibiotic Tolerance
13.6E: Finding New Antimicrobial Drugs
13.6F: Antimicrobial Peptides
13.6G: Antisense Agents
13.7: Antiviral Drugs
13.7A: Antiviral Agents that Prevent Virus Uncoating or Release
13.7B: Antiviral DNA Synthesis Inhibitors
13.7C: Nucleotide and Nonnucleotide Reverse Transcriptase Inhibitors
13.7D: Protease Inhibitors
13.8: Other Antimicrobial Drugs
13.8A: Antifungal Drugs
13.8B: Antiprotozoan and Antihelminthic Drugs

14: Pathogenicity
14.1: Entry into the Host
14.1A: Portals of Microbe Entry
14.1B: Colonization and Growth
14.1C: Pathogenicity Islands and Virulence Factors
14.1D: Adherence
14.1E: Host Risk Factors
14.1F: Innate Resistance
14.2: Overview of Microbe-Host Interactions
14.2A: Normal Microbiota and Host Relationships
14.2B: Opportunistic Microorganisms
14.2C: Cooperation Among Microorganisms
14.3: Penetrating Host Defenses
14.3A: Penetrating Host Defenses
14.3B: Pili and Pilus Assembly
14.3C: Biofilms and Infections
14.4: Damaging Host Cells
14.4A: Toxins
14.4B: Direct Damage
14.4C: Type III and Type IV Secretion
14.4D: Plasmids and Lysogeny
14.4E: Siderophores
14.5: Surviving Within the Host and Exiting the Host
14.5A: Intracellular Pathogens
14.5B: Extracellular Immune Avoidance
14.5C: Regulating Virulence

14.5D: Portals of Exit
14.6: Pathogenicity and Other Microbes
14.6A: Fungi
14.6B: Protozoa
14.6C: Helminths
14.6D: Algae

15: Diseases

15.1: Diagnosing Microbial Diseases
15.1A: Diagnosing Microbial Diseases
15.10: Protozoan and Helminthic Diseases of the Cardiovascular and Lymphatic Systems
15.10A: Chagas Disease (American Trypanosomiasis)
15.10B: Toxoplasmosis
15.10C: Malaria
15.10D: Leishmaniasis
15.10E: Babesiosis
15.10F: Schistosomiasis
15.10G: Swimmer’s Itch
15.11: Microbial Diseases of the Respiratory System
15.11A: Functional Anatomy of the Respiratory System
5.11B: Airborne Transmission of Disease
15.12: Bacterial Diseases of the Respiratory System
15.12A: Pharyngitis
15.12B: Scarlet Fever
15.12C: Diphtheria
15.12D: Otitis Media
15.12E: Whooping Cough
15.12F: Tuberculosis
15.12G: Bacterial Pneumonias
15.13: Viral Diseases of the Respiratory System
15.13A: Colds
15.13B: Viral Pneumonia
15.13C: Respiratory Syncytial Virus Infection
15.13D: Coryza and Influenza
15.14: Fungal Diseases of the Respiratory System
15.14A: Histoplasmosis
15.14B: Coccidiomycosis
15.14C: Pneumocystis Pneumonia
15.14D: Blastomycosis
15.14E: Other Fungi Involved in Respiratory Disease
15.15: Microbial Diseases of the Digestive System
15.15A: Anatomy of the Digestive System
15.15B: Normal Gastrointestinal Microbiota
15.16: Bacterial Diseases of the Mouth
15.16A: Tooth and Gum Infections

15.16B: Dental Caries
15.16C: Periodontal Disease
15.17: Bacterial Diseases of the Digestive System
15.17A: Bacterial Gastroenteritis
15.17B: Staphylococcal Food Poisoning
15.17C: Salmonellosis
15.17D: Typhoid Fever
15.17E: Cholera
15.17F: Noncholera Vibrios
15.17G: Pathogenic Escherichia coli
15.17H: Campylobacter
15.17I: Peptic Ulcer Disease
15.17J: Listeriosis
15.18: Viral Diseases of the Digestive System
15.18A: Mumps
15.18B: Hepatitis
15.18C: Viral Gastroenteritis
15.19: Fungal and Protozoan Diseases of the Digestive System
15.19A: Ergot Poisoning
15.19B: Aflatoxin Poisoning
15.19C: Giardiasis
15.19D: Cryptosporidiosis
15.19E: Cyclospora Diarrheal Infection
15.19F: Amoebic Dysentery (Amoebiasis)
15.19G: Legionellosis
15.2: Microbial Diseases of the Skin
15.1A: Structure of the Skin: Epidermis
15.1B: Microbiota of the Skin
15.1C: Bacterial Skin Diseases
15.1D: Viral Skin Diseases
15.1E: Fungal Skin and Nail Diseases
15.1F: Parasitic Skin Diseases
15.20: Helminthic Diseases of the Digestive System
15.20A: Tapeworms
15.20B: Hydatid Disease
15.20C: Nematodes
15.21: Microbial Diseases of the Genitourinary System
15.21A: Overview of the Male and Female Reproductive Systems
15.21B: Overview of the Urinary System
15.21C: Normal Genitourinary Microbiota
15.22: Bacterial Diseases of the Urinary System
15.22A: Urinary Tract Infection (UTI)
15.22B: Cystitis
15.22C: Pyelonephritis
15.22D: Leptospirosis

15.23: Bacterial Diseases of the Reproductive System
15.23A: Prostatitis
15.23B: Prostatitis
15.23C: Gonorrhea
15.23D: Nongonococcal Urethritis (NGU)
15.23E: Pelvic Inflammatory Disease (PID)
15.23F: Syphilis
15.23G: Genital Ulcer Diseases
15.23H: Lymphogranuloma Venereum
15.23I: Group B Streptococcus Colonization
15.23J: Chancroid (Soft Chancre)
15.23K: Bacterial Vaginosis
15.23L: Chlamydia
15.24: Viral Diseases of the Reproductive System
15.24A: Genital Herpes
15.24B: Genital Warts
15.24C: HIV and AIDS
15.24D: Human Papillomavirus (HPV)
15.25: Fungal and Protozoan Diseases of the Reproductive System
15.25A: Vulvovaginal Candidiasis
15.25B: Trichomoniasis
15.25C: The TORCH Panel of Tests
15.3: Microbial Diseases of the Eye
15.3A: Anatomy of the Eye
15.3B: Normal Eye Microbiota
15.3C: Bacterial Eye Diseases
15.3D: Other Infectious Eye Diseases
15.4: Microbial Diseases of the Nervous System
15.4A: Functions of the Nervous System
15.4B: Subdivisions of the Nervous System
15.4C: Meningitis
15.4D: Botulism
15.4E: Leprosy
15.4F: Tetanus
15.4G: Paralysis-Causing Bacterial Neurotoxins
15.5: Other Diseases of the Nervous System
15.5A: Rabies
15.5B: Poliomyelitis
15.5C: Hantavirus
15.5D: Arboviral Encephalitis
15.5E: Rickettsial Diseases
15.5F: Lyme Disease
15.5G: West Nile Virus
15.5H: Plague
15.6: Fungal, Protozoan, Prion, and Other Diseases of the Nervous System
15.6A: Cryptococcosis

15.6B: African Trypanosomiasis
15.6C: Amoebic Meningoencephalitis
15.6D: Bovine Spongiform Encephalopathy
15.6E: Variant Creutzfeldt-Jakob Disease
15.6F: Chronic Fatigue Syndrome
15.7: Microbial Diseases of the Cardiovascular and Lymphatic Systems
15.7A: Functions of the Lymphatic System
15.7B: The Cardiovascular System
15.7C: Structure of the Lymphatic System
15.7D: Cardiovascular and Lymphatic System Defenses
15.8: Bacterial Diseases of the Cardiovascular and Lymphatic Systems
15.8A: Sepsis and Septic Shock
15.8B: Bacterial Infections of the Heart
15.8C: Rheumatic Fever
15.8D: Tularemia
15.8E: Brucellosis (Undulant Fever)
15.8F: Anthrax
15.8G: Gangrene
15.9: Viral Diseases of the Cardiovascular and Lymphatic Systems
15.9A: Burkitt's Lymphoma
15.9B: Infectious Mononucleosis
15.9C: Other Diseases and Epstein-Barr Virus
15.9D: Cytomegalovirus Infections
15.9E: Chikungunya Fever
15.9F: Classic Viral Hemorrhagic Fevers
15.9G: Emerging Viral Hemorrhagic Fevers
16: Microbial Ecology
16.1: Microbial Ecology
16.1A: Microbes and Ecosystem Niches
16.1B: Organization of Ecosystems
16.1C: Role of Microbes in Biogeochemical Cycling
16.1D: Microbial Environments and Microenvironments
16.2: Soil and Plant Microbiology
16.2A: Soil Composition
16.2B: Physical Properties of Soil
16.2C: Mycorrhiza
16.2D: Wetland Soils
16.2E: Endophytes and Plants
16.2F: Mycorrhizae: The Symbiotic Relationship between Fungi and Roots
16.2F: Plant Pathogens
16.2G: Nitrogen Fixation: Root and Bacteria Interactions
16.3: Aquatic Microbiology
16.3A: Marine Habitats
16.3B: Planktonic Communities

16.3C: Planktonic Food Webs
16.3D: Ocean Floor
16.3E: Cold-Seep Ecosystems
16.3F: The Deep Sea and Barophilism
16.3G: Sea Coral and Sea Anemone Zooxanthellae
16.3H: Sponge Communities
16.3I: Freshwater Environments
16.4: Nutrient Cycles
16.4A: Sources and Sinks of Essential Elements
16.4B: The Carbon Cycle
16.4C: Syntrophy and Methanogenesis
16.4D: The Phosphorus Cycle
16.4E: The Nitrogen Cycle
16.4F: The Sulfur Cycle
16.4G: The Iron Cycle
16.5: Microbial Symbioses
16.5A: Mutualism vs. Symbiosis
16.5B: The Rumen and Ruminant Animals
16.5C: Hydrothermal Vent Microbial Ecosystems
16.5D: Squid-Aliivibrio Symbiosis
16.5E: Mutualistic Relationships with Fungi and Fungivores
16.5F: Agrobacterium and Crown Gall Disease
16.5G: The Legume-Root Nodule Symbiosis
16.6: Microbial Bioremediation
16.6A: Microbial Ore Leaching
16.6B: Petroleum Biodegradation
16.6C: The Degradation of Synthetic Chemicals in Soils and Water
17: Industrial Microbiology
17.1: Industrial Microbiology
17.1A: Industrial Microorganisms
17.1B: Molecular Products from Microbes
17.1C: Primary and Secondary Metabolites
17.1D: Large-Scale Fermentations
17.2: Microbial Products in the Health Industry
17.2A: Industrial Production of Antibiotics
17.2B: Vitamins and Amino Acids
17.2C: Steroids
17.2D: Enzymes Used in Industry
17.3: Wastewater Treatment and Water Purification
17.3A: Microorganisms and Water Quality
17.3B: Wastewater and Sewage Treatment
17.3C: Purification of Drinking Water
17.4: The Microbiology of Food
17.4A: Wine, Beer, and Alcohol

17.4B: Vinegar
17.4C: Citric Acid and Other Organic Compounds
17.4D: Edible Fungi
17.4E: Edible Algae
17.4F: Microbes and Dairy Products
17.5: Food Preservation
17.5A: Fermented Foods
17.5B: Food Spoilage by Microbes
17.5C: Food Preservation

2: Chemistry
2.1: Atomic Structure
2.1.1: Overview of Atomic Structure
2.1.2: Electronic Orbitals
2.2: Chemical Bonds
2.2.1: Ions and Ionic Bonds
2.2.2: Colvalent Bonds and Other Bonds and Interaction
2.2.3: Hydrogen Bonding
2.2.4: Avogadro's Number and the Mole
2.2.5: Average Atomic Mass
2.3: Chemical Reactions
2.3.1: The Chemical Basis of Life
2.3.2: Energy Changes in Chemical Reactions
2.4: Inorganic Compounds
2.4.1: Water's State: Gas, Liquid, and Solid
2.4.2: pH, Buffers, Acids, and Bases
2.4.3: Overview of the Acid- Base Properties of Salt
2.5: Organic Compounds
2.5.1: Carbohydrate Molecules
2.5.2: Lipid Molecules
2.5.3: DNA and RNA
2.5.4: Amino Acids
2.5.5: Types and Functions of Protiens
2.5.6: ATP: Adenosine Triphosphate
2.6: Energy
2.6.1: Metabolism of Carbohydrates
2.6.2: Free Energy Changes in Chemical Reactions
2.6.3: Internal Energy and Enthaply
2.7: Enzymes
2.7.1: Control of Metabolism Through Enzyme Regulation
2.7.2: Enzyme Active Site and Substrate Specificity

3: Microscopy
3.1: Looking at Microbes
3.1A: Microbe Size

3.1B: Units of Measurement for Microbes
3.1C: Refraction and Magnification
3.1D: Magnification and Resolution
3.2: Other Types of Microscopy
3.2A: Microscopy
3.2B: General Staining Methods
3.3: Other Types of Microscopy
3.3A: Dark-Field Microscopy
3.3B: Phase-Contrast Microscopy
3.3C: Interference Microscopy
3.3D: Fluorescence Microscopy
3.3E: Confocal Micropscopy
3.3F: Electron Microscopy
3.3G: Scanned-Probe Microscopy
3.3H: X-Ray Diffraction Analysis
4: Cell Structure of Bacteria, Archaea, and Eukaryotes
4.1: Overview of Prokaryotic and Eukaryotic Cells
4.1A: Characteristics of Prokaryotic Cells
4.2: The Cytoplasmic Membrane of Prokaryotic and Eukaryotic Cells
4.2A: Components of Plasma Membranes
4.3: Transport Across the Cell Membrane
4.3A: Facilitated Transport
4.3B: Primary Active Transport
4.3C: ABC Transporters
4.3D: Siderophores
4.3E: Group Translocation
4.4: Cell Walls of Prokaryotes
4.4A: The Cell Wall of Bacteria
4.4B: Gram-Negative Outer Membrane
4.4C: Gram-Positive Cell Envelope
4.4D: Mycoplasmas and Other Cell-Wall-Deficient Bacteria
4.4E: Cell Walls of Archaea
4.4F: Damage of the Cell Wall
4.5: Specialized External Structures of Prokaryotes
4.5A: Endospores
4.6: Specialized Internal Structures of Prokaryotes
4.6A: Ribosomes
4.6B: Cell Inclusions and Storage Granules
4.6C: Carboxysomes
4.6D: Magnetosomes
4.6E: Gas Vesicles
4.7: Internal Structures of Eukaryotic Cells
4.7A: The Nucleus and Ribosomes
4.7B: Mitochondria

4.7C: Comparing Plant and Animal Cells
4.7D: The Endoplasmic Reticulum
4.7E: The Golgi Apparatus
4.8: Other Eukaryotic Components
4.8A: Peroxisomes
4.8B: Lysosomes
4.8C: Intermediate Filaments and Microtubules
4.8D: Extracellular Matrix of Animal Cells
4.9: Protein Export and Secretion
4.9A: Endocytosis
4. 10: Studying Cells
4.10A: Microscopy
4.10B: Crystallographic Analysis
4.10C: Genetic Analysis

5: Microbial Metabolism
5.1: Types of Metabolism
5.1A: Photoautotrophs and Photohetrotrophs
5.1B: Chemoautotrophs and Chemohetrotrophs
5.2: Energy Production
5.2A: Control of Catabolic Pathways
5.2B: Transforming Chemical Energy
5.2C: Connecting Other Sugars to Glucose Metabolism
5.3: Catabolism
5.3A: Types of Catabolism
5.3B: Pyruvic Acid and Metabolism
5.4: Glycolysis
5.4A: Importance of Glycolysis
5.4B: Electron Donors and Acceptors
5.4C: ATP Yield
5.4D: Respiration and Proton Motive Force
5.5: Respiratory ETS and ATP Synthase
5.5A: Cofactors and Energy Transitions
5.5B: Oxidoreductase Protein Complexes
5.5C: F10 ATP Synthase
5.5D: Sodium Pumps as an Alternative to Proton Pump
5.6: The Citric Acid (Krebs) Cycle
5.6A: Citric Acid Cycle
5.6B: Breakdown of Pyruvate
5.6C: Acetyl CoA and the Citric Acid Cycle
5.7: Alternatives to Glycolysis

CHAPTER OVERVIEW

1: Introduction to Microbiology

Microbiology is a broad term which includes virology, mycology, parasitology, bacteriology, immunology, and other branches. A microbiologist is a specialist in microbiology and these related topics. Microbiological procedures usually must be aseptic and use a variety of tools such as light microscopes with a combination of stains and dyes. As microbes are absolutely required for most facets of human life (including the air we breathe and the food we eat) and are potential causes of many human diseases, microbiology is paramount for human society.

1.1A: Defining Microbes

Learning Objectives

- Explain the roles of microorganisms in ecosystems and biotechnology.

A microbe, or microorganism, is a microscopic organism that comprises either a single cell (unicellular); cell clusters; or multicellular, relatively complex organisms. The study of microorganisms is called microbiology, a subject that began with Anton van Leeuwenhoek's discovery of microorganisms in 1675, using a microscope of his own design.

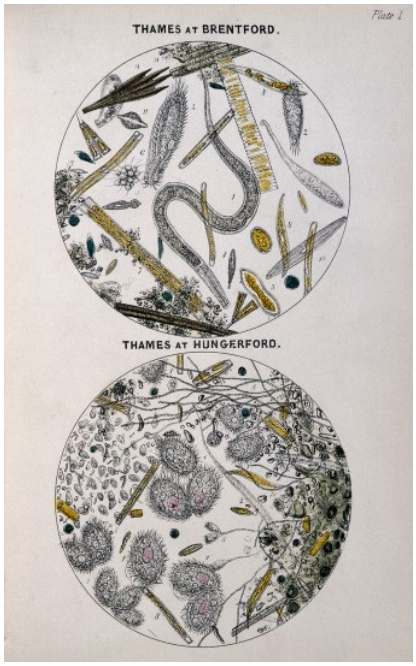

Figure: ***A Drawing of Microbes****: This is a drawing of what Arthur Hill Hassall saw under a microscope in a sample of water taken from the River Thames at two locations. Hassall was able to identify many microscopic organisms not perceptible to the unaided eye,.*

Microorganisms are very diverse; they include bacteria, fungi, algae, and protozoa; microscopic plants (green algae); and animals such as rotifers and planarians. Some microbiologists also include viruses, but others consider these as nonliving. Most microorganisms are unicellular, but this is not universal, since some multicellular organisms are microscopic. Some unicellular protists and bacteria, like *Thiomargarita namibiensis*, are macroscopic and visible to the naked eye.

Microorganisms live in all parts of the biosphere where there is liquid water, including soil, hot springs, on the ocean floor, high in the atmosphere, and deep inside rocks within the Earth's crust. Most importantly, these organisms are vital to humans and the environment, as they participate in the Earth's element cycles, such as the carbon cycle and the nitrogen cycle.

Microorganisms also fulfill other vital roles in virtually all ecosystems, such as recycling other organisms' dead remains and waste products through decomposition. Microbes have an important place in most higher-order multicellular organisms as symbionts, and they are also exploited by people in biotechnology, both in traditional food and beverage preparation, and in modern technologies based on genetic engineering. Pathogenic microbes are harmful, however, since they invade and grow within other organisms, causing diseases that kill humans, animals, and plants.

The Pathogenic Ecology of Microbes

Although many microorganisms are beneficial, many others are the cause of infectious diseases. The organisms involved include pathogenic bacteria, which cause diseases such as plague, tuberculosis, and anthrax. Biofilms —microbial communities that are very difficult to destroy—are considered responsible for diseases like bacterial infections in patients with cystic fibrosis, Legionnaires' disease, and otitis media (middle ear infection). They produce dental plaque; colonize catheters, prostheses, transcutaneous, and orthopedic devices; and infect contact lenses, open wounds, and burned tissue.

Biofilms also produce foodborne diseases because they colonize the surfaces of food and food-processing equipment. Biofilms are a large threat because they are resistant to most of the methods used to control microbial growth. Moreover, the excessive use of antibiotics has resulted in a major global problem since resistant forms of bacteria have been selected over time. A very dangerous strain, methicillin-resistant *Staphylococcus aureus* (MRSA), has wreaked havoc recently.

In addition, protozoans are known to cause diseases such as malaria, sleeping sickness, and toxoplasmosis, while fungi can cause diseases such as ringworm, candidiasis, or histoplasmosis. Other diseases such as influenza, yellow fever, and AIDS are caused by viruses.

Food-borne diseases result from the consumption of contaminated food, pathogenic bacteria, viruses, or parasites that contaminate food. ” Hygiene ” is the avoidance of infection or food spoiling by eliminating microorganisms from the surroundings. As microorganisms (bacteria, in particular) are found virtually everywhere, the levels of harmful microorganisms can be reduced to acceptable levels with proper hygiene techniques. In some cases, however, it is required that an object or substance be completely sterile (i.e., devoid of all living entities and viruses). A good example of this is a hypodermic needle.

Key Points

- While most microbes are unicellular, some multicellular animals and plants are also microscopic and are therefore broadly defined as “microbes.”
- Microbes serve many functions in almost any ecosystem on Earth, including decomposition and nitrogen fixation.
- Many microbes are either pathogens or parasitic organisms, both of which can harm humans.

Key Terms

- **symbiote**: An organism in a partnership with another, such that each profits from the other.
- **pathogenic**: Able to cause a harmful disease.
- **ecosystem**: The interconnectedness of plants, animals, and microbes, not only with each other but also with their environment.

1.1B: History of Microbiology - Hooke, van Leeuwenhoek, and Cohn

Learning Objectives

- Explain how Van Leeuwenhoek, Spallanzani, Pasteur, Cohn and Koch contributed to the field of microbiology

Pre-microbiology, the possibility that microorganisms existed was discussed for many centuries before their actual discovery in the 17th century. The existence of unseen microbiological life was postulated by Jainism, which is based on Mahavira's teachings as early as 6th century BCE. In his first century book, *On Agriculture*, Roman scholar Marcus Terentius Varro was the first known to suggest the possibility of disease spreading by yet unseen organisms. In his book, he warns against locating a homestead near swamps because "there are bred certain minute creatures that cannot be seen by the eyes, which float in the air and enter the body through the mouth and nose and there cause serious diseases. " In *The Canon of Medicine* (1020), Abū Alī ibn Sīnā (Avicenna) hypothesized that tuberculosis and other diseases might be contagious. In 1546, Girolamo Fracastoro proposed that epidemic diseases were caused by transferable seed-like entities that could transmit infection by direct or indirect contact, or even without contact over long distances. All these early claims about the existence of microorganisms were speculative and were not based on any data or science. Microorganisms were neither proven, observed, nor correctly and accurately described until the 17th century. The reason for this was that all these early studies lacked the microscope.

The Microscope and Discovery of Microorganisms

Antonie van Leeuwenhoek (1632–1723) was one of the first people to observe microorganisms, using a microscope of his own design, and made one of the most important contributions to biology. Robert Hooke was the first to use a microscope to observe living things. Hooke's 1665 book, *Micrographia*, contained descriptions of plant cells. Before Van Leeuwenhoek's discovery of microorganisms in 1675, it had been a mystery why grapes could be turned into wine, milk into cheese, or why food would spoil. Van Leeuwenhoek did not make the connection between these processes and microorganisms, but using a microscope, he did establish that there were forms of life that were not visible to the naked eye. Van Leeuwenhoek's discovery, along with subsequent observations by Spallanzani and Pasteur, ended the long-held belief that life spontaneously appeared from non-living substances during the process of spoilage.

Figure: ***Antoni van Leeuwenhoek****: A drawing of Antoni van Leeuwenhoek, one of the first scientists to use a microscope and identify microbes.*

Lazzaro Spallanzani (1729–1799) found that boiling broth would sterilize it and kill any microorganisms in it. He also found that new microorganisms could settle only in a broth if the broth was exposed to the air.

Louis Pasteur (1822–1895) expanded upon Spallanzani's findings by exposing boiled broths to the air in vessels that contained a filter to prevent all particles from passing through to the growth medium. He also did this in vessels with no filter at all, with air being admitted via a curved tube that prevented dust particles from coming in contact with the broth. By boiling the broth beforehand, Pasteur ensured that no microorganisms survived within the broths at the beginning of his experiment. Nothing grew in the broths in the course of Pasteur's experiment. This meant that the living organisms that grew in such broths came from outside, as spores on dust, rather than spontaneously generated within the broth. Thus, Pasteur dealt the death blow to the theory of spontaneous generation and supported germ theory instead.

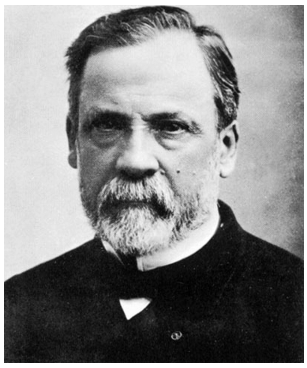

Figure: ***Louis Pasteur****: The famous scientist Louis Pasteur, one of the founders of microbiology.*

Ferdinand Julius Cohn (January 24, 1828 – June 25, 1898) was a German biologist. His classification of bacteria into four groups based on shape (sphericals, short rods, threads, and spirals) is still in use today. Among other things Cohn is remembered for being the first to show that *Bacillus* can change from a vegetative state to an endospore state when subjected to an environment deleterious to the vegetative state. His studies would lay the foundation for the classification of microbes and gave some of the first insights into the incredible complexity and diversity of microbial life.

In 1876, Robert Koch (1843–1910) established that microbes can cause disease. He found that the blood of cattle who were infected with anthrax always had large numbers of *Bacillus anthracis*. Koch found that he could transmit anthrax from one animal to another by taking a small sample of blood from the infected animal and injecting it into a healthy one, and this caused the healthy animal to become sick. He also found that he could grow the bacteria in a nutrient broth, then inject it into a healthy animal, and cause illness. Based on these experiments, he devised criteria for establishing a causal link between a microbe and a disease and these are now known as Koch's postulates. Although these postulates cannot be applied in all cases, they do retain historical importance to the development of scientific thought and are still being used today.

Key Points

- Van Leeuwenhoek is largely credited with the discovery of microbes, while Hooke is credited as the first scientist to describe live processes under a microscope.
- Spallanzani and Pasteur performed several experiments to demonstrate that microbial life does not arise spontaneously.
- Cohn laid the groundwork for discovering and cataloging microbes, while Koch conclusively showed that microbes can cause diseases.

Key Terms

- **classification**: the act of forming into a class or classes; a distribution into groups, as classes, orders, families, etc., according to some common relations or attributes.

This page titled 1.1B: History of Microbiology - Hooke, van Leeuwenhoek, and Cohn is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

1.1C: Pasteur and Spontaneous Generation

Learning Objectives

- Explain the concept of spontaneous generation

Spontaneous generation is an obsolete body of thought on the ordinary formation of living organisms without descent from similar organisms. Typically, the idea was that certain forms such as fleas could arise from inanimate matter such as dust or that maggots could arise from dead flesh. A variant idea was that of equivocal generation, in which species such as tapeworms arose from unrelated living organisms, now understood to be their hosts.

Doctrines held that these processes were commonplace and regular. Such ideas were in contradiction to that of univocal generation: effectively exclusive reproduction from genetically related parent(s), generally of the same species. The doctrine of spontaneous generation was coherently synthesized by Aristotle, who compiled and expanded the work of prior natural philosophers and the various ancient explanations of the appearance of organisms; it held sway for two millennia.

Today spontaneous generation is generally accepted to have been decisively dispelled during the 19th century by the experiments of Louis Pasteur. He expanded upon the investigations of predecessors, such as Francesco Redi who, in the 17th century, had performed experiments based on the same principles.

Louis Pasteur's 1859 experiment is widely seen as having settled the question. In summary, Pasteur boiled a meat broth in a flask that had a long neck that curved downward, like a goose. The idea was that the bend in the neck prevented falling particles from reaching the broth, while still allowing the free flow of air. The flask remained free of growth for an extended period. When the flask was turned so that particles could fall down the bends, the broth quickly became clouded. In detail, Pasteur exposed boiled broths to air in vessels that contained a filter to prevent all particles from passing through to the growth medium, and even in vessels with no filter at all, with air being admitted via a long tortuous tube that would not allow dust particles to pass. Nothing grew in the broths unless the flasks were broken open, showing that the living organisms that grew in such broths came from outside, as spores on dust, rather than spontaneously generated within the broth. This was one of the last and most important experiments disproving the theory of spontaneous generation.

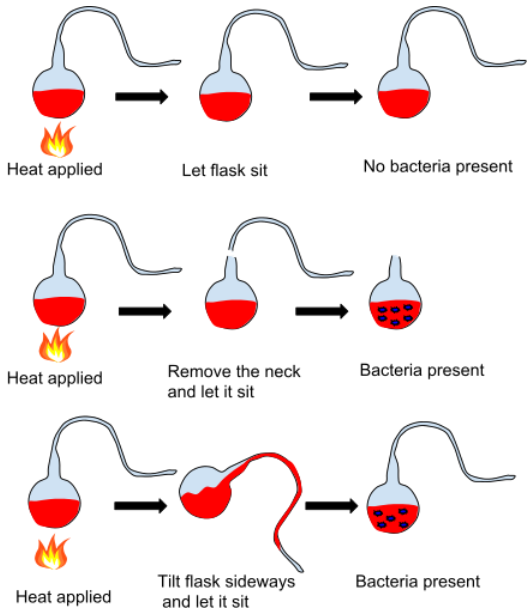

Figure: ***Pasteur's test of spontaneous generation****: By sterilizing a food source and keeping it isolated from the outside, Pasteur observed no putrefaction of the food source (top panel). Upon exposure to the outside environment, Pasteur observed the putrefaction of the food source (bottom panel). This strongly suggested that the components needed to create life do not spontaneously arise. Louis Pasteur's pasteurization experiment illustrates the fact that the spoilage of liquid was caused by particles in the air rather than the air itself. These experiments were important pieces of evidence supporting the idea of germ theory of disease. (CC BY-SA 4.0; Kgerow16).*

Despite his experiment, objections from persons holding the traditional views persisted. Many of these residual objections were routed by the work of John Tyndall, succeeding the work of Pasteur. Ultimately, the ideas of spontaneous generation were displaced

by advances in germ theory and cell theory. Disproof of the traditional ideas of spontaneous generation is no longer controversial among professional biologists. Objections and doubts have been dispelled by studies and documentation of the life cycles of various life forms. However, the principles of the very different matter of the original abiogenesis on this planet — of living from nonliving material — are still under investigation

Key Points

- Before the discovery of microbes, it was widely thought that life, as in the case of rotting food, arose from nothing. This idea was referred to as spontaneous generation.
- By sterilizing cultures and keeping them isolated from the open air, Pasteur found that contamination of the media only occurred upon exposure to the outside environment, showing that some element was needed to give rise to life. In other words, life does not arise spontaneously.
- Despite Pasteur's work and the work of others, it still took a better understanding of germ theory and cell theory to finally displace the concept of spontaneous generation.

Key Terms

- **abiogenesis**: The origination of living organisms from lifeless matter; such genesis as does not involve the action of living parents; spontaneous generation.
- **germ theory**: The germ theory of disease, also called the pathogenic theory of medicine, is a theory that proposes that microorganisms are the cause of many diseases. Although highly controversial when first proposed, germ theory was validated in the late 19th century and is now a fundamental part of modern medicine and clinical microbiology, leading to such important innovations as antibiotics and hygienic practices.

1.1D: Koch and Pure Culture

Learning Objectives

- Explain Robert Koch's postulates

Robert Koch was born in Clausthal in the Harz Mountains, then part of the Kingdom of Hanover, as the son of a mining official. He studied medicine at the University of Göttingen and graduated in 1866. He then served in the Franco-Prussian War and later became district medical officer in Wollstein (Wolsztyn), Prussian Poland. Working with very limited resources, he became one of the founders of bacteriology, the other major figure being Louis Pasteur.

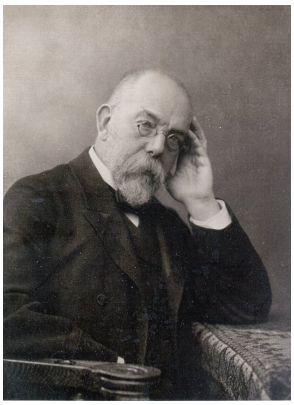

Figure: ***Robert Koch****: An image of Robert Koch, a pioneering microbiologist. Koch's research and methods helped link the causal nature of microbes to certain diseases, including anthrax.*

After Casimir Davaine demonstrated the direct transmission of the anthrax bacillus between cows, Koch studied anthrax more closely. He invented methods to purify the bacillus from blood samples and grow pure cultures. He found that, while it could not survive outside a host for long, anthrax built persisting endospores that could last a long time. These endospores, embedded in soil, were the cause of unexplained "spontaneous" outbreaks of anthrax. Koch published his findings in 1876 and was rewarded with a job at the Imperial Health Office in Berlin in 1880. In 1881, he urged for the sterilization of surgical instruments using heat.

Probably as important as his work on tuberculosis, for which he was awarded a Nobel Prize in 1905, are Koch's postulates. These postulates stated that to establish that an organism is the cause of a disease, it must be found in all cases of the disease examined. Additionally, it must be absent in healthy organisms prepared and maintained in a pure culture capable of producing the original infection, even after several generations in culture retrievable from an inoculated animal and cultured again. By using his methods, Koch's pupils found the organisms responsible for diphtheria, typhoid, pneumonia, gonorrhoea, cerebrospinal meningitis, leprosy, bubonic plague, tetanus, and syphilis.

Perhaps the key method Koch developed was the ability to isolate pure cultures, explained in brief here. Pure cultures of multicellular organisms are often more easily isolated by simply picking out a single individual to initiate a culture. This is a useful technique for pure culture of fungi, multicellular algae, and small metazoa. Developing pure culture techniques is crucial to the observation of the specimen in question. The most common method to isolate individual microbes and produce a pure culture is to prepare a streak plate. The streak plate method is a way to physically separate the microbial population and is done by spreading the inoculate back and forth with an inoculating loop over the solid agar plate. Upon incubation, colonies will arise and single cells will have been isolated from the biomass.

Key Points

- Koch's research and methods helped link the causal nature of microbes to certain diseases, such as anthrax.
- As developed by Koch, pure cultures allow the pure isolation of a microbe, which is vital in understanding how an individual microbe may contribute to a disease.
- According to Koch's postulates, for an organism to be the cause of a disease, it must be found in all cases of the disease and must be absent from healthy organisms, as well as maintained in pure culture capable of producing the original infection.

Key Terms

- **anthrax**: An infectious bacterial disease of herbivores than can also occur in humans through contact with infected animals, tissue from infected animals, or high concentrations of anthrax spores.
- **metazoa**: All those multicellular animals, of the subkingdom Metazoa, that have differentiated tissue.
- **tuberculosis**: An infectious disease of humans and animals caused by a species of mycobacterium mainly infecting the lungs where it causes tubercles characterized by the expectoration of mucus and sputum, fever, weight loss, and chest pain, and transmitted through inhalation or ingestion of bacteria.

SECTION OVERVIEW

1.2: Microbes and the World

Topic hierarchy

1.2A Types of Microorganisms

1.2B: Classification of Microorganisms

1.2C: Microbes and the Origin of Life on Earth

1.2D: Environmental Diversity of Microbes

This page titled 1.2: Microbes and the World is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

1.2A Types of Microorganisms

Microorganisms make up a large part of the planet's living material and play a major role in maintaining the Earth's ecosystem.

Learning Objectives

- Define the differences between microbial organisms.

Key Points

- Microorganisms are divided into seven types: bacteria, archaea, protozoa, algae, fungi, viruses, and multicellular animal parasites (helminths).
- Each type has a characteristic cellular composition, morphology, mean of locomotion, and reproduction.
- Microorganisms are beneficial in producing oxygen, decomposing organic material, providing nutrients for plants, and maintaining human health, but some can be pathogenic and cause diseases in plants and humans.

Key Terms

- **Gram stain**: A method of differentiating bacterial species into two large groups (Gram-positive and Gram-negative).
- **peptidoglycan**: A polymer of glycan and peptides found in bacterial cell walls.

Microorganisms or microbes are microscopic organisms that exist as unicellular, multicellular, or cell clusters. Microorganims are widespread in nature and are beneficial to life, but some can cause serious harm. They can be divided into six major types: bacteria, archaea, fungi, protozoa, algae, and viruses.

Bacteria

Bacteria are unicellular organisms. The cells are described as prokaryotic because they lack a nucleus. They exist in four major shapes: bacillus (rod shape), coccus (spherical shape), spirilla (spiral shape), and vibrio (curved shape). Most bacteria have a peptidoglycan cell wall; they divide by binary fission; and they may possess flagella for motility. The difference in their cell wall structure is a major feature used in classifying these organisms.

According to the way their cell wall structure stains, bacteria can be classified as either Gram-positive or Gram-negative when using the Gram staining. Bacteria can be further divided based on their response to gaseous oxygen into the following groups: aerobic (living in the presence of oxygen), anaerobic (living without oxygen), and facultative anaerobes (can live in both environments).

According to the way they obtain energy, bacteria are classified as heterotrophs or autotrophs. Autotrophs make their own food by using the energy of sunlight or chemical reactions, in which case they are called chemoautotrophs. Heterotrophs obtain their energy by consuming other organisms. Bacteria that use decaying life forms as a source of energy are called saprophytes.

Archaea

Archaea or Archaebacteria differ from true bacteria in their cell wall structure and lack peptidoglycans. They are prokaryotic cells with avidity to extreme environmental conditions. Based on their habitat, all Archaeans can be divided into the following groups: methanogens (methane-producing organisms), halophiles (archaeans that live in salty environments), thermophiles (archaeans that live at extremely hot temperatures), and psychrophiles (cold-temperature Archaeans). Archaeans use different energy sources like hydrogen gas, carbon dioxide, and sulphur. Some of them use sunlight to make energy, but not the same way plants do. They absorb sunlight using their membrane pigment, bacteriorhodopsin. This reacts with light, leading to the formation of the energy molecule adenosine triphosphate (ATP).

Fungi

Fungi (mushroom, molds, and yeasts) are eukaryotic cells (with a true nucleus). Most fungi are multicellular and their cell wall is composed of chitin. They obtain nutrients by absorbing organic material from their environment (decomposers), through symbiotic relationships with plants (symbionts), or harmful relationships with a host (parasites). They form characteristic filamentous tubes called hyphae that help absorb material. The collection of hyphae is called mycelium. Fungi reproduce by releasing spores.

Protozoa

Protozoa are unicellular aerobic eukaryotes. They have a nucleus, complex organelles, and obtain nourishment by absorption or ingestion through specialized structures. They make up the largest group of organisms in the world in terms of numbers, biomass, and diversity. Their cell walls are made up of cellulose. Protozoa have been traditionally divided based on their mode of locomotion: flagellates produce their own food and use their whip-like structure to propel forward, ciliates have tiny hair that beat to produce movement, amoeboids have false feet or pseudopodia used for feeding and locomotion, and sporozoans are non-motile. They also have different means of nutrition, which groups them as autotrophs or heterotrophs.

Algae

Algae, also called cyanobacteria or blue-green algae, are unicellular or multicellular eukaryotes that obtain nourishment by photosynthesis. They live in water, damp soil, and rocks and produce oxygen and carbohydrates used by other organisms. It is believed that cyanobacteria are the origins of green land plants.

Viruses

Viruses are noncellular entities that consist of a nucleic acid core (DNA or RNA) surrounded by a protein coat. Although viruses are classified as microorganisms, they are not considered living organisms. Viruses cannot reproduce outside a host cell and cannot metabolize on their own. Viruses often infest prokaryotic and eukaryotic cells causing diseases.

Multicellular Animal Parasites

A group of eukaryotic organisms consisting of the flatworms and roundworms, which are collectively referred to as the helminths. Although they are not microorganisms by definition, since they are large enough to be easily seen with the naked eye, they live a part of their life cycle in microscopic form. Since the parasitic helminths are of clinical importance, they are often discussed along with the other groups of microbes.

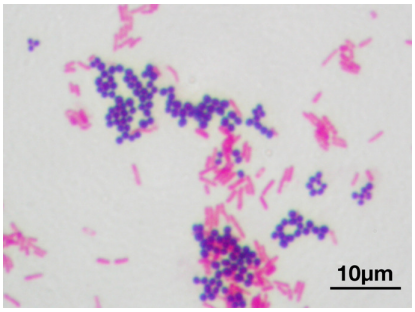

Figure: **Gram Stain**: This is a microscopic image of a Gram stain of mixed Gram-positive cocci (Staphylococcus aureus, purple) and Gram-negative bacilli (Escherichia coli, red).

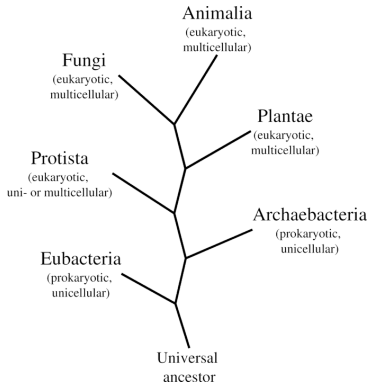

Figure: **Types of microorganisms**: This tree of life shows the different types of microorganisms.

This page titled 1.2A Types of Microorganisms is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

1.2B: Classification of Microorganisms

Microorganisms are classified into taxonomic categories to facilitate research and communication.

Learning Objectives

- Assess how early life changed the earth

Key Points

- The classification system is constantly changing with the advancement of technology.
- The most recent classification system includes five kingdoms that are further split into phylum, class, order, family, genus, and species.
- Microorganisms are assigned a scientific name using binomial nomenclature.

Key Terms

- **DNA fingerprinting**: A method of isolating and mapping sequences of a cell's DNA to identify it.

Life on Earth is famous for its diversity. Throughout the world we can find many millions of different forms of life. Biologic classification helps identify each form according to common properties (similarities) using a set of rules and an estimate as to how closely related it is to a common ancestor (evolutionary relationship) in a way to create an order. By learning to recognize certain patterns and classify them into specific groups, biologists are better able to understand the relationships that exist among a variety of living forms that inhabit the planet.

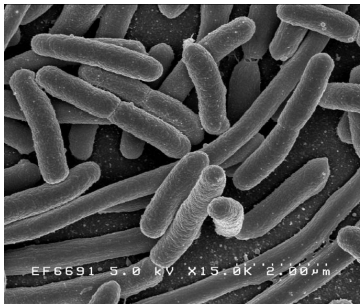

Figure: **Classification of E. coli**: Domain: Bacteria, Kingdom: Eubacteria, Phylum: Proteobacteria, Class: Gammaproteobacteria, Order: Enterobacteriales, Family: Enterobacteriaceae, Genus: Escherichia, Species: E. coli.

The first, largest, and most inclusive group under which organisms are classified is called a domain and has three subgroups: bacteria, archae, and eukarya. This first group defines whether an organism is a prokaryote or a eukaryote. The domain was proposed by the microbiologist and physicist Carl Woese in 1978 and is based on identifying similarities in ribosomal RNA sequences of microorganisms.

The second largest group is called a kingdom. Five major kingdoms have been described and include prokaryota (e.g. archae and bacteria), protoctista (e.g. protozoa and algae), fungi, plantae, and animalia. A kingdom is further split into phylum or division, class, order, family, genus, and species, which is the smallest group.

The science of classifying organisms is called taxonomy and the groups making up the classification hierarchy are called taxa. Taxonomy consists of classifying new organisms or reclassifying existing ones. Microorganisms are scientifically recognized using a binomial nomenclature using two words that refer to the genus and the species. The names assigned to microorganisms are in Latin. The first letter of the genus name is always capitalized. Classification of microorganisms has been largely aided by studies of fossils and recently by DNA sequencing. Methods of classifications are constantly changing. The most widely employed methods for classifying microbes are morphological characteristics, differential staining, biochemical testing, DNA fingerprinting or DNA base composition, polymerase chain reaction, and DNA chips.

This page titled 1.2B: Classification of Microorganisms is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

1.2C: Microbes and the Origin of Life on Earth

Life on Earth is thought to have originated from the oldest single-cell archaea and bacteria.

Learning Objectives

- Assess the characteristics of pre-life earth and which adaptations allowed early microbial life to flourish.

Key Points

- The proposed mechanisms for the origin of life on Earth include endosymbiosis and panspermia. Both are debatable theories.
- In these two theories, bacteria and extremophile archaea are thought to have initiated an oxygenated atmosphere creating new forms of life.
- Evolutionary processes over billions of years gave rise to the biodiversity of life on Earth.

Key Terms

- **endosymbiosis**: A condition of living within the body or cells of another organism.
- **panspermia**: The hypothesis that microorganisms may transmit life from outer space to habitable bodies; or the process of such transmission.

Scientific evidence suggests that life began on Earth some 3.5 billion years ago. Since then, life has evolved into a wide variety of forms, which biologists have classified into a hierarchy of taxa. Some of the oldest cells on Earth are single-cell organisms called archaea and bacteria. Fossil records indicate that mounds of bacteria once covered young Earth. Some began making their own food using carbon dioxide in the atmosphere and energy they harvested from the sun. This process (called photosynthesis) produced enough oxygen to change Earth's atmosphere.

Soon afterward, new oxygen-breathing life forms came onto the scene. With a population of increasingly diverse bacterial life, the stage was set for more life to form. There is compelling evidence that mitochondria and chloroplasts were once primitive bacterial cells. This evidence is described in the endosymbiotic theory. Symbiosis occurs when two different species benefit from living and working together. When one organism actually lives inside the other it's called endosymbiosis. The endosymbiotic theory describes how a large host cell and ingested bacteria could easily become dependent on one another for survival, resulting in a permanent relationship.

Over millions of years of evolution, mitochondria and chloroplasts have become more specialized and today they cannot live outside the cell. Mitochondria and chloroplasts have striking similarities to bacteria cells. They have their own DNA, which is separate from the DNA found in the nucleus of the cell. And both organelles use their DNA to produce many proteins and enzymes required for their function. A double membrane surrounding both mitochondria and chloroplasts is further evidence that each was ingested by a primitive host. The two organelles also reproduce like bacteria, replicating their own DNA and directing their own division.

Mitochondrial DNA (mtDNA) has a unique pattern of inheritance. It is passed down directly from mother to child, and it accumulates changes much more slowly than other types of DNA. Because of its unique characteristics, mtDNA has provided important clues about evolutionary history. For example, differences in mtDNA are examined to estimate how closely related one species is to another.

Figure: **Extremophiles**: Photosynthetic fossilized cyanobacteria in a billion year old rock formation of Glacier National Park, Montana, USA.

Conditions on Earth 4 billion years ago were very different than they are today. The atmosphere lacked oxygen, and an ozone layer did not yet protect Earth from harmful radiation. Heavy rains, lightning, and volcanic activity were common. Yet the earliest cells originated in this extreme environment. Extremophiles archaea still thrive in extreme habitats. Astrobiologists are now using archaea to study the origins of life on Earth and other planets. Because archaea inhabit places previously considered incompatible with life, they may provide clues that will improve our ability to detect extraterrestrial life. Interestingly, current research suggests archaea may be capable of space travel by meteorite. Such an event termed panspermia could have seeded life on Earth or elsewhere.

The presence of archaea and bacteria changed Earth dramatically. They helped establish a stable atmosphere and produced oxygen in such quantities that eventually life forms could evolve that needed oxygen. The new atmospheric conditions calmed the weather so that the extremes were less severe. Life had created the conditions for new life to be formed. This process is one of the great wonders of nature.

This page titled 1.2C: Microbes and the Origin of Life on Earth is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

1.2D: Environmental Diversity of Microbes

Learning Objectives

- Summarize how microbial diversity contributes to microbial occupation of diverse geographical niches.

The microbial world encompasses most of the phylogenetic diversity on Earth, as all Bacteria, all Archaea, and most lineages of the Eukarya are microorganisms. Microbes live in every kind of habitat (terrestrial, aquatic, atmospheric, or living host) and their presence invariably affects the environment in which they grow. Their diversity enables them to thrive in extremely cold or extremely hot environments. Their diversity also makes them tolerant of many other conditions, such as limited water availability, high salt content, and low oxygen levels.

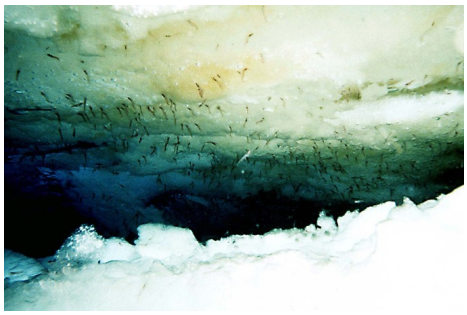

Figure: **Microorganisms in a cold environment**: Ice algae in Antartica.

Figure: **Microorganisms in a hot environment**: Algae growing in a hot pool in New Zealand.

Not every microbe can survive in all habitats, though. Each type of microbe has evolved to live within a narrow range of conditions. Although the vast majority of microbial diversity remains undetermined, it is globally understood that the effects of microorganisms on their environment can be beneficial. The beneficial effects of microbes derive from their metabolic activities in the environment, their associations with plants and animals, and from their use in food production and biotechnological processes.

In turn, the environment and the recent temperature anomalies play a crucial role in driving changes to the microbial communities. For instance, the assemblage of microbes that exists on the surface of seawater is thought to have undergone tremendous change with respect to composition, abundance, diversity, and virulence as a result of climate-driving sea surface warming.

For microbiologists, it is critical to study microbial adaptation to different environments and their function in those environments to understand global microbial diversity, ecology, and evolution. They rely on specific physical and chemical factors such as measuring temperature, pH, and salinity within a certain geography to formulate a comparison among microbial communities and the environment different species can tolerate. Researchers collect samples from geographical areas with different environmental conditions and between seasons to determine how dispersal patterns shape microbial communities and understand why organisms live where they do. As such, microbial communities from coastal and open oceans, polar regions, rivers, lakes, soils, atmosphere, and the human body can be tested. These samplings create a starting point to understand how the abundance and composition of microbial communities correlate with climatic perturbations, interact to effect ecosystem processes, and influence human health. Interfering with natural microbial biomass disrupts the balance of nature and the ecosystem and leads to loss of biodiversity.

Key Points

- Different microbial species thrive under different environmental conditions.
- Microbial communities occupy aquatic and terrestrial habitats and constitute the majority of biodiversity on Earth.
- Microbial diversities sustain the ecosystem in which they grow.

Key Terms

- **biodiversity**: The diversity (number and variety of species) of plant and animal life within a region.
- **biomass**: The total mass of all living things within a specific area or habitat.

SECTION OVERVIEW

1.3: The Science of Microbiology

Topic hierarchy

1.3A: Basic Microbiology

1.3B Applied Microbiology

1.3C: Immunization, Antiseptics, and Antibiotics

1.3D: Modern Microbiology

This page titled 1.3: The Science of Microbiology is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

1.3A: Basic Microbiology

Microbiology is the study of microscopic organisms and how they interact with humans and the environment.

Learning Objectives

- Evaluate the science of basic microbiology; understand the fundamental aspects of microbiology.

Key Points

- Microbiology focuses on organisms that are very small using various tools, which is a process done by microbiologists.
- As microbes are essential for human life and as microbes can cause human diseases, microbiology is therefore very important.
- The numbers of individual microbes and the number of microbes in and on the earth is staggering in proportions.

Key Terms

- **quantitation**: The process of quantitating.
- **immunology**: The branch of medicine that studies the body's immune system.
- **culturable**: Able to be cultured (grown in a suitable environment).

Microbiology is the study of microscopic organisms (microbes), which are defined as any living organism that is either a single cell (unicellular), a cell cluster, or has no cells at all (acellular). This includes eukaryotes, such as fungi and protists, and prokaryotes. Viruses and prions, though not strictly classed as living organisms, are also studied.

Microbiology typically includes the study of the immune system, or immunology. Generally, immune systems interact with pathogenic microbes; these two disciplines often intersect which is why many colleges offer a paired degree such as "Microbiology and Immunology. "

Figure: **Microbiologist**: A microbiology officer aboard a US naval ship examines wound cultures in the ship's microbiology laboratory.

Microbiology is a broad term which includes virology, mycology, parasitology, bacteriology, immunology, and other branches. A microbiologist is a specialist in microbiology and these related topics. Microbiological procedures usually must be aseptic and use a variety of tools such as light microscopes with a combination of stains and dyes. As microbes are absolutely required for most facets of human life (including the air we breathe and the food we eat) and are potential causes of many human diseases, microbiology is paramount for human society.

Research in the microbiology field is expanding, and in the coming years, we should see the demand for microbiologists in the workforce increase. It is estimated that only about one percent of the microorganisms present in a given environmental sample are culturable and the number of bacterial cells and species on Earth is still not possible to be determined. Recent estimates indicate that this number might be extremely high at five to the power of thirty. Although microbes were directly observed over three hundred years ago, the precise determination, quantitation, and description of its functions is far from complete, given the overwhelming diversity detected by genetic and culture-independent means.

This page titled 1.3A: Basic Microbiology is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

1.3B Applied Microbiology

The information gained by microbiologists can be applied to many medicinal and commercial endeavors.

Learning Objectives

- Explain applied microbiology

Key Points

- Using knowledge gained by microbiologists studying microbes, several fields of applied microbiology have formed.
- While food and medicinal applications are a big portion of applied microbiology, the study of microbes has lead to entire commercial industries which affect almost all aspects of human life.
- There are a myriad of practical applications that microbiology contributes to, including several parts of food production and medicinal applications.

Key Terms

- **rhizosphere**: The soil region subject to the influence of plant roots and their associated microorganisms.
- **biotechnology**: The use of living organisms (especially microorganisms) in industrial, agricultural, medical, and other technological applications.
- **pathogenic**: Able to cause harmful disease.

Microbiology is the study of microbes, which affect almost every aspect of life on the earth. In addition, there are huge commercial and medicinal benefits in understanding microbes. The application of this understanding is known as applied microbiology. There are many different types of applied microbiology which can be briefly defined as follows:

Medical Microbiology

Medical microbiology is the study of the pathogenic microbes and the role of microbes in human illness. This includes the study of microbial pathogenesis and epidemiology and is related to the study of disease pathology and immunology.

Pharmaceutical Microbiology

The study of microorganisms that are related to the production of antibiotics, enzymes, vitamins, vaccines, and other pharmaceutical products. Pharmaceutical microbiology also studies the causes of pharmaceutical contamination and spoil.

Industrial Microbiology

The exploitation of microbes for use in industrial processes. Examples include industrial fermentation and waste-water treatment. Closely linked to the biotechnology industry. This field also includes brewing, an important application of microbiology.

Microbial Biotechnology

The manipulation of microorganisms at the genetic and molecular level to generate useful products.

Food Microbiology and Dairy Microbiology

The study of microorganisms causing food spoilage and food-borne illness. Microorganisms can produce foods, for example by fermentation.

Figure: **Applied microbiology – Fermentation**: One of the oldest and well-known examples of applied microbiology is fermentation. In this picture the large tanks are being used for the fermentation of grapes to make wine.

Agricultural Microbiology

The study of agriculturally relevant microorganisms. This field can be further classified into the following subfields:

- Plant microbiology and plant pathology – The study of the interactions between microorganisms and plants and plant pathogens.
- Soil microbiology – The study of those microorganisms that are found in soil.
- Veterinary microbiology – The study of the role in microbes in veterinary medicine or animal taxonomy.
- Environmental microbiology – The study of the function and diversity of microbes in their natural environments. This involves the characterization of key bacterial habitats such as the rhizosphere and phyllosphere, soil and groundwater ecosystems, open oceans or extreme environments (extremophiles). This field includes other branches of microbiology such as: microbial ecology (microbially-mediated nutrient cycling), geomicrobiology, (microbial diversity), water microbiology (the study of those microorganisms that are found in water), aeromicrobiology (the study of airborne microorganisms) and epidemiology (the study of the incidence, spread, and control of disease).

This is by no means an exhaustive list of the different types of applied microbiology, but gives an indication of the expansive variety of the field and some of the benefits these studies entail.

1.3C: Immunization, Antiseptics, and Antibiotics

Understanding microbes gives us the ability to fight pathogens using immunization, antiseptics, and antibiotics.

Learning Objectives

- Compare immunization, antiseptics and antibiotics, and how they are used to combat human pathogens

Key Points

- Immunization is the fortification of our own immune system, priming it against potential future infections by specific microbes.
- Antiseptics are broadly defined as substances we can use on our body or surfaces around us to slow or kill microbes that could potentially harm us.
- Antibiotics, like antiseptics, can slow or kill microbes. However, unlike antiseptics, antibiotics can circulate in the human blood system and be used to fight microbial infections.

Key Terms

- **anaphylactic shock**: A severe and rapid systemic allergic reaction to an allergen, constricting the trachea and preventing breathing.
- **immunogen**: any substance that elicits a immune response; an antigen

Surprisingly, most microbes are not harmful to humans. In fact, they are all around us and even a part of us. However, some microbes are human pathogens; to combat these, we use immunization, antiseptics, and antibiotics.

Immunization is the process by which an individual's immune system becomes fortified against an agent (known as the immunogen).

Figure: **Flu Immunization**: A naval officer self-administers a nasal spray that immunizes him against the flu.

When the immune system is exposed to molecules that are foreign to the body, it will orchestrate an immune response. It will also develop the ability to respond quickly to subsequent encounters with the same substance, a phenomenon known as immunological memory. Therefore, by exposing a person to an immunogen in a controlled way, the body can learn to protect itself: this is called active immunization.

Vaccines against microorganisms that cause diseases can prepare the body's immune system, thus helping it fight or prevent an infection. The most important elements of the immune system that are improved by immunization are the T cells, the B cells, and the antibodies B cells produce. Memory B cells and memory T cells are responsible for the swift response to a second encounter with a foreign molecule. Through the use of immunizations, some infections and diseases have been almost completely eradicated throughout the United States and the world. For example, polio was eliminated in the U.S. in 1979. Active immunization and vaccination has been named one of the "Ten Great Public Health Achievements in the 20th Century. "

By contrast, in *passive* immunization, pre-synthesized elements of the immune system are transferred to a human body so it does not need to produce these elements itself. Currently, antibodies can be used for passive immunization. This method of immunization starts to work very quickly; however, it is short-lasting because the antibodies are naturally broken down and will disappear altogether if there are no B cells to produce more of them. Passive immunization occurs physiologically, when antibodies are transferred from mother to fetus during pregnancy, to protect the fetus before and shortly after birth. The antibodies can be produced in animals, called " serum therapy," although there is a high chance of anaphylactic shock because of immunity against animal serum itself. Thus, humanized antibodies produced *in vitro* by cell culture are used instead if available.

In early inquiries before there was an understanding of microbes, much emphasis was given to the prevention of putrefaction. Procedures were carried out to determine the amount of agent that needed to be added to a given solution in order to prevent the development of pus and putrefaction. However, due to a lack of understanding of germ theory, this method was inaccurate. Today, an antiseptic is judged by its effect on pure cultures of a defined microbe or on their vegetative and spore forms.

Antiseptics are antimicrobial substances that are applied to living tissue to reduce the possibility of infection, sepsis, or putrefaction. Their earliest known systematic use was in the ancient practice of embalming the dead. Antiseptics are generally distinguished from antibiotics by the latter's ability to be transported through the lymphatic system to destroy bacteria within the body, and from disinfectants, which destroy microorganisms found on non-living objects. Some antiseptics are true germicides, capable of destroying microbes (bacteriocidal), while others are bacteriostatic and only prevent or inhibit bacterial growth. Microbicides that destroy virus particles are called viricides or antivirals.

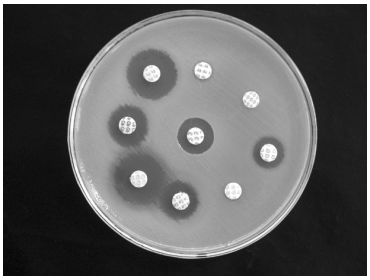

Figure: **Antibiotic Testing**: Discs soaked with various compounds are put onto a lawn of bacteria. If the compound on the disc kills or slows bacteria growth, a "halo" of clear media is seen.

An antibacterial is a compound or substance that kills or slows down the growth of bacteria. The term is often used synonymously with the term antibiotic; today, however, with increased knowledge of the causative agents of various infectious diseases, the term "antibiotic" has come to denote a broader range of antimicrobial compounds, including anti-fungal and other compounds.

The word "antibiotic" was first used in 1942 by Selman Waksman and his collaborators to describe any substance produced by a microorganism that is antagonistic to the growth of other microorganisms in high dilution. This definition excluded substances that kill bacteria but are not produced by microorganisms (such as gastric juices and hydrogen peroxide). It also excluded synthetic antibacterial compounds, such as the sulfonamides. Many antibacterial compounds are relatively small molecules with a molecular weight of less than 2000 amu. With advances in medicinal chemistry, most of today's antibacterials are semisynthetic modifications of various natural compounds.

This page titled 1.3C: Immunization, Antiseptics, and Antibiotics is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

1.3D: Modern Microbiology

Learning Objectives

- Discuss the fundamental aspects of microbiology

Modern microbiolgy began with the discovery of microbes, and the scope and scale of the field continues to expand today. While there is some debate, modern microbiology is accepted by most to begin with observations by the Dutch draper and haberdasher, Antonie van Leeuwenhoek, who lived for most of his life in Delft, Holland. In 1676, van Leeuwenhoek observed bacteria and other microorganisms, using a single-lens microscope of his own design. While van Leeuwenhoek is often cited as the first to observe microbes, Robert Hooke made the first recorded microscopic observation, of the fruiting bodies of molds, in 1665.

It has been suggested that a Jesuit priest called Athanasius Kircher was the first to observe microorganisms. One of his books contains a chapter in Latin, which reads in translation – "Concerning the wonderful structure of things in nature, investigated by Microscope." Here, he wrote "who would believe that vinegar and milk abound with an innumerable multitude of worms. " He noted that putrid material is full of innumerable creeping animalcule. These observations antedate Robert Hooke's Micrographia by nearly 20 years and were published some 29 years before van Leeuwenhoek saw protozoa.

Figure: ***Athanasius Kirche****: A portrait of the 17th century Jesuit priest Athanasius Kirche, who arguably discovered microbes.*

The field of bacteriology (later a subdiscipline of microbiology) was founded in the 19th century by Ferdinand Cohn, a botanist whose studies on algae and photosynthetic bacteria led him to describe several bacteria including Bacillus and Beggiatoa. Cohn was also the first to formulate a scheme for the taxonomic classification of bacteria and discover spores. Louis Pasteur and Robert Koch were contemporaries of Cohn's and are often considered to be the father of microbiology and medical microbiology, respectively. Pasteur is most famous for his series of experiments designed to disprove the then widely held theory of spontaneous generation, thereby solidifying microbiology's identity as a biological science. Pasteur also designed methods for food preservation (pasteurization) and vaccines against several diseases such as anthrax, fowl cholera, and rabies.

Koch is best known for his contributions to the germ theory of disease, proving that specific diseases were caused by specific pathogenic microorganisms. He developed a series of criteria that have become known as the Koch's postulates. Koch was one of the first scientists to focus on the isolation of bacteria in pure culture resulting in his description of several novel bacteria including *Mycobacterium tuberculosis*, the causative agent of tuberculosis. While Pasteur and Koch are often considered the founders of microbiology, their work did not accurately reflect the true diversity of the microbial world because of their exclusive focus on microorganisms having direct medical relevance.

It was not until the late 19th century and the work of Martinus Beijerinck and Sergei Winogradsky, the founders of general microbiology (an older term encompassing aspects of microbial physiology, diversity, and ecology), that the true breadth of microbiology was revealed. Beijerinck made two major contributions to microbiology: the discovery of viruses and the development of enrichment culture techniques. While his work on the tobacco mosaic virus (TMV) established the basic principles

of virology, it was his development of enrichment culturing that had the most immediate impact on microbiology by allowing for the cultivation of a wide range of microbes with wildly different physiologies. Winogradsky was the first to develop the concept of chemoautotrophy and to thereby reveal the essential role microorganisms played in geochemical processes. Specifically, he was responsible for the first isolation and description of both nitrifying and nitrogen-fixing bacteria.

Figure: ***Sergei Winogradsky****: An image of Sergei Winogradsky,who discovered nitrogen-fixing bacteria.*

Key Points

- There is some debate as to who was exactly first, but Antonie van Leeuwenhoek, Athanasius Kircher, and Robert Hooke were the first people to view microbes using some of the first self-built microscopes.
- Ferdinand Cohn, Louis Pasteur, and Robert Koch were pioneers in bacteriology, the discovery and understanding of the subset of microbes that are bacteria. This had a direct and immediate impact on food storage and disease causality.
- Martinus Beijerinck and Sergei Winogradsky are credited with the discovery of general microbiology, which laid the ground work for our understanding of microbial physiology, diversity, and ecology.

Key Terms

- **chemoautotrophy**: When a simple organism, such as a protozoan, derives its energy from chemical processes rather than photosynthesis.
- **pasteurization**: heat-treatment of a perishable food to destroy heat-sensitive vegetative cells followed by immediate cooling to limit growth of the surviving cells and germination of spores
- **rabies**: a viral disease that causes acute encephalitis in warm-blooded animals and people, characterised by abnormal behaviour such as excitement, aggressiveness, and dementia, followed by paralysis and death
- **animalcule**: An older term for a minute or microscopic animal or protozoan.

CHAPTER OVERVIEW

10: Epidemiology

Epidemiology is the study of the patterns, causes, and effects of health and disease conditions in defined populations. It is the cornerstone of public health, and informs policy decisions and evidence-based medicine by identifying risk factors for disease and targets for preventive medicine. Epidemiologists help with study design, collection and statistical analysis of data, and interpretation and dissemination of results. Epidemiology has helped develop methodology used in clinical research, public health studies and, to a lesser extent, basic research in the biological sciences.

SECTION OVERVIEW

10.1: Principles of Epidemiology

Epidemiology is the study of the patterns, causes, and effects of health and disease conditions in defined populations. It is the cornerstone of public health, and informs policy decisions and evidence-based medicine by identifying risk factors for disease and targets for preventive medicine. Epidemiologists help with study design, collection and statistical analysis of data, and interpretation and dissemination of results. Epidemiology has helped develop methodology used in clinical research, public health studies and, to a lesser extent, basic research in the biological sciences.

10.1A: History of Epidemiology

Learning Objectives

- Describe the key events in the development of the field of epidemiology

Epidemiology is the study of the patterns, causes, and effects of health and disease conditions in defined populations. It is the cornerstone of public health, and informs policy decisions and evidence-based medicine by identifying risk factors for disease and targets for preventive medicine. Epidemiologists help with study design, collection and statistical analysis of data, and interpretation and dissemination of results. Epidemiology has helped develop methodology used in clinical research, public health studies and, to a lesser extent, basic research in the biological sciences.

The Greek physician Hippocrates is known as the father of medicine, and was the first epidemiologist. Hippocrates sought a logic to sickness. He is the first person known to have examined the relationships between the occurrence of disease and environmental influences. Hippocrates believed sickness of the human body to be caused by an imbalance of the four Humors (air, fire, water and earth “atoms”). The cure to the sickness was to remove or add the humor in question to balance the body. This belief led to the application of bloodletting and dieting in medicine.

The distinction between “epidemic” and “endemic” was first drawn by Hippocrates, to distinguish between diseases that are “visited upon” a population (epidemic) from those that “reside within” a population (endemic). The term “epidemiology” appears to have first been used to describe the study of epidemics in 1802 by the Spanish physician Joaquín de Villalba in Epidemiología Española. Epidemiologists also study the interaction of diseases in a population, a condition known as a syndemic.

One of the earliest theories on the origin of disease was that it was primarily the fault of human luxury. This was expressed by philosophers such as Plato and Rousseau, and social critics like Jonathan Swift. In the middle of the 16th century, a doctor from Verona named Girolamo Fracastoro was the first to propose a theory that these very small, unseeable, particles that cause disease were alive. They were considered to be able to spread by air, multiply by themselves and to be destroyable by fire. In 1543 he wrote a book De contagione et contagiosis morbis, in which he was the first to promote personal and environmental hygiene to prevent disease. The development of a sufficiently powerful microscope by Anton van Leeuwenhoek in 1675 provided visual evidence of living particles consistent with a germ theory of disease.

Dr. John Snow is famous for his investigations into the causes of the 19th century cholera epidemics, and is also known as the father of (modern) epidemiology. He began by noticing the significantly higher death rates in two areas supplied by Southwark Company. His identification of the Broad Street pump as the cause of the Soho epidemic is considered the classic example of epidemiology. He used chlorine in an attempt to clean the water and had the handle removed, thus ending the outbreak. This has been perceived as a major event in the history of public health and regarded as the founding event of the science of epidemiology, having helped shape public health policies around the world. However, Snow’s research and preventive measures to avoid further outbreaks were not fully accepted or put into practice until after his death.

Figure: ***Snow cholera map****: A variant of the original map drawn by Dr. John Snow (1813-1858), a British physician who is one of the founders of medical epidemiology, showing cases of cholera in the London epidemics of 1854, clustered around the locations of water pumps.*

In the early 20th century, mathematical methods were introduced into epidemiology by Ronald Ross, Anderson Gray McKendrick and others. Another breakthrough was the 1954 publication of the results of a British Doctors Study, led by Richard Doll and Austin Bradford Hill, which lent very strong statistical support to the suspicion that tobacco smoking was linked to lung cancer.

Key Points

- The Greek physician Hippocrates is known as the father of medicine, and was the first epidemiologist.
- The distinction between ” epidemic ” and “endemic” was first drawn by Hippocrates, to distinguish between diseases that are “visited upon” a population (epidemic) from those that “reside within” a population (endemic).
- In the early 20th century, mathematical methods were introduced into epidemiology adding statistical support to the field (i.e. the suspicion that tobacco smoking was linked to lung cancer was backed by statistics).

Key Terms

- **endemic**: (Especially of diseases.) Prevalent in a particular area or region.
- **epidemic**: A widespread disease that affects many individuals in a population.
- **epidemiology**: The branch of a science dealing with the spread and control of diseases, computer viruses, concepts, etc., throughout populations or systems.

This page titled 10.1A: History of Epidemiology is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

10.1B: The Science of Epidemiology

Epidemiological studies include disease etiology, disease surveillance and screening, biomonitoring, and clinical trials.

Learning Objectives

- Discuss the various factors that characterize epidemiology

Key Points

- Epidemiologists rely on other scientific disciplines like biology to better understand disease processes, statistics to make efficient use of the data and draw appropriate conclusions, social sciences to better understand proximate and distal causes, and engineering for exposure assessment.
- Epidemiologists employ a range of study designs from the observational to experimental. Its study designs are generally categorized as descriptive, analytical, and experimental.
- The identification of causal relationships between disease exposures and outcomes is an important aspect of epidemiology.

Key Terms

- **epidemiologist**: A scientist (often a medical doctor) who specializes in epidemiology.
- **causal**: A cause of something; causing.

Major areas of epidemiological study include disease etiology, outbreak investigation, disease surveillance and screening, biomonitoring, and comparisons of treatment effects such as in clinical trials. Epidemiologists rely on other scientific disciplines like biology to better understand disease processes, statistics to make efficient use of the data and draw appropriate conclusions, social sciences to better understand proximate and distal causes, and engineering for exposure assessment.

Epidemiological studies are aimed, where possible, at revealing unbiased relationships between exposures such as alcohol or smoking, biological agents, stress, or chemicals to mortality or morbidity. Epidemiologists employ a range of study designs from the observational to experimental. Its study designs are generally categorized as descriptive, analytical (aiming to further examine known associations or hypothesized relationships), and experimental (a term often equated with clinical or community trials of treatments and other interventions).

In observational studies, nature is allowed to “take its course”, as epidemiologists observe from the sidelines. Observational studies have two components: descriptive or analytical. Descriptive observations pertain to the “who, what, where and when of health-related state occurrence”. On the other hand, analytical observations deal more with the “how” of a health-related event.

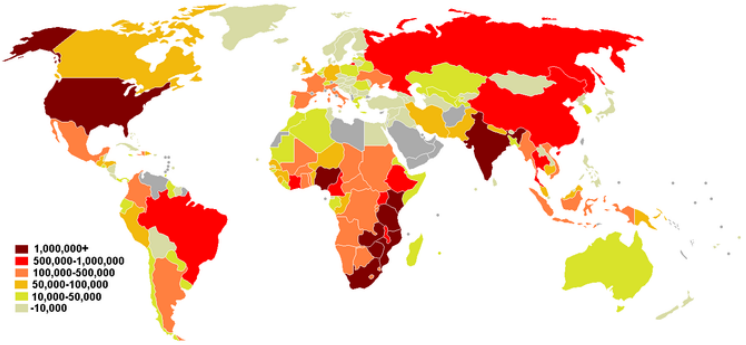

Figure: **World map of people living with HIV/AIDS**: This map captures the estimated number of people in the world living with HIV/AIDS in 2008.

Controversially, in experimental studies, the epidemiologist is the one in control of all of the factors relating to the particular case study. Experimental epidemiology contains three case types: randomized control trials (often used for new medicine or drug testing), field trials (conducted on those at a high risk of conducting a disease), and community trials (research on social originating diseases).

The identification of causal relationships between these exposures and outcomes is an important aspect of epidemiology. It is nearly impossible to say with perfect accuracy how even the most simple physical systems behave beyond the immediate future.

The complex field of epidemiology, which draws on biology, sociology, mathematics, statistics, anthropology, psychology, and policy only makes analysis even more challenging.

A common theme in much of the epidemiological literature is that “correlation does not imply causation. ” For epidemiologists, the key is in the term inference. Epidemiologists use gathered data and a broad range of biomedical and psychosocial theories in an iterative way to generate or expand theory, to test hypotheses, and to make educated, informed assertions about which relationships are causal, and about exactly how they are causal.

This page titled 10.1B: The Science of Epidemiology is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

10.1C: The Vocabulary Epidemiology

Learning Objectives

- Compare and contrast the following concepts: epidemic, endemic, pandemic; incidence vs prevalence; morbidity vs mortality; incubation, latency, acute, decline and convalescent periods

Epidemiology, literally meaning "the study of what is upon the people", is derived from Greek: *epi*, meaning "upon, among", *demos*, meaning "people, district", and *logos*, meaning "study, word, discourse", suggesting that it applies only to human populations. However, the term is widely used in studies of zoological populations (veterinary epidemiology) and of plant populations (botanical or plant disease epidemiology).

Outbreak is a term used in epidemiology to describe an occurrence of disease greater than would otherwise be expected at a particular time and place. It may affect a small and localized group or impact upon thousands of people across an entire continent. An *asymptomatic* carrier (healthy carrier or just carrier) is a person or other organism that has contracted an infectious disease, but who displays no symptoms. Although unaffected by the disease themselves, carriers can transmit it to others. A number of animal species act as vectors of human diseases.

Figure: **Mary Mallon**: Mary Mallon (1870-1938) was nicknamed "Typhoid Mary," an asymptomatic carrier of typhoid fever. She worked as a cook for several families in New York City at the beginning of the 20th century and infected many of them with typhoid. Note that in this 1909 newspaper illustration, she casts skulls into the skillet. However, this drawing inaccurately depicts the spread of typhoid, which was not by breathing, but by direct contamination from fecal particles.

EPIDEMIC, ENDEMIC OR PANDEMIC?

The distinction between "epidemic" and "endemic" was first drawn by Hippocrates, to distinguish between diseases that are "visited upon" a population (*epidemic*) from those that "reside within" a population (*endemic*). A *pandemic* is an epidemic of infectious disease that has spread through human populations across a large region; for instance multiple continents, or even worldwide. The term epidemiology is now widely applied to cover the description and causation of not only epidemic disease, but of disease in general, and even many non-disease health-related conditions, such as high blood pressure and obesity.

INCIDENCE VS. PREVALENCE

Incidence is a measure of the risk of developing some new condition within a specified period of time. Although sometimes loosely expressed simply as the number of new cases during a time period, it is better expressed as the incidence rate which is the number of new cases per population in a given time period. Incidence should not be confused with *prevalence*, which is a measure of the total number of cases of disease in a population rather than the rate of occurrence of new cases. Thus, incidence conveys

information about the risk of contracting the disease, whereas prevalence indicates how widespread the disease is. Prevalence is the proportion of the total number of cases to the total population and is more a measure of the burden of the disease on society.

MORBIDITY VS. MORTALITY

Morbidity is a diseased state, disability, or poor health due to any cause. The term may be used to refer to the existence of any form of disease, or to the degree that a health condition affects the patient. In epidemiology, the term morbidity rate can refer to either the incidence rate, or the prevalence of a disease, or medical condition. This measure of sickness is contrasted with the *mortality* rate of a condition, which is the proportion of people dying during a given time interval.

PHASES OF DISEASES

Epidemiologists are interested in determining the progression of a disease. In an infectious disease, the *incubation period* is the time between infection and the appearance of symptoms (acute period). The*latency period* is the time between infection and the ability of the disease to spread to another person, which may precede, follow, or be simultaneous with the appearance of symptoms. In most illnesses, the *acute period* is followed by the *decline period* (symptoms get better) and *convalescent* (or recovery) period.

Some viruses also exhibit a dormant phase, called *viral latency*, in which the virus hides in the body in an inactive state. For example, varicella zoster virus causes chickenpox in the acute phase; after recovery from chickenpox, the virus may remain dormant in nerve cells for many years, and later cause herpes zoster (shingles).

Key Points

- Outbreak is a term used in epidemiology to describe an occurrence of disease greater than would otherwise be expected at a particular time and place.
- An asymptomatic carrier is a person or other organism that has contracted an infectious disease, but who displays no symptoms.
- Diseases that are “visited upon” a population are epidemic, whereas those that “reside within” a population are endemic. A pandemic is an epidemic of infectious disease that has spread through human populations across a large region.
- Incidence is a measure of the risk of developing some new condition within a specified period of time. Prevalence is a measure of the total number of cases of disease in a population.
- Morbidity is a diseased state, disability, or poor health due to any cause. The mortality rate of a condition is the proportion of people dying from it during a given time interval.
- The progression of an infection usually follows these phases: infection, incubation period, acute period, decline period, and convalescent period.

Key Terms

- epidemiology: The branch of a science dealing with the spread and control of diseases, computer viruses, concepts, etc., throughout populations or systems.

This page titled 10.1C: The Vocabulary Epidemiology is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

10.1D: Koch's Postulates

Learning Objectives

- List Koch's postulates

Koch's postulates are four criteria designed to establish a causal relationship between a causative microbe and a disease. The postulates were formulated by Robert Koch and Friedrich Loeffler in 1884 and refined and published by Koch in 1890. Koch applied the postulates to establish the etiology of anthrax and tuberculosis, but they have been generalized to other diseases.

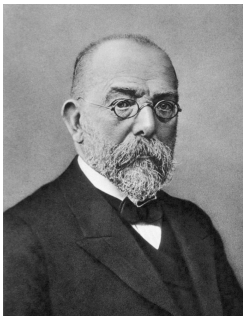

Figure: ***Robert Koch****: Robert Koch circa 1900. Koch's postulates are four criteria designed in the 1880's to establish a causal relationship between a causative microbe and a disease.*

Koch's postulates were developed in the 19th century as general guidelines to identify pathogens that could be isolated with the techniques of the day. Even in Koch's time, it was recognized that some infectious agents were clearly responsible for disease even though they did not fulfill all of the postulates. Attempts to rigidly apply Koch's postulates to the diagnosis of viral diseases in the late 19th century, at a time when viruses could not be seen or isolated in culture, may have impeded the early development of the field of virology. Currently, a number of infectious agents are accepted as the cause of disease despite their not fulfilling all of Koch's postulates. Therefore, while Koch's postulates retain historical importance and continue to inform the approach to microbiologic diagnosis, fulfillment of all four postulates is not required to demonstrate causality.

Koch's postulates

Koch's postulates are the following:

1. The microorganism must be found in abundance in all organisms suffering from the disease, but should not be found in healthy organisms.
2. The microorganism must be isolated from a diseased organism and grown in pure culture.
3. The cultured microorganism should cause disease when introduced into a healthy organism.
4. The microorganism must be reisolated from the inoculated, diseased experimental host and identified as being identical to the original specific causative agent.

Koch's postulates have also influenced scientists who examine microbial pathogenesis from a molecular point of view. In the 1980s, a molecular version of Koch's postulates was developed to guide the identification of microbial genes encoding virulence factors.

Key Points

- The postulates were formulated by Robert Koch and Friedrich Loeffler in 1884 and refined and published by Koch in 1890.
- Postulate 1: The microorganism must be found in abundance in all organisms suffering from the disease, but should not be found in healthy organisms.
- Postulate 2: The microorganism must be isolated from a diseased organism and grown in pure culture.
- Postulate 3: The cultured microorganism should cause disease when introduced into a healthy organism.
- Postulate 4: The microorganism must be reisolated from the inoculated, diseased experimental host and identified as being identical to the original specific causative agent.

Key Terms

- **Koch's postulates**: four criteria designed to establish a causal relationship between a causative microbe and a disease
- **postulate**: A fundamental element; a basic principle.

This page titled 10.1D: Koch's Postulates is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

10.1E: Exceptions to Koch's Postulates

Learning Objectives

- Recognize the exception to Koch's postulates

Koch's postulates were developed in the 19th century as general guidelines to identify pathogens that could be isolated with the techniques of the day. Even in Koch's time, it was recognized that some infectious agents were clearly responsible for disease, even though they did not fulfill all of the postulates. Currently, a number of infectious agents are accepted as the cause of diseases despite their not fulfilling all of Koch's postulates. Therefore, while Koch's postulates retain historical importance and continue to inform the approach to microbiologic diagnosis, fulfillment of all four postulates is not required to demonstrate causality.

Koch abandoned the requirement of the first postulate altogether when he discovered asymptomatic carriers of cholera and, later, of typhoid fever. Asymptomatic or subclinical infection carriers are now known to be a common feature of many infectious diseases, especially viruses such as polio, herpes simplex, HIV, and hepatitis C. Specifically, all doctors and virologists agree that the poliovirus causes paralysis in just a few infected subjects, and the success of the polio vaccine in preventing disease supports the conviction that the poliovirus is the causative agent.

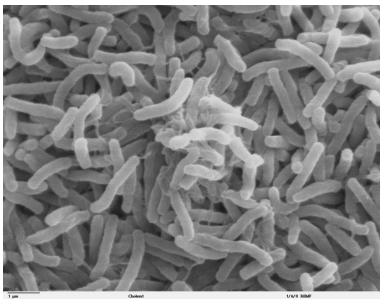

Figure: ***Cholera bacteria****: Scanning electron microscope image of Vibrio cholerae bacteria, which infect the digestive system.*

The second postulate may also be suspended for certain microorganisms or entities that cannot (at the present time) be grown in pure culture, such as prions responsible for Creutzfeldt–Jakob disease.

The third postulate specifies "should", not "must", because as Koch himself proved in regard to both tuberculosis and cholera, that not all organisms exposed to an infectious agent will acquire the infection. Noninfection may be due to such factors as general health and proper immune functioning; acquired immunity from previous exposure or vaccination; or genetic immunity, as with the resistance to malaria conferred by possessing at least one sickle cell allele.

In summary, a body of evidence that satisfies Koch's postulates is sufficient but not necessary to establish causation.

Key Points

- Koch abandoned the requirement of the first postulate altogether when he discovered asymptomatic carriers of cholera.
- The second postulate may also be suspended for certain microorganisms or entities that cannot (at the present time) be grown in pure culture, such as prions responsible for Creutzfeldt–Jakob disease.
- The third postulate specifies "should", not "must", because as Koch himself proved in regard to both tuberculosis and cholera, not all organisms exposed to an infectious agent will acquire the infection.

Key Terms

- **asymptomatic**: not exhibiting any symptoms of disease.

10.2A: Occurrence of a Disease

Learning Objectives

- Recognize the steps taken by epidemiologists when investigating disease outbreaks

Outbreak is a term used in epidemiology to describe an occurrence of disease greater than would otherwise be expected at a particular time and place. It may affect a small and localized group or impact thousands of people across an entire continent. Two linked cases of a rare infectious disease may be sufficient to constitute an outbreak. Outbreaks may also refer to endemics that affect a particular place or group, epidemics that affect a region in a country or a group of countries, and pandemics that describe global disease outbreaks.

Figure: **1918 Flu Victims**: With masks over their faces, members of the American Red Cross remove a victim of the Spanish Flu from a house at Etzel and Page Avenues, St. Louis, Missouri.

The epidemiology profession has developed a number of widely accepted steps when investigating disease outbreaks. As described by the Centers for Disease Control and Prevention, these include the following:

1. Verify the diagnosis related to the outbreak.
2. Identify the existence of the outbreak (if the group of ill persons is normal for the time of year, geographic area, etc.).
3. Create a case definition to define who/what is included as a case.
4. Map the spread of the outbreak.
5. Develop a hypothesis (if there appears to be a cause for the outbreak).
6. Study hypothesis (collect data and perform analysis).
7. Refine hypothesis and carry out further study.
8. Develop and implement control and prevention systems.
9. Release findings to greater communities.

There are several outbreak patterns that can be useful in identifying the transmission method or source and predicting the future rate of infection.

1. Common source – All victims acquire the infection from the same source (e.g. a contaminated water supply).
2. Continuous source – Common source outbreak where the exposure occurs over multiple incubation periods.
3. Point source – Common source outbreak where the exposure occurs in less than one incubation period.
4. Propagated – Transmission occurs from person to person.

Each has a distinctive epidemic curve, or histogram of case infections and deaths.

Outbreaks can also be:

1. Behavioral risk related (e.g. sexually transmitted diseases, increased risk due to malnutrition)
2. Zoonotic – The infectious agent is endemic to an animal population.

Key Points

- Outbreaks may also refer to endemics that affect a particular place or group, epidemics that affect a region in a country or a group of countries, or pandemics that describe global disease outbreaks.
- The epidemiology profession has developed a number of widely accepted steps to investigate a disease occurrence.

- Outbreak patterns, which can be useful in identifying the transmission method or source, and predicting the future rate of infection include common source, continuous source, point source, and propagated source.
- Outbreaks can be behavioral risk related (e.g., sexually transmitted diseases, increased risk due to malnutrition) or zoonotic (e.g. the infectious agent is endemic to an animal population).

Key Terms

- **outbreak**: A term used in epidemiology to describe an occurrence of disease greater than would otherwise be expected at a particular time and place.
- **epidemic**: A widespread disease that affects many individuals in a population.
- **pandemic**: A disease that hits a wide geographical area and affects a large proportion of the population.

This page titled 10.2A: Occurrence of a Disease is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

10.2B: Disease Severity and Duration

The severity and duration of diseases vary greatly and are important for epidemiological studies.

Learning Objectives

- Discuss the severity and various types of disease duration, including: acute, chronic, flare-up, refractory, progressive, remission and a cure

Key Points

- Severity of illness is defined as the extent of organ system derangement or physiologic decompensation of a patient, and in general an illness is classified into minor, moderate, major, and extreme.
- In an infectious disease, the incubation period is the time between infection and the appearance of symptoms, the latency period is the time between infection and the ability to spread to another person, and the viral latency is the time the virus hides in the body in an inactive state.
- Disease duration can encompass one or more of the following: an acute disease, a chronic disease, a flare-up, a refractory disease is a disease, a progressive disease, or a cure.
- The scope of a disease, whether it is localized, disseminated, or systemic also affects its severity and duration.
- The International Classification of Diseases (ICD) is known as a health care classification system that provides codes to classify diseases and a wide variety of signs, symptoms, abnormal findings, complaints, social circumstances, and external causes of injury or disease.

Key Terms

- **severity**: the degree of something undesirable; badness or seriousness.
- **duration**: an amount of time or a particular time interval

Severity of illness is defined as the extent of organ system derangement or physiologic decompensation of a patient. It gives a medical classification into minor, moderate, major, and extreme that is meant to provide a basis for evaluating hospital resource use or to establish patient care guidelines.

In an infectious disease, the incubation period is the time between infection and the appearance of symptoms. The latency period is the time between infection and the ability of the disease to spread to another person, which may precede, follow, or be simultaneous with the appearance of symptoms. Some viruses also exhibit a dormant phase, called viral latency, in which the virus hides in the body in an inactive state.

Disease duration can be one of the following:

1. An acute disease is a short-lived disease, like the common cold.
2. A chronic disease is one that lasts for a long time, usually at least six months. During that time, it may be constantly present, or it may go into remission and periodically relapse. A chronic disease may be stable (does not get any worse) or it may be progressive (gets worse over time). Some chronic diseases can be permanently cured. Most chronic diseases can be beneficially treated, even if they cannot be permanently cured.
3. A flare-up can refer to either the recurrence of symptoms or an onset of more severe symptoms.
4. A refractory disease is a disease that resists treatment, especially an individual case that resists treatment more than is normal for the specific disease in question.
5. A progressive disease is a disease whose typical natural course is the worsening of the disease until death, serious debility, or organ failure occurs. Slowly progressive diseases are also chronic diseases; many are also degenerative diseases. The opposite of progressive disease is stable disease or static disease: a medical condition that exists, but does not get better or worse.
6. A cure is the end of a medical condition or a treatment that is very likely to end it, while remission refers to the disappearance, possibly temporarily, of symptoms. Complete remission is the best possible outcome for incurable diseases.

The scope of a disease also affects its severity and duration:

1. A localized disease is one that affects only one part of the body, such as athlete's foot or an eye infection.
2. A disseminated disease has spread to other parts; with cancer, this is usually called metastatic disease.
3. A systemic disease is a disease that affects the entire body, such as influenza or high blood pressure.

The International Classification of Diseases (most commonly known by the abbreviation ICD) is according to its publisher, the United Nations-sponsored World Health Organization, and is considered “the standard diagnostic tool for epidemiology, health management and clinical purposes. ” It is known as a health care classification system that provides codes to classify diseases and a wide variety of signs, symptoms, abnormal findings, complaints, social circumstances, and external causes of injury or disease. Under this system, every health condition can be assigned to a unique category and given a code, up to six characters long. Such categories can include a set of similar diseases.The International Classification of Diseases is published by the World Health Organization (WHO) and is used worldwide for morbidity and mortality statistics, reimbursement systems, and automated decision support in health care. This system is designed to promote international comparability in the collection, processing, classification, and presentation of these statistics. The ICD is a core classification of the WHO Family of International Classifications (WHO-FIC).

10.2C: Extent of Host Involvement

Host-pathogen interactions are the interactions taking place between a pathogen (e.g. virus, bacteria) and their host (e.g. humans, plants).

Learning Objectives

- Differentiate between primary and opportunistic pathogens in regards to host involvement

Key Points

- All pathogens damage their host to some extent, usually resulting in an infectious disease from the interplay between the pathogens and the defenses of the hosts they infect.
- Clinicians classify infectious microorganisms or microbes according to the status of host defenses – either as primary pathogens or as opportunistic pathogens.
- Primary pathogens cause disease as a result of their presence or activity within the normal, healthy host, and their intrinsic virulence is, in part, a necessary consequence of their need to reproduce and spread.
- Organisms which cause an infectious disease in a host with depressed resistance are classified as opportunistic pathogens.

Key Terms

- **host**: A cell or organism which harbors another organism or biological entity, usually a parasite.
- **pathogen**: Any organism or substance, especially a microorganism, capable of causing disease, such as bacteria, viruses, protozoa, or fungi. Microorganisms are not considered to be pathogenic until they have reached a population size that is large enough to cause disease.

Host-pathogen interactions are the interactions that take place between a pathogen (e.g. virus, bacteria) and their host (e.g. humans, plants). By definition, all pathogens damage their host to some extent. Infectious diseases result from the interplay between the pathogens and the defenses of the hosts they infect. The appearance and severity of disease resulting from the presence of any pathogen depends upon the ability of that pathogen to damage the host as well as the ability of the host to resist the pathogen.

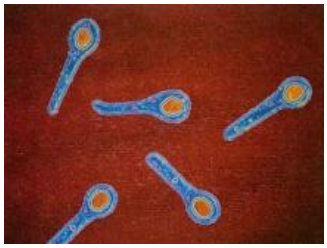

Figure: **Clostridium tetani**: Clostridium tetani are pathogenic bacteria.

Clinicians therefore classify infectious microorganisms or microbes according to the status of host defenses – either as primary pathogens or as opportunistic pathogens.

Primary pathogens cause disease as a result of their presence or activity within the normal, healthy host, and their intrinsic virulence is, in part, a necessary consequence of their need to reproduce and spread. Many of the most common primary pathogens of humans only infect humans; however many serious diseases are caused by organisms acquired from the environment or which infect non-human hosts.

Organisms which cause an infectious disease in a host with depressed resistance are classified as opportunistic pathogens. Opportunistic diseases may be caused by microbes that are ordinarily in contact with the host, such as pathogenic bacteria or fungi in the gastrointestinal or the upper respiratory tract, and they may also result from (otherwise innocuous) microbes acquired from other hosts or from the environment as a result of traumatic introduction. An opportunistic disease requires impairment of host defenses, which may occur as a result of several factors such as genetic defects, exposure to antimicrobial drugs or immunosuppressive chemicals, exposure to ionizing radiation, or as a result of an infectious disease with immunosuppressive activity. Primary pathogens may also cause more severe disease in a host with depressed resistance than would normally occur in an immunosufficient host.

This page titled 10.2C: Extent of Host Involvement is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

10.2D: Identification of Microbes Based on Molecular Genetics

Modern nucleic acid-based microbial detection methods make it possible to identify microbes that are associated with a disease.

Learning Objectives

- Describe the components of Molecular Koch's postulates

Key Points

- Nucleic acid -based detection methods are very sensitive.
- Molecular Koch's postulates are a set of experimental criteria that must be satisfied to show that a gene found in a pathogenic microorganism encodes a product that contributes to the disease caused by the pathogen.
- After virulent factors have been identified, it is possible to develop a vaccine against the factors.
- For many pathogenic microorganisms, it is not currently possible to apply molecular genetic techniques to a gene in question.

Key Terms

- **genetic**: Relating to genetics or genes.
- **nucleic acid**: Any acidic, chainlike biological macromolecule consisting of repeating units of phosphoric acid, sugar, and purine and pyrimidine bases; they are involved in the preservation, replication, and expression of hereditary information in every living cell.
- **virulent**: Highly infectious, malignant, or deadly.
- **genetics**: the branch of biology that deals with the transmission and variation of inherited characteristics, in particular chromosomes and DNA

Modern nucleic acid-based microbial detection methods make it possible to identify microbes that are associated with a disease. Nucleic acid-based detection methods are very sensitive, and they can often detect the very low levels of viruses that are found in healthy people without disease.

The use of these new methods has led to revised versions of Koch's postulates. Molecular Koch's postulates are a set of experimental criteria that must be satisfied to show that a gene found in a pathogenic microorganism encodes a product that contributes to the disease caused by the pathogen. Genes that satisfy molecular Koch's postulates are often referred to as virulence factors (i.e., what makes the pathogen virulent). The following set of Koch's postulates for the 21st century have been suggested:

1. A nucleic acid sequence belonging to a putative pathogen should be present in most cases of an infectious disease. Microbial nucleic acids should be found, preferentially in those organs or gross anatomic sites known to be diseased and not in those organs that lack pathology.
2. Fewer, or no, copies of the pathogen-associated nucleic acid sequences should occur in hosts or tissues without disease.
3. With resolution of the disease, the copy number of pathogen-associated nucleic acid sequences should decrease or become undetectable. With clinical relapse, the opposite should occur.
4. When sequence detection predates disease, or the sequence copy number correlates with severity of disease or pathology, the sequence-disease association is more likely to be a causal relationship.
5. The nature of the microorganism inferred from the available sequence should be consistent with the known biological characteristics of that group of organisms.
6. Tissue-sequence correlates should be sought at the cellular level. Efforts should be made to demonstrate specific in situ hybridization of microbial sequence to areas of tissue pathology and to visible microorganisms or to areas where microorganisms are presumed to be located.
7. These sequence-based forms of evidence for microbial causation should be reproducible.

Once virulent factors have been identified, it is possible to develop a vaccine against the factors. illustrates how the avian flu vaccine was developed using reverse genetic techniques.

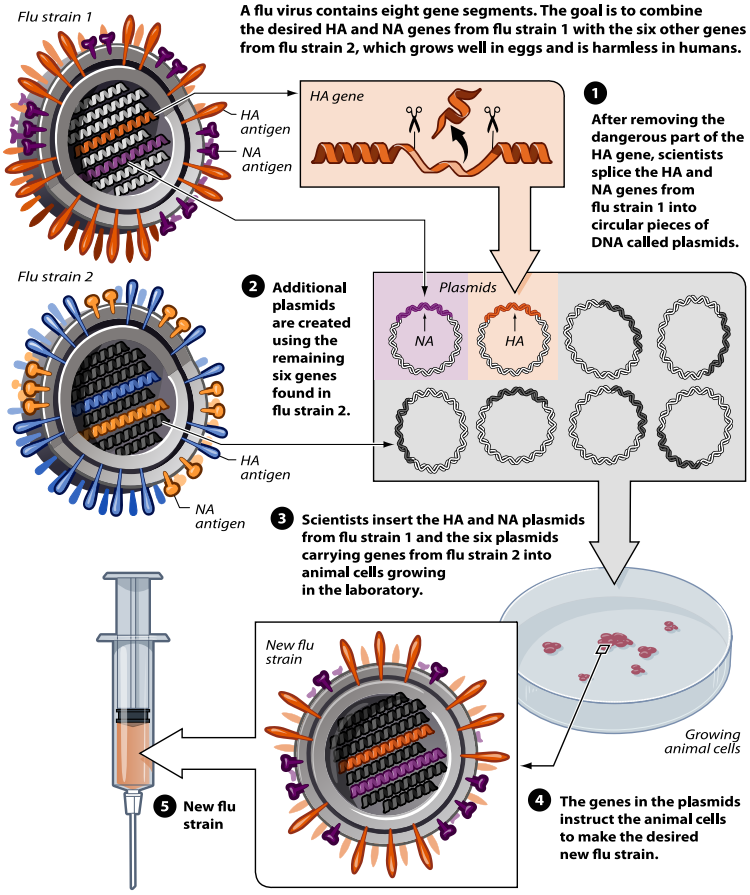

Figure: **Reserve genetics**: Avian flu vaccine development by reverse genetics technique.

For many pathogenic microorganisms, it is not currently possible to apply molecular genetic techniques to a gene in question. Testing a candidate virulence gene requires a relevant animal model of the disease being examined and the ability to genetically manipulate the microorganism that causes the disease. Suitable animal models are lacking for many important human diseases. Additionally, many pathogens cannot be manipulated genetically.

10.3A: Predisposing Factors

The spread and severity of infectious disease is influenced by many predisposing factors.

Learning Objectives

- Recognize factors that are classified as predisposing to infectious disease

Key Points

- Some predisposing factors of contracting infectious diseases can be anatomical, genetic, general and disease specific.
- Climate and weather, and other environmental factors that are affected by them, can also predispose people to infectious agents.
- Other factors such as overall health, age and diet are important considerations in the prevention of spreading infectious diseases.

Key Terms

- **cystic fibrosis**: Cystic fibrosis (also known as CF or mucoviscidosis) is an autosomal recessive genetic disorder that affects most critically the lungs, and also the pancreas, liver and intestine. It is characterized by abnormal transport of chloride and sodium across an epithelium, leading to thick, viscous secretions.
- **Chronic granulomatous disease**: Also known as CGD, is a diverse group of genetic diseases in which certain cells of the immune system have difficulty forming the reactive oxygen compounds (most importantly, the superoxide radical) used to kill certain ingested pathogens. This leads to the formation of granulomata (a special type of inflammation) in many organs.

The spread and severity of infectious disease is influenced by many predisposing factors. Some of these are more general and apply to many infectious agents, while others are disease specific. Others can be anatomical. For example, women suffer more frequently from urinary tract infections which can be attributed to their shorter urethra.

Genetics is another contributing factor. Cystic fibrosis is a genetic disease that causes alteration of the mucus in the lungs. This predisposes patients to chronic infections with bacteria which form biofilms in the lungs. The most common infectious agent is *Pseudomonas aeruginosa*. Another example is chronic granulomatous disease which directly affects the ability of the host immune system to fight invaders.

Climate and weather, and other environmental factors that are affected by them, can also predispose people to infectious agents. A long-standing puzzle has been why flu outbreaks occur seasonally. One possible explanation is that, because people are indoors more often during the winter, they are in close contact more often, and this promotes transmission from person to person. Another factor is that cold temperatures lead to drier air, which may dehydrate mucus, preventing the body from effectively expelling virus particles. The virus also survives longer on surfaces at colder temperatures and aerosol transmission of the virus is highest in cold environments (less than 5°C) with low relative humidity. Indeed, the lower air humidity in winter seems to be the main cause of seasonal influenza transmission in temperate regions. Some scientists speculate that the seasonal fluctuations of vitamin D levels can be a factor in the spread of influenza too.

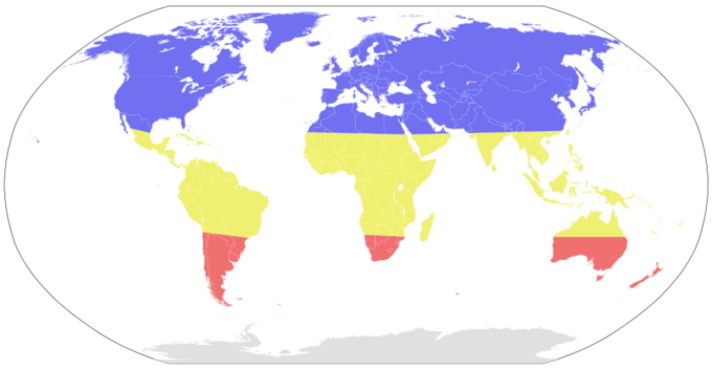

Figure: **Global map of Seasonal Influenza**: Seasonal risk areas: November–April (blue), April–November (red), and year-round (yellow)

Overall health is a very important factor in preventing disease. Some portions of the immune system itself have immuno-suppressive effects on other parts of the immune system, and immunosuppression may occur as an adverse reaction to treatment of other conditions. In general, deliberately-induced immunosuppression is performed to prevent the body from rejecting an organ

transplant, treating graft-versus-host disease after a bone marrow transplant, or for the treatment of autoimmune diseases such as rheumatoid arthritis and Crohn's disease. Of course, the immune system can be weak due to other reasons such as chemotherapy and HIV.

Age is another critical factor. Newborns and infants are more susceptible to infections as are the elderly.

Inadequate diet can raise the risks too. For example, globally, the severe malnutrition common in parts of the developing world causes a large increase in the risk of developing active tuberculosis and other opportunistic infections, due to its damaging effects on the immune system. Along with overcrowding, poor nutrition may contribute to the strong link observed between tuberculosis and poverty.

10.3B: Disease Development

After an pathogen invades a host, it undergoes a series of phases that eventually lead to multiplication of the pathogen.

Learning Objectives

- Outline the stages of disease: incubation, prodromal, acute and convalescence periods

Key Points

- The first phase is characterized by complete lack or very few symptoms.
- As the pathogen starts to reproduce actively, the symptoms intensify. Bacterial and viral infections can both cause the same kinds of symptoms but there are some differences too.
- The last phases are characterized by decline in symptoms severity until their disappearance. However, even if the patients recover and return to normal, they may continue to be a source of infection.

Key Terms

- **subclinical**: Of a disease or injury, without signs and symptoms that are detectable by physical examination or laboratory test; not clinically manifest.
- **clinical latency**: The period for which an infection is subclinical.
- **viral latency**: A form of viral dormancy in which the virus does not replicate at all.

Stages of Disease

After an infectious agent invades a host (patient), it undergoes a series of phases (stages) that will eventually lead to its multiplication and release from the host.

STAGE 1: INCUBATION PERIOD

This refers to the time elapsed between exposure to a pathogenic organism, and from when symptoms and signs are first apparent. It may be as short as minutes to as long as thirty years in the case of variant Creutzfeldt–Jakob disease. While the term latency period is used as synonymous, a distinction is sometimes made between incubation period, the period between infection and clinical onset of the disease, and latent period, the time from infection to infectiousness. Whichever is shorter depends on the disease.

A person may be a carrier of a disease, such as *Streptococcus* in the throat, without exhibiting any symptoms. Depending on the disease, the person may or may not be contagious during the incubation period. During clinical latency, an infection is subclinical. With respect to viral infections, in clinical latency the virus is actively replicating. This is in contrast to viral latency, a form of dormancy in which the virus does not replicate.

STAGE 2: PRODROMAL PERIOD

In this phase, the numbers of the infectious agents start increasing and the immune system starts reacting to them. It is characterized by early symptoms that might indicate the start of a disease before specific symptoms occur. Prodromes may be non-specific symptoms or, in a few instances, may clearly indicate a particular disease. For example fever, malaise, headache and lack of appetite frequently occur in the prodrome of many infective disorders. It also refers to the initial in vivo round of viral replication.

STAGE 3: ACUTE PERIOD

This stage is characterized by active replication or multiplication of the pathogen and its numbers peak exponentially, quite often in a very short period of time. Symptoms are very pronounced, both specific to the organ affected as well as in general due to the strong reaction of the immune system.

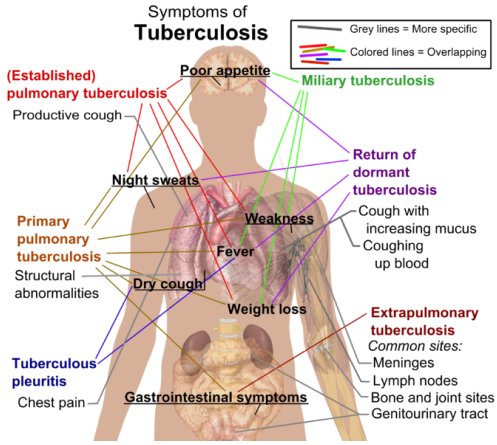

Figure: **Symptoms of tuberculosis**: Some of the symptoms are very specific for the disease while others are more general and can be caused by other pathogens.

Viral infections present with systemic symptoms. This means they involve many different parts of the body or more than one body system at the same time; i.e. a runny nose, sinus congestion, cough, body aches, etc. They can be local at times as in viral conjunctivitis or “pink eye” and herpes. Only a few viral infections are painful, like herpes. The pain of viral infections is often described as itchy or burning.

The classic symptoms of a bacterial infection are localized redness, heat, swelling and pain. One of the hallmarks of a bacterial infection is local pain, pain that is in a specific part of the body. For example, if a cut occurs and is infected with bacteria, pain occurs at the site of the infection. Bacterial throat pain is often characterized by more pain on one side of the throat. An ear infection is more likely to be diagnosed as bacterial if the pain occurs in only one ear.

After the pathogen reaches its peak in newly-produced cells or particles (for viruses), the numbers begin to fall sharply. Symptoms are still present but they are not as strong as in the acute illness phase.

STAGE 4: CONVALESCENCE PERIOD

The patient recovers gradually and returns to normal, but may continue to be a source of infection even if feeling better. In this sense, “recovery” can be considered a synonymous term.

This page titled 10.3B: Disease Development is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

10.3C: Disease Reservoirs and Epidemics

Once discovered, natural reservoirs elucidate the complete life cycle of infectious diseases, providing effective prevention and control.

Learning Objectives

- Give examples of disease reservoirs and distinguish between common source and propagated outbreaks

Key Points

- Often the natural reservoirs for a human infectious disease are animals such as bats for SARS and rats for plague. Some diseases have no non-human reservoirs: poliomyelitis and smallpox are prominent examples. The natural reservoir of some diseases remains unknown.
- In epidemiology, an epidemic occurs when new cases of a certain disease, in a given human population, and during a given period, substantially exceed what is expected based on recent experience.
- An epidemic may be restricted to one location; however, if it spreads to other countries or continents and affects a substantial number of people, it may be termed a pandemic.
- There are two types of epidemic outbreak: (1) In a common source outbreak, the affected individuals had exposure to a common agent. (2) In a propagated outbreak, the disease spreads person-to-person.

Key Terms

- **pandemic**: A disease that hits a wide geographical area and affects a large proportion of the population.
- **common source outbreak**: a type of epidemic outbreak where the affected individuals had an exposure to a common agent.
- **propagated outbreak**: a type of epidemic outbreak where the disease spreads person-to-person. Affected individuals may become independent reservoirs leading to further exposures.

Disease Reservoirs

A natural reservoir refers to the long-term host of the pathogen of an infectious disease. It is often the case that hosts do not get the disease carried by the pathogen or it is carried as a subclinical infection and so remains asymptomatic and non-lethal.

Once discovered, natural reservoirs elucidate the complete life cycle of infectious diseases, providing effective prevention and control. Some examples of natural reservoirs of infectious diseases include:

- Bubonic plague: marmots, black rats, prairie dogs, chipmunks, and squirrels for bubonic plague
- Chagas disease: armadillos and opossums and several species of New World Leishmania
- Babeiosis and Rocky Mountain spotted fever: ticks
- Colorado tick fever: ground squirrels, porcupines, and chipmunks
- Rabies: raccoons, skunks, foxes, and bats
- Cholera: shellfish
- Severe acute respiratory syndrome (SARS): bats
- Ebola: fruit bats, subhuman primates, and antelope called duikers

Some diseases have no non-human reservoir: poliomyelitis and smallpox are prominent examples. The natural reservoirs of some diseases still remain unknown.

DISEASE EPIDEMICS

In epidemiology, an epidemic occurs when new cases of a certain disease, in a given human population, and during a given period, substantially exceed what is expected, based on recent experience. Epidemiologists often consider the term outbreak to be synonymous to epidemic, but the general public typically perceives outbreaks to be more local and less serious than epidemics.

Epidemics of infectious disease are generally caused by:

- a change in the ecology of the host population (e.g. increased stress or increase in the density of a vector species)
- a genetic change in the parasite population
- the introduction of a new parasite to a host population (by movement of parasites or hosts)

Generally, an epidemic occurs when host immunity to a parasite population is suddenly reduced below that found in the endemic equilibrium and the transmission threshold is exceeded.

An epidemic may be restricted to one location; however, if it spreads to other countries or continents and affects a substantial number of people, it may be termed a pandemic. The declaration of an epidemic usually requires a good understanding of a baseline rate of incidence. Epidemics for certain diseases, such as influenza, are defined as reaching some defined increase in incidence above this baseline.

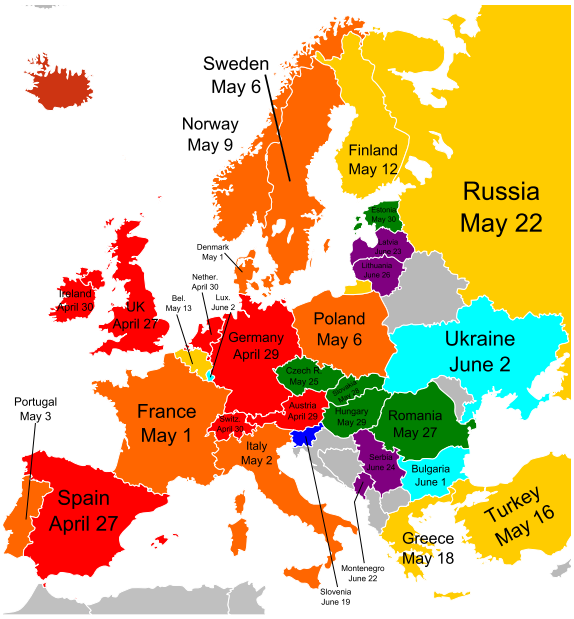

Figure: **Spread of H1N1 in Europe, 2009**: The World Health Organization declared the new flu strain H1N1 as a pandemic in June 2009.

A few cases of a very rare disease may be classified as an epidemic, while many cases of a common disease (such as the common cold) would not. An epidemic disease is not required to be contagious, and the term has been applied to West Nile fever.

EPIDEMIC OUTBREAKS

There are two types of epidemic outbreaks: (1) In a common source outbreak, the affected individuals had an exposure to a common agent. If the exposure is singular and all of the affected individuals develop the disease over a single exposure and incubation course, it can be termed a point-source outbreak. If the exposure was continuous or variable, it can be termed a continuous outbreak or intermittent outbreak, respectively.

(2) In a propagated outbreak, the disease spreads person-to-person. Affected individuals may become independent reservoirs leading to further exposures. Many epidemics will have characteristics of both common source and propagated outbreaks. For example, secondary person-to-person spread may occur after a common source exposure or environmental vectors may spread a zoonotic disease agent.

The conditions which govern the outbreak of epidemics include infected food supplies, such as drinking water contaminated by waste from people with cholera or typhoid fever or ‘fast food’ products contaminated with salmonella. The migrations of certain animals, such as rats, are in some cases responsible for the spread of plague, from which these animals die in great numbers.

Certain epidemics occur at certain seasons: for example, whooping-cough occurs in spring, whereas measles produces two epidemics – as a rule, one in winter and one in March. Influenza, the common cold, and other infections of the upper respiratory tract, such as sore throat, occur predominantly in the winter.

There is another variation, both as regards the number of persons affected and the number who die in successive epidemics: the severity of successive epidemics rises and falls over periods of five or ten years.

This page titled 10.3C: Disease Reservoirs and Epidemics is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

10.3D: Infectious Disease Transmission

Defining the means of transmission of a pathogen is important in understanding its biology and in addressing the disease it causes.

Learning Objectives

- Give examples of various modes of transmission, including direct and indirect transmission

Key Points

- Infectious organisms may be transmitted either by direct or indirect contact.
- Transmission may occur through several different mechanisms. Transmission of infectious diseases may also involve a vector. Vectors may be mechanical or biological.
- Pathogens can also be transmitted horizontally or vertically.

Key Terms

- **fomite**: An inanimate object capable of carrying infectious agents (such as bacteria, viruses and parasites), and thus passively enabling their transmission between hosts.
- **aerosolized**: Dispersed as an aerosol; particulate.
- **vector**: A carrier of a disease-causing agent.

For infecting organisms to survive and repeat the infection cycle in other hosts, they (or their progeny) must leave an existing reservoir and cause infection elsewhere. Defining the means of transmission plays an important part in understanding the biology of an infectious agent and in addressing the disease it causes.

Infectious organisms may be transmitted either by direct or indirect contact. Direct contact occurs when an individual comes into contact with the reservoir. Indirect contact occurs when the organism is able to withstand the harsh environment outside the host for long periods of time and still remains infective when specific opportunity arises.

Transmission may occur through several different mechanisms. Respiratory diseases and meningitis are commonly acquired by contact with aerosolized droplets, spread by sneezing, coughing, talking, kissing, or even singing. Gastrointestinal diseases are often acquired by ingesting contaminated food and water. Washing hands is an effective measure to prevent contaminating food and water. A common method of transmission in under-developed countries is fecal-oral transmission. In such cases, sewage water is used to wash food or is consumed. Sexually transmitted diseases are acquired through contact with bodily fluids, generally as a result of sexual activity. Some infectious agents may be spread as a result of contact with a contaminated, inanimate object (known as a fomite), such as a coin passed from one person to another, while other diseases penetrate the skin directly.

Figure: **Washing Hands**: Washing hands with soap and clean water (for at least 20 seconds) is the most effective measure to prevent the spread of infectious diseases.

Transmission of infectious diseases may also involve a vector. Vectors may be mechanical or biological. A mechanical vector picks up an infectious agent on the outside of its body and transmits it in a passive manner. An example of a mechanical vector is a housefly, which lands on cow dung, contaminating its appendages with bacteria from the feces and then lands on food. The pathogen never enters the body of the fly.

In contrast, biological vectors harbor pathogens within their bodies and deliver pathogens to new hosts in an active manner, usually a bite. Biological vectors are often responsible for serious blood-borne diseases, such as malaria, viral encephalitis, Chagas disease, Lyme disease, and African sleeping sickness. Biological vectors are usually, though not exclusively, arthropods, such as mosquitoes, ticks, fleas, and lice. Vectors are often required in the life cycle of a pathogen. A common strategy used to control vector borne infectious diseases is to interrupt the life cycle of a pathogen by killing the vector.

All of the above modes are examples of horizontal transmission because the infecting organism is transmitted from person to person in the same generation. There are also a variety of infections transmitted vertically, that is from mother to child during the birthing process or fetal development. Common disorders transmitted this way include AIDs, hepatitis, herpes, and cytomegalovirus.

10.3E: Ecology, Epidemiology, and Evolution of Pathogens

Pathogens have evolved to adapt to their environment and their host in order to survive.

Learning Objectives

- Discuss the contributing factors to pathogen evolution

Key Points

- Ecological competence is the ability of an organism, often a pathogen, to survive and compete in new habitats.
- Epidemiology is another important tool used to study disease in a population.
- In most cases, microorganisms live in harmony with their hosts via mutual or commensal interactions.
- Diseases can emerge when existing parasites become pathogenic or when new pathogenic parasites enter a new host.

Key Terms

- **zoonose**: Infectious diseases transmitted between different species of animals, usually from a vertebrate animal to a human
- **ecological competence**: The ability of an organism, often a pathogen, to survive and compete in new habitats.
- **virulence**: The degree of pathogenicity within a group or species of parasites as indicated by case fatality rates and/or the ability of the organism to invade the tissues of the host and it is determined by virulence factors.

Ecological competence is the ability of an organism, often a pathogen, to survive and compete in new habitats. If a pathogen does not have this, it will likely become extinct. In the case of plant pathogens, it is also their ability to survive between growing seasons. For example, peanut clump virus can survive in the spores of its fungal vector until a new growing season begins and it can proceed to infect its primary host again.

Epidemiology is another important tool used to study disease in a population. For infectious diseases, it helps to determine if a disease outbreak is sporadic (occasional occurrence), endemic (regular cases often occurring in a region), epidemic (an unusually high number of cases in a region), or pandemic (a global epidemic). The Black Death (plague) of the 14th century reduced the world population from an estimated 450 million to 350 – 375 million.

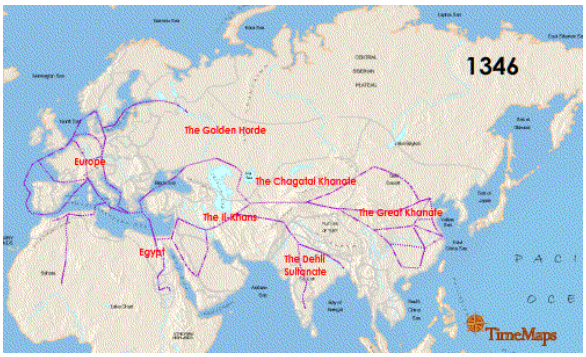

Figure: **The Black Death of the 14th century**: An animation of the plague that spread through the world during the pandemic in the 14th century.

In most cases, microorganisms live in harmony with their hosts via mutual or commensal interactions. Diseases can emerge when existing parasites become pathogenic or when new pathogenic parasites enter a new host. Coevolution between parasite and host can lead to hosts becoming resistant to the parasites or the parasites may evolve greater virulence, leading to immunopathological disease.

In addition, human activity is involved with many emerging infectious diseases, such as environmental change enabling a parasite to occupy new niches. When that happens, a pathogen that had been confined to a remote habitat has a wider distribution and possibly, a new host organism. Diseases transferred from nonhuman to human hosts are known as *zoonoses*.

Under disease invasion, when a parasite invades a new host species, it may become pathogenic in the new host. Several human activities have led to the emergence and spread of new diseases, such as encroachment on wildlife habitats, changes in agriculture, the destruction of rain forests, uncontrolled urbanization, modern transport.

According to evolutionary medicine, virulence increases with horizontal transmission (between non-relatives) and decreases with vertical transmission (from parent to child). Optimal virulence is a concept relating to the ecology of hosts and parasites. One definition of this is the host's parasite-induced loss of fitness. The parasite's fitness is determined by its success in transmitting its offspring to other hosts.

At one stage, the consensus was that over time, virulence moderated and parasitic relationships evolved toward symbiosis. This view has been challenged. A pathogen that is too restrained will lose out in competition to a more aggressive strain that diverts more host resources to its own reproduction. However, the host, being the parasite's resource and habitat in a way, suffers from this higher virulence. This might induce faster host death, and act against the parasite's fitness by reducing probability to encounter another host (killing the host too fast to allow for transmission).

Thus, there is a natural force providing pressure on the parasite to "self-limit" its virulence. The idea is then, that there exists an equilibrium point of virulence, where parasite's fitness is highest. Any movement on the virulence axis, towards higher or lower virulence, will result in lower fitness for the parasite, and this will be selected against.

10.3F: Safety in the Microbiology Laboratory

Working with microorganisms, especially pathogens, requires special equipment and safety practices.

Learning Objectives

- Distinguish between the different biohazard levels 1, 2, 3 and 4

Key Points

- The CDC categorizes various diseases in levels of biohazard: Level 1 being minimum risk and Level 4 being extreme risk.
- BSL-1 lab is used to perform research mostly on noninfectious microbes using standard equipment and routine lab safety procedures.
- BSL-2 work is performed with bacteria and viruses that cause only mild disease to humans, or are difficult to contract via aerosol in a lab setting. Safety regulations are stricter.
- In a BSL-3 setting, the work is with bacteria and viruses that can cause severe to fatal disease in humans, but for which vaccines or other treatments exist. The laboratory has special engineering and design features.
- BSL-4 level is mandatory for research on viruses and bacteria that cause severe to fatal disease in humans, and for which no vaccines or treatments are available. The use of a positive-pressure personnel suit is mandatory as well as many additional safety measures of the labs.

Key Terms

- **biohazards**: Biological substances that pose a threat to the health of living organisms, especially humans.

Keeping Safe in the Laboratory

Working with microorganisms, especially pathogens, requires special equipment and safety practices. Biological hazards, also known as biohazards, refer to biological substances that pose a threat to the health of living organisms, especially humans. The biohazard symbol is used in the labeling of biological materials that carry a significant health risk, including viral samples and used hypodermic needles.

Figure: **Biohazard symbol**: The international symbol used to label biohazards.

The United States' Centers for Disease Control and Prevention (CDC) categorize various diseases in levels of biohazard: Level 1 being minimum risk and Level 4 being extreme risk. Laboratories and other facilities are categorized as BSL (Biosafety Level) 1-4 or as P1 through P4 for short (Pathogen or Protection Level).

BIOHAZARD LEVEL 1:

Bacteria and viruses including *Bacillus subtilis*, *Escherichia coli* , canine hepatitis, varicella (chicken pox), as well as some cell cultures and non- infectious bacteria. Work is generally conducted on open bench tops using standard microbiological practices. At this level, precautions against the biohazardous materials in question are minimal, most likely involving gloves and some sort of facial protection. Decontamination procedures are similar in most respects to modern precautions against everyday microorganisms (i.e., washing one's hands with anti-bacterial soap, washing all exposed surfaces of the lab with disinfectants, etc.). In a lab environment all materials used for cell and/or bacteria cultures are decontaminated via autoclave. Laboratory personnel have specific training in the procedures conducted in the laboratory and are supervised by a scientist with general training in microbiology or a related science.

BIOHAZARD LEVEL 2:

Bacteria and viruses that cause only mild disease to humans, or are difficult to contract via aerosol in a lab setting, such as hepatitis A, B, and C, influenza A, Lyme disease, salmonella, mumps, measles, scrapie, dengue fever, and HIV. BSL-2 differs from BSL-1 in that:

- laboratory personnel have specific training in handling pathogenic agents and are directed by scientists with advanced training;
- access to the laboratory is limited when work is being conducted;
- extreme precautions are taken with contaminated sharp items;
- certain procedures in which infectious aerosols or splashes may be created are conducted in biological safety cabinets or other physical containment equipment.

BIOHAZARD LEVEL 3:

Bacteria and viruses that can cause severe to fatal disease in humans, but for which vaccines or other treatments exist, such as anthrax, West Nile virus, Venezuelan equine encephalitis, SARS virus, tuberculosis, typhus, Rift Valley fever, Rocky Mountain spotted fever, yellow fever, and malaria. Among parasites *Plasmodium falciparum*, which causes malaria, and *Trypanosoma cruzi*, which causes trypanosomiasis (sleeping sickness), also come under this level.

Laboratory personnel have specific training in handling pathogenic and potentially lethal agents, and are supervised by competent scientists experienced in working with these agents. All procedures involving the manipulation of infectious materials are conducted within biological safety cabinets, specially designed hoods, or other physical containment devices, or by personnel wearing appropriate protective clothing and equipment. The laboratory has special engineering and design features.

BIOHAZARD LEVEL 4:

Viruses and bacteria that cause severe to fatal disease in humans, and for which vaccines or other treatments are not available, such as Bolivian and Argentine hemorrhagic fevers, Dengue hemorrhagic fever, Marburg virus, Ebola virus, hantaviruses, Lassa fever virus, Crimean-Congo hemorrhagic fever, and other hemorrhagic diseases. Variola virus (smallpox) is an agent that is worked with at BSL-4 despite the existence of a vaccine.

When dealing with biological hazards at this level the use of a positive-pressure personnel suit, with a segregated air supply, is mandatory. The entrance and exit of a Level Four biolab will contain multiple showers, a vacuum room, an ultraviolet-light room, autonomous detection system, and other safety precautions designed to destroy all traces of the biohazard. All air and water services going to and coming from a Biosafety Level 4 (P4) lab will undergo similar decontamination procedures to eliminate the possibility of an accidental release.

Figure: **BSL-4 hazmat suit**: A researcher in a protective suit working with the Ebola virus.

10.3G: Finding Patient Zero and Tracking Diseases

The index case is identified in epidemiology studies by tracking down the infected patients to try to determine how the disease originated.

Learning Objectives

- Describe the concept of patient zero or the index case

Key Points

- The index or primary case is the initial patient in the population of an epidemiological investigation. It may indicate the source of the disease, the possible spread, and which reservoir holds the disease in-between outbreaks.
- In the early years of the AIDS epidemic, there was controversy about a so-called Patient Zero, who was the basis of a complex transmission scenario.
- Other prominent "Patient Zeroes" include Typhoid Mary.

Key Terms

- **"Patient Zero"**: A term used to refer to the index case in the spread of HIV in North America.
- **epidemiology**: The branch of a science dealing with the spread and control of diseases, computer viruses, concepts, etc., throughout populations or systems.

The index or primary case is the initial patient in the population of an epidemiological investigation. The index case may indicate the source of the disease, the possible spread, and which reservoir holds the disease in-between outbreaks. The index case is the first patient that indicates the existence of an outbreak. Earlier cases may be found and are labeled primary, secondary, tertiary, etc.

"Patient Zero" was used to refer to the index case in the spread of HIV in North America. The index case is identified in epidemiology studies by tracking down the infected patients to try to determine how the disease originated.

For example, in the early years of the AIDS epidemic there was controversy about a so-called Patient Zero, who was the basis of a complex transmission scenario. This epidemiological study showed how Patient Zero had infected multiple partners with HIV, and they in turn transmitted it to others and rapidly spread the virus to locations all over the world.

The CDC identified Gaëtan Dugas as the first person to bring HIV from Africa to the United States and to introduce it to gay bathhouses. Dugas was a flight attendant who was sexually promiscuous in several North American cities. He was vilified for several years as a "mass spreader" of HIV, and seen as the original source of the HIV epidemic among homosexual men. Later, the study's methodology and conclusions representation were repudiated.

A 2007 study published in the *Proceedings of the National Academy of Sciences* claimed that, based on the results of genetic analysis, current North American strains of HIV probably moved from Africa to Haiti and then entered the United States around 1969, probably through a single immigrant. However, the immigrant died in St. Louis, Missouri of complications from AIDS in 1969, and most likely became infected in the 1950s, so there were prior carriers of HIV strains in North America.

Ebola

In the eboloa outbreak of 2014, the Patient Zero was identified as a two year-old boy in Guinea who died on Dec. 2, 2013 of Ebolavirus during the fruitbat migration. His sister and mother and grandmother then died. Visitors from other villages came to pay their respects and tragically carried the virus back with them. As of November 2014, about 5,500 people had died of Ebolavirus.

Typhoid Mary

Other prominent "Patient Zeroes" include Typhoid Mary. She was the first person in the United States identified as an asymptomatic carrier of the pathogen associated with typhoid fever. She was presumed to have infected some 51 people, three of whom died, over the course of her career as a cook. She was forcibly isolated twice by public health authorities and died after a total of nearly three decades in isolation.

Figure: **Typhoid Mary poster**: Typhoid carrier. Food pollution. “In this manner the famous ‘Typhoid Mary’ infected family after family. “

SECTION OVERVIEW

10.4: Nosocomial Infections

A nosocomial infection is an infection that is acquired in a hospital or other health care facility. To emphasize both hospital and nonhospital settings, it is sometimes instead called a health care–associated infection. Such an infection can be acquired in hospital, nursing home, rehabilitation facility, outpatient clinic, or other clinical settings. Infection is spread to the susceptible patient in the clinical setting by various means.

Topic hierarchy

10.4A: Microorganisms in the Hospital

10.4B: Compromised Host

10.4C: Chain of Transmission

10.4D: Control of Nosocomial Infections

This page titled 10.4: Nosocomial Infections is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

10.4A: Microorganisms in the Hospital

Nosocomial infections can cause severe pneumonia and infections of the urinary tract, bloodstream, and other parts of the body.

Learning Objectives

- Give examples of hospital-acquired infections (HAI) or nosocomial infections

Key Points

- Some well known nosocomial infections include: ventilator-associated pneumonia, Methicillin resistant Staphylococcus aureus, Candida albicans, Acinetobacter baumannii, Clostridium difficile, Tuberculosis, Urinary tract infection, Vancomycin-resistant Enterococcus and Legionnaires' disease.
- Methicillin-resistant Staphylococcus aureus (MRSA) is a bacterium responsible for several difficult-to-treat infections in humans.
- Hospital acquired pneumonia is the second most common nosocomial infection (urinary tract infection is the most common) and accounts for 15-20% of the total.

Key Terms

- **nosocomial infection**: an infection whose development is favoured by a hospital environment, such as one acquired by a patient during a hospital visit or one developing among hospital staff
- **MRSA**: Methicillin-resistant Staphylococcus aureus (MRSA) is a bacterium responsible for several difficult-to-treat infections in humans. It is also called multidrug-resistant Staphylococcus aureus and oxacillin-resistant Staphylococcus aureus (ORSA).
- **pneumonia**: An acute or chronic inflammation of the lungs caused by viruses, bacteria or other microorganisms, or sometimes by physical or chemical irritants.
- **nosocomial**: A nosocomial infection, also known as a hospital-acquired infection or HAI, is an infection whose development is favoured by a hospital environment, such as one acquired by a patient during a hospital visit or one developing among hospital staff.

A nosocomial infection, also known as a hospital-acquired infection or HAI, is an infection whose development is favoured by a hospital environment, such as one acquired by a patient during a hospital visit, or one developed among hospital staff. Such infections include fungal and bacterial infections, and are aggravated by the reduced resistance of individual patients.

In the United States, the Centers for Disease Control and Prevention estimated roughly 1.7 million hospital-associated infections, from all types of microorganisms (including bacteria), cause or contribute to 99,000 deaths each year. In Europe, where hospital surveys have been conducted, the category of Gram-negative infections are estimated to account for two-thirds of the 25,000 deaths each year. Nosocomial infections can cause severe pneumonia and infections of the urinary tract, bloodstream, and other parts of the body. Many types are difficult to attack with antibiotics, and antibiotic resistance is spreading to Gram-negative bacteria that can infect people outside the hospital.

Known nosocomial infections include:

- Ventilator-associated pneumonia
- Staphylococcus aureus
- Methicillin resistant Staphylococcus aureus
- Candida albicans
- Pseudomonas aeruginosa
- Acinetobacter baumannii
- Stenotrophomonas maltophilia
- Clostridium difficile
- Tuberculosis
- Urinary tract infection
- Hospital-acquired pneumonia
- Gastroenteritis
- Vancomycin-resistant Enterococcus
- Legionnaires' disease.

Methicillin-resistant Staphylococcus aureus (MRSA) is a bacterium responsible for several difficult-to-treat infections in humans. It is also called multidrug-resistant Staphylococcus aureus and oxacillin-resistant Staphylococcus aureus (ORSA). MRSA is any strain of Staphylococcus aureus that has developed resistance to beta-lactam antibiotics, which include the penicillins (methicillin, dicloxacillin, nafcillin, oxacillin, etc.) and the cephalosporins. Strains unable to resist these antibiotics are classified as methicillin-sensitive Staphylococcus aureus, or MSSA. The development of such resistance does not cause the organism to be more intrinsically virulent than strains of Staphylococcus aureus that have no antibiotic resistance, but resistance does make MRSA infection more difficult to treat with standard types of antibiotics, and thus more dangerous.

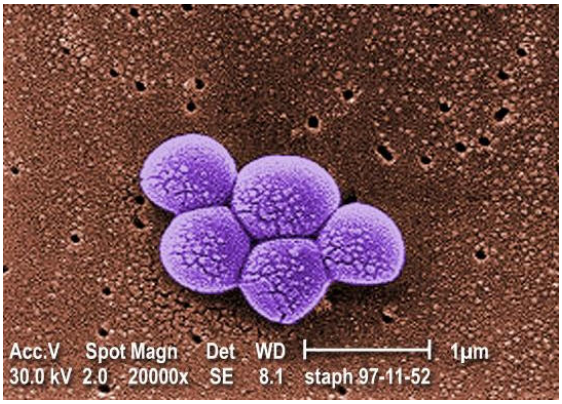

Figure: **Resistant bacterial strain**: Methicillin-resistant Staphylococcus aureus.

Hospital-acquired pneumonia (HAP), or nosocomial pneumonia, refers to any pneumonia contracted by a patient in a hospital at least 48-72 hours after being admitted. It is usually caused by a bacterial infection, rather than a virus. HAP is the second most common nosocomial infection (urinary tract infection is the most common), and accounts for 15-20% of the total. It is the most common cause of death among nosocomial infections, and is the primary cause of death in intensive care units.

10.4A: Microorganisms in the Hospital is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

10.4B: Compromised Host

Numerous risk factors in the hospital setting can predispose a patient to infection.

Learning Objectives

- Discuss the risk factors that contribute to the acquiring of nosocomial infections or hospital-acquired infections

Key Points

- People in hospitals are usually already in a “poor state of health,” impairing their defense against bacteria.
- Invasive devices bypass the body’s natural lines of defense against pathogens and provide an easy route for infection.
- Patients’ treatments can leave them vulnerable to infection.

Key Terms

- **infection**: An uncontrolled growth of harmful microorganisms in a host.
- **defense**: The action of defending or protecting from attack, danger, or injury.
- **Invasive**: Invasive species, also called invasive exotics or simply exotics, is a nomenclature term and categorization phrase used for flora and fauna, and for specific restoration-preservation processes in native habitats, with several definitions.

Susceptible Hosts

A nosocomial infection, also known as a hospital-acquired infection or HAI, is an infection whose development is favoured by a hospital environment, such as one acquired by a patient during a hospital visit or one developing among hospital staff. Such infections include fungal and bacterial infections. They are aggravated by the reduced resistance of individual patients. Numerous risk factors in the hospital setting predispose a patient to infection. These risk factors can broadly be divided into three areas.

- People in hospitals are usually already in a ‘poor state of health’, impairing their defense against bacteria. Advanced age or premature birth, along with immunodeficiency (due to drugs, illness, or irradiation) present a general risk, while other diseases can present specific risks; for instance, chronic obstructive pulmonary disease can increase chances of respiratory tract infection.
- Invasive devices, for instance intubation tubes, catheters, surgical drains, and tracheostomy tubes all bypass the body’s natural lines of defense against pathogens and provide an easy route for infection. Patients already colonized at the time of admission are instantly put at greater risk when they undergo invasive procedures.
- Patients’ treatments can leave them vulnerable to infection: immunosuppression and antacid treatment undermine the body’s defences, while antimicrobial therapy (removing competitive flora and only leaving resistant organisms) and recurrent blood transfusions have also been identified as risk factors.

Prevention

Hospitals have sanitation protocols regarding uniforms, equipment sterilization, washing, and other preventive measures. Thorough hand washing and/or use of alcohol rubs by all medical personnel before and after each patient contact is one of the most effective ways to combat nosocomial infections. More careful use of antimicrobial agents, such as antibiotics, is also considered vital. Despite sanitation protocol, patients cannot be entirely isolated from infectious agents. Furthermore, patients are often prescribed antibiotics and other antimicrobial drugs to help treat illness; this can increase the selection pressure for the emergence of resistant strains.

Figure: **Surgical drain**: Surgical drain on the left hand after surgery of Bennet's fracture basis MTC primi manus 1. sin (S62.20) which was treated by alignment of a fracture and inside fixation by two titanium screws MS.

10.4B: Compromised Host is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

10.4C: Chain of Transmission

Learning Objectives

- Differentiate between the various types of transmission: air-borne, common vehicle, vector borne, direct and indirect contact transmission

The drug-resistant Gram-negative bacteria, for the most part, threaten only hospitalized patients whose immune systems are weak. They can survive for a long time on surfaces in the hospital and they enter the body through wounds, catheters, and ventilators.

The most important and frequent mode of transmission of nosocomial infections is by direct contact. Transmission occurs when droplets containing microbes from the infected person are propelled a short distance through the air and deposited on the host's body; droplets are generated from the source person mainly by coughing, sneezing, and talking, and during the performance of certain procedures, such as bronchoscopy.

Dissemination can be either airborne droplet nuclei (small-particle residue {5 µm or smaller in size} of evaporated droplets containing microorganisms that remain suspended in the air for long periods of time) or dust particles containing the infectious agent. Microorganisms carried in this manner can be dispersed widely by air currents and may become inhaled by a susceptible host within the same room or over a longer distance from the source patient, depending on environmental factors; therefore, special air-handling and ventilation are required to prevent airborne transmission. Microorganisms transmitted by airborne transmission include Legionella, Mycobacterium tuberculosis and the rubeola and varicella viruses.

Common vehicle transmission applies to microorganisms transmitted to the host by contaminated items, such as food, water, medications, devices, and equipment. Vector borne transmission occurs when vectors such as mosquitoes, flies, rats, and other vermin transmit microorganisms.

Figure: ***Cross-transmission****: Contaminated surfaces increase cross-transmission.*

Contact transmission is divided into two subgroups: direct-contact transmission and indirect-contact transmission.

Direct-contact transmission involves a direct body surface-to-body surface contact and physical transfer of microorganisms between a susceptible host and an infected or colonized person, such as when a person turns a patient, gives a patient a bath, or performs other patient-care activities that require direct personal contact. Direct-contact transmission can also occur between two patients, with one serving as the source of the infectious microorganisms and the other as a susceptible host.

Indirect-contact transmission involves contact of a susceptible host with a contaminated intermediate object, usually inanimate, such as contaminated instruments, needles, or dressings, or contaminated gloves that are not changed between patients. In addition, the improper use of saline flush syringes, vials, and bags has been implicated in disease transmission in the US, even when healthcare workers had access to gloves, disposable needles, intravenous devices, and flushes.

Key Points

- Contact transmission is divided into two subgroups: direct-contact transmission and indirect-contact transmission.
- Direct-contact transmission involves a direct body surface-to-body surface contact and physical transfer of microorganisms.
- Indirect-contact transmission involves contact of a susceptible host with a contaminated intermediate object, usually inanimate.

Key Terms

- **microorganisms**: A microorganism or microbe is a microscopic organism that comprises either a single cell (unicellular), cell clusters, or multicellular relatively complex organisms.

- **susceptible**: likely to be affected by something; here, sensitive to growth inhibition by an antimicrobial drug.
- **transmission**: Transmission is the passing of a communicable disease from an infected host individual or group to a conspecific individual or group, regardless of whether the other individual was previously infected.

10.4C: Chain of Transmission is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

10.4D: Control of Nosocomial Infections

Learning Objectives

- Give examples of ways nosocomial infections can be controlled or prevented

Hospitals have sanitation protocols regarding uniforms, equipment sterilization, washing, and other preventive measures. Thorough hand washing and/or the use of alcohol rubs by all medical personnel before and after each patient contact is one of the most effective ways to combat nosocomial infections. More careful use of antimicrobial agents, such as antibiotics, is also considered vital.

Despite sanitation protocol, patients cannot be entirely isolated from infectious agents. Furthermore, patients are often prescribed antibiotics and other antimicrobial drugs to help treat illness; this may increase the selection pressure for the emergence of resistant strains. Sterilization goes further than just sanitizing. It kills all microorganisms on equipment and surfaces through exposure to chemicals, ionizing radiation, dry heat, or steam under pressure. Isolation precautions are designed to prevent transmission of microorganisms by common routes in hospitals. Because agent and host factors are more difficult to control, interruption of transfer of microorganisms is directed primarily at transmission.

The Importance of Handwashing

Handwashing is the single most important measure to reduce the risks of transmitting skin microorganisms from one person to another or from one site to another on the same patient. Washing hands as promptly and thoroughly as possible between patient contacts and after contact with blood, body fluids, secretions, excretions, and equipment or articles contaminated by them is an important component of infection control and isolation precautions.

Figure: ***Hand washing with soap****: Handwashing is the single most important measure to reduce the risks of transmitting skin microorganisms from one person to another or from one site to another on the same patient.*

The spread of nosocomial infections among immunocompromised patients is connected with health care workers' hand contamination in almost 40% of cases. This presents a challenging problem in the modern hospitals. The best way for workers to overcome this problem is by conducting correct hand- hygiene procedures; this is why in 2005 the WHO launched the GLOBAL Patient Safety Challenge.

Two categories of micro-organisms can be present on health care workers' hands: transient flora and resident flora. The first is represented by the micro-organisms taken by workers from the environment, and the bacteria in it. These are often capable of surviving on the human skin and sometimes to grow. The second group is represented by the permanent micro-organisms living on the skin surface, on the stratum corneum or immediately under it. They are capable of surviving on the human skin and of growing freely on it. They have low pathogenicity and infection rate, and they create a kind of protection from the colonization from other more pathogenic bacteria.

The skin of workers is colonized by 3.9 x 104 – 4.6 x 106 cfu/cm2. The microbes comprising the resident flora are: Staphylococcus epidermidis, S. hominis, and Micrococcus, Propionibacterium, Corynebacterium, Dermobacterium, and Pitosporum spp., while in the transitional could be found S. aureus, and Klebsiella pneumoniae, and Acinetobacter, Enterobacter and Candida spp. The goal of hand hygiene is to eliminate the transient flora with a careful and proper performance of hand washing, using different kinds of soap, both normal and antiseptic, and alcohol-based gels. The main problems found in the practice of hand hygiene are connected with the lack of available sinks and the time-consuming performance of hand washing. An easy way to resolve this problem could be the use of alcohol-based hand rubs, because of faster application compared to correct hand washing.

The Second Line of Defense: Gloves

Gloves play an important role in reducing the risks of transmission of microorganisms. Gloves are worn for three important reasons in hospitals.

- They are worn to provide a protective barrier and to prevent gross contamination of the hands when touching blood, body fluids, secretions, excretions, mucous membranes, and non-intact skin. In the USA, the Occupational Safety and Health Administration (OSHA) has mandated wearing gloves to reduce the risk of blood-borne pathogen infections.
- Gloves are worn to reduce the likelihood microorganisms present on the hands of personnel will be transmitted to patients during invasive or other patient-care procedures that involve touching a patient's mucous membranes and nonintact skin.
- They are worn to reduce the likelihood the hands of personnel contaminated with micro-organisms from a patient or a fomite (contaminated object) can be transmitted to another patient. In this situation, gloves must be changed between patient contacts, and hands should be washed after gloves are removed.

Surfaces

Sanitizing surfaces is an often overlooked, yet crucial, component of the strategy for the cycle of infection in health care environments. Modern sanitizing methods such as NAV-CO2 have been effective against gastroenteritis, MRSA, and influenza agents. Use of hydrogen peroxide vapor has been clinically proven to reduce infection rates and risk of acquisition. Hydrogen peroxide is effective against endospore-forming bacteria, such as Clostridium difficile, where alcohol has been shown to be ineffective.

Microorganisms are known to survive on inanimate "touch" surfaces for extended periods of time. This can be especially troublesome in hospital environments, where patients with immunodeficiencies are at enhanced risk for contracting nosocomial infections.

Wearing an apron during patient care reduces the risk of infection. The apron should either be disposable or be used only when caring for a specific patient.

Key Points

- Handwashing frequently is called the single most important measure to reduce the risks of transmitting skin microorganisms from one person to another or from one site to another on the same patient.
- Thorough hand washing and/or use of alcohol rubs by all medical personnel before and after each patient contact is one of the most effective ways to combat nosocomial infections.
- Sanitizing surfaces is an often overlooked, yet crucial, component of breaking the cycle of infection in health care environments.

Key Terms

- **sterilization**: Any process that eliminates or kills all forms of microbial life present on a surface, solution, or solid compound.
- **nosocomial**: contracted in a hospital, or arising from hospital treatment
- **sanitation**: The policy and practice of protecting health through hygienic measures.

SECTION OVERVIEW

10.5: Epidemiology and Public Health

Epidemiology is the study and analysis of the distribution (who, when, and where) and determinants of health and disease conditions in defined populations.

Topic hierarchy

10.5A: Descriptive Epidemiology

10.5B: Analytical Epidemiology

10.5C: Experimental Epidemiology

10.5D: Public Health Measures for Disease Control

10.5E: Global Health

10.5F: Emerging and Reemerging Infectious Diseases

10.5G: Biological Weapons

10.5H: Technology and New Infectious Agents

10.5I: Current Epidemics

10.5: Epidemiology and Public Health is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

10.5A: Descriptive Epidemiology

Descriptive epidemiology focuses on describing disease distribution by characteristics relating to time, place, and people.

Learning Objectives

- Describe the role of a descriptive epidemiology

Key Points

- Epidemiology is the science concerned with the study of the factors that influence and determine the frequency and distribution of disease, injury, and other health -related events and their causes in a defined human population.
- The more fully a descriptive epidemiologist can describe people, places and times, and any correlations between the three, the more likely it is that patterns will emerge which can be considered as risk factors for certain kinds of health issues.
- Epidemiologists use data as an information source for communicating information to people and to influence public policy.

Key Terms

- **socioeconomic**: Of or pertaining to social and economic factors.
- **epidemiology**: The branch of a science dealing with the spread and control of diseases, computer viruses, concepts, etc., throughout populations or systems.
- **risk factor**: A variable associated with an increased risk of disease or infection.

The goal of epidemiology is to establish causal factors for health issues in order to improve the health and safety of entire populations. A population can refer to a town, country, age group, or race. Health issues refer to anything that might impact health in the present or future. For epidemiologists, data on who is most likely to be injured in car crashes can be just as valuable as a topic of inquiry as data on what part of the population is most at risk for developing complications from the flu. In order to accomplish this, epidemiology has two main branches: descriptive and analytical.

Descriptive epidemiology evaluates and catalogs all the circumstances surrounding a person affected by a health event of interest. Analytical epidemiologists use data gathered by descriptive epidemiology experts to look for patterns suggesting causation. The end goal of both branches is to reduce the incidence of health events or diseases by understanding the risk factors for the health events or diseases. Both descriptive and analytical epidemiology often serve public health organizations by providing information that may reduce disease or reduce other kinds of events that impact people's health.

The primary considerations for descriptive epidemiology are frequency and pattern. Frequency evaluates the rate of occurrence, and pattern helps analytical epidemiologists suggest risk factors. Descriptive epidemiology evaluates frequency and pattern by examining the person, place, and time in relationship to health events.

Descriptive epidemiology examines factors like age, education, socioeconomic status, availability of health services, race, and gender. Evaluations of specific individuals may also include gathering information on behaviors like drug abuse, shift work, eating, and exercise patterns.

10.5A: Descriptive Epidemiology is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

10.5B: Analytical Epidemiology

Epidemiology draws statistical inferences, mostly about causes of disease in populations based on available samples of it.

Learning Objectives

- Describe the role of an analytical epidemiologist

Key Points

- Epidemiologists employ a range of study designs from the observational to experimental and they are generally categorized as descriptive, analytic, and experimental.
- Analytic epidemiology aims to further examine known associations or hypothesized relationships.
- Analytical observations deal more with the 'how' of a health -related event.

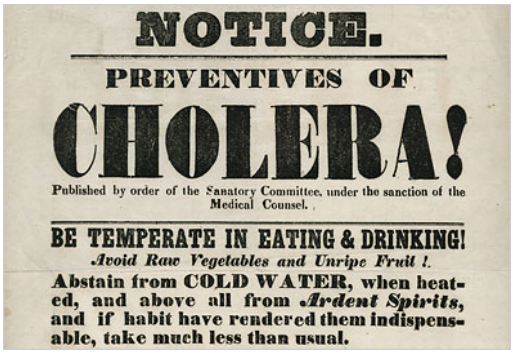
Key Terms

- **analytical**: pertaining to or emanating from analysis.
- **epidemiology**: Epidemiology is the study (or the science of the study) of the patterns, causes, and effects of health and disease conditions in defined populations.

Epidemiology is the study (or the science of the study) of the patterns, causes, and effects of health and disease conditions in defined populations. It is the cornerstone of public health, and informs policy decisions and evidence-based medicine by identifying risk factors for disease and targets for preventive medicine. Epidemiologists help with study design, collection and statistical analysis of data, and interpretation and dissemination of results (including peer review and occasional systematic review). Epidemiology has helped develop methodology used in clinical research, public health studies and, to some extent, basic research in the biological sciences.

Epidemiologists employ a range of study designs from observational to experimental and generally categorized as descriptive, analytic (aiming to further examine known associations or hypothesized relationships), and experimental (a term often equated with clinical or community trials of treatments and other interventions).

Where descriptive epidemiology describes occurrence of disease (or of its determinants) within a population, the analytical epidemiology aims to gain knowledge on the quality and the amount of influence that determinants have on the occurrence of disease. The usual way to gain this knowledge is by group comparisons. Such a comparison starts from one or more hypotheses about how the determinant may influence occurrence of disease. Analytical epidemiology attempts to determine the cause of an outbreak. Using the case control method, the epidemiologist can look for factors that might have preceded the disease. Often, this entails comparing a group of people who have the disease with a group that is similar in age, sex, socioeconomic status, and other variables, but does not have the disease. In this way, other possible factors, e.g., genetic or environmental, might be identified as factors related to the outbreak.



NOTICE.

PREVENTIVES OF

CHOLERA!

Published by order of the Sanatory Committee, under the sanction of the Medical Counsel.

BE TEMPERATE IN EATING & DRINKING!

Avoid Raw Vegetables and Unripe Fruit !.

Abstain from COLD WATER, when heated, and above all from *Ardent Spirits*, and if habit have rendered them indispensable, take much less than usual.

Figure: **Cholera Outbreak**: The outdated public health advice demonstrates the lack of understanding of the disease and its actual causative factors in the absence of epidemiological analysis.

10.5B: Analytical Epidemiology is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

10.5C: Experimental Epidemiology

Experimental epidemiology uses an experimental model to confirm a causal relationship suggested by observational studies.

Learning Objectives

- Summarize the purpose of experimental epidemiology and the three case types: randomized control, field and community trial

Key Points

- Experimental epidemiology is the study of the relationships of various factors determining the frequency and distribution of diseases in a community.
- Experimental epidemiology contains three case types: randomized control trial (often used for new medicine or drug testing), field trial (conducted on those at a high risk of conducting a disease), and community trial (research on social originating diseases).
- The method employs prospective population experiments designed to test epidemiological hypotheses, and usually attempt to relate the postulated cause to the observed effect. Trials of new anthelmintics are an example.

Key Terms

- **epidemiology**: Epidemiology is the study (or the science of the study) of the patterns, causes, and effects of health and disease conditions in defined populations.
- **Experimental**: An experiment is a methodical procedure carried out with the goal of verifying, falsifying, or establishing the validity of a hypothesis.
- **statistical**: of or pertaining to statistics

Epidemiology is the study (or the science of the study) of the patterns, causes, and effects of health and disease conditions in defined populations. It is the cornerstone of public health, and informs policy decisions and evidence-based medicine by identifying risk factors for disease and targets for preventive medicine. Epidemiologists help with study design, collection and statistical analysis of data, and interpretation and dissemination of results (including peer review and occasional systematic review). Epidemiology has helped develop methodology used in clinical research, public health studies and, to a lesser extent, basic research in the biological sciences.

Figure: **Early epidemiology**: Original map by John Snow showing the clusters of cholera cases in the London epidemic of 1854. John Snow's investigative work was one of the first examples of epidemiology. He discovered that families that drew their water from the Broad St well became infected with cholera.

Epidemiologists employ a range of study designs from the observational to experimental and they are generally categorized as descriptive, analytic (aiming to further examine known associations or hypothesized relationships), and experimental (a term often equated with clinical or community trials of treatments and other interventions). In observational studies, nature is allowed to "take its course", as epidemiologists observe from the sidelines. Controversially, in experimental studies, the epidemiologist is the one in control of all of the factors entering a certain case study. Epidemiological studies are aimed, where possible, at revealing unbiased

relationships between exposures such as alcohol or smoking, biological agents, stress, or chemicals to mortality or morbidity. The identification of causal relationships between these exposures and outcomes is an important aspect of epidemiology. Modern epidemiologists use informatics as a tool.

Experimental epidemiology contains three case types: randomized control trial (often used for new medicine or drug testing), field trial (conducted on those at a high risk of conducting a disease), and community trial (research on social originating diseases). Experimental epidemiology tests a hypothesis about a disease or disease treatment in a group of people. This strategy might be used to test whether or not a particular antibiotic is effective against a particular disease-causing organism. One group of infected individuals is divided randomly so that some receive the antibiotic and others receive a placebo—a “false” drug that is not known to have any medical effect. In this case, the antibiotic is the variable, i.e., the experimental factor being tested to see if it makes a difference between the two otherwise similar groups. If people in the group receiving the antibiotic recover more rapidly than those in the other group, it may logically be concluded that the variable—antibiotic treatment—made the difference. Thus, the antibiotic is said to be effective.

Although epidemiology is sometimes viewed as a collection of statistical tools used to elucidate the associations of exposures to health outcomes, a deeper understanding of this science is that of discovering causal relationships.

10.5C: Experimental Epidemiology is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

10.5D: Public Health Measures for Disease Control

Promotion of hand washing, breastfeeding, delivery of vaccinations, and distribution of condoms are examples of public health measures.

Learning Objectives

- Give examples of common public health measures that are recommended to control the spread of disease

Key Points

- Hand washing for hand hygiene is the act of cleaning the hands with or without the use of water or another liquid, or with the use of soap, for the purpose of removing soil, dirt, and/or microorganisms.
- Breastfeeding is the feeding of an infant or young child with breast milk directly from female human breasts (i.e., via lactation) rather than from a baby bottle or other container.
- Vaccination is the administration of antigenic material (a vaccine) to stimulate an individual's immune system to develop adaptive immunity to a pathogen.

Key Terms

- **hygiene**: Those conditions and practices that promote and preserve health.
- **immunity**: the state of being insusceptible to a specific thing.
- **vaccination**: inoculation with a vaccine in order to protect a particular disease or strain of disease.

Public Health Measures

The focus of public health intervention is to improve health and quality of life through the prevention and treatment of disease and other physical and mental health conditions. This can be done through surveillance of cases, and the promotion of healthy behaviors. Promotion of hand washing and breastfeeding, delivery of vaccinations, and distribution of condoms to control the spread of sexually transmitted diseases, are examples of common public health measures.

HAND WASHING

Hand washing for hand hygiene is the act of cleaning the hands with or without the use of water or another liquid, or with the use of soap, for the purpose of removing soil, dirt, and/or microorganisms. Medical hand hygiene pertains to the hygiene practices related to the administration of medicine and medical care that prevents or minimizes disease and the spreading of disease. The main medical purpose of washing hands is to cleanse the hands of pathogens (including bacteria or viruses) and chemicals, which can cause personal harm or disease. This is especially important for people who handle food or work in the medical field, but it is also an important practice for the general public. People can become infected with respiratory illnesses, such as influenza or the common cold; for example, if they don't wash their hands before touching their eyes, nose, or mouth. Indeed, the Centers for Disease Control and Prevention (CDC) has stated: "It is well documented that one of the most important measures for preventing the spread of pathogens is effective hand washing. "

Figure: **Hand Cleaning Station**: A hand cleaning station at the entrance of the Toronto General Hospital

As a general rule, however, handwashing protects people poorly or not at all from droplet- and airborne diseases, such as measles, chickenpox, influenza, and tuberculosis. It protects best against diseases transmitted through fecal-oral routes (such as many forms of stomach flu) and direct physical contact (such as impetigo). In addition to hand washing with soap and water, the use of alcohol

gels is another form of killing some kinds of pathogens and healthful bacteria, but their effectiveness is disputed, and may lead to antibiotica-resistant bacterial strains.

BREASTFEEDING

Breastfeeding is the feeding of an infant or young child with breast milk directly from female human breasts (i.e., via lactation) rather than from a baby bottle or other container. Babies have a sucking reflex that enables them to suck and swallow milk. It is recommended that mothers breastfeed for six months or more, without the addition of infant formula or solid food. After the addition of solid food, mothers are advised to continue breastfeeding for at least a year, and can continue for two years or more. Human breast milk is the healthiest form of milk for babies. There are few exceptions, such as when the mother is taking certain drugs or is infected with human T-lymphotropic virus, or has active untreated tuberculosis. Maternal HIV infection is always an absolute contraindication to breastfeeding in developed countries with access to infant formula and clean drinking water (regardless of maternal HIV viral load or antiretroviral treatment) due to the risk for mother to child HIV transmission. Breastfeeding promotes health and helps to prevent disease. Artificial feeding is associated with more deaths from diarrhea in infants in both developing and developed countries. Experts agree that breastfeeding is beneficial, and have concerns about artificial formulas but there are conflicting views about how long exclusive breastfeeding remains beneficial.

VACCINATION

Vaccination is the administration of antigenic material (a vaccine) to stimulate an individual's immune system to develop adaptive immunity to a pathogen. Vaccines can prevent or ameliorate morbidity from infection. The effectiveness of vaccination has been widely studied and verified; for example, the influenza vaccine, the HPV vaccine, and the chicken pox vaccine. Vaccination is the most effective method of preventing infectious diseases; widespread immunity due to vaccination is largely responsible for the worldwide eradication of smallpox and the restriction of diseases such as polio, measles, and tetanus from much of the world.

CONDOMS

A condom is a barrier device commonly used during sexual intercourse to reduce the probability of pregnancy and spreading sexually transmitted diseases. It is put on a man's erect penis and physically blocks ejaculated semen from entering the body of a sexual partner. Condoms are also used for collection of semen for use in infertility treatment. In the modern age, condoms are most often made from latex, but some are made from other materials such as polyurethane, polyisoprene, or lamb intestine. A female condom is also available, often made of nitrile.

10.5D: Public Health Measures for Disease Control is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

10.5E: Global Health

Global health is the health of populations in a global context and transcends the perspectives and concerns of individual nations.

Learning Objectives

- Outline the various perspectives that provide the framework for global health initiatives: epidemiological, medical, economic and political approaches

Key Points

- Health problems that transcend national borders or have a global political and economic impact are often emphasized.
- The major international agency for health is the World Health Organization (WHO). Other important agencies with impact on global health activities include UNICEF, World Food Programme (WFP), United Nations University – International Institute for Global Health, and the World Bank.
- Global health is a research field at the intersection of medical and social science disciplines, such as demography, economics, epidemiology, political economy and sociology.

Key Terms

- **health**: The state of being free from physical or psychological disease, illness, or malfunction; wellness.
- **populations**: A population is all the organisms that both belong to the same group or species and live in the same geographical area.
- **nations**: A nation may refer to a community of people who share a common language, culture, ethnicity, descent, or history. In this definition, a nation has no physical borders.

Global Health

Global health is the health of populations in a global context and transcends the perspectives and concerns of individual nations. Health problems that transcend national borders or have a global political and economic impact are often emphasized. It has been defined as “the area of study, research and practice that places a priority on improving health and achieving equity in health for all people worldwide. ” Thus, global health is about worldwide improvement of health, reduction of disparities, and protection against global threats that disregard national borders. The application of these principles to the domain of mental health is called global mental health.

The major international agency for health is the World Health Organization (WHO). Other important agencies with impact on global health activities include UNICEF, World Food Programme (WFP), United Nations University – International Institute for Global Health, and the World Bank. A major initiative for improved global health is the United Nations Millennium Declaration and the globally endorsed Millennium Development Goals.

Figure: **Flag of the World Health Organization**: This is the flag of the World Health Organization.

Global health is a research field at the intersection of medical and social science disciplines, such as demography, economics, epidemiology, political economy, and sociology. Through these different disciplinary perspectives, it focuses on determinants and the distribution of health in international contexts.

Global Health Perspectives

An epidemiological perspective identifies major global health problems. A medical perspective describes the pathology of major diseases, and promotes prevention, diagnosis, and treatment of these diseases.

An economic perspective emphasizes the cost-effectiveness and cost-benefit approaches for both individual and population health allocation. Aggregate analysis focuses on analysis for the health sector. For instance, governments and non-governmental organizations (NGOs) may engage in aggregate analysis.

Cost-effectiveness analysis compares the costs and health effects of an intervention to assess whether health investments are worthwhile from an economic perspective. It is necessary to distinguish between independent interventions and mutually exclusive interventions. For independent interventions, average cost-effectiveness ratios suffice. However, when mutually exclusive interventions are compared, it is essential to use incremental cost-effectiveness ratios. The latter comparisons suggest how to achieve maximal health care effects with the available resources.

Another ethical approach emphasizes distributional considerations. The Rule of Rescue, coined by A.R. Jonsen (1986), is one way to address distributional issues. This rule specifies that it is “a perceived duty to save endangered life where possible. ” John Rawls ideas on impartial justice is a contractual perspective on distribution. These ideas have been applied by Amartya Sen to address key aspects of health equity. Bioethics research also examines international obligations of justice, in three broadly clustered areas: When are international inequalities in health unjust? Where do international health inequalities come from? How do we meet health needs justly if we can’t meet them all?

A political approach emphasizes political economy considerations applied to global health. Political economy originally was the term for studying production, buying and selling, and their relations with law, custom, and government. Originating in moral philosophy (e.g., Adam Smith was professor of Moral Philosophy at the University of Glasgow), political economy of health is the study of how economies of states influence aggregate population health outcomes.

There are many perspectives and approaches to take when it comes to issues of global health, hence why the global health system is still struggling. Some perceive the immunization and prevention of disease to be a form of public democracy, others view it as a moral duty or an investment in self-protection. The journalist, Laurie Garrett explores the various perspectives shaping global health and suggests that it is due to perspective divergence that is hindering monetary funding and philanthropic efforts of organizations to properly control disease.

There are dangers to having divergent perspectives especially if it is a biased one; such as exemplified by Andrew Natsios of USAID, when he proclaimed that antiretrovirals should not be distributed to HIV-stricken Africa due to the occupants lacking a concept of time and clocks to properly facilitate the proper sequence of drug consumption. In addition, divergent perspectives can lead to “stove-piping”, which localizes funding to only specific causes while neglecting the larger and more important issues. The most important aspect in achieving global health is to take on a research approach and act accordingly to data and proven research because global health needs to be focused on as a whole, rather than specific causes.

10.5F: Emerging and Reemerging Infectious Diseases

An emerging infectious disease is a disease with a rate of incidence that has increased in the past 20 years, and could increase in the near future.

Learning Objectives

- Give examples of emerging and remerging infectious diseases

Key Points

- Emerging infections account for at least 12% of all human pathogens.
- Emerging infections deseases are caused by newly identified species or strains that may have evolved from a known infection or spread to a new population or area undergoing ecologic transformation, or be reemerging infections, such as drug resistant tuberculosis.
- Adverse synergistic interactions between emerging diseases and other infectious and non-infectious conditions leading to the development of novel syndemics are of growing concern.

Key Terms

- **emerging infectious disease**: An emerging infectious disease (EID) is an infectious disease with an incidence rate that has increased in the past 20 years and could increase in the near future. Emerging infections account for at least 12% of all human pathogens.
- **pathogens**: A pathogen or infectious agent (colloquially known as a germ) is a microorganism (in the widest sense, such as a virus, bacterium, prion, or fungus) that causes disease in its host. The host may be an animal (including humans), a plant, or even another microorganism.
- **species**: In biology, a species is one of the basic units of biological classification and a taxonomic rank. A species is often defined as a group of organisms capable of interbreeding and producing fertile offspring.

An emerging infectious disease (EID) is an infectious disease whose incidence has increased in the past 20 years, and could increase in the near future. Emerging infections account for at least 12% of all human pathogens. EIDs are caused by newly identified species or strains (e.g., SARS, AIDS) that may have evolved from a known infection (e.g., influenza), or spread to a new population (e.g., West Nile virus), or to an area undergoing ecologic transformation (e.g., Lyme disease). They could also be reemerging infections, such as drug resistant tuberculosis. Of growing concern are adverse synergistic interactions between emerging diseases and other infectious and non-infectious conditions leading to the development of novel syndemics.

SARS

Severe acute respiratory syndrome (SARS) is a viral respiratory disease in humans which is caused by the SARS coronavirus (SARS-CoV). Between November 2002 and July 2003, an outbreak of SARS in Hong Kong nearly became a pandemic, with 8,422 cases and 916 deaths worldwide (10.9% fatality), according to the World Health Organization (WHO). Within weeks, SARS spread from Hong Kong to infect individuals in 37 countries. The last infected human case of the outbreak occurred in June 2003, and there was a laboratory-induced infection case in 2004. SARS is not claimed to have been eradicated (unlike smallpox), as it may still be present in its natural host reservoirs (animal populations) and may return to the human population. During the outbreak, the fatality of SARS was less than 1% for people aged 24 or younger, 6% for those 25 to 44, 15% for those 45 to 64, and more than 50% for those over 65. For comparison, the fatality of influenza is usually under 0.03% (primarily among the elderly), but rose to 2% during the most severe pandemic to date.

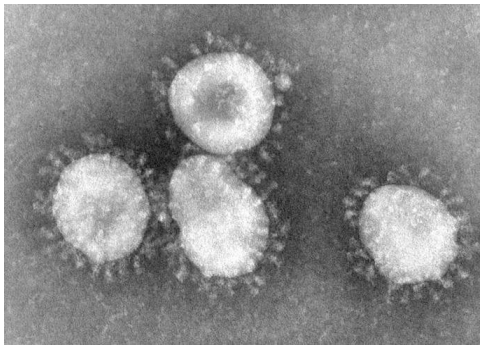

Figure: **Coronaviruses**: Coronaviruses are a group of viruses that have a halo, or crown-like (corona) appearance when viewed under an electron microscope. If you have a cold 10-15% of the time it is caused by a virus like this.

HIV

Human immunodeficiency virus infection/acquired immunodeficiency syndrome (HIV/AIDS) is a disease of the human immune system caused by the human immunodeficiency virus (HIV). During the initial infection a person may experience a brief period of influenza-like illness. This is typically followed by a prolonged period without symptoms. As the illness progresses it interferes more and more with the immune system, making people much more likely to get infections, including opportunistic infections, and tumors that do not usually affect people with working immune systems.

Influenza

Influenza, commonly known as the flu, is an infectious disease of birds and mammals caused by RNA viruses of the family Orthomyxoviridae, the influenza viruses. The most common symptoms are chills, fever, sore throat, muscle pains, headache (often severe), coughing, weakness/fatigue and general discomfort. Although it is often confused with other influenza-like illnesses, especially the common cold, influenza is a more severe disease caused by a different type of virus. Influenza may produce nausea and vomiting, particularly in children, but these symptoms are more common in the unrelated gastroenteritis, which is sometimes inaccurately referred to as “stomach flu” or “24-hour flu. ”

West Nile Virus

West Nile virus (WNV) is a mosquito-borne zoonotic arbovirus belonging to the genus flavivirus in the family flaviviridae. This flavivirus is found in temperate and tropical regions of the world. It was first identified in the West Nile subregion in the East African nation of Uganda in 1937. Prior to the mid 1990s, WNV disease occurred only sporadically and was considered a minor risk for humans. However, there was an outbreak in Algeria in 1994, with cases of WNV-caused encephalitis, and the first large outbreak in Romania in 1996, with a high number of cases with neuroinvasive disease. WNV has now spread globally, with the first case in the Western Hemisphere being identified in New York City in 1999; over the next 5 years, the virus spread across the continental United States, north into Canada, and southward into the Caribbean Islands and Latin America. WNV also spread to Europe, beyond the Mediterranean Basin. A new strain of the virus was recently (2012) identified in Italy. WNV is now considered to be an endemic pathogen in Africa, Asia, Australia, the Middle East, Europe and in the United States, which in 2012 has experienced one of its worst epidemics.

Tuberculosis

Tuberculosis, MTB, or TB (short for tubercle bacillus) is a common, and in many cases lethal, infectious disease caused by various strains of mycobacteria, usually Mycobacterium tuberculosis. Tuberculosis typically attacks the lungs, but can also affect other parts of the body. It is spread through the air when people who have an active TB infection cough, sneeze, or otherwise transmit their saliva through the air. Most infections are asymptomatic and latent, but about one in ten latent infections eventually progresses to active disease which, if left untreated, kills more than 50% of those so infected.

10.5F: Emerging and Reemerging Infectious Diseases is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

10.5G: Biological Weapons

Biological warfare (BW) is the use of biological toxins or infectious agents with the intent to kill or incapacitate.

Learning Objectives

- Recognize the characteristics of biological weapons

Key Points

- Biological weapons (often termed “bio-weapons”, “biological threat agents”, or “bio-agents”) are living organisms or replicating entities (viruses) that reproduce or replicate within their host victims.
- Biological weapons may be employed in various ways to gain a strategic or tactical advantage over an adversary, either by threats or by actual deployments.
- As a tactical weapon for military use, a significant problem with a BW attack is that it would take days to be effective, and therefore might not immediately stop an opposing force.

Key Terms

- **Biological warfare**: Biological warfare (BW) — also known as germ warfare — is the use of biological toxins or infectious agents such as bacteria, viruses, and fungi with the intent to kill or incapacitate humans, animals, or plants as an act of war.
- **psychochemical weapon**: Agents used within the context of military aggression.

Biological warfare (BW) — also known as germ warfare — is the use of biological toxins or infectious agents such as bacteria, viruses, and fungi with the intent to kill or incapacitate humans, animals, or plants as an act of war. Biological weapons (often termed “bio-weapons”, “biological threat agents”, or “bio-agents”) are living organisms or replicating entities (viruses) that reproduce or replicate within their host victims. Entomological (insect) warfare is also considered a type of BW.

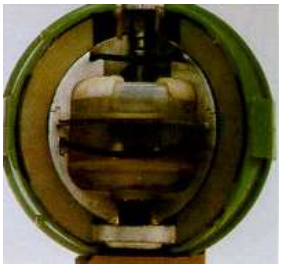

Figure: **Biological Bomblet**: The E120 biological bomblet was one of a number of spherical biological bomblets that were developed before the United States discontinued its offensive program in the 1970s. The vaned outer shell of this spherical bomblet was designed to provide rotation during flight. On impact, the outer shell would shatter; the bomblet was asymmetrically weighted so that agent would then be sprayed from the top of the bomblet. The E120 bomblet was developed in the early 1960s. Its 11.4 cm diameter carried 0.1 kg of liquid biological agent.

Biological weapons may be employed in various ways to gain a strategic or tactical advantage over an adversary, either by threats or by actual deployments. Like some chemical weapons, biological weapons may also be useful as area denial weapons. These agents may be lethal or non-lethal, and may be targeted against a single individual, a group of people, or even an entire population. They may be developed, acquired, stockpiled, or deployed by nation states or by non-national groups. In the latter case, or if a nation-state uses it clandestinely, it may also be considered bioterrorism.

There is an overlap between BW and chemical warfare, as the use of toxins produced by living organisms is considered under the provisions of both the Biological Weapons Convention and the Chemical Weapons Convention. Toxins and psychochemical weapons are often referred to as midspectrum agents. Unlike bioweapons, these midspectrum agents do not reproduce in their host and are typically characterized by shorter incubation periods.

Offensive biological warfare, including the mass production, stockpiling, and use of biological weapons, was outlawed by the 1972 Biological Weapons Convention (BWC). The rationale behind this treaty, which has been ratified or acceded to by 165 countries as of 2011, is to prevent a biological attack which could conceivably result in large numbers of civilian fatalities and cause severe disruption to economic and societal infrastructure. Many countries, including signatories of the BWC, currently pursue research into the defense or protection against BW, which is not prohibited by the BWC.

A nation or group that can pose a credible threat of mass casualty has the ability to alter the terms on which other nations or groups interact with it. Biological weapons allow for the potential to create a level of destruction and loss of life far in excess of nuclear, chemical, or conventional weapons, relative to their mass and cost of development and storage. Therefore, biological agents may be useful as strategic deterrents in addition to their utility as offensive weapons on the battlefield.

As a tactical weapon for military use, a significant problem with a BW attack is that it would take days to be effective, and therefore might not immediately stop an opposing force. Some biological agents (especially smallpox, plague, and tularemia) have the capability of person-to-person transmission via aerosolized respiratory droplets. This feature can be undesirable, as the agent or agents may be transmitted by this mechanism to unintended populations, including neutral or even friendly forces. While containment of BW is less of a concern for certain criminal or terrorist organizations, it remains a significant concern for the military and civilian populations of virtually all nations.

10.5H: Technology and New Infectious Agents

Technology aids in the identification of new infectious agents, but it also contributes to the emergence of new diseases.

Learning Objectives

- Give examples demonstrating the positive and negative impacts technology has had on new infectious agents

Key Points

- Advanced technology enables rapid identification of pathogens causing disease outbreaks and helps accelerate treatment strategies.
- The effect of new technology on the environment is related to the emergence of many new infectious diseases.
- Infectious diseases are sometimes called ” contagious ” when they are easily transmitted by contact with an ill person or their secretions (e.g., influenza).

Key Terms

- **infectious**: Infectious diseases, also known as transmissible diseases or communicable diseases, comprise clinically evident illness (i.e., characteristic medical signs and/or symptoms of disease) resulting from the infection, presence, and growth of pathogenic biological agents in an individual host organism.
- **pathogens**: A pathogen or infectious agent (colloquially known as a germ) is a microorganism (in the widest sense, such as a virus, bacterium, prion, or fungus) that causes disease in its host. The host may be an animal (including humans), a plant, or even another microorganism.

Technology: The Good

The use of advanced technology and molecular methods for detection, identification, and characterization of infectious agents is gaining importance in clinical microbiology laboratories. Emerging and re-emerging pathogens pose several challenges to diagnosis, treatment, and public health surveillance. Identification of an emerging pathogen by conventional methods is difficult and time-consuming due to the ‘novel’ nature of the agent. Identification requires a large array of techniques including cell cultures, inoculation of animals, cultivation using artificial media, histopathological evaluation of tissues (if available), and serological techniques using surrogate antigens.

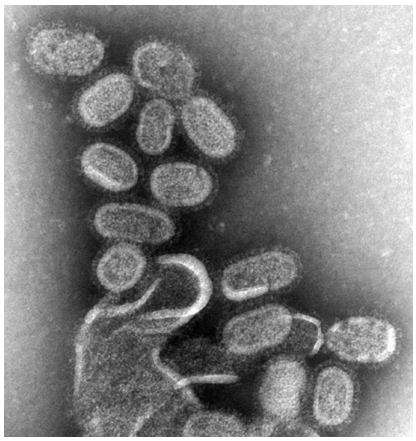

Figure: **Influenza**: TEM of negatively stained influenza virions, magnified approximately 100,000 times. Modern transport contributes in spreading diseases faster.

Looking back at past epidemics or outbreaks caused by previously unknown infectious agents, we realize that identification and characterization of a new infectious agent can take years, decades, or even centuries. Such time frames have been decreased to weeks or months by the use of powerful molecular techniques, as seen with the identification of severe acute respiratory syndrome coronavirus (SARS-CoV) within weeks of the first cases reported, the discovery of a new hantavirus in North America in 1993, and the detection of bacteria as etiological pathogens of human infections such as *Ehrlichia chaffeensis* and *Anaplasma phagocytophilum* in human monocytotropic ehrlichiosis and human granulocytotropic anaplasmosis, respectively.

Molecular techniques offer several advantages over conventional methods, including high sensitivity and specificity, speed, ease of standardization, and automation. Other advantages include identification of novel, non-cultivable or very slowly growing organisms, strain typing in epidemiological studies, antimicrobial susceptibility determination, and monitoring treatment by measuring bacterial or viral loads.

Technology: The Bad

The effects of new technology on the environment are related to the emergence of many infectious diseases. For example, Lyme disease, hantavirus pulmonary syndrome (HPS), and Lassa fever all emerged when humans began encountering the insect vector (for Lyme disease) or rodent host (for HPS and Lassa fever) of the causative agents in greater numbers than ever before. Factors related to the emergence of infectious diseases such as Legionnaire disease and hemolytic uremic syndrome include changing technologies: air conditioning systems and mass food production, respectively.

Technology: The Ugly

Several human activities have led to the emergence and spread of new diseases:

ENCROACHMENT ON WILDLIFE HABITATS

The construction of new villages and housing developments in rural areas forces animals to live in dense populations, creating opportunities for microbes to mutate and emerge.

CHANGES IN AGRICULTURE

The introduction of new crops attracts new crop pests and the microbes they carry to farming communities, exposing people to unfamiliar diseases.

DESTRUCTION OF RAIN FORESTS

As countries make use of their rain forests by building roads and clearing areas for settlement or commercial ventures, people encounter insects and other animals harboring previously unknown microorganisms.

UNCONTROLLED URBANIZATION

The rapid growth of cities in many developing countries tends to concentrate large numbers of people into crowded areas with poor sanitation. These conditions foster transmission of contagious diseases.

MODERN TRANSPORT

Ships and other cargo carriers often harbor unintended ‘passengers’ that can spread diseases to faraway destinations. With international air travel, people infected with a disease can carry it to distant lands, or home to their families, before their first symptoms appear.

10.5I: Current Epidemics

An epidemic occurs when new cases of a disease, in a given human population, and during a given period, substantially exceed expectations.

Learning Objectives

- Give examples of current epidemics

Key Points

- Epidemiologists often consider the term outbreak to be synonymous to epidemic, but the general public typically perceives outbreaks to be more local and less serious than epidemics.
- Epidemics of infectious disease are generally caused by a change in the ecology of the host population (e.g. increased stress or increase in the density of a vector species), a genetic change in the parasite population or the introduction of a new parasite to a host population.
- In the 20th century three influenza pandemics occurred, each caused by the appearance of a new strain of the virus in humans, and killed tens of millions of people.

Key Terms

- **epidemic**: A widespread disease that affects many individuals in a population.
- **population**: A collection of organisms of a particular species, sharing a particular characteristic of interest, most often that of living in a given area.
- **infectious**: Infectious diseases, also known as transmissible diseases or communicable diseases, comprise clinically evident illness (i.e., characteristic medical signs and/or symptoms of disease) resulting from the infection, presence, and growth of pathogenic biological agents in an individual host organism.

Epidemics

In epidemiology, an epidemic occurs when new cases of a certain disease, in a given human population, and during a given period, substantially exceed what is expected based on recent experience. Epidemiologists often consider the term outbreak to be synonymous to epidemic, but the general public typically perceives outbreaks to be more local and less serious than epidemics.

CAUSES

Epidemics of infectious disease are generally caused by a change in the ecology of the host population (e.g. increased stress or increase in the density of a vector species), a genetic change in the parasite population or the introduction of a new parasite to a host population (by movement of parasites or hosts). Generally, an epidemic occurs when host immunity to a parasite population is suddenly reduced below that found in the endemic equilibrium and the transmission threshold is exceeded.

EPIDEMIC VS. PANDEMIC

An epidemic may be restricted to one location; however, if it spreads to other countries or continents and affects a substantial number of people, it may be termed a *pandemic*. The declaration of an epidemic usually requires a good understanding of a baseline rate of incidence; epidemics for certain diseases, such as influenza, are defined as reaching some defined increase in incidence above this baseline. A few cases of a very rare disease may be classified as an epidemic, while many cases of a common disease (such as the common cold) would not.

INFLUENZA EPIDEMICS

Influenza is an infectious disease of birds and mammals caused by RNA viruses of the family Orthomyxoviridae, the influenza viruses. The most common symptoms are chills, fever, sore throat, muscle pains, headache (often severe), coughing, weakness/fatigue and general discomfort. Although it is often confused with other influenza-like illnesses, especially the common cold, influenza is a more severe disease caused by a different type of virus. Influenza may produce nausea and vomiting, particularly in children, but these symptoms are more common in the unrelated gastroenteritis, which is sometimes inaccurately referred to as “stomach flu” or “24-hour flu”.

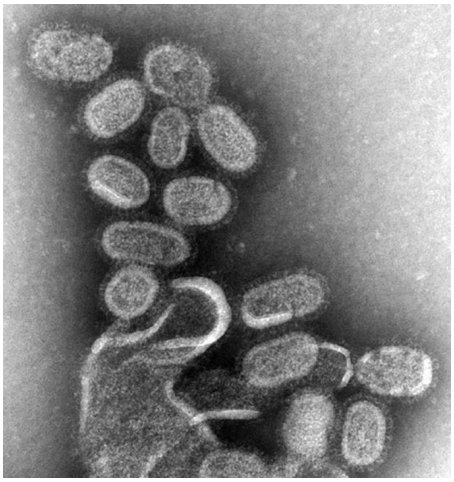

Figure: **Influenza**: TEM of negatively stained influenza virions, magnified approximately 100,000 times. Modern transport contributes in spreading diseases faster.

Typically, influenza is transmitted through the air by coughs or sneezes, creating aerosols containing the virus. Influenza can also be transmitted by direct contact with bird droppings or nasal secretions, or through contact with contaminated surfaces. Airborne aerosols have been thought to cause most infections, although which means of transmission is most important is not absolutely clear. Influenza viruses can be inactivated by sunlight, disinfectants and detergents. As the virus can be inactivated by soap, frequent hand washing reduces the risk of infection.

Influenza spreads around the world in seasonal epidemics, resulting in about three to five million yearly cases of severe illness and about 250,000 to 500,000 yearly deaths, rising to millions in some pandemic years.

In the 20th century three influenza pandemics occurred, each caused by the appearance of a new strain of the virus in humans, and killed tens of millions of people. Often, new influenza strains appear when an existing flu virus spreads to humans from another animal species, or when an existing human strain picks up new genes from a virus that usually infects birds or pigs. An avian strain named H5N1 raised the concern of a new influenza pandemic after it emerged in Asia in the 1990s, but it has not evolved to a form that spreads easily between people.

In April 2009 a novel flu strain evolved that combined genes from human, pig, and bird flu. Initially dubbed “swine flu” and also known as influenza A/H1N1, it emerged in Mexico, the United States, and several other nations. The World Health Organization officially declared the outbreak to be a pandemic level 6 on 11 June 2009. However, the WHO’s declaration of a pandemic level 6 was an indication of spread, not severity; the strain actually having a lower mortality rate than common flu outbreaks.

VACCINATIONS

Vaccinations against influenza are usually made available to people in developed countries. Farmed poultry is often vaccinated to avoid decimation of the flocks. The most common human vaccine is the trivalent influenza vaccine (TIV) that contains purified and inactivated antigens against three viral strains. Typically, this vaccine includes material from two influenza A virus subtypes and one influenza B virus strain. The TIV carries no risk of transmitting the disease, and it has very low reactivity. A vaccine formulated for one year may be ineffective in the following year, since the influenza virus evolves rapidly, and new strains quickly replace the older ones.

Antiviral drugs such as the neuraminidase inhibitor oseltamivir (Tamiflu) have been used to treat influenza; however, their effectiveness is difficult to determine due to much of the data remaining unpublished.

CHAPTER OVERVIEW

11: Immunology

Immunology is a branch of biology that covers the study of immune systems in all organisms. Immunology charts, measures, and contextualizes the: physiological functioning of the immune system in states of both health and diseases; malfunctions of the immune system in immunological disorders (such as autoimmune diseases, hypersensitivities, immune deficiency, and transplant rejection); the physical, chemical and physiological characteristics of the components of the immune system *in vitro*, *in situ*, and *in vivo*.

11.1A: Cells and Organs of the Immune System

The immune system includes primary lymphoid organs, secondary lymphatic tissues and various cells in the innate and adaptive immune systems.

Learning Objectives

- Recognize the cells and organs of the immune system and their functions

Key Points

- The key primary lymphoid organs of the immune system are the thymus and bone marrow, and secondary lymphatic tissues such as spleen, tonsils, lymph vessels, lymph nodes, adenoids, and skin and liver.
- Leukocytes (white blood cells) act like independent, single-celled organisms and are the second arm of the innate immune system.
- The innate leukocytes include the phagocytes (macrophages, neutrophils, and dendritic cells), mast cells, eosinophils, basophils, and natural killer cells. These cells identify and eliminate pathogens and are also important mediators in the activation of the adaptive immune system.
- The cells of the adaptive immune system are special types of leukocytes, called lymphocytes. B cells and T cells are the major types of lymphocytes and are derived from hematopoietic stem cells in the bone marrow.
- The lymphatic system is a part of the circulatory system, comprising a network of conduits called lymphatic vessels. The lymphatic system has multiple functions such as the transportation of white blood cells to and from the lymph nodes into the bones.

Key Terms

- **lymphocytes**: A lymphocyte is a type of white blood cell in the vertebrate immune system. The three major types of lymphocyte are T cells, B cells and natural killer (NK) cells. T cells (thymus cells) and B cells (bursa-derived cells) are the major cellular components of the adaptive immune response.
- **Leukocytes**: Cells of the immune system involved in defending the body against both infectious disease and foreign materials. Five different and diverse types of leukocytes exist.

Immune System Organs

The key primary lymphoid organs of the immune system include the thymus and bone marrow, as well as secondary lymphatic tissues including spleen, tonsils, lymph vessels, lymph nodes, adenoids, skin, and liver.

The thymus “educates” T cells and provides an inductive environment for the development of T cells from hematopoietic progenitor cells. The thymus is largest and most active during the neonatal and pre-adolescent periods of development. By the early teens, the thymus begins to atrophy and thymic stroma is replaced by adipose tissue. Nevertheless, residual T-lymphopoiesis continues throughout adult life.

Bone marrow is the flexible tissue found in the interior of bones. In humans, red blood cells are produced in the heads of long bones. The red bone marrow is a key element of the lymphatic system, being one of the primary lymphoid organs that generate lymphocytes from immature hematopoietic progenitor cells. Bone marrow and thymus constitute the primary lymphoid tissues involved in the production and early selection of lymphocytes.

The lymphatic system is a part of the circulatory system, comprising a network of conduits called lymphatic vessels that carry a clear fluid, called lymph, unidirectionally towards the heart. The lymphatic system has multiple interrelated functions including the transportation of white blood cells to and from the lymph nodes into the bones, and the transportation of antigen -presenting cells (such as dendritic cells) to the lymph nodes where an immune response is stimulated. Lymphoid tissue is found in many organs, particularly the lymph nodes.

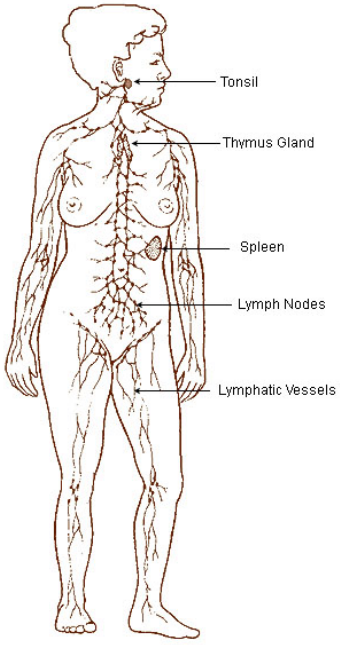

Figure: **The Lymph Nodes and Lymph Vessels in Human Beings**: The lymphatic system is a part of the circulatory system, comprising a network of conduits called lymphatic vessels that carry a clear fluid called lymph.

The spleen is similar in structure to a large lymph node and acts primarily as a blood filter. It synthesizes antibodies in its white pulp and removes antibody-coated bacteria along with antibody-coated blood cells by way of blood and lymph node circulation.

The palatine tonsils and the nasopharyngeal tonsil are lymphoepithelial tissues located near the oropharynx and nasopharynx. These immunocompetent tissues are the immune system's first line of defense against ingested or inhaled foreign pathogens. The fundamental immunological roles of tonsils aren't yet understood.

Lymph nodes are distributed widely throughout areas of the body, including the armpit and stomach, and linked by lymphatic vessels. Lymph nodes are garrisons of B, T and other immune cells. Lymph nodes act as filters or traps for foreign particles and are important in the proper functioning of the immune system. They are packed tightly with the white blood cells, called lymphocytes and macrophages.

The skin is one of the most important parts of the body because it interfaces with the environment, and is the first line of defense from external factors, acting as an anatomical barrier from pathogens and damage between the internal and external environment in bodily defense. Langerhans cells in the skin are part of the adaptive immune system.

The liver has a wide range of functions, including immunological effects—the reticuloendothelial system of the liver contains many immunologically active cells, acting as a "sieve" for antigens carried to it via the portal system.

Immune System Cells

Leukocytes (white blood cells) are immune system cells involved in defending the body against infectious disease and foreign materials. Five different types of leukocytes exist, all produced and derived from a multipotent cell in the bone marrow known as a hematopoietic stem cell. The innate leukocytes include the phagocytes, mast cells, eosinophils, basophils, and natural killer cells. These cells identify and eliminate pathogens and are important mediators in the activation of the adaptive immune system.

Neutrophils and macrophages are phagocytes that travel throughout the body in pursuit of invading pathogens. Neutrophils are normally found in the bloodstream and are the most abundant type of phagocyte. During the acute phase of inflammation neutrophils migrate toward the site of inflammation and are usually the first cells to arrive at the scene of infection. Macrophages reside within tissues and produce a wide array of chemicals. They also act as scavengers, ridding the body of worn-out cells and other debris, and as antigen-presenting cells that activate the adaptive immune system. Dendritic cells are phagocytes in tissues that are in contact with the external environment, and are located mainly in the skin, nose, lungs, stomach, and intestines. These cells serve as a link between the bodily tissues and the innate and adaptive immune systems, as they present antigen to T-cells, one of the key cell types of the adaptive immune system.

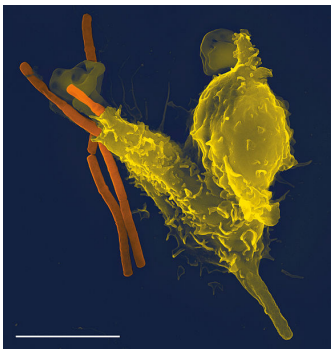

Figure: **A Phagocyte in Action**: Neutrophil engulfing anthrax bacteria. Taken with a Leo 1550 scanning electron microscope. Scale bar is 5 micrometers.

Mast cells reside in connective tissues and mucous membranes, and regulate the inflammatory response. They are most often associated with allergy and anaphylaxis.

Basophils and eosinophils are related to neutrophils. They secrete chemical mediators that are involved in defending against parasites, and play a role in allergic reactions, such as asthma.

Natural killer cells are leukocytes that attack and destroy tumor cells, or cells that have been infected by viruses.

The cells of the adaptive immune system are special types of leukocytes, called lymphocytes. B cells and T cells are the major types of lymphocytes and are derived from hematopoietic stem cells in the bone marrow.

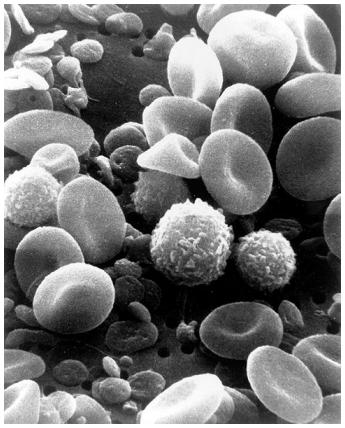

Figure: **Blood Cells**: Red blood cells, several white blood cells including lymphocytes, a monocyte, a neutrophil, and many small disc-shaped platelets.

T cells recognize a “non-self” target, such as a pathogen, only after antigens have been processed and presented in combination with a “self” receptor, called a major histocompatibility complex (MHC) molecule. There are two major subtypes of T cells: the killer T cell, which kills cells that are infected with viruses (and other pathogens) or are otherwise damaged or dysfunctional, and the helper T cell, which regulates both innate and adaptive immune responses and helps determine which immune responses the body makes to a particular pathogen. These cells have no cytotoxic activity and do not kill infected cells or clear pathogens directly. A third, minor subtype are the γ T cells that recognize intact antigens not bound to MHC receptors.

In contrast, the B cell antigen-specific receptor is an antibody molecule on the B cell surface, which recognizes whole pathogens without any need for antigen processing. Each lineage of B cell expresses a different antibody, so the complete set of B cell antigen receptors represent all the antibodies that the body can manufacture.

11.1B: Overview of Human-Microbial Reactions

Learning Objectives

- Outline the relationships between humans and microbes: non-pathogenic and pathogenic

The Human Microbiome Project

The Human Microbiome Project (HMP) is a United States National Institutes of Health initiative aimed at identifying and characterizing the microorganisms which are found in association with both healthy and diseased humans.

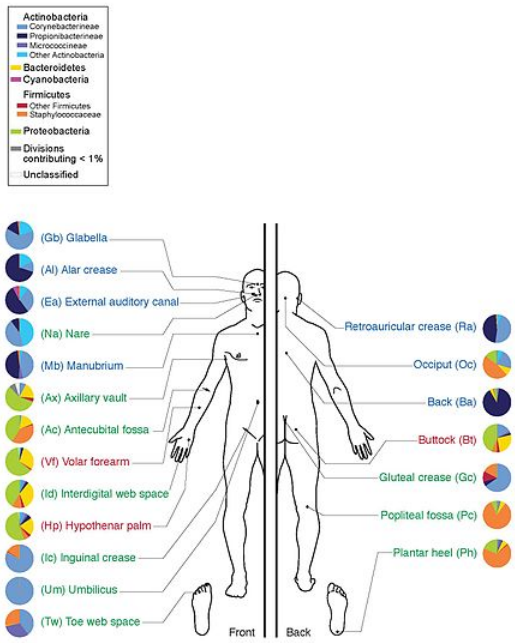

Figure: ***Bacteria commonly found in and on humans****: This is a depiction of the human body and bacteria that predominates throughout it.*

Total microbial cells found in association with humans may exceed the total number of cells making up the human body by a factor of ten-to-one. The total number of genes associated with the human microbiome could exceed the total number of human genes by a factor of 100-to-one.

Organisms expected to be found in the human microbiome may generally be categorized as bacteria (the majority), archaea, yeasts, and single-celled eukaryotes as well as various helminth parasites and viruses, such as those that infect cellular microbiome organisms.

The HMP project discovered several “surprises”, including:

- Bacterial protein -coding genes are estimated as 360 times more abundant than human genes.
- Microbial metabolic activities, for example, digestion of fats, are not always provided by the same bacterial species.
- Components of the human microbiome change over time, affected by a patient disease state and medication.

Examples of Non-pathogenic Interactions

Gut flora consists of microorganisms that live in the digestive tracts of animals and is the largest reservoir of human flora. The human body, consisting of about 10 trillion cells, carries about ten times as many microorganisms in the intestines. The metabolic activities performed by these bacteria resemble those of an organ, leading some to liken gut bacteria to a “forgotten” organ.

Bacteria make up most of the flora in the colon and up to 60% of the dry mass of feces. Between 300 and 1000 different species live in the gut. It is probable that 99% of the bacteria come from about 30 or 40 species. Fungi and protozoa also make up a part of the gut flora, but little is known about their activities.

The relationship between gut flora and humans is thought to be not merely commensal, but rather a mutualistic relationship. Though people can survive without gut flora, the microorganisms perform a host of useful functions, such as fermenting unused energy substrates, training the immune system, preventing growth of harmful, pathogenic bacteria, regulating the development of the gut, producing vitamins for the host, and producing hormones to direct the host to store fats. In certain conditions, some species can cause disease by producing infection or increasing the host's cancer risk.

The skin microbiota are composed mostly of bacteria of which there are around 1000 species upon human skin from 19 phyla. The total number of bacteria on an average human has been estimated at 10^{12}.

Skin flora are usually non-pathogenic and either commensal or mutualistic. The benefits of bacteria include preventing transient pathogenic organisms from colonizing the skin surface, either by competing for nutrients, secreting chemicals against them, or stimulating the skin's immune system. Resident microbes can cause skin diseases and enter the blood system creating life-threatening diseases particularly in immunosuppressed people.

Pathogenic Interactions

Among the almost infinite varieties of microorganisms, relatively few cause disease in otherwise healthy individuals. Infectious disease results from the interplay between those few pathogens and the defenses of the hosts they infect. Infectious diseases comprise clinically evident illness resulting from the infection, and the presence and growth of pathogenic biological agents in an individual host organism. Infectious pathogens include some viruses, bacteria, fungi, protozoa, multicellular parasites, and aberrant proteins known as prions. Primary pathogens cause disease as a result of their presence or activity within the normal, healthy host. Their intrinsic virulence is due to their need to reproduce and spread.

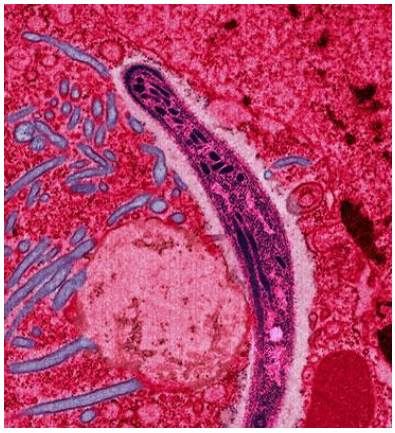

Figure: ***The malaria plasmodium****: Malaria is transmitted to people and animals by mosquitoes. Malarial sporozoites develop inside oocysts and are released in large numbers into the hemocoel of Anopheles stephensi mosquitoes. This false-colored electron micrograph shows a sporozoite migrating through the cytoplasm of midgut epithelia.*

Organisms which cause an infectious disease in a host with depressed resistance are classified as opportunistic pathogens. Opportunistic disease may be caused by microbes that are ordinarily in contact with the host, such as pathogenic bacteria or fungi in the gastrointestinal tract. They may also result from (otherwise innocuous) microbes acquired from other hosts or from the environment as a result of traumatic introduction (as in surgical wound infections). An opportunistic disease requires impairment of host defenses, which may occur as a result of genetic defects, exposure to antimicrobial drugs or immunosuppressive chemicals, exposure to ionizing radiation, or as a result of an infectious disease with immunosuppressive activity.

The success of any pathogen depends on its ability to elude host immune responses. Therefore, pathogens evolved several methods that allow them to successfully infect a host, while evading the immune system. Bacteria often overcome physical barriers by secreting enzymes that digest the barrier. An evasion strategy used by several pathogens to avoid the innate immune system is to hide within the cells of their host. The mechanisms used to evade the adaptive immune system are more complicated. The simplest approach is antigenic variation: rapid changes of non-essential epitopes on the surface of the pathogen, while keeping essential epitopes concealed.

Key Points

- Though people can survive without gut flora, the microorganisms perform a host of useful functions: fermenting unused energy substrates, training the immune system, preventing growth of harmful bacteria, regulating the development of the gut, and

producing vitamins and hormones for the host.

- Organisms expected to be found in the human microbiome may generally be categorized as bacteria (the majority), archaea, yeasts, and single-celled eukaryotes as well as various helminth parasites and viruses.
- Skin flora are usually either commensal or mutualistic. The benefits of bacteria include preventing transient pathogenic organisms from colonizing the skin surface. Resident microbes can cause skin diseases and create life-threatening illness particularly in immunosuppressed people.
- Among the almost infinite varieties of microorganisms, relatively few cause disease in otherwise healthy individuals. Infectious disease results from the interplay between those few pathogens and the defenses of the hosts they infect.
- Primary pathogens cause disease as a result of their activity in the healthy host and their intrinsic virulence is due to their need to reproduce and spread. Organisms that cause an infectious disease in a host with depressed resistance are classified as opportunistic.
- The success of any pathogen depends on its ability to elude host immune responses. Therefore, pathogens evolved several methods that allow them to successfully infect a host, while evading the immune system.

Key Terms

- **Human microbiome**: The aggregate of microorganisms that reside on the surface and in deep layers of skin, in the saliva and oral mucosa, in the conjunctiva, and in the gastrointestinal tracts. They include bacteria, fungi, and archaea. Some of these organisms perform tasks that are useful for the human host. However, the majority have no known beneficial or harmful effect.
- **Primary pathogen**: These pathogens cause disease as a result of their presence or activity within the normal, healthy host. Their intrinsic virulence (the severity of the disease they cause) is due to their need to reproduce and spread.
- **Opportunistic pathogen**: Organisms which cause an infectious disease in a host with depressed resistance are classified as opportunistic pathogens. Opportunistic disease may be caused by microbes that are ordinarily in contact with the host, such as pathogenic bacteria or fungi in the gastrointestinal or the upper respiratory tract. They may also result from (otherwise innocuous) microbes acquired from other hosts or from the environment as a result of traumatic introduction. An opportunistic disease requires impairment of host defenses.

11.1B: Overview of Human-Microbial Reactions is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.1C: Overview of the Immune System

The immune system is a system of biological structures and processes within an organism that protects against disease.

Learning Objectives

- Distinguish between innate and adaptive immunity

Key Points

- Pathogens can rapidly evolve and adapt to avoid detection and neutralization by the immune system. As a result, multiple defense mechanisms have also evolved to recognize and neutralize pathogens. The immune system protects from infection with layered defenses of increasing specificity.
- Physical barriers prevent pathogens from entering the organism. If these barriers are breached, the innate immune system provides an immediate, non-specific response. If pathogens successfully evade the innate response, vertebrates possess a second layer of protection, the adaptive immune system.
- Immunity is a biological term that describes a state of having sufficient biological defences to avoid infection, disease, or other unwanted biological invasion.
- Innate, or nonspecific, immunity is the natural resistance with which a person is born. It provides resistance through several physical, chemical, and cellular approaches.
- Adaptive immunity is often sub-divided into two major types acording to how the immunity was introduced. Naturally acquired immunity occurs through non-deliberate contact with a disease causing agent, whereas artificially acquired immunity develops through deliberate actions such as vaccination.
- Immunology is a branch of biomedical science that covers the study of all aspects of the immune system in all organisms. It deals with the physiological functioning of the immune system in states of both health and disease.

Key Terms

- **Adaptive (acquired) immunity**: The creation of immunological memory after an initial response to a specific pathogen, leading to an enhanced response to subsequent encounters with that same pathogen. This process of acquired immunity is the basis of vaccination.
- **Innate immunity**: The natural resistance with which a person is born. It provides resistance through several physical, chemical, and cellular approaches.
- **Self molecules**: Those components of an organism's body that can be distinguished by the immune system from foreign substances.

The immune system is a system of biological structures and processes within an organism that protects against disease. To function properly, an immune system must detect a wide variety of agents, from viruses to parasitic worms, and distinguish them from the organism's own healthy tissue.

Pathogens can rapidly evolve and adapt to avoid detection and neutralization by the immune system. As a result, multiple defense mechanisms have also evolved to recognize and neutralize pathogens. Even simple unicellular organisms, such as bacteria, possess a rudimentary immune system in the form of enzymes that protect against bacteriophage infections. Other basic immune mechanisms including include phagocytosis, antimicrobial peptides called defensins, and the complement system, which evolved in ancient eukaryotes and remain in modern descendants, such as plants and insects. Jawed vertebrates have even more sophisticated defense mechanisms, including the ability to adapt over time to recognize specific pathogens more efficiently. Adaptive (acquired) immunity creates immunological memory after an initial response to a specific pathogen, leading to an enhanced response to subsequent encounters with that same pathogen. This process of acquired immunity is the basis of vaccination.

Innate and Adaptive Immunity

The immune system protects organisms from infection with layered defenses of increasing specificity. Physical barriers prevent pathogens, such as bacteria and viruses, from entering the organism. If a pathogen breaches these barriers, the innate immune system provides an immediate, but non-specific response. Innate immune systems are found in all plants and animals. If pathogens successfully evade the innate response, vertebrates possess a second layer of protection, the adaptive immune system, which is activated by the innate response. The immune system adapts its response during an infection in order to improve its recognition of the pathogen. This improved response is then retained after the pathogen has been eliminated, in the form of an immunological

memory, and allows the adaptive immune system to mount faster and stronger attacks when this pathogen is encountered. Both innate and adaptive immunity depend on the ability of the immune system to distinguish between self and non- self molecules, where self molecules are those components of an organism's body that can be distinguished from foreign substances by the immune system.

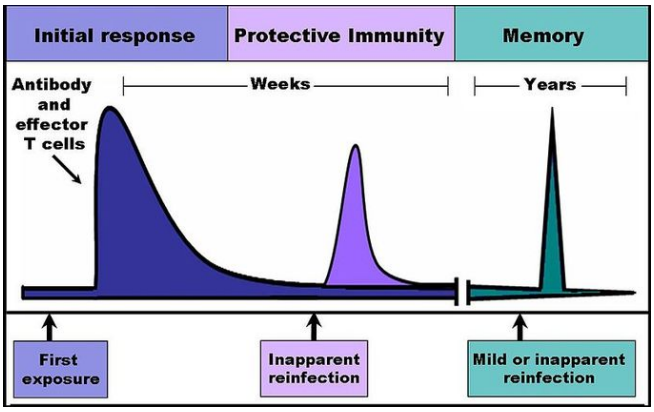

Figure: **The Time Course of an Immune Response**: Immune reactants, such as antibodies and effector T-cells, work to eliminate an infection, and their levels and activity rapidly increase following an encounter with an infectious agent, whether that agent is a pathogen or a vaccine. For several weeks these reactants remain in the serum and lymphatic tissues and provide protective immunity against reinfection by the same agent. During an early reinfection, few outward symptoms of illness are present, but the levels of immune reactants increase and are detectable in the blood and/or lymph. Following clearance of the infection, antibody level and effector T cell activity gradually declines. Because immunological memory has developed, reinfection at later times leads to a rapid increase in antibody production and effector T cell activity. These later infections can be mild or even inapparent.

Immunity is a biological term that describes a state of having sufficient biological defences to avoid infection, disease, or other unwanted biological invasion. Immunity involves both specific and non-specific components.

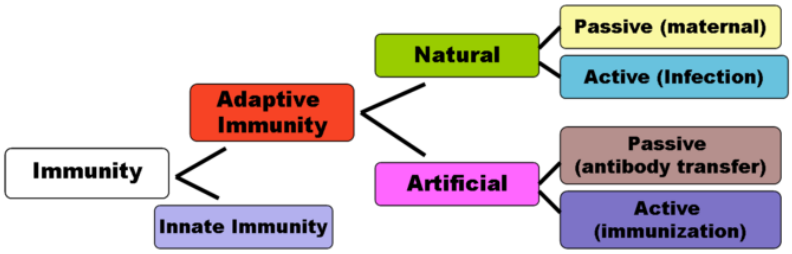

Figure: **Immunity**: Natural immunity occurs through contact with a disease causing agent, when the contact was not deliberate, where as artificial immunity develops only through deliberate actions of exposure. Both natural and artificial immunity can be further subdivided, depending on the amount of time the protection lasts. Passive immunity is short lived, and usually lasts only a few months, whereas protection via active immunity lasts much longer, and is sometimes life-long.

INNATE IMMUNITY

Innate, or nonspecific, immunity is the natural resistance with which a person is born. It provides resistance through several physical, chemical, and cellular approaches. Microbes first encounter the epithelial layers (physical barriers that line our skin and mucous membranes). Subsequent general defenses include secreted chemical signals (cytokines), antimicrobial substances, fever, and phagocytic activity associated with the inflammatory response. The phagocytes express cell surface receptors that can bind and respond to common molecular patterns expressed on the surface of invading microbes. Through these approaches, innate immunity can prevent the colonization, entry, and spread of microbes.

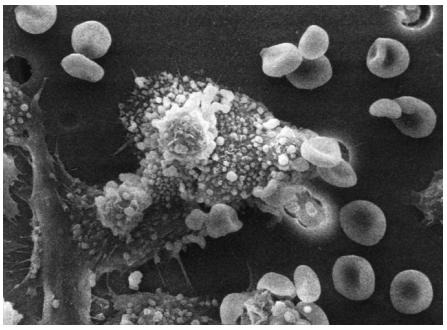

Figure: **An animal's immune response to a foreign body**: Macrophages begin to fuse with, and inject its toxins into, the cancer cell. The cell starts rounding up and loses its spikes. As the macrophage cell becomes smooth. The cancer cell appears lumpy in the last stage before it dies. These lumps are actually the macrophages fused within the cancer cell. The cancer cell then loses its morphology, shrinks up and dies. Photo magnification: 3: x8,000 Type: B & W print

ADAPTIVE IMMUNITY

Adaptive immunity is often sub-divided into two major types depending on how the immunity was introduced. Naturally acquired immunity occurs through contact with a disease causing agent, when the contact was not deliberate, whereas artificially acquired immunity develops only through deliberate actions such as vaccination. Both naturally and artificially acquired immunity can be further subdivided depending on whether immunity is induced in the host or passively transferred from an immune host. Passive immunity is acquired through transfer of antibodies or activated T cells from an immune host, and is short lived—usually lasting only a few months. Active immunity is induced in the host itself by antigen, and lasts much longer, sometimes the entire lifetime.

A further subdivision of adaptive immunity is characterized by the cells involved; humoral immunity is the aspect of immunity that is mediated by secreted antibodies, whereas the protection provided by cell-mediated immunity involves T lymphocytes alone. Humoral immunity is active when the organism generates its own antibodies, and passive when antibodies are transferred between individuals. Similarly, cell-mediated immunity is active when the organism's own T cells are stimulated and passive when T cells come from another organism.

11.3A: Natural Killer Cells

LEARNING OBJECTIVe

- Describe the role of natural killer cells in the immune response

Lymphocytes are leukocytes (white blood cells) that are histologically identifiable by their large, darkly-staining nuclei; they are small cells with very little cytoplasm. After a pathogen enters the body, infected cells are identified and destroyed by natural killer (NK) cells, which are a type of lymphocyte that can kill cells infected with viruses or tumor cells (abnormal cells that uncontrollably divide and invade other tissue). While NK cells are part of the innate immune response, they are best understood relative to their counterparts in the adaptive immune response,T cells, which are also classified as lymphocytes.

T cells are lymphocytes that mature in the thymus gland and identify intracellular infections, especially from viruses, by the altered expression of major histocompatibility class (MHC) I molecules on the surface of infected cells. MHC I molecules are proteins on the surfaces of all nucleated cells which help the immune system distinguish between “self” and “non-self.” If the cell is infected, the MHC I molecules display fragments of proteins from the infectious agents to T-cells. Healthy cells do not display any proteins and will be ignored by the immune system, while the cells identified as “non-self” by foreign proteins will be attacked by the immune system.

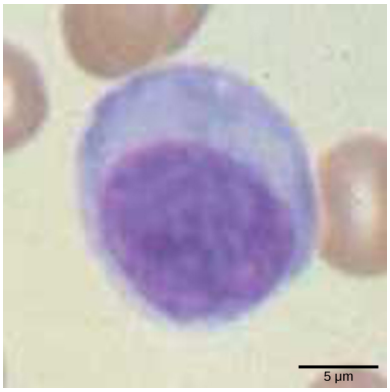

Figure: ***Lymphocytes****: Lymphocytes, such as NK cells, are characterized by their large nuclei that actively absorb Wright stain and, therefore, appear dark colored under a microscope.*

An infected cell (or a tumor cell) is often incapable of synthesizing and displaying MHC I molecules appropriately. The metabolic resources of cells infected by some viruses produce proteins that interfere with MHC I processing and/or trafficking to the cell surface. The reduced MHC I on host cells varies from virus to virus and results from active inhibitors being produced by the viruses. This process can deplete host MHC I molecules on the cell surface, which prevents T-cells from recognizing them, but which NK cells detect as “unhealthy” or “abnormal” while searching for cellular MHC I molecules. As such, NK cells offer a complementary check for unhealthy cells, relative to T cells. Similarly, the dramatically-altered gene expression of tumor cells leads to expression of extremely- deformed or absent MHC I molecules that also signal “unhealthy” or “abnormal.”

NK cells are always active; an interaction with normal, intact MHC I molecules on a healthy cell disables the killing sequence, causing the NK cell to move on. After the NK cell detects an infected or tumor cell, its cytoplasm secretes granules comprised of perforin: a destructive protein that creates a pore in the target cell. Granzymes are released along with the perforin in the immunological synapse. A granzyme, a protease that digests cellular proteins, induces the target cell to undergo programmed cell death, or apoptosis. Phagocytic cells then digest the cell debris left behind. NK cells are constantly patrolling the body. They are an effective mechanism for controlling potential infections and preventing cancer progression.

Key Points

- Natural killer (NK) cells are lymphocytes (a subclass of white blood cells) that recognize infected or tumorogenic cells and kill them.
- Unlike the related T cells, NK cells do not recognize fragments of the infecting particle, but rather the incorrect display of major histocompatibility complex (MHC) I molecules.
- NK cells are always active, but will not perform their killing function on cells with intact MHC I molecules.

- When NK cells detect an infected or tumor cell, they secrete granules that contain perforin, creating a pore in the target cell; granzymes then pass through these pores, degrading cellular proteins, causing cells to undergo apoptosis.

Key Terms

- **lymphocyte**: a type of white blood cell or leukocyte that is divided into two principal groups and a null group: B-cells, T-cells, and natural killer (NK) cells
- **major histocompatibility complex**: a protein present on the extracellular surface of the cell that displays portions of the proteins that are degraded inside the cell
- **T cell**: a lymphocyte, from the thymus, that can recognize specific antigens and can activate or deactivate other immune cells

11.3B: Physical and Chemical Barriers

The innate immune response has physical and chemical barriers that exist as the first line of defense against infectious pathogens.

Learning Objectives

- Describe physical and chemical barriers in the innate immune response

Key Points

- The skin, or epithelial surface, serves as the primary barrier to microbial entry into the body; skin peeling, drying out, and the skin's acidity all serve to dislodge or kill foreign pathogens.
- Orifices such as the eyes and mouth, which are not covered by skin, have other mechanisms by which they prevent entry; tears wash away microbes, while cilia in the nasal passages and respiratory tract push mucus (which traps pathogens) out of the body.
- Many chemical barriers also exist once pathogens make it past the outer physical barriers; the acidity of the stomach ensures that few organisms arriving with food survive the digestive system.

Key Terms

- **cilium**: a hairlike organelle projecting from a eukaryotic cell (such as unicellular organism or one cell of a multicelled organism), which serves either for locomotion by moving or as sensors
- **microbicidal**: functioning to reduce the infectivity of microbes

Physical and chemical barriers

The immune system comprises both innate and adaptive immune responses. Innate immunity occurs naturally due to genetic factors or physiology. It is not induced by infection or vaccination, but is constantly available to reduce the workload for the adaptive immune response. The adaptive immune response expands over time, storing information about past infections and mounting pathogen-specific defenses. Both the innate and adaptive levels of the immune response involve secreted proteins, receptor-mediated signaling, and intricate cell -to-cell communication. From an historical perspective, the innate immune system developed early in animal evolution, roughly a billion years ago, as an essential response to infection. In the innate immune response, any pathogenic threat triggers a consistent sequence of events that can identify the type of pathogen and either clear the infection independently or mobilize a highly-specialized adaptive immune response.

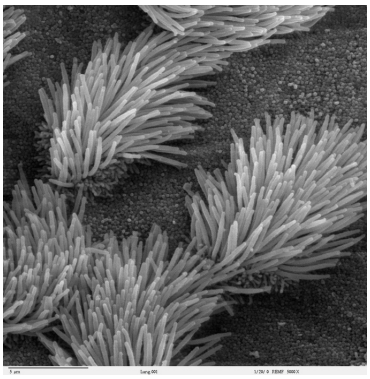

Figure: **Cilia up close**: Cilia are a type of organelle found in eukaryotic cells. In the innate immune system, they serve to move pathogens out of the respiratory system via a concerted sweeping motion.

Before any immune factors are triggered, the skin (also known as the epithelial surface) functions as a continuous, impassable barrier to potentially-infectious pathogens. The skin is considered the first defense of the innate immune system; it is the first of the nonspecific barrier defenses. Pathogens are killed or inactivated on the skin by desiccation (drying out) and by the skin's acidity. In addition, beneficial microorganisms that coexist on the skin compete with invading pathogens, preventing infection. Desquamation, or peeling skin, also serves to dislodge organisms that have adhered to the surface of the body and are awaiting entry. Regions of the body that are not protected by skin (such as the eyes and mucous membranes) have alternative methods of defense. These include tears in the eyes; mucous membranes that provide partial protection despite having to allow absorption and secretion; mucus secretions that trap and rinse away pathogens; and cilia (singular cilium) in the nasal passages and respiratory tract that push

the mucus with the pathogens out of the body. Furthermore, tears and mucus secretions contain microbicidal factors that prevent many infections from entering via these routes.

Despite these barriers, pathogens may enter the body through skin abrasions or punctures, or by collecting on mucosal surfaces in large numbers that overcome the mucus or cilia. Some pathogens have evolved specific mechanisms that allow them to overcome physical and chemical barriers.

Once inside, the body still has many other defenses, including chemical barriers. Some of these include the low pH of the stomach, which inhibits the growth of pathogens; blood proteins that bind and disrupt bacterial cell membranes; and the process of urination, which flushes pathogens from the urinary tract. The blood-brain barrier also protects the nervous system from pathogens that have already entered the blood stream, but would do significantly more damage if they entered the central nervous system.

11.3B: Physical and Chemical Barriers is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.3C: The Complement System

Around 20 soluble proteins comprise the complement system, which helps destroy extracellular microorganisms that have invaded the body.

Learning Objectives

- Explain how the complement system aids antibody response

Key Points

- The complement system is so named because it is complementary to the antibody response of the adaptive immune system.
- The complement system proteins are produced continuously by the liver and macrophages, are abundant in the blood serum, and are capable of immediate response to infecting microorganisms.
- The complement system works by first having several proteins bind to a target; this binding event then begins a series of highly-specific and regulated sequences wherein successive proteins are activated by cleavage and/or structural changes of the preceding proteins.
- The complement system serves as a marker to indicate targets for phagocytic cells; complement proteins can also combine to form attack complexes capable of opening pores in microbial cell membranes.

Key Terms

- **opsonization**: the process by which a pathogen is marked for ingestion and destruction by a phagocyte
- **complement system**: an aspect of the innate immune system that supplements the actions of the antibodies and phagocytic cells in clearing out pathogens from an organism

Complement

The innate immune system serves as a first responder to pathogenic threats that bypass natural physical and chemical barriers of the body. Using a combination of cellular and molecular attacks, the innate immune system identifies the nature of a pathogen and responds with inflammation, phagocytosis (where a cell engulfs a foreign particle), cytokine release, destruction by NK cells, and/or a complement system. In this concept, we will discuss the complement system.

An array of approximately 20 types of soluble proteins, called a complement system, functions to destroy extracellular pathogens. Cells of the liver and macrophages synthesize complement proteins continuously. These proteins are abundant in the blood serum and are capable of responding immediately to infecting microorganisms. The complement system is so named because it is complementary to the antibody response of the adaptive immune system. Complement proteins bind to the surfaces of microorganisms and are particularly attracted to pathogens that are already bound by antibodies. Binding of complement proteins occurs in a specific and highly-regulated sequence, with each successive protein being activated by cleavage and/or structural changes induced upon binding of the preceding protein(s). After the first few complement proteins bind, a cascade of sequential binding events follows in which the pathogen rapidly becomes coated in complement proteins.

Complement proteins perform several functions. They serve as a marker to indicate the presence of a pathogen to phagocytic cells, such as macrophages and B cells, to enhance engulfment. This process is called opsonization. Certain complement proteins can combine to form attack complexes that open pores in microbial cell membranes. These structures destroy pathogens by causing their contents to leak. When innate mechanisms are insufficient to clear an infection, the adaptive immune response is informed and mobilized.

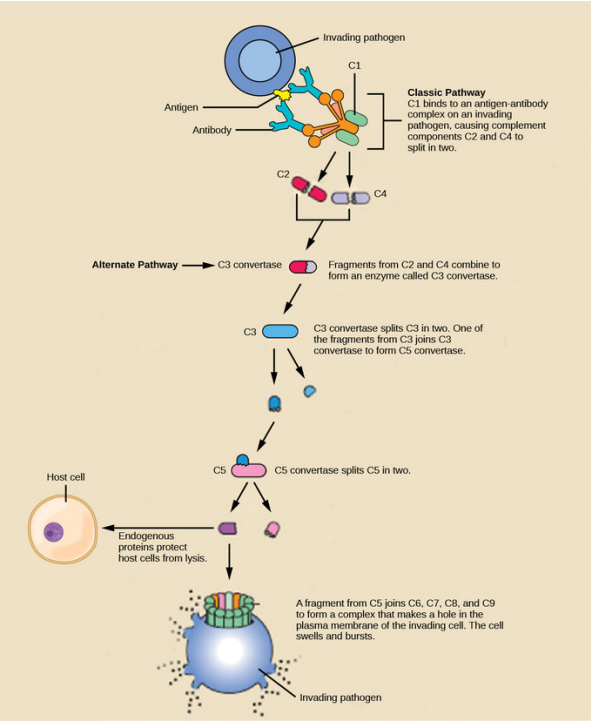

Figure: **Complement cascade in the innate immune response**: The classic pathway for the complement cascade involves the attachment of several initial complement proteins to an antibody-bound pathogen, followed by rapid activation and binding of many more complement proteins and the creation of destructive pores in the microbial cell envelope and cell wall. The alternate pathway does not involve antibody activation. Rather, C3 convertase spontaneously breaks down C3. Endogenous regulatory proteins prevent the complement complex from binding to host cells. Pathogens lacking these regulatory proteins are lysed.

11.3C: The Complement System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.3D: Pathogen Recognition

Upon pathogen entry to the body, the innate immune system uses several mechanisms to destroy the pathogen and any cells it has infected.

Learning Objectives

- Describe the role of PAMPs and PRRs, interferons, and other cytokines in innate immunity

Key Points

- Pathogens are recognized by a variety of immune cells, such as macrophages and dendritic cells, via pathogen-associated molecular patterns (PAMPs) on the pathogen surface, which interact with complementary pattern-recognition receptors (PRRs) on the immune cells' surfaces.
- Upon binding of PRRs with PAMPs (pathogen recognition), immune cells release cytokines to tell other cells to start fighting back.
- One class of cytokines, interferons, warn nearby uninfected cells of impending infection, cause cells to start cleaving RNA and reduce protein synthesis, and signal nearby infected cells to undergo apoptosis.
- Another class of cytokines, called inerleukins, mediate interactions between white blood cells (leukocytes) and help bridge the innate and adaptive immune responses.
- Inflammation (hot, red, swollen, painful tissue associated with infection) is encouraged by cytokines that are produced immediately upon pathogen recognition; the increase in blood flow associated with inflammation allows more leukocytes (a type of innate immune cell) to reach the infected area.

Key Terms

- **macrophage**: a white blood cell that phagocytizes necrotic cell debris and foreign material, including viruses, bacteria, and tattoo ink; part of the innate immune system
- **phagocytosis**: the process where a cell incorporates a particle by extending pseudopodia and drawing the particle into a vacuole of its cytoplasm
- **cytokine**: any of various small regulatory proteins that regulate the cells of the immune system; they are released upon binding of PRRs to PAMPS

Pathogen recognition

When a pathogen enters the body, cells in the blood and lymph detect the specific pathogen-associated molecular patterns (PAMPs) on the pathogen's surface. PAMPs are carbohydrate, polypeptide, and nucleic acid "signatures" that are expressed by viruses, bacteria, and parasites, but which differ from molecules on host cells. These PAMPs allow the immune system to recognize "self" from "other" so as not to destroy the host.

The immune system has specific cells with receptors that recognize these PAMPs. A macrophage is a large, phagocytic cell that engulfs foreign particles and pathogens. Macrophages recognize PAMPs via complementary pattern recognition receptors (PRRs). PRRs are molecules on macrophages and dendritic cells which are in contact with the external environment and can thus recognize PAMPs when present. A monocyte, a type of leukocyte (white blood cell) that circulates in the blood and lymph, differentiates into macrophages after it moves into infected tissue. Dendritic cells bind molecular signatures of pathogens, promoting pathogen engulfment and destruction.

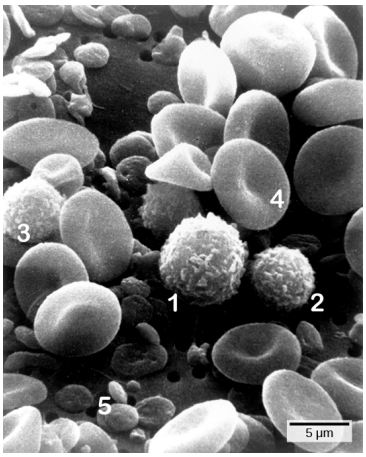

Figure: **Blood cells related to the innate immune response**: Cells of the blood include (1) monocytes, (2) lymphocytes, (3) neutrophils, (4) red blood cells, and (5) platelets. Leukocytes (1, 2, 3) are white blood cells that play an important role in the body's immune system.

Cell type	Characteristics	Location	Image
Mast cell	Dilates blood vessels and induces inflammation through release of histamines and heparin. Recruits macrophages and neutrophils. Involved in wound healing and defense against pathogens but can also be responsible for allergic reactions.	Connective tissues, mucous membranes	
Macrophage	Phagocytic cell that consumes foreign pathogens and cancer cells. Stimulates response of other immune cells.	Migrates from blood vessels into tissues.	
Natural killer cell	Kills tumor cells and virus-infected cells.	Circulates in blood and migrates into tissues.	
Dendritic cell	Presents antigens on its surface, thereby triggering adaptive immunity.	Present in epithelial tissue, including skin, lung and tissues of the digestive tract. Migrates to lymph nodes upon activation.	
Monocyte	Differentiates into macrophages and dendritic cells in response to inflammation.	Stored in spleen, moves through blood vessels to infected tissues.	
Neutrophil	First responders at the site of infection or trauma, this abundant phagocytic cell represents 50-60 percent of all leukocytes. Releases toxins that kill or inhibit bacteria and fungi and recruits other immune cells to the site of infection.	Migrates from blood vessels into tissues.	
Basophil	Responsible for defense against parasites. Releases histamines that cause inflammation and may be responsible for allergic reactions.	Circulates in blood and migrates to tissues.	
Eosinophil	Releases toxins that kill bacteria and parasites but also causes tissue damage.	Circulates in blood and migrates to tissues.	

Figure: **Cells involved in the innate immune system**: The immune system has specific cells whose job is to recognize pathogen-associated molecular patterns. The characteristics and location of cells involved in the innate immune system are described in this chart.

Once a pathogen is detected, the immune system must also track whether it is replicating intracellularly (inside the cell, as with most viruses and some bacteria) or extracellularly (outside of the cell, as with other bacteria, but not viruses). The innate immune system must respond accordingly by identifying the extracellular pathogen and/or by identifying host cells that have already been infected.

Cytokine release affect

The binding of PRRs with PAMPs triggers the release of cytokines, which signal that a pathogen is present and needs to be destroyed along with any infected cells. A cytokine is a chemical messenger that regulates cell differentiation (form and function), proliferation (production), and gene expression to affect immune responses. At least 40 types of cytokines exist in humans that differ in terms of the cell type that produces them, the cell type that responds to them, and the changes they produce.

One subclass of cytokines is the interleukin (IL), which mediates interactions between leukocytes (white blood cells). Interleukins are involved in bridging the innate and adaptive immune responses. In addition to being released from cells after PAMP recognition, cytokines are released by the infected cells which bind to nearby uninfected cells, inducing those cells to release cytokines, resulting in a cytokine burst.

A second class of cytokines is interferons, which are released by infected cells as a warning to nearby uninfected cells. A function an interferons is to inhibit viral replication, making them particularly effective against viruses. They also have other important functions, such as tumor surveillance. Interferons work by signaling neighboring uninfected cells to destroy RNA (often a very important biomolecule for viruses) and reduce protein synthesis; signaling neighboring infected cells to undergo apoptosis (programmed cell death); and activating immune cells.

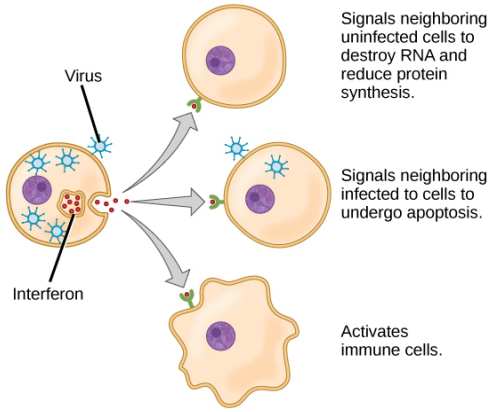

Figure: **Interferon release**: Interferons are cytokines that are released by a cell infected with a virus. The response of neighboring cells to interferons helps stem the infection.

Cytokines also send feedback to cells of the nervous system to bring about the overall symptoms of feeling sick, which include lethargy, muscle pain, and nausea. These effects may have evolved because the symptoms encourage the individual to rest, preventing them from spreading the infection to others. Cytokines also increase the core body temperature, causing a fever, which causes the liver to withhold iron from the blood. Without iron, certain pathogens (such as some bacteria) are unable to replicate; this is called nutritional immunity.

Phagocytosis and inflammation

The first cytokines to be produced are pro-inflammatory; that is, they encourage inflammation, or the localized redness, swelling (edema), heat, loss of function, and pain that result from the movement of leukocytes and fluid through increasingly-permeable capillaries to a site of infection. The population of leukocytes that arrives at an infection site depends on the nature of the infecting pathogen. Both macrophages and dendritic cells engulf pathogens and cellular debris through phagocytosis. A neutrophil is also a phagocytic leukocyte that engulfs and digests pathogens. Neutrophils, the most-abundant leukocytes of the immune system, have a nucleus with two to five lobes and contain organelles (lysosomes) that digest engulfed pathogens. An eosinophil is a leukocyte that works with other eosinophils to surround a parasite. It is involved in the allergic response and in protection against helminthes (parasitic worms).

Neutrophils and eosinophils are particularly important leukocytes that engulf large pathogens, such as bacteria and fungi. A mast cell is a leukocyte that produces inflammatory molecules, such as histamine, in response to large pathogens. A basophil is a leukocyte that, like a neutrophil, releases chemicals to stimulate the inflammatory response. Basophils are also involved in allergy and hypersensitivity responses and induce specific types of inflammatory responses. Eosinophils and basophils produce additional inflammatory mediators to recruit more leukocytes. A hypersensitive immune response to harmless antigens, such as in pollen, often involves the release of histamine by basophils and mast cells; this is why many anti-allergy medications are anti-histamines.

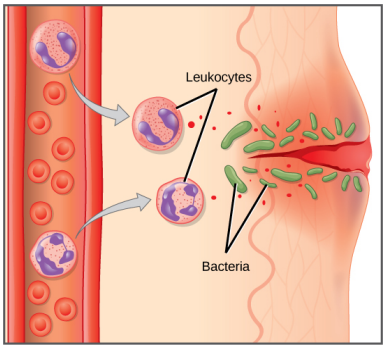

Figure: **Innate immune response to cuts**: In response to a cut, mast cells secrete histamines that cause nearby capillaries to dilate. Neutrophils and monocytes leave the capillaries. Monocytes mature into macrophages. Neutrophils, dendritic cells, and macrophages release chemicals to stimulate the inflammatory response. Neutrophils and macrophages also consume invading bacteria by phagocytosis.

11.4A: Phagocyte Migration and Phagocytosis

Learning Objectives

- Summarize phagocytosis and phagocyte migration

Phagocytosis is the process by which a cell takes in particles such as bacteria, parasites, dead host cells, and cellular and foreign debris. It involves a chain of molecular processes. Phagocytosis occurs after the foreign body, a bacterial cell, for example, has bound to molecules called “receptors” that are on the surface of the phagocyte. The phagocyte then stretches itself around the bacterium and engulfs it. *Phagocytosis* of bacteria by human neutrophils takes on average nine minutes to occur. Once inside the phagocyte, the bacterium is trapped in a compartment called a phagosome. Within one minute the phagosome merges with either a lysosome or a granule, to form a phagolysosome. The bacterium is then subjected to an overwhelming array of killing mechanisms and is dead a few minutes later. Dendritic cells and macrophages, on the other hand, are not so fast, and phagocytosis can take many hours in these cells. Macrophages are slow and untidy eaters; they engulf huge quantities of material and frequently release some undigested material back into the tissues. This debris serves as a signal to recruit more phagocytes from the blood. Phagocytes have voracious appetites; scientists have even fed macrophages with iron filings and then used a small magnet to separate them from other cells.

All phagocytes, and especially macrophages, exist in degrees of readiness. Macrophages are usually relatively dormant in the tissues and proliferate slowly. In this semi-resting state, they clear away dead host cells and other non-infectious debris and rarely take part in antigen presentation. But, during an infection, they receive chemical signals—usually interferon gamma—which increases their production of MHC II molecules and which prepares them for presenting antigens. In this state, macrophages are good antigen presenters and killers. However, if they receive a signal directly from an invader, they become “hyperactivated”, stop proliferating, and concentrate on killing. Their size and rate of phagocytosis increases—some become large enough to engulf invading protozoa. In the blood, neutrophils are inactive but are swept along at high speed. When they receive signals from macrophages at the sites of inflammation, they slow down and leave the blood. In the tissues, they are activated by cytokines and arrive at the battle scene ready to kill.

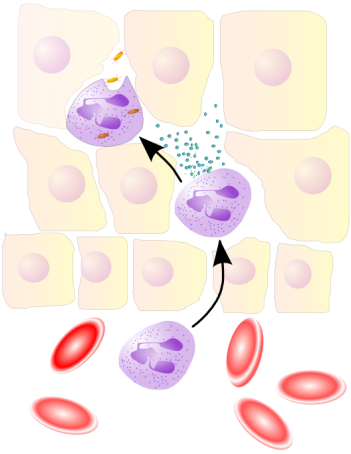

Figure: **Neutrophils**: Neutrophils move through the blood to the site of infection.

When an infection occurs, a chemical “SOS” signal is given off to attract phagocytes to the site. These chemical signals may include proteins from invading bacteria, clotting system peptides, complement products, and cytokines that have been given off by macrophages located in the tissue near the infection site. Another group of chemical attractants are cytokines that recruit neutrophils and monocytes from the blood. To reach the site of infection, phagocytes leave the bloodstream and enter the affected tissues. Signals from the infection cause the endothelial cells that line the blood vessels to make a protein called selectin, which neutrophils stick to when they pass by. Other signals called vasodilators loosen the junctions connecting endothelial cells, allowing the phagocytes to pass through the wall. Chemotaxis is the process by which phagocytes follow the cytokine “scent” to the infected spot. Neutrophils travel across epithelial cell-lined organs to sites of infection, and although this is an important component of fighting infection, the migration itself can result in disease-like symptoms. During an infection, millions of neutrophils are recruited from the blood, but they die after a few days.

Key Points

- Phagocytosis is needed to clear many things from a body, especially during an infection, when specialized cells “eat” things such as cellular debris or invading microbes.
- There are different cells that can engulf or phagocytose material in the body, these include macrophages, dendritic cells, and neutrophils.
- Phagocytic cells can migrate to a location where they are needed, through signaling events in the body.

Key Terms

- **neutrophil**: Neutrophil granulocytes are the most abundant type of white blood cells in mammals and form an essential part of the innate immune system.
- **metachromatic granule**: a granular cell inclusion present in many bacterial cells, having an avidity for basic dyes and causing irregular staining of the cell
- **macrophage**: A white blood cell that phagocytizes necrotic cell debris and foreign material, including viruses, bacteria, and tattoo ink. It presents foreign antigens on MHC II to lymphocytes. Part of the innate immune system.

11.4B: Antigen-presenting Cells - B and T cells

Learning Objectives

- Explain the role played by B and T cells in the adaptive immune system

The adaptive, or acquired, immune response to an initial infection takes days or even weeks to become established, much longer than the innate response. However, adaptive immunity is more specific to an invading pathogen and can fight back much more quickly than the innate response if it has seen the pathogen before. Adaptive immunity occurs after exposure to an antigen either from a pathogen or a vaccination. An antigen is a molecule that binds to a specific antibody, often stimulating a response in the immune system as a result.

The adaptive immune response activates when the innate immune response insufficiently controls an infection. In fact, without information from the innate immune system, the adaptive response could not be mobilized. There are two types of adaptive responses: the cell-mediated immune response, which is controlled by activated T cells, and the humoral immune response, which is controlled by activated B cells and antibodies. Upon infection, activated T and B cells that have surface binding sites with specificity to the molecules on the pathogen greatly increase in number and attack the invading pathogen. Their attack can kill pathogens directly or they can secrete antibodies that enhance the phagocytosis of pathogens and disrupt the infection. Adaptive immunity also involves a memory, which gives the host long-term protection from reinfection by the same type of pathogen; upon re-exposure, this host memory will facilitate a rapid and powerful response.

B and T Cells

Lymphocytes, which are white blood cells, are formed with other blood cells in the red bone marrow found in many flat bones, such as the shoulder or pelvic bones. The two types of lymphocytes of the adaptive immune response are B and T cells. Whether an immature lymphocyte becomes a B cell or T cell depends on where in the body it matures. The B cells remain in the bone marrow to mature (hence the name “B” for “bone marrow”), while T cells migrate to the thymus, where they mature (hence the name “T” for “thymus”).

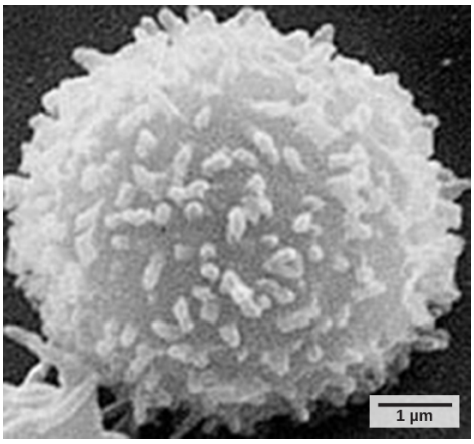

Figure: ***T cell by SEM****: This scanning electron micrograph shows a T lymphocyte. T and B cells are indistinguishable by light microscopy, but can be differentiated experimentally by probing their surface receptors.*

B Cell Receptors

The maturation of a B or T cell involves becoming immunocompetent, meaning that it can recognize and bind to a specific molecule or antigen. This recognition, which is central to the functioning of the adaptive immune response, results from the presence of highly specific receptors on the surfaces of B and T cells. On B cells, these receptors contain antibodies, which are responsible for antigen binding. An antibody is specific for one particular antigen; typically, it will not bind to anything else. Upon antigen binding to a B cell receptor, a signal is sent into the B cell to turn on an immune response.

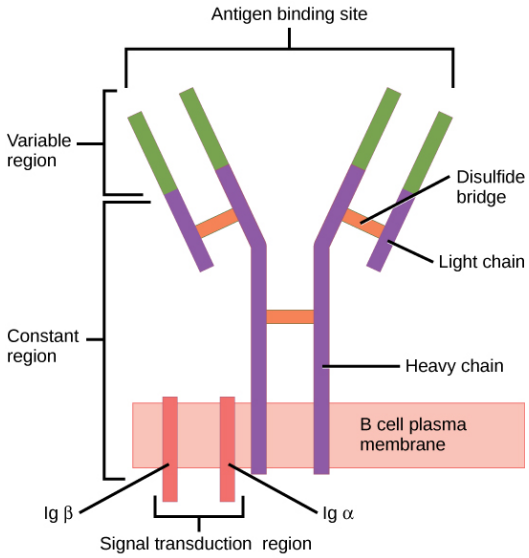

Figure: ***B cell receptors****: B cell receptors are embedded in the membranes of B cells and bind a variety of antigens through their variable regions, or antibodies. The signal transduction region transfers the signal into the cell.*

T Cell Receptors

Meanwhile, T cell receptors are responsible for the recognition of pathogenic antigens by T cells. Unlike B cells, T cells do not directly recognize antigens. Instead, they recognize antigens presented on major histocompatibility complexes (MHCs) that cells use to display which proteins are inside of them. If a cell is infected, it will present antigenic portions of the infecting pathogen on its MHC for recognition by T cells, which will then mount an appropriate immune response. Unlike antibodies, which can typically bind one and only one antigen, T cell receptors have more flexibility in their capacity to recognize antigens presented by MHCs.

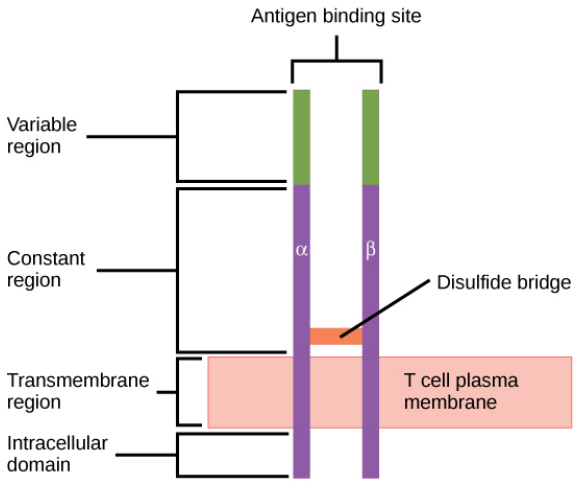

Figure: ***T cell receptors (TCRs)****: A T cell receptor spans the membrane and projects variable binding regions into the extracellular space to bind processed antigens via MHC molecules on APCs.*

It is the specific pathogen recognition (via binding antigens) of B and T cells that allows the adaptive immune response to adapt. During the maturation process, B and T cells that bind too strongly to the body's own cells' antigens are eliminated in order to minimize an immune response against the body's own tissues. Only those cells that react weakly to the body's own cells will remain. This process occurs during fetal development and continues throughout life. Once they are immunocompetent, the T and B cells migrate to the spleen and lymph nodes where they remain until they are called on during an infection. B cells are involved in the humoral immune response, which targets pathogens loose in blood and lymph, while T cells are involved in the cell-mediated immune response, which targets infected cells.

Key Points

- The adaptive immune response is slower to develop than the innate immune response, but it can act much more powerfully and quickly than the innate immune response against pathogens that it has seen before.
- B and T cells are lymphocytes, or white blood cells, which are able to recognize antigens that distinguish “self” from “other” in the body.
- B and T cells that recognize “self” antigens are destroyed before they can mature; this helps to prevent the immune system from attacking its own body.

Key Terms

- **B cell**: a lymphocyte, developed in the bursa of birds and the bone marrow of other animals, that produces antibodies and is responsible for the immune system
- **T cell**: a lymphocyte, from the thymus, that can recognize specific antigens and can activate or deactivate other immune cells
- **antigen**: a substance that binds to a specific antibody; may cause an immune response

11.4A: The Complement System

The complement system helps or “complements” the ability of antibodies and phagocytic cells to clear pathogens from an organism.

Learning Objectives

- Illustrate the key points of the complement system

Key Points

- Three biochemical pathways activate the complement system–the classical complement pathway, the alternative complement pathway, and the lectin pathway.
- The following are the basic functions of the complement: Opsonization (enhancing phagocytosis of antigens); chemotaxis (attracting macrophages and neutrophils); cell lysis (rupturing membranes of foreign cells); and clumping (antigen-bearing agents).
- The complement system consists of a number of small proteins found in the blood, generally synthesized by the liver, and normally circulating as inactive precursors (pro-proteins).

Key Terms

- **antibodies**: An antibody (Ab), also known as an immunoglobulin (Ig), is a large Y-shaped protein produced by B-cells that is used by the immune system to identify and neutralize foreign objects, such as bacteria and viruses. The antibody recognizes a unique part of the foreign target, called an “antigen. “
- **phagocytic**: Phagocytosis, meaning “cell,” and -osis, meaning “process,” is the cellular process of engulfing solid particles by the cell membrane to form an internal phagosome by phagocytes and protists.
- **pathogens**: A pathogen or infectious agent (colloquially known as a germ) is a microorganism (in the widest sense, such as a virus, bacterium, prion, or fungus) that causes disease in its host. The host may be an animal (including humans), a plant, or even another microorganism.
- **classical pathway**: a group of blood proteins that mediate the specific antibody response

The complement system helps or “complements” the ability of antibodies and phagocytic cells to clear pathogens from an organism. It is part of the immune system called the ” innate immune system ” that is not adaptable and does not change over the course of an individual’s lifetime. However, it can be recruited and brought into action by the adaptive immune system.

The complement system consists of a number of small proteins found in the blood, generally synthesized by the liver, and normally circulating as inactive precursors (pro-proteins). When stimulated by one of several triggers, proteases in the system cleave specific proteins to release cytokines and initiate an amplifying cascade of further cleavages. The end result of this activation cascade is massive amplification of the response and activation of the cell-killing membrane attack complex. Over 25 proteins and protein fragments make up the complement system, including serum proteins, serosal proteins, and cell membrane receptors. They account for about 5% of the globulin fraction of blood serum.

Three biochemical pathways activate the complement system: the classical complement pathway, the alternative complement pathway, and the lectin pathway. The following are the basic functions of the complement: opsonization (enhancing phagocytosis of antigens); chemotaxis (attracting macrophages and neutrophils); cell lysis (rupturing membranes of foreign cells); and clumping (antigen-bearing agents).

The proteins and glycoproteins that constitute the complement system are synthesized by the liver hepatocytes. But significant amounts are also produced by tissue macrophages, blood monocytes, and epithelial cells of the genitourinal tract and gastrointestinal tract. The three pathways of activation all generate homologous variants of the protease C3-convertase. The classical complement pathway typically requires antigen, antibody complexes for activation (specific immune response), whereas the alternative and mannose-binding lectin pathways can be activated by C3 hydrolysis or antigens without the presence of antibodies (non-specific immune response). In all three pathways, C3-convertase cleaves and activates component C3, creating C3a and C3b, and causing a cascade of further cleavage and activation events. C3b binds to the surface of pathogens, leading to greater internalization by phagocytic cells by opsonization. C5a is an important chemotactic protein, helping recruit inflammatory cells.

C3a is the precursor of an important cytokine (adipokine) named ASP and is usually rapidly cleaved by carboxypeptidase B. Both C3a and C5a have anaphylatoxin activity, directly triggering degranulation of mast cells, as well as increasing vascular

permeability and smooth muscle contraction. C5b initiates the membrane attack pathway, which results in the membrane attack complex (MAC), consisting of C5b, C6, C7, C8, and polymeric C9. MAC is the cytolytic endproduct of the complement cascade; it forms a transmembrane channel, which causes osmotic lysis of the target cell. Kupffer cells and other macrophage cell types help clear complement-coated pathogens. As part of the innate immune system, elements of the complement cascade can be found in species earlier than vertebrates, most recently in the protostome horseshoe crab species, putting the origins of the system back further than was previously thought.

n the classical pathway, C1 binds with its C1q subunits to Fc fragments (made of CH2 region) of IgG or IgM, which forms a complex with antigens. C4b and C3b are also able to bind to antigen-associated IgG or IgM, to its Fc portion.

Such immunoglobulin-mediated binding of the complement may be interpreted, as that the complement uses the ability of the immunoglobulin to detect and bind to non-self antigens as its guiding stick. The complement itself is able to bind non-self pathogens after detecting their pathogen-associated molecular patterns (PAMPs); however, utilizing specificity of antibody, complements are able to detect non-self enemies much more specifically. There must be mechanisms that complements bind to Ig but would not focus its function to Ig but to the antigen.

shows the classical and the alternative pathways with the late steps of complement activation schematically. Some components have a variety of binding sites. In the classical pathway, C4 binds to Ig-associated C1q and C1r2s2 enzyme cleaves C4 to C4b and 4a. C4b binds to C1q, antigen-associated Ig (specifically to its Fc portion), and even to the microbe surface. C3b binds to antigen-associated Ig and to the microbe surface. The ability of C3b to bind to antigen-associated Ig would work effectively against antigen-antibody immune complexes to make them soluble. In the figure, C2b refers to the larger of the C2 fragments.

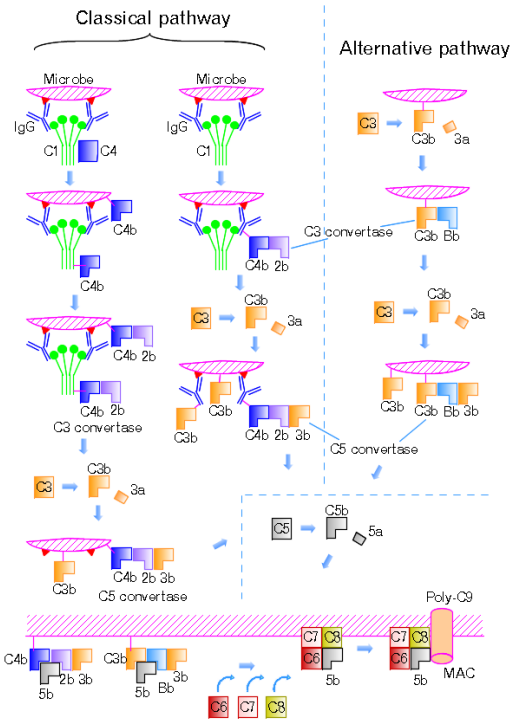

Figure: **Complement Pathways**: The classical and the alternative pathways with the late steps of complement activation.

11.4B: Interferons

Learning Objectives

- Identify interferons and their effects

Interferons (IFNs) are proteins made and released by host cells in response to the presence of pathogens such as viruses, bacteria, parasites, or tumor cells. IFNs belong to the large class of glycoproteins known as cytokines. Interferons are named after their ability to "interfere" with viral replication within host cells. IFNs have other functions: they activate immune cells, such as natural killer cells and macrophages, they increase recognition of infection or tumor cells by up-regulating antigen presentation to T lymphocytes, and they increase the ability of uninfected host cells to resist new infection by virus. Certain symptoms, such as aching muscles and fever, are related to the production of IFNs during infection.

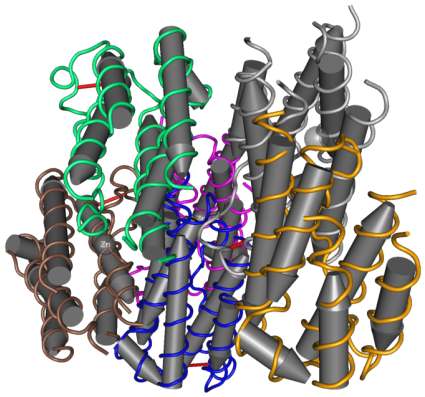

Figure: ***Interferon****: The molecular structure of human interferon-alpha.*

About ten distinct IFNs have been identified in mammals; seven of these have been described for humans. They are typically divided among three IFN classes: type I IFN, type II IFN, and type III IFN. IFNs belonging to all IFN classes are very important for fighting viral infections.

Based on the type of receptor through which they signal, human interferons have been classified into three major types:

- Interferon type I: All type I IFNs bind to a specific cell surface receptor complex, known as the IFN-α receptor (IFNAR) that consists of IFNAR1 and IFNAR2 chains. The type I interferons present in humans are IFN-α, IFN-β and IFN-ω.
- Interferon type II: These bind to IFNGR that consist of IFNGR1 and IFNGR2 chains. In humans this is IFN-γ.
- Interferon type III: These signal through a receptor complex consisting of IL10R2 (also called CRF2-4) and IFNLR1 (also called CRF2-12). Acceptance of this classification is less universal than that of type I and type II, and unlike the other two, it is not currently included in *Medical Subject Headings*.

Effects of Interferons

All interferons share several common effects; they are antiviral agents and can fight tumors. As an infected cell dies from a cytolytic virus, viral particles are released that can infect nearby cells. In addition, interferons induce production of hundreds of other proteins—known collectively as interferon-stimulated genes (ISGs)—that have roles in combating viruses. They also limit viral spread by increasing p53 activity, which kills virus-infected cells by promoting apoptosis. The effect of IFN on p53 is also linked to its protective role against certain cancers. Another function of interferons is to upregulate major histocompatibility complex molecules, MHC I and MHC II, and increase immunoproteasome activity. Interferons, such as interferon gamma, directly activate other immune cells, such as macrophages and natural killer cells. Interferons can inflame the tongue and cause dysfunction in taste bud cells, restructuring or killing taste buds entirely.

By interacting with their specific receptors, IFNs activate signal transducer and activator of transcription (STAT) complexes. STATs are a family of transcription factors that regulate the expression of certain immune system genes. Some STATs are activated by both type I and type II IFNs. However, each IFN type can also activate unique STATs.

STAT activation initiates the most well-defined cell signaling pathway for all IFNs, the classical Janus kinase-STAT (JAK-STAT) signaling pathway. In this pathway, JAKs associate with IFN receptors and, following receptor engagement with IFN,

phosphorylate both STAT1 and STAT2. As a result, an IFN-stimulated gene factor 3 (ISGF3) complex forms—this contains STAT1, STAT2 and a third transcription factor called IRF9—and moves into the cell nucleus. Inside the nucleus, the ISGF3 complex binds to specific nucleotide sequences called IFN-stimulated response elements (ISREs) in the promoters of certain genes, known as IFN stimulated genes ISGs. Binding of ISGF3 and other transcriptional complexes activated by IFN signaling to these specific regulatory elements induces transcription of those genes. Interferome is a curated online database of ISGs (www.interferome.org). Additionally, STAT homodimers or heterodimers form from different combinations of STAT-1, -3, -4, -5, or -6 during IFN signaling; these dimers initiate gene transcription by binding to IFN-activated site (GAS) elements in gene promoters. Type I IFNs can induce expression of genes with either ISRE or GAS elements, but gene induction by type II IFN can occur only in the presence of a GAS element.

In addition to the JAK-STAT pathway, IFNs can activate several other signaling cascades. Both type I and type II IFNs activate a member of the CRK family of adaptor proteins called CRKL, a nuclear adaptor for STAT5 that also regulates signaling through the C3G/Rap1 pathway. Type I IFNs further activate p38 mitogen-activated protein kinase (MAP kinase) to induce gene transcription. Antiviral and antiproliferative effects specific to type I IFNs result from p38 MAP kinase signaling. The phosphatidylinositol 3-kinase (PI3K) signaling pathway is also regulated by both type I and type II IFNs. PI3K activates P70-S6 Kinase 1, an enzyme that increases protein synthesis and cell proliferation; phosphorylates of ribosomal protein s6, which is involved in protein synthesis; and phosphorylates a translational repressor protein called eukaryotic translation-initiation factor 4E-binding protein 1 (EIF4EBP1) in order to deactivate it.

Key Points

- Interferons are named after their ability to “interfere” with viral replication within host cells.
- IFNs are divided into three classes: type I IFN, type II IFN, and type III IFNs.
- IFNs activate immune cells (natural killer cells and macrophages), increase recognition of infection and tumor cells by up-regulating antigen presentation to T lymphocytes, and increase the ability of uninfected host cells to resist new infection by virus.

Key Terms

- **Interferons**: Interferons (IFNs) are proteins made and released by host cells in response to the presence of pathogens such as viruses, bacteria, parasites or tumor cells. They allow for communication between cells to trigger the protective defenses of the immune system that eradicate pathogens or tumors.
- **pathogens**: A pathogen or infectious agent (colloquially known as a germ) is a microorganism (in the widest sense, such as a virus, bacterium, prion, or fungus) that causes disease in its host. The host may be an animal (including humans), a plant, or even another microorganism.
- **immune cells**: White blood cells, or leukocytes, are cells of the immune system involved in defending the body against both infectious disease and foreign materials.

11.4B: Interferons is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.4C: Natural Killer Cells

Learning Objectives

- Describe natural killer cells

Natural killer cells (or NK cells) are a type of cytotoxic lymphocyte critical to the innate immune system. The role NK cells play is similar to that of cytotoxic T cells in the vertebrate adaptive immune response. NK cells provide rapid responses to virally infected cells and to tumor formation, beginning around three days after infection. Typically immune cells detect MHC that is present on infected cell surfaces, triggering cytokine release and causing lysis or apoptosis. NK cells are unique, however, as they have the ability to recognize stressed cells in the absence of antibodies and MHC, allowing for a much faster immune reaction. They were named “natural killers” because of the initial notion that they do not require activation in order to kill cells that are missing “self” markers of major histocompatibility complex (MHC) class 1.

NK cells are defined as large granular lymphocytes (LGL) and constitute the third kind of cell differentiated from the common lymphoid progenitor generating B and T lymphocytes. NK cells are known to differentiate and mature in the bone marrow, lymph node, spleen, tonsils, and thymus, where they then enter into the circulation. NK cells differ from Natural Killer T cells (NKT) phenotypically, by origin, and by respective effector functions. Often NKT cell activity promotes NK cell activity by secreting IFNγ. In contrast to NKT cells, NK cells do not express T-cell antigen receptors (TCR) or Pan T marker CD3 or surface immunoglobulins (Ig) B cell receptors, but they usually express the surface markers CD16 (FcγRIII) and CD56 in humans, NK1.1 or NK1.2 in C57BL/6 mice. Up to 80% of human NK cells also express CD8.

Mechanism

NK cells paralyze target cells using the cytolytic protein perforin and a variety of protease enzymes. An NK cell will first use perforin to create pores in a target cell, allowing it to inject granzymes through an aqueous channel. The granzymes then break down the target cell, inducing death by either apoptosis or osmotic cell lysis.

NK cells also alert the greater immune system by secreting chemicals that are taken as a message that a threat has arrived.

Figure: ***Schematic diagram indicating the complementary activities of cytotoxic T-cells and NK cells.***: *Schematic diagram indicating the complementary activities of cytotoxic T-cells and NK cells.*

Natural Killer Cells Play Other Roles

Natural killer cells are not only effectors of innate immunity; recent research has also uncovered information on both activating and inhibitory NK cell receptors, which play roles in maintaining self-tolerance and sustaining NK cell activity. NK cells also play a role in the adaptive immune response. Numerous experiments have demonstrated their ability to adjust to the immediate environment and formulate antigen-specific immunological memory, which is fundamental for responding to secondary infections with the same antigen. The ability for NK cells to act in both innate and adaptive immune response is becoming increasingly important in research utilizing NK cell activity in potential cancer therapies.

NK cell receptors can also be differentiated based on function. Natural cytotoxicity receptors directly induce apoptosis after binding to ligands that directly indicate infection of a cell. The MHC dependent receptors (described above) use an alternate pathway to induce apoptosis in infected cells. Natural killer cell activation is determined by the balance of inhibitory and activating

receptor stimulation—for example, if the inhibitory receptor signaling is more prominent, then NK cell activity will be inhibited. Similarly, if the activating signal is dominant, then NK cell activation will result.

Functions of NK cells include: Cytolytic Granule Mediated Cell Apoptosis; Antibody-Dependent Cell-Mediated Cytotoxicity (ADCC); Cytokine induced NK and CTL activation; Missing 'self' hypothesis; Tumor cell surveillance; NK cell function in adaptive response; NK cell function in pregnancy; and NK cell evasion by tumor cells.

Key Points

- NK cells are defined as large granular lymphocytes (LGL).
- NK cells constitute the third kind of cells differentiated from the common lymphoid progenitor generating B and T lymphocytes.
- NK cells provide rapid responses to virally infected cells and respond to tumor formation, acting at around 3 days after infection.

Key Terms

- **Natural killer cells (or NK cells)**: Natural killer cells (or NK cells) are a type of cytotoxic lymphocyte critical to the innate immune system. The role NK cells play is analogous to that of cytotoxic T cells in the vertebrate adaptive immune response.
- **lymphocyte**: A type of white blood cell or leukocyte that is divided into two principal groups and a null group: B-lymphocytes, which produce antibodies in the humoral immune response, T-lymphocytes, which participate in the cell-mediated immune response, and the null group, which contains natural killer cells, cytotoxic cells that participate in the innate immune response.
- **innate immune system**: This is the initial line of defense that entails a cascade of cells and mechanisms that protect the host from infection by different organisms in an indeterminate pattern.

11.4C: Natural Killer Cells is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.4D: Toll-Like Receptors

Learning Objectives

- Summarize Toll-like receptors

Toll-like receptors (TLRs) are a class of proteins that play a key role in the innate immune system as well as the digestive system. They are single, membrane-spanning, non-catalytic receptors that recognize structurally conserved molecules derived from microbes. Once these microbes have breached physical barriers such as the skin or intestinal tract mucosa, they are recognized by TLRs, which activate immune cell responses.

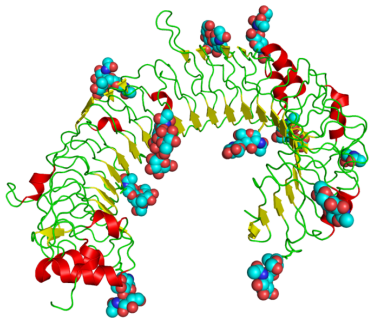

Figure: **TLR3**: The curved leucine-rich repeat region of Toll-like receptors, represented here by TLR3

TLRs are a type of pattern recognition receptor (PRR) and recognize molecules that are broadly shared by pathogens but distinguishable from host molecules, collectively referred to as pathogen-associated molecular patterns (PAMPs). TLRs together with the Interleukin-1 receptors form a receptor superfamily, known as the “Interleukin-1 Receptor/Toll-Like Receptor Superfamily”; all members of this family have in common a so-called TIR (Toll-IL-1 receptor) domain.

Because of the specificity of Toll-like receptors (and other innate immune receptors) they cannot easily be changed in the course of evolution, these receptors recognize molecules that are constantly associated with threats (i.e., pathogen or cell stress) and are highly specific to these threats (i.e., cannot be mistaken for self molecules). Pathogen-associated molecules that meet this requirement are usually critical to the pathogen’s function and cannot be eliminated or changed through mutation; they are said to be evolutionarily conserved. Well-conserved features in pathogens include bacterial cell-surface lipopolysaccharides (LPS), lipoproteins, lipopeptides, and lipoarabinomannan; proteins such as flagellin from bacterial flagella; double-stranded RNA of viruses; or the unmethylated CpG islands of bacterial and viral DNA; and certain other RNA and DNA. For most of the TLRs, ligand recognition specificity has now been established by gene targeting (also known as “gene knockout”): a technique by which individual genes may be selectively deleted in mice. See the table below for a summary of known TLR ligands.

TLRs are believed to function as dimers. Though most TLRs appear to function as homodimers, TLR2 forms heterodimers with TLR1 or TLR6, each dimer having a different ligand specificity. TLRs may also depend on other co-receptors for full ligand sensitivity, such as in the case of TLR4’s recognition of LPS, which requires MD-2. CD14 and LPS-Binding Protein (LBP) are known to facilitate the presentation of LPS to MD-2.

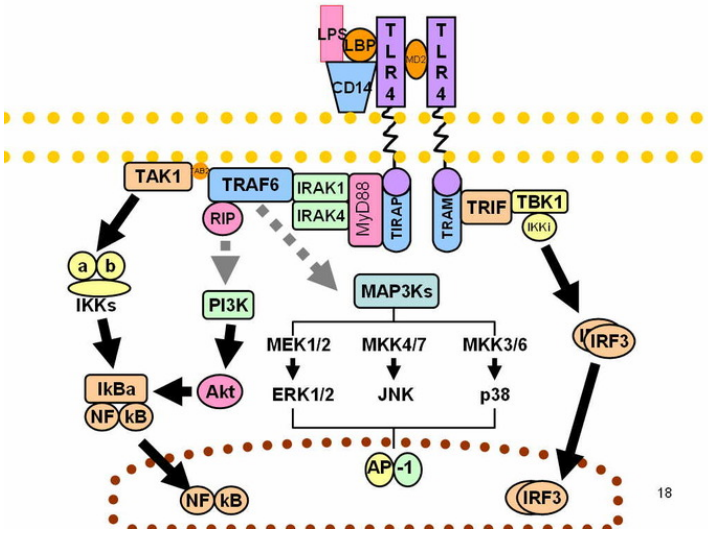

Figure: **Signaling pathway**: Signaling pathway of Toll-like receptors. Dashed grey lines represent unknown associations.

The adapter proteins and kinases that mediate TLR signaling have also been targeted. In addition, random germline mutagenesis with ENU has been used to decipher the TLR signaling pathways. When activated, TLRs recruit adapter molecules within the cytoplasm of cells in order to propagate a signal. Four adapter molecules are known to be involved in signaling. These proteins are known as MyD88, Tirap (also called Mal), Trif, and Tram.

TLR signaling is divided into two distinct signaling pathways, the MyD88-dependent and TRIF-dependent pathway. The MyD88-dependent response occurs on dimerization of the TLR receptor, and is utilized by every TLR except TLR3. Its primary effect is activation of NFκB. Ligand binding and conformational change that occurs in the receptor recruits the adaptor protein MyD88, a member of the TIR family. MyD88 then recruits IRAK 4, IRAK1 and IRAK2. IRAK kinases then phosphorylate and activate the protein TRAF6, which in turn polyubiquinates the protein TAK1, as well as itself in order to facilitate binding to IKKβ. On binding, TAK1 phosphorylates IKKβ, which then phosphorylates IκB causing its degradation and allowing NFκB to diffuse into the cell nucleus and activate transcription.

Both TRL3 and TRL4 utilize the TRIF-dependent pathway, which is triggered by dsRNA and LPS, respectively. For TRL3, dsRNA leads to activation of the receptor, recruiting the adaptor TRIF. TRIF activates the kinases TBK1 and RIP1, which creates a branch in the signaling pathway. The TRIF/TBK1 signaling complex phosphorylates IRF3 allowing its translocation into the nucleus and production of Type I interferons. Meanwhile, activation of RIP1 causes the polyubiquination and activation of TAK1 and NFκB transcription in the same manner as the MyD88-dependent pathway.

TLR signaling ultimately leads to the induction or suppression of genes that orchestrate the inflammatory response. In all, thousands of genes are activated by TLR signaling, and collectively, the TLRs constitute one of the most pleiotropic yet tightly regulated gateways for gene modulation.

Toll-like receptors bind and become activated by different ligands, which, in turn, are located on different types of organisms or structures. They also have different adapters to respond to activation and are located sometimes at the cell surface and sometimes to internal cell compartments.

Key Points

- TLRs are a type of pattern recognition receptor (PRR).
- TLRs recognize molecules that are broadly shared by pathogens but distinguishable from host molecules, collectively referred to as pathogen-associated molecular patterns (PAMPs).
- TLR signaling is divided into two distinct signaling pathways, the MyD88-dependent and TRIF-dependent pathway.

Key Terms

- **Toll-like receptor**: Toll-like receptors (TLRs) are a class of proteins that play a key role in the innate immune system as well as the digestive system. They are single, membrane-spanning, non-catalytic receptors that recognize structurally conserved molecules derived from microbes.

- **innate immune system**: This is the initial line of defense that entails a cascade of cells and mechanisms that protect the host from infection by different organisms in an indeterminate pattern.
- **signaling pathway**: Signal pathways occurs when an extracellular signaling molecule activates a cell surface receptor. In turn, this receptor alters intracellular molecules creating a response. There are two stages in this process:A signaling molecule activates a specific receptor protein on the cell membrane.A second messenger transmits the signal into the cell, eliciting a physiological response.In either step, the signal can be amplified. Thus, one signaling molecule can cause many responses.

11.4D: Toll-Like Receptors is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.4E: Iron-Binding Proteins

Iron binding proteins of the innate immune system include lactoferrin and transferrins.

Learning Objectives

- Describe Iron-Binding proteins

Key Points

- Lactoferrin (LF), also known as lactotransferrin (LTF), is a multifunctional protein of the transferrin family.
- Lactoferrin is a globular glycoprotein with a molecular mass of about 80 kDa that is widely represented in various secretory fluids such as milk, saliva, tears, and nasal secretions.
- Transferrins are iron -binding blood plasma glycoproteins that control the level of free iron in biological fluids.

Key Terms

- **transferrin**: A glycoprotein, a beta globulin, in blood serum that combines with and transports iron
- **Lactoferrin**: Lactoferrin (LF), also known as lactotransferrin (LTF), is a multifunctional protein of the transferrin family. Lactoferrin is a globular glycoprotein with a molecular mass of about 80 kDa. It is widely represented in various secretory fluids such as milk, saliva, tears, and nasal secretions.
- **iron**: Iron is a chemical element with the symbol Fe (from Latin: ferrum) and atomic number 26. It is a metal in the first transition series.

Iron-binding proteins are proteins generally used to play roles in metabolism. They are carrier proteins (those used to move ions and molecules across membranes) and more generally metalloproteins (those which contain a metal ion cofactor). Iron-binding proteins are serum proteins, found in the blood, and as their name suggests, are used to bind and transport iron.

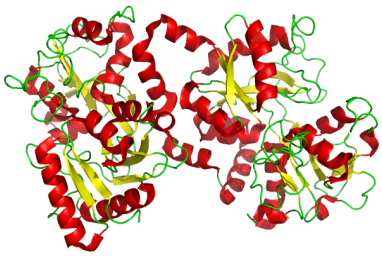

Figure: **Lactoferrin**: Richardson diagram of recombinant human lactoferrin. Based on PDB (Protein Data Bank) 1b0l

Lactoferrin (LF), also known as lactotransferrin (LTF), is a multifunctional protein of the transferrin family. Lactoferrin is a globular glycoprotein with a molecular mass of about 80 kDa. It is widely represented in various secretory fluids such as milk, saliva, tears, and nasal secretions. Lactoferrin is also present in secondary granules of PMN (Polymorphonucler neutrophil) and is secreted by some acinar cells. Lactoferrin can be purified from milk or produced recombinantly. Human colostrum ("first milk") has the highest concentration, followed by human milk, and then cow milk (150 mg/L).

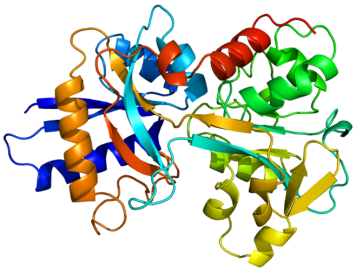

Figure: **Transferrin**: PDB (Protein Data Bank) rendering based on 1a8e.

Lactoferrin is one of the components of the immune system of the body. It has antimicrobial activity (bacteriocide, fungicide) and is part of the innate defense, mainly at mucoses. In particular, lactoferrin provides antibacterial activity to human infants.

Lactoferrin interacts with DNA and RNA, polysaccharides and heparin, and shows some of its biological functions in complexes with these ligands.

Transferrins are iron-binding blood plasma glycoproteins that control the level of free iron in biological fluids. Human transferrin is encoded by the TF gene. Transferrin glycoproteins bind iron very tightly, but reversibly. Although iron bound to transferrin is less than 0.1% (4 mg) of the total body iron, it is the most important iron pool, with the highest rate of turnover (25 mg/24 h). Transferrin has a molecular weight of around 80 KDa and contains two specific high- affinity Fe(III) binding sites. The affinity of transferrin for Fe(III) is extremely high (1023 M^{-1} at pH 7.4), but decreases progressively with decreasing pH below neutrality. When not bound to iron, it is known as “apotransferrin” (see also apoprotein).

11.4E: Iron-Binding Proteins is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.4F: Antimicrobial Peptides

Antimicrobial peptides are an evolutionarily conserved component of the innate immune response and are found among all classes of life.

Learning Objectives

- Describe the role of antimicrobial peptides in host defense

Key Points

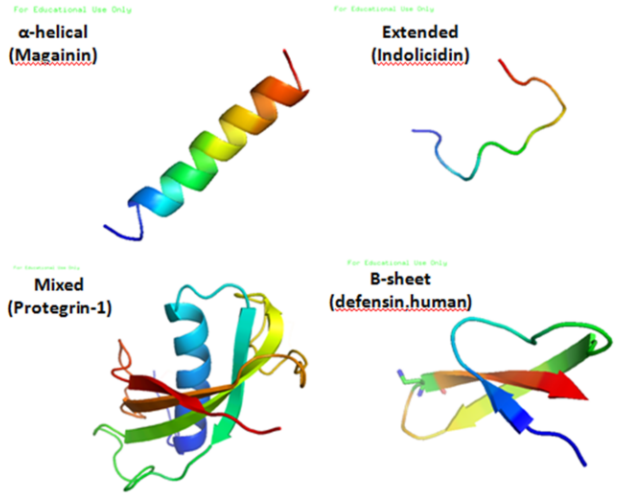
- Antimicrobial peptides are a unique and diverse group of molecules, which are divided into subgroups on the basis of their amino acid composition and structure.
- The modes of action by which antimicrobial peptides kill bacteria is varied and includes disrupting membranes, interfering with metabolism, and targeting cytoplasmic components.
- Antimicrobial peptides have been demonstrated to have a number of immunomodulatory functions that may be involved in the clearance of infection.

Key Terms

- **antimicrobial peptide**: Antimicrobial peptides (also called host defense peptides) are an evolutionarily conserved component of the innate immune response and are found among all classes of life.
- **innate immune**: The innate immune system, also known as non-specific immune system and first line of defense, comprises the cells and mechanisms that defend the host from infection by other organisms in a non-specific manner. This means that the cells of the innate system recognize and respond to pathogens in a generic way, but unlike the adaptive immune system, it does not confer long-lasting or protective immunity to the host.
- **molecules**: A molecule is an electrically neutral group of two or more atoms held together by covalent chemical bonds. Molecules are distinguished from ions by their lack of electrical charge. However, in quantum physics, organic chemistry, and biochemistry, the term molecule is often used less strictly, also being applied to polyatomic ions.

Antimicrobial peptides (also called host defense peptides) are an evolutionarily conserved component of the innate immune response and are found among all classes of life. Fundamental differences exist between prokaryotic and eukaryotic cells that may represent targets for antimicrobial peptides. These peptides are potent, broad spectrum antibiotics which demonstrate potential as novel therapeutic agents. Antimicrobial peptides have been demonstrated to kill Gram negative and Gram positive bacteria (including strains that are resistant to conventional antibiotics), mycobacteria (including Mycobacterium tuberculosis), enveloped viruses, fungi and even transformed or cancerous cells. Unlike the majority of conventional antibiotics, it appears as though antimicrobial peptides may also have the ability to enhance immunity by functioning as immunomodulators.

Antimicrobial peptides are a unique and diverse group of molecules, which are divided into subgroups on the basis of their amino acid composition and structure. Antimicrobial peptides generally consist of between 12 and 50 amino acids. These peptides include two or more positively charged residues provided by arginine, lysine or, in acidic environments, histidine, and a large proportion (generally >50%) of hydrophobic residues. The secondary structures of these molecules follow 4 themes, including:



Various AMPs: These are various antimicrobial peptide structures.

1. α-helical
2. β-stranded due to the presence of 2 or more disulfide bonds
3. β-hairpin or loop due to the presence of a single disulfide bond and/or cyclization of the peptide chain
4. Extended

Many of these peptides are unstructured in free solution, and fold into their final configuration upon partitioning into biological membranes. It contains hydrophilic amino acid residues aligned along one side and hydrophobic amino acid residues aligned along the opposite side of a helical molecule. This amphipathicity of the antimicrobial peptides allows the partition of the membrane lipid bilayer. The ability to associate with membranes is a definitive feature of antimicrobial peptides, although membrane permeabilisation is not necessary. These peptides have a variety of antimicrobial activities ranging from membrane permeabilization to action on a range of cytoplasmic targets.

The modes of action by which antimicrobial peptides kill bacteria is varied and includes disrupting membranes, interfering with metabolism, and targeting cytoplasmic components. The initial contact between the peptide and the target organism is electrostatic, as most bacterial surfaces are anionic, or hydrophobic, such as in the antimicrobial peptide Piscidin. Their amino acid composition, amphipathicity, cationic charge, and size allow them to attach to and insert into membrane bilayers to form pores by ‘barrel-stave’, ‘carpet’ or ‘toroidal-pore’ mechanisms. Alternately, they may penetrate into the cell to bind intracellular molecules which are crucial to cell living. Intracellular binding models include inhibition of cell wall synthesis, alteration of the cytoplasmic membrane, activation of autolysin, inhibition of DNA, RNA, and protein synthesis, and inhibition of certain enzymes. However, in many cases, the exact mechanism of killing is not known. One emerging technique for the study of such mechanisms is dual polarisation interferometry. In contrast to many conventional antibiotics these peptides appear to be bacteriocidal (bacteria killing) instead of bacteriostatic (bacteria growth inhibiting). In general the antimicrobial activity of these peptides is determined by measuring the minimal inhibitory concentration (MIC), which is the lowest concentration of drug that inhibits bacterial growth.

In addition to killing bacteria directly, they have been demonstrated to have a number of immunomodulatory functions that may be involved in the clearance of infection, including the ability to:

- Alter host gene expression
- Act as chemokines and/or induce chemokine production,
- Inhibit lipopolysaccharide induced pro-inflammatory cytokine production
- Promote wound healing
- Modulate the responses of dendritic cells and cells of the adaptive immune response

Animal models indicate that host defense peptides are crucial for both prevention and clearance of infection. It appears as though many peptides initially isolated and termed as “antimicrobial peptides” have been shown to have more significant alternative functions in vivo (e.g. hepcidin).

Several methods have been used to determine the mechanisms of antimicrobial peptide activity. In particular, solid-state NMR studies have provided an atomic-level resolution explanation of membrane disruption by antimicrobial peptides.

11.4G: The Complement System and Heart Disease

In autoimmune heart diseases, the body's immune defense system mistakes its own cardiac antigens as foreign, and attacks them.

Learning Objectives

- Identify autoimmune heart diseases

Key Points

- The commonest form of autoimmune heart disease is rheumatic heart disease, or rheumatic fever.
- The typical mechanism of autoimmunity involves auto-toxic T-lymphocyte, and the complement system.
- Inflammatory damage leads to the following: pericarditis, myocarditis, and endocarditis.

Key Terms

- **autoimmune**: Autoimmunity is the failure of an organism in recognizing its own constituent parts as self, which allows an immune response against its own cells and tissues. Any disease that results from such an aberrant immune response is termed an autoimmune disease. Autoimmunity is often caused by a lack of germ development of a target body, and as such the immune response acts against its own cells and tissues.
- **immune**: Immunity is a biological term that describes a state of having sufficient biological defences to avoid infection, disease, or other unwanted biological invasion. In other words, it is the capability of the body to resist harmful microbes from entering it. Immunity involves both specific and non-specific components.
- **antigen**: A substance that induces an immune response, usually foreign.

Causes

Autoimmune heart diseases result when the body's own immune defense system mistakes cardiac antigens as foreign, and attacks them, leading to inflammation of the heart as a whole, or in parts. The most common form of autoimmune heart disease is rheumatic heart disease, or rheumatic fever.

A typical mechanism of autoimmunity is autoantibodies, or auto-toxic T-lymphocyte mediated tissue destruction. The process is aided by neutrophils, the complement system, and tumor necrosis factor alpha.

Aetiologically, autoimmune heart disease is most commonly seen in children with a history of sore throat caused by a streptococcal infection. This is similar to the post-streptococcal glomerulonephritis. Here, the anti-bacterial antibodies cross react with the heart antigens causing inflammation.

Pericarditis, Myocarditis, and Endocarditis

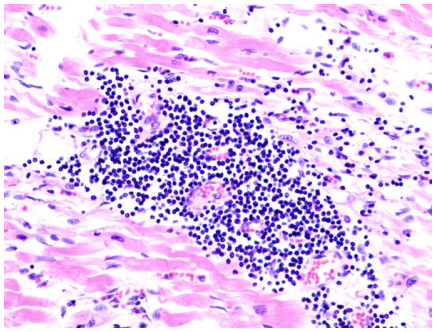

Figure: **Viral myocarditis**: Histopathological image of myocarditis at autopsy in a patient with acute onset of congestive heart failure

Inflammatory damage can lead to pericarditis, myocarditis, and endocarditis.

Pericarditis: Here the pericardium gets inflamed. Acutely, it can cause pericardial effusion leading to cardiac tamponade and death. After healing, there may be fibrosis and adhesion of the pericardium with the heart, leading to constriction of the heart and reduced cardiac function.

Myocarditis: Here the muscle bulk of the heart gets inflamed. Inflamed muscles have reduced functional capacity. This may be fatal if left untreated, as is in a case of pancarditis. On healing, there will be fibrosis and reduced functional capacity.

Endocarditis: Here the inner lining of the heart is inflamed, including the heart valves. This may cause a valve prolapse, adhesion of the adjacent cusps, of these valves, and occlusion of the flow tracts of blood through the heart, which causes disease known as valve stenosis.

Treatment

Specific clinical manifestations depend on the amount of inflammation. Therapy will involve intensive cardiac care and immunosuppressives, including corticosteroids, which are helpful in the acute stage of the disease. The chronic phase consists of mainly debility control and supportive care options.

SECTION OVERVIEW

11.5: The Adaptive Immune Response

Topic hierarchy

11.5A: Humoral Immune Response

11.5B: Development of the Dual Lymphocyte System

11.5: The Adaptive Immune Response is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.5A: Humoral Immune Response

The humoral immune response defends against pathogens that are free in the blood by using antibodies against pathogen-specific antigens.

Learning Objectives

- Summarize the humoral immune response

Key Points

- Antigens are proteins and other macromolecules that bind to a specific antibody and are used by the immune system to recognize pathogens.
- B cells express receptors (BCRs) on their membrane which contain antibodies; these antibodies allow B cells to detect pathogens and release further antibodies to fight the infection.
- Antibodies fight infections in three ways: they mark pathogens for destruction by phagocytic cells in a process known as opsonization, they coat key sites on pathogens necessary for infection, and they induce the complement cascade to occur against antibody-bound pathogens.
- Once the adaptive immune response has encountered an antigen, B cells will divide to produce plasma cells, which rapidly secrete antibodies to that antigen in a process called active immunity.

Key Terms

- **antibody**: a protein produced by B-lymphocytes that binds to a specific antigen
- **opsonize**: to make (bacteria or other cells) more susceptible to the action of phagocytes by use of opsonins
- **MHC**: an acronym for major histocompatibility complex; these extracellular protein receptors display antigens derived from extracellular (class I) or intracellular (class II) proteins and other biomolecules

The humoral immune response fights pathogens that are free in the bodily fluids, or “humours”. It relies on antigens (which are also often free in the humours) to detect these pathogens. An antigen is a biomolecule, such as a protein or sugar, that binds to a specific antibody. An antibody/antigen interaction may stimulate an immune response. Not every biomolecule is antigenic and not all antigens produce an immune response. B cells are the major cell type involved in the humoral immune response. When a foreign antigen (one coming from a pathogen, for example) is detected, B cells in the body that recognize that antigen will begin to produce antibodies as a means of fighting off the foreign invader.

B cell maturation

During maturation, B cells gain antigen receptor molecules, termed B cell receptors (BCRs), which are displayed in large numbers, extracellularly on their membrane. These membrane-bound protein complexes contain antibodies, which enable specific antigen recognition. Each B cell initially produced has only one kind of antibody (antigen receptor), which makes every B cell unique. It is the immense number of B cells in the body, each of which produces a unique antibody, that allows the immune system to detect such a wide variety of pathogenic antigens. B cells containing antibodies that recognize “self” antigens are destroyed before they can mature, preventing the immune system from attacking the host. Once B cells mature in the bone marrow, they migrate to lymph nodes or other lymphatic organs, where they may begin to encounter pathogens.

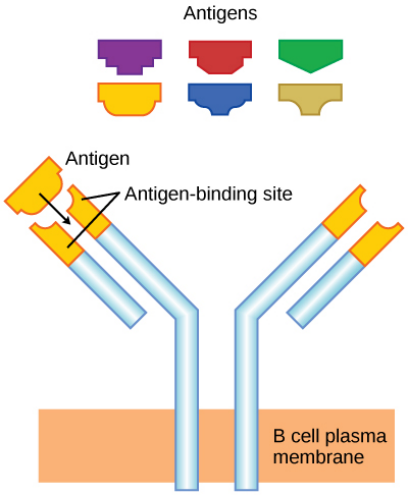

Figure: **B cell receptors**: B cell receptors, containing antibodies (termed antigen-binding site in the picture) are embedded in the membranes of B cells and bind a variety of antigens through their variable regions.

B cell activation

When a B cell encounters the antigen that binds to its receptor, the antigen molecule is brought into the cell by endocytosis, reappearing on the surface of the cell bound to an MHC class II molecule. When this process is complete, the B cell is sensitized. In most cases, the sensitized B cell must then encounter a specific kind of T cell, called a helper T cell, before it is activated. This activation of the helper T cell occurs when a dendritic cell presents an antigen on its MHC II molecule, allowing the T cell to recognize it and mature.

The helper T cell binds to the antigen-MHC class II complex and is induced to release cytokines that induce the B cell to divide rapidly, making thousands of identical (clonal) cells. These daughter cells become either plasma cells or memory B cells. The memory B cells remain inactive at this point. A later encounter with the antigen, caused by a reinfection by the same bacteria or virus, will result in them dividing into a new population of plasma cells. The plasma cells, on the other hand, produce and secrete large quantities, up to 100 million molecules per hour, of antibody molecules. An antibody, also known as an immunoglobulin (Ig), is a protein that is produced by plasma cells after stimulation by an antigen. Antibodies are the agents of humoral immunity. Antibodies occur in the blood, in gastric and mucus secretions, and in breast milk. Antibodies in these bodily fluids can bind pathogens and mark them for destruction by phagocytes before they are able to infect cells.

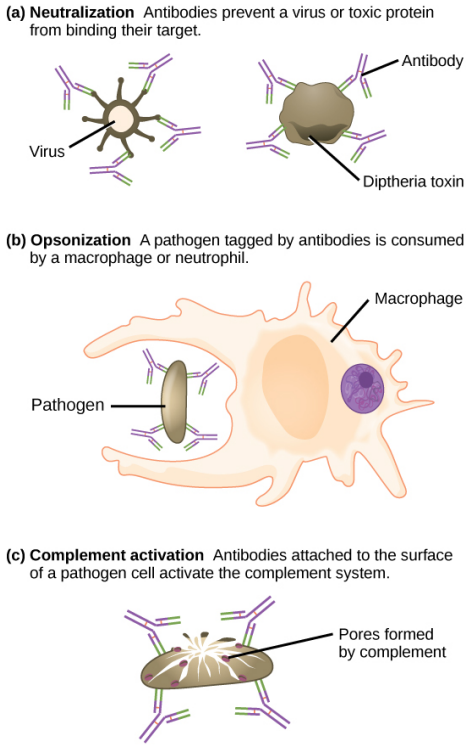

Figure: **Methods by which antibodies inhibit infection**: Antibodies may inhibit infection by (a) preventing the antigen from binding its target, (b) tagging a pathogen for destruction by macrophages or neutrophils, or (c) activating the complement cascade.

Antibodies

These antibodies circulate in the blood stream and lymphatic system, binding with the antigen whenever it is encountered. The binding can fight infection in several ways. Antibodies can bind to viruses or bacteria, which interferes with the chemical interactions required for them to infect or bind to other cells. The antibodies may create bridges between different particles containing antigenic sites, clumping them all together and preventing their proper functioning. Antibody neutralization can prevent pathogens from entering and infecting host cells. The neutralized antibody-coated pathogens can then be filtered by the spleen to be eliminated in urine or feces. The antigen-antibody complex stimulates the complement system described previously, destroying the cell bearing the antigen. Antibodies also opsonize pathogen cells, wherein they mark them for destruction by phagocytic cells, such as macrophages or neutrophils. Additionally, antibodies stimulate inflammation, while their presence in mucus and on the skin prevents pathogen attack.

The production of antibodies by plasma cells in response to an antigen is called active immunity. This describes the host's active response of the immune system to an infection or to a vaccination. There is also a passive immune response wherein antibodies are introduced into the host from an outside source, instead of the individual's own plasma cells. For example, antibodies circulating in a pregnant woman's body move across the placenta into the developing fetus. The child benefits from the presence of these antibodies for up to several months after birth. In addition, a passive immune response is possible by injecting antibodies into an individual in the form of an antivenom to a snake-bite toxin or antibodies in blood serum to help fight a hepatitis infection, giving immediate relief.

11.5B: Development of the Dual Lymphocyte System

Lymphocytes originate from a common progenitor in a process known as hematopoeisis.

Learning Objectives

- Examine dual lymphocyte development

Key Points

- B cells and T cells are the major types of lymphocytes.
- B cells mature into B lymphocytes in the bone marrow, while T cells migrate to, and mature in, a distinct organ called the thymus.
- Following maturation, the lymphocytes enter the circulation and peripheral lymphoid organs (e.g. the spleen and lymph nodes) where they survey for invading pathogens and/or tumor cells.
- The lymphocytes involved in adaptive immunity (i.e. B and T cells) differentiate further after exposure to an antigen to form effector and memory lymphocytes.

Key Terms

- **lymphocyte**: A type of white blood cell or leukocyte that is divided into two principal groups and a null group: B-lymphocytes, which produce antibodies in the humoral immune response, T-lymphocytes, which participate in the cell-mediated immune response, and the null group, which contains natural killer cells, cytotoxic cells that participate in the innate immune response.
- **leukocyte**: A white blood cell.
- **haematopoiesis**: Hematopoeisis is the formation of blood cellular components from a common progenitor stem cell.

The cells of the adaptive immune system are a type of leukocyte, called a lymphocyte. The human body has about 2 trillion lymphocytes, constituting 20-40% of white blood cells (WBCs); their total mass is about the same as the brain or liver. The peripheral blood contains 20–50% of circulating lymphocytes; the rest move within the lymphatic system. B cells and T cells are the major types of lymphocytes.

B Cell and T Cell Differentiation

Mammalian stem cells differentiate into several kinds of blood cell within the bone marrow. This process is called haematopoiesis. During this process, all lymphocytes originate from a common lymphoid progenitor before differentiating into their distinct lymphocyte types. The differentiation of lymphocytes into distinguishable types follows various pathways in a hierarchical fashion as well as in a more plastic fashion. The formation of lymphocytes is known as lymphopoiesis. B cells mature into B lymphocytes in the bone marrow, while T cells migrate to, and mature in, a distinct organ called the thymus. Following maturation, the lymphocytes enter the circulation and peripheral lymphoid organs (e.g. the spleen and lymph nodes) where they survey for invading pathogens and/or tumor cells.

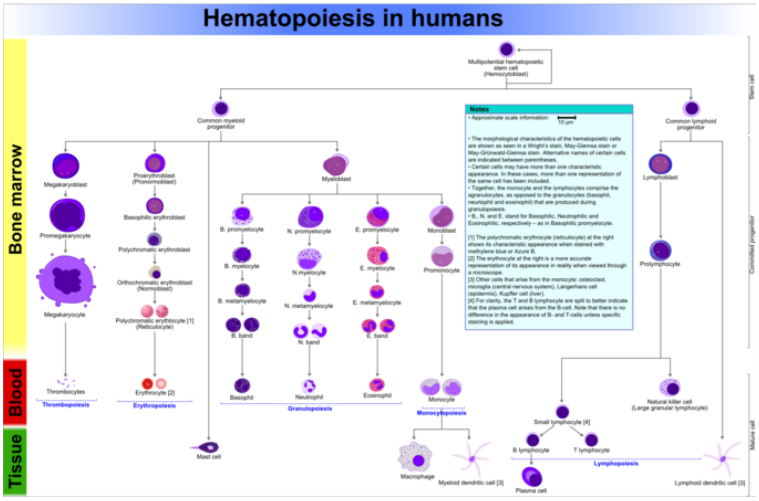

Figure: **Hematopoeisis in humans**: Mammalian stem cells differentiate into several kinds of blood cell within the bone marrow. This process is called haematopoiesis. All lymphocytes originate during this process from a common lymphoid progenitor before differentiating into their distinct lymphocyte types.

Further Differentiation

The lymphocytes involved in adaptive immunity (i.e. B and T cells) differentiate further after exposure to an antigen; they form effector and memory lymphocytes. Effector lymphocytes function to eliminate the antigen, either by releasing antibodies (in the case of B cells), cytotoxic granules (cytotoxic T cells) or by signaling to other cells of the immune system (helper T cells). Memory cells remain in the peripheral tissues and circulation for an extended time ready to respond to the same antigen upon future exposure.

Topic hierarchy

11.6A: Immunodeficiency

11.6B: Antibody Functions

11.6: Antigens and Antibodies is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.6A: Immunodeficiency

Immunodeficiency occurs when the immune system cannot appropriately respond to infections.

Learning Objectives

- Explain the problems associated with immunodeficiency

Key Points

- If a pathogen is allowed to proliferate to certain levels, the immune system can become overwhelmed; immunodeficiency occurs when the immune system fails to respond sufficiently to a pathogen.
- Immunodeficiency can be caused by many factors, including certain pathogens, malnutrition, chemical exposure, radiation exposure, or even extreme stress.
- HIV is a virus that causes immunodeficiency by infecting helper T cells, causing cytotoxic T cells to destroy them.

Key Terms

- **phagocyte**: a cell of the immune system, such as a neutrophil, macrophage or dendritic cell, that engulfs and destroys viruses, bacteria, and waste materials
- **lysis**: the disintegration or destruction of cells
- **immunodeficiency**: a depletion in the body's natural immune system, or in some component of it

Immunodeficiency

Failures, insufficiencies, or delays at any level of the immune response can allow pathogens or tumor cells to gain a foothold to replicate or proliferate to high enough levels that the immune system becomes overwhelmed, leading to immunodeficiency; it may be acquired or inherited. Immunodeficiency can be acquired as a result of infection with certain pathogens (such as HIV), chemical exposure (including certain medical treatments), malnutrition, or, possibly, by extreme stress. For instance, radiation exposure can destroy populations of lymphocytes, elevating an individual's susceptibility to infections and cancer. Dozens of genetic disorders result in immunodeficiencies, including Severe Combined Immunodeficiency (SCID), bare lymphocyte syndrome, and MHC II deficiencies. Rarely, primary immunodeficiencies that are present from birth may occur. Neutropenia is one form in which the immune system produces a below-average number of neutrophils, the body's most abundant phagocytes. As a result, bacterial infections may go unrestricted in the blood, causing serious complications.

HIV/AIDS

Human immunodeficiency virus infection / acquired immunodeficiency syndrome (HIV/AIDS), is a disease of the human immune system caused by infection with human immunodeficiency virus (HIV). During the initial infection, a person may experience a brief period of influenza-like illness. This is typically followed by a prolonged period without symptoms. As the illness progresses, it interferes more and more with the immune system. The person has a high probability of becoming infected, including from opportunistic infections and tumors that do not usually affect people who have working immune systems.

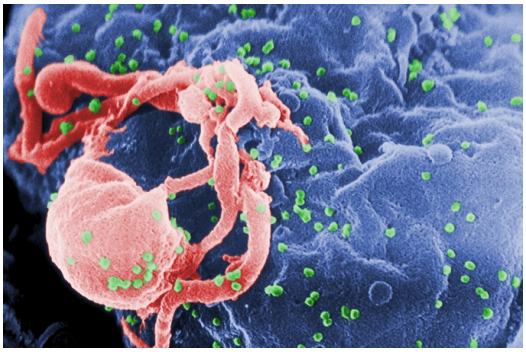

Figure: **Image of HIV: scanning electron micrograph of HIV-1 budding (in green, color added) from cultured lymphocyte**: Multiple round bumps on cell surface represent sites of assembly and budding of HIV. During primary infection, the level of HIV may reach several million virus particles per milliliter of blood.

After the virus enters the body, there is a period of rapid viral replication, leading to an abundance of virus in the peripheral blood. During primary infection, the level of HIV may reach several million virus particles per milliliter of blood. This response is accompanied by a marked drop in the number of circulating CD4+ T cells, cells that are or will become helper T cells. The acute viremia, or spreading of the virus, is almost invariably associated with activation of CD8+ T cells (which kill HIV-infected cells) and, subsequently, with antibody production. The CD8+ T cell response is thought to be important in controlling virus levels, which peak and then decline, as the CD4+ T cell counts recover.

Ultimately, HIV causes AIDS by depleting CD4+ T cells (helper T cells). This weakens the immune system, allowing opportunistic infections. T cells are essential to the immune response; without them, the body cannot fight infections or kill cancerous cells. The mechanism of CD4+ T cell depletion differs in the acute and chronic phases. During the acute phase, HIV-induced cell lysis and killing of infected cells by cytotoxic T cells accounts for CD4+ T cell depletion, although apoptosis (programmed cell death) may also be a factor. During the chronic phase, the consequences of generalized immune activation coupled with the gradual loss of the ability of the immune system to generate new T cells appear to account for the slow decline in CD4+ T cell numbers.

11.6B: Antibody Functions

Antibodies, part of the humoral immune response, are involved in pathogen detection and neutralization.

Learning Objectives

- Differentiate among affinity, avidity, and cross-reactivity in antibodies

Key Points

- Antibodies are produced by plasma cells, but, once secreted, can act independently against extracellular pathogen and toxins.
- Antibodies bind to specific antigens on pathogens; this binding can inhibit pathogen infectivity by blocking key extracellular sites, such as receptors involved in host cell entry.
- Antibodies can also induce the innate immune response to destroy a pathogen, by activating phagocytes such as macrophages or neutrophils, which are attracted to antibody-bound cells.
- Affinity describes how strongly a single antibody binds a given antigen, while avidity describes the binding of a multimeric antibody to multiple antigens.
- A multimeric antibody may have individual arms with low affinity, but have high overall avidity due to synergistic effects between binding sites.
- Cross reactivity occurs when an antibody binds to a different-but-similar antigen than the one for which it was raised; this can increase pathogen resistance or result in an autoimmune reaction.

Key Terms

- **avidity**: the measure of the synergism of the strength individual interactions between proteins
- **affinity**: the attraction between an antibody and an antigen

Antibody Functions

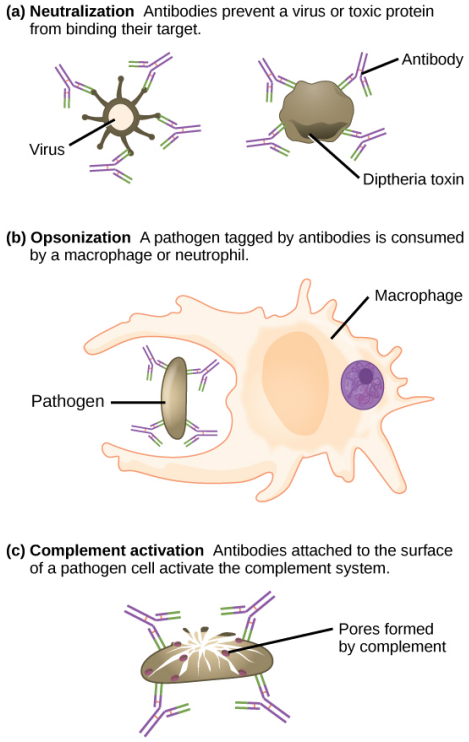

Figure: **Mechanisms of antibody action**: Antibodies may inhibit infection by (a) preventing the antigen from binding to its target, (b) tagging a pathogen for destruction by macrophages or neutrophils, or (c) activating the complement cascade.

Differentiated plasma cells are crucial players in the humoral immunity response. The antibodies they secrete are particularly significant against extracellular pathogens and toxins. Once secreted, antibodies circulate freely and act independently of plasma cells. Sometimes, antibodies can be transferred from one individual to another. For instance, a person who has recently produced a

successful immune response against a particular disease agent can donate blood to a non-immune recipient, confering temporary immunity through antibodies in the donor's blood serum. This phenomenon, called passive immunity, also occurs naturally during breastfeeding, which makes breastfed infants highly resistant to infections during the first few months of life.

Antibodies coat extracellular pathogens and neutralize them by blocking key sites on the pathogen that enhance their infectivity, such as receptors that "dock" pathogens on host cells. Antibody neutralization can prevent pathogens from entering and infecting host cells, as opposed to the cytotoxic T-cell-mediated approach of killing cells that are already infected to prevent progression of an established infection. The neutralized antibody-coated pathogens can then be filtered by the spleen and eliminated in urine or feces.

Antibodies also mark pathogens for destruction by phagocytic cells, such as macrophages or neutrophils, because they are highly attracted to macromolecules complexed with antibodies. Phagocytic enhancement by antibodies is called opsonization. In another process, complement fixation, IgM and IgG in serum bind to antigens, providing docking sites onto which sequential complement proteins can bind. The combination of antibodies and complement enhances opsonization even further, promoting rapid clearing of pathogens.

Affinity, avidity, and cross reactivity

Not all antibodies bind with the same strength, specificity, and stability. In fact, antibodies exhibit different affinities (attraction) depending on the molecular complementarity between antigen and antibody molecules. An antibody with a higher affinity for a particular antigen would bind more strongly and stably. It would be expected to present a more challenging defense against the pathogen corresponding to the specific antigen.

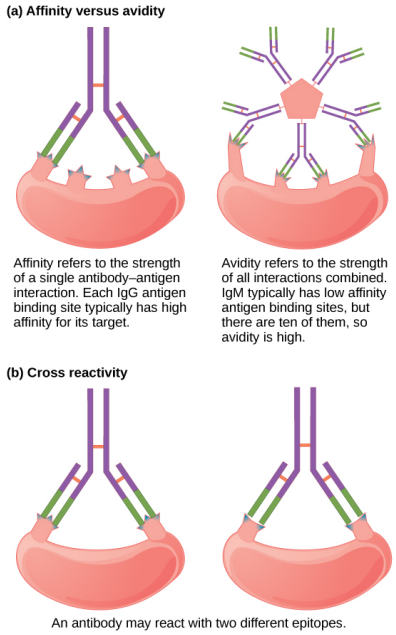

Figure: **Antibody affinity, avidity, and cross reactivity**: (a) Affinity refers to the strength of single interactions between antigen and antibody, while avidity refers to the strength of all interactions combined. (b) An antibody may cross-react with different epitopes.

The term avidity describes binding by antibody classes that are secreted as joined, multivalent structures (such as IgM and IgA). Although avidity measures the strength of binding, just as affinity does, the avidity is not simply the sum of the affinities of the antibodies in a multimeric structure. The avidity depends on the number of identical binding sites on the antigen being detected, as well as other physical and chemical factors. Typically, multimeric antibodies, such as pentameric IgM, are classified as having lower affinity than monomeric antibodies, but high avidity. Essentially, the fact that multimeric antibodies can bind many antigens simultaneously balances their slightly-lower-binding strength for each antibody/antigen interaction.

Antibodies secreted after binding to one epitope on an antigen may exhibit cross reactivity for the same or similar epitopes on different antigens. Cross reactivity occurs when an antibody binds not to the antigen that elicited its synthesis and secretion, but to a different antigen. Because an epitope corresponds to such a small region (the surface area of about four to six amino acids), it is possible for different macromolecules to exhibit the same molecular identities and orientations over short regions.

Cross reactivity can be beneficial if an individual develops immunity to several related pathogens despite having been exposed to or vaccinated against only one of them. For instance, antibody cross reactivity may occur against the similar surface structures of various Gram-negative bacteria. Conversely, antibodies raised against pathogenic molecular components that resemble self molecules may incorrectly mark host cells for destruction, causing autoimmune damage. Patients who develop systemic lupus erythematosus (SLE) commonly exhibit antibodies that react with their own DNA. These antibodies may have been initially raised against the nucleic acid of microorganisms, but later cross-reacted with self-antigens. This phenomenon is also called molecular mimicry.

11.7A: Antibody Proteins and Antigen Binding

A region at the tip of the antibody protein is very variable, allowing millions of antibodies with different antigen-binding sites to exist.

Learning Objectives

- Describe the general function and structure of an antibody

Key Points

- An antibody (Ab), also known as an immunoglobulin (Ig), is a large protein produced by B-cells that is used by the immune system to identify and neutralize foreign objects, such as bacteria and viruses. The antibody recognizes a unique part of the foreign target, called an antigen.
- Each tip of the "Y" of an antibody contains a paratope that is specific for one particular epitope (analogous to a lock and key) on an antigen, allowing these two structures to bind together with precision. Using this binding mechanism, an antibody can tag a microbe or an infected cell.
- The general structure of all antibodies is very similar: The Ig monomer is a Y-shaped molecule that consists of four polypeptide chains: two identical heavy chains and two identical light chains connected by disulphide bonds.
- Antibodies can occur in two physical forms, a soluble form that is secreted from the cell, and a membrane-bound form that is attached to the surface of a B-cell and is referred to as the B-cell receptor (BCR).

Key Terms

- **Hypervariable region**: In antibodies, hypervariable regions form the antigen-binding site and are found on both light and heavy chains. They also contribute to the specificity of each antibody. In a variable region, the 3 HV segments of each heavy or light chain fold together at the N-terminus to form an antigen binding pocket.

An antibody (Ab), also known as an immunoglobulin (Ig), is a large Y-shaped protein produced by B-cells that is used by the immune system to identify and neutralize foreign objects, such as bacteria and viruses. The antibody recognizes a unique part of the foreign target, called an antigen. Each tip of the "Y" of an antibody contains a paratope (a structure analogous to a lock) that is specific for one particular epitope (similarly analogous to a key) on an antigen, allowing these two structures to bind together with precision. Using this binding mechanism, an antibody can tag a microbe, or an infected cell, for attack by other parts of the immune system, or can neutralize its target directly; for example, by blocking a part of a microbe that is essential for its invasion and survival. The production of antibodies is the main function of the humoral immune system.

Antibody Functions

Antibody functions include the following:

- Combine with viruses/toxins to prevent them from invading cells
- Attach to flagella of bacterium, restricting their movement
- Multi-bind to many bacteria at once, causing them to accumulate and prevent movement around the body
- Burst bacteria cell walls
- Attach to bacteria, making it easier for phagocytes to ingest them

Antibody Structure

Antibodies are heavy (~150 kDa) globular plasma proteins. They have sugar chains added to some of their amino acid residues; in other words, they are glycoproteins. Antibodies are typically made of the same basic structural units, each with two large heavy chains and two small light chains.

Heavy and light chains, variable and constant regions of an antibody

There are several different types of antibody heavy chains, and several different kinds of antibodies, which are grouped into different isotypes based on which heavy chain they possess. Five different antibody isotypes are known in mammals, which perform different roles, and help direct the appropriate immune response for each different type of foreign object they encounter.

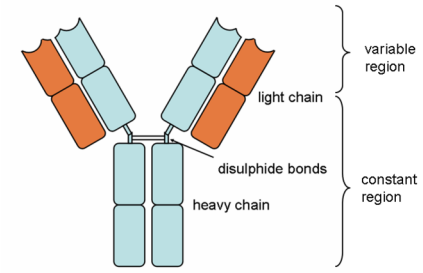

Figure: **Basic Antibody Structure**: Heavy and light chains, variable and constant regions of an antibody

The general structure of all antibodies is very similar. The Ig monomer is a Y-shaped molecule that consists of four polypeptide chains: two identical heavy chains, and two identical light chains connected by disulphide bonds. Each chain is composed of structural domains called immunoglobulin domains. These domains contain about 70-110 amino acids and are classified into different categories according to their size and function; for example, variable or IgV, and constant or IgC. The constant region determines the class of an immunoglobulin. All chains have a characteristic immunoglobulin fold in which two beta sheets create a "sandwich" shape, held together by interactions between conserved cysteines and other charged amino acids.

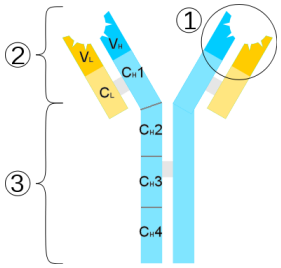

Figure: **Antigen Binding Fragment**: Scheme of an IgM/IgE with its costant (C) and variable (V) regions: 1) antigen binding fragment 2) Fab region 3) Fc regionblue: heavy chainsyellow: light chains

However, a small region at the tip of the protein is extremely variable, allowing millions of antibodies with slightly different tip structures, or antigen binding sites, to exist. This region is known as the hypervariable region. Each of these variants can bind to a different antigen. This enormous diversity of antibodies allows the immune system to recognize an equally wide variety of antigens. The large and diverse population of antibodies is generated by random combinations of a set of gene segments that encode different or paratopes, followed by random mutations in this area of the antibody gene, which create further diversity. The paratope is shaped at the amino terminal end of the antibody monomer by the variable domains from the heavy and light chains. The variable domain is also referred to as the FV region, and is the most important region for binding to antigens. More specifically, variable loops of β-strands, three each on the light (VL) and heavy (VH) chains are responsible for binding to the antigen.

Antibodies can occur in two physical forms, a soluble form that is secreted from the cell, and a membrane-bound form that is attached to the surface of a B cell and is referred to as the B cell receptor (BCR). The BCR is only found on the surface of B cells and facilitates the activation of these cells and their subsequent differentiation into either antibody factories called plasma cells, or memory B cells that will survive in the body and remember that same antigen so the B cells can respond faster upon future exposure. In most cases, interaction of the B cell with a T helper cell is necessary to produce full activation of the B cell and, therefore, antibody generation following antigen binding.

11.7B: Antibody Genes and Diversity

Complex genetic mechanisms evolved which allow vertebrate B cells to generate a diverse pool of antibodies from relatively few antibody genes.

Learning Objectives

- Outline the two stages which result in antibody diversity: somatic (V(D)J) and recombination stages

Key Points

- Virtually all microbes can trigger an antibody response. Successful recognition and eradication of many different types of microbes requires diversity among antibodies, a result of variation in amino acid composition that allows them to interact with many different antigens.
- Antibodies obtain their diversity through 2 processes. The first is called V(D)J (variable, diverse, and joining regions) recombination. During cell maturation, the B cell splices out the DNA of all but one of the genes from each region and combine the three remaining genes to form one VDJ segment.
- The second stage of recombination occurs after the B cell is activated by an antigen.In these rapidly dividing cells, the genes encoding the variable domains of the heavy and light chains undergo a high rate of point mutation, by a process called somatic hypermutation.
- As a consequence of these processes any daughter B cells will acquire slight amino acid differences in the variable domains of their antibody chains.This serves to increase the diversity of the antibody pool and impacts the antibody's antigen-binding affinity.
- Point mutations can result in the production of antibodies that have a lower or higher affinity with their antigen than the original antibody. B cells expressing antibodies with a higher affinity for the antigen will outcompete those with weaker affinities (called affinity maturation).

Key Terms

- **Somatic hypermutation**: a cellular mechanism by which the immune system adapts to the new foreign elements that confront it (for example, microbes). A major component of the process of affinity maturation, SHM diversifies B cell receptors used to recognize foreign elements (antigens) and allows the immune system to adapt its response to new threats during the lifetime of an organism.
- **V(D)J recombination**: Also known as somatic recombination, this is a mechanism of genetic recombination in the early stages of immunoglobulin (Ig) and T cell receptors (TCR) production of the immune system.

Virtually all microbes can trigger an antibody response. Successful recognition and eradication of many different types of microbes requires diversity among antibodies (glycoproteins belonging to the immunoglobulin superfamily). It is the variety in their amino acid composition that allows them to interact with many different antigens. It has been estimated that humans generate about 10 billion different antibodies, each capable of binding a distinct epitope of an antigen. Although a huge repertoire of different antibodies is generated in a single individual, the number of genes available to make these proteins is limited by the size of the human genome. Several complex genetic mechanisms have evolved that allow vertebrate B cells to generate a diverse pool of antibodies from a relatively small number of antibody genes.

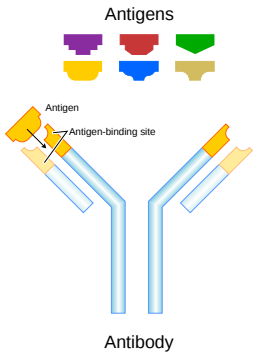

Figure: **Antibodies bind to specific antigens**: Schematic diagram of an antibody and antigens. Light chains are in lighter blue and orange, heavy chains in darker blue and orange. Each antibody binds to a specific antigen; an interaction similar to a lock and key.

Antibody Structure

Antibodies are typically made of basic structural units—each with two large heavy chains and two small light chains. There are several different types of antibody heavy chains, and several different kinds of antibodies, which are grouped into different isotypes based on which heavy chain they possess. Five different antibody isotypes are known in mammals, which perform different roles, and help direct the appropriate immune response for each different type of foreign object they encounter. Though the general structure of all antibodies is very similar, a small region at the tip of the protein is extremely variable, allowing millions of antibodies with slightly different antigen binding sites to exist. This region is known as the hypervariable region. Each of these variants can bind to a different antigen. This enormous diversity of antibodies allows the immune system to recognize an equally wide variety of antigens.

Antibodies obtain their diversity through two processes:

V(D)J Recombination

The first stage is called somatic, or V(D)J, which stands for variable, diverse, and joining regions recombination. Several sets of genes are located within each of the three regions. During cell maturation, the B cell will splice out the DNA of all but one of the genes from each region and combine the three remaining genes together to form one VDJ segment. This segment, along with a constant region gene, forms the basis for subsequent antibody production.

It is estimated that given the number of variants in each of the three regions, approximately 10,000-20,000 unique antibodies are producible. V(D)J recombination takes place in the primary lymphoid tissue (bone marrow for B cells, and thymus for T cells) and nearly randomly combines variable, diverse, and joining gene segments. It is due to this randomness in choosing different genes that it is able to diversely encode proteins to match antigens.

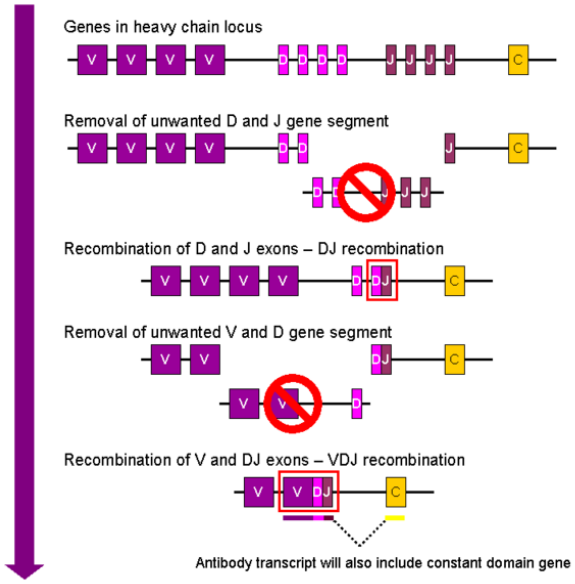

Figure: **Redistribution within the immunoglobulin (antibody) gene**: Schematic overview of V(D)J recombination.

Somatic Hypermutation

The second stage of recombination occurs after the B cell is activated by an antigen. In these rapidly dividing cells, the genes encoding the variable domains of the heavy and light chains undergo a high rate of point mutation, by a process called somatic hypermutation (SHM). SHM is a cellular mechanism by which the immune system adapts to the new foreign elements that confront it and is a major component of the process of affinity maturation. SHM diversifies B cell receptors used to recognize antigens and allows the immune system to adapt its response to new threats during the lifetime of an organism. Somatic hypermutation involves a programmed process of mutation affecting the variable regions of immunoglobulin genes. SHM results in approximately one nucleotide change per variable gene, per cell division. As a consequence, any daughter B cells will acquire slight amino acid differences in the variable domains of their antibody chains. This serves to increase the diversity of the antibody pool and impacts the antibody's antigen-binding affinity. Some point mutations will result in the production of antibodies that have a lower affinity

with their antigen than the original antibody, and some mutations will generate antibodies with a higher affinity. B cells that express higher affinity antibodies on their surface will receive a strong survival signal during interactions with other cells, whereas those with lower affinity antibodies will not, and will die by apoptosis. Thus, B cells expressing antibodies with a higher affinity for the antigen will outcompete those with weaker affinities for function and survival. The process of generating antibodies with increased binding affinities is called affinity maturation. Affinity maturation occurs after V(D)J recombination, and is dependent on help from helper T cells.

Antibody genes also re-organize in a process called class switching, which changes the base of the heavy chain to another. This creates a different isotype of the antibody while retaining the antigen specific variable region, thus allowing a single antibody to be used by several different parts of the immune system.

11.7C: Clonal Selection of Antibody-Producing Cells

The clonal selection hypothesis is a widely accepted model for the immune system's response to infection.

Learning Objectives

- Describe the clonal selection hypothesis in regards to the production of B cells

Key Points

- In 1954, immunologist Niels Jerne put forth the hypothesis that there is already a vast array of lymphocytes in the body before infection. The entrance of an antigen into the body results in the selection of only one type of lymphocyte to match it and produce a corresponding antibody to destroy it.
- B cells exist as clones derived from a particular cell. Thus the antibodies and their differentiated progenies can recognize and/or bind the same specific surface components composed of biological macromolecules of a given antigen. Clonality has important consequences for immunogenic memory.
- The clonal selection hypothesis states that an individual B cell expresses receptors specific to the distinct antigen, determined before the antibody ever encounters the antigen.

Key Terms

- **clonal selection**: An hypothesis which states that an individual lymphocyte (specifically, a B cell) expresses receptors specific to the distinct antigen, determined before the antibody ever encounters the antigen. Binding of Ag to a cell activates the cell, causing a proliferation of clone daughter cells.
- **clone**: A group of identical cells derived from a single cell.

The clonal selection hypothesis has become a widely accepted model for how the immune system responds to infection and how certain types of B and T lymphocytes are selected for destruction of specific antigens invading the body.

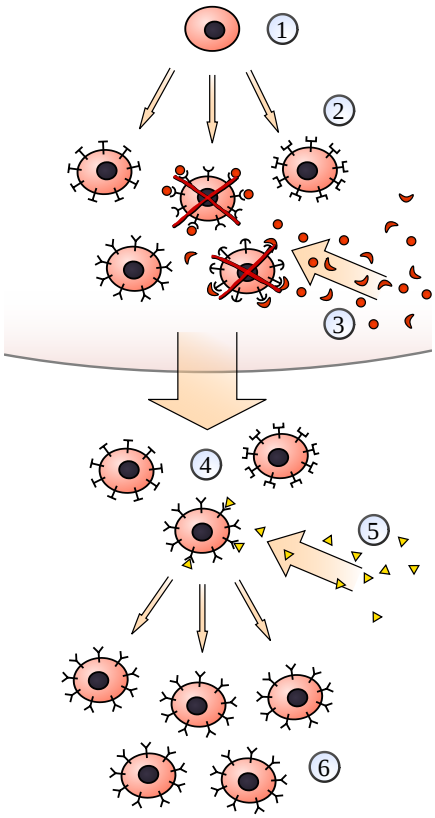

Figure: **A schematic view of clonal selection**: Clonal selection of lymphocytes: 1) A hematopoietic stem cell undergoes differentiation and genetic rearrangement to produce 2) immature lymphocytes with many different antigen receptors. Those that bind to 3) antigens from the body's own tissues are destroyed, while the rest mature into 4) inactive lymphocytes. Most of these will never encounter a matching 5) foreign antigen, but those that do are activated and produce 6) many clones of themselves.

Four predictions of the clonal selection hypothesis

- Each lymphocyte bears a single type of receptor with a unique specificity (by V(D)J recombination).
- Receptor occupation is required for cell activation.
- The differentiated effector cells derived from an activated lymphocyte will bear receptors of identical specificity as the parental cell.
- Those lymphocytes bearing receptors for self molecules will be deleted at an early stage.

In 1954, Danish immunologist Niels Jerne put forward a hypothesis which stated that there is already a vast array of lymphocytes in the body prior to any infection. The entrance of an antigen into the body results in the selection of only one type of lymphocyte to match it and produce a corresponding antibody to destroy the antigen. This selection of only one type of lymphocyte results in it being cloned or reproduced by the body extensively to ensure there are enough antibodies produced to inhibit and prevent infection. Australian immunologist Frank Macfarlane Burnet, with input from David W. Talmage, worked on this model and was the first to name it "clonal selection theory. " Burnet explained immunological memory as the cloning of two types of lymphocyte. One clone acts immediately to combat infection whilst the other is longer lasting, remaining in the immune system for a long time, which results in immunity to that antigen. In 1958, Sir Gustav Nossal and Joshua Lederberg showed that one B cell always produces only one antibody, which was the first evidence for clonal selection theory.

B cells exist as clones. All B cells derive from a particular cell, and as such, the antibodies and their differentiated progenies can recognize and/or bind the same specific surface components composed of biological macromolecules (epitope) of a given antigen. Such clonality has important consequences, as immunogenic memory relies on it. The great diversity in immune response comes about due to the up to 109 clones with specificities for recognizing different antigens. Upon encountering its specific antigen, a single B cell, or a clone of cells with shared specificity, divides to produce many B cells. Most of such B cells differentiate into

plasma cells that secrete antibodies into blood that bind the same epitope that elicited proliferation in the first place. A small minority survives as memory cells that can recognize only the same epitope. However, with each cycle, the number of surviving memory cells increases. The increase is accompanied by affinity maturation which induces the survival of B cells that bind to the particular antigen with high affinity. This subsequent amplification with improved specificity of immune response is known as secondary immune response. B cells that have not been activated by antigen are known as naive lymphocytes; those that have met their antigen, become activated, and have differentiated further into fully functional lymphocytes are known as effector B lymphocytes.

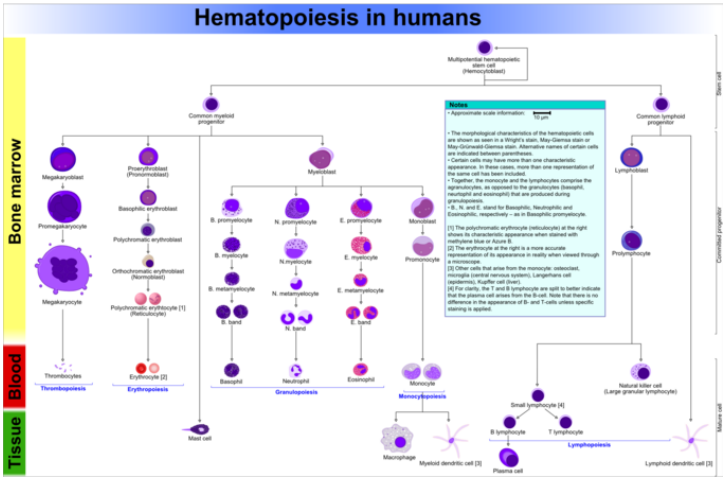

Figure: **Hematopoiesis in Humans**: This diagram shows hematopoiesis as it occurs in humans.

11.7D: Isotype Class Switching

Isotype class switching is a biological mechanism that changes a B cell's production of antibody from one class to another.

Learning Objectives

- Describe the process of class switch recombination that results in changes in the antibody-heavy chain

Key Points

- The antibody isotype of a B cell changes during cell development and activation. Immature B cells have never been exposed to an antigen and are known as naïve B cells. B cells begin to express both IgM and IgD when they reach maturity and renders the B cell 'mature' and ready to respond to antigen.
- If activated B cells encounter specific signaling molecules via their CD40 and cytokine receptors (both modulated by T helper cells), they undergo antibody class switching to produce IgG, IgA or IgE antibodies that have defined roles in the immune system.
- During class switch recombination the constant region portion of the antibody-heavy chain is changed, but the variable region of the heavy chain stays the same; thus, class switching does not affect antigen specificity.
- The antibody retains affinity for the same antigens, but can interact with different effector molecules. This allows different daughter cells from the same activated B cell to produce antibodies of different isotypes or subtypes (e.g. IgG1, IgG2 etc.).

Key Terms

- **isotype**: Antibodies can come in different varieties known as isotypes, which refer to the genetic variations or differences in the constant regions of the heavy and light chains of the antibody.
- **class switch recombination**: A biological mechanism that changes a B cell's production of antibody from one class to another; for example, from an isotype called IgM to an isotype called IgG.

Isotype Class Switching

Antibodies can come in different varieties, known as isotypes or classes. In placental mammals there are five antibody isotypes: IgA, IgD, IgE, IgG and IgM. They are each named with an "Ig" prefix that stands for immunoglobulin (another name for antibody) and differ in their biological properties, functional locations, and ability to deal with different antigens.

The antibody isotype of a B cell changes during cell development and activation. Immature B cells, which have never been exposed to an antigen, are known as naïve B cells and express only the IgM isotype in a cell surface bound form. B cells begin to express both IgM and IgD when they reach maturity; the co-expression of both of these immunoglobulin isotypes renders the B cell 'mature' and ready to respond to an antigen. B cell activation follows engagement of the cell-bound antibody molecule with an antigen, causing the cell to divide and differentiate into an antibody-producing cell, called a plasma cell. In this activated form, the B cell starts to produce antibody in a secreted form rather than a membrane-bound form. If these activated B cells encounter specific signaling molecules via their CD40 and cytokine receptors (both modulated by T helper cells), they undergo antibody class switching to produce IgG, IgA or IgE antibodies (from IgM or IgD) that have defined roles in the immune system.

Immunoglobulin class switching (or isotype switching, or isotypic commutation, or class switch recombination (CSR)) is a biological mechanism that changes a B cell's production of antibody from one class to another; for example, from an isotype called IgM to an isotype called IgG. During this process, the constant region portion of the antibody-heavy chain is changed, but the variable region of the heavy chain stays the same (the terms "constant" and "variable" refer to changes or lack thereof between antibodies that target different epitopes). Since the variable region does not change, class switching does not affect antigen specificity. Instead, the antibody retains affinity for the same antigens, but can interact with different effector molecules. This allows different daughter cells from the same activated B cell to produce antibodies of different isotypes or subtypes (e.g. IgG1, IgG2 etc.).

Class switching occurs by a mechanism called class switch recombination (CSR) binding. Class switch recombination is a biological mechanism that allows the class of antibody produced by an activated B cell to change during a process known as isotype or class switching. During CSR, portions of the antibody-heavy chain locus are removed from the chromosome, and the gene segments surrounding the deleted portion are rejoined to retain a functional antibody gene that produces antibody of a different isotype. Double-stranded breaks are generated in DNA at conserved nucleotide motifs, called switch (S) regions, which

are upstream from gene segments that encode the constant regions of antibody-heavy chains; these occur adjacent to all heavy chain constant region genes with the exception of the δ-chain. DNA is nicked and broken at two selected S-regions by the activity of a series of enzymes, including Activation-Induced (Cytidine) Deaminase (AID), uracil DNA glycosylase and apyrimidic/apurinic (AP)-endonucleases. The intervening DNA between the S-regions is subsequently deleted from the chromosome, removing unwanted μ or δ heavy chain constant region exons and allowing substitution of a γ, α or ε constant region gene segment. The free ends of the DNA are rejoined by a process called non-homologous end joining (NHEJ) to link the variable domain exon to the desired downstream constant domain exon of the antibody-heavy chain. In the absence of non-homologous end joining, free ends of DNA may be rejoined by an alternative pathway biased toward microhomology joins. With the exception of the μ and δ genes, only one antibody class is expressed by a B cell at any point in time.

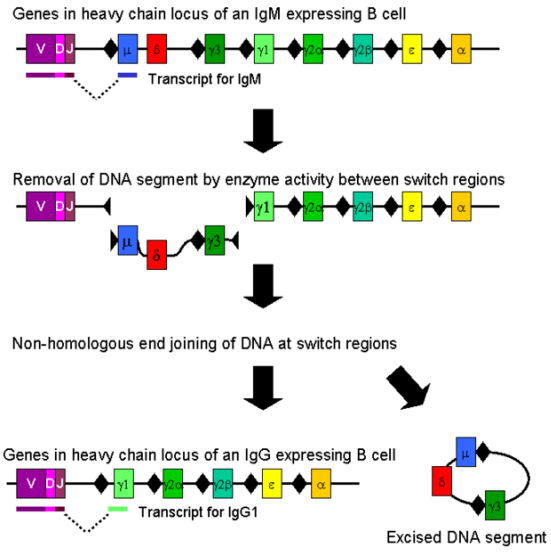

Figure: **Class Switch Recombination**: Mechanism of class switch recombination that allows isotype switching in activated B cells.

11.7E: Making Memory B Cells

Memory B cells are a B cell sub-type that are formed following primary infection.

Learning Objectives

- Outline the process of memory B cell production

Key Points

- In the wake of the first (primary response) infection involving a particular antigen, the responding naïve cells (ones which have never been exposed to the antigen) proliferate to produce a colony of cells, most of which differentiate into the plasma cells, also called effector B cells.
- Effector B cells (which produce the antibodies) clear away with the resolution of infection, and the rest persist as the memory cells that can survive for years, or even a lifetime.
- The antibody molecules present on a clone (a group of genetically identical cells) of B cells have a unique paratope. Some of the resulting paratopes (and the cells elaborating them) have a better affinity for the antigen and are more likely to proliferate than the others.

Key Terms

- **paratope**: That part of the molecule of an antibody that binds to an antigen
- **memory cell**: one of a number of types of white blood cells

Making Memory B Cells

Memory B cells are a B cell sub-type that are formed following a primary infection. In the wake of the first (primary response) infection involving a particular antigen, the responding naïve cells (ones which have never been exposed to the antigen) proliferate to produce a colony of cells. Most of them differentiate into the plasma cells, also called effector B cells (which produce the antibodies) and clear away with the resolution of infection. The rest persist as the memory cells that can survive for years, or even a lifetime.

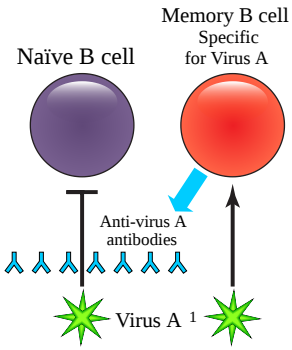

Figure: **B memory cells**: B lymphocytes are the cells of the immune system that make antibodies to invading pathogens like viruses. They form memory cells that remember the same pathogen for faster antibody production in future infections. The body's immune system has a propensity to preferentially utilize immunological memory based on a previous infection when a second slightly different version of that foreign entity is encountered.

To understand the events taking place, it is important to appreciate that the antibody molecules present on a clone (a group of genetically identical cells) of B cells have a unique paratope (the sequence of amino acids that binds to the epitope on an antigen).

Each time these cells are induced to proliferate due to an infection, the genetic region coding for the paratope undergoes spontaneous mutations with a frequency of about 1 in every 1600 cell divisions. This may not seem high, but because the cells divide so often, it ends up resulting in many mutations. The frequency of mutations in other cells is around 1 in 10^6, which is much lower.

All these events occur in the highly "eventful" germinal centers of lymphoid follicles, within the lymph nodes.

Some of the resulting paratopes (and the cells elaborating them) have a better affinity for the antigen (actually, the epitope) and are more likely to proliferate than the others.

Moreover, the number of different clones responding to the same antigen increases (polyclonal response) with each such exposure to the antigen and a greater number of memory cells persist. Thus, a stronger (basically, larger number of antibody molecules) and more specific antibody production is the hallmark of secondary antibody response.

The fact that all the cells of a single clone elaborate one (and only one) paratope, and that the memory cells survive for long periods, is what imparts a memory to the immune response. This is the principle behind vaccination and administration of booster.

The paratope is the part of an antibody which recognizes an antigen, the antigen-binding site of an antibody. It is a small region (15–22 amino acids) of the antibody's Fv region and contains parts of the antibody's heavy and light chains. The part of the antigen to which the paratope binds is called an epitope.

11.7F: Primary and Secondary Antibody Responses

The immune system protects organisms from infection first with the innate immune system, then with adaptive immunity.

Learning Objectives

- Generalize the role of the innate and adaptive immune system in regards to antibody response

Key Points

- When B cells and T cells are first activated by a pathogen, memory B-cells and T- cells develop.
- Throughout the lifetime of an animal these memory cells will “remember” each specific pathogen encountered, and are able to mount a strong response if the pathogen is detected again. This type of immunity is both active and adaptive.
- Active immunity often involves both the cell-mediated and humoral aspects of immunity as well as input from the innate immune system.

Key Terms

- **secondary response**: the immune response occurring on second and subsequent exposures to an antigen, with a stronger response to a lesser amount of antigen, and a shorter lag time compared to the primary immune response
- **primary response**: the immune response occurring on the first exposure to an antigen, with specific antibodies appearing in the blood after a multiple day latent period
- **adaptive immunity**: the components of the immune system that adapt themselves to each new disease encountered and are able to generate pathogen-specific immunity.

The immune system is a system of biological structures and processes within an organism that protects against disease. To function properly, an immune system must detect a wide variety of agents, from viruses to parasitic worms, and distinguish them from the organism’s own healthy tissue. Pathogens can rapidly evolve and adapt to avoid detection and neutralization by the immune system. As a result, multiple defense mechanisms have also evolved to recognize and neutralize pathogens. Even simple unicellular organisms such as bacteria possess a rudimentary immune system, in the form of enzymes that protect against bacteriophage infections. Other basic immune mechanisms evolved in ancient eukaryotes and remain in their modern descendants, such as plants and insects. These mechanisms include phagocytosis, antimicrobial peptides called defensins, and the complement system. Jawed vertebrates, including humans, have even more sophisticated defense mechanisms, including the ability to adapt over time to recognize specific pathogens more efficiently. Adaptive (or acquired) immunity creates immunological memory after an initial response to a specific pathogen, leading to an enhanced response to subsequent encounters with that same pathogen. This process of acquired immunity is the basis of vaccination.

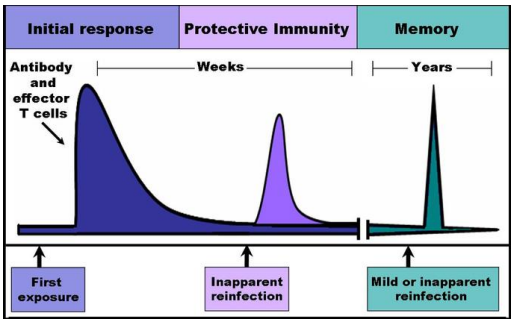

Figure: **The Time Course of an Immune Response**: Immune reactants, such as antibodies and effector T-cells, work to eliminate an infection, and their levels and activity rapidly increase following an encounter with an infectious agent, whether that agent is a pathogen or a vaccine. For several weeks these reactants remain in the serum and lymphatic tissues and provide protective immunity against reinfection by the same agent. During an early reinfection, few outward symptoms of illness are present, but the levels of immune reactants increase and are detectable in the blood and/or lymph. Following clearance of the infection, antibody level and effector T cell activity gradually declines. Because immunological memory has developed, reinfection at later times leads to a rapid increase in antibody production and effector T cell activity. These later infections can be mild or even inapparent.

Disorders of the immune system can result in autoimmune diseases, inflammatory diseases and cancer. Immunodeficiency occurs when the immune system is less active than normal, resulting in recurring and life-threatening infections. In humans, immunodeficiency can either be the result of a genetic disease such as severe combined immunodeficiency, acquired conditions such as HIV/AIDS, or the use of immunosuppressive medication. In contrast, autoimmunity results from a hyperactive immune

system attacking normal tissues as if they were foreign organisms. Common autoimmune diseases include Hashimoto's thyroiditis, rheumatoid arthritis, diabetes mellitus type 1, and systemic lupus erythematosus. Immunology covers the study of all aspects of the immune system.

The immune system protects organisms from infection with layered defenses of increasing specificity. In simple terms, physical barriers prevent pathogens such as bacteria and viruses from entering the organism. If a pathogen breaches these barriers, the innate immune system provides an immediate, but non-specific response. Innate immune systems are found in all plants and animals. If pathogens successfully evade the innate response, vertebrates possess a second layer of protection, the adaptive immune system, which is activated by the innate response. Here, the immune system adapts its response during an infection to improve its recognition of the pathogen. This improved response is then retained after the pathogen has been eliminated, in the form of an immunological memory, and allows the adaptive immune system to mount faster and stronger attacks each time this pathogen is encountered. Both innate and adaptive immunity depend on the ability of the immune system to distinguish between self and non-self molecules. In immunology, self molecules are those components of an organism's body that can be distinguished from foreign substances by the immune system. Conversely, non-self molecules are those recognized as foreign molecules. One class of non-self molecules are called antigens (short for antibody generators) and are defined as substances that bind to specific immune receptors and elicit an immune response.

When B cells and T cells are first activated by a pathogen, memory B-cells and T- cells develop. Throughout the lifetime of an animal these memory cells will "remember" each specific pathogen encountered, and are able to mount a strong response if the pathogen is detected again. This type of immunity is both *active* and *adaptive* because the body's immune system prepares itself for future challenges. Active immunity often involves both the cell-mediated and humoral aspects of immunity as well as input from the innate immune system. The *innate system* is present from birth and protects an individual from pathogens regardless of experiences, whereas adaptive immunity arises only after an infection or immunization and hence is "acquired" during life.

SECTION OVERVIEW

11.8: T Cells and Cellular Immunity

Topic hierarchy

11.8A: Cytotoxic T Lymphocytes and Mucosal Surfaces

11.8B: Classes of T Cells

11.8C: Cell-Mediated Immunity

11.8D: Regulatory T Cells

11.8E: T Cell Receptors

11.8F: Adaptive Immunity and the Immunoglobulin Superfamily

11.8: T Cells and Cellular Immunity is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.8A: Cytotoxic T Lymphocytes and Mucosal Surfaces

The lymphatic system houses large populations of immune cells which are released upon detection of a pathogen.

Learning Objectives

- Describe the features of the lymphatic system as they relate to the immune response

Key Points

- The lymphatic system contains lymph: a fluid that bathes tissues and organs and contains white blood cells (not red blood cells).
- Once B and T cells mature, the majority of them enter the lymphatic system, where they are stored in lymph nodes until needed.
- Lymph nodes also store dendritic cells and macrophages; as antigens are filtered through the lymphatic system, these cells collect them so as to present them to B and T cells.
- The spleen, which is to blood what lymph nodes are to lymph, filters foreign substances and antibody -complexed pathogens from the blood.

Key Terms

- **lymph**: a colorless, watery, bodily fluid carried by the lymphatic system, consisting mainly of white blood cells

Lymphatic system

Lymph, the watery fluid that bathes tissues and organs, contains protective white blood cells, but does not contain erythrocytes (red blood cells). Lymph moves about the body through the lymphatic system, which is made up of vessels, lymph ducts, lymph glands, and organs such as tonsils, adenoids, thymus, and spleen. Although the immune system is characterized by circulating cells throughout the body, the regulation, maturation, and intercommunication of immune factors occur at specific sites that are known as lymph nodes.

The blood circulates immune cells, proteins, and other factors through the body. Approximately 0.1 percent of all cells in the blood are leukocytes, which include monocytes (the precursor of macrophages) and lymphocytes. Most cells in the blood are red blood cells. Cells of the immune system can travel between the distinct lymphatic and blood circulatory systems, which are separated by interstitial space, by a process called extravasation (passing through to surrounding tissue).

Recall that cells of the immune system originate from stem cells in the bone marrow. B cell maturation occurs in the bone marrow, whereas progenitor cells migrate from the bone marrow and develop and mature into naïve T cells in the organ called the thymus. On maturation, T and B lymphocytes circulate to various destinations. Lymph nodes scattered throughout the body house large populations of T and B cells, dendritic cells, and macrophages. Lymph gathers antigens as it drains from tissues. These antigens are filtered through lymph nodes before the lymph is returned to circulation. Antigen-presenting cells (APCs) in the lymph nodes capture and process antigens, informing nearby lymphocytes about potential pathogens.

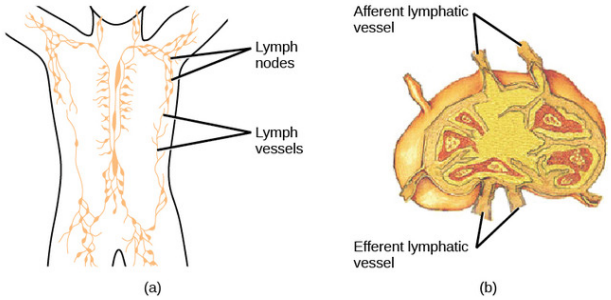

Figure: **Lymphatic system**: (a) Lymphatic vessels carry a clear fluid called lymph throughout the body. The liquid passes through (b) lymph nodes that filter the lymph that enters the node through afferent vessels, leaving through efferent vessels. Lymph nodes are filled with lymphocytes that purge infecting cells.

The spleen houses B and T cells, macrophages, dendritic cells, and NK cells. The spleen is also the site where APCs that have trapped foreign particles in the blood can communicate with lymphocytes. Antibodies are synthesized and secreted by activated plasma cells in the spleen, which filters foreign substances and antibody-complexed pathogens from the blood. Functionally, the spleen is to the blood as lymph nodes are to the lymph.

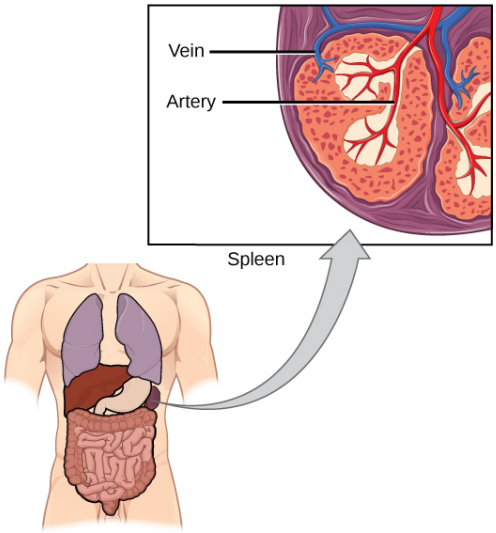

Figure: **Spleen in the lymphatic system**: The spleen functions to immunologically filter the blood and allow for communication between cells corresponding to the innate and adaptive immune responses.

11.8A: Cytotoxic T Lymphocytes and Mucosal Surfaces is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.8B: Classes of T Cells

T cells play a central role in cell-mediated immune response through the use of the surface T cell receptor to recognize peptide antigens.

Learning Objectives

- Distinguish between: naive, effector (helper and cytotoxic), memory and regulatory T cells

Key Points

- T cell progenitors are derived from the bone marrow but travel to the thymus where they mature.
- T cells can be divided into three main subtypes: effector, memory, and regulatory cells. Each type performs a distinct function during an immune response to foreign antigens.
- T cells subtypes are differentiated by the expression of unique cell surface markers, such as CD4 for helper T cells and CD8 for cytolytic or cytotoxic T cells.

Key Terms

- **cytotoxic**: of, relating to, or being a cytotoxin
- **cytolytic**: Of or pertaining to cytolysis

Cellular immunity is mediated by *T lymphocytes*, also called T cells. Their name refers to the organ from which they're produced: the thymus. This type of immunity promotes the destruction of microbes residing in phagocytes, or the killing of infected cells to eliminate reservoirs of infection. T cells do not produce antibody molecules. They have antigen receptors that are structurally related to antibodies. These structures help recognize antigens only in the form of peptides displayed on the surface of antigen-presenting cells.

T cells consist of functionally distinct populations. These include naive T cells that recognize antigens and are activated in peripheral lymphoid organs. This activation results in the expansion of the antigen-specific lymphocyte pool and the differentiation of these cells into effector and memory cells. Effector cells include helper T cells, and cytolytic or cytotoxic T cells. In response to antigenic stimulation, helper T cells (characterized by the expression of CD4 marker on their surface) secrete proteins called cytokines, whose function is to stimulate the proliferation and differentiation of the T cells themselves, as well as other cells, including B cells, macrophages, and other leukocytes. Cytolytic or cytotoxic T cells (characterized by the expression of CD8 marker on their surface) kill cells that produce foreign antigens, such as cells infected by viruses and other intracellular microbes.

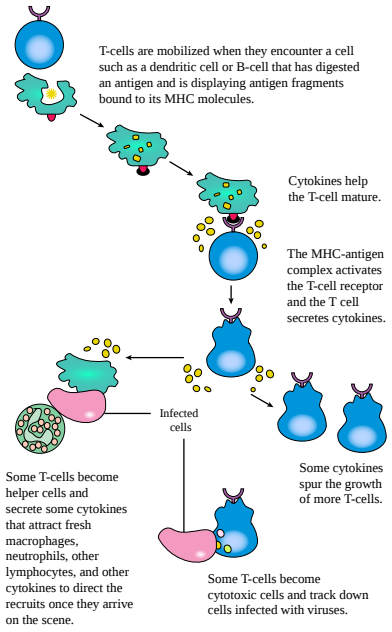

Figure: **Cell-mediated immunity**: T cells promote the killing of cells that have ingested microorganisms and present foreign antigens on their surface.

Memory T cells are an expanded population of T cells specific for antigens that can respond rapidly to subsequent encounter with that antigen and differentiate into effector cell to eliminate the antigen. Another class of T cells called regulatory T cells function to inhibit immune response and resolve inflammation. Their major role is to shut down T cell-mediated immunity toward the end of an immune reaction.

11.8B: Classes of T Cells is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.8C: Cell-Mediated Immunity

Cell-mediated immunity involves cytotoxic T cells recognizing infected cells and bringing about their destruction.

Learning Objectives

- Summarize the cell-mediated immune response

Key Points

- Once a pathogen enters a cell, it can no longer be detected by the humoral immune response; instead, the cell-mediated immune response must take over to kill the infected cell before it can allow the virus or bacteria to replicate and spread.
- T cells recognize infected cells by interacting with antigen present on their MHC II molecules; before a T cell can do so, it must be activated via interaction with an antigen presenting cell, or APC.
- Once a cytotoxic T cell (T_C) is activated, it will clone itself, producing many T_C cells with the correct receptors; some portion of the cells are active and will help destroy infected cells, while others are inactive memory cells that will create more active T_C cells if the infection returns.
- Helper T cells (T_H cells) also aid in cell-mediated immunity by releasing signaling molecules known as cytokines which can recruit natural killer cells and phagocytes to destroy infected cells and further activate T_C cells; they do not directly destroy pathogens.

Key Terms

- **cytotoxic T cell**: a subgroup of lymphocytes (white blood cells) that are capable of inducing death to infected somatic or tumor cells; part of cell-mediated immunity
- **cytokine**: any of various small regulatory proteins that regulate the cells of the immune system; they are released upon binding of PRRs to PAMPS

T cells

Just as the humoral immune response has B cells which mediate its response, the cellular immune response has T cells, which recognize infected cells and destroy them before the pathogen inside can replicate and spread to infect other cells. Unlike B cells, T lymphocytes (T cells) are unable to recognize pathogens without assistance. First, an antigen-presenting cell (APC, such as a dendritic cell or a macrophage) detects, engulfs (via phagocytosis in the case of macrophages or by entry of the pathogen of its own accord in the case of dendritic cells), and digests pathogens into hundreds or thousands of antigen fragments. These fragments are then transported to the surface of the APC, where they are presented on proteins known as Major Histocompatibility Complexes class II (MHC II, see). T cells become activated towards a certain antigen once they encounter it displayed on an MHC II. After a virus or bacteria enters a cell, it can no longer be detected by the humoral immune response. Instead, the cellular immune response must take over. To do so, a T cell will become activated by interacting with an antigen of the infecting cell or virus presented on the MHC II of an APC.

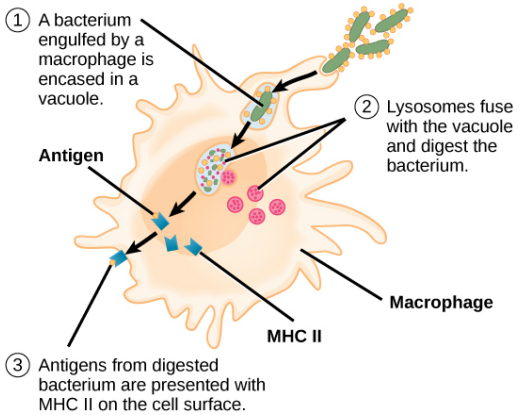

Figure: **APCs, MHCs and lymphocytes**: An antigen-presenting cell (APC), such as a macrophage, engulfs a foreign antigen, partially digests it in a lysosome, and then embeds it in an MHC class II molecule for presentation at the cell surface. Lymphocytes of the adaptive immune response must interact with antigen-embedded MHC class II molecules to mature into functional immune cells.

Cytotoxic T cells mediate one arm of the cellular immune response

There are two main types of T cells: helper T lymphocytes (T_H) and the cytotoxic T lymphocytes (T_C). The T_H lymphocytes function indirectly to tell other immune cells about potential pathogens, while cytotoxic T cells (T_C) are the key component of the cell-mediated part of the adaptive immune system which attacks and destroys infected cells. $T_C$cells are particularly important in protecting against viral infections because viruses replicate within cells where they are shielded from extracellular contact with circulating antibodies. Once activated, the $T_C$creates a large clone of cells with one specific set of cell-surface receptors, similar to the proliferation of activated B cells. As with B cells, the clone includes active T_C cells and inactive memory T_C cells. The resulting active T_C cells then identify infected host cells.

T_C cells attempt to identify and destroy infected cells by triggering apoptosis (programmed cell death) before the pathogen can replicate and escape, thereby halting the progression of intracellular infections. To recognize which cells to pursue, T_C recognize antigens presented on MHC I complexes, which are present on all nucleated cells. MHC I complexes display a current readout of intracellular proteins inside a cell and will present pathogen antigens if the pathogen is present in the cell. T_C cells also support NK lymphocytes to destroy early cancers.

Cytokines released by T_H cells recruit NK cells and phagocytes

Cytokines are signaling molecules secreted by a T_H cell in response to a pathogen-infected cell; they stimulate natural killer cells and phagocytes such as macrophages. Phagocytes will then engulf infected cells and destroy them. Cytokines are also involved in stimulating T_C cells, enhancing their ability to identify and destroy infected cells and tumors. A summary of how the humoral and cell-mediated immune responses are activated appears in. B plasma cells and T_C cells are collectively called effector cells because they are involved in “effecting” (bringing about) the immune response of killing pathogens and infected host cells.

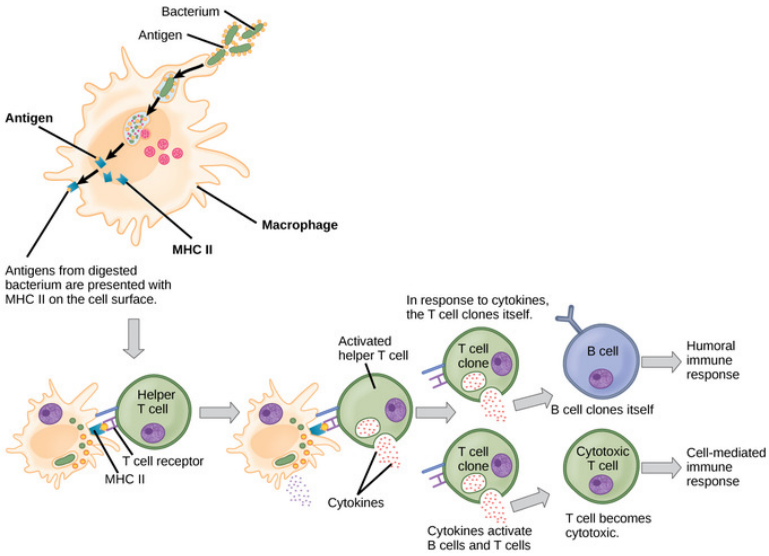

Figure: **Helper T cells in the immune response**: A helper T cell becomes activated by binding to an antigen presented by an APC via the MHCII receptor, causing it to release cytokines. Depending on the cytokines released, this activates either the humoral or the cell-mediated immune response.

11.8C: Cell-Mediated Immunity is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.8D: Regulatory T Cells

Regulatory T cells are a subset of T cells which modulate the immune system and keep immune reactions in check.

Learning Objectives

- Describe the function and types of regulatory T cells

Key Points

- Regulatory T cells (Tregs) are critical to the maintenance of immune cell homeostasis as evidenced by the consequences of genetic or physical ablation of the Treg population.
- Tregs are classified into natural or induced Tregs; natural Tregs are CD4+CD25+ T-cells which develop, and emigrate from the thymus to perform their key role in immune homeostasis.
- Adaptive Tregs are non-regulatory CD4+ T-cells which acquire CD25 (IL-2R alpha) expression outside of the thymus and are typically induced by inflammation and disease processes, such as autoimmunity and cancer.

Key Terms

- **autoimmunity**: The condition where one's immune system attacks one's own tissues, i.e., an autoimmune disorder.

Regulatory T cells are a component of the immune system that suppress immune responses of other cells. This is an important "self-check" built into the immune system to prevent excessive reactions and chronic inflammation. Regulatory T cells come in many forms, with the most well-understood being those that express CD4, CD25, and Foxp3. These cells are also called $CD4^+CD25^+$ regulatory T cells, or Tregs. These cells are involved in shutting down immune responses after they have successfully eliminated invading organisms, and also in preventing autoimmunity.

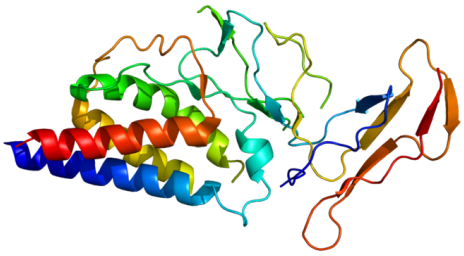

Figure: **CD25 is a component of the IL2 receptor**: Interleukin 2 receptor is composed of three subunits (alpha, beta, and gamma). CD25 constitutes the alpha chain of the IL2 receptor.

$CD4^+Foxp3^+$ regulatory T cells have been called "naturally-occurring" regulatory T cells, to distinguish them from "suppressor" T cell populations that are generated *in vitro*. Additional suppressor T cell populations include Tr1, Th3, $CD8^+CD28^-$, and Qa-1 restricted T cells. The contribution of these populations to self- tolerance and immune homeostasis is less well defined. FOXP3 can be used as a good marker for CD4+CD25+ T cells as well as recent studies showing evidence for FOXP3 in CD4+CD25- T cells.

An additional regulatory T cell subset, induced regulatory T cells, are also needed for tolerance and suppression. Induced Regulatory T (iTreg) cells ($CD4^+CD25^+Foxp3^+$) are suppressive cells involved in tolerance. iTreg cells have been shown to suppress T cell proliferation and experimental autoimmune diseases. iTreg cells develop from mature $CD4^+$ conventional T cells outside of the thymus: a defining distinction between natural regulatory T (nTreg) cells and iTreg cells. Though iTreg and nTreg cells share a similar function iTreg cells have recently been shown to be an essential non-redundant regulatory subset that supplements nTreg cells, in part by expanding TCR diversity within regulatory responses. Acute depletion of the iTreg cell pool in mouse models has resulted in inflammation and weight loss. The contribution of nTreg cells versus iTreg cells in maintaining tolerance is unknown, but both are important. Epigenetic differences have been observed between nTreg and iTreg cells, with the former having more stable Foxp3 expression and wider demethylation.

11.8D: Regulatory T Cells is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.8E: T Cell Receptors

Learning Objectives

- Discuss the role of the T cell receptor (TCR)

T lymphocytes have a dual specificity: they recognize polymorphic residues of self major histocompatibility complex (MHC) molecules, which accounts for their MHC restriction; they also recognize residues of peptide antigens displayed by these MHC molecules, which is responsible for their specificity. MHC molecules and peptides form complexes on the surface of antigen presenting cells (APCs). The receptor that recognizes these peptide-MHC complexes is called the T Cell Receptor (TCR). Clones of T cells with different specificities express different TCRs.

The biochemical signals that are triggered in T cells following antigen recognition are transduced not by the TCR itself, but by invariant proteins (CD3, and zeta), which are non-covalently linked to the antigen receptor to form the TCR complex. T cells also express other membrane receptors that do not recognize antigens but participate in responses to antigens; these are collectively called 'accessory molecules'. The physiologic role of some accessory molecules is to deliver signals to the T cells that function in concert with signals from the TCR complex to fully activate the cell.

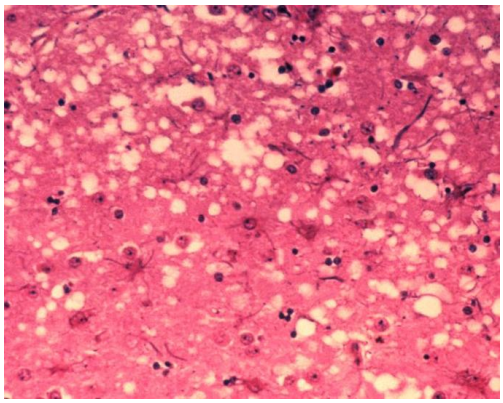

Figure: *Prion-affected tissue: This micrograph of brain tissue reveals the cytoarchitectural histopathologic changes found in bovine spongiform encephalopathy. The presence of vacuoles, i.e. microscopic "holes" in the gray matter, gives the brain of BSE-affected cows a sponge-like appearance when tissue sections are examined in the lab.*

The antigen receptor of MHC-restricted CD4 helper T cells and CD8 cytolytic T cell is a heterodimer consisting of two transmembrane polypeptide chains, designated alpha and beta, covalently linked to each other by disulfide bonds. Each alpha and beta chain consists of one variable domain (V), one constant domain (C), a hydrophobic transmembrane region, and a short cytoplasmic region. The V regions of the TCR contain short stretches of amino acids where the variability between different TCRs is concentrated, and these form the hypervariable or complementarity-determining regions (CDRs). The recognition of peptide-MHC complexes is mediated by CDRs formed by both the alpha and beta chains of the TCR.

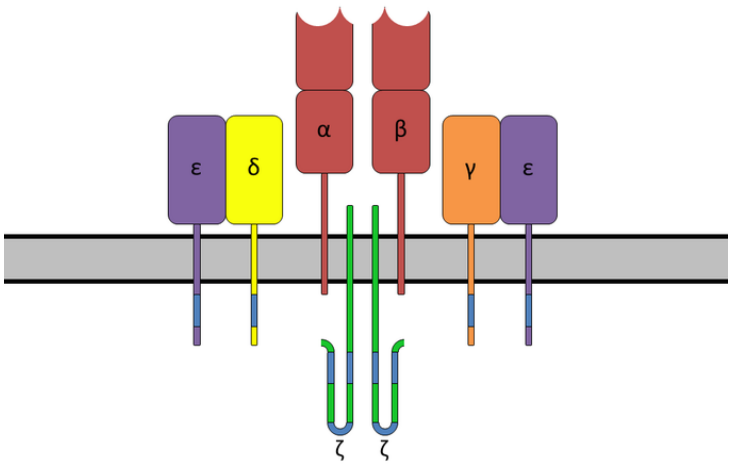

Figure: *T cell receptor: T cell receptor consists of alpha and beta chains, a transmembrane domain, and a cytoplasmic region.*

Key Points

- Many TCRs recognize the same antigen and many antigens are recognized by the same TCR.
- The TCR is composed of two different protein chains (that is, it is a heterodimer). In 95% of T cells, this consists of an alpha (α) and beta (β) chain, whereas in 5% of T cells this consists of gamma and delta (γ/δ) chains.
- When the TCR engages with antigen and MHC, the T lymphocyte is activated through a series of biochemical events mediated by associated enzymes, co- receptors, specialized accessory molecules, and activated or released transcription factors.

Key Terms

- polymorphic: relating to polymorphism (any sense), able to have several shapes or forms
- major histocompatibility complex: MHC is a cell surface molecule that mediate interactions of immune cells with other leukocytes or body cells. MHC determines compatibility of donors for organ transplants as well as one's susceptibility to an autoimmune disease. In humans, MHC is also called human leukocyte antigen (HLA).

11.8E: T Cell Receptors is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.8F: Adaptive Immunity and the Immunoglobulin Superfamily

Learning Objectives

- Describe the role of immunoglobulins in the adaptive immune response, specifically in humoral immunity

Adaptive immunity is stimulated by exposure to infectious agents and increases in magnitude and defensive capabilities with each successive exposure to a particular microbe. The defining characteristics of adaptive immunity are specificity for distinct molecules and an ability to “remember” and respond more vigorously to repeated exposures to the same microbe.

The components of adaptive immunity are lymphocytes and their products. There are two types of adaptive immune responses: *humoral immunity* and *cell-mediated immunity.* These are driven by different elements of the immune system and function to eliminate different types of microbes. Protective immunity against a microbe may be induced by the host ‘s response to the microbe or by the transfer of antibodies or lymphocytes specific for the microbe. Antibodies or Immunoglobulins bind antigens in the recognition phase and the effector phase of humoral immunity.

The Immunoglobulin Superfamily

Immunoglobulins are produced in a membrane -bound form by B lymphocytes. These membrane molecules function as B cell receptors for antigens. The interaction of antigens with membrane antibodies on naive B cells initiates B cell activation. These activated B cells produce a soluble form of immunoglobulin that triggers effector mechanisms to eliminate antigens.

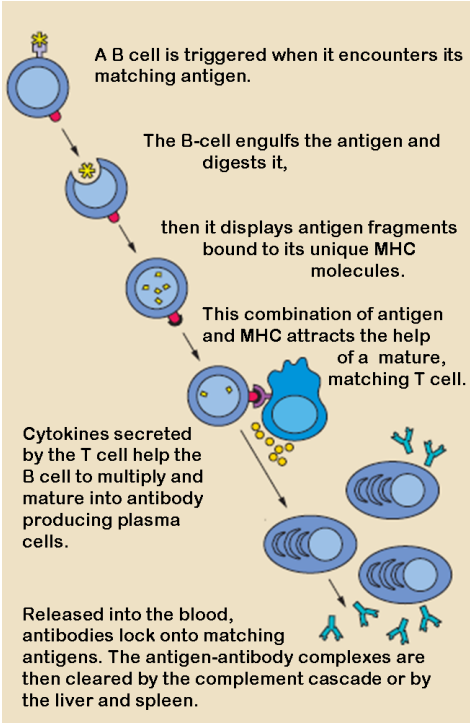

Figure: *B cell activation: When a B cell encounters its triggering antigen, it gives rise to many large cells known as plasma cells. Every plasma cell is essentially a factory for producing an antibody. Each of the plasma cells manufactures millions of identical antibody molecules and pours them into the bloodstream.*

These antibodies are part of a larger family called the i*mmunoglobulin superfamily*. The immunoglobulin superfamily (IgSF) is a large group of cell surface and soluble proteins that are involved in the recognition, binding, or adhesion processes of cells. Molecules are categorized as members of this superfamily based on structural features shared with immunoglobulins, which are also known as antibodies. They all possess a domain known as an *immunoglobulin domain* or *fold*. Members of the IgSF include cell surface antigen receptors, co-receptors, and co-stimulatory molecules of the immune system, molecules involved in antigen presentation to lymphocytes, cell adhesion molecules, certain cytokine receptors, and intracellular muscle proteins. They are commonly associated with roles in the immune system.

Key Points

- The concept of adaptive immunity suggests de novo generation in each individual of extremely large repertoires of diversified receptors and selective expansion of receptors that match the antigen /pathogen.
- Adaptive immune receptors of T and B lymphoid cells belong to the *immunoglobulin superfamily* and are created by rearrangement of gene segments.
- Immunoglobulins are glycoproteins in the immunoglobulin superfamily that function as antibodies.

Key Terms

- cytokine: Any of various small regulatory proteins that regulate the cells of the immune system.

SECTION OVERVIEW

11.9: Antigen-Presenting Cells

Topic hierarchy

11.9A: Dendritic Cells

11.9B: Macrophages

11.9: Antigen-Presenting Cells is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.9A: Dendritic Cells

Dendritic cells are immune cells that function to process antigens and present them to T cells.

Learning Objectives

- Discuss the mechanism of action for dendritic cells

Key Points

- Dendritic cells function as antigen presenting cells.
- Dendritic cells are present in small quantities in tissues that are in contact with the external environment, mainly the skin (where there is a specialized dendritic cell type called Langerhans cells) and the inner lining of the nose, lungs, stomach and intestines.
- Once activated, dendritic cells migrate to the lymphoid tissues where they interact with T cells and B cells to initiate and shape the adaptive immune response.

Key Terms

- **lymphoid organs**: lymph nodes, spleen, and gut-associated lymphoid tissue where lymphocytes reside.

Dendritic cells are present in lymphoid organs, the epithelia of the skin, the gastrointestinal and respiratory tracts, and in most parenchymal organs. These cells are identified morphologically by their membranous projections that resemble spines. All dendritic cells are thought to arise from bone marrow precursors. Most, called myeloid dendritic cells, are related in lineage to mononuclear phagocytes. Immature dendritic cells (e.g. Langerhans cells of the epidermis) are located in main portals of entry of microbes (skin and gut epithelia). The function of epithelial dendritic cells is to capture microbial protein antigens and to transport the antigens to draining lymph nodes. During their migration to the lymph nodes, the dendritic cells mature to become extremely efficient at presenting antigens and stimulating naive T cells, hence their classification as antigen presenting cells. Mature dendritic cells reside in the T cell zones of the lymph nodes, and in this location they display antigens to T cells. Subsets of dendritic cells can be distinguished by the expression of cell surface markers. Different subpopulations of dendritic cells may stimulate distinct types of T cell effector responses. Some may even inhibit T cell activation.

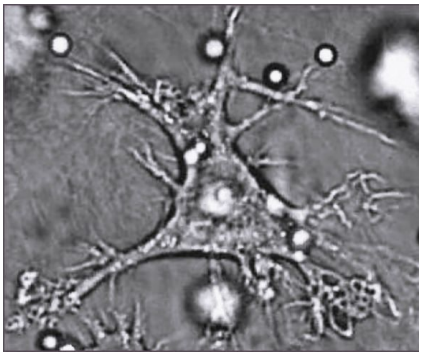

Figure: **Dendritic cell**: Dendritic cell characterized by membranous projections that resemble spines.

Dendritic cells are constantly in communication with other cells in the body. This communication can take the form of direct cell-to-cell contact based on the interaction of cell-surface proteins. An example of this includes the interaction of the membrane proteins of the B7 family of the dendritic cell with a CD28 cell surface molecule present on the lymphocyte. However, the cell-cell interaction can also take place at a distance via soluble factors such as cytokines. For example, stimulating dendritic cells *in vivo* with microbial extracts causes the dendritic cells to rapidly begin producing interleukin 12 (IL-12). IL-12 is a signal that helps differentiate naive CD4 T cells into a helper T cell phenotype. The ultimate consequence is priming and activation of the immune system for attack against the antigens which the dendritic cell presents on its surface.

11.9A: Dendritic Cells is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.9B: Macrophages

Phagocytosis is a front-line defense against pathogen attack requiring the concerted action of macrophages.

Learning Objectives

- Describe the role of macrophages in the immune system

Key Points

- Macrophages are cells produced by the differentiation of monocytes in tissues.
- They are specialized phagocytic cells that attack foreign substances and infectious microbes through destruction and ingestion.
- Macrophages can be identified by specific expression of a number of proteins measured by flow cytometry or immunohistochemistry.

Key Terms

- **phagocyte**: A cell of the immune system, such as a neutrophil, macrophage or dendritic cell, that engulfs and destroys viruses, bacteria and waste materials, or in the case of mature dendritic cells; displays antigens from invading pathogens to cells of the lymphoid lineage.
- **interferon-gamma**: a cytokine that is critical for innate and adaptive immunity against viral and intracellular bacterial infections.

Macrophages are antigen presenting cells that actively phagocytose large particles. Therefore, they play an important role in presenting antigens derived from phagocytosed infectious organisms such as bacteria and parasites. In the effector phase of cell-mediated immunity, differentiated effector T cells recognize microbial antigens on phagocytes and activate the macrophages to destroy these engulfed microbes. Most macrophages express high levels of interferon-gamma, a mechanism through which antigen presentation and T cell activation is enhanced. Macrophages can be identified by specific expression of a number of proteins including CD14, CD40, CD11b, F4/80(mice)/EMR1(human), lysozyme M, MAC-1/MAC-3 and CD68. They move by the action of amoeboid movement.

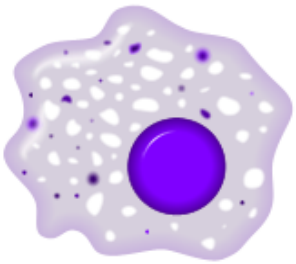

Figure: **Macrophage**: Macrophages are antigen presenting cells that engulf microbes.

Macrophages are not cells exclusive to the immune system; they also play a central function in many other aspects of embryonic development, homeostasis and wound repair. Resident macrophages become adapted to perform particular functions in different organs; so that brain macrophages (microglia) are very different from alveolar macrophages of the lung, Kupffer cells of the liver, or the largest tissue macrophage population, those lining the wall of the gut.

Monocytes are recruited into tissues in response to a very wide range of different stimuli. Where a pathogen is involved, they are commonly preceded by neutrophils, which release a range of toxic agents designed to kill extracellular pathogens. The macrophage then has the task of clearing both the dead pathogens and the dead neutrophils. To enter a tissue, the monocyte in peripheral blood must adhere to the vessel wall, cross the endothelial cell barrier, and then migrate towards the stimulus; a process known as chemotaxis.

The process of recruitment of neutrophils and macrophages involves the resident macrophages which act as sentinels. They respond to local stimuli by producing cytokines that make the endothelial cells more sticky (through the increased expression of cell adhesion molecules such as P-selectin) and so-called chemokines, that promote the directed migration of inflammatory cells. Monocytes may also migrate towards increasing concentrations of molecules produced by microorganisms themselves, by damaged tissues, or by the activation of the complement or clotting cascades which release bioactive peptides such as C5a.

9.10B: HIV Attachment and Host Cell Entry

The attachment and fusion of HIV virons to host cells are crucial to HIV infection.

Learning Objectives

- Define the unique aspects of HIV attachment and host cell entry

Key Points

- HIV proteins bind to specific receptors of host cells, most importantly HIV coat proteins gp41 and gp160.
- After attaching to the host, many of the receptors on both the cell and invading virus bind together for fusion of the virus with its host.
- Because HIV attachment is critical for the HIV replication cycle, understanding the specific mechanisms by which HIV attachment occurs has implications for potential treatments of HIV.

Key Terms

- **glycoprotein**: A protein with covalently bonded carbohydrates.
- **macrophages**: A type of white blood cell that targets foreign material, including bacteria and viruses.
- **capsid**: The outer protein shell of a virus.
- **chemokine**: Any of various cytokines, produced during inflammation, that organize the leukocytes.
- **T cells**: A lymphocyte, from the thymus, that can recognise specific antigens and can activate or deactivate other immune cells.

HIV entry is the earliest stage of infection in the HIV viral life cycle, occurring when the HIV virus comes into contact with the host cell and introduces viral material into the cell. HIV enters macrophages and CD4-positive T cells (CD4 is a glycoprotein receptor found on cells) by the adsorption of glycoproteins on its surface to receptors on the target cell, followed by fusion of the viral envelope with the cell membrane and the release of the HIV capsid into the cell.

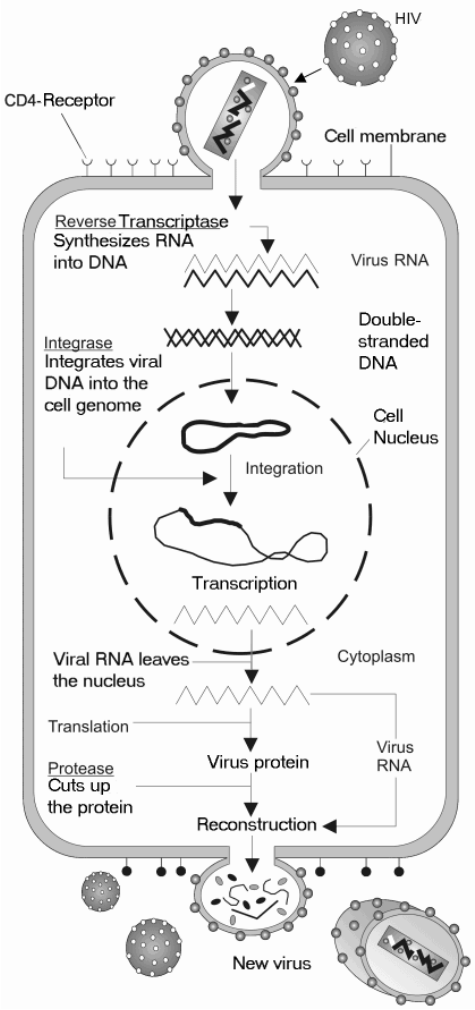

Figure: **HIV Replication**: Steps in the HIV Replication Cycle: Fusion of the HIV cell to the host cell surface.Cell Entry, HIV RNA, reverse transcriptase, integrase, and other viral proteins enter the host cell.Viral DNA is formed by reverse transcription.Viral DNA is transported across the nucleus and integrates into the host DNA.New viral RNA is used as genomic RNA to make viral proteins.New viral RNA and proteins move to cell surface and a new, immature, HIV virus forms.Virus maturation and protease release of individual HIV proteins.

Entry to the cell begins through interaction of the trimeric envelope complex and both CD4 and a chemokine receptor on the host cell on the cell surface. The HIV coat protein, gp120, binds to integrin α4β7, activating LFA-1 (the central integrin involved in the establishment of bridges known as “virological synapses”) which facilitate efficient cell-to-cell spreading of HIV-1.

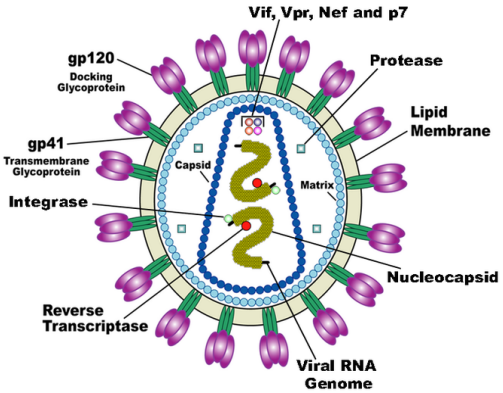

Figure: **Origin of HIV-1 M: An Example of Molecular Clock Application**: The attachment and fusion of HIV virons to host cells are crucial to allowing HIV infection to occur. Shown in purple is gp120 and in green gp41, two proteins crucial in viral docking to host cells.

After attachment, the HIV viron must next fuse with the host cell. The first step in fusion begins after the attachment of the CD4 binding domains of gp120 to CD4. Once gp120 is bound with the CD4 protein, the envelope complex undergoes a structural change, exposing the chemokine binding domains of gp120 and allowing them to interact with the target chemokine receptor. This allows for a more stable two-pronged attachment, which allows the N-terminal fusion peptide gp41 to penetrate the cell membrane. Repeat sequences in gp41, known as HR1 and HR2, then interact, causing the collapse of the extracellular portion of gp41 into a hairpin. This loop structure brings the virus and cell membranes close together, allowing fusion of the membranes and subsequent entry of the viral capsid.

After HIV has bound to the target cell, the HIV RNA and various enzymes (including reverse transcriptase, integrase, ribonuclease, and protease) are injected into the cell. Because HIV attachment is critical for the HIV replication cycle, understanding the specific mechanisms through which HIV attachment occurs has implications for potential treatments of HIV.

9.10C: Retroviral RNA Genome

Learning Objectives

- Discover the features of retroviral genomes

The retroviral while in the viral capsid consists of a dimer RNA. It has a cap at the 5′ end and a poly(A) tail at the 3′ end. The RNA genome also has terminal noncoding regions, which are important in replication, and internal regions that encode virion proteins for gene expression.

The 5′ end includes four regions, which are R, U5, PBS, and L.

- The R region is a short repeated sequence at each end of the genome during the reverse transcription in order to ensure correct end-to-end transfer in growing chain.
- U5, on the other hand, is a short unique sequence between R and PBS.
- PBS (primer binding site) consists of 18 bases complementary to 3′ end of the tRNA primer, which supplies an ‘OH group to initiate reverse transcription.
- The L region is an untranslated leader region that give the signal for packaging of genome RNA.

The 3′ end includes 3 regions, which are PPT (polypurine tract), U3, and R.

- PPT (or PP), polypurine tract is the primer for plus-strand DNA synthesis during reverse transcription.
- U3 is a sequence between PPT and R, which has signal that provirus can use in transcription.
- R is the terminal repeated sequence at 3′ end, the same as the R (i.e., repeat region of the 5′ end).

Inbetween the 5′ and 3′ region is the protein encoding region of the retrovirus, consisting of gag proteins, protease (PR), pol proteins and env proteins. Gag proteins are major components of the viral capsid, which are about 2,000-4,000 copies per virion. Protease is expressed differently in different viruses. It functions in proteolytic cleavages during virion maturation to make mature gag and pol proteins. Pol proteins, such as the reverse transcriptase (RT), are responsible for synthesis of viral DNA and integration into host DNA after infection. Finally, env proteins play a role in association and entry of virion into the host cell. Possessing a functional copy of an env gene is what makes retroviruses distinct from retroelements. The env gene serves three distinct functions: enabling the retrovirus to enter/exit host cells through endosomal membrane trafficking, protection from the extracellular environment via the lipid bilayer, and the ability to enter cells. The ability of the retrovirus to bind to its target host cell using specific cell-surface receptors is given by the surface component (SU) of the env, while the ability of the retrovirus to enter the cell via membrane fusion is imparted by the membrane-anchored trans-membrane component (TM). Thus, the env protein is what enables the retrovirus to be infectious.

Please refer to the figure, in it you see all the elements of a retroviral genome and how they interact to contribute to retroviral reverse transcription and integration.

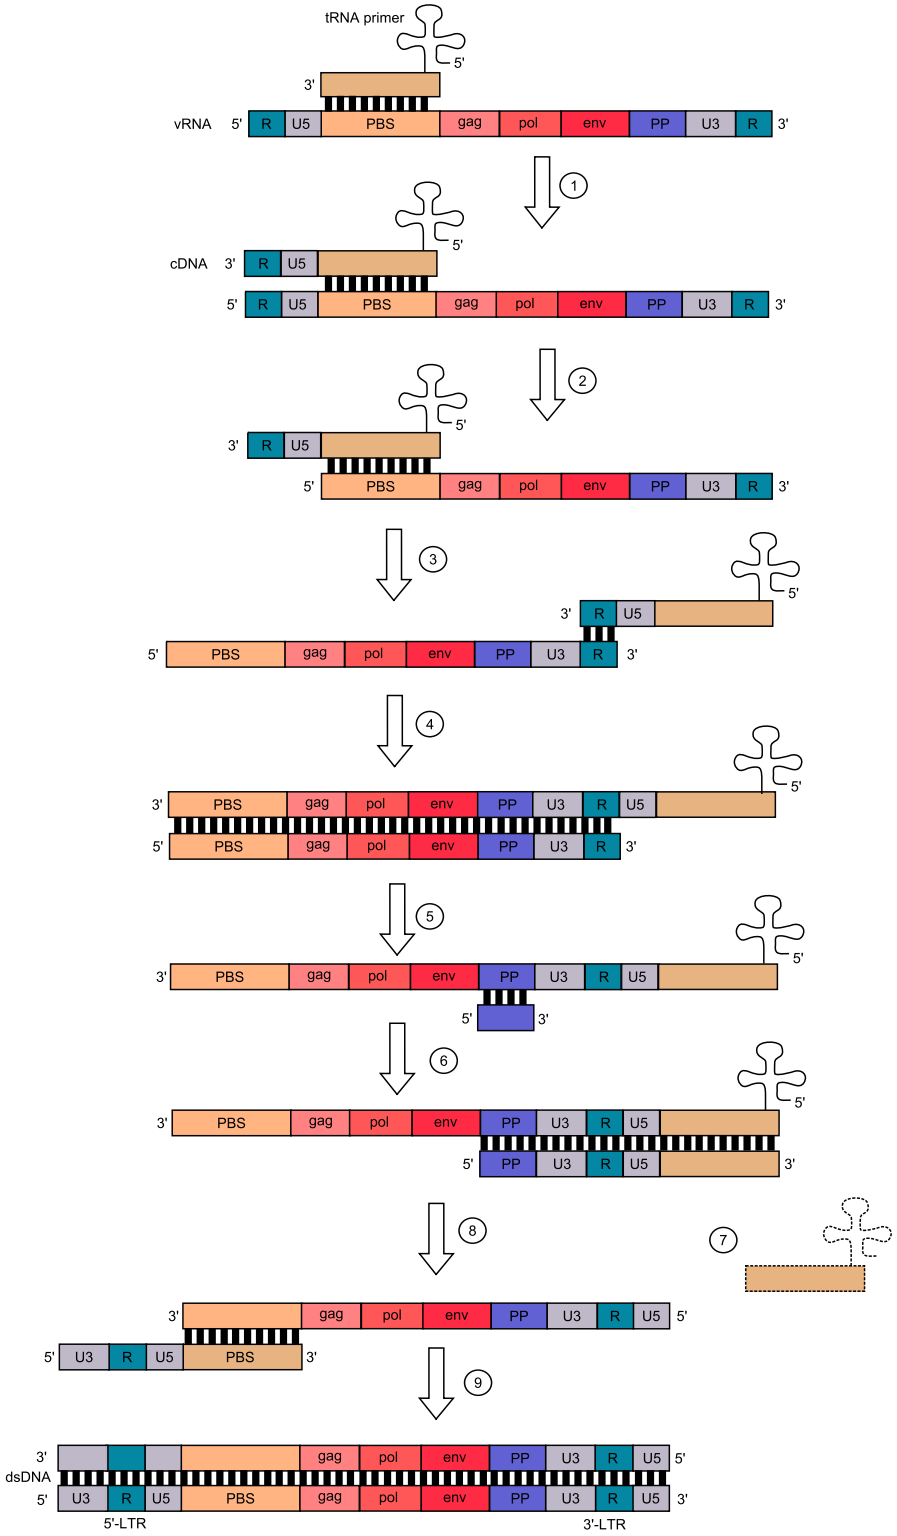

Figure: ***Retroviral genome****: Through the mechanism of reverse transcription by human immunodeficiency virus (HIV), we see what the different genomic elements of a retrovirus are. Reverse transcription occurs in the cytoplasm of host cell. In this process, viral ssRNA is transcribed by the viral reverse transcriptase (RT) into double stranded DNA. Reverse transcription takes place in 5'→3' direction. tRNA ("cloverleaf") hybridizes to PBS and provides -OH group for initiation of reverse transcription. 1) Complementary DNA (cDNA) is formed. 2) Template in RNA:DNA hybrid is degraded by RNase H domain of reverse transcriptase 3) DNA:tRNA is transferred to the 3'-end of the template. 4) First strand synthesis takes place. 5) The rest of viral ssRNA is degraded by RNase H, except for the PP site. 6) Synthesis of second strand of ssDNA is initiated from the 3'-end of the template. tRNA is necessary to synthesis of complementary PBS 7) tRNA is degraded 8) PBS from the second strand hybridizes with the complementary PBS on the first strand. 9) Synthesis of both strands is completed by the DNA Polmerase function of reverse transcriptase. Both dsDNA*

https://bio.libretexts.org/@go/page/9914

ends have U3-R-U5 sequences, so called long terminal repeat sequences (3'LTR and 5'LTR, respectively). LTRs mediate integration of the retroviral DNA into another region of the host genome.Key: U3 – promoter region, U5 – recognition site for viral integrase; PBS – primer binding site; PP – polypurine section (polypurine tract); gag, pol, and env. Colors mark complementary sequences.

Key Points

- The ends of a retrovirus, both the 5′ and 3′, contain many elements needed for the retroviral life cycle, including the regions referred to as R, U5, PBS, PPT, and U3.
- In between the 5′ and 3′ ends is the protein coding region which includes the gag, pol, and env encoding regions.
- Key to the unique attributes of a retrovirus is the pol region, which encodes a reverse trancriptase (RT), RT is the enzyme which takes the RNA form of the retrovirus genome and converts into DNA, the DNA form of which can integrate into the host genome.

Key Terms

- **protease**: An enzyme that cuts or cleaves proteins.
- **capsid**: The outer protein shell of a virus.

9.10D: Replicative Cycle of HIV

Learning Objectives

- Compare and contrast HIV replication to other viruses

Human immunodeficiency virus (HIV) is a lentivirus (a member of the retrovirus family) that causes acquired immunodeficiency syndrome (AIDS). AIDS is a condition in humans in which progressive failure of the immune system allows life-threatening opportunistic infections and cancers to thrive. HIV can infect dendritic cells (DCs). DCs are one of the first cells encountered by the virus during sexual transmission. They are currently thought to play an important role by transmitting HIV to T-cells when the virus is captured in the mucosa by DCs. HIV enters macrophages and T cells by the adsorption of glycoproteins on its surface to receptors on the target cell. This is followed by fusion of the viral envelope with the cell membrane and the release of the HIV capsid into the cell.

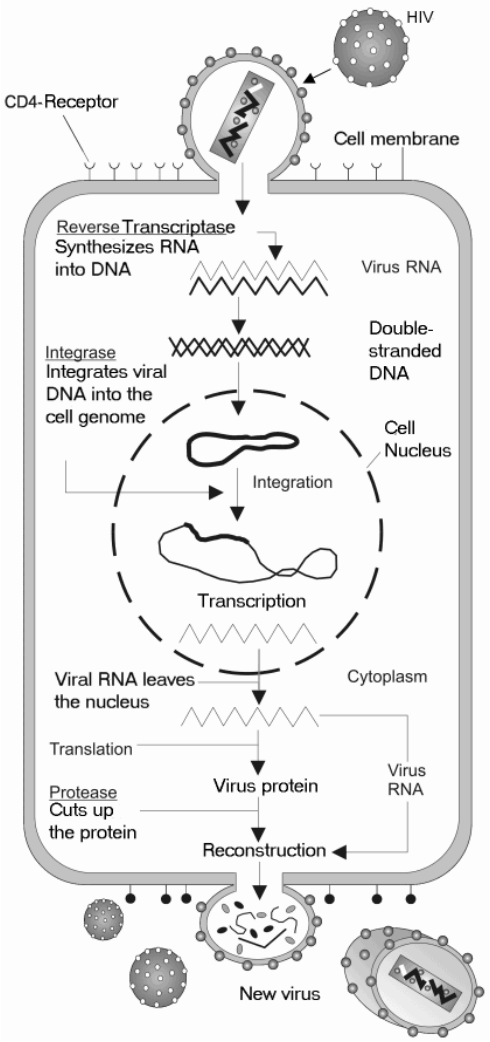

Figure: ***HIV Replication***: *Steps in the HIV Replication Cycle: Fusion of the HIV cell to the host cell surface.Cell Entry, HIV RNA, reverse transcriptase, integrase, and other viral proteins enter the host cell.Viral DNA is formed by reverse transcription.Viral DNA is transported across the nucleus and integrates into the host DNA.New viral RNA is used as genomic RNA to make viral proteins.New viral RNA and proteins move to cell surface and a new, immature, HIV virus forms.Virus maturation and protease release of individual HIV proteins.*

Shortly after the viral capsid enters the cell, an enzyme called reverse transcriptase liberates the single-stranded (+)RNA genome from the attached viral proteins and copies it into a complementary DNA (cDNA) molecule. The process of reverse transcription is extremely error-prone, and the resulting mutations may cause drug resistance or allow the virus to evade the body's immune system. The reverse transcriptase also has ribonuclease activity that degrades the viral RNA during the synthesis of cDNA, as well

as DNA-dependent DNA polymerase activity that creates a sense DNA from the antisense cDNA. Together, the cDNA and its complement form a double-stranded viral DNA that is then transported into the cell nucleus.

This integrated viral DNA may then lie dormant, in the latent stage of HIV infection. To actively produce the virus, certain cellular transcription factors need to be present. The most important of these is NF-κB (NF kappa B), which is upregulated when T-cells become activated. This means that those cells most likely to be killed by HIV are those currently fighting infection. During viral replication, the integrated DNA provirus is transcribed into mRNA, which is then spliced into smaller pieces. These small pieces are exported from the nucleus into the cytoplasm, where they are translated into the regulatory proteins Tat (which encourages new virus production) and Rev.

As the newly produced Rev protein accumulates in the nucleus, it binds to viral mRNAs and allows unspliced RNAs to leave the nucleus, where they are otherwise retained until spliced. At this stage, the structural proteins Gag and Env are produced from the full-length mRNA. The full-length RNA is actually the virus genome; it binds to the Gag protein and is packaged into new virus particles. The final step of the viral cycle, assembly of new HIV-1 virions, begins at the plasma membrane of the host cell. The Env polyprotein goes through the endoplasmic reticulum and is transported to the Golgi complex. There, it is cleaved by HIV protease and processed into the two HIV envelope glycoproteins, gp41 and gp120. These are transported to the plasma membrane of the host cell where gp41 anchors gp120 to the membrane of the infected cell. The Gag (p55) and Gag-Pol (p160) polyproteins also associate with the inner surface of the plasma membrane along with the HIV genomic RNA as the forming virion begins to bud from the host cell.

Maturation occurs either in the forming bud or in the immature virion after it buds from the host cell. During maturation, HIV proteases cleave the polyproteins into individual functional HIV proteins. This cleavage step can be inhibited by protease inhibitors. The various structural components then assemble to produce a mature HIV virion. The mature virion is then able to infect another cell.

Key Points

- First the HIV viron binds to host cell, after binding the virus and cell fuse, which releases the various enzymes HIV needs to reverse transcribe and integrate into the host genome.
- The reverse transcription of HIV viral RNA to DNA is error prone, causing HIV to have a high mutation rate. This makes it difficult to design treatments against HIV.
- The HIV provirus can stay dormant in the host genome for years. It may become active when the host T cell is itself activated by fighting an infection that the body is facing.
- Understanding the HIV life cycle will help in providing effective treatments against HIV.

Key Terms

- **provirus**: A virus genome, such as HIV, that integrates itself into the DNA of a host cell so as to be passively replicated along with the host genome.
- **reverse transcriptase**: An enzyme that catalyzes the formation of DNA from RNA; found in retroviruses.

9.11A: Plant DNA Viruses

DNA viruses are relatively rare in plants, but are responsible for a significant amount of crop damage worldwide.

Learning Objectives

- Differentiate between ssDNA and dsDNA plant viruses

Key Points

- DNA viruses are relatively rare in plants, compared to their RNA counterparts.
- Like most viruses, the genomes of most single stranded DNA viruses are small, encoding only a few proteins, and are therefore dependent on host cell factors for replication.
- Double stranded DNA viruses only infect lower species of plants, such as algae. These viruses are huge dsDNA viruses with genomes ranging from 160 to 560 kb with up to 600 protein-encoding genes, making them distinctly different from viruses infecting higher plants.
- Plant viruses are generally spread through vectors, such as insects, but can also be passed from generation to generation.

Key Terms

- **Baltimore Classification System**: The Baltimore classification, developed by David Baltimore, is a virus classification system that groups viruses into families, depending on their type of genome (DNA, RNA, single-stranded (ss), double-stranded (ds), etc.) and their method of replication.
- **plasmodesmata**: Plasmodesmata (singular: plasmodesma) are microscopic channels which traverse the cell walls of plant cells and some algal cells, enabling transport and communication between them.
- **capsid**: The outer protein shell of a virus.

A DNA virus is a virus with DNA as its genetic material and replicates using a DNA-dependent DNA polymerase. DNA viruses belong to either Group I (double-stranded DNA; dsDNA) or Group II (single-stranded DNA; ssDNA) of the Baltimore classification system for viruses. Single-stranded DNA is usually expanded to double-stranded in infected cells.

DNA viruses are relatively rare in plants. Seventeen percent of plant viruses are ssDNA, while dsDNA viruses infect only lower plants, such as eukaryotic algae. The rarity of dsDNA plant viruses is notable when compared to other taxonomic kingdoms; a quarter of animal viruses and three quarters of bacterial viruses are dsDNA.

Plant viruses are transmitted through a variety of different methods, and generally require breach of protective barriers. Viruses can be spread by direct transfer of sap by contact of a wounded plant with a healthy one, most commonly resulting from agricultural practices, as by damage caused by tools or hands. More often, viruses are spread through vector intermediaries such as insects, nematodes, or protozoa which pick up viruses by feeding on infected plants, and then spread the virus to healthy plants.

Viral transmission from generation to generation occurs in about 20% of plant viruses. When viruses are transmitted by seeds, the seed is infected in the generative cells and the virus is maintained in the germ cells, or occasionally in the seed coat. Little is known about the mechanisms involved in the transmission of plant viruses via seeds, though environment is known to play a key role.

Single-Stranded DNA Viruses

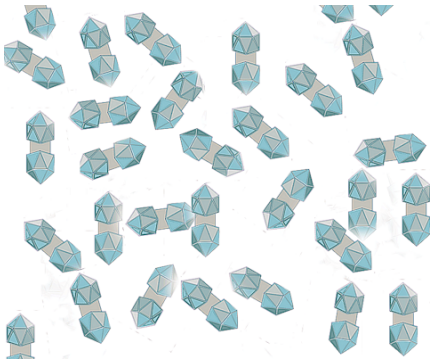

Figure: **Geminiviruses**: Drawing of geminiviruses, characterized by elongated, geminate capsids with two incomplete T=1 icosahedra joined at the missing vertex.

The *Geminiviridae* and *Nanoviridae* are the two families of ssDNA viruses known to infect plants. *Geminiviridae* is the largest known family of single-stranded DNA viruses. It contains a wide range of plant viruses including bean golden mosaic virus, beet curly top virus, maize streak virus, and tomato pseudo-curly top virus, which together are responsible for a significant amount of crop damage worldwide. The genome can either be a single component between 2500-3100 nucleotides, or, in the case of some begomoviruses, two similar-sized components each between 2600 and 2800 nucleotides. They have elongated, geminate capsids with two incomplete T=1 icosahedra joined at the missing vertex. The capsids range in size from 18-20 nm in diameter with a length of about 30 nm. Begomoviruses possess two component genomes separated into two different particles, both of which must usually be transmitted together to initiate a new infection within a suitable host cell. Like many viruses, geminivirus genomes encode only a few proteins, and are therefore dependent on host cell factors for replication. Geminiviruses replication occurs within the nucleus of an infected plant cell via a rolling circle mechanism, similar to that seen in bacteriophages, such as M13, and many plasmids. The resulting ssDNA is packaged into germinate particles in the nucleus. It is not clear if these particles can then leave the nucleus and be transmitted to surrounding cells as virions, or whether ssDNA is trafficked from cell to cell via the plasmodesmata. These viruses tend to be introduced into and initially infect differentiated plant cells, via the piercing mouthparts of the vector insect: however, these cells generally lack the host enzymes necessary for DNA replication, making it difficult for the virus to replicate. To overcome this block geminiviruses can induce plant cells to reenter the cell cycle from a quiescent state so that viral replication can occur.

The *Nanoviridae* are a family of single-stranded DNA viruses that infect plants. Their name is derived from the Greek word ‘nano’ (dwarf) because of their small genome and their stunting effect on infected plants.

Figure: **Maize Streak Virus**: The black-faced leafhopper (Graminella nigrifrons) transmits both maize fine streak virus and maize chlorotic dwarf virus.

Virions of this family have a capsid and are non-enveloped. The capsid is icosahedral with diameter of 18-20 nm. The genome is composed of 6 to 11 segments of single-stranded circular DNA each ~1 kb in length, with the exact number of segments varying depending on the genus. The segments each encode a single protein. There is a putative stem loop structure in the non-coding region of each segment which has a conserved 9-nucleotide sequence at its apex. Each member has up to 4 segments encoding replication proteins of ~33 kDa. The other segments encode products of 10-20 kDa in size and include a coat protein of ~19 kDa and a protein with a retinoblastoma binding motif.

Double-Stranded DNA Viruses

Double-stranded DNA viruses of plants are rare, and only infect lower plants, such as algae. These viruses (family *Phycodnaviridae*) are huge dsDNA viruses with genomes ranging from 160 to 560 kb with up to 600 protein-encoding genes, making them distinctly different from viruses infecting higher plants. They are found in aqueous environments throughout the world and play dynamic, albeit largely undocumented, roles in regulating algal communities such as the termination of massive algal blooms commonly referred to as red and brown tides.

This page titled 9.11A: Plant DNA Viruses is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

9.11B: Replication of Double-Stranded DNA Viruses of Animals

Most double-stranded DNA viruses replicate within the host cell nucleus.

Learning Objectives

- Differentiate the ways which different classes of dsDNA viruses replicate

Key Points

- From the perspective of the virus, the purpose of viral replication is to allow production and survival of its kind.
- Most double-stranded DNA viruses replicate within the host cell nucleus, including polyomaviruses, adenoviruses, and herpesviruses—poxviruses, however, replicate in the cytoplasm.
- Adenoviruses and herpes viruses encode their own replication factors.

Key Terms

- **Okazaki fragments**: Okazaki fragments are short, newly synthesized DNA fragments that are formed on the lagging template strand during DNA replication.
- **polymerase**: Any of various enzymes that catalyze the formation of polymers of DNA or RNA using an existing strand of DNA or RNA as a template.

Viral replication is the formation of biological viruses during the infection process in the target host cells. Viruses must first get into the cell before viral replication can occur. From the perspective of the virus, the purpose of viral replication is to allow production and survival of its kind. By generating abundant copies of its genome and packaging these copies into viruses, the virus is able to continue infecting new hosts. Replication between viruses is greatly varied and depends on the type of genes involved in them. Most DNA viruses assemble in the nucleus while most RNA viruses develop solely in cytoplasm.

Double-stranded DNA viruses usually must enter the host nucleus before they are able to replicate. Some of these viruses require host cell polymerases to replicate their genome, while others, such as adenoviruses or herpes viruses, encode their own replication factors. However, in either cases, replication of the viral genome is highly dependent on a cellular state permissive to DNA replication and, thus, on the cell cycle. The virus may induce the cell to forcefully undergo cell division, which may lead to transformation of the cell and, ultimately, cancer. An example of a family within this classification is the Adenoviridae.

Polyomaviruses, adenoviruses, and herpesviruses are all nuclear-replicating DNA viruses, each with their own specific approaches to replication. There is only one well-studied example in which a double-stranded DNA virus does not replicate within the nucleus. This is the Poxvirus family, which comprises highly pathogenic viruses that infect vertebrates.

Polyomaviruses

Polyomaviridae is a family of viruses whose natural hosts are primarily mammals and birds. Most of these viruses, such as BK virus and JC virus, are very common and typically asymptomatic in most human populations studied. However, some polyomaviruses are associated with human disease, particularly in immunocompromised individuals. Some members of the family are oncoviruses, meaning they can cause tumors; they often persist as latent infections in a host without causing disease, but may produce tumors in a host of a different species, or in individuals with ineffective immune systems. The name polyoma refers to the viruses' ability to produce multiple (poly-) tumors (-oma).

Replication

Prior to genome replication, the processes of viral attachment, entry and uncoating occur. Polyomavirus virions are subsequently endocytosed and transported first to the endoplasmic reticulum where a conformational change occurs; then by an unknown mechanism the virus is exported to the nucleus. Polyomaviruses replicate in the nucleus of the host.

Adenoviruses

Adenoviruses (members of the family Adenoviridae) are medium-sized (90–100 nm), nonenveloped (without an outer lipid bilayer) viruses with an icosahedral nucleocapsid containing a double stranded DNA genome.

Adenoviruses represent the largest nonenveloped viruses. They are able to be transported through the endosome (i.e., envelope fusion is not necessary). The virion also has a unique "spike" or fiber associated with each penton base of the capsid that aids in

attachment to the host cell via the receptor on the surface of the host cell.

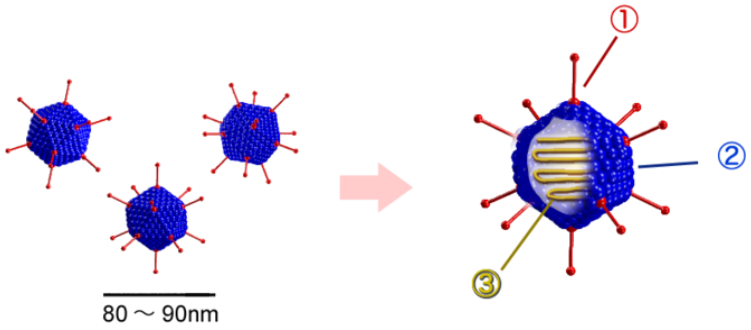

Figure: **Adenovirus structure**: Adenoviruses are non-enveloped (i.e., they have no external lipid bilayer) and are icosahedral (i.e., shaped like a polyhedron with 20 faces). They have fibers at their vertices that help them attach to host cells.

Replication

Adenoviruses possess a linear dsDNA genome and are able to replicate in the nucleus of vertebrate cells using the host's replication machinery.

Once the virus has successfully gained entry into the host cell, the endosome acidifies, which alters virus topology by causing capsid components to disband, which in turn destroys the endosome and allows the virion entry into the cytoplasm. It is transported to the nuclear pore, disassembles, and is released into the nucleus. At this point viral gene expression can occur and new virus particles can be generated.

Herpesviruses

Herpesviridae is a large family of DNA viruses that cause diseases in animals, including humans. The members of this family are also known as herpesviruses. The family name is derived from the Greek word herpein ("to creep"), referring to the latent, recurring infections typical of this group of viruses. Herpesviridae can cause latent or lytic infections.

At least five species of Herpesviridae – HSV-1 and HSV-2 (both of which can cause orolabial herpes and genital herpes), Varicella zoster virus (which causes chicken-pox and shingles), Epstein-Barr virus (which causes mononucleosis), and Cytomegalovirus – are extremely widespread among humans. More than 90% of adults have been infected with at least one of these, and a latent form of the virus remains in most people. In total, there are 8 herpesvirus types that infect humans: herpes simplex viruses 1 and 2, varicella-zoster virus, EBV (Epstein-Barr virus), human cytomegalovirus, human herpesvirus 6, human herpesvirus 7, and Kaposi's sarcoma-associated herpesvirus. There are more than 130 herpesviruses, and some are from mammals, birds, fish, reptiles, amphibians, and molluscs.

Replication

All herpesviruses are nuclear-replicating—the viral DNA is transcribed to mRNA within the infected cell's nucleus. Infection is initiated when a viral particle contacts a cell with specific types of receptor molecules on the cell surface. Following binding of viral envelope glycoproteins to cell membrane receptors, the virion is internalized and dismantled, allowing viral DNA to migrate to the cell nucleus. Within the nucleus, replication of viral DNA and transcription of viral genes occurs.

Poxviruses

Poxviridae is a family of viruses. Human, vertebrates, and arthropods serve as natural hosts. There are currently 69 species in this family, divided among 28 genera, which are divided into two subfamilies. Diseases associated with this family include smallpox.

Poxviridae viral particles (virions) are generally enveloped (external enveloped virion- EEV), though the intracellular mature virion (IMV) form of the virus, which contains different envelope, is also infectious. The virion is exceptionally large—around 200 nm in diameter and 300 nm in length.

Replication

The replication of poxvirus is unusual for a virus with double-stranded DNA genome (dsDNA) because it occurs in the cytoplasm, although this is typical of other large DNA viruses. Poxvirus encodes its own machinery for genome transcription, a DNA dependent RNA polymerase, which makes replication in the cytoplasm possible. Most dsDNA viruses require the host cell's DNA-dependent RNA polymerase to perform transcription. These host DNA are found in the nucleus, and therefore most dsDNA viruses carry out a part of their infection cycle within the host cell's nucleus.

9.11C: Double-Stranded DNA Viruses - Herpesviruses

Herpes viruses cause a wide range of latent, recurring infections including oral and genital herpes, cytomegalovirus, and chicken pox.

Learning Objectives

- Recognize the attributes of herpes viruses

Key Points

- Herpesviridae is a large family of DNA viruses that cause diseases in animals, including humans.
- The structure of herpes viruses consists of a relatively large double-stranded, linear DNA genome encased within an icosahedral protein cage called the capsid, which is wrapped in a lipid bilayer called the envelope.
- Notable herpes viruses include herpes simplex viruses 1 and 2, Varicella zoster virus (the causative agent of shingles and chicken pox), cytomegalovirus, and Kaposi's sarcoma virus.
- There is no method to eradicate herpes virus from the body, but antiviral medications, such as acyclovir, can reduce the frequency, duration, and severity of outbreaks.

Key Terms

- **tegument**: A natural covering of the body or of a bodily organ.
- **capsid**: The outer protein shell of a virus.
- **virion**: A single individual particle of a virus (the viral equivalent of a cell).

Herpesviridae is a large family of DNA viruses that cause diseases in animals, including humans. The members of this family are also known as herpes viruses. The family name is derived from the Greek word *herpein* ("to creep"), referring to the latent, recurring infections typical of this group of viruses.

Animal herpes viruses all share some common properties. The structure of these viruses consists of a relatively large double-stranded, linear DNA genome encased within an icosahedral protein cage called the capsid, which is wrapped in a lipid bilayer called the envelope. The envelope is joined to the capsid by means of a tegument. This complete particle is known as the virion. HSV-1 and HSV-2 each contain at least 74 genes within their genomes, although speculation over gene crowding allows as many as 84 unique protein-coding genes by 94 putative pen reading frames. These genes encode a variety of proteins involved in forming the capsid, tegument and envelope of the virus, as well as controlling the replication and infectivity of the virus.

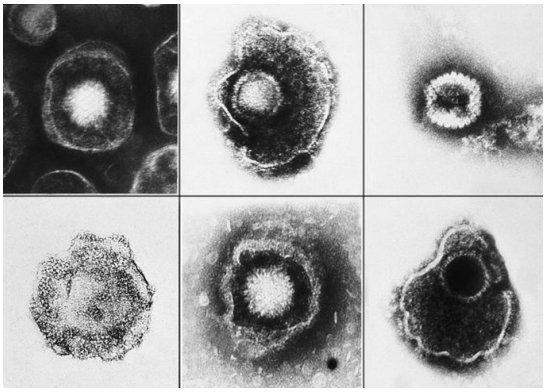

Figure: **Herpesviridae**: Various viruses from the Herpesviridae family seen using an electron micrograph Amongst these members is varicella-zoster (Chickenpox), and herpes simplex type 1 and 2 (HSV-1, HSV-2).

Types of herpes viruses

There are nine distinct herpes viruses which cause disease in humans:

- HHV-1 Herpes simplex virus-1 (HSV-1)
- HHV-2 Herpes simplex virus-2 (HSV-2)
- HHV-3 Varicella zoster virus (VZV)
- HHV-4 Epstein-Barr virus (EBV)

- HHV-5 Cytomegalovirus (CMV)
- HHV-6A/B Roseolovirus, Herpes lymphotropic virus
- HHV-7 Pityriasis Rosea
- HHV-8 Kaposi's sarcoma-associated herpesvirus

Of particular interest include HSV-1 and HSV-2, which cause oral and/or genital herpes, HSV-3 which causes chickenpox and shingles, and HHV-5 which causes mononucleosis-like symptoms, and HHV-8 which causes a Kaposi's sarcoma, a cancer of the lymphatic epithelium.

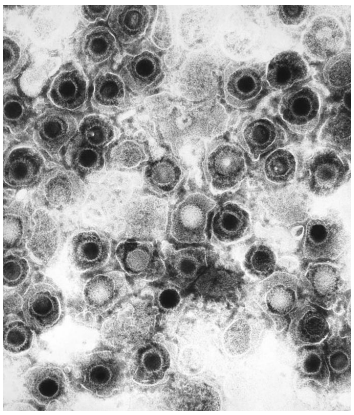

Figure: **Herpes Simplex Virions**: This negatively-stained transmission electron micrograph (TEM) revealed the presence of numerous herpes simplex virions, members of the Herpesviridae family. There are two strains of the herpes simplex virus, HSV-1, which is responsible for cold sores, and HSV-2, which is responsible for genital herpes. At the core of its icosahedral proteinaceous capsid, the HSV contains a double-stranded DNA linear genome.

Infection is caused through close contact with an infected individual. Infection is initiated when a viral particle comes in contact with the target cell specific to the individual herpes virus. Viral glycoproteins bind cell surface receptors molecules on the cell surface, followed by virion internalization and disassembly. Viral DNA then migrates to the cell nucleus where replication of viral DNA and transcription of viral genes occurs.

During symptomatic infection, infected cells transcribe lytic viral genes. In some host cells, a small number of viral genes termed *latency-associated transcripts* accumulate instead. In this fashion, the virus can persist in the cell (and thus the host) indefinitely. While primary infection is often accompanied by a self-limited period of clinical illness, long-term latency is symptom-free.

Reactivation of latent viruses

This has been implicated in a number of diseases (e.g. Shingles, Pityriasis Rosea). Following activation, transcription of viral genes transitions from latency-associated transcripts to multiple lytic genes; these lead to enhanced replication and virus production. Often, lytic activation leads to cell death. Clinically, lytic activation is often accompanied by emergence of non-specific symptoms such as low grade fever, headache, sore throat, malaise, and rash, as well as clinical signs such as swollen or tender lymph nodes, and immunological findings such as reduced levels of natural killer cells.

There is no method to eradicate the herpes virus from the body, but antiviral medications, such as *acyclovir*, can reduce the frequency, duration, and severity of outbreaks. Analgesics such as *ibuprofen* and *acetaminophen* can reduce pain and fever. Topical anesthetic treatments such as *prilocaine*, *lidocaine*, *benzocaine* or *tetracaine* can also relieve itching and pain.

9.11E: Attachment and Entry of Herpes Simplex

Herpes simplex virus attaches to a host's cells with viral envelope glycoproteins, which then allows entry of the viral capsid into the host cell.

Learning Objectives

- Illustrate HSV attachment to host cells

Key Points

- The genome encodes for 11 different glycoproteins, four of which, gB, gC, gD and gH, are involved in viral attachment.
- The sequential stages of HSV entry are analogous to those of other viruses.
- First, complementary viral and cell surface receptors bring the viral and host cell membranes into close proximity. Next, the two membranes begin to merge, forming a hemifusion state. Finally, a stable entry pore is formed through which the viral envelope contents are introduced to the host cell.

Key Terms

- **glycoprotein**: A protein with covalently bonded carbohydrates.
- **hemifusion**: Partial fusion, or the first stage in full fusion.
- **heparan sulfate**: A polysaccharide found, associated with protein, in all animal tissue; it has a regulatory function in several biological activities.

Herpes simplex viruses 1 and 2 (HSV-1 and HSV-2) are two members of the herpes virus family, *Herpesviridae*, that infect humans. Both HSV-1 (which produces most cold sores) and HSV-2 (which produces most genital herpes) are ubiquitous and contagious. They can be spread when an infected person is producing and shedding the virus.

The sequential stages of HSV entry are analogous to those of other viruses. At first, complementary receptors on the virus and the cell surface bring the viral and cell membranes into close proximity. In an intermediate state, the two membranes begin to merge, forming a hemifusion state. Finally, a stable entry pore is formed through which the viral envelope contents are introduced to the host cell.

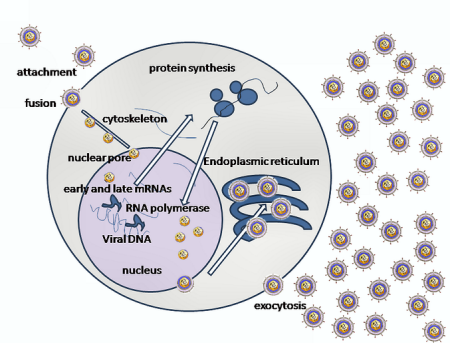

Figure: **Virus replication**: Herpes simplex virus attaches to host cell surface receptors using glycoproteins. Following attachment, the viral envelope fuses with the host cell membrane and the viral capsid gains entry into the cell.

The genome encodes for 11 different glycoproteins, four of which, gB, gC, gD and gH, are involved in viral attachment. Initial interactions occur when viral envelope glycoprotein C (gC) binds to a cell surface particle called heparan sulfate. A second glycoprotein, glycoprotein D (gD), binds specifically to at least one of three known entry receptors. These include herpesvirus entry mediator (HVEM), nectin-1 and 3-O sulfated heparan sulfate. The receptor provides a strong, fixed attachment to the host cell. These interactions bring the membrane surfaces into mutual proximity and allow for other glycoproteins embedded in the viral envelope to interact with other cell surface molecules. Once bound to the HVEM, gD changes its conformation and interacts with viral glycoproteins H (gH) and L (gL), which form a complex. The interaction of these membrane proteins results in the hemifusion state. Afterward, gB interaction with the gH/gL complex creates an entry pore for the viral capsid. Glycoprotein B interacts with glycosaminoglycans on the surface of the host cell.

This page titled 9.11E: Attachment and Entry of Herpes Simplex is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

9.11E: Replication of Herpes Simplex Virus

Interferons play pivotal roles in shaping the immune responses in mammals.

Learning Objectives

- List the treatments we have to combat viruses

Key Points

- Vaccines prime the body's immune system against specific pathogens, but are not effective for treating an infection.
- Many animal viruses are also important from a human medical perspective. The emergence of the SARS virus in the human population, coming from an animal source, highlights the importance of animals in bearing infectious agents. Avian influenza viruses can directly infect humans.
- Immune therapy using immunomodulatory factors, such as interferons, is effective for treatment of hepatitis B and C.
- Immune therapy using immunomodulatory factors, such as interferons, is effective for treatment of hepatitis B and C.

Key Terms

- **foot and mouth disease**: A highly variable and transmissible viral disease. The virus enters the body through inhalation and affects cattle worldwide.
- **interferon**: Any of a group of glycoproteins, produced by the immune system, that prevent viral replication in infected cells.

The study of animal viruses is important from a veterinary viewpoint. Many animal viruses are also important from a human medical perspective. The emergence of the SARS virus in the human population, coming from an animal source, highlights the importance of animals in bearing infectious agents. Avian influenza viruses can directly infect humans. In addition research into animal viruses has made an important contribution to our understanding of viruses in general, their replication, molecular biology, evolution, and interaction with the host.

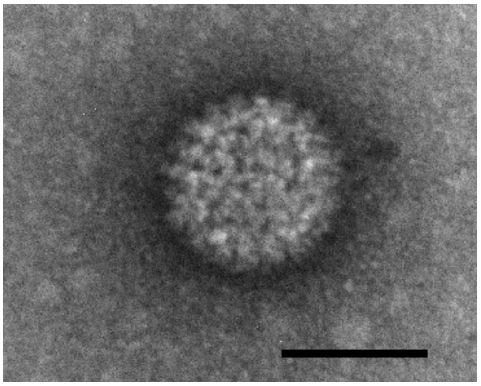

Figure: **TEM of the Bluetongue virus**: Bluetongue virus (BTV), a member of Orbivirus genus within the Reoviridae family causes serious disease in livestock (sheep, goat, cattle).

Rhabdoviruses are a diverse family of single stranded, negative sense RNA viruses that can successfully utilize a myriad of ecological niches, ranging from plants and insects, to fish and mammals. This virus family includes pathogens such as rabies virus, vesicular stomatitis virus, and potato yellow dwarf virus that are of tremendous public health, veterinary, and agricultural significance. Due to the relative simplicity of their genomes and morphology, in recent years rhabdoviruses have become powerful model systems for studying molecular virology.

Foot and mouth disease virus (FMDV) is the prototypic member of the Aphthovirus genus in the Picornaviridae family. This picornavirus is the etiological agent of an acute systemic vesicular disease that affects cattle worldwide, foot-and-mouth disease. FMDV is a highly variable and transmissible virus. It enters the body through inhalation. Soon after infection, the single stranded positive RNA that constitutes the viral genome is efficiently translated using a cap-independent mechanism driven by the internal ribosome entry site element (IRES). This process occurs concomitantly with the inhibition of cellular protein synthesis, caused by the expression of viral proteases. In depth knowledge of the molecular basis of the viral cycle is needed to control viral pathogenesis and disease spreading.

Pestiviruses account for important diseases in animals such as Classical swine fever (CSF) and Bovine viral diarrhea / Mucosal disease (BVD/MD). The molecular biology of pestiviruses shares many similarities and peculiarities with the human hepaciviruses. Genome organization and translation strategy are highly similar for the members of both genera. One hallmark of pestiviruses is their unique strategy to establish persistent infection during pregnancy.

Coronavirus (CoV) genome replication takes place in the cytoplasm in a membrane-protected microenvironment, and starts with the translation of the genome to produce the viral replicase.

The first line of defense against viral infections is usually antiviral vaccines, which prime the body's immune system against specific pathogens. Vaccines traditionally consist of an attenuated (weakened or killed) version of the virus, although many vaccines now target specific immunogenic targets unique to a particular pathogen. Both viral and cellular proteins are required for replication and transcription. CoVs initiate translation by cap-dependent and cap-independent mechanisms. Cell macromolecular synthesis may be controlled after CoV infection by locating some virus proteins in the host cell nucleus. Infection by different coronaviruses cause in the host alteration in the transcription and translation patterns, in the cell cycle, the cytoskeleton, apoptosis and coagulation pathways, inflammation, and immune and stress responses. The balance between genes up- and down-regulated could explain the pathogenesis caused by these viruses.

Antiviral drugs are a class of medication used specifically for treating viral infections. Like antibiotics for bacteria, antiviral drugs are usually specific for a particular virus. Unlike most antibiotics, antiviral drugs do not destroy their target pathogen; instead they inhibit their development.

In addition to targeting viral infections directly, some therapeutics work by enhancing the immune responses necessary for viral clearance. One of the best-known of this class of drugs are interferons, which inhibit viral synthesis in infected cells. Interferons (IFNs) play pivotal roles in shaping the immune responses in mammals and are particularly important for the control of viral infections, cell growth, and immune regulation. These proteins rapidly induce an "anti-viral state" in cells that surround infected cells. In order to survive, viruses have evolved multiple strategies to evade the anti-viral effects of IFNs. Elucidating the molecular and cellular biology of the virus-interferon interaction is key to understanding issues such as viral pathogenesis, latency, and the development of novel antivirals.

Figure: **Pediatric polio vaccination in India by a Stop Transmission of Polio (STOP) teams (2002)**: Vaccinations are the best defense against a wide range of viruses, but they are not effective in treating active infections.

9.11F: Immunodeficiency

Immunodeficiency occurs when the immune system cannot appropriately respond to infections.

Learning Objectives

- Explain the problems associated with immunodeficiency

Key Points

- If a pathogen is allowed to proliferate to certain levels, the immune system can become overwhelmed; immunodeficiency occurs when the immune system fails to respond sufficiently to a pathogen.
- Immunodeficiency can be caused by many factors, including certain pathogens, malnutrition, chemical exposure, radiation exposure, or even extreme stress.
- HIV is a virus that causes immunodeficiency by infecting helper T cells, causing cytotoxic T cells to destroy them.

Key Terms

- **phagocyte**: a cell of the immune system, such as a neutrophil, macrophage or dendritic cell, that engulfs and destroys viruses, bacteria, and waste materials
- **lysis**: the disintegration or destruction of cells
- **immunodeficiency**: a depletion in the body's natural immune system, or in some component of it

Immunodeficiency

Failures, insufficiencies, or delays at any level of the immune response can allow pathogens or tumor cells to gain a foothold to replicate or proliferate to high enough levels that the immune system becomes overwhelmed, leading to immunodeficiency; it may be acquired or inherited. Immunodeficiency can be acquired as a result of infection with certain pathogens (such as HIV), chemical exposure (including certain medical treatments), malnutrition, or, possibly, by extreme stress. For instance, radiation exposure can destroy populations of lymphocytes, elevating an individual's susceptibility to infections and cancer. Dozens of genetic disorders result in immunodeficiencies, including Severe Combined Immunodeficiency (SCID), bare lymphocyte syndrome, and MHC II deficiencies. Rarely, primary immunodeficiencies that are present from birth may occur. Neutropenia is one form in which the immune system produces a below-average number of neutrophils, the body's most abundant phagocytes. As a result, bacterial infections may go unrestricted in the blood, causing serious complications.

HIV/AIDS

Human immunodeficiency virus infection / acquired immunodeficiency syndrome (HIV/AIDS), is a disease of the human immune system caused by infection with human immunodeficiency virus (HIV). During the initial infection, a person may experience a brief period of influenza-like illness. This is typically followed by a prolonged period without symptoms. As the illness progresses, it interferes more and more with the immune system. The person has a high probability of becoming infected, including from opportunistic infections and tumors that do not usually affect people who have working immune systems.

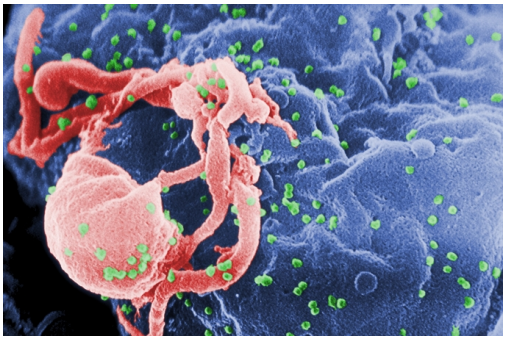

Figure: **Image of HIV: scanning electron micrograph of HIV-1 budding (in green, color added) from cultured lymphocyte**: Multiple round bumps on cell surface represent sites of assembly and budding of HIV. During primary infection, the level of HIV may reach several million virus particles per milliliter of blood.

After the virus enters the body, there is a period of rapid viral replication, leading to an abundance of virus in the peripheral blood. During primary infection, the level of HIV may reach several million virus particles per milliliter of blood. This response is accompanied by a marked drop in the number of circulating CD4+ T cells, cells that are or will become helper T cells. The acute viremia, or spreading of the virus, is almost invariably associated with activation of CD8+ T cells (which kill HIV-infected cells) and, subsequently, with antibody production. The CD8+ T cell response is thought to be important in controlling virus levels, which peak and then decline, as the CD4+ T cell counts recover.

Ultimately, HIV causes AIDS by depleting CD4+ T cells (helper T cells). This weakens the immune system, allowing opportunistic infections. T cells are essential to the immune response; without them, the body cannot fight infections or kill cancerous cells. The mechanism of CD4+ T cell depletion differs in the acute and chronic phases. During the acute phase, HIV-induced cell lysis and killing of infected cells by cytotoxic T cells accounts for CD4+ T cell depletion, although apoptosis (programmed cell death) may also be a factor. During the chronic phase, the consequences of generalized immune activation coupled with the gradual loss of the ability of the immune system to generate new T cells appear to account for the slow decline in CD4+ T cell numbers.

11.10A: Clonal Selection and Tolerance

Clonal selection and tolerance select for survival of lymphocytes that will protect the host from foreign antigens.

Learning Objectives

- Describe the importance of central and peripheral tolerance and distinguish between positive and negative clonal selection

Key Points

- Clonal selection occurs after immature lymphocytes express antigen receptors.
- Central tolerance is the mechanism by which newly developing T cells and B cells are rendered non-reactive to self.
- Both developing B cells and T cells are subject to negative selection during a short period after antigen receptors are expressed.
- If, during embryonic development, it encounters its programmed antigen as part of a normal host substance (self), the lymphocyte is somehow destroyed or inactivated. This mechanism removes lymphocytes that can destroy host tissues and thereby creates tolerance for self.

Key Terms

- **lymphocyte**: A type of white blood cell or leukocyte that is divided into two principal groups and a null group: B-lymphocytes, which produce antibodies in the humoral immune response, T-lymphocytes, which participate in the cell-mediated immune response, and the null group, which contains natural killer cells, cytotoxic cells that participate in the innate immune response.
- **antigens**: In immunology, an antigen is a substance that evokes the production of one or more antibodies.
- **T cells**: A lymphocyte, from the thymus, that can recognise specific antigens and can activate or deactivate other immune cells.

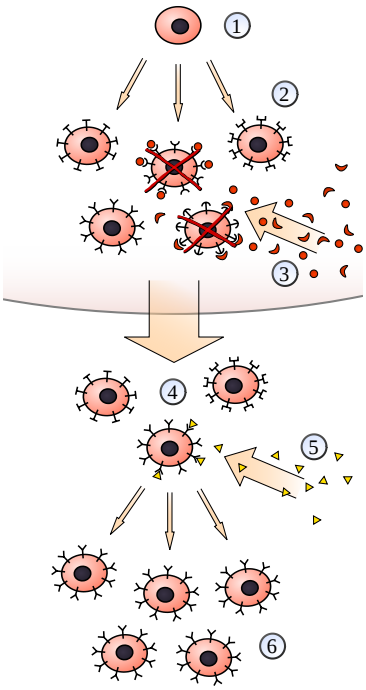

Figure: **Clonal Selection**: clonal selection of the B and T lymphocytes:1. Hematopoietic stem cell 2. Immature lymphocytes with various receptors 3. “Self”-antigens from the body’s own tissues 4. Mature, inactive lymphocytes 5. Foreign antigen 6. Cloned activated lymphocytes.

Central tolerance is the mechanism by which newly developing T cells and B cells are rendered non-reactive to self. The concept of central tolerance was proposed in 1959 as part of a general theory of immunity and tolerance. It was hypothesized that it is the age of the lymphocyte that defines whether an antigen that is encountered will induce tolerance, with immature lymphocytes being tolerance sensitive. The theory that self-tolerance is ‘learned’ during lymphocyte development was a major conceptual contribution to immunology. It was experimentally substantiated in the late 1980’s when tools to analyze lymphocyte development became

available. Central tolerance is distinct from periphery tolerance in that it occurs while cells are still present in the primary lymphoid organs (thymus and bone-marrow), prior to export into the periphery. Peripheral tolerance is generated after the cells reach the periphery. Regulatory T cells can be considered both central tolerance and peripheral tolerance mechanisms, as they can be generated from self (or foreign)-reactive T cells in the thymus during T cell differentiation. However, they exert their immune suppression in the periphery on other self (or foreign)-reactive T cells.

Clonal selection occurs after immature lymphocytes express antigen receptors. The cells with useful receptors are preserved, and many potentially harmful, self antigen-reactive cells are eliminated by processes of selection induced by antigen receptor engagement. The preservation of useful specificities is called positive selection. Positive selection ensures maturation of T cells whose receptors bind weakly to self major histocompatibility complex molecules. Negative selection is the process that eliminates developing lymphocytes whose antigen receptors bind strongly to self antigens present in the lymphoid organs. Both developing B cells and T cells are subject to negative selection during a short period after antigen receptors are expressed. Negative selection of developing lymphocytes is an important mechanism for maintaining central tolerance.

9.11G: Double-Stranded DNA Viruses - Pox Viruses

The poxviruses are a family of large, complex, enveloped DNA viruses that infect a variety of vertebrate and invertebrate hosts.

Learning Objectives

- Examine pox viruses for their relevance to human disease and research

Key Points

- The most famous of the poxviruses was smallpox. Smallpox is one of two infectious diseases to have been eradicated, the other being rinderpest, which was declared eradicated in 2011.
- The most abundant and simplest infectious form of the poxvirus particle, the mature virion, consists of the viral DNA genome encased in a proteinaceous core and an outer lipoprotein membrane.
- Poxviruses exhibit a temporally-regulated gene expression program: early, intermediate, and late genes drive DNA replication followed by expression of structural proteins necessary for progeny virion assembly.

Key Terms

- **recombinant**: This term refers to something formed by combining existing elements in a new combination. Thus, the phrase recombinant DNA refers to an organism created in the lab by adding DNA from another species.
- **lipoprotein**: Any of a large group of complexes of protein and lipid with many biochemical functions.

The poxviruses are a family of large, complex, enveloped DNA viruses that infect a variety of vertebrate and invertebrate hosts. Poxviruses are of significance both medically and scientifically due to their wide distribution, pathogenicity, and cytoplasmic replicative life cycle. Several prominent members, including variola virus (causative agent of smallpox), molluscum contagiosum virus (cause of a common skin infection of young children and immunosuppressed adults) and monkeypox virus (agent of a smallpox-like disease in parts of Africa), are of considerable concern for public health and biodefense.

The most famous of the poxviruses was smallpox. Smallpox was an infectious disease unique to humans, caused by either of two virus variants, Variola major and Variola minor. The disease is also known by the Latin names Variola or Variola vera, which is a derivative of the Latin varius, meaning “spotted,” or varus, meaning “pimple. ” The term “smallpox” was first used in Britain in the 15th century to distinguish variola from the “great pox” (syphilis). The last naturally occurring case of smallpox (Variola minor) was diagnosed on October 26, 1977. After vaccination campaigns throughout the 19th and 20thcenturies, the World Health Organization (WHO) certified the eradication of smallpox in 1979. Smallpox is one of two infectious diseases to have been eradicated, the other being rinderpest, which was declared eradicated in 2011.

The prototypic and most studied poxvirus, vaccinia virus (VACV), serves as an effective smallpox vaccine, a platform for recombinant vaccines against other pathogens, and an efficient gene expression vector for basic research. Along its approximate 195-kbp double-stranded DNA genome, VACV encodes approximately 200 proteins, ranging in function from viral RNA and DNA synthesis and virion assembly to modulation of host immune defenses.

The most abundant and simplest infectious form of the poxvirus particle, the mature virion (MV), consists of the viral DNA genome encased in a proteinaceous core and an outer lipoprotein membrane with approximately 60 and 25 associated viral proteins, respectively. Following attachment to cell surfaces and fusion with the plasma or endosomal membrane, poxvirus replication is initiated by entry of the viral core into the cytoplasm, where all subsequent steps of the life cycle take place. Poxvirus cores harbor the viral DNA-dependent RNA polymerase and transcription factors necessary for expression of early genes, which constitute nearly half of the viral genome and encode proteins needed for DNA replication and intermediate gene transcription, as well as a large number of immunomodulators.

Poxviruses exhibit a temporally-regulated gene expression program, i.e., expression of early genes encoding DNA replication and intermediate transcription factors triggers the expression of intermediate genes encoding late gene specific transcription factors. Late gene products primarily consist of structural proteins needed for progeny virion assembly, as well as those enzymes destined for incorporation into progeny virions, and used for early gene expression during the next round of infection. Assembly of the MV involves more than 80 viral gene products. In addition, during transit through the cytoplasm, a subset of progeny MVs acquires two additional membrane bilayers, one of which is lost during exocytosis of the particle, to yield the less abundant enveloped virion (EV). Thus, an EV is essentially an MV with an additional membrane in which at least six unique proteins are associated. EVs are

antigenically distinct from MVs and are important for efficient virus dissemination in the infected host and protection against immune defenses. In contrast, MVs are released upon cell lysis and may be important for animal-to-animal transmission.

Figure: **Girl infected with smallpox. Bangladesh, 1973.**: In ordinary type smallpox the bumps are filled with a thick, opaque fluid and often have a depression or dimple in the center. This is a major distinguishing characteristic of smallpox.

9.11H: Double-Stranded DNA Viruses- Adenoviruses

Learning Objectives

- Define the characteristics of adenoviruses

Adenoviruses are medium-sized (90–100 nm), non-enveloped, icosahedral viruses composed of a nucleocapsid and a linear, double-stranded DNA (dsDNA) genome. There are 57 described serotypes in humans, which are responsible for 5–10% of upper respiratory infections in children, and many infections in adults as well.

Diversity

Viruses of the family *Adenoviridae* infect vertebrates, including humans. Among human-tropic viruses classification can be complex; there are 57 accepted human adenovirus types (HAdV-1 to 57) in seven species (Human adenovirus A to G). Different species/serotypes are associated with different conditions:

- respiratory disease (mainly species HAdV-B and C)
- conjunctivitis (HAdV-B and D)
- gastroenteritis (HAdV-F types 40, 41, HAdV-G type 52)

In addition to human viruses, *Adenoviridae* can be divided into five genera: *Mastadenovirus*, *Aviadenovirus*, *Atadenovirus*, *Siadenovirus*, and *Ichtadenovirus*.

Genome

Structurally, adenoviruses represent the largest non-enveloped viruses. They possess non-segmented dsDNA genomes between 26 and 45 Kbp, significantly larger than other dsDNA viruses. The virion also has unique “spike” or fiber associated with each penton base of the capsid that aids in attachment to the host cell via host cell surface receptors.

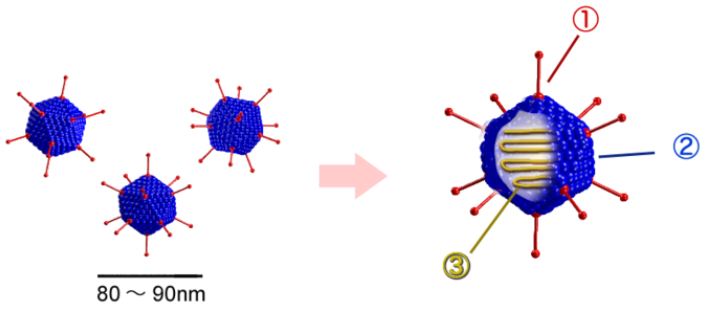

Figure: **Adenovirus Structure**: 1) Penton capsomeres 2) Hexon capsomeres 3) Viral genome (linear dsDNA)

Viral Entry and Replication

Entry of adenoviruses into the host cell involves two sets of interactions between the virus and the host cell. First, entry into the host cell is initiated by the knob domain of the fiber protein binding to a host cell receptor, either CD46 for the group B human adenovirus serotypes, or the coxsackievirus adenovirus receptor for all other serotypes. Next, a specialized motif in the penton base protein interacts with αv integrin, stimulating internalization of the adenovirus via clathrin-coated pits, resulting in entry of the virion into the host cell within an endosome.

Following internalization, the endosome acidifies, which alters virus topology, causing capsid components to disassociate. These changes, as well as the toxic nature of the pentons, result in the release of the virion into the cytoplasm. With the help of cellular microtubules, the virus is transported to the nuclear pore complex, where viral gene expression can occur.

The adenovirus life cycle is separated by the DNA replication process into two phases: an early and a late phase. In both, a primary transcript that is alternatively spliced to generate monocistronic mRNAs compatible with the host’s ribosome is generated, allowing for the products to be translated.

The early genes are responsible for expressing mainly non-structural, regulatory proteins. The goal of these proteins is threefold: to alter the expression of host proteins necessary for DNA synthesis; to activate other viral genes (such as the virus-encoded DNA polymerase); and to avoid premature death of the infected cell by the host-immune defenses (blockage of apoptosis, blockage of interferon activity, and blockage of MHC class I translocation and expression).

The late phase of the adenovirus lifecycle is focused on producing sufficient quantities of structural protein to pack all the genetic material produced by DNA replication. Once the viral components have successfully been replicated, the virus is assembled into its protein shells and released from the cell as a result of virally induced cell lysis.

Transmission

Adenoviruses are unusually stable to chemical or physical agents and adverse pH conditions, allowing for prolonged survival outside of the body and water. Adenoviruses are spread primarily via respiratory droplets; however, they can also be spread by fecal routes.

Humans infected with adenoviruses display a wide range of responses, from no symptoms at all to the severe infections typical of Adenovirus serotype 14. In the past, U.S. military recruits were vaccinated against two serotypes of adenoviruses, with a corresponding decrease in illnesses caused by those serotypes. Although the vaccine is no longer manufactured for civilians, military personnel can receive the vaccine as of 2014.

Infections

Viral transmission occurs primarily through expectorate, but can also be transmitted via contact with infected objects. Most adenovirus infections affect the upper respiratory tract. These often show up as conjunctivitis, tonsillitis, ear infection, or croup. Adenoviruses, types 40 and 41 can also cause gastroenteritis. A combination of conjunctivitis and tonsillitis is particularly common with adenovirus infections. Some children (especially small ones) can develop adenovirus bronchiolitis or pneumonia, both of which can be severe.

Utilization in Treatment of Unrelated Diseases

Adenovirus is used as a vehicle to administer targeted therapy in the form of recombinant DNA or protein. Specific modifications on fiber proteins are used to target Adenovirus to certain cell types; a major effort is made to limit hepatotoxicity and prevent multiple organ failure. Adenovirus dodecahedron serves as a potent delivery platform for foreign antigens to human myeloid dendritic cells (MDC), and is efficiently presented by MDC to M1-specific CD8+ T lymphocytes.

Key Points

- Adenoviruses are medium-sized (90–100 nm), non-enveloped, icosahedral viruses composed of a nucleocapsid and a linear double-stranded DNA (dsDNA) genome.
- There are 57 described serotypes in humans, which are responsible for 5–10% of upper respiratory infections in children, and many infections in adults as well.
- Adenoviruses bind cell surface receptors on host cells, resulting in entry of the virion into the host cell within an endosome.
- The adenovirus life cycle is separated by the DNA replication process into two phases: an early and a late phase. Early genes are responsible for expressing mainly non-structural, regulatory proteins, while late genes produce structural protein necessary for viral replication.

Key Terms

- **endosome**: An endocytic vacuole through which molecules are internalized during endocytosis pass, en route to lysosomes.
- **recombinant DNA**: DNA that has been engineered by splicing together fragments of DNA from multiple species and introduced into the cells of a host.
- **integrin**: Any of many heterodimeric transmembrane proteins that function as receptors in communication between cells.
- **penton**: A pentagonal capsomere of an adenovirus capsid.
- **capsid**: A capsid is the protein shell of a virus.

This page titled 9.11H: Double-Stranded DNA Viruses- Adenoviruses is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

9.11I: Retroviruses and Hepadnavirus

Hepadnaviruses, retroviruses, use virally encoded reverse transcriptase to convert RNA into DNA.

Learning Objectives

- Differentiate between retroviruses and hepadnaviruses

Key Points

- Retrovirus RNA serves as a template for reverse transcriptase and is copied into DNA.
- Hepadnaviruses are a family of viruses which can cause liver infections in humans and animals.

Key Terms

- **endogenous**: produced, originating or growing from within
- **episome**: A segment of DNA that can exist and replicate either autonomously in the cytoplasm or as part of achromosome, mainly found in bacteria.

A well-studied family of this class of viruses includes the retroviruses. One defining feature is the use of reverse transcriptase to convert the positive-sense RNA into DNA. Instead of using the RNA for templates of proteins, they use DNA to create the templates, which is spliced into the host genome using integrase. Replication can then commence with the help of the host cell's polymerases. A well-studied example of this includes HIV.

A special variant of retroviruses are endogenous retroviruses, which are integrated into the genome of the host and inherited across generations.

The virus itself stores its nucleic acid in the form of a +mRNA (including the 5'cap and 3'PolyA inside the virion) genome. This then serves as a means of delivery of that genome into cells it targets as an obligate parasite, and constitutes the infection. Once in the host's cell, the RNA strands undergo reverse transcription in the cytoplasm and are integrated into the host's genome, at which point the retroviral DNA is referred to as a provirus. It is difficult to detect the virus until it has infected the host.

In most viruses, DNA is transcribed into RNA, and then RNA is translated into protein. However, retroviruses function differently – their RNA is reverse-transcribed into DNA, which is integrated into the host cell's genome (when it becomes a provirus), and then undergoes the usual transcription and translational processes to express the genes carried by the virus. So, the information contained in a retroviral gene is used to generate the corresponding protein via the sequence: RNA → DNA → RNA → protein. This extends the fundamental process identified by Francis Crick, in which the sequence is: DNA → RNA → protein. Retroviruses are proving to be valuable research tools in molecular biology and have been used successfully in gene delivery systems.

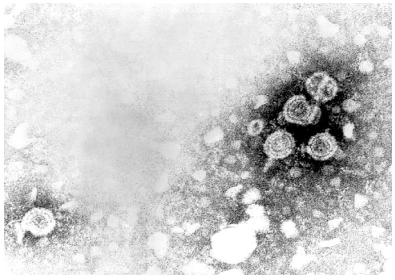

Figure: **Hepatitis B Virus**: TEM micrograph showing hepatitis B virions.

Hepadnaviruses are a family of viruses which can cause liver infections in humans and animals. There are two recognized genera:

- Genus *Orthohepadnavirus* ; type species: *Hepatitis B virus*
- Genus *Avihepadnavirus* ; type species: *Duck hepatitis B virus*

Hepadnaviruses have very small genomes of partially double-stranded, partially single stranded circular DNA. The genome consists of two uneven strands of DNA. One has a negative-sense orientation, and the other, shorter, strand has a positive-sense orientation.Hepadnaviruses replicate through an RNA intermediate (which they transcribe back into cDNA using reverse transcriptase). The reverse transcriptase becomes covalently linked to a short 3- or 4-nucleotide primer. Most hepadnaviruses will only replicate in specific hosts, and this makes experiments using in vitro methods very difficult.

HBV infection is initiated through viral attachment to an unknown cell surface receptor. The virally encoded DNA polymerase acts upon the DNA, leaving it fully double-stranded.

SECTION OVERVIEW

9. 12: Viruses and Cancer

Topic hierarchy

9.12A: Cancer Viruses

9.12B: DNA Oncogenic Viruses

9.12C: RNA Oncogenic Viruses

This page titled 9. 12: Viruses and Cancer is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

9.12A: Cancer Viruses

Viruses can cause cancer by transforming a normal cell into a malignant cell.

Learning Objectives

- Illustrate how cancer viruses turn normal cells into tumor cells

Key Points

- A direct oncogenic viral mechanism involves either the insertion of additional viral oncogenic genes into the host cell, or the enhancement of already existing oncogenic genes in the genome.
- Tumor viruses come in a variety of forms. Viruses with a DNA genome, such as adenovirus, and viruses with an RNA genome, like the Hepatitis C virus (HCV), can cause cancers. Retroviruses having both DNA and RNA genomes (Human T-lymphotropic virus and hepatitis B virus) can also cause cancers.
- Viruses can become carcinogenic when they integrate into the host cell genome as part of a biological accident, such as polyomaviruses and papillomaviruses.

Key Terms

- **oncogenic**: Tending to cause the formation of tumors.
- **transformation**: The alteration of a bacterial cell caused by the transfer of DNA from another, especially if pathogenic.

Worldwide, cancer viruses are estimated to cause 15-20% of all cancers in humans. Most viral infections, however, do not lead to tumor formation; several factors influence the progression from viral infection to cancer development. These factors include host's genetic makeup, mutation occurrence, exposure to cancer causing agents, and immune impairment.

Viruses typically initiate cancer development by suppressing the host's immune system, causing inflammation over a long period of time, or by altering host genes. Cancer cells have characteristics that differ from normal cells, such as acquiring the ability to grow uncontrollably. This can result from having control of their own growth signals, losing sensitivity to anti-growth signals, and losing the ability to undergo apoptosis, or programmed cell death.

Cancer cells don't experience biological aging, and maintain their ability to undergo cell division and growth. Transformation occurs when a virus infects and genetically alters a cell. The infected cell is regulated by the viral genes and has the ability to undergo abnormal new growth. Scientists have been able to discern some commonality among viruses that cause tumors. The tumor viruses or oncoviruses change cells by integrating their genetic material with the host cell's DNA. Unlike the integration seen in prophages, this is a permanent insertion; the genetic material is never removed.

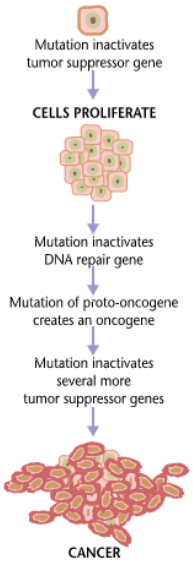

Figure: **Mutations Leading to Increased Cell Division**: Cancer is caused by a series of mutations. Viral infections contribute to the process through genetic alteration.

The insertion mechanism can differ depending on whether the nucleic acid in the virus is DNA or RNA. In DNA viruses, the genetic material can be directly inserted into the host's DNA. RNA viruses must first transcribe RNA to DNA and then insert the genetic material into the host cell's DNA.

This page titled 9.12A: Cancer Viruses is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

9.12B: DNA Oncogenic Viruses

An estimated 15 percent of all human cancers worldwide may be attributed to viruses.

Learning Objectives

- Outline DNA oncogenic viruses

Key Points

- Both DNA and RNA viruses have been shown to be capable of causing cancer in humans.
- Epstein-Barr virus, human papilloma virus, hepatitis B virus, and human herpes virus-8 are the four DNA viruses that are capable of causing the development of human cancers.
- The presence of viral gene products in tumor cells that require them to maintain their unchecked proliferation, can provide important targets for directed therapies that specifically can distinguish tumor cells from normal cells.

Key Terms

- **oncogenic**: Tending to cause the formation of tumors.

There are two classes of cancer viruses: DNA and RNA viruses. Several viruses have been linked to certain types of cancer in humans. These viruses have varying ways of reproduction and represent several different virus families.

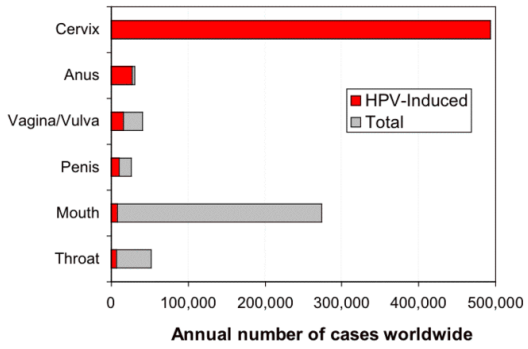

Figure: **Virus Causing Cervical Cancer**: Human papilloma virus is strongly linked to the development of cervical cancer among other types of cancers.

DNA Oncogenic Viruses include the following:

- The Epstein-Barr virus has been linked to Burkitt's lymphoma. This virus infects B cells of the immune system and epithelial cells.
- The hepatitis B virus has been linked to liver cancer in people with chronic infections.
- Human papilloma viruses have been linked to cervical cancer. They also cause warts and benign papillomas.
- Human herpes virus-8 has been linked to the development of Kaposi sarcoma. Kaposi sarcoma causes patches of abnormal tissue to develop in various area of the body including under the skin, in the lining of the mouth, nose, and throat or in other organs.

DNA tumor viruses have two life-styles. In permissive cells, all parts of the viral genome are expressed. This leads to viral replication, cell lysis and cell death. In cells that are non-permissive for replication, viral DNA is usually, but not always, integrated into the cell chromosomes at random sites. Only part of the viral genome is expressed. These are the early control functions of the virus. Viral structural proteins are not made, and no progeny virus is released.

The first DNA tumor viruses to be discovered were rabbit fibroma virus and Shope papilloma virus, both discovered by Richard Shope in the 1930s. Papillomas are benign growths, such as warts, of epithelial cells. They were discovered by making a filtered extract of a tumor from a wild rabbit and injecting the filtrate into another rabbit in which a benign papilloma grew. However, when the filtrate was injected into a domestic rabbit, the result was a carcinoma, a malignant growth. A seminal observation was that it was no longer possible to isolate infectious virus from the malignant growth because the virus had become integrated into the chromosomes of the malignant cells.

This page titled 9.12B: DNA Oncogenic Viruses is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

9.12C: RNA Oncogenic Viruses

An estimated 15% of all human cancers worldwide may be attributed to viruses.

Learning Objectives

- Classify the viruses with oncogenic properties

Key Points

- Both DNA and RNA viruses have been shown to be capable of causing cancer in humans.
- Human T lymphotrophic virus type 1 and hepatitis C viruses are the two RNA viruses that contribute to human cancers.
- Hepatitis C virus is an enveloped RNA virus capable of causing acute and chronic hepatitis in humans by infecting liver cells. It is estimated 3% of the world's population are carriers. Chronic infection with hepatitis C virus results in cirrhosis, which in turn can lead to liver cancer.

Key Terms

- **oncogenic**: Tending to cause the formation of tumors.
- **hepatocellular**: Of or pertaining to the cells of the liver

There are two classes of cancer viruses: DNA and RNA viruses. Several viruses have been linked to certain types of cancer in humans. These viruses have varying ways of reproduction and represent several different virus families. Specifically, RNA viruses have RNA as their genetic material and can be either single-stranded RNA (ssRNA) or double-stranded (dsRNA). RNA viruses are classified based on the Baltimore classification system and do not take into account viruses with DNA intermediates in their life cycle. Viruses which contain RNA for their genetic material but do include DNA intermediates in their life cycle are called "retroviruses. " There are numerous RNA oncogenic viruses that have been linked to various cancer types. These various oncogenic viruses include:

1. Human T lymphotrophic virus type 1 (HTLV-I), a retrovirus, has been linked to T-cell leukemia. 2. The hepatitis C virus has been linked to liver cancer in people with chronic infections.

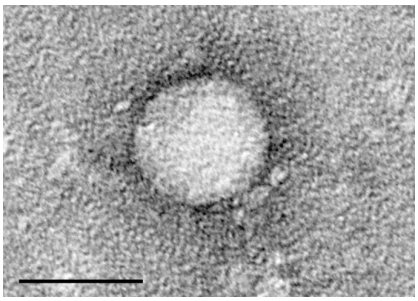

Figure: **Electron micrograph of Hepatitis C**: Hepatitis C viral infections have been linked to the development of liver cancer.

2. Hepatitis viruses includes hepatitis B and hepatitis C have been linked to hepatocellular carcinoma.

3. Human papillomaviruses (HPV) have been linked to cancer of the cervix, anus, penis, vagina/vulva, and some cancers of the head and neck.

4. Kaposi's sarcoma-associated herpesvirus (HHV-8) has been linked to Kaposi's sarcoma and primary effusion lymphoma.

5. Epstein-Barr virus (EBV) has been linked to Burkitt's lymphoma, Hodgkin's lymphoma, post-transplantation lymphoproliferative disease, and nasopharyngeal carcinoma.

RNA Retroviruses

Retroviruses are different from DNA tumor viruses in that their genome is RNA, but they are similar to many DNA tumor viruses in that the genome is integrated into host genome. Since RNA makes up the genome of the mature virus particle, it must be copied to DNA prior to integration into the host cell chromosome. This lifestyle goes against the central dogma of molecular biology in which that DNA is copied into RNA. The outer envelope comes from the host cell plasma membrane. Coat proteins (surface antigens) are encoded by env (envelope) gene and are glycosylated. One primary gene product is made, but this is cleaved so that

there are more than one surface glycoprotein in the mature virus (cleavage is by host enzyme in the Golgi apparatus). The primary protein (before cleavage) is made on ribosomes attached to the endoplasmic reticulum and is a transmembrane (type 1) protein. Inside the membrane is an icosahedral capsid containing proteins encoded by the gag gene (group-specific AntiGen). Gag-encoded proteins also coat the genomic RNA. Again, there is one primary gene product. This is cleaved by a virally-encoded protease (from the pol gene). There are two molecules of genomic RNA per virus particle with a 5′ cap and a 3′ poly A sequence. Thus, the virus is diploid. The RNA is plus sense (same sense as mRNA). About 10 copies of reverse transcriptase are present within the mature virus, these are encoded by the pol gene. Pol gene codes for several functions (again, as with gag and env, a polyprotein is made that is then cut up).

9.13A: Emergence of Viral Pathogens

Learning Objectives

- Demonstrate the ways a virus can go from benign to pathogenic

Humans or other potential viral hosts are constantly exposed to viruses, yet most viral exposure has no effect. However, many viruses that were once benign later become pathogens through a genetic change, which can occur by different mechanisms. One common evolutionary process whereby viral genes change over time is called genetic drift, where individual bases in the DNA or RNA mutate to other bases. Most of these point mutations are “silent”—they do not change the protein that the gene encodes—but others can confer evolutionary advantages such as resistance to antiviral drugs.

The transformation of viruses from benign to pathogenic occurs via two additional processes more specific to viruses. Viral genomes are constantly mutating, producing new forms of these antigens. If one of these new forms of an antigen is sufficiently different from the old antigen, it will no longer bind to the receptors and viruses with these new antigens can evade immunity to the original strain of the virus. When such a change occurs, people who have had the illness in the past will lose their immunity to the new strain and vaccines against the original virus will also become less effective. Two processes drive the antigens to change: antigenic drift and antigenic shift (antigenic drift being the more common).

Antigenic drift is a mechanism for variation by viruses that involves the accumulation of mutations within the antibody -binding sites so that the resulting viruses cannot be inhibited as well by antibodies against previous strains, making it easier for them to spread throughout a partially immune population. Antigenic drift occurs in both influenza A and influenza B viruses. The rate of antigenic drift is dependent on two characteristics: the duration of the epidemic and the strength of host immunity. A longer epidemic allows for selection pressure to continue over an extended period of time and stronger host immune responses increase selection pressure for the development of novel antigens.

Alternatively, the change can occur by antigenic shift. Antigenic shift is a specific case of reassortment or viral shift that confers a phenotypic change; it is the process by which two or more different strains of a virus, or strains of two or more different viruses, combine to form a new subtype having a mixture of the surface antigens of the two or more original strains. The term is often applied specifically to influenza, as that is the best-known example, but the process also occurs with other viruses, such as the visna virus in sheep. When this happens with influenza viruses, pandemics might result.

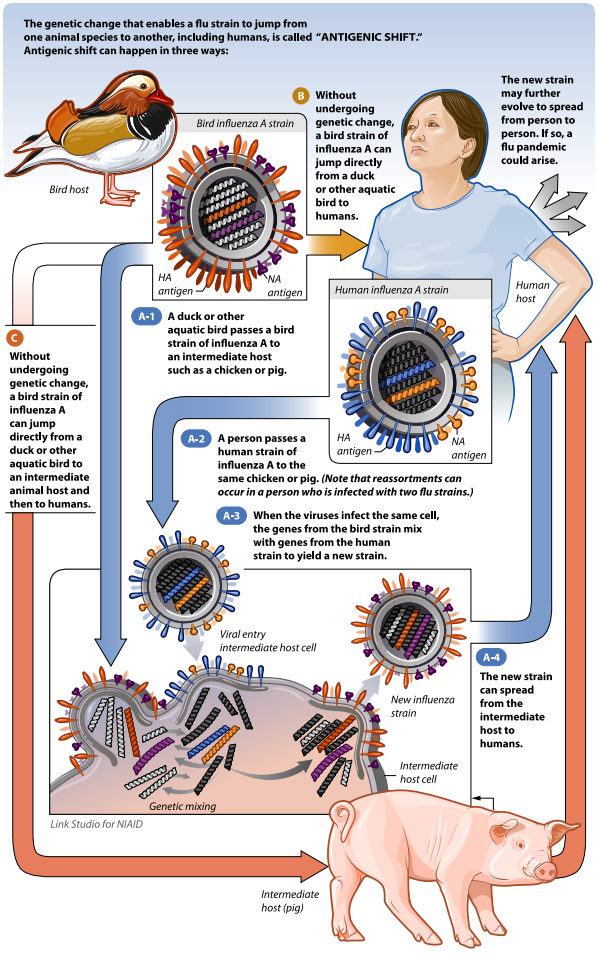

Figure: ***Pathogen emergence by antigenic shift***: *This figure describes in detail how a virus that cannot infect a human can gain the ability to infect a human.*

Antigenic shift occurs only in influenza A because it infects more than just humans. Affected species include other mammals and birds, giving influenza A the opportunity for a major reorganization of surface antigens. Influenza B and C principally infect humans, minimizing the chance that a reassortment will change its phenotype drastically.

For example, if a pig was infected with a human influenza virus and an avian influenza virus at the same time, an antigenic shift could occur, producing a new virus that had most of the genes from the human virus, but a hemagglutinin or neuraminidase from the avian virus. The resulting new virus would likely be able to infect humans and spread from person to person, but it would have surface proteins (hemagglutinin and/or neuraminidase) not previously seen in influenza viruses that infect humans, and therefore most people would have little or no immune protection. If this new virus causes illness in people and can be transmitted easily from person to person, an influenza pandemic can occur. The most recent 2009 H1N1 outbreak was a result of an antigenic shift and reassortment between human, avian, and swine viruses.

Key Points

- For a virus to become pathogenic, genetic changes must occur. These changes occur via mutations, antigenic shift, or antigenic drift.
- Antigenic drift is the natural mutation over time of known strains, thus small changes may cause a harmless virus to become dangerous.
- Antigenic shift is a specific case of reassortment or viral shift that confers a phenotypic change. It is the process by which two or more different strains of a virus, or strains of two or more different viruses, combine to form a new subtype that can be more pathogenic than the original strains.
- Antigenic shift is a major driving force behind viruses inhabiting new niches and is responsible for some of the more aggressive human viruses.

Key Terms

- **antigenic shift**: A specific case of reassortment or viral shift that confers a phenotypic change; it is the process by which two or more different strains of a virus, or strains of two or more different viruses, combine to form a new subtype having a mixture of the surface antigens of the two or more original strains.
- **antigenic drift**: A mechanism for variation by viruses that involves the accumulation of mutations within the antibody-binding sites so that the resulting viruses cannot be inhibited as well by antibodies against previous strains, making it easier for them to spread throughout a partially immune population.

11.10B: Cytokines and Chemokines

Cytokines and chemokines are both small proteins secreted by cells of the immune system.

Learning Objectives

- Summarize the role of cytokines and chemokines

Key Points

- Cytokines and chemokines are important in the production and growth of lymphocytes, and in regulating responses to infection or injury, such as inflammation and wound healing.
- Cytokines are the general category of messenger molecules, while chemokines are a special type of cytokine that directs the migration of white blood cells to infected or damaged tissues.
- A cytokine and a chemokine both use chemical signals to induce changes in other cells, but the latter are specialized to cause cell movement.

Key Terms

- **cytokine**: Any of various small regulatory proteins that regulate the cells of the immune system.
- **chemokine**: Any of various cytokines, produced during inflammation, that organize the leukocytes.
- **chemotaxis**: The movement of a cell or an organism in response to a chemical stimulant.

CYTOKINES

These are small cell-signaling protein molecules that are secreted by numerous cells, and are a category of signaling molecules used extensively in intercellular communication.

Cytokines can be classified as proteins, peptides, or glycoproteins. The term “cytokine” encompasses a large and diverse family of regulators produced throughout the body by cells of diverse embryological origin. The term has also been used to refer to the immunomodulating agents, such as interleukins and interferons.

Biochemists disagree as to which molecules should be termed cytokines and which hormones. As we learn more about each, anatomic and structural distinctions between the two are fading. Classic protein hormones circulate in nanomolar (10^{-9}) concentrations that usually vary by less than one order of magnitude. In contrast, some cytokines (such as IL-6) circulate in picomolar (10^{-12}) concentrations that can increase up to 1,000-fold during trauma or infection.

The widespread distribution of cellular sources for cytokines may be a feature that differentiates them from hormones. Virtually all nucleated cells, but especially endo/epithelial cells and resident macrophages (many near the interface with the external environment), are potent producers of IL-1, IL-6, and TNF-alpha. In contrast, classic hormones, such as insulin, are secreted from discrete glands (e.g., the pancreas).

As of 2008, the current terminology refers to cytokines as immunomodulating agents.

CHEMOKINES

These are a family of small cytokines, or proteins secreted by cells. Their name is derived from their ability to induce directed chemotaxis in nearby responsive cells; they are chemotactic cytokines.

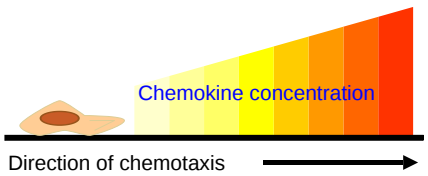

Figure: **Chemotaxis**: Effect of chemokine concentration gradient on chemotaxis direction.

Proteins are classified as chemokines according to shared structural characteristics, such as small size (they are all approximately 8-10 kilodaltons in size), and the presence of four cysteine residues in conserved locations that are key to forming their 3-dimensional shape. However, these proteins have historically been known under several other names including the SIS family of cytokines, SIG family of cytokines, SCY family of cytokines, Platelet factor-4 superfamily or intercrines.

Some chemokines are considered pro-inflammatory and can be induced during an immune response to recruit cells of the immune system to a site of infection, while others are considered homeostatic and are involved in controlling the migration of cells during normal processes of tissue maintenance or development.

Chemokines are found in all vertebrates, some viruses and some bacteria, but none have been described for other invertebrates. These proteins exert their biological effects by interacting with G protein-linked transmembrane receptors called chemokine receptors, that are selectively found on the surfaces of their target cells.

9.13B: Viral Roles in Ecosystems

Learning Objectives

- Show the roles viruses play on ecosystems

Metagenomics is a relatively recent field of study that tries to understand the diversity—especially microbial—of the world around us. Through these studies it is now known that the number of viral particles and number of different viral species in almost every environment on Earth is immense. It is largely believed that viruses by species are the most numerous of any biological entity on earth. This is typified by the role of viruses in marine ecology. A teaspoon of seawater contains about one million viruses.

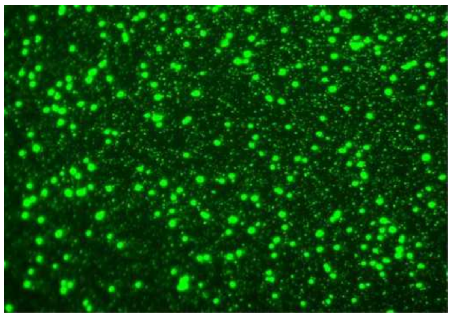

Figure: ***Viral diversity in seawater****: The large green dots are bacteria while the smaller green dots are viral particles. This represents a fraction of the viral diversity seen in teaspoon of marine water.*

Viruses are essential to the regulation of saltwater and freshwater ecosystems. Most of these viruses are bacteriophages, which are harmless to plants and animals. They infect and destroy the bacteria in aquatic microbial communities, comprising the most important mechanism of recycling carbon in the marine environment. The organic molecules released from the bacterial cells by the viruses stimulate fresh bacterial and algal growth.

Microorganisms constitute more than 90% of the biomass in the sea. It is estimated that viruses kill approximately 20% of this biomass each day, and that there are 15 times as many viruses in the oceans as there are bacteria and archaea. Viruses are the main agents responsible for the rapid destruction of harmful algal blooms, which often kill other marine life. The number of viruses in the oceans decreases further offshore and deeper into the water, where there are fewer host organisms. The effects of marine viruses are far-reaching; by increasing the amount of photosynthesis in the oceans, viruses are indirectly responsible for reducing the amount of carbon dioxide in the atmosphere by approximately 3 gigatonnes of carbon per year. Like any organism, marine mammals are susceptible to viral infections. In 1988 and 2002, thousands of harbor seals were killed in Europe by the phocine distemper virus. Many other viruses, including caliciviruses, herpesviruses, adenoviruses, and parvoviruses, circulate in marine mammal populations.

As mentioned, marine viruses are mostly bacteriophages, or phages. Phages are obligate intracellular parasites, meaning that they are able to reproduce only while infecting bacteria. Phages therefore are found only within environments that contain bacteria. Most environments contain bacteria, including our own bodies (called normal flora). Often these bacteria are found in large numbers. As a consequence, phages are found almost everywhere. As a rule of thumb, many phage biologists expect that phage population densities will exceed bacterial densities by a ratio of 10:1 or more (VBR or virus-to-bacterium ratio).

Estimates of bacterial numbers on Earth reach approximately 10^{30}; consequently, there is an expectation that 10^{31} or more individual virus (mostly phage) particles exist, making phages the most numerous category of “organisms” on our planet. Bacteria (along with archaea) appear to be highly diverse and there are possibly millions of species. Phage-ecological interactions therefore are quantitatively vast, with huge numbers of interactions. Phage-ecological interactions are also qualitatively diverse: there are huge numbers of environment types, bacterial-host types, and also individual phage types.

Key Points

- The diversity and numbers of different viruses is incredible.
- In the world’s oceans, 90% of the biomass is microbial, with viruses turning over 20% of that daily. Without the turnover of biomass driven by viruses, many sources of food would not be present for other organisms.
- As bacteria are incredibly diverse, then the viruses that infect them, phages, are even more diverse. As bacteria inhabit almost every niche of the earth, so do viruses.

Key Terms

- **ecological**: Relating to ecology, the interrelationships of organisms and their environment.
- **metagenomics**: The study of genomes recovered from environmental samples; especially the differentiation of genomes from multiple organisms or individuals, either in a symbiotic relationship, or at a crime scene.
- **intracellular**: Inside or within a cell.

Glossary

Anaplerotic reactions | Chemical reactions that form intermediates of a metabolic pathway.

citric acid cycle | The citric acid cycle (CAC) – also known as the TCA cycle (tricarboxylic acid cycle) or the Krebs cycle – is a series of chemical reactions used by all aerobic organisms to release stored energy through the oxidation of acetyl-CoA derived from carbohydrates, fats, and proteins. In addition, the cycle provides precursors of certain amino acids, as well as the reducing agent NADH, that are used in numerous other reactions. [Wikipedia]

FISH | Fluorescence in situ hybridization is a cytogenetic technique used to detect and localize the specific DNA or RNA sequences. [boundless]

fluorescence | The emission of light (or other electromagnetic radiation) by a material when stimulated by the absorption of radiation or of a subatomic particle [boundless]

GABA | Gamma-Aminobutyric acid is the chief inhibitory neurotransmitter in the developmentally mature mammalian central nervous system. Its principal role is reducing neuronal excitability throughout the nervous system. [Wikipedia]

GABA shunt | The GABA shunt a closed loop that is involved in the production and conservation of the pool of GABA.

glyoxylate Shunt | The glyoxylate shunt is a two-step metabolic pathway (via isocitrate lyase, aceA and malate synthase, glcB) as an alternative to the citric acid cycle.

hybridize | To combine complementary subunits of multiple biological macromolecules. [boundless]

Krebs cycle | The citric acid cycle (CAC) – also known as the TCA cycle (tricarboxylic acid cycle) or the Krebs cycle – is a series of chemical reactions used by all aerobic organisms to release stored energy through the oxidation of acetyl-CoA derived from carbohydrates, fats, and proteins. In addition, the cycle provides precursors of certain amino acids, as well as the reducing agent NADH, that are used in numerous other reactions. [Wikipedia]

Pyruvate Dehydrogenase | Pyruvate dehydrogenase is an enzyme that catalyzes the reaction of pyruvate and a lipoamide to give the acetylated dihydrolipoamide and carbon dioxide. The conversion requires the coenzyme thiamine pyrophosphate. [Wikipedia]

TCA cycle | The citric acid cycle (CAC) – also known as the TCA cycle (tricarboxylic acid cycle) or the Krebs cycle – is a series of chemical reactions used by all aerobic organisms to release stored energy through the oxidation of acetyl-CoA derived from carbohydrates, fats, and proteins. In addition, the cycle provides precursors of certain amino acids, as well as the reducing agent NADH, that are used in numerous other reactions. [Wikipedia]

11.10C: Superantigens

Superantigens are a class of antigens that cause activation of T-cells and massive cytokine release.

Learning Objectives

- Describe the mechanism of action for superantigens and the effects

Key Points

- Superantigens (SAgs) are microbial products that have the ability to promote massive activation of immune cells, leading to the release of inflammatory mediators that can ultimately result in hypotension, shock, organ failure, and death.
- They achieve this by simultaneously binding and activating major histocompatibility complex class II molecules on antigen - presenting cells and T-cell receptors on T lymphocytes bearing susceptible Vβ regions.
- The resulting Th1 response may divert the immune system from effective microbial clearance and/or result in the cytokine - mediated suppression and deletion of activated T cells.

Key Terms

- **interferon**: Any of a group of glycoproteins, produced by the immune system, that prevent viral replication in infected cells.
- **Kawasaki disease**: A disease in which the medium-sized blood vessels throughout the body become inflamed. Symptoms include fever, lymphadenopathy, and elevated platelet count.
- **superantigen**: an antigen, which has a powerful interaction with T-lymphocytes

Superantigens (SAgs) are proteins that cause the T-cells of the immune system to over-react to infection. They are produced by certain infectious bacteria and viruses. The immune system over-reaction to the antigen causes a group of diseases that manifest in fever and shock, such as food poisoning, toxic shock syndrome, and Kawasaki disease. Common bacterial species that may use a superantigen as part of their virulence strategy are staphylococci and streptococci.

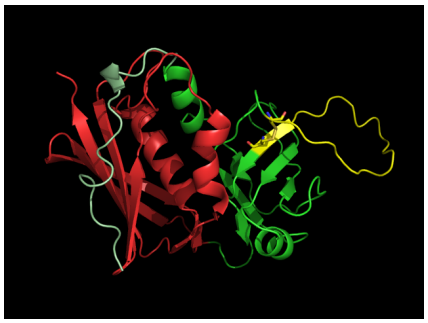

Figure: **A Superantigen**: Structure of a typical bacterial superantigen.

These bacteria usually live harmlessly on the body, but can cause infections in certain circumstances. The superantigens of each species are, like antigens, molecules the immune system recognizes as being foreign. Superantigens cause symptoms of illness by tricking the T-cells of the immune system into over-reacting to these molecules. Parts of a bacterium or a virus are usually recognized by the macrophage cells of the immune system. The macrophage ingests the foreign invaders and breaks them down. Then the macrophage takes parts of the broken-down invader or other molecules that it ingested and posts the fragments on the outside of the cell using a major histocompatibility complex (MHC) to hold the fragment.

The large number of activated T-cells generates a massive immune response which is not specific to any particular epitope on the SAg. This undermines one of the fundamental strengths of the adaptive immune system, that is, its ability to target antigens with high specificity. More importantly, the large number of activated T-cells secretes large amounts of cytokines, the most important of which is Interferon gamma. This excess amount of IFN-gamma is in turn what activates the macrophages.

11.10D: The Complement System

The complement system helps antibodies and phagocytic cells clear pathogens from an organism.

Learning Objectives

- Describe the function of the complement system

Key Points

- The complement system has originally been identified as the part of the immune system called the innate immune system.
- The complement system can also be recruited and brought into action by the adaptive immune system.
- The three biochemical pathways that activate the complement system are the classical complement pathway, the alternative complement pathway, and the lectin pathway.
- The complement system consists of small proteins found in the blood, generally synthesized by the liver, and normally circulating as inactive precursors. When stimulated by a trigger, proteases in the system cleave specific proteins to release cytokines that amplify further cleavages.
- The end-result of this activation cascade is the massive amplification of the response and activation of the cell-killing membrane attack complex.

Key Terms

- **opsonization**: the process of an antigen bound by antibody or complement to attract phagocytic cells.

The Complement System

The serum complement system, which represents a chief component of innate immunity, not only participates in inflammation but also acts to enhance the adaptive immune response. Specific activation of the complement via innate recognition proteins or secreted antibody releases cleavage products that interact with a wide range of cell surface receptors found on myeloid, lymphoid, and stromal cells. This intricate interaction among complement activation products and cell surface receptors provides a basis for the regulation of both B and T cell responses.

The complement system plays a crucial role in the innate defense against common pathogens. Activation of the complement leads to robust and efficient proteolytic cascades, which terminate in opsonization and lysis of the pathogen as well as in the generation of the classical inflammatory response through the production of potent proinflammatory molecules. More recently, however, the role of the complement in the immune response has been expanded due to observations that link complement activation to adaptive immune responses. It is now understood that the complement is a functional bridge between innate and adaptive immune responses that allows an integrated host defense to pathogenic challenges.

Activation of the Complement System

The complement system can be activated through three major pathways: classical, lectin, and alternative. Initiation of the classical pathway occurs when C1q, in complex with C1r and C1s serine proteases (the C1 complex), binds to the Fc region of complement-fixing antibodies (generally $IgG_1$and IgM) attached to pathogenic surfaces. Autocatalytic activation of C1r and C1s in turn cleaves C4 and C2 into larger (C4b, C2a) and smaller (C4a, C2b) fragments. The larger fragments associate to form C4bC2a on pathogenic surfaces, and the complex gains the ability to cleave C3 and is termed the C3 convertase.

Generation of the C3 convertase, which cleaves C3 into the anaphylatoxin C3a and the opsonin C3b, is the point at which all complement activation cascades converge. When C3 is cleaved into C3b, it exposes an internal thioester bond that allows stable covalent binding of C3b to hydroxyl groups on proximate carbohydrates and proteins. This activity underpins the entire complement system by effectively “tagging” microorganisms as foreign, leading to further complement activation on and around the opsonized surface and terminating in the production of anaphylatoxins and assembly of membrane attack complexes.

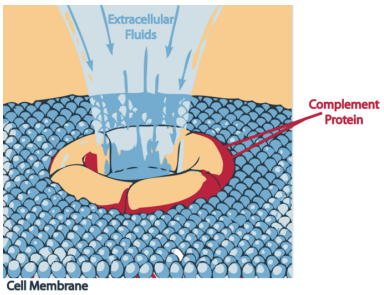

Figure: **Complement death**: A complement protein attacking an invader.

Functions of the Complement System

The functions of the complement system, oposonization, lysis, and generation of the inflammatory response through soluble mediators, are paradigmatic and represent a well-characterized component of an innate host defense. It has become increasingly understood that complement functions in host defense extend beyond innate immune responses. The finding that B lymphocytes bound C3 raised the question as early as in the 1970s as to whether the complement system was involved in adaptive immune responses. Subsequent work demonstrated that depletion of C3 impaired humoral immune responses and provided direct evidence that efficient adaptive responses were contingent on an intact complement system in some cases.

Further study in animals bearing natural complement deficiencies implicated the classical pathway as a crucial mechanism for efficient antigen trapping and retention in lymphoid tissues (e.g., splenic follicles), suggesting that a major function of the complement system was to localize foreign antigens into immune sites important for lymphocytes responses.

11.11: The Major Histocompatibility Complex (MHC) is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.11A: MHC Polymorphism and Antigen Binding

Learning Objectives

- Explain MHC polymorphism

Major histocompatibility complex (MHC) is a cell-surface molecule encoded by a large gene family in all vertebrates. MHC molecules display a molecular fraction called an epitope and mediate interactions of leukocytes with other leukocytes or body cells. The MHC gene family is divided into three subgroups—class I, class II, and class III. Diversity of antigen presentation, mediated by MHC classes I and II, is attained in multiple ways:

1. The MHC's genetic encoding is polygenic,
2. MHC genes are highly polymorphic and have many variants,
3. Several MHC genes are expressed from both inherited alleles (variants).

MHC gene families are found in all vertebrates, though they vary widely. Chickens have among the smallest known MHC regions (19 genes).

In humans, the MHC region occurs on chromosome 6. Human MHC class I and II are also called human leukocyte antigen (HLA). To clarify the usage, some of the biomedical literature uses HLA to refer specifically to the HLA protein molecules and reserves MHC for the region of the genome that encodes for this molecule, but this is not a consistent convention.

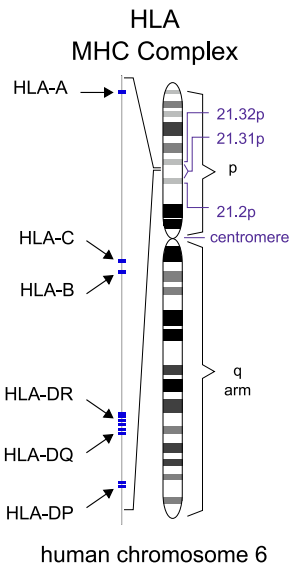

Figure: ***HLA MHC complex****: The human leukocyte antigen (HLA) system is the name of the major histocompatibility complex (MHC) in humans. The super locus contains a large number of genes related to immune system function in humans. This group of genes resides on chromosome 6, encodes cell-surface antigen-presenting proteins and has many other functions.*

The most intensely-studied HLA genes are the nine so-called classical MHC genes: HLA-A, HLA-B, HLA-C, HLA-DPA1, HLA-DPB1, HLA-DQA1, HLA-DQB1, HLA-DRA, and HLA-DRB1. In humans, the MHC is divided into three regions: classes I, II, and III. The A, B, C, E, F, and G genes belong to MHC class I, whereas the six D genes belong to class II. MHC genes are expressed in co-dominant fashion. This means that the alleles inherited from both progenitors are expressed in an equivalent way. As there are 3 Class-I genes, named in humans HLA-A, HLA-B and HLA-C, and as each person inherits a set of genes from each progenitor, that means that any cell in an individual can express 6 different types of MHC-I molecules.

In the Class-II locus, each person inherits a couple of genes HLA-DP (DPA1 and DPA2, which encode α and β chains), a couple of genes HLA-DQ (DQA1 and DQA2, for α and β chains), one gene HLA-DRα (DRA1) and one or two genes HLA-DRβ (DRB1 and DRB3, -4 o -5). That means that one heterozygous individual can inherit 6 or 8 Class-II alleles, three or four from each progenitor.

The set of alleles that is present in each chromosome is called MHC haplotype. In humans, each HLA allele is named with a number. Each heterozygous individual will have two MHC haplotypes, one in each chromosome (one of paternal origin and the

other of maternal origin).

The MHC genes are highly polymorphic; this means that there are many different alleles in the different individuals inside a population. The polymorphism is so high that in a mixed population (non-endogamic) there are not two individuals with exactly the same set of MHC genes and molecules, with the exception of identical twins.

The polymorphic regions in each allele are located in the region for peptide contact, which is going to be displayed to the lymphocyte. For this reason, the contact region for each allele of MHC molecule is highly variable, as the polymorphic residues of the MHC will create specific clefts in which only certain types of residues of the peptide can enter. This imposes a very specific link between the MHC molecule and the peptide, and it implies that each MHC variant will be able to bind specifically only those peptides that are able to properly enter in the cleft of the MHC molecule, which is variable for each allele. In this way, the MHC molecules have a broad specificity, because they can bind many, but not all, types of possible peptides.

The evolution of the MHC polymorphism ensures that a population will not succumb to a new pathogen or a mutated one, because at least some individuals will be able to develop an adequate immune response to win over the pathogen. The variations in the MHC molecules (responsible for the polymorphism) are the result of the inheritance of different MHC molecules, and they are not induced by recombination, as it is the case for the antigen receptors.

Because of the high levels of allelic diversity found within its genes, MHC has also attracted the attention of many evolutionary biologists.

Key Points

- Diversity of antigen presentation, mediated by MHC classes I and II, is attained in three ways: (1) the MHC's genetic encoding is polygenic, (2) MHC genes are highly polymorphic and have many variants, (3) several MHC genes are expressed from both inherited alleles.
- Human MHC class I and II are also called human leukocyte antigen (HLA).
- The MHC genes are highly polymorphic; this means that there are many different alleles in the different individuals inside a population.
- The evolution of the MHC polymorphism ensures that a population will not succumb to a new pathogen or a mutated one, because at least some individuals will be able to develop an adequate immune response to win over the pathogen.

Key Terms

- **allele**: One of a number of alternative forms of the same gene occupying a given position on a chromosome.
- **epitope**: That part of a biomolecule (such as a protein) that is the target of an immune response.
- **polygenic**: Having an infinite number of derivatives at a point (otherwise it is monogenic).

SECTION OVERVIEW

11.12: Classifying Immunities

Topic hierarchy

11.12A: Natural Active Immunity

11.12B: Natural Passive Immunity

11.12C: Artificial Immunity

11.12: Classifying Immunities is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.12A: Natural Active Immunity

Naturally acquired active immunity occurs when a person is exposed to a live pathogen, develops the disease, and then develops immunity.

Learning Objectives

- Compare and contrast: active natural and active artifical immunity

Key Points

- Once a microbe penetrates the body's skin, mucous membranes, or other primary defenses, it interacts with the immune system.
- Active immunization entails the introduction of a foreign molecule into the body, which causes the development of an immnune response via activation of the T cells and B cells.
- The principle behind immunization is to introduce an antigen, derived from a disease-causing organism, that stimulates the immune system to develop protective immunity against that organism, but which does not itself cause the pathogenic effects of that organism.

Key Terms

- **immunity**: the state of being insusceptible to a specific thing.
- **vaccination**: inoculation with a vaccine in order to protect a particular disease or strain of disease.

Immunity is the state of protection against infectious disease conferred either through an immune response generated by immunization or previous infection, or by other non-immunological factors. There are two ways to acquire active resistance against invading microbes: active natural and active artificial.

Figure: **Typhoid vaccination**: Immunization (commonly referred to as vaccination) is the deliberate induction of an immune response, and represents the single most effective manipulation of the immune system that scientists have developed.

Naturally acquired active immunity occurs when the person is exposed to a live pathogen, develops the disease, and becomes immune as a result of the primary immune response. Once a microbe penetrates the body's skin, mucous membranes, or other primary defenses, it interacts with the immune system. B-cells in the body produce antibodies that help to fight against the invading microbes. The adaptive immune response generated against the pathogen takes days or weeks to develop but may be long-lasting, or even lifelong. Wild infection, for example with hepatitis A virus (HAV) and subsequent recovery, gives rise to a natural active immune response usually leading to lifelong protection.

In a similar manner, administration of two doses of hepatitis A vaccine generates an acquired active immune response leading to long-lasting (possibly lifelong) protection. Immunization (commonly referred to as vaccination) is the deliberate induction of an immune response, and represents the single most effective manipulation of the immune system that scientists have developed. Immunizations are successful because they utilize the immune system's natural specificity as well as its inducibility. The principle behind immunization is to introduce an antigen, derived from a disease-causing organism, that stimulates the immune system to develop protective immunity against that organism, but which does not itself cause the pathogenic effects of that organism.

11.12A: Natural Active Immunity is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.12B: Natural Passive Immunity

Naturally acquired passive immunity occurs during pregnancy, when antibodies are passed from the maternal blood into the fetal bloodstream.

Learning Objectives

- Outline the various ways to obtain passive immunity

Key Points

- Immunity is transferred through the placenta in the form of antibodies, mainly IgG and IgA.
- Natural passive immunity can also be transferred through breast milk.
- Natural passive immunity is short-lived after the birth of the child.

Key Terms

- **IgG**: immunoglobulin G is an antibody isotype.
- **IgA**: immunoglobulin A is an antibody isotype.
- **passive immunity**: the translocation of active humoral immunity from one individual to another in the form of custom-made antibodies.

Immunity is the state of protection against infectious disease conferred either through an immune response generated by immunization or previous infection, or by other non-immunological factors. There are two ways to acquire passive resistance against disease: passive natural and passive artificial. Naturally acquired passive immunity occurs during pregnancy, in which certain antibodies are passed from the maternal blood into the fetal bloodstream in the form of IgG. Antibodies are transferred from one person to another through natural means such as in prenatal and postnatal relationships between mother and child. Some antibodies can cross the placenta and enter the fetal blood. This provides some protection for the child for a short time after birth, but eventually these deteriorate and the infant must rely on its own immune system. Antibodies may also be transferred through breast milk. The transfered IgG from mother to fetus during pregnancy generally lasts 4 to 6 months after birth. The immune responses reach full strength at about age 5.

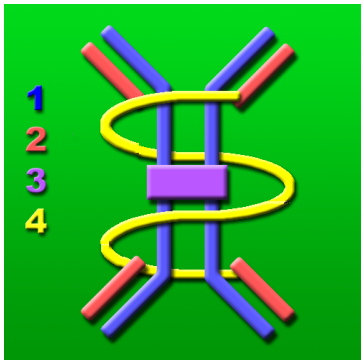

Figure: **IgA antibody**: The dimeric IgA molecule.1 H-chain2 L-chain3 J-chain4 secretory component. IgA antibodies are transferred from mother to child in colostrum and milk and confer passive immunity.

Passive immunity can also be in the form of IgA and IgG found in human colostrum and milk of babies who are nursed. In addition to the IgA and IgG, human milk also contains: oligosaccharides and mucins that adhere to bacteria and viruses to interfere with their attachment to host cells; lactoferrin to bind iron and make it unavailable to most bacteria; B_{12} binding protein to deprive bacteria of needed vitamin $B_{12;}$ bifidus factor that promotes the growth of Lactobacillus bifidus, normal flora in the gastrointestinal tract of infants that crowds out harmful bacteria; fibronectin that increases the antimicrobial activity of macrophages and helps repair tissue damage from infection in the gastrointestinal tract; gamma-interferon, a cytokine that enhances the activity of certain immune cells; hormones and growth factors that stimulate the baby's gastrointestinal tract to mature faster and be less susceptible to infection; and lysozyme to break down peptidoglycan in bacterial cell walls.

11.12B: Natural Passive Immunity is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

11.12C: Artificial Immunity

Artificial immunity is a mean by which the body is given immunity to a disease by intentional exposure to small quantities of it.

Learning Objectives

- Describe artificially acquired immunity and how it is obtained

Key Points

- The most common form of artificial immunity is classified as active and comes in the form of vaccinations, typically given to children and young adults.
- The passive form of artificial immunity involves introducing an antibody into the system once a person has already been infected with a disease, ultimately relieving the present symptoms of the sickness and preventing re-occurrence.
- Once the body has successfully rid itself of a disease caused by a certain pathogen, a second infection with the same pathogen would prove harmless.

Key Terms

- **gamma globulin**: a class of proteins in the blood, identified by their position after serum protein electrophoresis, such as antibodies
- **anaphylactic shock**: A severe and rapid systemic allergic reaction to an allergen, constricting the trachea and preventing breathing.
- **herd immunity**: the protection given to a community against an epidemic of a contagious disease when a sufficient number of the population are immunised or otherwise develop immunity to it

Immunity is the state of protection against infectious disease conferred either through an immune response generated by immunization or by previous infection or other non-immunological factors.

Artificial immunity can be active or passive.

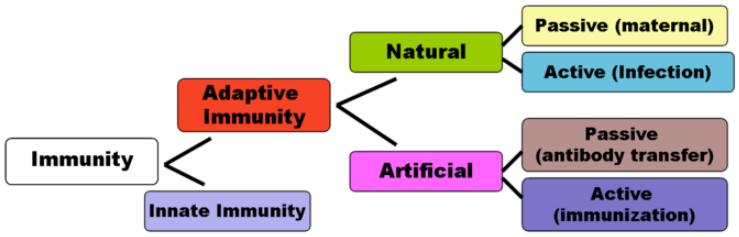

Figure: **Immunity**: Natural immunity occurs through contact with a disease causing agent, when the contact was not deliberate, where as artificial immunity develops only through deliberate actions of exposure. Both natural and artificial immunity can be further subdivided, depending on the amount of time the protection lasts. Passive immunity is short lived, and usually lasts only a few months, whereas protection via active immunity lasts much longer, and is sometimes life-long.

Artificially-acquired passive immunity is an immediate, but short-term immunization provided by the injection of antibodies, such as gamma globulin, that are not produced by the recipient's cells. These antibodies are developed in another individual or animal and then injected into another individual. Antiserum is the general term used for preparations that contains antibodies.

Artificial active immunization is where the microbe, or parts of it, are injected into the person before they are able to take it in naturally. If whole microbes are used, they are pre-treated, attenuated vaccines. This vaccine stimulates a primary response against the antigen in the recipient without causing symptoms of the disease.

Artificial passive immunization is normally administered by injection and is used if there has been a recent outbreak of a particular disease or as an emergency treatment for toxicity, as in for tetanus. The antibodies can be produced in animals, called " serum therapy," although there is a high chance of anaphylactic shock because of immunity against animal serum itself. Thus, humanized antibodies produced in vitro by cell culture are used instead if available.

The first record of artificial immunity was in relation to a disease known as smallpox. Individuals were exposed to a minor strain of smallpox in a controlled environment. Once their bodies built up a natural immunity or resistance to the weakened strain of smallpox, they became much less likely to become infected with the more deadly strains of the disease. In essence, patients were

given the disease in order to help fight it later in life. Although this method was an effective one, the scientists of the time had no real scientific knowledge of why it worked.

12.1A: Passive Immunization

Learning Objectives

- Describe how artificial and natural passive immunity function to provide antibody protection against microorganisms

There are two types of passive immunity: artificial and natural. Artificial passive immunity is achieved by infusion of serum or plasma containing high concentrations of antibody. This form of passive immunity provides immediate antibody protection against microorganisms such as hepatitis A by administering preformed antibodies. These antibodies have been produced by another person or animal that has been actively immunized, but the ultimate recipient has not produced them. The recipient will only temporarily benefit from passive immunity for as long as the antibodies persist in their circulation.This type of immunity is short acting, and is typically seen in cases where a patient needs immediate protection from a foreign body and cannot form antibodies quickly enough independently.

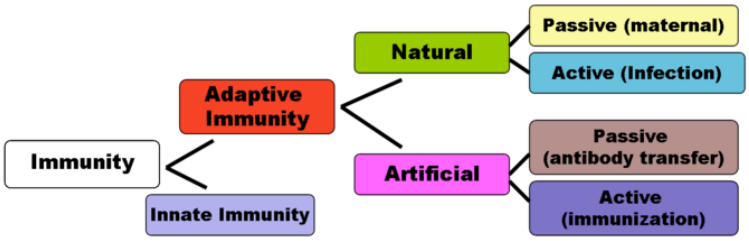

Figure: ***Immunity****: Natural immunity occurs through contact with a disease causing agent, when the contact was not deliberate, where as artificial immunity develops only through deliberate actions of exposure. Both natural and artificial immunity can be further subdivided, depending on the amount of time the protection lasts. Passive immunity is short lived, and usually lasts only a few months, whereas protection via active immunity lasts much longer, and is sometimes life-long.*

Passive immunity can also be acquired naturally by the fetus due to the transfer of antibodies by the maternal circulation in utero through the placenta around the third month of gestation. Immunity in newborn babies is only temporary and starts to decrease after the first few weeks, or months. Breast milk also contains antibodies, which means that babies who are breastfed have passive immunity for longer periods of time. The thick, yellowish milk (colostrum) that is produced during the first few days after birth is particularly rich in antibodies. For the newborn to have lasting protection, active immunity must be received. The first immunisation, given when a baby is two months old, includes whooping cough and Hib (haemophilus influenza type b) because immunity to these diseases decreases the fastest. Passive immunity to measles, mumps and rubella (MMR) usually lasts for about a year, which is why the MMR is given just after the baby's first birthday.

Key Points

- Passive immunization provides humoral immunity.
- Artificial passive immunization is the injection of preformed antibody solution when a patient is incapable of producing antibodies fast enough to combat a disease.
- Natural passive immunization is the transfer of antibodies through the placenta of a pregnant woman to the fetus. Immunity lasts for a couple of months after the baby is born, after which active immunization is required.

Key Terms

- **in utero**: Occurring or residing within the uterus or womb; unborn.

12.1A: Passive Immunization is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.1B: Vaccination

Vaccination is a proven way to prevent and even eradicate widespread outbreaks of life-threatening infectious diseases.

Learning Objectives

- Describe how active immunity to diseases can be acquired by natural exposure or by vaccination

Key Points

- Immunization is the administration of antigenic solution, usually orally or via injection, to protect against infectious bacterial and viral diseases.
- Vaccinations are usually given at specific ages and dates as per the recommended schedule provided by The Center for Disease Control.
- Vaccines stimulate the body to produce antibodies without manifesting clinical signs and symptoms of the disease in immunocompetent hosts.

Key Terms

- **toxoids**: bacterial toxins whose toxicity has been inactivated or suppressed.
- **immunity**: the state of being insusceptible to a specific thing.
- **immunocompetent**: Having a functioning immune system.

Active immunity to diseases can be acquired by natural exposure (in response to actually contracting an infectious disease) or it may be acquired intentionally, via the administration of an antigen, commonly known as vaccination.

Figure: **Vaccination:**: a child receiving an oral polio vaccine.

Vaccination has proven to be an effective way to stimulate the human body's natural ability to produce antibodies, without contracting the disease and suffering any of its effects. This is also known as 'acquired' resistance.

The various antigenic materials used in these vaccinations (or immunization) may be of animal or plant origin. Some vaccinations are composed of live suspensions of weak or attenuated cells or viruses, deadened cells or viruses, or extracted bacterial products such as the *toxoids* used to immunize against diphtheria and tetanus.

Vaccinations are developed to stimulate the body's production of antibodies without the manifestation of clinical signs and symptoms of the disease in *immunocompetent* hosts. Moreover, active immunization should cause permanent antigenic memory or lifelong immunity.

Vaccinations are usually given at specific ages and dates according to the recommended schedule provided by The Center for Disease Control. Sometimes booster vaccinations are needed to provide additional *immunity* in certain individuals and in certain cases.

Once your immune system has been trained to resist a disease, you are said to be immune to it. Before vaccines were developed, the only way to acquire immunity to a disease was to actually get it and, with luck, survive it. Even today, the risk of contracting some of these infectious diseases, like measles and chicken pox, can have devastating, long-term complications, like blindness.

Despite some of the various controversies surrounding vaccines over the years, the tiny proportion of risk is far outweighed by the numerous benefits. Certain infectious diseases, such as Smallpox, have been completely eradicated. Global mass vaccination drives have met with enormous success in reducing the incidence of many diseases.

Another consideration is that the newer vaccination programs also protect older age groups. By these vaccinated children not contracting these diseases, their parents, grandparents, friends and relatives (not vaccinated against these diseases themselves) will also be protected.

12.1B: Vaccination is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.1C: Development of New Vaccines

New vaccines are being developed to control recent infectious disease epidemics and cancers.

Learning Objectives

- Describe how new vaccines are being developed to help eradicate several infectious global diseases

Key Points

- The World Health Organization (WHO) oversees the development and distribution of vaccines for underdeveloped countries.
- Vaccines for rotavirus diarrhea, pneumococcal disease, and meningococcal infections have been licensed and are approved for development.
- Vaccines for cancer treatment are gaining traction and are based on training the body to recognize cancer cells as foreign.

Key Terms

- **vaccine**: a substance given to stimulate the body's production of antibodies and provide immunity against a disease, prepared from the agent that causes the disease, or a synthetic substitute.
- **immunization**: the process by which an individual is exposed to a material that is designed to prime his or her immune system against that material.

National Immunization Programs

The implementation of large-scale, comprehensive national immunization programs, and the considerable successes that were achieved in the eradication of smallpox and the reduction of polio, measles, pertussis, tetanus, and meningitis, were among the most notable achievements of the 20th century. Even in the poorest countries, immunizations have been able to achieve significant progress in disease control. There is good reason to expect that these advances will be sustained and will progress even further in the 21stcentury.

Vaccines for Infectious Diseases

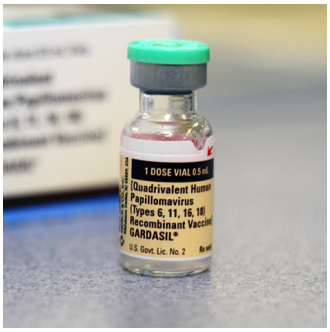

Figure: **Human papillomavirus vaccine**: Gardasil is a human papillomavirus vaccine on the market and it protects against HPV-16 and HPV-18 which cause 70% of cervical cancers, 80% of anal cancers, 60% of vaginal cancers, and 40% of vulvar cancers.

A number of new vaccines with major potential for controlling infectious diseases have just been licensed or are at advanced stages of development. Among the illnesses targeted are rotavirus diarrhea, pneumococcal disease, and cervical cancer (as caused by human papillomavirus), which together kill more than a million people each year, most of them in developing countries.

In addition to these efforts against global diseases, progress is being made on a vaccine for the regional menace posed by meningococcal meningitis serogroup A, which causes frequent epidemics and high death rates and disability in African countries south of the Sahara. Continuing intensive efforts are under way to develop effective vaccines for AIDS, malaria, tuberculosis, dengue, leishmaniasis, and enteric diseases, among others and to adapt new technologies to improve formulation and delivery. The World Health Organization (WHO) facilitates the development of vaccines against infectious diseases of major public health importance, helps improve existing immunization technologies, and ensures that these advances are made available to the people who need them the most.

12.1C: Development of New Vaccines is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.1D: Vaccine Safety

Vaccines carry risks, ranging from rashes or tenderness at the site of injection to fever-associated seizures.

Learning Objectives

- Describe the possible side effects of vaccine administration

Key Points

- Vaccines can cause side effects in immunocompromised people, and allergic reactions due to the ingredients used to make them stable.
- Side effects from vaccines are rare and most reported ailments after vaccination have not been proven to be caused by vaccination (e.g. autism, asthma).
- Researchers continue to ameliorate vaccines composition making them safer and effective.

Key Terms

- **convulsion**: An intense, paroxysmal, involuntary muscular contraction.
- **subunit vaccine**: a vaccine that presents an antigen to the immune system without introducing viral particles, whole or otherwise
- **limpness**: Property of being limp.

Vaccines are biological products with biological effects. Vaccines are made with a variety of ingredients including antigens, stabilizers, adjuvants, and preservatives; they may also contain residual by-products from the production process. These might be the cause of allergic reactions and side effects.

Vaccines carry risks, ranging from rashes or tenderness at the site of injection to fever-associated seizures called febrile convulsions and dangerous infections in those with compromised immune systems. Technological advances have made modern vaccines purer and safer than their historical counterparts. Most developed countries have switched to the inactivated polio vaccine and stopped using whole-cell pertussis (whooping cough) vaccines, which are made from killed bacteria and cause relatively high rates of arm swelling, febrile convulsions and periods of limpness or unresponsiveness.

Researchers have long known that some individuals are more susceptible to vaccine risks than others. Immunocompromised individuals have generally been discouraged from receiving live-virus vaccines. Some speculate that children with metabolic disorders might be prone to vaccine side effects. Safer vaccines and manufacturing processes are also in the works. New influenza vaccine doses are produced in cell culture, rather than the industry-standard chicken eggs. This process will improve reliability and reduce allergic reactions to egg proteins. Researchers are also developing replacements for vaccines that can be risky for vulnerable groups. These include current smallpox vaccines that cannot safely be given to immunocompromised people; the tuberculosis vaccine, which is not recommended for HIV-positive infants; and the yellow-fever vaccine, which puts elderly people at particular risk of a yellow-fever-like illness. Researchers are quick to emphasize that the benefits of vaccines still greatly outweigh the risks.

Figure: **Preparation of Measles Vaccine**: Workers preparing measles vaccine in chicken eggs.

This page titled 12.2: Immunoassays for Disease is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

12.2A: Immunoassays for Disease

Immunoassays are laboratory techniques based on the detection of antibody production in response to foreign antigens.

Learning Objectives

- Describe how immunoassays aid in the diagnosis of disease

Key Points

- When microbial agents penetrate the body, they elicit an immune response that involves cellular and humoral components.
- An immune response is usually characterized by antibody secretions. These can be measured in the laboratory through various biochemical and serological techniques.
- Most immunoassays rely on the formation of antibody- antigen complexes that can be identified using an indicator molecule.

Key Terms

- **humoral**: Of or relating to the body fluids or humours.
- **antibody**: A protein produced by B-lymphocytes that binds to a specific antigen.

The Immune System

Immunology is the study of molecules, cells, and organs that make up the immune system. The function of the immune system is to recognize self antigens from non-self antigens and defend the body against non-self (foreign) agents. Through specific and non-specific defense mechanisms, the body's immune system is able to react to microbial pathogens and protect against disease. The first line of defense against infection is intact skin, mucosal membrane surfaces, and secretions that prevent pathogens from penetrating into the body.

When a foreign agent penetrates the first line of resistance, an immune reaction is elicited and immune cells are recruited into the site of infection to clear microorganisms and damaged cells by phagocytosis. If the inflammation remains aggravated, antibody-mediated immune reaction is activated and different types of immune cells are engaged to resolve the disease. The immune system is composed of cellular and humoral elements. The cellular component includes mast cells, neutrophils, macrophages, T and B lymphocytes, and plasma cells. The humoral component includes complement, lyzozyme, interferon, antibodies, and cytokines. All work cooperatively to eliminate immunogenic foreign substances from the body.

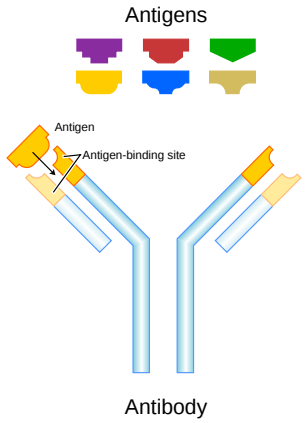

Figure: **Immune complex**: This is the complex formation of a specific antibody-antigen.

Immunoassays

To aid in the diagnosis of disease caused by infectious microorganisms, immunoassays have been developed. These biochemical and serological techniques are based on the detection and quantitation of antibodies generated against an infectious agent, a microbe, or non-microbial antigen.

Because antibodies can be produced against any type of macromolecule, antibody-based techniques are useful in identifying molecules in solution or in cells. A blood sample is collected from the patient during the acute phase of the disease when antibody levels are high. Serum is then isolated and the concentration of antibodies is measured through various methods. Most assays rely

on the formation of large immune complexes when an antibody binds to a specific antigen which can be detected in solution or in gels. Recent methods employ pure antibodies or antigens that have been immobilized on a platform and that can be measured using an indicator molecule. These methods provide high sensitivity and specificity and have become standard techniques in diagnostic immunology.

12.2A: Immunoassays for Disease is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.2B: Antibody Functions

Antibodies, part of the humoral immune response, are involved in pathogen detection and neutralization.

Learning Objectives

- Differentiate among affinity, avidity, and cross-reactivity in antibodies

Key Points

- Antibodies are produced by plasma cells, but, once secreted, can act independently against extracellular pathogen and toxins.
- Antibodies bind to specific antigens on pathogens; this binding can inhibit pathogen infectivity by blocking key extracellular sites, such as receptors involved in host cell entry.
- Antibodies can also induce the innate immune response to destroy a pathogen, by activating phagocytes such as macrophages or neutrophils, which are attracted to antibody-bound cells.
- Affinity describes how strongly a single antibody binds a given antigen, while avidity describes the binding of a multimeric antibody to multiple antigens.
- A multimeric antibody may have individual arms with low affinity, but have high overall avidity due to synergistic effects between binding sites.
- Cross reactivity occurs when an antibody binds to a different-but-similar antigen than the one for which it was raised; this can increase pathogen resistance or result in an autoimmune reaction.

Key Terms

- **avidity**: the measure of the synergism of the strength individual interactions between proteins
- **affinity**: the attraction between an antibody and an antigen

Antibody Functions

Differentiated plasma cells are crucial players in the humoral immunity response. The antibodies they secrete are particularly significant against extracellular pathogens and toxins. Once secreted, antibodies circulate freely and act independently of plasma cells. Sometimes, antibodies can be transferred from one individual to another. For instance, a person who has recently produced a successful immune response against a particular disease agent can donate blood to a non-immune recipient, confering temporary immunity through antibodies in the donor's blood serum. This phenomenon, called passive immunity, also occurs naturally during breastfeeding, which makes breastfed infants highly resistant to infections during the first few months of life.

Antibodies coat extracellular pathogens and neutralize them by blocking key sites on the pathogen that enhance their infectivity, such as receptors that "dock" pathogens on host cells. Antibody neutralization can prevent pathogens from entering and infecting host cells, as opposed to the cytotoxic T-cell-mediated approach of killing cells that are already infected to prevent progression of an established infection. The neutralized antibody-coated pathogens can then be filtered by the spleen and eliminated in urine or feces.

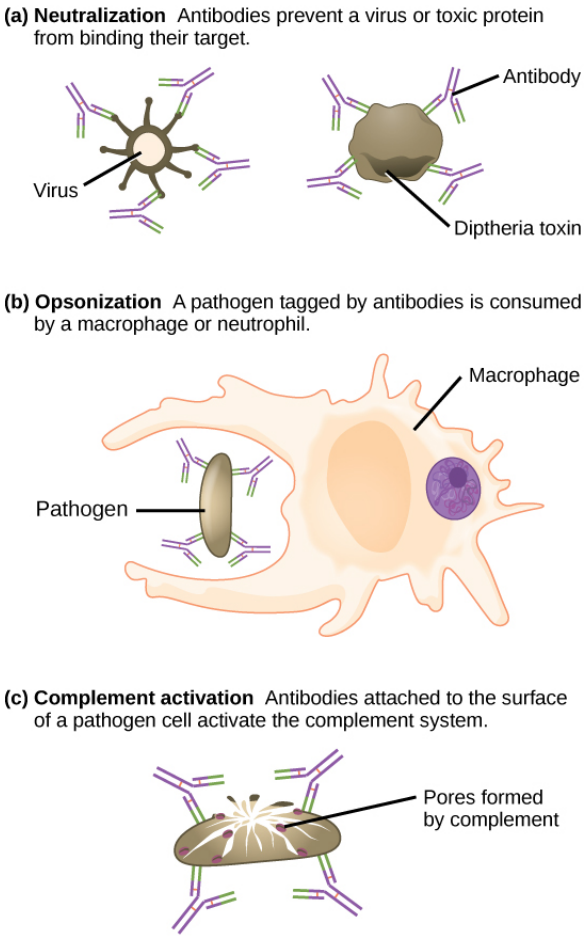

Figure: **Mechanisms of antibody action**: Antibodies may inhibit infection by (a) preventing the antigen from binding to its target, (b) tagging a pathogen for destruction by macrophages or neutrophils, or (c) activating the complement cascade.

Antibodies also mark pathogens for destruction by phagocytic cells, such as macrophages or neutrophils, because they are highly attracted to macromolecules complexed with antibodies. Phagocytic enhancement by antibodies is called opsonization. In another process, complement fixation, IgM and IgG in serum bind to antigens, providing docking sites onto which sequential complement proteins can bind. The combination of antibodies and complement enhances opsonization even further, promoting rapid clearing of pathogens.

Affinity, avidity, and cross reactivity

Not all antibodies bind with the same strength, specificity, and stability. In fact, antibodies exhibit different affinities (attraction) depending on the molecular complementarity between antigen and antibody molecules. An antibody with a higher affinity for a particular antigen would bind more strongly and stably. It would be expected to present a more challenging defense against the pathogen corresponding to the specific antigen.

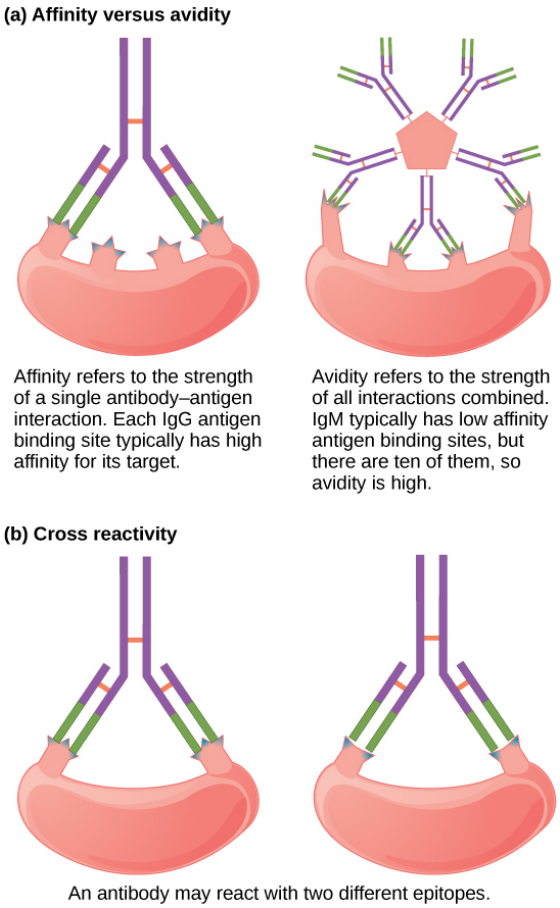

Figure: **Antibody affinity, avidity, and cross reactivity**: (a) Affinity refers to the strength of single interactions between antigen and antibody, while avidity refers to the strength of all interactions combined. (b) An antibody may cross-react with different epitopes.

The term avidity describes binding by antibody classes that are secreted as joined, multivalent structures (such as IgM and IgA). Although avidity measures the strength of binding, just as affinity does, the avidity is not simply the sum of the affinities of the antibodies in a multimeric structure. The avidity depends on the number of identical binding sites on the antigen being detected, as well as other physical and chemical factors. Typically, multimeric antibodies, such as pentameric IgM, are classified as having lower affinity than monomeric antibodies, but high avidity. Essentially, the fact that multimeric antibodies can bind many antigens simultaneously balances their slightly-lower-binding strength for each antibody/antigen interaction.

Antibodies secreted after binding to one epitope on an antigen may exhibit cross reactivity for the same or similar epitopes on different antigens. Cross reactivity occurs when an antibody binds not to the antigen that elicited its synthesis and secretion, but to a different antigen. Because an epitope corresponds to such a small region (the surface area of about four to six amino acids), it is possible for different macromolecules to exhibit the same molecular identities and orientations over short regions.

Cross reactivity can be beneficial if an individual develops immunity to several related pathogens despite having been exposed to or vaccinated against only one of them. For instance, antibody cross reactivity may occur against the similar surface structures of various Gram-negative bacteria. Conversely, antibodies raised against pathogenic molecular components that resemble self molecules may incorrectly mark host cells for destruction, causing autoimmune damage. Patients who develop systemic lupus erythematosus (SLE) commonly exhibit antibodies that react with their own DNA. These antibodies may have been initially raised against the nucleic acid of microorganisms, but later cross-reacted with self-antigens. This phenomenon is also called molecular mimicry.

12.2B: Antibody Functions is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.2C: Serology

Serology is the study of blood serum and other bodily fluids for the identification of antibodies.

Learning Objectives

- Describe how serology can be used to identify antibodies in blood serum and other bodily fluids

Key Points

- Serology is based on detecting immunoglobulin levels during the course of an infection.
- Serological techniques can differentiate between IgM and IgG antibodies, thus determining the stage of the infection.
- Serological techniques are important for the diagnosis of immunological diseases.

Key Terms

- **immunoglobulin G**: Most abundant antibody isotype secreted by plasma B cells.
- **immunoglobulin M**: largest antibody produced by B cells and the first to appear in response to initial exposure to antigen.
- **serology**: the scientific study of blood serum and other bodily fluids.

Serology is the scientific study of blood serum and other bodily fluids. In practical immunological terms, serology is the diagnostic identification of antibodies in the serum. Serological tests are performed on blood serum, and body fluids such as semen and saliva. In practice, the term usually refers to the diagnostic identification of antibodies in the serum or the detection of antigens of infectious agents in serum. Such antibodies are typically formed in response to an infection (against a given microorganism), against other foreign proteins (in response, for example, to a mismatched blood transfusion), or to one's own proteins (in instances of autoimmune disease).

A primary immune response occurs when a B cell sees an antigen for the first time. Antigen binding to the surface of the B cell stimulates the production of antibodies that are capable of binding directly to the antigen. Because this first recognition process takes time for antibody development, there is an initial delay for the body to fight the invading antigens. Immunoglobulin M (IgM) is an antibody produced during the primary immune response and plays a significant role fighting infection. When an antigen is introduced into the body for the first time, large quantities of IgM are produced. Meanwhile, the B cells are producing highly specific Immunoglobulin G (IgG) more slowly. Once IgG is produced in quantity, the IgG plays a greater role in the removal of antigens from the body due to its ability to bind to the antigen molecules more tightly. Through the course of an infection, a rapid spike of circulating IgM can be seen in the bloodstream. This is followed by a decrease of IgM as the amount of IgG increases. Medical laboratory personnel can identify the course and duration of an infection by measuring the ratio of IgM to IgG in the bloodstream. A ratio high in IgM indicates that an infection is in its early stages, while a ratio high in IgG indicates that the infection is in its later stage.

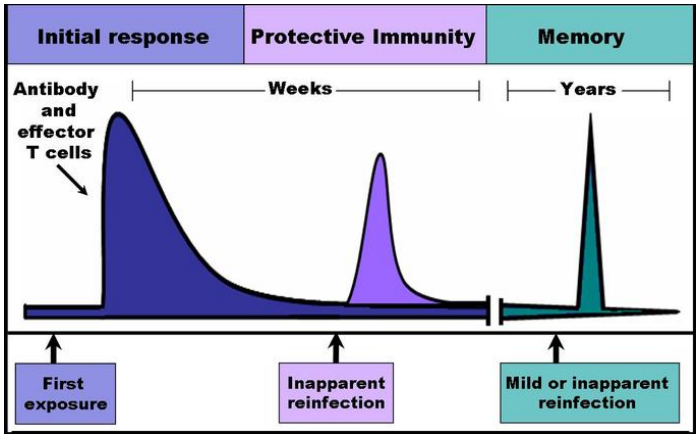

Figure: **Immune response**: When B and T cells begin to replicate, some of the offspring that they produce will end up becoming long-lived memory cells. These memory cells will remember all specific pathogens encountered during the animal's lifetime and can thus call forth a strong response if the pathogen ever invades the body again.

12.2C: Serology is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.2D: Precipitation Reactions

Precipitation reactions are serological assays for the detection of immunoglobulin levels from the serum of a patient with infection.

Learning Objectives

- Describe how precipitation reactions can be used for the detection of immunoglobulin levels in the serum of a patient

Key Points

- Precipitation assays are performed in semi-solid media such as agar or agarose where antibodies and antigens can diffuse toward one another and form a visible line of precipitation.
- There are several precipitation methods applied in the diagnostic laboratory. These include single, double, and electroimmunodiffusion.
- The most widely used gold standard precipitation methods are Ouchterlony test and Mancini test.

Key Terms

- **precipitin**: Any antibody which reacts with an antigen to form a precipitate.

Precipitation reactions are based on the interaction of antibodies and antigens. They are based on two soluble reactants that come together to make one insoluble product, the precipitate. These reactions depend on the formation of lattices (cross-links) when antigen and antibody exist in optimal proportions. Excess of either component reduces lattice formation and subsequent precipitation. Precipitation reactions differ from agglutination reactions in the size and solubility of the antigen and sensitivity. Antigens are soluble molecules and larger in size in precipitation reactions. There are several precipitation methods applied in clinical laboratory for the diagnosis of disease. These can be performed in semisolid media such as agar or agarose, or non-gel support media such as cellulose acetate.

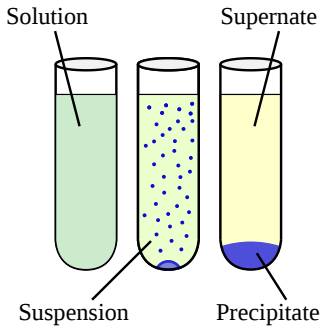

Figure: **Precipitation reaction**: Difference in the visual appearance of an aggregate and a precipitate.

Precipitation methods include double immunodiffusion (qualitative gel technique that determines the relationship between antigen and antibody), radial immunodiffusion (semi-quantitation of proteins by gel diffusion using antibody incorporated in agar), and electroimmunodiffusion (variation of the double immunodiffusion method reaction that uses an electric current to enhance the mobility of the reactants toward each other). Precipitation reactions are less sensitive than agglutination reactions but remain gold standard serological techniques. The most commonly used serologic precipitation reactions are the Ouchterlony test (based on double immunodiffusion and named after the Swedish physician who invented it), and the Mancini method (based on single radial immunodiffusion). In the double immunodiffusion technique, three basic reaction patterns result from the relationship of antigens and antibodies. These patterns are identity, non-identity, and partial identity. The Mancini method results in precipitin ring formation on a thin agarose layer. The diameter of the ring correlates with the concentration of proteins in the precipitin.

12.2D: Precipitation Reactions is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.2E: Agglutination Reactions

Agglutination reactions are used to assess the presence of antibodies in a specimen by mixing it with particulate antigens.

Learning Objectives

- Describe how agglutination reactions can be used to assess the presence of antibodies in a specimen

Key Points

- Agglutination reactions produce visible aggregates of antibody – antigen complexes when antibodies or antigens are conjugated to a carrier.
- Carriers used in agglutination methods could be artificial (e.g., latex or charcoal) or biological (e.g., erythrocytes).
- There are various methods of agglutination reactions that follow the same principle, but they differ in the elements they employ based on the desired endpoint and the main purpose of the test.

Key Terms

- **avidity**: The measure of the synergism of the strength of individual interactions between proteins.
- **erythrocytes**: Red blood cells.
- **agglutination**: the clumping together of red blood cells or bacteria, usually in response to a particular antibody

Agglutination is the visible expression of the aggregation of antigens and antibodies. Agglutination reactions apply to particulate test antigens that have been conjugated to a carrier. The carrier could be artificial (such as latex or charcoal particles) or biological (such as red blood cells). These conjugated particles are reacted with patient serum presumably containing antibodies. The endpoint of the test is the observation of clumps resulting from that antigen-antibody complex formation. The quality of the result is determined by the time of incubation with the antibody source, amount and avidity of the antigen conjugated to the carrier, and conditions of the test environment (e.g., pH and protein concentration). Various methods of agglutination are used in diagnostic immunology and these incude latex agglutination, flocculation tests, direct bacterial agglutination, and hemagglutination.

In latex agglutination, many antibody molecules are bound to latex beads (particles), which increases the number of antigen-binding sites. If an antigen is present in a test specimen, it will bind to the antibody and form visible, cross-linked aggregates. Latex agglutination can also be performed with the antigen conjugated to the beads for testing the presence of antibodies in a serum specimen.

Flocculation tests are designed for antibody detection and are based on the interaction of soluble antigens with antibodies, producing a precipitate of fine particles that can be seen with the naked eye.

Direct bacterial agglutination uses whole pathogens as a source of antigen. It measures the antibody level produced by a host infected with that pathogen. The binding of antibodies to surface antigens on the bacteria results in visible clumps.

Hemagglutination uses erythrocytes as the biological carriers of bacterial antigens, and purified polysaccharides or proteins for determining the presence of corresponding antibodies in a specimen.

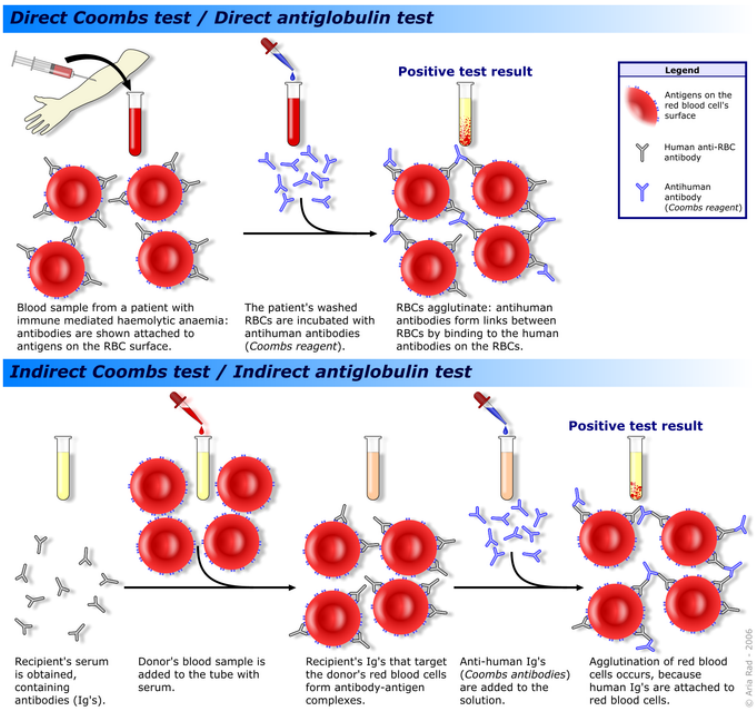

Figure: **Hemagglutination assay**: Red blood cells are used as carriers to detect antibodies from a patient's serum.

Agglutination tests are easy to perform and in some cases are the most sensitive tests currently available. These tests have a wide range of applications in the clinical diagnosis of non- infectious immune disorders and infectious disease.

12.2E: Agglutination Reactions is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.2F: Neutralization Reaction

Neutralization reactions are used to inactivate viruses and evaluate neutralizing antibodies.

Learning Objectives

- Describe how neutralizing antibodies serve to block viral attachment to cells thus inhibiting viral replication

Key Points

- When a vertebrate is infected with a virus, antibodies are produced against it. Some of the antibodies can block viral infection by neutralization which is usually the result of a formation of a virus-antibody complex. This complex can prevent viral infections in many ways.
- Neutralizing antibodies have shown potential in the treatment of retroviral infections such as HIV. Recently, potent and broadly neutralizing human antibodies against influenza have been reported.
- In diagnostic immunology and virology laboratories, the evaluation of neutralizing antibodies, which destroy the infectivity of viruses, can be measured by the neutralization method.

Key Terms

- **neutralization**: In the immunological sense refers to the ability of antibodies to block the site(s) on bacteria or viruses that they use to enter their target cell. One example of this within biology is a neutralizing antibody.
- **virion**: A single individual particle of a virus (the viral equivalent of a cell).
- **endosomes**: membrane-bound compartments inside eukaryotic cells.

A neutralizing antibody defends a cell from an antigen or infectious body by inhibiting or neutralizing any effect it has biologically. The antibody response is crucial for preventing many viral infections and may also contribute to the resolution of an infection. When a vertebrate is infected with a virus, antibodies are produced against many epitopes of multiple virus proteins. A subset of these antibodies can block viral infection by a process called neutralization. This usually involves the formation of a virus-antibody complex.

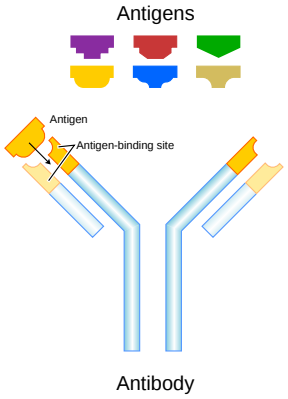

Figure: **Neutralizing antibody**: Antibody neutralizing an antigen and preventing its biological effect.

This virus-antibody complex can prevent viral infections in many ways. It may interfere with virion binding to receptors, block uptake into cells, prevent uncoating of the genomes in endosomes, or cause aggregation of virus particles. Many enveloped viruses are lysed when antiviral antibodies and serum complement disrupt membranes. Antibodies can also neutralize viral infectivity by binding to cell surface receptors.

Neutralizing antibodies have shown potential in the treatment of retroviral infections. Medical professionals and researchers have shown how the encoding of genes which influence the production of this particular type of antibody could help in the treatment of infections that attack the immune system. Experts in the field have used HIV treatment as an example of infections these antibodies can treat. Recently, potent and broadly neutralizing human antibodies against influenza have been reported, and have suggested possible strategies to generate an improved vaccine that would confer long-lasting immunity. Another disease which has been linked to the production of neutralizing antibodies is multiple sclerosis.

In diagnostic immunology and virology laboratories, the evaluation of neutralizing antibodies, which destroy the infectivity of viruses, can be measured by the neutralization method. In this procedure, patient serum is mixed with a suspension of infectious virus particles of the same type as those suspected of causing disease in the patient. A control suspension of virus is mixed with normal serum and is then inoculated into an appropriate cell culture. If the patient serum contains antibody to the virus, the antibody will bind to the virus particles and prevent them from invading the cells in culture, thereby neutralizing the infectivity of the virus. This technique is labor-intensive, demanding, and time consuming. It application is restricted to laboratories that perform routine viral cultures and related diagnosis.

12.2F: Neutralization Reaction is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.2G: Complement Fixation

Complement fixation is a method that demonstrates antibody presence in patient serum.

Learning Objectives

- Describe how the complement fixation assay can be used to test for the presence of a specific antibody in a patient's serum

Key Points

- Complement fixation method is more demanding than other systems used to detect antibodies and has been replaced by more sensitive techniques.
- Complement fixation requires several elements mixed together in optimum concentrations.
- The indicator system for the complement fixation assay is sheep red blood cells bound to anti-sheep immunoglobulin G.

Key Terms

- **immunoglobulin G**: Most abundant antibody isotype secreted by plasma B cells.

Complement fixation is a classic method for demonstrating the presence of antibody in patient serum. The complement fixation test consists of two components. The first component is an indicator system that uses combination of sheep red blood cells, complement-fixing antibody such as immunoglobulin G produced against the sheep red blood cells and an exogenous source of complement usually guinea pig serum. When these elements are mixed in optimum conditions, the anti-sheep antibody binds on the surface of red blood cells. Complement subsequently binds to this antigen -antibody complex formed and will cause the red blood cells to lyse.

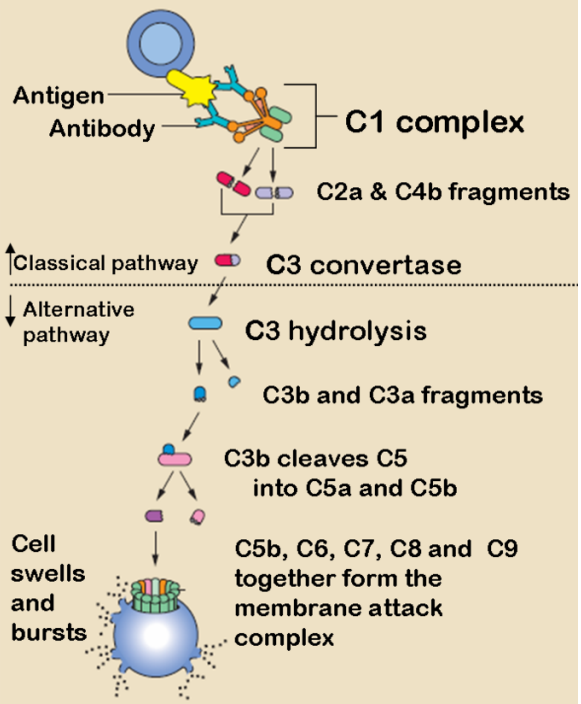

Figure: **The complement pathway**: Complement binds to antigen-antibody complex and leads to cell lysis.

The second component is a known antigen and patient serum added to a suspension of sheep red blood cells in addition to complement. These two components of the complement fixation method are tested in sequence. Patient serum is first added to the known antigen, and complement is added to the solution. If the serum contains antibody to the antigen, the resulting antigen-antibody complexes will bind all of the complement. Sheep red blood cells and the anti-sheep antibody are then added. If complement has not been bound by an antigen-antibody complex formed from the patient serum and known antigens, it is available to bind to the indicator system of sheep cells and anti-sheep antibody. Lysis of the indicator sheep red blood cells signifies both a lack of antibody in patient serum and a negative complement fixation test. If the patient's serum does contain a complement-fixing antibody, a positive result will be indicated by the lack of red blood cell lysis.

12.2G: Complement Fixation is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.2H: Fluorescent Antibodies

Fluorescent antibodies are antibodies that have been tagged with a fluorescent compound to facilitate their detection in the laboratory.

Learning Objectives

- Describe how fluorescent antibody conjugates can be used in immunoassays for protein detection

Key Points

- Fluorescent labeling of antibodies is used in place of radioisotopes and enzymes to enhance the sensitivity and specificity of immunological tests.
- Fluorescent antibodies can be used to stain proteins from patient serum or tissue sections fixed on a slide or live cells in suspension.
- Fluorescent antibodies can be detected with a fluorescent microscope or a flow cell sorter.

Key Terms

- **radioisotope**: A radioactive isotope of an element.

Fluorescent labeling is another method of demonstrating the complexity of antigens and antibodies. Fluorescent molecules are used as substitutes for radioisotope or enzyme labels. The fluorescent antibody technique consists of labeling antibody with dyes such as fluorescein isothiocyanate (FITC). These compounds have high affinity for proteins with which they conjugate.

Fluorescent techniques are very specific and sensitive, so fluorescent antibody-based techniques require a fluorescent microscope. A fluorescent substance absorbs light of one wavelength and emits light of a longer wavelength. Fluorescein fluoresces an intense apple-green color when excited under fluorescent microscopy. The chemical manipulation in labeling antibodies with fluorescent dyes to permit detection by direct microscopy examination does not impair antibody activity.

Figure: **Flow cell sorter**: This instrument is used to analyze live cells in suspension after staining them with fluorescent antibodies.

After the labeling of a specific antibody with a fluorescent molecule, it can still be reacted with its antigen and identified microscopically. Fluorescent antibody conjugates are commonly used in immunoassays. The basic methods utilizing fluorescent antibodies include direct, inhibition, and indirect immunofluorescent assay.

In the direct technique, a fluorescent antibody is used to detect antigen-antibody reactions at a microscopic level. The inhibition immunofluorescent assay is a blocking test in which an antigen is first exposed to an unlabeled antibody, then to a fluorescent antibody, and is finally washed and examined. Indirect immunofluorescence assay is based on the ability of antibodies to react with antigens as well as act as antigens and react with anti-antibody (anti-immunoglobulin). This technique is used extensively for the detection of autoantibodies and antibodies to tissue and cellular antigens. The methods described are mostly performed on glass slides with patient serum or tissue sections. Immunofluorescence can also be performed to identify specific antigens on live cells in suspension. This method is known as flow cytometry and requires a flow cell sorter rather than a fluorescent microscope.

12.2H: Fluorescent Antibodies is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.2I: Enzyme-Linked Immunosorbent Assay (ELISA)

Enzyme-linked immunosorbent assay (ELISA) is a solid-phase enzyme immunoassay used to detect the presence of a substance in solution.

Learning Objectives

- Describe how the Enzyme-linked immunosorbent assay (ELISA) can be used to detect and quantitate antigens, antibodies and allergens

Key Points

- ELISA is a quantitative technique that measures serum concentration of antigens, antibodies, and allergens.
- Standard ELISA uses antibody-antigen-antibody trapping principle with the second antibody coupled to an enzyme. If the complex is formed, the enzyme converts a clear solution into a colored one that can be measured with a spectrophotometer.
- ELISA is performed in a muti-well microtiter plate. In addition to the test solution, standard solutions are added with known antigen concentration. These solutions will be used to infer the concentration of the antigen being tested.

Key Terms

- **spectrophotometrically**: By using spectrophotometry.
- **epitope**: That part of a biomolecule (such as a protein) that is the target of an immune response.

Enzyme-linked immunosorbent assay (ELISA) is a method of quantifying an antigen immobilized on a solid surface. ELISA uses a specific antibody with a covalently coupled enzyme. The amount of antibody that binds the antigen is proportional to the amount of antigen present, which is determined by spectrophotometrically measuring the conversion of a clear substance to a colored product by the coupled enzyme.

Several variations of ELISA, seen in, exist but the most commonly used method is the sandwich ELISA. The sandwich assay uses two different antibodies that are reactive with different epitopes on the antigen with a concentration that needs to be determined. A fixed quantity of one antibody is attached to a series of replicate solid supports, such as plastic microtiter multi-well plate. Test solutions containing antigen at an unknown concentration are added to the wells and allowed to bind. Unbound antigen is removed by washing, and a second antibody which is linked to an enzyme is allowed to bind. This second antibody-enzyme complex constitutes the indicator system of the test. The antigen serves as bridge, so the more antigen in the test solution, the more enzyme-linked antibody will bind. The test solution is used in parallel with a series of standard solutions with known concentrations of antigen that serve as control and reference. The results obtained from the standard solutions are used to construct a binding curve of the second antibody as a function of antigen concentration. The concentration of antigens can be inferred from absorbance readings of standard solutions.

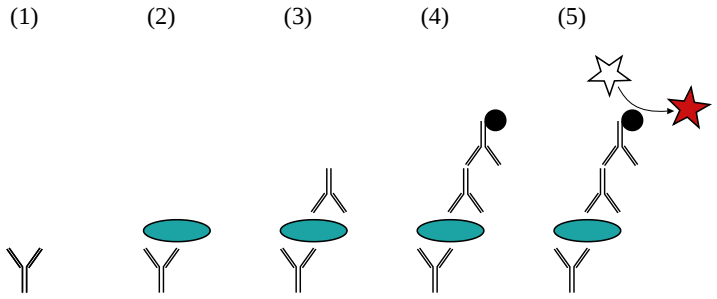

Figure: **Sandwich ELISA**: Two antibodies recognize different epitopes on same antigen.

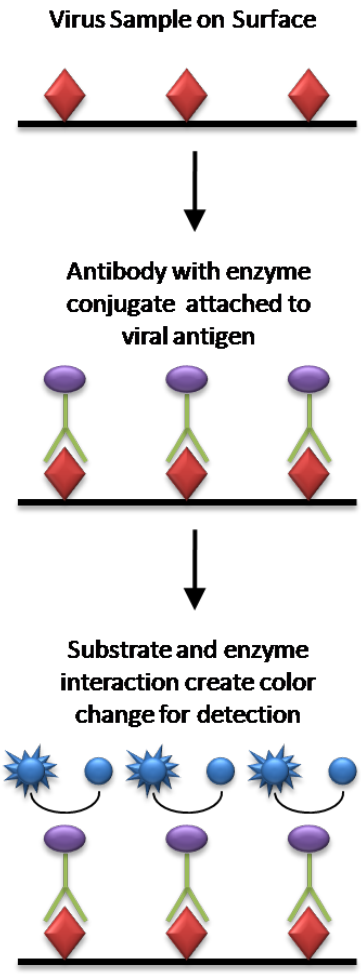

Figure: **ELISA**: Direct ELISA diagram using a viral antigen as an example.

12.2I: Enzyme-Linked Immunosorbent Assay (ELISA) is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.2J: Immunoblot Procedures

Immunoblot is a technique for analyzing proteins via antigen-antibody specific reactions.

Learning Objectives

- Describe how Western blotting allows individuals to detect specific solubilized proteins from serum or cell or tissue extracts

Key Points

- In immunoblot techniques such as Western blot analysis, proteins are separated by electrophoresis and transferred onto nitrocellulose sheets, then are identified by their reaction with labeled antibodies.
- Electrophoresis uses an electric current to separate proteins based on their size. Big proteins migrate slower and are represented by the highest bands on the blot, while small proteins migrate faster and are indicated by the lowest bands on the blot.
- Immunoblot assays are usually performed to confirm results obtained by other techniques such as ELISA.

Key Terms

- **sodium dodecyl sulfate**: strong detergent agent used to reduce and unfold native protein.
- **blot**: method of transferring protein, DNA, or RNA onto a carrier membrane.

Immunoblot procedures like protein blotting, or Western blotting, allow individuals to detect specific solubilized proteins from extracts made from cells or tissues, before or after any purification steps.

Immunoblotting Procedures

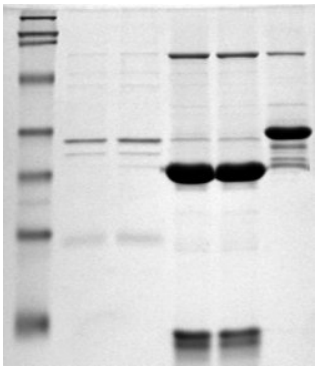

Figure: **Immunoblot**: proteins separated by molecular weight and represented by a dark band on a blot.

This analytic technique proceeds in the following steps. Proteins are generally separated by size using sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis. After this, they are transferred to a synthetic membrane via dry, semi-dry, or wet blotting methods. In the electric field generated by a power supply, the proteins coated with negatively charged SDS migrate toward the positive electrode. As the proteins migrate out of the gel, they are captured on a membrane. Protein binding to the membrane is an irreversible mechanism. Membranes can be of the nitrocellulose, polyvinylidene difluoride (PVDF), or nylon variety. The membrane can then be blocked with serum albumin or milk solution to prevent non-specific antibody binding. This is followed by probing with antibodies specific to the protein being studied on the membrane, a method that is similar to immunohistochemistry, but without a need for fixation. This technique exploits the specificity inherent in antigen-antibody recognition. Detection is typically performed using chromogen or peroxide-linked secondary antibodies to catalyze a chromogenic or chemiluminescent reaction.

Applications of Immunoblotting

Western blotting is a routine molecular biology method that can be used to semi-quantitatively compare protein levels between extracts. The size separation, prior to blotting, allows the protein molecular weight to be gauged, as compared with known molecular weight markers. Immunoblots are most often used in research settings and are usually performed to confirm results from ELISA or other immunoassays. In clinical diagnostic settings, immunoelectrophoresis is applied, which involves the

electrophoresis of serum or urine followed by immunodiffusion. The size and position of precipitation bands provides the same type of information about antibody amount as the double immunodiffusion method.

12.2J: Immunoblot Procedures is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.2K: Tests That Differentiate Between T Cells and B cells

Methods used to differentiate T cells and B cells include staining cell surface receptors and functional assays like the T lymphocyte cytotoxicity assay.

Learning Objectives

- Describe how T cells and B cells can be differentiated using staining of cell surface receptors and functional assays like the T lymphocyte cytotoxicity assay

Key Points

- There are two types of lymphocytes: B cells and T cells. These two components of the immune system have different functions but cooperate to fight infection.
- T cells elicit cell-mediated immune response, while B cells elicit humoral immunity.
- Lymphocytes are the only immunologically specific cellular components of the immune system.

Key Terms

- **cytotoxic**: of, relating to, or being a cytotoxin

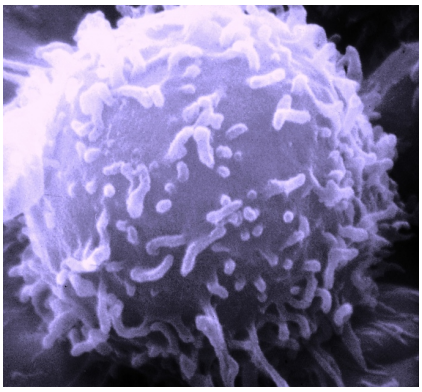

Figure: **SEM Lymphocyte**: A scanning electron microscope (SEM) image of a single human lymphocyte.

Lymphocytes are the only immunologically specific cellular components of the immune system. They are divided into two types based on the pathogen recognition receptors they express on their surface. T cells or T lymphocytes belong to a group of white blood cells known as lymphocytes. They are called T cells because they mature in the thymus. They play a central role in cell-mediated immunity along with initiating rejection of foreign tissues following organ transplantation. B-cells are also white blood cells and are a vital part of the humoral immunity branch of the adaptive immune system. These two cell types can function independently or cooperatively to defend the body against pathogens. T-lymphocytes can be distinguished from other lymphocytes like B cells and natural killer cells (NK cells) by the presence of a T cell receptor (TCR) on the cell surface. Alternatively, B-cells can be distinguished from other lymphocytes like T cells and natural killer cells (NK cells) by the presence of a protein on the B-cell's outer surface called a B-cell receptor (BCR).

Traditionally, T-lymphocytes were defined by their ability to form E-rosettes when they bind selectively to sheep erythrocytes. T-lymphocytes express CD3, CD4, CD8, or CD25 markers. B-lymphocytes express CD19 marker. The expression of different markers allows the separation/ differentiation of T and B cells. Another functional assay used to identify T-lymphocyte is the cytotoxic activity assay. This assay is based on measuring the killing ability that a determined number of T lymphocytes have for a certain number of target cells when both populations are placed together. B-lymphocytes have membrane-bound immunoglobulins that can be stained with anti-immunoglobulin labeled with fluorescent dyes and detected with a fluorescent microscope. More modern techniques like flow cytometry and immunohistochemistry are commonly used and rely on the use of fluorescent antibodies. These techniques are based on staining B and T cells for unique cell surface markers known as cluster of differentiation (CD).

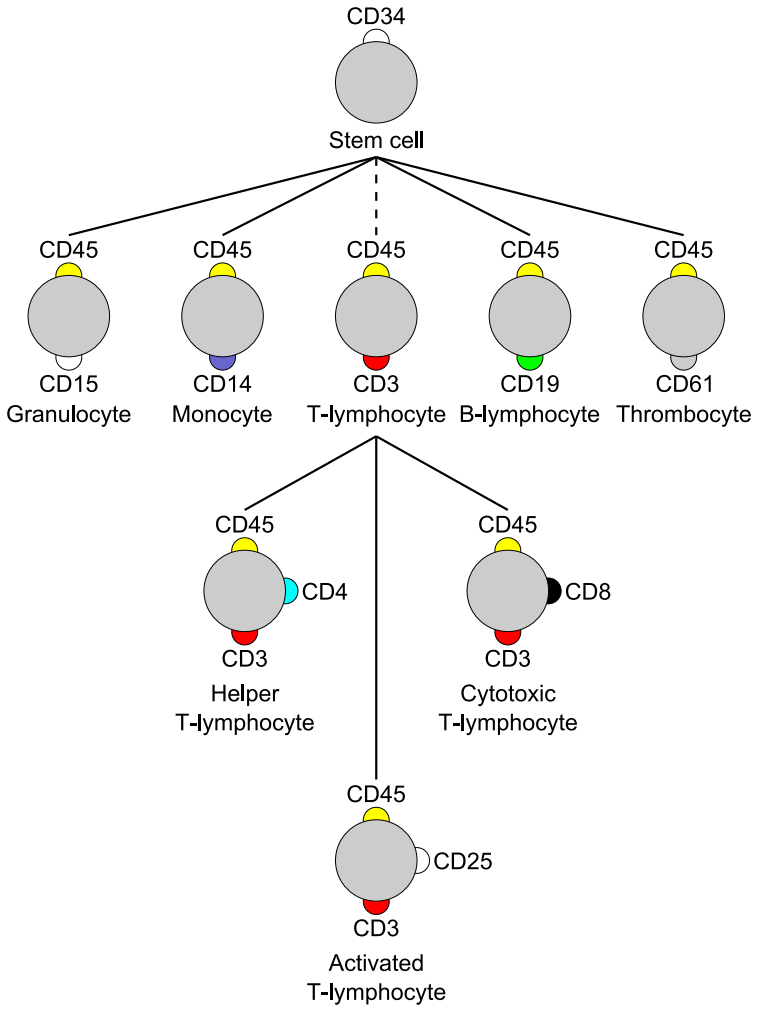

Figure: **Cluster of differentiation**: T and B lymphocytes express unique CD markers.

12.2K: Tests That Differentiate Between T Cells and B cells is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.2L: In Vivo Testing

In vivo testing using animal models of disease help discover new ways of solving complex health problems.

Learning Objectives

- Describe how animals can be used for diagnostic antibody production

Key Points

- In vivo testing is necessary for medical and research purposes. The medical field benefits from animal models to test the safety of drugs before they are used on patients. The research field benefits from in vivo testing by validating in vitro findings in vertebrates closest to humans.
- The most used animal models are mice, rats, and other rodents.
- In vivo testing is useful for the production of polyclonal antibodies applied in immunoassays and diagnostic immunology.

Key Terms

- **in vitro**: In an artificial environment outside the living organism.
- **antiserum**: a serum prepared from human or animal sources containing antigens specific for combatting an infectious disease
- **in vivo**: Within a living organism.

In Vivo Testing

In vivo methods refer to the use of animals as a conduit to generate purified polyclonal antibody solutions (antiserum) for research purposes. Polyclonal antibodies are applied in immunological assays to diagnose disease.

In vivo testing follows strict guidelines and humane animal use ethics. The protocol for diagnostic antibody production in animals follows multiple steps. Animals are injected with microbes or antigenic fragments that elicit an immune response; the immune response is allowed to develop for 1-2 weeks, after which blood is harvested. This blood now contains antibodies created from the antigens that were introduced into the animals. Antibodies are purified from the serum to make antiserum or a purified antibody solution for one particular antigen.

Figure: **A white laboratory rat**: Animals are used in laboratory experiments to translate in vitro findings.

These preparations will produce multiple antibody types that recognize different epitopes on the antigen, hence the term polyclonal. Polyclonal antibodies have various applications in the clinic and in research laboratories. Animals are also used to model human diseases in the research field. They are useful vehicles to understand how our bodies work, find cures and treatments for diseases, test new drugs for safety, and evaluate medical procedures before they are used on patients.

Mice, and other rodents such as rats and hamsters, make up over 90% of the animals used in biomedical research. In addition to having bodies that work similar to humans and other animals, rodents are small in size, easy to handle, relatively inexpensive to buy and keep, and produce many offspring in a short period of time. In vivo testing remains a crucial step for the evaluation of in vitro experimental findings and the production of immunological solutions needed for the diagnosis of human diseases.

12.2L: In Vivo Testing is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.2M: The Future of Diagnostic Immunology

The future of diagnostic immunology lies in the production of specific antibody-based assays and the development of improved vaccines.

Learning Objectives

- Describe how immunologic methods are used in the treatment and prevention of infectious diseases and immune-mediated diseases

Key Points

- Diagnostic immunology has considerably advanced due to the development of automated methods.
- New technology takes into account saving samples, reagents, and reducing cost.
- The future of diagnostic immunology faces challenges in the vaccination field for protection against HIV and as anti-cancer therapy.

Key Terms

- **ELISA**: enzyme-linked immunosorbent assay; assay based on the principle of antibody-antigen interaction.

The Future of Diagnostic Immunology

Modern immunology relies heavily on the use of antibodies as highly specific laboratory reagents. The diagnosis of infectious diseases, the successful outcome of transfusions and transplantations, and the availability of biochemical and hematologic assays with extraordinary specificity and sensitivity capabilities all attest to the value of antibody detection.

Immunologic methods are used in the treatment and prevention of infectious diseases and in the large number of immune -mediated diseases. Advances in diagnostic immunology are largely driven by instrumentation, automation, and the implementation of less complex and more standardized procedures. Examples of such processes are as follows:

- miniaturization (use of microtiter plates to save samples and reagents),
- amplified immunoassays (chemiluminesent ELISA),
- flow cytometry with monoclonal antibodies,
- immunoglobulins,
- molecular methods (polymerase chain reactions).

These methods have facilitated the performance of tests and have greatly expanded the information that can be developed by a clinical laboratory. The tests are now used for clinical diagnosis and the monitoring of therapies and patient responses. Immunology is a relatively young science and there is still so much to discover. Immunologists work in many different disease areas today that include allergy, autoimmunity, immunodeficiency, transplantation, and cancer.

Interestingly, no matter what the areas of expertise, vaccine development and understanding how vaccines work pose the greatest challenges. The vaccines currently used primarily generate an antibody response, which is able to attack free-moving pathogens, but is unable to fight bacteria and viruses, such as human immunodeficiency virus (HIV). In the cancer research field, vaccines that stimulate the immune system to attack tumor cells are undergoing clinical trials.

Figure: **Antibody sculpture**: Angel of the West is a sculpture by Julian Voss-Andreae based on the antibody structure.

12.3A: Specimen Collection

Laboratory diagnosis of diseases begins with the collection of a clinical specimen for examination or processing in the laboratory.

Learning Objectives

- Describe how laboratory diagnosis of disease begins with the collection of a clinical specimen for examination and processing

Key Points

- Specimen collection requires withdrawing blood, cerebrospinal fluid, collecting urine, or swabs from mucosal surfaces.
- Specimen collection is performed using aseptic techniques to ensure sterility of the sample and avoid contamination from bacteria or other bodily fluids.
- The types of biological samples accepted in most clinical laboratories are: serum samples, virology swab samples, biopsy and necropsy tissue, cerebrospinal fluid, whole blood for PCR, and urine samples. These are collected in specific containers for successful processing in the laboratory.

Key Terms

- **PCR**: polymerase chain reaction
- **necropsy**: The pathological dissection of a corpse; particularly to determine cause of death. Applicable to the examination of any life form.
- **biopsy**: The removal and examination of a sample of tissue from a living body for diagnostic purposes.

Laboratory diagnosis of an infectious disease begins with the collection of a clinical specimen for examination or processing in the laboratory.

The laboratory, with the help of well-chosen techniques and methods for rapid isolation and identification, confirms the diagnosis.

It has been observed that the most important and frequent factor affecting laboratory analysis, even in a well-functioning laboratory, is not the laboratory investigation itself but specimen preparation and errors in identification or labeling. Proper collection of an appropriate clinical specimen is, hence, the first step in obtaining an accurate laboratory diagnosis of an infectious disease.

Applying one's knowledge of microbiology and immunology for the collection, transportation and storage of specimens is as important as it is in the laboratory. For starters, the interpretation of the observation may be misleading if the specimen is inadequate.

There are several types of specimens recommended for diagnosis of immunological diseases including: serum samples, virology swab samples, biopsy and necropsy tissue, cerebrospinal fluid, whole blood for PCR, and urine samples.

Serum is the preferred specimen source for serologic testing. Blood specimens are obtained aseptically using approved venipuncture techniques by qualified personnel. Specimens are allowed to clot at room temperature and then are centrifuged. Serum is transferred to tightly-closing plastic tubes and stored at 2 – 8°C before shipment–which should always be prompt. Acute serum should be collected at the onset of symptoms. Convalescent specimens should follow two to four weeks later. Paired sera are tested together.

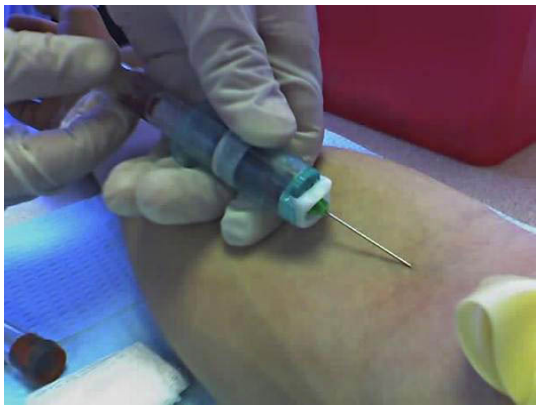

Figure: **Venipuncture**: Performed to draw blood sample using a vacutainer

Plasma is also collected for a very limited number of tests. Lipemic, hemolyzed, or contaminated sera may cause erroneous results and should be avoided as should repeated freeze-thaw cycles.

Another type of specimen used for disease diagnosis is cerebrospinal fluid (CSF). This should be transported in tightly-closing plastic tubes. Refrigerated CSF is acceptable for a limited number of serologic tests; however, if PCR is to be performed for the viral panels, the specimen must be frozen and shipped on dry ice. CSF specimens should be clear of any visible contamination or blood. A lumbar puncture (or LP, and colloquially known as a spinal tap) is performed to collecte CSF. This consists of the insertion of a hollow needle beneath the arachnoid membrane of the spinal cord in the lumbar region to withdraw cerebrospinal fluid for diagnostic purposes or to administer medication.

12.3A: Specimen Collection is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.3B: Immediate Direct Examination of Specimen

Following collection in appropriate containers, clinical specimens undergo a rapid examination in the laboratory.

Learning Objectives

- Describe how immediate direct examination of a specimen is useful to determine microscopic and macroscopic morphology

Key Points

- Immediate direct examination methods depend on the nature of the specimen.
- Diagnostic laboratory techniques include direct testing using a microscope, and immunological or genetic methods that provide immediate clues as to the identity of the microbe or microbes in the sample.
- Phenotypic methods include the examination of microscopic, macroscopic, and biochemical characteristics of a pathogen.

Key Terms

- **biopsied**: to remove and examine a sample of tissue from a living body for diagnostic purposes.

Immediate Direct Examination of Specimen

For specimen collection at sites that normally contain resident microflora, care should be taken to sample only the infected site and not the surrounding areas. For example, throat and nasopharyngeal swabs should not touch the tongue, cheek, or saliva. Saliva is an especially undesirable contaminant because it contains millions of bacteria, of which are normal flora. Sputum, the mucous secretion that coats the lower respiratory surfaces, especially the lungs, is discharged by coughing or taken by a catheterization to avoid contamination with saliva. Also the mucous lining of the vagina, cervix, or urethra can be sampled with a swabbed or applicator stick.

Additional sources of specimens are the vagina, eye, ear canal, nasal cavity (all by swab), and diseased tissue that has been surgically removed (biopsied). Urine is taken aseptically from the bladder with a catheter. Another method called the “clean catch” is taken by washing the external urethra and collecting the urine in midstream. Some diagnostic techniques require first-voided “dirty catch” urine. Sterile materials such as blood, cerebrospinal fluid, and tissue fluid must be taken by sterile needle aspiration.

Diagnostic laboratory techniques include direct testing using a microscope, immunological, or genetic methods that provide immediate clues as to the identity of the microbe or microbes in the sample, and cultivation, isolation, and identification of pathogens using a wide variety of general and specific tests (such as blood or other fluids).

Most tests fall into two categories: presumptive data, which place the isolated microbe in a preliminary category such as genus, and more specific, confirmatory data, which provide more definitive evidence of a species. Some diseases are diagnosed without the need to identify microbes from specimens. Serological tests on a patient’s serum can detect signs of an antibody response. One method that clarifies whether a positive test indicates current or prior infection is to take two samples several days apart and see if the antibody titer is raising. Skin testing can pinpoint a delayed allergic reaction to a microorganism. These tests are important in screening the general population for exposure to an infectious agent such as rubella or tuberculosis.

The main phenotypic methods include the direct examination of specimens, observing the growth of specimen cultures on special media, and biochemical testing of specimen cultures.

MICROSCOPIC MORPHOLOGY

Traits that can be valuable aids to identification of cell shape and size, Gram-stain reaction, acid-fast reaction and special structures, including endospores, granules, and capsules. Electron microscopes can pinpoint additional features such as cell wall flagella, pili, and fimbriae.

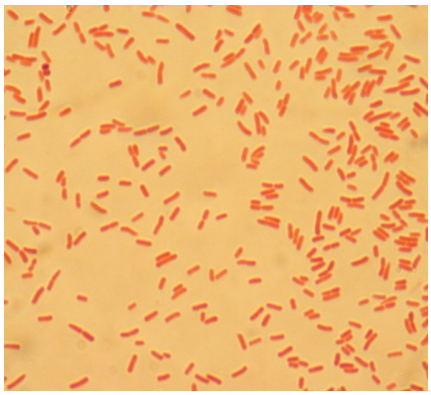

Figure: **Microscopic examination of E. coli**: Gram negative E. coli examined under the microscope from a patient with urinary tract infection.

MACROSCOPIC MORPHOLOGY

Traits that can be assessed with the naked eye are also useful in diagnosis. These include the appearance of colonies, including texture, shape, size, pigment, speed of growth, and patterns of growth in broth and gelatin.

PHYSIOLOGICAL AND BIOCHEMICAL CHARACTERISTICS

Enzymes and other biochemical properties of bacteria are reliable and stable expressions of the chemical identity of each species. Diagnostic tests exist for determining the presence of specific enzymes and assessing nutritional and metabolic activities.

Test examples include: fermentation of sugars, capacity to digest or metabolize complex polymers such as proteins and ploysaccharides; production of gas; presence of enzymes such as catalase, oxidase, and decarboxylase; and sensitivity to antimicrobial drugs.

CHEMICAL ANALYSIS

This involves analyzing the types of specific structural substances that the microorganism contains, such as the chemical composition of peptides in the cell wall and lipids in the membrane.

12.3B: Immediate Direct Examination of Specimen is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.3C: Cultivation of Specimen

Following direct examination, clinical specimens are cultivated to generate more confirmatory data.

Learning Objectives

- Describe how direct microscope observation of a fresh or stained specimen is one of the most rapid methods of determining its characteristics

Key Points

- The success of pathogen identification and treatment depends on how the specimen is collected, handled, and stored.
- Diagnostic laboratory techniques include direct testing using a microscope, and immunological or genetic methods that provide immediate clues as to the identity of the microbe or microbes in the sample.
- Following direct testing, cultivation, isolation, and identification of pathogens using a wide variety of general and specific tests is required.

Key Terms

- **mannitol**: A polyhydroxy alcohol, an isomer of sorbitol, used as an artificial sweetener.
- **MacConkey agar**: A culture medium designed to grow Gram-negative bacteria and differentiate them from lactose fermentation.

Cultivation of Specimen

The success of pathogen identification and treatment depends on how the specimen is collected, handled, and stored. It is also critical that the pathogen is isolated in a pure culture first. Direct microscope observation of a fresh or stained specimen is one of the most rapid methods of determining characteristics. Stains most often employed for bacteria are the gram stain, though they do not work on some organisms.

The direct florescence antibody (DFA) test can highlight the presence of the microbe in patient specimens by means of labeled antibodies. This test is useful for bacteria such as syphilis spirochete, which are not readily cultivated in a laboratory, or if a rapid diagnosis is essential for the survival of a patient.

Figure: **Blood culture**: This blood is cultured in a bottle to detect bloodstream infections.

In most cases, specimens are also inoculated into differential media that define such characteristics as fermentation patters (mannitol salt and MacConkey agar) and as reactions in blood (blood agar). A patient's blood is usually cultured in a special bottle of broth that can be periodically sampled for growth. Work must be done from isolated colonies or pure cultures, as working with mixed or contaminated cultures gives misleading and inaccurate results. From such isolates, clinical microbiologists obtain information about a pathogen's microscopic morphology and staining reactions, culture appearance, motility, oxygen requirements, and biochemical characteristics.

Serological testing uses in-vitro diagnostic testing of serum, has a high degree of specificity and sensitivity, and is based on the specificity an antibody has for its antigen. These techniques do not necessitate a cultivation step. Serum can be directly used in agglutination, precipitation, complement fixation, fluorescent microscopy, and enzyme-linked assays. Results of specimen analysis are entered in the patient's summary chart.

12.3C: Cultivation of Specimen is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.3D: DNA Analysis Using Genetic Probes and PCR

Genotyping of pathogenic isolates provides valuable support during investigations of suspected outbreaks and when tracing infectious diseases.

Learning Objectives

- Describe how genetic probes can be used to detect unique nucleotide sequences within the DNA or RNA or a microorganism

Key Points

- Hybridization can identify a bacterial species by analyzing segments of its DNA.
- Genetic probes are small fragments of DNA or RNA that are complementary to the specific sequences of DNA from a particular microbe.
- This approach is most useful in the detection of infections due to microorganisms that are difficult to culture.

Key Terms

- **polymerase chain reaction**: A technique in molecular biology for creating multiple copies of DNA from a sample; used in genetic fingerprinting etc.

Genetic probes are based on the detection of unique nucleotide sequences with the DNA or RNA of a microorganism. Once such a unique nucleotide sequence, which may represent a portion of a virulence gene or of chromosomal DNA, is found, it is isolated and inserted into a cloning vector (plasmid), which is then transformed into Escherichia coli to produce multiple copies of the probe. The sequence is then reisolated from plasmids and labeled with an isotope or substrate for diagnostic use. Hybridization of the sequence with a complementary sequence of DNA or RNA, follows cleavage of the double-stranded DNA of the microorganism in the specimen. The use of molecular technology in the diagnoses of infectious diseases has been further enhanced by the introduction of gene amplication techniques, such as the polymerase chain reaction (PCR) in which DNA polymerase is able to copy a strand of DNA by elongating complementary strands of DNA that have been initiated from a pair of closely spaced oligonucleotide primers. This approach has had major applications in the detection of infections due to microorganisms that are difficult to culture (e.g., the human immunodeficiency virus), or that have not as yet been successfully cultured (e.g., the Whipple's disease bacillus).

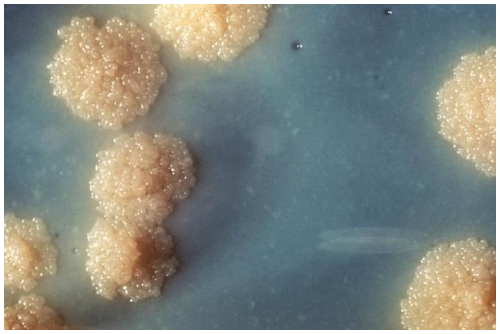

Figure: **Mycobacterium Tuberculosis**: a Mycobacterium tuberculosis culture revealing the organism's colonial morphology.

It is well established that genotyping of pathogenic isolates provides valuable support for the investigation of suspected outbreaks, the detection of unsuspected transmission, the tracing of infectious agents within a community, and the identification of possible sources of infection for newly diagnosed cases. At the national or international level, fingerprinting allows strains from different geographic areas to be compared, and the movement of individual strains to be tracked. Fingerprinting technique requires high-quality genomic DNA, which is not only difficult to prepare but also requires culturing of the organism, resulting in a long turnaround time. In addition, fingerprint interpretation and matching can be complicated and require sophisticated computer software for large-scale analysis.

In contrast, nucleic acid amplification-based assays do not require culturing of the organisms, allowing the analysis of samples in real time. In many PCR-based typing assays, the target DNA of interest is amplified and labeled by PCR, and the labeled products are hybridized to an array of immobilized diagnostic probes. This method has been successfully used for the detection of mutations in drug resistance genes of Mycobacterium tuberculosis, and for Mycobacterium species identification. Spoligotyping, a reverse dot

blot assay that detects the presence of a series of unique spacers in the direct repeat (DR) locus, meets the need for a simple and rapid method by which to distinguish M. tuberculosis complex strains. However, spoligotyping has significantly less discriminatory power than fingerprinting.

12.3E: Nucleic Acid Sequencing and rRNA Analysis

Nucleic acid sequencing and rRNA analysis consist of comparing nitrogen bases in rRNA.

Learning Objectives

- Describe how the 16SrRNA gene can be used for phylogenetic studies and in medical microbiology for bacterial identification

Key Points

- This method is effective in identifying general group differences of pathogens.
- 16S rRNA gene sequences contain hypervariable regions that can provide species -specific signature sequences useful for bacterial identification.
- This method can also be fine-tuned to identify pathogens at the species level.

Key Terms

- **ribosomes**: Large and complex molecular machine, found within all living cells, that serves as the primary site of biological protein synthesis.

Sixteen S ribosomal RNA (or 16S rRNA) is a component of the 30S small subunit of prokaryotic ribosomes. It is approximately 1.5kb (or 1500 nucleotides) in length. The genes coding for it are referred to as 16S rDNA, and are used in reconstructing phylogenies. Multiple sequences of 16S rRNA can exist within a single bacterium.

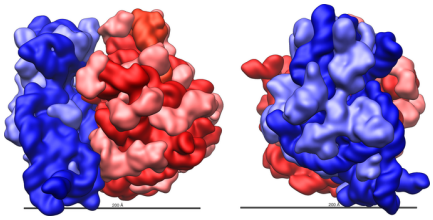

Figure: **Ribosomal RNA**: Structure and shape of the E.coli 70S ribosome. The large 50S ribosomal subunit (red) and small 30S ribosomal subunit (blue) are shown with a 200 Ångstrom (20 nm) scale bar. For the 50S subunit, the 23S (dark red) and 5S (orange red) rRNAs and the ribosomal proteins (pink) are shown. For the 30S subunit, the 16S rRNA (dark blue) and the ribosomal proteins (light blue) are shown.

The 16SrRNA gene is used for phylogenetic studies, as it is highly conserved between different species of bacteria and archaea. Carl Woese pioneered this use of 16S rRNA. In addition, mitochondrial and chloroplastic rRNA are also amplified. Unfortunately, while primers can be defined to amplify this gene from single genomes, this method is not accurate enough to estimate the diversity of microbial communities from their environments. Principal limits are the lack of real universal primers; DNA amplification biases and reference database selection impact the annotation of reads.

Paradoxically, methodological denial is now a rule in published articles that use 16S rRNA gene amplicon surveys to study unknown microbial communities. In these articles, one pair of primers (although many of them are designed, and provide different results) is used to amplify a region of the 16S rRNA gene. In addition to highly conserved primer binding sites, 16S rRNA gene sequences contain hypervariable regions that can provide species-specific signature sequences useful for bacterial identification. As a result, 16S rRNA gene sequencing has become prevalent in medical microbiology as a rapid and cheap (while inaccurate) alternative to phenotypic methods of bacterial identification. Although it was originally used to identify bacteria, 16S sequencing was subsequently found to be capable of reclassifying bacteria into completely new species, or even genera. It has also been used to describe new species that have never been successfully cultured.

12.4: Immunity Disorders: Hypersensitivity

Topic hierarchy

12.4A: Type I (Anaphylactic) Reactions

12.4B: Diagnosis and Treatment of Allergy

12.4C: Type II (Cytotoxic) Reactions

12.4D: Type III (Immune Complex) Reactions

12.4E: Type IV (Delayed Cell-Mediated) Reactions

This page titled 12.4: Immunity Disorders: Hypersensitivity is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

12.4A: Type I (Anaphylactic) Reactions

Type I (or immediate/anaphylactic) hypersensitivity can be caused by the body's response to a foreign substance.

Learning Objectives

- Describe Type I hypersensitivity reactions

Key Points

- Common triggers for anaphylaxis include venom from insect bites or stings, foods, and medication.
- People with atopic diseases such as asthma, eczema, or allergic rhinitis have a high risk of anaphylaxis from food, latex, and radiocontrast agents.
- Anaphylaxis is a severe allergic reaction that starts suddenly and affects many body systems due to the release of inflammatory mediators and cytokines from mast cells and basophils.

Key Terms

- **anaphylaxis**: A severe and rapid systemic allergic reaction to an allergen, causing a constriction of the trachea, preventing breathing; anaphylactic shock.
- **hives**: Itchy, swollen, red areas of the skin which can appear quickly in response to an allergen or due to other conditions.
- **mast cells**: A mast cell is a resident cell of several types of tissues and contains many granules rich in histamine and heparin. Mat cells play a role in allergy, anaphylaxis, wound healing and defense against pathogens.

Type I hypersensitivity is also known as immediate or anaphylactic hypersensitivity. Anaphylaxis typically produces many different symptoms over minutes or hours. Symptoms typically include raised bumps on the skin (; hives), itchiness, red face or skin (flushing), or swollen lips.

Figure: **Hives and flushing on the back of a person with anaphylaxis**: Hives and flushing on the back of a person with anaphylaxis

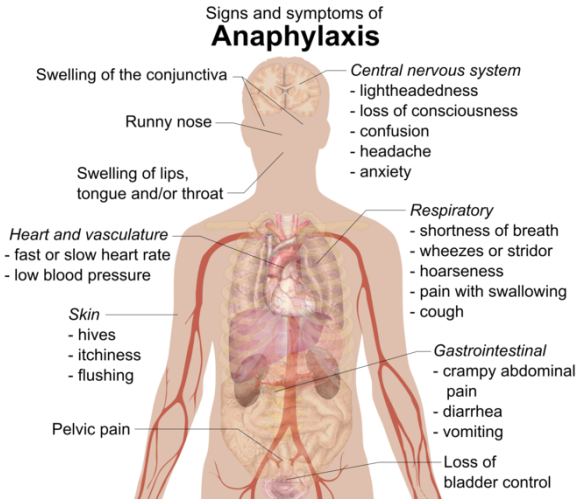

Figure: **Anaphylaxis**: A representation of the signs and symptoms of anaphylaxis that result from an allergic reaction.

Anaphylaxis can be caused by the body's response to almost any foreign substance. Common triggers include venom from insect bites or stings, foods, and medication. Foods are the most common trigger in children and young adults. Medications and insect bites and stings are more common triggers in older adults. Less common causes include physical factors, biological agents (such as semen), latex, hormonal changes, food additives (e.g. monosodium glutamate (MSG) and food coloring), and medications that are applied to the skin (topical medications). Exercise or temperature (either hot or cold) may also trigger anaphylaxis by causing tissue cells known as mast cells to release chemicals that start the allergic reaction.

Anaphylaxis caused by exercise is often also linked to eating certain foods. If anaphylaxis occurs while a person is receiving anesthesia, the most common causes are certain medications that are given to produce paralysis (neuromuscular blocking agents), antibiotics, and latex. Many foods can trigger anaphylaxis, even when the food is eaten for the first time. In Western cultures, the most common causes are eating or being in contact with peanuts, wheat, tree nuts, shellfish, fish, milk, and eggs.

People with atopic diseases such as asthma, eczema, or allergic rhinitis have a high risk of anaphylaxis from food, latex, and radiocontrast agents. These people do not have a higher risk from injectable medications or stings. People who have disorders caused by too many mast cells in their tissues (mastocytosis) or who are wealthier are at increased risk. The longer the time since the last exposure to an agent that caused anaphylaxis, the lower the risk of a new reaction.

Anaphylaxis is a severe allergic reaction that starts suddenly and affects many body systems. It results from the release of inflammatory mediators and cytokines from mast cells and basophils. This release is typically associated with an immune system reaction, but may also be caused by damage to cells that are not related to an immune reaction. When anaphylaxis is caused by an immune response, immunoglobulin E (IgE) binds to the foreign material that starts the allergic reaction (the antigen). The combination of IgE bound to the antigen activates FcεRI receptors on mast cells and basophils. The mast cells and basophils react by releasing inflammatory mediators such as histamine. These mediators increase the contraction of bronchial smooth muscles, cause blood vessels to widen (vasodilation), increase the leakage of fluid from blood vessels, and depress the actions of the heart muscle. There is also an immunologic mechanism that does not rely on IgE, but it is not known if this occurs in humans. When anaphylaxis is not caused by in immune response, the reaction is due to an agent that directly damages mast cells and basophils, causing them to release histamine and other substances that are usually associated with an allergic reaction (degranulation). Agents that can damage these cells include contrast medium for X-rays, opioids, temperature (hot or cold), and vibration.

12.4A: Type I (Anaphylactic) Reactions is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.4B: Diagnosis and Treatment of Allergy

Allergy testing can help confirm or rule out allergies, reducing adverse reactions and limiting unnecessary avoidance and medications.

Learning Objectives

- Describe how the skin prick test and the allergy blood test work to assess the presence of allergen specific antibodies in an individual

Key Points

- To assess the presence of allergen -specific IgE antibodies, you can use one of two methods: a skin-prick test or an allergy blood test.
- Challenge testing is when small amounts of a suspected allergen are introduced to the body orally, through inhalation, or via other routes.
- Patch testing is used to help ascertain the cause of skin contact allergy (contact dermatitis).
- Traditional treatment and management of allergies consisted of simply avoiding the allergen in question.
- Several antagonistic drugs are used to block the action of allergic mediators or to prevent activation of cells and degranulation processes.

Key Terms

- **allergen**: a substance that causes an allergic reaction
- **antihistamine**: a drug or substance that counteracts the effects of a histamine. Commonly used to alleviate the symptoms of hay fever and other allergies
- **skin prick test**: Skin-prick testing is also known as “puncture testing” and “prick testing” because of the series of tiny punctures or pricks made in the patient’s skin. Small amounts of suspected allergens or their extracts (pollen, grass, mite proteins, peanut extract, etc.) are introduced to sites on the skin marked with pen or dye.

Allergy testing can help confirm or rule out allergies, reducing adverse reactions and limiting unnecessary avoidance and medications. Correct diagnosis, counseling, and avoidance advice based on valid allergy test results will help reduce the incidence of symptoms and medications and will improve quality of life. Earlier and more accurate diagnoses save costs due to a reduction in consultations, referrals to secondary care, misdiagnoses, and emergency admissions.

For assessing the presence of allergen-specific IgE antibodies, you can use two different methods: a skin prick test or an allergy blood test. Both methods are recommended by the NIH guidelines, are equally cost-effective, and have similar diagnostic value in terms of sensitivity and specificity. A healthcare provider can use the test results to identify the specific allergic triggers that may be contributing to symptoms.

Figure: **Allergy Skin Testing**: Skin testing on an arm.

Allergies undergo dynamic changes over time. Regular allergy testing for relevant allergens provides information on if and how patient management can be changed in order to improve health and quality of life. Annual testing is often the practice for determining whether allergies to milk, eggs, soy, and wheat have been outgrown. The testing interval is extended to two to three

years for allergies to peanuts, tree nuts, fish, and crustacean shellfish. Results of followup testing can guide decision-making regarding whether and when it is safe to introduce or re-introduce allergenic food into the diet.

Skin testing is also known as “puncture testing” and “prick testing” because of the series of tiny punctures or pricks made in the patient’s skin. Small amounts of suspected allergens or their extracts are introduced to sites on the skin marked with pen or dye (the dye should be carefully selected, lest it cause an allergic response itself). Sometimes, the allergens are injected “intradermally” into the patient’s skin with a needle and syringe. Common areas for testing include the inside forearm and the back. If the patient is allergic to the substance, then a visible inflammatory reaction will usually occur within 30 minutes. This response will range from a slight reddening of the skin to a full-blown hive (called “wheal and flare”) similar to a mosquito bite in more sensitive patients. Interpretation of the results of the skin-prick test is normally done by allergists on a scale of severity, with +/- meaning borderline reactivity and 4+ indicating a severe reaction.

In contrast, an allergy blood test is quick and simple and can be performed irrespective of age, skin condition, medication, symptom, disease activity, and pregnancy. In addition, multiple allergens can be detected with a single blood sample. Allergy blood tests are very safe, since the patient is not exposed to any allergens during the testing procedure. The test measures the concentration of specific IgE antibodies in the blood.

Challenge testing is when small amounts of a suspected allergen are introduced to the body orally, through inhalation, or via other routes. Challenge tests are utilized most often with foods or medicines. If the patient experiences significant improvement while avoiding a suspected allergen, she may then be “challenged” by reintroducing it to see if symptoms can be reproduced.

Patch testing is used to help ascertain the cause of skin contact allergy (contact dermatitis). Adhesive patches, usually treated with a number of different commonly allergenic chemicals or skin sensitizers, are applied to the back. The skin is then examined for possible local reactions at least twice, usually 48 hours after application and then again two or three days later.

Traditional treatment and management of allergies consisted of simply avoiding the allergen in question. However, while avoidance of allergens may reduce symptoms and avoid life-threatening anaphylaxis, it is difficult to do for those with allergies to pollen or other airborne allergens. Several antagonistic drugs are used to block the action of allergic mediators or to prevent activation of cells and degranulation processes. These include antihistamines, glucocorticoids, epinephrine (adrenaline), theophylline, and cromolyn sodium.

Desensitization or hyposensitization is a treatment in which the patient is gradually vaccinated with progressively larger doses of the allergen in question. This can either reduce the severity or eliminate hypersensitivity altogether. It relies on the progressive skewing of IgG antibody production to block excessive IgE production seen in atopys. In effect, the person builds up immunity to increasing amounts of the allergen. Studies have demonstrated the long-term efficacy and the preventive effect of immunotherapy in reducing the development of new allergies. A second form of immunotherapy involves the intravenous injection of monoclonal anti-IgE antibodies. These bind to free- and B cell-associated IgE, signaling their destruction.

12.4B: Diagnosis and Treatment of Allergy is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.4C: Type II (Cytotoxic) Reactions

In type II (cytotoxic) hypersensitivity, the antibodies produced by the immune response bind to antigens on the patient's own cell surfaces.

Learning Objectives

- Describe Type II hypersensitivity reactions

Key Points

- The antigens recognized in this way may either be intrinsic ("self" antigen, innately part of the patient's cells) or extrinsic (adsorbed onto the cells during exposure to some foreign antigen, possibly as part of infection with a pathogen).
- Mediators of acute inflammation are generated at the site where a foreign antigen is recognized and membrane attack complexes cause cell lysis and death.
- In antibody -dependent cell-mediated cytotoxicity (ADCC), cells exhibiting the foreign antigen are tagged with antibodies (IgG or IgM) and they are then recognised by natural killer (NK) cells and macrophages which in turn kill these tagged cells.

Key Terms

- **macrophages**: A type of white blood cell that targets foreign material, including bacteria and viruses.
- **dendritic cells**: Dendritic cells are immune cells that function to process antigen material and present it on the surface of other cells of the immune system. They act as messengers between innate and adaptive immunity.
- **cytotoxic hypersensitivity**: In type II hypersensitivity, the antibodies produced by the immune response bind to antigens on the patient's own cell surfaces.

In type II hypersensitivity (or cytotoxic hypersensitivity), the antibodies produced by the immune response bind to antigens on the patient's own cell surfaces. The antigens recognized in this way may either be intrinsic ("self" antigen, innately part of the patient's cells) or extrinsic (adsorbed onto the cells during exposure to some foreign antigen, possibly as part of infection with a pathogen). These cells are recognized by macrophages or dendritic cells, which act as antigen-presenting cells. This causes a B cell response, wherein antibodies are produced against the foreign antigen.

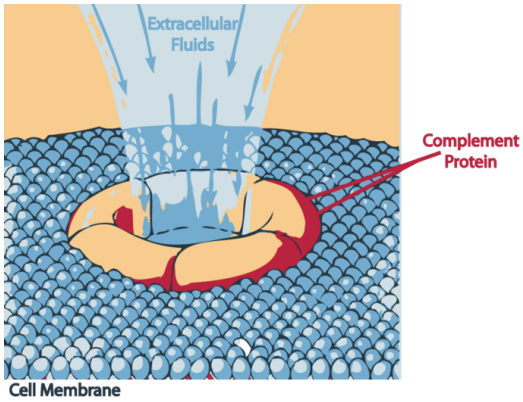

Figure: **Complement death**: A complement protein attacking an invader.

An example of type II hypersensitivity is the reaction to penicillin wherein the drug can bind to red blood cells, causing them to be recognized as different; B cell proliferation will take place and antibodies to the drug are produced. IgG and IgM antibodies bind to these antigens to form complexes that activate the classical pathway of complement activation to eliminate cells presenting foreign antigens (which are usually, but not in this case, pathogens). That is, mediators of acute inflammation are generated at the site and membrane attack complexes cause cell lysis and death. The reaction takes hours to a day. The membrane attack complex (MAC;) is typically formed on the surface of pathogenic bacterial cells as a result of the activation of the alternative pathway and the classical pathway of the complement system, and it is one of the effector proteins of the immune system. The membrane-attack complex (MAC) forms transmembrane channels. These channels disrupt the phospholipid bilayer of target cells, leading to cell lysis and death.

Another form of type II hypersensitivity is called antibody-dependent cell-mediated cytotoxicity (ADCC). Here, cells exhibiting the foreign antigen are tagged with antibodies (IgG or IgM). These tagged cells are then recognised by natural killer (NK) cells and

macrophages (recognised via IgG bound (via the Fc region) to the effector cell surface receptor, CD16 (FcγRIII)), which in turn kill these tagged cells.

Autoimmune diseases resemble type II-IV hypersensitivity reactions. They differ from hypersensitivity reactions in that the antigens driving the immune process are self-antigens rather than non-self as in hypersensitivity reactions. Below are some examples of Type II hypersensitivity-like autoimmunity.

12.4C: Type II (Cytotoxic) Reactions is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.4D: Type III (Immune Complex) Reactions

Type III hypersensitivity occurs when there is little antibody and an excess of antigen, leading to the formation of small immune complexes.

Learning Objectives

- Describe Type III hypersensitivity reactions

Key Points

- It is characterized by solvent antigens that are not bound to cell surfaces (which is the case in type II hypersensitivity) but bind antibodies to form immune complexes of different sizes.
- Large complexes can be cleared by macrophages but small immune complexes cannot be cleared and they insert themselves into small blood vessels, joints, and glomeruli, causing symptoms.
- The cause of damage is as a result of the action of cleaved complement anaphylotoxins C3a and C5a, which, mediate the onset of the inflammatory response and eventual tissue damage.

Key Terms

- **glomerulonephritis**: A form of nephritis characterized by inflammation of the glomeruli
- **immune complex**: An immune complex is formed from the integral binding of an antibody to a soluble antigen. The bound antigen acting as a specific epitope, bound to an antibody is referred to as a singular immune complex.
- **Arthus reaction**: The Arthus reaction is a type of local type III hypersensitivity reaction which involves the deposition of antigen/antibody complexes mainly in the vascular walls, serosa (pleura, pericardium, synovium) and glomeruli.

Type III hypersensitivity occurs when there is little antibody and an excess of antigen, leading to small immune complexes being formed that do not fix complement and are not cleared from the circulation. It is characterized by solvent antigens that are not bound to cell surfaces (which is the case in type II hypersensitivity). When these antigens bind antibodies, immune complexes of different sizes form. Large complexes can be cleared by macrophages but macrophages have difficulty in the disposal of small immune complexes. These immune complexes insert themselves into small blood vessels, joints, and glomeruli, causing symptoms. Unlike the free variant, small immune complex bound to sites of deposition (like blood vessel walls) are far more capable of interacting with complement. These medium-sized complexes, formed in the slight excess of antigen, are viewed as being highly pathogenic.

Such depositions in tissues often induce an inflammatory response, and can cause damage wherever they precipitate. The cause of damage is as a result of the action of cleaved complement anaphylotoxins C3a and C5a, which, respectively, mediate the induction of granule release from mast cells (from which histamine can cause urticaria), and recruitment of inflammatory cells into the tissue (mainly those with lysosomal action, leading to tissue damage through frustrated phagocytosis by polymorphonuclear neutrophils and macrophages).

Immune complex glomerulonephritis, as seen in Henoch-Schönlein purpura is an example of IgA involvement in a nephropathy. The reaction can take hours, days, or even weeks to develop, depending on whether or not there is immunlogic memory of the precipitating antigen. Typically, clinical features emerge a week following initial antigen challenge, when the deposited immune complexes can precipitate an inflammatory response. Because of the nature of the antibody aggregation, tissues that are associated with blood filtration at considerable osmotic and hydrostatic gradient (e.g. sites of urinary and synovial fluid formation, kidney glomeruli and joint tissues respectively) bear the brunt of the damage. Hence, vasculitis, glomerulonephritis and arthritis are commonly-associated conditions as a result of type III hypersensitivity responses. As observed under methods of histopathology, acute necrotizing vasculitis within the affected tissues is observed concomitant to neutrophilic infiltration, along with notable eosinophilic deposition (fibrinoid necrosis).

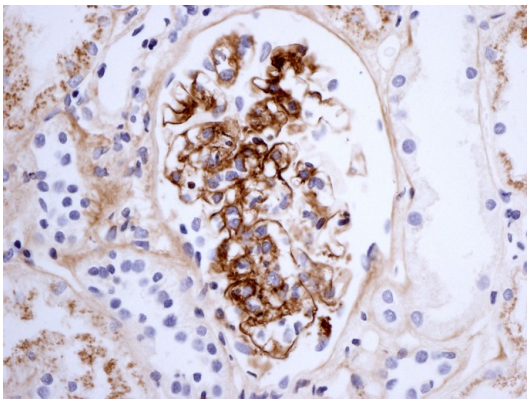

Figure: **Henoch-Schönlein nephritis IgA immunostaining**: Immune Complex Glomerulonephritis, as seen in Henoch-Schönlein purpura; this is an example of IgA involvement in a nephropathy.

Often, immunofluorescence microscopy can be used to visualize the immune complexes. Skin response to a hypersensitivity of this type is referred to as an Arthus reaction, and is characterized by local erythema and some induration. Platelet aggregation, especially in microvasculature, can cause localized clot formation, leading to blotchy hemorrhages. This typifies the response to injection of foreign antigen sufficient to lead to the condition of serum sickness. An immune complex is formed from the integral binding of an antibody to a soluble antigen. The bound antigen acting as a specific epitope, bound to an antibody, is referred to as a singular immune complex. After an antigen-antibody reaction, the immune complexes can be subject to any of a number of responses, including complement deposition, opsonization, phagocytosis, or processing by proteases.

Red blood cells carrying CR1-receptors on their surface may bind C3b-decorated immune complexes and transport them to phagocytes, mostly in liver and spleen, and return back to the general circulation. Immune complexes may themselves cause disease when they are deposited in organs, e.g. in certain forms of vasculitis. This is the third form of hypersensitivity in the Gell-Coombs classification, called Type III hypersensitivity. Immune complex deposition is a prominent feature of several autoimmune diseases, including systemic lupus erythematosus, cryoglobulinemia, rheumatoid arthritis, scleroderma and Sjögren's syndrome.

12.4E: Type IV (Delayed Cell-Mediated) Reactions

Type IV hypersensitivity reactions are cell-mediated and take 2 to 3 days to develop.

Learning Objectives

- Describe Type IV cell-mediated reactions and explain why they take two to three days to develop

Key Points

- Cell-mediated immunity is an immune response that does not involve antibodies but rather involves the activation of phagocytes, natural killer cells (NK), antigen -specific cytotoxic T-lymphocytes, and the release of various cytokines in response to an antigen.
- In type IV hypersensitivity reactions, CD4+ helper T cells recognize antigen in a complex with Class 2 major histocompatibility complex on macrophages (the antigen-presenting cells).
- A classic example of delayed type IV hypersensitivity is the Mantoux tuberculin test in which skin induration indicates exposure to tuberculosis.

Key Terms

- **cellular immunity**: Cellular immunity protects the body by: activating antigen-specific cytotoxic T-lymphocytes, activating macrophages and natural killer cells and stimulating cytokine secretion to stimulate other cells involved in adaptive immune responses and innate immune responses.
- **type IV hypersensitivity**: A cell-mediated immune response that takes two to three days to develop.

Cell-mediated immunity is an immune response that does not involve antibodies, but rather involves the activation of phagocytes, natural killer cells (NK), antigen-specific cytotoxic T-lymphocytes, and the release of various cytokines in response to an antigen. Historically, the immune system was separated into two branches: humoral immunity, for which the protective function of immunization could be found in the humor (cell-free bodily fluid or serum) and cellular immunity, for which the protective function of immunization was associated with cells. CD4 cells or helper T cells provide protection against different pathogens. Cytotoxic T cells cause death by apoptosis without using cytokines. Therefore in cell mediated immunity cytokines are not always present.

Cellular immunity protects the body by:

1. activating antigen-specific cytotoxic T-lymphocytes that are able to induce apoptosis in body cells displaying epitopes of foreign antigen on their surface, such as virus-infected cells, cells with intracellular bacteria, and cancer cells displaying tumor antigens

2. activating macrophages and natural killer cells, enabling them to destroy pathogens

3. stimulating cells to secrete a variety of cytokines that influence the function of other cells involved in adaptive immune responses and innate immune responses

Cell-mediated immunity is directed primarily at microbes that survive in phagocytes and microbes that infect non-phagocytic cells. It is most effective in removing virus-infected cells, but also participates in defending against fungi, protozoans, cancers, and intracellular bacteria. It also plays a major role in transplant rejection.

Type IV hypersensitivity is often called delayed type hypersensitivity as the reaction takes two to three days to develop. Unlike the other types, it is not antibody mediated but rather is a type of cell-mediated response. CD4+ helper T cells recognize antigen in a complex with Class 2 major histocompatibility complex. The antigen-presenting cells in this case are macrophages that secrete IL-12, which stimulates the proliferation of further CD4+ Th1 cells. CD4+ T cells secrete IL-2 and interferon gamma, further inducing the release of other Th1 cytokines, thus mediating the immune response. Activated CD8+ T cells destroy target cells on contact, whereas activated macrophages produce hydrolytic enzymes and, on presentation with certain intracellular pathogens, transform into multinucleated giant cells.

A classic example of delayed type IV hypersensitivity is the Mantoux tuberculin test in which skin induration indicates exposure to tuberculosis. Other examples include: temporal arteritis, Hashimoto's thyroiditis, symptoms of leprosy, symptoms of tuberculosis, coeliac disease, graft-versus-host disease and chronic transplant rejection.

Figure: **Mantoux test**: The reaction is read by measuring the diameter of induration (palpable raised, hardened area) across the forearm (perpendicular to the long axis) in millimeters. If there is no induration, the result should be recorded as "0 mm". Erythema (redness) should not be measured. If a person has had a history of a positive tuberculin skin test, or had a recent tuberculin skin test (within one year), another skin test should be used.

Figure: **Mantoux tuberculin test**: The Mantoux test (also known as the Mantoux screening test, tuberculin sensitivity test, Pirquet test, or PPD test for purified protein derivative) is a diagnostic tool for tuberculosis. A standard dose of tuberculin is injected intradermally (between the layers of dermis) and read 48 to 72 hours later.

12.5A: Immunodeficiency

Immunodeficiency occurs when the immune system cannot appropriately respond to infections.

Learning Objectives

- Explain the problems associated with immunodeficiency

Key Points

- If a pathogen is allowed to proliferate to certain levels, the immune system can become overwhelmed; immunodeficiency occurs when the immune system fails to respond sufficiently to a pathogen.
- Immunodeficiency can be caused by many factors, including certain pathogens, malnutrition, chemical exposure, radiation exposure, or even extreme stress.
- HIV is a virus that causes immunodeficiency by infecting helper T cells, causing cytotoxic T cells to destroy them.

Key Terms

- **phagocyte**: a cell of the immune system, such as a neutrophil, macrophage or dendritic cell, that engulfs and destroys viruses, bacteria, and waste materials
- **lysis**: the disintegration or destruction of cells
- **immunodeficiency**: a depletion in the body's natural immune system, or in some component of it

Immunodeficiency

Failures, insufficiencies, or delays at any level of the immune response can allow pathogens or tumor cells to gain a foothold to replicate or proliferate to high enough levels that the immune system becomes overwhelmed, leading to immunodeficiency; it may be acquired or inherited. Immunodeficiency can be acquired as a result of infection with certain pathogens (such as HIV), chemical exposure (including certain medical treatments), malnutrition, or, possibly, by extreme stress. For instance, radiation exposure can destroy populations of lymphocytes, elevating an individual's susceptibility to infections and cancer. Dozens of genetic disorders result in immunodeficiencies, including Severe Combined Immunodeficiency (SCID), bare lymphocyte syndrome, and MHC II deficiencies. Rarely, primary immunodeficiencies that are present from birth may occur. Neutropenia is one form in which the immune system produces a below-average number of neutrophils, the body's most abundant phagocytes. As a result, bacterial infections may go unrestricted in the blood, causing serious complications.

HIV/AIDS

Human immunodeficiency virus infection / acquired immunodeficiency syndrome (HIV/AIDS), is a disease of the human immune system caused by infection with human immunodeficiency virus (HIV). During the initial infection, a person may experience a brief period of influenza-like illness. This is typically followed by a prolonged period without symptoms. As the illness progresses, it interferes more and more with the immune system. The person has a high probability of becoming infected, including from opportunistic infections and tumors that do not usually affect people who have working immune systems.

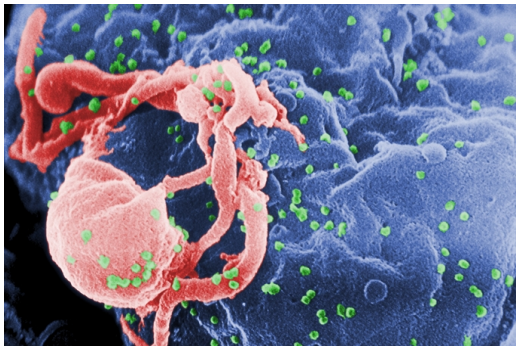

Figure: **Image of HIV: scanning electron micrograph of HIV-1 budding (in green, color added) from cultured lymphocyte**: Multiple round bumps on cell surface represent sites of assembly and budding of HIV. During primary infection, the level of HIV may reach several million virus particles per milliliter of blood.

After the virus enters the body, there is a period of rapid viral replication, leading to an abundance of virus in the peripheral blood. During primary infection, the level of HIV may reach several million virus particles per milliliter of blood. This response is accompanied by a marked drop in the number of circulating CD4+ T cells, cells that are or will become helper T cells. The acute viremia, or spreading of the virus, is almost invariably associated with activation of CD8+ T cells (which kill HIV-infected cells) and, subsequently, with antibody production. The CD8+ T cell response is thought to be important in controlling virus levels, which peak and then decline, as the CD4+ T cell counts recover.

Ultimately, HIV causes AIDS by depleting CD4+ T cells (helper T cells). This weakens the immune system, allowing opportunistic infections. T cells are essential to the immune response; without them, the body cannot fight infections or kill cancerous cells. The mechanism of CD4+ T cell depletion differs in the acute and chronic phases. During the acute phase, HIV-induced cell lysis and killing of infected cells by cytotoxic T cells accounts for CD4+ T cell depletion, although apoptosis (programmed cell death) may also be a factor. During the chronic phase, the consequences of generalized immune activation coupled with the gradual loss of the ability of the immune system to generate new T cells appear to account for the slow decline in CD4+ T cell numbers.

12.5B: The Roles of Genetics and Gender in Autoimmune Disease

Autoimmunity is the failure of an organism in recognizing “self” which results in an immune response against its own cells and tissues.

Learning Objectives

- Define autoimmunity and explain how it gives rise to autoimmune disease

Key Points

- Autoimmune diseases are very often treated with steroids which will dampen the immune response.
- Certain individuals are genetically susceptible to developing autoimmune diseases and susceptibility is linked to immunoglobulin, T-cell receptor, and MHC complex genes.
- Women are more likely than men to develop an autoimmune disease, but the severity of the disease is more accentuated in men.

Key Terms

- **autoimmunity**: The condition where one’s immune system attacks one’s own tissues, i.e., an autoimmune disorder.
- **alloimmunity**: Immunity, obtained from another, against one’s own cells.

Autoimmunity is the failure of an organism in recognizing its own constituent parts as self, which allows an immune response against its own cells and tissues. Any disease that results from such an aberrant immune response is termed an autoimmune disease. Autoimmunity is often caused by a lack of germ development of a target body and as such the immune response acts against its own cells and tissues. Prominent examples include Coeliac disease, diabetes mellitus type 1 (IDDM), Sarcoidosis, systemic lupus erythematosus (SLE), Sjögren’s syndrome, Churg-Strauss Syndrome, Hashimoto’s thyroiditis, Graves’ disease, idiopathic thrombocytopenic purpura, Addison’s Disease, rheumatoid arthritis (RA), and allergies.

Autoimmune diseases are very often treated with steroids. The misconception that an individual’s immune system is totally incapable of recognizing self antigens is not new. Paul Ehrlich, at the beginning of the 20th century, proposed the concept of horror autotoxicus, wherein a ‘normal’ body does not mount an immune response against its own tissues. Therefore, any autoimmune response was perceived to be abnormal and postulated to be connected with human disease. Now, it is accepted that autoimmune responses are an integral part of vertebrate immune systems (sometimes termed ‘natural autoimmunity’), normally prevented from causing disease by the phenomenon of immunological tolerance to self-antigens.

Autoimmunity should not be confused with alloimmunity. While a high level of autoimmunity is unhealthy, a low level of autoimmunity may actually be beneficial. First, low-level autoimmunity might aid in the recognition of neoplastic cells by CD8+ T cells, and thus reduce the incidence of cancer. Second, autoimmunity may have a role in allowing a rapid immune response in the early stages of an infection when the availability of foreign antigens limits the response (i.e., when there are few pathogens present).

Certain individuals are genetically susceptible to developing autoimmune diseases. This susceptibility is associated with multiple genes plus other risk factors. However, genetically predisposed individuals do not always develop autoimmune diseases. Three main sets of genes are suspected in many autoimmune diseases. These genes are related to immunoglobulins, T-cell receptors, and the major histocompatibility complexes (MHC). Immunoglobulins and T-cell receptors are involved in the recognition of antigens and they are inherently variable and susceptible to recombination. These variations enable the immune system to respond to a very wide variety of invaders, but may also give rise to lymphocytes capable of self-reactivity. Scientists such as H. McDevitt, G. Nepom, J. Bell, and J. Todd have also provided strong evidence to suggest that certain MHC class II allotypes are strongly correlated with disease. For example:

1. HLA DR2 is strongly positively correlated with Systemic Lupus Erythematosus, narcolepsy and multiple sclerosis, and negatively correlated with DM Type 1.

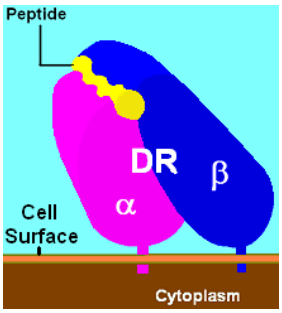

Figure: **MHC Class II, DR**: HLA-DR is a MHC class II cell surface receptor encoded by the human leukocyte antigen complex on chromosome 6 region 6p21.31. The complex of HLA-DR and its ligand, a peptide of 9 amino acids in length or longer, constitutes a ligand for the T-cell receptor (TCR).

2. HLA DR3 is correlated strongly with Sjögren's syndrome, myasthenia gravis, SLE, and DM Type 1.

3. HLA DR4 is correlated with the genesis of rheumatoid arthritis, Type 1 diabetes mellitus, and pemphigus vulgaris.

Fewer correlations exist with MHC class I molecules. The most notable and consistent is the association between HLA B27 and ankylosing spondylitis. Correlations may exist between polymorphisms within class II MHC promoters and autoimmune disease. The contributions of genes outside the MHC complex remain the subject of research, in animal models of disease (Linda Wicker's extensive genetic studies of diabetes in the NOD mouse), and in patients (Brian Kotzin's linkage analysis of susceptibility to SLE).

A person's sex also seems to have some role in the development of autoimmunity, classifying most autoimmune diseases as sex-related diseases. Nearly 75% of the more than 23.5 million Americans who suffer from autoimmune disease are women, although it is less-frequently acknowledged that millions of men also suffer from these diseases. However, autoimmune diseases that develop in men tend to be more severe. A few autoimmune diseases that men are just as or more likely to develop as women, include: ankylosing spondylitis, type 1 diabetes mellitus, Wegener's granulomatosis, and Crohn's disease. The reasons for the sex role in autoimmunity are unclear. However, women appear to generally mount larger inflammatory responses than men when their immune systems are triggered, increasing the risk of autoimmunity. In addition, involvement of sex steroids is indicated by the fact that many autoimmune diseases tend to fluctuate in accordance with hormonal changes, for example, during pregnancy. Interestingly, a history of pregnancy also appears to leave a persistent increased risk for autoimmune disease. Indeed, it has been suggested that the slight exchange of cells between mothers and their children during pregnancy may induce autoimmunity. This would tip the gender balance in the direction of the female. Another theory suggests the female high tendency to get autoimmunity is due to an imbalanced X chromosome inactivation.

12.5B: The Roles of Genetics and Gender in Autoimmune Disease is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.5C: Cytotoxic Autoimmune Reactions

Autoimmunity is a result of the failure of an organism's immune system to recognize "self".

Learning Objectives

- Define autoimmunity and describe how it can lead to disease

Key Points

- Autoimmunity is often caused by a lack of germ development of a target body and, as such, the immune response acts against its own cells and tissues.
- Certain individuals are genetically susceptible to developing autoimmune diseases but genetically predisposed individuals do not always develop an autoimmune disease.
- Three main sets of genes are suspected in many autoimmune diseases: immunoglobulins, T-cell receptors and the major histocompatibility complexes (MHC).
- Women are more likely to develop an autoimmune disease.

Key Terms

- **alloimmunity**: Immunity, obtained from another, against one's own cells.
- **autoimmunity**: The condition where one's immune system attacks one's own tissues, i.e., an autoimmune disorder.

Autoimmunity is the failure of an organism in recognizing its own constituent parts as self, creating an immune response against its own cells and tissues. Any disease that results from such an aberrant immune response is termed an *autoimmune* disease.

Autoimmunity is often caused by a lack of germ development of a target body and, as such, the immune response acts against its own cells and tissues. Prominent examples include Coeliac disease, diabetes mellitus type 1 (IDDM), Sarcoidosis, systemic lupus erythematosus (SLE), Sjögren's syndrome, Churg-Strauss Syndrome, Hashimoto's thyroiditis, Graves' disease, idiopathic thrombocytopenic purpura, Addison's Disease, rheumatoid arthritis (RA) and allergies.

Autoimmune diseases are very often treated with steroids. The misconception that an individual's immune system is totally incapable of recognizing self antigens is not new. Paul Ehrlich, at the beginning of the twentieth century, proposed the concept of horror autotoxicus, wherein a 'normal' body does not mount an immune response against its own tissues. Thus, any autoimmune response was perceived to be abnormal and postulated to be connected with human disease. Now, it is accepted that autoimmune responses are an integral part of vertebrate immune systems (sometimes termed 'natural autoimmunity'), normally prevented from causing disease by the phenomenon of immunological tolerance to self-antigens.

Autoimmunity should not be confused with *alloimmunity*. Certain individuals are genetically susceptible to developing autoimmune diseases. This susceptibility is associated with multiple genes plus other risk factors. Genetically predisposed individuals do not always develop autoimmune diseases. Three main sets of genes are suspected in many autoimmune diseases: immunoglobulins, T-cell receptors and the major histocompatibility complexes (MHC).

Immunoglobulins and the T-cell receptors are involved in the recognition of antigens and they are inherently variable and susceptible to recombination. These variations enable the immune system to respond to a very wide variety of invaders, but may also give rise to lymphocytes capable of self-reactivity. Scientists such as H. McDevitt, G. Nepom, J. Bell and J. Todd have also provided strong evidence to suggest that certain MHC class II allotypes are strongly correlated with autoimmunity.

For example:

1. HLA DR2 is strongly positively correlated with Systemic Lupus Erythematosus, narcolepsy and multiple sclerosis, and negatively correlated with DM Type 1.

2. HLA DR3 is correlated strongly with Sjögren's syndrome, myasthenia gravis, SLE, and DM Type 1.

3. HLA DR4 is correlated with the genesis of rheumatoid arthritis, Type 1 diabetes mellitus, and pemphigus vulgaris.

Fewer correlations exist with MHC class I molecules. The most notable and consistent is the association between HLA B27 and ankylosing spondylitis. Correlations may exist between polymorphisms within class II MHC promoters and autoimmune disease. The contributions of genes outside the MHC complex remain the subject of research both in animal models of disease (Linda

Wicker's extensive genetic studies of diabetes in the NOD mouse), and in patients (Brian Kotzin's linkage analysis of susceptibility to SLE).

A person's sex also seems to have some role in the development of autoimmunity, classifying most autoimmune diseases as sex-related diseases. Nearly 75% of the more than 23.5 million Americans who suffer from autoimmune disease are women, although it is less-frequently acknowledged that millions of men also suffer from these diseases.

According to the American Autoimmune Related Diseases Association (AARDA), autoimmune diseases that develop in men tend to be more severe. A few autoimmune diseases that men are just as or more likely to develop as women, include: ankylosing spondylitis, type 1 diabetes mellitus, Wegener's granulomatosis, Crohn's disease, Primary sclerosing cholangitis and psoriasis.

The reasons for the sex role in autoimmunity are unclear. Women appear to generally mount larger inflammatory responses than men when their immune systems are triggered, increasing the risk of autoimmunity. Similarly, involvement of sex steroids is indicated by the fact that many autoimmune diseases tend to fluctuate in accordance with hormonal changes. Interestingly, a history of pregnancy also appears to leave a persistent increased risk for autoimmune disease. Indeed, it has been suggested that the slight exchange of cells between mothers and their children during pregnancy may induce autoimmunity. This would tip the gender balance in the direction of the female.

Another theory suggests the female-high tendency to get autoimmunity is due to an imbalanced X chromosome inactivation. The X-inactivation skew theory, proposed by Princeton University's Jeff Stewart, has recently been confirmed experimentally in scleroderma and autoimmune thyroiditis.

12.5D: Immune Complex Autoimmune Reactions

An immune complex is formed from the integral binding of an antibody to a soluble antigen and can function as an epitope.

Learning Objectives

- Describe how immune complex autoimmune reactions arise

Key Points

- After an antigen – antibody reaction, the immune complexes can be subject to any of a number of responses including complement deposition, opsonization, phagocytosis, or processing by proteases.
- Immune complexes may cause disease when they are deposited in organs.
- The Arthus reaction involves the in situ formation of antigen/antibody complexes after the intradermal injection of an antigen (as seen in passive immunity).

Key Terms

- **epitope**: That part of a biomolecule (such as a protein) that is the target of an immune response.
- **immune complex**: An immune complex is formed from the integral binding of an antibody to a soluble antigen. The bound antigen acting as a specific epitope, bound to an antibody is referred to as a singular immune complex.

An immune complex is formed from the integral binding of an antibody to a soluble antigen. The bound antigen acting as a specific epitope, bound to an antibody is referred to as a singular immune complex. After an antigen-antibody reaction, the immune complexes can be subject to any of a number of responses, including complement deposition, opsonization, phagocytosis, or processing by proteases. Red blood cells carrying CR1-receptors on their surface may bind C3b-decorated immune complexes and transport them to phagocytes, mostly in liver and spleen, and return back to the general circulation. Immune complexes may cause disease when they are deposited in organs, e.g. in certain forms of vasculitis. This is the third form of hypersensitivity in the Gell-Coombs classification, called Type III hypersensitivity. Immune complex deposition is a prominent feature of several autoimmune diseases, including systemic lupus erythematosus, cryoglobulinemia, rheumatoid arthritis, scleroderma, and Sjögren's syndrome.

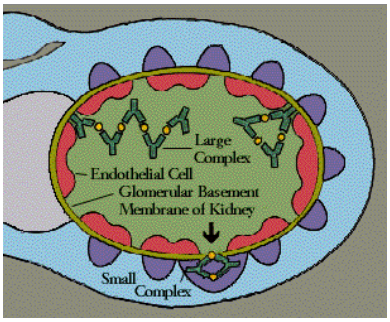

Figure: **Immune Complex Diseases**: An immune complex is formed from the integral binding of an antibody to a soluble antigen. The bound antigen acting as a specific epitope, bound to an antibody is referred to as a singular immune complex.

In immunology, the Arthus reaction is a type of local type III hypersensitivity reaction. Type III hypersensitivity reactions are immune complex-mediated. They involve the deposition of antigen/antibody complexes mainly in the vascular walls, serosa (pleura, pericardium, synovium), and glomeruli. The Arthus reaction involves the in situformation of antigen/antibody complexes after the intradermal injection of an antigen (as seen in passive immunity). If the animal/patient was previously sensitized (has circulating antibody), an Arthus reaction occurs. Typical of most mechanisms of the type III hypersensitivity, Arthus manifests as local vasculitis due to deposition of IgG-based immune complexes in dermal blood vessels. Activation of complement primarily results in cleavage of soluble complement proteins forming C5a and C3a, which activate recruitment of PMNs and local mast cell degranulation (requiring the binding of the immune complex onto FcγRIII), resulting in an inflammatory response. Further aggregation of immune complex-related processes induces a local fibrinoid necrosis with ischemia-aggravating thrombosis in the tissue vessel walls. The end result is a localized area of redness and induration that typically lasts a day or so. Arthus reactions have been infrequently reported after vaccination against diphtheria and tetanus.

12.5E: Cell-Mediated Autoimmune Reactions

Cell-mediated autoimmunity can happen by several mechanisms involving cells of the immune system and their receptors.

Learning Objectives

- Define cell-mediated autoimmunity and describe the mechanisms that are thought to operate in the pathogenesis of autoimmune disease

Key Points

- Superantigens can bypass the T-cell requirement for B cell activation.
- In some instances such as celiac disease, B cells can be activated to produce antibodies to epitope A by T cells activated by epitope B.
- Autoreactive B cells in spontaneous autoimmunity survive due to subversion both of the T cell help pathway and of the feedback signal through B cell receptor, leading to loss of the negative signals responsible for B cell self- tolerance without necessarily requiring loss of T cell self-tolerance.
- DQ therefore is involved in recognizing common self- antigens and presenting those antigens to the immune system in order to develop tolerance from a very young age.

Key Terms

- **autoimmunity**: The condition where one's immune system attacks one's own tissues, i.e., an autoimmune disorder.
- **tolerance**: The process by which the immune system does not attack an antigen

Several mechanisms are thought to be operative in the pathogenesis of autoimmune diseases, against a backdrop of genetic predisposition and environmental modulation. Four of the important mechanisms are described below.

T Cell Bypass

A normal immune system requires the activation of B cells by T cells before the former can produce antibodies in large quantities. This requirement of a T cell can be bypassed in rare instances, such as infection by organisms producing super-antigens, which are capable of initiating polyclonal activation of B cells, or even of T cells, by directly binding to the β-subunit of T cell receptors in a non-specific fashion.

T Cell to B Cell Discordance

A normal immune response is assumed to involve B and T cell responses to the same antigen, where B cells recognize conformations on the surface of a molecule for B cells, and T cells recognize pre-processed peptide fragments of proteins for T cells. However, there is no evidence that this response is required. All that is required is that a B cell that recognizes antigen X endocytoses processes a protein Y (normally =X) and presents it to a T cell. Roosnek and Lanzavecchia showed that B cells recognizing IgGFc could get help from any T cell that responds to an antigen co-endocytosed with IgG by the B cell as part of an immune complex. In coeliac disease it seems likely that B cells that recognize transglutamine tissue are helped by T cells that recognize gliadin.

Aberrant B Cell Receptor-Mediated Feedback

A feature of human autoimmune disease is that it is largely restricted to a small group of antigens, several of which have known signaling roles in the immune response (for example DNA, C1q, IgGFc, Ro, Con. A receptor, Peanut agglutinin receptor(PNAR)). This fact gave rise to the idea that spontaneous autoimmunity may result when the binding of antibody to certain antigens leads to aberrant signals being fed back to parent B cells through membrane bound ligands. These ligands include B cell receptor (for antigen), IgG Fc receptors, CD21 (which binds complement C3d), Toll-like receptors 9 and 7 (which can bind DNA and nucleoproteins) and PNAR. More indirect aberrant activation of B cells can also be envisaged with autoantibodies to acetyl choline receptor (on thymic myoid cells) and hormone binding proteins. Together with the concept of T cell-B cell discordance, this idea forms the basis of the hypothesis of self-perpetuating autoreactive B cells. Autoreactive B cells in spontaneous autoimmunity are seen as surviving because of subversion both of the T cell help pathway and of the feedback signal through the B cell receptor. This reaction thereby overcomes the negative signals responsible for B cell self-tolerance without necessarily requiring loss of T cell self-tolerance.

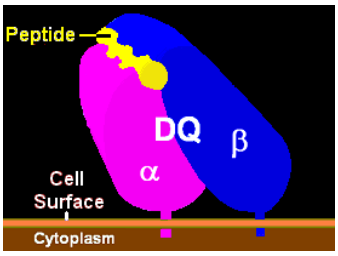

Figure: **MHC Class II, DQ**: HLA-DQ (DQ) is a cell surface receptor type protein found on antigen presenting cells (APC). DQ is an alpha-beta heterodimer of the MHC class II type.

Immune system cells called dendritic cells present antigens to active lymphocytes. Dendritic cells that are defective in apoptosis can lead to inappropriate systemic lymphocyte activation and consequent decline in self-tolerance.

HLA-DQ (DQ) is a cell surface receptor type protein found on antigen presenting cells. DQ is an α heterodimer of the MHC Class II type. The α and β chains are encoded by HLA-DQA1 and HLA-DQB1, respectively. These two loci are adjacent to each other on chromosome 6p21.3. Both the α-chain and β-chain vary greatly. A person often produces two α-chain and two β-chain variants and thus four DQ isoforms.

DQ isoforms can bind to and present foreign and self antigens to T-cells. In this process T-cells are stimulated to grow and can signal B-cells to produce antibodies. DQ therefore is involved in recognizing common self-antigens and presenting those antigens to the immune system in order to develop tolerance from a very young age. When tolerance to self proteins is lost, DQ may become involved in autoimmune disease. Two autoimmune diseases in which HLA-DQ is involved are celiac disease and diabetes mellitus type 1. DQ is one of several antigens involved in rejection of organ transplants. As a variable cell surface receptor on immune cells, these D antigens, originally HL-A4 antigens, are involved in graft versus host disease when lymphoid tissues are transplanted between people.

SECTION OVERVIEW

12.6: Immunity Disorders: Immunodeficiencies

Topic hierarchy

12.6A: Primary Immunodeficiency Diseases

12.6B: Secondary Immunodeficiency Diseases

12.6C: Immunotherapy for Cancer

12.6: Immunity Disorders: Immunodeficiencies is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.6A: Primary Immunodeficiency Diseases

Primary immunodeficiencies are disorders in which part of the body's immune system is missing, or does not function properly.

Learning Objectives

- Describe primary immunodeficiency disorders and explain what treatment options are available

Key Points

- To be considered a primary immunodeficiency, the cause of the immune deficiency must not be secondary in nature (caused by other disease, drug treatment, or environmental exposure to toxins).
- Most primary immunodeficiencies are genetic disorders; the majority are diagnosed in children under the age of one, although milder forms may not be recognized until adulthood.
- The precise symptoms of a primary immunodeficiency depend on the type of defect but generally include recurrent or persistent infections or developmental delay as a result of infection.

Key Terms

- **genetic disorder**: An illness caused by abnormalities in genes or chromosomes, especially a condition that is present prior to birth. Most genetic disorders are quite rare and affect one person in every several thousands or millions.
- **immunodeficiency**: A depletion in the body's natural immune system, or in some component of it.

Primary immunodeficiencies are disorders in which a part of the body's immune system is missing or does not function properly. To be considered a primary immunodeficiency, the cause of the immune deficiency must not be secondary in nature (caused by another disease, drug treatment, or environmental exposure to toxins). Most primary immunodeficiencies are genetic disorders; the majority are diagnosed in children under the age of one, although milder forms may not be recognized until adulthood.

Symptoms

The precise symptoms of a primary immunodeficiency depend on the type of defect. Generally, the symptoms and signs that lead to the diagnosis of an immunodeficiency include recurrent or persistent infections, or developmental delay as a result of infection. Particular organ problems; such as diseases involving the skin, heart, facial development and skeletal system; may be present in certain conditions. Others predispose to autoimmune disease, where the immune system attacks the body's own tissues, or tumors (sometimes specific forms of cancer, such as lymphoma). The nature of the infections, as well as the additional features, may provide clues as to the exact nature of the immune defect.

Diagnostic Tests

The basic tests performed when an immunodeficiency is suspected should include a full blood count (including accurate lymphocyte and granulocyte counts) and immunoglobulin levels. Tthe three most important types of antibodies are IgG, IgA and IgM.

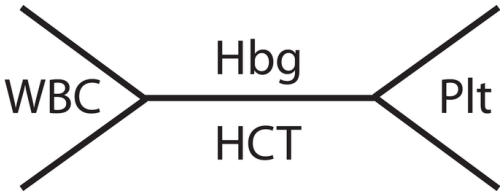

Figure: **Complete Blood Count**: Schematics (also called "fishbones") of shorthand commonly used by clinicians for complete blood count. The shorthand on the right is used more often in the U.S. Hgb=Hemoglobin, WBC=White blood cells, Plt=Platelets, Hct=Hematocrit.

Other tests are performed depending on the suspected disorder:

- Quantification of the different types of mononuclear cells in the blood (lymphocytes and monocytes): different groups of T lymphocytes (dependent on their cell surface markers, e.g. CD4+, CD8+, CD3+, TCRα and TCRγ); groups of B lymphocytes (CD19, CD20, CD21 and Immunoglobulin); natural killer cells and monocytes (CD15+); as well as activation markers (HLA-DR, CD25, CD80 (B cells)

- Tests for T cell function: skin tests for delayed-type hypersensitivity, cell responses to mitogens and allogeneic cells, cytokine production by cells
- Tests for B cell function: antibodies to routine immunizations and commonly acquired infections, quantification of IgG subclasses
- Tests for phagocyte function: reduction of nitro blue tetrazolium chloride, assays of chemotaxis, bactericidal activity

Due to the rarity of many primary immunodeficiencies, many of the above tests are highly specialized and tend to be performed in research laboratories.

Immunodeficiency Disorders

In genetic immunodeficiency disorders, both T lymphocytes and often B lymphocytes—regulators of adaptive immunity—are dysfunctional or decreased in number. The main members are various types of severe combined immunodeficiency (SCID).

In primary antibody deficiencies, one or more isotypes of immunoglobulin are decreased or don't function properly. These proteins, generated by plasma cells, normally bind to pathogens, targeting them for destruction.

A number of syndromes, including the following, escape formal classification but are otherwise recognisable by particular clinical or immunological features:

- Wiskott-Aldrich syndrome
- DNA repair defects not causing isolated SCID; for example ataxia telangiectasia and ataxia-like syndrome
- DiGeorge syndrome (when associated with thymic defects)
- Various immuno-osseous dysplasias (abnormal development of the skeleton with immune problems);for example, cartilage-hair hypoplasia, Schimke syndrome

In certain conditions, including the following, the regulation rather than the intrinsic activity of parts of the immune system is the predominant problem:

- Immunodeficiency with hypopigmentation or albinism; for example, Chediak-Higashi syndrome, Griscelli syndrome type two
- Familial hemophagocytic lymphohistiocytosis; for example, perforin deficiency, MUNC13D deficiency, syntaxin 11 deficiency
- X-linked lymphoproliferative syndrome

Phagocytes are the cells that engulf and ingest pathogens (phagocytosis), and destroy them with chemicals. Monocytes/macrophages as well as granulocytes are capable of this process. In certain conditions, either the number of phagocytes is reduced or their functional capacity is impaired. Several rare conditions are due to defects in the innate immune system, which is a basic line of defense independent of the more advanced lymphocyte-related systems. Many of these conditions are associated with skin problems.

Rather than predisposing for infections, most of the autoinflammatory disorders lead to excessive inflammation. Many manifest themselves as periodic fever syndromes. They may involve various organs directly, as well as predisposing for long-term damage by leading to amyloid deposition.

The complement system is part of the innate as well as the adaptive immune system; it is a group of circulating proteins that can bind pathogens and form a membrane attack complex. Complement deficiencies are the result of a lack of any of these proteins. They may predispose to infections but also to autoimmune conditions.

Treatment

The treatment of primary immunodeficiencies depends foremost on the nature of the abnormality. This may range from immunoglobulin replacement therapy in antibody deficiencies—in the form of intravenous immunoglobulin (IVIG) or subcutaneous immunoglobulin (SCIG)—to hematopoietic stem cell transplantation for SCID and other severe immunodeficiences. SCID can now be treated with a bone marrow transplant. Reduction of exposure to pathogens may be recommended, and in many situations prophylactic antibiotics may be advised.

12.6A: Primary Immunodeficiency Diseases is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.6B: Secondary Immunodeficiency Diseases

Secondary immunodeficiencies refer to acquired immune system disorders.

Learning Objectives

- Define immunodeficiency and list the types that occur

Key Points

- A deficit in the immune system can lead to unusually severe or uncommon recurrent infections.
- Secondary immune deficiencies or acquired deficiencies, more frequent than primary immune deficiencies, are problems of the immune system that are not genetic and which are caused by external factors.
- Secondary immunodeficiency disorders can occur in, for example, malnutrition, aging, many types of cancer (such as leukemia, lymphoma, multiple myeloma), and certain chronic infections such as acquired immunodeficiency syndrome (AIDS).
- Immunosuppression is one form of secondary immunodeficiency performed to prevent the body from rejecting an organ transplant, treating graft-versus-host disease after a bone marrow transplant, or for the treatment of auto-immune diseases, such as rheumatoid arthritis or Crohn's disease.
- A person who is undergoing immunosuppression or whose immune system is weak for other reasons (for example, chemotherapy, HIV, and Lupus), is said to be immunocompromised.

Key Terms

- **immunodeficiency**: A depletion in the body's natural immune system, or in some component of it.
- **immunocompromised**: Having an immune system that has been impaired by disease or treatment.
- **immunosuppressive**: Having the capability to suppress the immune system, capable of immunosuppression.
- **secondary infection**: any infection that arises subsequent to a pre-existing infection; but especially a nosocomial infection

Immunodeficiency (or immune deficiency) is a state in which the immune system's ability to fight infectious disease is compromised or entirely absent. Immunodeficiency may also decrease cancer immunosurveillance. Most cases of immunodeficiency are acquired ("secondary") but some people are born with defects in their immune system, or primary immunodeficiency. Transplant patients take medications to suppress their immune system as an anti-rejection measure, as do some patients suffering from an over-active immune system. A person who has an immunodeficiency of any kind is said to be immunocompromised. An immunocompromised person may be particularly vulnerable to opportunistic infections, in addition to normal infections that could affect everyone. Distinction between primary versus secondary immunodeficiencies are based on, respectively, whether the cause originates in the immune system itself or is, in turn, due to insufficiency of a supporting component of it or an external decreasing factor of it.

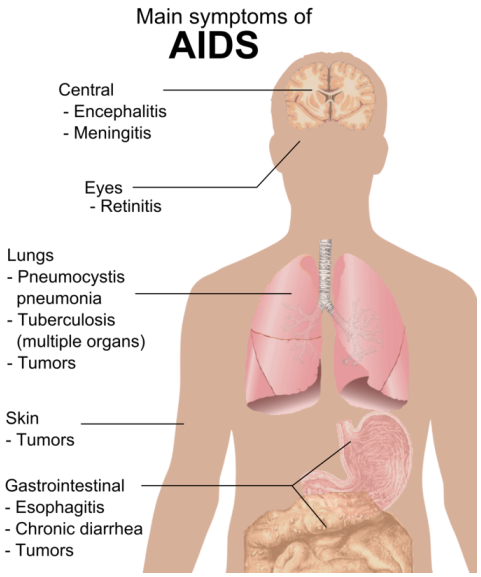

Figure: **Main Symptoms of AIDS**: Acquired immunodeficiency syndrome (AIDS) is defined in terms of either a CD4+ T cell count below 200 cells per µL or the occurrence of specific diseases in association with an HIV infection. In the absence of specific treatment, around half the people infected with HIV develop AIDS within 10 years. The most common initial conditions that alert to the presence of AIDS are pneumocystis pneumonia and cachexia.

Primary Immunodeficiency (PID)

A number of rare diseases feature a heightened susceptibility to infections from childhood onward. Primary Immunodeficiency is also known as “congenital immunodeficiencies. ” Many of these disorders are hereditary and are autosomal recessive or X-linked. There are over 80 recognized primary immunodeficiency syndromes; they are generally grouped by the part of the immune system that is malfunctioning, such as lymphocytes or granulocytes. The treatment of primary immunodeficiencies depends on the nature of the defect and may involve antibody infusions, long-term antibiotics, and (in some cases) stem cell transplantation.

Secondary Immunodeficiencies

Secondary immunodeficiencies, also known as acquired immunodeficiencies, can result from various immunosuppressive agents, for example, malnutrition, aging and particular medications (e.g., chemotherapy, disease-modifying antirheumatic drugs, immunosuppressive drugs after organ transplants, glucocorticoids). For medications, the term immunosuppression generally refers to both beneficial and potential adverse effects of decreasing the function of the immune system, while the term immunodeficiency generally refers solely to the adverse effect of increased risk for infection. Many specific diseases directly or indirectly cause immunosuppression. This includes many types of cancer, particularly those of the bone marrow and blood cells (leukemia, lymphoma, multiple myeloma), and certain chronic infections. Immunodeficiency is also the hallmark of acquired immunodeficiency syndrome (AIDS), caused by the human immunodeficiency virus (HIV). HIV directly infects a small number of T helper cells and also impairs other immune system responses indirectly.

12.6B: Secondary Immunodeficiency Diseases is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

12.6C: Immunotherapy for Cancer

Cancer immunotherapy is the use of the body's own immune system to reject cancer.

Learning Objectives

- Describe the use of immunotherapy in cancer treatment

Key Points

- Cancer immunotherapy can involve immunization of the patient with a cancer vaccine, administration of therapeutic antibodies as drugs, or cell-based immunotherapy.
- Vaccines can be raised against antigens that are inappropriate either for the cell type or for its environment.
- Adoptive cell-based immunotherapy involves isolating either allogenic or autologous immune cells, enriching them outside the body, and transfusing them back into the patient.
- Monoclonal antibodies can be raised against unusual antigens that are presented on the surfaces of tumors.

Key Terms

- **immunotherapy**: the treatment of cancer by improving the ability of the host to reject a tumor immunologically
- **allogenic**: genetically distinct, but of the same species
- **autologous**: derived from part of the same individual (i.e., from the recipient rather than the donor)

Cancer immunotherapy is the use of the body's own immune system to reject cancer. The main idea is stimulating the patient's immune system to attack the malignant tumor cells that are responsible for the disease. This can be either through immunization of the patient (e.g., by administering a cancer vaccine such as Dendreon's Provenge), in which case the patient's own immune system is trained to recognize tumor cells as targets to be destroyed, or through the administration of therapeutic antibodies as drugs, in which case the patient's immune system is recruited to destroy tumor cells by the therapeutic antibodies. Cell-based immunotherapy is another major entity of cancer immunotherapy. This involves immune cells such as the natural killer cells (NK cells), lymphokine-activated killer cells (LAK cells), cytotoxic T lymphocytes (CTLs), and dendritic cells (DC). These immune cells are either activated *in vivo* by administering certain cytokines such as interleukins, or they are isolated, enriched, and transfused back into the patient to fight against cancer.

Since the immune system responds to the environmental factors it encounters on the basis of discrimination between self and non-self, many kinds of tumor cells that arise as a result of the onset of cancer are more or less tolerated by the patient's own immune system since the tumor cells are essentially the patient's own cells that are growing, dividing, and spreading without proper regulatory control. In spite of this fact, however, many kinds of tumor cells display unusual antigens that are inappropriate for either the cell type or its environment or that are only normally present during the organism 's development (e.g. fetal antigens). Examples of such antigens include the glycosphingolipid GD2, a disialoganglioside that is normally only expressed at a significant level on the outer surface membranes of neuronal cells, where its exposure to the immune system is limited by the blood-brain barrier.

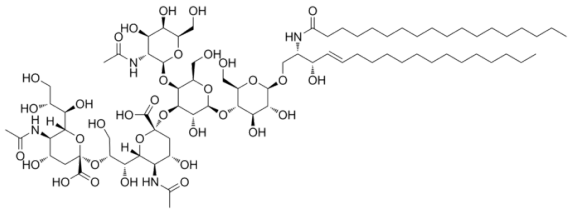

Figure: **Structure of GD2**: GD2 is a disialoganglioside expressed on tumors of neuroectodermal origin, including human neuroblastomas and melanomas, with highly restricted expression on normal tissues, principally to the cerebellum and peripheral nerves in humans. The relatively tumor-specific expression of GD2 makes it a suitable target for immunotherapy with monoclonal antibodies or with artificial T-cell receptors.

GD2 is expressed on the surfaces of a wide range of tumor cells, including neuroblastomas, medulloblastomas, astrocytomas, melanomas, small-cell lung cancer, osteosarcomas, and other soft tissue sarcomas. GD2 is thus a convenient tumor-specific target for immunotherapies.

Adoptive cell-based immunotherapy involves isolating either allogenic or autologous immune cells, enriching them outside the body, and transfusing them back to the patient. The injected immune cells are highly cytotoxic to the cancer cells and so help to

fight them.

Antibodies are a key component of the adaptive immune response. They play a central role in both the recognition of foreign antigens and the stimulation of an immune response to them. It is not surprising, therefore, that many immunotherapeutic approaches involve the use of antibodies. The advent of monoclonal antibody technology has made it possible to raise antibodies against specific antigens, such as the unusual antigens that are presented on the surfaces of tumors. A number of therapeutic monoclonal antibodies have been approved for use in humans, such as alemtuzumab, an anti-CD52 humanized IgG1 monoclonal antibody indicated for the treatment of chronic lymphocytic leukemia (CLL). Radioimmunotherapy in turn involves the use of radioactively conjugated murine antibodies against cellular antigens, mostly for treatment of lymphomas.

The development and testing of second-generation immunotherapies is already under way. While antibodies targeted to disease-causing antigens can be effective under certain circumstances, in many cases their efficacy may be limited by other factors. In the case of cancer tumors, the microenvironment is immunosuppressive, allowing even those tumors that present unusual antigens to survive and flourish in spite of the immune response generated by the cancer patient against his own tumor tissue. Certain members of a group of molecules known as cytokines, such as interleukin-2, also play a key role in modulating the immune response. Cytokines have been tested in conjunction with antibodies in order to generate an even more devastating immune response against the tumor. While the therapeutic administration of such cytokines may cause systemic inflammation, resulting in serious side effects and toxicity, there is a new generation of chimeric molecules consisting of an immune-stimulatory cytokine attached to an antibody that targets a tumor. These chimeric molecules are able to generate a very effective yet localized immune response against the tumor tissue, destroying the cancer-causing cells without the unwanted side effects.

Dermatologists use new creams and injections in the management of benign and malignant skin tumors. Topical immunotherapy utilizes an immune enhancement cream (imiquimod), which is an interferon producer, causing the patient's own killer T cells to destroy warts, actinic keratoses, basal cell carcinoma, squamous cell carcinoma, cutaneous T cell lymphoma, and superficial spreading melanoma. Injection immunotherapy uses mumps, candida, or trichophytin antigen injections to treat warts (HPV-induced tumors).

CHAPTER OVERVIEW

13: Antimicrobial Drugs

An antimicrobial is an agent that kills microorganisms or stops their growth. Antimicrobial medicines can be grouped according to the microorganisms they act primarily against. For example, antibiotics are used against bacteria and antifungals are used against fungi

13.1A: Origins of Antimicrobial Drugs

The era of antimicrobials begins when Pasteur and Joubert discover that one type of bacteria could prevent the growth of another.

Learning Objectives

- Recall the technical defintion of antibiotics

Key Points

- Antibiotics are only those substances that are produced by one microorganism that kill, or prevent the growth, of another microorganism.
- In today's common usage, the term antibiotic is used to refer to almost any drug that attempts to rid your body of a bacterial infection.
- The discovery of antimicrobials like penicillin and tetracycline paved the way for better health for millions around the world.

Key Terms

- **antimicrobial**: An agent that destroys microbes, inhibits their growth, or prevents or counteracts their pathogenic action.
- **penicillin**: Any of a group of broad-spectrum antibiotics obtained from Penicillium molds or synthesized; they have a beta-lactam structure; most are active against gram-positive bacteria and used in the treatment of various infections and diseases.

The history of antimicrobials begins with the observations of Pasteur and Koch, who discovered that one type of bacteria could prevent the growth of another. They did not know at that time that the reason one bacterium failed to grow was that the other bacterium was producing an antibiotic. Technically, antibiotics are only those substances that are produced by one microorganism that kill, or prevent the growth, of another microorganism.

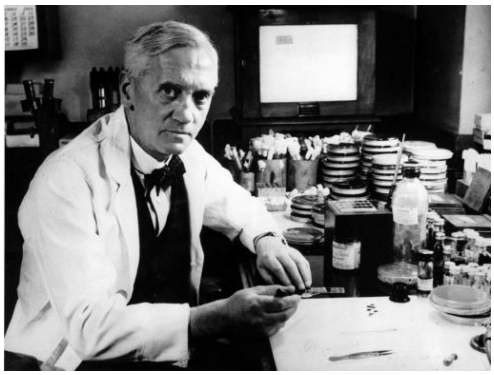

Figure: **Alexander Fleming**: In 1928 Alexander Fleming observed antibiosis against bacteria by a fungus of the genus Penicillium and postulated the effect was mediated by an antibacterial compound, penicillin, and that its antibacterial properties could be exploited for chemotherapy.

The discovery of antimicrobials like penicillin by Alexander Fleming and tetracycline paved the way for better health for millions around the world. Before penicillin became a viable medical treatment in the early 1940s, no true cure for gonorrhea, strep throat, or pneumonia existed. Patients with infected wounds often had to have a wounded limb removed, or face death from infection. Now, most of these infections can be cured easily with a short course of antimicrobials.

The term antibiotic was first used in 1942 by Selman Waksman and his collaborators in journal articles to describe any substance produced by a microorganism that is antagonistic to the growth of other microorganisms in high dilution. This definition excluded substances that kill bacteria, but are not produced by microorganisms (such as gastric juices and hydrogen peroxide). It also excluded synthetic antibacterial compounds such as the sulfonamides. Many antibacterial compounds are relatively small molecules with a molecular weight of less than 2000 atomic mass units. With advances in medicinal chemistry, most of today's antibacterials chemically are semisynthetic modifications of various natural compounds.

13.1A: Origins of Antimicrobial Drugs is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.1B: Antibiotic Discovery

Observations of antibiosis between micro-organisms led to the discovery of natural antibacterials produced by microorganisms.

Learning Objectives

- Describe the concept of ‘antibiosis’ and the contributions of the different scientists who discovered it

Key Points

- Before the early 20th century, treatments for infections were based primarily on medicinal folklore.
- Louis Pasteur observed, “if we could intervene in the antagonism observed between some bacteria, it would offer perhaps the greatest hopes for therapeutics”.
- The term ‘antibiosis’, meaning “against life,” was introduced by the French bacteriologist Vuillemin as a descriptive name of the phenomenon exhibited by these early antibacterial drugs.

Key Terms

- **micro-organism**: A microorganism (from the Greek: μ, mikrós, “small” and ὀ, organismós, “organism”; also spelled micro-organism, micro organism or microörganism) or microbe is a microscopic organism that comprises either a single cell (unicellular), cell clusters, or multicellular relatively complex organisms.
- **chemotherapy**: Any chemical treatment intended to be therapeutic with respect to a disease state.
- **infection**: An uncontrolled growth of harmful microorganisms in a host.

Before the early 20th century, treatments for infections were based primarily on medicinal folklore. Mixtures with antimicrobial properties that were used in treatments of infections were described over 2000 years ago. Many ancient cultures, including the ancient Egyptians and ancient Greeks, used specially selected mold and plant materials and extracts to treat infections. More recent observations made in the laboratory of antibiosis between micro- organisms led to the discovery of natural antibacterials produced by microorganisms.

Louis Pasteur observed, “if we could intervene in the antagonism observed between some bacteria, it would offer perhaps the greatest hopes for therapeutics”. The term ‘antibiosis’, meaning “against life,” was introduced by the French bacteriologist Vuillemin as a descriptive name of the phenomenon exhibited by these early antibacterial drugs. Antibiosis was first described in 1877 in bacteria when Louis Pasteur and Robert Koch observed that an airborne bacillus could inhibit the growth of Bacillus anthracis. These drugs were later renamed antibiotics by Selman Waksman, an American microbiologist, in 1942.

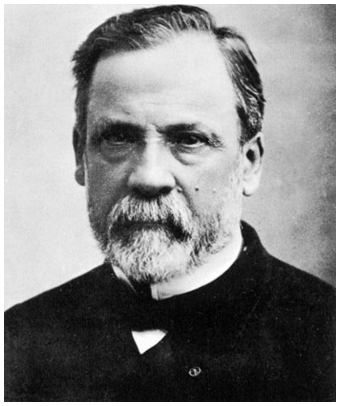

Figure: **Louis Pasteur**: Louis Pasteur was a French microbiologist and chemist best known for their experiments supporting the Germ theory of disease, and for his vaccinations, most notably the first vaccine against rabies.

John Tyndall first described antagonistic activities by fungi against bacteria in England in 1875. Synthetic antibiotic chemotherapy as a science and development of antibacterials began in Germany with Paul Ehrlich in the late 1880s. Ehrlich noted certain dyes would color human, animal, or bacterial cells, while others did not. He then proposed the idea that it might be possible to create chemicals that would act as a selective drug that would bind to and kill bacteria without harming the human host. After screening hundreds of dyes against various organisms, he discovered a medicinally useful drug, the synthetic antibacterial Salvarsan now called arsphenamine. In 1895, Vincenzo Tiberio, physician of the University of Naples discovered that a mold (Penicillium) in a water well has an antibacterial action. After this initial chemotherapeutic compound proved effective, others pursued similar lines

of inquiry, but it was not until in 1928 that Alexander Fleming observed antibiosis against bacteria by a fungus of the genus Penicillium. Fleming postulated the effect was mediated by an antibacterial compound named penicillin, and that its antibacterial properties could be exploited for chemotherapy. He initially characterized some of its biological properties, but he did not pursue its further development.

13.1C: Antibiotics and Selective Toxicity

Antibiotics are able to selectively target specific types of bacteria without harming the infected host.

Learning Objectives

- Describe selective toxicity

Key Points

- Their mechanism of action, chemical structure, or spectrum of activity are ways in which antibiotics are classified.
- Broad spectrum antibiotics affect a wide range of bacteria, while narrow spectrum antibiotics are able to target specific types.
- Antibiotics must go through a screening process, where they are isolated, cultured, and then tested for production of diffusible products that inhibit the growth of specific test organisms.
- Due to potential adverse side effects, antibiotics must also be tested for their selective toxicities.

Key Terms

- **antibacterial**: A drug having the effect of killing or inhibiting bacteria.
- **bactericidal**: An agent that kills bacteria.
- **bacteriostatic**: A drug that prevents bacterial growth and reproduction but does not necessarily kill them. When it is removed from the environment the bacteria start growing again.

Selective Toxicity in Antibiotics

Synthetic antibiotic chemotherapy as a science and development of antibacterials began in Germany with Paul Ehrlich in the late 1880s. Ehrlich noted that certain dyes would color human, animal, or bacterial cells, while others did not. He then proposed the idea that it might be possible to create chemicals that would act as a selective drug that would bind to and kill bacteria without harming the human host. After screening hundreds of dyes against various organisms, he discovered a medicinally useful drug, the synthetic antibacterial Salvarsan now called arsphenamine.

Antibiotics are commonly classified based on their mechanism of action, chemical structure, or spectrum of activity. More specifically, narrow spectrum antibiotics target specific types of bacteria, such as Gram-negative or Gram-positive bacteria, whereas broad spectrum antibiotics affect a wide range of bacteria. Following a 40-year hiatus in discovering new classes of antibacterial compounds, three new classes of antibacterial antibiotics have been brought into clinical use: cyclic lipopeptides (such as daptomycin), glycylcyclines (such as tigecycline), and oxazolidinones (such as linezolid).

Figure: **Bacterial Cultures**: In antibacterial production, microorganisms must be isolated, cultured, and tested for growth inhibition of target organisms and for their selective toxicity.

Some antibacterials have been associated with a range of adverse effects. Side-effects range from mild to very serious depending on the antibiotics used, the microbial organisms targeted, and the individual patient. Safety profiles of newer drugs are often not as well established as for those that have a long history of use. Adverse effects range from fever and nausea to major allergic reactions, including photodermatitis and anaphylaxis. Common side-effects include diarrhea, resulting from disruption of the

species composition in the intestinal flora, resulting, for example, in overgrowth of pathogenic bacteria, such as *Clostridium difficile*. Antibacterials can also affect the vaginal flora, and may lead to overgrowth of yeast species of the genus *Candida* in the vulvo-vaginal area. Additional side-effects can result from interaction with other drugs, such as elevated risk of tendon damage from administration of a quinolone antibiotic with a systemic corticosteroid.

Antibacterial Production

Despite the wide variety of known antibiotics, less than 1% of antimicrobial agents have medical or commercial value. For example, whereas penicillin has a high therapeutic index as it does not generally affect human cells, this is not so for many antibiotics. Other antibiotics simply lack advantage over those already in use, or have no other practical applications. Useful antibiotics are often discovered using a screening process. To conduct such a screen, isolates of many different microorganisms are cultured and then tested for production of diffusible products that inhibit the growth of test organisms. Most antibiotics identified in such a screen are already known and must therefore be disregarded. The remainder must be tested for their selective toxicities and therapeutic activities, and the best candidates can be examined and possibly modified. A more modern version of this approach is a rational design program. This involves screening directed towards finding new natural products that inhibit a specific target, such as an enzyme only found in the target pathogen, rather than tests to show general inhibition of a culture.

13.1C: Antibiotics and Selective Toxicity is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.1D: Spectrum of Antimicrobial Activity

An antibiotic's spectrum can be broad or narrow.

Learning Objectives

- Compare narrow and broad spectrum antibiotics

Key Points

- Broad spectrum antibiotics act against a larger group of bacteria.
- Narrow spectrum antibiotis target specific bacteria such as Gram positive or Gram negative.
- Three new classes of antibacterial antibiotics have been brought into clinical use: cyclic lipopeptides (such as daptomycin), glycylcyclines (such as tigecycline), and oxazolidinones (such as linezolid).

Key Terms

- **Gram stain**: A method of differentiating bacterial species into two large groups (Gram-positive and Gram-negative).
- **narrow spectrum antibiotic**: A type of antibiotic that targets specific types of Gram positive or Gram negative bacteria.
- **broad spectrum antibiotic**: A type of antibiotic that can affect a wide range of bacteria.

The range of bacteria that an antibiotic affects can be divided into narrow spectrum and broad spectrum. Narrow spectrum antibiotics act against a limited group of bacteria, either gram positive or gram negative, for example sodium fusidate only acts against staphylococcal bacteria. Broad spectrum—antibiotics act against gram positive and gram negative bacteria, for example amoxicillin.

Gram staining (or Gram's method; is a method of differentiating bacterial species into two large groups (Gram-positive and Gram-negative). It is based on the chemical and physical properties of their cell walls. Primarily, it detects peptidoglycan, which is present in a thick layer in Gram positive bacteria. A Gram positive results in a purple/blue color while a Gram negative results in a pink/red color. The Gram stain is almost always the first step in the identification of a bacterial organism, and is the default stain performed by laboratories over a sample when no specific culture is referred. While Gram staining is a valuable diagnostic tool in both clinical and research settings, not all bacteria can be definitively classified by this technique, thus forming Gram-variable and Gram-indeterminate groups as well.

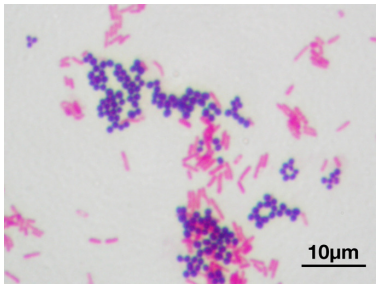

Figure: **Gram Stain**: This is a microscopic image of a Gram stain of mixed Gram-positive cocci (*Staphylococcus aureus*, purple) and Gram-negative bacilli (*Escherichia coli*, red).

A broad spectrum antibiotic acts against both Gram-positive and Gram-negative bacteria, in contrast to a narrow spectrum antibiotic, which is effective against specific families of bacteria. An example of a commonly used broad-spectrum antibiotic is ampicillin. Broad spectrum antibiotics are properly used in the following medical situations: empirically (i.e., based on the experience of the practitioner), prior to the formal identification of the causative bacteria and when there is a wide range of possible illnesses and a potentially serious illness would result if treatment is delayed. This occurs, for example, in meningitis, where the patient can become fatally ill within hours if broad-spectrum antibiotics are not initiated. Broad spectrum antibiotics are also used for drug resistant bacteria that do not respond to other, more narrow spectrum antibiotics and in the case of superinfections, where there are multiple types of bacteria causing illness, thus warranting either a broad-spectrum antibiotic or combination antibiotic therapy.

Following a 40-year hiatus in discovering new classes of antibacterial compounds, three new classes of antibacterial antibiotics have been brought into clinical use: cyclic lipopeptides (such as daptomycin), glycylcyclines (such as tigecycline), and oxazolidinones (such as linezolid).

13.1D: Spectrum of Antimicrobial Activity is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.1E: Antibiotic Classifications

Learning Objectives

Compare the two classes of antibiotics: bactericidal and bacteriostatic antibiotic

Antibiotics can be divided into two classes based on their mechanism of action. Bactericidal antibiotics kill bacteria; bacteriostatic antibiotics inhibit their growth or reproduction.

One way that bactericidal antibodies kill bacteria is by inhibiting cell wall synthesis. Examples include the Beta-lactam antibiotics (penicillin derivatives (penams)), cephalosporins (cephems), monobactams, and carbapenems) and vancomycin. Other ways that bactericidal antibiotics kill bacteria include inhibiting bacterial enzymes or protein translation. Other batericidal agents include daptomycin, fluoroquinolones, metronidazole, nitrofurantoin, co-trimoxazole and telithromycin. Aminoglycosidic antibiotics are usually considered bactericidal, although they may be bacteriostatic with some organisms. The MBC (minimum bactericidal concentration) is the minimum concentration of drug which can kill 99.99% of the population.

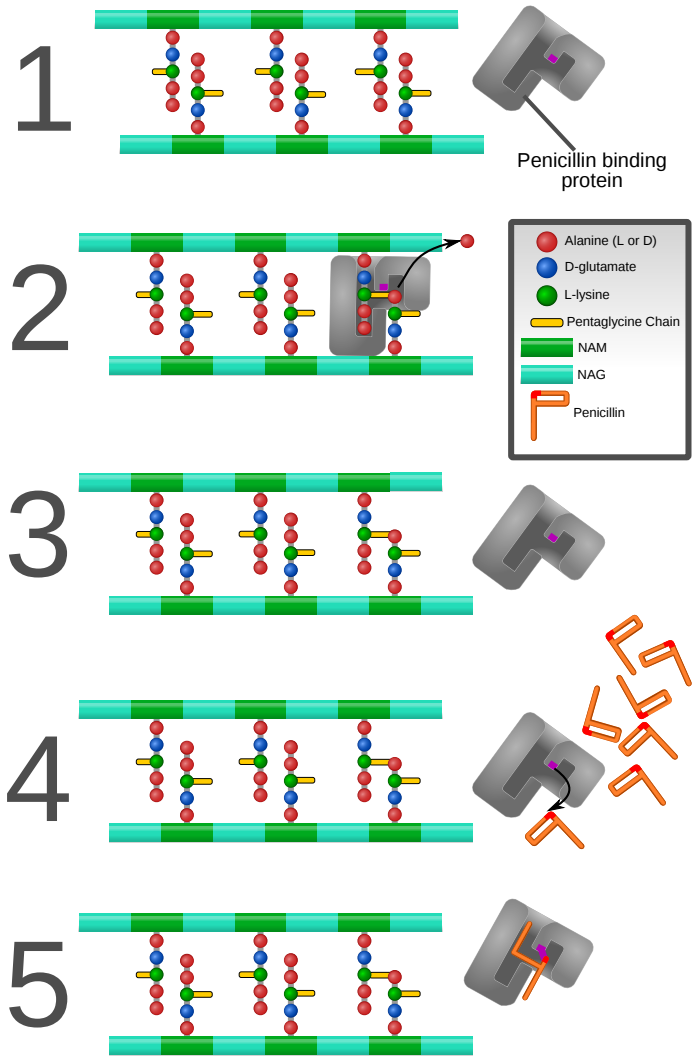

Figure: **Mechanism of penicillin inhibition**: Penicillin and most other β-lactam antibiotics act by inhibiting penicillin-binding proteins, which normally catalyze cross-linking of bacterial cell walls.

Bacteriostatic antibiotics limit the growth of bacteria by interfering with bacterial protein production, DNA replication, or other aspects of bacterial cellular metabolism. This group includes: tetracyclines, sulfonamides, spectinomycin, trimethoprim, chloramphenicol, macrolides and lincosamides. They must work together with the immune system to remove the microorganisms from the body. However, there is not always a precise distinction between them and bactericidal antibiotics. High concentrations of

some bacteriostatic agents are also bactericidal. The MIC (minimum inhibitory concentration) is the minimum concentration of drug which can inhibit the growth of the microorganism.

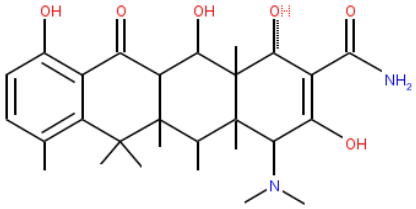

Figure: ***Structure of tetracycline****: Tetracycline antibiotics are protein synthesis inhibitors, inhibiting the binding of aminoacyl-tRNA to the mRNA-ribosome complex. They do so mainly by binding to the 30S ribosomal subunit in the mRNA translation complex.*

Further categorization is based on their target specificity. "Narrow-spectrum" antibacterial antibiotics target specific types of bacteria, such as Gram-negative or Gram-positive bacteria, whereas broad-spectrum antibiotics affect a wide range of bacteria, usually both gram positive and gram negative cells. Following a 40-year hiatus in discovering new classes of antibacterial compounds, three new classes of antibacterial antibiotics have been brought into clinical use: cyclic lipopeptides (such as daptomycin), glycylcyclines (such as tigecycline), and oxazolidinones (such as linezolid).

Key Points

- Bactericidal antibodies inhibit cell wall synthesis.
- Bacteriostatic antibiotics limit the growth of bacteria by interfering with bacterial protein production, DNA replication, or other aspects of bacterial cellular metabolism.
- Bacteriostatic antibiotics must work together with the immune system to remove the microorganisms from the body.

Key Terms

- **bactericidal**: An agent that kills bacteria.
- **bacteriostatic**: A drug that prevents bacterial growth and reproduction but does not necessarily kill them. When it is removed from the environment the bacteria start growing again.

13.2: Functions of Antimicrobial Drugs

Topic hierarchy

13.2A: Inhibiting Cell Wall Synthesis

13.2B: Injuring the Plasma Membrane

13.2C: Inhibiting Nucleic Acid Synthesis

13.2D: Inhibiting Protein Synthesis

13.2E: Inhibiting Essential Metabolite Synthesis

This page titled 13.2: Functions of Antimicrobial Drugs is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

13.2A: Inhibiting Cell Wall Synthesis

β-Lactam (beta-lactam) and glycopeptide antibiotics work by inhibiting or interfering with cell wall synthesis of the target bacteria.

Learning Objectives

- Describe the two types of antimicrobial drugs that inhibit cell wall synthesis: beta-lactam and glycopeptide antibiotics

Key Points

- The peptidoglycan layer is important for cell wall structural integrity, being the outermost and primary component of the wall.
- β-Lactam antibiotics are a broad class of antibiotics that includes penicillin derivatives (penams), cephalosporins (cephems), monobactams, and carbapenems.
- β-Lactam antibiotics are bacteriocidal and act by inhibiting the synthesis of the peptidoglycan layer of bacterial cell walls.
- Glycopeptide antibiotics include vancomycin, teicoplanin, telavancin, bleomycin, ramoplanin, and decaplanin.
- Glycopeptide antibiotics inhibit the synthesis of cell walls in susceptible microbes by inhibiting peptidoglycan synthesis.

Key Terms

- **beta-lactam antibiotic**: A broad class of antibiotics that inhibit cell wall synthesis, consisting of all antibiotic agents that contains a β-lactam nucleus in their molecular structures. This includes penicillin derivatives (penams), cephalosporins (cephems), monobactams, and carbapenems.
- **Glycopeptide antibiotic**: Glycopeptide antibiotics are composed of glycosylated cyclic or polycyclic nonribosomal peptides. Significant glycopeptide antibiotics include vancomycin, teicoplanin, telavancin, bleomycin, ramoplanin, and decaplanin. This class of drugs inhibit the synthesis of cell walls in susceptible microbes by inhibiting peptidoglycan synthesis.
- **peptidoglycan**: A polymer of glycan and peptides found in bacterial cell walls.

Two types of antimicrobial drugs work by inhibiting or interfering with cell wall synthesis of the target bacteria. Antibiotics commonly target bacterial cell wall formation (of which peptidoglycan is an important component) because animal cells do not have cell walls. The peptidoglycan layer is important for cell wall structural integrity, being the outermost and primary component of the wall.

The first class of antimicrobial drugs that interfere with cell wall synthesis are the β-Lactam antibiotics (beta-lactam antibiotics), consisting of all antibiotic agents that contains a β-lactam nucleus in their molecular structures. This includes penicillin derivatives (penams), cephalosporins (cephems), monobactams, and carbapenems. β-Lactam antibiotics are bacteriocidal and act by inhibiting the synthesis of the peptidoglycan layer of bacterial cell walls. The final step in the synthesis of the peptidoglycan is facilitated by penicillin-binding proteins (PBPs). PBPs vary in their affinity for binding penicillin or other β-lactam antibiotics.

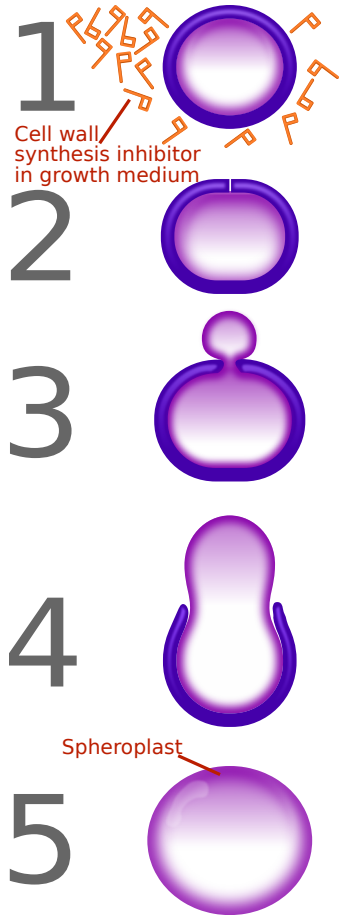

Figure: **Penicillin spheroplast generation**: Diagram depicting the failure of bacterial cell division in the presence of a cell wall synthesis inhibitor (e.g. penicillin, vancomycin).1- Penicillin (or other cell wall synthesis inhibitor) is added to the growth medium with a dividing bacterium.2- The cell begins to grow, but is unable to synthesize new cell wall to accommodate the expanding cell.3- As cellular growth continues, cytoplasm covered by plasma membrane begins to squeeze out through the gap(s) in the cell wall.4- Cell wall integrity is further violated. The cell continues to increase in size, but is unable to "pinch off" the extra cytoplasmic material into two daughter cells because the formation of a division furrow depends on the ability to synthesize new cell wall.5- The cell wall is shed entirely, forming a spheroplast, which is extremely vulnerable relative to the original cell. The loss of the cell wall also causes the cell to lose control over its shape, so even if the original bacterium were rod-shaped, the sphereoplast is generally spherical. Finally, the fact that the cell has now doubled much of its genetic and metabolic material further disrupts homeostasis, which usually leads to the cell's death.

Bacteria often develop resistance to β-lactam antibiotics by synthesizing a β-lactamase, an enzyme that attacks the β-lactam ring. To overcome this resistance, β-lactam antibiotics are often given with β-lactamase inhibitors such as clavulanic acid.

The second class of antimicrobial drugs that interfere with cell wall synthesis are the glycopeptide antibiotics, which are composed of glycosylated cyclic or polycyclic nonribosomal peptides. Significant glycopeptide antibiotics include vancomycin, teicoplanin, telavancin, bleomycin, ramoplanin, and decaplanin. This class of drugs inhibit the synthesis of cell walls in susceptible microbes by inhibiting peptidoglycan synthesis. They bind to the amino acids within the cell wall preventing the addition of new units to the peptidoglycan.

13.2A: Inhibiting Cell Wall Synthesis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.2B: Injuring the Plasma Membrane

Several types of antimicrobial drugs function by disrupting or injuring the plasma membrane.

Learning Objectives

- Discuss the function of the plasma membrane and how antimicrobial drugs target it

Key Points

- The plasma membrane or cell membrane is a biological membrane that separates the interior of all cells from the outside environment.
- Plasma membranes are involved in a variety of cellular processes such as cell adhesion, ion conductivity, and cell signaling. They serve as the attachment surface for several extracellular structures, including the cell wall, glycocalyx, and intracellular cytoskeleton.
- Disrupting the plasma membrane causes rapid depolarization, resulting in a loss of membrane potential leading to inhibition of protein, DNA and RNA synthesis, which results in bacterial cell death.

Key Terms

- **plasma membrane**: The semipermeable membrane that surrounds the cytoplasm of a cell.
- **cell wall**: A thick, fairly rigid layer formed around individual cells of bacteria, Archaea, fungi, plants, and algae, the cell wall is external to the cell membrane and helps the cell maintain its shape and avoid damage.
- **plasma cell**: a form of lymphocyte that produces antibodies when reacted with a specific antigen; a plasmacyte

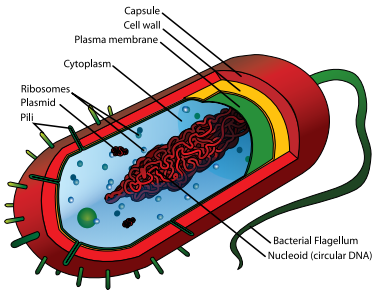

Figure: **Prokaryotic Cell**: Diagram of a typical gram-negative bacterium, with the thin cell wall sandwiched between the red outer membrane and the thin green plasma membrane.

The plasma membrane or cell membrane is a biological membrane that separates the interior of all cells from the outside environment. The plasma membrane is selectively permeable to ions and organic molecules. It controls the movement of substances in and out of cells. The membrane basically protects the cell from outside forces. It consists of the lipid bilayer with embedded proteins. Plasma membranes are involved in a variety of cellular processes such as cell adhesion, ion conductivity, and cell signaling. It serves as the attachment surface for several extracellular structures, including the cell wall, glycocalyx, and intracellular cytoskeleton. Fungi, bacteria, and plants also have the cell wall which provides a mechanical support for the cell and precludes the passage of larger molecules. The plasma membrane also plays a role in anchoring the cytoskeleton to provide shape to the cell and in attaching to the extracellular matrix and other cells to help group cells together to form tissues.

There are several types of antimicrobial drugs that function by disrupting or injuring the plasma membrane. One example is daptomycin, a lipopeptide which has a distinct mechanism of action, disrupting multiple aspects of bacterial cell membrane function. It appears to bind to the membrane causes rapid depolarization, resulting in a loss of membrane potential leading to inhibition of protein, DNA and RNA synthesis, which results in bacterial cell death. Another example is polymyxins antibiotics which have a general structure consisting of a cyclic peptide with a long hydrophobic tail. They disrupt the structure of the bacterial cell membrane by interacting with its phospholipids.

13.2C: Inhibiting Nucleic Acid Synthesis

Antimicrobial drugs inhibit nucleic acid synthesis through differences in prokaryotic and eukaryotic enzymes.

Learning Objectives

- State the steps where inhibitors of nucleic acid synthesis can exert their function

Key Points

- Some antimicrobial drugs interfere with the initiation, elongation or termination of RNA transcription.
- Some antimicrobial drugs interfere with various aspects of DNA replication.
- The antimicrobial actions of these drugs are a result of differences in the prokaryotic and eukaryotic enzymes involved in nucleic acid synthesis.

Key Terms

- **transcription**: The synthesis of RNA under the direction of DNA.
- **replication**: Process by which an object, person, place or idea may be copied mimicked or reproduced.

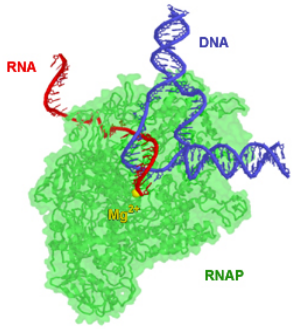

Figure: **Diagram of Transcription**: RNA Polymerase, an enzyme that produces RNA, from T. aquaticus pictured during elongation. Portions of the enzyme were made transparent so as to make the path of RNA and DNA more clear. The magnesium ion (yellow) is located at the enzyme active site.

Antimicrobial drugs can target nucleic acid (either RNA or DNA) synthesis. The antimicrobial actions of these agents are a result of differences in prokaryotic and eukaryotic enzymes involved in nucleic acid synthesis.

Prokaryotic transcription is the process in which messenger RNA transcripts of genetic material are produced for later translation into proteins. The transcription process includes the following steps: initiation, elongation and termination. Antimicrobial drugs have been developed to target each of these steps. For example, the antimicrobial rifampin binds to DNA-dependent RNA polymerase, thereby inhibiting the initiation of RNA transcription.

Other antimicrobial drugs interfere with DNA replication, the biological process that occurs in all living organisms and copies their DNA and is the basis for biological inheritance. The process starts when one double-stranded DNA molecule produces two identical copies of the molecule. In a cell, DNA replication begins at specific locations in the genome, called “origins. ” Uncoiling of DNA at the origin, and synthesis of new strands, forms a replication fork. In addition to DNA polymerase, the enzyme that synthesizes the new DNA by adding nucleotides matched to the template strand, a number of other proteins are associated with the fork and assist in the initiation and continuation of DNA synthesis. DNA replication, like all biological polymerization processes, proceeds in three enzymatically catalyzed and coordinated steps: initiation, elongation and termination. Any of the steps in the process of DNA replication can be targeted by antimicrobial drugs. For instance, quinolones inhibit DNA synthesis by interfering with the coiling of DNA strands.

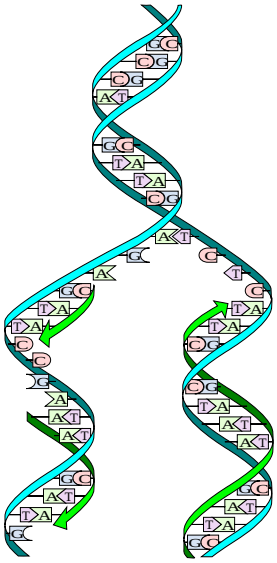

Figure: **DNA Replication**: The double helix is unwound and each strand acts as a template for the next strand. Bases are matched to synthesize the new partner strands.

13.2D: Inhibiting Protein Synthesis

Protein synthesis inhibitors are substances that disrupt the processes that lead directly to the generation of new proteins in cells.

Learning Objectives

- Paraphrase the general mechanism of action of protein synthesis inhibitors

Key Points

- Protein synthesis inhibitors usually act at the ribosome level, taking advantage of the major differences between prokaryotic and eukaryotic ribosome structures.
- Protein synthesis inhibitors work at different stages of prokaryotic mRNA translation into proteins like initiation, elongation (including aminoacyl tRNA entry, proofreading, peptidyl transfer, and ribosomal translocation), and termination.
- By targeting different stages of the mRNA translation, antimicrobial drugs can be changed if resistance develops.

Key Terms

- **translation**: A process occurring in the ribosome, in which a strand of messenger RNA (mRNA) guides assembly of a sequence of amino acids to make a protein.

A protein synthesis inhibitor is a substance that stops or slows the growth or proliferation of cells by disrupting the processes that lead directly to the generation of new proteins. It usually refers to substances, such as antimicrobial drugs, that act at the ribosome level. The substances take advantage of the major differences between prokaryotic and eukaryotic ribosome structures which differ in their size, sequence, structure, and the ratio of protein to RNA. The differences in structure allow some antibiotics to kill bacteria by inhibiting their ribosomes, while leaving human ribosomes unaffected.

Translation in prokaryotes involves the assembly of the components of the translation system which are: the two ribosomal subunits (the large 50S & small 30S subunits), the mRNA to be translated, the first aminoacyl tRNA, GTP (as a source of energy), and three initiation factors that help the assembly of the initiation complex. The ribosome has three sites: the A site, the P site, and the E site (not shown in). The A site is the point of entry for the aminoacyl tRNA. The P site is where the peptidyl tRNA is formed in the ribosome. The E site which is the exit site of the now uncharged tRNA after it gives its amino acid to the growing peptide chain.

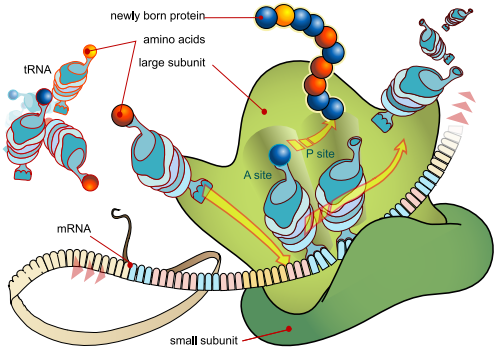

Figure: **Simplified diagram of protein synthesis**: Diagram showing how the translation of the mRNA and the synthesis of proteins is made by ribosomes.

In general, protein synthesis inhibitors work at different stages of prokaryotic mRNA translation into proteins like initiation, elongation (including aminoacyl tRNA entry, proofreading, peptidyl transfer, and ribosomal translocation), and termination. The following is a list of common antibacterial drugs and the stages which they target.

- Linezolid acts at the initiation stage, probably by preventing the formation of the initiation complex, although the mechanism is not fully understood.
- Tetracyclines and Tigecycline (a glycylcycline related to tetracyclines) block the A site on the ribosome, preventing the binding of aminoacyl tRNAs.
- Aminoglycosides, among other potential mechanisms of action, interfere with the proofreading process, causing an increased rate of error in synthesis with premature termination.

- Chloramphenicol blocks the peptidyl transfer step of elongation on the 50S ribosomal subunit in both bacteria and mitochondria.
- Macrolides, clindamycin, and aminoglycosides have evidence of inhibition of ribosomal translocation.
- Streptogramins also cause premature release of the peptide chain.

By targeting different stages of the mRNA translation, antimicrobial drugs can be changed if resistance develops to one or many of the drugs.

13.2E: Inhibiting Essential Metabolite Synthesis

An antimetabolite is a chemical that inhibits the use of a metabolite, a chemical that is part of normal metabolism.

Learning Objectives

- Distinguish between the three main types of antimetabolite antibiotics (antifolates, pyrimidine and purine analogues)

Key Points

- The presence of antimetabolites can have toxic effects on cells, such as halting cell growth or cell division.
- Antimetabolites are also used as antibiotics.
- The three main types of antimetabolite antibiotics are antifolates, pyrimidine analogues and purine analogues.

Key Terms

- **antimetabolite**: Any substance that competes with or inhibits the normal metabolic process, often by acting as an analogue of an essential metabolite

An antimetabolite is a chemical that inhibits the use of a metabolite, a chemical that is part of normal metabolism. Such substances are often similar in structure to the metabolite that they interfere with, such as antifolates that interfere with the use of folic acid. The presence of antimetabolites can have toxic effects on cells, such as halting cell growth or cell division.

Antimetabolites are also used as antibiotics. There are three main types of antimetabolite antibiotics. The first, antifolates impair the function of folic acid leading to disruption in the production of DNA and RNA. For example, methotrexate is a folic acid analogue, and owing to structural similarity with folic acid, methotrexate binds and inhibits the enzyme dihydrofolate reductase, and thus prevents the formation of tetrahydrofolate. Because tetrahydrofolate is essential for purine and pyrimidine synthesis, its deficiency can lead to inhibited production of DNA, RNA and proteins.

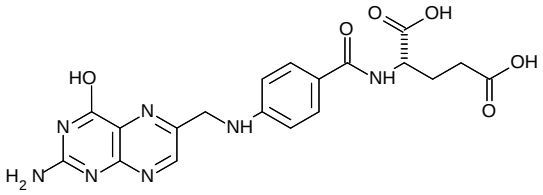

Figure: **Folic Acid Structure**: This is the chemical structure of folic acid.

The second type of antimetabolite antibiotics consist of pyrimidine analogues which mimic the structure of metabolic pyrimidines. Three nucleobases found in nucleic acids, cytosine (C), thymine (T), and uracil (U), are pyrimidine derivatives and the pyrimidine analogues disrupt their formation and consequently disrupt DNA and RNA synthesis.

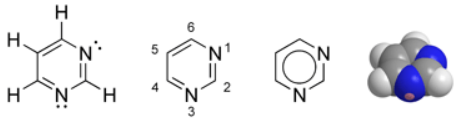

Figure: **Pyrimidine Structure**: This is the chemical structure of pyrimidine.

The purine analogues are the third type of antimetabolite antibiotics and they mimic the structure of metabolic purines. Two of the four bases in nucleic acids, adenine and guanine, are purines. Purine analogues disrupt nucleic acid production. For example, azathioprine is the main immunosuppressive cytotoxic substance that is widely used in transplants to control rejection reactions by inhibiting DNA synthesis in lymphocytes.

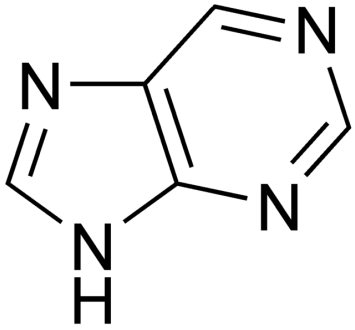

Figure: **Purine Structure**: This is the chemical structure of purine.

13.3A: Synthetic Antimicrobial Drugs

An antimicrobial is a substance that kills or inhibits the growth of microorganisms such as bacteria, fungi, or protozoans.

Learning Objectives

- Recall the synthetic antimicrobial drugs that are sulfonamide and sulphonamide based

Key Points

- The discovery of antimicrobials like penicillin and tetracycline paved the way for better health for millions around the world.
- With the development of antimicrobials, microorganisms have adapted and become resistant to previous antimicrobial agents.
- Synthetic agents include: sulphonamides, cotrimoxazole, quinolones, anti-virals, anti-fungals, anti-cancer drugs, anti-malarials, anti-tuberculosis drugs, anti-leprotics, and anti-protozoals.

Key Terms

- **antimicrobial**: An agent that destroys microbes, inhibits their growth, or prevents or counteracts their pathogenic action.
- **microorganism**: An organism that is too small to be seen by the unaided eye, especially a single-celled organism, such as a bacterium.
- **bacteria**: A type, species, or strain of bacterium.

An antimicrobial is a substance that kills or inhibits the growth of microorganisms such as bacteria, fungi, or protozoans. Antimicrobial drugs either kill microbes (microbiocidal) or prevent the growth of microbes (microbiostatic). Disinfectants are antimicrobial substances used on non-living objects or outside the body.

The history of antimicrobials begins with the observations of Pasteur and Joubert, who discovered that one type of bacteria could prevent the growth of another. They did not know at that time that the reason one bacterium failed to grow was that the other bacterium was producing an antibiotic. Technically, antibiotics are only those substances that are produced by one microorganism that kill, or prevent the growth, of another microorganism. Of course, in today's common usage, the term antibiotic is used to refer to almost any drug that attempts to rid your body of a bacterial infection. Antimicrobials include not just antibiotics, but synthetically formed compounds as well.

The discovery of antimicrobials like penicillin and tetracycline paved the way for better health for millions around the world. Before penicillin became a viable medical treatment in the early 1940s, no true cure for gonorrhea, strep throat, or pneumonia existed. Patients with infected wounds often had to have a wounded limb removed, or face death from infection. Now, most of these infections can be cured easily with a short course of antimicrobials.

However, with the development of antimicrobials, microorganisms have adapted and become resistant to previous antimicrobial agents. The old antimicrobial technology was based either on poisons or heavy metals, which may not have killed the microbe completely, allowing the microbe to survive, change, and become resistant to the poisons and/or heavy metals.

Antimicrobial nanotechnology is a recent addition to the fight against disease-causing organisms, replacing heavy metals and toxins, and may some day be used as a viable alternative.

Infections that are acquired during a hospital visit are called "hospital acquired infections" or nosocomial infections. Similarly, when the infectious disease is picked up in the non-hospital setting, it is considered "community acquired".

Synthetic agents include: sulphonamides, cotrimoxazole, quinolones, anti-virals, anti-fungals, anti-cancer drugs, anti-malarials, anti-tuberculosis drugs, anti-leprotics, and anti-protozoals.

Sulfonamide or sulphonamide is the basis of several groups of drugs. The original antibacterial sulfonamides (sometimes called sulfa drugs or sulpha drugs) are synthetic antimicrobial agents that contain the sulfonamide group. Some sulfonamides are also devoid of antibacterial activity, e.g., the anticonvulsant sultiame. The sulfonylureas and thiazide diuretics are newer drug groups based on the antibacterial sulfonamides.

Sulfa allergies are common, and medications containing sulfonamides are prescribed carefully. It is important to make a distinction between sulfa drugs and other sulfur-containing drugs and additives, such as sulfates and sulfites, which are chemically unrelated to the sulfonamide group and do not cause the same hypersensitivity reactions seen in the sulfonamides.

In bacteria, antibacterial sulfonamides act as competitive inhibitors of the enzyme dihydropteroate synthetase (DHPS), an enzyme involved in folate synthesis. As such, the microorganism will be “starved” of folate and die.

The sulfonamide chemical moiety is also present in other medications that are not antimicrobials, including thiazide diuretics (including hydrochlorothiazide, metolazone, and indapamide, among others), loop diuretics (including furosemide, bumetanide, and torsemide), sulfonylureas (including glipizide, glyburide, among others), and some COX-2 inhibitors (e.g., celecoxib), and acetazolamide.

13.3B: Naturally Occurring Antimicrobial Drugs: Antibiotics

An antimicrobial is a substance that kills or inhibits the growth of microorganisms such as bacteria, fungi, or protozoans.

Learning Objectives

- Discuss the mechanism of action for protein synthesis inhibitors used as antimicrobial drugs, and recognize various naturally occuring antimicrobial drugs

Key Points

- There are mainly two classes of antimicrobial drugs: those obtained from natural sources (i.e. beta-lactam antibiotic (such as penicillins, cephalosporins) or protein synthesis inhibitors (such as aminoglycosides, macrolides, tetracyclines, chloramphenicol, polypeptides); and synthetic agents.
- A β-lactam (beta-lactam) ring is a four-membered lactam. A lactam is a cyclic amide. It is named as such because the nitrogen atom is attached to the β-carbon relative to the carbonyl.
- A protein synthesis inhibitor is a substance that stops or slows the growth or proliferation of cells by disrupting the processes that lead directly to the generation of new proteins.

Key Terms

- **β-lactam**: A β-lactam (beta-lactam) ring is a four-membered lactam. A lactam is a cyclic amide. It is named as such, because the nitrogen atom is attached to the β-carbon relative to the carbonyl. The simplest β-lactam possible is 2-azetidinone.
- **antimicrobial**: An agent that destroys microbes, inhibits their growth, or prevents or counteracts their pathogenic action.
- **microorganism**: An organism that is too small to be seen by the unaided eye, especially a single-celled organism, such as a bacterium.

An antimicrobial is a substance that kills or inhibits the growth of microorganisms bacteria, fungi, or protozoans. Antimicrobial drugs either kill microbes (microbiocidal) or prevent the growth of microbes (microbiostatic). Disinfectants are antimicrobial substances used on non-living objects or outside the body.

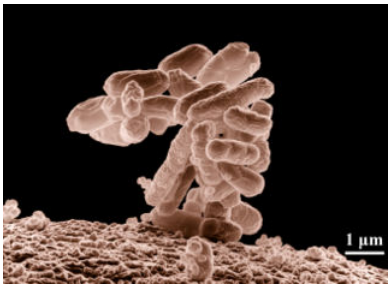

Figure: **A cluster of Escherichia coli Bacteria magnified 10,000 times.**: A cluster of Escherichia coli Bacteria magnified 10,000 times.

The discovery of antimicrobials, like penicillin and tetracycline, paved the way for better health for millions of people around the world. Before penicillin became a viable medical treatment in the early 1940's, no true cure for gonorrhea, strep throat, or pneumonia existed. Patients with infected wounds often had to have a wounded limb removed or face death from infection. Now, most of these infections can be cured easily with a short course of antimicrobials.

However, with the development of antimicrobials, microorganisms have adapted and become resistant to previous antimicrobial agents. The old antimicrobial technology was based either on poisons or heavy metals, which may not have killed the microbe completely. This allowed the microbe to survive, change, and become resistant to the poisons and/or heavy metals.

Antimicrobial nanotechnology is a recent addition to the fight against disease causing organisms. It replaces heavy metals and toxins and may someday be a viable alternative.

Infections that are acquired during a hospital visit are called "hospital acquired infections" or nosocomial infections. Similarly, when the infectious disease is picked up in the non-hospital setting it is considered "community acquired. "

There are mainly two classes of antimicrobial drugs: those obtained from natural sources (i.e. beta-lactam) antibiotic (such as penicillins, cephalosporins) or protein synthesis inhibitors (such as aminoglycosides, macrolides, tetracyclines, chloramphenicol,

polypeptides); and synthetic agents.

A β-lactam (beta-lactam) ring is a four-membered lactam. A lactam is a cyclic amide. It is named as such, because the nitrogen atom is attached to the β-carbon relative to the carbonyl. The simplest β-lactam possible is 2-azetidinone.

A protein synthesis inhibitor is a substance that stops or slows the growth or proliferation of cells by disrupting the processes that lead directly to the generation of new proteins. While a broad interpretation of this definition could be used to describe nearly any antibiotic, in practice, it usually refers to substances that act at the ribosome level (either the ribosome itself or the translation factor), taking advantage of the major differences between prokaryotic and eukaryotic ribosome structures. Toxins such as ricin also function via protein synthesis inhibition. Ricin acts at the eukaryotic 60S.

In general, protein synthesis inhibitors work at different stages of prokaryotic mRNA translation into proteins, like initiation, elongation (including aminoacyl tRNA entry, proofreading, peptidyl transfer, and ribosomal translocation), and termination. Rifamycin inhibits prokaryotic DNA transcription into mRNA by inhibiting DNA-dependent RNA polymerase by binding its beta-subunit. Linezolid acts at the initiation stage probably by preventing the formation of the initiation complex, although the mechanism is not fully understood.

Tetracyclines and Tigecycline (a glycylcycline related to tetracyclines) block the A site on the ribosome, preventing the binding of aminoacyl tRNAs. Aminoglycosides, among other potential mechanisms of action, interfere with the proofreading process, causing increased rate of error in synthesis with premature termination. Chloramphenicol blocks the peptidyl transfer step of elongation on the 50S ribosomal subunit in both bacteria and mitochondria. Macrolides (as well as inhibiting ribosomal translocation and other potential mechanisms) bind to the 50s ribosomal subunits, inhibiting peptidyl transfer. Quinupristin/dalfopristin act synergistically, with dalfopristin, enhancing the binding of quinupristin as well as inhibiting peptidyl transfer. Quinupristin binds to a nearby site on the 50S ribosomal subunit and prevents elongation of the polypeptide. It also causes incomplete chains to be released. Macrolides, clindamycin, and aminoglycosides (with all these three having other potential mechanisms of action as well) have evidence of inhibition of ribosomal translocation. Fusidic acid prevents the turnover of elongation factor G (EF-G) from the ribosome. Macrolides and clindamycin (both also having other potential mechanisms) cause premature dissociation of the peptidyl-tRNA from the ribosome. Puromycin has a structure similar to that of the tyrosinyl aminoacyl-tRNA. Therefore, it binds to the ribosomal A site and participates in peptide bond formation, producing peptidyl-puromycin. However, it does not engage in translocation and quickly dissociates from the ribosome, causing a premature termination of polypeptide synthesis.

13.3C: Beta-Lactam Antibiotics: Penicillins and Cephalosporins

The β-lactam ring is part of the core structure of several antibiotic families.

Learning Objectives

- Recognize the classes of beta-lactams and their mechanisms of action

Key Points

- The principal antibiotic families of which the β-lactam ring is part of the core structure are the penicillins, cephalosporins, carbapenems, and monobactams, which are also called β-lactam antibiotics.
- A β-lactam (beta-lactam) ring is a four-membered lactam (cyclic amide). -Lactams are classified according to their core ring structures.
- The cephalosporins are a class of β-lactam antibiotics originally derived from the fungus Acremonium, which was previously known as “Cephalosporium”.

Key Terms

- **cephalosporins**: The cephalosporins are a class of β-lactam antibiotics originally derived from the fungus Acremonium, which was previously known as “Cephalosporium”.
- **antibiotic**: Any substance that can destroy or inhibit the growth of bacteria and similar microorganisms.
- **β-lactam**: A β-lactam (beta-lactam) ring is a four-membered lactam. A lactam is a cyclic amide. It is named as such, because the nitrogen atom is attached to the β-carbon relative to the carbonyl. The simplest β-lactam possible is 2-azetidinone.
- **β-lactam**: Any of a class of cyclic amides, that are the nitrogen analogs of lactones, formed by heating amino acids; the tautomeric enol forms are known as lactims.

A β-lactam (beta-lactam) ring, is a four-membered lactam. It is named as such, because the nitrogen atom is attached to the β-carbon relative to the carbonyl. The simplest β-lactam possible is 2-azetidinone.

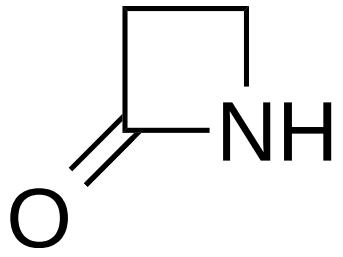

Figure: **β-Lactam**: β-Lactam ring is a four-membered lactam.

The β-lactam ring is part of the core structure of several antibiotic families, the principal ones being the penicillins, cephalosporins, carbapenems, and monobactams, which are, therefore, also called β-lactam antibiotics. Nearly all of these antibiotics work by inhibiting bacterial cell wall biosynthesis. This has a lethal effect on bacteria. Bacteria do, however, contain within their populations, in smaller quantities, bacteria that are resistant against β-lactam antibiotics. They do this by expressing the β-lactamase gene. When bacterial populations have these resistant subgroups, treatment with β-lactam can result in the resistant strain becoming more prevalent and so, more virulent.

β-Lactams are classified according to their core ring structures:

- β-Lactams fused to saturated five-membered rings;
- β-Lactams containing thiazolidine rings are named *penams*;
- β-Lactams containing pyrrolidine rings are named *carbapenams*;
- β-Lactams fused to oxazolidine rings are named *oxapenams* or *clavams*;
- β-Lactams fused to unsaturated five-membered rings;
- β-Lactams containing 2,3-dihydrothiazole rings are named *penems*;
- β-Lactams containing 2,3-dihydro-1H-pyrrole rings are named *carbapenems*;
- β-Lactams fused to unsaturated, six-membered rings;
- β-Lactams containing 3,6-dihydro-2H-1,3-thiazine rings are named *cephems*;
- β-Lactams containing 1,2,3,4-tetrahydropyridine rings are named *carbacephems*;

- β-Lactams containing 3,6-dihydro-2H-1,3-oxazine rings are named *oxacephems*; and
- β-Lactams not fused to any other ring are named *monobactams*.

Penicillin (sometimes abbreviated PCN or pen) is a group of antibiotics derived from *Penicillium fungi.* They include penicillin G, procaine penicillin, benzathine penicillin, and penicillin V. Penicillin antibiotics are historically significant because they are the first drugs that were effective against many previously serious diseases, such as syphilis, and infections caused by staphylococci and streptococci. Penicillins are still widely used today, though many types of bacteria are now resistant. All penicillins are β-lactam antibiotics and are used in the treatment of bacterial infections caused by susceptible, usually Gram-positive, organisms.

The cephalosporins (sg. /ˌsɛfələʊspɔːrɨn/) are a class of β-lactam antibiotics originally derived from the fungus Acremonium, which was previously known as “Cephalosporium”. Together with cephamycins, they constitute a subgroup of β-lactam antibiotics called *cephems*. Cephalosporins are indicated for the prophylaxis and treatment of infections caused by bacteria susceptible to this particular form of antibiotic. First-generation cephalosporins are active predominantly against Gram-positive bacteria, and successive generations have increased activity against Gram-negative bacteria (albeit often with reduced activity against Gram-positive organisms).

13.3C: Beta-Lactam Antibiotics: Penicillins and Cephalosporins is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.3D: Antibiotics from Prokaryotes

Most of the currently available antibiotics are produced by prokaryotes mainly by bacteria from the genus *Streptomyces*.

Learning Objectives

- Explain the role of Streptomyces and other prokaryotes in antibiotic production

Key Points

- Gramicidin is one of the first antibiotics to be manufactured commercially. It is a heterogeneous mixture of six antibiotic compounds, all of which are obtained from the soil bacterial species Bacillus brevis.
- Streptomyces is the largest antibiotic-producing genus, producing antibacterial, antifungal, and antiparasitic drugs, and also a wide range of other bioactive compounds, such as immunosuppressants. They produce over two-thirds of the clinically useful antibiotics of natural origin.
- Members of the Streptomyces genus are the source for numerous antibacterial pharmaceutical agents; among the most important of these are: Chloramphenicol (from S. venezuelae), Lincomycin (from S. lincolnensis), Neomycin (from S. fradiae), Tetracycline (from S. rimosus and S. aureofaciens).
- Some Pseudomonas spp. might produce compounds antagonistic to other soil microbes, such as phenazine-type antibiotics or hydrogen cyanide.

Key Terms

- **antibiotic**: Any substance that can destroy or inhibit the growth of bacteria and similar microorganisms.
- **beta-lactamase**: An enzyme produced by certain bacteria, responsible for their resistance to beta-lactam antibiotics such as penicillin.

Even though penicillin drugs, antibiotics produced by molds, were the first antibiotics successfully used to treat many serious infections, most of the naturally produced antibiotics are synthesized by bacteria. In 1939 the French microbiologist René Dubos isolated the substance tyrothricin and later showed that it was composed of two substances, gramicidin (20%) and tyrocidine (80%). These were the first antibiotics to be manufactured commercially. Gramicidin is a heterogeneous mixture of six antibiotic compounds, all of which are obtained from the soil bacterial species *Bacillus brevis* and called collectively gramicidin D.

Streptomyces is the largest antibiotic-producing genus, producing antibacterial, antifungal, and antiparasitic drugs, and also a wide range of other bioactive compounds, such as immunosuppressants. They produce over two-thirds of the clinically useful antibiotics of natural origin. The now uncommonly-used streptomycin takes its name directly from *Streptomyces*. Aminoglycosides, class of antibiotics, that are derived from bacteria of the *Streptomyces* genus are named with the suffix -mycin, whereas those that are derived from *Micromonospora* are named with the suffix -micin. However, this nomenclature system is not specific for aminoglycosides.

Figure: **Supernatant of a Streptomyces davawensis culture**: The picture shows the typical red color of the antibiotic Roseoflavin secreted by the Streptomyces cells in the culture.

Streptomycetes are characterised by a complex secondary metabolism. Almost all of the bioactive compounds produced by *Streptomyces* are initiated during the time coinciding with the aerial hyphal formation from the substrate mycelium.

Streptomycetes produce numerous antifungal compounds of medicinal importance, including nystatin (from *S. noursei*), amphotericin B (from *S. nodosus*), and natamycin (from *S. natalensis*).

Members of the *Streptomyces* genus are the source for numerous antibacterial pharmaceutical agents; among the most important of these are: Chloramphenicol (from *S. venezuelae*), Daptomycin (from *S. roseosporus*), Fosfomycin (from *S. fradiae*), Lincomycin (from *S. lincolnensis*), Neomycin (from *S. fradiae*), Puromycin (from *S. alboniger*), Streptomycin (from *S. griseus*), Tetracycline (from *S. rimosus* and *S. aureofaciens*).

Clavulanic acid (from *S. clavuligerus*) is a drug used in combination with some antibiotics (like amoxicillin) to block and/or weaken some bacterial-resistance mechanisms by irreversible beta-lactamase inhibition.

Other bacterial species produce antibiotics as well. Such an example are some *Pseudomonas* species which produce antimicrobial compounds. *P. aurantiaca* produces di-2,4-diacetylfluoroglucylmethane, a compound antibiotically active against Gram-positive organisms. Other *Pseudomonas* spp. might produce compounds antagonistic to other soil microbes, such as phenazine-type antibiotics or hydrogen cyanide.

13.3E: Antimycobacterial Antibiotics

Antimycobacterial antibiotics target microbes classified as mycobacterium.

Learning Objectives

- Compare and contrast the drugs used for treatment of Mycobacterium tuberculosis and Mycobacterium leprae

Key Points

- The standard “short” course treatment for TB is isoniazid, rifampicin, pyrazinamide, and ethambutol for two months, then isoniazid and rifampicin alone for another four months.
- The standard treatment for leprosy is a multidrug therapy that includes dapsone, clofazimine and rifampicin.
- Mycobacterium are defined by their ability to grow in a mold-like fashion on the surface of liquids when cultured.

Key Terms

- **tuberculosis**: Tuberculosis, MTB, or TB (short for tubercle bacillus) is a common, and in many cases lethal, infectious disease caused by various strains of mycobacteria, usually Mycobacterium tuberculosis.
- **infectious disease**: Infectious diseases, also known as transmissible diseases or communicable diseases comprise of clinically evident illness (i.e., characteristic medical signs and/or symptoms of disease) resulting from the infection, presence and growth of pathogenic biological agents in an individual host organism. In certain cases, infectious diseases may be asymptomatic for much or even all of their course in a given host. In the latter case, the disease may only be defined as a “disease” (which by definition means an illness) in hosts who secondarily become ill after contact with an asymptomatic carrier. An infection is not synonymous with an infectious disease, as some infections do not cause illness in a host.
- **leprosy**: Leprosy, also known as Hansen’s disease (HD), is a chronic disease caused by the bacteria Mycobacterium leprae and Mycobacterium lepromatosis.
- **isoniazid**: a medication used in the prevention and treatment of tuberculosis, having the chemical formula C6H7N3O

Antimycobacterial antibiotics are a class of antimicrobial drugs that target mycobacterium. Mycobacterium is a genus of Actinobacteria that includes pathogens known to cause serious and infectious disease. The types of pathogens considered to be mycobacterium include Mycobacterium tuberculosis (tuberculosis) and Mycobacterium leprae (leprosy). Mycobacterium grow in a mold-like manner on the surface of liquids when cultured. Antiomycobacterial antibiotics specifically target these types of microbes.

A type of antimycobacterial antibiotic includes the class of drugs used for tuberculosis (TB) treatment. The standard “short” course treatment for TB is isoniazid, rifampicin (also known as rifampin in the United States), pyrazinamide and ethambutol for two months, then isoniazid and rifampicin alone for another four months. The patient is considered cured at six months (although there is still a relapse rate of 2 to 3%). For latent tuberculosis, the standard treatment is six to nine months of isoniazid alone.

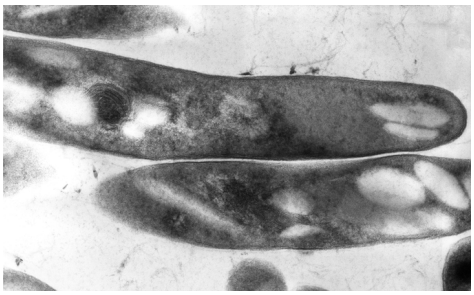

Figure: **Mycobacterium**: Mycobacterium are a class of bacteria defined by their ability to grow in a mold-like manner. Here, a TEM of Mycobacterium tuberculosis, the causative agent of tuberculosis. Antimycobacterial antibiotics target mycobacterium.

If the organism is known to be fully sensitive, then it is treated with isoniazid, rifampicin and pyrazinamide for two months, followed by isoniazid and rifampicin for four months. Ethambutol need not be used. Most regimens have an initial high-intensity phase, followed by a continuation phase (also called a consolidation phase or eradication phase) – the high-intensity phase is given first, then the continuation phase.

There are six classes of second-line drugs (SLDs) used for the treatment of TB. A drug may be classed as second-line instead of first-line for one of three possible reasons: it may be less effective than the first-line drugs (e.g., p-aminosalicylic acid); or, it may

have toxic side-effects (e.g., cycloserine); or it may be unavailable in many developing countries (e.g., fluoroquinolones): aminoglycosides: e.g., amikacin (AMK), kanamycin (KM); polypeptides: e.g., capreomycin, viomycin, enviomycin; Fluoroquinolones: e.g., ciprofloxacin (CIP), levofloxacin, moxifloxacin (MXF); thioamides: e.g. ethionamide, prothionamide.

For treatment of leprosy, caused by Mycobacterium leprae, the traditional antimycobacterial drugs include promin (the first treatment introduced to fight leprosy) and dapsone (which eventually become obsolete as Mycobacterium leprae quickly evolved resistance). Modern drugs which were developed in response to the resistance was clofazimine and rifampicin. The use of multidrug therapies including dapsone, clofazimine and rifampicin were advantageous due to the low risk of antibiotic resistance. However, the use of these multidrug treatments was costly and only adopted in endemic countries when the World Health Assembly passed a resolution to eliminate leprosy in 1991.

13.4A: Organ Toxicity

The accumulation of antimicrobial drugs and their metabolic byproducts in organs can be toxic, leading to organ damage.

Learning Objectives

- Outline the two major types of organ toxicity and their effects, recognizing additional types of toxicity

Key Points

- Antimicrobial drugs can have unintended side effects, including being toxic to organs.
- The liver and kidney are particularly susceptible to organ toxicity as they are the sites of toxin filtration and toxin metabolic breakdown.
- Almost any organ or tissue in the human body can be affected by antimicrobial toxicity.
- The toxic effects of antimicrobial drugs, while potentially harmful are very rare.

Key Terms

- **antimicrobrial drugs**: A drug administered to a patient, with the purpose of killing or slowing the growth of a microorganism, including protozoans, fungi and bacteria.
- **antibiotics**: A chemical that slows the growth of, or kills a bacteria.

The use of antimicrobial drugs can have many unintended side-effects. The use, particularly when repeated, of many drugs can lead to an accumulation of a drug, or harmful byproducts from the metabolism of a drug, in tissues or organs. This accumulation of toxic chemicals can lead to organ damage, and in extreme cases, even organ failure and death. Two severe types of organ toxicity associated with antimicrobial drugs are nephrotoxicity and hepatotoxicity, toxicity of the kidneys and liver respectively.

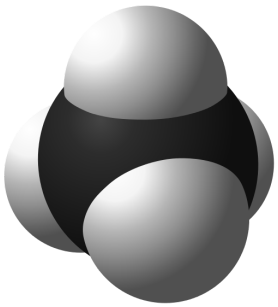

Figure: **Methane**: This space-filling model of methane shows the approximately spherical nature of this molecule.

The liver and kidneys are common organs affected by chemical toxicity. The kidneys are responsible for the filtration of the blood, so it is not surprising that deleterious agents in the blood may accumulate there. The liver is an important site for the breakdown of most metabolites in the body, and is referred to as the “metabolic clearing house” of the body. As drugs are quite often broken down in the liver, they can accumulate there and cause damage, or the byproducts of a drug’s metabolism can be toxic. In addition to direct damage to the liver by an antimicrobial drug, antimicrobial drugs can lead to the formation of dangerous toxins through the breakdown of microbes or due to interaction with other tissues in the body. These secondary toxins from drug metabolism then accumulate in the liver, potentially causing damage. Drug damage to the liver or kidneys can be particularly catastrophic as these organs are needed for the proper “cleaning” of the body. If they are compromised, this leads to further accumulation of potentially toxic metabolites further damaging organs in the body.

Figure: **Sun Poisoning**: This rash seen on a forearm is a typical reaction observed when an antibiotic causes phototoxicity.

Some of the toxic effects can be more benign, as is the case with ototoxicity, or damage to the ear. Use of some antibiotics, such as gentamicin, can cause a lose of hearing, or tinnitus (“ringing in the ears”). Ototoxicity is usually temporary with antibiotics, but permanent hearing damage, while rare, has been reported. Some antibiotics such as Tetracycline can cause phototoxicity, also known as sun poisoning; the result of which is that very short exposures to direct sunlight can cause severe skin irritation, with the appearance being quite similar to a rash or sunburn. The Tetracycline in a patient’s skin becomes toxic when exposed to sunlight, which causes an allergic reaction and leads to rash on the affected area. Broad-spectrum antibiotics in the family of fluoroquinolones can cause neurotoxicity by directly damaging neuronal receptors. This can lead to any number of psychological effects from mild cognitive dysfunction (brain fog) to more severe effects, such as hallucinations and suicidal thoughts.

While a few specific examples have been outlined here, toxic effects are not limited to the organs mentioned. In fact, almost any tissue or organ can be affected by antimicrobial drugs. However, it should be noted that the side-effects due to broad-spectrum antibiotics are actually quite rare, with organ damage being even more rare.The potential side-effects of antibiotics or other antimicrobial drugs are offset by the benefits of combating the microbial infection.

13.4B: Allergic Responses to Drugs

Antimicrobrial drugs can cause immune responses which can be fatal.

Learning Objectives

- Explain the physiology of an immune response responsible for an allergic reaction to drugs

Key Points

- Antimicrobial drugs, can like almost any other substance, act as an allergen.
- Using a drug may not induce an allergic response the first time it is taken, however, subsequent use of the antimicrobial drugs may lead to allergic reactions.
- The most common antimicrobial drug allergy is penicillin. 1-5% of people who have taken it have suspected penicillin allergies.

Key Terms

- **allergen**: A substance, known as an antigen, which stimulates an immune response from a sensitive individual.
- **anaphylaxis**: A rapid and severe allergic reaction which can lead to death
- **Beta-lactam antibiotics**: A broad class of antibiotics of which penicillin is a member.

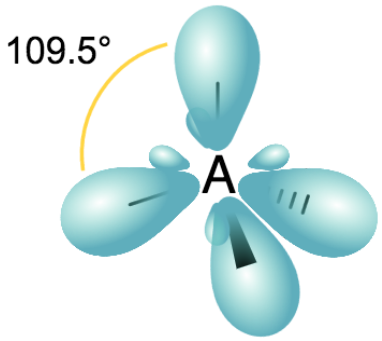

Figure: **sp3 hybridization**: In the process of sp^3 hybridization in methane, the single 2s and three 2p orbitals of carbon mix into four sp^3 hybrid orbitals, which are chemically and geometrically identical. Bond angles are 109.5°.

Virtually any substance, when exposed internally or externally to the body, can act as an allergen and illicit an immune system response, such is the case with antimicrobial drugs. While the drug acts as an allergen, the drug itself is not causing direct damage to the individual, but rather it is the response of an individual's immune system which is deleterious. An allergic reaction is the body's response to clear a foreign substance. Once the body recognizes a substance as foreign (in this case an antimicrobial drug), it starts producing antibodies, specifically immunoglobulin E (IgE) against the drug. The IgE binds directly to the drug and sets off a cascade of events, including the activation of receptors on immune system cells. This results in the production of histamines. The worst allergic reactions can be very severe and result in anaphylaxis. Anaphylaxis is an extremely severe allergic reaction caused when histamines are overproduced leading to severe contraction of bronchial muscles. In the most extreme cases, the airways close, which can lead to death. Other less severe symptoms of an allergic reaction can include, hives, angioedema (tissue swelling under the skin, often on the face), tight throat, coughing, wheezing, or watery eyes.

The exposure to a drug may not elicit an allergic reaction during the first exposure, but after the first exposure, the body creates antibodies and memory lymphocyte cells against the drug, therefore later exposures to the drug will illicit an immune response. There are many factors that can determine if an individual is sensitive to an antimicrobial drug, as with other allergens. Some factors include genetics and past exposures to other allergens, typically a person who has allergies to other things, such as various foods, is more prone to have or develop drug allergies. The most reported drug allergy is to Beta-lactam antibiotics, of which penicillin is the most well-known type, affecting 1-5% of people who take penicillin. While the most severe cases can result in anaphylaxis, most reactions are not severe. Additionally the allergic reaction may not even be due to the penicillin, as dyes and other chemicals added to antimicrobial drugs may in fact cause the allergic response instead. Taken together, recent studies show that perhaps only 1/5 people who suspect they have an allergy to penicillin do indeed have such an allergy.

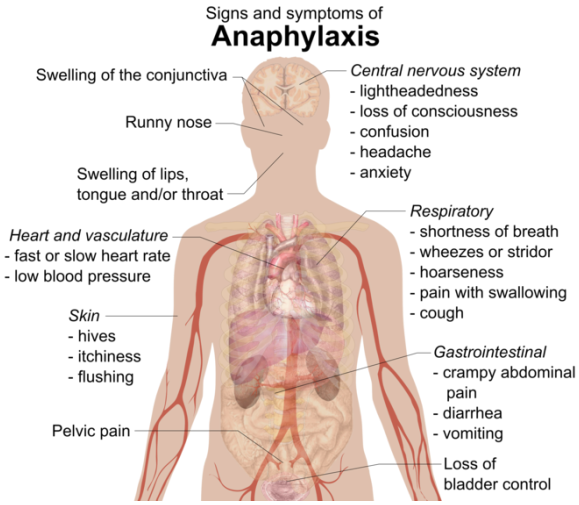

Figure: **Anaphylaxis**: A representation of the signs and symptoms of anaphylaxis that result from an allergic reaction. Signs include CNS symptoms such as confusion or lightheadedness, respiratory symptoms such as shortness of breath, gastrointestinal issues such as pain or vomiting, skin issues such as hives or itchiness, vascular symptoms such as change in heart rate or low blood pressure, and swelling of the mouth or eyes.

13.4C: Suppression and Alteration of Microbiota by Antimicrobials

Our bodies depend upon, and host, a vast number of complex microbial flora that can be affected negatively by antimicrobial treatments.

Learning Objectives

- Describe the role and function of the microbiota

Key Points

- The intestinal system has many different species of microbes and huge numbers of individual microbes; we rely on these microbes for proper metabolism of food.
- The use of antimicrobial agents to slow down or kill pathogenic microbes can often kill beneficial bacteria, causing deleterious health effects.
- Our body hosts some microbes that inhibit the growth of pathogenic microbes; using antimicrobial agents can alter the flora allowing pathogenic microbes to overgrow and cause diseases.

Key Terms

- **Candidal vulvovaginitis**: Candidal vulvovaginitis or vaginal thrush, or yeast infection, is an infection of the vagina's mucous membranes by Candida albicans.
- **microbiota**: The microbial flora harbored by normal, healthy individuals.
- **pathogenic bacteria**: Bacteria which infect and cause deleterious health effects.

The human body hosts thousands of different species of microbial organisms, known as the microbial flora or microbiota. Microbiota serve many functions in our body; most notable is the gut flora, crucial for the proper digestion of food, carbohydrate fermentation, and nutrient absorption. The gut flora in the human intestinal system has hundreds of species of microbes and over 100 trillion individual microbes; in comparison, the human body has around 10 trillion cells. Most of these microbes are bacterial and fungal. This is especially a problem when broad-spectrum antimicrobial agents are used, as antimicrobial treatments while helping to clear up pathogenic microbes from the body will often kill symbiotic bacteria. In addition, some microbial infections are due to translocation, the movement of advantageous bacteria to parts of the body where they might be harmful. An example is gut flora getting into the body's blood stream. The treatment of translocated or pathogenic bacteria may necessitate the use of antibiotics that will kill symbiotic bacteria. Antimicrobial agents which can kill beneficial gut flora can reduce the numbers of individual microbes or reduce the species of beneficial bacteria. In the case of the gut flora, this may impair the ability of a patient to properly metabolize food. If advantageous bacteria do not repopulate the intestine, this can lead to serious malnutrition problems.

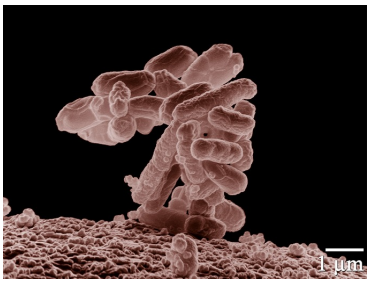

Figure: **Gut bacteria**: This is an electron micrograph, at 10,000X magnification. The oblong structures are Escherichia coli (E. coli), a symbiotic bacteria found in the human intestinal system.

In addition to serving a necessary function as gut flora due in metabolism of food, some microbiota in our bodies serve the function of keeping pathogenic microbes from inhabiting or dominating other flora at locations in our body. This is exemplified by Candida albicans, a yeast which is often found on humans. C. albicans is normally harmless, but when women take some antibiotics this can kill beneficial bacteria, specifically lactobacilli, in the vulvo-vaginal area. Without lactobacilli, C. albicans growth is not suppressed and can thus overgrow. This causes candidal vulvovaginitis, or yeast infections, a potentially painful infection of the vaginal mucous membranes by overgrown C. albicans. Yeast infections can be caused by antibiotics, as well as using aggressive topical cleaning agents such as detergents which again kill off beneficial lactobacilli allowing C. albicans to overgrow.

Fortunately there are antimicrobial agents that specifically target pathogenic bacterial species, which opposed to broad-spectrum treatments can reduce harmful effects on beneficial microbes. Sometimes the use of broad-spectrum antimicrobial agents is unavoidable; in these situations, consuming foods such as yogurt which contains beneficial bacteria can replenish the body's symbiotic microbes. In extreme cases microbes can be transplanted from a healthy individual to someone with whose symbiotic microbes have been compromised.

13.4C: Suppression and Alteration of Microbiota by Antimicrobials is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.4D: Effects of Drug Combinations

Antimicrobial drugs can interact with other drugs in deleterious ways or can be used in combination to combat microbial infections.

Learning Objectives

- Give examples of interactions that can render an antimicrobial ineffective

Key Points

- The interaction between one antimicrobial agent and another is very complex, along with the way they target microbes and the organism.
- While it is not certain that a drug may interact with antibiotics, it is considered wise to err on the side that there are potentially unknown and harmful interactions from mixing drugs.
- The use of more than one antimicrobial agent is an effective and widely used practice to reduce the chance that microbes will resist a treatment.

Key Terms

- **contraindication**: In medicine, a contraindication is a condition or factor that serves as a reason to withhold a certain medical treatment.
- **tuberculosis**: An infectious disease of humans and animals caused by a species of mycobacterium mainly infecting the lungs where it causes tubercles characterized by the expectoration of mucus and sputum, fever, weight loss, and chest pain, and transmitted through inhalation or ingestion of bacteria.
- **combination therapy**: Combination therapy is the use of more than one medication or other therapy. Most often, these terms refer to the simultaneous administration of two or more medications to treat a single disease.

Pharmacodynamics is the field that attempts to understand the unintended effects of the use of two or more drugs. Pharmacodynamics is the study of the biochemical and physiological effects of drugs on the body or on microorganisms or parasites within or on the body. It also looks at the mechanisms of drug action and the relationship between drug concentration and effect. These changes are extraordinarily difficult to classify given the wide variety of modes of action that exist and the fact that many drugs can cause their effect through a number of different mechanisms. This wide diversity also means that, in all but the most obvious cases, it is important to investigate and understand these mechanisms. The well-founded suspicion exists that there are more unknown interactions than known ones.

Two well described interactions between antimicrobial drugs and other drugs are between antibiotics and alcohol and antibiotics and the birth control pill. Interactions between alcohol and certain antibacterials may occur, cause side-effects, and decrease effectiveness of antibacterial therapy. Potential risks of side-effects and effectiveness depend on the type of antibacterial administered. Despite the lack of a categorical contraindication, the belief that alcohol and antibacterials should never be mixed is widespread. Some antibacterials may inhibit the breakdown of alcohol, which may result in alcohol-induced vomiting, nausea, and shortness of breath. Other effects of alcohol on antibacterial activity include altered activity of the liver enzymes that break down the antibacterial compound. In addition, serum levels bacteriostatic antibacterials may be reduced by alcohol consumption, resulting in reduced efficacy and diminished pharmacotherapeutic effect.

Another well studied interaction is between antibiotics and the contraceptive pill. The majority of studies indicate that antibiotics do not interfere with contraceptive pills. In cases where antibacterials have been suggested to affect the efficiency of birth control pills may be due to an increase in the activities of hepatic liver enzymes causing increased breakdown of the pill's active ingredients. Effects on the intestinal flora, which might result in reduced absorption of estrogens in the colon, have also been suggested, but such suggestions have been inconclusive and controversial. Clinicians have recommended that extra contraceptive measures be applied during therapies using antibacterials that are suspected to interact with oral contraceptives.

Additionally, when dealing with a microbial infection, sometimes the use of two or more antibiotics can effectively combat the infection while each drug individually has little or no effect. This method is called combination therapy and is used when the nature of a microbial infection is unknown, as typified by the combination of the antibiotics ampicillin and sulbactam. The use of two antibiotics with different modes of microbial inhibition increases the chance that the treatment will combat the microbial infection. Further, tuberculosis has been treated with combination therapy for over fifty years. This is due to the phenomenon of resistance, whereby a micro-organism gains the ability to resist an antimicrobial drug, while initially the drug effectively slowed the growth of

or even killed the target micro-organism. Treating tuberculosis, or other pathogenic microbes with more than one antibiotic reduces the chance that the microbe will adapt and survive the treatment, especially if the two drugs have different methods of reducing the microbe's normal functions.

Figure: **Tuberculosis**: This x-ray of a tuberculosis patient shows the lung on the left side completely infected and the right lung partially infected (the dark areas), with tuberculosis.

13.5: Measuring Drug Susceptibility

Topic hierarchy

13.5A: Minimal Inhibitory Concentration (MIC)

13.5B: Kirby-Bauer Disk Susceptibility Test

13.5: Measuring Drug Susceptibility is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.5A: Minimal Inhibitory Concentration (MIC)

Minimum Inhibitory Concentration is the lowest drug concentration that prevents visible microorganism growth after overnight incubation.

Learning Objectives

- Analyze data to interpret minimal inhibitory concentration values

Key Points

- Minimum inhibitory concentration (MIC) can be determined by culturing microorganisms in liquid media or on plates of solid growth medium.
- A lower MIC value indicates that less drug is required for inhibiting growth of the organism; therefore, drugs with lower MIC scores are more effective antimicrobial agents.
- By identifying appropriate drugs and their effective concentrations, MIC scores aid in improving outcomes for patients and preventing evolution of drug-resistant microbial strains.

Key Terms

- **culture**: The process of growing a bacterial or other biological entity in an artificial medium.
- **minimum inhibitory concentration**: This is the lowest concentration of an antimicrobial drug that prevents visible growth of a microorganism after overnight incubation with media.
- **bacteriostatic**: A drug that prevents bacterial growth and reproduction but does not necessarily kill them. When it is removed from the environment the bacteria start growing again.

Definition and Measurement

In microbiology, minimum inhibitory concentration (MIC) is the lowest concentration of an antimicrobial (like an antifungal, antibiotic or bacteriostatic) drug that will inhibit the visible growth of a microorganism after overnight incubation. MICs can be determined on plates of solid growth medium (called agar, shown in the “Kirby-Bauer Disk Susceptibility Test” atom) or broth dilution methods (in liquid growth media, shown in) after a pure culture is isolated. For example, to identify the MIC via broth dilution, identical doses of bacteria are cultured in wells of liquid media containing progressively lower concentrations of the drug. The minimum inhibitory concentration of the antibiotic is between the concentrations of the last well in which no bacteria grew and the next lower dose, which allowed bacterial growth. There are also several commercial methods available to experimentally measure MIC values.

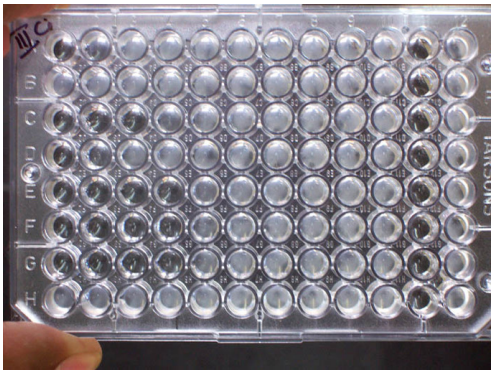

Figure: **Microbroth Dilution Method**: To identify the lowest concentration required for a given antibiotic to inhibit bacterial growth, an identical amount of bacteria is introduced into wells of liquid media containing progressively lower concentrations of the drug. (Here, the dilution series of the drug is set up from left to right: for example, well E1 might contain 100 units of drug; E2, 50 units; E3, 25 units; E4, 12.5 units; etc.). Because bacterial growth made the media in well E5 cloudy and the media in well E4 is indistinguishable from clear media, this indicates that the minimum inhibitory concentration is between the drug concentrations in wells E4 and E5. (Image courtesy of Microrao, Dept. of Microbiology, JJMMC, Davangere).

Significance and Applications

An MIC is generally regarded as the most basic laboratory measurement of the activity of an antimicrobial agent against an organism. Because a lower MIC value indicates that less of the drug is required in order to inhibit growth of the organism, drugs with lower MIC scores are more effective antimicrobial agents. Currently, there are a few web-based, freely accessible MIC databases. MIC scores are important in diagnostic laboratories to confirm resistance of microorganisms to an antimicrobial agent and also to monitor the activity of new antimicrobial agents. Clinicians use MIC scores to choose which antibiotics to administer to patients with specific infections and to identify an effective dose of antibiotic. This is important because populations of bacteria exposed to an insufficient concentration of a particular drug or to a broad-spectrum antibiotic (one designed to inhibit many strains of bacteria) can evolve resistance to these drugs. Therefore, MIC scores aid in improving outcomes for patients and preventing evolution of drug-resistant microbial strains.

13.5A: Minimal Inhibitory Concentration (MIC) is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.5B: Kirby-Bauer Disk Susceptibility Test

Learning Objectives

- Review the procedure for the Kirby-Bauer antibiotic tes

Kirby-Bauer antibiotic testing (also called KB testing or disk diffusion antibiotic sensitivity testing) uses antibiotic-containing wafers or disks to test whether particular bacteria are susceptible to specific antibiotics. First, a pure culture of bacteria is isolated from the patient. Then, a known quantity of bacteria are grown overnight on agar (solid growth media) plates in the presence of a thin wafer that contains a known amount of a relevant antibiotic. If the bacteria are susceptible to the particular antibiotic from a wafer, an area of clear media where bacteria are not able to grow surrounds the wafer, which is known as the zone of inhibition. A larger zone of inhibition around an antibiotic-containing disk indicates that the bacteria are more sensitive to the antibiotic in the disk.

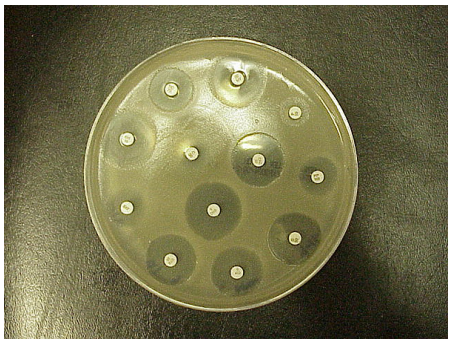

Figure: ***Kirby-Bauer test****: In Kirby–Bauer testing, discs containing antibiotics are placed on agar where bacteria are growing, and the antibiotics diffuse out into the agar. If an antibiotic stops the bacteria from growing, one can see circular areas around the wafers where bacteria have not grown.*

KB tests are performed under standardized conditions and standard-sized zones of inhibition have been established for each antibiotic. KB test results are usually reported as sensitive, intermediate, or resistant, based on the size of the zone of inhibition. If the observed zone of inhibition is greater than or equal to the size of the standard zone, the microorganism is considered to be sensitive to the antibiotic. Conversely, if the observed zone of inhibition is smaller than the standard size, the microorganism is considered to be resistant. The size of a zone of inhibition in a KB test is inversely related to the minimum inhibitory concentration (MIC), which is the amount of antibiotic required to prevent bacterial growth in an overnight culture. The MIC (in µg/ml) can be calculated from known standard-curve (linear regression) graphs based on the diameter of the observed inhibition zone diameter (in millimeters).

Clinicians can use KB test results to choose appropriate antibiotics to combat a particular infection in a patient. Administering antibiotics that specifically target the particular bacteria that are causing the infection can avoid using broad-spectrum antibiotics, which target many types of bacteria. Thus, clinical application of KB testing results can decrease the frequency with which antibiotic-resistant bacteria evolve.

Key Points

- KB tests are performed under standard conditions, so the minimum inhibitory concentration for a given antibiotic can be calculated by comparing the observed zone of inhibition ‘s size to known values.
- Clinicians use KB test results to choose antibiotics effective against the specific bacteria causing a patient’s infection. Using specifically-targeted antibiotics helps decrease the frequency of drug-resistant bacteria evolving.

Key Terms

- **Kirby-Bauer antibiotic testing**: This is a method to determine the sensitivity of microorganisms to specific antimicrobial drugs; greater drug efficacy yields larger microbe-free zones surrounding drug-containing disks after overnight growth on solid media.
- **zone of inhibition**: This is an area of media where bacteria are unable to grow, due to presence of a drug that impedes their growth.

- **minimum inhibitory concentration**: This is the lowest concentration of an antimicrobial drug that prevents visible growth of a microorganism after overnight incubation with media.

13.6A: Mechanisms of Resistance

Development of microbial resistance to antimicrobial agents requires alterations in the microbe's cell physiology and structure.

Learning Objectives

- Describe the mechanisms bacteria use to develop antimicrobial resistance and the factors that can lead to it

Key Points

- Antimicrobial resistance can be mediated by the environment or the microorganism itself.
- Environmentally-mediated antimicrobial resistance results from physical or chemical characteristics of the environment that can affect the antimicrobial agent or the microorganism.
- Microorganism-mediated antimicrobial resistance can be intrinsic or acquired.

Key Terms

- **intrinsic**: innate, inherent, inseparable from the thing itself, essential.

Development of microbial resistance to antimicrobial agents requires alterations in the microbe ‘s cell physiology and structure. Antimicrobial resistance is defined as the loss of susceptibility to an extent that the drug is no longer effective for clinical use against an organism. Resistance can be mediated by the environment or the microorganism itself.

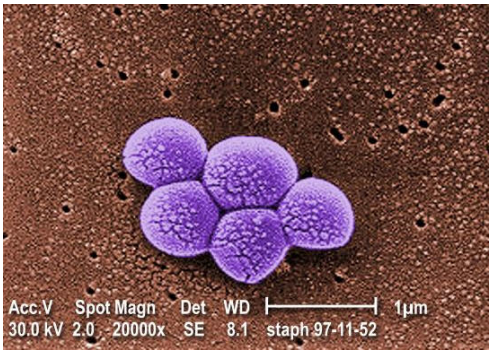

Figure: **Resistant bacterial strain**: Methicillin-resistant Staphylococcus aureus.

Environmentally-mediated antimicrobial resistance is affected by the environment's chemical and physical properties such as pH, anaerobic conditions, cation concentrations (calcium, magnesium), and thymine-thymidine content (available metabolites and nutrients).

Microorganism-mediated antimicrobial resistance is due to genetically-encoded traits of the microorganism and can be divided into intrinsic or acquired. Intrinsic resistance is considered to be a natural and inherited property with high predictability. Once the identity of the organism is known, the aspects of its anti-microbial resistance are also recognized. On the other hand, acquired resistance results from a change in the organism's genetic makeup. This trait is associated with only some strains of an organism's group but not the others. It is also an unpredictable trait and necessitates the development of laboratory methods to detect it. Microorganism-mediated antimicrobial resistance is acquired by gene change or exchange such as genetic mutations, acquisition of genes from other organisms via gene transfer mechanisms, or a combination of mutational and gene transfer events. Some common pathways bacteria use to effect antimicrobial resistance include: enzymatic degradation or modification of the antimicrobial agent, decreased uptake or accumulation of the antimicrobial agent, altered antimicrobial target, circumvention of consequences of antimicrobial actions, uncoupling of antimicrobial agent-target interaction, or any combination of these mechanisms.

13.6A: Mechanisms of Resistance is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.6B: Antibiotic Misuse

Learning Objectives

- Explain the effects of antibiotic misuse

With the introduction of antibiotics into medical practice, clinically-relevant bacteria have had to adopt resistance mechanisms as part of their survival strategy. Antibiotic resistance occurs when antibiotics no longer work against disease-causing bacteria. These infections are difficult to treat and can mean longer-lasting illnesses, more doctor visits or extended hospital stays, and the need for more expensive and toxic medications. Some resistant infections can even cause death. Developing new antibiotics and other treatments to keep pace with antibiotic-resistant strains of bacteria is necessary. However, using antibiotics wisely is equally important for preventing the spread of resistant strains.

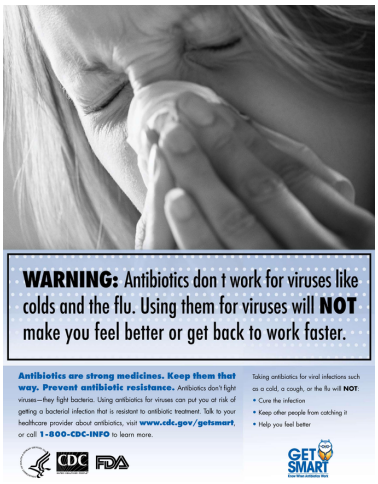

Figure: ***Figure 13.6B.1****: Antibiotic misuse. Antibiotics are not effective against viral infections. Misusing them leads to resistant bacterial strains.*

Antibiotic misuse has contributed largely to the emergence of new resistant strains. It is caused by taking an antibiotic too often for a condition it cannot treat such as viral infections and the common cold or in the wrong doses. It can also be manifested by not finishing a course of antibiotics as prescribed (stopping the antibiotic before the infection is fully cleared from the body). Overuse of antibiotics affects the bodsy's normal flora and disrupts the balance between beneficial bacteria that help digestion for example, and harmful bacteria. Excessive use of antibiotics in intensive farming units, particularly pig and poultry farms, is also seen as a growing threat. Scientists say antimicrobial resistance may be passing between animals and humans through food consumption, making the need to cut unnecessary use of antibiotics in farming even more urgent. Responsible antibiotic use in industry, and good practice for patients and physicians, are essential to keep resistant bacterial strains curable, and antibiotic treatment affordable to patients.

Key Points

- Antimicrobial resistance is a major public health concern.
- Antimicrobial resistance is brought about by antibiotic misuse, such as overuse, misuse, or interrupted treatment.
- Food industries, physicians, and patients play a role in minimizing the spread of resistance by adhering to good antibiotic practice.

Key Terms

- **course of antibiotics**: a period of continuous treatment with a drug.

13.6B: Antibiotic Misuse is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.6C: Cost and Prevention of Resistance

Learning Objectives

- Examine the causes and effects of multidrug-resistant organisms on healthcare

Prevention and control of microbial-resistant organisms is one of the most complex management issues that health care professionals face. The clinical and financial burden to patients and health care providers is staggering. Patients who are infected with bacterial strains resistant to more than one type or class of drugs (multidrug-resistant organisms, MDRO) often have an increased risk of prolonged illness, extended hospital stay, and mortality.

The cost of care for these patients can be more than double compared to those without an MDRO infection. The alternative medication they are prescribed to overcome the infection is often substantially more costly. Multidrug resistance forces healthcare providers to use antibiotics that are more expensive or more toxic to the patient.

Figure: ***Antibiotics****: Antibiotic misuse is a major cause of the staggering healthcare costs for the treatment of resistant bacterial strains.*

When no antibiotic is effective, healthcare providers may be limited to providing supportive care rather than directly treating an infection. In a 2008 study of attributable medical costs for antibiotic resistant infections, it was estimated that infections in 188 patients from a single healthcare institution cost between $13.35 and $18.75 million dollars.

Research and development of new drugs effective against resistant bacterial strains also comes at a cost. To prevent antimicrobial resistance, the patient and the healthcare provider should discuss the appropriate medicine for the illness. Patients should follow prescription directions and should not share or take medicine that was prescribed for someone else; these virtues should be strictly practiced. Healthy lifestyle habits, including proper diet, exercise, and sleeping patterns, as well as good hygiene such as frequent hand washing, can help prevent illness. These practices, therefore, also help prevent the overuse or misuse of antibiotics and the emergence of problematic resistant strains.

Key Points

- Antimicrobial resistance to available drugs requires the development of new drugs to effectively treat resistant strains and reduce mortality from bacterial infections.
- Antimicrobial resistance can be prevented by practicing good hygiene, and being responsible with antibiotic use.
- Treating antibiotic-resistant bacterial strains is expensive for both the patient and the healthcare provider. The treatment requires extended hospital stay and costly medications.

Key Terms

- **multidrug resistance**: A condition enabling a disease-causing organism to resist distinct drugs or chemicals of a wide variety of structure and function targeted at eradicating the organism.

13.6C: Cost and Prevention of Resistance is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.6D: Biofilms, Persisters, and Antibiotic Tolerance

Biofilms and persisters are bacterial communities responsible for chronic diseases and antibiotic tolerance.

Learning Objectives

- Explain the role of biofilms and persisters in multidrug tolerance, distinguishing this from multidrug resistance

Key Points

- Biofilms are aggregates of microbial cells that form to avoid antimicrobial agents or attack by the immune system.
- Persisters are slow-growing, dormant microbial cells that can tolerate antibiotic treatment.
- Biofilms and persisters are responsible for chronic bacterial infections and recurrent disease.
- Antibiotic tolerance is different from antibiotic resistance but equally important as a public health burden for eradication of serious bacterial diseases.

Key Terms

- **gingivitis**: inflammation of the gums or gingivae
- **extracellular matrix**: All the connective tissues and fibers that are not part of a cell, but rather provide support.

Biofilms are bacteria that have formed a gated community. Biofilms are composed of an aggregate of bacterial cells and are essentially considered a multi-cellular organism. They are characterized by structural heterogeneity, genetic diversity, complex community interactions, and an extracellular matrix of polymeric substances. They live on solid surfaces (e.g., catheters,) and the extracellular material they produce protects them from external threats, such as attacks by the body's immune cells. The property of biofilms constitute a penetration barrier for most antibiotics therefore preventing the drug from reaching the microbes. It is being widely recognized that bacterial biofilms are responsible for several chronic diseases that are difficult to treat, hence hard to eradicate (e.g., cystitis, endocarditis, urinary tract infections, gingivitis, dental plaque, and other yet to be identified conditions). They differ from free-floating or planktonic bacteria that cause acute infections and are managed by antimicrobial drugs.

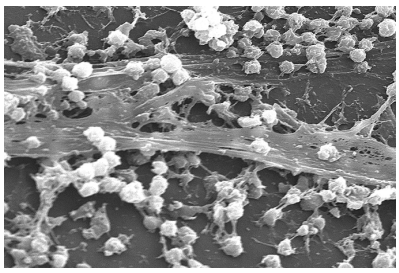

Figure: **Staphylococcus aureus biofilm**: Staphylococcus aureus forming a biofilm on a catheter.

Persisters are multidrug tolerant cells present in all bacterial populations. Bacterial populations that produce persister cells that neither grow nor die in the presence of microbicidal antibiotics are largely responsible for high levels of biofilm tolerance to antimicrobials. Persisters are not mutants, but rather phenotypic variants of the wild-type that upon inoculation produce a culture with similar levels of tolerance. Elimination of persisters remains an obstacle for the eradication of some tenacious and highly recurrent bacterial infections. Biofilms and persisters are the cause of multidrug tolerance. Multidrug tolerance differs from multidrug resistance in that it is not caused by mutant microbes but rather by microbial cells that exist in a transient, dormant state. These non-dividing cells often survive antibiotic exposure targeted to kill highly proliferating bacteria.

13.6D: Biofilms, Persisters, and Antibiotic Tolerance is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.6E: Finding New Antimicrobial Drugs

Antimicrobial resistance has created a public health crisis in the treatment of infectious diseases and necessitates the discovery of new drugs.

Learning Objectives

- Explain the reasons for low production of new antibiotics and discuss the proposed mechanisms to evade antimicrobial resistance

Key Points

- Finding new antimicrobial drugs requires researchers, pharmaceutical, and biotech companies to invest in new technology and discover new sources for antibiotic development.
- Proposed mechanisms to circumvent antimicrobial resistance range from exploring the list of resistance genes to antibody-based therapy and vaccines.
- Finding new candidates to target is essential but it needs to be accompanied by awareness on antibiotic misuse with the prospect to eliminate the root of the problem.

Key Terms

- **mimetic**: A substance with similar pharmacological effects to another substance.

Antimicrobial resistance: the problem

Antibiotics, more than any other medicines, have improved the life expectancy of mankind, however, multi-drug resistance has become common in pathogenic bacteria and multiple drugs are losing efficacy. Recent reports on the occurrence of panresistant gram-negative strains, i.e. strains resistant to every registered antibacterial drug, indicate that we are on the verge to lose the battle, taking us back to the pre-antibiotic era. There is world-wide consensus that the medical need for novel antiinfective drugs is enormous and that we are running out of time. Many achievements of modern medicine, not only treatment of infectious diseases, depend on the availability of efficacious antibiotics, still, the antibacterial development pipeline is slow and the number of new drugs reaching the market is alarmingly low. There are many reasons for this at all levels of the discovery and development process. Investments into antibiotic research and technologies is minimal; socioeconomic considerations together with regulatory hurdles have prompted pharmaceutical companies to exit the field and innovative biotech companies were confronted with problems beyond their control. Answers are needed as to where and how we can find new lead compounds with unprecedented activities?

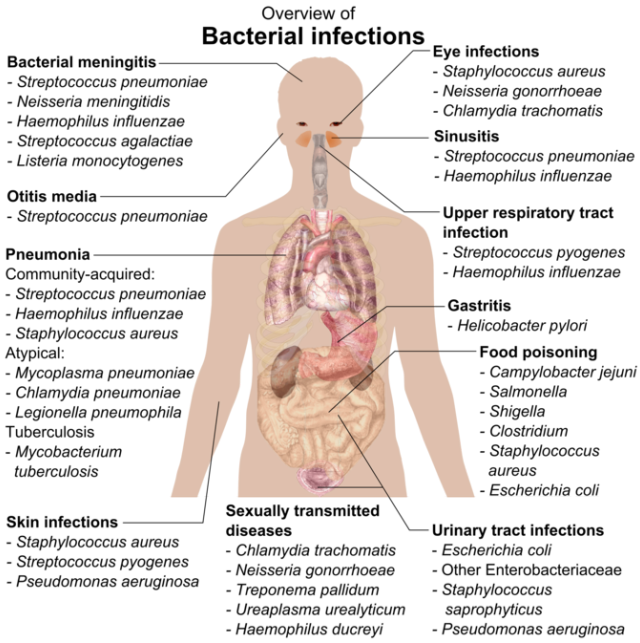

Figure: **Bacterial infections of the human body**: most bacterial species listed in this figure have developed resistance to available antibiotics necessitating new drug discovery.

Finding new antimicrobial drugs: the solution

Research on new antimicrobial compounds is geared towards innovative targets to circumvent resistance. Some of the proposed areas to investigate include: collecting and examining the list of antimicrobial resistance genes (e.g. exploring the resistome), targeting teichoic acid biosynthesis as a new method to compromise the bacterial wall integrity, producing ribosomal inhibitors to target protein synthesis, targeting outer-membrane transporters with protein epitope mimetics (e.g. mimetics of the cationic antimicrobial peptides that form part of the immune response to microbes), and developing antibody-based strategies and vaccines. The initiative to develop new antimicrobial agents is urgently needed but is a long process from invention, to development, to actual clinical application. It is also necessary to initiate a worldwide awareness on antibiotic misuse and overuse as a mean to address the root of the problem for antimicrobial resistance.

13.6E: Finding New Antimicrobial Drugs is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.6F: Antimicrobial Peptides

Antimicrobial peptides exhibit cytotoxic activity against all microbes.

Learning Objectives

- Discuss the structure, mechanism, and targets of antimicrobial peptides

Key Points

- Antimicrobial peptides (AMPs) are a unique and assorted group of molecules produced by living organisms of all types, considered to be part of the innate immunity of a host.
- These peptides demonstrate potent antimicrobial activity and are rapidly mobilized to neutralize a broad range of microbes, such as viruses, bacteria, protozoa, and fungi.
- The ability of these natural molecules to kill multidrug-resistant microorganisms has gained them considerable attention and clinical interest.

Key Terms

- **neutropenia**: A hematological disorder characterized by an abnormally low neutrophil count.
- **atopic dermatitis**: An atopic, hereditary, and non-contagious skin disease characterized by chronic inflammation of the skin.

A first line of defense against pathogenic insult is called the innate immune system, which is followed by acquired immune responses associated with the activation of T and B cells aimed against specific antigens. In contrast to the clonal, acquired adaptive immunity, endogenous peptide antibiotics or antimicrobial peptides provide a fast and energy-effective mechanism as front-line defense.

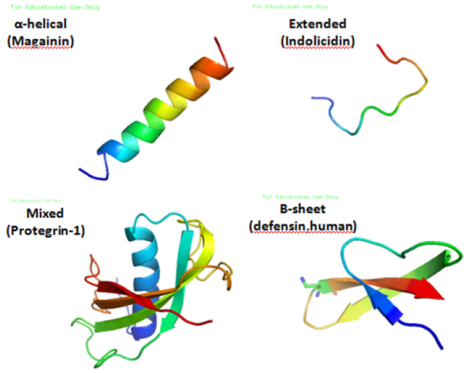

Figure: **Various AMPs**: These are various antimicrobial peptide structures.

Antimicrobial peptides (AMPs) are small molecular weight proteins with broad spectrum antimicrobial activity against bacteria, viruses, and fungi. They are classified on the basis of their structure and amino acid motifs. Peptides of the defensin, cathelicidin, and histatin classes are found in humans. These evolutionarily conserved peptides are usually positively charged and have both a hydrophobic and hydrophilic side that enables the molecule to be soluble in aqueous environments yet also enter lipid-rich membranes. Once in a target microbial membrane, the peptide kills target cells through diverse mechanisms. AMPs secrete lytic enzymes, nutrient-binding proteins or contain sites that target specific microbial macromolecules.

Cathelicidins and defensins are major groups of epidermal AMPs. Decreased levels of these peptides have been noted for patients with atopic dermatitis and Kostmann's syndrome, a congenital neutropenia. AMPs have proven effective against multidrug-resistant microbes. In addition to important antimicrobial properties, growing evidence indicates that AMPs alter the host immune response through receptor-dependent interactions. AMPs have been shown to be important in such diverse functions as angiogenesis, wound healing, cytokine release, chemotaxis, and regulation of the adaptive immune system. These peptides qualify as innovative drugs that might be used as antibiotics, anti-lipopolysaccharide drugs, or modifiers of inflammation reactions.

13.6F: Antimicrobial Peptides is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.6G: Antisense Agents

Learning Objectives

- Discuss the mechanism of antisense agents and the advantages and disadvantages of antisense therapy.

Antisense agents are synthetic, single-stranded short sequences of DNA bases designed to hybridize to specific sequences of messenger RNA (mRNA) forming a duplex. This DNA-RNA coupling attracts an endogenous nuclease, RNase H that destroys the bound RNA and frees the DNA antisense to rehybridize with another copy of mRNA. In this way, the effect is not only highly specific but prolonged because of the recycling of the antisense DNA sequence. When this agent binds to the pathogen DNA or messenger RNA, the biosynthesis of target proteins is disrupted. Therefore, there are at least two ways in which antisense agents act to effectively reduce the amount of pathogenic protein being synthesized – RNase H based degradation of RNA and prevention of ribosomal assembly and translation. This approach has a great advantage. It prevents a pathogenic protein from being produced, rather than trying to selectively neutralize it once it is made.

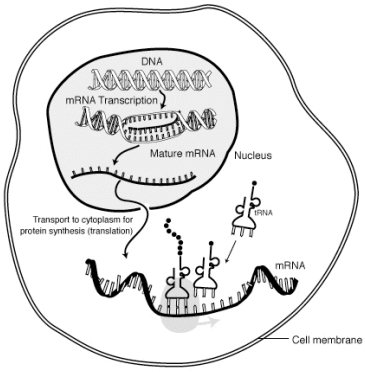

Figure: **DNA to Protein**: Role of messenger RNA in protein synthesis.

Antisense agents can be specifically targeted to genes that control expression of antibiotic resistance mechanisms, thereby potentially restoring an antibiotic-sensitive phenotype to the cell. A limiting factor in their potential application as therapeutic agents for bacterial infections is their poor uptake by bacterial cells. These agents have been successfully developed for the treatment of viral infections such as cytomegalovirus, hepatitis C, and HIV infections. The advantage of antisense therapy is that they can be manufactured fairly fast, they produce a lasting clinical effect, and they are highly specific to the target. Antisense agents also exhibit efficacy in broader clinical applications such as cancer therapy.

Key Points

- Antisense agents have broad applications in several diseases. Their use for treating microbial infections is promising.
- They are synthetic oligonucleotides that can be manufactured quickly and their biological effect is long-lasting.
- Their use for the treatment of antibiotic resistant bacterial infections is possible but limited by their poor uptake by the bacterial cell. Studies are being developed to improve their penetration into the cell.

Key Terms

- **messenger RNA**: RNA that encodes and carries information from DNA during transcription to sites of protein synthesis to undergo translation in order to yield a protein
- **nuclease**: Any of several enzymes capable of cleaving the phosphodiester bonds between the nucleotide subunits of nucleic acids.
- **hybridize**: To combine complementary subunits of multiple biological macromolecules.

13.6G: Antisense Agents is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

SECTION OVERVIEW

13.7: Antiviral Drugs

Topic hierarchy

13.7A: Antiviral Agents that Prevent Virus Uncoating or Release

13.7B: Antiviral DNA Synthesis Inhibitors

13.7C: Nucleotide and Nonnucleotide Reverse Transcriptase Inhibitors

13.7D: Protease Inhibitors

13.7: Antiviral Drugs is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.7A: Antiviral Agents that Prevent Virus Uncoating or Release

Different approches are used to target the initial and final steps of a virus life cycle.

Learning Objectives

- Compare the mechanisms of the discussed antiviral drugs

Key Points

- The attachment step is targeted by molecules that will block the receptor on the host cell surface, or on the viral capsid region responsible for binding to the host receptor.
- Drugs that target the uncoating step bind to, and inactivate, proteins on the capsid surface responsible for the uncoating.
- The release step is targeted by drugs that inhibit the activity of neuraminidase, an enzyme on the viral surface.

Key Terms

- **sialic acid**: A derivative of neuraminic acid (a nine-carbon monosaccharide) that is often the sugar part of glycoproteins.

A viral infection starts with entry of the virus into the cell. The entry mechanism is complex, consists of multiple steps and involves host cell structures.

Targeting the Attachment Step

Virus infection starts with a virus attaching to the host cell by binding to a receptor molecule. There are two main strategies used to design antiviral drugs at this step:

- Using molecules that will bind to the cell receptor and inactivate it; thus preventing the virus from attachment. Examples include anti-receptor antibodies or natural ligands that can bind to the receptor.
- Using receptor-like molecules to bind to the virus and inactivate it before it meets the cell. These include anti-virus antibodies (with specificity against the viral structure that binds to the receptor) or synthetic molecules that mimic the receptor.

The search for such drugs, however, is very expensive and time-consuming.

Targeting the Uncoating Step

Another drug target is the uncoating step during viral infection. Uncoating is the process of capsid disintegration, which leads to the release of the genomic material. This step is performed by viral or host enzymes, or by capsid dissociation alone. Drugs that can perform such functions are used against the influenza virus, rhinoviruses (the cause of the common cold), and enteroviruses (gastrointestinal infections, meningitis, etc.). It is believed that such drugs prevent the virus from uncoating by blocking the proteins on the capsid responsible for uncoating, such as ion channel proteins. An example of such a drug is Rimantadine, which blocks the ion channel in the influenza virus. The ion channel has an important role in disintegrating the viral capsid.

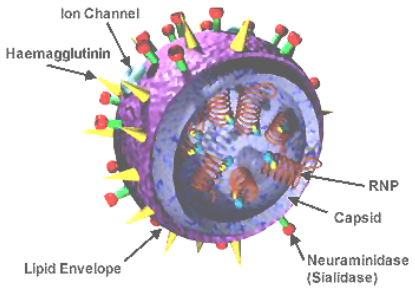

Figure: **Structure (3D) of the Influenza Virus**: The image depicts the major components of the virus structure, including the neuraminidase.

Targeting the Release of the Newly Formed Viral Particles

The last step in the virus life cycle—release from the cell—has been targeted by drugs as well. Neuraminidase is an enzyme on the capsid of influenza virus. It cleaves sialic acid from glycoproteins on the surface of the host cell and allows the viral particles to leave the cell. Tamiflu and Relenza are trend names of two drugs used to treat influenza infections by targeting neuraminidase.

Since viruses use many structures in the host cells to replicate, designing or discovering good antiviral drugs that will not affect the eukaryotic cells is a challenging task. Serious side effects are often observed with the use of antiviral drugs, as is resistance against the drugs. Developing drugs that inhibit different steps in the virus life cycle is of critical importance.

13.7A: Antiviral Agents that Prevent Virus Uncoating or Release is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.7B: Antiviral DNA Synthesis Inhibitors

Inhibiting DNA synthesis during viral replication is another key approach in battling viral infections.

Learning Objectives

- Review the mechanism of action for antiviral DNA synthesis inhibitors and recognize the types of these inhibitors

Key Points

- Drugs such as acyclovir, are nucleoside analogues that lack a free 3′ group that is needed for the addition of the next nucleotide. When added into a growing DNA chain they stop its synthesis.
- Another drug, foscarnet, mimics pyrophosphates and inactivates the activity of the viral DNA polymerase.
- Resistance can develop against both of these groups of drugs.

Key Terms

- **CMV retinitis**: An inflammation of the eye's retina caused by CMV. It can lead to blindness.

Inhibiting DNA synthesis during viral replication is another approach to battle viral infections.

The most common strategy used for this approach is to use molecules that mimic the structure of a nucleoside. The similarity is good enough to ensure its incorporation into the newly synthesized DNA chain. However, the nucleoside analogue lacks free 3′ end needed for the addition of the next nucleotide. This prevents the incorporation of the next nucleotide and terminates the elongation of the DNA chain.

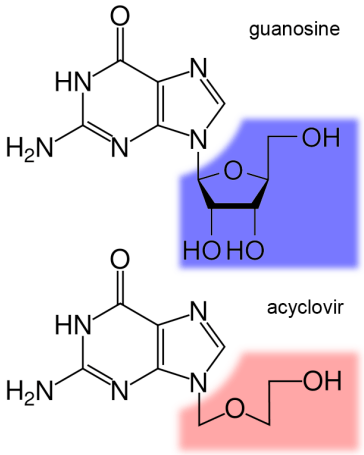

Figure: **Comparison of acyclovir and guanosine**: Acyclovir does not contain a sugar molecule with a 3′-OH group and will interrupt the synthesis of a newly synthesized nucleotide chain if added to it. The guanosine depicted in this specific image is used for RNA synthesis but acyclovir inhibits the synthesis of DNA synthesis.

One of the most often used antiviral drugs that works with the described mechanism is acyclovir (aciclovir), a guanosine analogue. It is used to treat herpes simplex virus infections (type 1 and type 2) as well as chicken pox and shingles. It was designed based on nucleosides isolated from a Caribbean sponge. After administration, the molecule gets activated by phosphorylation both by viral and host cell kinases and the resulting nucleotide incorporated into the newly synthesized DNA resulting in premature chain termination. The drug has very low cytotoxicity and there is low resistance to it.

Other drugs that are also nucleoside analogues and have the same mode of actions are ganciclovir (a synthetic analogue of 2′-deoxy-guanosine) and vidarabine(an adenosine analog). However, both drugs are more toxic and have more serious side effects than acyclovir.

Another type of drug that is a DNA synthesis inhibitor is foscarnet. It mimics pyrophosphate and inactivates the activity of the DNA polymerase. This inhibitor is active against the viral DNA polymerases at doses much lower than the ones needed to inhibit the human polymerases. This drug is used in cases of resistance against acyclovir and ganciclovir nucleoside analogue chemicals. It is also used to treat cytomegalovirus infection (CMV) and specifically CMV retinitis.

Another antiviral drug that targets DNA synthesis is hydroxycarbamide, commonly referred to as a hydroxyurea. Hydroxycarbamide can be used an antiretroviral drug against HIV/AIDS. The mechanism of hydroxycarbamide is thought to be based on the reduction of production of deoxyribonucleotides; therefore, inhibiting DNA synthesis. Hydroxycarbamide is thought to inhibit the enzyme ribonucleotide reductase.

13.7B: Antiviral DNA Synthesis Inhibitors is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.7C: Nucleotide and Nonnucleotide Reverse Transcriptase Inhibitors

Reverse transcriptase in viruses is inhibited by nucleoside (nucleotide) analogues or drugs that change the conformation of the enzyme.

Learning Objectives

- Summarize the mechanism of action for reverse transcriptase inhibitors

Key Points

- Nucleoside and nucleotide inhibitors are competitive substrate inhibitors that mimic the structure of a normal nucleotide but lack the 3′ hydroxyl group needed for the addition of the next nucleotide for DNA elongation.
- Non-nucleotide inhibitors bind to a site different than the active one and cause rearrangements of the protein domains needed for DNA polymerization.
- Mutations in the reverse transcriptase gene can cause resistance to both types of drugs.

Key Terms

- **competitive substrate inhibitors**: Molecules that bind to the active site of an enzyme and prevent the real substrate from binding to it.
- **non-competitive inhibitors**: Molecules that bind to sites other than the active site of an enzyme while still being able to indirectly inhibit its function.
- **nucleotide**: the monomer comprising DNA or RNA biopolymer molecules, consisting of a nitrogenous heterocyclic base; a five-carbon pentose sugar; and a phosphate group

Reverse transcriptase is an enzyme that has the ability to transcribe single-stranded DNA from a single-stranded RNA chain. This is the reverse of the usual flow of information when RNA is synthesized from DNA. Viruses that use reverse transcriptase to convert their genetic material (RNA) into DNA are called retroviruses. One of the most prominent representative of a retrovirus is HIV. Due to the high prevalence of HIV/AIDS in the world, it is important to have drugs that will prevent or cure the infection. This enzyme is also found in tumors and cancer cells.

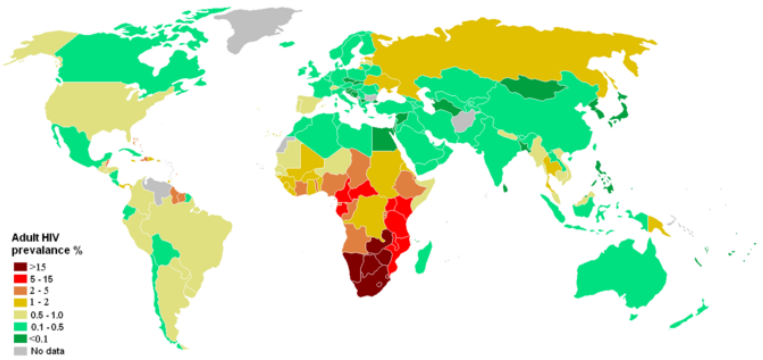

Figure: **Estimation of adults with HIV/AIDS by country**: The data shows the people, between 18-49 years, by country who are affected by HIV/AIDS. The information is provided by UNAIDS based on a report from July 2008

Drugs that inhibit the function of this enzyme are divided into three groups:

- nucleoside analog reverse transcriptase inhibitors
- nucleotide analog reverse transcriptase inhibitors
- non-nucleoside reverse transcriptase inhibitors

The first two inhibitors act on the same principle. They mimic, respectively, nucleosides or nucleotides but lack a free hydroxyl group at the 3′ end. The major difference between them is that the nucleosides need to be phosphorylated by cellular kinases. The enzyme reverse transcriptase recognizes them as regular nucleotides and inserts them into the newly synthesized DNA chain. But once inserted the elongation stops at them because no more nucleotides can be added due to the lack of the 3′ hydroxyl group and the inability of the formation of 5′-3′ phosphodiester bond. This process is called chain termination. Nucleoside and nucleotide inhibitors are also called competitive substrate inhibitors. Examples of such drugs are Zidovudine (AZT) and Lamivudine. AZT was the first FDA approved drug for the treatment of HIV. Lamivudine is used for the treatment of both HIV and hepatitis B. Since

some viruses, such as hepatitis B, carry RNA-dependent DNA polymerases reverse transcriptase inhibitors can be used to treat these infections as well.

Non-nucleotide reverse transcriptase inhibitors bind to a different site, not the active one, of the reverse transcriptase enzyme. That leads to conformational changes that distort the position of the DNA binding sites in the enzyme and lead to halt in DNA polymerization. Non-nucleotide inhibitors are non-competitive inhibitorsof reverse transcriptase. Such drugs are Efavirenz and Nevirapine.

Resistance occurs to all drug groups. The mechanisms for resistance against the nucleoside (nucleotide) inhibitors are two. The first one is due to mutations in the N-terminal polymerase domain of the reverse transcriptase that makes it less likely to incorporate the analogues. The second mechanism is caused by mutations in the transcriptase that allow the removal of the incorporated inhibitor and hence restart of DNA replication.

Resistance to the non-nucleotide inhibitors is caused by mutations in the inhibitor binding site of the enzyme. Such mutations prevent the binding of the inhibitor to the enzyme.

13.7C: Nucleotide and Nonnucleotide Reverse Transcriptase Inhibitors is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.7D: Protease Inhibitors

Protease inhibitors target viral proteases which are key enzymes for the completion of viral maturation.

Learning Objectives

- Describe the mechanism of action for protease inhibitors

Key Points

- Protease inhibitors mimic peptides or are chemicals that can be inserted in the active site of a protease. They prevent it from binding the viral polyproteins.
- Such drugs were one of the first to be used against HIV. They are an inseparable part of the HIV/AIDS therapy.
- Mutations in the enzyme active site and other sites, which cause conformational changes, can cause resistance.

Key Terms

- **cross-resistance**: Bacterial or viral resistance to a chemical which causes resistance to other chemicals of the same group.

Proteases are enzymes that have the ability to cut proteins into peptides. They are used by some viruses (e.g., HIV) to cleave precursor long protein chains into individual proteins. This allows the completion of the assembly step in the viral life cycle where the proteins and the viral RNA come together to form virion particles ready to exit the cell.

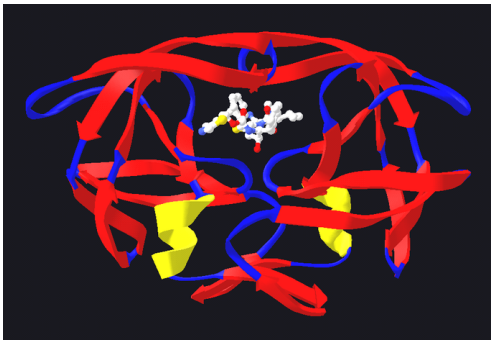

Figure: **HIV protease with bound protease inhibitor**: The drug is ritonavir depicted here with a white molecule in the middle of the enzyme structure.

The design of protease inhibitors, that could be used to battle HIV, started soon after the discovery of the virus. The first approved protease inhibitor drug was released on the market in 1995, only 10 years after the discovery of HIV. These drugs are an inseparable part of an HIV therapy. Natural protease inhibitors are found in Shiitake mushrooms. The experimental protease inhibitor drugs Zmapp and Brincidofovir are currently being tested to treat the ebola virus disease.

Protease inhibitors are short peptide-like molecules that are competitive inhibitors of the enzyme. Instead of -NH-CO- peptide link, they contain -(CH_2-CH(OH)-). When such a peptide gets into the enzyme active site, the protease is unable to cut the linkage and gets inactivated. This leads to a lack of cleavage of the polypeptide chains of two crucial viral proteins, Gag and Pol, which are essential structural and enzymatic proteins of HIV. Their absence blocks the formation of mature virion particles.

Saquinavir is the first clinically used peptide-like inhibitor. Some protease inhibitors do not mimic peptides in their structure. One such drug is *Nelfinavir*. In general, protease inhibitors exhibit the unusual side effect of fat storage in non-typical organs and tissues. The reasons for this are still unclear.

Mutations in the enzyme active site and other sites, which cause conformational changes, can cause resistance. Quite often one mutation can lead to resistance to many different drugs simultaneously since they all share the same mode of action. This is called cross-resistance. It is one of the major drawbacks of protease inhibitors therapy.

13.8: Other Antimicrobial Drugs

Topic hierarchy

13.8A: Antifungal Drugs

13.8B: Antiprotozoan and Antihelminthic Drugs

13.8: Other Antimicrobial Drugs is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.8A: Antifungal Drugs

Learning Objectives

- Compare and contrast the mechanisms of action for: polyene, azole,allylamine and echinocandin antifungals

The field of mycology deals with the study of fungi and has resulted in the identification of over 60,000 species of fungi. Fungi are classified as eukaryotic organisms which are primarily classified based on spore production. The classification and identification of a species of fungi by spore class, in combination with the basic biological mechanism(s) it uses to sustain life, is key in developing anti-fungal drugs.

The development of antifungal drugs focuses on the classes of mycotic diseases for which fungi are responsible. These classes include hypersensitivity—allergic reactions based on the presence of mold and spores; mycotoxicoses—diseases based on the presence of fungi that produce toxins in animal feed and human food products; mycetismus—mushroom poisoning; and lastly, mycoses—characterized by infection.

Disease-causing fungi are targeted and then drug classes are classified based on drug structure or mechanism. Some of the major classes of antifungal medication include polyene antifungals, azole antifungals, allylamines, and echinocandins. It is important to note that antifungal drugs are not limited to these classes, as there are additional drugs capable of targeting fungi that do not fall into these categories.

Polyene Antifungals

Polyene antifungals are characterized by the presence of multiple conjugated double bonds in the drug structure. This specific antifungal drug class targets the fungal cell membrane. The target sterol is ergosterol, which is specific to fungi cell membranes; in animal cell membranes cholesterol is the key sterol. The fungal cell membrane becomes leaky, resulting in movement of essential cellular contents, such as organic molecules and ions, out of the cell. Amphotericin B is an example of a polyene antifungal; it is selective for ergosterol and can be used as a broad spectrum drug administered intravenously.

Azole Antifungals

Azole antifungals are characterized by the ability to inhibit ergosterol synthesis in fungal membranes. The biosynthesis of ergosterol requires the enzyme lanosterol 14 α-demethylase. This enzyme is needed to convert lanosterol to ergosterol. Targeting this enzyme prevents ergosterol production. Thus, the fungal membrane structure is depleted of ergosterol and the fungus dies. The various types of azole classified drugs include imidazole, triazole and thiazole antifungals. Azole drugs are broad-spectrum drugs and treat fungal infections of the skin or mouth. An example of an azole drug is Clotrimazole, commonly used to treat athlete's foot, ringworm, vaginal yeast infections, and oral thrush.

Figure: **Ringworm**: Ringworm on a human leg.

Allylamine Antifungals

Allylamine antifungals are characterized by the ability to inhibit fungal squalene metabolism. The biosynthesis of ergosterol requires an enzyme called squalene peroxidase. Squalene peroxidase is responsible for catalyzing the first step in ergosterol biosynthesis; inhibition of this enzyme results in disruption of ergosterol synthesis. The inhibition of squalene metabolism is toxic to the fungi because of the buildup of squalene and the inhibition of ergosterol synthesis. An example of an allylamine drug is Terbinafine, which is commonly used to treat fungal skin infections.

Echinocandin Antifungals

Echinocandins are characterized by their ability to inhibit synthesis of a key component of the *fungal cell wall*, while previously discussed drugs target the *fungal cell membrane*. Cell wall synthesis requires the production of glucan by the enzyme 1,3-β glucan synthase. Echinocandins specifically inhibit glucan synthesis by targeting that enzyme. This class of drug is most effective when administered by injection, as it is poorly absorbed when administered orally. Echinocandin injection allows the drug to treat a systemic infection of the sort typically seen in immunocompromised patients. An example of an echinocandin based drug is Caspofungin. Caspofungin blocks cell-wall synthesis by disrupting glucan synthesis; it can target invasive candidiasis and aspergillus.

Additional Antifungal Drugs

The major classes of antifungal drugs are discussed above are not the only drugs capable of effectively targeting fungi. The emergence of alternative medicine as a hot field of research has also increased the list of available antifungal compounds. For example, numerous compounds and essential oils found in nature have been found to have antifungal properties that could be utilized for treatment. Examples of these include coconut oil, orange oil, olive leaf, and zinc.

The identification of additional antifungal compounds is key to the development of drugs that can replace existing drugs to which fungi have developed resistance. The discovery process for effective and fungi-specific drugs is enduring and laborious, as the drugs must be specific for fungi cells. However, with the expansion of molecular studies in fungal organisms, the opportunity to identify novel and fungal specific mechanisms will allow for the development of new drugs.

Key Points

- The various classes of antifungal drugs exploit the unique fungal structure.
- The synthesis of both cell membrane and cell wall components are key targets for antifungal drugs.
- Classes of antifungal medications include: polyene antifungals, azole drugs, allylamines and echinocandins.

Key Terms

- **ergosterol**: major component of fungal cell membranes.
- **mycology**: the study of fungi

13.8A: Antifungal Drugs is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

13.8B: Antiprotozoan and Antihelminthic Drugs

Antiprotozoan and antihelminthic drugs are characterized based on structure and the mechanism of action by which they target the organism.

Learning Objectives

- Describe the objective of drugs against helminths anf the disadvantages to developing drugs against protozoa

Key Points

- Antiprotozoan drugs are typically species specific.
- It is essential that antiprotozoan drugs target pathways and mechanisms specific to protozoa as overlap in the basic biology can result in inaccurate targeting of the drug to both the host and protozoa.
- Antihelminthic drugs typically focus on the disruption of structural mechanisms that maintain body structure resulting in paralysis of the helminth which promotes expulsion.

Key Terms

- **helminth**: A parasitic roundworm or flatworm.
- **protozoa**: Protozoa are a diverse group of unicellular eukaryotic organisms, many of which are motile. Originally, protozoa had been defined as unicellular protists with animal-like behavior, e.g., movement. Protozoa were regarded as the partner group of protists to protophyta, which have plant-like behavior, e.g., photosynthesis.
- **Parasite**: Parasitism is a non-mutual relationship between organisms of different species where one organism, the parasite, benefits at the expense of the other, the host.

Parasites are organisms that live on or in a host organism to obtain food. Two major classes of parasitic organisms include protozoa and helminths.

Protozoa are unicellular eukaryotic organisms that are classified as either free-living or parasitic organisms. Protozoa are further classified based on their mode of locomotion and include: Sarcodina (amoeba); Mastigophora (flagellates); Ciliophora (ciliates); and Sporozoa (non motile in adult form). Some examples of diseases caused by protozoa include: Malaria, Giardia, Trichomoniasis, and Leishmaniasis.

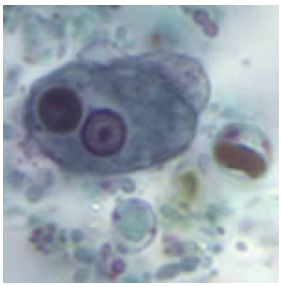

Figure: **Entamoeba histolytica**: Entamoeba histolytica is classified as a protozoa, specifically a Sarcodina.

Helminths are multicellular eukaryotic organisms that are also classified as either free-living or parasitic chemoheterotrophic organisms. Helminths are parasitic worms and are divided into three major groups including: flatworms (platyhelminths); thorny-headed worms (acanthocephalins); and roundworms (nematodes and hookworms).

Figure: **Hookworms**: Hookworms attached to the intestinal mucosa.

The variation that exists between protozoa contributes to complications associated with developing effective drugs. The lack of similarities between protozoans demands the need for highly specific drugs and medications against individual pathogens. In addition, protozoa are eukaryotic and exhibit similar properties and metabolic pathways as human cells. Therefore, the drugs that are developed to target protozoans are classified by either their mechanism of action or the organism for which they target. In terms of mechanism of actions, most antiprotozoan drugs specifically target the organism to prevent its growth and reproduction.

Protozoal diseases can also be prevented by targeting the route of transmission and/or targeting vector organisms. For example, Malaria is caused by the protozoan Plasmodia. This parasite is injected into humans via mosquitoes. The development of antimalarial drugs are based on the life cycle of Plasmodiain both the mosquito and human host.

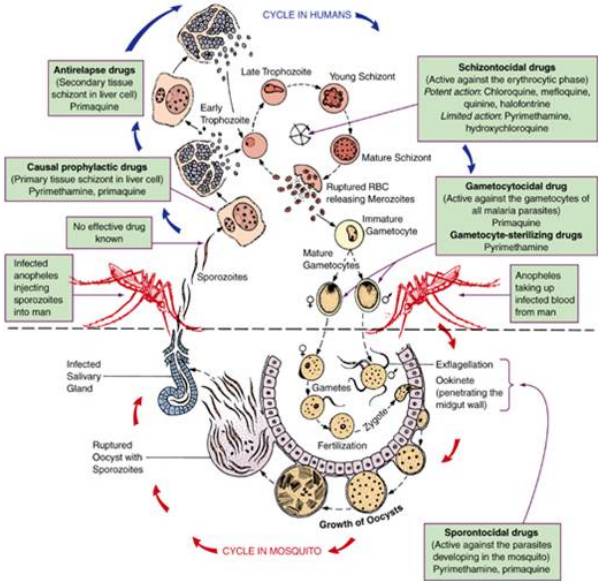

Figure: **Life Cycle of Plasmodium**: Malaria, a protzoan based disease, is transmitted via an arthropod vector. The development of antimalarial drugs focuses on the life cycle in both the mosquito and human hosts.

Other types of antiprotozan drugs specifically target metabolic mechanisms utilized by the parasite. For example, African sleeping sickness is caused by trypanosomes. The drug Eflornithine attacks this parasite by targeting an enzyme responsible for regulating cell division.

Helminths are characterized as various types of parasitic worms, which are effectively targeted by promoting expulsion from the body. Parasitic helminths worms include: tapeworms, flukes, leeches and hookworms. The drugs utilized to target helminths are characterized based on chemical structure and mechanism of action. A few examples of the major drug classes include: piperazine, benzimidazole, levamisole, pyrantel, morantel and emodepside.

CHAPTER OVERVIEW

14: Pathogenicity

Pathogenicity refers to the ability of an organism to cause disease (ie, harm the host). This ability represents a genetic component of the pathogen and the overt damage done to the host is a property of the host-pathogen interactions. Commensals and opportunistic pathogens lack this inherent ability to cause disease.

14.1A: Portals of Microbe Entry

Microbes gain access to human tissues via mucosal surfaces within the body or epithelial surfaces on the outside of the body.

Learning Objectives

- Recognize the various methods and types of microorganism transmission: vectors, hosts, horizontal, vertical transmissions

Key Points

- Transmission can be direct (vertically or horizontally) or indirect.
- Infectious agents are generally specialized for a particular method of transmission.
- A locus is the point on the body where a pathogen enters.

Key Terms

- **infectious**: Infectious diseases, also known as transmissible diseases or communicable diseases, comprise clinically evident illness (i.e., characteristic medical signs and/or symptoms of disease) resulting from the infection, presence, and growth of pathogenic biological agents in an individual host organism.
- **pathogen**: Any organism or substance, especially a microorganism, capable of causing disease, such as bacteria, viruses, protozoa, or fungi. Microorganisms are not considered to be pathogenic until they have reached a population size that is large enough to cause disease.
- **contagious**: Of a person, having a disease that can be transmitted to another person by touch.

Microbes gain access to human tissues via two main types of routes: mucosal surfaces within the body (linings of the respiratory, digestive, reproductive, or urinary tracts) or epithelial surfaces on the outside of the body (areas of skin that are either undamaged or compromised due to insect bites, cuts/scrapes, or other wounds).

Transmission of Microorganisms

Transmission of microorganisms occurs directly from one person to another by one or more of the following means:

- droplet contact by coughing or sneezing on another person
- direct physical contact by touching an infected person
- direct physical contact (usually by touching soil contamination or a contaminated surface)
- airborne transmission (if the microorganism can remain in the air for long periods)
- fecal-oral transmission (usually from contaminated food or water sources)
- contamination via intravenous drug us
- contamination from blood given via transfusion or organ transplants

Transmission can also be indirect via another organism, either a vector (like a mosquito) or an intermediate host (like how a tapeworm from a pig can be transmitted to humans who ingest improperly cooked pork).

Horizontal or Vertical Transmission

Disease can also be directly transmitted in two ways: horizontally or vertically. Horizontal disease transmission occurs from one individual to another in the same generation (peers in the same age group), and can occur by either direct contact (licking, touching, biting), or indirect contact. Vertical disease transmission involves passing a disease causing agent vertically from parent to offspring.

Pathogens must have a way to be transmitted from one host to another to ensure their species ‘ survival. Infectious agents are generally specialized for a particular method of transmission. Taking an example from the respiratory route, from an evolutionary perspective a virus or bacteria that causes its host to develop coughing and sneezing symptoms has a great survival advantage: it is much more likely to be ejected from one host and carried to another.

A locus is the point on the body where a pathogen enters. In droplet contact and other airborne transmission it is generally the respiratory system through the nose, mouth, or eye surfaces. In direct physical and indirect contact it is generally through a wound in the skin or through a mucous membrane. In fecal-oral transmission, it is through the mouth. In vector-borne transmission, it is at the bite or sting of the vector. Other common indirect routes include contaminated food or water.

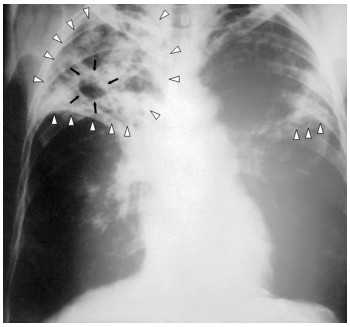

Figure: **Chest x-ray of a patient with tuberculosis.**: In this chest X-ray of a person with advanced tuberculosis, the infections in both lungs are marked by white arrowheads and the formation of a cavity is marked by black arrows. The boundary between contagious and non-contagious infectious diseases is not perfectly drawn, as illustrated by tuberculosis, which is clearly transmissible from person to person, but was not classically considered a contagious disease.

Sexual Transmission

In sexual transmission, infection originates directly between surfaces in contact during intercourse (the usual route for bacterial infections and those infections causing sores) or from secretions (semen or the fluid secreted by the excited female). Sexually transmitted diseases such as HIV and Hepatitis B are thought to be transmitted through unprotected sexual intercourse (including anal and oral routes), contaminated blood transfusions, sharing hypodermic needles, and from mother to child during pregnancy, delivery, or breastfeeding. Bodily fluids such as saliva and tears do not transmit HIV. Oral sexual practices have increased the incidence of herpes simplex virus 1 (which is usually responsible for oral infections) in genital infections and the increased incidence of the type 2 virus (more common genitally) in oral infections. Herpes diseases that are transmitted primarily by oral means may be caught through direct contact with an infectious area of the skin.

Direct Contact: Contagious Diseases

Diseases that can be transmitted by direct contact are called contagious (contagious is not the same as infectious). Although all contagious diseases are infectious, not all infectious diseases are contagious. Interestingly, some contagious diseases like tuberculosis were not classically considered to be contagious even though they are transmissible from person to person. Direct transmission can also occur by sharing a towel (where the towel is rubbed vigorously on both bodies) or items of clothing in close contact with the body (socks, for example) if they are not washed thoroughly between uses. Some diseases that are transmissible by direct contact include Athlete's foot and impetigo.

14.1A: Portals of Microbe Entry is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.1B: Colonization and Growth

Infection begins when an organism successfully colonizes a host by entering the host's body, growing and multiplying from there.

Learning Objectives

- Distinguish between colonization and infection

Key Points

- Some virulent bacteria produce special proteins that allow them to colonize parts of the host body.
- Wound colonization refers to nonreplicating microorganisms within the wound, while in infected wounds replicating organisms exist and tissue is injured.
- While a few organisms can grow at the initial site of entry, many migrate and cause systemic infection in different organs.

Key Terms

- **infection**: An uncontrolled growth of harmful microorganisms in a host.

Infection begins when an organism successfully colonizes by entering the body, growing and multiplying from there. Most humans are not easily infected. Those who are weak, sick, malnourished, have cancer or are diabetic possess an increased susceptibility to chronic or persistent infections. Individuals who have a suppressed immune system are particularly susceptible to opportunistic infections.

Entrance to the host generally occurs through the mucosa in orifices like the oral cavity, nose, eyes, genitalia, anus, or open wounds. While a few organisms can grow at the initial site of entry, many migrate and cause systemic infection in different organs. Some pathogens grow within the host cells (intracellular) whereas others grow freely in bodily fluids. Some virulent bacteria produce special proteins that allow them to colonize parts of the host body. Helicobacter pylori is able to survive in the acidic environment of the human stomach by producing the enzyme urease. Colonization of the stomach lining by this bacterium can lead to gastric ulcer and cancer. The virulence of various strains of Helicobacter pylori tends to correlate with the level of production of urease.

Wound colonization refers to nonreplicating microorganisms within the wound, while in infected wounds replicating organisms exist and tissue is injured. All multicellular organisms are colonized to some degree by extrinsic organisms and the vast majority of these exist in either a mutualistic or commensal relationship with the host. An example of the former is the anaerobic bacteria species, which colonizes the mammalian colon, and an example of the latter is various species of staphylococcus that exist on human skin. Neither of these colonizations are considered infections.

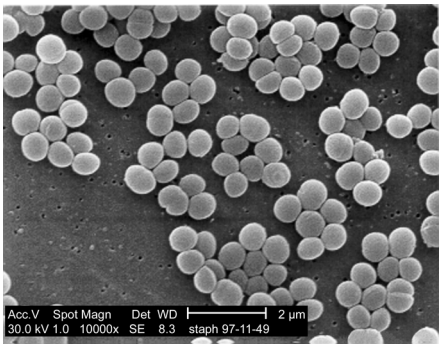

Figure: **Staphylococcus aureus**: Staphylococcus is a Gram-positive bacteria which includes several species that can cause a wide variety of infections in humans and other animals through infection or the production of toxins.

The difference between an infection and a colonization is often only a matter of circumstance. Non-pathogenic organisms can become pathogenic given specific conditions and even the most virulent organism requires certain circumstances to cause a compromising infection. Some colonizing bacteria, such as Corynebacteria sp. and viridans streptococci, prevent the adhesion and colonization of pathogenic bacteria. They thus have a symbiotic relationship with the host, preventing infection and speeding wound healing.

The variables involved in the outcome of a host becoming inoculated by a pathogen and the ultimate outcome include: the route of entry of the pathogen and the access to host regions that it gains, the intrinsic virulence of the particular organism, the quantity or

load of the initial inoculant, and the immune status of the host being colonized. As an example, the Staphylococcus species remains harmless on the skin. But when present in a normally sterile space, such as in the capsule of a joint or the peritoneum the Staphylococcus species multiplies without resistance and creates a burden on the host.

14.1B: Colonization and Growth is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.1C: Pathogenicity Islands and Virulence Factors

Pathogenicity islands (PAIs) are a distinct class of genomic islands acquired by microorganisms through horizontal gene transfer.

Learning Objectives

- Describe the traits characterizing a pathogenicity island and its advantages

Key Points

- Pathogenicity islands are discrete genetic units flanked by direct repeats, insertion sequences or tRNA genes, which act as sites for recombination into the DNA.
- PAIs are incorporated in the genome of pathogenic organisms, but are usually absent from those nonpathogenic organisms of the same or closely related species.
- PAIs carry genes encoding one or more virulence factors, including, but not limited to, adhesins, toxins, or invasins.

Key Terms

- **pathogenicity island**: A distinct class of genomic islands acquired by microorganisms through horizontal gene transfer.
- **virulence factor**: Molecules expressed and secreted by pathogens (bacteria, viruses, fungi and protozoa) that enable them to achieve colonization of a niche in the host, immunoevasion, immunosuppression, entry into and out of the cells, and obtaining nutrition from the host.

Pathogenicity Islands and Virulence Factors

Pathogenicity islands (PAIs) are a distinct class of genomic islands acquired by microorganisms through horizontal gene transfer. They are incorporated in the genome of pathogenic organisms, but are usually absent from those nonpathogenic organisms of the same or closely related species. These mobile genetic elements may range from 10-200 kb, and may encode genes contributing to the virulence of the respective pathogen. Typical examples are adherence factors, toxins, iron uptake systems, invasion factors and secretion systems.

Pathogenicity islands are discrete genetic units flanked by direct repeats, insertion sequences or tRNA genes, which act as sites for recombination into the DNA. Cryptic mobility genes may also be present, indicating the provenance as transduction.

One species of bacteria may have more than one PAI (i.e. salmonella has at least five). PAIs are transferred through horizontal gene transfer events such as transfer by a plasmid, phage, or conjugative transposon. PAIs carry genes encoding one or more virulence factors, including, but not limited to, adhesins, toxins, or invasins. They may be located on a bacterial chromosome or may be transferred within a plasmid. The GC-content of pathogenicity islands often differs from that of the rest of the genome, potentially aiding in their detection within a given DNA sequence.

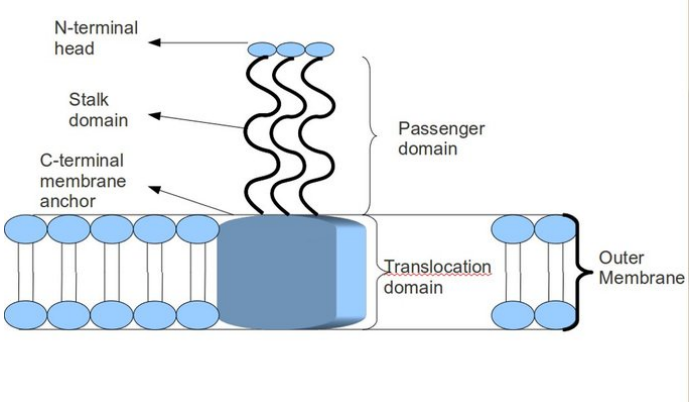

Figure: **Trimeric Autotransporter Adhesin structure**: The structure on the top (outside) of the outer membrane is a TAA protein. Various parts of the TAA are labelled, including the N-terminal head, stalk domain and C-terminal membrane anchor.

PAIs are flanked by direct repeats; the sequence of bases at two ends of the inserted sequence are the same. They carry functional genes such as integrases, transposases, or part of insertion sequences, to enable insertion into host DNA. PAIs are often associated with tRNA genes, which target sites for this integration event. They can be transferred as a single unit to new bacterial cells, thus conferring virulence to formerly benign strains.

14.1C: Pathogenicity Islands and Virulence Factors is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.1D: Adherence

Adhesins are cell-surface components or appendages of bacteria that facilitate bacterial adhesion to other cells or to inanimate surfaces.

Learning Objectives

- Review the role of adhesins, including fimbriae and the Dr family, in pathogenic bacteria

Key Points

- Adhesins are a type of virulence factor.
- Adherence is an essential step in bacterial pathogenesis or infection, required for colonizing a new host.
- Fimbriae are believed to be involved in attachment to solid surfaces or to other cells and are essential for the virulence of some bacterial pathogens.

Key Terms

- **adhesin**: Any of several factors that enable bacteria to adhere to epithelial surfaces as a step towards infection.
- **fimbriae**: Fine filaments of protein distributed over the surface of bacteria that are believed to be involved in attachment to solid surfaces or to other cells, and are essential for the virulence of some bacterial pathogens.

Adhesins are cell-surface components or appendages of bacteria that facilitate bacterial adhesion or adherence to other cells or to inanimate surfaces. Adhesins are a type of virulence factor. Adherence is an essential step in bacterial pathogenesis or infection, required for colonizing a new host. For example, nontypeable Haemophilus influenzae expresses the adhesins Hia, Hap, Oap, and a hemagglutinating pili.

Fimbriae are fine filaments of protein, just 3–10 nanometers in diameter and up to several micrometers in length. They are distributed over the surface of the cell, and resemble fine hairs when seen under the electron microscope. Fimbriae are believed to be involved in attachment to solid surfaces or to other cells, and are essential for the virulence of some bacterial pathogens. Most fimbriae of Gram-negative bacteria function as adhesins, but in many cases the actual adhesin is a minor subunit protein at the tip of the fimbriae. In Gram-positive bacteria, a protein or polysaccharide surface layer serves as the specific adhesin. To effectively achieve adherence to host surfaces, many bacteria produce multiple adherence factors called adhesins.

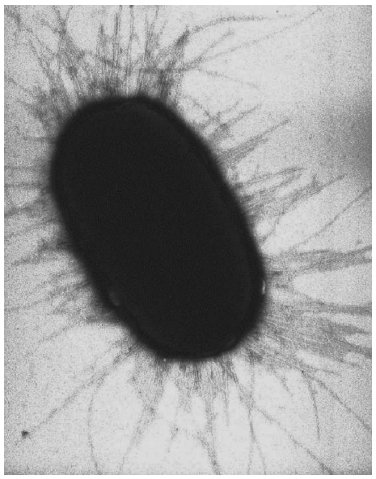

Figure: **E. coli fimbriae**: In bacteriology, a fimbria (plural fimbriae; abbreviated FIM) is an appendage composed of curlin proteins that can be found on many Gram-negative and some Gram-positive bacteria that is thinner and shorter than a flagellum. This appendage ranges from 3-10 nanometers in diameter and can be up to several micrometers long.

The Dr family of adhesins bind to the Dr blood group antigen component of decay-accelerating factor (DAF). These proteins contain both fimbriated and afimbriated adherence structures and mediate adherence of uropathogenic Escherichia coli to the urinary tract. They do so by inducing the development of long cellular extensions that wrap around the bacteria. They also confer the mannose-resistant hemagglutination phenotype, which can be inhibited by chloramphenicol. The N-terminal portion of the mature protein is thought to be responsible for chloramphenicol sensitivity. Also, they induce activation of several signal

transduction cascades, including activation of PI-3 kinase. The Dr family of adhesins are particularly associated with cystitis and pregnancy-associated pyelonephritis.

Adhesins are attractive vaccine candidates because they are often essential to infection and are surface-located, making them readily accessible to antibodies. The effectiveness of anti-adhesin antibodies is illustrated by studies with FimH, the adhesin of uropathogenic Escherichia coli (UPEC). In animal models, passive immunization with anti FimH-antibodies and vaccination with the protein significantly reduced colonization by UPEC. Moreover, the Bordetella pertussis adhesins FHA and pertactin are components of 3 of the 4 acellular pertussis vaccines currently licensed for use in the U.S.

14.1E: Host Risk Factors

Individuals who are weak, sick, malnourished, have cancer, or are diabetic have increased susceptibility to chronic or persistent infections.

Learning Objectives

- Recognize the risk factors that increase chance of disease

Key Points

- Risk of infection is a nursing diagnosis; “the state in which an individual is at risk to be invaded by an opportunistic or pathogenic agent (virus, fungus, bacteria, protozoa, or other parasite) from endogenous or exogenous sources” is the diagnostic definition of risk.
- Examples of risk factors includes decreased immune system secondary to disease, compromised circulation secondary to peripheral vascular disease, compromised skin integrity secondary to surgery, or repeated contact with contagious agents.
- Techniques like hand washing, wearing gowns, and wearing face masks can help prevent infections from being passed from the surgeon to the patient or vice versa.

Key Terms

- **opportunistic infection**: Any infection that causes disease and occurs only when the host’s immune system is impaired.
- **colitis**: inflammation of the colon.
- **vaccination**: inoculation with a vaccine in order to protect a particular disease or strain of disease.

Most humans are not easily infected. Those who are weak, sick, malnourished, have cancer, or are diabetic have increased susceptibility to chronic or persistent infections. Individuals who have a suppressed immune system or who are on immunosuppressive drugs are particularly susceptible to opportunistic infections.

Risk of infection is a nursing diagnosis which is defined as “the state in which an individual is at risk to be invaded by an opportunistic or pathogenic agent (virus, fungus, bacteria, protozoa, or other parasite) from endogenous or exogenous sources. ” The risk of infection depends on a number of endogenous sources. Skin damage from incision can increase a patient’s risk of infection, as can very young or old age, due to a naive or compromised immune system respectively. Examples of risk factors include decreased immune system resulting from disease, compromised circulation caused by peripheral vascular disease, compromised skin integrity as a result of surgery, or repeated contact with contagious agents.

Risk Reduction

Techniques like hand washing, wearing gowns, and wearing face masks can help prevent infections from being passed between the surgeon and the patient. Frequent hand washing remains the most important defense against the spread of unwanted organisms. Good nutrition is necessary to reduce risk. So is a healthy lifestyle. By avoiding illicit drugs, using a condom, and entering an exercise program one can improve one’s risk factors. Foods should be cooked to recommended temperatures; avoid foods that have been left outside for long. One should not take antibiotics for longer than needed or when they are not needed—long term use of antibiotics leads to resistance and increased the chance of developing opportunistic infections like clostridium difficile colitis. Vaccination is another vital means of preventing infections by encouraging the development of immune resistance in vaccinated hosts.

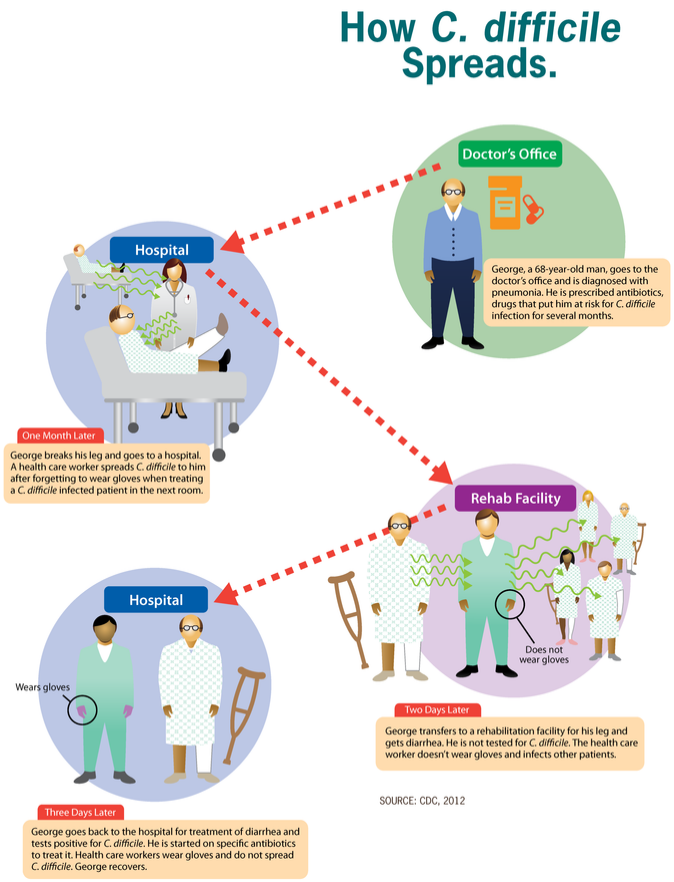

Figure: **How C. difficile spreads**: C. difficile is transmitted from person to person by the fecal-oral route. The organism forms large numbers of heat-resistant spores. These are not killed by alcohol-based hand cleansers or routine cleaning of surfaces. These spores remain viable in the hospital or nursing home environment for long periods of time. Because of this, the bacteria can be cultured from almost any surface in the hospital. Once spores are ingested by a patient, they pass through the stomach unscathed because of their acid-resistance. They germinate into vegetative cells in the colon upon exposure to bile acids, and multiply.

14.1E: Host Risk Factors is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.1F: Innate Resistance

Several barriers protect organisms from infection including mechanical, chemical, and biological barriers.

Learning Objectives

- Discuss the various innate barriers within humans that provide protection from infection

Key Points

- The flushing action of tears and urine also mechanically expels pathogens, while mucus secreted by the respiratory and gastrointestinal tract serves to trap and entangle microorganisms.
- The human microbiome (or human microbiota) is the aggregate of microorganisms that reside on the surface and in deep layers of skin, in the saliva and oral mucosa, in the conjunctiva, and in the gastrointestinal tracts.
- Some of these organisms perform tasks that are useful for the human host, but the majority have no known beneficial or harmful effect.

Key Terms

- **lysozyme**: A bacteriolytic (or antibiotic) enzyme found in many animal secretions and in egg white.
- **microbiota**: The microbial flora harbored by normal, healthy individuals.
- **flora**: the microorganisms that inhabit some part of the body, such as intestinal flora

Several barriers protect organisms from infection, including mechanical, chemical, and biological barriers. However, as organisms cannot be completely sealed against their environments, other systems act to protect body openings such as the lungs, intestines, and the genitourinary tract. In the lungs, coughing and sneezing mechanically eject pathogens and other irritants from the respiratory tract. The flushing action of tears and urine also mechanically expels pathogens, while mucus secreted by the respiratory and gastrointestinal tract serves to trap and entangle microorganisms.

Chemical barriers also protect against infection. The skin and respiratory tract secrete antimicrobial peptides such as the β-defensins. Enzymes such as lysozyme and phospholipase A2 in saliva, tears, and breast milk are also antibacterials. Vaginal secretions serve as a chemical barrier following menarche, when they become slightly acidic, while semen contains defensins and zinc to kill pathogens. In the stomach, gastric acid and proteases serve as powerful chemical defenses against ingested pathogens. Within the genitourinary and gastrointestinal tracts, commensal flora serve as biological barriers by competing with pathogenic bacteria for food and space and, in some cases, by changing the conditions in their environment, such as pH or available iron. This reduces the probability that pathogens will reach sufficient numbers to cause illness. However, since most antibiotics non-specifically target bacteria and do not affect fungi, oral antibiotics can lead to an “overgrowth” of fungi and cause conditions such as a vaginal candidiasis (a yeast infection). There is good evidence that re-introduction of probiotic flora, such as pure cultures of the lactobacilli normally found in unpasteurized yogurt, helps restore a healthy balance of microbial populations in intestinal infections in children and encouraging preliminary data in studies on bacterial gastroenteritis and inflammatory bowel diseases. Inflammation is one of the first responses of the immune system to infection.

The human microbiome (or human microbiota) is the aggregate of microorganisms that reside on the surface and in deep layers of skin, in the saliva and oral mucosa, in the conjunctiva, and in the gastrointestinal tracts. They include bacteria, fungi, and archaea. Some of these organisms perform tasks that are useful for the human host. However, the majority have no known beneficial or harmful effect. Those that are expected to be present, and that under normal circumstances do not cause disease, but instead participate in maintaining health, are deemed members of the normal flora.

Populations of microbes (such as bacteria and yeasts) inhabit the skin and mucosa. Their role forms part of normal, healthy human physiology. However, if microbe numbers grow beyond their typical ranges (often due to a compromised immune system) or if microbes populate atypical areas of the body (such as through poor hygiene or injury), disease can result.

Many of the bacteria in the digestive tract are collectively referred to as the gut flora. In this context, *gut* is synonymous with intestinal, and *flora* with microbiota and microflora, the word microbiome is also in use. They are able to break down certain nutrients such as carbohydrates that humans otherwise could not digest. The majority of these commensal bacteria are anaerobes, meaning they survive in an environment with no oxygen. Normal flora bacteria can act as opportunistic pathogens at times of lowered immunity.

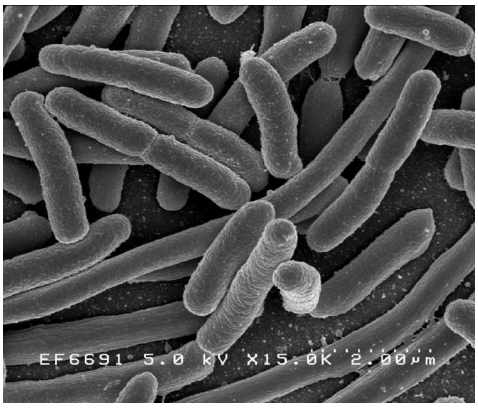

Figure: **Gut Flora**: Gut flora consists of microorganisms such as Escherichia Coli that live in the digestive tracts of animals. It is the largest reservoir of human flora. In this context, gut is synonymous with intestinal, and flora with microbiota and microflora. The word microbiome is also in use.

Archaea are present in the human gut, but, in contrast to the enormous variety of bacteria in this organ, the numbers of archaeal species are much more limited. Fungi, in particular yeasts, are present in the human gut. The best-studied of these are Candida species. This is because of their ability to become pathogenic in immune compromised hosts. Yeasts are also present on the skin, particularly Malassezia species, where they consume oils secreted from the sebaceous glands.

A small number of bacteria are normally present in the conjunctiva. Staphylococcus epidermidis and certain coryneforms such as Propionibacterium acnes are dominant. The lachrymal glands continuously secrete, keeping the conjunctiva moist, while intermittent blinking lubricates the conjunctiva and washes away foreign material. Tears contain bactericides such as lysozyme, so that microorganisms have difficulty in surviving the lysozyme and settling on the epithelial surfaces.

The gut flora is the human flora of microorganisms that normally live in the digestive tract and can perform a number of useful functions for their hosts. Though people can survive with no gut flora, the microorganisms perform a host of useful functions such as fermenting unused energy substrates, training the immune system, preventing growth of harmful species, regulating the development of the gut, producing vitamins for the host (such as biotin and vitamin K), and producing hormones to direct the host to store fats. However, in certain conditions, some species are thought to be capable of causing disease by causing infection or increasing cancer risk for the host.

SECTION OVERVIEW

14.2: Overview of Microbe-Host Interactions

Topic hierarchy

14.2A: Normal Microbiota and Host Relationships

14.2B: Opportunistic Microorganisms

14.2C: Cooperation Among Microorganisms

This page titled 14.2: Overview of Microbe-Host Interactions is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

14.2A: Normal Microbiota and Host Relationships

Normal microbiota are the microorganisms that reside in the bodies of all humans.

Learning Objectives

- Explain the relationship between the normal microbiota and the host upon infection of a pathogen

Key Points

- The phrase “normal microbiota ” refers to the microorganisms that reside on the surface and deep layers of skin, in the saliva and oral mucosa, in the conjunctiva, and in the gastrointestinal tracts of every human being.
- These microbiota are not harmful to humans; some are even beneficial and most help maintain our health.
- Our normal microbiota consists of various bacteria, fungi, and archaea.
- While our bodies are happy to host the array of microbiota that are considered “normal,” the human body does not take a back seat when infection tries to use it as a host.
- Resistance to and recovery from viral infections depends on the interactions that occur between virus and host. The host has a variety of barriers that it uses to prevent infection. One of the first lines of defense is mucus, which has a range of normal microbiota.
- There are a number of other humoral components of the nonspecific immune system as well.

Key Terms

- **host**: A cell or organism which harbors another organism or biological entity, usually a parasite.
- **microorganism**: An organism that is too small to be seen by the unaided eye, especially a single-celled organism, such as a bacterium.
- **interferon**: Any of a group of glycoproteins, produced by the immune system, that prevent viral replication in infected cells.

Normal Microbiota

The phrase “normal microbiota” refers to the microorganisms that reside on the surface and deep layers of skin, in the saliva and oral mucosa, in the conjunctiva, and in the gastrointestinal tracts of every human being. These microorganisms are not harmful to humans; in fact, some are even beneficial and all help maintain our health. Our normal microbiota consists of various bacteria, fungi, and archaea. An example of our bacterial microbiota is *E. coli* . Many people think of *E. coli* as the bacteria that makes you sick; however while it has that capacity, it can also remain dormant and benign in your gastrointestinal tract for your entire life. All humans actually acquire *E. coli*shortly after birth with the intake of food or water. Other forms of bacteria present in the human gut are necessary for proper digestion of carbohydrates.

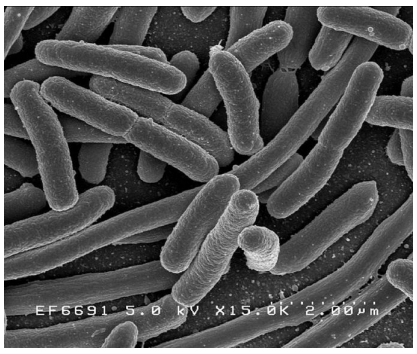

Figure: **Escherichia coli**: This is a magnified view of Escherichia coli (or E. coli).

Host Relationships

While our bodies are happy to host the array of microbiota that are considered “normal,” the human body does not take a back seat when infection tries to use it as a host. Interestingly, normal microbiota can be key players helping the body fight off infection. Resistance to and recovery from viral infections depends on the interactions that occur between the virus and its host. The host has a variety of defenses that it uses to prevent infection. One of the first lines of defense is mucus, which has a range of normal microbiota that compete with and may even attack invading bacteria and virae.

Once a virus or bacteria makes its way past the skin and mucosa, there may be changes that occur in the host to diminish the invader's effectiveness. An example of such a change is a fever. There are a number of other humoral components of the nonspecific immune system as well. Specific immune responses are produced by antibodies. Different interferons (IgA, IgG, IgM, etc.) play roles in defeating viruses located in our membranes. The body does not easily become a host to infection; it has a line up of defenses to try to protect you from harm.

14.2A: Normal Microbiota and Host Relationships is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.2B: Opportunistic Microorganisms

Learning Objectives

- Describe the traits of an opportunistic microorganism

In the general realm of biology, an opportunist is an organism that is able sustain its life from a number of different sources, but when favorable conditions arise, the organism immediately takes advantage of the opportunity to thrive. When the focus is turned more specifically to microbiology, scientists call organisms that behave this way opportunistic microorganisms. A microorganism is a microscopic organism that can either be a single cell, cell cluster, or multicellular. Microorganisms are very diverse and include bacteria, fungi, algae, and protozoa. Opportunistic microorganisms are typically non-pathogenic microorganisms that act as a pathogen in certain circumstances. They lay dormant for long periods of time until the hosts' immune system is suppressed and then they seize the opportunity to attack.

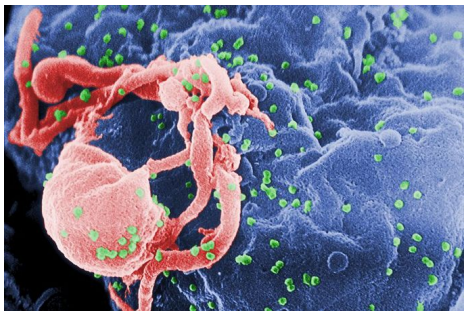

Figure: **HIV**: This is a magnified view of HIV budding from a lymphocyte.

Patients with Human Immunodeficiency Virus (HIV) are particularly susceptible to opportunistic infections. HIV can develop into Acquired Immune Deficiency Syndrome (AIDS), which infects and destroys helper T cells (specifically CD4+ T cells). When the number of CD4+ T cell numbers fall below a critical level, cell-mediated immunity is lost. When immunity is lost, the opportunistic microorganisms can easily infect the AIDS patient without being destroyed by the immune system. These opportunistic pathogens thrive while the human body slowly deteriorates.

An example of an opportunistic microorganism is *Haemophilus ducreyi*. This microorganism infects its host through broken skin or epidermis. In other words, without an open wound, this sexually transmitted disease would be unable to use the human body as a host. It takes advantage of the opportunity to infect the lymphocytes, macrophages and granulocytes as soon as it enters the area of broken skin.

Key Points

- A microorganism is a microscopic organism that can either be a single cell, cell cluster, or multicellular. Microorganisms are very diverse and include bacteria, fungi, algae, and protozoa.
- Opportunistic microorganisms are typically non-pathogenic microorganisms that act as a pathogen in certain circumstances. They lay dormant for long periods of time until the host 's immune system is suppressed and then they take that opportunity to attack.
- Haemophilus ducreyi, a microorganism, infects its host through broken skin or epidermis. Without the open wound, this sexually transmitted disease would be unable to use the human body as a host.

Key Terms

- **microorganism**: An organism that is too small to be seen by the unaided eye, especially a single-celled organism, such as a bacterium.
- **Opportunistic**: Taking advantage of situations that arise.
- **immunodeficiency**: A depletion in the body's natural immune system, or in some component of it.

14.2B: Opportunistic Microorganisms is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.2C: Cooperation Among Microorganisms

Cooperative behavior, includes mutualism and altruism, benefits one party while the other performs a certain behavior.

Learning Objectives

- Compare and contrast the following cooperative behavior: mutalism and altruism

Key Points

- In microbial systems, there are two main types of cooperation, altruism and mutualism.
- Mutualism is a relationship between microorganisms that is mutually beneficial (+/+). This means that both parties are receiving positive things from their interaction.
- Altruism is a relationship between microorganisms that is beneficial to one party, but harmful to the the (+/-). Scientists believe that the individual that is at a loss performs the action because they believe it will ultimately benefit others whom they share a relationship with (like family).

Key Terms

- **Cooperation**: Association for mutual benefit.
- **mutualism**: A relationship between individuals of different species in which both individuals benefit
- **altruism**: Regard for others, both natural and moral; devotion to the interests of others; brotherly kindness; – opposed to egoism or selfishness.

Microbial Cooperation

Figure: **Methanogenic Bacteria in Termites**: Methanogenic bacteria have a syntrophic relationship with protozoans living in the guts of termites. The protozoans break down cellulose, releasing H2 which is then used in methanogenesis.

A cooperative behavior benefits one party while the other performs a certain behavior or takes a particular action. In microbial systems, there are two main types of cooperation, altruism and mutualism. It is important to remember that microorganisms include bacteria, archaea, fungi, and protists. They are too small to be seen with the naked eye, but they play a huge role in the world as we know it and have a great deal of biological diversity.

Mutualism

Mutualism is a relationship between microorganisms that is mutually beneficial (+/+). This means that both parties benefit from their interaction. A microbial example is the interaction between protozoa and archaea in the digestive tracts of some animals. These animals eat cellulose which is broken down by the protozoa to obtain energy. This process releases hydrogen as a waste

product, which in turn reduces energy production. Specialized archaea convert the hydrogen (which they need) to methane, which allows energy production to increase. Both the protozoa and archaea benefit from this relationship.

Altruism

Altruism is a relationship between microorganisms that is beneficial to one party, but harmful to the the (+/-). Most scientists believe that the individual that is harmed, or at a loss, performs the action because they believe it will ultimately benefit others whom it is close to or share a relationship with (like family). On a microscopic level, this happens with programmed cell death, or apoptosis. Although it does not seem like it would be beneficial for the cell to die, it has been suggested that the resources it was using could be better utilized by other cells for growth and survival.

14.3A: Penetrating Host Defenses

Learning Objectives

- Recognize the ways a host can be infected by, and resist, pathogens

The human microbiome (or human microbiota) is the aggregate of microorganisms that reside on the surface and in deep layers of skin, in the saliva and oral mucosa, in the conjunctiva, and in the gastrointestinal tracts. They include bacteria, fungi, and archaea. Some of these organisms perform tasks that are useful for the human host. However, the majority have no known beneficial or harmful effect. Organisms that are expected to be present, and that under normal circumstances do not cause disease, but participate in maintaining health, are deemed members of the normal flora.

Many of the bacteria in the digestive tract, collectively referred to as the gut flora, are able to break down certain nutrients such as carbohydrates that humans otherwise could not digest. The majority of these commensal bacteria are anaerobes, meaning they survive in an environment with no oxygen. Normal flora bacteria can act as opportunistic pathogens at times of lowered immunity. *Escherichia coli* (*E. coli*) is a bacterium that lives in the colon. It is an extensively studied model organism. Certain mutated strains of these gut bacteria do cause disease. An example is *E. coli* O157:H7.

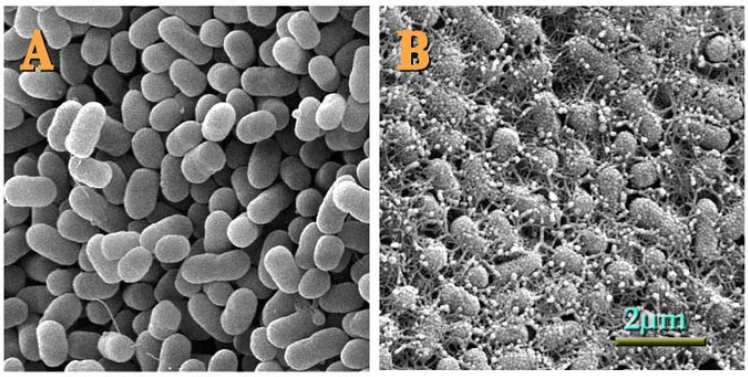

Figure: **Escherichia coli O157:H7**: Topographical images of colonies of *E. coli* O157:H7 strains (A) 43895OW (curli non-producing) and (B) 43895OR (curli producing) grown on agar for 48 h at 28°C. Escherichia coli O157:H7 is an enterohemorrhagic strain of the bacterium Escherichia coli and a cause of food borne illness. Infection often leads to hemorrhagic diarrhea and occasionally to kidney failure, especially in young children and elderly persons. Transmission is via the fecal-oral route. Most illness has been associated with eating under cooked, contaminated ground beef or ground pork, swimming in or drinking contaminated water, or eating contaminated vegetables.

Infection is the invasion of a host organism's bodily tissues by disease-causing organisms, their multiplication, and the host's reaction to these organisms and the toxins they produce. Infections are caused by pathogens such as viruses, prions, bacteria, and viroids, and larger organisms like macroparasites and fungi.

It is important to keep in mind that although the immune system has evolved to be able to control many pathogens, pathogens themselves have evolved ways to evade the immune response. An example already mentioned is in *Mycobactrium tuberculosis*, which has evolved a complex cell wall that is resistant to the digestive enzymes of the macrophages that ingest them, and thus persists in the host, causing the chronic disease tuberculosis. This section briefly summarizes other ways in which pathogens can "outwit" immune responses. But keep in mind, although it seems as if pathogens have a will of their own, they do not. All of these evasive "strategies" arose strictly by evolution, driven by selection.

Bacteria sometimes evade immune responses because they exist in multiple strains, such as different groups of *Staphylococcus aureus*. *S. aureus* is commonly found in minor skin infections, such as boils, and some healthy people harbor it in their nose. One small group of strains of this bacterium, however, called methicillin-resistant *Staphylococcus aureus*, has become resistant to multiple antibiotics and is essentially untreatable. Different bacterial strains differ in the antigens on their surfaces. The immune response against one strain (antigen) does not affect the other; thus, the species survives.

Another method of immune evasion is mutation. Because viruses' surface molecules mutate continuously, viruses like influenza change enough each year that the flu vaccine for one year may not protect against the flu common to the next. New vaccine formulations must be derived for each flu season.

Genetic recombination—the combining of gene segments from two different pathogens—is an efficient form of immune evasion. For example, the influenza virus contains gene segments that can recombine when two different viruses infect the same cell. Recombination between human and pig influenza viruses led to the 2010 H1N1 swine flu outbreak.

Pathogens can produce immunosuppressive molecules that impair immune function, and there are several different types. Viruses are especially good at evading the immune response in this way, and many types of viruses have been shown to suppress the host immune response in ways much more subtle than the wholesale destruction caused by HIV.

Key Points

- Infections are caused by pathogens such as viruses, prions, bacteria, and viroids, and larger organisms like macroparasites and fungi.
- Mammalian hosts react to infections with an innate response, often involving inflammation, followed by an adaptive response.
- Pathogens can evade the body's immune responses through means that include specialized adaptations, mutation, evolved resistance to treatments, genetic recombination, and the production of immunosuppressive molecules that impair immune function.

Key Terms

- **Human microbiome**: The aggregate of microorganisms that reside on the surface and in deep layers of skin, in the saliva and oral mucosa, in the conjunctiva, and in the gastrointestinal tracts.

14.3B: Pili and Pilus Assembly

Learning Objectives

- Describe the function of the pili in regards to pathogenecity

A pilus (Latin for “hair;” plural: pili) is a hairlike appendage found on the surface of many bacteria. The terms pilus and fimbria (Latin for “thread” or “fiber,” plural: fimbriae) can be used interchangeably, although some researchers reserve the term pilus for the appendage required for bacterial conjugation. All pili are primarily composed of oligomeric pilin proteins.

Dozens of these structures can exist on the bacteria. Some bacterial viruses or bacteriophages attach to receptors on pili at the start of their reproductive cycle. Pili are antigenic. They are also fragile and constantly replaced, sometimes with pili of different composition, resulting in altered antigenicity. Specific host responses to old pili structure are not effective on the new structure. Recombination genes of pili code for variable (V) and constant (C) regions of the pili (similar to immunoglobulin diversity).

Conjugative pili allow the transfer of DNA between bacteria, in the process of bacterial conjugation. They are sometimes called “sex pili”, in analogy to sexual reproduction, because they allow for the exchange of genes via the formation of “mating pairs”. Perhaps the most well-studied is the F pilus of Escherichia coli, encoded by the F plasmid or fertility factor.

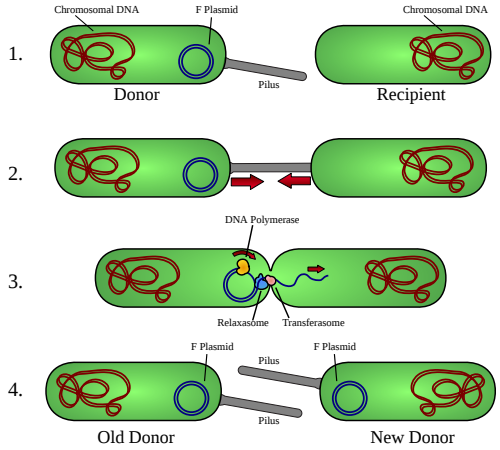

Figure: **Bacterial Conjugation**: A schematic drawing of bacterial conjugation. Conjugation diagram 1- Donor cell produces pilus. 2- Pilus attaches to recipient cell, brings the two cells together. 3- The mobile plasmid is nicked, and a single strand of DNA is then transferred to the recipient cell. 4- Both cells recircularize their plasmids, synthesize second strands, and reproduce pili; both cells are now viable donors.

A pilus is typically 6 to 7 nm in diameter. During conjugation, a pilus emerging from donor bacterium ensnares the recipient bacterium, draws it in close, and eventually triggers the formation of a mating bridge, which establishes direct contact and the formation of a controlled pore that allows transfer of DNA from the donor to the recipient. Typically, the DNA transferred consists of the genes required to make and transfer pili (often encoded on a plasmid), and is a kind of selfish DNA; however, other pieces of DNA often are co-transferred, and this can result in dissemination of genetic traits, such as antibiotic resistance, among a bacterial population. Not all bacteria can make conjugative pili, but conjugation can occur between bacteria of different species.

Some pili, called “type IV pili,” generate motile forces. The external ends of the pili adhere to a solid substrate, either the surface to which the bacteria are attached or to other bacteria, and when the pilus contracts, it pulls the bacteria forward, like a grappling hook. Movement produced by type IV pili is typically jerky, and so it is called “twitching motility,” as distinct from other forms of bacterial motility, such as motility produced by flagella. However, some bacteria, for example Myxococcus xanthus, exhibit gliding motility. Bacterial type IV pilins are similar in structure to the component flagellins of Archaeal flagella.

Attachment of bacteria to host surfaces is required for colonization during infection or to initiate formation of a biofilm. A fimbria is a short pilus that is used to attach the bacterium to a surface. Fimbriae are either located at the poles of a cell or are evenly spread over its entire surface. Mutant bacteria that lack fimbriae cannot adhere to their usual target surfaces and, thus, cannot cause diseases. Some fimbriae can contain lectins. The lectins are necessary to adhere to target cells, because they can recognize oligosaccharide units on the surface of these target cells. Other fimbriae bind to components of the extracellular matrix. Fimbriae are found in both Gram-negative and Gram-positive bacteria. In Gram-positive bacteria, the pilin subunits are covalently linked.

Key Points

- The process of bacterial conjugation allow for the exchange of genes via the formation of “sex pili”.
- All pili are primarily composed of oligomeric pilin proteins.
- Conjugative pili allow the transfer of DNA between bacteria in the process of bacterial conjugation.

Key Terms

- **pilus**: A hair-like appendage found on the cell surface of many bacteria.

14.3C: Biofilms and Infections

Biofilms will form on virtually every non-shedding surface in a non-sterile aqueous (or very humid) environment.

Learning Objectives

- Discuss the importance of biofilms in the biomedical community

Key Points

- Biofilms have been found to be involved in a wide variety of microbial infections in the body.
- Microbes form a biofilm in response to many factors, which may include cellular recognition of specific or non-specific attachment sites on a surface and nutritional cues.
- Bacterial biofilms may impair cutaneous wound healing and reduce topical antibacterial efficiency in healing or treating infected skin wounds.

Key Terms

- **biofilm**: A thin film of mucus created by and containing a colony of bacteria and other microorganisms.
- **sterile**: unable to reproduce (or procreate)

A biofilm is an aggregate of microorganisms in which cells adhere to each other on a surface. These adherent cells are frequently embedded within a self-produced matrix of extracellular polymeric substance (EPS).

Microbes form a biofilm in response to many factors, which may include cellular recognition of specific or non-specific attachment sites on a surface, nutritional cues, or in some cases, by exposure of planktonic cells to sub-inhibitory concentrations of antibiotics. When a cell switches to the biofilm mode of growth, it undergoes a phenotypic shift in behavior in which large suites of genes are differentially regulated.

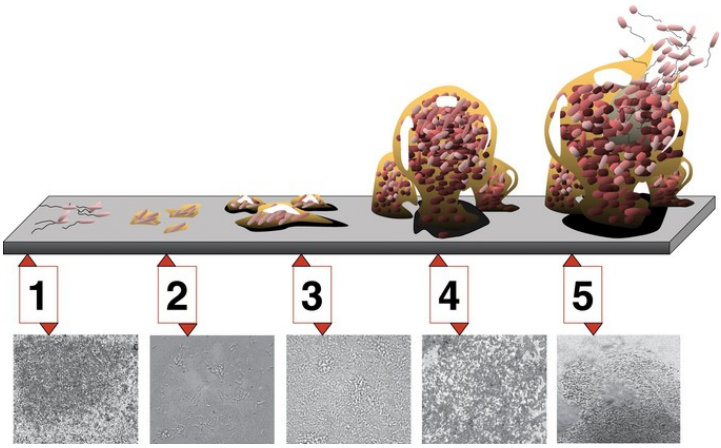

Figure: **Biofilm development**: 5 stages of biofilm development. Stage 1, initial attachment; stage 2, irreversible attachment; stage 3, maturation I; stage 4, maturation II; stage 5, dispersion. Each stage of development in the diagram is paired with a photomicrograph of a developing Pseudomonas aeruginosa biofilm. All photomicrographs are shown to same scale.

Biofilms are ubiquitous. Nearly every species of microorganism, not only bacteria and archaea, have mechanisms by which they can adhere to surfaces and to each other. Biofilms will form on virtually every non-shedding surface in a non-sterile aqueous (or very humid) environment.

Biofilms have been found to be involved in a wide variety of microbial infections in the body, by one estimate in 80% of all infections. Infectious processes in which biofilms have been implicated include common problems such as urinary tract infections, catheter infections, middle-ear infections, formation of dental plaque, gingivitis, and coating contact lenses. Biofilms have also been implicated in less common but more lethal processes such as endocarditis, infections in cystic fibrosis, and infections of permanent indwelling devices such as joint prostheses and heart valves.

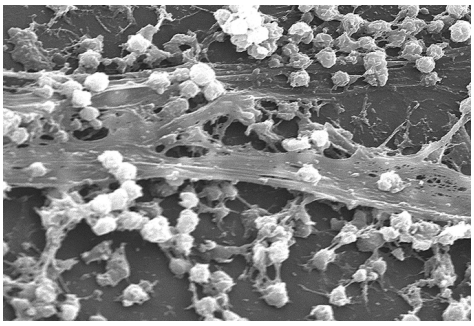

Figure: **Staphylococcus aureus biofilm**: Staphylococcus aureus forming a biofilm on a catheter.

More recently it has been noted that bacterial biofilms may impair cutaneous wound healing and reduce topical antibacterial efficiency in healing or treating infected skin wounds. It has recently been shown that biofilms are present on the removed tissue of 80% of patients undergoing surgery for chronic sinusitis. The patients with biofilms were shown to have been denuded of cilia and goblet cells, unlike the controls without biofilms who had normal cilia and goblet cell morphology. Biofilms were also found on samples from two of 10 healthy controls mentioned. The species of bacteria from interoperative cultures did not correspond to the bacteria species in the biofilm on the respective patient's tissue. In other words, the cultures were negative though the bacteria were present.

Biofilms can also be formed on the inert surfaces of implanted devices such as catheters, prosthetic cardiac valves, and intrauterine devices. New staining techniques are being developed to differentiate bacterial cells growing in living animals, e.g. from tissues with allergy-inflammations.

Pseudomonas aeruginosa biofilms

The achievements of medical care in industrialized societies are markedly impaired due to chronic opportunistic infections that have become increasingly apparent in immunocompromised patients and the aging population. Chronic infections remain a major challenge for the medical profession and are of great economic relevance because traditional antibiotic therapy is usually not sufficient to eradicate these infections.

Pseudomonas aeruginosa is not only an important opportunistic pathogen and causative agent of emerging nosocomial infections but can also be considered a model organism for the study of diverse bacterial mechanisms that contribute to bacterial persistence. In this context the elucidation of the molecular mechanisms responsible for the switch from planktonic growth to a biofilm phenotype and the role of inter-bacterial communication in persistent disease should provide new insights. It should help researchers learn about the pathogenicity of P. aeruginosa, contribute to a better clinical management of chronically infected patients, and lead to the identification of new drug targets for the development of alternative anti-infective treatment strategies.

Dental plaque

Dental plaque is a biofilm that adheres to teeth surfaces and consists of bacterial cells, salivary polymers, and bacterial extracellular products. This accumulation of microorganisms subject the teeth and gingival tissues to high concentrations of bacterial metabolites which results in dental disease. The biofilms attached to the surfaces of some dental alloys, impression materials, dental implants, restorative and cement materials play an essential role concerning the biofilms establishment dynamics toward the physical-chemical properties of the materials which biofilms are attached to.

Legionellosis

Legionella bacteria are known to grow under certain conditions in biofilms, in which they are protected against disinfectants. Workers in cooling towers, persons working in air conditioned rooms, and people taking a shower are exposed to Legionella by inhalation when the systems are not well designed, constructed, or maintained. Neisseria gonorrhoeae is an exclusive human pathogen. Recent studies have demonstrated that it utilizes two distinct mechanisms for entry into human urethral and cervical epithelial cells involving different bacterial surface ligands and host receptors. In addition, it has been demonstrated that the gonococcus can form biofilms on glass surfaces and over human cells. There is evidence for the formation of gonococcal biofilms on human cervical epithelial cells during natural disease. Evidence also suggests that the outer membrane blebbing by the gonococcus is crucial in biofilm formation over human cervical epithelial cells.

14.4A: Toxins

Learning Objectives

- Describe the major toxin types (bacterial toxins and mycotoxins) and their mechanisms of action

Toxins are poisonous substances produced within living cells or organisms and can include various classes of small molecules or proteins that cause disease on contact. The severity and type of diseases caused by toxins can range from minor effects to deadly effects. The organisms which are capable of producing toxins include bacteria, fungi, algae, and plants. Some of the major types of toxins include, but are not limited to, environmental, marine, and microbial toxins. Microbial toxins may include those produced by the microorganisms bacteria (i.e. bacterial toxins) and fungi (i.e. mycotoxins).

Bacterial Toxins

Bacterial toxins are typically classified under two major categories: exotoxins or endotoxins. Exotoxins are immediately released into the surrounding environment whereas endotoxins are not released until the bacteria is killed by the immune system. The release of toxins into the surrounding environment, regardless of when released, results in the disruption of metabolic pathways in the host eukaryote. These metabolic pathways include damaging cell membranes, disrupting protein synthesis, inhibiting neurotransmitter release, or activating the host immune system. The mechanisms of action by which toxins disrupt eukaryotic cell processes are dependent on the target. For example, the bacteria *Listeria monocytogenes*, associated with food-borne illnesses, specifically targets cholesterol by producing a pore-forming toxin protein, listeriolysin O. This exotoxin affects intracellular processes and creates unregulated pores within the cell membranes of the host. Another example of an exotoxin includes an enterotoxin produced by the bacteria *Staphlycoccal aureus. S. aureus* can producestaphylococcal enterotoxin B (SEB), associated with intestinal illness, which promotes activation of the immune system. Upon activation of the immune system, the release of large amounts of cytokines, inflammatory related molecules, causes significant inflammation. Lastly, an example of an endotoxin, includes the protein lipopolysaccharide (LPS) produced by gram-negative bacteria. The LPS is a component of the bacteria's outer membrane and promotes structural integrity. Upon destruction of the membrane by an immune response, the LPS is released and functions as a toxin.

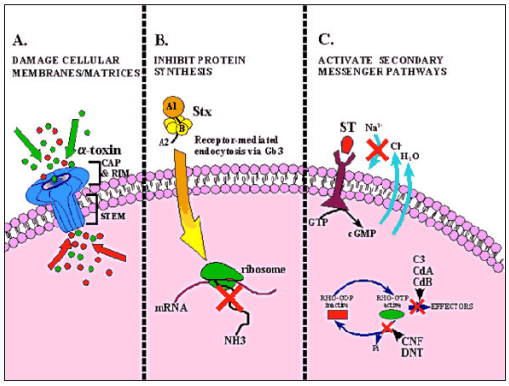

Figure: ***Bacterial Toxin Mechanism of Action****: A schematic of various processes utilized by bacterial toxins to damage host cells.*

However, bacterial toxins are also currently serving as new sources for potential drug development. Toxins have been shown to exhibit anticancer characteristics and fight again microbial virulence. The investigation of toxins as potential medicinal compounds is currently underway.

Mycotoxins

Mycotoxins are the classes of toxins produced by fungi. Mycotoxins are numerous and production of a specific mycotoxin is not restricted to one specific species. Mycotoxins are secondary metabolites that are toxic to humans and produced by fungi. There are various types of mycotoxins including, but not limited to, aflatoxins, ochratoxins, citrinin, and ergot alkaloids.

Aflatoxins

Aflatoxins are a type of mycotoxin that are produced by certain strains of *Aspergillus* fungi. The aflatoxins are further broken down into types: AFB1, AFB2, AFG1, and AFG2. These strains are present in a wide range of agricultural commodities associated with

tropic and subtropic zones. These commodities include species of peanuts and corn. The most potent toxin is AFB1 and it is associated with carcinogenic effects.

Ochratoxin

Ochratoxin is a type of toxin produced by both *Penicillium* and *Aspergillus* species. Ochratoxins are further classified in types A, B and C and differ in structure. Ochratoxins have demonstrated carcinogenic properties and are often found in beverages such as beer and wine, as the fungal species which produce ochratoxins are often found on the plants used to produce these products.

Citrinin

Citrinin is a mycotoxin that has been isolated in numerous species of both *Penicillium* and *Aspergillus*. Many of these fungal species are utilized in food processing and are often found in foods including cheese, wheat, rice, corn, and soy sauce. Citrinin is known to function as a nephrotoxin, indicating it has toxic effects on kidney function.

Ergot Alkaloids

Ergot Alkaloids are specific compounds that are produced as toxic alkaloids in *Claviceps*, a group of fungi associated with grasses, rye, and related plants. The disease caused by ingestion of this fungi is called ergotism. Ergotism is characterized by detrimental effects on the vascular system in particular, including vasoconstriction of blood vessels resulting in gangrene, and eventually, limb loss if left untreated. Additionally, ergotism can present as hallucinations and convulsions as ergot alkaloids target the central nervous system. Due to the vascular system effects of ergot alkaloids, they have been used for medicinal purposes.

Key Points

- Microbial toxins may include those produced by the microorganisms bacteria (i.e. bacterial toxins) and fungi (i.e. mycotoxins).
- Bacterial toxins can include both endotoxins and exotoxins, which vary in mechanism of action and are species -specific.
- Exotoxins are immediately released into the surrounding environment whereas endotoxins are not released until the bacteria is killed by the immune system.
- Mycotoxins can be classified into numerous categories and are not species-specific because the same mycotoxin can be produced by different fungal species.

Key Terms

- **endotoxin**: Any toxin secreted by a microorganism and released into the surrounding environment only when it dies.
- **exotoxin**: Any toxin secreted by a microorganism into the surrounding environment.
- **cytokines**: Regulatory proteins that function in the regulation of the cells involved in immune system function

14.4A: Toxins is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.4B: Direct Damage

Direct damage to the host is a general mechanism utilized by pathogenic organisms to ensure infection and destruction of the host cell.

Learning Objectives

- Describe the different processes used by pathogens to damage the host and ensure infection

Key Points

- Pathogenic organisms must have mechanisms in place to evade attack by the immune system.
- Pathogens can produce enzymes that disrupt normal tissue and allow for further invasion into the tissues.
- Pathogens can produce toxins that interfere with protein function deemed necessary by the host cell for proper maintenance.

Key Terms

- **diphtheria**: A disease of the upper respiratory tract caused by a toxin secreted by Corynebacterium diphtheriae.
- **phagocytosis**: the process by which a cell incorporates foreign particles intracellularly.

Direct damage to the host is a general mechanism utilized by pathogenic organisms to ensure infection and destruction of the host cell. The pathogenic organism typically causes damage due to its own growth process. The promotion of disease is characterized by the ability of a pathogenic organism to enter a host and inflict damage and destruction onto the host cell. The pathogenic organism must exhibit specific characteristics that promote its growth into a host cell including, but not limited to, the ability to invade, colonize, and attach to host cells.

The ability of a pathogen to gain entrance to a host cell is fundamental in the ability of the pathogen to promote and cause disease. The ability to manipulate the process of phagocytosis is a mechanism often utilized by bacteria to ensure they effectively invade a host. Phagocytosis is a process utilized by phagocytes (white blood cells) as a defense mechanism to protect from foreign bodies. The phagocytes engulf invaders and present them to additional factors within the immune system that result in their destruction. However, a successful and destructive pathogen often exhibits the ability to evade phagocytosis.

The mechanism(s) utilized by pathogens to avoid phagocytosis include avoiding both contact and engulfment. Pathogens that exhibit the ability to avoid contact utilize various processes to accomplish this, including: the ability to grow in regions of the body where phagocytes are incapable of reaching; the ability to inhibit the activation of an immune response; inhibiting and interfering with chemotaxis which drives the phagocytes to site of infection; and ‘tricking’ the immune system to identify the bacteria as ‘self. ‘ Additional mechanism(s) by which bacteria can avoid destruction is by avoiding engulfment. This is accomplished by the ability of the bacteria to exhibit produce molecules that interfere with the phagocytes ability to internalize the bacteria. Molecules that interfere with this process include certain types of proteins and sugars that block engulfment.

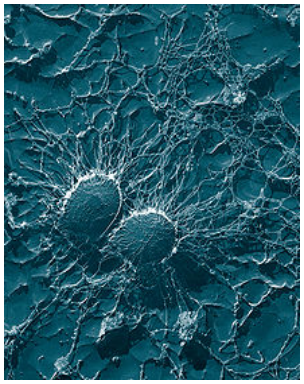

Figure: **Protected from Phagocytosis**: Staphylococcus aureus exhibit physical properties, specifically a capsule, that protect the bacteria from phagocytosis.

Once the pathogen has successfully evaded engulfment and destruction by the immune system, it is detrimental because the bacteria then multiply. Often times, bacteria will directly attach themselves to host cells and utilize nutrients from the host cell for their own cellular processes. Upon the use of host nutrients for its own cellular processes, the bacteria may also produce toxins or enzymes that will infiltrate and destroy the host cell. The production of these destructive products results in the direct damage of

the host cell. The waste products of the microbes will also damage to the cell. Examples of bacteria that will damage tissue by producing toxins, include, *Corynebacterium diphtheriae* and *Streptococcus pyogenes*. Specifically, *Corynebacterium diphtheriae* causes diphtheria, which isa disease of the upper respiratory tract. It produces a toxin, diphtheria toxin, which alters host protein function. The toxin can then result in damage to additional tissues including the heart, liver, and nerves. *Streptococcus pyogenes* is associated with strep throat and “flesh-eating disease. ” The bacteria produce enzymes which function in disrupting fibrin clots. Fibrin clots will form at sites of injury, in this case, at the site of foreign invasion. The enzymes, capable of digesting fibrin, will open an area within the epithelial cells and promote invasion of the bacteria into the tissues.

14.4B: Direct Damage is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.4C: Type III and Type IV Secretion

Type III and IV secretion systems are utilized by pathogenic bacteria to transfer molecules from the bacterial cell to the host cell.

Learning Objectives

- Distinguish between Type III and IV secretion systems

Key Points

- Type III secretion system use a process which injects the secretory molecule into the host cell.
- Type IV secretion systems use a process which is similar to the bacterial conjugation machinery.
- Type IV secretion systems require attachment to the host cell by direct cell-to-cell contact or via a bridge-like apparatus.
- Type IV secretion systems can be used to both transport and receive molecules.
- Type III secretion systems requires a large protein complex to ensure proper transfer of secretory molecules.

Key Terms

- **peptidoglycan**: A polymer of glycan and peptides found in bacterial cell walls.
- **effector**: a small molecule that effects additional molecules
- **bacterial conjugation**: transfer of genetic material between bacterial cells by direct contact

In regards to pathogenecity, secretion in microorganisms such as bacterial species involves the movement of effector molecules from the interior of a pathogenic organism to the exterior. The secretion of specific molecules allows for adaptation to occur, thereby promoting survival. Effector molecules secreted include proteins, enzymes or toxins. The mechanisms by which pathogenic bacteria secrete proteins involve complex and specialized secretion systems. Specifically, Type III and Type IV secretion systems are utilized by gram-negative pathogenic bacteria to transport proteins that function as pathogenic components.

Type III Secretion Systems

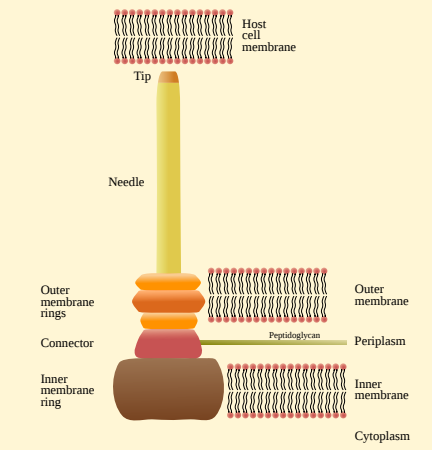

Figure: **Type III Secretion System**: The type III secretion system is characterized by the ability to inject secretory molecules into the host eukaryotic cell.

Type III secretion systems are characterized by the ability to inject a protein directly from the bacterial cell to the eukaryotic cell. It is often compared to the bacterial flagellar basal body which functions as a motor unit and extracellular appendage that is comprised of numerous proteins. The pathogenic bacteria which exhibit this capability contain a critical structural component, considered a protein appendage, that allows the injection of the protein into the host cell. The type III secretion system involves the formation of a complex, roughly ~20 proteins, that reside within the cytoplasmic membrane of the bacterial cell. The process of injecting or transferring the secretory protein from the bacterial cell to the host eukaryotic cell requires a membrane-associated ATPase. Certain species of pathogenic bacteria, including: *Salmonella*, *Shigella*, *Yersinia* and *Vibrio* exhibit type III secretion systems. The system is regulated by Ca2+ concentrations which regulate the opening and closing of gates present in the membrane by which the type III secretion system complexes can utilize for translocation. For example, in *Salmonella*, most commonly associated with *Enteritis salmonellosis*, or food poisoning, the bacteria injects a toxin, AvrA, that inhibits activation of the innate immune system of the host. The mechanism by which AvrA is injected involves exact and proper assembly of proteins which

promote invasion of the host cell. Misalignment or improper organization of proteins involved in the type III secretion system prevent injection of secretory substances from the pathogen into the host cell. Another pathogen, *Shigella*, which utilizes type III secretion systems is able to successfully carry out its infection by evading the immune system. The movement between neighboring cells and evading the immune system, enhances its ability to inject its secretory protein into the host cell.

Type IV Secretion Systems

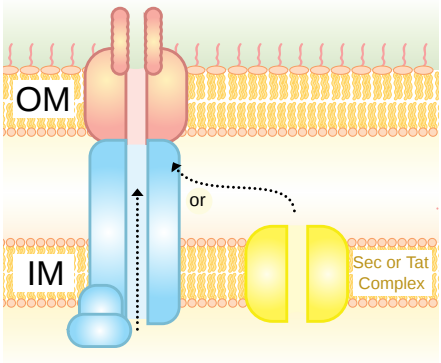

Figure: **Type IV Secretion System**: Type IV secretion systems are characterized by the ability to transfer material using machinery similar to the bacterial conjugation machinery.

Type IV secretion systems are characterized by the ability to transfer secretory molecules via a mechanism similar to the bacterial conjugation machinery. The type IV secretion systems can either secrete or receive molecules. The bacterial conjugation machinery allows transfer of genetic material to occur via direct cell-to-cell contact or by a bridge-like apparatus between the two cells. The type IV secretion system utilizes a process similar to this. However, the exact mechanism(s) this process utilizes is unknown but there is a general understanding.

This specific secretion system can transport both DNA and proteins. An example of a pathogenic bacteria that utilizes the type IV secretion system is *Helicobacter pylori*. *H. pylori*, most commonly associated with stomach ulcers, attaches itself to epithelial cells within the stomach, then via a type IV secretion system, injects a secretory molecule. The secretory molecule injected into the epithelial cells is an inflammation-inducing agent derived from their own cellular wall. The secretory molecule, peptidoglycan, is recognized by the host system as a foreign substance and activates expression of cytokines which promotes an inflammatory response. This inflammatory response of the stomach is a key characteristic of individuals with ulcers. Peptidoglycan is not the only secretory molecule transferred to the stomach epithelial cells but additional proteins, such as CagA, which function in disruption of host cell cellular activities can be transferred as well.

14.4D: Plasmids and Lysogeny

Learning Objectives

- Distinguish between plasmids and lysogeny in regards to pathogenecity

Plasmids

Plasmids are DNA molecules that are capable of replicating independently from the chromosomal DNA. Plasmids are often characterized by their circular appearance and double-strands; they also vary in size and number. Plasmids are present in the three major domains (Archaea, Bacteria and Eukarya) and are considered to be 'naked DNA'. 'Naked DNA' refers to a specific type of DNA which does not encode for genes promoting the transfer of genetic material to a new host. The plasmids are present within the cells as extra chromosomal genomes and are a common tool used in molecular biology to integrate new DNA into a host. In the field of molecular biology, plasmid DNA is often referred to as ' vectors ' due to their ability to transfer DNA between organisms. The use of plasmid DNA in molecular biology is considered to be recombinant DNA technology. In addition, plasmid DNA provides a mechanism by which horizontal gene transfer can occur, contributing to antibiotic resistance.

Horizontal gene transfer is a major mechanism promoting bacterial antibiotic resistance, as the plasmid DNA can transfer genes from one species of bacteria to another. The plasmid DNA which is transferred often has developed genes that encode for resistance against antibiotics. The ability to transfer this resistance from one species to another is increasingly becoming an issue in clinics for treatment of bacterial infections. The process of horizontal gene transfer can occur via three mechanisms: transformation, transduction and conjugation. Plasmid DNA transfer is associated with conjugation as the host-to-host transfer requires direct mechanical transfer. The advantages of plasmid DNA transfer allow for survival advantages.

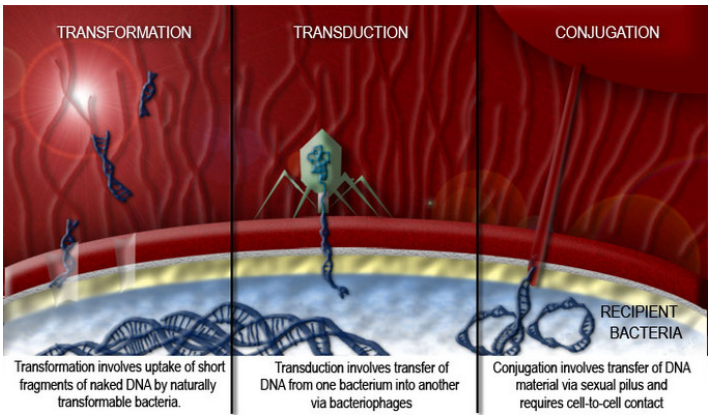

Figure: **Horizontal Gene Transfer**: There are three mechanisms by which horizontal gene transfer can occur. Specifically, the exchange of plasmid DNA falls under transformation.

Lysogeny

Lysogeny is the process by which a bacteriophageintegrates its nucleic acids into a host bacterium's genome. Lysogeny is utilized by viruses to ensure the maintenance of viral nucleic acids within the genome of the bacterium host. The virus displays the ability to infect the bacterium host and integrate its own genetic materials into the host bacterium genome. The bacteriophages newly integrated genetic material, called a prophage, is transferred to new bacterial daughter cells upon cell division. The prophage is integrated into the bacterium genome at this point. The lysogenic cycle is key to ensure the transmittance of bacteriophage nucleic acids to host bacterium's genome. Lysogeny is one of two major methods of viral reproduction utilized by viruses.

Lysogenic cycles are utilized by specific types of viruses to ensure viral reproduction, but they also need the second major method of viral reproduction, the lytic cycle, as well. The lytic cycle, considered the primary method of viral replication, results in the actual destruction of the infected cell. Upon destruction of the infected cell, the new viruses, which have developed after undergoing biosynthesis and maturation, are free to infect other cells. The lytic cycle is characterized by the breakdown of the bacteria cell wall intracellularly. The viruses cause disruption of the bacterial cell by producing enzymes which facilitate this process. An example of a virus which can promote the transformation of bacterium from a nontoxic to toxic strain via lysogeny is the CTXφ virus. Specifically, the bacterium, *Vibrio cholerae*, is transformed into a toxic strain upon infection with the bacteriophage. This bacterium is then able to produce a cholera toxin, the cause of the disease cholera.

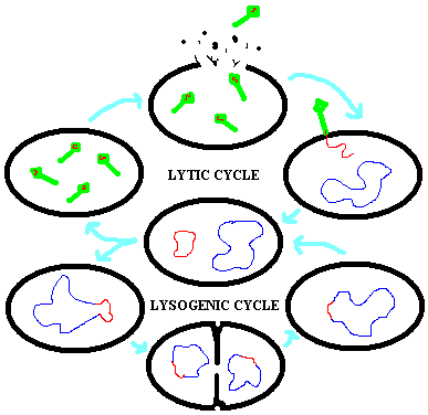

Figure: ***Lysogenic and lytic cycles****: Schematic of lysogenic and lytic cycle utilized by viruses to ensure viral reproduction.*

Key Points

- Plasmids are double-stranded circular forms of ‘naked DNA ‘.
- Plasmids are responsible for horizontal gene transfer which promotes the development of antibiotic resistance in bacterium.
- Lysogeny is a major method of viral reproduction characterized by the integration of viral nucleic acids in the bacterium genome.

Key Terms

- **bacteriophage**: A virus that specifically infects bacteria.
- **lysogeny**: the process by which a bacteriophage incorporates its nucleic acids into a host bacterium

14.4E: Siderophores

Learning Objectives

- Compare and contrast the role of various siderophores in pathogenecity, including: yersiniabactin, enterobactin and ferrichromes

Siderophores are specific types of molecules utilized by microorganisms to obtain iron from the environment. Specifically, in regards to pathogenicity, organisms that exhibit the ability to produce siderophores release these iron-specific molecules and scavenge iron from their hosts organisms. The siderophores are then utilized by the pathogen to obtain iron. Therefore, siderophores are chelating agents that bind the iron ions. The ability of pathogens to obtain iron from the host is essential for survival because the iron is limited in the host environment, in particular, the host tissues and fluids. The iron is used to allow for formation of soluble ferric ion (Fe^{3+}) complexes that are necessary for maintenance of homeostatic mechanisms within the pathogen.

The ability to form water soluble Fe^{3+} complexes is a key component to the active transport of the Fe-siderophore complex across the cellular membrane. In iron deficient environments, the siderophores are released and allow for the formation of water soluble-Fe^{3+} complexes to increase iron acquisition. The complexes then generally bind to the cellular membrane using cell specific receptors. They are transported across the membrane utilized for the necessary processes. However, there are differences in the mechanisms employed by various sideorophobes to obtain iron and the specific type of siderophore utilized varies.

Yersiniabactin

The pathogenic bacteria, *Yersinia pestis*, *Yersinia pseduotuberculosis*, and *Yersinia enterocolitica* have the ability to produce a siderophore called yersiniabactin. Pathogenic yersinia is responsible for numerous diseases including the bubonic plague. The ability of pathogenic Yersinia to establish and spread disease is based on its ability to obtain iron for fundamental cellular processes. In areas of low iron, the organism will release yersiniabactin to form Fe^{3+} complexes. The yersiniabactin-Fe^{3+} complex will then bind to the outer membrane of the bacteria based on specific receptor recognition. The complex is then translocated through the membrane via membrane-embedded proteins and iron is released from the yersiniabactin. The iron will then be utilized in numerous cellular processes.

Enterobactin

Pathogenic bacteria such as *Escherichia coli* and *Salmonella typhimurium* have the ability to produce a siderophore called enterobactin. This specific type of siderophore is the strongest identified siderophore, to date, with an extremely high binding affinity to Fe^{3+}. Upon a decrease in iron, the bacterial cells release enterobactin which forms a complex with Fe^{3+}. The complex is then transported intracellularly via an ATP-binding cassette transporter. Once the enterobactin-Fe^{3+} complex arrives intracellularly, it is necessary to remove the Fe^{3+} from the complex. Due to the high-binding affinity of enterobactin, the bacteria require a highly specific enzyme, ferrienterobactin esterase, to cleave the iron from the complex. The iron released from the complex will then be utilized in metabolic processes.

Ferrichrome

Another type of siderophore produced by pathogenic fungi includes a ferrichrome. Fungi that have been shown to produce ferrichromes include those in the genera Aspergillus, Ustilago, and Penicillum. The ferrichrome allows for formation of a ferrichrome-iron complex which can then interact with a protein receptor on the cell surface. The ferrichrome promotes iron transport within the organism to allow metabolic processes to occur.

The discovery and identification of siderophores have allowed for the development of treatments targeting these siderophore-iron complexes. By targeting these complexes, the pathogenic microorganisms can be targeted by inhibiting necessary cellular processes. The production and importance of these siderophores to pathogenic organisms is key to their survival.

Key Points

- Siderophore – iron complexes are necessary for iron acquisition to various pathogenic organisms for metabolic processes.
- The types of siderophores produced are species specific and exhibit different properties.

- The siderophores are necessary to obtain iron by binding to cell surfaces and transporting the siderophore-iron complexes intracellularly.
- Siderophores are produced in environments that have low iron concentration, such as host tissues and fluids. They are considered advantageous to pathogenic organisms.

Key Terms

- **siderophore**: Any medium-sized molecule that has a high specificity for binding or chelating iron; they are employed by microorganisms to obtain iron from the environment
- **chelating agent**: A compound that reacts with a metal ion to produce a chelate.

SECTION OVERVIEW

14.5: Surviving Within the Host and Exiting the Host

Topic hierarchy

14.5A: Intracellular Pathogens

14.5B: Extracellular Immune Avoidance

14.5C: Regulating Virulence

14.5D: Portals of Exit

This page titled 14.5: Surviving Within the Host and Exiting the Host is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

14.5A: Intracellular Pathogens

Learning Objectives

- Recognize examples of intracellular pathogens

A pathogen or infectious agent is a microorganism such as a virus, bacterium, prion, or fungus that causes disease in its host. The host may be an animal, a plant, or even another microorganism. Not all pathogens are undesirable to humans. In entomology, pathogens are one of the "Three P's" (predators, pathogens, and parasitoids) that serve as natural or introduced biological controls to suppress arthropod pest populations.

There are several types of intracellular pathogens. Pathogenic viruses are mainly those of the families of Adenoviridae, bacteria Picornaviridae, Herpesviridae, Hepadnaviridae, Flaviviridae, Retroviridae, Orthomyxoviridae, Paramyxoviridae, Papovaviridae, Polyomavirus, Rhabdoviridae, and Togaviridae. Viruses typically range between 20 to 300 nanometers in length. Although the vast majority of bacteria are harmless or beneficial, a few pathogenic bacteria can cause infectious diseases. Bacteria can often be killed by antibiotics because the cell wall in the outside is destroyed, expelling the DNA out of the body of the pathogen, therefore making the pathogen incapable of producing proteins, so it dies. They typically range between 1 and 5 micrometers in length.

Figure: ***Stanley Prusiner****: Stanley Prusiner discovered prions, which are a class of infectious self-reproducing pathogens primarily or solely composed of protein.*

Pathogenic fungi comprise a eukaryotic kingdom of microbes that are usually saprophytes but can cause diseases in humans, animals, and plants. Fungi are the most common cause of diseases in crops and other plants. The typical fungal spore size is 1 to 40 micrometers in length.

Some eukaryotic organisms, such as protists and helminths, cause disease. According to the prion theory, prions are infectious pathogens that do not contain nucleic acids. These abnormally-folded proteins are found characteristically in some diseases such as scrapie, bovine spongiform encephalopathy (mad cow disease), and Creutzfeldt–Jakob disease. Although prions fail to meet the requirements laid out by Koch's postulates, the hypothesis of prions as a new class of pathogen led Stanley B. Prusiner to receive the Nobel Prize in Physiology or Medicine in 1997.

Key Points

- The host may be an animal, a plant, or even another microorganism.
- Pathogenic viruses are mainly those of the families of Adenoviridae, bacteria Picornaviridae, Herpesviridae, Hepadnaviridae, Flaviviridae, Retroviridae, Orthomyxoviridae, Paramyxoviridae, Papovaviridae, Polyomavirus, Rhabdoviridae, and Togaviridae.
- Although the vast majority of bacteria are harmless or beneficial, a few pathogenic bacteria can cause infectious diseases.

Key Terms

- **prion**: A self-propagating misfolded conformer of a protein that is responsible for a number of diseases that affect the brain and other neural tissue.
- **pathogen**: Any organism or substance, especially a microorganism, capable of causing disease, such as bacteria, viruses, protozoa, or fungi. Microorganisms are not considered to be pathogenic until they have reached a population size that is large enough to cause disease.

14.5A: Intracellular Pathogens is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.5B: Extracellular Immune Avoidance

A pathogen's success depends on its ability to evade the host's immune responses.

Learning Objectives

- List the mechanisms that bacteria use for intracellular pathogenesis

Key Points

- Bacteria usually overcome physical barriers by secreting enzymes to digest the barrier in the manner of a type II secretion system.
- Some pathogens avoid the immune system by hiding within the cells of the host, a process referred to as intracellular pathogenesis.
- Other pathogens invade the body by changing the non-essential epitopes on their surface rapidly, while keeping the essential epitopes hidden.

Key Terms

- **pathogen**: Any organism or substance, especially a microorganism, capable of causing disease, such as bacteria, viruses, protozoa, or fungi. Microorganisms are not considered to be pathogenic until they have reached a population size that is large enough to cause disease.
- **biofilm**: A thin film of mucus created by and containing a colony of bacteria and other microorganisms.
- **antigenic variation**: The mechanism by which an infectious organism changes its surface proteins in favor of circumventing a host immune response.

Extracellular Immune Avoidance

A pathogen's success depends on its ability to evade the host's immune responses. Thus, pathogens have evolved several methods that allow them to successfully infect a host by evading the immune system's detection and destruction. Bacteria usually overcome physical barriers by secreting enzymes that digest the barrier in the manner of a type II secretion system. They also use a type III secretion system that allows bacteria to insert a hallow tube, which provides proteins a direct route to enter the host cell. These proteins often shutdown the defenses of the host.

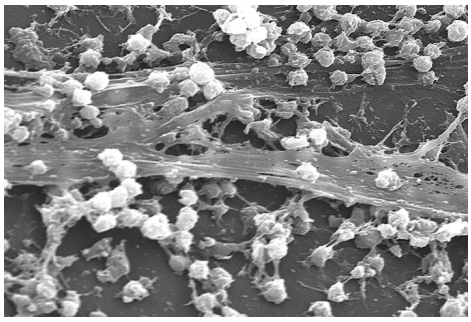

Figure: **Staphylococcus aureus biofilm**: Staphylococcus aureus forming a biofilm on a catheter.

Some pathogens avoid the immune system by hiding within the cells of the host, a process referred to as intracellular pathogenesis. The pathogen hides inside the host cell where it is protected from direct contact with the complement, antibodies, and immune cells. A lot of pathogens release compounds that misdirect or diminish the host's immune response. Some bacteria even form biofilms which protect them from the proteins and cells of the immune system. Many successful infections often involve biofilms. Some bacteria create surface proteins, such as Streptococcus, that will bind to antibodies making them ineffective.

Other pathogens invade the body by changing the non-essential epitopes on their surface rapidly while keeping the essential epitopes hidden. This is referred to as antigenic variation. HIV rapidly mutates so the proteins that are on its viral envelope, which are essential for its entry into the host's target cell, are consistently changing. The constant change of these antigens is why vaccines have not been created. Another common strategy that is used is to mask antigens with host molecules in order to evade detection by the immune system. With HIV, the envelope covering the viron is created from the host cell's outermost membrane making it difficult for the immune system to identify as a non-self structure.

14.5B: Extracellular Immune Avoidance is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.5C: Regulating Virulence

Virulence regulation is a combination of the specific traits of the pathogen and the evolutionary pressures that lead to virulent traits.

Learning Objectives

- Compare and contrast the hypotheses that explain why a pathogen evolves as it does: Trade-Off, Short-Sighted Evolution and Coincidental Evolution Hypotheses

Key Points

- Virulence is the degree of pathogenicity within a group or species of parasites as indicated by case fatality rates and/or the ability of the organism to invade the tissues of the host.
- The ability of a microorganism to cause disease is described in terms of the number of infecting bacteria, the route of entry into the body, the effects of host defense mechanisms, and intrinsic characteristics of the microorganism called virulence factors.
- Optimal virulence increases with horizontal transmission (between non-relatives) and decreases with vertical transmission (from parent to child).
- The pathogen population can evolve once it is in the host.
- The three main hypotheses about why a pathogen evolves as it does are the Trade-Off Hypothesis, the Short-Sighted Evolution Hypothesis, and the Coincidental Evolution Hypothesis.

Key Terms

- **virulence**: The degree of pathogenicity within a group or species of parasites as indicated by case fatality rates and/or the ability of the organism to invade the tissues of the host and it is determined by virulence factors.

Virulence is the degree of pathogenicity within a group or species of parasites as indicated by case fatality rates and/or the ability of the organism to invade the tissues of the host. The pathogenicity of an organism – its ability to cause disease – is determined by its virulence factors. In an ecological context, virulence can be defined as the host's parasite-induced loss of fitness. Virulence can be understood in terms of proximate causes—those specific traits of the pathogen that help make the host ill—and ultimate causes—the evolutionary pressures that lead to virulent traits occurring in a pathogen strain.

The ability of a microorganism to cause disease is described in terms of the number of infecting bacteria, the route of entry into the body, the effects of host defense mechanisms, and intrinsic characteristics of the microorganism called virulence factors. Host-mediated pathogenesis is often important because the host can respond aggressively to infection with the result that host defense mechanisms do damage to host tissues while the infection is being countered.

According to evolutionary medicine, optimal virulence increases with horizontal transmission (between non-relatives) and decreases with vertical transmission (from parent to child). This is because the fitness of the host is bound to the fitness in vertical transmission but is not so bound in horizontal transmission.The pathogen population can evolve once it is in the host. There are three main hypotheses about why a pathogen evolves as it does. These three models help to explain the life history strategies of parasites, including reproduction, migration within the host, virulence, etc.

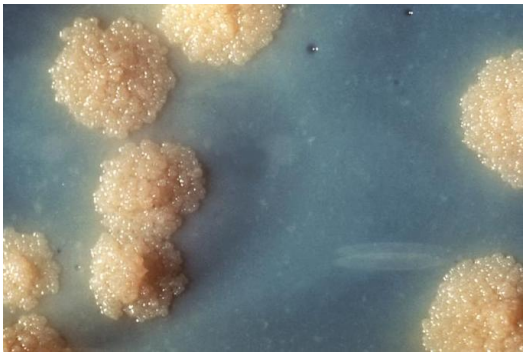

Figure: **Tuberculosis Culture**: The bacteria Mycobacterium tuberculosis can evolve to subvert the protection offered by immune defenses. This close-up reveals this organism's colonial morphology. Note the colorless rough surface, which are typical morphologic characteristics seen in Mycobacterium tuberculosis colonial growth. Macroscopic examination of colonial growth patterns is still one of the ways microorganisms are often identified.

1. Trade-off hypothesis argues that pathogens tend to evolve toward ever decreasing virulence because the death of the host (or even serious disability) is ultimately harmful to the pathogen living inside. For example, if the host dies, the pathogen population inside may die out entirely. Therefore, it was believed that less virulent pathogens that allowed the host to move around and interact with other hosts should have greater success reproducing and dispersing. But this is not necessarily the case. Pathogen strains that kill the host can increase in frequency as long as the pathogen can transmit itself to a new host, whether before or after the host dies. The evolution of virulence in pathogens is a balance between the costs and benefits of virulence to the pathogen.
2. Short-sighted evolution hypothesis suggests that the traits that increase reproduction rate and transmission to a new host will rise to high frequency within the pathogen population. These traits include the ability to reproduce sooner, reproduce faster, reproduce in higher numbers, live longer, survive against antibodies, or survive in parts of the body the pathogen does not normally infiltrate. These traits typically arise due to mutations, which occur more frequently in pathogen populations than in host populations, due to the pathogens' rapid generation time and immense numbers. After only a few generations, the mutations that enhance rapid reproduction or dispersal will increase in frequency. The same mutations that enhance the reproduction and dispersal of the pathogen also enhance its virulence in the host, causing much harm (disease and death). If the pathogen's virulence kills the host and interferes with its own transmission to a new host, virulence will be selected against. But as long as transmission continues despite the virulence, virulent pathogens will have the advantage.
3. Coincidental evolution hypothesis argues that some forms of pathogenic virulence did not co-evolve with the host. For example, tetanus is caused by the soil bacterium Clostridium tetani. After C. tetani bacteria enter a human wound, the bacteria may grow and divide rapidly, even though the human body is not their normal habitat. While dividing, C. tetani produce a neurotoxin that is lethal to humans. But it is selection in the bacterium's normal life cycle in the soil that leads it to produce this toxin, not any evolution with a human host. The bacterium finds itself inside a human instead of in the soil by mere happenstance. We can say that the neurotoxin is not directed at the human host.

14.5C: Regulating Virulence is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.5D: Portals of Exit

Pathogens must have a way to be transmitted from one host to another to ensure their species' survival.

Learning Objectives

- Distinguish between horizontal and vertical disease transmission

Key Points

- Transmission of microorganisms can happen directly from one person to another by: droplet contact, direct physical contact, indirect physical contact, airborne transmission, or fecal-oral transmission.
- Transmission can also be indirect, via another organism, either a vector or an intermediate host.
- Disease can also be transmitted in two ways: horizontally from one individual to another in the same generation and vertically from parent to offspring, such as through perinatal transmission.

Key Terms

- **transmission**: Transmission is the passing of a communicable disease from an infected host individual or group to a conspecific individual or group, regardless of whether the other individual was previously infected.

Transmission is the passing of a communicable disease from an infected host individual or group to a conspecific individual or group by one or more of the following means: droplet contact, direct physical contact, indirect physical contact, airborne transmission, and fecal-oral transmission.

Transmission can also be indirect, via another organism. Indirect transmission could involve zoonoses or, more typically, larger pathogens like macroparasites with more complex life cycles. Disease can be directly transmitted in two ways. The first is horizontal disease transmission – from one individual to another in the same generation by either direct contact, or indirect contact air, such as via a cough or sneeze. The second is vertical disease transmission – passing a disease causing agent vertically from parent to offspring, such as through perinatal transmission.

Pathogens must have a way to be transmitted from one host to another to ensure their species ' survival. Infectious agents are generally specialized for a particular method of transmission. For example, a virus or bacteria that causes its host to develop coughing and sneezing symptoms has a great survival advantage – it is much more likely to be ejected from one host and carried to another. This is also the reason that many microorganisms cause diarrhea.

The respiratory route is a typical mode of transmission among many infectious agents. If an infected person coughs or sneezes on another person, the microorganisms, suspended in warm, moist droplets, may enter the body through the nose, mouth, or eye surfaces. Diseases that are commonly spread by coughing or sneezing include: bacterial meningitis and chickenpox.

Figure: **Sneezing**: Sneezing can spread disease by launching disease vectors into the air.

When viruses are shed by an infected person through coughing or sneezing into the air, the mucus coating on the virus starts to evaporate. Once this mucus shell evaporates the remaining viron is called a droplet nucleus or quanta. The mucus evaporation rate is determined by the temperature and humidity inside the room. The lower the humidity, the quicker the mucus shell evaporates thus allowing the droplet nuclei to stay airborne and not drop to the ground. The low indoor humidity levels in wintertime buildings ensure that higher levels of droplet nuclei will survive: droplet nuclei are so microscopic that they are able to stay airborne indefinitely on the air currents present within indoor spaces. When an infected person coughs or sneezes, a percentage of their

viruses will become droplet nuclei. If these droplet nuclei gain access to the eyes, nose, or mouth of an uninfected person (known as a susceptible) – either directly, or indirectly by touching a contaminated surface – then the droplet nuclei may penetrate into the deep recesses of their lungs. Viral diseases that are commonly spread by coughing or sneezing droplet nuclei include the common cold and influenza.

Direct fecal-oral transmission is rare for humans at least. More common are the indirect routes: foodstuffs or water become contaminated and the people who eat and drink them become infected. This is the typical mode of transmission for infectious agents such as cholera, hepatitis A, and polio.

Sexual transmission refers to any disease that can be caught during sexual activity with another person, including vaginal or anal sex or (less commonly) through oral sex. Transmission is either directly between surfaces in contact during intercourse or from secretions which carry infectious agents that get into the partner's blood stream through tiny tears in the penis, vagina, or rectum. Some diseases transmissible by the sexual route include: HIV/AIDS and chlamydia.

Sexually transmitted diseases such as HIV and Hepatitis B are thought to not normally be transmitted through mouth-to-mouth contact, although it is possible to transmit some STDs between the genitals and the mouth during oral sex. In the case of HIV this possibility has been established. It is also responsible for the increased incidence of herpes simplex virus 1 (which is usually responsible for oral infections) in genital infections and the increased incidence of the type 2 virus (more common genitally) in oral infections.

Diseases that can be transmitted by direct contact are called contagious. These diseases can also be transmitted by sharing a towel (where the towel is rubbed vigorously on both bodies) or items of clothing in close contact with the body (socks, for example) if they are not washed thoroughly between uses.

SECTION OVERVIEW

14.6: Pathogenicity and Other Microbes

Topic hierarchy

14.6A: Fungi

14.6B: Protozoa

14.6C: Helminths

14.6D: Algae

This page titled 14.6: Pathogenicity and Other Microbes is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

14.6A: Fungi

A fungus is a member of a large group of eukaryotic organisms that includes microorganisms that exhibit pathogenicity.

Learning Objectives

- Give examples of pathogenic fungi

Key Points

- There are various examples of pathogenic fungi including but not limited too: Candida species, Aspergillosis, Cryptococcus, Histoplasma, Pneumocystis and Stachybotrys.
- Many fungal species produce bioactive compounds called mycotoxins, such as alkaloids and polyketides that are toxic to animals including humans, contributing to pathogenecity and disease.
- The study of pathogenic fungi is referred to as a medical mycology.

Key Terms

- **symbiont**: An organism that lives in a symbiotic relationship; a symbiote.
- **mycotoxin**: Any substance produced by a mold or fungus that is injurious to vertebrates upon ingestion, inhalation, or skin contact.
- **opportunist**: when an organism takes advantage of any opportunity to advance its own situation.

A fungus is a member of a large group of eukaryotic organisms that includes microorganisms such as yeasts and molds. These organisms are classified as kingdom Fungi, separate from plants, animals, and bacteria. Fungi have a worldwide distribution and cangrow in a wide range of habitats, including extreme environments such as deserts or areas with high salt concentrations or ionizing radiation, as well as in deep sea sediments. Most fungi are inconspicuous because of the small size of their structures and their cryptic lifestyles in soil, on dead matter, and as symbionts of plants, animals, or other fungi. Fungi perform an essential role in the decomposition of organic matter and have fundamental roles in nutrient cycling and exchange. Many fungal species produce bioactive compounds called mycotoxins, such as alkaloids and polyketides that are toxic to animals including humans, contributing to pathogenecity and disease.

The study of pathogenic fungi is referred to as a medical mycology. There are various examples of pathogenic fungi including but not limited too: Candida species, Aspergillosis, Cryptococcus, Histoplasma, Pneumocystis and Stachybotrys.

Candida species are commonly known to cause opportunist infections in immunocompromised hosts. The immunocompromised hosts that commonly become infected with Candida include transplant patients, cancer patients and AIDS sufferers. Candida infections are difficult to treat and can result in systemic infections leading to death.

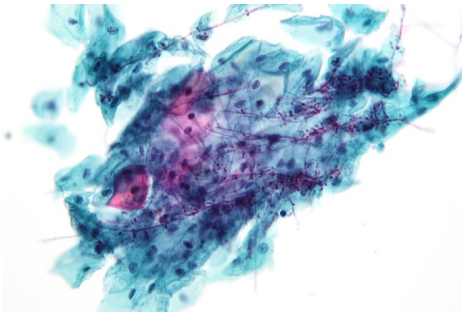

Figure: **Candida**: A Candida infection seen from a pap test specimen.

One of the most commons fungal pathogenic species includes Aspergillus strains, specifically Aspergillus fumigatus and Aspergillus flavus. Aspergillus can cause disease via production of mycotoxins, induction of allergic responses and through localized or systemic infections. Aspergillus flavus specifically produces aflatoxin which is both a toxin and carcinogen whereas Aspergillus fumigatus causes allergic disease. Symptoms of diseases caused by Aspergillus can include fever, cough, chest pain or breathlessness.

Cryptococcus neoformans causes severe forms of meningitis and meningo-encephalitis in patients with HIV infection and AIDS. Cryptococcus species live in the soil and do not cause disease in humans thus, Cryptococcus neoformans is the major pathogen in

both human and animals.

Histoplasma capsulatum results in the formation of histoplasmosis in humans, dogs and cats. This specific fungus is endemic in certain areas of the United States and infection is due to inhaling contaminated air.

Pneumocystis jirovecii results in the formation of pneumonia in individuals with weakened immune systems including premature children, the elderly and AIDS patients.

Stachybotrys chartarum, also referred to as black mold, causes respiratory damage and severe headaches. This type of black mold frequently occurs in households that are chronically damp.

14.6A: Fungi is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.6B: Protozoa

Protozoa are a diverse group of unicellular eukaryotic organisms, many of which can cause disease.

Learning Objectives

- Compare and contrast the proliferative and dormant stages in pathogenic protozoa and the diseases protazoa cause

Key Points

- Examples of human diseases caused by protozoa are: malaria, amoebiasis, giardiasis, toxoplasmosis, cryptosporidiosis, trichomoniasis, Chagas disease, leishmaniasis, and dysentery.
- The life stages of these protozoa play a major role in their ability to function as pathogens and infect various hosts.
- Protozoa were regarded as the partner-group of protists to protophyta, which have plant-like behavior (e.g., photosynthesis). In general, protozoa are referred to as animal-like protists because they are capable of movement, or motile.
- Some protozoa are human parasites, causing diseases.

Key Terms

- **trophozoite**: A protozoan in the feeding stage of its life cycle.
- **protozoa**: Protozoa are a diverse group of unicellular eukaryotic organisms, many of which are motile. Originally, protozoa had been defined as unicellular protists with animal-like behavior, e.g., movement. Protozoa were regarded as the partner group of protists to protophyta, which have plant-like behavior, e.g., photosynthesis.
- **dormant cyst**: A resting or dormant stage of a microorganism
- **cyst**: a pouch or sac without opening, usually membranous and containing morbid matter, which develops in one of the natural cavities or in the substance of an organ

Protozoa (or protozoans) are a diverse group of unicellular eukaryotic organisms, many of which are motile. Originally, protozoa had been defined as unicellular protists with animal-like behavior (e.g., movement). Protozoa were regarded as the partner-group of protists to protophyta, which have plant-like behavior (e.g., photosynthesis). In general, protozoa are referred to as animal-like protists because they are capable of movement, or *motile*. While there is no exact definition for the term protozoa, it often refers to a unicellular heterotrophic protist, such as the amoebas and ciliates.

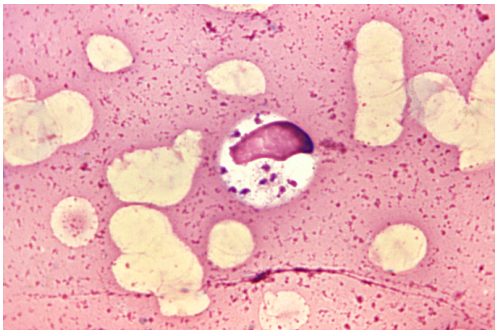

Figure: **Leishmania donovani**: Leishmania donovani, (a species of protozoa) in a bone marrow cell.

Protozoa can display pathogenicity and are the cause of various diseases. The life stages of these protozoa play a major role in their ability to function as pathogens and infect various hosts. Some protozoa have life stages alternating between proliferative stages (e.g., trophozoites) and dormant cysts. As cysts, protozoa can survive harsh conditions, such as exposure to extreme temperatures or harmful chemicals, or long periods without access to nutrients, water, or oxygen for a period of time. The ability of protozoa to thrive under extreme environments contributes to their ability to evade immune system responses, drug therapies and survive for prolonged periods of time before infection. Being a cyst enables parasitic species to survive outside of a host, and allows their transmission from one host to another. When protozoa are in the form of trophozoites they actively feed. The conversion of a trophozoite to cyst form is known as encystation, while the process of transforming back into a trophozoite is known as excystation.

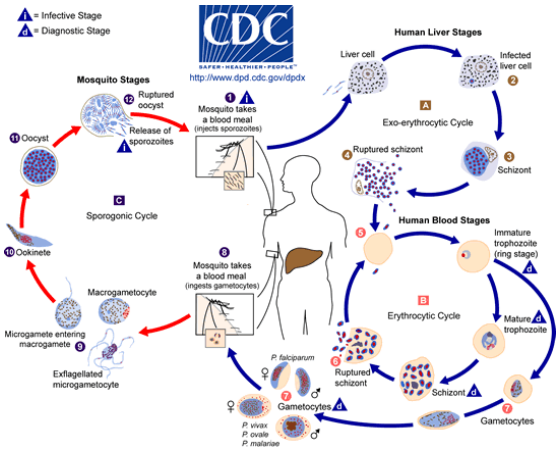

Figure: **Malaria Life Cycle**: Example of a life cycle promoting pathogenicity of a protozoa, specifically the malaria parasite.

Protozoa such as the malaria parasites (Plasmodium spp.), trypanosomes, and leishmania are also important as parasites and symbionts of multicellular animals. Examples of human diseases caused by protozoa are: malaria, amoebiasis, giardiasis, toxoplasmosis, cryptosporidiosis, trichomoniasis, Chagas disease, leishmaniasis, and dysentery. The life cycle of protozoan are successful based on successful transmission between hosts and host and environment. Infection and disease by protozoan parasites are often times associated with developing countries with poor hygiene and sanitation conditions that may promote transmission of these protozoa.

14.6B: Protozoa is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.6C: Helminths

Parasitic worms, often referred to as helminths, are a division of eukaryotic parasites.

Learning Objectives

- List the four groups of parasitic worms (helminths), routes of transmission and risk factors

Key Points

- Helminths are worm-like organisms that live and feed off of living hosts, receiving nourishment and protection while disrupting the nutrient absorption of their hosts, which causes weakness and disease.
- Helminths that live inside the digestive tract are called intestinal parasites.
- Helminths often find their way into a host through contaminated food or water, soil, mosquito bites, and sexual acts.
- Response to worm infection in humans is a Th2 response in the majority of cases.

Key Terms

- **helminth**: A parasitic roundworm or flatworm.
- **lymphatic system**: In mammals, including humans, a network of lymph vessels and lymph nodes that transport fluid, fats, proteins, and lymphocytes to the bloodstream as lymph, and remove microorganisms and other debris from tissues.

Parasitic worms, often referred to as helminths, are a division of eukaryotic parasites. They are worm-like organisms that live and feed off of living hosts, receiving nourishment and protection while disrupting the nutrient absorption of their hosts, which causes weakness and disease. Those that live inside the digestive tract are called intestinal parasites. They can live inside humans as well as other animals.

Figure: **Hookworms**: The hookworms attached to the intestinal mucosa.

Parasitic worms belong to four groups:

- Monogeneans
- Cestodes (tapeworms)
- Nematodes (roundworms)
- Trematodes (flukes)

Helminths often find their way into a host through contaminated food or water, soil, mosquito bites, and even sexual acts. Poorly washed vegetables eaten raw may contain eggs of nematodes such as Ascaris, Enterobius, Thichuris, and or cestodes such as Taenia, Hymenolepis, and Echinococcus. Plants may also be contaminated with fluke metacercaria, such as Fasciola. Schistosomes and nematodes such as hookworms (Ancylostoma an Necator) and Strongyloides can penetrate the skin. Finally, Wuchereria, Onchocerca, and Dracunculus are transmitted by mosquitoes and flies.

Populations in the developing world are at particular risk for infestation with parasitic worms. Risk factors include the following:

- Inadequate water treatment
- Use of contaminated water for drinking, cooking, washing food, and irrigation
- Undercooked food of animal origin
- Walking barefoot

Simple measures—such as use of shoes, soaking vegetables with 1.5% bleach, adequate cooking of foods (not microwaving), and sleeping under mosquito-proof nets—can have a strong impact on prevention.

Response to worm infection in humans is a Th2 response in the majority of cases. Inflammation of the gut may also occur, resulting in cyst-like structures forming around the egg deposits throughout the body. The host's lymphatic system is also increasingly taxed the longer helminths propagate, as they excrete toxins after feeding. These toxins are released into the intestines and absorbed by the host's bloodstream, making the host susceptible to more common diseases such as seasonal viruses and bacterial infections.

Parasitic worms have been used as a medical treatment for various diseases, particularly those involving an overactive immune response. As humans have evolved with parasitic worms, proponents argue that they are needed for a healthy immune system. Scientists are looking to see if there is a connection between the prevention and control of parasitic worms and the increase in allergies such as hay-fever in developed countries. Parasitic worms may be able to damp down the immune system of their host, making it easier for them to live in the intestine without coming under attack. This may be one mechanism for their proposed medicinal effect.

14.6C: Helminths is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

14.6D: Algae

Algae can act as pathogens like any other microbe.

Learning Objectives

- Discuss the various types of pathogenic algae

Key Points

- While algal blooms can lead to negative consequences, the effect of an algal bloom are often indirect, the alga is not directly infecting a host.
- Cephaleuros are a genus of parasitic alga which infect plants, causing red rust, which affects many commercial crops that humans consume.
- Prototheca are a type of green alga that lack chlorophyll, that can infect mammals including humans causing the disease protothecosis.
- To some degree the distribution of algae is subject to floristic discontinuities caused by geographical features, such as Antarctica, long distances of ocean, or general land masses.

Key Terms

- **thalloid**: Of a plant, alga, or fungus lacking complex organization, especially lacking distinct stems, roots, or leaves.
- **alga**: any of many aquatic photosynthetic organisms, whose size ranges from a single cell to giant kelps and whose form is very diverse
- **basionym**: An earlier valid scientific name of a species that has since been renamed and from which the new name is partially derived.

Figure: **Cephaleuros virescens**: Infestation of the algal leaf spot (Cephaleuros virescens) on ther southern magnolia (Magnolia grandiflora); Green-orange algal spots or “green scruf” on leaf surface. The grayish-white and darker “crusts” are lichens of the genus Strigula resulting from fungal colonization of the alga.

Algae, are not normally considered common pathogens. Algal blooms are often associated with negative impacts on humans and the surrounding environment in which they occur. A harmful algal bloom (HAB) is an algal bloom that causes negative impacts to other organisms via production of natural toxins, mechanical damage to other organisms, or by other means. HABs are often associated with large-scale marine mortality events and have been associated with various types of shellfish poisonings. However, the damage to other organisms is not due to the algae infecting a host but rather indirectly excreting a toxin, or in some cases blocking out light or competing for resources.

However notable examples of algae acting as pathogens are known. For example Cephaleuros which is a genus of parasitic thalloid alga comprising approximately 14 species. Its common name is red rust. Chrooderma is its basionym. Specimens can reach around 10 mm in size. Dichotomous branches are formed. The alga is parasitic on some important economic plants of the tropics and

subtropics such as tea, coffee, mango and guava causing damage limited to the area of algal growth on leaves (algal leaf spot), or killing new shoots, or disfiguring fruit. Members of the genera may also grow with a fungus to form a lichen that does not damage the plants.

Examples of algae acting as a mammalian pathogen are known as well, notably the disease Protothecosis. Protothecosis is a disease found in dogs, cats, cattle, and humans caused by a type of green alga known as Prototheca that lacks chlorophyll. It and its close relative Helicosporidium are unusual in that they are actually green algae that have become parasites.The two most common species are Prototheca wickerhamii and Prototheca zopfii. Both are known to cause disease in dogs, while most human cases are caused by P. wickerhami. Prototheca is found worldwide in sewage and soil. Infection is rare despite high exposure, and can be related to a defective immune system. In dogs, females and Collies are most commonly affected. The first human case was identified in 1964 in Sierra Leone.

SECTION OVERVIEW

15.1: Diagnosing Microbial Diseases

Topic hierarchy

15.1A: Diagnosing Microbial Diseases

15.1: Diagnosing Microbial Diseases is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.1A: Diagnosing Microbial Diseases

Learning Objectives

- Compare and contrast the various methods used to diagnose microbial diseases: microbial culture, microscopy, biochemical tests and molecular diagnostics

The process of identifying infectious diseases is complex and requires identification of the agent through direct or indirect means. In regards to many microbial diseases, it is often difficult to diagnose an individual based on clinical presentation. As such, further testing is required. The methods used to diagnose microbial disease include microbial culture, microscopy, biochemical tests, and molecular diagnostics.

Microbial Culture

The first tool in diagnosing microbial disease is microbial cultures. The sample is obtained from the infected individual and tested for the presence of an infectious agent or microbe that is capable of growing in specific media. It is critical to isolate the infectious agent in a pure culture containing *only* the infectious bacteria. The most common method to isolate individual cells and produce a pure culture is to prepare a streak plate. The streak plate method is a way to physically separate the microbial population, and is done by spreading the inoculate back and forth with an inoculating loop over the solid agar plate. Upon incubation, colonies will arise and single cells will have been isolated from the biomass.

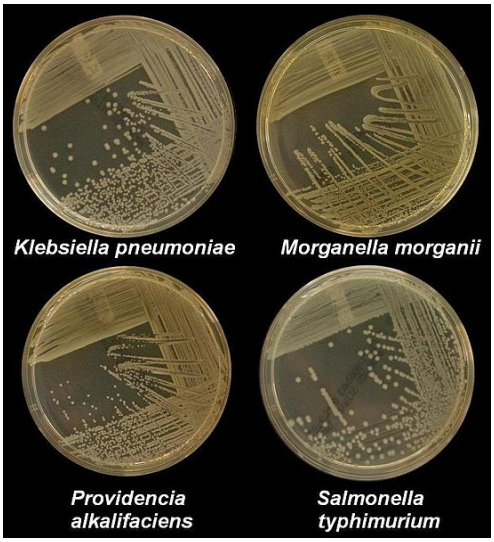

Figure: **Common bacteria that cause disease in humans**: This represents four nutrient agar plates with various bacterial species represented. The use of plates for microbial culture aid in identification of microbes based on size, shape, colony formation and nutrient requirement.

It is established that most pathogenic bacteria can be grown on nutrient agar, and the addition or subtraction of specific nutrients can aid in further identification. The use of microbial cultures is common to help in the clinical identification of pathogenic microbes. However, there are specific classes of microbe that require culture within live animals. The bacteria *Mycobacterium leprae* is such a microbe, as it can only be cultured in animals.

There are also specific types of infectious agents that require the use of xenodiagnosis to promote growth. The parasite responsible for Chagas disease, *Trypanosoma cruzi*, requires a vector for diagnosis. For example, an uninfected reduviid bug is used to feed from an individual suspected of having Chagas. Once the blood is taken, the bug will be analyzed for *Trypanosoma cruzi* growth.

Microscopy

An additional tool utilized for microbial disease diagnosis is microscopy. To ensure proper identification of a pathogen, microscopy, in combination with biochemical staining techniques, is often used to ensure definitive identification. Biochemical staining techniques that are used to aid in identification include stains such as Giemsa, crystal violet, and other stains that help distinguish between gram positive and gram negative.

Biochemical Tests

Biochemical tests are also used to help in microbial disease diagnosis. They will specifically test for metabolic and enzymatic products that an infectious agent may use. Biochemical tests will also test for fermentation products, acids, alcohol or gases that may be products of metabolic pathways.

Molecular Diagnostics

The identification of infectious agents is now often done by using molecular based techniques such as polymerase chase reactions (PCR). PCR allows for the identification and testing for nucleic acids which are specific to the infectious agent. The need of an infectious agent to amplify its own nucleic acids to ensure successful infection has allowed us to use PCR to detect the presence of these nucleic acids. In combination with the advances made in genome sequencing, the tools and information needed to establish PCR as the gold-standard for diagnosing microbial disease is present.

Key Points

- Microbial culture is a technique utilized to help in microbial disease diagnosis and can include nutrient plates, liquid cultures, culture within live animals, and use of a vector as well.
- Microscopy is an additional technique used to identify pathogenic microbes by utilizing specialized stains to help identification and characterization based on specific principes.
- Biochemical tests are used to help identify pathogenic microbes and focus on metabolic or enzymatic products that are specific to microbes based on their metabolic pathways.

Key Terms

- **xenodiagnosis**: The diagnosis of an infectious disease by exposure to a vector of that disease and performing analysis on the vector for the disease.

15.10A: Chagas Disease (American Trypanosomiasis)

Learning Objectives

- Describe the life cycle of Trypanosoma cruzi

Chagas disease, also known as American trypanosomiasis, is caused by the parasite *Trypanosoma cruzi*. It is transmitted to humans via the reduviid bug (the “kissing bugs”), and is therefore characterized as a zoonotic disease.

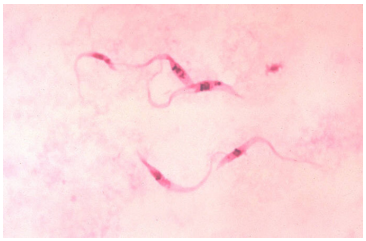

Figure: **Trypanasoma cruzi**

Chagas disease is similar to African sleeping sickness which is caused by the African trypanosome. The risk factors for Chagas disease include living where reduviid bugs live, including areas of Central and South America. In addition, it is possible to obtain Chagas via blood transfusion from an individual with the active disease.

Figure: **Reduviid bug**: In Chagas-endemic areas, the main mode of transmission is through an insect vector called a triatomine or reduviid bug.The bugs emerge at night, when the inhabitants are sleeping. Because they tend to feed on people’s faces, triatomine bugs are also known as “kissing bugs.” After they bite and ingest blood, they defecate on the person. Triatomines pass T. cruzi parasites (called trypomastigotes) in feces left near the site of the bite wound.

The reduviid bug itself becomes infected by feeding on the blood of an already-infected person or animal. The bugs are nocturnal, emerge at night and typically feed on an individual’s face. The bug then proceeds to defecate on the person, passing *Trypanosoma cruzi* parasites in its feces in posterior station infection. These parasites surround the bite wound and, when the bite is scratched, the parasites are able to pass into the host. The reduviid bud often bites the tender skin around the eyes, leaving a swollen bump called a chagoma or Ramona’s sign.

Figure: **Romaña's sign**: The most recognized marker of acute Chagas disease is called Romaña's sign, which includes swelling of the eyelids on the side of the face near the bite wound or where the bug feces were deposited or accidentally rubbed into the eye.

At this specific stage, the parasites are referred to as trypomastigotes, and these invade the host cells and differentiate into intracellular amastigotes where they continue to multiply by binary fission. These amastigotes then differentiate into trypomastigotes which circulate into the bloodstream. At this time, if the infected individual is re-bitten by a reduviid bug, the cycle will start again.

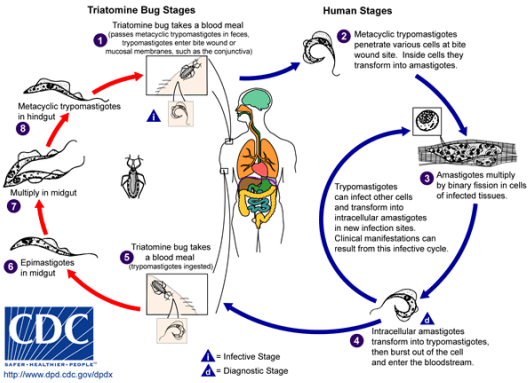

Figure: **Lifecycle of Trypanasoma cruzi**: Chagas disease can be characterized by two phases: acute and chronic. The acute phase is characterized by mild symptoms which include fever, swelling of an eye or area surrounding the insect bite. However, the acute phase will enter remission and then, over time, additional symptoms will develop that include: constipation, gastrointestinal issues, heart failure, abdominal pain and difficulties swallowing.

Chagas disease can be characterized by two phases: acute and chronic. The acute phase is presents with mild symptoms which include: fever, swelling of an eye and/or the area surrounding the insect bite.

The acute phase will then enter remission and, over time, additional symptoms will develop that include: constipation, gastrointestinal issues, heart failure, abdominal pain and difficulties swallowing. It can sometime take upwards of 20 years from the time of infection for these later heart and digestive issues to present. American trypanosomiasis causes megacolon and megaesophagus and an enlarged heart in pediatric patients and is very serious.

Key Points

- Chagas disease is prevalent in areas with reduviid bugs such as Central and South America.
- Chagas disease is transmitted via a vector, the reduviid bug, which becomes infected when it bites an already-infected individual.
- The life cycle of Trypanosoma cruzi requires two hosts, the reduviid bug and the human or animal host.

Key Terms

- **zoonotic**: of or relating to zoonosis, the transmission of an infectious disease between species.

15.10A: Chagas Disease (American Trypanosomiasis) is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.10B: Toxoplasmosis

Learning Objectives

- Compare and contrast: acute and latent toxoplasmosis and outline the life cycle of the protazoan that causes it

Toxoplasmosis is an infection caused by the parasite *Toxoplasma gondii.* Toxoplasmosis is found in humans worldwide, but the definitive hosts are cats. Humans may become infected as a result of infected blood transfusions, organ transplants, ingesting contaminated soil, raw or undercooked meat, and most commonly from the careless handling of cat litter, which can lead to accidental ingestion of the parasite. Toxoplasmosis can also be passed from an infected mother to her baby via the placenta (transplacentally). Symptoms that may occur from toxplasmosis include: enlarged lymph nodes, headache, fever, muscle pain, and sore throat. Individuals with immunocompromised or weakened systems display more severe symptoms, such as: confusion, fever, headache, blurred vision and seizures. The three categories of toxoplasmosis include acute, latent, and cutaneous toxoplasmosis.

Symptoms

Acute toxoplasmosis is characterized by swollen lymph nodes found in the neck or under the chin, followed by the axillae, and the groin area. Enlarged lymph nodes will occur at different times after the initial infection. Latent toxoplasmosis is characterized by the formation of cysts in both the nervous and muscle tissue due to the bradyzoite form of the parasite. Often times, individuals infected with latent toxoplasmosis do not present with symptoms, as the infection enters a latent phase. In individuals with cutaneous toxoplasmosis, skin lesions will occur due to the tachyzoite form of the parasite and its presence in the epidermis.

Hosts, Life Cycle

The known definitive hosts for *Toxoplasma gondii* are members of family Felidae (domestic cats and their relatives). In the life cycle of this parasite, unsporulated oocysts are shed in the cat's feces. The cat will shed large numbers of these cysts over a short period of time. The oocysts will then take 1-5 days to sporulate in the environment and become infective. The intermediate hosts in nature (including birds and rodents) become infected after ingesting contaminated soil, water, or plant material. The oocysts, upon ingestion, will transform into tachyzoites, which will localize in the neural and muscle tissue. After localizing to these sites, they will develop into tissue cyst bradyzoites. Cats, can become infected after consuming intermediate hosts that are infected with tissue cysts or by ingesting sporulated oocysts.

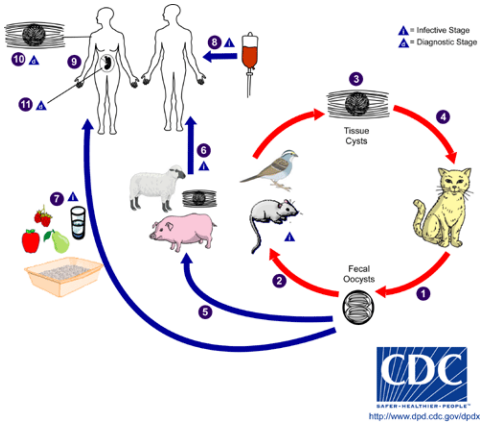

Figure: **Toxoplasmosis Life Cycle**: Overview of the life cycle of Toxoplasmosis godii.

Key Points

- Cats are the definitive hosts for Toxoplasma gondii and are the primary source of infection to humans.
- Toxoplasmosis can occur in either acute, latent or cutaneous forms.
- Toxoplasmosis is found worldwide and can be transmitted by eating undercooked meat of animals which may contain cysts, ingesting contaminated food or water, transplacentally or from coming in contact with infected cat feces.

Key Terms

- **definitive host**: a host in which the parasite reaches maturity and, if possible, reproduces sexually
- **axillae**: The armpit
- **transplacental**: Through or across the placenta

15.10B: Toxoplasmosis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.10C: Malaria

Learning Objectives

- Reconstruct the route of transmission and life cycle for Plasmodium species that cause malaria and describe its symptoms

Malaria is a parasitic disease that is caused by the bite of an infected Anopheles mosquito. Malaria can be transmitted from mother to baby and by blood transfusions. The Anopheles mosquito transmits the parasites, called sporozoites, upon biting the hosts, into the bloodstream to the liver, where the parasites continue their life cycle. In the liver, the parasites mature and release another form called merozoites, which enter the bloodstream and infect the red blood cells. In the red blood cells, they develop into ring forms called trophozoites and schizonts that in turn, produce further merozoites. Upon infection of the red blood cells, the parasite is able to multiply within the cell, break open and continue infecting additional red blood cells. The symptoms occur in a cyclical manner every 48-72 hours. Malaria is characterized by the development of symptoms that include high fevers, shaking chills, flu-like symptoms, and anemia. The symptoms that persist due to parasitic infection are a result of the release of merozoites into the bloodstream, destruction of the red blood cells and the free circulation of large amounts of hemoglobin in the red blood cells due to disruption.

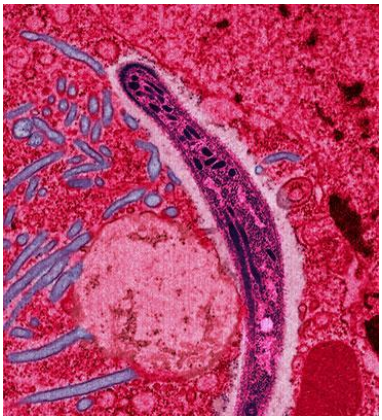

Figure: **The malaria plasmodium**: Malaria is transmitted to people and animals by mosquitoes. Malarial sporozoites develop inside oocysts and are released in large numbers into the hemocoel of Anopheles stephensi mosquitoes. This false-colored electron micrograph shows a sporozoite migrating through the cytoplasm of midgut epithelia.

The five types of malaria parasites include species of Plasmodium. The fives species include: *Plasmodium falciparum, Plasmodium vivax, Plasmodium ovale, Plasmodium malariae,* and *Plasmodium knowlesi*. *Plasmodium falciparum* is responsible for the majority of deaths caused by infection and *Plasmodium vivax, ovale and malariae*cause a milder form of malaria. The species, *Plasmodium knowlesi*, commonly causes malaria in macaques but can also cause severe infections in humans.

Malaria is common in temperate climates and the Centers for Disease Control and Prevention (CDC) estimates 300-500 million cases each year. In addition, it is estimated that 1 million people die from it each year as well. Malaria is typically diagnosed by microscopic examination of blood or with antigen-based rapid diagnostic tests. Disease transmission can be reduced by preventing mosquito bites through the use of mosquito nets and insect repellents. However, the mosquitoes which transmit malaria have begun to develop resistance to insecticides and the parasite itself has developed resistance to commonly used antibiotics. As a result of increased resistance, it is extremely difficult to contain the spread of this disease.

Key Points

- The five common species of Plasmodium that cause malaria include: Plasmodium falciparum, Plasmodium vivax, Plasmodium ovale, Plasmodium malariae and Plasmodium knowlesi.
- Mosquitoes transmit the protists by injecting sporozoites into the bloodstream of humans.
- The sporozoites injected into the bloodstream, travel to the liver where they multiply into merozoites, rupture the liver cells, and then return to the bloodstream.
- A mosquito, upon feeding off an already infected individual, will carry the protists and become infectious.
- The symptoms of malaria can present in a cyclic manner.

Key Terms

- **merozoites**: the organisms formed by multiple fission of a sporozoite within the body of the host.
- **antigen**: A substance that induces an immune response, usually foreign.
- **sporozoites**: Any of the minute active bodies into which a sporozoan divides just before it infects a new host cell.

15.10C: Malaria is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.10D: Leishmaniasis

Learning Objectives

- Outline the life cycle of Leishmania and distinguish between cutaneous or viseral leishmaniasiss within the Ideal Gas Law

Leishmaniasis is a disease transmitted by the bite of a female sandfly. There various types of leishmaniasis that exist including cutaneous leishmaniasis, systemic, or visceral leishmaniasis. Cutaneous leishmaniasis is characterized by infection of the skin and mucous membranes. The symptoms include skin sores which present at the site of the sandfly bite. In addition, cutaneous leishmaniasis includes breathing difficulty, stuffy nose, runny nose, nose bleeds, swallowing difficulty and ulcers in the mouth, tongue, gums, lips, nose, and inner nose. Systemic or visceral leishmaniasis present as an infection of the entire body. There is a delay of symptoms, ranging from 2-8 months post bite, and the effects on the immune system can result in deadly complications. The parasites damage the immune system by targeting the disease-fighting cells. Symptoms present much more quickly in children and include a cough, diarrhea, fever, and vomiting. In adults, there is fatigue, weakness, loss of appetite, abdominal pain, night sweats, fever, weight loss, and changes in the color and texture of the skin. In combination, cutaneous and visceral leishmaniasis are caused by more than 20 different leishmanial species.

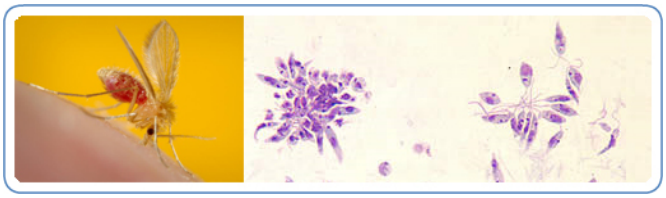

Figure: **Leishmaniasis**: A Phlebotomus papatasi sand fly that transmits one type of leishmaniasis, next to an image of Leishmania sp. promastigotes from culture. This is the stage of the parasite that occurs inside the mid-gut of the sand fly.

Leishmaniasis is vector-borne because it is transmitted via a bite from a sandfly. The sandflies that cause leishmaniasis are infected by an obligate intracellular protozoa of the genus Leishmania. The species of Leishmania that can cause leishmaniasis include: L. donovani complex with 2 species (L. donovani, L. infantum, also known as L. chagasi); the L. mexicana complex with 3 main species (L. mexicana, L. amazonensis, and L. venezuelensis); L. tropica; L. major; L. aethiopica; and the subgenus Viannia with 4 main species (L. (V.) braziliensis, L. (V.) guyanensis, L. (V.) panamensis, and L. (V.) peruviana). These various species are indistinguishable via morphology but can be identified using advanced techniques such as isoenzyme analysis.

Leishmaniasis is transmitted by the bite of infected female phlebotomine sandflies which can transmit the infection Leishmania. The sandflies inject the infective stage, metacyclic promastigotes, during blood meals. Metacyclic promastigotes that reach the puncture wound are phagocytized by macrophages and transform into amastigotes. Amastigotes multiply in infected cells and affect different tissues, depending in part on which Leishmania species is involved. These differing tissue specificities cause the differing clinical manifestations of the various forms of leishmaniasis. Sandflies become infected during blood meals on infected hosts when they ingest macrophages infected with amastigotes. In the sandfly's midgut, the parasites differentiate into promastigotes, which multiply, differentiate into metacyclic promastigotes, and migrate to the proboscis.

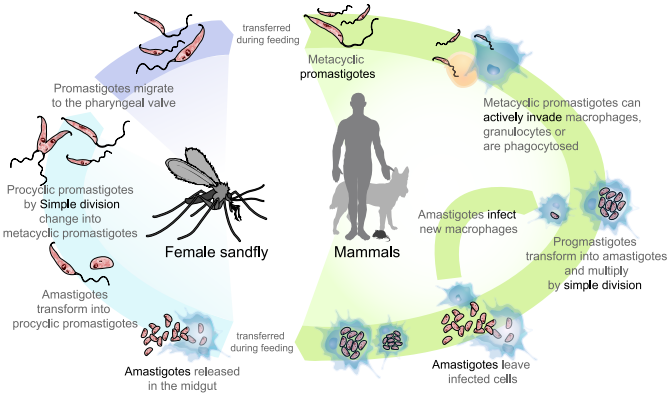

Figure: **Leishmaniasis life cycle**: Leishmaniasis is a vector-borne disease and is transmitted by the sand fly.

Key Points

- Leishmaniasis is a vector-borne disease and is transmitted by the sand fly.
- Cutaneous leishmaniasis is the most common form of leishmaniasis and symptoms include skin sores.
- Visceral leishmaniasis is more severe and is characterized by the migration of parasites to the vital organs and tissues.

Key Terms

- **visceral**: of or relating to the viscera – the internal organs of the body
- **cutaneous**: of, relating to, existing on, or affecting the exterior skin; especially the cutis
- **phagocytosis**: the process by which a cell incorporates foreign particles intracellularly.

15.10E: Babesiosis

Learning Objectives

- Outline the life cycle of the Babesia microti parasite that causes babesiosis

Babesiosis is a malaria-like parasitic disease caused by Babesia. Babesia is a genus of protozoal piroplasms which are characterized by their ability to divide by binary fission. Also, protozoal piroplasms are sporozoan parasites, and so they possess both sexual and asexual phases. The piroplasm is categorized under Phylum Apicomplexa and specifically, Babesia, is a parasite transmitted via a tick vector. Many of the cases of Babesia infection are asymptomatic but can include mild fevers and diarrhea. The more severe cases are plagued with high fevers, shaking chills, and severe anemia, similar to symptoms seen in individuals infected with malaria. If the disease progresses without treatment and it is severe, the infected individual can suffer from organ failure and adult respiratory distress syndrome. Recently, there has been an increase in babesiosis diagnosis due to an increase in the number of individuals with immunodeficiencies coming into contact with ticks.

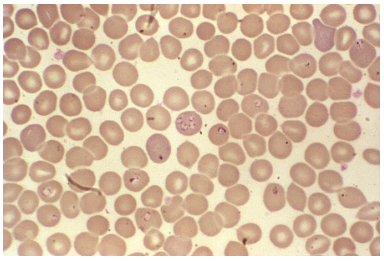

Figure: **Babesia parasites**: Other hemoprotozoan parasites such as these Babesia sp. resemble Plasmodium falciparum organisms. Though developmentally the Babesia spp. organisms resemble Plasmodium falciparum, these parasites present several distinguishing features: they vary more in shape and in size; and they do not produce pigment.

The life cycle of Babesia parasites is characterized by their ability to undergo reproduction in the erythrocytes. These parasites, within the red blood cells, form a distinctive structure called a “Maltese Cross” that is composed of four attached merozoites undergoing asexual budding. This asexual process results in hemolytic anemia. The Babesia microti life cycle includes two hosts, a rodent, primarily the white-footed mouse, and a tick.

During a blood meal, the tick introduces sporozoites into the mouse host. The sporozoites enter the erythrocytes and undergo asexual reproduction as previously mentioned. In the blood, the parasites will then differentiate into male and female gametes. The definitive host, the tick, will then ingest both types of gametes (upon another blood meal). The gametes will unite and undergo a sporogonic cycle resulting in sporozoite. The humans play a role in this cycle if they are bitten by an infected tick. The tick will introduce the sporozoites and the cycle will proceed. Diagnosis of babesiosis is performed using a Giemsa-test for parasitic identification. The “Maltese Cross” is observed on blood films and both serological testing for antibodies and PCR testing for Babesia from the peripheral blood is performed.

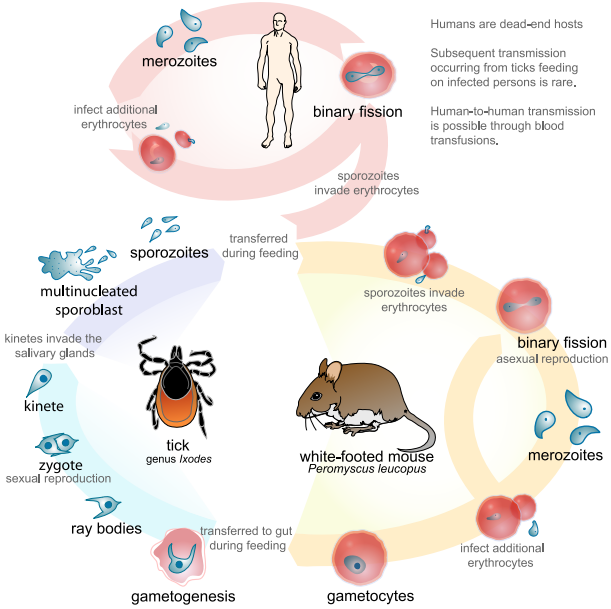

Figure: **The life cycle of Babesia parasites**: Babesia is capable of undergoing both sexual and asexual reproduction in its life cycle. Ticks transmit the human form of Babesiosis, so it often presents with other tick-borne illnesses such as Lyme disease.

Key Points

- Babesia, the parasite, is capable of undergoing both sexual and asexual reproduction in its life cycle.
- A majority of individuals infected with babesiosis are asymptomatic but severe cases display malaria-like symptoms which include high fevers, chills, shakes, and hemolytic anemia.
- A definitive characteristic of Babesia infection is the formation of a “Maltese Cross” structure within the erythrocytes that represents the asexual budding of four attached merozoites.

Key Terms

- **piroplasms**: a protozoan parasite of the phylum Apicomplexa.
- **sporozoite**: any of the minute active bodies into which a sporozoan divides just before it infects a new host cell
- **hemolytic**: producing hemolysis; destroying red blood cells

15.10E: Babesiosis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.10F: Schistosomiasis

Learning Objectives

- Outline the life cycle of the trematodes of the genus Schistosoma that cause schistosoomiasis

Schistosomiasis is a parasitic disease caused by various species of trematodes or "flukes," which are of the genus *Schistosoma*. For parasites categorized as schistosomes, the snail is the intermediary agent between the mammalian hosts. Schistosomiasis is common in countries that lack the facilities to maintain proper water supplies and sanitation facilities. These supplies and facilities are often exposed to contaminated water that contains infected snails. Individuals infected with schistosomiasis display chronic illness that can result in the damage of internal organs and in children, targets growth and cognitive development. Children will often acquire the disease by swimming or playing in contaminated water. Upon contact with contaminated water, the parasitic larvae can penetrate the skin and mature within the organ tissues.

The life cycle of the various human schistosomes is similar. The parasitic eggs are released into the environment from already-infected individuals and hatch on contact with water, releasing free-swimming miracidia. These infect freshwater snails by penetrating their skin. The site of penetration will promote the transformation of the miracidium into a primary sporocyst. This contains germ cells which will divide to produce secondary sporocysts. In turn, these migrate to the snails' hepatopancreas and the germ cells, now present within the secondary sporocysts, will divide to form thousands of new parasites called *cercariae*. These are the larvae capable of infecting mammals.

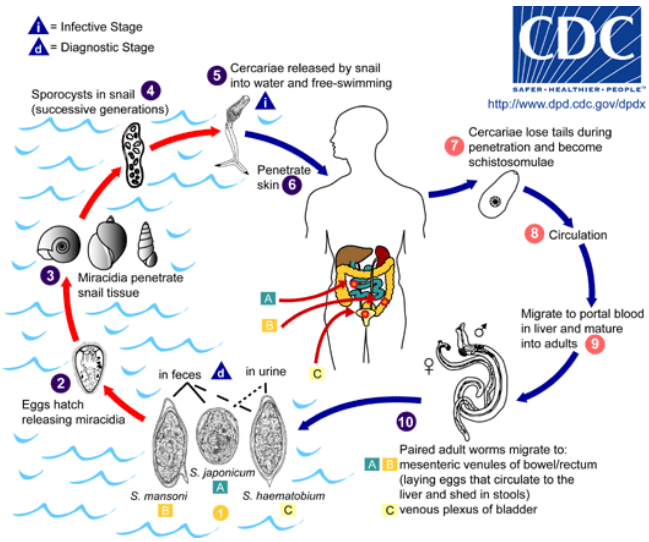

Figure: **Schistosome Life Cycle**: Overview of Schistosome generalized life cycle.

Interestingly, the cercariae are released from the snail host in a circadian rhythm and depend on ambient temperature and light. Penetration of the human skin occurs after the cercariae have attached to and explored the skin. The parasite secretes enzymes that break down the skin's protein to enable penetration of the cercarial head through the skin. As the cercaria penetrates the skin, it transforms into a migrating schistosomulum stage.

The various species which can infect humans include:

- *Schistosoma mansoni*, *Schistosoma intercalatum*: cause intestinal schistosomiasis
- *Schistosoma haematobium*: causes urinary schistosomiasis
- *Schistosoma japonicum*, *Schistosoma mekongi:* cause Asian intestinal schistosomiasis
- *Avian schistosomiasis* species: cause swimmer's itch and clam digger itch

Key Points

- For parasites categorized as schistosomes, the snail is the intermediary agent between the mammalian hosts.
- Schistosomiasis is common in countries that lack the facilities to maintain proper water supplies and sanitation facilities. These supplies and facilities are often exposed to contaminated water that contains infected snails.

- Individuals infected with schistosomiasis display chronic illness that can result in the damage of internal organs and in children, affects target growth and cognitive development.

Key Terms

- **hepatopancreas**: An organ of the digestive tract of arthropods and fish which provides the function which in mammals is provided separately by the liver and pancreas.

15.10F: Schistosomiasis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.10G: Swimmer's Itch

Swimmer's itch is a result of an immune reaction in response to the penetration of the skin by a schistosome.

Learning Objectives

- Outline the general life cycle of the Schistosomatidae parasite that causes schistosome cercarial dermatitis

Key Points

- Swimmer's itch is commonly referred to as lake itch, duck itch, cercarial dermatitis and Schistosome cercarial dermatitis.
- The cercaria, the larvae stage of the parasite, will accidentally penetrate the skin of a human host and die within the skin. The cercaria cannot continue the life cycle in a human and requires its normal host, a waterfowl.
- The penetration of the skin by the cercaria result in an inflammatory immune reaction that causes itchy spots and raised papules in humans.

Key Terms

- **swimmer's itch**: Swimmer's itch, also known as lake itch, duck itch, cercarial dermatitis, and Schistosome cercarial dermatitis, is a short-term, immune reaction occurring in the skin of humans that have been infected by water-borne schistosomatidae.
- **papules**: A small, inflammatory, irritated spot on skin; similar in appearance to a pimple, without containing pus.
- **cercaria**: The parasitic larva of trematodes; its tail disappears when adult.

Swimmer's itch is a condition often referred to as lake itch, duck itch, cercarial dermatitis and Schistosome cercarial dermatitis. It is caused by an immune response that is activated upon the entry of a water-borne flatworm parasite named schistosomatidae into the skin. The schistosomatidae results in an immune reaction in the skin that results in itchy, raised papules that occur within hours of infection.

There are numerous types of flatworm parasites within the family Schistosomatidae that can cause swimmer's itch. The schistosomatidae which are responsible for swimmer's itch include the genera Trichobilharzia and Gigantobilharzia. A species that is often implicated in cases of cercarial dermatitis is Austrobilharzia variglandis. The hosts of this species are ducks and the snail is the intermediate host for this species.

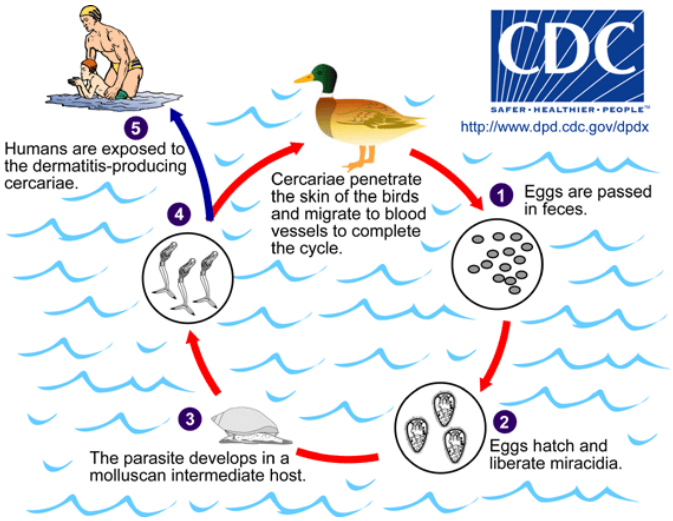

Figure: **Life cycle of schistosomes**: An overview of the life cycle of a schistosome and how they can cause swimmer's itch in humans.

The life cycle of these parasites is characterized by their use of both freshwater snails and vertebrates as hosts. More specifically, waterfowl are used as the vertebrate host. During the life stage of these parasites, the larvae of the parasite, cercaria, exit the water snails and can accidentally come into contact with the skin of a swimmer. Upon contact with the skin of the swimmer, the cercaria will penetrate the skin and immediately die in the skin. Interestingly, the cercaria are unable to survive within a human host and cause infection. The symptoms and reactions exhibited in individuals diagnosed with swimmer's itch are a result of the dead cercaria larvae.

If indeed the cercaria encounter a water bird, their normal host, the cercaria will penetrate the skin of the birds and migrate to the blood vessels to complete the cycle. For completion of the cycle, adult worms will form in the blood vessels and produce eggs which are passed in the feces. The eggs, upon exposure to water, will hatch into a miracidium that is ciliated. This form in the life cycle infects the snail intermediate host. In turn, the cercaria which are responsible for swimmer's itch are produced.

5.11B: Airborne Transmission of Disease

15.11: Microbial Diseases of the Respiratory System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.11A: Functional Anatomy of the Respiratory System

The respiratory system include lungs, airways and respiratory muscles. Ventilation is the rate at which gas enters or leaves the lung.

Learning Objectives

- Summarize the the functional anatomy of the respiratory system

Key Points

- Ventilation occurs under the control of the autonomic nervous system from parts of the brain stem—the medulla oblongata and the pons —that together form the respiration regulatory center.
- The three types of ventilation are minute ventilation, alevolar ventilation, and dead space ventilation.
- Inhalation is initiated by the diaphragm and supported by the external intercostal muscles. Additional accessory muscles include sternocleidomastoid, platysma, the scalene muscles of the neck, pectoral muscles, and the latissimus dorsi.
- When the diaphragm contracts, the ribcage expands and the contents of the abdomen are moved downward, resulting in a larger thoracic volume and negative pressure (with respect to atmospheric pressure) inside the chest.
- Exhalation is generally a passive process since the lungs have a natural elasticity; they recoil from the stretch of inhalation and air flows back out until the pressures in the chest and the atmosphere reach equilibrium.
- Gas exchange occurs at the alveoli, the tiny sacs that are the basic functional component of the lungs. The alveoli are interwoven with capillaries that connect to the larger bloodstream.

Key Terms

- **elastic recoil**: The lungs' rebound from the stretch of inhalation that passively removes air from the lungs during exhalation.
- **Dead space**: Any space in the airways that is not involved in alveolar gas exhange, such as the conducting zones.
- **ventilation**: The bodily process of breathing, the inhalation of air to provide oxygen, and the exhalation of spent air to remove carbon dioxide.

The Respiratory System

The primary function of the respiratory system is gas exchange between the external environment and an organism 's circulatory system. In humans and other mammals, this exchange balances oxygenation of the blood with the removal of carbon dioxide and other metabolic wastes from the circulation.

As gas exchange occurs, the acid-base balance of the body is maintained as part of homeostasis. If proper ventilation is not maintained, two opposing conditions could occur: respiratory acidosis (a life threatening condition) and respiratory alkalosis.

At the molecular level, gas exchange occurs in the alveoli—tiny sacs which are the basic functional component of the lungs. The alveolar epithelial tissue is extremely thin and permeable, allowing for gas exchange between the air inside the lungs and the capillaries of the blood stream. Air moves according to pressure differences, in which air flows from areas of high pressure to areas of low pressure.

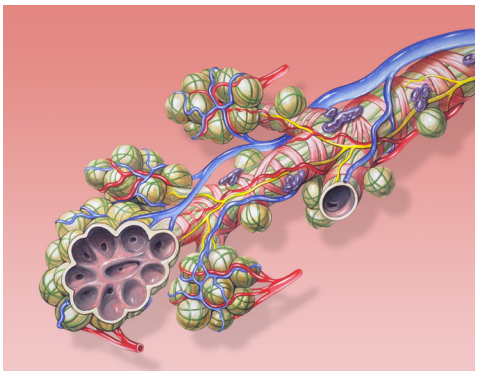

Figure: **Bronchial anatomy**: The pulmonary alveoli are the terminal ends of the respiratory tree, outcropping from either alveolar sacs or alveolar ducts, which are both sites of gas exchange with the blood.

The Ventilation Rate

In respiratory physiology, ventilation rate is the rate at which gas enters or leaves the lung. There are several different terms used to describe the nuances of the ventilation rate.

- Minute Ventilation (V_E): The amount of air entering the lungs per minute. It can be defined as tidal volume (the volume of air inhaled in a single breath) times the amount of breaths in a minute.
- Alveolar Ventilation (V_A): The amount of gas per unit of time that reaches the alveoli (the functional part of the lungs where gas exchange occurs). It is defined as tidal volume minus dead space (the space in the lungs where gas exchange does not occur) times the respiratory rate.
- Dead Space Ventilation (V_D): The amount of air per unit of time that doesn't reach the alveoli. It is defined as volume of dead space times the respiratory rate.

Dead space is any space that isn't involved in alveolar gas exchange itself, and it typically refers to parts of the lungs that are conducting zones for air, such as the trachea and bronchioles.

If someone breathes through a snorkeling mask, the length of their conducting zones increases, which increases dead space and reduces on alveolar ventilation. Feedback mechanisms increase the ventilation rate in such a case, but if dead space becomes too great, they won't be able to counteract the effect.

The ventilation rate is controlled by several centers of the autonomic nervous system in the brain, primarily the medulla and the pons.

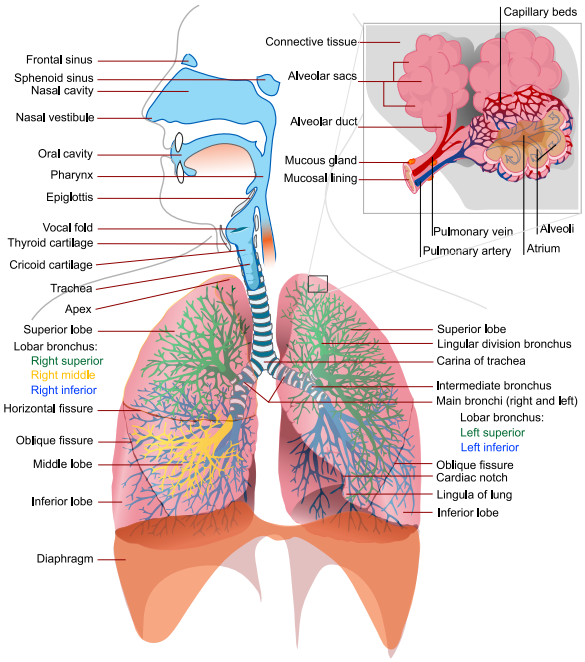

Figure: **The human respiratory system**: A complete, schematic view of the human respiratory system with its parts and functions.

Mechanisms of Inhalation

Inhalation is initiated by the activity of the diaphragm and supported by the external intercostal muscles. A normal human respiratory rate is 10 to 18 breaths per minute.

During vigorous inhalation (at rates exceeding 35 breaths per minute), or in approaching respiratory failure, accessory muscles—such as the sternocleidomastoid, platysma, and the scalene muscles of the neck—are recruited to help sustain the increased respiratory rate. Pectoral muscles and latissimus dorsi are also accessory muscles for the activity of the lungs.

Under normal conditions, the diaphragm is the primary driver of inhalation. When the diaphragm contracts, the rib cage expands and the contents of the abdomen are moved downward, resulting in a larger thoracic volume and negative pressure (with respect to atmospheric pressure) inside the thorax.

As air moves from zones of high pressure to zones of low pressure, the contraction of the diaphragm allows the air to enter the conducting zone (such as the trachea, bronchioles, etc.), where it is filtered, warmed, and humidified as it flows to the lungs.

Mechanisms of Exhalation

Exhalation is generally a passive process. The lungs have high degree of elastic recoil, so they rebound from the stretch of inhalation and air flows out until the pressures in the lungs and the atmosphere reach equilibrium.

The reason for the elastic recoil of the lung is the surface tension from water molecules on the epithelium of the lungs. A molecule called surfactant (secreted by the alveoli) prevents the surface tension from becoming too great and collapsing the lungs.

Active or forced exhalation is achieved by the abdominal and the internal intercostal muscles. During this process, air is forced or exhaled out. During forced exhalation, as when blowing out a candle, the expiratory muscles, including the abdominal muscles and internal intercostal muscles, generate abdominal and thoracic pressure that force air out of the lungs.

Forced exhalation is often used as an indicator to measure airway health, as people with obstructive lung diseases (such as emphysema, asthma, and bronchitis) will not be able to actively exhale as much as a healthy person because of obstruction in the conducting zones from inhlation, or from a loss of elastic recoil of the lungs.

5.11B: Airborne Transmission of Disease

Airborne diseases are characterized by diseases that are transmitted through the air via the presence of a pathogen.

Learning Objectives

- Give examples of airborne pathogens and various routes of transmission

Key Points

- Airborne transmission results in the inhalation of pathogens that can affect an individual's respiratory system or the rest of the body.
- Airborne diseases are caused by pathogens which can ride on either dust particles or small respiratory droplets that can stay suspended in the air and travel distances on air currents.
- Airborne diseases are commonly seen in unsanitary household conditions and overcrowded areas, and thrive in areas of poverty and poor hygienic conditions.

Key Terms

- **droplet nuclei**: Droplet nuclei are an important mode of transmission among many infectious viruses such as Influenza A. When viruses are shed by an infected person through coughing or sneezing into the air, the mucus coating on the virus starts to evaporate. Once this mucus shell evaporates the remaining viron is called a droplet nucleus or quanta.

Airborne Transmission of Disease

Figure: **Airborne transmission**: Infection of the respiratory system via airborne transmission.

Airborne diseases are characterized by diseases that are transmitted through the air via the presence of a pathogen. These pathogens can include both viruses and bacteria that are spread by coughing, sneezing, laughing, or through personal contact. The pathogens are capable of traveling distances on air currents when they are present on either dust particles or small respiratory droplets. The airborne transmission that occurs utilizes small particles or droplet nucleithat contains these infectious agents or pathogens. These particles and droplets are capable of remaining suspended in air for extended periods of time. Inhalation of these particles results in respiratory tract infection. The ability of these droplets to remain suspended for long periods of time result in the lack of face-to-face contact for infection. The ability of these pathogens to survive and retain their ability to infect for relatively long periods of time add to the difficulty encountered in their prevention and targeting.

Often times, these airborne pathogens can result in inflammation in the nose, throat, sinuses, and the lungs. The symptoms such as sinus congestion, coughing, and sore throats are examples of inflammation of the upper respiratory airway. Many types of infections that can be a result of airborne transmission include: Anthrax, Chickenpox, Influenza, Measles, Smallpox, and Tuberculosis. Airborne diseases are caused by exposure to a source such as an infected individual or animal.

Airborne transmission of disease is common in unsanitary household conditions and overcrowded areas, and pathogens that are transmitted in this manner thrive in areas of poverty and poor hygienic conditions. For example, tuberculosis is common in individuals from developing areas in the world, adding to 95% of cases worldwide.

15.12A: Pharyngitis

Pharyngitis is an inflammation of the throat that has many causes, some of which are bacterial infections.

Learning Objectives

- List the symptoms and bacterial causes associated with pharyngitis

Key Points

- In most cases, pharyngitis is caused by a systemic viral infection and is typified by a painful swelling inflammation of the throat. This can cause difficulty swallowing or breathing.
- The most common bacterial cause of pharyngitis is streptococcus.
- Several types of bacteria can cause pharyngitis. The most common and effective treatment for these infections are antibiotics.

Key Terms

- **hemolytic**: producing hemolysis; destroying red blood cells
- **peritonsillar abscess**: Peritonsillar abscess (PTA), also called a quinsy, or abbreviated as a PTA, is a recognized complication of tonsillitis. It consists of a collection of pus beside the tonsil in what is referred to as Peritonsilar space (Peri – meaning surrounding).

Pharyngitis

Pharyngitis is an inflammation of the throat. In most cases, it is quite painful and is the most common cause of a sore throat. Like many types of inflammation, pharyngitis can be acute or chronic. Acute cases are characterized by a rapid onset and, typically, a relatively short course of inflammation. Pharyngitis can result in very large tonsils. This can make swallowing and breathing difficult. It can be accompanied by a cough or fever, for example, if it is caused by a systemic infection. Most acute cases are caused by viral infections (40–80%). The remainder are caused by bacterial infections, fungal infections, or irritants such as pollutants or chemical substances. The treatment of viral causes is mainly symptomatic. Bacterial or fungal causes are often amenable to antibiotics and anti-fungal treatments, respectively.

Bacterial Causes of Pharyngitis

A number of different bacteria can infect the human throat. The most common is Group A streptococcus, but others include Corynebacterium diphtheriae, Neisseria gonorrhoeae, Chlamydophila pneumoniae, and Mycoplasma pneumoniae.

Figure: **Streptococcal pharyngitis**: A severe case of strep throat or Streptococcal pharyngitis.

Streptococcal pharyngitis, more commonly known as strep throat, is caused by group A beta-hemolytic streptococcus (GAS). This is the most common bacterial cause of pharyngitis (15–30%). Common symptoms of strep throat include fever, sore throat, and large lymph nodes. It is a contagious infection, spread by close contact with an infected individual. A throat culture is the gold standard for the diagnosis of streptococcal pharyngitis, with a sensitivity of 90–95%. A rapid strep test (also called rapid antigen detection testing, or RADT) is also occasionally used as a diagnostic. While the rapid strep test is quicker, it has a lower sensitivity

(70%) and a statistically equal specificity (98%) as a throat culture. For step throat, antibiotics are useful in preventing complications and expediting recovery.

Fusobacterium necrophorum are normal inhabitants of the oropharyngeal flora. Occasionally, however, these bacteria can create a peritonsillar abscess. In 1 out of 400 untreated cases, Lemierre's syndrome can occur as a result of these abscesses.

Diphtheria is a potentially life threatening upper respiratory infection caused by Corynebacterium diphtheriae. As a result of childhood vaccination programs, diphtheria has has been largely eradicated in developed nations, but it is still reported in the Third World, and, increasingly, in some areas in Eastern Europe. Antibiotics are effective in the early stages, but recovery is generally slow.

15.12A: Pharyngitis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.12B: Scarlet Fever

Learning Objectives

- Describe the bacterium *Streptococcus pyogenes* that causes scarlet fever

A Bacteriophage Hitchhiker

Scarlet fever is an infectious disease which most commonly affects 4-8 year-old children. Symptoms include sore throat, fever, and a characteristic red rash. It is usually spread by inhalation. There is no vaccine, but the disease is effectively treated with antibiotics. Scarlet fever is caused by an erythrogenic toxin, a substance produced by the bacterium Streptococcus pyogenes (group A strep.) when it is infected by a certain bacteriophage.

Figure: **Scarlet Fever**: The rosy cheeks and white area around the mouth are typical symptoms of scarlet fever.

Scarlet fever is caused by secretion of pyrogenic (fever inducing) exotoxins by the infected Streptococcus. Exotoxin A (speA) is probably the best studied of these toxins. It is carried by the bacteriophage T12, which integrates into the Streptococcal genome, from where the toxin is transcribed.

The phage itself integrates into a serine tRNA gene on the chromosome. The T12 virus itself has not been placed into a taxon by the International Committee on Taxonomy of Viruses. It has a double stranded DNA genome; on morphological grounds it appears to be a member of the Siphoviridae. The speA gene was cloned and sequenced in 1986. It is 753 base pairs in length and encodes a 29.244 kiloDalton (kDa) protein. The protein contains a putative 30 amino acid signal peptide. Removal of the signal sequence gives a predicted molecular weight of 25.787 (kDa) for the secreted protein. Both a promoter and a ribosome-binding site (Shine-Dalgarno sequence) are present upstream of the gene. A transcriptional terminator is located 69 bases downstream from the translational termination codon. The carboxy terminal portion of the protein exhibits extensive homology with the carboxy terminus of Staphylococcus aureus enterotoxins B and C1. Streptococcal phages other than T12 may also carry the speA gene.

Key Points

- Scarlet fever usually affects children. Historically, it had devastating effects.
- While antibiotics are effective against scarlet fever, the illness is actually caused by a bacteriophage infecting Streptococcus that has infected a person.
- The bacteriophage T12 inserts into the genome of Streptococcus. This leads to the expression of an exotoxin, which causes scarlet fever.

Key Terms

- **scarlet fever**: a streptococcal infection, mainly occurring among children, and characterized by a red skin rash, sore throat and fever
- **Shine-Dalgarno sequence**: A ribosomal binding site in the mRNA of prokaryotes.
- **exotoxin**: Any toxin secreted by a microorganism into the surrounding environment.
- **enterotoxin**: Any of several toxins produced by intestinal bacteria

15.12B: Scarlet Fever is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.12C: Diphtheria

Diphtheria is an upper respiratory infection that is largely benign unless left untreated, at which point very harmful toxins are produced.

Learning Objectives

- Discuss the role of diphtheria toxin in diphtheria

Key Points

- Diptheria is caused bu the bacteria Corynebacterium diphtheriae, and is easily treated with antibiotics. It is now a fairly rare disease in developed countries.
- If left untreated and if infected by a bacteriophage, then Corynebacterium diphtheriae produces toxins that can lead to mortality.
- Diphtheria toxinis comprised of two fragments, fragment A and fragment B;. Fragment B binds to the target cell surface and allows entry into cells through endosomes; fragment A inhibits protein translation.
- Fragment A inhibits protein synthesis by catalyzing EF-2 a protein essential for tRNA movement during protein translation.

Key Terms

- **ribosylation**: The attachment of a ribose or ribosyl group to a molecule, especially to a polypeptide or protein
- **translation**: A process occurring in the ribosome, in which a strand of messenger RNA (mRNA) guides assembly of a sequence of amino acids to make a protein.

Overview of Diphtheria

Diphtheria is an upper respiratory tract illness caused by *Corynebacterium diphtheriae*, a facultative, anaerobic, Gram-positive bacterium. It is characterized by sore throat, low fever, and an adherent membrane (a pseudomembrane) on the tonsils, pharynx, and/or nasal cavity. A milder form of diphtheria can be restricted to the skin. Less common consequences include myocarditis (about 20% of cases) and peripheral neuropathy (about 10% of cases).

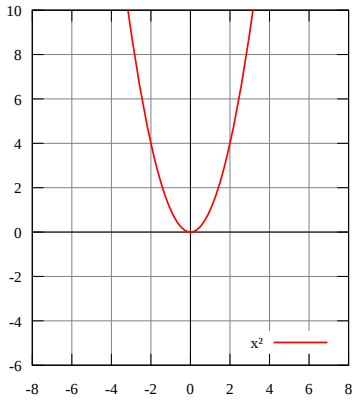

Figure: **Graph of $y=x^2$**

Diphtheria is a contagious disease spread by direct physical contact or breathing the aerosolized secretions of infected individuals. Historically quite common, diphtheria has largely been eradicated in industrialized nations through widespread vaccination. In the United States, for example, there were 52 reported cases of diphtheria between 1980 and 2000; between 2000 and 2007, there were only three cases as the diphtheria–pertussis–tetanus (DPT) vaccine is recommended for all school-age children. Boosters of the vaccine are recommended for adults, since the benefits of the vaccine decrease with age without constant re-exposure; they are particularly recommended for those traveling to areas where the disease has not been eradicated.

Advanced Cases of Diphtheria

In cases that progress beyond a throat infection, diphtheria toxin spreads through the blood and can lead to potentially life-threatening complications that affect other organs, such as the heart and kidneys. The toxin can cause damage to the heart that

affects its ability to pump blood or the kidneys' ability to clear wastes. It can also cause nerve damage, eventually leading to paralysis. About 40% to 50% of those left untreated can die.

Diphtheria toxin is produced by *C. diphtheriae* only when it is infected with a bacteriophage that integrates the toxin-encoding genetic elements into the bacteria. Diphtheria toxin is a single, 60,000 dalton molecular weight protein composed of two peptide chains, fragment A and fragment B, held together by a disulfide bond. Fragment B is a recognition subunit that gains the toxin entry into the host cell by binding to the EGF-like domain of heparin-binding EGF-like growth factor (HB-EGF) on the cell surface. This signals the cell to internalize the toxin within an endosome via receptor-mediated endocytosis. Inside the endosome, the toxin is split by a trypsin-like protease into its individual A and B fragments. The acidity of the endosome causes fragment B to create pores in the endosome membrane, thereby catalyzing the release of fragment A into the cell's cytoplasm.

Fragment A inhibits the synthesis of new proteins in the affected cell. It does this by catalyzing ADP-ribosylation of elongation factor EF-2—a protein that is essential to the translation step of protein synthesis. This ADP-ribosylation involves the transfer of an ADP-ribose from NAD+ to a diphthamide (a modified histidine) residue within the EF-2 protein. Since EF-2 is needed for the moving of tRNA from the A-site to the P-site of the ribosome during protein translation, ADP-ribosylation of EF-2 prevents protein synthesis. ADP-ribosylation of EF-2 is reversed by giving high doses of nicotinamide (a form of vitamin B3), since this is one of the reaction 's end-products, thus high amounts will drive the reaction in the opposite direction counteracting the toxin.

Figure: **Diphtheria toxin induced lesion**: Corynebacterium diphtheriae produces toxins that can affect the skin by causing skin lesions, as shown here.

15.12C: Diphtheria is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.12D: Otitis Media

Otitis media, or earache, is the inflammation of the middle ear and is often due to bacterial infections.

Learning Objectives

- Discuss the causes and symptoms associated with otitis media

Key Points

- Bacterial-caused earaches are often due to Streptococcus pneumoniae, a common bacterial infection.
- Trimeric Autotransporter Adhesins on the surface of bacteria are the proteins responsible for earaches.
- TAA proteins bind to host cells, allowing the invading bacteria to transfer virulence factors which then cause inflammation of the middle ear.

Key Terms

- **Eustachian tube**: In humans and other land vertebrates, a tube that links the pharynx to the cavity of the middle ear to allow the equalization of the pressure on both sides of the eardrum.
- **tympanic**: relating to the eardrum or middle ear; tympanal

Otitis media is inflammation of the middle ear. It occurs in the area between the tympanic membrane and the inner ear, also effecting a duct known as the eustachian tube. It is one of the two most common causes of earache – the other being otitis externa. Diseases other than ear infections can also cause ear pain, including various cancers of any structure that share nerve supply with the ear. Though painful, otitis media is not threatening and usually heals on its own within 2–6 weeks. Typically, acute otitis media follows a cold. After a few days of a stuffy nose, the ear becomes involved and can cause severe pain. The pain will usually settle within a day or two, but can last over a week. Sometimes the ear drum ruptures, discharging pus from the ear, but the ruptured drum will usually heal rapidly.

Figure: **Acute Otitis Media**: This is a view of the tympanic membrane showing inflammation and redness, typical of acute otitis media.

Otitis media is most commonly caused by infection with viral, bacterial, or fungal pathogens. The most common bacterial pathogen is Streptococcus pneumoniae. Others include Pseudomonas aeruginosa, nontypeable Haemophilus influenzae and Moraxella catarrhalis. Among older adolescents and young adults, the most common cause of ear infections is Haemophilus influenzae. Viruses like respiratory syncytial virus (RSV) and those that cause the common cold may also result in otitis media by damaging the normal defenses of the epithelial cells in the upper respiratory tract. A major risk factor for developing otitis media is Eustachian tube dysfunction, which leads to the ineffective clearing of bacteria from the middle ear.

Otitis media caused by bacterial infections are due to Trimeric Autotransporter Adhesins (TAA; proteins found on the outer membrane of Gram-negative bacteria. Bacteria use TAAs in order to infect their host cells via a process called cell adhesion. TAAs are virulence factors; an infective agent that infects the host cell by attaching to them and secreting the virulence factor by a secretion pathway. The UspA1 protein domain is a TAA found in the bacteria Moraxella catarrhalis, which causes middle ear infections in humans.

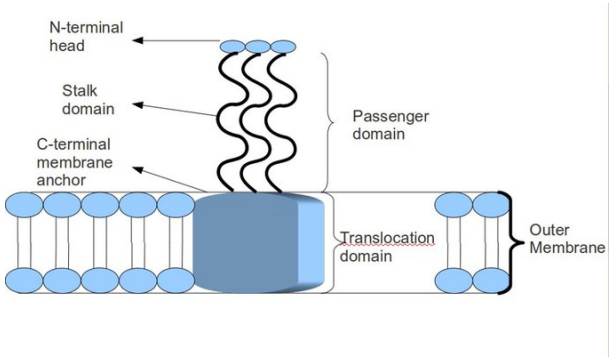

Figure: **Trimeric Autotransporter Adhesin structure**: The structure on the top (outside) of the outer membrane is a TAA protein. Various parts of the TAA are labelled, including the N-terminal head, stalk domain and C-terminal membrane anchor.

15.12D: Otitis Media is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.12E: Whooping Cough

Pertussis, more commonly known as whooping cough, is a bacterial infection of the upper respiratory system.

Learning Objectives

- Describe the mechanism of action and causes of pertussis causing bacteria

Key Points

- Whooping cough is caused by the bacteria Bordetella pertussis, which infects the respiratory system.
- There is no zoonotic reservoir of Bordetella pertussis, meaning that humans appear to be the only host of this bacteria.
- Bordetella pertussis produces a number of virulence factors, notably Ptx, which inhibits the ability of phagocytes to respond to infections. This helps Bordetella pertussis spread throughout a host.

Key Terms

- **zoonotic**: of or relating to zoonosis, the transmission of an infectious disease between species.
- **glottis**: an organ of speech, located in the larynx, and consisting of the true vocal cords and the opening between them
- **lymphocytes**: type of white blood cells in the vertebrate immune system

Pertussis

Pertussis, also known as whooping cough, is an infection of the respiratory system characterized by a “whooping” sound that an afflicted person makes when breathing inwards. Only 50% of patients actually display the classic sound as they attempt to draw breath over a partially closed glottis. In the U.S., the infection was responsible for 5,000 to 10,000 deaths per year before a vaccine was developed and made available. Vaccination has transformed this. Between 1985 and 1988, fewer than 100 children died from pertussis. In 2000, according to the WHO, around 39 million people worldwide were being infected annually. Of these, about 297,000 died.

Causes of Pertussis

Pertussis is caused by the bacteria, Bordetella pertussis, a gram-negative, aerobic coccobacillus capsulate of the genus Bordetella. Bordetella pertussis infects its host by colonizing lung epithelial cells. The bacterium contains a surface protein, filamentous haemagglutinin adhesin, which binds to the sulfatides found on the cilia of epithelial cells. Once anchored, the bacterium produces tracheal cytotoxin, which stops the cilia from beating. This prevents the cilia from clearing debris from an organism ‘s lungs, and the body responds by sending the host into a coughing fit. These coughs expel some bacteria into the air, which are free to infect other hosts. There does not appear to be a zoonotic reservoir for B. pertussis. Humans are its only host. The bacterium is spread by airborne droplets, and its incubation period is one to two weeks.

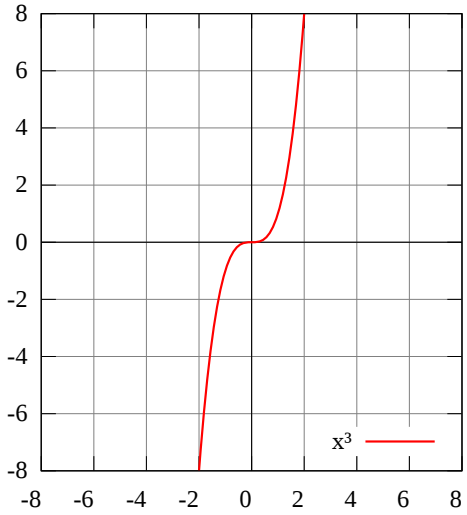

Figure: **Graph of $y=x^3$**

https://bio.libretexts.org/@go/page/12271

B. pertussis has the ability to inhibit the function of a host's immune system, through virulence factors. Its virulence factors include pertussis toxin, filamentous hæmagglutinin, pertactin, fimbria, and tracheal cytotoxin. The pertussis toxin, or PTx, inhibits G protein coupling that regulates an adenylate cyclase-mediated conversion of ATP to cyclic AMP. The end result is that phagocytes convert too much ATP to cyclic AMP, which can cause disturbances in cellular signaling mechanisms. This prevents phagocytes from correctly responding to an infection. PTx, formerly known as lymphocytosis -promoting factor, causes a decrease in the entry of lymphocytes into lymph nodes. This can lead to a condition known as lymphocytosis, which is a large increase in the number of lymphocytes in an organism's blood.

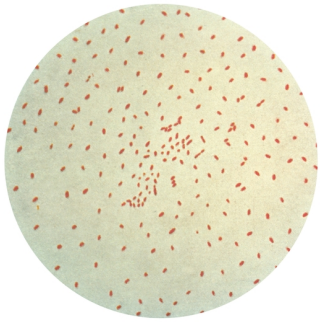

Figure: **Bordetella pertussis**: Bordetella pertussis, the bacteria that causes whooping cough

15.12E: Whooping Cough is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.12F: Tuberculosis

Tuberculosis is a common, and in many cases lethal, infectious bacterial disease that mainly affects the lungs.

Learning Objectives

- Summarize the risk factors associated with tuberculosis (TB)

Key Points

- Tuberculosis is spread through the air when people who have an active TB infection cough, sneeze, or otherwise transmit their saliva through the air.
- The classic symptoms of active TB infection are a chronic cough with blood -tinged sputum, fever, night sweats, and weight loss.
- Diagnosis of active TB relies on radiology (commonly chest x-rays) as well as microscopic examination and microbiological culture of body fluids. Diagnosis of latent TB relies on the Mantoux tuberculin skin test.
- Antibiotic resistance is a growing problem in the treatment of tuberculosis.

Key Terms

- **latent**: Existing or present but concealed or inactive.
- **tuberculosis**: An infectious disease of humans and animals caused by a species of mycobacterium mainly infecting the lungs where it causes tubercles characterized by the expectoration of mucus and sputum, fever, weight loss, and chest pain. It is transmitted through inhalation or ingestion of bacteria.
- **pleurisy**: inflammation of lung pleura
- **sputum**: Matter coughed up and expectorated from the mouth, composed of saliva and discharges from the respiratory passages such as mucus, phlegm, or pus.

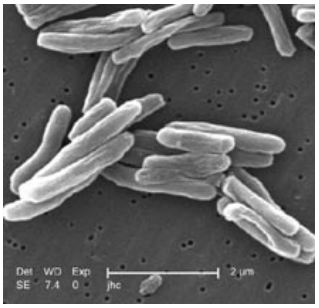

Figure: **Electron micrograph of Mycobacterium tuberculosis.**: This bacteria is primarily responsible for TB.

Tuberculosis (TB; short for tubercle bacillus) is a common, and in many cases lethal, infectious disease caused by various strains of mycobacteria, usually Mycobacterium tuberculosis . Tuberculosis typically attacks the lungs, but can also affect other parts of the body. It is spread through the air when people who have an active TB infection cough, sneeze, or otherwise transmit their saliva through the air. Most infections are asymptomatic and latent, but about one in 10 latent infections eventually progresses to active disease which, if left untreated, kills more than 50% of those infected. One third of the world's population is thought to have been infected with M. tuberculosis with new infections occurring at a rate of about one per second.

Symptoms

The classic symptoms of active TB infection are a chronic cough with blood-tinged sputum, fever, chills night sweats, and weight loss. Tuberculosis may infect any part of the body, but most commonly occurs in the lungs, known as pulmonary tuberculosis. Extrapulmonary TB occurs when tuberculosis develops outside of the lungs, but may co-exist with pulmonary TB as well. Extrapulmonary TB occurs more commonly in immunosuppressed persons and young children. In those with HIV this occurs in more than 50% of cases. Notable extrapulmonary infection sites include the pleura (in tuberculous pleurisy), the central nervous system (in tuberculous meningitis), the lymphatic system (in scrofula of the neck), the genitourinary system (in urogenital tuberculosis), and the bones and joints (osseous tuberculosis). Tuberculosis may become a chronic illness and cause extensive scarring in the upper lobes of the lungs.

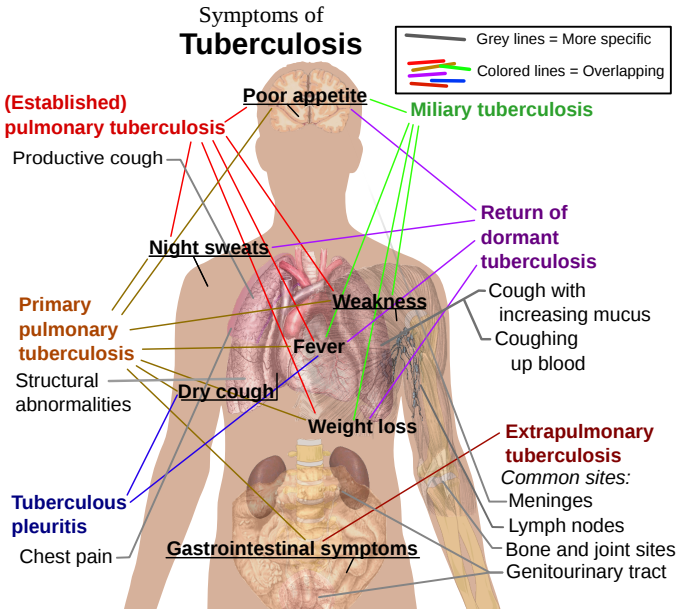

Figure: **Tuberculosis Symptoms.**: Diagram depicting various TB symptoms.

Diagnostics

Diagnosing active tuberculosis based merely on signs and symptoms is difficult, as is diagnosing the disease in those who are immunosuppressed. A diagnosis of TB should, however, be considered in those with signs of lung disease or constitutional symptoms lasting longer than two weeks. A chest x-ray and multiple sputum cultures for acid-fast bacilli are typically part of the initial evaluation. A definitive diagnosis of TB is made by identifying M. tuberculosis in a clinical sample such as sputum, pus, or a tissue biopsy. However, the difficult culture process for this slow-growing organism can take two to six weeks for blood or sputum culture.

The Mantoux tuberculin skin test is often used to screen people at high risk for TB. It involves injecting an protein extraction of the tuberculosis bacteria under the skin, and then examining the site 36-48 hours later. A person who has been exposed to the bacteria and has previously formed antibodies is expected to mount an immune response, displaying a raised, red area of skin at the site of injection. The test does have limited accuracy, especially in immunosuppressed people, and is typically used in combination with clinical findings and x-rays to reach a diagnosis.

Risk Factors

A number of factors make people more susceptible to TB infections. The most important risk factor globally is HIV; 13% of all TB cases are infected by the virus. This is a particular problem in sub-Saharan Africa, where rates of HIV are high. Tuberculosis is closely linked to both overcrowding and malnutrition, making it one of the principal diseases of poverty. Those at high risk thus include: people who inject illicit drugs, inhabitants and employees of locales where vulnerable people gather, such as prisons and homeless shelters; medically underprivileged and resource-poor communities; high-risk ethnic minorities, children in close contact with high-risk category patients, and health care providers serving these clients. Chronic lung disease is another significant risk factor. Those who smoke cigarettes have nearly twice the risk of TB than non-smokers. Other disease states can also increase the risk of developing tuberculosis, including alcoholism and diabetes mellitus. Certain medications that cause immunosuppression such as corticosteroids and infliximab, are becoming increasingly important risk factors, especially in the developed world.

Treatment

Treatment of TB uses antibiotics to kill the bacteria. Effective TB treatment is difficult, due to the unusual structure and chemical composition of the mycobacterial cell wall, which hinders the entry of drugs and makes many antibiotics ineffective. The two antibiotics commonly used are isoniazid and rifampicin. Treatments can be prolonged, from months to even years. A barrier to effective treatment is patient noncompliance. Due to the long duration of treatment, patients will often forget to take their antibiotics periodically or stop taking them altogether. This contributes to the development of drug-resistant tuberculosis. Many strains of tuberculosis have already become resistant to previous treatments, including a strain that is resistant to all antibiotics.

Latent TB treatment usually employs a single antibiotic, while active TB disease is best treated with combinations of several antibiotics to reduce the risk of the bacteria developing antibiotic resistance. People with latent infections are also treated to prevent them from progressing to active TB disease later in life.

15.12G: Bacterial Pneumonias

Pneumonia is an inflammatory lung disease that can lead to problems with breathing, often caused by bacterial infections.

Learning Objectives

- List the various causes of bacterial pneumonia

Key Points

- Most cases of pneumonia are caused by bacterial infections, and most of the bacterial infections are caused by the bacteria Streptococcus pneumoniae.
- The bacteria that cause pneumonia are split into three groups, gram-negative, gram-positive and atypical.
- Alcoholism is asociated with Streptococcus pneumoniae induced pneumonia and smoking exacerbates the situation.

Key Terms

- **pneumonia**: Pneumonia is an inflammatory condition of the lung, affecting primarily the microscopic air sacs known as alveoli.
- **infection**: An uncontrolled growth of harmful microorganisms in a host.
- **Alveoli**: alveolus (plural alveoli) a small air sac in the lungs, where oxygen and carbon dioxide are exchanged with the blood.

Pneumonia is an inflammatory condition of the lung, affecting primarily the microscopic air sacs known as alveoli. It is usually caused by infection with viruses or bacteria and less commonly other microorganisms, certain drugs and other conditions such as autoimmune diseases. Typical symptoms include a cough, chest pain, fever, and difficulty breathing. Diagnostic tools include x-rays and culture of the sputum. Vaccines to prevent certain types of pneumonia are available. Treatment depends on the underlying cause. Presumed bacterial pneumonia is treated with antibiotics. If the pneumonia is severe, the affected person is generally admitted to hospital.

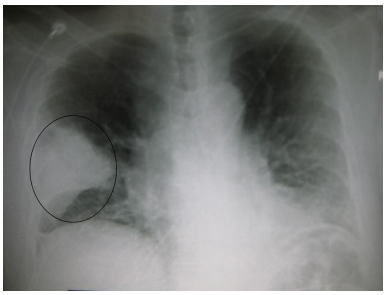

Figure: **Bacterial pneumonia**: A chest X-ray showing a very prominent wedge-shaped bacterial pneumonia in the right lung.

Bacteria are the most common cause of community-acquired pneumonia (CAP), with Streptococcus pneumoniae isolated in nearly 50% of cases. Other commonly isolated bacteria include: Haemophilus influenzae in 20%, Chlamydophila pneumoniae in 13%, and Mycoplasma pneumoniae in 3% of cases; Staphylococcus aureus; Moraxella catarrhalis; Legionella pneumophila and Gram-negative bacilli. A number of drug-resistant versions of the above infections are becoming more common, including drug-resistant Streptococcus pneumoniae (DRSP) and methicillin-resistant Staphylococcus aureus (MRSA). The spreading of organisms is facilitated when risk factors are present. Alcoholism is associated with Streptococcus pneumoniae, anaerobic organisms and Mycobacterium tuberculosis; smoking facilitates the effects of Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis, and Legionella pneumophila. Exposure to birds is associated with Chlamydia psittaci; farm animals with Coxiella burnetti; aspiration of stomach contents with anaerobic organisms; and cystic fibrosis with Pseudomonas aeruginosa and Staphylococcus aureus. Streptococcus pneumoniae is more common in the winter, and should be suspected in persons who aspirate a large amount anaerobic organisms.

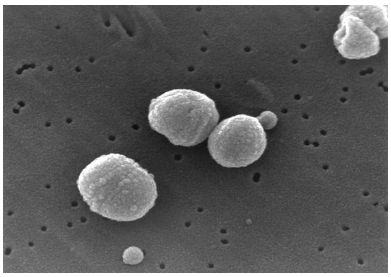

Figure: **Streptococcus pneumoniae**: The bacterium Streptococcus pneumoniae, a common cause of pneumonia, imaged by an electron microscope

Bacteria caused pneumonia fall into 3 groups:

1. Gram Positive. Streptococcus pneumoniae is the most common bacterial cause of pneumonia in all age groups except newborn infants. Streptococcus pneumoniae is a Gram-positive bacterium that often lives in the throat of people who do not have pneumonia. Other important Gram-positive causes of pneumonia are Staphylococcus aureus and Bacillus anthracis.
2. Gram Negative. Gram-negative bacteria are seen less frequently: Haemophilus influenzae, Klebsiella pneumoniae, Escherichia coli, Pseudomonas aeruginosa, and Moraxella catarrhalis are the most common. These bacteria often live in the gut and enter the lungs when contents of the gut (such as vomit or faeces) are inhaled.
3. Atypical bacteria. “Atypical” bacteria are Coxiella burnetii, Chlamydophila pneumoniae, Mycoplasma pneumoniae, and Legionella pneumophila. Many people falsely believe they are called “atypical” because they are uncommon and/or do not respond to common antibiotics and/or cause atypical symptoms. In reality, they are “atypical” because they do not gram stain as well as gram-negative and gram-positive organisms. Pneumonia caused by Yersinia pestis is usually called pneumonic plague.

Topic hierarchy

15.13A: Colds

15.13B: Viral Pneumonia

15.13C: Respiratory Syncytial Virus Infection

15.13D: Coryza and Influenza

15.13: Viral Diseases of the Respiratory System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.13A: Colds

The common cold is caused by several different viruses and is the most common human viral infection.

Learning Objectives

- Recognize the major viruses known to cause the common cold: rhinovirus, human parainfluenza virus and the human respiratory syncytial virus (RSV)

Key Points

- Over 200 virus types have been found that cause the common cold, with rhinoviruses being the most common.
- Rhinoviruses are a sub-type of picornavirus, a non-enveloped RNA virus, which is very small in size.
- The symptoms of the common cold are not due to the viral infection directly but rather the bodies response to the virus.
- There is no cure for the common cold, and in fact antibiotics which often prescribed are detrimental to patients.

Key Terms

- **serotypes**: A group of microorganisms characterized by a specific set of antigens; serovar.
- **capsid**: The outer protein shell of a virus.

The common cold (also known as nasopharyngitis, rhinopharyngitis, acute coryza, or a cold) is a viral infectious disease of the upper respiratory tract which affects primarily the nose. Symptoms include coughing, sore throat, runny nose, and fever which usually resolve in seven to ten days, with some symptoms lasting up to three weeks. Well over 200 viruses are implicated in the cause of the common cold. The most commonly implicated virus is a rhinovirus (30–80%), a type of picornavirus with 99 known serotypes. A picornavirus is a virus belonging to the family Picornaviridae. Picornaviruses are non-enveloped RNA viruses with an icosahedral capsid. The name is derived from pico, meaning small, and RNA, referring to the ribonucleic acid genome, so "picornavirus" literally means small RNA virus. Others include: coronavirus (10–15%), human parainfluenza viruses, human respiratory syncytial virus, adenoviruses, enteroviruses, and metapneumovirus. Frequently more than one virus is present.

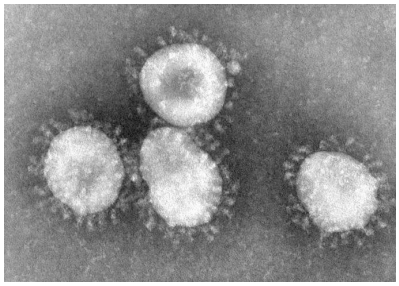

Figure: **Coronaviruses**: Coronaviruses are a group of viruses that have a halo, or crown-like (corona) appearance when viewed under an electron microscope. If you have a cold 10-15% of the time it is caused by a virus like this.

The symptoms of the common cold are believed to be primarily related to the immune response to the virus. The mechanism of this immune response is virus specific. For example, the rhinovirus is typically acquired by direct contact; it binds to human ICAM-1 receptors through unknown mechanisms to trigger the release of inflammatory mediators. These inflammatory mediators then produce the symptoms. It does not generally cause damage to the nasal epithelium. The respiratory syncytial virus (RSV) on the other hand is contracted by both direct contact and air born droplets. It then replicates in the nose and throat before frequently spreading to the lower respiratory tract. RSV does cause epithelium damage. Human parainfluenza virus typically results in inflammation of the nose, throat, and bronchi. In young children when it affects the trachea it may produce the symptoms of croup due to the small size of their airway.

No cure for the common cold exists, but the symptoms can be treated. Antibiotics have no effect against viral infections and thus have no effect against the viruses that cause the common cold. Due to their side effects they cause overall harm; however, they are still frequently prescribed.It is the most frequent infectious disease in humans with the average adult contracting two to three colds a year and the average child contracting between six and twelve. These infections have been with humanity since antiquity.

15.13A: Colds is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.13B: Viral Pneumonia

Viral pneumonia, one of the two leading causes of pneumonia, more commonly affects children.

Learning Objectives

- Outline the route of infection for a virus that causes pneumonia

Key Points

- Viral pneumonia is caused by both viral infection which leads to cell death. The body's response to clear the cellular debris leads to further inflammation and the blockage of respiration.
- Many different viruses can cause viral pneumonia, but they all enter the lungs and damage the alveoli.
- The best prevention for viral pneumonia is to vaccinate against the viruses that can cause pneumonia.

Key Terms

- **Alveoli**: alveolus (plural alveoli) a small air sac in the lungs, where oxygen and carbon dioxide are exchanged with the blood.
- **cytokines**: Regulatory proteins that function in the regulation of the cells involved in immune system function
- **apoptosis**: The process of programmed cell death by which cells undergo an ordered sequence of events which lead to death of the cell. This occurs during growth and development of the organism, as a part of normal cell aging, or as a response to cellular injury.

Pneumonia is an inflammatory condition of the lung that particularly affects microscopic air sacs (alveoli). It is associated with fever and chest symptoms, and it appears as a lack of space on a chest x-ray. The inflammation may be caused by infection from viruses, bacteria, or other microorganisms. Less commonly, it is caused by certain drugs and other conditions. Viruses and bacteria are the two leading causes of pneumonia, while fungi and parasites are less common. Viruses are the most common cause of pneumonia in children, while bacteria are the most common cause in adults.

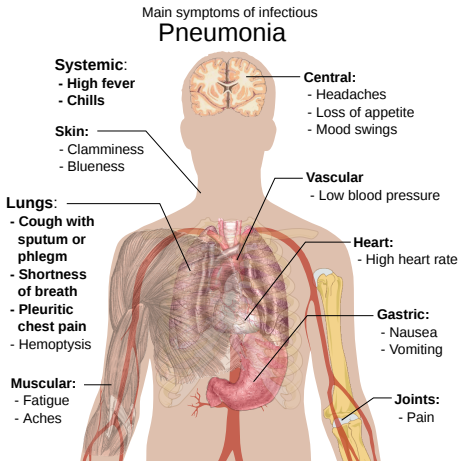

Figure: **Symptoms of pneumonia**: Typical symptoms associated with pneumonia.

How Viruses Cause Pneumonia

Many types of viral infections can cause pneumonia, but in order to do this, these viruses must first invade cells in order to reproduce. Typically, a virus will reach the lungs by traveling in droplets through the mouth and nose during inhalation. Once there, the virus will invade the cells that line the airways and the alveoli. This invasion often leads to cell death, in which either the virus directly kills the cell, or the cell self-destructs through apoptosis. Further damage to the lungs occurs when the immune system responds to the infection. White blood cells, in particular lymphocytes, are responsible for activating a variety of chemicals (cytokines) which cause fluid to leak into the alveoli. The combination of cellular destruction and fluid-filled alveoli interrupts the transportation of oxygen into the bloodstream. Thus, in large part, as with other viral infections, it is the body's response to the virus that causes the symptoms of pneumonia, and not necessarily the viral infection itself. In addition to their effects on the lungs, many viruses affect other organs and can lead to illnesses that affect other bodily functions. Viruses also make the body more susceptible to bacterial infection. For this reason, bacterial pneumonia often complicates viral pneumonia.

Which Viruses Cause Pneumonia

Common viruses that cause pneumonia include influenza viruses A and B, respiratory syncytial viruses (RSV), and human parainfluenza viruses (hPIV), the last of which particularly affects children. Rarer viruses that commonly cause pneumonia include adenoviruses (in military recruits), metapneumoviruses, and severe acute respiratory syndrome virus (SARS coronavirus). Viruses that primarily cause other diseases, but sometimes cause pneumonia, include herpes simplex virus (HSV, mainly in newborns), varicella- zoster virus (VZV), measles virus, rubella virus, and cytomegalovirus (CMV, mainly in people with immune system problems). In children with pneumonia, the most commonly identified agents are respiratory syncytial virus, rhinovirus, human metapneumovirus, human bocavirus, and parainfluenza viruses. Because of this, the best prevention against viral pneumonia is vaccination against influenza, adenovirus, chickenpox, herpes zoster, measles, and rubella.

15.13B: Viral Pneumonia is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.13C: Respiratory Syncytial Virus Infection

Human respiratory syncytial virus (RSV) causes respiratory tract infections in humans.

Learning Objectives

- Recognize the traits associated with the human respiratory syncytial virus (RSV) and its mode of infection

Key Points

- RSV is a single stranded virus, the genome of which encodes 11 proteins which play different roles in RSV infection.
- RSV can induce syncytia (aggregates of host cells), providing further fertile ground for RSV to propagate.
- There is no direct treatment of RSV except to mitigate the symptoms, giving the patient's body time to fight off the infection.

Key Terms

- **cannula**: A hose or tube that connects directly to an oxygen (O2) bottle/source from the user's nose, commonly used by aircraft pilots or others needing a direct oxygen breathing apparatus.
- **prophylactic**: A medicine that preserves or defends against disease; a preventive.
- **hypertonic**: Having a greater osmotic pressure than another.

Respiratory Syncytial Virus Infection

Human respiratory syncytial virus (RSV) is a virus that causes respiratory tract infections. It is a major cause of lower respiratory tract infections and hospital visits during infancy and childhood. A prophylactic medication (not a vaccine) exists for preterm-birth (under 35 weeks gestation) infants, and for infants with a congenital heart defect or bronchopulmonary dysplasia. Of those infected with RSV, 2–3% will develop bronchiolitis, necessitating hospitalization.

RSV is a negative-sense, single-stranded RNA virus of the family Paramyxoviridae, which includes common respiratory viruses such as those causing measles and mumps. RSV is a member of the paramyxovirus subfamily Pneumovirinae. RSV has ten genes encoding 11 proteins. There are two open reading frames of M2. NS1 and NS2 inhibit type I interferon activity. N encodes the nucleocapsid protein that associates with the genomic RNA forming the nucleocapsid. M encodes the matrix protein required for viral assembly. SH, G and F form the viral coat. The G protein is a surface protein; it functions as the attachment protein, the protein which attaches the virus to target cells. The F protein is another important surface protein. RSV's name comes from the fact that F proteins on the surface of the virus cause the cell membranes on nearby cells to merge, forming syncytia.

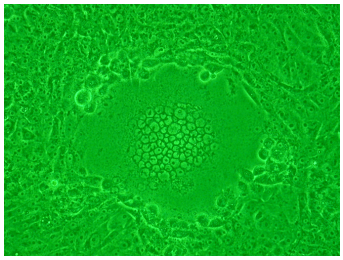

Figure: **Syncytium**: The mass or "ball" of cells in the middle of the image are a syncytium of cells that formed due to infection by the HIV virus.

Syncytia are aggregates of cells that can form when cells are infected with certain types of viruses, notably HIV and paramyxoviruses such as RSV. During infection, viral fusion proteins used by the virus to enter the cell are transported to the cell surface where they can cause the host cell membrane to fuse with neighboring cells. This presumably works to the virus's advantage, as aggregates of target cells provide more hosts for the virus to infect and multiply. F proteins also mediate viral fusion, allowing entry of the virus into the cell cytoplasm and also allowing the formation of syncytia. Antibodies directed at the F protein are neutralizing. M2 is the second matrix protein required for viral transcription; it encodes M2-1 (elongation factor) and M2-2 (transcription regulation), while L encodes the RNA polymerase. The phosphoprotein P is a cofactor for L. The genome is transcribed sequentially from NS1 to L with reduction in expression levels along its length.

Treatment of RSV is limited to supportive care, including oxygen therapy. Studies of nebulized hypertonic saline (HS) have shown that the "use of nebulized 3% HS is a safe, inexpensive, and effective treatment for infants hospitalized with moderately severe viral bronchiolitis" where "RSV accounts for the majority of viral bronchiolitis cases. " Supportive care includes fluids and oxygen

until the illness runs its course. Increased airflow, humidified and delivered via nasal cannula, may be supplied in order to reduce the effort required for respiration.

15.13D: Coryza and Influenza

Influenza is an infectious disease caused by RNA viruses of the family Orthomyxoviridae that affects birds and mammals.

Learning Objectives

- Differentiate between the respiratory system disorders of influenza and coryza

Key Points

- The most common symptoms of the disease are chills, fever, sore throat, muscle pains, severe headache, coughing, weakness/fatigue, and general discomfort.
- Influenza is transmitted through the air by coughs or sneezes, by direct contact with bird droppings or nasal secretions, or through contact with contaminated surfaces.
- Coryza is a word describing the symptoms of a cold and refers to the inflammation of the mucous membranes lining the nasal cavity which usually gives rise to the symptoms of congestion.

Key Terms

- **coryza**: Inflammation of the mucous membranes lining the nasal cavity, usually causing a running nose, nasal congestion, and loss of smell.
- **RNA virus**: Any of many viruses that possess ribonucleic acid as their genetic material and do not replicate using DNA.
- **influenza**: An acute contagious disease of the upper airways and lungs, caused by a virus, which rapidly spreads around the world in seasonal epidemics.

Influenza, commonly referred to as the flu, is an infectious disease caused by RNA viruses of the family Orthomyxoviridae that affects birds and mammals. The most common symptoms of the disease are chills, fever, sore throat, muscle pains, severe headache, coughing, weakness/fatigue, and general discomfort. Although it is often confused with other influenza-like illnesses, especially the common cold, influenza is a more severe disease than the common cold. The general symptoms of influenza are summarized in.

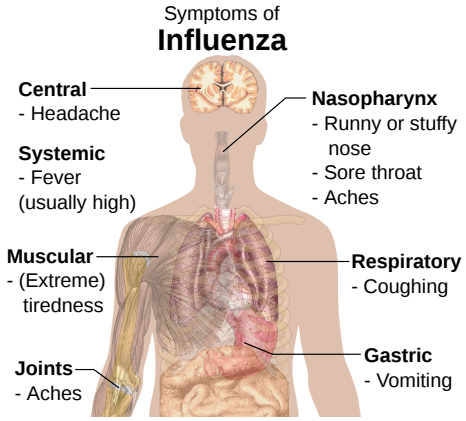

Figure: **Symptoms of influenza**: Symptoms of influenza with fever and cough the most common symptoms.

Typically, influenza is transmitted through the air by coughs or sneezes, creating aerosols containing the virus. Influenza can also be transmitted by direct contact with bird droppings or nasal secretions, or through contact with contaminated surfaces. Reasonably effective ways to reduce the transmission of influenza include good personal health and hygiene habits such as: not touching your eyes, nose or mouth; frequent hand washing, covering coughs and sneezes, avoiding close contact with sick people and staying home yourself if you are sick.

Vaccinations against influenza are usually made available to people in developed countries. The most common human vaccine is the trivalent influenza vaccine (TIV) that contains purified and inactivated antigens against three viral strains. Typically, this vaccine includes material from two influenza A virus subtypes and one influenza B virus strain. The TIV carries no risk of transmitting the disease, and it has very low reactivity. A vaccine formulated for one year may be ineffective in the following year, since the influenza virus evolves rapidly, and new strains quickly replace the older ones.

Influenza viruses A, B, and C are very similar in overall structure and a diagram of the structure of the virus can be seen in Figure 2. The viral particles of all influenza viruses are similar in composition. They are made of a viral envelope containing two main types of glycoproteins, wrapped around a central core. The central core contains the viral RNA genome and other viral proteins that package and protect this RNA. RNA tends to be single stranded, but in special cases it is double. Unusually for a virus, its genome is not a single piece of nucleic acid but seven or eight pieces of segmented negative-sense RNA. Each piece of RNA contain either one or two genes, which code for a gene product (protein). Hemagglutinin (HA) and neuraminidase (NA) are the two large glycoproteins on the outside of the viral particles. HA is a lectin that mediates binding of the virus to target cells and entry of the viral genome into the target cell, while NA is involved in the release of progeny virus from infected cells, by cleaving sugars that bind the mature viral particles. Furthermore, they are antigens to which antibodies can be raised. Influenza A viruses are classified into subtypes based on antibody responses to HA and NA. These different types of HA and NA form the basis of the H and N distinctions in, for example, H5N1. There are 16 H and 9 N subtypes known, but only H 1, 2, and 3, and N 1 and 2 are commonly found in humans.

Antiviral medication can be effective, but some strains of influenza can show resistance to the standard antiviral drugs. The two classes of antiviral drugs used against influenza are neuraminidase inhibitors and M2 protein inhibitors (adamantane derivatives). Neuraminidase inhibitors are currently preferred for flu virus infections since they are less toxic and more effective.

Coryza is a word describing the symptoms of a “cold. ” It describes the inflammation of the mucous membranes lining the nasal cavity which usually gives rise to the symptoms of nasal congestion and loss of smell, among other symptoms. Coryza may not always have an infectious or allergenic etiology and can be due to something as innocuous as a cold wind, spicy food, or tender points in the muscles of the neck such as the sternocleidomastoid. It is also a symptom of narcotic withdrawal. Coryza is classically used in association with the “four Cs” of measles infection: cough, conjunctivitis, Koplik’s spots, and coryza.

Treatment of coryza depends on etiology. Coryza from any allergic causes usually gets relieved if contact with the allergen (dust, pollen, cold wind, etc.) is avoided. Nasal sprays, antihistamines, and decongestants are beneficial. However, if it is due to any virus it usually takes three to seven days to improve.

SECTION OVERVIEW

15.14: Fungal Diseases of the Respiratory System

Topic hierarchy

15.14A: Histoplasmosis

15.14B: Coccidiomycosis

15.14C: Pneumocystis Pneumonia

15.14D: Blastomycosis

15.14E: Other Fungi Involved in Respiratory Disease

15.14: Fungal Diseases of the Respiratory System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.14A: Histoplasmosis

Histoplasmosis is a disease caused by the fungus Histoplasma capsulatum.

Learning Objectives

- Describe the traits associated with and mode of transmission for Histoplasma capsulatum

Key Points

- Histoplasmosis is s a disease caused by the fungus Histoplasma capsulatum, which is usually found in soil, and often associated with decaying bat guano or bird droppings.
- Cases of histoplasmosis have declined acutely since the Industrial Revolution as quality of life improved dramatically and humans were no longer living in their own squalor.
- Symptoms of this infection vary greatly, but the disease affects primarily the lungs. Occasionally, other organs are affected, and it can be fatal if left untreated.

Key Terms

- **Histoplasmosis**: Histoplasmosis is a disease caused by the fungus Histoplasma capsulatum. Symptoms of this infection vary greatly, but the disease primarily affects the lungs. Other organs are occassionally affected; this is called disseminated histoplasmosis and can be fatal if left untreated.
- **fungus**: Any member of the kingdom Fungi; a eukaryotic organism typically having chitin cell walls but no chlorophyll or plastids. Fungi may be unicellular or multicellular.

Histoplasmosis (also known as “Cave disease,” “Darling’s disease,” “Ohio valley disease,” “Reticuloendotheliosis,” “Spelunker’s Lung,” and “Caver’s disease”) is a disease caused by the fungus Histoplasma capsulatum. Symptoms of this infection vary greatly, but the disease primarily affects the lungs. Other organs are occasionally affected; this is called disseminated histoplasmosis and can be fatal if left untreated. Histoplasmosis is common among AIDS patients due to their suppressed immune system.

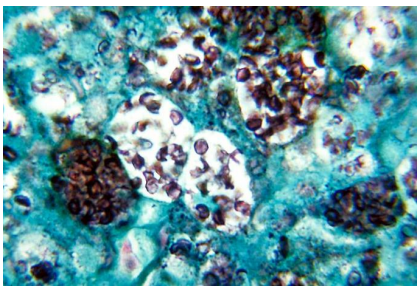

Figure: **Histoplasmosis**: This is a Methenamine silver strain of Histoplasma capsulatum that shows histopathologic changes in the histoplasmosis.

If symptoms of histoplasmosis infection occur, they will start within 3 to 17 days after exposure, with the average being 12 to 14 days. Most affected individuals have clinically silent manifestations and show no apparent ill effects. The acute phase of histoplasmosis is characterized by non-specific respiratory symptoms, often cough or flu-like. Chest X-ray findings are normal in 40 to 70% of cases. Chronic histoplasmosis cases can resemble tuberculosis, and disseminated histoplasmosis affects multiple organ systems and is fatal unless treated.

Figure: **Acute pulmonary histoplasmosis**: This is a chest X-ray of a patient with acute pulmonary histoplasmosis.

Histoplasmosis may be divided into the following types: primary pulmonary histoplasmosis, progressive disseminated histoplasmosis, primary cutaneous histoplasmosis, and African histoplasmosis.

Histoplasma capsulatum is found throughout the world. It is endemic in certain areas of the United States, particularly in states bordering the Ohio River valley and the lower Mississippi River. It is also common in caves in southern and East Africa. Positive histoplasmin skin tests occur in as many as 90% of the people living in areas where Histoplasma capsulatum is common, such as the eastern and central United States.

Histoplasma capsulatum grows in soil and material contaminated with bird or bat droppings (guano). The fungus has been found in poultry house litter, caves, areas harboring bats, and in bird roosts (particularly those of starlings). The fungus is thermally dimorphic: in the environment it grows as a brownish mycelium, and at body temperature (37 °C in humans) it morphs into a yeast. The inoculum is represented principally by microconidia that, once inhaled into the alveolar spaces, germinate and then transform into budding yeast cells. Histoplasmosis is not contagious, but is contracted by inhalation of the spores from disturbed soil or guano.

Histoplasmosis can be diagnosed by samples containing the fungusken from sputum, blood, or infected organs. It can also be diagnosed by detection of antigens in blood or urine samples by ELISA or PCR. It can also be diagnosed by a test for antibodies against Histoplasma in the blood. Histoplasma skin tests indicate whether a person has been exposed, but do not indicate whether they have the disease. Formal histoplasmosis diagnoses are often confirmed only by culturing the fungus directly. Cutaneous manifestations of disseminated disease are diverse and often present as a nondescript rash with systemic complaints. Diagnosis is best established by urine antigen testing. Blood cultures may take up to 6 weeks for diagnostic growth to occur and serum antigen testing often comes back with a false negative before 4 weeks of disseminated infection.

It is not practical to test or decontaminate most sites that may be contaminated with Histoplasma capsulatum, so precautions to reduce a person's risk of exposure are important. Precautions common to all geographical locations would be to avoid accumulations of bird or bat droppings.

Antifungal medications are used to treat severe cases of acute histoplasmosis and all cases of chronic and disseminated disease. Typical treatment of severe disease first involves treatment with amphotericin B, followed by oral itraconazole. Treatment with itraconazole will need to continue for at least a year in severe cases.

In many milder cases, oral itraconazole or ketoconazole is sufficient. Asymptomatic disease is typically not treated. Past infection results in partial protection against ill effects if reinfected.

15.14A: Histoplasmosis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.14B: Coccidiomycosis

Coccidioidomycosis is a fungal disease caused by *Coccidioides immitis* or *C. posadasii*.

Learning Objectives

- Describe the mode of transmission, symptoms and diagnostic test associated with Coccidioidomycosis immitis

Key Points

- C. immitis resides in the soil in certain parts of the southwestern United States, northern Mexico, and parts of Central and South America.
- Infection is caused by inhalation of the particles.
- The disease is usually mild, with flu-like symptoms and rashes.

Key Terms

- **Coccidioidomycosis**: Coccidioidomycosis is a fungal disease caused by Coccidioides immitis or C. posadasii. It is endemic in certain parts of Arizona, California, Nevada, New Mexico, Texas, Utah and northwestern Mexico.
- **fungal**: Of or pertaining to a fungus or fungi
- **inhalation**: The substance (medicament) which is inhaled.

Coccidioidomycosis (commonly known as “Valley fever”, as well as “California fever”, “Desert rheumatism”, and “San Joaquin Valley fever”) is a fungal disease caused by *Coccidioides immitis* or *C. posadasii*. It is endemic in certain parts of Arizona, California, Nevada, New Mexico, Texas, Utah and northwestern Mexico.

Figure: **Coccidioidomycosis**: Histopathological changes in a case of coccidioidomycosis of the lung showing a large fibrocaseous nodule.

C. immitis resides in the soil in certain parts of the southwestern United States, northern Mexico, and parts of Central and South America. It is dormant during long dry spells, then develops as a mold with long filaments that break off into airborne spores when the rains come. The spores, known as arthroconidia, are swept into the air by disruption of the soil, such as occurs during construction, farming, or an earthquake.

Infection is caused by inhalation of the particles. The disease is not transmitted from person to person. The infection ordinarily resolves leaving the patient with a specific immunity to re-infection. *C. immitis* is a dimorphic saprophytic organism that grows as a mycelium in the soil and produces a spherule form in the host organism.

The disease is usually mild, with flu-like symptoms and rashes. The Mayo Clinic estimates that half the population in some affected areas have suffered from the disease. On occasion, those particularly susceptible may develop a serious or even fatal illness. Serious complications include severe pneumonia, lung nodules, and disseminated disease, where the fungus spreads throughout the body. The disseminated form of Valley Fever can devastate the body, causing skin ulcers, abscesses, bone lesions, severe joint pain, heart inflammation, urinary tract problems, meningitis, and often death. In order of decreasing risk, people of Filipino, African, Native American, Hispanic, and Asian descent are susceptible to the disseminated form of the disease. Men and pregnant women, and people with weakened immune systems (such as from AIDS), are more susceptible than non-pregnant women.

It has been known to infect humans, cattle, deer, dogs, elk, fish, mules, livestock, apes, kangaroos, wallabies, tigers, bears, badgers, otters and marine mammals.

Symptomatic infection (40% of cases) usually presents as an influenza-like illness with fever, cough, headaches, rash, and myalgia (muscle pain). Some patients fail to recover and develop chronic pulmonary infection or widespread disseminated infection

(affecting meninges, soft tissues, joints, and bone). Severe pulmonary disease may develop in HIV-infected persons.

An additional risk is that health care providers who are unfamiliar with it or are unaware that the patient has been exposed to it may misdiagnose it as cancer and subject the patient to unnecessary surgery.

Coccidioidomycosis may be divided into the following types: Primary pulmonary coccidioidomycosis; Disseminated coccidioidomycosis; and Primary cutaneous coccidioidomycosis.

The fungal infection can be demonstrated by microscopic detection of diagnostic cells in body fluids, exudates, sputum and biopsy-tissue. With specific nucleotide primers, *C.immitis* DNA can be amplified by PCR. It can also be detected in cultures by morphological identification, or by using molecular probes that hybridize with *C.immitis* RNA. An indirect demonstration of fungal infection can be achieved also by serologic analysis detecting fungal antigen or host antibody produced against the fungus.

There are no published prospective studies that examine optimal antifungal therapy for coccidioidomycosis. Mild cases often do not require treatment. Oral Fluconazole and intravenous Amphotericin B are used in progressive or disseminated disease, or in which patients are immunocompromised. Alternatively, itraconazole or ketoconazole may be used. Posaconazole and voriconazole have also been used. There is currently no practical preventative measures available for people who live or travel through Valley Fever endemic areas. It is recommended to avoid airborne dust or dirt, though this is not a guaranteed manner of prevention. People in certain occupations may be advised to wear face masks.

15.14B: Coccidiomycosis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.14C: Pneumocystis Pneumonia

Pneumocystis pneumonia (PCP) or pneumocystosis is a form of pneumonia, caused by the yeast-like fungus Pneumocystis jirovecii.

Learning Objectives

- Review the symptoms associated with pneumocystis pneumonia and the methods of diagnosis

Key Points

- Pneumocystis jirovecii is a pathogen that is specific to humans.
- Pneumocystis is commonly found in the lungs of healthy people, but, being a source of opportunistic infection, it can cause a lung infection in people with a weak immune system.
- Symptoms of PCP include fever, non-productive cough, shortness of breath, weight loss, and night sweats.

Key Terms

- **Pneumocystis pneumonia**: Pneumocystis pneumonia (PCP) or pneumocystosis is a form of pneumonia, caused by the yeast-like fungus Pneumocystis jirovecii. This pathogen is specific to humans; it has not been shown to infect other animals.
- **Opportunistic**: An opportunistic infection is an infection caused by pathogens, particularly opportunistic pathogens—those that take advantage of certain situations—such as bacterial, viral, fungal or protozoan infections that usually do not cause disease in a healthy host, one with a healthy immune system. A compromised immune system, however, presents an "opportunity" for the pathogen to infect.
- **Symptoms**: A symptom is a departure from normal function or feeling which is noticed by a patient, indicating the presence of disease or abnormality. A symptom is subjective, observed by the patient, and cannot be measured directly.

Pneumocystis pneumonia (PCP) or pneumocystosis is a form of pneumonia, caused by the yeast-like fungus (which had previously been erroneously classified as a protozoan) Pneumocystis jirovecii. This pathogen is specific to humans; it has not been shown to infect other animals. Other species of Pneumocystis that parasitize other animals have not been shown to infect humans.

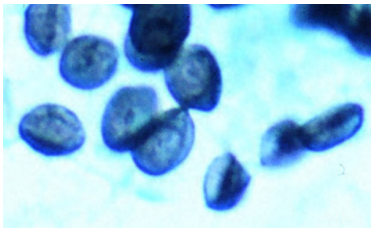

Figure: **Pneumocystis jirovecii pneumonia**: Pneumocystis jirovecii cysts from bronchoalveolar lavage, stained with Toluidin blue O stain

Pneumocystis is commonly found in the lungs of healthy people, but being a source of opportunistic infection, it can cause a lung infection in people with a weak immune system. Pneumocystis pneumonia is especially seen in people with cancer, HIV/AIDS and the use of medications that affect the immune system.

Nomenclature of Pneumocystis Pneumonia

The older name Pneumocystis carinii (which now only applies to the Pneumocystis species that is found in rats), is still in common usage. As a result, Pneumocystis pneumonia (PCP) is also known as Pneumocystis jiroveci[i] pneumonia and (incorrectly) as Pneumocystis carinii pneumonia.

Regarding nomenclature, when the name of Pneumocystis pneumonia changed from P. carinii pneumonia to P. jirovecii pneumonia, it was at first felt that it could no longer be referred to as "PCP". However, because the term PCP was already in common usage, it was rationalized that the term PCP could continue to be used, as it stood for PneumoCystis (jirovecii) Pneumonia.

Symptoms of Pneumocystis Pneumonia

Symptoms of PCP include fever, non-productive cough (because sputum is too viscous to become productive), shortness of breath (especially on exertion), weight loss, and night sweats. There is usually not a large amount of sputum with PCP unless the patient

has an additional bacterial infection. The fungus can invade other visceral organs (such as the liver, spleen, and kidney), but only in a minority of cases.

Pneumothorax is a well-known complication of PCP. An acute history of chest pain with breathlessness and diminished breath sounds is typical of pneumothorax.

The risk of pneumonia due to Pneumocystis jirovecii increases when CD4 positive cell levels are less than 200 cells/µl. In these immunosuppressed individuals the manifestations of the infection are highly variable. The disease attacks the interstitial, fibrous tissue of the lungs, with marked thickening of the alveolar septa and alveoli, leading to significant hypoxia which can be fatal if not treated aggressively. In this situation LDH levels increase and gas exchange is compromised. Oxygen is less able to diffuse into the blood, leading to hypoxia. Hypoxia, along with high arterial carbon dioxide (CO_2) levels, stimulates hyper-ventilatory effort, thereby causing dyspnea (breathlessness).

Diagnosis and Treatment of Pneumocystis Pneumonia

The diagnosis can be confirmed by the characteristic appearance of the chest x-ray, which shows widespread pulmonary infiltrates, and an arterial oxygen level (PaO2) that is strikingly lower than would be expected from symptoms. Gallium 67 scans are also use in the diagnosis. They are abnormal in approximately 90% of cases and are often positive before the chest x-ray becomes abnormal. The diagnosis can be definitively confirmed by histological identification of the causative organism in sputum or bronchio-alveolar lavage (lung rinse). Staining with toluidine blue, silver stain, periodic-acid schiff stain, or an immunofluorescence assay will show the characteristic cysts. The cysts resemble crushed ping-pong balls and are present in aggregates of 2 to 8 (and not to be confused with Histoplasma or Cryptococcus, which typically do not form aggregates of spores or cells). A lung biopsy would show thickened alveolar septa with fluffy eosinophilic exudate in the alveoli. Both the thickened septa and the fluffy exudate contribute to dysfunctional diffusion capacity which is characteristic of this pneumonia.

Pneumocystis infection can also be diagnosed by immunofluorescent or histochemical staining of the specimen, and more recently by molecular analysis of polymerase chain reaction products comparing DNA samples. Notably, simple molecular detection of Pneumocystis jirovecii in lung fluids does not mean that a person has Pneumocystis pneumonia or infection by HIV. The fungus appears to be present in healthy individuals in the general population.

Antipneumocystic medication is used with concomitant steroids in order to avoid inflammation, which causes an exacerbation of symptoms about four days after treatment begins if steroids are not used. By far the most commonly used medication is trimethoprim-sulfamethoxazole, but some patients are unable to tolerate this treatment due to allergies. Other medications that are used, alone or in combination, include pentamidine, trimetrexate, dapsone, atovaquone, primaquine, pafuramidine maleate (under investigation), and clindamycin. Treatment is usually for a period of about 21 days. However, pneumocystis pneumonia can be prevented by the drug TMP-SMX.

Pentamidine is less often used as its major limitation is the high frequency of side effects. These include acute pancreatitis, renal failure, hepatotoxicity, leukopenia, rash, fever, and hypoglycemia.

15.14C: Pneumocystis Pneumonia is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.14D: Blastomycosis

Blastomycosis is a fungal infection caused by the organism Blastomyces dermatitidis.

Learning Objectives

- Describe the causes and symptoms of blastomycosis

Key Points

- Infection occurs by inhalation of the fungus from its natural soil habitat.
- Once suspected, the diagnosis of blastomycosis can usually be confirmed by demonstration of the characteristic, broad-based budding organisms in sputum or tissues by KOH prep, cytology, or histology.
- Once inhaled in the lungs, Blastomycosis multiply and may disseminate through the blood and lymphatics to other organs, including the skin, bone, genitourinary tract, and brain.

Key Terms

- **fungal**: Of or pertaining to a fungus or fungi
- **Blastomycosis**: Blastomycosis is a fungal infection caused by the organism Blastomyces dermatitidis. Endemic to portions of North America, blastomycosis causes clinical symptoms similar to histoplasmosis.
- **inhalation**: The substance (medicament) which is inhaled.

Blastomycosis (also known as “North American blastomycosis,” “Blastomycetic dermatitis,” and “Gilchrist’s disease”) is a fungal infection caused by the organism Blastomyces dermatitidis. Endemic to portions of North America, blastomycosis causes clinical symptoms similar to histoplasmosis.

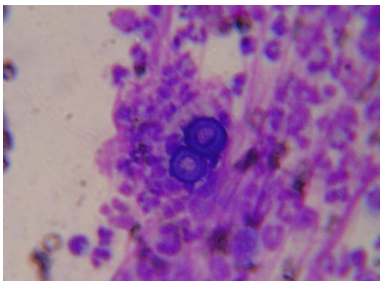

Figure: **Blastomycosis**: Blastomyces dermatitidis, the causative agent of blastomycosis.

Symptoms

Blastomycosis can present in one of the following ways:

- A flu-like illness with fever, chills, myalgia, headache, and a nonproductive cough which resolves within days
- An acute illness resembling bacterial pneumonia, with symptoms of high fever, chills, a productive cough, and pleuritic chest pain
- A chronic illness that mimics tuberculosis or lung cancer, with symptoms of low-grade fever, a productive cough, night sweats, and weight loss
- A fast, progressive, and severe disease that manifests as ARDS, with fever, shortness of breath, tachypnea, hypoxemia, and diffuse pulmonary infiltrates
- Skin lesions, usually asymptomatic, that appear as ulcerated lesions with small pustules at the margins
- Bone lytic lesions that can cause bone or joint pain.
- Prostatitis may be asymptomatic or may cause pain on urinating. Laryngeal involvement causes hoarseness.

Infection occurs by inhalation of the fungus from its natural soil habitat. Once inhaled in the lungs, Blastomycosis multiply and may disseminate through the blood and lymphatics to other organs, including the skin, bone, genitourinary tract, and brain. The incubation period is 30 to 100 days, although infection can be asymptomatic.

Diagnosis

Once suspected, the diagnosis of blastomycosis can usually be confirmed by demonstration of the characteristic, broad-based budding organisms in sputum or tissues by KOH prep, cytology, or histology. Tissue biopsy of skin or other organs may be required in order to diagnose extra-pulmonary disease. Blastomycosis is histologically associated with granulomatous nodules. Commercially available urine antigen testing appears to be quite sensitive in suggesting the diagnosis in cases where the organism is not readily detected. While culture of the organism remains the definitive diagnostic standard, its slow growing nature can lead to delays in treatment of up to several weeks.

Treatment

Itraconazole given orally is the treatment of choice for most forms of the disease. Ketoconazole may also be used. Cure rates are high, and the treatment over a period of months is usually well tolerated. Amphotericin B is considerably more toxic, and is usually reserved for immunocompromised patients who are critically ill and those with central nervous system disease. Fluconazole has also been tested on patients in Canada.

15.14D: Blastomycosis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.14E: Other Fungi Involved in Respiratory Disease

Sporotrichosis is a disease caused by the fungus *Sporothrix schenckii*.

Learning Objectives

- Compare and contrast the various forms of sporotrichosis: cutaneous/skin, pulmonary and disseminated sporotrichosis

Key Points

- In cases of sporotrichosis affecting the lungs, the fungal spores enter through the respiratory pathways.
- Sporotrichosis progresses slowly – the first symptoms may appear from one to 12 weeks (average three weeks) after the initial exposure to the fungus.
- Forms and symptoms of sporotrichosis include: cutaneous or skin sporotrichosis; pulmonary sporotrichosis; and disseminated sporotrichosis.

Key Terms

- **fungus**: Any member of the kingdom Fungi; a eukaryotic organism typically having chitin cell walls but no chlorophyll or plastids. Fungi may be unicellular or multicellular.
- **Sporotrichosis**: A disease caused by the infection of the fungus Sporothrix schenckii, usually affecting the skin, although other rare forms can affect the lungs, joints, bones, and even the brain. Because roses can spread the disease, it is often referred to as rose-thorn or rose-gardeners' disease.

Sporotrichosis (also known as "Rose gardener's disease") is caused by the infection of the fungus *Sporothrix schenckii* . This fungal disease usually affects the skin, although other rare forms can affect the lungs, joints, bones, and even the brain. Because roses can spread the disease, it is one of a few diseases referred to as rose-thorn or rose-gardeners' disease.

Because S. schenckii is naturally found in soil, hay, sphagnum moss, and plants, it usually affects farmers, gardeners, and agricultural workers. It enters through small cuts and abrasions in the skin to cause the infection. In cases of sporotrichosis affecting the lungs, the fungal spores enter through the respiratory pathways. Sporotrichosis can also be acquired from handling cats with the disease; it is an occupational hazard for veterinarians.

Sporotrichosis progresses slowly – the first symptoms may appear from one to 12 weeks (average three weeks) after the initial exposure to the fungus. Serious complications can also develop in patients who have a compromised immune system.

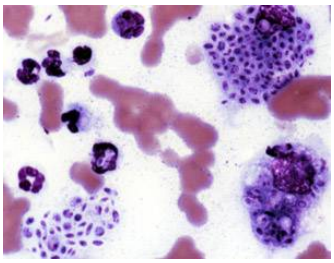

Figure: **Sporotrichosis**: Cytologic preparation from a case of feline sporotrichosis; phagocytic cells show numerous variably-shaped yeast forms within.

Forms and symptoms of sporotrichosis include: cutaneous or skin sporotrichosis; pulmonary sporotrichosis; and disseminated sporotrichosis.

Cutaneous or skin sporotrichosis: This is the most common form of the disease. Symptoms include nodular lesions or bumps in the skin at the point of entry and also along lymph nodes and vessels. The lesion starts off small and painless, and ranges in color from pink to purple. Left untreated, the lesion becomes larger and looks similar to a boil. More lesions will appear, until a chronic ulcer develops. Usually, cutaneous sporotrichosis lesions occur in the finger, hand, and arm.

Pulmonary sporotrichosis: This rare form of the disease occurs when S. schenckii spores are inhaled. Symptoms include productive coughing, nodules and cavitations of the lungs, fibrosis, and swollen hilar lymph nodes. Patients with this form of sporotrichosis are susceptible to developing tuberculosis and pneumonia.

Disseminated sporotrichosis: this occurs when the infection spreads from the primary site to secondary sites in the body and develops into a rare and critical form. The infection can spread to joints and bones (called osteoarticular sporotrichosis) as well as the central nervous system and the brain (called sporotrichosis meningitis). The symptoms include weight loss, anorexia, and the appearance of bony lesions.

SECTION OVERVIEW

15.15: Microbial Diseases of the Digestive System

Topic hierarchy

15.15A: Anatomy of the Digestive System

15.15B: Normal Gastrointestinal Microbiota

15.15: Microbial Diseases of the Digestive System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.15A: Anatomy of the Digestive System

The human gastrointestinal tract refers to the stomach and intestine, and sometimes to all the structures from the mouth to the anus.

Learning Objectives

- Outline the anatomical organization of the digestive system

Key Points

- The major organs of the digestive system are the stomach and intestine.
- The upper gastrointestinal tract consists of the esophagus, stomach, and duodenum.
- The lower gastrointestinal tract includes the small intestine and the large intestine.
- Digestive juices are produced by the pancreas and the gallbladder.
- The small intestine includes the duodenum, jejunum, and ileum.
- The large intestine includes the cecum, colon, rectum, and anus.

Key Terms

- **upper gastrointestinal tract**: This tract consists of the esophagus, stomach, and duodenum.
- **lower gastrointestinal tract**: This tract includes most of the small intestine and all of the large intestine.

The human gastrointestinal tract refers to the stomach and intestine, and sometimes to all the structures from the mouth to the anus.

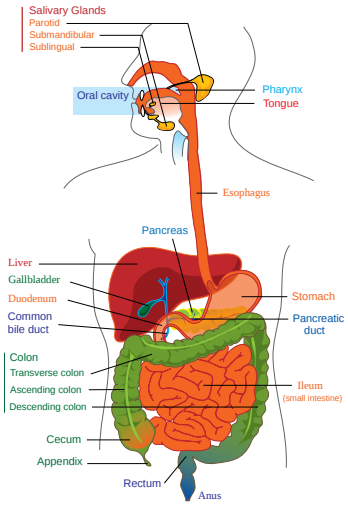

Figure: **Upper and lower gastrointestinal tract**: The major organs of the human gastrointestinal system.

Upper Gastrointestinal Tract

The upper gastrointestinal tract consists of the esophagus, stomach, and duodenum. The exact demarcation between upper and lower can vary. Upon gross dissection, the duodenum may appear to be a unified organ, but it is often divided into two parts based upon function, arterial supply, or embryology.

The upper gastrointestinal tract includes the:

- Esophagus, the fibromuscular tube that food passes through—aided by peristaltic contractions—the pharynx to the stomach.
- Stomach, which secretes protein -digesting enzymes called proteases and strong acids to aid in food digestion, before sending the partially digested food to the small intestines.
- Duodenum, the first section of the small intestine that may be the principal site for iron absorption.

Lower Gastrointestinal Tract

The lower gastrointestinal tract includes most of the small intestine and all of the large intestine. According to some sources, it also includes the anus.

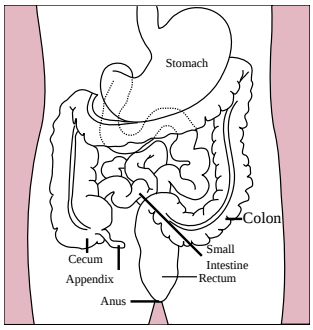

Figure: **Small intestine**: This image shows the position of the small intestine in the gastrointestinal tract.

The small intestine has three parts:

- Duodenum: Here the digestive juices from the pancreas (digestive enzymes) and the gallbladder (bile) mix together. The digestive enzymes break down proteins and bile and emulsify fats into micelles. The duodenum contains Brunner's glands that produce bicarbonate, and pancreatic juice that contains bicarbonate to neutralize hydrochloric acid in the stomach.
- Jejunum: This is the midsection of the intestine, connecting the duodenum to the ileum. It contains the plicae circulares and villi to increase the surface area of that part of the GI tract.
- Ileum: This has villi, where all soluble molecules are absorbed into the blood (through the capillaries and lacteals).

The large intestine has four parts:

1. Cecum, the vermiform appendix that is attached to the cecum.
2. Colon, which includes the ascending colon, transverse colon, descending colon, and sigmoid flexure. The main function of the colon is to absorb water, but it also contains bacteria that produce beneficial vitamins like vitamin K.
3. Rectum.
4. Anus.

The ligament of Treitz is sometimes used to divide the upper and lower GI tracts.

15.15A: Anatomy of the Digestive System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.15B: Normal Gastrointestinal Microbiota

Gut flora consist of microorganisms that live in the digestive tracts of animals and are the largest reservoir of human flora.

Learning Objectives

- Summarize the relationship between the nonpathogenic gastrointestinal microbiota and the human hosts

Key Points

- The relationship between gut flora and humans is not merely commensal (a non-harmful coexistence), but rather a mutualistic relationship.
- Gut flora perform functions, such as fermenting unused energy substrates, training the immune system, preventing growth of harmful bacteria, regulating the development of the gut, producing vitamins for the host, and producing hormones to direct the host to store fats.
- In certain conditions, some gutflora are thought to be capable of causing disease by producing infection or increasing cancer risk for the host.

Key Terms

- **commensal**: A term for a form of symbiosis in which one organism derives a benefit while the other is unaffected
- **microflora**: Microscopic plant life, especially the bacterial colonies found in the gut of normal, healthy animals and humans.

Gut flora consists of microorganisms that live in the digestive tracts of animals and is the largest reservoir of human flora. In this context, gut is synonymous with intestinal, and flora with microbiota and microflora; the word microbiome is also in use.

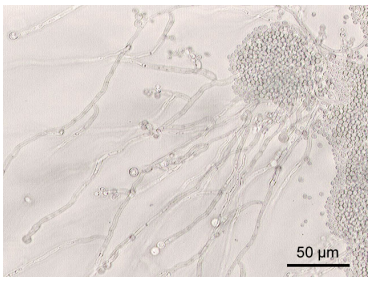

Figure: **Canidida albicans**: Candida albicans, a dimorphic fungus that grows as a yeast in the gut. Microscopic image (200-fold magnification) of Candida albicans ATCC 10231, grown on cornmeal agar medium with 1% Tween80.

The human body, consisting of about 10 trillion cells, carries about ten times as many microorganisms in the intestines. The metabolic activities performed by these bacteria resemble those of an organ, leading some to liken gut bacteria to a “forgotten” organ. It is estimated that these gut flora have around 100 times as many genes in aggregate as there are in the human genome.

Bacteria make up most of the flora in the colon and up to 60% of the dry mass of feces. Somewhere between 300 and 1000 different species live in the gut, with most estimates at about 500. However, it is probable that 99% of the bacteria come from about 30 or 40 species. Fungi and protozoa also make up a part of the gut flora, but little is known about their activities.

Research suggests that the relationship between gut flora and humans is not merely commensal (a non-harmful coexistence), but rather a mutualistic relationship. Though people can survive without gut flora, the microorganisms perform a host of useful functions, such as: fermenting unused energy substrates, training the immune system, preventing growth of harmful, pathogenic bacteria, regulating the development of the gut, producing vitamins for the host (such as biotin and vitamin K), and producing hormones to direct the host to store fats. However, in certain conditions, some species are thought to be capable of causing disease by producing infection or increasing cancer risk for the host.

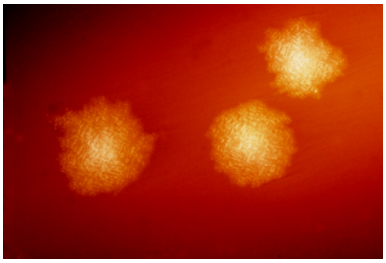

Figure: **This photograph depicts Clostridium difficile colonies after 48hrs growth on a blood agar plate; Magnified 4.8X.**: C. difficile, an anaerobic gram-positive rod, is the most frequently identified cause of antibiotic-associated diarrhea (AAC). It accounts for approximately 15-25% of all episodes of AAC.

Over 99% of the bacteria in the gut are anaerobes, but in the cecum, aerobic bacteria reach high densities. Not all the species in the gut have been identified because most cannot be cultured, and identification is difficult. Populations of species vary widely among different individuals but stay fairly constant within an individual over time, even though some alterations may occur with changes in lifestyle, diet and age. An effort to better describe the microflora of the gut and other body locations has been initiated (such as the Human Microbiome Project). In 2009, scientists from INRA (France) highlighted the existence of a small number of species shared by all individuals constituting the human intestinal microbiota phylogenetic core. Most bacteria belong to the genera Bacteroides, Clostridium, Fusobacterium, Eubacterium, Ruminococcus, Peptococcus, Peptostreptococcus, and Bifidobacterium. Other genera, such as Escherichia and Lactobacillus, are present to a lesser extent. Species from the genus Bacteroides alone constitute about 30% of all bacteria in the gut, suggesting that this genus is especially important in the functioning of the host. The currently known genera of fungi of the gut flora include Candida, Saccharomyces, Aspergillus, and Penicillium. An enterotype is a classification of living organisms based on its bacteriological ecosystem in the human gut microbiome. Three human enterotypes have been discovered.

Bacteria in the gut fulfill a host of useful functions for humans, including digestion of unutilized energy substrates, stimulating cell growth, repressing the growth of harmful microorganisms, training the immune system to respond only to pathogens, and defending against some diseases.

SECTION OVERVIEW

15.16: Bacterial Diseases of the Mouth

Topic hierarchy

15.16A: Tooth and Gum Infections

15.16B: Dental Caries

15.16C: Periodontal Disease

15.16: Bacterial Diseases of the Mouth is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.16A: Tooth and Gum Infections

The mouth contains a wide variety of oral bacteria, but only a few specific species of bacteria are believed to cause tooth and gum infections.

Learning Objectives

- List the types of bacteria and issues associated with oral bacteria: Streptococci spp and Lactobaccilus acidophilus

Key Points

- Dental caries, also known as tooth decay or cavity, is a bacterial infection that causes demineralization and destruction of the hard tissues (enamel, dentin, and cementum).
- Tooth decay results from the production of acid by bacterial fermentation of the food debris accumulated on the tooth surface.
- Bacteria occupy the ecological niche provided by both the tooth surface and gingival epithelium. However, a highly efficient innate host defense system constantly monitors the bacterial colonization and prevents bacterial invasion of local tissues.
- Porphyromonas gingivalis is a Gram-negative oral anaerobe strongly associated with chronic adult periodontitis.
- Dental plaque is the material that adheres to the teeth and consists of bacterial cells (mainly S. mutans and S. sanguis), salivary polymers, and bacterial extracellular products.

Key Terms

- **cavity**: A soft area in a decayed tooth.
- **plaque**: a clearing in a bacterial lawn caused by a virus
- **dental plaque**: Dental plaque is the material that adheres to the teeth and consists of bacterial cells (mainly S. mutans and S. sanguis), salivary polymers, and bacterial extracellular products.
- **biofilm**: A thin film of mucus created by and containing a colony of bacteria and other microorganisms.

Tooth and Gum Infections

Dental caries, also known as tooth decay or cavity, is a bacterial infection that causes demineralization and destruction of the hard tissues (enamel, dentin, and cementum). This usually happens from the production of acid by bacterial fermentation of the food debris accumulated on the tooth surface. If demineralization exceeds saliva and other remineralization factors, such as from calcium and fluoridated toothpastes, these hard tissues progressively break down, producing dental caries (cavities, holes in the teeth). The bacteria most responsible for dental cavities are the mutans streptococci, most prominently Streptococcus mutans and Streptococcus sobrinus, and lactobacilli. If left untreated, the disease can lead to pain, tooth loss, and infection. Today, caries remain one of the most common diseases throughout the world.

The mouth contains a wide variety of oral bacteria, but only a few specific species of bacteria are believed to cause dental caries: Streptococcus mutans and Lactobacilli among them. Lactobacillus acidophilus, Actinomyces viscosus, Nocardia spp., and Streptococcus mutans are most closely associated with caries, in particular root caries. Bacteria collect around the teeth and gums in a sticky, creamy-colored mass called plaque, which serves as a biofilm. Some sites collect plaque more commonly than others. Grooves on the occlusal surfaces of molar and premolar teeth provide microscopic retention sites for plaque bacteria, as do the approximal sites. Plaque may also collect above or below the gingiva where it is referred to as supra- or sub-gingival plaque respectively.

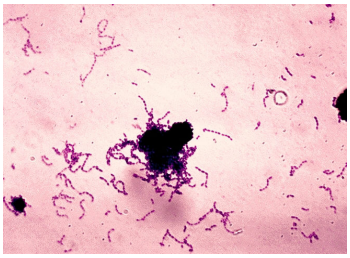

Figure: **Gram stain of Streptococcus mutans.**: Morphology is rod-like with chains when cultured on broth. Can cause subacute bacterial endocarditis and dental caries.

Oral bacteria have evolved mechanisms to sense their environment and evade or modify the host. Bacteria occupy the ecological niche provided by both the tooth surface and gingival epithelium. However, a highly efficient innate host defense system constantly monitors the bacterial colonization and prevents bacterial invasion of local tissues. A dynamic equilibrium exists between dental plaque bacteria and the innate host defense system. The oral cavity of the newborn baby does not contain bacteria but rapidly becomes colonized with bacteria such as Streptococcus salivarius. With the appearance of the teeth during the first year, colonization by Streptococcus mutans and Streptococcus sanguinis occurs as these organisms colonize the dental surface and gingiva. Other strains of streptococci adhere strongly to the gums and cheeks but not to the teeth. The gingival crevice area (supporting structures of the teeth) provides a habitat for a variety of anaerobic species. Bacteroides and spirochetes colonize the mouth around puberty.

Figure: **Dental caries**: This image shows destruction of a tooth by cervical decay from dental caries. This type of decay is also known as root decay.

The levels of oral spirochetes are elevated in patients with periodontal diseases. Among this group, Treponema denticola is the most studied and is considered one of the main etiological bacteria of periodontitis. Treponema denticola is a motile and highly proteolytic bacterium.

Spirochetes and fusi-form bacilli live as normal flora in the mouth, but the bacteria can cause infection and diseases to the oral cavity.

Porphyromonas gingivalis is a Gram-negative oral anaerobe strongly associated with chronic adult periodontitis. The bacterium produces a number of well-characterized virulence factors and can be manipulated genetically. The availability of the genome sequence is aiding our understanding of the biology of P. gingivalis and how it interacts with the environment, other bacteria, and the human host.

Aggregatibacter actinomycetemcomitans is considered an oral pathogen due to its virulence factors, its association with localized aggressive periodontitis in young adolescents, and studies indicating that it can cause bone loss.

Dental plaque is the material that adheres to the teeth and consists of bacterial cells (mainly S. mutans and S. sanguis), salivary polymers, and bacterial extracellular products. Plaque is a biofilm on the surfaces of the teeth. This accumulation of microorganisms subject the teeth and gingival tissues to high concentrations of bacterial metabolites which results in dental disease. If not taken care of, via brushing or flossing, the plaque can turn into tartar (its hardened form) and lead to gingivitis or periodontal disease.

15.16B: Dental Caries

Dental caries cause demineralization of the hard tissues and destruction of the organic matter of the tooth.

Learning Objectives

- Explain how dental caries can be prevented

Key Points

- Dentin is produced continuously throughout life by odontoblasts.
- Caries can be classified by location, etiology, rate of progression, and affected hard tissues.
- Enamel is a highly mineralized acellular tissue. Enamel rods, which are the basic unit of the enamel structure, run perpendicularly from the surface of the tooth to the dentin.
- There are four main criteria required for caries formation: a tooth surface (enamel or dentin), caries-causing bacteria, fermentable carbohydrates (such as sucrose), and time.
- Dental caries can occur on any surface of a tooth that is exposed to the oral cavity, but not the structures that are retained within the bone.
- The two bacteria most commonly responsible for dental cavities are Streptococcus mutans and Lactobacillus.
- The use of dental sealants is a means of prevention.
- Professional hygiene care consists of regular dental examinations and cleanings.
- An extraction can also serve as treatment for dental caries.
- In general, early treatment is less painful and less expensive than treatment of extensive decay.
- Recurrent caries, also described as secondary, are caries that appears at a location with a previous history of caries.
- Dentin is produced continuously throughout life by odontoblasts.
- Personal hygiene care consists of proper brushing and flossing daily. The purpose of oral hygiene is to minimize any etiologic agents of disease in the mouth.
- Primary diagnosis involves inspection of all visible tooth surfaces using a good light source, dental mirror and explorer. Dental radiographs (X-rays) may show dental caries before it is otherwise visible, in particular caries between the teeth.
- Caries can be classified by location, etiology, rate of progression, and affected hard tissues.
- In dentin from the deepest layer to the enamel, the distinct areas affected by caries are the advancing front, the zone of bacterial penetration, and the zone of destruction.
- Intrauterine and neonatal lead exposure promote tooth decay. Other divalent cations, such as cadmium, mimic the calcium ion and therefore exposure may promote tooth decay.
- From the deepest layer of the enamel to the enamel surface, the identified areas are the: translucent zone, dark zones, body of the lesion, and surface zone.
- Enamel is a highly mineralized acellular tissue. Enamel rods, which are the basic unit of the enamel structure, run perpendicularly from the surface of the tooth to the dentin.
- Some brands of smokeless tobacco contain high sugar content, increasing susceptibility to caries. Tobacco use is a significant risk factor for periodontal disease, which can cause the gingiva to recede.
- Reduced saliva is associated with increased caries.
- There are four main criteria required for caries formation: a tooth surface (enamel or dentin); caries-causing bacteria; fermentable carbohydrates (such as sucrose); and time.
- If demineralization exceeds saliva and other remineralization factors such as from calcium and fluoridated toothpastes, these tissues progressively break down, producing dental caries (cavities, holes in the teeth).
- The presentation of caries is highly variable.
- Bacteria collect around the teeth and gums in a sticky, creamy-coloured mass called plaque, which serves as a biofilm.
- Dental caries can occur on any surface of a tooth that is exposed to the oral cavity, but not the structures that are retained within the bone.
- The mineral content of teeth is sensitive to increases in acidity from the production of lactic acid.
- Radiographs are used for less visible areas of teeth and to judge the extent of destruction.
- Depending on the extent of tooth destruction, various treatments can be used to restore teeth to proper form, function, and aesthetics, but there is no known method to regenerate large amounts of tooth structure. Instead, dental health organizations advocate preventive and prophylactic measures, such as regular oral hygiene and dietary modifications, to avoid dental caries.

- Tooth decay disease is caused by specific types of bacteria that produce acid in the presence of fermentable carbohydrates such as sucrose, fructose, and glucose.
- Before the cavity forms, the process is reversible, but once a cavity forms, the lost tooth structure cannot be regenerated.
- The two bacteria most commonly responsible for dental cavities are Streptococcus mutans and Lactobacillus.

Key Terms

- **cementum**: A bony substance that covers the root of a tooth; cement.
- **enamel**: The hard covering on the exposed part of a tooth.
- **dentin**: The hard, dense calcareous material that makes up the bulk of a tooth

Dental caries, also known as tooth decay or a cavity, is an infection, usually bacterial in origin, that causes demineralization of the hard tissues (enamel, dentin, and cementum) and destruction of the organic matter of the tooth, usually by production of acid by hydrolysis of the food debris accumulated on the tooth surface. If demineralization exceeds saliva and other remineralization factors such as from calcium and fluoridated toothpastes, these tissues progressively break down, producing dental caries (cavities, holes in the teeth). The two bacteria most commonly responsible for dental cavities are Streptococcus mutans and Lactobacillus. If left untreated, the disease can lead to pain, tooth loss, and infection. Today, caries remain one of the most common diseases throughout the world.

Caries can be classified by location, etiology, rate of progression, and affected hard tissues. These forms of classification can be used to characterize a particular case of tooth decay in order to more accurately represent the condition to others and also indicate the severity of tooth destruction.

Tooth decay disease is caused by specific types of bacteria that produce acid in the presence of fermentable carbohydrates such as sucrose, fructose, and glucose. The mineral content of teeth is sensitive to increases in acidity from the production of lactic acid. To be specific, a tooth (which is primarily mineral in content) is in a constant state of back-and-forth demineralization and remineralization between the tooth and surrounding saliva. For people with little saliva, especially due to radiation therapies that may destroy the salivary glands, there also exists remineralization gel. These patients are particularly susceptible to dental caries. When the pH at the surface of the tooth drops below 5.5, demineralization proceeds faster than remineralization (meaning that there is a net loss of mineral structure on the tooth's surface). Most foods are in this acidic range and without remineralization result in the ensuing decay.

As the enamel and dentin are destroyed, the cavity becomes more noticeable. The affected areas of the tooth change color and become soft to the touch. Once the decay passes through enamel, the dentinal tubules, which have passages to the nerve of the tooth, become exposed, causing a toothache. The pain may worsen with exposure to heat, cold, or sweet foods and drinks. Dental caries can also cause bad breath and foul tastes. In highly progressed cases, infection can spread from the tooth to the surrounding soft tissues. Complications such as cavernous sinus thrombosis and Ludwig's angina can be life-threatening.

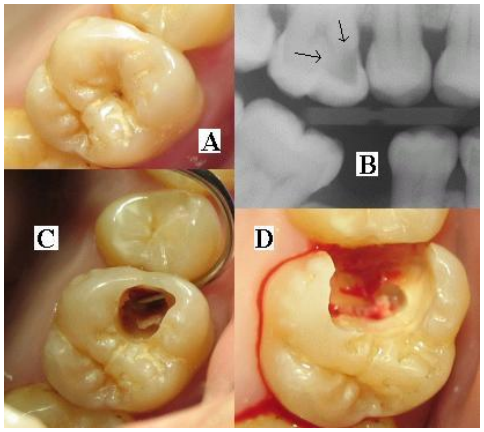

Figure: **Dental caries**: (A) A small spot of decay visible on the surface of a tooth. (B) The radiograph reveals an extensive region of demineralization within the dentin (arrows). (C) A hole is discovered on the side of the tooth at the beginning of decay removal. (D) All decay removed.

There are four main criteria required for caries formation: a tooth surface (enamel or dentin) caries-causing bacteria, fermentable carbohydrates (such as sucrose), and time. The caries process does not have an inevitable outcome, and different individuals will be susceptible to different degrees depending on the shape of their teeth, oral hygiene habits, and the buffering capacity of their saliva.

Dental caries can occur on any surface of a tooth that is exposed to the oral cavity, but not the structures that are retained within the bone. All caries occur from acid demineralization that exceeds saliva and fluoride remineralization, and almost all acid demineralization occurs where food (containing carbohydrate like sugar) is left on teeth. Though most trapped food is left between teeth, over 80% of cavities occur inside pits and fissures on chewing surfaces where brushing, fluoride, and saliva cannot reach to remineralize the tooth as they do on easy-to-reach surfaces that develop few cavities.

In most people, disorders or diseases affecting teeth are not the primary cause of dental caries. Ninety-six percent of tooth enamel is composed of minerals. These minerals, especially hydroxyapatite, will become soluble when exposed to acidic environments. Enamel begins to demineralize at a pH of 5.5. Dentin and cementum are more susceptible to caries than enamel because they have lower mineral content. Thus, when root surfaces of teeth are exposed from gingival recession or periodontal disease, caries can develop more readily. Even in a healthy oral environment, however, the tooth is susceptible to dental caries.

Bacteria in a person's mouth convert glucose, fructose, and most commonly sucrose (table sugar) into acids such as lactic acid through a glycolytic process called fermentation. If left in contact with the tooth, these acids may cause demineralization, which is the dissolution of its mineral content. The process is dynamic, however, as remineralization can also occur if the acid is neutralized by saliva or mouthwash.

At times, pit and fissure caries may be difficult to detect. Bacteria can penetrate the enamel to reach dentin, but then the outer surface may remineralize, especially if fluoride is present. These caries, sometimes referred to as "hidden caries", will still be visible on x-ray radiographs, but visual examination of the tooth would show the enamel intact or minimally perforated.

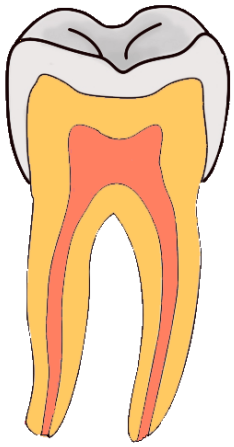

Figure: **Pit and fissure caries.**: The progression of pit and fissure caries resembles two triangles with their bases meeting along the junction of enamel and dentin.

15.16C: Periodontal Disease

Plaque-induced inflammatory lesions make up the vast majority of periodontal diseases, which are divided into peridontitis or gingivitis.

Learning Objectives

- Differentiate between peridontitis and gingivitis

Key Points

- Peridontal tissues are the cementum, or the outer layer of the roots of teeth; the gingiva, or gums; the alveolar bone, or the bony sockets into which the teeth are anchored; and the periodontal ligament, which are the connective tissue fibers that run between the cementum and the alveolar bone.
- Periodontitis is an inflammatory disease affecting the periodontium, or the tissues that surround and support the teeth. Periodontitis involves progressive loss of the alveolar bone around the teeth, and if left untreated, can lead to the loosening and subsequent loss of teeth.
- Periodontitis is caused by microorganisms that adhere to and grow on the tooth ‘s surfaces, along with an overly aggressive immune response against these microorganisms.
- In the early stages, periodontitis has very few symptoms and in many individuals the disease has progressed significantly before they seek treatment. The gingival inflammation and bone destruction of peridontitis are largely painless.
- Gingivitis, or inflammation of the gums, is a non-destructive peridontal disease. The primary cause of gingivitis is poor oral hygiene which leads to the accumulation dental plaque at the gum line. Gingivitis can progress to periodontitis.
- Daily oral hygiene measures to prevent periodontal disease include brushing and flossing daily and using an antiseptic mouthwash.
- There are many surgical approaches used in treatment of advanced periodontitis, including open flap debridement, osseous surgery, as well as guided tissue regeneration and bone grafting.
- Several conditions and diseases, including Down syndrome, diabetes, and other diseases that affect one’s resistance to infection also increase susceptibility to periodontitis.
- The primary etiology (cause) of gingivitis is poor oral hygiene which leads to the accumulation of a mycotic and bacterial matrix at the gum line, called dental plaque. Other contributors are poor nutrition and underlying medical issues such as diabetes.
- Once successful periodontal treatment has been completed, with or without surgery, an ongoing regimen of “periodontal maintenance” is required.
- In the early stages, periodontitis has very few symptoms and in many individuals the disease has progressed significantly before they seek treatment. Symptoms may include the following: redness or bleeding of gums, gum swelling that recurs, spitting out blood after brushing teeth, halitosis, or bad breath, and a persistent metallic taste in the mouth, gingival recession, resulting in apparent lengthening of teeth, deep pockets between the teeth and the gums, and loose teeth
- Periodontitis is caused by microorganisms that adhere to and grow on the tooth’s surfaces.
- The extent of disease refers to the proportion of the dentition affected by the disease in terms of percentage of sites. Generally, six probing sites around each tooth are recorded, as follows: mesiobuccal, mid-buccal, distobuccal, mesiolingual, mid-lingual, and distolingual.
- The severity of disease refers to the amount of periodontal ligament fibers that have been lost, termed clinical attachment loss.
- Smoking is a factor that increases the occurrence of periodontitis
- The 1999 classification system for periodontal diseases and conditions listed seven major categories of periodontal diseases, of which the last six are termed destructive periodontal disease because the damage is essentially irreversible. The seven categories are as follows:
- Gingivitis
- Chronic periodontitis
- Aggressive periodontitis
- Periodontitis as a manifestation of systemic disease
- Necrotizing ulcerative gingivitis/periodontitis
- Abscesses of the periodontium
- Combined periodontic-endodontic lesions

Key Terms

- **periodontitis**: An inflammatory disease that affects the periodontium—the tissues that surround and support the teeth–and can lead to tooth loss.
- **periodontium**: The specialized tissues that both surround and support the teeth, maintaining them in the maxillary and mandibular bones; the tissues including alveolar bone, cementum, gums, and periodontal ligament.
- **gingivitis**: Inflammation of the gums or gingivae.

Periodontal disease is a type of disease that affects one or more of the periodontal tissues, which include:

- the cementum, or the outer layer of the roots of teeth
- the gingiva, or gum tissue
- the alveolar bone, or the bony sockets into which the teeth are anchored
- the periodontal ligament, which are the connective tissue fibers that run between the cementum and the alveolar bone.

While many different diseases affect the tooth-supporting structures, plaque-induced inflammatory lesions make up the vast majority of periodontal diseases and have traditionally been divided into two categories: peridontitis or gingivitis.

Peridontitis

Periodontitis is an inflammatory disease affecting the periodontium, or the tissues that surround and support the teeth. Periodontitis involves progressive loss of the alveolar bone around the teeth, and if left untreated, can lead to the loosening and subsequent loss of teeth. Periodontitis is caused by microorganisms that adhere to and grow on the tooth's surfaces, along with an overly aggressive immune response against these microorganisms.

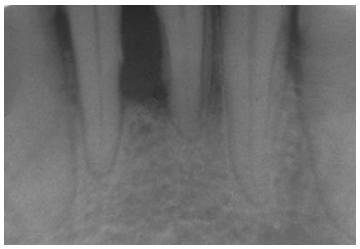

Figure: **Periodontal disease**: This radiograph shows significant bone loss between the two roots of a tooth (black region). The spongy bone has receded due to infection under the tooth, reducing the bony support for the tooth.

In the early stages, periodontitis has very few symptoms and in many individuals the disease has progressed significantly before they seek treatment. Symptoms may include the following:

- Redness or bleeding of gums while brushing teeth, using dental floss, or biting into hard food
- Gum swelling that recurs
- Spitting out blood after brushing teeth
- Halitosis, or bad breath, and a persistent metallic taste in the mouth
- Gingival recession, resulting in apparent lengthening of teeth
- Deep pockets between the teeth and the gums, that are sites where the attachment has been gradually destroyed by collagen-destroying enzymes, known as collagenases
- Loose teeth, in the later stages

The gingival inflammation and bone destruction of peridontitis are largely painless. Hence, people may wrongly assume that painless bleeding after teeth cleaning is insignificant, although this may be a symptom of progressing periodontitis in that patient.

A diagnosis of periodontitis is established by inspecting the soft gum tissues around the teeth with a probe and by evaluating the patient's x-ray films to determine the amount of bone loss around the teeth.

Figure: **Gingivitis**: Severe gingivitis before (top) and after (bottom) treatment.

Gingivitis

Gingivitis, or inflammation of the gums, is a non-destructive peridontal disease. The primary cause of gingivitis is poor oral hygiene which leads to the accumulation of bacterial matrix at the gum line, called dental plaque. Other contributors are poor nutrition and underlying medical issues such as diabetes.

In some people, gingivitis progresses to periodontitis –- with the destruction of the gingival fibers, the gum tissues separate from the tooth, forming pockets between the tooth and gum. Subgingival microorganism (those that exist under the gum line) colonize the periodontal pockets and cause further inflammation in the gum tissues and progressive bone loss.

If left undisturbed, microbic plaque calcifies to form calculus, which is commonly called tartar. Calculus above and below the gum line must be removed completely by the dental hygienist or dentist to treat gingivitis and periodontitis. Although the primary cause of both gingivitis and periodontitis is the microbic plaque that adheres to the tooth surface, there are many other modifying factors. A very strong risk factor is one's genetic susceptibility. Several conditions and diseases, including Down syndrome, diabetes, and other diseases that affect one's resistance to infection also increase susceptibility to periodontitis.

Prevention

Daily oral hygiene measures to prevent periodontal disease include:

- Brushing teeth properly at least twice daily, with the patient attempting to direct the toothbrush bristles underneath the gum-line, to help disrupt the bacterial-mycotic growth and formation of subgingival plaque.
- Flossing daily and using interdental brushes as well as cleaning behind the last tooth, the third molar, in each quarter.
- Using an antiseptic mouthwash. Chlorhexidine gluconate-based mouthwash in combination with careful oral hygiene may cure gingivitis, although they cannot reverse any attachment loss due to periodontitis.
- Using periodontal trays to maintain dentist-prescribed medications at the source of the disease. The use of trays allows the medication to stay in place long enough to penetrate the biofilms where the microorganism are found.

Regular dental check-ups and professional teeth cleaning as required. Dental check-ups serve to monitor the person's oral hygiene methods and levels of attachment around teeth, identify any early signs of periodontitis, and monitor response to treatment.

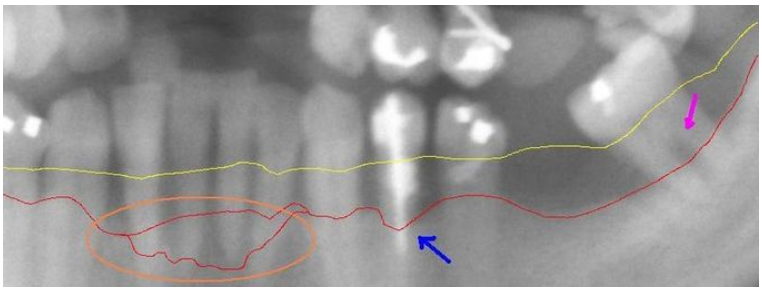

Figure: **Extensive periodontal disease**: This section from a panoramic x-ray film depicts the teeth of the lower left quadrant, exhibiting generalized severe bone loss of 30–80%. The red line depicts the existing bone level, and the yellow line depicts where the gingiva was originally (1–2 mm above the bone), prior to the patient developing periodontal disease. The pink arrow, on the right, points to a furcation involvement, or the loss of enough bone to reveal the location at which the individual roots of a molar begin to branch from the single root trunk; this is a sign of advanced periodontal disease.

15.17A: Bacterial Gastroenteritis

Gastroenteritis is characterized by inflammation of the gastrointestinal tract that involves both the stomach and the small intestine.

Learning Objectives

- Describe the cause and effect of bacterial gastroenteritis

Key Points

- Gastroenteritis typically involves both diarrhea and vomiting, or less commonly, presents with only one or the other.
- Transmission rates are also related to poor hygiene, especially among children, in crowded households, and in those with pre-existing poor nutritional status.
- A supply of easily accessible uncontaminated water and good sanitation practices are important for reducing rates of infection and clinically significant gastroenteritis.

Key Terms

- **inflammation**: A condition of any part of the body, consisting in congestion of the blood vessels, with obstruction of the blood current, and growth of morbid tissue. It is manifested outwardly by redness and swelling, attended with heat and pain.
- **gastroenteritis**: Inflammation of the mucous membranes of the stomach and intestine; often caused by an infection.

Gastroenteritis is a medical condition characterized by inflammation ("-itis") of the gastrointestinal tract that involves both the stomach ("gastro"-) and the small intestine ("entero"-), resulting in some combination of diarrhea, vomiting, and abdominal pain and cramping. Although unrelated to influenza, it has also been called 'stomach flu' and 'gastric flu'.

Globally, most cases in children are caused by rotavirus. Less common causes include other bacteria (or their toxins) and parasites. Transmission may occur due to consumption of improperly prepared foods, contaminated water, or via close contact with individuals who are infectious. The foundation of management for this illness is adequate hydration. For mild or moderate cases, this can typically be achieved via oral rehydration solution. For more severe cases, intravenous fluids may be needed. Gastroenteritis primarily affects children and those in the developing world. Gastroenteritis typically involves both diarrhea and vomiting, or less commonly, presents with only one or the other. Abdominal cramping may also be present.

Signs and symptoms usually begin 12–72 hours after contracting the infectious agent. Some bacterial infections may be associated with severe abdominal pain and may persist for several weeks. In the developed world, *Campylobacter jejuni* is the primary cause of bacterial gastroenteritis, with half of these cases associated with exposure to poultry. In children, bacteria are the cause in about 15% of cases, with the most common types being *Escherichia coli*, *Salmonella*, *Shigella*, and *Campylobacter* species. If food becomes contaminated with bacteria and remains at room temperature for a period of several hours, the bacteria multiply and increase the risk of infection in those who consume the food. Toxigenic *Clostridium difficile* is an important cause of diarrhea that occurs more often in the elderly. Infants can carry these bacteria without developing symptoms. It is a common cause of diarrhea in those who are hospitalized and is frequently associated with antibiotic use. *Staphylococcus aureus* infectious diarrhea may also occur in those who have used antibiotics. "Traveler's diarrhea" is usually a type of bacterial gastroenteritis. Acid-suppressing medication appears to increase the risk of significant infection after exposure to a number of organisms, including *Clostridium difficile*, *Salmonella*, and *Campylobacter* species.

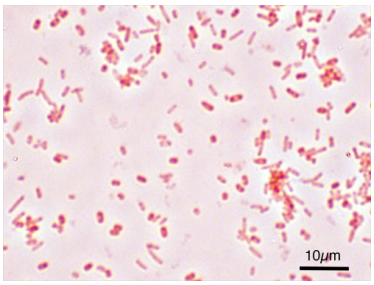

Figure: **Salmonella Typhimurium**: Salmonella enterica serovar Typhimurium as seen with a microscope at 1000 fold magnification and following Gram staining. Salmonella is a common cause of gastroenteritis in children.

Transmission rates are also related to poor hygiene, especially among children, in crowded households, and in those with pre-existing poor nutritional status. After developing tolerance, adults may carry certain organisms without exhibiting signs or

symptoms, and thus act as natural reservoirs of contagion. While some agents (such as *Shigella*) only occur in primates, others may occur in a wide variety of animals (such as *Giardia*).

Gastroenteritis is typically diagnosed clinically, based on a person's signs and symptoms. Determining the exact cause is usually not needed as it does not alter management of the condition. However, stool cultures should be performed in those with blood in the stool, those who might have been exposed to food poisoning, and those who have recently traveled to the developing world. Electrolytes and kidney function should also be checked when there is a concern about severe dehydration.

A supply of easily accessible uncontaminated water and good sanitation practices are important for reducing rates of infection and clinically significant gastroenteritis. Personal measures (such as hand washing) have been found to decrease incidence and prevalence rates of gastroenteritis in both the developing and developed world by as much as 30%.

15.17A: Bacterial Gastroenteritis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.17B: Staphylococcal Food Poisoning

Staphylococcal toxins are a common cause of food poisoning, as they can be produced in improperly-stored food.

Learning Objectives

- Recognize the causes of staphylococcal food poisoning

Key Points

- Staphylococcus is a Gram-positive bacteria which includes several species that can cause a wide variety of infections in humans and other animals through infection or the production of toxins.
- Foodborne illness usually arises from improper handling, preparation, or storage of food.
- Good hygiene practices before, during, and after food preparation can reduce the chances of contracting an illness.

Key Terms

- **toxin**: A toxic or poisonous substance produced by the biological processes of biological organisms.
- **norovirus**: The genus of a number of species of virus, family Caliciviridae, causing human gastroenteritis, of which Norwalk virus is the prototype.

Staphylococcus is a Gram-positive bacteria which includes several species that can cause a wide variety of infections in humans and other animals through infection or the production of toxins. Staphylococcal toxins are a common cause of food poisoning, as they can be produced in improperly-stored food. The main coagulase-positive staphylococcus is *Staphylococcus aureus*. These bacteria can survive on dry surfaces, increasing the chance of transmission.

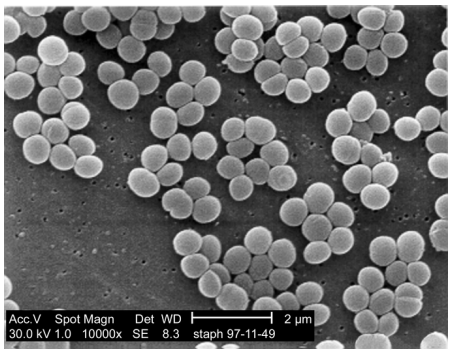

Figure: **Staphylococcus aureus**: Staphylococcus is a Gram-positive bacteria which includes several species that can cause a wide variety of infections in humans and other animals through infection or the production of toxins.

Any *S. aureus* infection can cause the staphylococcal scalded skin syndrome, a cutaneous reaction to exotoxin absorbed into the bloodstream. It can also cause a type of septicaemia called pyaemia. The infection can be life-threatening. Problematically, Methicillin-resistant *Staphylococcus aureus* (MRSA) has become a major cause of hospital-acquired infections and is being recognized with increasing frequency in community-acquired infections.

Foodborne illness usually arises from improper handling, preparation, or food storage. Good hygiene practices before, during, and after food preparation can reduce the chances of contracting an illness. There is a consensus in the public health community that regular hand-washing is one of the most effective defenses against the spread of foodborne illness. The action of monitoring food to ensure that it will not cause foodborne illness is known as food safety.

Foodborne disease can also be caused by a large variety of toxins that affect the environment, such as pesticides or medicines in food, and naturally toxic substances such as poisonous mushrooms or reef fish. In the past, bacterial infections were thought to be more prevalent because few places had the capability to test for norovirus and no active surveillance was being done for this particular agent. Toxins for bacterial infections are delayed because the bacteria need time to multiply. Their symptoms are usually not seen until 12–72 hours or more after eating contaminated food.

15.17B: Staphylococcal Food Poisoning is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.17C: Salmonellosis

Salmonellosis is an infection by the Salmonella bacteria that results in diarrhea, fever, vomiting, and abdominal cramps.

Learning Objectives

- Distinguish between nontyphoidal and typhoidal Salmonella

Key Points

- In severe cases, the Salmonella infection may spread from the intestines to the bloodstream, and then to other body sites, and can cause death unless the person is treated with antibiotics.
- The type of Salmonella usually associated with infections in humans, nontyphoidal Salmonella, is often contracted from contaminated food or reptiles.
- The Salmonella bacterium induces responses in the animal it is infecting, and this is what typically causes the symptoms, rather than any direct toxin that is produced.

Key Terms

- **typhoid fever**: An illness caused by the bacterium Salmonella typhi. Not to be confused with typhus.
- **endotoxin**: Any toxin secreted by a microorganism and released into the surrounding environment only when it dies.
- **arthritis**: Inflammation of a joint or joints causing pain and/or disability, swelling, and stiffness; and due to various causes such as infection, trauma, degenerative changes, or metabolic disorders.

Salmonellosis is an infection with the Salmonella bacteria. Most people infected with Salmonella develop diarrhea, fever, vomiting, and abdominal cramps 12 to 72 hours after infection. In most cases, the illness lasts four to seven days, and most people recover without treatment. However, in some cases the diarrhea may be so severe that the patient becomes dangerously dehydrated and must be taken to a hospital. At the hospital, the patient may receive intravenous fluids to treat the dehydration, and may be given medications to relieve symptoms, such as fever reducers. In severe cases, the Salmonella infection may spread from the intestines to the bloodstream, and then to other body sites, and can cause death unless the person is promptly treated with antibiotics. The elderly, infants, and those with impaired immune systems are more likely to develop severe illness. Some people afflicted with Salmonellosis later experience reactive arthritis, which can have long-lasting, disabling effects.

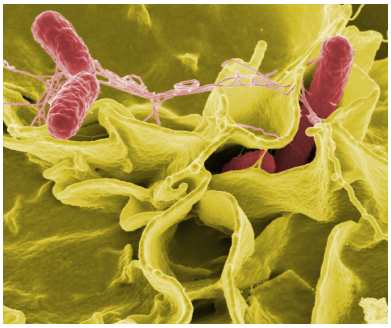

Figure: **Salmonella**: Salmonella is a genus of rod-shaped, gram-negative, non-spore-forming, predominantly motile enterobacteria (shown here in red).

Different Kinds of Salmonella

The different kinds of Salmonella include *S. bongori* and *S. enterica*. The type of Salmonella usually associated with infections in humans, nontyphoidal Salmonella, is usually contracted from: poultry, pork, and beef when the meat is prepared incorrectly or is infected with the bacteria after preparation; infected eggs, egg products, and milk when not prepared, handled, or refrigerated properly; reptiles (such as turtles, lizards, and snakes) which can carry the bacteria in their intestines; and tainted fruits and vegetables.

The typhoidal form of Salmonella can lead to typhoid fever. Typhoid fever is a life-threatening illness, and about four hundred cases are reported in the United States each year, with 75% of those acquired while traveling out of the country. It is carried only by humans and is usually contracted through direct contact with the fecal matter of an infected person. Typhoidal Salmonella is more

commonly found in poorer countries, where unsanitary conditions are more likely to occur, and can affect as many as 21.5 million people a year.

Salmonella Infection

The Salmonella bacterium induces responses in the animal it is infecting, and this is what typically causes the symptoms rather than any direct toxin that is produced. Symptoms are usually gastrointestinal, including nausea, vomiting, abdominal cramps, and bloody diarrhea with mucus. Headache, fatigue, and rose spots are also possible. These symptoms can be severe, especially in young children and the elderly. Symptoms last generally up to a week, and can appear 12 to 72 hours after ingesting the bacterium. After bacterial infections, reactive arthritis (Reiter's syndrome) can develop.

An infectious process can only begin after living salmonellae (not only their toxins) reach the gastrointestinal tract. Some of the microorganisms are killed in the stomach, while the surviving salmonellae enter the small intestine and multiply in tissues (this is the localized form). By the end of the incubation period, the macro-organisms are poisoned by endotoxins that are released from the dead salmonellae. The local response to the endotoxins is enteritis and gastrointestinal disorder. In the generalized form of the disease, salmonellae pass through the lymphatic system of the intestine into the blood of the patients (typhoid form) and are carried to various organs (liver, spleen, kidneys) to form secondary foci (septic form).

Endotoxins first act on affected organs' vascular and nervous systems, manifested by: increased permeability and decreased tone of the vessels, upset thermal regulation, vomiting, and diarrhea. In severe forms of the disease, enough liquid and electrolytes are lost to upset the body's metabolism of water and salt, decreasing the circulating blood volume and arterial pressure to enough of a degree to cause hypovolemic shock. Septic shock may also develop. Shock of mixed character (with signs of both hypovolemic and septic shock) is more common in severe salmonellosis. Oliguria and azotemia develop in severe cases as a result of kidney involvement due to hypoxia and bacteremia.

15.17C: Salmonellosis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.17D: Typhoid Fever

Learning Objectives

- Summarize the four stages of untreated typhoid fever and methods of preventing it

Typhoid fever, also known as typhoid, is a common, worldwide bacterial disease. It is transmitted by the ingestion of food or water that has been contaminated with the feces of a person infected by the bacterium Salmonella typhi, serotype Typhi. The disease has been known by many names, such as gastric fever, abdominal typhus, infantile remittant fever, slow fever, nervous fever or pythogenic (originating from filth or putrefaction) fever. The name “typhoid” means “resembling typhus” and comes from the neuropsychiatric symptoms common to typhoid and typhus. The term “enteric fever” is a collective term that refers to typhoid and paratyphoid. The impact of this disease fell sharply with the improved sanitation techniques of the 20th century.

STAGES

Classically, the course of untreated typhoid fever is divided into four individual stages, each lasting approximately one week.

First stage: the temperature rises slowly and fever fluctuations are seen with relative bradycardia (slow pulse), malaise, headache and cough. Nose bleeds (epistaxis) are seen in 25% of cases and abdominal pain can occur. There is leukopenia (a decrease in the number of circulating white blood cells), with eosinopenia and relative lymphocytosis. The classic Widal test is negative in the first week.

Second stage: the patient lies prostrate with high fever in plateau around 40 °C (104 °F) and bradycardia, classically with a dicrotic pulse wave. Delirium is frequent; patients may be calm, but sometimes agitated. This delirium gives typhoid its nickname of “nervous fever”. Rose spots appear on the lower chest and abdomen in around a third of patients. The Widal test is strongly positive with antiO and antiH antibodies. Blood cultures may be still positive at this stage. (The major symptom of typhoid is that the fever usually rises in the afternoon in the first and second stages.)

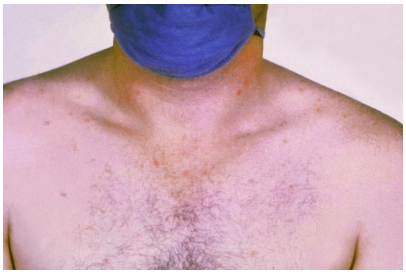

Figure: **Typhoid Fever**: Rose spots on the chest of a patient with typhoid fever due to the bacterium Salmonella typhi

Third stage: a number of complications can occur: intestinal hemorrhage due to bleeding in congested Peyer’s patches and intestinal perforation in the distal ileum.

Fourth stage: by the end of the third week the fever starts subsiding (defervescence). This carries on into the fourth and final week.

PREVENTION

The bacteria which cause typhoid fever may be spread through poor hygiene habits and public sanitation conditions and, sometimes, also by flying insects feeding on infected feces. Public education campaigns encouraging people to wash their hands after defecating and before handling food are an important component in controlling the spread of the disease. A person may become an asymptomatic carrier of typhoid fever, suffering no symptoms, but capable of infecting others.

DIAGNOSIS

Diagnosis is made by any blood, bone marrow or stool cultures and with the Widal test (demonstration of salmonella antibodies against antigens O-somatic and H-flagellar). In epidemics and less wealthy countries, after excluding malaria, dysentery or pneumonia, a therapeutic trial time with chloramphenicol is generally undertaken while awaiting the results of the Widal test, and cultures of the blood and stool. The Widal test is time-consuming and often, when a diagnosis is reached, it is too late to start an antibiotic regimen.

VACCINATION

There are two vaccines licensed for use for the prevention of typhoid: the live, oral Ty21a vaccine (sold as Vivotif Berna) and the injectable Typhoid polysaccharide vaccine (sold as Typhim Vi by Sanofi Pasteur and Typherix by GlaxoSmithKline).

TREATMENT

The rediscovery of oral rehydration therapy in the 1960s provided a simple way to prevent many of the deaths of diarrheal diseases in general. Where resistance is uncommon, the treatment of choice is a fluoroquinolone such as ciprofloxacin otherwise, a third-generation cephalosporin such as ceftriaxone or cefotaxime. Cefixime is a suitable oral alternative. Typhoid fever in most cases is not fatal. Antibiotics, such as ampicillin, chloramphenicol, trimethoprim-sulfamethoxazole, amoxicillin and ciprofloxacin have been commonly used to treat typhoid fever.

Key Points

- The impact of Typhoid fever fell sharply with the improved sanitation techniques of the 20th century.
- Classically, the course of untreated typhoid fever is divided into four individual stages, each lasting approximately one week.
- Diagnosis is made by any blood, bone marrow or stool cultures and with the Widal test (demonstration of salmonella antibodies against antigens O-somatic and H-flagellar).

Key Terms

- **dicrotic**: A type of pulse associated with low systemic vascular resistance and a compliant aorta, e.g sepsis
- **Peyer's patch**: Peyer's patches (or aggregated lymphoid nodules) are usually found in the lowest portion of the small intestine, the ileum, in humans.
- **Widal test**: The agglutination test for typhoid fever.
- **eosinopenia**: Eosinopenia is a form of agranulocytosis where the number of eosinophil granulocyte is lower than expected; usually a predictor of bacterial infection.
- **lymphocytosis**: An increase in the number or proportion of lymphocytes in the blood.

15.17D: Typhoid Fever is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.17E: Cholera

Cholera is an infection in the small intestine caused by the bacterium *Vibrio cholerae*.

Learning Objectives

- Describe the mode of transmission for Vibrio cholerae and the steps that can be taken to prevent this

Key Points

- The primary symptoms of cholera are profuse, painless diarrhea and vomiting of clear fluid.
- V. cholerae bacteria that survive the gastric juices produce the hollow cylindrical protein flagellin to make flagella, the cork-screw helical fibers they rotate to propel themselves through the mucus of the small intestine.
- A number of safe and effective oral vaccines for cholera are available.

Key Terms

- **flagella**: A flagellum is a lash-like appendage that protrudes from the cell body of certain prokaryotic and eukaryotic cells.
- **electrolyte**: any of the various ions (such as sodium or chloride) that regulate the electric charge on cells and the flow of water across their membranes

Vibrio Cholerae

Cholera is an infection in the small intestine caused by the bacterium *Vibrio cholerae*. The primary symptoms of cholera are profuse, painless diarrhea and vomiting of clear fluid. These symptoms usually start suddenly, one to five days after ingestion of the bacteria. The diarrhea is frequently described as “rice water” in nature and may have a fishy odor. If the severe diarrhea is not treated with intravenous rehydration, it can result in life-threatening dehydration and electrolyte imbalances.

Figure: **Adult cholera patient**: A person with severe dehydration due to cholera – note the sunken eyes and decreased skin turgor which produces wrinkled hands.

Transmission

Cholera is typically transmitted by either contaminated food or water. In the developed world, seafood is the usual cause, while in the developing world it is more often water. Cholera is rarely spread directly from person to person. Both toxic and nontoxic strains exist.

Most *V. cholerae* bacteria, when consumed, do not survive the acidic conditions of the human stomach. The few surviving bacteria conserve their energy and stored nutrients during the passage through the stomach by shutting down much protein production. When the surviving bacteria exit the stomach and reach the small intestine, they need to propel themselves through the thick mucus that lines the small intestine to get to the intestinal walls, where they can thrive. *V. cholerae* bacteria begin production of the hollow cylindrical protein flagellin to make flagella. These flagella are cork-screw helical fibers that rotate to propel the bacteria through the mucus of the small intestine.

Once the cholera bacteria reach the intestinal wall, they no longer need the flagella to move. The bacteria stop producing the protein flagellin, again conserving energy and nutrients by changing the mix of proteins they manufacture in response to the changed chemical surroundings. The *V. cholerae* start producing the toxic proteins that give the infected person a watery diarrhea.

The diarrhea carries new generations of *V. cholerae* bacteria out into the drinking water of the next host if proper sanitation measures are not in place. A rapid dip-stick test is available to determine the presence of *V. cholerae* in a water supply. Samples

that test positive should be further tested to determine antibiotic resistance. In epidemic situations, a clinical diagnosis may be made by taking a patient history and doing a brief examination. Treatment is usually started without or before confirmation by laboratory analysis. Although cholera may be life-threatening, prevention of the disease is normally straightforward if proper sanitation practices are followed. In developed countries, due to nearly universal advanced water treatment and sanitation practices, cholera is no longer a major health threat.

Breaking the Transmission Path

Effective sanitation practices, if instituted and adhered to in time, are usually sufficient to stop an epidemic. There are several points along the cholera transmission path at which its spread may be halted.

- Sterilization or proper disposal and treatment of infected fecal waste water produced by cholera victims and all contaminated materials (e.g. clothing, bedding, etc.) is essential. All materials that come in contact with cholera patients should be sanitized by washing in hot water, using chlorine bleach if possible. Hands that touch cholera patients or their clothing, bedding, etc., should be thoroughly cleaned and disinfected with chlorinated water or other effective antimicrobial agents.
- Antibacterial treatment of general sewage by chlorine, ozone, ultraviolet light or other effective treatment before it enters the waterways or underground water supplies helps prevent undiagnosed patients from inadvertently spreading the disease.
- Warnings about possible cholera contamination should be posted around contaminated water sources with directions on how to decontaminate the water (boiling, chlorination etc.) for possible use.
- All water used for drinking, washing, or cooking should be sterilized by either boiling, chlorination, ozone water treatment, ultraviolet light sterilization (e.g. by solar water disinfection), or antimicrobial filtration in any area where cholera may be present.
- Public health education and adherence to appropriate sanitation practices are of primary importance to help prevent and control transmission of cholera and other diseases.

Prevention and Treatment

A number of safe and effective oral vaccines for cholera are available. In most cases, cholera can be successfully treated with oral rehydration therapy (ORT), which is effective, safe, and simple to administer. Rice-based solutions are more efficient than glucose-based ones. In cases of severe dehydration, intravenous rehydration may be necessary. Antibiotic treatments for one to three days shorten the course of the disease and reduce the symptoms. People will recover without them, however, if sufficient hydration is maintained. Doxycycline is typically used first line, although some strains of V. cholerae have shown resistance. Testing for resistance during an outbreak can help determine appropriate future choices. Other antibiotics proven to be effective include cotrimoxazole, erythromycin, tetracycline, chloramphenicol, and furazolidone. Fluoroquinolones, such as norfloxacin, also may be used, but resistance has been reported.

15.17E: Cholera is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.17F: Noncholera Vibrios

Vibrio is a Gram-negative bacteria possessing a curved rod shape (comma shape), several species of which can cause foodborne infection.

Learning Objectives

- Discuss the difference between cholera and noncholera causing Vibrios

Key Points

- Vibrio species are prevalent in estuarine and marine environments. Seven species can cause food borne infections associated with seafood.
- Patients with noncholera Vibrio wound infection or septicemia are much more ill and frequently have other medical conditions.
- Early medical intervention is paramount and consists of antimicrobial therapy, intensive medical therapy for disease symptoms, and surgical removal of infected tissues if necessary.

Key Terms

- **necrotizing fasciitis**: Necrotizing fasciitis, commonly known as flesh-eating disease or flesh-eating bacteria syndrome, is a rare infection of the deeper layers of skin and subcutaneous tissues, that easily spreads across the fascial plane within the subcutaneous tissue.
- **hemolysin**: any substance that damages the membranes of red blood cells and thus releases hemoglobin
- **septicemia**: A disease caused by the presence of pathogenic organisms, especially bacteria or their toxins in the bloodstream, characterized by chills and fever.
- **vibrio**: Any of several bacteria, of the genus Vibrio, shaped like a curved rod.

Vibrio is a genus of Gram-negative bacteria possessing a curved rod shape (comma shape). Several species of Vibro can cause food borne infection, usually associated with eating undercooked seafood. Vibrio species are prevalent in estuarine and marine environments. Seven species can cause food borne infections associated with seafood. Vibrio cholerae O1 and O139 serovtypes produce cholera toxin and are agents of cholera. Vibrio species are facultative anaerobes that test positive for oxidase and do not form spores. All members of the genus are motile and have polar flagella with sheaths.

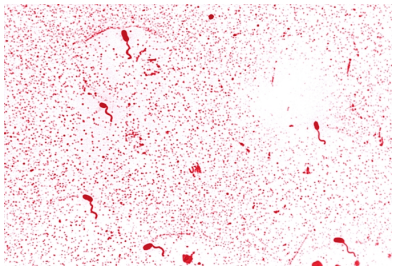

Figure: **Vibrio Cholerae**: Flagellar stain of V. cholerae

Patients with noncholera Vibrio wound infection or septicemia are much more ill and frequently have other medical conditions. Medical therapy consists of the following: prompt initiation of effective antibiotic therapy (doxycycline or a quinolone), intensive medical therapy with aggressive fluid replacement, vasopressors for hypotension and septic shock, early fasciotomy within 24 hours after development of clinical symptoms in patients with necrotizing fasciitis, early debridement of the infected wound, expeditious and serial surgical evaluation and intervention to prevent rapid deterioration, especially in patients with necrotizing fasciitis or compartment syndrome. Reconstructive surgery, such as skin graft, is indicated in the recovery phase.

Fecal-oral route infections in the terrestrial environment are responsible for epidemic cholera. Most strains cause gastroenteritis such as V. cholerae non-O1/O139 strains and Vibrio parahaemolytitcus strains capable of producing thermostable direct hemolysin (TDH) and/or TDH-related hemolysin. Vibrio vulnificus is responsible for seafood borne primary septicemia. Its infectivity depends primarily on the risk factors of the host. V. vulnificus infection has the highest fatality rate (50%) of any food borne pathogen. Four other species (V. mimicus, V. hollisae, V. fluvialis, and V. furnissii) can cause gastroenteritis. Some strains of these species produce known toxins, but the pathogenic mechanism is largely not understood.

15.17F: Noncholera Vibrios is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.17G: Pathogenic Escherichia coli

Most E. coli strains are harmless, but some serotypes are pathogenic and can cause serious food poisoning in humans and other species.

Learning Objectives

- Distinguish between the different types of pathogenic E. coli in regards to classification and mode of transmission

Key Points

- Pathogenic E. coli strains can be categorized based on elements that can elicit an immune response in animals. The different categories are: O antigen, K antigen, H antigen, and F antigen in the lipopolysaccharide.
- In humans and in domestic animals, virulent strains of E. coli can cause gastroenteritis, urinary tract infections, and neonatal meningitis.
- Bacterial infections are usually treated with antibiotics.

Key Terms

- **bacteraemia**: The medical condition of having bacteria in the bloodstream.
- **lipopolysaccharide**: any of a large class of lipids conjugated with polysaccharides
- **flora**: the microorganisms that inhabit some part of the body, such as intestinal flora
- **enterohemorrhagic E. coli**: strains of the bacterium Escherichia coli that, when infecting humans, have been linked with the severe complication hemolytic-uremic syndrome

Escherichia coli (E. coli) is a Gram-negative, rod-shaped bacterium that is commonly found in the lower intestine of warm-blooded organisms (endotherms). Most E. coli strains are harmless, but some serotypes are pathogenic and can cause serious food poisoning in humans and other species. The harmless strains are part of the normal flora of the gut, and can benefit their hosts by producing vitamin K2, and by preventing the establishment of pathogenic bacteria within the intestine.

Pathogenic E. coli

Pathogenic E. coli strains can be categorized based on elements that can elicit an immune response in animals, namely: O antigen, K antigen, H antigen, and F antigen in the lipopolysaccharide (LPS) molecules found in the outer membrane of the E. coli cell. The O antigen is a polymer of immunogenic repeating oligosaccharides which is used for serotyping E.coli. It should be noted though that antibodies towards several O antigens cross-react with other O antigens and partially to K antigens not only from E. coli, but also from other Escherichia species and Enterobacteriaceae species. There are two separate groups of K-antigen groups, named group I and group II (while a small in-between subset (K3, K10, and K54/K96) has been classified as group III). Group I consists of 100 kDa (large) capsular polysaccharides, while those in Group II, associated with extraintestinal diseases, are under 50 kDa in size.

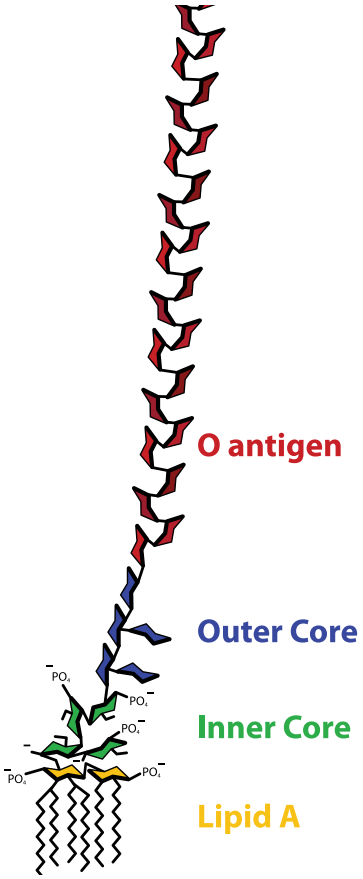

Figure: **Lipopolysaccharide**: Structure of a lipopolysaccharide showing the O antigen, core region and lipid A.

In humans and in domestic animals, virulent strains of E. coli can cause various diseases. In humans, gastroenteritis, urinary tract infections, and neonatal meningitis can occur. In rarer cases, virulent strains are also responsible for haemolytic-uremic syndrome, peritonitis, mastitis, septicemia, and Gram-negative pneumonia. Certain strains of E. coli produce potentially lethal toxins. Food poisoning caused by E. coli can result from eating unwashed vegetables or undercooked meat. If E. coli bacteria escape the intestinal tract through a perforation (for example from an ulcer, a ruptured appendix, or due to a surgical error) and enter the abdomen, they usually cause peritonitis that can be fatal without prompt treatment.

Transmission of pathogenic E. coli often occurs via fecal–oral transmission. Common routes of transmission include unhygienic food preparation, farm contamination due to manure fertilization, irrigation of crops with contaminated greywater or raw sewage, feral pigs on cropland, or direct consumption of sewage-contaminated water. According to the U.S. Food and Drug Administration, the fecal-oral cycle of transmission can be disrupted by cooking food properly, preventing cross-contamination, instituting barriers such as gloves for food workers, instituting health care policies so food industry employees seek treatment when they are ill, pasteurization of juice or dairy products and proper hand washing requirements.

Uropathogenic E. coli

Uropathogenic E. coli (UPEC) is responsible for approximately 90% of urinary tract infections (UTI) seen in individuals with ordinary anatomy. In ascending infections, fecal bacteria colonize the urethra and spread up the urinary tract to the bladder, as well as to the kidneys (causing pyelonephritis), or the prostate in males. Because women have a shorter urethra than men, they are 14 times more likely to suffer from an ascending UTI. Uropathogenic E. coli use P fimbriae (pyelonephritis-associated pili) to bind urinary tract endothelial cells and colonize the bladder. UPEC can evade the body's innate immune defences (e.g. the complement system) by invading superficial umbrella cells to form intracellular bacterial communities (IBCs). They also have the ability to form K antigen, capsular polysaccharides that contribute to biofilm formation. Descending infections in turn, though relatively rare, occur when E. coli cells enter the upper urinary tract organs (kidneys, bladder or ureters) from the blood stream.

E. coli and Meningitis

Neonatal meningitis is produced by a serotype of E. coli that contains a capsular antigen called K1. The colonization of the newborn's intestines with these stems, that are present in the mother's vagina, lead to bacteraemia, which leads to meningitis. Severe meningitis in the neonates are caused because of the absence of the IgM antibodies from the mother (these do not cross the placenta because FcRn only mediates the transfer of IgG), plus the fact that the body recognizes as self the K1 antigen, as it resembles the cerebral glicopeptides. In stool samples, microscopy will show Gram-negative rods, with no particular cell arrangement.

Treating E. coli

Bacterial infections are usually treated with antibiotics. However, the antibiotic sensitivities of different strains of E. coli vary widely. As Gram-negative organisms, E. coli are resistant to many antibiotics that are effective against Gram-positive organisms. Antibiotics which may be used to treat E. coli infection include amoxicillin, as well as other semisynthetic penicillins, many cephalosporins, carbapenems, aztreonam, trimethoprim-sulfamethoxazole, ciprofloxacin, nitrofurantoin, and the aminoglycosides. Researchers have actively been working to develop safe, effective vaccines to lower the worldwide incidence of E. coli infection.

15.17G: Pathogenic Escherichia coli is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.17H: Campylobacter

Campylobacter (meaning ‘twisted bacteria’) is a genus of bacteria that are Gram-negative, spiral, and microaerophilic.

Learning Objectives

- Discuss the method of transmission for Campylobacter

Key Points

- Campylobacter jejuni is now recognized as one of the main causes of bacterial foodborne disease in many developed countries.
- The common routes of transmission are fecal-oral, ingestion of contaminated food or water, and the eating of raw meat.
- It produces an inflammatory, sometimes bloody, diarrhea, periodontitis or dysentery syndrome, mostly including cramps, fever and pain.

Key Terms

- **microaerophilic**: living and thriving in an environment low in oxygen
- **enteritis**: Inflammation of the intestines, generally the small intestine, that may lead to diarrhea.
- **flagella**: A flagellum is a lash-like appendage that protrudes from the cell body of certain prokaryotic and eukaryotic cells.

Description of Campylobacter Bacteria

Campylobacter is a genus of bacteria that are Gram-negative, spiral, and microaerophilic. The name means “twisted bacteria” because of the spiral formation; motile, with either unipolar or bipolar flagella, the organisms have a characteristic spiral/corkscrew appearance and are oxidase-positive.

Figure: **Epsilonproteobacteria**: Campylobacter bacteria are the number-one cause of food-related gastrointestinal illness in the United States. To learn more about this pathogen, ARS scientists are sequencing multiple Campylobacter genomes. This scanning electron microscope image shows the characteristic spiral, or corkscrew, shape of C. jejuni cells and related structures.

Campylobacter jejuni is now recognized as one of the main causes of bacterial foodborne disease in many developed countries. At least a dozen species of Campylobacter have been implicated in human disease, with C. jejuni and C. coli the most common. C. fetus is a cause of spontaneous abortions in cattle and sheep, as well as an opportunistic pathogen in humans.

Campylobacter species contain two flagellin genes in tandem for motility: flaA and flaB. These genes undergo intergenic recombination, further contributing to their virulence. Nonmotile mutants do not colonize.

Methods of Transmission and Treatment

The common routes of transmission are fecal-oral; the bacteria are introducted through ingestion of contaminated food or water and by the eating of raw meat. Infection produces an inflammatory, sometimes bloody diarrhea, periodontitis, or dysentery syndrome, mostly including cramps, fever and pain. The infection is usually self-limiting. In most cases symptomatic treatment by liquid and electrolyte replacement is enough in human infections. The use of antibiotics, on the other hand, is controversial.

Diagnosis

Symptoms typically last for five to seven days. The sites of tissue injury include the jejunum, the ileum, and the colon. Most strains of C. jejuni produce a toxin (cytolethal distending toxin) that hinders the cells from dividing and activating the immune system. This symptom helps the bacteria evade the immune system and survive for a limited time in the cells. A cholera-like enterotoxin was also once thought to be made, but this appears not to be the case. The organism produces diffuse, bloody, edematous, and exudative enteritis. Although rarely has the infection been considered a cause of hemolytic uremic syndrome and thrombotic thrombocytopenic purpura, no unequivocal case reports exist. In some cases, a Campylobacter infection can be the underlying cause of Guillain-Barré syndrome. Gastrointestinal perforation is a rare complication of ileal infection.

Diagnosis of the illness is made by testing a specimen of faeces (bowel motion). Standard treatment is now azithromycin and, on occassion, terbinafine. Quinolone antibiotics such as ciprofloxacin or levofloxacin are no longer as effective due to resistance. Dehydrated children may require intravenous (by vein) fluid treatment in a hospital. The illness is contagious, and children must be kept at home until they have been clear of symptoms for at least two days. Good hygiene is important to avoid contracting the illness or spreading it to others.

15.17H: Campylobacter is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.17I: Peptic Ulcer Disease

A peptic ulcer, also known as peptic ulcer disease, is an erosion in the wall of the stomach, duodenum, or esophagus.

Learning Objectives

- List the causes of and treatments for peptic ulcer disease

Key Points

- 70–90% of peptic ulcers are associated with Helicobacter pylori, a spiral-shaped bacterium that lives in the acidic environment of the stomach.
- Diagnosis is mainly established based on the characteristic symptoms. Stomach pain is usually the first signal of a peptic ulcer.
- Treatment of H. pylori usually leads to clearing of infection, relief of symptoms, and eventual healing of ulcers.
- Gas in the peritoneal cavity, shown on an erect chest x-ray or supine lateral abdominal x-ray, is an omen of perforated peptic ulcer disease, which requires emergency surgery.
- Gastrointestinal bleeding is the most common complication. Sudden large bleeding can be life-threatening. It occurs when the ulcer erodes one of the blood vessels, such as the gastroduodenal artery.
- Most bleeding ulcers require endoscopy urgently to stop bleeding with cautery, injection, or clipping.
- During the active phase, the base of the ulcer shows 4 zones: inflammatory exudate, fibrinoid necrosis, granulation tissue and fibrous tissue.
- A gastric peptic ulcer is a mucosal defect which penetrates the muscularis mucosae and muscularis propria, produced by acid-pepsin aggression.
- Ulcers are not purely an infectious disease and that psychological factors do play a significant role.
- Diagnosis is mainly established based on the characteristic symptoms. Stomach pain is usually the first signal of a peptic ulcer.
- Gastric ulcers are most often localized on the lesser curvature of the stomach.
- Gas in the peritoneal cavity, shown on an erect chest X-ray or supine lateral abdominal X-ray, is an omen of perforated peptic ulcer disease.
- Gastrointestinal bleeding is the most common complication. Sudden large bleeding can be life-threatening. It occurs when the ulcer erodes one of the blood vessels, such as the gastroduodenal artery.
- Burning or gnawing feeling in the stomach area lasting between 30 minutes and 3 hours commonly accompanies ulcers.
- Typical ulcers tend to heal and recur and as a result the pain may occur for few days and weeks and then wane or disappear.

Key Terms

- **prostaglandin**: Any of a group of naturally occurring lipids derived from the C20 acid prostanoic acid; they have a number of physiological functions and may be considered to be hormones.
- **NSAID**: Any drug of the non-steroidal anti-inflammatory class used as a pain reliever.
- **gastrin**: A hormone that stimulates the production of gastric acid in the stomach.
- **gastritis**: Inflammation of the lining of the stomach, characterized by nausea, loss of appetite, and upper abdominal discomfort or pain.

A peptic ulcer, also known as peptic ulcer disease, is an erosion in the wall of the stomach, duodenum, or esophagus. As many as 70–90% of such ulcers are associated with Helicobacter pylori, a spiral-shaped bacterium that lives in the acidic environment of the stomach. Ulcers can also be caused or worsened by drugs such as aspirin, ibuprofen, and other NSAIDs.

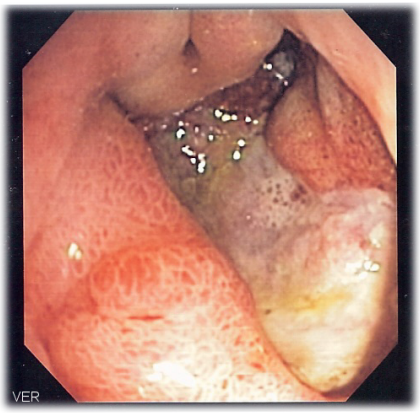

Figure: **Deep gastric ulcer**: This image, acquired via endoscope, shows a deep gastric ulcer.

Symptoms

Symptoms of a peptic ulcer include abdominal pain, classically near the stomach with severity relating to mealtimes, about three hours after eating a meal; bloating and abdominal fullness; nausea; copious vomiting; loss of appetite and weight loss; vomiting of blood; and melena, which are tarry, foul-smelling feces due to oxidized iron from hemoglobin. Rarely, an ulcer can lead to a gastric or duodenal perforation, which leads to acute peritonitis. This is extremely serious and requires immediate surgery.

Causes

A major causative factor of ulcers is chronic inflammation due to Helicobacter pylori that colonizes the mucosa. The immune system is unable to clear the infection, despite the appearance of antibodies. Thus, the bacterium can cause a chronic active gastritis, resulting in a defect in the regulation of gastrin production by that part of the stomach. Gastrin secretion can either be increased, or as in most cases, decreased, resulting in a too basic or too acidic stomach environment, respectively. A decrease in acid can promote H. pylori growth and an increase in acid can contribute to the erosion of the mucosa and therefore ulcer formation.

Another major cause is the use of NSAIDs. The gastric mucosa protects itself from gastric acid with a layer of mucus, the secretion of which is stimulated by certain prostaglandins. NSAIDs block the function of cyclooxygenase 1 (cox-1), which is essential for the production of these prostaglandins.

Researchers also continue to look at stress as a possible cause, or at least complication, in the development of ulcers. There is debate as to whether psychological stress can influence the development of peptic ulcers. Burns and head trauma, however, can lead to physiologic stress ulcers, which are reported in many patients who are on mechanical ventilation.

Diagnosis

The diagnosis is mainly established based on the characteristic symptoms. Stomach pain is usually the first signal of a peptic ulcer. In some cases, doctors may treat ulcers without diagnosing them with specific tests and observe whether the symptoms resolve, this indicating that their primary diagnosis was accurate.

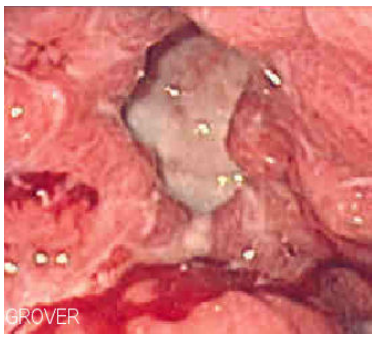

Figure: **Gastric ulcer**: This endoscopic image shows a gastric ulcer, which upon biopsy was shown to be gastric cancer.

Confirmation of the diagnosis is made with the help of tests such as endoscopies or barium contrast x-rays. The tests are typically ordered if the symptoms do not resolve after a few weeks of treatment. Tests are also given when first appear in a person who is

over age 45 or who has other symptoms such as weight loss, because stomach cancer can cause similar symptoms. Also, when severe ulcers resist treatment, particularly if a person has several ulcers or the ulcers are in unusual places, a doctor may suspect an underlying condition that causes the stomach to overproduce acid.

An esophagogastroduodenoscopy (EGD), a form of endoscopy, also known as a gastroscopy, is carried out on patients in whom a peptic ulcer is suspected. By direct visual identification, the location and severity of an ulcer can be described. Moreover, if no ulcer is present, EGD can often provide an alternative diagnosis.

If a peptic ulcer perforates, air will leak from the inside of the gastrointestinal tract (which always contains some air) to the peritoneal cavity (which normally never contains air). This leads to “free gas” within the peritoneal cavity. If the patient stands erect, as when having a chest x-ray, the gas will float to a position underneath the diaphragm. Therefore, gas in the peritoneal cavity, shown on an erect chest x-ray or supine lateral abdominal x-ray, is an omen of perforated peptic ulcer disease.

Treatment

Figure: **Benign gastric ulcer**: This gastric ulcer was found in tissue removed during a gastrectomy.

Younger patients with ulcer-like symptoms are often treated with antacids. The ability of antacids to neutralize acidity by increasing the pH or blocking the secretion of acid by gastric cells is critical in reducing acidity in the stomach. Patients who are taking NSAIDs may also be prescribed a prostaglandin analogue in order to help prevent peptic ulcers by replacing the prostaglandins whose formation is blocked by NSAID use.

When H. pylori infection is present, the most effective treatments are combinations of two antibiotics, such as Clarithromycin, Amoxicillin, Tetracycline, and Metronidazole; and one proton pump inhibitor, sometimes in combination with antacids. In complicated, treatment-resistant cases, three antibiotics may be used together with a proton pump inhibitor. Treatment of H. pylori usually leads to clearing of infection, relief of symptoms and eventual healing of ulcers. Recurrence of infection can occur and retreatment may be required, if necessary with other antibiotics.

Perforated peptic ulcer is a surgical emergency and requires surgical repair of the perforation. Most bleeding ulcers require endoscopy urgently to stop bleeding with cautery, injection, or clipping.

15.17J: Listeriosis

Listeriosis is a bacterial infection caused by a Gram-positive, motile bacterium called Listeria monocytogenes.

Learning Objectives

- Discuss the mechanism of action for listeriosis

Key Points

- Listeriosis has a low incidence in humans and occurs in pregnant women, newborn infants, elderly patients, and patients who are immunocompromised.
- Listeria can invade through unusually tough barriers in humans: the blood-brain barrier and the feto-placental barrier, which contain high levels of cadherin protein on their membrane.
- The main route of acquisition of Listeria is through the ingestion of contaminated food products.

Key Terms

- **incidence**: a measure of the risk that a person develops a new condition within a specified period of time, usually a year
- **listeriosis**: An infectious disease of humans and animals caused by the bacteria Listeria monocytogenes and Listeria ivanovii, often through contaminated food.
- **meningitis**: Inflammation of the meninges, characterized by headache, neck stiffness and photophobia and also fever, chills, vomiting, and myalgia.
- **cadherin**: Any of a class of transmembrane proteins important in maintaining tissue structure.
- **blood-brain barrier**: a structure in the central nervous system (CNS) that keeps various substances found in the bloodstream out of the brain while allowing in the substances essential to metabolic function

Listeriosis is a bacterial infection caused by a Gram-positive, motile bacterium, *Listeria monocytogenes*. Listeriosis has a low incidence in humans and occurs in pregnant women, newborn infants, elderly patients, and patients who are immunocompromised. Pregnant women are the most susceptible and infection can lead to early delivery, infection of the newborn, and death of the baby.

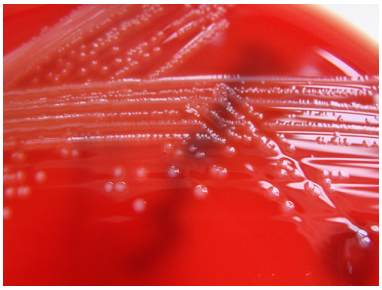

Figure: **Listeria monocytogenes**: A bacterial infection caused by a Gram-positive, motile bacterium, Listeria monocytogenes which is shown here on a blood agar plate.

The symptoms of listeriosis usually last 7–10 days, with the most common symptoms being fever, muscle aches, and vomiting. Diarrhea is another symptom, but less common. If the infection spreads to the nervous system it can cause meningitis, an infection of the covering of the brain and spinal cord.

Listeria originally evolved to invade membranes of the intestines, as an intracellular infection, and developed a chemical mechanism to do so. This involves a bacterial protein “internalin” which attaches to a protein on the intestinal cell membrane “cadherin. ” These adhesion molecules are also to be found in two other unusually tough barriers in humans – the blood-brain barrier and the feto-placental barrier, and this may explain the apparent affinity that Listeria has for causing meningitis and affecting babies in-utero. Particular strains of a food-borne bacteria are able to invade the heart, leading to serious and difficult-to-treat heart infections.

Listeria monocytogenes is ubiquitous in the environment. The main route of acquisition is by the ingestion of contaminated food products. Listeria has been isolated from raw meat, dairy products, vegetables, fruit and seafood. Soft cheeses, unpasteurized milk and unpasteurised pâté are potential dangers too. The main prevention is through the promotion of safe handling, cooking and consumption of food. This includes washing raw vegetables and cooking raw food thoroughly, as well as reheating leftover or

ready-to-eat foods, like hot dogs, until steaming hot. Another preventative measure is to advise high-risk groups such as pregnant women and immunocompromised patients to avoid unpasteurized pâtés and foods such as soft cheeses.

In the advent of listeriosis, bacteremia should be treated for two weeks, meningitis for three weeks, and brain abscess for at least six weeks. Ampicillin generally is considered the antibiotic of choice and gentamicin is added frequently for its synergistic effects. About 10 percent of serious listeria infections involve cardiac infections that are difficult to treat, with more than one-third proving fatal.

SECTION OVERVIEW

15.18: Viral Diseases of the Digestive System

Topic hierarchy

15.18A: Mumps

15.18B: Hepatitis

15.18C: Viral Gastroenteritis

15.18: Viral Diseases of the Digestive System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.18A: Mumps

Mumps was a common childhood viral disease, but widespread vaccination has now made it rare in developed countries.

Learning Objectives

- Analyze the cause, symptoms, and prevention of mumps

Key Points

- Mumps is a contagious disease that is spread from person to person through contact with respiratory secretions, such as saliva from an infected person. The common symptoms of mumps include inflammation of the salivary glands, pancreas, and testicles; fever; and headache.
- A physical examination confirms the presence of the swollen glands. Usually, the disease is diagnosed on clinical grounds and no confirmatory laboratory testing is needed.
- The most common preventative measure against mumps is a vaccination with a mumps vaccine. The vaccine may be given separately or as part of the routine MMR immunization vaccine which also protects against measles and rubella.
- Like many other viral illnesses, there is no specific treatment for mumps, other than supportive treatment. Death from mumps is very unusual. The disease is self-limiting, and general outcome is good. Known rare complications of mumps include infertility in men and profound hearing loss.

Key Terms

- **orchitis**: A painful inflammation of one or both testes.
- **salivary gland**: Any of several exocrine glands that produce saliva to break down carbohydrates in food enzymatically.
- **prodromal symptoms**: A prodrome is an early symptom (or set of symptoms) that might indicate the start of a disease before specific symptoms occur.
- **parotid gland**: Either of a pair of salivary glands located in front of, and below each ear in humans.

Mumps, also known as epidemic parotitis, was a common childhood viral disease caused by the mumps virus. Before the development of vaccination and the introduction of a vaccine in 1949, it was common worldwide, but now, outbreaks are largely confined to developed countries.

Symptoms

The common symptoms of mumps include inflammation of the salivary glands, pancreas, and testicles; fever, and headache. Swelling of the salivary glands, specifically the parotid gland, is known as parotitis, and it occurs in 60–70% of infections and 95% of patients with symptoms. Parotitis causes swelling and local pain, particularly when chewing. It can occur on one side but is more common on both sides in about 90% of cases. Painful inflammation of the testicles in mumps in known as orchitis. Other symptoms of mumps can include dry mouth, sore face and/or ears and occasionally, in more serious cases, loss of voice. In addition, up to 20% of persons infected with the mumps virus do not show symptoms, so it is possible to be infected and spread the virus without knowing it. Fever and headache are prodromal symptoms of mumps, together with malaise and loss of appetite.

Figure: **Child with mumps**: This child with mumps displays the typical swelling of the salivary glands caused by the mumps virus.

Causes

Mumps is a contagious disease that is spread from person to person through contact with respiratory secretions, such as saliva from an infected person. When an infected person coughs or sneezes, the droplets aerosolize and can enter the eyes, nose, or mouth of

another person. Mumps can also be spread by sharing food and drinks. The virus can survive on surfaces and then be spread after contact in a similar manner. A person infected with mumps is contagious from approximately six days before the onset of symptoms until about nine days after symptoms start. The incubation period can be anywhere from 14–25 days, but is more typically 16–18 days.

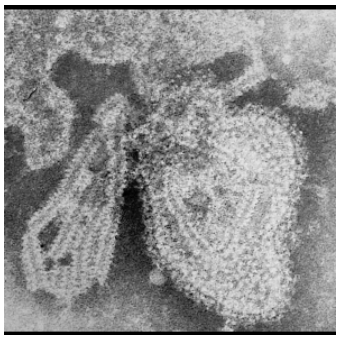

Figure: **Mumps virus**: This transmission electron micrograph (TEM) shows the ultrastructure of the mumps virus. It is a roughly spherical particle made up of layers of fatty lipids, large protein molecules, and nucleic acids. The virus is dotted with large protein "spikes" that enable it to gain entry to host cells. Inside lies a core of a single, long molecule of RNA wrapped up in protein that is released into the host cell.

Diagnostics

A physical examination confirms the presence of the swollen glands. Usually, the disease is diagnosed on clinical grounds, and no confirmatory laboratory testing is needed. If there is uncertainty about the diagnosis, a test of saliva or blood may be carried out. An estimated 20–30% of cases are asymptomatic. As with any inflammation of the salivary glands, the level of amylase in the blood is often elevated.

Prevention

The most common preventative measure against mumps is a vaccination with a mumps vaccine. The vaccine may be given separately or as part of the routine MMR immunization vaccine which also protects against measles and rubella. The MMR vaccine is given at ages 12–15 months and then again at four to six years.

Treatment and Complications

Like many other viral illnesses, there is no specific treatment for mumps. Symptoms may be relieved by the application of intermittent ice or heat to the affected neck/testicular area and by the acetaminophen or ibuprofen for pain relief. Warm salt water gargles, soft foods, and extra fluids may also help relieve symptoms. Patients are advised to avoid acidic foods and beverages, since these stimulate the salivary glands, which can be painful.

Death from mumps is very unusual. The disease is self-limiting, and general outcome is good, even if other organs are involved. Known complications of mumps include:

- In teenage males and men, complications from orchitis such as infertility or sub-fertility are rare, but present.
- Spontaneous abortion in about 27% of cases during the first trimester of pregnancy.
- Mild forms of meningitis in up to 10% of cases.
- Profound hearing loss is very rare, but mumps was the leading cause of acquired deafness before the advent of the mumps vaccine.

After the illness, life-long immunity to mumps generally occurs; re-infection is possible but tends to be mild and atypical.

15.18A: Mumps is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.18B: Hepatitis

Hepatitis is the inflammation of the liver. Causes include viruses, bacterial infections, alcohol, autoimmune disorders, drugs, and toxins.

Learning Objectives

- Differentiate between acute and chronic hepatitis

Key Points

- Hepatitis is acute when it lasts less than six months and chronic when it persists longer.
- The initial symptoms of hepatitis are nonspecific flu-like symptoms, common to almost all acute viral infections and may include malaise, muscle and joint aches, fever, nausea or vomiting, diarrhea, and headache.
- A diagnosis of hepatitis is usually made by a combination of blood work and physical examination. When the liver is inflamed, levels of certain liver enzymes that are found in the blood will be elevated. If a patient has viral hepatitis, the presence of the virus can be detected in the blood.
- There are many causes of liver inflammation or hepatitis. The most common cause of acute hepatitis is infection with the Hepatitis B, C, or D viruses. Bacterial diseases can also cause liver inflammation, such as tuberculosis and tick-borne diseases.
- Non-infectious causes of hepatitis include alcohol, autoimmune conditions, drugs, circulatory insufficiency, metabolic diseases, pregnancy, and toxins.
- For those with alcohol-induced hepatitis, cessation of drinking is recommended, as alcoholic hepatitis is often the beginning of more serious drinking-related liver disorders.

Key Terms

- **ascites**: An accumulation of fluid in the peritoneal cavity, frequently symptomatic of liver disease.
- **jaundice**: A yellowish pigmentation of the skin, the whites of the eyes (sclera), and other mucous membranes caused by increased levels of bilirubin in the blood that build up in extracellular fluid, usually due to liver disease.
- **cirrhosis**: A chronic disease of the liver caused by damage from toxins (including alcohol), metabolic problems, hepatitis, or nutritional deprivation. It is characterized by an increase of fibrous tissue and the destruction of liver cells.
- **hepatitis**: inflammation of the liver, sometimes caused by a viral infection

Hepatitis is the inflammation of the liver. The condition can be self-limiting (healing on its own) or can progress to fibrosis (scarring) and cirrhosis.

Hepatitis may occur with limited or no symptoms, but often leads to jaundice, poor appetite, and malaise. Hepatitis is acute when it lasts less than six months and chronic when it persists longer. A group of viruses, known as the hepatitis viruses, cause most cases of hepatitis worldwide, but it can also be due to toxins, notably alcohol, certain medications, some industrial organic solvents, and plants.

Symptoms

The initial symptoms of hepatitis are nonspecific flu-like symptoms, common to almost all acute viral infections and may include malaise, muscle and joint aches, fever, nausea or vomiting, diarrhea, and headache. More specific symptoms, which can be present in acute hepatitis from any cause, are profound loss of appetite, aversion to smoking among smokers, dark urine, yellowing of the eyes and skin and abdominal discomfort. Physical findings are usually minimal, apart from jaundice and liver swelling. Some patients exhibit enlarged lymph nodes or enlargement of the spleen.

Figure: **Jaundice**: Jaundice, seen here as yellowing of the eyes, is often a symptom of hepatitis.

Acute Hepatitis

Acute viral hepatitis is more likely to be asymptomatic in younger people. Symptomatic individuals may present after convalescent stage of 7 to 10 days, with the total illness lasting 2 to 6 weeks.

A small proportion of people with acute hepatitis progress to acute liver failure, in which the liver is unable to clear harmful substances from the circulation, leading to confusion and coma due liver insufficiency, and unable to produce blood proteins, leading to peripheral edema and bleeding. This may become life-threatening and, occasionally, requires a liver transplant.

Chronic Hepatitis

Chronic hepatitis often leads to nonspecific symptoms, such as malaise, tiredness and weakness, and often causes no symptoms at all. It is commonly identified on blood tests performed either for screening or to evaluate nonspecific symptoms. The occurrence of jaundice indicates advanced liver damage. On physical examination, there may be enlargement of the liver.

Extensive damage and scarring of liver, known as cirrhosis, leads to weight loss, easy bruising and bleeding tendencies, peripheral edema and accumulation of ascites, or fluid in the abdominal cavity. Eventually, cirrhosis may lead to various complications, including esophageal varices, which are enlarged veins in the wall of the esophagus that can cause life-threatening bleeding; hepatic encephalopathy, which causes confusion and coma; and kidney dysfunction.

Diagnoses

A diagnosis of hepatitis is usually made by a combination of blood work and physical examination. When the liver is inflamed, levels of certain liver enzymes that are found in the blood will be elevated. If a patient has viral hepatitis, the presence of the virus can be detected in the blood. Patients with progressing liver damage will often display jaundice, or yellowing of the whites of the eyes and skin, and their livers will be visibly enlarged.

Causes

There are many causes of liver inflammation, or, hepatitis. The most common cause of acute hepatitis is infection with the Hepatitis B, C, or D viruses. Bacterial diseases can also cause liver inflammation, such as tuberculosis and tick-borne diseases.

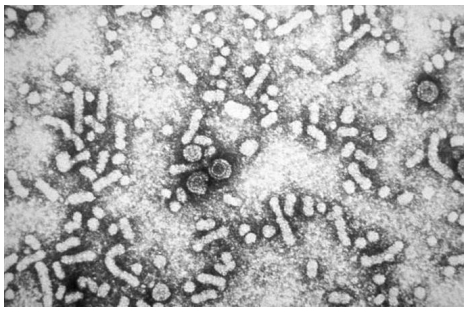

Figure: **Hepatitis B Virus**: The hepatitis B virus is a common cause of liver inflammtion.

Non-infectious causes of hepatitis include alcohol, autoimmune conditions, drugs, circulatory insufficiency, metabolic diseases, pregnancy, and toxins.

Alcohol is a significant cause of hepatitis worldwide. Usually alcoholic hepatitis comes after a period of increased alcohol consumption. Alcoholic hepatitis is characterized by a variable constellation of symptoms, which may include feeling unwell,

enlargement of the liver, development of fluid in the abdomen ascites, and a modest elevation of liver blood tests. Alcoholic hepatitis can vary from mild with only liver test elevation to severe liver inflammation with development of jaundice and liver failure.

Alcoholic hepatitis is distinct from cirrhosis caused by long-term alcohol consumption. Alcoholic hepatitis can occur in patients with chronic alcoholic liver disease and alcoholic cirrhosis. Alcoholic hepatitis by itself does not lead to cirrhosis, but cirrhosis is more common in patients with long-term alcohol consumption.

Treatment

Treatment of hepatitis typically involves treating the underlying condition that caused the inflammation.

In acute hepatitis caused by the hepatitis viruses, often, the liver inflammation will subside when the viral illness has subsided. Antiviral medications, such as interferon, can be used to treat the hepatitis viruses. There is currently a vaccination for Hepatitis B, but not for C or D. Similarly, hepatitis caused by a bacterial disease will typically resolve once the bacterial illness is treated with antibiotics.

For non-infectious causes of hepatitis, treatment of the underlying cause is necessary. For those with alcohol-induced hepatitis, cessation of drinking is recommended, as alcoholic hepatitis is often the beginning of more serious drinking-related liver disorders.

15.18B: Hepatitis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.18C: Viral Gastroenteritis

Gastroenteritis is caused by two different virus types in adults and children.

Learning Objectives

- Recognize the viruses that cause gastroenteritis and their mode of transmission

Key Points

- Rotaviruses typically causes gastroenteritis in children. These are double-stranded viruses, which have two coats or capsids.
- Noroviruses, which cause most adult cases of gastroenteritis, are fast mutating viruses.
- The key to the treatment of gastroenteritis is rehydration, either orally or, in severe cases, intravenously.

Key Terms

- **replication**: Process by which an object, person, place or idea may be copied mimicked or reproduced.
- **kbp**: kilobase pair
- **substitutions per site per year**: A DNA mutation where one DNA base pair is replaced with another; often used synonymous with the term mutation rate.

Gastroenteritis is a medical condition characterized by inflammation ("-itis") of the gastrointestinal tract that involves both the stomach ("gastro"-) and the small intestine ("entero"-), resulting in some combination of diarrhea, vomiting, abdominal pain and cramping. Gastroenteritis has also been referred to as gastro, stomach bug, and stomach virus. Although unrelated to influenza, it has also been called stomach flu and gastric flu.

Viruses that are known to cause gastroenteritis include rotavirus, norovirus, adenovirus, and astrovirus. Globally, Rotavirus is the most common cause of gastroenteritis in children, and produces similar incidence rates in both the developed and developing world. In adults, norovirus and Campylobacter are more common causes.

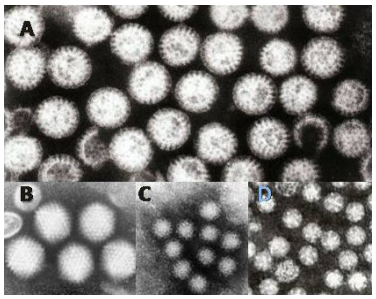

Figure: **Gastroenteritis Viruses**: Electron Micrographs of viruses that cause gastroenteritis in humans. A = rotavirus, B = adenovirus, C = norovirus and D = astrovirus. They are shown at the same magnification of approximately x 200,000

Viruses cause about 70% of episodes of infectious diarrhea in the pediatric age group. Rotavirus is a genus of double-stranded RNA virus in the family Reoviridae. Reoviruses are non-enveloped and have an icosahedral capsid composed of an outer and inner protein shell. The genomes of viruses in Reoviridae contains 10-12 segments which are grouped into three categories corresponding to their size: L (large), M (medium) and S (small). Segments range from ~ 3.9 kbp – 1kbp and each segment encodes 1-3 proteins. Since these viruses have dsRNA genomes, replication occurs exclusively in the cytoplasm and the virus encodes several proteins which are needed for replication.

The virus can enter the host cell via a receptor on the cell surface. The receptor is not known. After binding to the receptor the outer shell is partially digested to allow cell entry. The inner shell particle then enters the cytoplasm by a yet unknown process to start replication. Viral particles begin to assemble in the cytoplasm 6–7 hours after infection.

Rotavirus is a less common cause in adults due to their acquired immunity. Norovirus is the leading cause of gastroenteritis among adults in America, causing greater than 90% of outbreaks. Noroviruses contain an RNA genome of approximately 7.5 kbp, encoding a major structural protein (VP1) and a minor capsid protein (VP2). The virus particles demonstrate an amorphous surface structure when visualized using electron microscopy and are between 27-38 nm in size.

The most variable region between different viruses of the same type is a portion of the viral capsid. Specifically a region which contains antigen-presenting sites and carbohydrate-receptor binding regions, which is probably the region of the virus that binds to

target cells. The estimated mutation rate (1.21×10^{-2} to 1.41×10^{-2} substitutions per site per year) in this virus is high, even compared with other RNA viruses. Norovirus epidemics typically occur when groups of people spend time in close physical proximity to each other, such as on cruise ships, in hospitals, or in restaurants. People may remain infectious even after their diarrhea has ended. Norovirus is the cause of about 10% of cases in children.

The foundation of management of gastroenteritis, viral-caused or otherwise, is adequate hydration. For mild or moderate cases, this can be typically achieved via oral rehydration solution. For more severe cases, intravenous fluids may be needed. Gastroenteritis primarily affects children and those in the developing world.

15.19A: Ergot Poisoning

Ergot poisoning is caused by ingestion of the alkaloids produced by the ergot fungi.

Learning Objectives

- List the causes and effects of ergot poisoning

Key Points

- Ergot fungi typically infect rye, wheat and forage plants.
- Ingestion of the alkaloid toxins produced by the fungi can result in ergot poisoning in humans and foraging animals.
- Ergot poisoning can have either convulsive central nervous system effects or gangrenous symptoms caused by vasoconstriction effects.

Key Terms

- **alkaloids**: A class of organic heterocyclic bases.
- **gangrenous**: To be afflicted with gangrene.

Ergot poisoning is a type of illness associated with the ingestion of alkaloids produced by the fungi *Claviceps purpurea (C. purpurea)*. *Claviceps purpurea* is a fungus classified under the fungi genus *Claviceps*. This specific type of fungus is found on rye, and also on crops like wheat and barley. In addition, *Claviceps purpurea* can effect plants and crops that are typically considered forage plants. Thus, this type of fungus can also result in diseases within livestock.

The life cycle of *C. purpurea* begins when an ergot kernel, called a sclerotium, infects the host. The fungi continues to undergo proliferation and destroys the plant ovary. The first stage of ergot infection is a white soft tissue, called Sphacelia segetum, that drops out of the host. The white soft tissue contains asexual spores which infect additional host plants. This tissue, present within the host, is then converted into a hard Sclerotium clavus within the husk. At this specific stage, the alkaloids and lipids accumulate.

Figure: **Example of Ergot on Wheat**: This image shows ergot on a wheat spike.

The alkaloids, responsible for the ergot poisoning, are naturally occurring compounds that are mainly comprised of basic nitrogen atoms. Alkaloids are produced within various organisms as a secondary metabolite. Secondary metabolites are most commonly produced in plants as a defense system. The alkaloids produced by fungi are often toxic. Specifically, the alkaloid produced by *Claviceps purpurea* is ergoline based.

In cases of ergot poisoning (also known as ergotoxicosis or traditionally, Saint Anthony's Fire) alkaloids accumulate in the system due to the consumption of contaminated grain products. The symptoms which present in individuals with ergot poisoning can be classified as convulsive symptoms and gangrenous symptoms. The convulsive symptoms include seizures and effects on the central nervous system that range from hallucinations to psychotic episodes. The gangrenous symptoms are a result of vasoconstriction induced by the alkaloids. Peripheral systems, such as fingers and toes, are typically affected. More recently, ergot poisoning has been associated with an increased intake of ergot-based drugs. These drugs include those that promote vasoconstriction for treating migraines and Parkinson's disease.

15.19A: Ergot Poisoning is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.19B: Aflatoxin Poisoning

Aflatoxin poisoning is a result of ingestion of aflatoxins produced by *Aspergillus* that have contaminated a food source.

Learning Objectives

- Summarize the causes and effects of alfatoxin poisoning

Key Points

- Aspergillus flavus and Aspergillus parasiticus are two commonly known species of Aspergillus that can aflatoxin poisoning.
- Aflatoxin poisoning can result in either acute aflatoxicosis, which is a result of moderate to high level ingestion; or chronic aflatoxicosis, which results from ingestion of low to moderate levels of aflatoxins.
- Aspergillus species which cause aflatoxin poisoning are often found in crops in underdeveloped countries, due to lack of detection techniques and inadequate harvesting and storage.

Key Terms

- **mycotoxins**: a substance produced by a mold or fungus.

Aflatoxins are categorized as mycotoxins that are typically produced by species of *Aspergillus*. Aflatoxins, although only synthesized by a few *Aspergillus* species, are considered to be one of the most important mycotoxins identified to date. Both *Aspergillus flavus* and *Aspergillus parasiticus* are well known for their production of aflatoxins. Aflatoxins are most commonly transmitted to humans through the diet. Aflatoxins grow on whole grains and contaminate food supplies during processing, storage, or transport when there are favorable conditions for mold growth, specifically for the *Aspergillus* species.

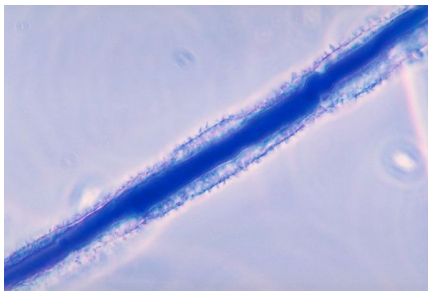

Figure: **Aspergillus flavus**: A species of Aspergillus that causes aflatoxin poisoning.

Aflatoxin poisoning, or aflatoxicosis, occurs when there is ingestion of aflatoxin contaminated foods. Upon ingestion or exposure to aflatoxin, it is common to see injury to the liver. Aflatoxicosis is a primarily hepatic disease, as the liver is the target organ for this toxin in mammals. Although the liver demonstrates the ability to metabolize the ingested aflatoxins, the intermediate formed is a reactive epoxide or a less harmful hydroxylated form referred to as M1. There have been various studies stating that metabolic activation of aflatoxins is required for the aflatoxin to exert its carcinogenic effects. These metabolites are harmful to the liver and have been implicated in liver cancer development. The aflatoxins produced by these *Aspergillus* species have been show to produce adducts (altered forms of DNA). These adducts are now used as a diagnostic factor to test for aflatoxin exposure by testing blood and urine.

Aflatoxin poisoning or aflatoxicosis is rarely diagnosed in developed countries but continues to be an issue in underdeveloped countries. In developed countries, commercial crops are screened for the presence of aflatoxins. However, in underdeveloped or developing countries, screening methods are lacking, or are in the process of being introduced. Interestingly, a rise in homegrown food has been correlated with a slight increase in aflatoxin exposure via diet.

Aflatoxin poisoning can be diagnosed as either acute or chronic. In cases of acute aflatoxicosis, an individual has been exposed to moderate to high levels of aflatoxins. Acute aflatoxicosis is characterized by symptoms such as hemorrhaging; acute liver damage and issues with digestion; and absorption and metabolism of nutrients. In cases of chronic aflatoxicosis, an individual has been exposed to low to moderate levels of aflatoxins. Chronic aflatoxicosis is characterized by symptoms such as dysfunctional food conversion and slow growth rates.

15.19B: Aflatoxin Poisoning is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.19C: Giardiasis

Giardiasis, sometimes referred to as beaver fever, is caused by the protozoan Giardia lamblia and results in diarrheal illness.

Learning Objectives

- Summarize the life cycle and route of transmission for Giardia lamblia

Key Points

- Giardia lamblia is transmitted by exposure or ingestion of fecal contaminated sources such as soil, food, and water.
- Giardiasis is a common worldwide cause of gastroenteritis.
- The structure and life cycle of Giardia lamblia allow for survival in harsh environments and resistance against numerous types of disinfectants.

Key Terms

- **giardiasis**: an infectious diarrheal disease caused by the Giardia lamblia parasite
- **zoonotic**: of or relating to zoonosis, the transmission of an infectious disease between species.
- **hematuria**: The presence of blood in the urine.

Giardiasis is a protozoan disease caused by *Giardia lamblia*. Giardiasis, referred to as beaver fever, is a common cause of gastroenteritis worldwide. The protozoa, *Giardia lamblia*, also referred to as *Giardia intestinalis* or *Giardia duodenalis*, infects humans via the fecal-oral route and is also suspected to be zoonotic. The organism is commonly found in soil, food, or water that has been contaminated with fecal matter from infected humans or animals. Beavers typically spread the parasite in their fecal matter in rivers and streams hence, giardiasis is commonly referred to as beaver fever. Individuals susceptible to infection by *Giardia lamblia* are those who come in frequent contact with individuals already infected. Travelers that spend time in wilderness area are at an increased risk due to ingestion of contaminated food or water sources and a lack of medical care or supplies.

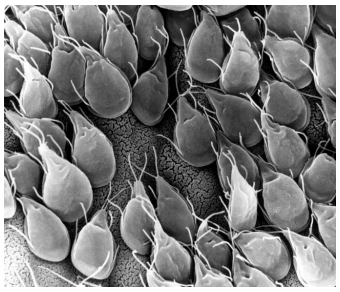

Figure: **Giardia infecting a small intestine**: A scanning electron micrograph of the surface of the small intestine of a gerbil infested with Giardia sp. protozoal, present in the trophozoite stage.

The life cycle, structure, and organization of *Giardia lamblia* promotes its survival for long periods of time outside the body. The organism itself is protected by an outer shell that provides protection against numerous harsh environments. In addition, the shell provides protection against disinfectants including chlorine. The cysts and trophozoites, found in the fecal matter, are extremely resistant to harsh environments. It is the cysts that are ingested and passed from exposure to contaminated food, water, or by the fecal-oral route. Once in the host, the trophozoites multiply via binary fission. They can either remain free within the lumen or attach to the mucosa by a sucking disk. Once the parasites move towards the colon, the encystation phase occurs and the cysts are infectious when passed in the stool.

Giardiasis is characterized as a disease of the gastrointestinal system. The symptoms include from fever, diarrhea, hematuria, stomach cramping, vomiting, flatulence, and loose stool. The symptoms are typically present one to two weeks post infection and can disappear and reappear cyclically. The pathogenecity of *Giardia lamblia* is characterized by its ability to coat the inside of the intestinal wall and inhibit nutrient absorption. The ability of the protozoan to block nutrient absorption can result in vitamin B12 deficiency. Additionally, a development of lactose intolerance is often associated with giardiasis infection.

15.19C: Giardiasis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.19D: Cryptosporidiosis

Learning Objectives

- Outline the life cycle of Cryptosporidium

Cryptosporidiosis is a type of parasitic disease caused by the parasite *Cryptosporidium*. Cryptosporidiosis is typically spread through the fecal-oral route and can be spread through contaminated water as well. Cryptosporiodiosis is one of most common waterborne diseases identified worldwide. The transmission of *Cryptosporidium* is based on successful ingestion of oocysts which are able to implant and infect the epithelial tissue of the intestine, hence, the gastrointestinal symptoms associated with cryptosporidiosis.

Cryptosporidium is classified as a protozoan within the Phylum Apicomplexa. Other pathogens classified in this phylum include the malaria parasite and the parasite that causes toxoplasmosis. The life cycle of *Cryptosporidium* allows for growth in a single host. The spore phase of the life cycle, also referred to as the oocyst stage, is the stage that allows survival of the pathogen in numerous harsh environments. The oocyst allows for survival against harsh chemicals including harsh disinfectants such as chlorine. The life cycle is characterized by the presence of both an asexual and sexual stage. The oocysts, once ingested, excyst within the small intestine and release sporozoites which attach to the microvilli. The sporozoites then develop into trophozoites and undergo asexual reproduction via schizogony. The trophozoites then develop into Type 1 and Type 2 merozoites which can either cause auto infection (Type 1) or undergo releasal and attach the epithelial cells (Type 2). Once released and attached, they will either develop in macrogamonts or microgamonts which correlate with male and female forms. Sexual reproduction occurs than zyogotes are developed. The zygote further develops into the oocyst which can either reinfect the host by rupturing and releasing sporozoites or be excreted into the environment.

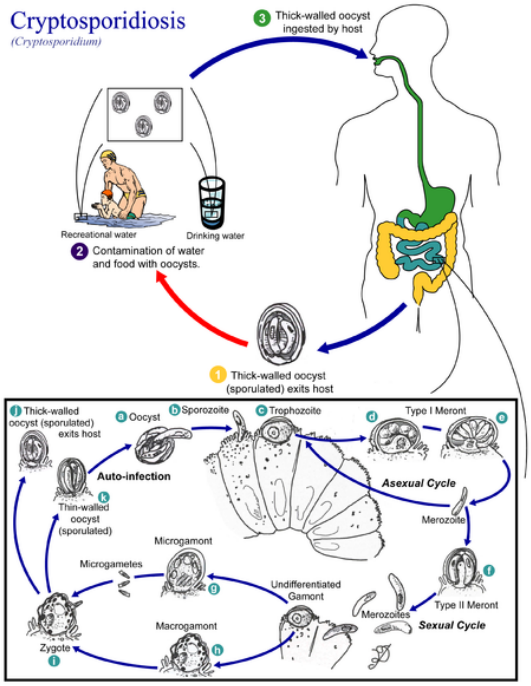

Figure: **Life cycle of Cryptosporidium**: An overview of the life cycle of Cryptosporidium.

The major symptom associated with individuals infected with *Cryptosporidium* is diarrhea. However, cryptosporidiosis is prevalent in immunocompromised individuals, such as those infected with the HIV virus. The symptoms of cryptosporidiosis in these cases are much more severe and can be fatal. The oocysts can initiate infections by attaching to the brush border of the small intestine and attacking the epithelial cells. Additional symptoms associated with cryptosporidiosis include abdominal cramping, malnutrition, weight loss, and nausea.

Key Points

- Cryptosporidium is commonly transmitted through food and water that has been contaminated with the feces of an infected individual.
- Cryptosporidium is commonly found in immunocompromised individuals that exhibit symptoms associated with this disease such as acute or persistent diarrhea.
- The life cycle of Cryptosporidium involves both asexual and sexual reproduction.

Key Terms

- **excyst**: The break down of a cyst wall.
- **schizogony**: A form of asexual reproduction in protozoans characterized by multiple divisions.

15.19D: Cryptosporidiosis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.19E: Cyclospora Diarrheal Infection

Cyclospora diarrheal infection is commonly referred to as traveler's diarrhea and is caused by the parasite Cyclospora cayetanensis.

Learning Objectives

- Outline the life cycle of Cyclospora cayetanensis

Key Points

- The life cycle of Cyclospora begins as the host ingests the oocyst form.
- Cyclospora is transmitted through fecal matter and is commonly found on contaminated fruits and vegetables in countries or areas with a lack of stringent health regulations.
- Cyclospora causes gastroenteritis with symptoms ranging from diarrhea to loss of appetite, weight loss, cramping, nausea and fatigue.

Key Terms

- **meronts**: After infecting a host cell, a trophozoite increases in size and during this process, the organism is referred to as a meront.
- **sporocysts**: a cysts that develops from a sporoblasts and results in the production of sporozoites.

Cyclospora diarrheal infection, commonly referred to as travelers diarrhea or cyclosporiasis, is caused by a specific species of *Cyclospora*. The protozoan that are categorized as cyclospora are defined by the spherical shape of the sporocysts. Specifically, *Cyclospora cayetanensis* is the species associated with the disease in both humans and primates. Cyclospora can be transmitted by consuming contaminated food or water. In 2012, cyclospora caused about 500 infections in 2012 in the US from a salad mix imported from Mexico and used in restaurants in Texas and Arkansas.

Life Cycle of Cyclospora

The life cycle of Cyclospora begins when the host is exposed and ingests the pathogen either in its oocyst or spore form. The oocyst is comprised of sporocytes which contain sporozoites. Upon release of the sporozoites, the epithelial cells of the intestine are penetrated. Within the intestinal cells, the sporozoites undergo multiple fission and develop into meronts which contain merozoites. The merozoites then undergo division and produce micro- and macro-gametes representing male and female gametes, respectively.

These gametes then reproduce and result in the formation of oocysts. It is the oocysts which pass through the intestinal tract and are released into the feces. The oocysts demonstrate the ability to undergo sporulation in a crop and water host as well beginning with the oocyst stage. It is during the oocyst stage that cyclospora exhibit a high resistance to disinfectants.

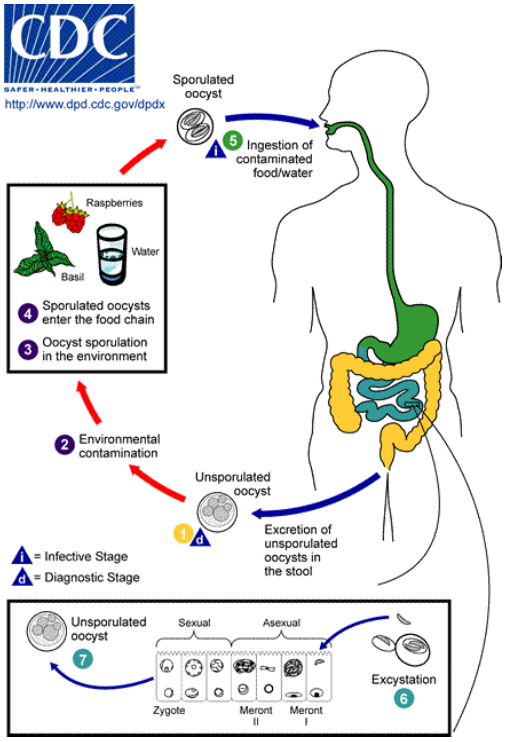

Figure: **Life cycle of cyclospora**: Cyclosporiasis (Cyclospora cayetanesis) When freshly passed in stools, the oocyst is not infective (1) (thus, direct fecal-oral transmission cannot occur; this differentiates Cyclospora from another important coccidian parasite, Cryptosporidium). In the environment (2), sporulation occurs after days or weeks at temperatures between 22°C to 32°C, resulting in division of the sporont into two sporocysts, each containing two elongate sporozoites (3). Fresh produce and water can serve as vehicles for transmission (4) and the sporulated oocysts are ingested (in contaminated food or water) (5). The oocysts excyst in the gastrointestinal tract, freeing the sporozoites which invade the epithelial cells of the small intestine (6). Inside the cells they undergo asexual multiplication and sexual development to mature into oocysts, which will be shed in stools (7). The potential mechanisms of contamination of food and water are still under investigation.

Symptoms of Cyclospora

The symptoms associated with this disease are categorized as gastroenteritis based issues. The symptoms range from watery, loose stool, weight loss, cramping, fatigue, vomiting, fever and nausea. The symptoms can be extremely severe if presented in an immunocompromised patient, such as a patient living with AIDS. The transmission of cyclospora to humans most often occurs by ingesting contaminated foods. In regions of the world where there is lack of health regulations, the chances of cyclospora exposure is increased. Often times, the contaminants include fresh fruits and vegetables which have been exposed to contaminated soil. Individuals exposed to these pathogens in these of regions are at high risk for developing cyclosporiasis, hence, the origin of the commonly known name, traveler's diarrhea.

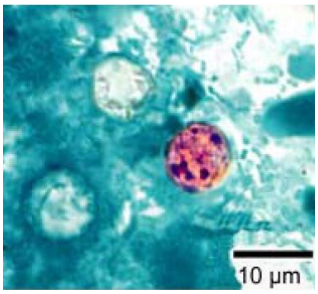

Figure: **Cyclospora cayetanensis oocysts**: A photomicrograph of oocysts from Cyclospora cayetanensis derived from a fresh stool sample.

15.19E: Cyclospora Diarrheal Infection is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.19F: Amoebic Dysentery (Amoebiasis)

Amoebic dysentery is caused by the parasite *Entamoeba histolytica* and infected individuals suffer from severe diarrhea, cramps, and fever.

Learning Objectives

- Outline the life cycle of Entamoeba histolytica

Key Points

- Amoebiasis is transmitted via food or water contaminated with fecal matter from an infected individual.
- The pathogen, Entamoeba histolytica, is mainly found in tropical areas and is protected from degradation and destruction by its protective shell, formed during its cyst stage.
- The cyst stage is typically passed in the feces and then ingested to cause infection.
- The amoebas are able to burrow into the walls of the intestines, causing damage.

Key Terms

- **trophozoites**: A protozoan in the feeding stage of its life cycle.

Amoebic dysentery, also referred to as amoebiasis, is caused by the ameoba *Entamoeba histolytica.* Dysentery is characterized as an inflammatory disorder of the intestine that results in severe diarrhea containing both mucus and blood in the feces, often accompanied with fever and abdominal pain.

The route of transmission for ameobic dysentery is the fecal-oral route. Transmission and infection occur upon exposure or ingestion of contaminated food and water. The infective cysts are passed via infected stool. The ameoba also demonstrates the ability to spread as free amoebae or trophozoites, meaning the cysts are not absolutely necessary; however, these states do not survive long outside of the host.

Ameobic dysentery is seen in both developing and industrialized countries, although it is most common in tropical areas. Ameobic cysts are often found in areas of the world where the use of human feces for fertilizer is common, often referred to as ‘night soil’. Upon ingestion of contaminated foods or water, the cysts will move into the intestinal area. These cysts are protected from stomach acids and are able to evade destruction. Once in the intestine, the cyst breaks open and releases the amoebas which then burrow into and damage the intestinal walls.

The amoebae or trophozoites are able to divide via binary fission and and produce cysts. If they are passed in the feces as is, instead of developing into cysts, their survival rate decreases as they are unable to survive in harsh environments. Interestingly, individuals can be asymptomatic if infected with trophozoites and can function as carriers by passing cysts in their stool.

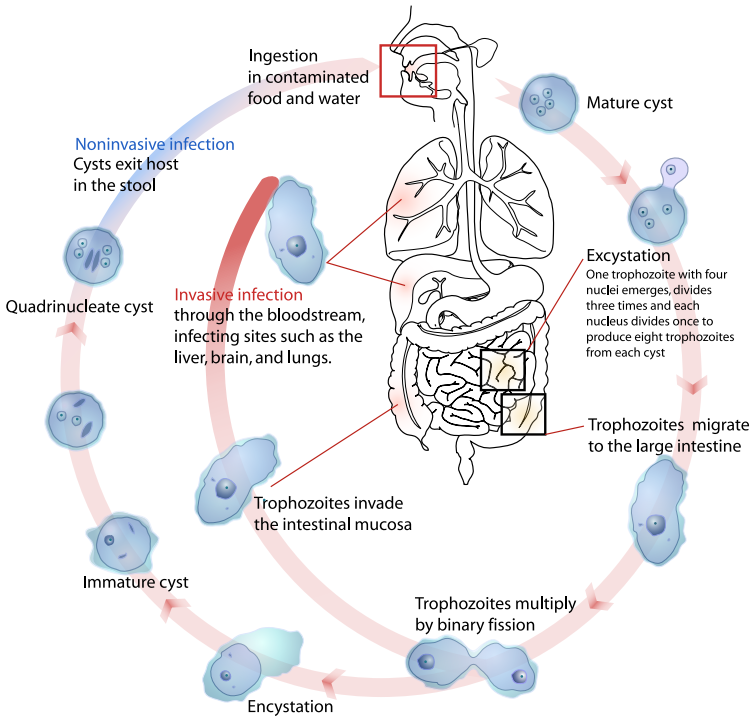

Figure: **Life Cycle of Entamoeba histolytica**: An overview of the life cycle of E. histolytica, the source of amoebic dysentery.

Symptoms of individuals infected with *Entamoeba histolytica* include ulcers, abdominal cramps, diarrhea, bloody stools, liquid stools, fever and vomiting.

15.19G: Legionellosis

Legionellosis is most commonly caused by the Gram-negative bacteria *Legionella pneumophila* which is an aquatic organism.

Learning Objectives

- Discuss the mode of infection for the bacteria Legionella

Key Points

- Legionella pneumophila is an aquatic organism that is transmitted via aerosols.
- Legionellosis is caused by exposure to contaminated water sources including water towers, spas, fountains, swimming pools and cooling towers.
- Legionellosis-infected individuals have pneumonia -like symptoms with moderate to high fever ranges, chills and a dry cough.

Key Terms

- **macrophages**: A type of white blood cell that targets foreign material, including bacteria and viruses.
- **Legionnaire's disease**: The more severe form of legionellosis which produces high fever and pneumonia.

Legionellosis, commonly referred to as Legionnaire's disease, is caused by the pathogenic, gram-negative bacteria *Legionella*. It is characterized by flu- and pneumonia -like symptoms, including fevers and chills. In advanced stages of the disease, there are gastrointestinal and nervous system issues which result in diarrhea and nausea.

Legionella are a type of bacterium that reside within amoebae in the natural environment. The specific species most associated with legionellosis is *Legionella pneumophilia*, an aquatic organism. Legionella transmission occurs via aerosols and infection occurs when upon inhalation of the bacteria. After being inhaled, the bacteria infect the *macrophages* of the alveolar and exploit the host machinery to create an environment that promotes bacterial replication. However, the bacteria are not spread from one person to another. In the 1970s, the CDC investigated a large outbreak of legionellosis at Baptist Hospital that was spread through its air conditioner.

Figure: **Legionella pneumophila**: A microscopic image of Legionella pneumophila, the cause of Legionellosis.

Individuals infected with legionellosis have similar symptoms as those diagnosed with pneumonia. Symptoms include high fevers, chills, cough, muscle aches and headaches. For a diagnosis of legionellosis, x-rays and diagnostic tests are used to identify the bacteria. Individuals particularly at risk are older individuals, those immunocompromised or with chronic lung disease.

Legionellosis can take on two distinct forms commonly referred to as legion fever or pontiac fever. Legion fever resembles acute influenza and is the more severe form of the disease, characterized by high fever and pneumonia. Pontiac fever is a milder version and results in mild respiratory illness without the development of pneumonia.

Common sources of Legionella include swimming pools, cooling towers, hot-water systems such as spas, fountains, freshwater ponds and creeks. As seen, the major source for Legionella bacteria is infected water. The bacteria can become suspended in water droplets which are then inhaled into the lungs.

15.1A: Structure of the Skin: Epidermis

The epidermis includes five main layers: the stratum corneum, stratum lucidium, stratum granulosum, stratum spinosum, and stratum germinativum.

LEARNING OBJECTIVES

Describe the layers of the epidermis

KEY TAKEAWAYS

Key Points

- The epidermis provides a protective waterproof barrier that also keeps pathogens at bay and regulates body temperature.
- The main layers of the epidermis are: stratum corneum, stratum lucidium, stratum granulosm, stratum spinosum, stratum germinativum (also called stratum basale).
- Keratinocytes in the stratum basale proliferate during mitosis and the daughter cells move up the strata, changing shape and composition as they undergo multiple stages of cell differentiation.

Key Terms

- **keratinocyte**: the predominant cell type in the epidermis, the outermost layer of the skin, constituting 95% of the cells found there. Those keratinocytes found in the basal layer (stratum germinativum) of the skin are sometimes referred to as basal cells or basal keratinocytes.
- **stratum germinativum**: the basal layer—sometimes referred to as stratum basale—is the deepest of the five layers of the epidermis.
- **stratum corneum**: the most superficial layer of the epidermis from which dead skin sheds.
- **epidermis**: the outermost layer of skin.
- **stratum lucidum**: a layer of our skin that is found on the palms of our hands and the soles of our feet.

Layers of the Epidermis

The epidermis is the outermost layer of our skin. It is the layer we see with our eyes. It contains no blood supply of its own—which is why you can shave your skin and not cause any bleeding despite losing many cells in the process. Assuming, that is, you don't nick your skin to deep, where the blood supply is actually found. The epidermis is itself divided into at least four separate parts. A fifth part is present in some areas of our body. In order from the deepest layer of the epidermis to the most superficial, these layers (strata) are the:

- Stratum basale
- Stratum spinosum
- Stratum granulosum
- Stratum lucidum
- Stratum corneum

Stratum Basale

The stratum basale, also called the stratum germinativum, is the basal (base) layer of the epidermis. It is the layer that's closest to the blood supply lying underneath the epidermis.

This layer is one of the most important layers of our skin. This is because it contains the only cells of the epidermis that can divide via the process of mitosis, which means that skin cells germinate here, hence the word germinativum.

In this layer, the most numerous cells of the epidermis, called keratinocytes, arise thanks to mitosis. Keratinocytes produce the most important protein of the epidermis.

This protein is appropriately called keratin. Keratin makes our skin tough and provides us with much-needed protection from microorganisms, physical harm, and chemical irritation.

Millions of these new cells arise in the stratum basale on a daily basis. The newly produced cells push older cells into the upper layers of the epidermis with time. As these older cells move up toward the surface, they change their shape, nuclear, and chemical composition. These changes are, in part, what give the strata their unique characteristics.

Stratum Spinosum and Granulosum

From the stratum basale, the keratinocytes move into the stratum spinosum, a layer so called because its cells are spiny-shaped cells. The stratum spinosum is partly responsible for the skin's strength and flexibility. From there the keratinocytes move into the next layer, called the stratum granulosum. This layer gets its name from the fact that the cells located here contain many granules. The keratinocytes produce a lot of keratin in this layer—they become filled with keratin. This process is known as keratinization. The keratinocytes become flatter, more brittle, and lose their nuclei in the stratum granulosum as well.

Stratum Lucidum

Once the keratinocytes leave the stratum granulosum, they die and help form the stratum lucidum. This death occurs largely as a result of the distance the keratinocytes find themselves from the rich blood supply the cells of the stratum basale lie on top off. Devoid of nutrients and oxygen, the keratinocytes die as they are pushed towards the surface of our skin. The stratum lucidum is a layer that derives its name from the lucid (clear/transparent) appearance it gives off under a microscope. This layer is only easily found in certain hairless parts of our body, namely the palms of our hands and the soles of our feet. Meaning, the places where our skin is usually the thickest.

Stratum Corneum

From the stratum lucidum, the keratinocytes enter the next layer, called the stratum corneum (the horny layer filled with cornified cells). This the only layer of skin we see with our eyes. The keratinocytes in this layer are called corneocytes. They are devoid of almost all of their water and they are completely devoid of a nucleus at this point. They are dead skin cells filled with the tough protein keratin. In essence, they are a protein mass more so than they are a cell. The corneocytes serve as a hard protective layer against environmental trauma, such as abrasions, light, heat, chemicals, and microorganism. The cells of the stratum corneum are also surrounded by lipids (fats) that help repel water as well. These corneocytes are eventually shed into the environment and become part of the dandruff in our hair or the dust around us, which dust mites readily munch on. This entire cycle, from new keratinocyte in the straum basale to a dead cell flaked off into the air, takes between 25–45 days.

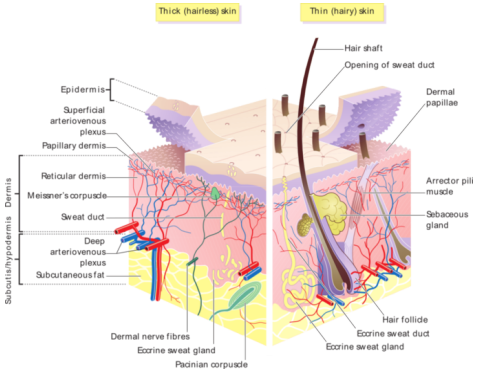

Figure: **Skin overview**: skin layers, of both hairy and hairless skin.

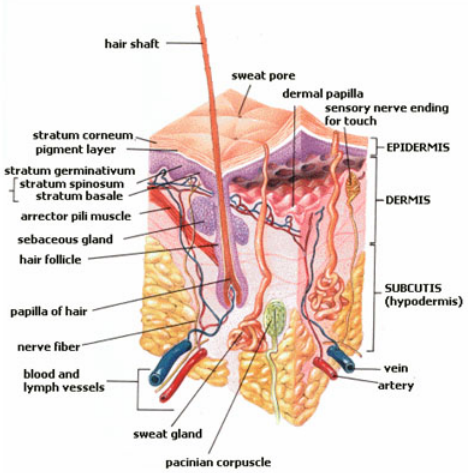

Figure: **Human skin**: This image details the parts of the integumentary system.

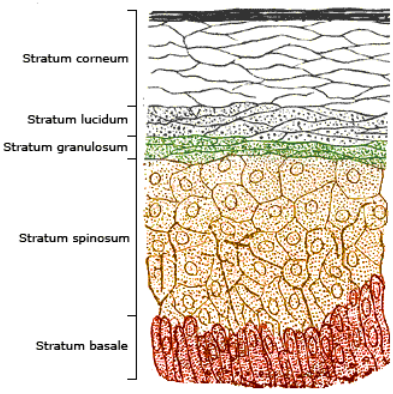

Layers of the epidermis: The epidermis is made up of 95% keratinocytes but also contains melanocytes, Langerhans cells, Merkel cells, and inflammatory cells. The stratum basale is primarily made up of basal keratinocyte cells, which can be considered the stem cells of the epidermis. They divide to form the keratinocytes of the stratum spinosum, which migrate superficially.

15.1B: Microbiota of the Skin

The skin flora, more properly referred to as the skin microbiome or skin microbiota, are the microorganisms that reside on the skin.

Learning Objectives

- Describe the types of skin flora and how they can be beneficial for the organism

Key Points

- Most bacteria on the skin are found in the superficial layers of the epidermis and the upper parts of hair follicles.
- Skin flora are usually non-pathogenic, and either commensals (are not harmful to their host) or mutualistic (offer a benefit).
- The benefits bacteria can offer include preventing transient pathogenic organisms from colonizing the skin surface, either by competing for nutrients, secreting chemicals against them, or stimulating the skin's immune system.
- Resident microbes can cause skin diseases and enter the blood system creating life-threatening diseases particularly in immunosuppressed people.

Key Terms

- **skin flora**: the skin flora, more properly referred to as the skin microbiome or skin microbiota, are the microorganisms which reside on the skin.
- **commensal**: a term for a form of symbiosis in which one organism derives a benefit while the other is unaffected
- **mutualistic**: mutually beneficial.

The skin flora, more properly referred to as the skin microbiome or skin microbiota, are the microorganisms that reside on the skin. Most bacteria on the skin are found in the superficial layers of the epidermis and the upper parts of hair follicles. Skin flora are usually non-pathogenic, and either commensals (are not harmful to their host) or mutualistic (offer a benefit). The benefits bacteria can offer include preventing transient pathogenic organisms from colonizing the skin surface, either by competing for nutrients, secreting chemicals against them, or stimulating the skin's immune system. However, resident microbes can cause skin diseases and enter the blood system creating life-threatening diseases particularly in immunosuppressed people. Hygiene to control such flora is important in preventing the transmission of antibiotic resistant hospital-acquired infections.

A major nonhuman skin flora is Batrachochytrium dendrobatidis, a chytrid and non-hyphal zoosporic fungus that causes chytridiomycosis, an infectious disease thought to be responsible for the decline in amphibian populations. The estimate of the number of species present on skin bacteria has been radically changed by the use of 16S ribosomal RNA to identify bacterial species present on skin samples direct from their genetic material. Previously such identification had depended upon microbiological culture upon which many varieties of bacteria did not grow and so were hidden to science. Staphylococcus epidermidis and Staphylococcus aureus were thought from cultural based research to be dominant. However, 16S ribosomal RNA research found that while common these species make up only 5% of skin bacteria. However, skin variety provides a rich and diverse habitat for bacteria. Most come from four phyla: Actinobacteria (51.8%), Firmicutes (24.4%), Proteobacteria (16.5%), and Bacteroidetes (6.3%).

There are three main ecological areas for skin flora: sebaceous, moist, and dry. Propionibacteria and Staphylococci species are the main species in sebaceous areas. In moist places on the body Corynebacteria together with Staphylococci dominate. In dry areas, there is a mixture of species, but b-Proteobacteria and Flavobacteriales are dominant. Ecologically, sebaceous areas have greater species richness than moist and dry ones. The areas with least similarity between people in species are the spaces between fingers, the spaces between toes, axillae, and umbilical cord stump. Most similar are beside the nostril, nares (inside the nostril), and on the back.

Skin microflora can be commensals, mutualistic, or pathogens. Often they can be all three depending upon the strength of the person's immune system. Research on the immune system in the gut and lungs has shown that microflora aids immunity development. However, such research has only started upon whether this is the case with the skin. Pseudomonas aeruginosa is an example of a mutualistic bacterium that can turn into a pathogen and cause disease. If it gains entry into the blood system it can result in infections in bone, joint, gastrointestinal, and respiratory systems and it can also cause dermatitis. However,

Pseudomonas aeruginosa produces antimicrobial substances such as pseudomonic acid (that are exploited commercially such as Mupirocin). This works against staphylococcal and streptococcal infections. Pseudomonas aeruginosa also produces substances that inhibit the growth of fungus species such as Candida krusei, Candida albicans, Torulopsis glabrata, Saccharomyces cerevisiae,

and Aspergillus fumigatus. It can also inhibit the growth of Helicobacter pylori. Fatty acids (caproic acid) on the skin inhibit bacteria, especially after puberty, when undecylic acid becomes the primary fatty acid on the skin. Undecylic acid provides resistance to ringworm fungus and other skin infections.

Another aspect of bacteria is the generation of body odor. Sweat is odorless. However, several bacteria may consume it and create byproducts which may be considered putrid by man (as in contrast to flies, for example, that may find them attractive/appealing). For example, Propionibacteria in adolescent and adult produce propionic acid in sebaceous glands.

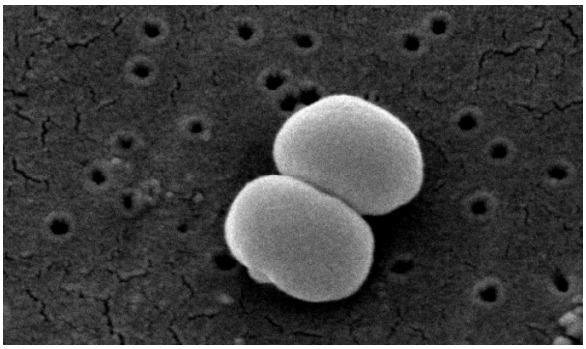

Figure: **Staphylococcus epidermidis**: Scanning electron microscope image of Staphylococcus epidermidis one of roughly 1,000 bacteria species present on human skin. Though usually not pathogenic, it can cause skin infections and even life threatening illnesses in those that are immunocompromised.

15.1B: Microbiota of the Skin is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.1C: Bacterial Skin Diseases

Bacterial skin infections include impetigo, erysipelas, and cellulitis.

LEARNING OBJECTIVES

Describe how impetigo, erysipelas and cellulitis are acquired and the treatment options available

KEY TAKEAWAYS

Key Points

- Impetigo is a highly contagious bacterial skin infection most common among pre-school children primarily caused by Staphylococcus aureus and sometimes by Streptococcus pyogenes.
- Erysipelas is an acute streptococcus bacterial infection of the upper dermis and superficial lymphatics.
- Cellulitis is a diffuse inflammation of connective tissue with severe inflammation of dermal and subcutaneous layers of the skin.
- Antimicrobial therapy is available for impetigo, erysipelas, and cellulitis.

Key Terms

- **erysipelas**: a severe skin disease caused by streptococcus infection in surface and surrounding tissue, marked by continued spreading inflammation
- **impetigo**: a contagious bacterial skin disease forming pustules and yellow crusty sores, chiefly on the face and hands. It is common in children. Infection is often through cuts or insect bites.
- **cellulitis**: an inflammation of subcutaneous or connective tissue caused by a bacterial infection

Figure: Facial impetigo.

Common Bacterial Skin Infections

Bacterial skin infections include impetigo, erysipelas, and cellulitis.

IMPETIGO

Impetigo is a highly contagious bacterial skin infection most common among pre-school children. It is primarily caused by Staphylococcus aureus and sometimes by Streptococcus pyogenes. The infection is spread by direct contact with lesions or with nasal carriers. The incubation period is 1–3 days. Dried streptococci in the air are not infectious to intact skin. Scratching may spread the lesions. Impetigo generally appears as honey-colored scabs formed from dried serum and is often found on the arms, legs, or face . For generations, the disease was treated with an application of the antiseptic *gentian violet*. Today, topical or oral antibiotics are usually prescribed.

Figure: **Facial erysipelas**. Erysipelas of the face due to invasive Streptococcus.

ERYSIPELAS

Erysipelas is an acute streptococcus bacterial infection of the upper dermis and superficial lymphatics. This disease is most common among the elderly, infants, and children. People with immune deficiency, diabetes, alcoholism, skin ulceration, fungal infections, and impaired lymphatic drainage (e.g., after mastectomy, pelvic surgery, bypass grafting) are also at increased risk. Patients typically develop symptoms including high fevers, shaking, chills, fatigue, headaches, vomiting, and general illness within 48 hours of the initial infection. The erythematous skin lesion enlarges rapidly and has a sharply demarcated raised edge. It appears as a red, swollen, warm, hardened and painful rash, similar in consistency to an orange peel. More severe infections can result in vesicles, bullae, and petechiae, with possible skin necrosis. Lymph nodes may be swollen and lymphedema may occur. Occasionally, a red streak extending to the lymph node can be seen. Most cases of erysipelas are due to Streptococcus pyogenes (also known as beta-hemolytic group A streptococci), although non-group A streptococci can also be the causative agent. Beta-hemolytic, non-group A streptococci include Streptococcus agalactiae, also known as group B strep or GBS. Depending on the severity, treatment involves either oral or intravenous antibiotics, using penicillins, clindamycin, or erythromycin. While illness symptoms resolve in a day or two, the skin may take weeks to return to normal.

Figure: **Cellulitis**. Left shin infected with cellulitis.

CELLULITIS

Cellulitis is a diffuse inflammation of connective tissue with severe inflammation of dermal and subcutaneous layers of the skin. Cellulitis can be caused by normal skin flora or by exogenous bacteria, and often occurs where the skin has previously been broken. Common points of infection include cracks in the skin, cuts, blisters, burns, insect bites, surgical wounds, intravenous drug injection, or sites of intravenous catheter insertion. Group A Streptococcus and Staphylococcus are the most common of these bacteria, which are part of the normal flora of the skin, but normally cause no actual infection while on the skin's outer surface. Skin on the face or lower legs is most commonly affected by this infection, though cellulitis can occur on any part of the body. The mainstay of therapy remains treatment with appropriate antibiotics Recovery periods last from 48 hours to six months. The typical signature symptom of cellulitis is an area which is red, hot, and tender . Cellulitis is most often a clinical diagnosis, and local

cultures do not always identify the causative organism. Blood cultures usually are positive only if the patient develops generalized sepsis.Treatment consists of resting the affected area, cutting away dead tissue, and administration of antibiotics (either oral or intravenous).

15.1C: Bacterial Skin Diseases is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.1D: Viral Skin Diseases

Virus-related cutaneous conditions include cold sores, shingles, and warts.

Learning Objectives

- Describe what causes cold sores, shingles and warts and the treatment options available

Key Points

- Oral herpes, the visible symptoms of which are colloquially called cold sores or fever blisters, is an infection of the face or mouth and is the most common form of infection by herpes simplex.
- Herpes zoster (or simply zoster), commonly known as shingles, is a viral disease caused by reactivation of latent varizella zoster virus and characterized by a painful skin rash with blisters in a limited area on one side of the body, often in a stripe.
- A wart is generally a small, rough growth, typically on a human's hands or feet that can resemble a cauliflower or a solid blister and it is caused by infection by the human papilloma virus.

Key Terms

- **shingles**: a viral disease characterized by a painful skin rash with blisters in a limited area on one side of the body, often in a stripe
- **wart**: a type of deformed growth occurring on the skin caused by the human papillomavirus (HPV).
- **cold sore**: a small bump on the lips resulting from infection by the herpes virus.
- **zoster**: the disease called herpes zoster (from the typically beltlike pattern of its rash); shingles.

Virus-related cutaneous conditions are caused by two main groups of viruses–DNA and RNA types–both of which are obligatory intracellular parasites.

A cutaneous condition is any medical condition that affects the integumentary system — the organ system that comprises the entire surface of the body and includes skin, hair, nails, and related muscle and glands. Conditions of the human integumentary system constitute a broad spectrum of diseases, also known as dermatoses. While only a small number of skin diseases account for most visits to the physician, thousands of skin conditions have been described. Three common skin conditions that result from viral infections are cold sores, shingles, and warts.

Herpes

Herpes simplex is a viral disease from the herpesviridae family caused by both Herpes simplex virus type 1 (HSV-1) and type 2 (HSV-2). Infection with the herpes virus is categorized into one of several distinct disorders based on the site of infection. Oral herpes , the visible symptoms of which are colloquially called cold sores or fever blisters, is an infection of the face or mouth and is the most common form of infection. Genital herpes, known simply as herpes, is the second most common form of herpes. Herpes simplex is most easily transmitted by direct contact with a lesion or the body fluid of an infected individual. Transmission may also occur through skin-to-skin contact during periods of asymptomatic shedding. Barrier protection methods are the most reliable method of preventing transmission of herpes, but they merely reduce rather than eliminate risk. Oral herpes is easily diagnosed if the patient presents with visible sores or ulcers. Once infected, the virus remains in the body for life. Recurrent infections (outbreaks) may occur from time to time, especially in times of immune impairment such as HIV and cancer-related immune suppression. However, after several years, outbreaks become less severe and more sporadic, and some people will become perpetually asymptomatic and will no longer experience outbreaks, though they may still be contagious to others. Treatments with antivirals can reduce viral shedding and alleviate the severity of symptomatic episodes.

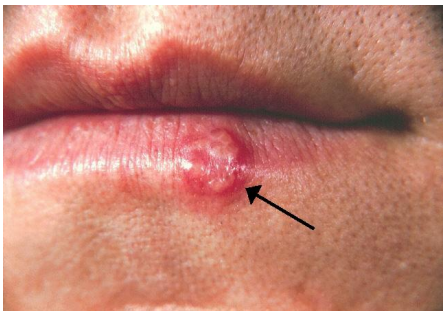

Figure: **Herpes simplex**. Herpes labialis or cold sore of the lower lip. Note the blisters in a group marked by an arrow.

Herpes Zoster

Herpes zoster (or simply zoster), commonly known as shingles, is a viral disease characterized by a painful skin rash with blisters in a limited area on one side of the body, often in a stripe. The initial infection with varicella zoster virus (VZV) causes the acute (short-lived) illness chickenpox which generally occurs in children and young people. Once an episode of chickenpox has resolved, the virus is not eliminated from the body but remains latent and can go on to cause shingles—an illness with very different symptoms—often many years after the initial infection. Although the zoster rash usually heals within two to four weeks, some sufferers experience residual nerve pain for months or years, a condition called postherpetic neuralgia. Exactly how the virus remains latent in the body, and subsequently re-activates is not understood. The earliest symptoms of herpes zoster, which include headache, fever, and malaise, are nonspecific, and may result in an incorrect diagnosis. In most cases after 1–2 days, but sometimes as long as three weeks, the initial phase is followed by the appearance of the characteristic skin rash. The pain and rash most commonly occurs on the torso, but can appear on the face, eyes, or other parts of the body.

At first the rash appears similar to the first appearance of hives. However, unlike hives, herpes zoster causes skin changes limited to a dermatome, normally resulting in a stripe or belt-like pattern that is limited to one side of the body and does not cross the midline. The goals of treatment are to limit the severity and duration of pain, shorten the duration of a shingles episode, and reduce complications. Symptomatic treatment is often needed for the complication of postherpetic neuralgia. Topical lotions containing calamine can be used on the rash or blisters and may be soothing. Antiviral drugs inhibit VZV replication and reduce the severity and duration of herpes zoster with minimal side effects, but do not reliably prevent postherpetic neuralgia. Of these drugs, acyclovir has been the standard treatment.

Figure: **Herpes Zoster**. Neck Herpes zoster blisters on the neck and shoulder.

A wart is generally a small, rough growth, typically on a human’s hands or feet , but often other locations, that can resemble a cauliflower or a solid blister. They are caused by a viral infection, specifically by one of the many types of human papillomavirus (HPV). It is possible to get warts from others. They are contagious and usually enter the body in an area of broken skin. They typically disappear after a few months but can last for years and can recur. Gardasil is an HPV vaccine aimed at preventing cervical cancers and genital warts. There are many treatments and procedures associated with wart removal.

Figure: Warts. Warts on the big toe.

15.1D: Viral Skin Diseases is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.1E: Fungal Skin and Nail Diseases

Common fungal skin diseases include athlete's foot, jock itch, and ringworm.

Learning Objectives

- Describe how fungal skin and nail diseases arise, their characteristic symptoms and the treatment options available

Key Points

- Athlete's foot (also known as ringworm of the foot and tinea pedis) is an infection of the skin that causes scaling, flaking, and itching of affected areas and is caused by a fungi in the genus Trichophyton.
- Tinea cruris, also known as jock itch, is a dermatophyte fungal infection of the groin region in any sex, though more often seen in males.
- Dermatophytosis or ringworm is a clinical condition caused by fungal infection of the skin in humans, pets such as cats, and domesticated animals such as sheep and cattle.

Key Terms

- **jock itch**: a fungal infection, tinea cruris, of the groin region, due to the fungus Trichophyton rubrum and others.
- **ringworm**: a contagious fungal affliction of the skin, characterized by ring-shaped discoloured patches, covered by vesicles or scales.
- **athlete's foot**: a fungal infection of the skin of the foot, usually between the toes, caused by the pathogen fungi. Scientific name: tinea pedis.

A cutaneous condition is any medical condition that affects the integumentary system — the organ system that comprises the entire surface of the body and includes skin, hair, nails, and related muscle and glands. Conditions of the human integumentary system constitute a broad spectrum of diseases, also known as dermatoses, as well as many nonpathologic states (like, in certain circumstances, melanonychia and racquet nails). Common fungal skin and nail diseases include athlete's foot, jock itch, and ringworm.

Athlete's foot (also known as ringworm of the foot and tinea pedis;) is an infection of the skin that is caused by a fungi in the genus Trichophyton. While it is typically transmitted in moist communal areas where people walk barefoot, the disease requires a warm moist environment, such as the inside of a shoe, in order to incubate. Athlete's foot causes scaling, flaking, and itching of the affected skin. Blisters and cracked skin may also occur, leading to exposed raw tissue, pain, swelling, and inflammation. Secondary bacterial infection can accompany the fungal infection, sometimes requiring a course of oral antibiotics. Athlete's foot can usually be diagnosed by visual inspection of the skin, but where the diagnosis is in doubt direct microscopy of a potassium hydroxide preparation (known as a KOH test) may help rule out other possible causes, such as eczema or psoriasis. Without medication athlete's foot resolves in 30–40% of cases and topical antifungal medication consistently produce much higher percentages of a cure. Conventional treatment typically involves daily or twice daily application of a topical medication in conjunction with hygiene measures outlined in the above section on prevention. Keeping feet dry and practicing good hygiene is crucial to preventing reinfection. Severe or prolonged fungal skin infections may require treatment with oral antifungal medication.

Figure: **Athlete's Foot**. A severe case of athlete's foot.

Tinea cruris, also known as crotch itch, crotch rot, Dhobie itch, eczema marginatum, gym itch, jock itch, jock rot, and ringworm of the groin is a dermatophyte fungal infection of the groin region in any sex, though more often seen in males. As the common name for this condition implies, it causes itching or a burning sensation in the groin area, thigh skin folds, or anus. It may involve the

inner thighs and genital areas, as well as extending back to the perineum and perianal areas. Affected areas may appear red, tan, or brown, with flaking, rippling, peeling, or cracking skin. Opportunistic infections (infections that are caused by a diminished immune system) are frequent. Fungus from other parts of the body (commonly tinea pedis or 'athlete's foot') can contribute to this itch. A warm, damp environment allowing the fungus to cultivate greatly contributes; especially with tight, sweaty, or rubbing clothing such as a jockstrap. Medical professionals suggest keeping the groin area clean and dry by drying off thoroughly after bathing and putting on dry clothing right away after swimming or perspiring. Other recommendations to prevent this infection are: not sharing clothing or towels with others, showering immediately after athletic activities, wearing loose cotton underwear, avoiding tight-fitting clothes, and using antifungal powders. Tinea cruris is best treated with topical antifungal medications of the allylamine or azole type.

Dermatophytosis or ringworm is a clinical condition caused by fungal infection of the skin in humans, pets such as cats, and domesticated animals such as sheep and cattle. The term "ringworm" is a misnomer, since the condition is caused by fungi of several different species and not by parasitic worms. The fungi that cause parasitic infection (dermatophytes) feed on keratin, the material found in the outer layer of skin, hair, and nails. These fungi thrive on skin that is warm and moist, but may also survive directly on the outsides of hair shafts or in their interiors. In pets, the fungus responsible for the disease survives in skin and on the outer surface of hairs. Advice often given to prevent this infection includes: avoiding sharing clothing, sports equipment, towels, or sheets and washing clothes in hot water with fungicidal soap after suspected exposure to ringworm. After being exposed to places where the potential of being infected is high, one should wash with an antibacterial and anti-fungal soap or one that contains tea tree oil, which contains terpinen-4-ol. Antifungal treatments include topical agents such as miconazole, terbinafine, clotrimazole, ketoconazole, or tolnaftate applied twice daily until symptoms resolve — usually within one or two weeks

15.1F: Parasitic Skin Diseases

Learning Objectives

- Describe how the parasitic skin infections creeping eruption, lice and scabies arise and the treatment options available

A cutaneous condition is any medical condition that affects the integumentary system — the organ system that comprises the entire surface of the body and includes skin, hair, nails, and related muscle and glands. The major function of this system is as a barrier against the external environment. Conditions of the human integumentary system constitute a broad spectrum of diseases, also known as dermatoses, as well as many nonpathologic states (like, in certain circumstances, melanonychia and racquet nails). Common parasitic skin diseases include creeping eruption, lice, and scabies.

Cutaneous larva migrans (abbreviated CLM) is a skin disease in humans caused by the larvae of various nematode parasites of the hookworm family (Ancylostomatidae). The most common species that cayse this disease in the Americas is Ancylostoma braziliense. Colloquially called creeping eruption due to the way it looks, the disease is also somewhat ambiguously known as “ground itch” or (in some parts of the southern U.S.) “sandworms,” as the larvae like to live in sandy soil. Another vernacular name is plumber’s itch. The medical term CLM literally means “wandering larvae in the skin. ” These parasites are found in dog and cat feces and although they are able to infect the deeper tissues of these animals (through to the lungs and then the intestinal tract), in humans they are only able to penetrate the outer layers of the skin and thus create the typical wormlike burrows visible underneath the skin . The parasites apparently lack the collagenase enzymes required to penetrate through the basement membrane deeper into the skin. The infection causes a red, intense itching eruption. The itching can become very painful and if scratched may allow a secondary bacterial infection to develop but it will stop after the parasites are dead. Systemic (oral) agents to treat this infection include albendazole (trade name Albenza) and ivermectin (trade name Stromectol).

Figure: **Larva Migrans Cutanea**. Typical “creeping eruption” associated with cutaneous larva migrans.

Louse (plural: lice) is the common name for members of over 3,000 species of wingless insects of the order Phthiraptera, three of which are classified as human disease agents. They are obligate ectoparasites of every avian and mammalian order except for monotremes (the platypus and echidnas), bats, whales, dolphins, porpoises, and pangolins. Most lice are scavengers, feeding on skin and other debris found on the host’s body, but some species feed on sebaceous secretions and blood. Most are found only on specific types of animals, and, in some cases, only to a particular part of the body. Some animals are known to host up to 15 different species, although one to three is typical for mammals, and two to six for birds. For example, in humans, different species of louse inhabit the scalp and pubic hair. Lice generally cannot survive for long if removed from their host. Humans host three different kinds of lice: head lice, body lice, and pubic lice. Lice infestations can be controlled with lice combs and medicated shampoos or washes.

Scabies (from Latin: scabere, “to scratch”), known colloquially as the seven-year itch, is a contagious skin infection that occurs among humans and other animals. The disease may be transmitted from objects, but is most often transmitted by direct skin-to-skin contact, with a higher risk with prolonged contact. Initial infections require four to six weeks to become symptomatic. Reinfection, however, may manifest symptoms within as little as 24 hours. Because the symptoms are allergic, their delay in onset is often mirrored by a significant delay in relief after the parasites have been eradicated. The characteristic symptoms of a scabies infection include intense itching and superficial burrows . The burrow tracks are often linear, to the point that a neat “line” of four or more closely placed and equally developed mosquito-like “bites” is almost diagnostic of the disease. Scabies may be diagnosed clinically in geographical areas where it is common when diffuse itching presents along with either lesions in two typical spots or there is

itchiness of another household member. The classical sign of scabies is the burrows made by the mites within the skin. To detect the burrow, the suspected area is rubbed with ink from a fountain pen or a topical tetracycline solution, which glows under a special light. A number of medications are effective in treating scabies with permethrin being the most effective treatment. However, treatment must often involve the entire household or community to prevent re-infection. Options to improve itchiness include antihistamines.

Figure: **Acarodermatitis**. Scabies of the foot.

Key Points

- Cutaneous larva migrans is a skin disease in humans caused by the larvae of various nematode parasites of the hookworm family (Ancylostomatidae) and characterized by a red, intense itching eruption.
- Humans host three different kinds of lice (head lice, body lice, and pubic lice). Lice infestations can be controlled with lice combs and medicated shampoos or washes.
- Scabies, known colloquially as the seven-year itch, is a contagious skin infection that occurs among humans and other animals.

Key Terms

- **scabies**: an infestation of parasitic mites, Sarcoptes scabiei, causing intense itching caused by the mites burrowing into the skin of humans and other animals. It is easily transmissible from human to human; secondary skin infection may occur.
- **cutaneous larva migrans**: a skin disease in humans, caused by the larvae of various nematode parasites of the hookworm family (Ancylostomatidae).
- **louse**: a small parasitic wingless insect of the order Phthiraptera.

15.20A: Tapeworms

Learning Objectives

- Compare and contrast the routes of transmission for various tapeworms and describe their life cycles

Tapeworms are characterized as adult parasitic flatworms that target and infect the digestive tract. Typically, transmission occurs by ingestion of a live tapeworm larva which is found in undercooked or contaminated food. Once inside the digestive tract, the larvae can then grow and develop into a large tapeworm. There are various types of tapeworms identified to date that are capable of infecting humans. A few common tapeworms include the pork tapeworm (*Taenia solium*), the beef tapeworm (*Taenia saginata*), and the fish tapeworm (*Diphyllobothrium spp*.).

Taenia solium

Taenia solium, the pork tapeworm, infects both pigs and humans. Humans are typically infected by ingesting infected pork. *Taenia solium* will target the intestinal area in humans. Using the four suckers and two rows of hooks present on its scolex, it lodges itself against the intestinal wall. Once anchored, the tapeworm continues to grow in the intestine and will pass its eggs through the feces. When *Taenia solium* is in its larval stage, it is referred to as a cysticercus and can cause cysticercosis. Cysticercosis occurs when the cysticerci reach the central nervous system and cause neurological issues.

Figure: ***Scolex of the Taenia solium****: An image of the scolex of the Taenia solium.*

Taenia saginata

Taenia saginata, the beef tapeworm, is capable of infecting both cattle and humans. Infection by *Taenia saginata* is referred to as taeniasis in humans and occurs by ingestion of contaminated meat that has been improperly handled. Taeniasis is caused by the ability of the tapeworm to lodge itself in the small intestine of the human and release fertilized eggs through the feces. The eggs can then infect cattle upon ingestion. Upon infection of the cattle, the fertilized eggs will develop into zygotes which will exit the digestive tract and enter into the circulatory system. The larval stages will then form cysts, referred to as Cysticercus bovis, within the muscular system of the cattle. Therefore, if humans ingest under prepared meat with cysts, the cysts will break open into the digestive system and develop into an adult tapeworm in the human host.

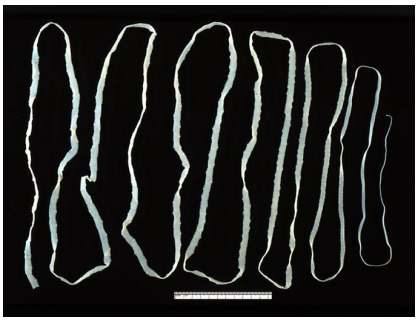

Figure: ***Tapeworm****: An adult Taenia saginata.*

Diphyllobothrium spp.

Diphyllobothrium spp, the fish tapeworm, encompasses various species that can infect humans upon ingestion of under cooked or raw fish. For example, these tapeworms include those found on broad fish and salmon. Interestingly, only a few species of these tapeworms are found to infect humans on a frequent basis. The tapeworms found in fish exhibit the ability to also infect canines, felines, bears, and mussels.

The life cycle for fish tapeworms includes movement through numerous hosts. The mammal host is considered the definitive host as this is the site of worm reproduction. The immature eggs are passed through the feces of the mammal host and then infect a freshwater host. This freshwater host is considered to be the intermediate host. The intermediate host is then ingested by a second intermediate host which includes the fish. The larvae, which developed in the first intermediate host, then migrate out into the flesh of the fish (the second intermediate host). The larvae develop into a more mature form and constitute the infective stage for the definitive host. It is important to note that many second intermediate hosts are ingested by larger predator species that are utilized as a food source for humans. Therefore, it is not necessary for humans to directly eat the second intermediate host in order to be infected.

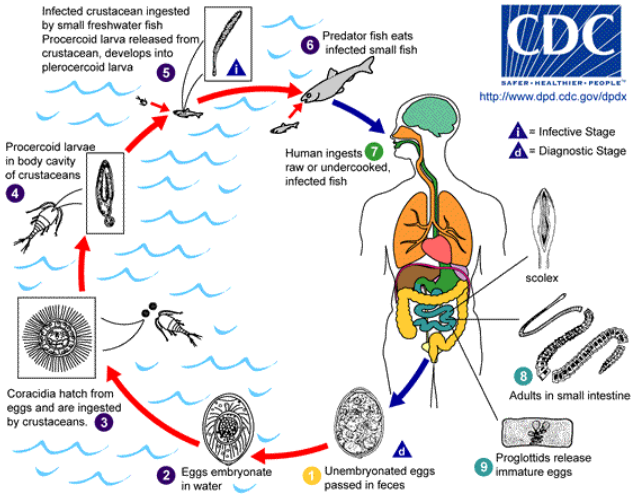

Figure: ***Diphylloborthrium latum life cycle****: Overview of the life cycle of Diphylloborthrium latum. Note the various hosts which are necessary for successful transmission.*

Key Points

- There are numerous types of tapeworms capable of infecting humans including beef, pork, and fish tapeworms.
- Taenia solium, the pork tapeworm, are passed via infected feces to the pig host but requires ingestion of under cooked pork by a human to ensure transmission.
- Taenia saginata, the beef tapeworm, are passed to humans by ingesting under cooked or raw beef that has been infected with the cyst stage in the life cycle.
- Diphyllobothrium spp, the fish tapeworm, requires multiple hosts to successfully infect a human host.

Key Terms

- **scolex**: The “head” of the tapeworm that contains suckers and rows of hooks by which it attaches itself to the host.

15.20A: Tapeworms is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.20B: Hydatid Disease

Learning Objectives

- Outline the life cycle of Echinococcus granulosus

Hydatid disease, commonly referred to as echinococcosis, is a result of infection by the tapeworm included in the *Echinococcus spp*. *Echinococcus multilocularis* results in alveolar echinococcosis and *Echinococcus vogeli* can cause polycystic echinococcosis. In individuals that develop alveolar echinococcosis, which is extremely rare, cysts develop and grow within the alveolar, liver, lungs, and brain. In the cases of alveolar echinococcosis, the parasite responsible, *Echinococcus multilocularis*, is associated with dogs, cats, wolves and most commonly, foxes, serving as the definitive hosts. The intermediate hosts include small rodents. In individuals that develop polycystic echinococcosis, there is the development of slow growing cysts within the body that exhibit the capability to infiltrate surrounding areas. Cysts are typically found in the liver and in the thorax or abdominal cavity. The parasite responsible for polycystic echinococcosis, *Echinococcus vogeli*, uses dogs or bush dogs as a definitive host and rodents as an intermediate hosts.

Echinococcus granulosus is a tapeworm found in dogs, who function as the definitive host, as well as sheep, cattle, goats, and pigs who serve as intermediate hosts. *Echinococcus granulosus* are capable of infecting humans, resulting in hydatid disease, and cause slowly enlarging cysts that develop in vital organs such as the liver or lungs, also referred to as cystic echinococcosis. However, the growth of these cysts are slow and may go unnoticed for a significant duration of time. This form of echinococcosis is more prevalent and commonly found in humans. The adult *Echinococcus granulosus* targets the small bowel of the definitive hosts and release eggs through the feces. After ingestion by the intermediate hosts, the eggs will hatch and penetrate the intestinal wall. The exiting of the intestinal wall results in circulation of oncospheres that will target various organs, including the liver and lungs. The oncospheres undergo further growth and form cysts. The definitive host will then become infected upon ingestion of the cyst-containing organs of the infected intermediate host. It is within the definitive host that the cyst will develop into the adult stage and the cycle continues and repeats.

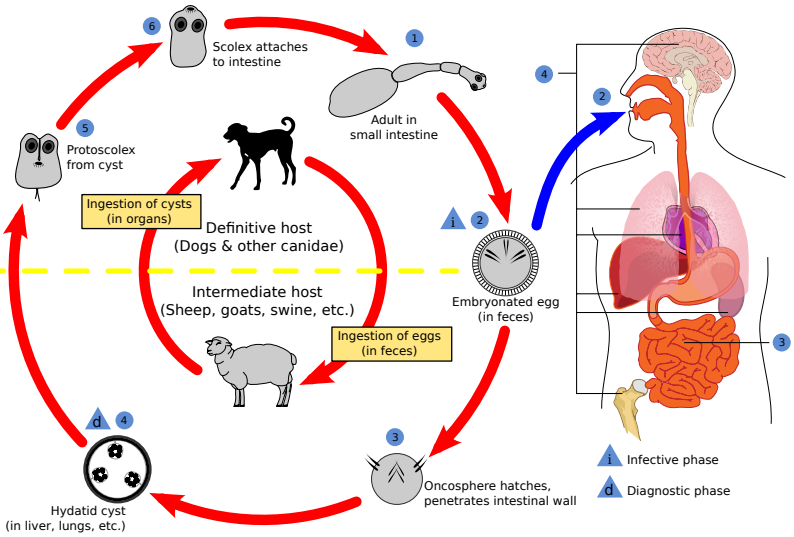

Figure: ***Overview of the Echinococcus life cycle****: A general overview of the various hosts and steps involved in the life cycle of Echinococcus species.*

Hydatid disease is characterized by the growth of these cysts into the adult stage for the tapeworm. Individuals infected with Echinococcus species that develop hydatid disease may not develop symptoms for many years after infection. However, if symptoms develop, it may present in the form of pain or discomfort due to the growing cysts in the upper abdominal regions. Additionally, rupture of fluid within the cysts can result in various medical issues including allergic reactions or death.

Key Points

- *Echinococcus granulosus* causes hydatid disease, or cystic echinococcus and causes slowly enlarging cysts to develop in vital organs.

https://bio.libretexts.org/@go/page/12321

- *Echinococcus multilocularis* results in alveolar echinococcosis and *Echinococcus vogeli* can cause polycystic echinococcosis.
- Individuals infected with *Echinococcus* species who develop hydatid disease may not develop symptoms for many years after infection.

Key Terms

- **echinococcosis**: a parasitic disease of both animals and humans, also known as hydatid disease.

15.20B: Hydatid Disease is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.20C: Nematodes

Learning Objectives

- Compare and contrast mechanisms of infection for the parasitic nematodes: *Ascaris lumbricoides* and *Enterobius*

Nematodes, or roundworms, are the most diverse phylum of pseudocoelomates and one of the most diverse animal phyla. Nematodes are characterized by the presence of a tubular digestive system with openings at both ends. They can be found in various ecosystems ranging from the polar regions to the tropics, fresh to marine water and various terrestrial environments ranging from mountains, deserts and oceanic floors. Nematodes are also capable of exhibiting parasitic behavior that contribute to digestive system diseases. Analysis of parasitic nematodes reveals the presence of specific body structures which promote parasitic behaviors such as ridges, rings or bristles that allow for attachment. Parasitic nematodes that commonly infect humans include ascarids (*Ascaris*), pinworms (*Enterobius*), whipworms (*Trichuris trichiura*), filarias and hookworms. The following is a brief overview of two of these types of roundworms, including *Ascaris* and *Enterobious*.

Ascariasis

Ascariasis is a disease that is caused by the parasitic roundworm *Ascaris lumbricoides.* Ascariasis is commonly found in tropical and sub-tropical regions and is transmitted by ingesting food contaminated with *Ascaris* eggs that are typically present in the feces of an infected individual. Upon ingestion of *Ascaris* eggs, the larvae continue development and hatch within the intestine of the host. The larvae burrow through the intestinal wall and begin circulation in the system and migrate to the lungs. Once they have migrated to the lungs, the larvae break into the alveoli and continue to move through the trachea and esophagus where they are eventually coughed up and swallowed. For a second time, the larvae enter into the intestine and mature into adult worms. Individuals affected with ascariasis can be asymptomatic or suffer from visceral damage due to the travel of the larvae through the body. The presence of the worms within the intestine may also result in malabsorption or intestinal blockage.

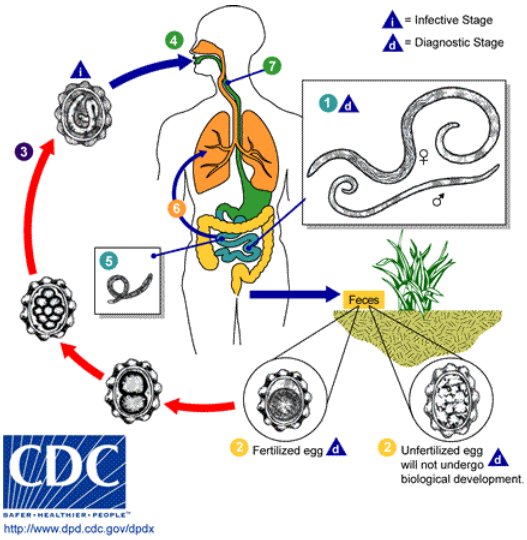

Figure: **Ascariasis Life Cycle**: An overview and summary of the life cycle leading to Ascariasis.

Enterobius

Enterobius, referred to as pinworm, is a type of parasitic nematode that is commonly found in the intestine of children. This infection is often called enterobiasis. The entire life cycle of the pinworm occurs within the human gastrointestinal tract. The life cycle begins with ingestion or insertion of eggs in the anus that have been transmitted via human-to-human contact. The life cycle of the *Enterobious* ends with eggs laid in the anus and transfered to surfaces that come in contact with this region, such as fingernails, hands, night-clothing and bed linens. Infection by pinworm is more prevalent in children due to their behaviors. Upon infection with eggs, they travel to the small intestine and hatch. The pinworm larvae will then migrate towards the colon and undergo molting which allows for further development. After two molt cycles, the larvae have developed into adults. The pinworms exhibit the ability to mate in the small intestine. Shortly after mating, the male worms die and are passed out via the feces. However, the female pinworms will attach to the mucus and wait for the egg-laying process to begin. The egg-laying process

begins with the migration of the females towards the rectum. The eggs, which are covered with a sticky covering, are then released and deposited on the outside or near the anus. The cycle begins again once eggs are ingested and infect an additional host.

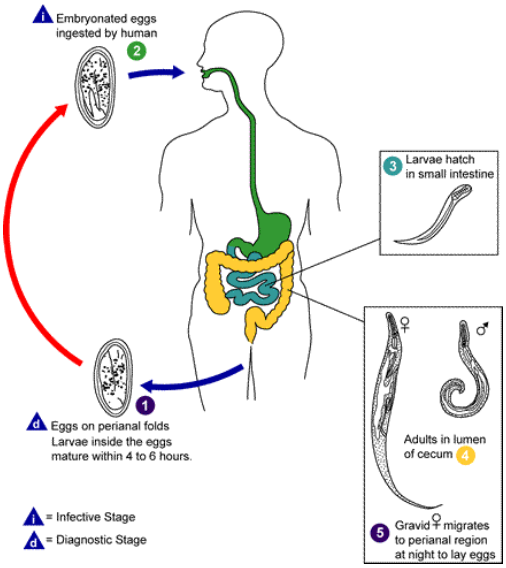

Figure: ***Overview of the pinworm life cycle****: Overview of the pinworm life cycle, specifically Enterobius vermicularis.*

Key Points

- Parasitic nematodes often contain specific body structures which promote parasitic behaviors such as ridges, rings or bristles that allow for attachment.
- Two major types of roundworms that commonly infect humans include Ascaris and Enterobious.
- Ascariasis is a disease that is caused by the parasitic roundworm Ascaris lumbricoides and is transmitted by ingesting food contaminated with Ascaris eggs.
- Enterobius, referred to as pinworm, causes enterobiasis and is commonly found in the intestine of children. The entire life cycle of the pinworm occurs within the human gastrointestinal tract.

Key Terms

- **visceral**: of or relating to the viscera – the internal organs of the body
- **nematode**: A small invertebrate animal of the phylum Nematoda.

15.21A: Overview of the Male and Female Reproductive Systems

The human reproductive system functions to produce human offspring, with the male providing sperm and the female providing the ovum.

Learning Objectives

- Summarize the reproductive systems of men and women

Key Points

- The male reproductive system consists of external organs. The testes in the scrotum produce the male gamete, sperm, which is ejaculated in seminal fluid by the penis.
- The female reproductive system primarily consists of internal organs. The female gamete, ovum, is produced in the ovaries and is released monthly to travel to the uterus via the Fallopian tubes.
- Fertilization can occur if the penis is inserted through the vulva into the vagina and sperm is ejaculated towards the cervix. If an ovum is currently in the uterus, it can then be fertilized by sperm that manage to enter the cervix.
- Once fertilized, an ovum becomes a zygote and if all goes well, develops into a fetus in the uterus.
- Natural birth occurs when the fetus is pushed from the vagina after nine months in the uterus.

Key Terms

- **fallopian tubes**: The Fallopian tubes, also known as oviducts, uterine tubes, and salpinges (singular salpinx) are two very fine tubes lined with ciliated epithelia leading from the ovaries of female mammals into the uterus, via the utero-tubal junction.
- **penis**: The male sexual organ for copulation and urination; the tubular portion of the male genitalia (excluding the scrotum).
- **vagina**: A fibromuscular tubular tract which is the female sex organ and has two main functions: sexual intercourse and childbirth.

The reproductive system or genital system is a set of organs within an organism that work together to produce offspring. Many non-living substances, such as fluids, hormones, and pheromones, are important accessories to the reproductive system. Unlike most organ systems, the sexes of differentiated species often have significant differences. These differences allow for a combination of genetic material between two individuals and thus the possibility of greater genetic fitness of the offspring.

The Reproductive Process

Human reproduction takes place as internal fertilization by sexual intercourse. During this process, the erect penis of the male is inserted into the female's vagina until the male ejaculates semen, which contains sperm, into the vagina. The sperm travels through the vagina and cervix into the uterus for potential fertilization of an ovum. Upon successful fertilization and implantation, gestation of the fetus occurs within the female's uterus for approximately nine months (pregnancy). Gestation ends with labor resulting in birth. In labor, the uterine muscles contract, the cervix dilates, and the baby passes out through the vagina. Human babies and children are nearly helpless and require high levels of parental care for many years. One important type of parental care is the use of the mammary glands in the female breasts to nurse the baby.

The Male Reproductive System

The human male reproductive system is a series of organs located outside of the body and around the pelvic region. The primary direct function of the male reproductive system is to provide the male gamete or spermatozoa for fertilization of the ovum. The major reproductive organs of the male can be grouped into three categories. The first category is sperm production and storage. Production takes place in the testes, housed in the temperature-regulating scrotum. Immature sperm then travel to the epididymis for development and storage. The second category, the ejaculatory fluid-producing glands, includes the seminal vesicles, prostate, and vas deferens. The final category, used for copulation and deposition of the spermatozoa (sperm) within the female, includes the penis, urethra, vas deferens, and Cowper's gland.

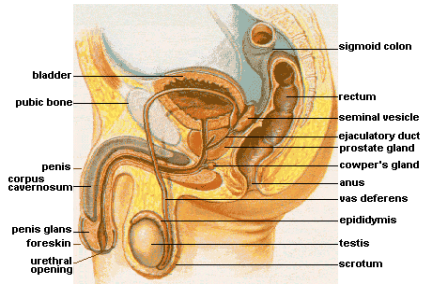

Figure: **The Human Male Reproductive System**: Cross-sectional diagram of the male reproductive organs.

Only our species has a distinctive mushroom-capped glans, which is connected to the shaft of the penis by a thin tissue of frenulum (the delicate tab of skin just beneath the urethra). One of the most significant features of the human penis is the coronal ridge underneath the gland around the circumference of the shaft. Magnetic imaging studies of heterosexual couples having sex reveal that during coitus, the typical penis expands to fill the vaginal tract, and with full penetration can even reach the woman's cervix and lift her uterus. This combined with the fact that human ejaculate is expelled with great force and considerable distance (up to two feet if not contained), suggests that men are designed to release sperm into the uppermost portion of the vagina. This may be an evolutionary adaptation to expel the semen left by other males while at the same time increasing the possibility of fertilization with the current male's semen.

The Female Reproductive System

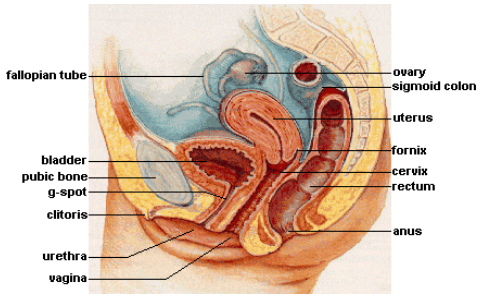

Figure: **The Human Female Reproductive System**: The female reproductive system is largely internal.

The human female reproductive system is a series of organs primarily located inside the body and around the pelvic region. It contains three main parts: the vagina, which leads from the vulva, the vaginal opening, to the uterus; the uterus, which holds the developing fetus; and the ovaries, which produce the female's ova. The breasts are also a reproductive organ during parenting, but are usually not classified as part of the female reproductive system. The vagina meets the outside at the vulva, which also includes the labia, clitoris, and urethra. During intercourse, this area is lubricated by mucus secreted by the Bartholin's glands. The vagina is attached to the uterus through the cervix, while the uterus is attached to the ovaries via the Fallopian tubes. At certain intervals, approximately every 28 days, the ovaries release an ovum that passes through the Fallopian tube into the uterus.

If the ova is fertilized by sperm, it attaches to the endometrium and the fetus develops. In months when fertilization does not occur, the lining of the uterus, called the endometrium, and unfertilized ova are shed each cycle through a process known as menstruation.

15.21B: Overview of the Urinary System

Learning Objectives

- Review the urinary system

The Renal System

The renal system, which is also called the urinary system, is a group of organs in the body that filters out excess fluid and other substances from the bloodstream. The purpose of the renal system is to eliminate wastes from the body, regulate blood volume and pressure, control levels of electrolytes and metabolites, and regulate blood pH.

The renal system organs include the kidneys, ureters, bladder, and urethra. Metabolic wastes and excess ions are filtered out of the blood, along with water, and leave the body in the form of urine.

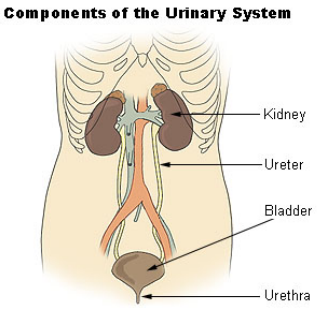

Figure: **Components of the renal system**: Here are the major organs of the renal system.

Renal System Functions

The renal system has many functions. Many of these functions are interrelated with the physiological mechanisms in the cardiovascular and respiratory systems.

1. Removal of metabolic waste products from the body (mainly urea and uric acid).
2. Regulation of electrolyte balance (e.g., sodium, potassium, and calcium).
3. Osmoregulation controls the blood volume and body water contents.
4. Blood pressure homeostasis: The renal system alters water retention and thirst to slowly change blood volume and keep blood pressure in a normal range.
5. Regulation of acid-base homeostasis and blood pH, a function shared with the respiratory system.

Many of these functions are related to one another as well. For example, water follows ions via an osmotic gradient, so mechanisms that alter sodium levels or sodium retention in the renal system will alter water retention levels as well.

Organs of the Renal System

Kidneys and Nephrons

Kidneys are the most complex and critical part of the urinary system. The primary function of the kidneys is to maintain a stable internal environment (homeostasis) for optimal cell and tissue metabolism. The kidneys have an extensive blood supply from the renal arteries that leave the kidneys via the renal vein.

Nephrons are the main functional component inside the parenchyma of the kidneys, which filter blood to remove urea, a waste product formed by the oxidation of proteins, as well as ions like potassium and sodium. The nephrons are made up of a capsule capillaries (the glomerulus) and a small renal tube. The renal tube of the nephron consists of a network of tubules and loops that are selectively permeable to water and ions. Many hormones involved in homeostasis will alter the permeability of these tubules to change the amount of water that is retained by the body.

Ureter

Urine passes from the renal tube through tubes called ureters and into the bladder.

Bladder

The bladder is flexible and is used as storage until the urine is allowed to pass through the urethra and out of the body.

Urethra

The female and male renal system are very similar, differing only in the length of the urethra.

Human Osmoregulation

The kidneys play a very large role in human osmoregulation by regulating the amount of water reabsorbed from the glomerular filtrate in kidney tubules, which is controlled by hormones such as antidiuretic hormone (ADH), renin, aldosterone, and angiotensin I and II.

A basic example is that a decrease in water concentration of blood is detected by osmoreceptors in the hypothalamus, which stimulates ADH release from the pituitary gland to increase the permeability of the wall of the collecting ducts and tubules in the nephrons. Therefore, a large proportion of water is reabsorbed from fluid to prevent a fair proportion of water from being excreted.

The extent of blood volume and blood pressure regulation facilitated by the kidneys is a complex process. Besides ADH secretion, the renin-angiotensin feedback system is critically important to maintain blood volume and blood pressure homeostasis.

Key Points

- The renal system eliminate wastes from the body, controls levels of electrolytes and metabolites, controls the osmoregulation of blood volume and pressure, and regulates blood pH.
- The renal system organs include the kidneys, ureter, bladder, and urethra. Nephrons are the main functional component of the kidneys.
- The respiratory and cardiovascular systems have certain functions that overlap with renal system functions.
- Metabolic wastes and excess ions are filtered out of the blood, combined with water, and leave the body in the form of urine.
- A complex network of hormones controls the renal system to maintain homeostasis.

Key Terms

- **ureter**: These are two long, narrow ducts that carry urine from the kidneys to the urinary bladder.
- **osmoregulation**: The most important function of the renal system, in which blood volume, blood pressure, and blood osmolarity (ion concentration) is maintained in homeostasis.

15.21B: Overview of the Urinary System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.21C: Normal Genitourinary Microbiota

The vaginal microflora consist mostly of various lactobacillus species.

Learning Objectives

- Recognize the types of bacteria present in the vaginal microflora

Key Points

- If microbe numbers grow beyond their typical ranges (often due to a compromised immune system) or if microbes populate atypical areas of the body (such as through poor hygiene or injury), disease can result.
- Disturbance of the vaginal flora can lead to bacterial vaginosis.

Key Terms

- **urinary tract infection**: Finding bacteria or other microorganisms, such as yeasts, in bladder urine with or without clinical symptoms and with or without renal disease.

The Genitourinary Microbiome

The human microbiome, or human microbiota, is the aggregate of microorganisms that reside on the surface and in deep layers of skin, in the saliva and oral mucosa, in the conjunctiva, and in the gastrointestinal tracts. They include bacteria, fungi, and archaea. Some of these organisms perform tasks that are useful for the human host. However, the majority have no known beneficial or harmful effect. Those that are expected to be present and that under normal circumstances do not cause disease, but instead participate in maintaining health, are deemed members of the normal flora.

Populations of microbes inhabit the skin and mucosa. Their role forms part of normal, healthy human physiology; however, if microbe numbers grow beyond their typical ranges (often due to a compromised immune system) or if microbes populate atypical areas of the body (such as through poor hygiene or injury), disease can result.

Proportions of Microbes

It is estimated that 500 to 1000 species of bacteria live in the human gut and a roughly similar number on the skin. Bacterial cells are much smaller than human cells, and there are at least ten times as many bacteria as human cells in the body (approximately 10^{14} versus 10^{13}). Normal flora bacteria can act as opportunistic pathogens at times of lowered immunity.The vaginal microflora consist mostly of various lactobacillus species. It was long thought that the most common of these species was Lactobacillus acidophilus, but it has later been shown that the most common one is L. iners followed by L. crispatus. Other lactobacilli found in the vagina are L. jensenii, L. delbruekii and L. gasseri. Disturbance of the vaginal flora can lead to bacterial vaginosis.

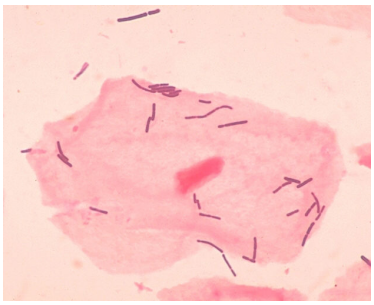

Figure: **Lactobacillus**: Lactobacilli and a vaginal squamous cell.

15.22: Bacterial Diseases of the Urinary System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.22A: Urinary Tract Infection (UTI)

A urinary tract infection (UTI) is an infection affecting the urinary tract; about 150 million people develop UTIs each year.

LEARNING OBJECTIVES

Summarize the various categories of urinary tract infection (UTI): complicated, uncomplicated, upper and lower UTIs

KEY TAKEAWAYS

Key Points

- About 150 million people develop a urinary tract infection each year, and they are more common in women than men.
- A urinary tract infection (UTI) is an infection that affects part of the urinary tract. When it affects the lower urinary tract it is known as a bladder infection (cystitis); when it affects the upper urinary tract it is known as kidney infection (pyelonephritis).
- UTIs are generally treatable with antibiotics, though resistance to some of the medications is growing.

Key Terms

- **urinary tract infection**: A bacterial infection that affects part of the urinary tract.

About 150 million people develop a urinary tract infection each year. They are more common in women than men. In women, they are the most common form of bacterial infection. Up to 10% of women have a urinary tract infection in a given year and half of women having at least one infection at some point in their lives. They occur most frequently between the ages of 16 and 35 years. Recurrences are common. Urinary tract infections have been described since ancient times with the first documented description in the Ebers Papyrus dated to c. 1550 BC.

A urinary tract infection (UTI) is an infection that affects part of the urinary tract. When it affects the lower urinary tract it is known as a bladder infection (cystitis); when it affects the upper urinary tract it is known as kidney infection (pyelonephritis). Symptoms from a lower urinary tract include pain with urination, frequent urination, and feeling the need to urinate despite having an empty bladder. Symptoms of a kidney infection include fever and flank pain usually in addition to the symptoms of a lower UTI. Rarely the urine may appear bloody. In the very old and the very young, symptoms may be vague or non-specific.

The most common cause of infection is Escherichia coli, though other bacteria or fungi may rarely be the cause. Risk factors include female anatomy, sexual intercourse, diabetes, obesity, and family history. Although sexual intercourse is a risk factor, UTIs are not classified as sexually transmitted infections (STIs). Kidney infection, if it occurs, usually follows a bladder infection but may also result from a blood-borne infection. Diagnosis in young healthy women can be based on symptoms alone. In those with vague symptoms, diagnosis can be difficult because bacteria may be present without there being an infection. In complicated cases or if treatment fails, a urine culture may be useful.

Categories of UTI

Uncomplicated UTIs

In uncomplicated cases, a diagnosis may be made and treatment given based on symptoms alone without further laboratory confirmation, and treatment involves a short course of antibiotics such as nitrofurantoin or trimethoprim / sulfamethoxazole. Resistance to many of the antibiotics used to treat this condition is increasing.

Complicated UTIs

In complicated cases, it may be useful to confirm the diagnosis via urinalysis, looking for the presence of urinary nitrites, white blood cells (leukocytes), or leukocyte esterase. Another test, urine microscopy, looks for the presence of red blood cells, white blood cells, or bacteria. A longer course or intravenous antibiotics may be needed. If symptoms do not improved in two or three days, further diagnostic testing may be needed. Phenazopyridine may help with symptoms. In those who have bacteria or white blood cells in their urine but have no symptoms, antibiotics are generally not needed, although during pregnancy is an exception. In those with frequent infections, a short course of antibiotics may be taken as soon as symptoms begin or long term antibiotics may be used as a preventative measure.

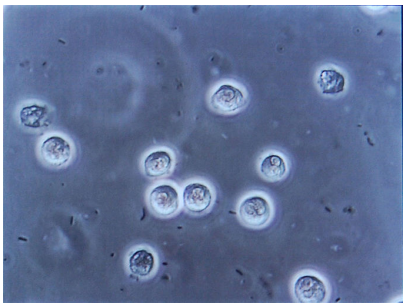

Figure: **Bacteriuria and Pyuria**: Multiple bacilli (rod-shaped bacteria, here shown as black and bean-shaped) shown between white blood cells in urinary microscopy. These changes are indicative of a urinary tract infection.

Lower UTI

Lower urinary tract infection is also referred to as a bladder infection. The most common symptoms are burning with urination and having to urinate frequently (or an urge to urinate) in the absence of vaginal discharge and significant pain. These symptoms may vary from mild to severe and in healthy women last an average of six days. Some pain above the pubic bone or in the lower back may be present.

Upper UTI

People experiencing an upper urinary tract infection, or pyelonephritis, may experience flank pain, fever, or nausea and vomiting in addition to the classic symptoms of a lower urinary tract infection. Rarely the urine may appear bloody or contain visible pus in the urine.

Prevention

A number of measures have not been confirmed to affect UTI frequency including: urinating immediately after intercourse, the type of underwear used, personal hygiene methods used after urinating or defecating, or whether a person typically bathes or showers. There is similarly a lack of evidence surrounding the effect of holding one's urine, tampon use, and douching. In those with frequent urinary tract infections who use spermicide or a diaphragm as a method of contraception, they are advised to use alternative methods. In those with benign prostatic hyperplasia urinating in a sitting position appears to improve bladder emptying which might decrease urinary tract infections in this group.

For those with recurrent infections, taking a short course of antibiotics when each infection occurs is associated with the lowest antibiotic use. A prolonged course of daily antibiotics is also effective. Medications frequently used include nitrofurantoin and trimethoprim/sulfamethoxazole (TMP/SMX). Methenamine is another agent used for this purpose as in the bladder where the acidity is low it produces formaldehyde to which resistance does not develop. Some recommend against prolonged use due to concerns of antibiotic resistance.

15.22A: Urinary Tract Infection (UTI) is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.22B: Cystitis

Learning Objectives

- Differentiate among the distinct types of cystitis: traumatic, interstitial, eosinophilic, hemorrhagic cystitis, and cystitis cystica, recognizing their causes and risk factors

A urinary tract infection (UTI), a bacterial infection that affects the lower urinary tract, is also known as a simple cystitis (a bladder infection). Symptoms from a lower urinary tract infection include painful urination and either frequent urination or the urge to urinate (or both). Cystitis is a urinary bladder inflammation that can result from any one of a number of distinct syndromes. It is most commonly caused by a bacterial infection in which case it is referred to as a urinary tract infection.

Figure: ***Proteus vulgaris on MacConkey agar****: After 24 hours, this inoculated MacConkey agar culture plate cultivated colonial growth of Gram-negative, rod-shaped, and facultatively anaerobic Proteus vulgaris bacteria. Normally found in the humans gastrointestinal tract, Proteus spp. are opportunistic pathogens, which means that they usually do not cause disease. However, under immunocompromised circumstances, i.e., weakened immunity, these bacteria can be found the culprit responsible for urinary tract infections such as cystitis and pyelonephritis.*

Signs and Symptoms

- Pressure in the lower pelvis
- Painful urination (dysuria)
- Frequent urination (polyuria) or urgent need to urinate (urinary urgency)
- Need to urinate at night (nocturia)
- Urine that contains traces of blood (haematuria)
- Dark, cloudy or strong-smelling urine
- Pain above the pubic bone, or in the lower back or abdomen
- Feeling unwell, weak, or feverish

There are several medically distinct types of cystitis, each having a unique etiology and therapeutic approach:

- Traumatic cystitis is probably the most common form of cystitis in the female. It is due to bruising of the bladder, usually by abnormally forceful sexual intercourse. This is often followed by bacterial cystitis, frequently by coliform bacteria being transferred from the bowel through the urethra into the bladder.
- Interstitial cystitis (IC) is considered more of an injury to the bladder resulting in constant irritation and rarely involves the presence of infection. IC patients are often misdiagnosed with UTI/cystitis for years before they are told that their urine cultures are negative. Antibiotics are not used to treatment of IC. The cause of IC is unknown, although some suspect it may be autoimmune where the immune system attacks the bladder. Several therapies are now available.
- Eosinophilic cystitis (EC) is a rare form of cystitis that is diagnosed via biopsy. In these cases, the bladder wall is infiltrated with a high number of eosinophils. The cause of EC may be attributed to infection by Schistosoma haematobium or by certain medications in afflicted children. Some consider it a form of interstitial cystitis.
- Hemorrhagic cystitis can occur as a side effect of cyclophosphamide, ifosfamide, and radiation therapy. Radiation cystitis, one form of hemorrhagic cystitis is a rare consequence of patients undergoing radiation therapy for the treatment of cancer. Several adenovirus serotypes have been associated with an acute, self-limited hemorrhagic cystitis, which occurs primarily in boys. It is

characterized by hematuria, and virus can usually be recovered from the urine. In sexually active women the most common cause of urinary tract infection is from E. coli and Staphylococcus saprophyticus.

- Cystitis cystica is a chronic cystitis glandularis accompanied by the formation of cysts. This disease can cause chronic urinary tract infections. It appears as small cysts filled with fluid and lined by one or more layers of epithelial cells. These are due to hydropic degeneration in center of Brunn's nests

Key Points

- Cystitis is a urinary bladder inflammation that is most commonly caused by a bacterial infection in which case it is referred to as a urinary tract infection. Symptoms from a lower urinary tract include painful urination and either frequent urination or urge to urinate (or both), but neither may be present.
- Traumatic cystitis is probably the most common form of cystitis in the female. It is due to bruising of the bladder, usually by abnormally forceful sexual intercourse.
- Interstitial cystitis (IC) is considered more of an injury to the bladder resulting in constant irritation and rarely involves the presence of infection.

Key Terms

- **cystitis**: Cystitis is a urinary bladder inflammation that can result from any one of a number of distinct syndromes. It is most commonly caused by a bacterial infection in which case it is referred to as a urinary tract infection.

15.22B: Cystitis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.22C: Pyelonephritis

Learning Objectives

- Identify the main symptoms of pyelonephritis

Pyelonephritis is an inflammation of the kidney tissue, calyces, and renal pelvis. It is commonly caused by bacterial infection that has spread up the urinary tract or travelled through the bloodstream to the kidneys. A similar term is “pyelitis” which means inflammation of the pelvis and calyces. In other words, pyelitis together with nephritis is collectively known as pyelonephritis. Severe cases of pyelonephritis can lead to pyonephrosis (pus accumulation around the kidney), sepsis (a systemic inflammatory response of the body to infection), kidney failure and even death.

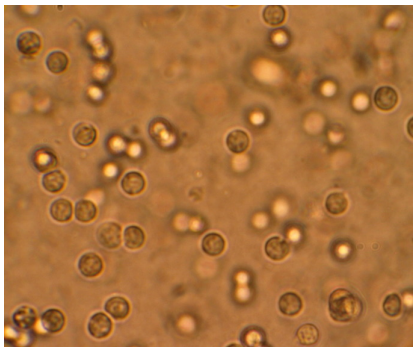

Figure: ***Urinary tract infection (UTI)****: White blood cells in the urine of someone with a UTI, seen under a microscope.*

Pyelonephritis presents with fever, accelerated heart rate, painful urination, abdominal pain radiating to the back, nausea, and tenderness at the costovertebral angle on the affected side. Pyelonephritis that has progressed to urosepsis may be accompanied by signs of septic shock, including rapid breathing, decreased blood pressure, violent shivering, and occasionally delirium. Pyelonephritis requires antibiotic therapy, and sometimes surgical intervention, as well as treatment of any underlying causes to prevent its recurrence.

Key Points

- Pyelonephritis is an inflammation of the kidney tissue and renal area of the pelvis.
- Pyelonephritis is most commonly caused by a bacterial infection ascending up the upper urinary tract.
- Severe cases of pyelonephritis can lead to sepsis, kidney failure, and death.
- Pyelonephritis presents with fever, accelerated heart rate, painful urination, abdominal pain, and nausea.
- Pyelonephritis requires antibiotic therapy, and sometimes surgical intervention, as well as treatment of any underlying causes to prevent recurrence.

Key Terms

- **pyelonephritis**: An ascending urinary tract infection that has reached the pelvis or the kidney.
- **Urinary tract**: The organ system that produces, stores, and eliminates urine. In humans it includes two kidneys, two ureters, the bladder, and the urethra.

15.22C: Pyelonephritis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.22D: Leptospirosis

Learning Objectives

- Generalize the causes and mode of transmission for leptospirosis

Leptospirosis (also known as Weil's Syndrome, canicola fever, canefield fever, nanukayami fever, 7-day fever, Rat Catcher's Yellows, Fort Bragg fever, black jaundice, and Pretibial fever) is caused by bacteria of the genus *Leptospira*, and affects humans as well as other animals. Symptoms can range from none to mild such as headaches, muscle pains, and fevers; to severe with bleeding from the lungs or meningitis. If the infection causes the person to turn yellow, have kidney failure and bleeding it is then known as Weil's disease. If the infection causes lots of bleeding from the lungs it is known as severe pulmonary haemorrhage syndrome.

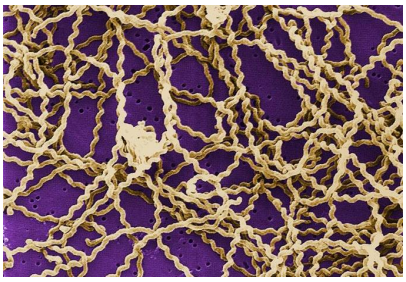

Figure: ***Leptospira bactera that cause Leptospirosis****: Scanning electron micrograph of a number of Leptospira sp. bacteria atop a 0.1 µm polycarbonate filter.*

Leptospirosis is among the world's most common diseases transmitted to people from animals. The infection is commonly transmitted to humans by allowing water that has been contaminated by animal urine to come in contact with unhealed breaks in the skin, eyes, or mucous membranes. Outside of tropical areas, leptospirosis cases have a relatively distinct seasonality, with most cases occurring in spring and autumn.

Leptospirosis is caused by a spirochaete bacterium called *Leptospira spp*. There are at least five serotypes of importance in the United States and Canada, all of which cause disease in dogs (Icterohaemorrhagiae, Canicola, Pomona, Grippotyphosa, and Bratislava).There are other (less common) infectious strains as well. Leptospirosis is transmitted by the urine of an infected animal and is contagious as long as it is still moist. Although rats, mice, and moles are important primary hosts, a wide range of other mammals (including dogs, deer, rabbits, hedgehogs, cows, sheep, raccoons, opossums, skunks, and certain marine mammals) are able to carry and transmit the disease as secondary hosts. Dogs may lick the urine of an infected animal off the grass or soil or drink from an infected puddle.

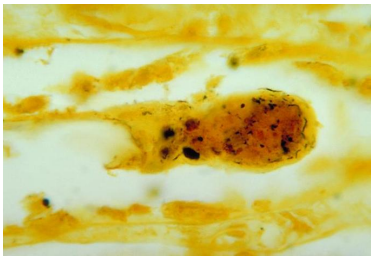

Figure: ***Leptospirosis in kidney****: Photomicrograph of kidney tissue, using a silver staining technique, revealing the presence of Leptospira bacteria.*

There have been reports of "house dogs" contracting leptospirosis from licking the urine of infected mice that enter the house. The type of habitats most likely to carry infectious bacteria are muddy riverbanks, ditches, gullies, and muddy livestock-rearing areas where there is regular passage of either wild or farm mammals. There is a direct correlation between the amount of rainfall and the incidence of leptospirosis, making it seasonal in temperate climates and year-round in tropical climates. Leptospirosis is also transmitted by the semen of infected animals. Humans become infected through contact with water, food, or soil containing urine from these infected animals. This may result from swallowing contaminated food and water or through skin contact. The disease is not known to be spread from person to person, and cases of bacterial dissemination in convalescence are extremely rare in humans. Leptospirosis is common among water-sport enthusiasts in specific areas, as prolonged immersion in water is known to promote the entry of the bacteria. Surfers and whitewater paddlers are at especially high risk in areas that have been shown to contain the

bacteria, and can contract the disease by swallowing contaminated water, splashing contaminated water into their eyes or nose, or exposing open wounds to infected water.

Key Points

- Leptospirosis symptoms can range from none to mild such as headaches, muscle pains, and fevers; to severe with bleeding from the lungs or meningitis.
- Outside of tropical areas, leptospirosis cases have a relatively distinct seasonality, with most cases occurring in spring and autumn.
- Leptospirosis is transmitted by the urine of an infected animal and is contagious as long as it remains moist.
- There is a direct correlation between the amount of rainfall and the incidence of leptospirosis, making it seasonal in temperate climates and year-round in tropical climates.

Key Terms

- **leptospirosis**: an acute, infectious, febrile disease of both humans and animals, caused by spirochetes of the genus Leptospira

SECTION OVERVIEW

15.23: Bacterial Diseases of the Reproductive System

Topic hierarchy

15.23A: Prostatitis

15.23B: Prostatitis

15.23C: Gonorrhea

15.23D: Nongonococcal Urethritis (NGU)

15.23E: Pelvic Inflammatory Disease (PID)

15.23F: Syphilis

15.23G: Genital Ulcer Diseases

15.23H: Lymphogranuloma Venereum

15.23I: Group B Streptococcus Colonization

15.23J: Chancroid (Soft Chancre)

15.23K: Bacterial Vaginosis

15.23L: Chlamydia

15.23: Bacterial Diseases of the Reproductive System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.23A: Prostatitis

Prostatitis is an inflammation of the prostate which can be caused by bacteria.

Learning Objectives

- Define the symptoms, diagnostic tests and treatments used for prostatitis

Key Points

- Bacteria can cause acute and chronic prostatitis.
- Acute prostatitis is a serious condition that needs immediate treatment with antibiotics. If treated promptly complications are rare.
- Chronic prostatitis is a rare disease that is harder to treat and has high recurrence rate. In the case of remission, combinations of antibiotics may be a better therapy than a single antibiotic.

Key Terms

- **bactericidal**: An agent that kills bacteria.
- **bacteriostatic**: A drug that prevents bacterial growth and reproduction but does not necessarily kill them. When it is removed from the environment the bacteria start growing again.
- **cystitis**: An inflammation of the urinary bladder.

Prostatitis is an inflammation of the prostate which can be caused by bacteria. Bacterial infections can cause both acute and chronic prostatitis.

Symptoms and diagnosis

Acute prostatitis is relatively easy to diagnose because it presents the general infection symptoms which may include: fever, chills, groin and lower back pain, issues during urination, and general body aches. The prostate is usually enlarged. Testing of urine samples reveals the presence of bacteria and white blood cells. Blood samples can contain bacteria. White blood cells counts are elevated in the complete blood count.

Chronic prostatitis is a rare condition. It usually causes intermittent urinary tract infections (UTIs) which can lead to cystitis. Sometimes there are no symptoms. The diagnosis is made after culturing urine or prostate liquid. Semen analysis can also be used for diagnosis it. PSA (prostate specific antigen) levels may be elevated.

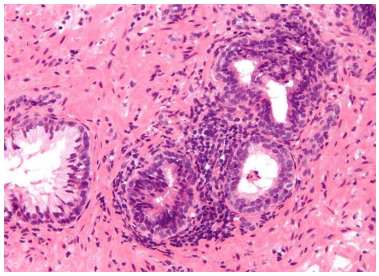

Figure: **Histologic image of chronic prostatitis**: The single gland on the left is healthy, while the glands on the right are inflamed

INFECTIOUS AGENTS

Common bacteria that cause acute prostatitis include gram negative bacteria such as *Escherichia coli*, *Klebsiella*, *Proteus*, *Enterobacter*, *Pseudomonas*, as well as gram positive bacteria such as *Staphylococcus aureus*. E. coli is the major infectious agent that causes chronic prostatitis.

TREATMENT

Acute prostatitis is a serious condition that requires immediate treatment to prevent complications such as sepsis. The antibiotics of choice should be bactericidal (e.g., quinolone) not bacteriostatic (e.g., tetracycline) if the infection is life-threatening. Other commonly used antibiotics are doxycycline and ciprofloxacin. Severe infections may require hospitalization, while milder cases (no sepsis) can be treated with antibiotic administration combined with bed rest at home. The infection is usually cured successfully

with antibiotics and the recovery is complete without further complications. Treatment of chronic prostatitis requires courses of antibiotic administration for one to two months or a longer course with low doses. The recurrence of the disease is high. In these cases higher success rates of treatment are achieved when a combination of antibiotics is used. Animal studies have shown that *E. coli* extract with cranberry can prevent chronic prostatitis. The choice of antibiotic for chronic prostatitis also depends on its ability to penetrate the prostatic capsule. Good penetrators of the barrier are quinolones, doxycycline, macrolides and sulfas (Bactrim). In the case of acute prostatitis, the prostate-blood barrier is damaged by the infection so the penetrating ability of the antibiotic is not as important.

15.23C: Gonorrhea

Gonorrhea (also colloquially known as the clap) is a common human sexually transmitted infection caused by the bacterium Neisseria gonorrhoeae.

Learning Objectives

- Describe gonorrhea

Key Points

- The usual symptoms of gonorrhea in men are burning with urination and penile discharge.
- Women with gonorrhea, on the other hand, are asymptomatic half the time or have vaginal discharge and pelvic pain.
- If gonorrhea is left untreated, it may spread locally causing epididymitis or pelvic inflammatory disease or throughout the body, affecting joints and heart valves.Treatment is commonly with ceftriaxone as antibiotic resistance has developed to many previously used medications.

Key Terms

- **ceftriaxone**: A synthetic cephalosporin antibiotic used to treat gonorrhea.

Gonorrhea (also colloquially known as the clap) is a common human sexually transmitted infection. The usual symptoms in men are burning with urination and penile discharge. Women, on the other hand, are asymptomatic half the time or have vaginal discharge and pelvic pain. In both men and women if gonorrhea is left untreated, it may spread locally causing epididymitis or pelvic inflammatory disease or throughout the body, affecting joints and heart valves.Treatment is commonly with ceftriaxone as antibiotic resistance has developed to many previously used medications. In 2011, there were reports of some strains of gonorrhea showing resistance to ceftriaxone. Half of women with gonorrhea are asymptomatic while others have vaginal discharge, lower abdominal pain or pain with intercourse.

The most common male symptoms are urethritis associated with burning with urination and discharge from the penis. Either sex may also acquire gonorrhea of the throat from performing oral sex on an infected partner, usually a male partner. Such infection is asymptomatic in 90% of cases, and produces a sore throat in the remaining 10%. The incubation period is 2 to 14 days with most of these symptoms occurring between 4–6 days after being infected. Rarely, gonorrhea may cause skin lesions and joint infection (pain and swelling in the joints) after traveling through the blood stream. Very rarely it may settle in the heart causing endocarditis or in the spinal column causing meningitis (both are more likely among individuals with suppressed immune systems, however).

CAUSE

Gonorrhea is caused by the bacteria Neisseria gonorrhoeae. The infection is transmitted from one person to another through vaginal, oral, or anal sex. Men have a 20% risk of getting the infection from a single act of vaginal intercourse with an infected woman. The risk for men who have sex with men is higher. Women have a 60–80% risk of getting the infection from a single act of vaginal intercourse with an infected man. A mother may transmit gonorrhea to her newborn during childbirth; when affecting the infant's eyes, it is referred to as ophthalmia neonatorum. It cannot be spread by toilets or bathrooms.

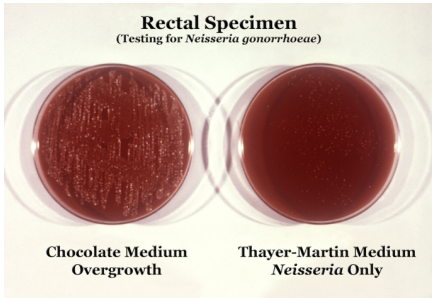

Figure: **Neisseria gonorrhoeae**: Neisseria gonorrhoeae cultured on two different media types and presented in stereoscopic 3d.

15.23C: Gonorrhea is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.23D: Nongonococcal Urethritis (NGU)

Nongonococcal urethritis (NGU) is an urethral inflammation that is not caused by *Neisseria gonorrhoeae*.

Learning Objectives

- Recognize the symptoms, causes and treatments for nongonococcal urethritis (NGU)

Key Points

- The general symptoms are pain on urination, frequent urination, and white or cloudy discharge.
- It can be caused by many infectious agents, with the most common being chlamydia.
- Since many different infectious agents can be causing NGU, the initial treatment should be with a broad spectrum antibiotic.

Key Terms

- **epididymitis**: An inflammation of the epididymis, a structure in the testicles where sperm matures.

Nongonococcal urethritis (NGU) is a urethral inflammation that is not caused by *Neisseria gonorrhoeae*, *a* classification used by doctors for treatment purposes. The general symptoms are pain on urination, frequent need to urinate and white or cloudy discharge. The most common symptoms unique to men are discharge from the penis, itching, and tenderness. In women, the symptoms include vaginal discharge, abdominal pain. If irregular menstrual bleeding is present it may indicate that the infection has progressed into pelvic inflammatory disease.

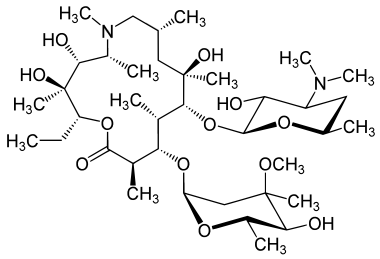

Figure: **Azithromycin**: The structure of azithromycin, a microlide antibiotic used to treat NGU.

Diagnosing NGU is based on the lack of *Neisseria gonorrhoeae* in laboratory testsin a patient with urethritis. In men, it can be diagnosed with Gram staining of urethral discharge; the same is not true for women, since they may have other Gram negative bacteria that are part of their normal vaginal microflora. There are multiple infectious agents that can cause nongonococcal inflammation of the urethra. The most common bacterial agent is *Chlamydia trachomatis* (about a quarter to half of all NGU cases), though others include *Ureaplasma urealyticum*, *Haemophilus vaginalis* and *Mycoplasma genitalium*. Viral infections can be caused sometimes by the Herpes simplex virus or adenovirus. Parasites such as *Trichomonas vaginalis* can cause inflammation too, although rarely. NGU can be caused by reasons different than infection, such as the use of some chemicals or physical injuries. Since many different infectious agents can be causing NGU, the initial treatment should be with a broad spectrum antibiotic. Studies indicate that therapies with doxycycline or azithromycin with tinidazole can be more effective than doxycycline or azithromycin alone. Sexual partners of infected patients should be treated as well. Prompt treatment is critical in both men and women. Women are at risk of developing pelvic inflammatory disease (PID), while in men the infection can progress to epididymitis and cause infertility.

15.23D: Nongonococcal Urethritis (NGU) is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.23E: Pelvic Inflammatory Disease (PID)

Pelvic inflammatory disease (PID) is an inflammation of the female reproductive organs that is most often caused by infection.

Learning Objectives

- Describe the causes, symptoms and long-term effects of pelvic inflammatory disease

Key Points

- Different agents can cause the infection but the most common are Chlamydia trachomatis and Neisseria gonorrhoeae.
- PID can cause permanent damage to the affected organs leading to issues such as infertility and chronic pelvic pain.
- Single antibiotics or combinations of antibiotics are used for the treatment of PID.

Key Terms

- **ectopic**: Being out of place, such as a pregnancy occurring inside the fallopian tubes instead of the uterus.
- **pelvic inflammatory disease**: inflammation of the uterus, fallopian tubes, and/or ovaries as it progresses to scar formation with adhesions to nearby tissues and organs
- **asymptomatic**: not exhibiting any symptoms of disease.

Pelvic inflammatory disease (PID) is an inflammation of the uterus, fallopian tubes and/or the ovaries. It is most often caused by a sexually transmitted infection (STI) but there are other predisposing conditions (e.g., postpartum period, the use of intrauterine device). It should be treated promptly to avoid serious complications like scarring and adhesions which can cause infertility, ectopic pregnancy and chronic pelvic pain.

Symptoms and diagnosis

PID can be asymptomatic or present with acute symptoms. About two thirds of patients whose laparoscopies indicated a previous PID were unaware of it. Asymptomatic infections should be treated as well, since they can still cause permanent damage to the reproductive tract.

Symptoms include fever, lower abdominal pain, unusual discharge, irregular menstrual bleeding, painful intercourse.

Different tests can be used for diagnosis such as pelvic ultrasound and laboratory tests for STIs. Usually, more than one test is needed for proper diagnosis. Early diagnosis and treatment are critical to limit the spread of the infection to the lower part of the tract and to avoid long term consequences.

Infectious agents

PID can be caused by many different infectious agents like viruses, fungi or bacteria. The most common infectious agents are *Chlamydia trachomatis* and *Neisseria gonorrhoeae* which are sexually transmitted.

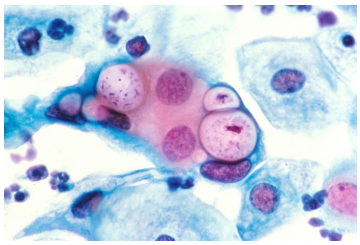

Figure: **Pap smear with Chlamydia**: Cells of Chlamydia are visible in the vacuoles. Magnification 500x, stained with hematoxylin and eosin stain (HE)

The normal vaginal flora can also cause PID under certain circumstances. Co-infection with multiple species is also possible.

Treatment

The primary mode of therapy is an antibiotic regimen. In serious cases, intravenous administration of drugs may be necessary. Usually, improvement of symptoms should be noticed within a few days.

Sexual partners of patients with PID should be treated as well. Some of the most commonly used antibiotics and combinations of antibiotics are: *cefoxitin* or *cefotetan* plus *doxycycline*, *cefoxitin* plus *doxycycline*, *clindamycin* plus *gentamycin*, *ampicillin* and *sublactam* plus *doxycycline.*

15.23E: Pelvic Inflammatory Disease (PID) is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.23F: Syphilis

Learning Objectives

- Describe syphilis, its affect on the spinal cord, and its methods of transmission

Syphilis is a sexually transmitted infection (STI) caused by the spirochete bacterium *Treponema pallidum*.

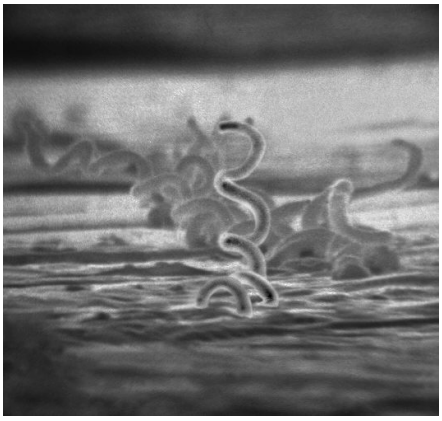

Figure: **Electron Microscopy of Treponema Pallidum**: This electron micrograph shows Treponema pallidum on cultures of cotton-tail rabbit epithelium cells (Sf1Ep). It is the causative agent of syphilis.

FOUR STAGES OF SYPHILIS

The signs and symptoms of syphilis vary depending on which of the four stages it presents (primary, secondary, latent, or tertiary). The primary stage classically presents itself with a single chancre (a firm, painless, non-itchy skin ulceration) as shown in. Secondary syphilis shows itself with a diffuse rash that frequently involves the palms of the hands and soles of the feet. Latent syphilis displays little to no symptoms, and neurosyphilis (tertiary) can result in neurological and cardiac symptoms because the syphilis has been undiagnosed or untreated for many years.

Figure: **Secondary Syphilitic Infection on the Posterior Aspect of the Torso**: Dermatologic manifestations are the hallmark of secondary syphilis. Copper-red papules are most common, but macular, pustular, acneiform, psoriasiform, nodular, annular, or follicular variants can appear. The lesions characteristically do not itch, but may itch in some patients.

Figure: **Primary Syphilitic Infection of the Finger**: The chancre is usually firm, round, small, and painless, appearing at the spot where syphilis entered the body. It lasts three to six weeks and heals on its own. If adequate treatment is not administered, the infection progresses to the secondary stage.

DIAGNOSIS AND TREATMENT

Diagnosis is usually via blood tests, but the bacteria can also be visualized under a microscope. Syphilis can be effectively treated with antibiotics, specifically the preferred intramuscular penicillin G (given intravenously for neurosyphilis), or else ceftriaxone, and in those who have a severe penicillin allergy, oral doxycycline or azithromycin.

Syphilis is believed to have infected 12 million people globally in 1999, with more than 90 percent of cases in the developing world. Rates decreased dramatically after the widespread availability of penicillin in the 1940s. However, rates of infection have increased since the turn of the century in many countries, often in combination with human immunodeficiency virus (HIV). By some accounts, this has been attributed, in part, to unsafe sexual practices among men who have sex with men, increased promiscuity among all genders, prostitution, and decreasing use of barrier protection.

PRIMARY SYPHILIS

Primary syphilis is typically acquired by direct sexual contact with the infectious lesions of another person. Approximately three to 90 days after the initial exposure (average 21 days) a skin lesion, called a chancre, appears at the point of contact. This chancre is classically a single, firm, painless, non-itchy skin ulceration with a clean base and sharp borders between 0.3 and 3.0 cm in size. However, the lesion may take on almost any form. In the classic form, it evolves from a macule to a papule and finally to an erosion or ulcer. Occasionally, multiple lesions may be present, with multiple lesions more common when co-infected with HIV. Lesions may be painful or tender (in 30 percent of those infected), and they may occur outside of the genitals (2 to 7 percent). The lesion may persist for three to six weeks without treatment.

SECONDARY SYPHILIS

Secondary syphilis occurs approximately four to 10 weeks after the primary infection. While secondary disease is known for the many different ways it can manifest, symptoms most commonly involve the skin, mucous membranes, and lymph nodes. There may be a symmetrical, reddish-pink, non-itchy rash on the trunk and extremities, including the palms and soles of the feet. The rash may become maculopapular or pustular. It may form flat, broad, whitish, wart-like lesions known as condyloma latum on mucous membranes. All of these lesions harbor bacteria and are infectious.

Other symptoms may include fever, sore throat, malaise, weight loss, hair loss, and headache. Rare manifestations include hepatitis, kidney disease, arthritis, periostitis, optic neuritis, uveitis, and interstitial keratitis. The acute symptoms usually resolve after three to six weeks; however, about 25 percent of people may experience a recurrence of secondary symptoms.

NEUROSYPHILIS

Neurosyphilis occurs when syphilis is left untreated from many years. The brain and spinal cord become infected with the syphilis bacterium, Treponema pallidum, during the secondary stage of infection and can remain latent for 10 to 20 years after the initial infection. Eventually, this infection begins to damage the tissues of the brain and spinal cord, resulting in neurosyphilis. Neurosyphilis is characterized by neurological and psychiatric symptoms, such as confusion, blindness, abnormal gait and dementia. Left untreated, neurosyphilis symptoms will worsen over time and can lead to death. Treatment for neurosyphilis is the same as any other stage of syphilis, requiring only a short course of penicillin.

TRANSMISSION AND PREVENTION

Syphilis is transmitted primarily by sexual contact or during pregnancy from a mother to her fetus. The spirochete is able to pass through intact mucous membranes or compromised skin. Therefore, it is transmissible by kissing, or oral, vaginal, and anal sex. Approximately 30 to 60 percent of those exposed to primary or secondary syphilis will get the disease. It can be transmitted via blood products, but, many countries test for it, and thus the risk is low. The risk of transmission from sharing needles appears limited. Syphilis cannot be contracted through toilet seats, daily activities, hot tubs, or sharing eating utensils or clothing.

As of 2010, there is no vaccine effective for prevention. Abstinence from intimate physical contact with an infected person is effective at reducing the transmission of syphilis, as is the proper use of a latex condom. However, condom use does not completely eliminate the risk.

Key Points

- In addition to sexual contact, syphilis may also be transmitted from mother to child during pregnancy or at birth, resulting in congenital syphilis.

- Primary syphilis is typically acquired by direct sexual contact with the infectious lesions of another person, and usually presents with a single skin ulceration called a chancre.
- Secondary syphilis occurs approximately four to 10 weeks after the primary infection and may present as a symmetrical, reddish-pink, non-itchy rash on the trunk and extremities, including the palms and soles of the feet.
- Primary syphilis typically presents with a single skin ulceration called a chancre.
- Neurosyphilis refers to a syphilis infection that affects the central nervous system, and cardiovascular syphilis affects the cardiovascular system.
- Blood tests for syphilis are either treponemal or nontreponemal.
- The Tuskegee syphilis study, where African American men in rural Alabama were told they were receiving free health care and instead were given syphilis in order to study its symptoms and progression, is one of the most infamous cases of questionable medical ethics in US history.

Key Terms

- **congenital syphilis**: syphilis present in utero and at birth
- **Treponema pallidum**: A Gram-negative spirochaete bacterium with subspecies that cause treponemal diseases such as syphilis, bejel, pinta, and yaws.
- **chancre**: A skin lesion, sometimes associated with certain contagious diseases like syphilis.
- **syphilis**: a disease spread via sexual activity, caused by the bacterium Treponema pallidum
- **syphilis**: A disease spread via sexual activity, caused by the bacterium Treponema pallidum.

15.23F: Syphilis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.23G: Genital Ulcer Diseases

Genital ulcers are skin ulcers on the genital area caused by sexually transmitted diseases or noninfectious conditions.

Learning Objectives

- List the causes and symptoms of genital ulcers

Key Points

- The most common STDs that present with genital ulcers are genital herpes, syphilis, chlamydia and chancroid.
- Other than ulceration, enlarged lymph nodes in the groin area may be present, along with blisters and sores.
- To improve the outcome, treatment often starts before identification is complete, with medications chosen based on symptoms and epidemiological circumstances.

Key Terms

- **Behcet's syndrome**: Behcet's syndrome, or Behcet's disease, is an immune disorder that leads to inflammation of the blood vessels. Common symptoms include mouth and genital ulcers, as well as ocular issues.

Genital ulcers are skin ulcers located on the genital area and can be caused by a number of sexually transmitted diseases or other noninfectious conditions such as yeasts, trauma, lupus, rheumatoid arthritis or Behcet's syndrome.

Sexually Transmitted Genital Ulcers

When the reason for a genital ulcer is an infection, it can be caused by a number of sexually transmitted diseases. Among the most common are Herpes simplex virus (HSV), the genital herpes agent; *Treponema pallidum*, that causes syphilis; *Chlamydia trachomatis*, the cause of chlamydia; and *Haemophilus ducreyi*, the chancroid agent. In the United States, the most common reasons for genital ulcers in young and sexually active patients are genital herpes and syphilis.

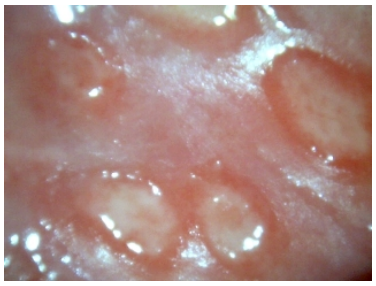

Figure: **Genital Ulcers**: Ulcers caused by genital herpes.

Symptoms and Diagnosis

Genital ulcers can be painful or painless depending on the type of infection. Their appearance can be slightly different from one disease to another. Other than ulceration, enlarged lymph nodes in the groin area can be present, along with blisters and sores. Proper diagnosis cannot be obtained solely through examination and medical history. Testing for a specific infectious agent depends on the likelihood of its presence. In the U.S., testing is recommended for syphilis (by serology and darkfield microscopy) and HSV (culture, serology or PCR), and in cases of chancroid outbreaks or based on the medical history, for the presence of *Haemophilus ducreyi*. In about 25% of the cases, the reason for the ulcer will not be identified by laboratory testing. Syphilis, genital herpes and chancroid have all been associated with increasing the risk for HIV transmission. The CDC recommends routine HIV screening for all patients who present with genital ulcers.

Treatment

Since the ulcers are symptoms of a number of infectious agents, the treatment is chosen according to the disease agent if it can be identified. Quite often, therapy has to start before identification is complete in order to decrease the chances for transmission and to increase the probability of successful treatment. The choice of medication is made, after careful examination of the symptoms and all epidemiological circumstances, based on the most likely causative agent.

15.23H: Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is a sexually transmitted disease which causes an infection of the lymph nodes.

Learning Objectives

- Outline the causes and disease stages for lymphogranuloma venereum (LGV)

Key Points

- The infectious agents are a few serovars of Chlamydia trachomatis: L1, L2, L2a, L2b and L3.
- The symptoms of LGV include enlarged and inflamed lymph nodes and lymph passages as well as infection of the surrounding tissues in the genital and abdominal areas.
- Treatment of LGV includes antibiotics and may require drainage of inflamed nodes.

Key Terms

- **serovar**: A group of microorganisms (viruses or bacteria), belonging to the same species, that are characterized by the presence of a specific antigen on their surface.
- **bubo**: An inflamed swelling of a lymph node, especially in the armpit or the groin, due to an infection such as bubonic plague, gonorrhea, tuberculosis or syphilis.

Lymphogranuloma venereum (LGV) is a sexually transmitted disease which was considered rare in the developed world until about a decade ago. LGV is an infection of the lymph nodes. The infectious agent enters the body through breaks in the skin or through the epithelial layer of mucous membranes.

Infectious Agents

The infectious agents are a few serovars of *Chlamydia trachomatis:* L1, L2, L2a, L2b and L3.

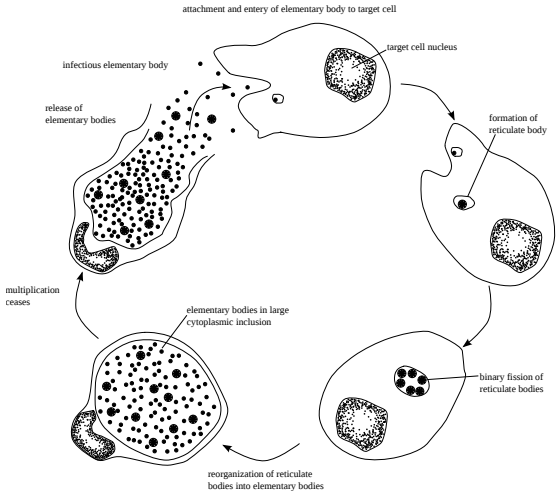

Figure: **Chlamydiae Life Cycle**: Basic diagram of the life cycle of the Chlamydiae. The infectious agents of Lymphogranuloma venereum are a few serovars of Chlamydia trachomatis: L1, L2, L2a, L2b and L3.

Symptoms and Diagnosis

The general symptoms may include fever, malaise and decreased appetite. The disease progresses in stages. In the primary stage, symptoms appear within days after infection. The first symptom is usually painless ulcers at the contact area.The secondary stage can manifest from days to months later. The infectious agent spreads to the lymph nodes through the lymphatic drainage pathways, causing inflammation of the lymph nodes and lymphatic channels. In males with genital infection, these symptoms will usually be in the inguinal or/and femoral areas. In women, an inflammation of the cervix, the fallopian tubes or/and peritonitis may appear as well as inflammation and infection of the lymphatic system. If the infection started in the anal area, it may cause inflammation of the rectum or the colonic mucosa, presenting with symptoms such as anorectal pain, discharge, abdominal cramps and diarrhea.

The enlarged lymph nodes are called buboes and are painful, inflamed and can fixate to the skin. These changes can further progress to necrosis, abscesses and fistulas. As healing starts, fibrosis may occur in the inflamed areas and cause obstruction of the lymphatic system and edema. The fibrosis and edema are considered the third stage of LGV and are mainly permanent. Diagnosis is made after serological analysis and exclusion of other reasons for genital ulcers and lymphatic issues. Culturing is also used for identification of serotypes. Other tests include direct fluorescent antibody analysis (DFA) and PCR tests.

Treatment

Treatment is performed with antibiotics, usually tetracycline, doxycycline or erythromycin. Sometimes drainage of the buboes or abscesses is performed as well. Prognosis is best if treatment starts early in the infection process. Severe complications include bowel obstruction or perforation, which can lead to death.

15.23H: Lymphogranuloma Venereum is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.23I: Group B Streptococcus Colonization

Group B streptococcus is part of the natural microflora in some people, but can sometimes cause life-threatening infections.

Learning Objectives

- Describe the pathogenic characteristics, symptoms and diagnostic test used for Group B streptococcus (GBS)

Key Points

- The most vulnerable groups of people to infection are newborns, the elderly, and people with compromised immune system.
- To prevent infections in infants, many countries routinely screen pregnant women for GBS in the third trimester.
- GBS infection is treated with antibiotics, with penicillin and ampicillin as the primary choice.

Key Terms

- **sepsis**: A life-threatening medical condition caused by a severe inflammatory response of the human body triggered by the presence of an infectious agent.

Group B Streptococcus Colonization

Group B streptococcus (GBS), also called *streptococcus agalactiae* or simply strep B, is part of the natural genital and intestinal microflora in some people. Studies indicate that as many as 40% of women can be carriers. It is usually harmless but under certain circumstances (in newborns, the elderly, and in people with compromised immune systems) it can cause life-threatening infections. The bacteria is gram-positive streptococcus, and possesses the group B antigen from the Lancefield classification. Its infectivity is due to the presence of a antiphagocytic polysaccharide capsule. If a pregnant woman is a carrier of strep B, the baby can become infected during vaginal delivery.

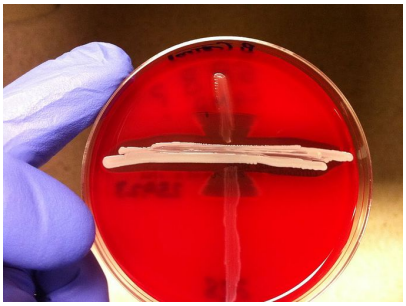

Figure: **The CAMP Test**: The collected sample is streaked on a blood agar plate (vertical streaks) next to staphylococcus aureus culture (horizontal streak). Strep B has weak hemolytic activity, which is enhanced substantially (arrow-like area) when streaked next to s. aureus. The reason for that is the interaction between the CAMP factor from strep B and the s. aureus hemolysin.

Symptoms and diagnosis

Healthy adults are usually asymptomatic carriers of the bacteria. Sometimes it can manifest with urinary tract infections (UTIs) in both pregnant and nonpregnant women. In newborns, the first symptoms are breathing difficulties and pneumonia, which can progress to meningitis and sepsis. In elderly people, it can cause pneumonia and/or UTI and is linked to congestive heart failure. A number of different tests are used as diagnostic tools. Screening pregnant women for GBS, usually in the third trimester, is currently routine in many countries. In the cases of positive status, antibiotics are administered during labor to substantially lower the risk of infection for the baby. This strategy has lead to a significant drop in the rates of infant infection in these countries. A very common diagnostic test is the CAMP test named after the three people that discovered it. Sometimes, before plating, enrichment of the gathered probe is performed. This includes sample growth in special medium that will favor its growth over the other bacteria collected with the specimen. The method of enrichment followed by the CAMP tests is currently the gold standard for GBS diagnosis. It lowers significantly the rates of false negatives. However, culturing takes days and is not feasible if labor starts before screening was completed or in cases when it was not performed at all. The best diagnostic tool will allow identification during labor. PCR techniques are faster but they are still complicated and not fast enough to be used widely for diagnostics once labor has started. TreatmentPregnant women who are carriers of GBS are administered penicillin or ampicillin during labor. These antibiotics are the primary choice for GBS therapy in general, since the bacteria are becoming increasingly resistant to many other common antibiotics.

15.23I: Group B Streptococcus Colonization is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.23J: Chancroid (Soft Chancre)

Chancroid is a sexually transmitted disease caused by *Haemophilus ducreyi*.

Learning Objectives

- Recognize the symptoms, causes and treatment for chancroid

Key Points

- Chancroid is becoming rarer worldwide but there are sporadic outbreaks even in countries where it is uncommon.
- The most common symptoms for chancroid are enlarged lymph nodes and painful, bleeding ulcers with distinctive characteristics.
- Chancroid is treated with single doses of antibiotics like azythromycin or ceftriaxone, or with erythromycin for a week.

Key Terms

- **fastidious**: Microorganisms that are difficult to culture since they need specific nutrients in their medium to grow.
- **lymphadenopathy**: An abnormal enlargement of the lymph nodes

Chancroid (soft chancre) is a sexually transmitted disease and can only be spread through sexual contact. It is becoming rarer worldwide with sporadic outbreaks in countries where it is uncommon. This disease is a risk factor for HIV infection.

Infectious Agent

Chancroid is caused by *Haemophilus ducreyi*, a gram-negative fastidious organism. It enters the body through breaks in the skin.

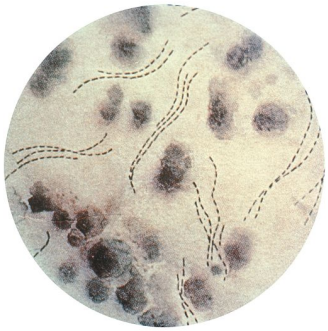

Figure: **Haemophilus ducreyi**: A microscopic image of the bacteria that causes chancroid. The stain used is Gentian Violet and the bacteria are bacilli organized in chains.

Symptoms and Diagnosis

The incubation period of chancroid is between one to fourteen days. The area of infection gets inflamed as cells of the immune system gather to fight the invading organism. Between 30-60% of the patients can also develop lymphadenopathy. Quite often, these enlarged lymph nodes can rupture through the skin and produce draining abscesses.The first symptoms after infection are small painless bumps which quickly become painful ulcers. These ulcers can be quite different in size. The base of the ulcers is usually covered in a gray or yellow substance and bleeds easily. They are typically located in specific ares for men and women. Men often have only one ulcer while women present with multiple ulcers. Women have other symptoms as well such as pain during urination and intercourse. For proper diagnosis, the other two infectious agents that can present with similar although not identical ulcers need to be excluded. Tests for the identification of *Treponema pallidium* (causes syphilis) and HSV (Herpes Simplex Virus, type 2) may be performed to exclude the possibility that ulcers are caused by those agents instead of *Haemophilus ducreyi*. For identification, samples from patients are cultured on chocolate agar. Even though serological and genetic tests can be used for identification, they are not widely used and culturing is the main tool for identifying *Haemophilus ducreyi*.

Treatment

Chancroid is treated with single doses of antibiotics like azythromycin or ceftriaxone, or with erythromycin for a week.

15.23J: Chancroid (Soft Chancre) is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.23K: Bacterial Vaginosis

Bacterial vaginosis (BV) is a condition of disrupted balance of the vaginal microflora.

Learning Objectives

- Describe the symptoms, causes and methods of diagnosis for bacterial vaginosis

Key Points

- The most common symptom is white or gray discharge, that can be thin, with fish-like odor (especially strong after intercourse).
- Common bacterial species that can overgrow and cause symptoms of BV are Gardnerella vaginalis, Mobiluncus, Bacteroides and Mycoplasma.
- The treatment regimen is most often metronidizole (for seven days) or clindamycin. BV has high recurrence rates.

Key Terms

- **recurrence**: The returning of a disease that was already treated successfuly.

Bacterial vaginosis (BV) is a condition where the vaginal microflora in women have become disrupted. BV is not a typical sexually transmitted disease since women who have never had sexual contact can suffer from this condition, too. However, having sex with a new partner or multiple partners increases the risk of getting BV but it is unclear how and why that happens. BV is a very common condition and it is estimated that about 1 in 3 women will develop it in their lifetime.

Symptoms and diagnosis

Bacterial vaginosis may be completely asymptomatic. The most common symptom is white or gray discharge, that can be thin, with fish-like odor (especially strong after intercourse). Sometimes itching outside of the vagina or/and burning during urination can also be present. For diagnosis in the clinical practice, a swab from the vaginal wall is obtained and examined with a few different tests called the *Amsel* criteria:

- the discharge should be thin, white, yellow and homogenous
- clue cells must be present in the specimen when observed under the microscope
- pH > 4.5
- the release of fishy odor after the addition of 10% KOH to the specimen

At least three of these tests have to be positive for conclusive diagnosis. Alternative tests can be performed as well and they usually involve Gram staining of the specimen and observing the types of bacteria present in it. Infectious agentsThe normal vaginal microflora contains many species with *Lactobacillus* as the dominant representative. Some *Lactobacilli* produce hydrogen peroxide which can prevent the overgrowth of bacteria that will disturb the balance and cause BV. Some of the bacteria that will produce BV symptoms are *Gardnerella vaginalis*, *Mobiluncus*, *Bacteroides*, and *Mycoplasma*. Factors that are known to disturb the balance are: antibiotics, pH imbalance (douching can alter vaginal pH), psychosocial stress, iron deficiency anemia in pregnant women and women with STD.

Women who already have BV are at increased risk for sexually transmitted diseases including HIV. Bacterial vaginosis during pregnancy increases the risk of premature birth. TreatmentThe treatment regimen is most often *metronidizole* (for seven days) or *clindamycin*. The treatment is usually successful but BV has high rates of recurrence. Treatment of male sex partners is usually not recommended but BV can be transferred to female sex partners.

15.23K: Bacterial Vaginosis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.23L: Chlamydia

Chlamydia infection is a common sexually transmitted infection (STI) in humans caused by the bacterium Chlamydia trachomatis.

Learning Objectives

- Describe the effects of chlamydia in men and women

Key Points

- Chlamydia infection is one of the most common sexually transmitted infections worldwide; it is estimated that about 1 million individuals in the United States are infected with chlamydia.
- Between half and three-quarters of all women who have a chlamydia infection of the cervix (cervicitis) have no symptoms and do not know that they are infected.
- C. trachomatis infection can be effectively cured with antibiotics once it is detected. Current guidelines recommend azithromycin, doxycycline, erythromycin, or ofloxacin.Agents recommended for pregnant women include erythromycin or amoxicillin.

Key Terms

- **azithromycin**: A macrolide antibiotic derived from erythromycin.
- **sexually transmitted disease**: any of various diseases that are usually contracted through sexual contact

Chlamydia infection (from the Greek meaning “cloak”) is a common sexually transmitted infection (STI) in humans caused by the bacterium Chlamydia trachomatis. The term Chlamydia infection can also refer to infection caused by any species belonging to the bacterial family Chlamydiaceae. C. trachomatis is found only in humans.

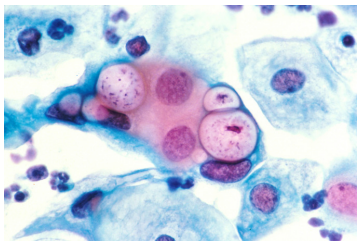

Figure: **Chlamydia**: Pap smear showing C. trachomatis (H&E stain).

Chlamydia is a major infectious cause of human genital and eye disease. Chlamydia infection is one of the most common sexually transmitted infections worldwide; it is estimated that about 1 million individuals in the United States are infected with chlamydia. C. trachomatis is naturally found living only inside human cells. Chlamydia can be transmitted during vaginal, anal, or oral sex, and can be passed from an infected mother to her baby during vaginal childbirth. Between half and three-quarters of all women who have a chlamydia infection of the cervix (cervicitis) have no symptoms and do not know that they are infected. In men, infection of the urethra (urethritis) is usually symptomatic, causing a white discharge from the penis with or without pain on urinating (dysuria).

Occasionally, the condition spreads to the upper genital tract in women (causing pelvic inflammatory disease) or to the epididymis in men (causing epididymitis). If untreated, chlamydial infections can cause serious reproductive and other health problems with both short-term and long-term consequences.

Genital disease

Chlamydial cervicitis in a female patient characterized by mucopurulent cervical discharge, erythema, and inflammation. Male patients may develop a white, cloudy or watery discharge from the tip of the penis.

Women

Chlamydial infection of the neck of the womb (cervicitis) is a sexually transmitted infection which is asymptomatic for about 50-70% of women infected with the disease. The infection can be passed through vaginal, anal, or oral sex. Of those who have an asymptomatic infection that is not detected by their doctor, approximately half will develop pelvic inflammatory disease (PID), a generic term for infection of the uterus, fallopian tubes, and/or ovaries. PID can cause scarring inside the reproductive organs,

which can later cause serious complications, including chronic pelvic pain, difficulty becoming pregnant, ectopic (tubal) pregnancy, and other dangerous complications of pregnancy.Chlamydia is known as the “Silent Epidemic” because in women, it may not cause any symptoms in 75% of cases, and can linger for months or years before being discovered. Symptoms that may occur include unusual vaginal bleeding or discharge, pain in the abdomen, painful sexual intercourse (dyspareunia), fever, painful urination or the urge to urinate more frequently than usual (urinary urgency).

Men

In men, chlamydia shows symptoms of infectious urethritis (inflammation of the urethra) in about 50% of cases. Symptoms that may occur include: a painful or burning sensation when urinating, an unusual discharge from the penis, swollen or tender testicles, or fever. Discharge, or the purulent exudate, is generally less viscous and lighter in color than for gonorrhea. If left untreated, it is possible for chlamydia in men to spread to the testicles causing epididymitis, which in rare cases can cause sterility if not treated within 6 to 8 weeks. Chlamydia is also a potential cause of prostatitis in men, although the exact relevance in prostatitis is difficult to ascertain due to possible contamination from urethritis.

Treatment

C. trachomatis infection can be effectively cured with antibiotics once it is detected. Current guidelines recommend azithromycin, doxycycline, erythromycin, or ofloxacin. Agents recommended for pregnant women include erythromycin or amoxicillin.

An option for treating partners of patients (index cases) diagnosed with chlamydia or gonorrhea is *patient-delivered partner therapy*(PDT or PDPT), which is the clinical practice of treating the sex partners of index cases by providing prescriptions or medications to the patient to take to his/her partner without the health care provider first examining the partner.

SECTION OVERVIEW

15.24: Viral Diseases of the Reproductive System

Topic hierarchy

15.24A: Genital Herpes

15.24B: Genital Warts

15.24C: HIV and AIDS

15.24D: Human Papillomavirus (HPV)

15.24: Viral Diseases of the Reproductive System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.24A: Genital Herpes

Herpes genitalis (or genital herpes) refers to a genital infection by Herpes simplex virus.

Learning Objectives

- Recognize the causes and symptoms of herpes simplex virus (HSV) 1 and 2

Key Points

- Although genital herpes is largely believed to be caused by HSV-2, genital HSV-1 infections are increasing and now exceed 50% in certain populations.
- In males, symptoms of genital herpes include lesions that occur on the glans penis, shaft of the penis or other parts of the genital region, on the inner thigh, buttocks, or anus. In females, lesions appear on or near the pubis, labia, clitoris, vulva, buttocks or anus.
- Presently, genital herpes cannot be cured. Moreover, genital herpes can be transmitted by viral shedding prior to and following the visual signs of symptoms. There are however some drugs that can shorten outbreaks and make them less severe or even stop them from happening.

Key Terms

- **acyclovir**: An antiviral drug used in the treatment of genital herpes.
- **viral shedding**: the successful reproduction, expulsion, and host-cell infection caused by virus progeny.

Herpes genitalis (or genital herpes) refers to a genital infection by Herpes simplex virus. Following the classification HSV into two distinct categories of HSV-1 and HSV-2 in the 1960s, it was established that “HSV-2 was below the waist, HSV-1 was above the waist”.

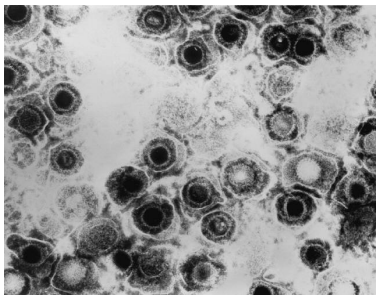

Figure: **Transmission electron micrograph of herpes simplex virus.**: TEM micrograph of a herpes simplex virus.

Although genital herpes is largely believed to be caused by HSV-2, genital HSV-1 infections are increasing and now exceed 50% in certain populations, and that rule of thumb no longer applies. HSV is believed to be asymptomatic in the majority of cases, thus aiding contagion and hindering containment. When symptomatic, the typical manifestation of a primary HSV-1 or HSV-2 genital infection is clusters of genital sores consisting of inflamed papules and vesicles on the outer surface of the genitals, resembling cold sores. These usually appear 4–7 days after sexual exposure to HSV for the first time. Genital HSV-1 infection recurs at rate of about one sixth of that of genital HSV-2.

In males, the lesions occur on the glans penis, shaft of the penis or other parts of the genital region, on the inner thigh, buttocks, or anus. In females, lesions appear on or near the pubis, labia, clitoris, vulva, buttocks or anus. Other common symptoms include pain, itching, and burning. Less frequent, yet still common, symptoms include discharge from the penis or vagina, fever, headache, muscle pain (myalgia), swollen and enlarged lymph nodes and malaise. Women often experience additional symptoms that include painful urination (dysuria) and cervicitis. Herpetic proctitis (inflammation of the anus and rectum) is common for individuals participating in anal intercourse.After 2–3 weeks, existing lesions progress into ulcers and then crust and heal, although lesions on mucosal surfaces may never form crusts. In rare cases, involvement of the sacral region of the spinal cord can cause acute urinary retention and one-sided symptoms and signs of myeloradiculitis (a combination of myelitis and radiculitis): pain, sensory loss, abnormal sensations (paresthesia) and rash. Historically this has been termed Elsberg syndrome, although this entity is not clearly defined.

Treatment

Medical research has not been able to find a way to halt the spread of herpes and the number of infected people keeps growing. In the United States alone, 45 million people are infected, with an additional one million new infections occurring every year. Presently, genital herpes cannot be cured. Moreover, genital herpes can be transmitted by viral shedding prior to and following the visual signs of symptoms. There are however some drugs that can shorten outbreaks and make them less severe or even stop them from happening.

Among these drugs are: acyclovir, valacyclovir and famciclovir.Acyclovir is an antiviral drug used against herpes viruses, varicella-zoster, and Epstein-Barr Viruses. This drug reduces the pain and the number of lesions in the initial case of genital herpes. Furthermore, it decreases the frequency and severity of recurrent infections. It comes in capsules, tablets, suspension, injection, powder for injection, and ointment. The ointment is used topically and it decreases pain, reduces healing time, and limits the spread of the infection.Valacyclovir is also used to treat herpes virus infections. Once in the body, it becomes the anti-herpes medicine, acyclovir. It helps relieve the pain and discomfort and the sores heal faster. It only comes in caplets and its advantage is that it has a longer duration of action than acyclovir. Famciclovir is another antiviral drug that belongs to the same class of acyclovir and valacyclovir. Famciclovir is a prodrug that is converted to penciclovir in the body. The latter is the one active against the viruses. This drug has a longer duration of action than acyclovir and it only comes in tablets.

15.24A: Genital Herpes is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.24B: Genital Warts

Genital warts is a highly contagious sexually transmitted disease caused by some sub-types of human papillomavirus (HPV).

Learning Objectives

- List the causes and various management procedures for genital warts

Key Points

- Warts are the most easily recognized symptom of genital HPV infection, where types 6 and 11 are responsible for 90% of genital warts cases.
- Genital warts spread through direct skin-to-skin contact during oral, genital, or anal sex with an infected partner.
- Genital warts, histopathologically, characteristically rise above the skin surface due to enlargement of the dermal papillae, have parakeratosis and the characteristic nuclear changes typical of HPV infections (nuclear enlargement with perinuclear clearing).
- There is no cure for HPV, but there are methods to treat visible warts, which could reduce infectivity, although there are no trials studying the effectiveness of removing visible warts in reducing transmission.

Key Terms

- **human papillomavirus**: A virus that affects humans, sometimes causing cervical or other cancer; it is sometimes classified as a sexually transmitted disease.

Genital warts (or Condylomata acuminata, venereal warts, anal warts and anogenital warts) is a highly contagious sexually transmitted disease caused by some sub-types of human papillomavirus (HPV). It is spread through direct skin-to-skin contact during oral, genital, or anal sex with an infected partner. Throat, mouth, and eye genital warts can also be transmitted through oral, genital, or anal sex. Warts are the most easily recognized symptom of genital HPV infection, where types 6 and 11 are responsible for 90% of genital warts cases.

Although it is estimated that only a “small percentage” (between 1% and 5%) of those infected with genital HPV develop genital warts, those infected can still transmit the virus. Other types of HPV also cause cervical cancer and probably most anal cancers, however it is important to underline that the types of HPV that cause the overwhelming majority of genital warts are not the same as those that can potentially increase the risk of genital or anal cancer. HPV prevalence at any one time has been observed in some studies at 27% over all sexually active people, rising to 45% between the ages of 14 and 19.

Diagnosis

Genital warts, histopathologically, characteristically rise above the skin surface due to enlargement of the dermal papillae, have parakeratosis and the characteristic nuclear changes typical of HPV infections (nuclear enlargement with perinuclear clearing).

Prevention

Gardasil (sold by Merck & Co.) is a vaccine that protects against human papillomavirus types 16, 18, 6, and 11. Types 6 and 11 cause genital warts, while 16 and 18 cause cervical cancer. The vaccine is preventive, not therapeutic, and must be given before exposure to the virus type to be effective, ideally before the beginning of sexual activity. The vaccine is widely approved for use by young women, it is being tested for young men, and has been approved for males in some areas, such as the UK, the US and Canada.

Management

There is no cure for HPV, but there are methods to treat visible warts, which could reduce infectivity, although there are no trials studying the effectiveness of removing visible warts in reducing transmission. Every year, Americans spend $200 million on the treatment of genital warts. Genital warts may disappear without treatment, but sometimes eventually develop a fleshy, small raised growth. There is no way to predict whether they will grow or disappear.

Warts can sometimes be identified because they show up as white when acetic acid is applied, but this method is not recommended on the vulva because microtrauma and inflammation can also show up as acetowhite. Magnifying glasses or colposcope may also be used to aid in identifying small warts. Depending on the sizes and locations of warts (as well as other factors), a doctor will offer one of several ways to treat them. Podofilox is the first-line treatment due to its low cost.Almost all treatments can potentially

cause depigmentation or scarring. A 0.15% – 0.5% podophyllotoxin (also called podofilox) solution in a gel or cream. Marketed as Condylox (0.5%), Wartec (0.15%) and Warticon (0.15%), it can be applied by the patient to the affected area and is not washed off. It is the purified and standardized active ingredient of the podophyllin (see below). Podofilox is safer and more effective than podophyllin. Skin erosion and pain are more commonly reported than with imiquimod and sinecatechins. Its use is cycled (2 times per day for 3 days then 4–7 days off); one review states that it should only be used for four cycles.

Imiquimod (Aldara) is a topical immune response cream, applied to the affected area. It causes less local irritation than podofilox but may cause fungal infections (11% in package insert) and flu-like symptoms (less than 5% disclosed in package insert). Sinecatechins (marketed as Veregen and Polyphenon E) is an ointment of catechins (55% epigallocatechin gallate) extracted from green tea and other components. Mode of action is undetermined. It appears to have higher clearance rates than podophyllotoxin and imiquimod and causes less local irritation, but clearance takes longer than with imiquimod. Liquid nitrogen cryosurgery is safe for pregnancy. It kills warts 71–79% of the time, but recurrence is 38% to 73% 6 months after treatment. Local infections have been reported. Trichloroacetic acid (TCA) is less effective than cryosurgery, and is not recommended for use in the vagina, cervix, or urinary meatus. Surgical excision is best for large warts, and has a greater risk of scarring. Laser ablation does not seem to be any more effective than other physician-applied methods, but is often used as a last resort and is extremely expensive. A 20% podophyllin anti-mitotic solution, applied to the affected area and later washed off. However, this crude herbal extract is not recommended for use on vagina, urethra, perianal area, or cervix, and must be applied by a physician.

Reported reactions include nausea, vomiting, fever, confusion, coma, renal failure, ileus, and leukopenia; death has been reported with extensive topical application, or application on mucous membranes. Interferon can be used; it is effective, but it is also expensive and its effect is inconsistent. Electrocauterization can be used; it is an older procedure but recovery time is generally longer. In severe cases of genital warts, treatment may require general or spinal anesthesia. This is a surgical procedure. More effective than cryosurgery and recurrence is at a much lower rate. Oral Isotretinoin is a therapy that has proven effective in experimental use, but is rarely used due to potentially severe side effects. In a small-scale study, low dose oral isotretinoin showed considerable efficacy and may represent an alternative systemic form of therapy for Genital Warts. Yet, albeit this indicative evidence not many studies have been conducted to further confirm the findings. In most countries this therapy is currently unapproved and only used as an alternative therapy if other therapies failed.

15.24B: Genital Warts is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.24C: HIV and AIDS

Human immunodeficiency virus infection/acquired immunodeficiency syndrome is a disease of the human immune system caused by HIV.

Learning Objectives

- Describe the mode of transmission, mechanisms of infection, treatment options, and WHO and CDC classifications for the human immunodeficiency virus (HIV)

Key Points

- During the initial HIV infection a person may experience a brief period of influenza-like illness. This is typically followed by a prolonged period without symptoms.
- HIV is transmitted primarily via unprotected sexual intercourse (including anal and even oral sex), contaminated blood transfusions and hypodermic needles, and from mother to child during pregnancy, delivery, or breastfeeding.
- Abacavir, a nucleoside analog reverse transcriptase inhibitor (NARTI or NRTI) is used to treat HIV. Current HAART options are combinations (or “cocktails”) consisting of at least three medications belonging to at least two types, or “classes,” of antiretroviralagents.

Key Terms

- **immunodeficiency**: A depletion in the body’s natural immune system, or in some component of it.
- **AIDS**: an infectious disease, caused by HIV, that causes the gradual degeneration of the body’s immune system

Human immunodeficiency virus infection / acquired immunodeficiency syndrome (HIV/ AIDS) is a disease of the human immune system caused by the human immunodeficiency virus (HIV). During the initial infection a person may experience a brief period of influenza-like illness. This is typically followed by a prolonged period without symptoms. As the illness progresses it interferes more and more with the immune system, making people much more likely to get infections, including opportunistic infections, and tumors that do not usually affect people with working immune systems.

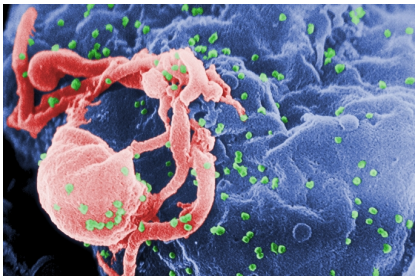

Figure: **HIV-1**: Scanning electron micrograph of HIV-1, colored green, budding from a cultured lymphocyte.

HIV is transmitted primarily via unprotected sexual intercourse (including anal and even oral sex), contaminated blood transfusions and hypodermic needles, and from mother to child during pregnancy, delivery, or breastfeeding. Some bodily fluids, such as saliva and tears, do not transmit HIV. Prevention of HIV infection, primarily through safe sex and needle-exchange programs, is a key strategy to control the spread of the disease. There is no cure or vaccine; however, antiretroviral treatment can slow the course of the disease and may lead to a near-normal life expectancy. While antiretroviral treatment reduces the risk of death and complications from the disease, these medications are expensive and may be associated with side effects.

Virology

HIV is the cause of the spectrum of disease known as HIV/AIDS. HIV is a retrovirus that primarily infects components of the human immune system such as CD4+ T cells, macrophages and dendritic cells. It directly and indirectly destroys CD4+ T cells.HIV is a member of the genus Lentivirus, part of the family of Retroviridae. Lentiviruses share many morphological and biological characteristics. Many species of mammals are infected by lentiviruses, which are characteristically responsible for long-duration illnesses with a long incubation period. Lentiviruses are transmitted as single-stranded, positive-sense, enveloped RNA viruses. Upon entry into the target cell, the viral RNA genome is converted (reverse transcribed) into double-stranded DNA by a virally encoded reverse transcriptase that is transported along with the viral genome in the virus particle. The resulting viral DNA is

then imported into the cell nucleus and integrated into the cellular DNA by a virally encoded integrase and host co-factors. Once integrated, the virus may become latent, allowing the virus and its host cell to avoid detection by the immune system. Alternatively, the virus may betranscribed, producing new RNA genomes and viral proteins that are packaged and released from the cell as new virus particles that begin the replication cycle anew. Two types of HIV have been characterized: HIV-1 and HIV-2. HIV-1 is the virus that was originally discovered (and initially referred to also as LAV or HTLV-III). It is more virulent, more infective, and is the cause of the majority of HIV infections globally. The lower infectivity of HIV-2 as compared with HIV-1 implies that fewer people exposed to HIV-2 will be infected per exposure. Because of its relatively poor capacity for transmission, HIV-2 is largely confined to West Africa.

Classifications of HIV infection

Two main clinical staging systems are used to classify HIV and HIV-related disease for surveillance purposes: the WHO disease staging system for HIV infection and disease, and the CDC classification system for HIV infection. The CDC's classification system is more frequently adopted in developed countries. Since the WHO's staging system does not require laboratory tests, it is suited to the resource-restricted conditions encountered in developing countries, where it can also be used to help guide clinical management. Despite their differences, the two systems allow comparison for statistical purposes.

The World Health Organization first proposed a definition for AIDS in 1986. Since then, the WHO classification has been updated and expanded several times, with the most recent version being published in 2007. The WHO system uses the following categories:

Primary HIV infection: May be either asymptomatic or associated with acute retroviral syndrome.

Stage I: HIV infection is asymptomatic with a CD4+ T cell count (also known as CD4 count) greater than 500/uL. May include generalized lymph node enlargement.

Stage II: Mild symptoms which may include minor mucocutaneous manifestations and recurrent upper respiratory tract infections. A CD4 count of less than 500/uL.

Stage III: Advanced symptoms which may include unexplained chronic diarrhea for longer than a month, severe bacterial infections including tuberculosis of the lung as well as a CD4 count of less than 350/uL.

Stage IV or AIDS: severe symptoms which includes toxoplasmosis of the brain, candidiasis of the esophagus, trachea, bronchi or lungs and Kaposi's sarcoma. A CD4 count of less than 200/uL.

The United States Center for Disease Control and Prevention also created a classification system for HIV, and updated it in 2008. In this system HIV infections are classified based on CD4 count and clinical symptoms, and describes the infection in three stages:

Stage 1: CD4 count ≥ 500 cells/uL and no AIDS defining conditions

Stage 2: CD4 count 200 to 500 cells/uL and no AIDS defining conditions

Stage 3: CD4 count ≤ 200 cells/uL or AIDS defining conditions

Unknown: if insufficient information is available to make any of the above classificationsFor surveillance purposes, the AIDS diagnosis still stands even if, after treatment, the CD4+ T cell count rises to above 200 per µL of blood or other AIDS-defining illnesses are cured.

Antiviral therapy

Abacavir, a nucleoside analog reverse transcriptase inhibitor (NARTI or NRTI) is used to treat HIV. Current HAART options are combinations (or "cocktails") consisting of at least three medications belonging to at least two types, or "classes," of antiretroviralagents. Initially treatment is typically a non-nucleoside reverse transcriptase inhibitor (NNRTI) plus two nucleoside analogue reverse transcriptase inhibitors(NRTIs). Typical NRTIs include: zidovudine (AZT) or tenofovir (TDF) and lamivudine (3TC) or emtricitabine (FTC). Combinations of agents which include a protease inhibitors (PI) are used if the above regime loses effectiveness.

15.24C: HIV and AIDS is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.24D: Human Papillomavirus (HPV)

Human papillomavirus (HPV) is a virus from the papillomavirus family that is capable of infecting humans.

Learning Objectives

- Discuss the relationship between the human papillomavirus (HPV) and the development of cancer

Key Points

- HPVs establish productive infections only in keratinocytes of the skin or mucous membranes.
- While the majority of the known types of HPV cause no symptoms in most people, some types can cause warts (verrucae), while others can – in a minority of cases – lead to cancers of the cervix, vulva, vagina, penis, oropharynx and anus.
- In more developed countries, cervical screening using a Papanicolaou (Pap) test or liquid-based cytology is used to detect abnormal cells that may develop into cancer. If abnormal cells are found, women are invited to have a colposcopy.
- HPV vaccines (Cervarix and Gardasil), which prevent infection with the HPV types (16 and 18) that cause 70% of cervical cancer, may lead to further decreases in cervical cancer.

Key Terms

- **verrucae**: warts
- **Papanicolaou (Pap) test**: screening of the cervical cells used to detect abnormal cells that may develop into cancer.

Human papillomavirus (HPV) is a virus from the papillomavirus family that is capable of infecting humans. Like all papillomaviruses, HPVs establish productive infections only in keratinocytes of the skin or mucous membranes. While the majority of the known types of HPV cause no symptoms in most people, some types can cause warts (verrucae), while others can – in a minority of cases – lead to cancers of the cervix, vulva, vagina, penis, oropharynx and anus. Recently, HPV has been linked with an increased risk of cardiovascular disease. In addition, HPV 16 and 18 infections are strongly associated with an increased odds ratio of developing oropharyngeal (throat) cancer.

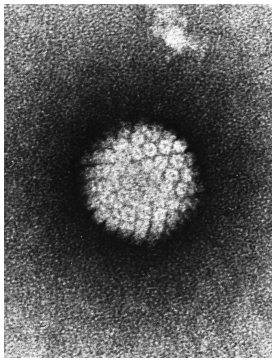

Figure: **EM of HPV**: TEM of papillomavirus.

More than 30 to 40 types of HPV are typically transmitted through sexual contact and infect the anogenital region. Some sexually transmitted HPV types may cause genital warts. Persistent infection with “high-risk” HPV types — different from the ones that cause skin warts — may progress to precancerous lesions and invasive cancer. HPV infection is a cause of nearly all cases of cervical cancer. However, most infections with these types do not cause disease.

Most HPV infections in young females are temporary and have little long-term significance. Seventy percent of infections are gone in 1 year and ninety percent in 2 years. However, when the infection persists — in 5% to 10% of infected women — there is high risk of developing precancerous lesions of the cervix, which can progress to invasive cervical cancer. This process usually takes 10–15 years, providing many opportunities for detection and treatment of the pre-cancerous lesion. Progression to invasive cancer can be almost always prevented when standard prevention strategies are applied, but the lesions still cause considerable burden necessitating preventive surgeries, which do in many cases involve loss of fertility.

In more developed countries, cervical screening using a Papanicolaou (Pap) test or liquid-based cytology is used to detect abnormal cells that may develop into cancer. If abnormal cells are found, women are invited to have a colposcopy. During a colposcopic inspection, biopsies can be taken and abnormal areas can be removed with a simple procedure, typically with a cauterizing loop or,

more commonly in the developing world — by freezing (cryotherapy). Treating abnormal cells in this way can prevent them from developing into cervical cancer.

Pap smears have reduced the incidence and fatalities of cervical cancer in the developed world, but even so there were 11,000 cases and 3,900 deaths in the U.S. in 2008. Cervical cancer has substantial mortality in resource-poor areas; worldwide, there are an estimated 490,000 cases and 270,000 deaths each year.

HPV vaccines (Cervarix and Gardasil), which prevent infection with the HPV types (16 and 18) that cause 70% of cervical cancer, may lead to further decreases.

SECTION OVERVIEW

15.25: Fungal and Protozoan Diseases of the Reproductive System

Topic hierarchy

15.25A: Vulvovaginal Candidiasis

15.25B: Trichomoniasis

15.25C: The TORCH Panel of Tests

15.25: Fungal and Protozoan Diseases of the Reproductive System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.25A: Vulvovaginal Candidiasis

Candidal vulvovaginitis is an infection of the vagina's mucous membranes caused by Candida albicans.

Learning Objectives

- Analyze the symptoms and factors involved in vulvovaginal candidiasis

Key Points

- Up to 75% of women will have this infection at some point in their lives, and approximately 5% will have recurring episodes. It is the second most common cause of vaginal inflammation after bacterial vaginosis.
- The Candida species of fungus is found naturally in the vagina, and is usually harmless.
- It is not known exactly how changes in the vagina trigger thrush, but it may be due to a hormone (chemical) imbalance. In most cases, the cause of the hormonal changes is unknown. Some possible risk factors have been identified, such as taking antibiotics.

Key Terms

- **Candida albicans**: a diploid asexual fungus (a form of yeast). An overgrowth results in candidiasis in immunocompromised patients.
- **vulvovaginal candidiasis**: candidal vulvovaginitis or vaginal thrush is an infection of the vagina's mucous membranes by Candida albicans.

Candidal vulvovaginitis or vaginal thrush is an infection of the vagina's mucous membranes by Candida albicans. Up to 75% of women will have this infection at some point in their lives, and approximately 5% will have recurring episodes. It is the second most common cause of vaginal inflammation after bacterial vaginosis.

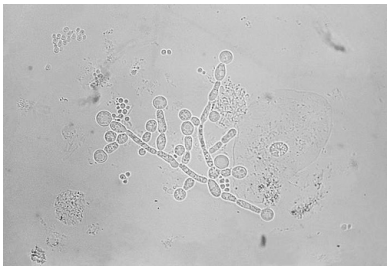

Figure: **Candida albicans**: Tramsmission photomicrograph showing a number of Candida albicans chlamydospores.

It is most commonly caused by a type of fungus known as Candida albicans. The Candida species of fungus is found naturally in the vagina, and is usually harmless. However, if the conditions in the vagina change, Candida albicans can cause the symptoms of thrush. Symptoms of thrush can also be caused by Candida glabrata, Candida krusei, Candida parapsilosis, and Candida tropicalis. Non-albican Candida are commonly found in complicated cases of vaginal thrush such that first line treatment is ineffective. These cases are more likely in immunocompromised patients.

It is not known exactly how changes in the vagina trigger thrush, but it may be due to a hormone (chemical) imbalance. In most cases, the cause of the hormonal changes is unknown. Some possible risk factors have been identified, such as taking antibiotics.

The symptoms of vaginal thrush include vulval itching, vulval soreness and irritation, pain or discomfort during sexual intercourse (superficial dyspareunia), pain or discomfort during urination (dysuria) and vaginal discharge, which is usually odorless. The discharge can be thin and watery, or thick and white, like cottage cheese.

In addition to the above symptoms of thrush, vulvovaginal inflammation can also be present. The signs of vulvovaginal inflammation include erythema (redness) of the vagina and vulva, vagina fissuring (cracked skin), oedema (swelling from a build-up of fluid), also in severe cases, satellite lesions (sores in the surrounding area). This is rare, but may indicate the presence of another fungal condition, or the herpes simplex virus (the virus that causes genital herpes).

While vulvovaginal candidiasis is caused by a the yeast Candida there are many predisposing factors:

- Infection occurs in about 30% of women who are taking a course of oral antibiotics. The evidence of the effect of oral contraceptives is controversial.

- In pregnancy, changes in the levels of female sex hormones, such as estrogen, make a woman more likely to develop a yeast infection. During pregnancy, the Candida fungus is more prevalent (common), and recurrent infection is also more likely.
- Frequency of sexual intercourse appears to be related to the frequency of infections, however infections often occur without sex. Tight-fitting clothing, such as tights and thong underwear, do not appear to increase the risk. Neither do personal hygiene methods.
- Those with poorly controlled diabetes have increased rates of infection while those with well-controlled diabetes do not.
- The risk of developing thrush is also increased in a immunodeficiency, for example, by an immunosuppressive condition, such as HIV or AIDS, or receiving chemotherapy. This is because in these circumstances the body's immune system, which usually fights off infection, is unable to effectively control the spread of the Candida fungus.

15.25A: Vulvovaginal Candidiasis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.25B: Trichomoniasis

Trichomoniasis is primarily an infection of the urogenital tract; the most common site of infection is the urethra and the vagina in women.

Learning Objectives

- Outline the causes and symptoms associated with trichomoniasis

Key Points

- Trichomoniasis is a sexually transmitted disease, and is caused by the single-celled protozoan parasite Trichomonas vaginalis producing mechanical stress on host cells and then ingesting cell fragments after cell death.
- Symptoms usually appear in women within 5 to 28 days of exposure. In many cases, men may hold the parasite for some years without any signs (dormant).
- Trichomoniasis is diagnosed by visually observing the trichomonads via a microscope.

Key Terms

- **trichomoniasis**: A common sexually transmitted disease caused by the parasite Trichomonas vaginalis and infecting the urinary tract or vagina.
- **vaginitis**: Inflammation of the vagina.
- **trichomonads**: flagellate protozoa of the genus Trichomonas.

Trichomoniasis, sometimes referred to as “trich”, is a common cause of vaginitis. It is a sexually transmitted disease, and is caused by the single-celled protozoan parasite Trichomonas vaginalis producing mechanical stress on host cells and then ingesting cell fragments after cell deat. Trichomoniasis is primarily an infection of the urogenital tract; the most common site of infection is the urethra and the vagina in women. Typically, only women experience symptoms associated with Trichomonas infection.

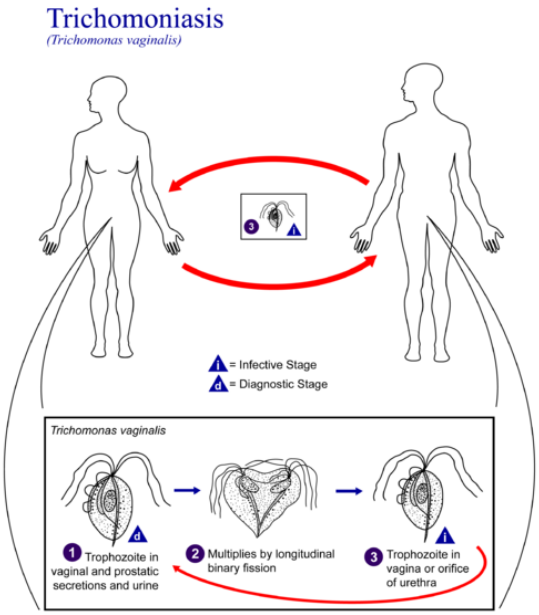

Figure: **Trichomoniasis vaginalis**: Trichomoniasis is primarily an infection of the urogenital tract; the most common site of infection is the urethra and the vagina in women.

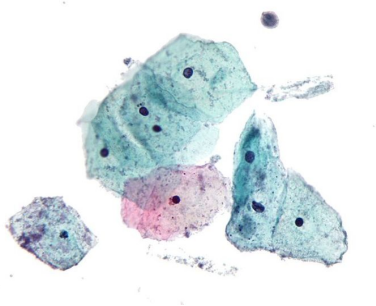

Figure: **Micrograph showing Trichomoniasis**: Micrograph showing a positive result for trichomoniasis. A trichomonas organism is seen on the top-right of the image.

Symptoms include inflammation of the cervix (cervicitis), urethra (urethritis), and vagina (vaginitis) which produces an itching or burning sensation. Discomfort may increase during intercourse and urination. There may also be a yellow-green, itchy, frothy, foul-smelling ("fishy" smell) vaginal discharge. In rare cases, lower abdominal pain can occur. Symptoms usually appear in women within 5 to 28 days of exposure. In many cases, men may hold the parasite for some years without any signs (dormant). Some sexual health specialists have stated that the condition can probably be carried in the vagina for years, despite standard tests being negative. While symptoms are most common in women, some men may temporarily exhibit symptoms such as an irritation inside the penis, mild discharge or slight burning after urination or ejaculation. Trichomoniasis is diagnosed by visually observing the trichomonads via a microscope. In women, the examiner collects the specimen during a pelvic examination by inserting a speculum into the vagina and then using a cotton-tipped applicator to collect the sample. The sample is then placed onto a microscopic slide and sent to a laboratory to be analyzed.

15.25B: Trichomoniasis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.25C: The TORCH Panel of Tests

TORCH infections are a group of viral, bacterial, and protozoan infections that gain access to the fetal bloodstream from the mother.

Learning Objectives

- Summarize the importance of a TORCH panel of tests

Key Points

- The TORCH complex acronym spells out: T – Toxoplasmosis / Toxoplasma gondii; O – Other infections; R – Rubella; C – Cytomegalovirus; H – Herpes simplex virus.
- TORCH infections cause a syndrome characterized by microcephaly, sensorineural deafness, chorioretinitis, hepatosplenomegaly, and thrombocytopenia.
- Symptoms of a TORCH infection may include fever and difficulty feeding, with the newborn often small for their gestational age.

Key Terms

- **haematogenous**: Spread by blood.
- **petechial**: Characterised by, pertaining to, or resembling petechiae (small, nonraised haemorrhages on the skin).
- **TORCH complex**: TORCH complex is a medical acronym for a set of perinatal infections (which are infections that are passed from a pregnant woman to her fetus).

TORCH complex is a medical acronym for a set of perinatal infections (which are infections passed from a pregnant woman to her fetus). TORCH infections can lead to severe fetal anomalies or even fetal loss. They are a group of viral, bacterial, and protozoan infections that gain access to the fetal bloodstream through the placenta via the chorionic villi. Haematogenous transmission may occur at any time during gestation or occasionally at the time of delivery via maternal-to-fetal transfusion. The TORCH panel is used to screen for certain infectious diseases that can cause birth defects in a baby if the mother contracts them during the pregnancy. The TORCH panel of tests acronym spells out as follows:

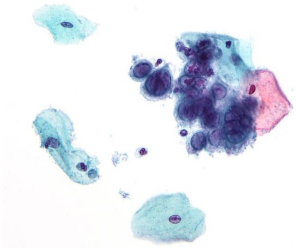

Figure: **Herpes Simplex Virus**: Micrograph of a pap test showing changes (upper-right of image) associated with Herpes Simplex Virus, a TORCH infection.

- T – Toxoplasmosis / Toxoplasma gondii
- O – Other infections
- R – Rubella
- C – Cytomegalovirus
- H – Herpes simplex virus

The “other infections” included under the letter O include Coxsackievirus, Syphilis, Varicella-Zoster Virus, HIV, and Parvovirus B19. Hepatitis B is also sometimes included among “other infections,” but Hepatitis B is a large virus and does not cross the placenta, hence it cannot infect the fetus unless there have been breaks in the maternal-fetal barrier, such as can occur due to bleeding during childbirth or during amniocentesis.

TORCH infections cause a syndrome characterized by microcephaly, sensorineural deafness, chorioretinitis, hepatosplenomegaly, and thrombocytopenia. Symptoms of a TORCH infection may include fever and difficultly feeding. The newborn is often small for their gestational age. A petechial rash on the skin may be present, with small reddish or purplish spots due to bleeding from capillaries under the skin. An enlarged liver and spleen (hepatosplenomegaly) is common, as is jaundice. However, jaundice is less common in Hepatitis B because a newborn’s immune system is not developed well enough to mount a response against liver cells,

as would normally be the cause of jaundice in an older child or adult. Hearing impairment, eye problems, mental retardation, autism, and death can be caused by TORCH infections. The TORCH panel is valuable for checking for infections because the mother often has a mild infection with few or no symptoms. It is also possible for genetic conditions (such as Aicardi-Goutieres syndrome) to present in a similar manner.

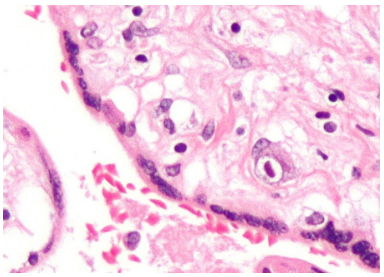

Figure: **Cytomegalovirus infection**: Hematoxylin and Eosin stain showing cytomegalovirus (CMV) infection of the placenta (CMV placentitis), a TORCH infection. The characteristic large nucleus of a CMV infected cell is seen off-center at the bottom-right of the image.

Topic hierarchy

15.3A: Anatomy of the Eye

15.3B: Normal Eye Microbiota

15.3C: Bacterial Eye Diseases

15.3D: Other Infectious Eye Diseases

This page titled 15.3: Microbial Diseases of the Eye is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by Boundless.

15.3A: Anatomy of the Eye

Many structures in the human eye, such as the cornea and fovea, process light so it can be deciphered by rods and cones in the retina.

Learning Objectives

- Explain how eyes have evolved to benefit organisms

Key Points

- The cornea and the lens bend light to focus the image on the retina; the iris and pupil regulate the amount of light entering the eye.
- The aqueous humour maintains the convex shape of the cornea; the vitreous humour supports the lens and maintains the shape of the entire eye.
- Presbyopia occurs because the image focuses behind the retina; it is similar to hyperopia (farsightedness), which is caused by an eyeball that is too short.
- Myopia (nearsightedness) occurs when an eyeball is elongated; images in the distance appear blurry, but images nearby are clear.
- Rods are used for peripheral and nighttime vision; cones are used for daytime and color vision.
- The fovea is responsible for acute vision because it has a high density of cones.

Key Terms

- **rod**: a rod-shaped cell located in the outer retina of the eye that is extremely sensitive to light
- **retina**: the thin layer of cells at the back of the eyeball where light is converted into neural signals sent to the brain
- **cone**: cell located near the center of the retina that is weakly photosensitive and is responsible for color vision in relatively bright light

Anatomy of the Eye

The retina, a thin layer of cells located on the inner surface of the back of the eye, consists of photoreceptive cells, which are responsible for the transduction of light into nervous impulses. However, light does not enter the retina unaltered; it must first pass through other layers that process it so that it can be interpreted by the retina.

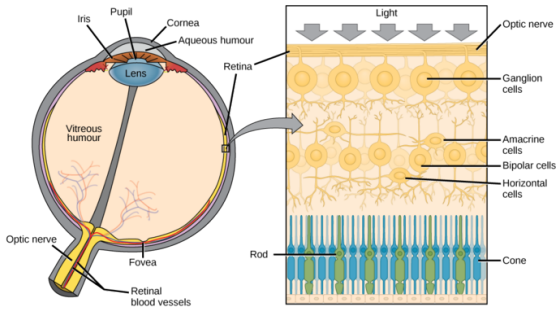

Figure: **Retina**: (a) The human eye is shown in cross section. The human eye contains structures, such as the cornea, iris, lens, and fovea, that process light so it can be deciphered by the retina. Other structures like the aqueous humor and the vitreous humor help maintain the shape of the eye. (b) A blowup shows the layers of the retina. The retina contains photoreceptive cells. In the retina, light is converted into neural signals sent to the brain.

The cornea, the front transparent layer of the eye, along with the crystalline lens, refract (bend) light to focus the image on the retina. After passing through the cornea, light passes through the aqueous humour, which connects the cornea to the lens. This clear gelatinous mass also provides the corneal epithelium with nutrients and helps maintain the convex shape of the cornea. The iris, which is visible as the colored part of the eye, is a circular muscular ring lying between the lens and the aqueous humour that regulates the amount of light entering the eye. Light passes through the center of the iris, the pupil, which actively adjusts its size to maintain a constant level of light entering the eye. In conditions of high ambient light, the iris contracts, reducing the size of the pupil. In conditions of low light, the iris relaxes and the pupil enlarges.

The main function of the lens is to focus light on the retina and fovea centralis. The lens is a transparent, convex structure located behind the cornea. On the other side of the lens is the vitreous humour, which lets light through without refraction, maintains the shape of the eye, and suspends the delicate lens. The lens focuses and re-focuses light as the eye rests on near and far objects in the visual field. The lens is operated by muscles that stretch it flat or allow it to thicken, changing the focal length of light coming through to focus it sharply on the retina. With age comes the loss of the flexibility of the lens; a form of farsightedness called presbyopia results. Presbyopia occurs because the image focuses behind the retina. It is a deficit similar to a different type of farsightedness, hyperopia, caused by an eyeball that is too short. For both defects, images in the distance are clear, but images nearby are blurry. Myopia (nearsightedness) occurs when an eyeball is elongated and the image focus falls in front of the retina. In this case, images in the distance are blurry, but images nearby are clear.

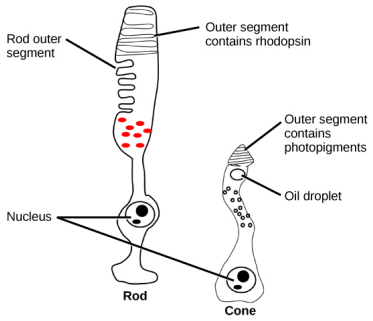

Figure: **Rods and cones**: Rods and cones are photoreceptors in the retina. Rods respond in low light and can detect only shades of gray. Cones respond in intense light and are responsible for color vision.

There are two types of photoreceptors in the retina: rods and cones. Both are named for their general appearance. Rods, strongly photosensitive, are located in the outer edges of the retina. They detect dim light and are used primarily for peripheral and nighttime vision. Cones, weakly photosensitive, are located near the center of the retina. They respond to bright light; their primary role is in daytime, color vision.

The fovea is the region in the center back of the eye that is responsible for acute (central) vision. The fovea has a high density of cones. When you bring your gaze to an object to examine it intently in bright light, the eyes orient so that the object's image falls on the fovea. However, when looking at a star in the night sky or other object in dim light, the object can be better viewed by the peripheral vision because it is the rods at the edges of the retina, rather than the cones at the center, that operate better in low light. In humans, cones far outnumber rods in the fovea.

15.3B: Normal Eye Microbiota

A small number of bacteria are normally present in the conjunctiva.

Learning Objectives

- Give examples of the microorganisms found in the normal eye microbiota

Key Points

- The lachrymal glands continuously secrete tears keeping the conjunctiva moist, while intermittent blinking lubricates the conjunctiva and washes away foreign material.
- Tears contain bactericides such as lysozyme, so that microorganisms have difficulty in surviving the lysozyme and settling on the epithelial surfaces.
- Some pathogens able to infect the conjunctiva, such as Neisseria gonorrhoeae and Chlamydia trachomatis are thought to have special processes allowing them to attach to the conjunctival epithelium.

Key Terms

- **lachrymal gland**: The lacrimal glands are paired almond-shaped glands, one for each eye, that secrete the aqueous layer of the tear film.
- **conjunctiva**: A clear mucous membrane that lines the inner surface of the eyelid and the exposed surface of the eyeball or sclera.
- **lysozyme**: A bacteriolytic (or antibiotic) enzyme found in many animal secretions and in egg white.

Normal Eye Microbiota

The human microbiome (or human microbiota) is the aggregate of microorganisms that reside on the surface and in deep layers of skin, in the saliva and oral mucosa, in the conjunctiva, and in the gastrointestinal tracts. They include bacteria, fungi, and archaea. Some of these organisms perform tasks that are useful for the human host. However, the majority have been too poorly researched to understand the role they play. Those that are expected to be present and do not cause disease (under normal circumstances), but instead participate in maintaining health, are deemed members of the normal flora.

A small number of bacteria are normally present in the conjunctiva. These include: Chlamydia trachomatis, Chlamydophila pneumoniae, Haemophilus aegyptius, Haemophilus influenzae, Moraxella spp, Neisseria spp, Staphylococcus aureus, Staphylococcus epidermidis and Streptococcus viridians. Staphylococcus epidermidis and certain coryneforms such as Propionibacterium acnes are dominant. Staphylococcus aureus, streptococci, Haemophilus sp. and Neisseria sp. sometimes occur. The lachrymal glands continuously secrete tears keeping the conjunctiva moist, while intermittent blinking lubricates the conjunctiva and washes away foreign material. Tears contain bactericides such as lysozyme, so that microorganisms have difficulty in surviving the lysozyme and settling on the epithelial surfaces.

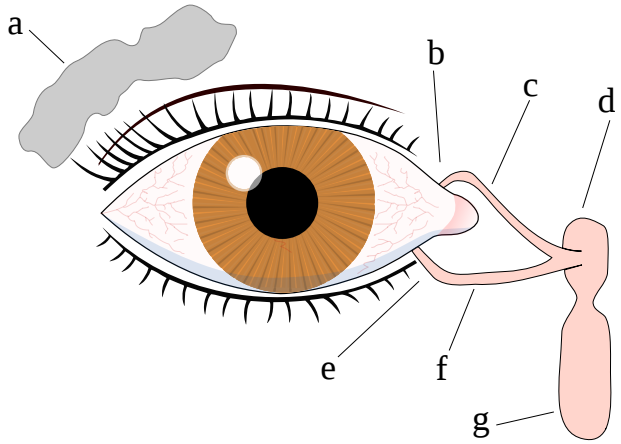

Figure: **The Tear System**: The tear system. Tears are secretions that clean and lubricate the eyes: A) Tear gland/Lacrimal gland, B) Superior lacrimal punctum, C) Superior lacrimal canal lacrimation leads to tears, D) Tear sac/Lacrimal sac, E) Inferior lacrimal punctum, F) Inferior lacrimal canal, G) Nasolacrimal canal.

Some pathogens able to infect the conjunctiva, such as Neisseria gonorrhoeae and Chlamydia trachomatis, are thought to have special processes allowing them to attach to the conjunctival epithelium. Newborn infants are particularly prone to bacterial attachment. Chlamydia and Neisseria may be present in an infected mother and show up on the cervical and vaginal epithelium. In such cases the newborn's eyes may be treated with silver nitrate or antibiotics.

15.3C: Bacterial Eye Diseases

Conjunctivitis is inflammation of the conjunctiva, most commonly due to an infection.

LEARNING OBJECTIVES

Describe the various causes of conjunctivitis and keratitis and its symptoms

KEY TAKEAWAYS

Key Points

- Classification can be either by extent of the inflamed area or by cause (allergic, bacterial, viral, or chemical).
- Red eye (hyperaemia), irritation (chemosis) and watering (epiphora) of the eyes are symptoms common to all forms of conjunctivitis.
- Keratitis, a condition in which the eye's cornea becomes inflamed, is often marked by moderate to intense pain and usually involves impaired eyesight.

Key Terms

- **conjunctivitis**: An inflammation of the conjunctiva often due to infection.
- **keratitis**: Inflammation of the cornea.

Common Eye Infections

CONJUNCTIVITIS

Conjunctivitis, also called pink eye or Madras eye, is inflammation of the conjunctiva, which consists of the outermost layer of the eye and the inner surface of the eyelids. Conjunctivitis most commonly caused by a viral infection or, less commonly, a bacterial infection, or by an allergic reaction. Classification can be either by extent of the inflamed area or by cause (allergic, bacterial, viral or chemical). Neonatal conjunctivitis is often defined separately due to different organisms.

Symptoms and Diagnosis

An inflamed, red eye (hyperaemia), irritation (chemosis), and watering (epiphora) of the eyes are symptoms common to all forms of conjunctivitis. However, the pupils should be normally reactive and the visual acuity normal. Bacterial conjunctivitis due to common pyogenic (pus-producing) bacteria causes marked grittiness/irritation and a stringy, opaque, greyish or yellowish mucopurulent discharge that may cause the lids to stick together, especially after sleep. Another symptom that could be caused by bacterial conjunctivitis is severe crusting of the infected eye and the surrounding skin.

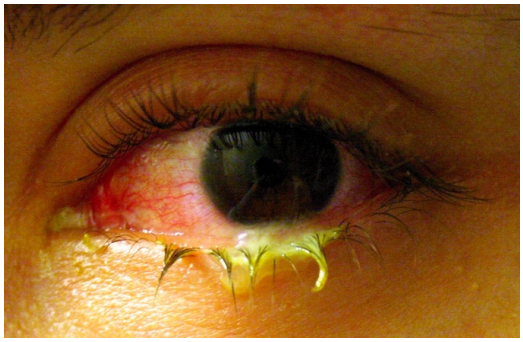

Figure: **Conjunctivitis**: An eye with bacterial conjunctivitis.

Contrary to popular belief, discharge is not essential to the diagnosis. Bacteria such as *Chlamydia trachomatis* or *Moraxella* can cause a non-exudative but persistent conjunctivitis without much redness. The gritty and/or scratchy feeling is sometimes localized enough for patients to insist they must have a foreign body in the eye. The more acute pyogenic infections can be painful. Like viral conjunctivitis, it usually affects only one eye but may spread easily to the other eye.

Corynebacterium diphtheriae causes membrane formation in conjunctiva of non immunized children. Bacterial conjunctivitis usually resolves without treatment. Antibiotics, eye drops, or ointment may only be needed if no improvement is observed after three days.

Chlamydiaconjunctivitis or *trachoma* was once the most important cause of blindness worldwide. The infection can be spread from eye to eye by fingers, shared towels or cloths, coughing and sneezing, and by eye-seeking flies. Newborns can also develop *chlamydia* eye infection through childbirth. *Chlamydia* can affect infants by causing spontaneous abortion, premature birth, and conjunctivitis, which may lead to blindness and pneumonia. Conjunctivitis due to *chlamydia* typically occurs one week after birth (compared with chemical causes (within hours) or gonorrhea (2–5 days)).

KERATITIS

Keratitis is a condition in which the eye's cornea, the front part of the eye, becomes inflamed. The condition is often marked by moderate to intense pain and usually involves impaired eyesight. Superficial keratitis involves the superficial layers (i.e. the epithelium) of the cornea. After healing, this form of keratitis does not generally leave a scar. Deep keratitis involves deeper layers of the cornea (i.e. the epithelium, Bowman's membrane and often stroma), and the natural course leaves a scar upon healing that impairs vision if it occurs on or near the visual axis. This can be reduced or avoided with the use of topical corticosteroid eyedrops.

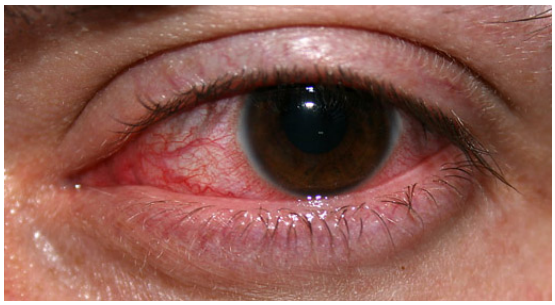

Figure: **Keratitis**: An eye with non-ulcerative sterile keratitis.

Causes and Treatment

Keratitis has multiple causes. Bacterial infection of the cornea can follow from an injury or from result from wearing contact lenses. The bacteria involved are *Staphylococcus aureus* and, for contact lens wearers, *Pseudomonas aeruginosa*. *Pseudomonas aeruginosa* contains enzymes that can digest the cornea. Treatment depends on the cause of the keratitis. Infectious keratitis can progress rapidly, and generally requires urgent antibacterial, antifungal, or antiviral therapy to eliminate the pathogen. Treatment is usually carried out by an ophthalmologist and can involve prescription eye medications, systemic medication, or even intravenous therapy. It is inadvisable to use over-the-counter eye drops as they are typically not helpful in treating infections; using them could also delay crucial correct treatment, increasing the likelihood of sight-threatening complications. In addition, contact lens wearers are typically advised to discontinue contact lens wear and replace contaminated contact lenses and contact lens cases.

15.3C: Bacterial Eye Diseases is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.3D: Other Infectious Eye Diseases

Fungi and viruses such as herpes simplex can cause eye infections.

LEARNING OBJECTIVES

Summarize the various types of herpes simplex keratitis: dendritic ulcer (epithelial keratitis) and disciform keratitis (stromal keratitis)

KEY TAKEAWAYS

Key Points

- Improper hygiene is a major cause of fungal contamination of contact lenses.
- Herpetic simplex keratitis is a form of keratitis caused by recurrent herpes simplex virus in cornea.
- Primary infection most commonly manifests as blepharoconjunctivitis i.e. infection of lids and conjunctiva that heals without scarring.

Key Terms

- **ulcer**: An open sore of the skin, eyes, or mucous membrane, often caused by an initial abrasion and generally maintained by an inflammation and/or an infection.
- **keratitis**: Inflammation of the cornea.
- **conjunctivitis**: An inflammation of the conjunctiva often due to infection.

Microbial corneal infection is the most serious and “most common vision threatening” complication of wearing contact lenses, which is believed to be strongly associated with contact lens cases. Such infections “are being increasingly recognized as an important cause of morbidity and blindness” and “may even be life-threatening. ” While the cornea is believed to be the most common site for fungal eye infections, other parts of the eye such as the orbit, sclera, and eyelids may also be involved.

Fungal Infections of the Eye

Factors that contribute to fungal contamination of contact lenses include, but not limited to, hygiene negligence such as: improper sterilization and disinfection of contact lenses, use of contaminated lenses, contaminated contact lens case, contaminated contact lens solution, wearing of contact lenses during eye infections and introduction of micro-organisms from the environment.

Diagnosis is determined”by recognition of typical clinical features and through direct microscopic detection of fungi in scrapes, biopsy specimens, and other samples. “Ultimately, cultures that are made from the samples isolated from patients is what “confirms diagnosis. ” Other tests that may also be used if needed include “histopathological, immunohistochemical, or DNA -based tests. Pathogenesis of the fungal contaminants includes a wide range of factors such as invasiveness, toxigenicity, and host factors. Once diagnosis is accessed, specific anti-fungal therapy can be administered. One of the most popular and common treatments used”for life-threatening and severe ophthalmic mycoses is amphotericin B which is a specific anti-fungal drug. For the treatment for filamentous fungal keratitis, “topical natamycin is usually the first choice. For the treatment of yeast keratitis, topical amphotericin B is usually the first choice. Current advances in further treatments include evaluations of triazoles such as itraconazole and fluconazole” as therapeutic options in ophthalmic mycoses.

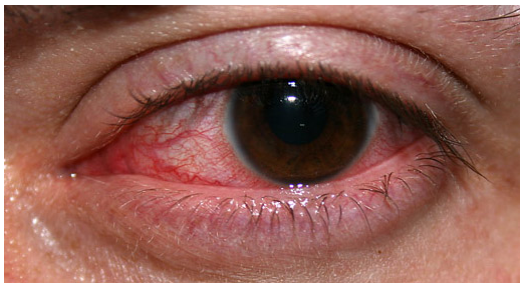

Figure: **Keratitis**: An eye with non-ulcerative sterile keratitis.

Viral Infections of the Eye

Herpes Simplex Virus

Herpetic simplex keratitis is a form of keratitis caused by recurrent herpes simplex virus in cornea. Herpes simplex virus (HSV) infection is very common in humans. HSV is a double-stranded DNA virus that has icosahedral capsid. HSV-1 infections are found more commonly in the oral area and HSV-2 in the genital area. Primary infection most commonly manifests as blepharoconjunctivitis i.e. infection of lids and conjunctiva that heals without scarring. Lid vesicles and conjunctivitis are seen in primary infection. Corneal involvement is rarely seen in primary infection. Recurrent herpes of the eye in turn is caused by reactivation of the virus in a latently infected sensory ganglion, transport of the virus down the nerve axon to sensory nerve endings, and subsequent infection of ocular surface. The following classification of herpes simplex keratitis is important for understanding this disease:

Figure: **Herpes simplex blepharitis**: Primary eye infection with herpes simplex virus most commonly manifests as blepharoconjunctivitis i.e. infection of lids and conjunctiva that heals without scarring. Lid vesicles and conjunctivitis are seen in primary infection.

Dendritic Ulcer (Epithelial Keratitis)

This classic herpetic lesion consists of a linear branching corneal ulcer (dendritic ulcer). During eye exam the defect is examined after staining with fluorescein dye. The underlying corneal has minimal inflammation. Patients with epithelial keratitis complain of foreign-body sensation, light sensitivity, redness, and blurred vision. Focal or diffuse reduction in corneal sensation develops following recurrent epithelial keratitis. In immune deficient patients or with the use of corticosteroids the ulcer may become large and in these cases it is called geographic ulcer.

Disciform Keratitis (Stromal Kieratitis)

Stromal keratitis manifests as a disc-shaped area of corneal edema. Longstanding corneal edema leads to permanent scarring. It is the major cause of decreased vision associated with HSV. Localized endotheliis (localized inflammation of corneal endothelial layer) is the cause of disciform keratitis.

Diagnostic testing is seldom needed because of its classic clinical features and is not useful in stromal keratitis as there is usually no live virus. Laboratory tests are indicated in complicated cases when the clinical diagnosis is uncertain and in all cases of suspected neonatal herpes infection. Corneal smears or impression cytology specimens can be analyzed by culture, antigen detection, or fluorescent antibody testing. Demonstration of HSV is possible with viral culture. Serologic tests in turn may show a rising antibody titer during primary infection but are of no diagnostic assistance during recurrent episodes.

Treatment of herpes of the eye is different based on its presentation. Epithelial keratitis is caused by live virus. Stromal disease is an immune response. Metaherpetic ulcer results from inability of the corneal epithelium to heal. Epithelial keratitis is treated with topical antivirals, which are very effective with low incidence of resistance. Acyclovir ophthalmic ointment and Trifluridine eye drops have similar effectiveness but are more effective than Idoxuridine and Vidarabine eye drops. Topical antiviral medications are not absorbed by the cornea through an intact epithelium, but orally administered acyclovir penetrates an intact cornea and anterior chamber.

Cytomegalovirus Retinitis

Cytomegalovirus retinitis, also known as CMV retinitis, is an inflammation of the retina of the eye that can lead to blindness. Caused by human cytomegalovirus, it occurs predominantly in people whose immune system has been compromised.

Parasitic Infections of the Eye

Acanthamoeba

Acanthamoeba is a microscopic, free-living ameba (single-celled living organism) commonly found in the environment that can cause rare, but severe, eye illness. Acanthamoeba causes three main types of illness involving the eye (Acanthamoeba keratitis), the brain and spinal cord (Granulomatous Encephalitis), and infections that can spread throughout the entire body (disseminated infection).

Toxoplasma gondii

A single-celled parasite called Toxoplasma gondii causes a disease known as toxoplasmosis. While the parasite is found throughout the world, more than 60 million people in the United States may be infected with the Toxoplasma parasite. Of those who are infected, very few have symptoms because a healthy person's immune system usually keeps the parasite from causing illness.

Signs and symptoms of ocular toxoplasmosis can include reduced vision, blurred vision, pain (often with bright light), redness of the eye, and sometimes tearing. Ophthalmologists sometimes prescribe medicine to treat active disease. Whether or not medication is recommended depends on the size of the eye lesion, the location, and the characteristics of the lesion (acute active, versus chronic not progressing). An ophthalmologist will provide the best care for ocular toxoplasmosis.

15.4A: Functions of the Nervous System

The primary function of the nervous system is to coordinate and control the various body functions.

Learning Objectives

- Describe the functions of the nervous system

Key Points

- The nervous system is a highly integrated system. The nervous system has three overlapping functions based on sensory input, integration, and motor output.
- At a more integrative level, the primary function of the nervous system is to control and communicate information throughout the body.

Key Terms

- **hormone**: A molecule released by a cell or a gland in one part of the body that sends out messages affecting cells in other parts of the organism.
- **nervous system**: The organ system that coordinates the activities of muscles, monitors organs, constructs and processes data received from the senses, and initiates actions.

The nervous system has three overlapping functions based on the sensory input, integration, and motor output. The nervous system is a highly integrated system.

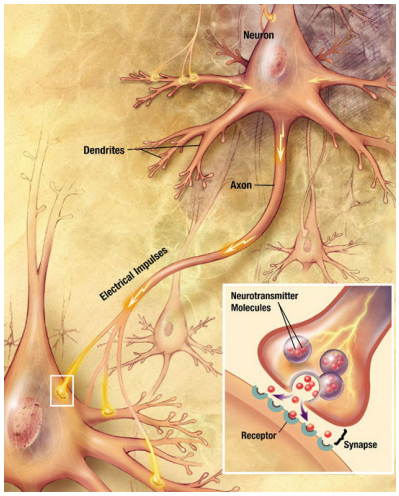

Figure: **Major elements in neuron-to-neuron communication**: Electrical impulses travel along the axon of a neuron. When this signal reaches a synapse, it provokes release of neurotransmitter molecules, which bind to receptor molecules located in the the target cell.

Sensory Input

Sensory input comes from the many sensory receptors that monitor changes occurring both inside and outside the body. The total sum of the information gathered by these receptors is called sensory input. The nervous system processes and interprets sensory input and decides what actions should be taken. The nervous system activates effector organs such as muscles and glands to cause a response called motor output.

Integration

At a more integrative level, the primary function of the nervous system is to control and communicate information throughout the body. It does this by extracting information from the environment using sensory receptors. This sensory input is sent to the central nervous system, which determines an appropriate response.

Motor Response

Once the response is activated, the nervous system sends signals via motor output to muscles or glands to initiate the response.

In humans, the sophistication of the nervous system allows for language, abstract representation of concepts, transmission of culture, and many other features of society that would not otherwise exist.

15.4B: Subdivisions of the Nervous System

The CNS includes the brain and spinal cord, while the PNS is a network of nerves linking the body to the brain and spinal cord.

Learning Objectives

- Describe the subdivisions of the nervous system

Key Points

- The nervous system is often divided into components called gray matter and white matter. Gray matter contains a relatively high proportion of neuron cell bodies and white matter is composed mainly of axons.
- The peripheral nervous system is subdivided into nerves, the autonomic system, and the somatic system. The autonomic nervous system is further subdivided into the parasympathetic and sympathetic nervous systems.
- The enteric nervous system is an independent subsystem of the peripheral nervous system.
- The central nervous system includes the brain and spinal cord and has various centers that integrate of all the information in the body. These can be subdivided into lower centers that carry out essential body functions and higher centers that control more sophisticated information processing.

Key Terms

- **gray matter**: A major component of the central nervous system, consisting of neuronal cell bodies, neuropil (dendrites and unmyelinated axons), glial cells (astroglia and oligodendrocytes), and capillaries.
- **central nervous system**: In vertebrates, the part of the nervous system comprising the brain, brainstem, and spinal cord.
- **white matter**: A region of the central nervous system containing myelinated nerve fibers and no dendrites.
- **peripheral nervous system**: This system consists of the nerves and ganglia outside of the brain and spinal cord.

The nervous system is comprised of two major subdivisions, the central nervous system (CNS) and the peripheral nervous system (PNS).

Central Nervous System

The CNS includes the brain and spinal cord along with various centers that integrate all the sensory and motor information in the body. These centers can be broadly subdivided into lower centers, including the spinal cord and brain stem, that carry out essential body and organ-control functions and higher centers within the brain that control more sophisticated information processing, including our thoughts and perceptions. Further subdivisions of the brain will be discussed in a later section.

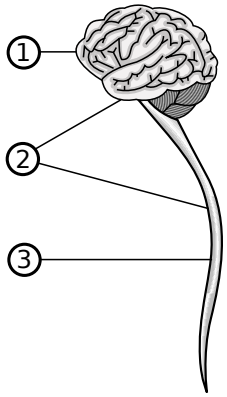

Figure: **The Central Nervous System**: The central nervous system (2) is a combination of the brain (1) and the spinal cord (3).

Gray Matter and White Matter

The nervous system is often divided into components called gray matter and white matter. Gray matter, which is gray in preserved tissue but pink or light brown in living tissue, contains a relatively high proportion of neuron cell bodies. Conversely, white matter is composed mainly of axons and is named because of the color of the fatty insulation called myelin that coats many axons. White

matter includes all of the nerves of the PNS and much of the interior of the brain and spinal cord. Gray matter is found in clusters of neurons in the brain and spinal cord and in cortical layers that line their surfaces.

By convention, a cluster of neuron cell bodies in the gray matter of the brain or spinal cord is called a nucleus, whereas a cluster of neuron cell bodies in the periphery is called a ganglion. However, there are a few notable exceptions to this rule, including a part of the brain called the basal ganglia, which will be discussed later.

Peripheral Nervous System

The PNS is a vast network of nerves consisting of bundles of axons that link the body to the brain and the spinal cord. Sensory nerves of the PNS contain sensory receptors that detect changes in the internal and external environment. This information is sent to the CNS via afferent sensory nerves. Following information processing in the CNS, signals are relayed back to the PNS by way of efferent peripheral nerves.

Autonomic and Somatic Nervous Systems

The PNS is further subdivided into the autonomic nervous system (ANS) and the somatic nervous system. The autonomic system has involuntary control of internal organs, blood vessels, and smooth and cardiac muscles. The somatic system has voluntary control of our movements via skeletal muscle.

As mentioned, the autonomic nervous system acts as a control system and most functions occur without conscious thought. The ANS affects heart rate, digestion, respiratory rate, salivation, perspiration, pupil diameter, urination, and sexual arousal. While most of its actions are involuntary, some, such as breathing, work in tandem with the conscious mind. The ANS is classically divided into two subsystems: the parasympathetic nervous system (PSNS) and sympathetic nervous system (SNS).

Parasympathetic and Sympathetic Nervous Systems

Broadly, the parasympathetic system is responsible for stimulation of “rest-and-digest” activities that occur when the body is at rest, including sexual arousal, salivation, lacrimation (tears), urination, digestion, and defecation. The sympathetic nervous syste is responsible for stimulating activities associated with the “fight-or-flight” response: mobilizing the systems of the body for escape or attacking sources of danger. In truth, the functions of both the parasympathetic and sympathetic nervous systems are not so straightforward, but this division is a useful rule of thumb.

The enteric nervous system (ENS) controls the gastrointestinal system and is sometimes considered part of the autonomic nervous system. However, it is sometimes considered an independent system because it can operate independently of the brain and the spinal cord.

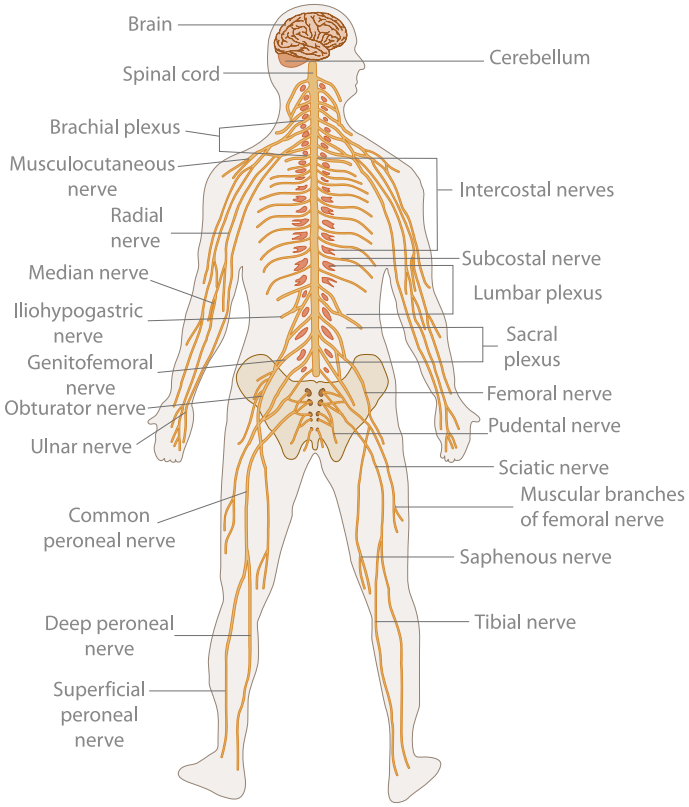

Figure: **The Nervous System of a Vertebrate**: The brain and the spinal cord are the central nervous system (CNS) (shown in yellow). The left-right pair of cranial nerves, spinal nerves, and ganglia make up the peripheral nervous system (shown in dark gold).

15.4B: Subdivisions of the Nervous System is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.4C: Meningitis

Learning Objectives

- Discuss the various causes (viral, bacteria, fungi and protozoa) and modes of transmission for meningitis

Meningitis is inflammation of the protective membranes covering the brain and spinal cord, known collectively as the meninges. The inflammation may be caused by infection with viruses, bacteria, or other microorganisms, and less commonly by certain drugs. Meningitis can be life-threatening because of the inflammation's proximity to the brain and spinal cord. Therefore, the condition is classified as a medical emergency.

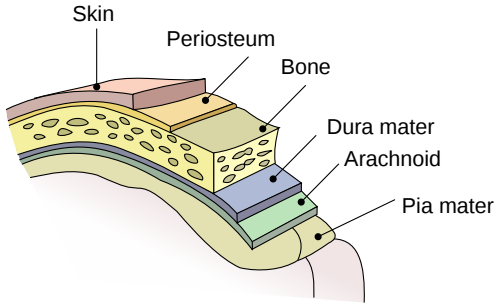

Figure: **The Meninges**: This figure displays the meninges with respect to the skull and surface of the brain.

The most common symptoms of meningitis are headache and neck stiffness associated with fever, confusion or altered consciousness, vomiting, and an inability to tolerate light (photophobia) or loud noises (phonophobia). Children often exhibit only nonspecific symptoms, such as irritability and drowsiness. If a rash is present, it may indicate a particular cause of meningitis. For instance, meningitis caused by the bacterium Neisseria meningitidis (known as "meningococcal menigitis") can be differentiated from meningitis with other causes by a rapidly spreading petechial rash, which may precede other symptoms. The rash consists of numerous small, irregular purple or red spots ("petechiae") on the trunk, lower extremities, mucous membranes, conjuctiva, and (occasionally) the palms of the hands or soles of the feet. Meningococcal bacteria may be accompanied by a characteristic rash. Seizures may also occur for various reasons. In children, seizures are common in the early stages of meningitis and do not necessarily indicate an underlying cause.

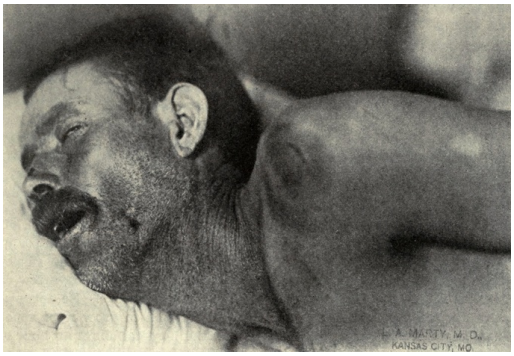

Figure: **Neck stiffness**: Neck stiffness, Texas meningitis epidemic of 1911–12. Nuchal rigidity occurs in 70% of bacterial meningitis in adults.

Meningitis can lead to serious long-term consequences such as deafness, epilepsy, hydrocephalus, and cognitive deficits, especially if not treated quickly. Some forms of meningitis (such as those associated with meningococci, Haemophilus influenzae type B, pneumococci, or mumps virus infections) may be prevented by immunization.

Meningitis is typically caused by an infection with microorganisms. Most infections are due to viruses (such as enteroviruses or herpes simplex virus), with bacteria (for example group B streptococci), fungi, and protozoa being the next most common causes. It may also result from various non-infectious causes. The term aseptic meningitis refers to cases of meningitis in which no bacterial infection can be demonstrated. This type of meningitis is usually caused by viruses, but it may be due to bacterial infection that has already been partially treated, when bacteria disappear from the meninges, or pathogens infect a space adjacent to the meninges (e.g. sinusitis). Endocarditis (an infection of the heart valves which spreads small clusters of bacteria through the bloodstream) may

cause aseptic meningitis. Aseptic meningitis may also result from infection with spirochetes, a type of bacteria that includes Treponema pallidum (the cause of syphilis) and Borrelia burgdorferi (known for causing Lyme disease).

A lumbar puncture diagnoses or excludes meningitis. A needle is inserted into the spinal canal to extract a sample of cerebrospinal fluid (CSF) which envelops the brain and spinal cord. The CSF is examined in a medical laboratory. In someone suspected of having meningitis, blood tests are performed for markers of inflammation (e.g. C-reactive protein, complete blood count) as well as blood cultures.

The first treatment in acute meningitis consists of antimicrobial and sometimes antiviral therapy. In addition, corticosteroids can also be used to prevent complications from excessive inflammation. The introduction of pneumococcal vaccine has lowered rates of pneumococcal meningitis in both children and adults. Recent skull trauma potentially allows nasal cavity bacteria to enter the meningeal space. Similarly, devices in the brain and meninges such as cerebral shunts carry an increased risk of meningitis.

Bacterial and viral meningitis are contagious and can be transmitted through droplets of respiratory secretions during close contact such as kissing, sneezing, or coughing on someone, but cannot be spread by only breathing the air where a person with meningitis has been. Since the 1980's, many countries have included immunization against Haemophilus influenzae type B in their routine childhood vaccination schemes. This has practically eliminated this pathogen as a cause of meningitis in young children in those countries.

Key Points

- Meningitis can be caused by viruses, bacteria, fungi, and protozoa.
- The most common symptoms of meningitis are headache and neck stiffness associated with fever, confusion or altered consciousness, vomiting, and an inability to tolerate light (photophobia) or loud noises (phonophobia).
- A lumbar puncture diagnoses or excludes meningitis.
- The first treatment in acute meningitis consists of antimicrobial and sometimes antiviral therapy.

Key Terms

- **meninges**: The three membranes that envelop the brain and spinal cord.
- **meningitis**: Inflammation of the meninges, characterized by headache, neck stiffness and photophobia and also fever, chills, vomiting, and myalgia.
- **lumbar puncture**: A diagnostic and at times therapeutic procedure performed to collect a sample of cerebrospinal fluid for biochemical, microbiological, and cytological analysis, or rarely to relieve increased intracranial pressure.

15.4C: Meningitis is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.4D: Botulism

Learning Objectives

- Compare and contrast the three major modes of entry for Botulinium toxin (infant botulism or adult intestinal toxemia, foodborne botulism, and wound botulism) and describe its mechanism of action

Overview of Botulism

Botulism is a rare, but sometimes fatal, paralytic illness caused by botulinum toxin. It can affect a wide range of mammals, birds and fish. This toxin is a protein produced under anaerobic conditions by the bacterium Clostridium botulinum. The toxin enters the human body in one of three ways: by colonization of the digestive tract by the bacterium in children (infant botulism) or adults (adult intestinal toxemia), by ingestion of toxin from foods (foodborne botulism), or by contamination of a wound by the bacterium (wound botulism). Person-to-person transmission of botulism does not occur. All forms lead to paralysis that typically starts with the muscles of the face and then spreads towards the limbs. In severe forms, it leads to paralysis of the breathing muscles and causes respiratory failure. In light of this life-threatening complication, all suspected cases of botulism are treated as medical emergencies, and public health officials are usually involved to prevent further cases from the same source. Botulism can be prevented by killing the spores by pressure cooking or autoclaving at 121 °C (250 °F) for 30 minutes or providing conditions that prevent the spores from growing. Additional precautions for infants include not feeding them honey.

Figure: **Botulism**: A 14-year-old with botulism. Note the bilateral total ophthalmoplegia with ptosis in the left image and the dilated, fixed pupils in the right image. This child was fully conscious.

C. botulinum is an anaerobic, Gram positive, spore-forming rod. Botulinium toxin is one of the most powerful known toxins: about one microgram is lethal to humans. It acts by blocking nerve function (neuromuscular blockade) through inhibition of the release of the excitatory neurotransmitter acetyl choline from the presynaptic membrane of neuromuscular junctions in the somatic nervous system. This causes paralysis. Advanced botulism can cause respiratory failure by paralyzing the muscles of the chest, which can progress to respiratory arrest. In all cases, illness is caused by the botulinium toxin produced by the bacterium C. botulinum in anaerobic conditions, and not by the bacterium itself. The pattern of damage occurs because the toxin affects nerves that fire (depolarize) at a higher frequency first.

MODES OF ENTRY

Three main modes of entry for the toxin are known. The most common form in Western countries is infant botulism. This occurs in small children who are colonized with the bacterium during the early stages of their lives. The bacterium then releases the toxin into the intestine, which is absorbed into the bloodstream. The consumption of honey during the first year of life has been identified as a risk factor for infant botulism and it is a factor in a fifth of all cases. The adult form of infant botulism is termed adult intestinal toxemia, and is exceedingly rare. Foodborne botulism results from contaminated foodstuffs in which C. botulinum spores have been allowed to germinate in anaerobic conditions. This typically occurs in home-canned food substances and fermented uncooked dishes. Given that multiple people often consume food from the same source, it is common for more than a single person to be affected simultaneously. Symptoms usually appear 12–36 hours after eating, but can also appear within 6 hours to 10 days. Wound botulism results from the contamination of a wound with the bacteria, which then secrete the toxin into the bloodstream. This has become more common in intravenous drug users since the 1990s, especially people using black tar heroin and those injecting heroin into the skin rather than the veins

TREATMENT

The only drug currently available to treat infant botulism is Botulism Immune Globulin Intravenous-Human (BIG-IV or BabyBIG). BabyBIG was developed by the Infant Botulism Treatment and Prevention Program at the California Department of Public Health. There are two primary Botulinum Antitoxins available for treatment of wound and foodborne botulism. Trivalent (A,B,E) Botulinum Antitoxin is derived from equine sources utilizing whole antibodies (Fab & Fc portions). This antitoxin is available from the local health department via the CDC. The second antitoxin is heptavalent (A,B,C,D,E,F,G) Botulinum Antitoxin which is derived from “despeciated” equine IgG antibodies which have had the Fc portion cleaved off leaving the F(ab’)2 portions. This is a less immunogenic antitoxin that is effective against all known strains of botulism where not contraindicated. This is available from the US Army.

Key Points

- The toxin (s) enters the human body by colonization of the digestive tract by the bacterium, by ingestion of toxin from foods or by contamination of a wound by the bacterium.
- All forms lead to paralysis that typically starts with the muscles of the face and then spreads towards the limbs.
- Botulism can be prevented by killing the spores by pressure cooking or autoclaving at 121 °C (250 °F) for 30 minutes or providing conditions that prevent the spores from growing.

Key Terms

- **infant botulism**: poisoning caused by the toxin from Clostridium botulinum where the gastro-intestinal tract is colonized by spores prior to the protective intestinal bacterial flora having developed
- **spore**: A thick resistant particle produced by a bacterium or protist to survive in harsh or unfavorable conditions.
- **botulism**: Poisoning caused by the toxin from Clostridium botulinum, a type of anaerobic bacteria that grows in improperly-prepared food.
- **wound botulism**: poisoning caused by the toxin from Clostridium botulinum when spores enter a wound under the skin, and, in the absence of oxygen are activated and release toxin
- **toxin**: A toxic or poisonous substance produced by the biological processes of biological organisms.

15.4D: Botulism is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.4E: Leprosy

Learning Objectives

- Describe the causative agents of leprosy: Mycobacterium leprae and Mycobacterium lepromatosis

Leprosy, also known as Hansen's disease (HD), is a chronic disease caused by the bacteria Mycobacterium leprae and Mycobacterium lepromatosis. Named after physician Gerhard Armauer Hansen, leprosy is primarily a granulomatous disease of the peripheral nerves and mucosa of the upper respiratory tract. Skin lesions are the primary external sign. Left untreated, leprosy can be progressive, causing permanent damage to the skin, nerves, limbs, and eyes.

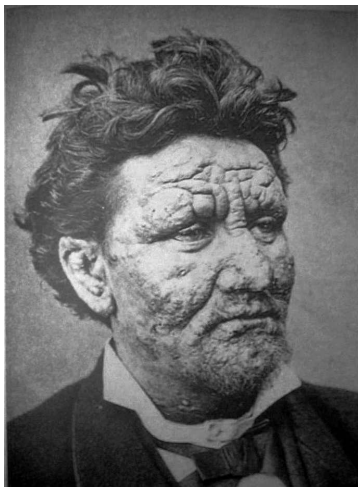

Figure: **Leprosy**: A 23-year-old man infected with leprosy.

Diagnosis

Diagnosis in the U.S. is often delayed because healthcare providers are unaware of leprosy and its symptoms. Early diagnosis and treatment prevents nerve involvement, the hallmark of leprosy, and the disability it causes. There are many kinds of leprosy, but there are common symptoms, including:

- Runny nose
- Dry scalp
- Eye problems
- Skin lesions
- Muscle weakness
- Reddish skin
- Smooth, shiny, diffuse thickening of skin on the face, ears, and hands
- Loss of sensation in fingers and toes
- Thickening of peripheral nerves
- Flat nose due to destruction of nasal cartilage

There is also phonation and resonation of sound during speech. Often there is atrophy of the testes and impotency.

Causative Agents

Mycobacterium leprae and *Mycobacterium lepromatosis* are the causative agents of leprosy. *M. lepromatosis* is a comparatively recently identified mycobacterium that was isolated from a fatal case of diffuse lepromatous leprosy in 2008. An intracellular, acid-fast bacterium, *M. leprae* is aerobic and rod-shaped, and is surrounded by the waxy cell membrane coating characteristic of Mycobacterium species. Due to extensive loss of genes necessary for independent growth, *M. leprae* and *M. lepromatosis* are obligate pathogens, and are unculturable in the laboratory, a factor that leads to difficulty in definitively identifying the organism under a strict interpretation of Koch's postulates. The use of non-culture-based techniques such as molecular genetics has allowed for alternative establishment of causation.

Routes of Infection

M. leprae is usually spread from person to person in respiratory droplets. Studies have shown that leprosy can be transmitted to humans through contact with armadillos, too. Leprosy is not known to be either sexually transmitted or highly infectious after treatment. Approximately 95% of people are naturally immune, and sufferers are no longer infectious after as little as two weeks of treatment. In 1988, Jacinto Convit was nominated for the Nobel Prize in Medicine for developing a vaccine to fight leprosy using a combination of tuberculosis (TB) vaccines with Mycobacterium Leprae. A number of synthetic pharmaceuticals that are effective against leprosy have now been identified, allowing doctors a flexible choice of treatments.

Key Points

- Left untreated, leprosy can be progressive, causing permanent damage to the skin, nerves, limbs, and eyes.
- M. leprae and M. lepromatosis are obligate pathogens, and are unculturable in the laboratory, a factor that leads to difficulty in definitively identifying the organism under a strict interpretation of Koch's postulates.
- There is now a vaccination and extensive pharmaceutical options for treatment and prevention of leprosy.

Key Terms

- **leprosy**: Leprosy, also known as Hansen's disease (HD), is a chronic disease caused by the bacteria Mycobacterium leprae and Mycobacterium lepromatosis.
- **mycobacterium**: Any of many rod-shaped, aerobic bacteria, of the genus Mycobacterium, that cause diseases such as tuberculosis and leprosy

15.4F: Tetanus

Tetanus is a medical condition characterized by a prolonged contraction of skeletal muscle fibers.

Learning Objectives

- Describe the mode of transmission and mechanism of action for *Clostridium tetani*

Key Points

- Infection generally occurs through wound contamination and often involves a cut or deep puncture wound.
- There are currently no blood tests that can be used to diagnose tetanus.
- Tetanus can be prevented by vaccination with tetanus toxoid.

Key Terms

- **tetanus**: A serious and often fatal disease caused by the infection of an open wound with the anaerobic bacterium Clostridium tetani, found in soil and the intestines and feces of animals.
- **opisthotonos**: A tetanic spasm in which the body is bent backwards and stiffened.
- **neurotoxin**: A toxin that specifically acts upon neurons, their synapses, or the nervous system in its entirety.
- **tetanospasmin**: The A-B toxin produced by C. tetani which is responsible for the symptoms of tetanus.

Overview

Tetanus is a medical condition characterized by a prolonged contraction of skeletal muscle fibers. The primary symptoms are caused by tetanospasmin, a neurotoxin produced by the Gram-positive, rod-shaped, obligate anaerobic bacterium *Clostridium tetani*.

Infection and Symptomatic Effects

Infection generally occurs through wound contamination and often involves a cut or deep puncture wound. C. tetani is not invasive, and the infection is normally confined to a wound. Here the bacteria multiply and produce tetanospasmin, which is able to travel throughout the body. Tetanospasmin is an A-B toxin. The B subunit binds to the receptors on motor neurons, while the A subunit induces endocytosis to enter the neuron. Early symptoms of the disease include restlessness, irritability and difficulty swallowing. As the infection progresses, muscle spasms develop in the jaw (thus the name “lockjaw”) and elsewhere in the body. Infection can be prevented by proper immunization and by post-exposure prophylaxis. Tetanus often begins with mild spasms in the jaw muscles (lockjaw). The spasms can also affect the chest, neck, back, and abdominal muscles. Back muscle spasms often cause arching, called opisthotonos. Prolonged muscular action causes sudden, powerful, and painful contractions of muscle groups. This is called tetany.

Figure: **Opisthotonus**: Muscular spasms (specifically opisthotonos) in a patient suffering from tetanus. Painting by Sir Charles Bell, 1809.

Tetanus affects skeletal muscle, a type of striated muscle used in voluntary movement. The other type of striated muscle, cardiac or heart muscle, is not affected by the toxin because of its intrinsic electrical properties. The incubation period of tetanus can be long, and may be as long several months, but is usually about eight days. In general, the further the injury site is from the central nervous system, the longer the incubation period. The shorter the incubation period, the more severe the symptoms.

Sources of Infection

Tetanus is often associated with rust, especially rusty nails, but this concept is somewhat misleading. Objects that accumulate rust are often found outdoors, or in places that harbor anaerobic bacteria, but the rust itself does not cause tetanus nor does it contain *C. tetani* bacteria. The rough surface of rusty metal merely provides a prime habitat for a *C. tetani* endospore to reside, and the nail affords a means to puncture skin and deliver endospore into the wound. An endospore is a non-metabolizing survival structure that begins to metabolize and cause infection once in an adequate environment. Because *C. tetani* is an anaerobic bacterium, it and its endospores survive well in an environment that lacks oxygen. Hence, stepping on a nail, rusty or not, may result in a tetanus infection, as the low-oxygen (anaerobic) environment is provided by the same object that causes a puncture wound, delivering endospores to a suitable environment for growth.

Diagnosis, Treatment, and Prevention

There are currently no blood tests that can be used to diagnose tetanus. The diagnosis is based on the presentation of tetanus symptoms. Diagnosis does not depend upon isolation of the bacteria, which is recovered from the wound in only 30% of cases and can be isolated from patients without tetanus. The “spatula test” is a clinical test for tetanus that involves touching the posterior pharyngeal wall with a sterile, soft-tipped instrument, and observing the effect. A positive test result is the involuntary contraction of the jaw (biting down on the “spatula”); a negative test result would normally be a gag reflex attempting to expel the foreign object.

Unlike many infectious diseases, recovery from naturally acquired tetanus does not usually result in immunity to tetanus. This is due to the extreme potency of the tetanospasmin toxin; even a lethal dose of tetanospasmin is insufficient to provoke an immune response.Tetanus can be prevented by vaccination with tetanus toxoid. The CDC recommends that adults receive a booster vaccine every ten years, and standard care practice in many places is to give the booster to any patient with a puncture wound who is uncertain of when he or she was last vaccinated, or if he or she has had fewer than three lifetime doses of the vaccine. The booster may not prevent a potentially fatal case of tetanus from the current wound as it can take up to two weeks for tetanus antibodies to form.

A person infected with *C. tetani* can be treated with antibiotics, which will kill the multiplying bacteria but will have no effect on the endospores or the toxin. To combat the effects of the toxin, tetanus immune globulin (TIG) antitoxin can be given to the patient. These antibodies are able to neutralize the tetanospasmin if they are not already bound to motor neurons, and can confer passive immunity.

15.4F: Tetanus is shared under a CC BY-SA 4.0 license and was authored, remixed, and/or curated by LibreTexts.

15.4G: Paralysis-Causing Bacterial Neurotoxins

Botulinum toxin is a protein and neurotoxin, which blocks neuromuscular transmission through decreased acetylcholine release.

Learning Objectives

- Describe the mechanism of action for botulinum toxin

Key Points

- Botulinum toxin is produced by Clostridium botulinum, C. butyricum, C. baratii and C. argentinense.
- The light chain of botulinum toxin is an enzyme (a protease) that attacks one of the fusion proteins (SNAP-25, syntaxin or synaptobrevin) at a neuromuscular junction, preventing vesicles from anchoring to the membrane and releasing acetylcholine.
- The heavy chain of the toxin is particularly important for targeting the toxin to specific types of axon terminals.

Key Terms

- **neurotoxin**: A toxin that specifically acts upon neurons, their synapses, or the nervous system in its entirety.
- **acetylcholine**: A neurotransmitter in humans and other animals. It is an ester of acetic acid and choline with chemical formula CH3COOCH2CH2N⁺(CH3)3.
- **axon**: A nerve fibre, which is a long slender projection of a nerve cell, and which conducts nerve impulses away from the body of the cell to a synapse.

Botulinum toxin is a protein and neurotoxin produced by Clostridium botulinum, C. butyricum, C. baratii and C. argentinense. Botulinum toxin can cause botulism, a serious and life-threatening illness in humans and animals. In 1949, Arnold Burgen's group discovered, through an elegant experiment, that botulinum toxin blocks neuromuscular transmission through decreased acetylcholine release. In 1973, Alan Scott used botulinum toxin type A (BTX-A) in monkey experiments. In 1980, he officially used BTX-A for the first time in humans to treat "crossed eyes" (strabismus), a condition in which the eyes are not properly aligned with each other, as well as "uncontrollable blinking" (blepharospasm). In 1993, Pasricha and colleagues showed that botulinum toxin could be used for the treatment of achalasia, a spasm of the lower esophageal sphincter. In 1994, Bushara showed botulinum toxin injections inhibit sweating; this was the first demonstration of non-muscular use of BTX-A in humans. The cosmetic effect of BTX-A on wrinkles was first reported by J. D. and J. A. Carruthers in a 1992 study on BTX-A for the treatment of glabellar frown lines. The acceptance of BTX-A use for the treatment of muscle pain disorders is growing, with approvals pending in many European countries. The efficacy of BTX-A in treating a variety of other medical conditions (including prostatic dysfunction, asthma, and others) is an area of continued study.

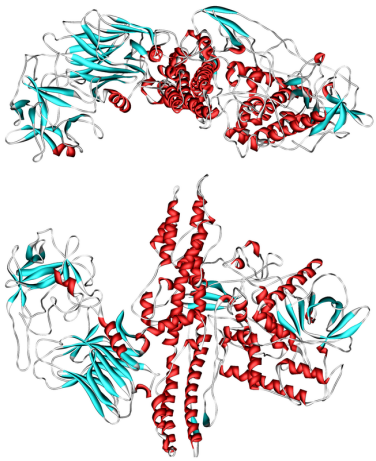

Figure: **Botulinum Toxin**: Structure of Botulinum toxin, a protein and neurotoxin produced by the bacterium Clostridium botulinum

Foodborne botulism can be transmitted through food that has not been heated correctly prior to being canned, or food from a can that has not been cooked correctly. Most infant botulism cases cannot be prevented because the bacteria that cause this disease are in soil and dust. The bacteria can also be found inside homes on floors, carpet, and countertops, even after cleaning. Honey can contain the bacteria that cause infant botulism, so children less than 12 months old should not be fed honey.

Botulinum toxin is a two-chain polypeptide with a 100-kDa heavy chain joined by a disulfide bond to a 50-kDa light chain. This light chain is an enzyme (a protease) that attacks one of the fusion proteins (SNAP-25, syntaxin or synaptobrevin) at a neuromuscular junction, preventing vesicles from anchoring to the membrane to release acetylcholine. By inhibiting acetylcholine release, the toxin interferes with nerve impulses and causes flaccid (sagging) paralysis of muscles in botulism, as opposed to the spastic paralysis seen in tetanus. The heavy chain of the toxin is particularly important for targeting the toxin to specific types of axon terminals. The toxin must get inside the axon terminals to cause paralysis. Following the attachment of the toxin heavy chain to proteins on the surface of axon terminals, the toxin can be taken into neurons by endocytosis. The light chain is able to cleave endocytotic vesicles and reach the cytoplasm. The light chain of the toxin has protease activity. The type A toxin proteolytically degrades the SNAP-25 protein, a type of SNARE protein. The SNAP-25 protein is required for vesicle fusion that releases neurotransmitters from the axon endings (in particular acetylcholine). Botulinum toxin specifically cleaves these SNAREs, and so prevents neurosecretory vesicles from docking/fusing with the nerve synapse plasma membrane and releasing their neurotransmitters.
