Members belonging to the family *Enterobacteriaceae* are gram-negative, facultative anaerobic rods or coccobacilli ranging in width from 0.3 to 1.0 μm and in length from 0.6 to 6.0 μm. A proposed subspecies of *Serratia, S. marcescens* subsp. *sakuensis,* is the only reportedly spore-forming organism in this family (2). Prototrophic strains grow readily on ordinary media. Among these genera, auxotrophic strains from clinical specimens are rare. However, cysteine-requiring urinary isolates of *K. pneumoniae,* which grow as pinpoint colonies on routine media, do occur. If encountered, these strains require supplementation of biochemical media or commercial identification systems with 0.63 mM cysteine for accurate identification. A number of newer genera are not culturable in vitro but have been assigned to the *Enterobacteriaceae* based upon analysis of the genetic sequences of their genome. A proposal to create a "*Candidatus*" status for these types of organisms has been made (108). Other genera, including *K. (C.) granulomatis* and many insect symbionts, are culturable only by cell culture techniques.

Of the organisms in Tables 1 and 2 isolated from human specimens, all *Klebsiella, Leminorella, Moellerella, Tatumella,* and *Enterobacter asburiae* strains are nonmotile, although any strain of any genus may be nonmotile and recent data for *E. asburiae* indicate that some strains may be motile (62). Some strains of *S. plymuthica* may not grow at 37°C, but most other members of the genera discussed in this chapter grow well between 25 and 37°C. Essentially only *Klebsiella* and *Raoultella* (previously *Klebsiella*) spp. are encapsulated, but strains from all genera may grow as mucoid or rough colonies. Five genera produce pigment. Some strains of *S. marcescens* and most *S. rubidaea* and *S. plymuthica* strains produce a red pigment, prodigiosin, which may appear throughout the entire colony or only as a red center or margin. Most strains of *E. sakazakii* and some strains of *P. agglomerans, Leclercia adecarboxylata,* and *Photorhabdus asymbiotica* form yellow-pigmented colonies that range from bright to pale yellow. Weak pigment producers may be detected only by observing growth placed on a swab or filter paper. Yellow pigment may be enhanced by incubation at 25°C. *Photorhabdus luminescens* and *P. asymbiotica* cultures are luminescent, giving a visible glow in a darkroom after 5 min. *S. odorifera,* as indicated by its name, and some *Cedecea* spp. strains, produce a pungent (potato-like) odor due to the

production of alkyl-methoxypyrazines (50). Species of *Proteus* and *Providencia* oxidatively deaminate α-amino acids, producing pyruvic acids. L-phenylalanine deamination yields a green color when ferric chloride is added; however, deamination of *dl*-tryptophan produces the deep reddish brown pigment often seen in media inoculated with these organisms without the addition of ferric chloride (120). *Proteus* species also produce swarmer cells, which are elongated forms that are created when cells fail to septate or divide. These cells, which are profusely covered with flagella, act in concert to produce swarming motility on solid media (14).

Plesiomonas shigelloides organisms are also gram-negative, facultative anaerobes growing as straight rods similar in size to other *Enterobacteriaceae*. However, unlike other *Enterobacteriaceae, P. shigelloides* strains are oxidase positive, do not produce gas from glucose (*Enterobacteriaceae* are variable), and are susceptible to vibriostatic agent O/129 (2,4-diamino-6,7-diisopropylpteridine). Both *P. shigelloides* and enterobacteria grow at similar salt concentrations (0 to 5%) and pH ranges (4.0 to 8.0).

NATURAL HABITAT AND CLINICAL SIGNIFICANCE

The *Enterobacteriaceae* are widespread throughout the environment (Tables 1 and 2). Many species of the genera in Table 1 are commonly recognized nosocomial pathogens. The *Enterobacteriaceae* comprise 50% of all isolates from hospital-acquired infections and 80% of all gram-negative isolates (83). *Enterobacter* and *Klebsiella* spp. rank between fifth and ninth among common agents of bloodstream infections (35, 82, 143). Although less prevalent than a number of other etiologic agents, *Klebsiella* and *Enterobacter* cause significant infections. In one study, when found intraoperatively, *Klebsiella* and *Enterobacter* species had a 68 and 100% probability, respectively, of causing a wound infection; probability rates for *Escherichia coli* or *Staphylococcus aureus,* which were isolated three times more often during surgery, were only 31 and 55%, respectively (137). While *K. pneumoniae* and *E. cloacae* cause sepsis four to five times less often than gram-positive organisms, they are twice as likely to cause patient mortality (138). Species of both genera were among the most common organisms involved in relapse or reinfection in a study on recurrent bacteremia (139). *S. marcescens* and *Citrobacter* spp. constitute 1 to 2% and <1% of bloodstream infections, respectively (143). *Klebsiella* spp. rank as the second to fourth most common species in hospital-acquired UTIs and are the third to fourth most common agent in community-acquired UTIs (42, 49). In 2000, *Klebsiella* spp. accounted for 20, 23, and 58% of UTIs in Latin America, Europe, and North America, respectively (49). In this survey, *P. mirabilis, Enterobacter* spp., and *Citrobacter* spp. ranked as the fifth, sixth, and seventh most common agents of UTIs in Latin America, Europe, and North America, respectively (49). *Proteus mirabilis* continues to be an important cause of UTIs in Europe and North America, causing 4 to 6% of community-acquired UTIs and 3 to 6% of nosocomial infections including pyelonephritis (42, 49).

Klebsiella is carried in the nasopharynx and the bowel; however, feces are probably the most significant source of patient infections (103). Approximately one-third of patients carry *Klebsiella* in their stool, but rates may increase as much as threefold with hospitalization and antimicrobial usage in adults. Fecal carriage rates for children may be as high as 90 to 100% without antimicrobial therapy. *K. pneumoniae* has emerged as an important cause of community-acquired pyogenic liver abscess (PLA) worldwide (91, 121, 146). Diabetes and underlying biliary disease are major risk factors. The majority of patients with PLA due to *Klebsiella* are Asian males, 50 to 60 years of age, who present primarily with a right-lobe, solitary, monomicrobial abscess. *Klebsiella*-associated PLA mortality rates are lower than rates seen with other bacterial agents. *K. rhinoscleromatis* and *K. ozaenae* cause granulomatous infections termed rhinoscleroma and atrophic rhinitis, respectively. Both are chronic diseases of the upper respiratory tract; although atrophic rhinitis is restricted to the nose, rhinoscleroma may spread to the trachea and larynx (71). Both diseases occur most frequently in tropical areas of the world; transmission is thought to be from person to person, although prolonged contact with persons producing airborne nasal secretions is required. *K. (C.) granulomatis* causes chronic genital ulcers and also occurs predominantly in tropical countries (56). It is believed that *K. (C.) granulomatis* is sexually transmitted and that the only known reservoir is humans. *Raoultella (Klebsiella) planticola* and *Raoultella (Klebsiella) terrigena* are difficult to distinguish from *Klebsiella pneumoniae* without special tests. Studies in Europe have found that 3.5 to 19% of clinical strains initially identified as *Klebsiella* are actually *R. planticola* and that these strains have pathogenicity characteristics similar to those found in *K. pneumoniae* (119). In a survey of 436 *Klebsiella* strains isolated from newborns in the United States, however, only one isolate could be identified as *R. planticola,* indicating that its prevalence may vary geographically (141). Notably, all of the human strains of the new species *K. variicola* were reportedly isolated from blood (124). No further information on the human isolates was presented, but it would appear that this species is, at the very least, an opportunistic pathogen. As with other klebsiellae, plants appear to be the natural habitat of this organism.

Nosocomial *Enterobacter* colonization and infection are frequently associated with contaminated medical devices and instrumentation; however, *Enterobacter* spp. are commonly consumed in food and an endogeneous source should also be considered (71). *E. ludwigii* and the three subspecies of *E. hormaechei* are isolated from a variety of human sources including blood (63, 64). A nonhuman source for *E. ludwigii* has not been reported, but plants appear to be the natural habitat of *E. hormaechei* subspecies. A number of *Enterobacter* spp. were previously members of the genus *Erwinia* and are isolated from plants or trees (Table 1), where they may cause disease. The clinical microbiologist should be aware of these species as potential transients or commensals in clinical specimens.

Although *Serratia* spp. are seldom a cause of primary infections, they are notorious nosocomial pathogens and colonizers. The predominant mode of transmission is from person to person, but various medical apparatuses, intravenous fluids, and other solutions have often been implicated as well (71). Patients with indwelling catheters, particularly those for UTIs, serve as a primary reservoir for transmission via hospital personnel. For children, the gastrointestinal tract is a common source of infections. Outbreaks transmitted by hand are often insidious, occurring over long periods of time, and may subside and peak a number of times before recognition and infection control efforts can contain them. Pigment production in *S. marcescens* appears to be a marker that the strain is environmental in origin and of low virulence (11). Community-acquired infections are rare, except for *S. marcescens* contact lens-induced acute red eye (66). Most of the other species of *Serratia* have also been isolated from humans, where they too are usually transients or cause opportunistic infections.

The citrobacteria are considered inhabitants of the intestinal tract primarily, and their presence in the environment may reflect fecal excretion by humans and animals; however, the natural habitat of some newer *Citrobacter* species is unknown. Sepsis involving *Citrobacter* is often polymicrobic, with reported mortality rates as high as 48 to 50%; death is associated more often with polymicrobic than with monomicrobic infections (71). *Citrobacter* meningitis is almost exclusively associated with *C. koseri* and involves children less than 2 months of age, with the highest onset rates noted in neonates with a mean age of 7 days (71). An exceedingly high number (>75%) of these infants develop brain abscesses, and those who survive are generally afflicted with neurological defects. The most prominent risk factor is prior colonization; during outbreaks, colonization rates of 27% have been noted, in contrast to the normal rate of <1% (94, 142). Person-to-person spread from hospital personnel and, less often, mother-to-offspring infections are the most likely pathways; sampling of inanimate or environmental reservoirs in hospitals usually fails to yield *Citrobacter. Citrobacter* species previously belonging to the *Citrobacter freundii* complex, including *C. gillenii* and *C. murlinae,* have been found in human clinical, animal, food, and environmental specimens (21, 23). It is unclear what role many of these species may play in human infections; for some, the numbers of strains available are insufficient to either determine clinical significance in humans or establish a reservoir for infections. *C. rodentium* is the cause of murine colonic hyperplasia (97). This disease is self-limiting in adult mice but causes significant morbidity and mortality in infant mice when outbreaks occur in mouse colonies (97).

Proteus, Providencia, and *Morganella* are widespread in the environment and are normal inhabitants of the gut. While *Proteus* spp., especially *P. mirabilis,* are common causes of uncomplicated UTI, they frequently affect the upper urinary tract as well, causing renal scarring and kidney stone formation (102). Ammonia and CO_2 production from urine caused by the urease of *Proteus* lowers the pH, causing precipitation of soluble ions and the formation of stones, composed of struvite and apatite crystals, within the urinary tract. These crystals, which can be visualized within urine agar (filter-sterilized human urine solidified with agar) that has been inoculated with *Proteus,* are composed of magnesium ammonium phosphate or calcium phosphate (102). Since *P. mirabilis, P. penneri, Morganella,* and *P. alcalifaciens* have been isolated with greater frequency from diarrheal stools than from normal stools, it has been speculated that they may cause diarrhea. However, of these agents, only *P. alcalifaciens* plays a potential role in gastroenteritis. Studies by several groups have shown that *P. alcalifaciens* is invasive in HEp-2 cell assays (6, 77) and elicits diarrhea in the RITARD (reversible intestinal tie-adult rabbit diarrhea) model (6). However, some strains isolated in pure culture or in large numbers from diarrheal stools have failed to invade cell lines. The inability of non-invasive strains to penetrate epithelial cells may be explained by the fact that they appear unable to adhere to cell lines, a prerequisite to invasion (86).

Hafnia alvei has also been linked to gastrointestinal disease. *Hafnia* isolated from the diarrheal stool of a 9-month-old child in pure culture has been found to produce fluid in a rabbit intestinal tie model (5). A 1994 study of tourists returning to Finland found that 5% of patients with diarrhea had *Hafnia* in their stool whereas >300 asymptomatic individuals were negative for *Hafnia* (123). To date, putative virulence characteristics have not been demonstrated in hafniae. Prototypal *Hafnia alvei* isolates from Bangladesh originally identified as diarrheal strains, thought to possess the *eae* gene (attaching-effacing) and thus giving credence to *Hafnia*'s role in diarrhea, were eventually found to be a new species of *Escherichia, E. albertii* (7, 67, 73). Extraintestinal infections caused by *H. alvei* are unusual but can occur in immunocompetent individuals as well as those with underlying diseases, although the latter group is more likely to be affected (122). These infections are often community acquired and are believed to arise from the gastrointestinal tract. *Hafnia* appears to have a predilection for the biliary tree and may produce abscesses at the site of infection (122).

Averyella dalhousiensis is predominantly isolated from human wounds, where it is probably a contaminant since it appears to play no role in these infections (78). However, a recent isolation from blood indicates that it may be an opportunistic pathogen in compromised patients.

In humans, *Plesiomonas shigelloides* is primarily associated with diarrheal disease in infections occurring most frequently in individuals who live in or travel to tropical countries; a history of seafood consumption is common (76, 84). Bacteremia, which is primarily community acquired, is rare, with underlying biliary tract disease and advanced age (>75 years) as major risk factors (145). *Plesiomonas* bacteremias are polymicrobial; the gastrointestinal tract appears to serve as the primary source of infection since concomitantly isolated bacteria are all gastrointestinal agents. A retrospective study of *Plesiomonas* diarrheal infections undertaken in Hong Kong found an infection rate of 5.9% over a four-year period, with increasing numbers of isolations during three of the four years of the study (144). Most infections are self-limiting; however, hospitalization may be required for severe infections and/or for patients with underlying conditions. Symptoms associated with *Plesiomonas* diarrhea vary, and patients may present with either a secretory or a dysenteric type of disease. In the study of Wong et al. (144), 73% of cases had watery diarrhea and 25% had bloody diarrhea. Of 38 Bangladeshi children with monomicrobial *Plesiomonas* diarrhea, 76% were < 2 years of age and 74% were male (84). Vomiting was a significant feature (71%) of infections in these children, but in contrast to other reports, dehydration and fever were less prominent symptoms (23 and 8%, respectively), and the majority of infections were treated with oral rehydration alone. Patients may also report chronic diarrhea for 2 weeks or longer (76, 84). Association of *P. shigelloides* with diarrheal disease has been hampered by the inability to demonstrate putative virulence factors and the lack of an animal model. However, *Plesiomonas* has recently been observed both in membrane-bound vacuoles and free within the cytosol of cultured human colon cells examined by transmission electron microscopy (136). A beta-hemolysin described previously and now shown to be calcium and iron dependent probably plays a role in the infectious process by releasing *P. shigelloides* from intracellular vacuoles (12, 72). The dysenteric form of diarrhea seen with some patients may be explained by the ability to invade and multiply within human gastrointestinal cells. Association of *Plesiomonas* with secretory diarrheal infections is more tenuous, although cholera-like, heat-stable, and heat-labile toxins have been described (70). The lipopolysaccharide of *Plesiomonas* may also play a role in the infectious process in view of the fact that the O17 antigen belonging to the most common serogroup of *Plesiomonas* and the form 1 antigen of *S. sonnei* share almost identical gene regions (29). Although plesiomonads have an aquatic reservoir, wound infections associated with water contact and similar to those found with *Aeromonas* spp. are not encountered. *Plesiomonas* has been isolated from a wide range of mammals (other than humans),

birds, fish, and water-dwelling reptiles and amphibians, but with the possible exception of cats, there is no evidence to suggest that it plays a role in diarrheal disease in any of these species (69).

Edwardsiella tarda is typically associated with animals that inhabit water. It is an infrequent cause of gastroenteritis in humans, with most infections occurring after contact with fish or turtles. However, a low carriage rate in humans, except in tropical areas of the world, and the ability to produce a cell-associated hemolysin and invade HEp-2 cells suggest that *E. tarda* is a diarrheal agent (76). Serious wound infections, including myonecrosis, have been reported in immunocompetent individuals who had aquatic exposure (132). Systemic infections usually occur in patients with liver disease or iron overload conditions.

Except for *E. tarda*, the other *Enterobacteriaceae* listed in the left-hand column of Table 2 cause opportunistic infections and are not frequently encountered in clinical laboratories (71). Some, like *Cedecea* spp., *Leminorella* spp., *Moellerella,* and *Tatumella,* are rarely isolated from nonhuman sources, making it difficult to determine reservoirs for these organisms (53, 59, 60, 65, 71). Strains of *Ewingella, Leclercia,* and *Kluyvera* spp. have been found in a variety of foods, water, or animals (snails and slugs) and are probably, like many *Enterobacteriaceae,* ubiquitous in the environment (40, 54, 71, 135). Other genera that have been isolated from human specimens have more specific natural habitats. These include *Rahnella* (71), all of whose initially described isolates were recovered from water, which probably serves as the reservoir for human infections, or *Yokenella* and both subspecies of *Photorhabdus asymbiotica,* which are common in insects and have caused infections following insect bites (3, 41, 88).

ISOLATION

For the most part, none of the clinically relevant strains covered in this chapter present difficulties in isolation from sterile body sites. Cockerill et al. (31) did find, however, that in blood cultures both *E. cloacae* and *S. marcescens* grew significantly better in aerobic culture than in nonvented or anaerobic culture; no difference was noted for other major species of the genera included in this chapter. Isolation from nonsterile body or environmental sites may require specialized media.

A number of chromogenic media have been developed to isolate and differentiate urinary tract pathogens based on the colony color produced by the enzymatic action of the organism on chromogenic substrates in the medium. Of these, CHROMagar Orientation (Becton Dickinson, Sparks, Md.) and CPS ID2 (bioMérieux, Hazelwood, Mo.) perform similarly for the detection of the UTI pathogens covered in this chapter and can reliably replace commonly used media such as MacConkey and blood agars (BA) (26, 128). However, CHROMagar is more sensitive for the isolation of *E. coli* because it detects beta-galactosidase while CPS ID2 detects beta-glucuronidase (26, 128). Although *Proteus, Providencia, Morganella, Klebsiella, Citrobacter,* and *Enterobacter* are all easily identified on both of these media, further biochemical tests are required to identify them to the species level. Both media prevent swarming of *Proteus,* and mucoid colonies allowing for easier detection of multiple pathogens and antimicrobial susceptibility tests can be performed directly without the need for subculturing. Ohkusu (115) expanded the usage of CHROMagar Orientation to cover isolation of pathogenic organisms from wound, stool, and a variety of other specimens in addition to urine. Using colony color on CHROMagar in combination with indole, lysine, and ornithine decarboxylase tests and serology, 466 of 472 (98.7%) isolates were correctly identified.

Both of the diarrheal pathogens covered in this chapter are easily isolated. *E. tarda,* which is a lactose-negative, H_2S-positive organism, is indistinguishable from *Salmonella* on enteric plating media (opaque or opaque with black centers). A positive indole reaction and lack of agglutination in specific *Salmonella* antisera differentiate *E. tarda* strains. *Plesiomonas* grows as 2- to 3-mm, opaque, convex colonies on BA or as non-lactose-, non-sucrose-fermenting colonies on enteric plating media. It does not grow on thiosulfate-citrate-bile salts-sucrose medium but does grow well on, and can be isolated from, cefsulodin-irgasan-novobiocin (CIN) medium. Because *Plesiomonas* does not ferment mannitol, the colonies are opaque without a pink center on CIN medium. It must be distinguished from other oxidase-positive organisms *(Pseudomonas, Aeromonas)* that can also grow on this medium, although *Aeromonas* should have a pink center with an opaque apron. Inositol fermentation and a positive reaction in Moeller's lysine, arginine, and ornithine tests differentiate *Plesiomonas* from other organisms.

Other *Enterobacteriaceae* that are involved in opportunistic infections and that may be isolated from a variety of specimen types generally grow well on commonly used laboratory media (71). Some genera are lactose or sucrose fermenters and give the appearance of normal flora on enteric plating media, while others may produce H_2S and appear *Salmonella*-like. *Rahnella, Ewingella,* and *Tatumella* may require 48 h for growth. *Tatumella* also grows poorly on Mueller-Hinton agar, and a broth dilution method may be required for susceptibility testing. Strains of *Tatumella* do not survive well at room temperature and should be stored at −70°C.

K. (C.) granulomatis, as with many of the organisms in the third column of Table 2, does not grow on conventional laboratory media. Since it does not stain well with gram reagents, Giemsa- or Wright-stained Donovan bodies have been the method most commonly used to detect this organism. However, Donovan bodies, which are pleomorphic, bipolar staining bodies shaped like a closed safety pin, are not always present and are not reliable for diagnosis. Recently, growth in HEp-2 monolayers has been achieved (27). Primers to the *phoE* and *scrA* (sucrose regulon) genes have been used to identify and distinguish *K. (C.) granulomatis* (*phoE* positive) from *Klebsiella* species (*phoE* and *scrA* positive) (28).

IDENTIFICATION

The biochemical tests most useful for differentiating species within each genus are given in Tables 3 through 13. Full biochemical profiles for most species can be found in chapter 42. Correct identification to the species level is increasingly important in recognizing strains that are of high risk for carrying extended-spectrum beta-lactamases, cephalosporinases, or carbapenemases (95). Identification problems arising from the use of commercial systems vary with each genus. Of the *Klebsiella, K. ozaenae* and *K. rhinoscleromatis* do the poorest in commercial systems, probably as a result of slow growth. These species can be difficult to distinguish using conventional biochemicals as well. *R. (Klebsiella) planticola* and R. *(Klebsiella) terrigena* cannot be readily separated from other *Klebsiella* without temperature growth or carbon assimilation tests, neither of which are readily available in most clinical laboratories.

[b] Fermentation reactions in commercial systems should be similar to reactions in conventional fermentation broths (1% carbohydrate in broth with indicator).

Growth at 10°C, utilization of histamine, and no gas production from lactose at 44.5°C can be used to separate *Raoultella* spp. from *K. pneumoniae* and *K. oxytoca; R. terrigena* can be distinguished from *R. planticola* by fermentation of β-gentibiose. The new species, *K. variicola*, is not in commercial systems; *K. variicola* strains do not ferment adonitol (some strains are L-rhamnose negative as well), and reportedly only this trait separates it from *K. pneumoniae* (124).

Members of the genus *Enterobacter* appear to confound commercial systems more often than other genera in the *Enterobacteriaceae,* probably because of the heterogeneity of several of the species (71). Most major commercial systems include at least nine *Enterobacter* species, and they all identify the three major *Enterobacter* species *(E. cloacae, E. aerogenes,* and *E. sakazakii)* at an acceptable accuracy rate of ≥90% (71). The percentage of correct identifications with many

[d] *K. variicola* is separated from *K. pneumoniae* by negative adonitol reaction; some strains are also L-rhamnose negative.

commercial systems increases significantly when "low probability" identifications are included as correct identifications or when additional biochemical tests are performed following initial testing results. Neither *E. ludwigii* nor the subspecies of *E. hormaechei* can be separated from other clinically relevant *Enterobacter* spp. by biochemicals readily available in most clinical laboratories. In the Biotype 100 system (bioMerieux, Marcy l'Etoile, France), *E. ludwigii* can be separated from *E. cloacae,* the most common species that it resembles phenotypically, by growth on 3-0-methyl-D-glucopyranose and putrescine (64). Likewise, *E. hormaechei* subspecies can be separated from *E. cloacae* in the Biotype 100 system by growth on L-fucose and 1-0-methyl-α-galactopyranoside for subsp. *hormaechei,* growth on D-arabitol and adonitol for subsp. *steigerwaltii,* and growth on 3-hydroxybutyrate for subsp. *oharae* (63).

Serratia spp. are generally easily identified by commercial systems, except for the *S. liquefaciens* group; differentiation of members within this group requires carbon assimilation tests (71). These tests can be performed using a combination of API 50 CH and API ZYM (carbohydrate and enzymatic panels, respectively) (bioMérieux, Hazelwood, Mo.) strips (50).

Most automated system databases now contain the newer *Citrobacter* spp., at least to subgroups *(C. braakii-C. freundii-C. sedlakii, C. werkmanii-C. youngae,* and *C. koseri-C. amalonaticus)*; however, subgroup identification requires further biochemical testing by standard methodologies to identify strains to the species level, and this delays final identification (71). A PYR (L-pyroglutamic acid to detect pyrrolidonyl peptidase [Oxoid PYR Test]) test may be useful for separating biochemically atypical strains of *Citrobacter* (positive) and *Salmonella* (negative) (15).

Two members of the genus *Proteus* can be rapidly identified with minimal testing. Gram-negative and oxidase-negative organisms with colonies that swarm on BA and appear flat with tapered edges on MacConkey agar may be reported as *Proteus*. *Proteus* spp. that are spot indole negative and ampicillin susceptible may be reported as *P. mirabilis* (13).

TABLE 6 Biochemical characterization of members of the genus *Serratia*[a,b]

Species	LDC	ODC	Mal	Acid[c] from:								Red pigment	Odor
				Arabinose	L-Rhamnose	D-Xylose	Sucrose	Adonitol	D-Sorb	Cello	D-Ara

M. *morganii* subsp. *sibonii*	V	−[d]	+	+[e]	−	−	−	+	−

[a] Abbreviations and symbols: H_2S, hydrogen sulfide; ODC, ornithine decarboxylase; +, ≥90%; V, 11 to 89%; −, ≤10%.
[b] See Table 3, footnote *b*.
[c] *P. vulgaris* genomospecies 4, 5, and 6 cannot be differentiated phenotypically.
[d] Some members of some biogroups are H_2S positive.
[e] Some members of some biogroups are ornithine decarboxylase negative.

P. penneri, which is a rare clinical isolate, also fits the above description but can be separated from *P. mirabilis* by its negative reactions in ornithine decarboxylase and maltose. Spot indole-positive, ampicillin-resistant strains are reported as *P. vulgaris* (13). *P. hauseri,* previously a subgroup of *P. vulgaris,* can be differentiated from *P. vulgaris* by a negative salicin or esculin reaction (110). Although it is found in clinical specimens, *P. hauseri* is infrequently seen in the laboratory (75). If an organism does not fit any of the above qualifications, it must be fully identified by commercial or conventional biochemical methods (13). Most commercially available systems satisfactorily identify *Proteus,* with reports varying between 95 and 100% accuracy for different systems. *Providencia* spp., however, are not identified with the same level of accuracy in commercial systems, and the rates vary from 79 to 100% (110). When *Providencia* spp. are misidentified, they are usually called *Morganella* or *Proteus*. Urea-positive *P. stuartii* may be misidentified as *P. rettgeri,* or the system may require additional tests for identification. *P. heimbachae* is not in commercial system databases (110). M. *morganii* subsp. *morganii* is identified 100% of the time in commercial systems according to most studies, although 2-h identification methods misidentify it about 66% of the time. M. *morganii* subsp. *sibonii* is not included in most databases and may be distinguished from subsp. *morganii* only by a positive reaction in trehalose.

Hafnia alvei, which biochemically most closely resembles members of the genus *Enterobacter,* and *Yokenella regensburgei* (Table 11) are usually correctly identified in commercial systems. Biogroup 2 strains of *H. alvei* can be separated from *H. alvei* sensu stricto by a positive malonate reaction (74).

Averyella dalhousiensis is not included in commercial system databases; it is an indole-, VP-, H_2S-negative, lysine decarboxylase-positive organism that gives variable reactions in citrate, urea, and dulcitol (78). It most closely resembles *Kluyvera ascorbata* but differs from it by negative reactions in indole, melibiose, and mucate. It also may be misidentified as *Salmonella enterica* in commercial systems but can be differentiated from *Salmonella* subgroup 1 strains by a negative reaction in H_2S, a positive reaction for urease at 48 h, and fermentation of cellobiose. *Averyella* strains are *o*-nitrophenyl-β-D-galactopyranoside (ONPG)-, malonate-, and potassium cyanide-positive and ferment dulcitol and salicin, traits shared with *Salmonella* subgroups 2, 3, and 4.

The two agents of gastroenteritis, *Plesiomonas* (Table 13) and *E. tarda* (Table 12), are easily separated both from other

TABLE 8 Separation of *Cedecea* from selected *Enterobacter* species (VP, ADH, and ODC variable or positive)[a]

Organism	Acid[b] from:					
	D-Sorbitol	Raffinose	L-Rhamnose	Melibiose	D-Arabitol	Sucrose

TABLE 9 Differentiation of *Kluyvera* from commonly seen indole-positive, VP-negative organisms[a]

Organism	Citrate	Urea	LDC	KCN
Kluyvera[b]	−	−	+	+
C. koseri	+	V	−	−
Morganella	−	+	−	+
Providencia	V	+	−	+
E. coli	−	−	+	−

[a] Abbreviations and symbols: VP, Voges-Proskauer; LDC, lysine decarboxylase; KCN, potassium cyanide; +, ≥90%; V, 11 to 89%; −, ≤10%. *Leclercia* and *E. tarda* are also indole positive and VP negative and can be found in Tables 10 and 12, respectively.

[b] Includes *K. intermedia* (*K. cochleae* and *Enterobacter intermedius* combined) (118).

enteric pathogens and from normal flora, and their identification presents no difficulty in either conventional or commercial systems. Sequencing data have shown that the somatic antigen that occurs in the most common serogroup of *Plesiomonas* (serogroup O17) and the form 1 antigen of *S. sonnei* share almost identical gene regions (29). Thus, if *Shigella* serotyping is mistakenly performed with strains of *Plesiomonas,* cross-reactions may occur.

Reactions to identify other enterobacteria isolated from clinical specimens can be found in Tables 8 through 12. The organisms are grouped with the genera with which they would most likely be confused and from which they must be differentiated. Many of the agents in these tables are in commercial system databases. Unfortunately, the number of strains available for use in challenge studies is very limited; therefore, the ability of these systems to accurately identify these organisms is really unknown. *Ewingella* and *Tatumella* are biochemically inactive, and the latter organism grows poorly in vitro. *Kluyvera* can be identified only to genus level by these systems; species determination requires an ascorbate test and irgasan susceptibility and/or gas-liquid chromatography profiles (71). *Photorhabdus asymbiotica* is not included in most commercial databases. *Pantoea dispersa, P. ananatis,* and *Erwinia persicinus* most closely resemble *P. agglomerans*. *P. dispersa* and *E. persicinus* may be distinguished from *P. agglomerans* by negative reactions for raffinose, salicin, and sucrose and by negative reactions for maltose and D-xylose, respectively. *P. ananatis* is more difficult to differentiate, and all suspected isolates of this organism, as with other rare *Enterobacteriaceae,* should be sent to a reference laboratory for confirmation.

At this time, 16S rRNA sequencing is not used extensively to identify this group of organisms and not all species are included in currently available databases. The use of molecular methods (see chapter 16) to determine the presence and/or identity of bacteria directly from clinical specimens or from isolates is increasingly reported but not universally available. These methods offer a great advantage when bacteria are difficult or impossible to culture, such as *K. (C.) granulomatis,* or in the case of diseases such as keratitis, where cultures are negative 40 to 60% of the time (87). Testing of specimens from sterile sites with universal primers based on conserved regions of the bacterial chromosome (with the exception of *K. granulomatis*) can be used to determine if a patient has a bacterial infection in 1 h (16). Normally sterile clinical specimens found negative by these assays would not then require culturing, saving considerably on laboratory resources. However, numerous problems remain to be worked out with these methods for bacterial identification. For rRNA sequencing these include, but are not limited to, DNA extraction protocols, ambiguous profiles arising from testing mixed cultures, the presence of too few species in the databases, and percent similarity cutoff guidelines for identification to the species or genus level (36).

The ability to trace the spread or involvement of nosocomial pathogens in outbreaks caused by the *Enterobacteriaceae* has become a major responsibility for the laboratory. Biotyping using commercially available identification systems is seldom suitably discriminating, unless an unusual marker or profile is present. Biotyping schemes using carbon assimilation tests have been developed, particularly for *Serratia,* but may be difficult and costly to perform (50). Typing all genera for which traditional typing methods are available (serotyping, bacteriocins, and bacteriophages) would necessitate multiple sets of reagents, which are not readily available and/or are economically prohibitive. Molecular techniques including plasmid analysis, ribotyping, pulsed-field gel electrophoresis (PFGE), and various PCR methodologies all appear satisfactorily discriminatory, some working better for a specific genus or species than others (see chapter 16). The variety of PCR techniques is proliferating at an astonishing pace, especially repetitive-element PCR methods for the *Enterobacteriaceae*. Care in the performance and interpretation of these assays is critical since many PCR techniques have not been standardized (38, 48). For now, since a single method applicable to the most strains is preferable, at least economically, PFGE remains the most universally accepted standardized technique for epidemiological studies.

TABLE 10 Separation of LDC-, ODC-, and ADH-negative unusual *Enterobacteriaceae* found in clinical specimens[a]

Organism	Motility	Gas from glucose	KCN	VP	Acid[b] from:		
					Sucrose	L-Arabitol	Trehalose
Ewingella	V	−	−	+	−	−	+
Leclercia	+	+	+	−	+	+	+
Moellerella	+	+	V	−	−	+	+
Rahnella	−	+	−	+	+	+	+
Tatumella	−	−	−	−	+	−	+
Photorhabdus asymbiotica[c]	+	−	−	−	−	−	−

[a] Abbreviations and symbols: LDC, lysine decarboxylase; ODC, ornithine decarboxylase; ADH, arginine dihydrolase; KCN, potassium cyanide; VP, Voges-Proskauer; +, ≥90%; V, 11 to 89%; −, ≤10%. *Budvicia* is also LDC, ODC, and ADH negative and can be found in Table 12.

[b] See Table 3, footnote *b*.

[c] *Photorhabdus* subsp. *australis* can be separated from subsp. *asymbiotica* by fermentation of maltose and glycerol.

TABLE 11 Separation of *Yokenella* from *Hafnia*[a]

Organism	VP	Malonate	Citrate	Acid[b] from:

H. alvei biogroup 2	+	−	V	−	+

[a] Abbreviations and symbols: VP, Voges-Proskauer; +, ≥90%; V, 11 to 89%; −, ≤10%. Data from reference 74.
[b] See Table 3, footnote *b*.

The disadvantage of a long turn-around time (usually 4 days) has been partially overcome by a rapid PFGE protocol that is suitable for most enteric bacteria as well as other common clinical strains (45).

ANTIMICROBIAL SUSCEPTIBILITY

The number of strains harboring extended-spectrum β-lactamases (ESBL), cephalosporinases and carbapenemases that mediate resistance to the β-lactam antibiotics (Table 14) (for resistance mechanisms, see chapters 71, 74, and 78), and the increase in resistance to quinolones are major issues with members of the *Enterobacteriaceae* (10, 143). In one study, of >380,000 blood, respiratory, and urine isolates of *Enterobacteriaceae* tested against 14 antimicrobials, susceptibilities of <90% were recorded for eight (46 to 89%) and three (57 to 84%) drugs for intensive care unit (ICU) and non-ICU patients, respectively (83). Ceftazidime, cefotaxime, and ceftriaxone susceptibility rates were up to 10% lower for isolates from ICU patients than from non-ICU patients; however, only three isolates were carbapenem resistant, two of which were *E. aerogenes*. Only fluoroquinolone susceptibility decreased over a 4-year period, and fluoroquinolone-resistant *Enterobacteriaceae* were frequently resistant to extended-spectrum cephalosporins, aminoglycosides, and trimethoprim-sulfamethoxazole (SXT) (83). Ciprofloxacin resistance, influenced by antibiotic usage and clonal spread of strains containing ESBLs among patients, has been found in strains of *K. pneumoniae* and *K. oxytoca,* with rates as high as 7.2 and 3.4%, respectively (24). Imipenem resistance has been noted worldwide among the *Enterobacteriaceae;* it typically emerges during long therapy to treat ceftazidime- and aminoglycoside-resistant strains and appears reversible with cessation of therapy (1, 19). Cefepime resistance in *Enterobacter* spp. and *K. oxytoca* strains has been reported (126).

The spread of ESBL-producing strains can be controlled, without restricting antimicrobial usage, by using barrier precautions and cohorting patients after discharge from ICUs, since transmission occurs primarily on the hands of hospital staff (96, 117). However, Paterson and Yu (117) recommend a three-prong effort to control ESBL-producing organisms, which includes enhancing surveillance and control within the ICU, increasing laboratory capability in the detection of ESBLs, and limiting empirical use of antibiotics. Restriction of specific antimicrobials may reduce resistance in one or several species but select for resistance in others, substituting one problem for another (90). Further, resistance to one drug found in a multi-drug-resistant isolate will be maintained or accelerate in patient populations even if use of the drug is discontinued, as long as the other drugs to which the strain is also resistant are prescribed (83).

The effective infection control of organisms harboring ESBLs necessitates that the laboratory provides testing methods that will detect these strains. The question of whether it is cost-effective for laboratories to test for ESBL-producing organisms because their detection isn't likely to affect patient outcome has not been resolved (39). Studies to determine the outcomes of serious infections caused by organisms considered cephalosporin "susceptible" or "intermediate" in vitro found that 54% of patients who were treated with a cephalosporin experienced therapy failure (116). These patients either succumbed to their infections or required a change in therapy to achieve a cure. UTIs caused by ESBL-producing organisms can be successfully treated with cephalosporins, eliminating the need to test urine isolates for ESBL production for therapeutic consideration; however, testing may be required for infection control efforts to prevent horizontal transfer of these strains. Appropriate broth microdilution and disk diffusion testing procedures for ESBL-producing *Klebsiella* spp. are described in chapter 74.

Strains of *P. mirabilis* are resistant to nitrofurantoin but susceptible to trimethoprim-sulfamethoxazole, ampicillin, amoxicillin, piperacillin, cephalosporins, aminoglycosides, and imipenem. Although most strains are susceptible to ciprofloxacin, resistance occurs with unrestricted use of the drug (110). *P. penneri* and *P. vulgaris* have resistance profiles similar to that of *Morganella,* although *P. penneri* is more resistant to penicillin than *P. vulgaris*. All three organisms are susceptible to broad-spectrum cephalosporins, cefoxitin,

TABLE 12 Separation of *Enterobacteriaceae* that may be H_2S positive[a]

Organism	LDC	ODC	Urea	Acid[b] from L-arabinose	Citrate	KCN	ONPG

Trabulsiella guamensis[d]	+	+	−	+	V	+	+
Salmonella subgroup 1	+	+	−	+	+	−	−
Citrobacter	−	V	V	+	V	+	+
Proteus	−	V	+	−	V	+	−

[a] Abbreviations and symbols: LDC, lysine decarboxylase; ODC, ornithine decarboxylase; KCN, potassium cyanide; ONPG, *o*-nitrophenol-β-D-galactopyranoside; +, ≥90%; V, 11 to 89%; −, ≤10%.
[b] See Table 3, footnote *b*.
[c] *L. grimontii* is positive, *L. richardii* is negative.
[d] Found in clinical specimens but of questionable or no significance.

TABLE 13 Differentiation of *P. shigelloides* from other clinically significant members of the *Vibrionaceae* and the *Aeromonadaceae*[a]

Organism	LDC	ODC	ADH	Gas from glucose	Acid[b] from:		Growth in:		O/129 susceptibility
					Sucrose	Inositol	TCBS	0% NaCl	
Plesiomonas	+	+	+	−	−	+	−	+	+
Aeromonas spp.	V	−[c]	+	V	V	−	−	+	−
Vibrio spp.[d]	+	+	−	−	V	−	+	V	+

[a] Abbreviations and symbols: LDC, lysine decarboxylase; ODC, ornithine decarboxylase; ADH, arginine dihydrolase; TCBS, thiosulfate-citrate-bile salts-sucrose agar; O/129, 2,4-diamino-6,7-diisopropylpteridine; +, ≥90%; V, 11 to 89%; −, ≤10%.
[b] See Table 3, footnote *b*.
[c] Only *A. veronii* biotype *veronii* is positive.
[d] *V. hollisae* is LDC, ODC, and ADH negative; only *V. fluvialis* and *V. furnissii* are ADH positive; *V. furnissii* produces gas; *V. cincinnatiensis* ferments *myo*-inositol; *V. cholerae* and *V. mimicus* grow in 0% NaCl.

cefepime, aztreonam, aminoglycosides, and imipenem. They are resistant to piperacillin, amoxicillin, ampicillin, cefoperazone, cefuroxime, and cefazolin. *Providencia rettgeri* and *P. stuartii* are resistant to gentamicin and tobramycin but susceptible to amikacin. Urine isolates are susceptible to broad- and expanded-spectrum cephalosporins, ciprofloxacin, amoxicillin-clavulanic acid, imipenem, and SXT. *Providencia heimbachae,* although infrequently seen in humans, is resistant to tetracycline, most cephalosporins, gentamicin, and amikacin. Human isolates of *E. tarda* are susceptible to cephalosporins, aminoglycosides, imipenem, ciprofloxacin, aztreonam, and antibiotic-β-lactamase inhibitor combination agents (30). Isolates from fish and fish ponds may be more resistant because of the prophylactic use of antibiotics in fish farming. Most strains of *E. tarda* produce β-lactamases, even though they are susceptible to β-lactams. *P. shigelloides* is resistant to ampicillin, carbenicillin, piperacillin, and ticarcillin and is variably resistant to most aminoglycosides and tetracycline (70). Cephalosporins, quinolones, carbapenems, and SXT show good activity against *P. shigelloides*.

Freney et al. (44) performed susceptibility studies with 120 isolates of uncommonly seen species of *Klebsiella, Enterobacter,* and *Serratia* and found their susceptibilities to be similar to those of conventional species within each genus. Because they are infrequently seen in clinical laboratories, resistance profiles of many of the other *Enterobacteriaceae* are found only in individual case reports. Susceptibilities vary from isolate to isolate even within a genus, so that no empirical guidelines are available for therapy prior to susceptibility testing of the suspected strain.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

When any of the species included in this chapter are identified with a high level of accuracy (>90% probability) by a commercial system, the identification is probably reliable. However, if the organism is isolated from a source where it may be considered significant, such as blood or

Table 14 Extended-spectrum β-lactamases, cephalosporinases, and carbapenemases of the *Enterobacteriaceae*[a]

cerebrospinal fluid, and the identification has a probability of <90%, the isolate should be identified by conventional methods or sent to a reference laboratory using these techniques. In the interim, the isolate may be reported to the physician with a presumptive identification. For those strains seen more commonly, the antimicrobial susceptibility profile may be a helpful adjunct for deciding if identifications with lower probabilities are reliable. Rare species that are identified with low probabilities should always be sent to a reference laboratory accompanied by a brief history. Colony appearance on MacConkey and blood agar plates, spot oxidase and indole reactions, and ampicillin susceptibility or resistance are sufficient for reporting *P. mirabilis* and *P. vulgaris* (13). At the very least, susceptibility testing of strains of *Klebsiella* that appear to contain ESBLs should be tested by the methods described in chapter 74. Any strain of *Enterobacteriaceae* that has been shown to have an ESBL or AmpC cephalosporinase should be reported as resistant to all penicillins, expanded-spectrum cephalosporins, and aztreonam (117).

Aeromonas

AMY J. HORNEMAN, AFSAR ALI, AND SHARON L. ABBOTT

46

TAXONOMY

The genus *Aeromonas* resides within the family *Aeromonadaceae* (8) and the newly proposed order *Aeromonadales,* ord. nov., along with the genera *Oceanimonas* and *Tolumonas* (30). *Aeromonas* is the only one of these three genera that is pathogenic for humans. The frequent reclassifications and constant amended or extended descriptions within *Aeromonas* taxonomy can often be initially puzzling to microbiologists not working with these organisms on a daily basis; however, the information in this chapter should clarify the identification and significance of those species most often associated with human disease (Table 1). DNA hybridization group numbers, which no longer serve a meaningful purpose, and synonymous species designations for *Aeromonas veronii* bv. sobria *(A. ichthiosmia)* and *A. trota (A. enteropelogenes)* (7) are not included for simplicity. *Aeromonas* group 501, which is made up of *A. schubertii*-like organisms, and *Aeromonas* sp. DNA hybridization group 11 (31), which is made up of *A. eucrenophila*/*A. encheleia*-like organisms, are also not addressed in the table. These groups contain few strains, their taxonomic status has yet to be resolved and is still highly debated, and most importantly, neither group has been shown to be significant in human or animal disease. Newly proposed *Aeromonas* species and subspecies since the publication of the previous edition of this Manual include *A. hydrophila* subspecies *hydrophila,* sensu stricto (19); *A. hydrophila* subsp. *dhakensis,* isolated from pediatric diarrheal cases in Bangladesh (19); *A. hydrophila* subsp. *ranae,* isolated from septic frogs in Thailand (20); *A. culicicola,* isolated from mosquitoes and drinking water (11, 38); *A. simiae,* isolated from monkey feces (16); and *A. molluscorum,* isolated from bivalve mollusks (34). Because of its clinical significance, it should be noted that clinical strains formerly referred to as "*A. sobria*" are, in fact, *A. veronii* bv. sobria (esculin hydrolysis and ornithine decarboxylase negative and arginine dihydrolase positive) and should be reported as such. Nearly all rapid identification databases, excepting API 20E strips (BioMerieux, Hazelwood, Mo.), have converted their *A. sobria* identifications to *A. veronii* bv. sobria. This is especially important because of *A. veronii* bv. sobria's association with more severe, extraintestinal infections, such as septicemia, meningitis following leech therapy, and disseminated intravascular gas production (36, 43). It usually is not necessary to definitively separate members of the *A. hydrophila* complex (*A. hydrophila, A. bestiarum,* and *A. salmonicida)* or the *A. caviae* complex (*A. caviae, A. media,* and *A. eucrenophila),* especially when they are isolated from feces (see "Interpretation and Reporting of Results" below).

The type strain *Aeromonas hydrophila* ATCC 7966^T recently had its 4.7-megabase genome completely sequenced and is undergoing manual annotation at The Institute for Genomic Research (TIGR). Preliminary data can be accessed at the TIGR Homepage at http://www.tigr.org under the link for "Unfinished Genomes," and the entire genome will eventually be available in GenBank at NCBI.

DESCRIPTION OF THE GENUS

Members of the genus *Aeromonas* are gram-negative facultative anaerobes that are straight, coccobacillary to bacillary cells with rounded ends, 0.3 to 1.0 μm in diameter and 1.0 to 3.5 μm in length. They can occur singly, in pairs, or rarely in short chains. Most species are motile by a single, polar flagellum of 1.7-μm wavelength, but peritrichous flagella may be formed on solid media in young cultures and lateral flagella occur in some species. Aeromonads are usually oxidase positive and catalase positive and are generally resistant to 150 μg of the vibriostatic agent 2,4 diamino-6,7-diisopropylpteridine (O/129). They are chemoorganotrophic, displaying oxidative and fermentative metabolism of glucose. Acid and often acid with gas are produced from many carbohydrates, especially glucose, and nitrate is reduced to nitrite. A variety of exoenzymes such as arylamidases, amylase, DNase, esterases, peptidases, proteases, chitinase, chondroitinase, and hemolysins are produced. The main cellular fatty acids produced are hexadecanoic acid (16:0), hexadecenoic acid (16:1), and octadecenoic acid (18:1). Human (mesophilic) strains grow between 10 and 42°C, but occasional isolates may be more active in some biochemical assays at 22 to 25°C. Psychrophilic strains from fish and the environment *(A. popoffii* and *A. salmonicida)* seldom grow above 37°C and preferentially grow at 22 to 25°C. In brain heart infusion broth at 28°C, growth occurs between pH 4.5 and 9.0 and at salt concentrations between 0 and 4%. The mol% G+C of the DNA is 57 to 63%.

NATURAL HABITATS

Aeromonads are inhabitants of aquatic ecosystems worldwide. These include groundwater and drinking water at treatment plants and in distribution systems and reservoirs as well as

TABLE 1 Members of the genus *Aeromonas*[a]

Organism	Human isolation (extraintestinal/fecal)	Human pathogen (extraintestinal/fecal)	Frequency in humans	Pathogenic for animals, fish, reptiles

[a] Abbreviations and symbols: bv., biovar; —, not applicable.
[b] There are motile strains of *A. salmonicida* that grow at 37°C and resemble clinical *A. hydrophila* strains that have been isolated from human feces; these can be distinguished using the tests in Table 3.

clean or polluted lakes and rivers. *Aeromonas* may also be found in marine environments but only in brackish water or water with a low saline content. Most *Aeromonas* species, particularly those associated with human infections, are found in a wide variety of fresh produce, meat (beef, poultry, and pork), and dairy products (raw milk and ice cream) (24). *A. veronii* bv. sobria is a symbiont in the gut of medicinal leeches, where it may grow as a pure culture (15). In fisheries, psychrophilic strains of *Aeromonas* cause severe infections resulting in considerable economic loss. Infections in frogs, pigs, cattle, birds, and marine animals have also been reported (24).

CLINICAL SIGNIFICANCE

Aeromonas gastroenteritis ranges from an acute watery diarrhea (most common form) to dysenteric illness to chronic illness. Stools from acute watery diarrhea are loose (take the shape of their container), and erythrocytes and fecal leukocytes are absent. Accompanying symptoms include abdominal pain (60 to 70%), fever and vomiting (20 to 40%), and nausea (40%) (22). Infections are usually self-limiting, but children may require hospitalization due to dehydration. *A. caviae* is the most common species associated with these infections and can even mimic inflammatory bowel disease in children (48). *A. veronii* bv. sobria strains may be associated with rare cholera-like disease characterized by abdominal pain (60%) and fever and nausea (20%) (22). In dysenteric diarrhea resembling shigellosis, patients suffer from severe abdominal pain and have bloody stools containing mucus and polymorphonuclear leukocytes. About 10 to 15% of patients with either cholera-like or dysenteric diarrhea are coinfected with another enteric pathogen(s).

A comprehensive study done in Bangladesh in 2000 found that the presence of loose stools was associated with *Aeromonas* strains possessing an *alt* gene encoding a heat-labile cytotonic enterotoxin (4). Patients with more severe disease and watery diarrhea had strains that possessed both the *alt* gene and a second gene, *ast,* which encodes a heat-stable cytotonic enterotoxin. A total of seven different *Aeromonas* species were associated with diarrhea in this study. This was followed by a large 2003 study of traveler's diarrhea associated with *Aeromonas* species in Spain, where the predominant species isolated were *A. veronii* bv. veronii and *A. caviae* (49). Finally, a large 2004 study completed in Kolkata, India, found seven different species of *Aeromonas* among hospitalized diarrheal cases, with *A. caviae* predominating, followed by *A. hydrophila* and *A. veronii* bv. sobria. They also found the *alt* and *act* genes in 71.9 and 20.1% of the isolates, respectively, and only 2.4% of the isolates carried the *ast* gene (44).

Complications from *Aeromonas* diarrheal disease include hemolytic uremic syndrome (5) or kidney disease requiring

kidney transplantation (12). These more severe infections are usually associated with *A. hydrophila* or *A. veronii* bv. sobria. Also, nonresolvable, intermittent diarrhea can occur months after the initial infection and may persist for months or several years.

Aeromonas can also be isolated from a variety of extraintestinal sites, although blood and wounds are the most common sources. *Aeromonas* septicemia occurs rarely in immunocompetent hosts; most cases involve patients with liver disease and hematological malignancies. The more commonly isolated species from septicemia are *A. hydrophila, A. veronii* bv. sobria, and *A. jandaei,* with a recent third case report (33) of septicemia with an *A. veronii* bv. veronii strain (arginine dihydrolase negative, esculin hydrolysis positive, and ornithine decarboxylase positive). Fatality rates in these infections range from 30 to 50%. Wound infections are usually preceded by traumatic injury that occurs in contact with water, where the predominant species is *A. hydrophila.* These infections range from uncomplicated cases of cellulitis to myonecrotic infections with a poor prognosis. Two such scenarios are the reported outbreak of wound infections with *A. hydrophila* associated with mud football (47) and wound infections among the 2004 Asian tsunami survivors (29). Surveys indicate that only 17 to 52% of *Aeromonas* wound infections are monomicrobic (24). Use of medicinal leeches postoperatively to enhance blood flow to surgical sites has resulted in wound infection rates of 20%, primarily with *A. veronii* bv. sobria (15). Other extraintestinal infections include ocular, respiratory, and urinary tract infections; meningitis; osteomyelitis; cholecystitis; endocarditis; and peritonitis (23). Two recent examples were the isolation of *A. caviae* from keratitis associated with contact lens wear (39) and the isolation of *A. popoffii* from a urinary tract infection (18).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Aeromonads survive well in specimens; any of the widely used transport media are acceptable for transport, including buffered glycerol in saline (chapter 20). Feces are always preferable to rectal swabs for isolation of enteric pathogens, and stools should be collected in the acute phase of disease.

ISOLATION PROCEDURES

Aeromonads generally grow well on a variety of enteric differential and selective agars, although sucrose- and/or lactose-fermenting strains usually resemble nonpathogens on these media. Blood agar (BA) with 20 μg of ampicillin per ml (ABA) is useful for isolating all *Aeromonas* species except *A. trota,* which is intrinsically susceptible to ampicillin, and a substantial percentage (15 to 57%) of *A. caviae* isolates (6, 27). Since most clinically relevant species are beta-hemolytic, including an increasing number of *A. caviae* strains, beta-hemolytic colonies on BA should be screened with oxidase and a spot indole test. Any colonies positive for both tests should be characterized further, although occasional indole-negative *A. caviae* isolates and nearly all known *A. schubertii* strains (which are generally associated with severe aquatic wounds) are indole negative (2). Modified cefsulodin-Irgasan-novobiocin (CIN) (which contains 4 μg of cefsulodin per ml versus 15 μg/ml in unmodified CIN) is also an excellent isolation medium for aeromonads. On this medium, *Aeromonas* colonies have a pink center with an uneven, clear apron and are indistinguishable from *Yersinia enterocolitica* morphologically. One can incubate CIN at 25°C to enhance the recovery of *Yersinia* and still be able to recover *Aeromonas* within 24 h at this temperature. For optimal isolation, use of both ABA and modified CIN is recommended (26). A xylose-galactosidase medium (XGM), containing novobiocin, bile salts, xylose, and two galactopyranosides, has been evaluated in Europe for the isolation of *Aeromonas, Salmonella, Shigella,* and *Yersinia* spp. (14). *Aeromonas* species, which form green colonies, were isolated more frequently from XGM agar (36%) than from any other medium except CIN (43%), but XGM had fewer false positives (11% for XGM versus 60% for CIN). Thiosulfate-citrate-bile salts-sucrose (TCBS) medium is usually inhibitory to aeromonads. Enrichment in alkaline peptone water enhances recovery of *Aeromonas* from populations that generally would be expected to shed low numbers of organisms (carriers, convalescent-phase patients, and those with subclinical infections). For patients with acute diarrhea, enrichment is probably unnecessary (40).

IDENTIFICATION

Aeromonas spp. are most easily confused in the laboratory with other oxidase-positive fermenters, i.e., *Vibrio* and *Plesiomonas* spp. *Plesiomonas* is easily differentiated from *Aeromonas* by positive reactions in Moeller's lysine, ornithine, and arginine tests and by fermentation of *m*-inositol. Vibrios may be more difficult to distinguish from aeromonads (1), which is particularly true for *Vibrio fluvialis* and *A. caviae,* and in laboratories where the sole means of identification is a rapid miniaturized system (21, 45). Resistance to the vibriostatic agent O/129 and the inability to grow in salt concentrations of ≥6% usually indicate the genus *Aeromonas*. *Vibrio cholerae* O139, a cholera toxin-positive, non-salt-requiring, O/129-resistant vibrio, is a major exception to this rule. However, the decarboxylase pattern (positive for lysine and ornithine) and negative reactions for arginine dihydrolase, production of gas from glucose, and fermentation of salicin separate this organism from most aeromonads. Unfortunately, strains of "ornithine decarboxylase-positive" *A. veronii* bv. veronii yield an "excellent to very good ID" for *V. cholerae* with a rapid identification kit, and serotyping and/or additional testing are required to resolve the issue. *A. veronii* bv. veronii would be String test negative, O/129 resistant, and able to produce gas from glucose fermentation, would not require additional salt for growth, and would be inhibited on TCBS agar, whereas *V. cholerae* strains would have the opposite reactions. Once it has been determined that you have a glucose-fermenting, oxidase-positive, motile gram-negative rod that is resistant to O/129, a small number of biochemical tests can be used for separating *Aeromonas* species into the three major species complexes (Table 2). If warranted, even more discriminatory tests for separating members of each complex can be found in boldface type in Table 3 (2), which should replace earlier published tests for species identification (3).

The sequencing of a single housekeeping gene 16S rRNA (32) and the development of an extended method using 16S rRNA restricted fragment length polymorphism analysis that followed (10) were both initially promising as methods to identify aeromonads to the species level. However, very recently published data on the intragenomic heterogeneity within the 16S rRNA gene in *Aeromonas* strains suggest caution in using this gene for anything beyond genus level identification (35). Therefore, the use of other housekeeping genes as multiple molecular markers, such as *gyrB* and *rpoD*

TABLE 2 Biochemical identification of *Aeromonas* to complex level

Test	No. of strains identified as belonging to[a]:		
	A. hydrophila complex (*A. hydrophila, A. bestiarum, A. salmonicida*)	*A. caviae* complex (*A. caviae, A. media, A. eucrenophila*)	*A. veronii* complex (*A. veronii* HG8,[b] *A. jandaei, A. schubertii, A. trota*)
Esculin	87 (92, 81, 85)	71 (76, 55, 78)	0
Voges-Proskauer	75 (88, 63, 62)	0	54 (88, 87, 17, 0)
Glucose (gas)	81 (92, 69, 77)	16 (0, 0, 78)	87 (92, 100, 0, 69)
L-Arabinose	93 (84, 100, 100)	96 (100, 100, 78)	4 (12, 0, 0, 0)

[a] The first number is the overall percent positive for each complex for a given trait; the numbers in parentheses are the percentages of positives for each species listed within that complex. Data are derived and modified from Table 5 in reference 2.

[b] Biovar sobria (DNA hybridization group 8); the separation of *A. veronii* biovar veronii (DNA hybridization group 10) from *A. veronii* biovar sobria is achieved with *A. veronii* bv. veronii having positive reactions for ornithine decarboxylase and esculin hydrolysis and a negative reaction for arginine dihydrolase.

(46), or an even broader approach using multilocus sequence typing seems to be the future avenue for accurate species identification.

Because isolates do not survive well at room or refrigerator temperature in the laboratory for long periods (>1 month), placing aeromonads in media such as Trypticase soy broth with 30% glycerol and deep freezing at −80°C are recommended for their long-term storage.

SEROLOGIC RESPONSE

Most serologic assays that have been used to detect antibodies to *Aeromonas* (tube agglutination, immunoblot, and enzyme-linked immunoassay) have low sensitivity and specificity and are not considered reliable. An immunoglobulin A (IgA fecal antibody) response to *Aeromonas* somatic lipopolysaccharides and exotoxins has been reported (9). Crivelli et al. (9) found secretory IgA to *Aeromonas* in 10 of 13 stools from patients when the stool was extracted with Jacalin, a lectin with high affinity for human IgA.

ANTIBIOTIC SUSCEPTIBILITIES

Two recent articles on *Aeromonas* antimicrobial susceptibilities (25, 37) included only strains well characterized to the species level and expand previously known susceptibility information on aeromonads isolated less frequently from clinical specimens. A general antimicrobial susceptibility profile for *Aeromonas* derived from both of these investigations as well as other studies (22, 28, 50) is given in Table 4. Ciprofloxacin, commonly used to treat gram-negative infections, remains active against all species of *Aeromonas,* with little or no resistance reported in studies in the United States and most of Europe (25, 37). However, a recent Spanish study of 43 strains, identified as *A. hydrophila, A. veronii* bv. sobria, and *A. caviae,* found 26 and 20% of the *A. caviae* and *A. hydrophila* strains, respectively, and 88% of the *A. veronii* bv. sobria strains to be resistant to nalidixic acid and pipemidic acid. This means that these organisms, though still susceptible to ciprofloxacin, are known to already have a mutation in the *gyrA* gene and could easily develop a second mutation resulting in resistance to ciprofloxacin (49). Two to three percent of *A. caviae, A. hydrophila,* and *A. veronii* bv. sobria strains in Asia have been reported to be ciprofloxacin resistant (28). Antimicrobial susceptibility testing of local isolates is necessary for the detection of species-related patterns, such as continued susceptibility to cephalothin in *A. veronii* bv. sobria isolates, and because susceptibilities may differ from one geographic area to another. *Aeromonas* species can express three chromosomal β-lactam-induced β-lactamases, including a group 1 molecular class C cephalosporinase, a group 2d molecular class D penicillinase, and a group 3 molecular class B metallo-β-lactamase (carbapenemase) (42). The presence of these β-lactamases in *Aeromonas,* in particular the carbapenemase, may not be detected by conventional susceptibility methods (42). It may be necessary to test strains of species known to potentially carry carbapenemases *(A. hydrophila, A. veronii* bv. sobria, *A. veronii* bv. veronii, and *A. jandaei)* with a higher-than-standard inoculum if imipenem or meropenem therapy is being considered. CphA, one of several enzymes responsible for resistance to carbapenems, hydrolyzes nitrocefin poorly or not at all, indicating that the nitrocefin test is not reliable for detecting carbapenemases (17, 42). A case of sepsis due to an extended-spectrum β-lactamase (ESBL)-producing *A. hydrophila* in a pediatric patient with diarrhea and pneumonia (41) and a case of *A. hydrophila* necrotizing fasciitis with probable "in vivo" transfer of a TEM-24 plasmid-borne ESBL gene from *Enterobacter aerogenes* have been reported (13).

INTERPRETATION AND REPORTING OF RESULTS

Regardless of the site of isolation (intestinal or extraintestinal), aeromonads should be identified either as belonging to the *A. hydrophila* or *A. caviae* complex or as *A. veronii* bv. sobria and not "*A. sobria.*" For routine isolates recovered from uncomplicated cases of gastroenteritis, this level of identification may be sufficient. Although there is strong evidence that some aeromonads are gastrointestinal pathogens, there is no convincing evidence at present that all fecal isolates of *Aeromonas* are involved in diarrheal disease. Thus, the significance of the recovery of aeromonads from stool specimens should be interpreted cautiously and must rely on both laboratory information and clinical interpretation. Because of this, the relative quantity of *Aeromonas* recovered on enteric media (few colonies, moderate growth, or predominant organism) should be reported in conjunction with the *Aeromonas* complex or species identification. For complicated cases of diarrhea, i.e., prolonged bloody diarrhea in pediatric patients or chronic gastroenteritis of >1-month duration or in cancer patients with positive fecal cultures in whom *Aeromonas* tends to disseminate, a definitive species identification is warranted.

For extraintestinal isolates (from blood or wounds), the same general rules should apply to species identification of aeromonads. Although it is clear that both the in vitro and in vivo pathogenic potentials of *Aeromonas* species and strains vary considerably, for the present, there are no universal markers or indicators available that dictate when

[a] +, ≥85% of the strains positive; −, <15% positive; V, 15 to 85% positive (results at 48 h); numbers in parentheses indicate the percentages of positives for the test at the final day of reading: gluconate, 2 days; DL-lactate and urocanic acid, 3 days; citrate, 4 days; carbohydrates, indole, and lipase, 7 days; PZA (pyrazinamidase), 2 days; Amp^r, resistance to 10 μg of ampicillin, 1 day; Voges-Proskauer, 3 days; ND, not done. For each of the three *Aeromonas* species complexes, the discriminatory reactions between the species within each complex are in boldface type.

[b] Biovar sobria (DNA hybridization group 8); the separation of *A. veronii* biovar veronii (DNA hybridization group 10) from *A. veronii* biovar sobria is achieved with *A. veronii* bv. veronii having positive reactions for ornithine decarboxylase and esculin hydrolysis and a negative reaction for arginine dihydrolase.

TABLE 4 *Aeromonas* species susceptibilities

Susceptibility[a]	Antibiotic agent
Resistant	Ampicillin (except *A. trota* [100% susceptible] and *A. caviae* [35% susceptible][b])
Variable	Ticarcillin or piperacillin (except *A. veronii* bv. veronii [100% resistant] and *A. trota* [100% susceptible])
	Cephalothin
	Cefazolin
	Cefoxitin (except *A. veronii* bv. veronii [100% susceptible])
	Cefuroxime
	Ceftriaxone
	Cefotaxime
Susceptible	Ciprofloxacin[c]
	Gentamicin
	Amikacin
	Tobramycin (*A. veronii* bv. veronii [42% resistant])
	Imipenem (*A. jandaei* [65% resistant], *A. veronii* bv. veronii [67% resistant])
	Trimethoprim-sulfamethoxazole

[a] Resistant or susceptible, ≥90% of all isolates are resistant or susceptible; variable, 10 to 90% of isolates are susceptible (data from reference 2).

[b] Data for *A. caviae* susceptibility are from references 6 and 27.

[c] Data for resistance to nalidixic acid and pipemidic acid in 26 and 20% of *A. caviae* and *A. hydrophila* isolates, respectively, and 88% in *A. veronii* clinical strains suggest possible future resistance to fluoroquinolones (49).

isolates should be definitively identified to the species level. Thus, for extraintestinal isolates, identification of aeromonads beyond complexes should be reserved for strains isolated from sterile body sites (blood or cerebrospinal fluid) and serious wound infections (cellulitis and necrotizing fasciitis); for strains exhibiting unusual resistance patterns, associated with nosocomial outbreaks; or for publications describing traditional species associated with new disease processes or newly described species isolated from new anatomic sites.

Vibrio and Related Organisms*

SHARON L. ABBOTT, J. MICHAEL JANDA, JUDITH A. JOHNSON,
AND J. J. FARMER III

47

TAXONOMY

Vibrio is the type genus of the family *Vibrionaceae,* with *V. cholerae*, the causative agent of pandemic cholera, as the type species (25, 26). The genus is extremely diverse with greater than 75 validly published species to date (http://www.bacterio.cict.fr/). Of these 75 named species, 12 have been associated with or isolated from infections in humans. Phylogenetic investigations indicate that multiple clades (separate or distant groups in a phylogenetic sense) exist within this genus, indicating that many *Vibrio* species may eventually be reclassified to different genera (58). Several formal proposals have already been made over the years (26) including the classification of *V. hollisae* in the genus *Grimontia* as *G. hollisae* (77) and the classification of *V. damsela* in the genus *Photobacterium* as *P. damselae* (73).

Changes in Classification for This Edition

In this chapter we accept the taxon *Grimontia hollisae* and use it rather than *Vibrio hollisae*. Studies based on DNA-DNA hybridization, 16S rRNA and *rec*A sequencing, biochemical reactions, and other phenotypic characters (antibiotic susceptibility, poor growth on thiosulfate-citrate-bile salts-sucrose [TCBS], fastidious nature, metabolic inactivity, etc.) all indicate that *Vibrio hollisae* has diverged significantly from *Vibrio cholerae* and *V. mimicus*, the core species of the genus *Vibrio* (26). We suggest that clinical microbiology reports list both names to avoid confusion, with the reporter's choice listed first, i.e., *Grimontia hollisae (Vibrio hollisae)* or *Vibrio hollisae (Grimontia hollisae)*.

DESCRIPTION OF THE GENUS *VIBRIO*

A majority of *Vibrio* species have the following characteristics: gram-negative, facultatively anaerobic straight, curved, or comma-shaped rods, 0.5 to 0.8 μm in width and 1.4 to 2.6 μm in length, that are catalase and oxidase positive (26). Vibrios are motile by means of sheathed monotrichous or multitrichous polar flagella when grown in liquid media. Strains of some species, such as *V. parahaemolyticus* and *V. alginolyticus,* swarm on solid media by production of numerous lateral flagella (26, 51). All *Vibrio* species require Na^+ for growth, and the halophilic species usually require that NaCl be added to media (such as commercial decarboxylase broths) that do not include NaCl in their formulas. Most media formulated with peptone and meat extracts contain enough salt for *V. cholerae* and *V. mimicus* to grow. The minimal concentration for optimum growth varies from 0.029 to 4.1% NaCl (26). Vibrios ferment D-glucose but rarely produce gas, reduce nitrate to nitrite, and grow on TCBS medium. The G+C content of the DNA is 38 to 51 mol% (26). Key properties or characteristics useful in separating members of the genus *Vibrio* from phylogenetically or phenotypically related species are listed in Table 1. The description of the genus *Grimontia* is based on its single species and is given in Tables 2 and 4.

NATURAL HABITATS

Vibrios are primarily aquatic residents, and their relative distributions in such environs are typically dependent upon temperature, Na^+ concentration, available nutrients in the water column, and the presence of various plants and vertebrate and invertebrate animal species that inhabit such ecosystems (78). Vibrios that require small amounts of Na^+ for growth, such as *V. cholerae* and *V. mimicus,* can be found in freshwater rivers and lakes as well as estuarine and marine environments. Some *Vibrio* species, such as *V. fischeri* and *V. harveyi,* have evolved close symbiotic associations over thousands of years with marine inhabitants such as *Eupryema scolopes,* the Hawaiian small bobtail squid (59). In marine and estuarine environments, vibrios are commonly isolated from sediment, the water column, plankton, various bivalves (oysters, clams, and mussels), crabs, shrimp, and prawns (30, 47, 78). In temperate climates, *Vibrio* concentrations peak during the warmer months of the year (7). A "viable but nonculturable" state has been described for several *Vibrio* species including *V. cholerae* and *V. vulnificus* (9). It is unclear if the term "viable but nonculturable" represents a new idea or is just a subpart of the well-documented term "injured bacterial cell" that has been known for many decades, particularly in water microbiology. In either instance its significance is unknown.

CLINICAL SIGNIFICANCE

Vibrios are isolated from and actually cause a wide variety of human illnesses, both intestinal and extraintestinal. These

* This chapter contains information presented in chapter 46 by J. J. Farmer III, J. Michael Janda, and Karen Birkhead in the eighth edition of this Manual.

TABLE 1 Properties of the genus *Vibrio* and differentiation from other phenotypically similar genera

Test or property	Reaction or property of[a]:				
	Vibrio	*Photobacterium*	*Aeromonas*	*Plesiomonas*	*Enterobacteriaceae*
Associated with diarrhea and extraintestinal infections in humans	+	–[d]	+	+	+
Oxidase reaction	+	+	+	+	–
Na^+ is required for growth or stimulates growth	+	+	–	–	–
Sensitive to the vibriostatic compound O/129[b]	+	+	–	+	–
D-Mannitol fermentation	+	–	+	–	+
Growth on TCBS[c]	+	+	+	–	–

[a] Symbols: +, most species and strains are positive; –, most species and strains are negative.
[b] 2,4-diamino-6,7-diisopropylpteridine phosphate (150 μg per disk); resistance to O/129 has become common in *V. cholerae* from parts of India and Bangladesh.
[c] Relative growth of *Aeromonas* on TCBS is dependent on the commercial manufacturer.
[d] *Photobacterium damselae* is an exception if this classification is used.

include diarrhea, localized (cellulitis) and invasive (necrotizing fasciitis) wound infections, eye and ear infections, and septicemia (26). In individual cases of both diarrhea and extraintestinal infection it may be difficult to determine if a positive culture result represents true infection, colonization, or simply the transient presence of the organism because of its occurrence in sea- and estuarine water. Twelve vibrio species occur in human clinical specimens: *V. alginolyticus, V. cholerae, V. cincinnatiensis, V. damsela (P. damselae), V. fluvialis, V. furnissii, V. harveyi (= V. carchariae), Grimontia hollisae (V. hollisae), V. metschnikovii, V. mimicus, V. parahaemolyticus,* and *V. vulnificus* (26, 55). The clinical importance of some of these species in individual cases of infection is sometimes unclear. *V. cholerae* is the only species that causes endemic, epidemic, and pandemic cholera (68), but several other species are important causes of intestinal infections. *V. parahaemolyticus* is the foremost cause of food poisoning in Japan and Southeast Asia and is the leading cause of intestinal infections due to vibrios in the United States (81, 84).

Extraintestinal *Vibrio* infections are frequently associated with injuries or exposure to estuarine or marine waters and may result in severe tissue destruction and/or lead to systemic infection (63). Primary septicemia may occur after ingestion of raw seafood (oysters) or as a secondary bacteremia subsequent to a wound infection. Septicemia due to *V. vulnificus* tends to be fulminant with a fatality rate exceeding 50% (56) and is often accompanied by secondary skin lesions called bullae (63). *Vibrio vulnificus* is the most common cause of vibrio septicemia, but other vibrios may also cause bacteremia including *V. cholerae* non-O1.

V. cholerae

V. cholerae is the most important species in the genus *Vibrio*. It has caused many epidemics of cholera and millions of deaths (21, 68). It is now divided into three major subgroups: *V. cholerae* O1, *V. cholerae* O139, and *V. cholerae* non-O1.

V. cholerae O1

V. cholerae serogroup O1 is the organism responsible for seven pandemics of cholera (1816–1817, 1829, 1852, 1863, 1881, 1889, and 1961–present) (66, 68). While the majority of persons ingesting toxigenic *V. cholerae* O1 have asymptomatic infections or self-limiting diarrhea (≥75%), severe cholera ("cholera gravis") usually results in massive diarrhea and large volumes of "rice water stools" (clear fluid with flecks of mucus) passed painlessly; fluid loss can reach 200 ml/kg of body weight/day. If left untreated, the patient becomes prostrate with symptoms of severe dehydration, electrolyte imbalance, painful muscle cramps, watery eyes, loss of skin elasticity, and anuria. Dehydration subsequently leads to hypovolemic shock, acidosis, circulatory collapse, and death, even in healthy adults (42). Interestingly, there is a correlation between human blood types and susceptibility to *V. cholerae* infection with persons of O blood group presenting with more severe symptoms. In the United States, occasional cases of cholera are seen in travelers returning from regions of endemicity; rarely such illnesses are due to an O1 strain indigenous to the Gulf of Mexico. Treatment consists of fluid replacement by oral rehydration therapy and/or intravenous fluids.

The ability of *V. cholerae* serogroup O1 to uniquely cause this fulminant form of diarrhea is due to the presence of virulence "cassette" regions and pathogenicity islands on the bacterial chromosome. These regions encode a number of key virulence factors including cholera enterotoxin responsible for the large excretion of fluids and electrolytes into the lumen and the toxin coregulated pilus responsible for attachment of *V. cholerae* to the gastrointestinal epithelium (27). Traditional (classic) cholera can be produced by two different biotypes of *V. cholerae* O1, designated Classical and El Tor. These biotypes can be differentiated by a number of phenotypic tests including hemolysis of sheep erythrocytes, production of acetylmethylcarbinol (Voges-Proskauer test), and resistance to polymyxin B, all positive for the El Tor biotype (40). The first six pandemics were thought to be due to the Classical biotype, whereas the ongoing seventh pandemic that began in 1961 is caused by the El Tor biotype, which was first isolated in 1905 (68).

Although extremely rare, O1 strains have been known to cause severe extraintestinal infections. A 2001 report from Malawi describes three cases of *V. cholerae* O1 bacteremia in two adults and one neonate (34). All three patients died as a direct or indirect result of their infections.

V. cholerae O139

Until the last decade, only *V. cholerae* serogroup O1 was believed to cause epidemic cholera. In 1992, cholera cases due to a new serogroup of *V. cholerae*, O139 (synonym, *V. cholerae* O139 Bengal), appeared in India and Bangladesh and spread rapidly throughout Asia (4). This new serogroup probably resulted from the lateral transfer of a novel somatic antigen and capsule from an unknown bacterium to an El Tor strain (4). O139 strains carry cholera enterotoxin and other critical virulence factors that O1 strains harbor including the toxin coregulated pilus (54). The clinical diseases due to O1 and

O139 *V. cholerae* are strikingly similar, except that adults are more frequently affected than children since previous infection with O1 cholerae is not protective (2, 28). *V. cholerae* O139 replaced O1 as the cause of epidemic cholera between 1994 and 1995 in many areas of Southeast Asia, including Bangladesh. However, in this setting O1 reemerged in 1996. In 2002, O139 reemerged in Bangladesh, causing an estimated 30,000 cases of cholera, mostly in older patients than typically observed with O1 infections (28). Some researchers speculate that the emergence of O139 may be the beginning of the eighth cholera pandemic (4).

V. cholerae Non-O1

V. cholerae non-O1 strains do not agglutinate in O1 or O139 antisera but are otherwise phenotypically identical to O1 and O139 *V. cholerae* strains in their biochemical reactions. *V. cholerae* non-O1 strains are the third most commonly isolated vibrios in clinical laboratories in the United States, following *V. parahaemolyticus* and *V. vulnificus* (37). They typically do not produce cholera toxin and are usually isolated from patients with mild watery diarrhea, although the diarrhea is occasionally severe (57). However, unlike O1 strains, non-O1 isolates are commonly associated with extraintestinal infections such as septicemia. Persons at increased risk of developing non-O1 bacteremia include those with liver disease/cirrhosis or hematologic malignancies. The case fatality rate ranges from 47 to 65% (44, 69). Strains have also been isolated from ears, wounds, the respiratory tract, and urine (39, 56).

V. mimicus

V. mimicus is a nonhalophilic vibrio species that is biochemically similar to *V. cholerae* except that it is sucrose negative. It has been recovered from patients with diarrhea, which usually occurred after the consumption of uncooked seafood, particularly raw oysters (23). Rare strains carry the cholera toxin gene and can produce cholera-like symptoms. Human infections are uncommon. Symptoms include abundant watery diarrhea, vomiting, and severe dehydration. There has been one recent report of *V. mimicus* diarrhea in Costa Rica that involved 33 patients over a 3-year period (12).

V. parahaemolyticus

In Asia, *V. parahaemolyticus* is the leading cause of foodborne intestinal infections, almost always associated with the consumption of raw fish or shellfish (84). Fifty to 70% of the cases of foodborne diarrhea in Japan alone are due to *V. parahaemolyticus*. It is also the *Vibrio* species most frequently isolated from clinical specimens in the United States and is primarily associated with diarrhea, but it has occasionally been isolated from extraintestinal sites. *V. parahaemolyticus* causes gastroenteritis with nausea, vomiting, abdominal cramps, low-grade fever, and chills. The diarrhea is usually watery but can on rare occasions be bloody. Fatalities are extremely rare but can occur in cases of severe dehydration. Rehydration is usually the only treatment needed, but in some severe cases the patient requires hospital admission. Antimicrobial therapy may be beneficial.

A pandemic clone of *V. parahaemolyticus* serotype O3:K6 emerged worldwide in 1997 (62). Strains of this serotype caused an unusually high proportion of *V. parahaemolyticus* foodborne disease outbreaks in Taiwan from 1996 to 1999, suggesting something unusual in the organism's ecology, epidemiology, or virulence (17). This pandemic clone has continued to spread throughout Asia, to the United States, Canada, Russia, Chile, and Mozambique (6, 32). Recently, new pandemic serogroups have emerged that have been shown to be genetically closely related to the O3:K6 strain. These include O4:K68, O1:K25, O1:K41, and O1:KUT (UT, untypeable) (17).

V. vulnificus

V. vulnificus causes primary septicemia and wound infection and is responsible for more than 90% of deaths due to vibrios in the United States each year (63). Primary septicemia has a fatality rate that exceeds 50% even with hospitalization (15, 74) and occurs predominantly in men over 50. Cases generally have predisposing conditions such as liver disease, immunosuppression, increased serum iron, or other chronic diseases (74). Data from CDC showed that more than 95% of patients had consumed raw oysters within the last 7 days. Patients typically present with symptoms including a sudden onset of fever and chills, vomiting, diarrhea, and abdominal pain. Secondary skin lesions often appear, progressing to bulla formation and necrosis. Endotoxic shock often occurs and can rapidly lead to death. Blood cultures and biopsy specimens (scrapings) from skin lesions are usually positive.

V. vulnificus also causes severe wound infections usually after trauma and exposure to marine animals or the marine environment (63). Wound infections may progress to cellulitis with extensive necrosis (often requiring surgical debridement), myositis, necrotizing fasciitis that may mimic gas gangrene, and secondary septicemia. The fatality rate for wound infections ranges from 20 to 30%.

Three biogroups have now been defined for *V. vulnificus*. Most infections in the United States are due to biogroup 1 (see Table 5). *V. vulnificus* biogroup 2 was originally isolated from diseased eels, but in 1995 Amaro and Biosca (5) isolated it from a human wound infection from Rhode Island. To date, no other isolations of biogroup 2 from clinical specimens have been reported. *V. vulnificus* biogroup 3 was described in 1999 by Bisharat et al. (10), who isolated it from patients with wound infections and bacteremia. Cases have been limited to Israel and were acquired from exposure to live fish (tilapia) grown in aquaculture. One case report strongly suggests that *V. vulnificus* biogroup 3 can survive on fish skin for at least 24 h (19).

V. alginolyticus

V. alginolyticus is very common in the marine environment and is the fourth most commonly isolated *Vibrio* species in the United States. *V. alginolyticus* has most frequently been isolated from ear infections (otitis externa and otitis media) (29) and wound infections following exposure to seawater. *V. alginolyticus* has also been isolated from ocular infections and from infrequent cases of monomicrobic or polymicrobic bacteremia, mostly in immunocompromised persons (16). It is occasionally isolated from diarrheal stool (79), but there is no strong evidence that it can actually cause diarrhea or intestinal infections.

V. damsela (Photobacterium damselae)

V. damsela, originally isolated from wound infections in damselfish, is an important though infrequent cause of serious and aggressive wound infections (necrotizing fasciitis) and bacteremia (31, 33, 83). Risk factors for infection include puncture wounds (from a fish fin or a fish hook) and exposure of open wounds to seawater. Although the case fatality rate is unknown, many reports in the literature describe fatal *V. damsela* infections, suggesting a fairly high case fatality rate. The enhanced virulence of this species is thought to be related to the production of a damselysin (phospholipase-D).

V. fluvialis

V. fluvialis appears to cause sporadic cases of diarrhea worldwide (75). Although in the past it has only rarely been isolated from extraintestinal sites, several recent reports of cellulitis, cerebritis, peritonitis, and bacteremia have been attributed to *V. fluvialis* (38, 45, 67).

V. furnissii

V. furnissii is rarely isolated from human clinical specimens, but when it is recovered it is invariably from fecal specimens of patients with diarrhea (22). There is no convincing evidence that it can actually infect the intestinal tract or cause diarrhea, although this merits further investigation (22).

V. harveyi (originally known as *V. carchariae*)

A single case of a *V. harveyi* (the name *V. carchariae* was used in the report describing this organism [64]) wound infection, resulting from a shark bite, has been published (64). Subsequently, it was shown by DNA-DNA hybridization that the type strains of *V. carchariae* and *V. harveyi* are 88% related (65). The two organisms also have identical or almost identical 16S rRNA sequences. Since the two species appear to be synonyms (subjective), *V. harveyi,* being the older name, has priority.

Grimontia hollisae (Vibrio hollisae)

G. hollisae is a halophilic vibrio species that is primarily associated with moderate to severe cases of diarrhea (1), for which there is evidence for a causative role. It has been rarely isolated from extraintestinal sites such as bacteremia (35).

V. metschnikovii

V. metschnikovii has frequently been isolated from fresh, brackish, and marine waters. In 1981 Jean-Jacques et al. (41) reported that it caused peritonitis and bacteremia in a patient with an inflamed gallbladder. Subsequently, *V. metschnikovii* has been isolated from additional patients with bacteremia and rarely from wound infections (46). It has also been isolated from cases of cholecystitis, diarrhea, and pneumonia (46, 80). There is no convincing evidence that it can actually infect the intestinal tract or cause diarrhea, although this merits further investigation (46).

V. cincinnatiensis

V. cincinnatiensis was first reported by Brayton et al. (11) from a patient with bacteremia and meningitis. Subsequent isolates have been from feces (intestine), the ear, a foot or leg wound, animals, and water.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

As with all stools, specimens should be collected in the acute stage of disease before initiation of treatment (13). If stool is unavailable, rectal swabs (or vomitus) are reliable from acute cases but should not be used when the numbers of organisms present may be small, as occurs with contacts to known cases or for convalescing patients. Vibrios are particularly susceptible to desiccation; therefore, any specimen that cannot be inoculated onto plating media within 2 to 4 h should be placed in a transport medium. Cary-Blair, which maintains the viability of vibrios up to 4 weeks, or most commercially available transport media are satisfactory; but because some lots of glycerol may be toxic to vibrios, buffered glycerol in saline is unacceptable. Specimens collected in the field may be transported in tellurite-taurocholate-peptone or alkaline peptone water enrichment broths only if they can be plated within 12 to 24 h and are delivered by courier. If necessary, liquid stool may be placed on strips of blotting paper or gauze, inserted in airtight plastic bags with a few drops of saline to maintain moisture, and submitted to the laboratory. Detailed information on the collection and transport of specimens for vibrio isolation is available (13).

Direct microscopic detection of vibrios in stool is not routinely recommended, since it may not be possible to distinguish pathogenic vibrios from other enteric flora. Detection of *V. cholerae* directly from stool using an "O1 (or O139) serum immobilization" method is described in a subsequent section.

Special methods for the collection and processing of extraintestinal specimens (blood and wounds, etc.) for vibrio isolation are not required; vibrios are, as a rule, isolated in pure culture from these sites, and the concentration of salt in primary plating media is usually sufficient for their recovery. Once isolated, however, salt may need to be added to subsequent media to attain growth of salt-requiring vibrios.

ISOLATION PROCEDURES

Since it is not common practice to use special isolation media for vibrios, inclusion of pertinent clinical history (when known) should accompany specimens to alert the laboratory to include vibrio isolation techniques (media or reagents) in their stool workup (49). Such information includes consumption of seafood, any activity associated with marine or brackish water or wounds associated with such exposure, and hobbies associated with aquaria. Examination of blood agar plates for oxidase-positive colonies may also improve recovery of vibrios as well as *Aeromonas* spp. and *Plesiomonas shigelloides*.

Vibrios associated with human disease generally grow on MacConkey agar and when present appear as colorless colonies (with the exception of the lactose-fermenting species, *V. vulnificus*). Sucrose-fermenting vibrios associated with human disease such as *V. cholerae, V. fluvialis,* or *V. alginolyticus* cannot be differentiated from other sucrose-fermenting normal enteric flora on sucrose-containing agars such as Hektoen or xylose-lysine-desoxycholate. Additionally, *Grimontia hollisae* may grow poorly or not at all on any enteric isolation medium, including TCBS, and is most reliably isolated from blood agar. Plating efficiency on TCBS may be less for *V. cincinnatiensis* than that observed for other vibrio species, and it may be reduced for *V. metschnikovii* when the plate is incubated at 36°C. Although there are a number of selective media suitable for the isolation of vibrios, TCBS is generally used for the isolation of vibrios associated with human disease and is readily available from a number of commercial sources (26). Since this medium does not require autoclaving, powdered media may be kept available in the laboratory and readily prepared by boiling whenever needed. The use of TCBS is particularly useful in coastal areas, where vibrios are isolated with greater frequency. It is not cost-effective to use it for every stool specimen. The inclusion of sucrose in TCBS allows for preliminary differentiation of *Vibrio* species, with *V. cholerae*, *V. fluvialis*, and *V. alginolyticus* producing yellow colonies whereas *V. parahaemolyticus*, *V. mimicus*, and most strains of *V. vulnificus* produce green colonies, indicating sucrose was not fermented. Yellow colonies on TCBS may convert to green colonies if plates are refrigerated after incubation. It should be noted that oxidase testing is unreliable when performed directly on colonies growing on TCBS and should not be attempted. A chromogenic agar, CHROMagar

Vibrio (CHROMagar Microbiology, Paris, France), has been developed primarily for the recovery of *V. parahaemolyticus* from seafood and supports the growth of other vibrios as well (36). Vibrio colonies on this medium range in color from milk white to pale blue to violet; other enteric flora, with the exception of *Proteus mirabilis* and *Providencia rettgeri,* which also produce milk white colonies, do not grow. Marine agar (BD Biosciences, Sparks, Md.), which does not contain any inhibitory or selective ingredients, may be more appropriate for isolation of vibrios from the environment, especially salt-requiring vibrios. It is common for pure cultures of vibrios to produce multiple colony morphologies on any medium, but this is most readily noticeable on nonselective media such as blood or heart infusion agars. Morphologies can range from smooth, convex to flat, spreading colonies to rough; occasionally, rugose (extremely wrinkled) colonies are encountered.

Alkaline peptone water (1% NaCl, pH 8.5) is the most commonly used enrichment broth for human specimens and is available from a number of commercial sources. Alkaline peptone water is incubated at 36°C and subcultured at 18 h. Occasionally, vibrios are recovered only when subcultured after 6 h of incubation. Longer incubation times of such specimens may fail to yield a vibrio, probably due to overgrowth by other flora.

DIRECT DETECTION OF *V. CHOLERAE* O1 IN FECES

Direct detection of *V. cholerae* from stool requires experience to correctly interpret results and is typically done only in laboratories in areas where cholera is common or in situations where laboratory services are unavailable. One of the oldest assays, the microscopic immobilization test, detects loss of motility of *V. cholerae* O1 organisms in the presence of O1 antibody and can be used to detect *V. cholerae* O139 by using O139 antibody (66). Coagglutination, direct fluorescent-antibody (New Horizons Diagnostics Corp., Columbia, Md.; FDA approval pending), and latex agglutination (Denka Seiken, Tokyo, Japan; not FDA approved for human clinical specimens) assays are all commercially available.

IDENTIFICATION

Biochemical properties that separate members of the *Vibrionaceae* from the *Enterobacteriaceae* (including *Plesiomonas shigelloides*) and the *Aeromonadaceae* are listed in Table 1. Useful tests for separating *Vibrio* species are described in Tables 2 and 3, and comprehensive biochemical profiles of the 12 species that occur in human clinical specimens are given in Table 4. All vibrios are negative to 10% positive for H_2S in triple sugar iron agar, urea (except *V. parahaemolyticus* [15%]), phenylalanine deaminase (except *V. vulnificus* biogroup 1 [35%]), malonate, mucate production, yellow pigment production, and fermentation of D-adonitol, dulcitol, erythritol, melibiose (except *V. vulnificus* biogroup 1 [40%]), raffinose, L-rhamnose (except *V. furnissii* [45%]), D-sorbitol (except *V. metschnikovii* [45%]), and α-methyl-β-D-galactoside and D-xylose (except for 57 and 43% of *V. cincinnatiensis* isolates, respectively). Variable reactions are seen with methyl red, growth in potassium cyanide broth, D-galactose, glycerol, Jordan's tartrate, sodium acetate, DNase at 25°C, lipase, and tyrosine clearing. All vibrio species are 99 to 100% positive for growth in 1% NaCl, and fermentation of maltose (except *V. hollisae* [0%]) and D-mannose (except *V. cholerae* [78%] and *V. harveyi* [50%]). Many commercial standard tube tests have sufficient

TABLE 2 Key differential tests for the six groups of 12 *Vibrio* species that occur in clinical specimens

Test	Reactions of the species in[a]:

[a] The numbers indicate the percentages of strains that are positive after 48 h of incubation at 36°C (unless other conditions are indicated). Most of the positive reactions occur during the first 24 h.

salt to support growth without salt supplementation (0.5 to 1%), but the Microbial Disease Laboratory adds 1% salt to all biochemicals (except for the 0% salt broth) for all NaCl-requiring species. Voges-Proskauer, Moeller's decarboxylases and dihydrolase, and nitrate broth may contain no or insufficient NaCl to support growth of some NaCl-requiring strains, and these biochemicals should always have salt added (to a final concentration of 1%) to them when testing these species. Sensitivity to the vibriostatic compound O/129 (Remel, Lenexa, Kans.) should be used with caution, as many *V. cholerae* isolates from Bangladesh and surrounding areas are now resistant to O/129.

Correct identification of vibrios by commercial identification systems is problematic at best, and published evaluations of these kits are based upon specific lot numbers, software versions, and microbial databases. No commercial automated or manual identification system includes all 12 clinical vibrio species in their databases, and some manual systems do not contain any vibrio species (60, 61). Six commonly used identification systems claim that they are capable of identifying *V. cholerae, V. parahaemolyticus, V. vulnificus, V. alginolyticus,* and *V. damsela* (61). However, even when tested against only those species listed in their databases, the API 20E (bioMerieux Inc., Durham, N.C.), Crystal E/NF (BD Biosciences), MicroScan Neg ID type 2 and type 3 (MicroScan, West Sacramento, Calif.), and Vitek GNI+ and ID-GNB cards (bioMerieux) correctly identified only 63.1 to 80.9% of vibrios to the species level (61). Accurate identification by these systems for the three most commonly isolated species varied. Correct identification of *V. cholerae* ranged from 50.0 to 96.7%, with API 20E and Crystal being the least and most accurate, respectively; for *V. parahaemolyticus* the range was 40.0 to 96.6%, with Rapid Neg ID3 faring the worst and API 20E and GNI+ being the best; and for *V. vulnificus* (biogroup 1 strains) the range was 50.0 to 90%, with GNI+ and Crystal showing the lowest and highest correct identification rates, respectively. Only Crystal was able to correctly identify ≥90% of *V. cholerae* or *V. vulnificus* strains, and only API 20E and the two Vitek cards correctly identified ≥90% of *V. parahaemolyticus* strains. For *V. vulnificus* biotype 3 strains, the MicroScan (98.0%) and Phoenix (90.2%) systems did the best in identifying 51 well-characterized isolates to the correct species, while the identification rate obtained by Vitek (13.7%) was much less satisfactory (20). The manufacturer's instructions should be checked prior to testing salt-requiring vibrios to determine if salt supplementation is required. Identification of vibrios from seafood and environmental sources is problematic. Many newly identified "nonclinical" species are published with poor phenotypic descriptions, and identification is based on 16S rRNA.

In areas of the world where cholera is common, isolates of *V. cholerae* may be presumptively identified simply by agglutination with O1 or O139 antisera. In other areas of the world, complete biochemical testing should be performed, and cultures identified as *V. cholerae* should be sent to public health laboratories for O1 and O139 agglutination and cholera toxin testing. *V. cholerae* O1 isolates should be biotyped (see "*V. cholerae* O1" under "Clinical Significance" above) to determine whether they are El Tor or Classical biotypes. *V. cholerae* O139 strains are phenotypically similar to *V. cholerae* O1 El Tor. Strains of *V. cholerae* that fail to agglutinate in either O1 or O139 antisera are reported as *V. cholerae* non-O1. These strains may also be serotyped; however, this testing is available only in a limited number of reference laboratories. *V. cholerae* is distinguished from other vibrios, except *V. mimicus,* by Na^+ requirement (Table 2), and *V. cholerae* can be differentiated from *V. mimicus* by sucrose and Voges-Proskauer tests (Table 3). Strains of *V. mimicus* may produce cholera toxin.

Strains of *V. parahaemolyticus, V. alginolyticus,* and *V. damsela* may be urea positive. As with most vibrios isolated from humans, these species produce a buff or tan pigment; occasional strains of *V. parahaemolyticus* may produce a dark brown pigment. *G. hollisae* generally grows poorly, especially in Moeller's decarboxylases and dihydrolase broths even after salt supplementation, and produce extremely large zones of inhibition, often necessitating the use of two plates when performing antimicrobial susceptibility testing. Because it is oxidase negative, *V. metschnikovii* is the most difficult vibrio to detect, but it is easily separated from other vibrios by negative reactions for nitrate reduction, indole production (most strains), and ornithine decarboxylase and fermentation of sucrose. *V. fluvialis* and *V. furnissii* are frequently confused with *Aeromonas caviae,* especially as some strains are poorly halophilic and only moderately susceptible to O/129, and some strains of *A. caviae* grow on TCBS. *V. furnissii* is the only vibrio isolated from humans that is positive for gas production from glucose. Rapid, correct identification of *V. vulnificus* strains is critical because of the mortality associated with this organism. Occasionally, strains of *V. vulnificus* are sucrose positive, which may add to the confusion in identifying it; it is unique among human *Vibrio*

TABLE 4 Biochemical test results and other properties of the 12 *Vibrio* species that occur in human clinical specimens

[a] Symbols and abbreviations: *, the test is recommended as part of the routine set for *Vibrio* identification; 1% NaCl, 1% NaCl has been added to the standard media to enhance growth; HIB, heart infusion broth; TSI, triple sugar iron agar; ONPG, *o*-nitrophenyl-β-D-galactopyranoside; a positive string test indicates that cells are lysed when they are suspended in a 0.5% sodium deoxycholate solution.

[b] The numbers indicate the percentages of strains that are positive after 48 h of incubation at 36°C (unless other conditions are indicated). Most of the positive reactions occur during the first 24 h.

[c] The content of the disk was 150 μg.

species because it ferments lactose, salicin, and cellobiose and is ONPG (*o*-nitrophenyl-β-D-galactopyranoside) positive. Table 5 gives biochemicals useful in separating the biogroups of *V. vulnificus* (10).

Although identification of vibrios by conventional methods is challenging, there is limited use of molecular methods for detection and identification of vibrios. Molecular methods are expensive, and vibrios are relatively rare pathogens in areas where cholera is not endemic. 16S sequencing has been used to identify clinically important *Vibrio* spp. The use of 16S sequencing alone is less than ideal for identification of vibrios, as the sequence differences between some species are very small and polymorphism has been shown to be fairly common in 16S rRNA genes of vibrios (53). There are few if any commercial molecular products with FDA approval for human clinical specimens. In-house molecular methods used in the United States for testing human clinical specimens will require extensive efforts to evaluate and implement in order to comply with all the Clinical Laboratory Improvement Amendments (CLIA) regulations. In a research setting, molecular methods for vibrios have proved to be very useful.

COMMERCIAL PRODUCTS FOR DETECTING CHOLERA TOXIN AND THE THERMOSTABLE DIRECT HEMOLYSIN OF *V. PARAHAEMOLYTICUS*

In reference laboratories, cholera toxin may be detected by fluid accumulation in animal assays or detection of a cytopathic effect in Y1 adrenal or Chinese hamster ovary cell cultures (40). However, a reverse passive latex agglutination assay produced by Denka Seiken, Tokyo, Japan, is commercially available (Oxoid, Inc., Ogdensburg, N.Y.).

The majority of human strains of *V. parahaemolyticus* produce a thermostable direct hemolysin (TDH) encoded by two genes, *tdh* and *tdh2x*. These toxins are rarely encountered in environmental strains of *V. parahaemolyticus* but have been detected in *V. cholerae* non-O1, *V. mimicus,* and *G. hollisae* strains. This hemolysin can be detected by observing hemolysis of red blood cells on Watgatsuma agar (Kanagawa test), a specialized agar, difficult to make. Like cholera toxin, TDH can be detected by a commercial latex assay (also available from Oxoid), but there are no commercial products that detect a second hemolysin seen in *V. parahaemolyticus* strains, i.e., thermostable-related hemolysin. PCR assays for TDH and thermostable-related hemolysin have been developed but are not commercially available (24).

TABLE 5 Differentiation of the three biogroups of *V. vulnificus*[a]

Test	Result for biogroup[b]:		
	1	2	3

D-Sorbitol	−	+	−
Cellobiose	+	+	−
Salicin	+	+	−

[a] Data from reference 10.
[b] V, variable (11 to 89% of strains are positive); +, positive (90 to 100% positive); −, negative (0 to 10% positive).

TYPING SYSTEMS

The usefulness of typing systems for determining strain relatedness among *Vibrio* isolates of the same species has very limited applicability for most clinical laboratories in the United States since, with the exception of very rare *V. parahaemolyticus* outbreaks, virtually all other *Vibrio* illnesses are sporadic in nature. Even then, state or federal reference laboratories will probably perform such extensive typing procedures. These typing schemes can basically be broken down into two groups, conventional (traditional) and molecular.

Among conventional techniques, serotyping is by far the most widely utilized procedure. Typing schemes have been described for a number of vibrio species including *V. cholerae, V. parahaemolyticus,* and *V. vulnificus* (40, 71, 72). However, commercial-grade typing sera are available only for *V. cholerae* and *V. parahaemolyticus*. *V. cholerae* O1 (polyclonal, serovars Inaba and Ogawa) and O139 antisera in one of several forms (slide, colorimetric) are available from Difco (Beckton Dickinson), Denka Seiken (Campbell, Calif.), Oxoid (Remel), and New Horizons (Columbia, Md.). *V. parahaemolyticus* antisera (O-group O1-O11 and K-group K1-K32) are available from Denka Seiken. *V. cholerae* isolates can also be typed by determining the sensitivity pattern to lytic bacteriophages (not commercially available), which may be another useful tool for tracking the spread of cholera. Phage (not commercially available) can be used for differentiating Classical from El Tor biotypes of *V. cholerae* O1 and O139 isolates (3, 14). The use of phage typing is limited to a few reference laboratories by the availability of typing phage and a lack of consensus in the typing schemes. Antibiograms, such as resistance to streptomycin, trimethoprim, and furazolidone, have been used to subtype *V. cholerae* O1 and O139 strains on a limited basis (8, 50). Such techniques are more useful in Southeast Asia, where unusual resistance patterns in isolates are observed more frequently than in the United States.

A large number of molecular typing methods have been successfully used in tracking the spread of *V. cholerae* epidemics and the clonal migration of *V. parahaemolyticus* strains and for phylogenetic analysis. However, these are primarily epidemiologic and taxonomic research techniques and not commercially available or easily adapted to clinical laboratories. Pulsed-field gel electrophoresis has been used extensively for both *V. cholerae* and *V. parahaemolyticus* (50, 52). Sequencing of single genes such as *ctx*A, *ctx*B, *hsp*60, and *rec*A shows promise as a molecular typing method (42).

SEROLOGIC TESTS

Serodiagnosis of cholera can be established with a high degree of certainty by titration of acute- and convalescent-phase sera in agglutination, vibriocidal, or antitoxin tests (48). The reagents are not commercially available, so this technique will normally be limited to a few reference laboratories.

ANTIMICROBIAL SUSCEPTIBILITY TESTING

Antibiotic resistance is more uncommon in *Vibrio* than in members of the family *Enterobacteriaceae*. However, all clinical *Vibrio* isolates should be tested against a number of therapeutically active compounds, since resistance can be acquired through plasmid transfer or exposure to antimicrobials and spread quickly through global travel. The Clinical and Laboratory Standards Institute (CLSI, formerly NCCLS) has interpretive guidelines only for *V. cholerae* limited to ampicillin, tetracyclines, folate pathway inhibitors,

and chloramphenicol (18). Because most vibrios grow rapidly and are similar to enteric bacteria in many ways, a first approximation might be to use interpretive guidelines for the *Enterobacteriaceae* for *Vibrio* species other than *V. cholerae* when testing agents that are not currently covered by the CLSI document.

There have been only limited susceptibility studies involving vibrios in recent times. Most strains of *V. cholerae* (O1, O139, and non-O1) are susceptible (>90%) in vitro to aminoglycosides, azithromycin, fluoroquinolones, extended-spectrum cephalosporins, carbapenems, and monobactams (70, 82). However, O1 El Tor and O139 strains from India and Bangladesh demonstrate moderate to high-level resistance to sulfamethoxazole, trimethoprim, and chloramphenicol (82). The fluoroquinolones alone or the synergistic combination of ciprofloxacin and cefotaxime shows excellent in vitro activity against *V. vulnificus* strains (43, 76). Most vibrios are also susceptible to tetracyclines, gentamicin, chloramphenicol (except *V. damsela*), monobactams, carbapenems, and fluoroquinolones.

INTERPRETATION AND REPORTING OF RESULTS

The isolation of *V. cholerae* O1 or O139 should be reported immediately to the attending physician because of the severe dehydration that cholera can produce. The case should also be reported by telephone to public health authorities, and the isolate should be sent to a public health laboratory for confirmation and toxin testing. Similarly, isolation of a vibrio from a sterile body site or a wound should be reported by telephone to the attending physician immediately so that rapid and appropriate antibiotic therapy can be initiated. *Vibrio* septicemia and/or meningitis have a high mortality rate associated with infection, and wound infections can frequently cause extensive tissue damage.

The clinical significance of *Vibrio* strains in many other specimens is more difficult to determine. Since physicians are not familiar with many *Vibrio* species, it would be helpful to provide a telephone consultation when a *Vibrio* isolate is identified. *Vibrio* isolates should also be submitted to public health laboratories, as they are monitored under the CDC emerging infections program and Vibrio Surveillance System; they may also be needed for confirmation and toxin testing. *Vibrio* species that are known to cause diarrhea should be considered clinically significant, particularly if they are present in large numbers and no other potential pathogens are present. Isolation of vibrios from stool in small numbers may reflect only transitory colonization. *V. cholerae*, *V. mimicus*, and *V. parahaemolyticus* have documented virulence factors that correlate with their ability to cause intestinal infections. Laboratory tests are helpful in determining pathogenic potential but are likely to be done only in reference laboratories. The same warning should be emphasized for *Vibrio* isolates from other specimens such as ears or wounds. The isolation of vibrios could represent infection, transient colonization, or merely the vibrio flora that is always present in seawater or brackish water.

*Pseudomonas**

EDITH BLONDEL-HILL, DEBORAH A. HENRY, AND DAVID P. SPEERT

48

TAXONOMY

Pseudomonas is a large and complex genus of gram-negative bacteria of importance, as it includes species with both clinical and environmental implications. The genus *Pseudomonas* first proposed by Migula in 1894 (91) has undergone many taxonomic revisions as methodologies of identification to the species level continue to improve. The genus *Pseudomonas* was comprised of five unrelated groups, as determined by ribosomal RNA-DNA hybridization studies in the early 1970s. *Pseudomonas* (sensu stricto) is rRNA homology group I (28), in the gamma subclass of the *Proteobacteria*. The other rRNA homology groups are II, *Burkholderia* species; III, *Comamonas, Acidovorax,* and *Hydrogenophaga* genera; IV, *Brevundimonas* species; and V, *Stenotrophomonas* and *Xanthomonas* genera (69). Currently there are 160 species within the *Pseudomonas* genus, with only 12 (described herein) of clinical interest. The closest phylogenetic neighbors of the *Pseudomonas* genus are the genera of *Azomonas, Azotobacter, Cellvibrio, Chrysomonas,* and *Flavimonas.*

Several of the clinically relevant *Pseudomonas* species demonstrate marked heterogeneity and have been subdivided into biovars or genomovars. Genomovars are genetically distinct groups that warrant species designation but lack phenotypically defining characteristics and that are determined by DNA-DNA reassociation experiments and 16S rRNA gene sequencing in combination with chemotaxonomic total fatty acid analysis and total protein pattern analysis (49).

The highest level of genetic diversity of any species known is found in *Pseudomonas stutzeri,* which has at least 18 genomovars (131), with clinical isolates being found in genomovars 1 and 2. There are no consistent phenotypic differences to justify splitting *P. stutzeri* into unique species (49).

Pseudomonas fluorescens was originally divided into biotypes A, B, C, D, E, F, and G (biotypes A to E are also referred to as biovars I, II, III, IV, and V). Biotype B was reclassified as *Pseudomonas marginalis.* Biotypes D and E *(Pseudomonas chlororaphis* and *Pseudomonas aureofaciens)* have now been combined into the single species *P. chlororaphis,* which is no longer considered a member of the fluorescent pseudomonad group.

Pseudomonas putida consists of biovars A and B. Biovar A should be regarded as the typical *P. putida* (34), while biovar B may have a closer affinity with *P. fluorescens.* More biovars of *P. putida* are warranted (34).

Great heterogeneity is found within the species of *P. stutzeri, P. fluorescens,* and *P. putida,* which are of interest mainly to plant, marine, soil, and biotechnical sciences. They are of limited importance in clinical medicine. As polyphasic taxonomy continues to advance, more changes will doubtlessly arise; the clinical laboratory must keep abreast of such changes in order to differentiate these isolates from the more clinically important *Pseudomonas* species.

GENERAL DESCRIPTION

Pseudomonas spp. are aerobic, non-spore-forming, gram-negative rods which are straight or slightly curved and 0.5 to 1.0 by 1.5 to 5.0 μm in size (63). They are usually motile, with one or several polar flagella. They possess a strictly aerobic respiratory metabolism with oxygen as the terminal electron acceptor; in some cases nitrate can be used as an alternative electron acceptor that allows anaerobic growth. Most species of clinical interest are oxidase positive (except *Pseudomonas luteola* and *Pseudomonas oryzihabitans*). *Pseudomonas* spp. are catalase positive and are chemolithotrophs.

NATURAL HABITATS

Most *Pseudomonas* species can reside in a wide variety of environmental niches. Since their preferred temperature requirements are between 4 and 36°C and they can utilize an extraordinarily varied range of nutrients, they can be found throughout nature, provided that a moist environment is available. For example, *P. putida* is commonly found in soil, water, plants, and hospital sources such as sinks and floors. When isolated from human specimens, they are usually of indeterminate clinical significance. Due to their opportunistic nature, *Pseudomonas* species such as *Pseudomonas veronii,* found in mineral water (32), may account for unusual isolates that may infect immunocompromised patients.

*This chapter contains information presented in chapter 47 by Deanna L. Kiska and Peter H. Gilligan in the eighth edition of this Manual.

EPIDEMIOLOGY AND TRANSMISSION

P. aeruginosa is hydrophilic and can be readily recovered from moist environments, such as sink drains, vegetables, river water, and even antiseptic solutions. The propensity of *P. aeruginosa* to colonize raw vegetables might pose a risk to immunocompromised (particularly neutropenic) patients (118). However, none of these environmental reservoirs poses a great risk to most individuals; ingestion does not appear to induce gastrointestinal colonization unless antibiotic therapy has altered the normal bacterial flora.

Pseudomonas species, and in particular the human pathogen *P. aeruginosa,* rarely colonize healthy humans (136). The throat, intact skin, or stools of healthy individuals are heavily colonized by normal flora, which does not include *Pseudomonas* species. Indeed, if *P. aeruginosa* (and in particular the mucoid variant) is recovered from a throat culture of an otherwise healthy individual, an explanation should usually be sought. The gastrointestinal tracts of healthy humans and mice are heavily colonized with other bacteria that likely provide colonization resistance against *P. aeruginosa*. Healthy mice fed 10^7 CFU of *P. aeruginosa* fail to sustain intestinal colonization unless they have been pretreated with antibiotics (72).

Individuals (such as neutropenic cancer patients) receiving frequent courses of antibiotic therapy are at risk of gastrointestinal colonization with *P. aeruginosa;* it is from this reservoir that they are then at risk for *P. aeruginosa* septicemia. Such autoinfection has been demonstrated by recovering *P. aeruginosa* from the stools of neutropenic hosts prior to a bout of sepsis with the same strain (149). Similar observations have been made for neutropenic mice (72).

P. aeruginosa can be recovered from body sites that remain moist, such as the outer ear of children who swim frequently or the endotracheal tubes of patients receiving mechanical ventilation (93). For reasons which remain poorly understood, *P. aeruginosa* can also colonize the upper respiratory tracts of patients in intensive care units; this may be due in part to the alteration of the buccal epithelial cells with loss of fibronectin and attendant loss of the cells' antiadhesive properties (163). Adults receiving mechanical ventilation or neutropenic patients are at high risk for developing ventilator-associated or other pneumonias caused by *P. aeruginosa* (17), particularly after or during treatment with broad-spectrum antimicrobial agents (121). Patients at greatest risk are adults undergoing cancer chemotherapy or marrow ablation for bone marrow transplantation; children with similar conditions are at lesser risk for *P. aeruginosa* bacteremia. Individuals with congenital neutropenia or cyclic neutropenia do not appear to be at much risk for invasive infection with *P. aeruginosa*. Normal skin does not support *P. aeruginosa* colonization, but burned skin is an attractive site for this bacterium, which is one of the leading causes of burn wound sepsis.

P. aeruginosa is the predominant respiratory tract pathogen in patients with cystic fibrosis (CF) (47), but its mode of acquisition is poorly understood (133). Several studies have each demonstrated a common clone in particular groups of patients who have received their care at the same center (7, 18, 68); this is most likely due to patient-to-patient spread. However, in most patients with CF, it appears that the infecting strain undergoes a switch from the environmental phenotype (lipopolysaccharide [LPS] smooth, nonmucoid, and motile) to the CF phenotype (LPS rough, mucoid, and nonmotile) during the course of infection (135). That patients each tend to carry a unique strain during the course of infection (101, 137) suggests that the infection was acquired from an environmental source. One large study performed in Vancouver, Canada, over more than 20 years failed to demonstrate patient-to-patient spread of *P. aeruginosa* except between siblings (137). Infection control policies applicable to CF patients for transmission prevention should be determined by local epidemiological experience (154).

CLINICAL SIGNIFICANCE

P. aeruginosa

Individuals with intact host defenses are not at risk for serious infection with *P. aeruginosa,* but those whose circulating neutrophil counts are profoundly depressed (such as patients with cancer receiving chemotherapy) are at risk for invasive infection (134). Neutropenic hosts who develop antibodies against specific serotypes of *P. aeruginosa* appear to be protected against infection with those types during periods of neutropenia (109), illustrating the important role for opsonization in protection against blood-borne infection. Individuals with thermal burns are at risk for invasive disease because the dermal barrier can be breached, and patients on mechanical ventilation are at risk for pneumonia because the normal respiratory mucociliary clearance is compromised.

Recovery of *P. aeruginosa* from respiratory tract cultures of patients receiving mechanical ventilation may not indicate a true infection, and the significance of its presence in the culture should be interpreted with caution.

P. aeruginosa has a particular tropism for CF epithelial cells and can resist normal respiratory tract host defenses. Once infection is established, it usually persists, and the bacteria undergo a transition to the CF phenotype consisting of the following: (i) a rough LPS (53), in which the O-polysaccharide is incompletely expressed, rendering the bacteria susceptible to the bactericidal effect of human serum; (ii) mucoid colonial morphology (80) resulting from the exuberant production of a mucoid expolysaccharide composed of O-acetylated guluronic and mannuronic acids; (iii) nonmotility (87), meaning that the bacteria lack normal functional flagellar function; and (iv) hypoexpression of various exotoxins and other exoproducts (11). Some of these changes may be under global regulation, but they can also be expressed individually. Transition of *P. aeruginosa* from nonmucoid to mucoid in the CF patient's lung is usually associated with an accelerated decline in pulmonary function and an adverse prognosis (106), perhaps because of the capacity of the mucoid exopolysaccharide to interfere with normal host phagocytic defenses (47, 136) and to facilitate the formation of biofilms (76). Biofilm formation may also be enhanced by another colonial form, small-colony variants (previously known as dwarf colonies) (56). Furthermore, CF patients receive frequent courses of antipseudomonas antimicrobial therapy, often rendering the bacterium with which they are chronically infected resistant to a wide range of antimicrobial agents (54).

Thermal burns of the skin inhibit an essential component of the body's defense against infection, the physical barrier of the intact dermis (113). The resulting damaged tissue is a rich culture medium and is at great risk for colonization and infection by *P. aeruginosa;* such infections have been one of the leading causes of morbidity and mortality in victims of burns. Topical therapy is designed to prevent *P. aeruginosa* and other pathogens from causing infection. Infections of burn wounds with gram-negative bacteria (in particular *P. aeruginosa*) typically occur about 1 week after the injury. The extent of the burn has a profound influence on the risk of infection and prognosis (113). Prevention of bacterial

burn wound infection has become so effective over the past decade that it is now very rare, and in many centers fungal infections predominate.

P. aeruginosa is the most common cause of osteochondritis of the dorsum of the foot following penetrating wounds (20). The typical scenario involves a child who has stepped on a nail which pierces the foot after passing through the sole of a running shoe. The prevalence of *P. aeruginosa* as the etiological agent may be due to its propensity to survive in the rubber of old running shoes (35).

Because *P. aeruginosa* can survive up to 42°C, hot tub users are at risk of *P. aeruginosa* folliculitis (48), a self-limiting condition for normal hosts that resolves rapidly. People who spend extended periods for time swimming are at risk for external ear infections ("swimmer's ear"), another self-limiting condition in immunocompetent people that responds readily to therapy with topical antimicrobial agents (9). The cornea is relatively resistant to infection except when its integrity has been broken. Users of contact lenses are at risk of *P. aeruginosa* conjunctivitis, especially if hygiene is poor or lenses are worn for extended periods of time (142).

P. aeruginosa can cause meningitis (usually following trauma or surgery) (36), malignant otitis externa in diabetics (122), sepsis and meningitis in newborns (145), endocarditis or osteomyelitis in intravenous drug users (126), community-acquired pneumonia in people with underlying lung disease such as bronchiectasis (43), urinary tract infections in patients with complex urinary tract abnormalities (120), and peritonitis (97). Each of these presentations is unusual and is superimposed on some inhibition of normal host defenses.

Other *Pseudomonas* Species

Healthy individuals are resistant to serious infections by all *Pseudomonas* species, including *P. aeruginosa*. However, immunocompromised hosts are occasionally infected with one of the many non-*P. aeruginosa* species (Table 1). Several of these species have been recovered from the respiratory secretions of patients with CF, but their role in pathogenesis of lung disease has not been determined. Some of these species have the capacity, like *P. aeruginosa,* to grow in hostile environments, such as antiseptic solutions; they can therefore be the cause of pseudobacteremia. Because of their low virulence, infections due to these species are often iatrogenic and are associated with the administration of contaminated solutions, medicines, and blood products or with the presence of indwelling catheters. *P. fluorescens* and *P. putida* have the ability to grow at 4°C, and *P. fluorescens* can be isolated from the skin of a small proportion of blood donors (128), resulting in occasional transfusion-associated septicemia in the recipient.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Pseudomonas spp. are able to survive in diverse environments. These organisms are easily recovered from clinical specimens by using standard collection, transport, and storage techniques as outlined in chapters 5 and 20.

DIRECT EXAMINATION

Pseudomonas organisms are gram-negative, non-spore-forming, straight or slightly curved bacilli measuring 0.5 to 0.8 μm by

TABLE 1 Non-*P. aeruginosa* isolates of *Pseudomonas* spp. recovered from human clinical specimens

Organism	Source	Reference(s)
P. fluorescens	Respiratory isolates from CF patients, transfusion-associated septicemia, pseudobacteremia	128
P. putida	Nosocomial infections including bacteremia, pneumonia, and urinary tract infections following external instrumentation/ catheterization. CF, elderly, and immunocompromised patients are most vulnerable.	74, 165
P. veronii	Associated with an intestinal inflammatory pseudotumor	19
P. monteilii	Recovered from stool, bile, placenta, bronchial aspirates, pleural fluid, and urine, but of uncertain clinical significance	33
P. mosseilii	Various clinical specimens of uncertain clinical significance	26
P. stutzeri	Respiratory isolates of CF patients, alcoholics with pneumonia; immunocompromised patients with bacteremia, meningitis, and pneumonia; and patients with osteomyelitis, iatrogenic endophthalmitis, pseudobacteremia, and bacteremia from contaminated hemodialysis fluid. Also recovered from respiratory tracts of intubated patients, from urine, and from wound specimens in which pathogenic role was uncertain.	15, 45, 67, 70, 99, 112, 117, 119
P. mendocina	Rare cases of endocarditis	6
P. alcaligenes	One reported case of catheter-related endocarditis in a bone marrow transplant recipient	90
P. pseudoalcaligenes	A case of meningitis. Also isolated from sputum and urine. May be coisolated with other pathogens in wounds in which clinical significance is uncertain.	24
P. luteola	Associated with bacteremia, cellulitis, osteomyelitis, peritonitis, endocarditis, and postsurgical meningitis	115, 116
P. oryzihabitans	Bacteremia in immunocompromised patients with central venous access devices, peritonitis in peritoneal dialysis patients, cellulitis, abscesses, wound infections, and postsurgical meningitis	89, 115

1.5 to 3.0 μm. The Gram stain morphology cannot easily distinguish *Pseudomonas* spp. from other nonfermenting bacilli, although they are usually thinner than *Enterobacteriaceae*. Among the pseudomonads, there is some variation in Gram stain morphology. Certain strains of *P. putida* can appear elongated. Organisms from older cultures may appear slightly pleomorphic. Mucoid strains may be distinguished on direct examination by the presence of clusters or long filaments of short gram-negative bacilli surrounded by darker pink staining material (alginate). It is important to note this on direct examination since the organisms may grow very slowly or not at all. The presence of these mucoid forms should be documented on clinical reports. Because *Pseudomonas* spp. may be colonizers, their isolation does not always link them to clinical disease. However, their intracellular presence in polymorphonuclear cells is clinically significant and should be documented and direct further workup. Flagellar stains reveal one or more polar flagella (Table 2). *P. aeruginosa* has a single polar flagellum.

NUCLEIC ACID DETECTION TECHNIQUES

P. aeruginosa and other *Pseudomonas* species are detected ordinarily by culture techniques; these methods are particularly important for determining antimicrobial susceptibility, as these organisms have a high degree of intrinsic and acquired resistance (54, 83). When a more rapid method is desired, such as for screening environmental niches or for rapidly evaluating the sputum of patients with CF (22, 138), methods that can be used include PCR amplification of various genomic regions, such as genes for ribosomal RNA (65), heat shock protein (22), or exotoxin A (71). Conventional and real-time PCR (RT-PCR) (65) are both useful, and the amplification of multiple targets is valuable in the identification of non-*aeruginosa Pseudomonas* species (114). Fluorescence in-situ hybridization (FISH) is very specific, although it lacks sensitivity below 10^4 CFU (62). Both RT-PCR and FISH are rapid, cost-effective methods, and FISH doesn't require costly technical equipment (159). Probes directed at species-specific 16S rRNA (50, 141) may have a role in the identification of clinically relevant, biochemically inactive *Pseudomonas* species including certain strains of *P. aeruginosa* (114). PCR amplification of 16S rRNA followed by restriction fragment length polymorphism (RFLP) analysis has been used to successfully identify and characterize members of the fluorescent pseudomonad group (75). Since RFLP of the 16S gene does not provide sufficient resolution among genomovars of a species, a more discriminatory test may be used, such as sequencing the internally transcribed 16S-23S rRNA spacer internal transcribed spacer 1 regions, believed to have more genetic variability among genomovars (49). It should be noted that commercial probes are not yet available.

CULTURE AND ISOLATION

Pseudomonas species have very simple nutritional requirements and grow well on standard broth and solid laboratory media such as tryptic soy or columbia agar with 5% sheep blood, chocolate agar, and MacConkey agar, which are recommended to isolate *Pseudomonas* spp. from clinical specimens. MacConkey agar is also a differential medium helpful in identifying different strains of *Pseudomonas* spp., including mucoid strains of *P. aeruginosa* from CF patients. Multiple selective media containing inhibitors such as acetamide, nitrofurantoin, phenanthroline, 9-chloro-9-[4-(diethyamino)phenyl]-9,10-dihydro-10-phenylacridine hydrochloride (C-390), and cetrimide (14, 58) have been used for the isolation and presumptive identification of *P. aeruginosa* from clinical and environmental samples. Inhibition of some strains of *P. aeruginosa* from CF sputum specimens has been reported to occur with the use of a selective agar containing cetrimide (200 mg/liter) and nalidixic acid (15 mg/liter) (37), emphasizing the need to use both selective and nonselective media for recovery of bacteria from these patients. Some of the non-*aeruginosa* pseudomonads may grow better at lower temperatures of 28 to 30°C. Good growth is usually achieved after 24 to 48 h of incubation. For cultures from CF patients, it is recommended that solid media plates be held at 35 to 37°C for 5 days.

IDENTIFICATION

Fluorescent Group

Members of the fluorescent pseudomonad group produce pyoverdin (fluorescein), a water-soluble yellow-green or yellow-brown pigment that fluoresces under short-wavelength UV light. Many strains of *P. aeruginosa* can produce the blue pigment pyocyanin. When pyoverdin combines with the blue water-soluble phenazine pigment pyocyanin, the bright green color characteristic of *P. aeruginosa* is created. This organism may also produce other water-soluble pigments such as pyorubrin (red) or pyomelanin (brown/black). Conditions of iron limitation enhance pigment production, as these pigments act as siderophores in iron uptake systems of the bacteria. Non-dye-containing media enhance visualization of pigments.

P. aeruginosa

Most *P. aeruginosa* are easily recognizable on primary isolation media on the basis of characteristic colonial morphology, production of diffusible pigments, and a grape-like odor. Older cultures may exhibit a corn taco-like odor. Colonies are usually flat and spreading and have a serrated edge and a metallic sheen that is often associated with autolysis of the colonies (166). Other morphologies exist, including smooth, mucoid, and dwarf (small-colony variants) (104, 155). Mucoid colonial variants are particularly prevalent in respiratory tract specimens from CF patients.

P. aeruginosa is distinct from the rest of the clinically relevant fluorescent pseudomonads in its ability to grow at 42°C (see Table 2 for other tests). In addition to pigment production, other tests that confirm its identification are positive oxidase and arginine tests and an alkaline over no-change reaction in a triple-sugar iron agar slant.

Microbiologists must be aware of certain variations in the phenotypes of *P. aeruginosa*. Isolates lacking oxidase activity have occasionally been reported, but they exhibit the other characteristic features; prior antibiotic therapy with agents that affect protein synthesis may cause the aberrant phenotype (52). Mucoid isolates of *P. aeruginosa* from CF patients may undergo several phenotypic changes including slow growth, loss of motility, and loss of pigment production. Small colony variants may require prolonged incubation, lack motility, be hyperpiliated, adhere to agar surface, and show autoaggregative properties in liquid medium (155).

P. fluorescens and *P. putida*

P. fluorescens and *P. putida* do not possess distinctive colony morphology or odor. Their inability to reduce nitrates to

nitrogen gas and their ability to produce acid from xylose distinguish these two species from the other fluorescent pseudomonads. *P. fluorescens* can be differentiated from *P. putida* by its ability to grow at 4°C and to hydrolyze gelatin. *P. fluorescens* isolates may require 4 to 7 days of incubation for accurate detection of gelatin hydrolysis. The package insert for API 20NE (bioMérieux Vitek, Hazelwood, Mo.) states that only 39% of *P. fluorescens* isolates hydrolyze gelatin in 24 to 48 h in this test system.

P. veronii, P. monteilii, and *P. mosselii*

P. veronii can reduce nitrates to nitrogen gas but is unable to hydrolyze acetamide. The type strain of *P. veronii* (LMG 17761) is negative for acid from lactose and maltose and does not grow at 36°C (D. A. Henry, personal observation). *P. monteilii* can be distinguished from the other members of the fluorescent group by its inability to reduce nitrates to nitrites or nitrogen gas, to hydrolyze gelatin, or to produce acid from xylose. *P. mosselii* can reduce nitrates neither to nitrites nor to nitrogen gas, nor can it produce acid from xylose; but most isolates (92%) can hydrolyze gelatin (Table 2).

Other fluorescent pseudomonads are rarely encountered in clinical specimens. Many of these isolates are negative for arginine dihydrolase activity. Identification as "*Pseudomonas* species not *aeruginosa*" and susceptibility testing of the isolates, when appropriate, are sufficient in most circumstances. When necessary, these isolates can be referred to reference laboratories.

Nonfluorescent Group

P. stutzeri and *P. mendocina*

Most *P. stutzeri* isolates are easily recognized on primary isolation media by their distinctive dry, wrinkled colony morphology, similar to that of *Burkholderia pseudomallei. P. stutzeri* can be distinguished from the latter species by its lack of arginine dihydrolase activity and inability to produce acid from lactose. *P. stutzeri* colonies can pit or adhere to the agar and are buff to brown in color. The adherence can make removal of colonies from agar medium difficult. Because of the difficulty in making suspensions of specific turbidity, commercial susceptibility systems may not work well with this organism. Not all isolates of *P. stutzeri* produce wrinkled colonies; such strains can be distinguished from other pseudomonads by their ability to hydrolyze starch, a unique reaction for this species.

P. mendocina colonies are smooth and flat and produce a brownish yellow pigment. Key biochemical characteristics include the ability to reduce nitrates to nitrogen gas, positive arginine dihydrolase activity, and inability to hydrolyze acetamide.

P. alcaligenes and *P. pseudoalcaligenes*

P. alcaligenes and *P. pseudoalcaligenes* have rarely been encountered in clinical samples and do not have a distinctive colony morphology. Compared to other pseudomonads, they are biochemically inactive. Characteristics that distinguish them from other biochemically inactive gram-negative rods are a positive oxidase reaction, motility due to a polar flagellum, and growth on MacConkey agar. *P. alcaligenes* is distinguished from *P. pseudoalcaligenes* by its inability to oxidize fructose. Although growth at 42°C was thought to be a distinguishing feature between them, further studies now indicate that growth at 41°C (and probably 42°C) is also present in most strains of *P. alcaligenes* (N. Palleroni, personal communication). These organisms are difficult to identify by many commercial systems, and for most clinical situations they can simply be referred to as "*Pseudomonas* spp. not *aeruginosa*." If the clinical situation dictates a definitive identification, assistance from reference laboratories should be sought.

P. luteola and *P. oryzihabitans*

P. luteola and *P. oryzihabitans* (formerly CDCVe-1 and CDCVe-2, respectively) can be distinguished from other pseudomonads by their negative oxidase reaction and production of an intracellular, nondiffusible yellow pigment. Both organisms typically exhibit rough, wrinkled, adherent colonies or, more rarely, smooth colonies. *P. luteola* can be differentiated from *P. oryzihabitans* on the basis of its ability to hydrolyze *o*-nitrophenyl-β-D-galactopyranoside (ONPG) and esculin.

Use of Commercial Identification Systems

Commercial identification systems are used increasingly in many laboratories to identify *Pseudomonas* spp. Commercial products can be divided into manual and automated systems. The more frequently used manual systems are the API 20NE (bioMérieux Vitek), Crystal E/NF (Becton Dickinson, Sparks, Md.), and RapID NF Plus (Remel Inc., Lenexa, Kans.). The manual systems usually provide accurate identification of *P. aeruginosa,* including mucoid isolates as well as other *Pseudomonas* species, and are preferred over automated systems for isolates from CF patients.

Automated systems (see chapter 15) are commonly used in many medium-to-large clinical laboratories. As *P. aeruginosa* is easily identified by a few conventional biochemical tests, it is not necessary to use a more expensive commercial system. Several of the automated systems are not very accurate and may require additional testing for non-*P. aeruginosa* species; thus, their labor-, cost-, and time-saving benefits are lost. Automated systems can identify *P. aeruginosa* from non-CF patient sources with 90 to 100% accuracy (40, 103), but some systems such as the Autoscan-W/A (Dade Behring Microscan Inc., West Sacramento, Calif.) may require additional tests to achieve these results (102, 147). Most reviews focus on the evaluation of *P. aeruginosa* with only a few, if any, other *Pseudomonas* species represented in the organisms being tested. When other *Pseudomonas* species were included, the new Vitek 2GN panel performed well (39, 103) while the Autoscan and BD Phoenix (Becton Dickinson) often relied on additional testing to obtain an identification (30, 102, 140, 147). Hence, it is wise to consider carefully the clinical significance, colonial morphology, and other key features before accepting results from automated systems.

Identification of *Pseudomonas* species, especially those isolated from CF patients, is not always optimal with rapid systems. The Autoscan-W/A system (Negative Combo 15) performed poorly for CF isolates when they were incubated for 20 to 24 h according to the manufacturer's method, with only 57% of nonmucoid and 40% of mucoid *P. aeruginosa* isolates correctly identified (125). Extension of incubation to 48 h improved accuracy to 86 and 83%, respectively. Misidentified species were most commonly identified as either *Alcaligenes* spp. or *P. fluorescens/P. putida.* Other automated systems have not been evaluated to date specifically for the identification of CF patient isolates, so caution in interpreting results is advised.

TYPING SYSTEMS

Genotypic methods have generally supplanted conventional schemes based on phenotypic characteristics (reviewed in

reference 133) such as LPS serotyping and phage typing. Several different genotypic methods for typing *P. aeruginosa* for epidemiological purposes are useful, even for typing isolates from patients with CF, but they are not available in most clinical diagnostic laboratories, and their use is often dependent upon local availability.

RFLP

This method relies upon the genetic diversity that exists upstream of the gene for exotoxin A (*exoA*) in *P. aeruginosa* (101). In a study of different typing methods, *exoA* RFLP proved superior to all phenotypic methods for typing *P. aeruginosa* (151). Pilin gene RFLP has demonstrated that individual CF patients are durably infected with the same strain despite changes in pilin protein expression (101). The disadvantages of RFLP are its relatively weak discriminatory power compared to that of newer methods, its cumbersome nature, and its predominant use of radioactive probes.

PFGE

P. aeruginosa has substantial genetic plasticity, so there can be more than three band differences among isolates typed by pulsed-field gel electrophoresis (PFGE) (see chapter 11) and considered epidemiologically to be from the same strain, even though Tenover's criteria state that if there are three or fewer banding differences between two isolates, they should be considered to be from the same strain, as such differences are likely to be due to only one genetic event (150). The advantages of PFGE are its universal utility for typing virtually any bacterial species and its high discriminatory power. The major disadvantages are its requirement for specialized equipment and its inability to evaluate a large number of isolates rapidly.

PCR-Based Typing Methods

PCR-based methods used for typing *P. aeruginosa* are directed at known elements within the genome or against random but relatively frequently encoded sequences. The latter method, random amplified polymorphic DNA analysis (RAPD), has proved quite robust for typing *P. aeruginosa* (88), but it must be run consistently on the same equipment to yield reproducible results. Data from RAPD analysis usually are highly consistent with those from PFGE. PCR-amplified products can be digested with restriction enzymes to yield more discriminatory data (127).

Multilocus Sequence Typing

Multilocus sequence typing has only recently been employed for typing *P. aeruginosa*. It is likely to be the most highly discriminatory among the genetic typing tools, but it is extremely time-consuming and expensive to employ. The method entails PCR amplification of specific genes and then sequencing of the gene products. This can be done only in very specialized centers, but it has the power to provide highly reliable data on relatedness among isolates. Standards are currently being developed, and a large study is evaluating the suitability of this method for typing *P. aeruginosa* (25).

ANTIMICROBIAL SUSCEPTIBILITY

P. aeruginosa possesses intrinsic resistance to many antibiotic classes and has the ability to develop resistance by mutations in different chromosomal loci or by horizontal acquisition of resistance genes carried on plasmids, transposons, or integrons. The frequent acquisition of antimicrobial resistance in *P. aeruginosa* limits the utility of antimicrobial susceptibility patterns as a tool in epidemiologic typing.

Mechanisms of Resistance

Intrinsic Resistance

P. aeruginosa has two main mechanisms of intrinsic resistance: an inducible chromosomal AmpC β-lactamase that renders it resistant to ampicillin, amoxicillin, amoxicillin-clavulanate, narrow-spectrum and expanded-spectrum cephalosporins, cefotaxime, and ceftriaxone (81); and several efflux pump systems (83).

Acquired Resistance

Various antibiotics overcome the intrinsic resistance of *P. aeruginosa*. These include extended-spectrum penicillins (piperacillin and ticarcillin), certain expanded-spectrum cephalosporins (ceftazidime and cefipime), carbapenems (imipenem and meropenem), monobactams (aztreonam), fluoroquinolones (ciprofloxacin and levofloxacin), aminoglycosides (gentamicin, tobramycin, and amikacin), and colistin. Unfortunately, mutational resistance to all the antipseudomonal antibiotics can develop.

A mutation at the AmpD locus, selected by therapy with antipseudomonal penicillins or ceftazidime (82), can result in partial or total derepression of the AmpC enzyme, which may account for 30% of β-lactamase resistance in *P. aeruginosa* (16).

Target mutations to topoisomerases II (*gyrA* and *gyrB* subunits) and IV (*parC* and *parE* subunits) confer quinolone resistance more readily in *P. aeruginosa* than in *Enterobacteriaceae*. Selection of mutants occurs after exposure to quinolones, and evidence suggests that levofloxacin has a greater potential to induce these mutations than ciprofloxacin (44).

Although multidrug efflux pump systems play a significant role in the intrinsic resistance of *P. aeruginosa*, they also are critical to the development of multidrug resistance (98). MexAB-OprM is expressed constitutively in all strains of *P. aeruginosa*. Upregulation or a mutation in the *mexR* repressor gene (*nalB* mutant) results in efflux pump overproduction and significant increase in the MICs of multiple antibiotics (111).

Efflux pump mutants may appear under conditions favoring high bacterial density as found in abscesses, empyemas, diabetic foot infections, and chronic lung infections. In one study, efflux pump-overproducing mutants were found in isolates from 80% of CF patients who had received earlier treatment with ciprofloxacin (66). Overexpression of efflux pumps may also be selected by the use of antiseptics and biocides (79). Evidence of multiple resistance determinants including an efflux transport system encoded by a transmissible plasmid in environmental bacteria (148) would be of grave concern if these genetic elements were to be transferred to *Pseudomonas* species.

Impermeability mutations may result in resistance to carbapenem, aminoglycosides, colistin, and quinolones. They are important in carbapenem resistance and result from the loss of the OprD porin, which is associated with low-level (MIC, 8 to 32 μg/ml) imipenem resistance and decreased susceptibility to meropenem (73). Resistance by this mechanism depends on the continued expression of the chromosomal AmpC β-lactamase. Selection of imipenem resistance following imipenem therapy is more frequent than selection of resistance to any other β-lactam agent (152).

Mutational impermeability is also associated with reduced aminoglycoside transport into the cell and lack of

susceptibility to all aminoglycosides. Impermeability may be the major mechanism of aminoglycoside resistance, especially in CF patients (85), but it is clear that efflux systems also contribute (3).

Membrane changes most likely account for colistin resistance, which is rare but increasing, especially in CF patients who receive inhalational colistin (78). It appears that regulatory genes for the outer membrane protein OprH, specifically the LPS component of the outer membrane, may be involved in both aminoglycoside and colistin resistance (77, 110). Decreased uptake as a result of porin reduction contributes to quinolone resistance but seems to be synergistically linked to upregulation of efflux pumps (79).

The acquisition of β-lactamases is not as common for *P. aeruginosa* as it is for *Enterobacteriaceae* (81). Nevertheless, β-lactamases are being recognized increasingly and are very diverse in this organism. The most common β-lactamases are PSE-1 and PSE-4, which do not affect ceftazidime, cefipime, aztreonam, or carbapenems (83). Other enzymes have been found in limited geographic locations, suggesting a specific ecological niche. More recently, extended-spectrum β-lactamases (ESBLs) in *P. aeruginosa* have been described. Genes for ESBLs are carried on plasmids, integrons in plasmids, or in the bacterial chromosome (83, 157). This group of enzymes is inhibited by clavulanic acid and only marginally inhibited by tazobactam. With minor variations, substrates for most of these enzymes include antipseudomonal penicillins, ceftazidime, cefipime, and aztreonam (64).

The OXA family of enzymes (Ambler Molecular Class D) (4) are found most commonly in *P. aeruginosa* (96, 146). Genes for these enzymes are located in plasmids, on transposons, or on integrons, making their further dissemination likely. They confer resistance predominantly to antipseudomonal penicillins, ceftazidime, cefipime, and aztreonam but not carbapenems. Their activity is inhibited poorly by clavulanic acid or tazobactam (108).

With the exception of GES-2 (an ESBL that hydrolyzes carbapenems), all carbapenemases in *P. aeruginosa* belong to Ambler Class B, commonly referred to as metalloenzymes. Metalloenzymes are not inhibited by clavulanic acid but are inhibited by divalent ion chelators such as EDTA. They hydrolyze all β-lactam antibiotics, except aztreonam, and are associated with high-level (MIC, >32 μg/ml) carbapenem resistance. Underreporting of carbapenem resistance may occur, as expression of the carbepenemases varies, resulting in a wide range of MIC values (2 to 128 μg/ml) that may go undetected in clinical laboratories that rely only on automated systems. In many cases, carbapenem resistance, especially to meropenem, is derived from a synergistic combination of mechanisms (105), resulting in enhanced resistance. For example, diminished expression of OprD porin or activation of an efflux system enhances the activity of a β-lactamase by increasing extracellular accumulation of the antibiotic.

Although impermeability mutations can result in aminoglycoside resistance, especially in CF and intensive care patients, drug inactivation by plasmid or chromosomally encoded enzymes is the most common mechanism for resistance worldwide to aminoglycosides (110). Aminoglycoside-modifying enzymes have been detected in *P. aeruginosa* for over 30 years, resulting in various combinations of resistance to gentamicin, tobramycin, and/or amikacin. These enzymes are often encoded on transposons and/or integrons that carry resistance determinants for other classes of antibiotics such as sulfonamides, β-lactams, and chloramphenicol. Multiresistance genes for both aminoglycosides and extended-spectrum β-lactamases and metalloenzymes are of particular concern (110). Aminoglycoside-modifying enzymes can occur together with impermeability mutations (92), resulting in broad-spectrum aminoglycoside resistance.

The discovery of a plasmid-borne quinolone resistance determinant *(qnr)* in gram-negative organisms (156) is of significance for several reasons: it has been transferred by conjugation to multiple organisms including *P. aeruginosa;* it is associated with high-level quinolone resistance (up to 250-fold increase in MICs); it appears to be associated with integrons that carry resistance determinants to β-lactams and aminoglycosides; and it expands the spectrum of high-level plasmid-mediated resistance to quinolones.

Antibiotic Tolerance

Biofilm-producing *P. aeruginosa* isolates appear to be protected from killing by antibiotics (144). Although this is widely accepted to indicate antibiotic resistance, a more appropriate term is antibiotic tolerance. Although slower or stationary growth phase has classically been thought to account for relative antibiotic tolerance, many other mechanisms have been proposed. These include quorum sensing (130), decreased diffusion of antibiotics through the matrix polysaccharide alginate (59), synthesis of glucans that specifically bind antibiotics (86), phenotypic variability (31, 38), presence of persister cells (139), and anaerobic growth of biofilm bacteria, which affects the activity of multiple antibiotics (10, 55).

Multidrug Resistance

Worldwide, antimicrobial resistance, including multidrug (three or more antimicrobial classes) resistance among *P. aeruginosa,* is widespread and increasing. In 2003, the European MYSTIC study group reported considerable country-to-country variation in the proportion of multidrug-resistant *P. aeruginosa* isolates within Europe, ranging from 50% to less than 3% (46). The SENTRY Antimicrobial Surveillance Program confirmed geographic variation in Latin America but emphasized the rapid increase in multidrug-resistant strains with rates approaching 35% (123). From 1993 to 2002, in the United States, the rates of multidrug resistance increased from 4 to 14%, with highest rates of increase reported for ciprofloxacin, imipenem, tobramycin, and aztreonam (100). Globally, multidrug resistance was found in 10% of *P. aeruginosa* strains analyzed (41).

Antimicrobial Susceptibility Testing

It may be difficult to estimate the true prevalence of antimicrobial resistance in *P. aeruginosa* because detection of resistance by routine tests agrees poorly with MIC data (5, 60). Susceptibility testing of *P. aeruginosa* is challenging due to multiple mechanisms of resistance, both intrinsic and acquired, which are frequently expressed concurrently, often at low levels.

In clinical laboratories, susceptibility testing for *Pseudomonas* species may be performed by disk diffusion, agar or broth dilution, E test (AB Biodisk, Solna, Sweden), or automated susceptibility systems using broth microdilution. Disk diffusion tests are standardized in North America and perform satisfactorily for most clinical isolates of *P. aeruginosa* (23). Limitations of this method include the lack of a quantitative result (MIC) and the potential to miss low-level resistance. Agar dilution is a well-accepted, reliable MIC method, especially for mucoid isolates, but it is time-consuming and too expensive for most routine clinical

laboratories. The E test (see chapter 73) has been shown to correlate well with agar dilution for isolates from CF (13) and non-CF patients (29).

Good correlation with reference methods has been reported for most automated systems (57, 140) when testing *Pseudomonas* isolates from non-CF patients. Results evaluating the performance of various automated systems must be interpreted with caution, as the numbers of isolates tested is often limited, especially for non-*P. aeruginosa* strains. Whereas most *P. aeruginosa* isolates grow well on agar media, growth of some isolates in broth is variable and may pose difficulties for laboratories that rely solely on automated systems. Alternatively, a liquid medium improves the detection of the efflux resistance phenotype, which may not be detected by solid-media-based testing (2, 30). This may account for some of the discrepancies reported when comparing different susceptibility methods.

Several antibiotics pose specific challenges to susceptibility testing. Carbapenem susceptibility testing results are difficult to interpret due to several factors that include rapid imipenem degradation (153), variable levels of efflux pump expression, and unstable impermeability mutations. Carbapenemase detection is especially challenging because it is associated with a wide range of MICs and lacks a simple test for detection. Susceptibility testing of imipenem with and without EDTA (disks or E-test strips) may be used but has been associated with variable results (164). Meropenem or ceftazidime, with or without EDTA, may be better substrates than imipenem, and testing these combinations may increase the sensitivity of the test (107). Reproducibility of carbapenem resistance results by using various susceptibility methods is poor, and it is recommended that initial carbapenem resistance be confirmed by a second antimicrobial susceptibility method (143). Although still restricted to reference laboratories, there are PCR-based methods for detection of carbapenemase production (158).

Colistin is being used more frequently in the treatment of multidrug-resistant *P. aeruginosa*. Disk diffusion testing does not correlate well with MIC results, and underreporting of resistance has been reported (42). Susceptibility testing of colistin should be performed by an MIC method such as agar dilution, E test, or broth microdilution. Prolonged incubation of 48 h is recommended for broth microdilution (61).

Isolates of *P. aeruginosa* from CF patients pose specific difficulties for microbiology laboratories. Isolates from these patients often exhibit mixed morphotypes including mucoid phenotypes, small-colony variants, and bacterial microcolonies in biofilms. Susceptibility testing is complicated by several factors including lack of correlation between susceptibility results and clinical response (132), different susceptibility patterns within a morphotype (38), lack of reproducibility of susceptibility tests, falsely positive susceptibility results, and the presence of hypermutable strains (51, 104). Mucoid and nonmucoid phenotypes of *P. aeruginosa* are often coisolated in specimens from patients with CF. Mucoid isolates tend to be more susceptible and have lower β-lactamase activity than nonmucoid isolates (21). One explanation may be that these isolates are protected from selective antibiotic pressure. Selective antibiotic pressure, notably from inhalational tobramycin or colistin therapy, gives rise to small-colony variants of *P. aeruginosa* with properties of increased antimicrobial resistance, autoaggregative growth behavior, and enhanced ability to form biofilms (155). In turn, bacterial cells in biofilms adapt into symbiotic bacterial communities in which the mucoid alginate-producing bacterial cells provide physical protection to the biofilm, while the highly antibiotic-resistant nonmucoid cells protect against antibiotic killing (21). The increased ability of biofilm bacteria to acquire resistance phenotypes (27) and the selection of hypermutable strains following antimicrobial therapy (51, 104) may explain the lack of eradication of *P. aeruginosa* from chronically infected CF patients. Since for bacteria found in biofilms MICs are 100- to 1,000-fold greater than for free-living, planktonic bacteria (95), routine susceptibility testing may underestimate resistance and may contribute to treatment failures. In a study of 597 CF isolates (13), both disk diffusion and E test were found to be generally acceptable as routine susceptibility testing methods. However, poor correlation was found with disk diffusion testing of mucoid isolates for piperacillin, piperacillin-tazobactam, and meropenem. Underreporting of resistance was more frequent with disk diffusion than with E test, especially when ceftazidime, piperacillin, and piperacillin-tazobactam were tested.

Hypermutable strains may be detected using either disk diffusion or E-test methods by the presence of resistant subpopulations within the inhibition zones of three or more antibiotics (84).

Mucoid isolates pose a specific challenge for automated systems (8, 12, 30). Overestimation of susceptibility may occur, as mucoid isolates often demonstrate insufficient growth at 24 h. Automated systems that allow for longer incubation may be preferable. On the other hand, overcalling resistance may result from the presence of large amounts of exopolysaccharide, resulting in turbidity without adequate bacterial growth. These limitations have led many microbiologists who routinely work with mucoid isolates of *P. aeruginosa* to choose alternative methods for susceptibility testing.

Isolating and individually testing all the morphotypes of *P. aeruginosa* is labor-intensive and time-consuming and may not provide clinically relevant susceptibility results. Mixed-morphotype testing using phenotypically different colonies directly from sputum cultures or from subcultures of isolated colonies has been shown to correlate well with disk diffusion and MIC susceptibility methods (162) and may provide clinically useful susceptibility data with significant time and cost savings. However, the correlation appears to be better for susceptible strains than for resistant strains (94). Direct sputum susceptibility testing using the E-test method has been suggested as an alternative to morphotype testing in assessing the in vivo situation by evaluating bacterial population susceptibility as well as potential interactions with other organisms, including commensal flora (129).

Other methods have been recommended in an attempt to better predict susceptibility results. Biofilm susceptibility assays which confirm that biofilm inhibitory concentrations are much higher than conventionally determined MICs for multiple antibiotics have been developed (95). Synergy testing, using microtiter checkerboard, time-kill test, broth macrodilution breakpoint combination sensitivity test, or E-test methods (129, 161), has been used to assess the activity of antibiotic combinations in vitro in order to predict in vivo synergistic activity. This testing is labor-intensive, time-consuming, and difficult to reproduce and does not result in better clinical and bacteriological outcomes than those obtained with therapy directed by standard culture and sensitivity techniques (1).

Susceptibility testing of *Pseudomonas* species other than *P. aeruginosa* is rarely indicated, and clinical correlation is required before susceptibility testing is performed. These

organisms are generally susceptible to most antipseudomonal antibiotics as well as to trimethoprim-sulfamethoxazole (except most *P. fluorescens* or *P. putida* strains), a property that differentiates them from *P. aeruginosa. P. fluorescens, P. putida,* and *P. oryzihabitans* may be more resistant to aztreonam and ticarcillin-clavulanic acid. *P. stutzeri* is usually very susceptible to all antipseudomonal agents (124).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Pseudomonas species represent a diverse group of organisms widely distributed in nature. *P. aeruginosa* may be associated with colonization or clinically significant infections. It is a major pathogen in CF patients and represents an important nosocomial and opportunistic pathogen. Interpretation of the Gram stain often directs the further workup of this organism. The presence of small clusters of gram-negative organisms surrounded by amorphous material is indicative of biofilm formation compatible with a chronic infection. This finding should be reported to physicians, and incubation should be prolonged because these strains usually exhibit slower-growth characteristics. The intracellular presence of these organisms in polymorphonuclear cells is clinically significant. Isolation of *P. aeruginosa* from sterile body sites should always be interpreted as indicative of probable infection. Pseudoinfection from contaminated skin disinfectant solutions can occur and should be considered if the patient is not severely ill and especially if there is a cluster of infections with the same strain of *Pseudomonas* spp. Disinfection solutions should be cultured using the same methods as those recommended for *Pseudomonas* species. Isolation in mixed culture requires correlation with the direct smear, other organisms isolated, and clinical history. Identification of this organism requires only a few simple tests, and commercial tests are not usually needed. Isolates from sites of chronic infection often exhibit multiple morphotypes, frequently with altered characteristics, which can make identification more difficult. Molecular methods increasingly are finding a role in the identification of this organism, especially for epidemiological studies. Susceptibility testing of these organisms is difficult, especially for mucoid isolates, due to increasing resistance, lack of reproducibility of results, and lack of clinical correlation. A basic understanding of the multiple mechanisms of resistance, both intrinsic and acquired, is essential to interpret susceptibility testing results and give therapeutic recommendations to physicians. Optimal treatment to eradicate infection and prevent resistance, especially in chronic infections, remains controversial. Judicious use of antibiotics is necessary to eradicate infections and avoid resistance. Combination therapy is prudent in serious infections such as endocarditis, septicemia, nosocomial pneumonia, central nervous system and prosthetic material-related infections, and bacteremia in neutropenic patients. Strict adherence to infection control measures, including handwashing, is essential to prevent the spread of these organisms within hospitals. Other *Pseudomonas* species are infrequently isolated in the laboratory and are usually not clinically significant. Clinical correlation and correlation with the Gram stain are essential before further workup is undertaken.

TAXONOMY

In 1973, the taxonomic heterogeneity of the genus *Pseudomonas* was revealed by the work of Palleroni and coworkers, who identified five major species clusters (referred to as rRNA homology groups) among the pseudomonads (169). DNA-rRNA hybridization experiments led to the gradual dissection of the genus during the following decades (131). The name *Pseudomonas* was confined to rRNA homology group I organisms because they constituted the type species, *Pseudomonas aeruginosa* (see chapter 48).

The nomenclatural rearrangements of the genus *Pseudomonas* entailed the creation of several new genera. Some of these encompassed complete rRNA homology groups (e.g., both rRNA homology group IV species were reclassified into the genus *Brevundimonas*), whereas others encompassed only partial groups. rRNA group II pseudomonads belong to the class of the *β-Proteobacteria* and were reclassified into the genera *Burkholderia* and *Ralstonia* (233, 234). The rRNA group II pseudomonads form a remarkable group of primary and opportunistic human, animal, and plant pathogens, as well as environmental species with considerable potential for biological control, remediation, and plant growth promotion. During the past decade, the interest in several peculiar characteristics of these organisms led to the discovery and description of a multitude of novel species. The genus *Burkholderia* now contains more than 35 validly named species, most of which have been isolated from soil and water samples. Some other novel *Burkholderia*-like species were found to represent a distinct phylogenetic lineage with a position intermediate between those of the genera *Burkholderia* and *Ralstonia* and were classified into the novel genus *Pandoraea* (41).

More recently, Vaneechoutte et al. (205) reported that results of comparative 16S rRNA gene sequence analysis, further supported by phenotypic differences, indicated that two distinct sublineages existed within the genus *Ralstonia*. It was proposed that species of the *Ralstonia eutropha* lineage be classified into a novel genus named *Wautersia*. The name *Ralstonia* was preserved for the sublineage comprising *Ralstonia pickettii,* the type species. Shortly thereafter, Vandamme and Coenye (201) reported that *Wautersia eutropha*, the name of the type species of the genus *Wautersia,* was a junior synonym of *Cupriavidus necator*, the name of the type (and only) species of the genus *Cupriavidus,* an environmental organism which was validly named in 1987, i.e., long before 16S rRNA gene sequence studies were performed routinely (152). Thus, to conform to the International Code of Nomenclature of Bacteria (191), the name *Wautersia* was replaced by *Cupriavidus* and all species of the genus *Wautersia* became species of the genus *Cupriavidus*. Although renaming and subsequent further renaming of bacterial species cause confusion and irritation in the wider microbiological community, adhering to the rules of nomenclature is essential for establishing a truly systematic taxonomy.

Several *Burkholderia* species have been isolated from human clinical samples, but only the *Burkholderia cepacia* complex, *B. mallei*, and *B. pseudomallei* are generally recognized as human or animal pathogens. Recent taxonomic studies using 16S rRNA and *recA* sequence analysis, DNA-DNA hybridization experiments, whole-cell protein and fatty acid analyses, and biochemical characterization revealed that *B. cepacia*-like bacteria belong to at least nine distinct genomic species (genomovars), referred to collectively as the *B. cepacia* complex (54, 204). Ongoing surveys of the diversity of *B. cepacia*-like bacteria recovered from specimens from cystic fibrosis (CF) patients and other specimens revealed the presence of several additional groups in the *B. cepacia* complex which cannot be assigned to one of the established species within this complex by using traditional or molecular identification approaches (178). Further polyphasic taxonomic analyses are needed to determine if these groups represent additional novel species within the *B. cepacia* complex or if they represent new variants of established species. All *B. cepacia* complex species have been recovered from human clinical samples, but primarily *B. multivorans* and *B. cenocepacia* are important opportunistic pathogens in CF patients (99, 178).

Apart from the *B. cepacia* complex species, *B. mallei,* and *B. pseudomallei*, the genus *Burkholderia* now comprises an additional 26 validly described species. Most of these organisms are not associated with human disease and are not discussed further here. Organisms associated with human infections include *B. fungorum, B. gladioli* (including strains previously classified as *B. cocovenenans*[45]), and *B. thailandensis* (*20, 46*). A complete overview of validly named species can be obtained through Internet sites such as http://www.bacterio.cict.fr/ and http://www.dsmz.de/bactnom/genera1.htm.

*This chapter contains information presented in chapter 48 by Peter H. Gilligan, Gary Lum, Peter A. R. Vandamme, and Susan Whittier in the eighth edition of this Manual.

There are now five species in the genus *Ralstonia*. The human pathogens include *Ralstonia pickettii*, *R. mannitolilytica* (previously known as *R. pickettii* biovar 3/'*thomasii*') (72), and *R. insidiosa* (43). *R. paucula* (previously known as Centers for Disease Control group IVc-2) (202), *R. gilardii* (42), *R. respiraculi* (56), *R. taiwanensis* (31), and five additional species, which occur primarily in environmental samples, are now all classified as *Cupriavidus* species (201).

Five distinct species of *Pandoraea*, *Pandoraea apista* (the type species), *P. pulmonicola*, *P. pnomenusa, P. sputorum*, and *P. norimbergensis*, were distinguished by sodium dodecyl sulfate-polyacrylamide gel electrophoresis of whole-cell proteins, amplified fragment length polymorphism fingerprinting, DNA-DNA hybridization, and 16S rRNA gene sequence analysis. In addition, four strains, each representing a distinct novel *Pandoraea* species, presently remain unnamed (41, 70).

Organisms in the *Pseudomonas* rRNA homology group III also belong to the *β-Proteobacteria* and are now classified in the family *Comamonadaceae*, which includes the genera *Comamonas*, *Delftia*, and *Acidovorax* (216, 223). The genus *Comamonas* was originally created in 1985 and included a single species, *Comamonas terrigena*. Two years later, *Pseudomonas acidovorans* and *Pseudomonas testosteroni* were reclassified as members of the genus *Comamonas*. *Comamonas acidovorans* was subsequently again reclassified as *Delftia acidovorans* (216). *Comamonas terrigena* encompassed three strain clusters on the basis of DNA-rRNA and DNA-DNA hybridization data and data from protein electrophoretic patterns and immunotyping (226). Wauters et al. (214) reported biochemical differences between these three clusters and consequently described them as separate species. They proposed to rename *Comamonas terrigena* DNA groups 2 and 3 as *Comamonas aquatica* and *Comamonas kerstersii,* respectively. *Comamonas terrigena, Comamonas aquatica,* and *Comamonas kerstersii* all occur in human clinical samples. Additional novel species have been isolated from environmental samples (27, 83, 102, 196).

Originally, *Acidovorax facilis* was classified as *Hydrogenomonas facilis* based on its ability to oxidize hydrogen. Poly-β-hydroxybutyrate metabolism studies resulted in the transfer of this species to the genus *Pseudomonas*, along with a new species called *Pseudomonas delafieldii*. A new genus, *Acidovorax*, was proposed which included three species, *A. facilis*, *A. delafieldii*, and *A. temperans*, all members of rRNA homology group III (224). An additional five plant-pathogenic pseudomonads and novel environmental species have been classified as *Acidovorax* species (89, 90, 185, 225).

The genus *Brevundimonas,* consisting of the species *Brevundimonas diminuta* and *Brevundimonas vesicularis,* was proposed for bacteria originally classified as members of *Pseudomonas* rRNA homology group IV (186) and is a member of the *α-Proteobacteria*. Phylogenetic studies by Abraham et al. (2) revealed that the taxonomy of the genera *Brevundimonas* and *Caulobacter* was intertwined. Six *Caulobacter* species and two novel environmental species were therefore described as novel *Brevundimonas* species (2, 87, 139).

Finally, *Pseudomonas maltophilia* represented *Pseudomonas* rRNA homology group V (115). Based on genotypic and phenotypic characteristics, including DNA-rRNA hybridizations, cellular fatty acid composition, and growth parameters, its transfer to the genus *Xanthomonas*, a member of the *γ-Proteobacteria,* was proposed (195). However, many differences were also noted, including flagellum number, nitrate reduction characteristics, fimbriation, and plant pathogenicity. Therefore, the organism was once again reclassified into a novel genus, *Stenotrophomonas* (168). More recently, a novel species, *Stenotrophomonas africana,* was proposed (81). However, Coenye et al. (57) demonstrated that *S. maltophilia* and *S. africana* are the same species and nomenclatural priority was given to the former. Three additional environmental *Stenotrophomonas* species were described recently (11, 85, 228).

DESCRIPTION OF THE AGENTS

Burkholderia, Ralstonia, Cupriavidus, Pandoraea, Brevundimonas, Comamonas, Delftia, and *Acidovorax* spp. are aerobic, non-spore-forming, straight or slightly curved gram-negative rods. They are 1 to 5 μm in length and 0.5 to 1.0 μm in width (113). *Stenotrophomonas* spp. are straight rods and tend to be slightly smaller than members of the other genera (0.7 to 1.8 μm in length and 0.4 to 0.7 μm in width) (113). With the exception of *B. mallei*, these organisms are motile due to the presence of one or more polar flagella (167). These bacteria are catalase positive, and most, with the exception of *Stenotrophomonas* and *B. gladioli*, are either weakly or strongly oxidase positive. All grow on MacConkey agar, except for certain strains of *Brevundimonas vesicularis*, and appear as nonfermenters. The majority of species degrade glucose oxidatively, and most degrade nitrate into either nitrite or nitrogen gas. Certain species have distinctive colony morphologies or pigmentation. They are nutritionally quite versatile, with different species being able to utilize a variety of simple and complex carbohydrates, alcohols, and amino acids as carbon sources. Certain species can multiply at 4°C, but most are mesophilic, with optimal growth temperatures of between 30 and 37°C (167). For some genera, growth at higher temperatures (i.e., up to 42°C) can be useful for species identification.

EPIDEMIOLOGY AND TRANSMISSION

Burkholderia, Ralstonia, Cupriavidus, Pandoraea, *Comamonas, Delftia, Acidovorax, Brevundimonas,* and *Stenotrophomonas* spp. are environmental organisms found in water, soil, and the rhizosphere and in and on plants including fruits and vegetables. They have a worldwide distribution. Members of these genera are widely recognized as phytopathogens, and many species were first described in that context. Because of their ability to survive in aqueous environments, these organisms have become particularly problematic as opportunistic nosocomial pathogens in hospitals and health care settings.

The natural distribution of *B. cepacia* complex species is being intensively studied because of interest in their biotechnological properties and their pathogenicity in persons with CF (99, 144). *B. cepacia* complex bacteria often have antifungal, antinematodal, or plant growth-promoting properties, which makes them attractive as biological pesticides and fertilizers (170). Because of their nutritional versatility, *B. cepacia* complex bacteria also have applications for bioremediation of contaminated soils. Unlike *P. aeruginosa*, *B. cepacia* complex bacteria are rarely recovered from environmental sites such as sinks, swimming pools, showers, and salad bars (99, 157). However, they are frequently recovered from soil and environmental water samples (12, 176), provided that appropriate growth conditions are used to inhibit the growth of vast numbers of other environmental bacteria. Studies of a variety of foodstuffs and bottled water have shown that *B. cepacia* complex bacteria have been found in unpasteurized dairy products (17, 156). Due to their intrinsic resistance to antibiotics and disinfectants, *B. cepacia* complex bacteria are also notorious contaminants of pharmaceutical preparations and medical equipment such as nebulizers, which may be sterilized with contaminated anti-infectives (116, 163).

Genotypic and conventional epidemiologic investigations provide compelling evidence for interpatient transmission of common or epidemic *B. cepacia* complex strains among persons with CF (142). One such strain, referred to as the ET12 (for electrophoretic type 12) lineage, is common among CF patients in eastern Canada and the United Kingdom (124, 174). This organism is a *B. cenocepacia* strain that is characterized by the presence of a distinctive cable-like pilus and an associated adhesin that mediates adherence to the respiratory epithelium (181). *B. cenocepacia* strain PHDC dominates among infected CF patients in the mid-Atlantic region of the United States and has recently been identified in agricultural soil as well as in CF patients in several European countries (30, 53, 148).

B. pseudomallei and *B. thailandensis* are found primarily in tropical and subtropical areas. *B. pseudomallei* is endemic in rodents and is found in moist soil, on vegetables, and on fruit. Both species are particularly prevalent in the rice-growing regions of northern Thailand and southern and central Vietnam because of high concentrations of the organisms in rice paddy surface water (171). Reports have suggested that *B. pseudomallei* can also be found with some frequency on the Indian subcontinent but goes unrecognized (69).

Because of the increasing frequency of nosocomial infections due to *S. maltophilia*, its presence in hospital environments is being more closely examined. Like *P. aeruginosa*, *S. maltophilia* is ubiquitous in aqueous environments and can be readily cultured from water sources in homes and hospitals (77).

Unlike that of certain *B. cepacia* complex strains, evidence for person-to-person transmission of *B. gladioli*, *B. pseudomallei*, *B. mallei*, *S. maltophilia,* and the other species discussed in this chapter is lacking.

CLINICAL SIGNIFICANCE

B. cepacia Complex and *B. gladioli*

B. cepacia has long been recognized as an occasional opportunistic human pathogen capable of causing a variety of infections, including bacteremia, urinary tract infection, septic arthritis, peritonitis, and pneumonia in persons with underlying illness (144, 166). Persons with chronic granulomatous disease (CGD), a primary immunodeficiency in which white blood cells are unable to generate the superoxide and reactive oxidants necessary for intracellular microbicidal activity, are particularly susceptible to infection (227). *B. cepacia* also has a history as a nosocomial pathogen, causing infections associated with contaminated hospital equipment, medications, and disinfectants including povidone-iodine and benzalkonium chloride (143). Nosocomial outbreaks of respiratory tract infections in patients on mechanical ventilation in intensive care units have been attributed to contamination of nebulizers or nebulized medications such as albuterol (177). Contamination of blood culture systems or disinfectants resulting in pseudobacteremia has been described following the isolation of *B. cepacia* from the blood of multiple patients over a short period (60).

During the 1980s, *B. cepacia* emerged as a life-threatening pathogen in persons with CF, which is the most common inherited lethal disease in Caucasians in North America and Europe, affecting about 1 in 2,750 live births (144). Early reports of infection in CF described patients with acute pulmonary deterioration and sepsis (referred to as cepacia syndrome) or chronic respiratory tract infections associated with an accelerated decline in lung function (121, 198). Clinical outcome studies consistently identified *B. cepacia* infection as a significant independent risk factor for morbidity and mortality in CF (59, 140).

The recognition that several closely related species can be distinguished from among organisms previously identified as *B. cepacia* has stimulated interest in the clinical significance of each of these species (141). Approximately 3% of CF patients in the United States are infected with *B. cepacia* complex species, although rates of infection vary from 0 to 20% among CF treatment centers (68). Rates of infection increase with increasing patient age; approximately 6 to 7% of adults with CF are infected (68). Most strains are inherently resistant to currently available antimicrobial agents (see below), and pulmonary infection is generally refractory to therapy. Furthermore, due to the poor postoperative prognosis associated with *B. cepacia* complex infection, most CF treatment centers consider infection to be an absolute contraindication for lung transplantation, which at present is the only therapeutic option for successful intermediate-term survival of persons with end-stage pulmonary disease (142). Thus, respiratory tract infection with these species is a cause of great concern to CF patients and their caregivers.

Although all nine species of the *B. cepacia* complex have been recovered from persons with CF, the distribution of species in this patient population is disproportionate. In the United States, *B. multivorans* and *B. cenocepacia* together account for approximately 85% of infections (178). In Canada and some European countries, *B. cenocepacia* alone accounts for as much as 80% of infections (4, 192). Some *B. cepacia* complex species are recovered only rarely. In a recent survey, *B. stabilis, B. ambifaria, B. anthina,* and *B. pyrrocinia* each accounted for less than 1% of *B. cepacia* complex infections among 1,218 infected CF patients (178).

Emerging data suggest that *B. cepacia* complex species also vary with respect to their virulence levels and clinical impacts in CF. Studies with lung transplant recipients, for example, indicate that rates of postoperative mortality are greater for persons infected preoperatively with *B. cenocepacia* than for patients infected with other *B. cepacia* complex species (8, 80). However, although it is almost certainly true that *B. cenocepacia* is the species most frequently associated with cepacia syndrome, it remains to be shown whether this species, in general, is disproportionately associated with poor outcome; recent reports document fatal infection associated with other *B. cepacia* complex species, including *B. multivorans*, *B. stabilis*, and *B. dolosa* (18, 73, 164). Thus, although a positive correlation between species frequency and poor clinical outcome seems likely, firm conclusions regarding the relative virulence of *B. cepacia* complex species must await more definitive study. Recent studies also suggest that epidemic strains, particularly ET12, are relatively more virulent in CF (125, 136), but again, further comparative outcome studies are needed before firm conclusions about relative virulence can be drawn.

B. gladioli is most notable as a plant pathogen but is also well recognized to be capable of causing infection in persons with CF or CGD and, occasionally, other immunocompromised patients (101, 180). Anecdotal reports describe acute pulmonary deterioration and recurrent soft tissue abscesses, as well as severe post-lung transplantation infections due to *B. gladioli* in CF patients (15, 126, 132). A more complete appreciation of the epidemiology and clinical significance of *B. gladioli* infection in CF has been confounded by difficulty with accurate identification of this species, which typically is capable of growth on selective media used to isolate the *B. cepacia* complex (38) and is frequently misidentified as a member of the *B. cepacia* complex by commercial test systems (40, 189).

B. pseudomallei and *B. mallei*

B. pseudomallei is the causative agent of the human and animal disease melioidosis, which is endemic in Southeast Asia and tropical northern Australia and is being increasingly recognized on the Indian subcontinent and in Central and South America (32). In locations where the disease is endemic, infection is seasonal, with up to 85% of cases occurring during the monsoon wet season. As travel to Southeast Asia and northern Australia has become more frequent, reports of melioidosis in travelers returning to Europe and the United States are becoming more common (69), including those of infections in persons with CF (162, 184, 211). Infection with this organism should be considered in the differential diagnosis of any individual with a fever of unknown origin or a tuberculosis-like illness who has a history of travel to a region where *B. pseudomallei* infection is endemic.

B. pseudomallei is present in soil and surface water and is acquired either by inoculation through cut or abraded skin or by inhalation. Zoonotic disease is described but is exceedingly uncommon, as are person-to-person transmission and laboratory-acquired infection (32). The association of severe weather events with respiratory infection and high mortality rates has been attributed to a shift from percutaneous inoculation to inhalation (65). This idea supports the potential of *B. pseudomallei* as a bioterrorism agent; its isolation from patients who do not give a history of travel to an area where melioidosis is endemic should be immediately reported to local or state public health authorities. For further details, see chapter 9 or http://www.bt.cdc.gov.

The majority of persons infected with *B. pseudomallei* remain asymptomatic, with rates of seropositivity of over 20% in some locations (128). Latent infection with subsequent reactivation is well recognized, with a recent description of disease onset in the United States, where melioidosis is not endemic, 62 years after presumed infection in Thailand (159). Nevertheless, the vast majority of cases of melioidosis are from recent infection, with an incubation period of 1 to 21 days (mean, 9 days) (64). Risk factors for clinical disease following infection with *B. pseudomallei* include diabetes, excessive alcohol consumption, chronic renal disease, and chronic lung disease (66). Around 20% of patients have no identified risk factor, and mortality in this group is usually low. Disease in children is also uncommon, although parotid abscesses are well recognized as an important manifestation of melioidosis in children in Thailand. Overall rates of mortality from melioidosis vary from 15% in centers where state-of-the-art intensive care therapy is available to over 50% in locations with poor resources (32, 222). Fifty percent of cases present with pneumonia, which can be part of a fatal septicemia or a less severe unilateral infection indistinguishable from other community-acquired pneumonias or a chronic illness mimicking tuberculosis (29, 61). Chronic melioidosis, defined as illness present for over 2 months, occurs in only 10% of cases. Overall, 50% of cases are bacteremic; the presence of >100 CFU/ml of blood and a blood culture showing growth in the first 24 h of incubation are markers for high mortality (199). Other common presentations with or without bacteremia are genitourinary infections, septic arthritis, and osteomyelitis (32, 63, 222). Prostatic abscesses are especially common (63). Abscesses can also occur in the spleen, liver, kidneys, and adrenal glands. Parotitis, lymphadenitis, sinusitis, orchitis, myositis (especially psoas abscesses), mycotic aneurysms, and pericardial and mediastinal collections have all been described. Lesions can be frankly purulent and may include microabscesses or granulomas or a combination of these features. Clinical meningitis is rare, but melioidosis encephalomyelitis syndrome (62, 63, 229) and brain abscesses have also been reported (135). The one presentation that has yet to be described is *B. pseudomallei* endocarditis.

B. mallei is the etiologic agent of glanders, a highly communicable disease of livestock, particularly horses, mules, and donkeys. It can be transmitted to humans and is also identified as a potential agent of bioterrorism. Unlike *B. pseudomallei*, *B. mallei* is a host-adapted pathogen that does not persist in the environment outside its host. Glanders has been eradicated from most countries, but enzootic foci persist in the Middle East, Asia, Africa, and South America. The only human case of glanders in the past 50 years in the United States was a recent laboratory-acquired case in a biodefense scientist (26). Like melioidosis, human glanders can be acute or chronic, with the clinical presentation and course depending on the mode of infection, the inoculation dose, and host risk factors. Respiratory inoculation can result in pneumonia with potential for dissemination to internal organs and septicemia. Cutaneous inoculation can result in skin nodules and regional lymphadenitis, also with potential for disseminated disease. Involvement of lymph nodes, both mediastinal and peripheral, is much more common in glanders than in melioidosis, often with suppurative abscesses in untreated cases.

S. maltophilia

S. maltophilia, although typically not pathogenic for healthy persons, is a well-known opportunistic human pathogen. It is among the most common causes of wound infection due to trauma involving agricultural machinery (3). It is also an important nosocomial pathogen associated with substantial morbidity and mortality, particularly in debilitated or immunocompromised patients and patients requiring ventilatory support in intensive care units (5, 88, 107, 158). The incidence of human infection appears to have increased in recent years, and a variety of clinical syndromes have been described, including bacteremia, pneumonia, urinary tract infection, ocular infection, endocarditis, meningitis, soft tissue and wound infection, mastoiditis, epididymitis, cholangitis, osteochondritis, bursitis, and peritonitis (76, 183). Septicemia can be accompanied by ecthyma gangrenosa, a skin lesion more commonly associated with *P. aeruginosa* and *Vibrio* spp. (206).

The incidence of *S. maltophilia* respiratory tract infection in persons with CF also appears to be increasing (74, 197); however, the unreliability of historical data limits firm conclusions. Approximately 11% of CF patients included in the CF Foundation's patient registry were culture-positive for *S. maltophilia* in 2003 (68). In large multicenter clinical trials, however, *S. maltophilia* was found in a larger proportion of CF patients, being second only to *P. aeruginosa* in frequency of isolation from study subjects (25). Infection or colonization was most frequently transient, with 30% of subjects having at least one sputum culture positive for *S. maltophilia* during the course of 6 months (100). Several case control studies have drawn conflicting conclusions regarding the role that *S. maltophilia* plays in contributing to pulmonary decline in CF (74, 98).

Ralstonia and *Cupriavidus* spp.

As described above, the taxonomy of the genus *Ralstonia* has been recently revised, with several species being assigned to the genus *Cupriavidus* (201). Among the species in these two genera, *R. pickettii* is best known with respect to human infection. Older reports describe this species as being recovered

from a variety of clinical specimens (179) and as causing various infections including bacteremia, meningitis, endocarditis, and osteomyelitis (217). *R. pickettii* also has been identified in cases of pseudobacteremias and nosocomial outbreaks due to contamination of intravenous medications, sterile water, saline, chlorhexidine solutions, respiratory therapy solutions, and intravenous catheters (19, 36, 84). This species has also been recovered from the respiratory tracts of persons with CF (25). However, *R. pickettii* is easily confused with *Pseudomonas fluorescens* and members of the *B. cepacia* complex (25, 72, 111). Furthermore, several newly recognized *R. pickettii*-like species are also now known to be involved in human infection, particularly in CF (52). Thus, the role of *R. pickettii* as a human pathogen is difficult to assess based on historical data.

R. mannitolilytica (formerly known as *R. pickettii* biovar 3/'*thomasii*') was recently described as causing nosocomial outbreaks and a case of recurrent meningitis (72). This species accounts for the majority of *Ralstonia* infections in CF patients, being found in more than twice as many CF patients as *R. pickettii* (52). *R. insidiosa* and *Cupriavidus respiraculi* are recently described species recovered from persons with CF (43, 56). *Cupriavidus gilardii* has been recovered from cerebrospinal fluid (42), and cases of *Cupriavidus paucula* bacteremia, peritonitis, and tenosynovitis have been reported (202). Both of these species may be found in sputa from patients with CF (52). Although *Cupriavidus metallidurans* and *Cupriavidus basilensis* are not known to cause human infection, they too have been recovered recently from sputum cultures from patients with CF (52). Despite these observations, the roles of *Ralstonia* and *Cupriavidus* species in human infection, particularly in persons with CF, require further elucidation.

Other Genera

In general, *Brevundimonas*, *Comamonas*, *Delftia*, *Acidovorax*, and *Pandoraea* spp. infrequently cause human infection. Interest in these species focuses primarily on their roles as plant pathogens or on studies of microbial biodiversity and biodegradation.

Brevundimonas spp. are occasionally recovered from clinical specimens (37). *Brevundimonas vesicularis* bacteremia in patients with various underlying illnesses has been reported (92), and the organism has been recognized in cervical specimens because of its ability to produce bright orange colonies on Thayer-Martin agar (165). *Brevundimonas diminuta* has been recovered from blood, urine, and pleural fluid from patients with cancer (105).

Among the *Comamonas* species, *Comamonas testosteroni* has been implicated most often in human infection, with recent reports describing endocarditis, meningitis, and catheter-associated bacteremia due to this species (7, 58, 137). *D. acidovorans* has similarly been reported to cause infection, being identified in cases of bacteremia, endocarditis, ocular infection, and suppurative otitis (82). *Acidovorax* spp. have been isolated from a variety of clinical sources (224), including blood from a patient with a hematological malignancy (232). *Acidovorax* spp., *Comamonas testosteroni,* and *D. acidovorans* have also been recovered from sputa of persons with CF (44; J. J. LiPuma, unpublished data); however, the roles of these species in contributing to lung disease in CF have not been established.

In addition to causing infections in CF (123, 127), *Pandoraea* spp. have been recovered from blood and from patients with chronic obstructive pulmonary disease or CGD (70). Although the roles of these species in contributing to poor outcomes in persons with underlying diseases are unclear, a recent report describes sepsis, multiple organ failure, and death in a patient who underwent lung transplantation due to sarcoidosis (194).

COLLECTION, TRANSPORT, AND STORAGE

The genera described in this chapter include organisms that can survive in a variety of hostile environments and at temperatures found in clinical settings. Therefore, standard collection, transport, and storage techniques as outlined in chapters 5, 6, and 20 are sufficient to ensure the recovery of these organisms from clinical specimens.

DIRECT EXAMINATION

Members of these genera have similar morphologies and, with the exception of *B. pseudomallei*, are not easily distinguished from one another on the basis of Gram staining. *B. pseudomallei* often appears as small, gram-negative bacilli with bipolar staining, making the cells resemble safety pins (Fig. 1). It is not uncommon for the presumptive laboratory diagnosis of *B. pseudomallei* infection to be made upon the examination of the initial Gram-stained smear.

Although PCR-based assays have been described for the identification of *B. cepacia* complex species, *B. pseudomallei, B. gladioli*, several *Ralstonia* and *Cupriavidus* species, *Pandoraea* species, and *S. maltophilia* following culture and isolation (see "Identification" below), the use of PCR for direct detection of these species in clinical specimens remains a research tool (71, 153, 220). Studies of CF sputum samples have indicated that some specimens may be PCR positive but culture negative for certain *B. cepacia* complex species, raising important questions about the natural history of infection in CF. However, the sensitivities and specificities of such PCR assays for the intended target species are difficult to determine in the absence of reliable "gold standards." The development of assays employing real-time PCR technology may yield reliable approaches to direct detection of these species in clinical specimens in the near future.

Because septicemia with *B. pseudomallei* is frequently fatal, several rapid direct detection methods have been developed in research laboratories, including urinary antigen detection using latex agglutination (LA) and enzyme immunoassay (EIA), direct fluorescent-antibody (DFA) staining, and PCR (78, 103, 190, 212). The EIA for the detection of urinary antigens is more sensitive than LA, with an overall sensitivity of 71% for patients with melioidosis compared with an LA sensitivity of 62% (with concentrated urine) or only 17.5% (with unconcentrated urine). The EIA has higher sensitivity (84%) with samples from septicemic patients. Cross-reactions with other urinary tract pathogens including *Klebsiella pneumoniae* and *Escherichia coli* have been reported with EIA but not LA; therefore, EIA results must be interpreted cautiously (78, 190).

Antibodies raised against heat-killed whole cells of *B. pseudomallei* have been used to prepare a reagent for DFA staining. When this DFA reagent was used to stain clinical specimens from patients with suspected melioidosis, it showed a sensitivity of 73%, similar to those of other bacterial DFA stains. The reagent (not available commercially) apparently does not cross-react with other organisms, although the number of isolates tested for cross-reaction was small (212).

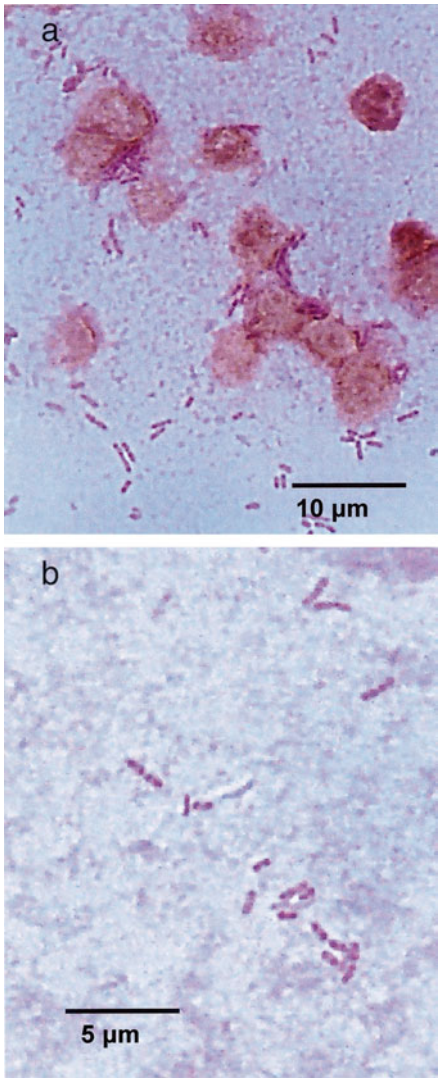

FIGURE 1 (a) Gram stain of *B. pseudomallei* in a blood culture; (b) Gram stain of *B. pseudomallei* from a colony on blood agar.

Reports on the use of PCR for the direct detection of *B. pseudomallei* in clinical specimens indicate that the currently used primer sets and assay conditions are sensitive but lack specificity, resulting in positive predictive values of only 70% (103).

CULTURE AND ISOLATION

These species grow well on standard laboratory media such as 5% sheep blood and chocolate agars. Such media can be used to recover the organisms from sterile fluid or tissue where a mixed flora is not anticipated (see chapter 20). All species that have been reported to be recovered from blood, including *B. pseudomallei* (199), grow in broth-based blood culture systems within the standard 5-day incubation period, so special blood culture techniques such as lysis-centrifugation and extended incubation periods are not required. The use of selective media facilitates the isolation of these organisms from specimens with mixed microbiota. With the exception of *Brevundimonas vesicularis*, MacConkey agar can be used to isolate most species of these genera.

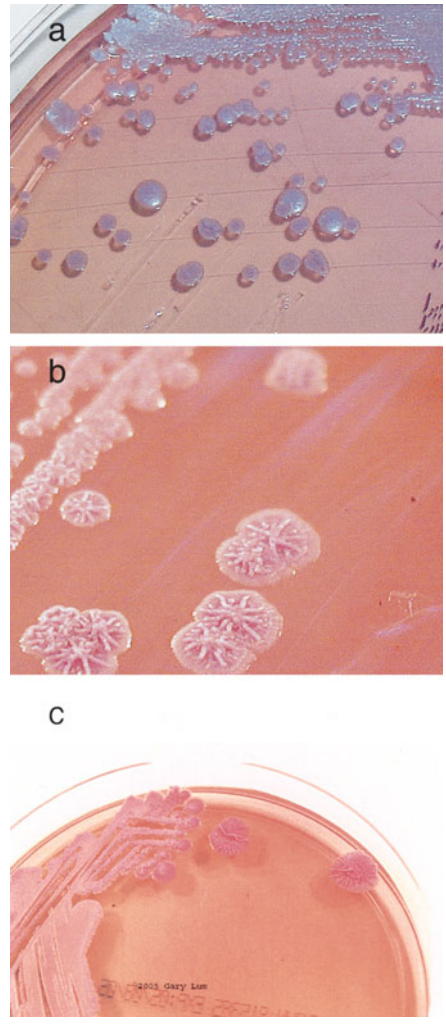

FIGURE 2 (a) *B. pseudomallei* colonies on MacConkey agar; (b) *B. pseudomallei* colonies on blood agar; (c) *B. pseudomallei* colonies on Ashdown medium agar.

Burkholderia species grow on MacConkey agar (Fig. 2), but the use of specific selective media with the ability to inhibit *P. aeruginosa* is preferred for the isolation of *B. cepacia* complex species and *B. pseudomallei*. Several selective media have been described, and some are commercially available. A multicenter comparison of three media, PC (for *Pseudomonas cepacia*) agar (BD Diagnostics, Franklin Lakes, N.J.) (94), OFPBL (for oxidation-fermentation base-polymyxin b-bacitracin-lactose) agar (BD Diagnostics) (215), and BCSA (for *B. cepacia* selective agar; Hardy Diagnostics, Santa Maria, Calif.) (109), showed that BCSA was superior, being both more sensitive (more *B. cepacia* isolates were recovered) and more specific (fewer other types of organisms grew) than PC or OFPBL agar (109, 110). More recently, the sensitivities of TB-T (for trypan blue-tetracycline) (104), PC-AT (for *Pseudomonas cepacia* azelaic acid) (23), and BCSA (109, 110) were compared with those of three commercial media, i.e., *B. cepacia* media from MAST Diagnostics (Bootle, Merseyside, United Kingdom), LAB M Ltd. (Bury, United Kingdom), and Oxoid Ltd. (Basingstoke, United Kingdom), through the analysis of 142 clinical and environmental isolates representing all species within the *B. cepacia* complex (209).

BCSA and MAST *B. cepacia* medium supported the growth of *B. cepacia* complex isolates most efficiently. The latter two media were also compared in a study to evaluate the sensitivities and specificities for the isolation of *B. cepacia* complex species from sputum specimens from CF patients (230). BCSA was reported to be equally sensitive as MAST agar but more selective.

Ashdown medium is effective for the isolation of *B. pseudomallei* (Fig. 2); crystal violet and gentamicin act as selective agents. It has been shown to be superior to MacConkey agar or MacConkey agar supplemented with colistin for the recovery of *B. pseudomallei* from clinical specimens containing mixed bacterial microbiota, such as throat, rectal, and sputum specimens (231). An enrichment broth consisting of Ashdown medium supplemented with 50 mg of colistin per liter allowed the recovery of 25% more *B. pseudomallei* isolates than direct plating of clinical specimens on Ashdown agar (213).

For the recovery of *B. pseudomallei* from rectal and throat swabs, selective broth should be inoculated at the bedside and incubated for up to 7 days at 35 to 37°C. The broth can be subcultured to selective media in the laboratory, and solid-phase agar can be kept for an additional 7 days at 35 to 37°C. During the monsoon season, specimens such as sputa, urine (male patients), and wound swabs should be inoculated onto Ashdown agar (213, 229). Subculture from broth should be done earlier if a pellicle at the liquid-air interface is observed or if the broth changes from a deep purple to a deep pink hue due to a change in pH affecting the neutral red indicator.

Recently, a new selective agar, BPSA (for *B. pseudomallei* selective agar), was reported to improve the recovery of *B. pseudomallei* over that with other media (114). BPSA was more inhibitory to *P. aeruginosa* and *B. cepacia* complex species and made recognition of *Burkholderia* species easier due to their distinctive colony morphology. However, in clinical practice this medium may offer only a modest advantage over current commercially available media.

The use of selective media (130) increases the isolation rates for *S. maltophilia* from clinical and environmental samples (75). Denton et al. (75) studied the sensitivity of a selective medium incorporating vancomycin, imipenem, and amphotericin B as selective agents (VIA medium) for isolating *S. maltophilia* from sputum samples collected from children with CF. This study compared the use of VIA medium to an existing in-house method that utilized an imipenem disk placed upon bacitracin-chocolate agar (BC medium) and reported improved detection using VIA medium as a selective medium.

IDENTIFICATION

B. cepacia Complex and *B. gladioli*

Accurate identification of *B. cepacia* complex species presents a challenge (154). Commercial bacterial identification systems are not able to reliably distinguish among the species of the *B. cepacia* complex and often fail to differentiate these species from other closely related species such as *B. gladioli* and *Ralstonia, Cupriavidus,* and *Pandoraea* spp. (21, 111, 133, 189). This failure presents a serious problem for CF patients and their caregivers as detailed in "Clinical Significance" above. The identification of *B. cepacia* complex species from CF sputum culture has a dramatic impact on patient management and is a cause of considerable anxiety for patients with CF (142, 143). Consequently, when *Burkholderia, Ralstonia, Cupriavidus,* or *Pandoraea* species are tentatively identified in a patient with CF by using a commercial system, the identity of the isolate should be confirmed by conventional biochemical testing (111) and, if necessary, molecular techniques. To aid clinical microbiologists in the United States, the CF Foundation has established a *B. cepacia* reference laboratory, which uses a combination of phenotypic and genotypic methods (described below) to confirm the identity of suspected *B. cepacia* complex isolates (146). Further information concerning the *B. cepacia* reference laboratory can be found on the CF Foundation website (http://www.cff.org).

B. cepacia complex species may require 3 days of incubation before colonies are seen on selective media. On MacConkey or Mueller-Hinton agar, these colonies may be punctate and tenacious, and on blood agar or a selective medium such as BCSA, PC agar, or OFPBL agar, the colonies are smooth and slightly raised; occasional isolates are mucoid. On MacConkey agar, colonies of the *B. cepacia* complex frequently become dark pink to red due to oxidation of lactose after extended incubation (4 to 7 days). Most clinical isolates are nonpigmented, but on iron-containing media such as a triple sugar iron slant, many strains produce a bright yellow pigment. *B. cepacia* complex species have a characteristic dirt-like odor.

The species of the *B. cepacia* complex are phenotypically very similar, making their differentiation, even with an extended panel of biochemical tests, rather difficult (Table 1) (111). *B. multivorans*, *B. stabilis*, and *B. dolosa* rarely oxidize sucrose. *B. stabilis* is ornithine decarboxylase positive, as are most *B. cenocepacia* strains, but is distinctive in that more than two-thirds of strains are *o*-nitrophenyl-β-D-galactopyranoside (ONPG) negative. *B. stabilis* and most *B. ambifaria* strains show poor growth at 42°C. *B. dolosa* is usually lysine decarboxylase negative, whereas only approximately half of *B. multivorans* strains are negative. Other *B. cepacia* complex species are usually lysine decarboxylase positive. *B. vietnamiensis* and most *B. anthina* strains do not oxidize adonitol. *B. anthina* strains show a distinctive creamy morphology on BCSA, which also turns pink (i.e., alkaline) despite the ability of this species to utilize sucrose (203).

Phenotypic differentiation of *B. cepacia* complex species from *B. gladioli* and *Pandoraea* spp. is also difficult (Table 1). Cellular fatty acid analysis is unable to differentiate *B. cepacia* complex species from *B. gladioli* (193). However, in contrast to *B. cepacia* complex species, most *B. gladioli* strains are oxidase negative and whereas most *B. cepacia* complex strains oxidize maltose and lactose, *B. gladioli* typically oxidizes neither. *Pandoraea* spp. do not oxidize maltose, lactose, xylose, sucrose, or adonitol, and most are ONPG negative. *B. cepacia* complex species also may be difficult to differentiate from *Ralstonia* and *Cupriavidus* species. However, several of the latter species show a fast and strong oxidase reaction whereas *B. cepacia* complex species produce a slow, weak-positive oxidase reaction. Further, in contrast to most *B. cepacia* complex species, *Ralstonia* and *Cupriavidus* species are lysine decarboxylase negative and most often ONPG negative.

The difficulty in differentiating *B. cepacia* complex species has prompted the development of molecular genetic diagnostic tests capable of identifying these species individually and distinguishing them (as a group) from biochemically similar species. DNA sequence differences in 16S and 23S rRNA genes have been used to develop species-specific PCR assays for the identification of several *B. cepacia* complex species (16, 146, 207), as well as *B. gladioli* (221). *B. multivorans*, *B. vietnamiensis*, and *B. dolosa* can be reliably identified with 16S rRNA-targeted assays, but insufficient sequence variation in rRNA genes exists to enable reliable separation of the remaining *B. cepacia* complex species. Fortunately, species-specific

[a] The number of strains of each species tested was as follows: *B. cepacia*, 122; *B. multivorans*, 715; *B. cenocepacia*, 768; *B. stabilis*, 49; *B. vietnamiensis*, 145; *B. dolosa*, 57; *B. ambifaria*, 51; *B. anthina*, 24; *B. pyrrocinia*, 14; *B. gladioli*, 280; and *Pandoraea* spp., 75. Data are from references 111 and 203 and J. J. LiPuma (unpublished data) and D. A. Henry (unpublished data).

[b] The number of strains of each species tested was as follows: *B. cepacia*, 23; *B. multivorans*, 109; *B. cenocepacia*, 139; *B. stabilis*, 27; *B. vietnamiensis*, 36; *B. dolosa*, 9; *B. ambifaria*, 18; *B. anthina*, 16; *B. pyrrocinia*, 3; *B. gladioli*, 27; and *Pandoraea* spp., 9. Data are from references 111 and 203 and D. A. Henry (unpublished data).

[c] Oxidation test results were recorded after 7 days of incubation (data in parentheses were recorded after 3 days of incubation).

[d] PNPG, *p*-nitrophenyl-β-D-glucoside.

[e] Results presented are from the API 20 NE test strip.

sequence variation does exist in the *recA* gene, and PCR assays targeting this locus enable the reliable identification of *B. multivorans, B. cenocepacia*, and *B. ambifaria* (49, 150, 208). Other 16S rRNA- and *recA*-based PCR assays identify all *Burkholderia* spp. (i.e., at the genus level) or all species within the *B. cepacia* complex (i.e., as a group) (146, 150, 172).

Another molecular genetic approach to identifying *B. cepacia* complex species involves restriction fragment length polymorphism (RFLP) analysis of either 16S rRNA or *recA* genes (150, 187). Again, insufficient sequence variation in the 16S rRNA gene limits the use of RFLP analysis of this locus, even when multiple restriction enzymes are used (86, 187, 210). In contrast, *recA* RFLP analysis has proved quite useful in reliably distinguishing all species within the *B. cepacia* complex (150, 172, 208).

Other genomic approaches, including amplified fragment length polymorphism typing, ribotyping, and whole-cell protein profiling, have been proposed for the differentiation of *B. cepacia* complex species (22, 50, 204). However, these methods are time-consuming and expensive and require an extensive validated database before isolates can be reliably identified. These limitations render them impractical for use in a routine diagnostic laboratory. Cellular fatty acid methyl ester analysis is useful for identification of *Burkholderia* strains at the genus level but is not reliable for identification of individual *B. cepacia* complex species and does not differentiate *B. gladioli* (40, 202).

B. pseudomallei and *B. mallei*

If *B. pseudomallei* is suspected, all efforts should be made to confirm or exclude a positive oxidase reaction, production of gas from nitrate, multitrichous polar flagella, and arginine dihydrolase and gelatinase activities (Table 2). The bacterium gives off a distinctive earthy odor such that a clue to its presence can be gleaned upon opening a petri dish (even with a mixed culture). However, active sniffing of cultures is strongly discouraged in order to prevent infection (10). Cellular fatty acid profiles may be useful for differentiating *B. pseudomallei* from other genera, but reports vary on their utility in differentiating *B. thailandensis* and *B. pseudomallei* (117) or other pathogenic *Burkholderia* species including *B. mallei*, *B. cepacia* complex species, and *B. gladioli*.

B. pseudomallei must be differentiated from *Pseudomonas stutzeri* and *B. cepacia* complex species in clinical specimens. *Pseudomonas stutzeri* appears very similar to *B. pseudomallei* after a few days of incubation, and both *B. pseudomallei* and *B. cepacia* complex species may be isolated from persons with CF (162, 184, 211). Whereas *B. pseudomallei* produces gas from nitrate and is arginine dihydrolase positive, most *B. cepacia* complex isolates are negative for both characteristics. *Pseudomonas stutzeri* is negative for arginine dihydrolase, oxidation-fermentation glucose, and gelatin hydrolysis. *Pseudomonas stutzeri* also has only one flagellum, and *B. pseudomallei* has more than one.

There have been reports linking a lack of virulence of *B. pseudomallei* with the ability to assimilate arabinose (6). Environmental strains tend to be arabinose assimilators, and those that do not assimilate arabinose are almost always found as clinical isolates. The name *B. thailandensis* is used to describe arabinose-utilizing strains with low virulence (20).

The Microbact 24E strip (MedVet, Adelaide, Australia) appears to more accurately identify *B. pseudomallei* than does the API 20NE system (bioMérieux, Hazelwood, Mo.) (118). Limited experience with automated systems such as Vitek-1 and Vitek-2 (bioMérieux, Durham, N.C.) and MicroScan WalkAway (Dade International Inc., West Sacramento, Calif.) indicates that they reliably identify *B. pseumomallei*. However, further evaluation of commercially available identification systems is required (96, 119). Because of the difficulty with accurate laboratory identification, referral to a reference laboratory is advised when isolation of *B. pseudomallei* is suspected. This is especially important with the advent of emerging bioterrorism legislation in many countries (see chapter 9).

Ralstonia and *Cupriavidus* spp.

Although *R. pickettii* was considered to be the *Ralstonia* species most frequently isolated from clinical specimens (179), the recent recognition that several other *Ralstonia* and *Cupriavidus* species can be identified from among *R. pickettii*-like isolates limits previous observations. As is the case with *B. cepacia* complex species, *Ralstonia* and *Cupriavidus* species are phenotypically similar, requiring rather extensive biochemical testing to reliably differentiate them; species-level identification with standard biochemical testing is difficult (Table 3). These species may grow slowly on primary isolation media, requiring ≥72 h of incubation before colonies are visible. They are lysine decarboxylase negative and generally catalase positive, although catalase-negative *R. pickettii* strains have been described (42, 202). Most species show a fast and strong oxidase reaction; however, the intensity of the oxidase reaction varies for *R. mannitolilytica*, *R. pickettii,* and *Cupriavidus gilardii*, with some strains showing a weakly positive reaction (42, 202; LiPuma, unpublished). *R. pickettii, R. mannitolilytica,* and *R. insidiosa* grow on BCSA; growth of other species is strain dependent. These species do not produce acid from sucrose.

Most *R. mannitolilytica* strains acidify lactose, whereas most strains from other species do not. *R. insidiosa, Cupriavidus respiraculi*, *Cupriavidus gilardii,* and *Cupriavidus paucula* are differentiated from *R. pickettii* and *R. mannitolilytica* in failing to acidify glucose. *Cupriavidus gilardii* has a characteristic cellular fatty acid profile different from that of other *Ralstonia* species (42, 72).

Molecular genetic tests have proved quite helpful in differentiating these species. A recently described 16S rRNA-directed PCR assay reliably identifies all *Ralstonia* and *Cupriavidus* species (as a group), allowing their differentiation from the phenotypically similar species in the genera *Burkholderia* and *Pandoraea* (52). Species-specific 16S rRNA-based PCR assays have also been developed recently; these enable the accurate identification of *R. pickettii*, *R. mannitolilytica*, *R. insidiosa*, and *Cupriavidus respiraculi* (52, 55, 56).

Pandoraea spp.

Overall, the biochemical profiles of *Pandoraea* strains are similar to those of *Burkholderia* and *Ralstonia* strains isolated from clinical specimens (Table 1) (41, 70, 111). A lack of saccharolytic activity is indicative of *Pandoraea* but is also seen with some *Ralstonia* species. Definitive identification of putative *Pandoraea* isolates requires molecular confirmation. Coenye et al. (48) described 16S rDNA-based PCR assays for the identification of these bacteria. A PCR assay was developed for the identification of *Pandoraea* isolates to the genus level. PCR assays for the identification of *P. apista* and *P. pulmonicola* (as a group), *P. pnomenusa*, *P. sputorum*, and *P. norimbergensis* were also developed. *Pandoraea* strains can be differentiated from *Burkholderia* and *Ralstonia* strains by their specific 16S rDNA restriction profile (111, 188) and can be identified at the species level through MspI restriction analysis of the *gyrB* gene (47). A quantitative comparison of the whole-cell fatty acid profiles of the members of these three genera allows the differentiation of *Pandoraea* strains from the others (42, 70). However, with the use of the commercially available microbial identification system database (Microbial ID, Inc., Newark, Del.), these organisms are mostly identified with low identification scores as *Burkholderia* or *Ralstonia* species (42, 111) due to a lack of discriminatory fatty acids.

S. maltophilia

Key features for identifying *S. maltophilia* include a negative oxidase reaction, oxidation of glucose and maltose with a more intense reaction with the latter, positive reactions for DNase and lysine decarboxylase, and a tuft of polar flagella (Table 4) (218). Detection of extracellular DNase activity by *S. maltophilia* is a key to differentiating this species from most other glucose-oxidizing, gram-negative bacilli. It can be detected in tube-based or plated DNase medium with a methyl green indicator. DNase-positive organisms produce a zone of clearing around the colonies on this medium. Care must be taken in interpreting the DNase reaction, since one report documented the misidentification of *S. maltophilia* as *B. cepacia* based partially on false-negative DNase reactions that were finalized with 48 h of incubation rather than 72 h (24). Selected isolates of *Flavobacterium* and *Shewanella* spp. may also be DNase positive (see chapters 14 and 21). On sheep blood agar, colonies appear rough and lavender-green and have an ammonia-like odor. *S. maltophilia* has a characteristic cellular fatty acid profile with large amounts (>30%) of 13-methyl tetradecanoic acid ($C_{15:0\ iso}$) and lesser amounts (>10%) of 12-methyl tetradecanoic acid ($C_{15:0\ anteiso}$) and *cis*-9-hexadecanoic acid ($C_{16:1\ cis9}$) (218). To overcome the problems associated with definitive identification of *S. maltophilia*, Whitby et al. (219) developed a species-specific PCR assay targeting the 23S rRNA gene and reported sensitivity and specificity of 100%. This PCR test was recently

used as a standard to evaluate the identification of *S. maltophilia* using the API 20NE strip and the Vitek-2 ID-GNB card (95). Both systems showed good reliability compared to PCR. A multiplex PCR assay to identify *P. aeruginosa*, *B. cepacia* complex species, and *S. maltophilia* directly in sputum and oropharyngeal specimens from CF patients has been reported, but only a limited number of *S. maltophilia* isolates were examined (71).

Acidovorax, Brevundimonas, Delftia, and *Comamonas* spp.

Characteristics of *Acidovorax*, *Brevundimonas*, *Delftia*, and *Comamonas* spp. are given in Table 4.

Acidovorax species, rarely encountered in clinical and environmental samples, are straight to slightly curved gram-negative bacilli which occur either singly or in short chains. They are oxidase positive and nonpigmented and have a single polar flagellum. Urease activity varies among strains (218, 224).

Brevundimonas diminuta and *Brevundimonas vesicularis*, infrequently encountered in clinical and environmental samples, have growth requirements for specific vitamins, including pantothenate, biotin, and cyanocobalamin. An additional growth requirement for *Brevundimonas diminuta* is cysteine. Most strains of *Brevundimonas diminuta* grow on MacConkey agar, while only approximately 25% of *Brevundimonas vesicularis* strains do so. On primary isolation media, *Brevundimonas diminuta* colonies are chalk white whereas many strains of *Brevundimonas vesicularis* are characterized by an orange intracellular pigment. These organisms are oxidase positive, have a single polar flagellum, and weakly oxidize glucose *(Brevundimonas vesicularis* more so than *Brevundimonas diminuta),* and the vast majority fail to reduce nitrate to nitrite. The most reliable method for differentiating these two species is the test for esculin hydrolysis. Almost all strains of *Brevundimonas vesicularis* (88%) are reported to hydrolyze this substrate, while *Brevundimonas diminuta* strains rarely do (5%) (Table 4) (218).

Comamonas spp. are straight to slightly curved gram-negative bacilli which occur singly or in pairs. The organisms are catalase and oxidase positive and have a single tuft of polar flagella. All human clinical *Comamonas* species reduce nitrate to nitrite. Phenotypic differentiation of *Comamonas terrigena* from *Comamonas testosteroni* is difficult, and as a result isolates are typically reported as *Comamonas* spp. (Table 4).

D. acidovorans is phenotypically similar to *Comamonas*. Key characteristics of the species include abilities to oxidize fructose and mannitol. One-quarter of the strains produce a fluorescent pigment, and approximately half of the strains may produce a soluble yellow to tan hue (218, 223).

TYPING SYSTEMS

Several molecular genetic methods are available to assess the relatedness of isolates of these genera during nosocomial outbreak investigations. These methods are preferred over phenotypically based systems, which are less discriminatory and reproducible. Analysis of whole-genome macrorestriction profiles with pulsed-field gel electrophoresis (PFGE) has gained acceptance as a preferred genotyping method and has proved useful in numerous studies of *Burkholderia*, *Ralstonia,* and *S. maltophilia* (36, 51, 200). The endonucleases XbaI and SpeI are most frequently used and typically yield a dozen or more DNA fragments for analysis. Care must be taken in interpreting PFGE profiles of *Burkholderia* species, however. These species have unusually large and dynamic multichromosome genomes that are prone to large-scale alterations in content and arrangement (138). Consequently, epidemiologically irrelevant genomic polymorphisms may arise in the short term and confound outbreak investigations (51).

Ribotyping, which relies on polymorphisms in and around rRNA operons, has been used to investigate the epidemiology of the *B. cepacia* complex and *B. pseudomallei* (120, 145, 147). Both PFGE and ribotyping are relatively time-consuming and expensive to perform and are therefore not particularly well suited for routine analysis in clinical microbiology laboratories. A variety of PCR-based methods, including randomly amplified polymorphic DNA typing and repetitive-sequence PCR typing, offer attractive alternatives for genotyping *S. maltophilia* and *Burkholderia*, *Ralstonia,* and *Pandoraea* spp. (30, 44, 134, 151, 188). These methods are inexpensive and can provide rapid, reliable results. Multilocus sequence typing, which assesses DNA sequence variation at several chromosomal loci, has been developed for numerous bacterial species, including the *B. cepacia* complex, *B. pseudomallei,* and *B mallei* (13, 34, 97). This genotyping strategy provides robust, reproducible, and portable results and is quickly becoming the preferred method for investigating bacterial epidemiology, evolution, and population structure. Despite these attributes, however, multilocus sequence typing carries considerable expense and at present is largely a research tool. Typing methods have not been reported for *Brevundimonas*, *Delftia*, *Comamonas*, or *Acidovorax* spp.

SEROLOGIC TESTS

Of the organisms discussed in this chapter, serologic tests have been used clinically to diagnose only infections with *B. pseudomallei.* The indirect hemagglutination assay (IHA), although not available commercially, is the most widely used test in regions where infection is endemic (67). It is performed by using a prepared antigen from strains of *B. pseudomallei* sensitized to sheep cells and includes unsensitized cells as a control. This assay can be adapted to a microtiter plate test system. Because of high antibody background levels in healthy individuals, cross-reactions with other organisms including the *B. cepacia* complex, and the rapid onset of septicemic disease, IHA is of limited clinical value. Interpretation is difficult in areas where infection is endemic, and all results must be viewed in a clinical context. IHA titers may rise to high levels in culture-negative individuals, and a specific titer cutoff that indicates disease has not been established. In regions where infection is endemic, single titers may be reported without interpretation. The need for acute- and convalescent-phase titers along with relevant clinical information to aid in interpretation is paramount in attempting to establish serologically the diagnosis of subacute or chronic *B. pseudomallei* infection (160). Evaluation of recently developed rapid immunochromatographic test kits (Pan-Bio, Windsor, Queensland, Australia) suggests that the immunoglobulin G test may be useful for investigating travelers presenting with possible melioidosis after returning from regions where the disease is endemic but the immunoglobulin M test has low specificity (161).

ANTIMICROBIAL SUSCEPTIBILITY

Specific susceptibility testing interpretative criteria are not available for all of the species discussed in this chapter. For some species, such as the *B. cepacia* complex and *S. maltophilia,*

interpretive criteria for disk diffusion testing are available for only a limited number of antibiotics. In general, MIC broth microdilution tests or E tests are preferred for this group of organisms.

B. cepacia complex species are among the most antimicrobial-resistant bacteria encountered in the clinical laboratory. These species are intrinsically resistant to aminoglycoside and polymyxin antibiotics and are often resistant to β-lactam antibiotics due to inducible chromosomal β-lactamases and altered penicillin-binding proteins (106). Antibiotic efflux pumps may mediate resistance to chloramphenicol, fluoroquinolones, and trimethoprim (175). Clinical strains may be susceptible to only a handful of agents, including trimethoprim-sulfamethoxazole (TMP-SMX), ceftazidime, chloramphenicol, minocycline, imipenem, meropenem, and some fluoroquinolones (1, 112, 173). Clinical and Laboratory Standards Institute (formerly NCCLS) interpretative criteria for disk diffusion susceptibility testing are available only for ceftazidime, meropenem, minocycline, and TMP-SMX (39). MIC broth microdilution tests or E tests are preferred methodologies for susceptibility testing of these species. Because isolates that are initially susceptible may become resistant during the course of therapy, susceptibility testing of repeat isolates may be warranted. Furthermore, strains recovered from patients with CF who have received repeated courses of antibiotic therapy are frequently resistant to all currently available antimicrobial agents (1, 93). Combinations of antimicrobial agents may provide synergistic activity against resistant strains; however, antagonism with combinations is also observed in vitro (1). Testing for synergy with both double and triple combinations of agents is available in reference laboratories (http://synergy.columbia.edu) (1). The value of such testing is controversial, however; studies have yet to correlate in vitro synergy testing results with patient response to therapy (1, 155).

B. pseudomallei is resistant to penicillin, aminoglycosides, and macrolides, but several agents have antimicrobial activity in vitro, including ceftazidime, meropenem and imipenem, cefoperazone, amoxicillin-clavulanate, ampicillin-sulbactam, ticarcillin-clavulanate, chloramphenicol, and doxycycline. TMP-SMX is often used clinically; although reported in vitro susceptibility results are variable, most isolates are susceptible by agar dilution testing (122, 129). Resistance to fluoroquinolones is common, and their use has been associated with higher relapse rates (28). E tests have proved satisfactory for determining in vitro resistance or susceptibility, especially for TMP-SMX (158). Disk diffusion techniques have been disappointing, and inaccurate results suggest that they should probably be avoided (149).

Current trends in the management of melioidosis involve an initial 10- to 14-day intensive therapy phase with ceftazidime with or without TMP-SMX, followed by eradication therapy with TMP-SMX with or without doxycycline for at least 3 months (32, 222). Amoxicillin-clavulanate is recommended for eradication therapy in pregnancy and is an alternative to TMP-SMX in children. In critically ill patients requiring intensive care, meropenem or imipenem may be superior to ceftazidime, and granulocyte colony-stimulating factor is being used in some centers (33, 35, 122). According to molecular genotyping studies, relapse following antimicrobial therapy has been observed in as many as 15% of patients (79).

Because of the potential role of *B. mallei* as a bioterrorism agent, studies have been done recently to determine the activities of a variety of agents against this species. *B. mallei* has a susceptibility profile similar to that of *B. pseudomallei*, except that *B. mallei* is susceptible to aminoglycosides and newer macrolides such as clarithromycin and azithromycin whereas *B. pseudomallei* is resistant (108, 129). Current recommended treatment and duration of therapy for glanders are the same as those for melioidosis.

S. maltophilia is intrinsically resistant to many classes of antibiotics. Resistance can also develop rapidly during infection (91). Resistance to β-lactam agents is mediated by at least two β-lactamases, one of which is zinc dependent and resistant to β-lactamase inhibitors and confers resistance to imipenem. Aminoglycoside and quinolone resistance results from mutations in outer membrane proteins. In a recent study of isolates recovered from patients with CF, doxycycline was the most active agent in vitro (182). TMP-SMX is usually active and is often used in combination with ticarcillin-clavulanate, minocycline, or piperacillin-tazobactam (182). Other combinations that may be effective include ciprofloxacin paired with ticarcillin-clavulanate, ciprofloxacin and piperacillin-tazobactam, or doxycycline and ticarcillin-clavulanate. Clinical and Labaratory Standards Institute interpretive criteria for disk diffusion susceptibility testing are available for minocycline, levofloxacin, and TMP-SMX (39). However, broth microdilution, E test, or agar dilution methods are the preferred susceptibility testing methods (9, 235). Many U.S. laboratories comment only on the activity of TMP-SMX but will test additional antibiotics such as minocycline, ceftazidime, ticarcillin-clavulanate, and ciprofloxacin or levofloxacin upon request.

In general, *Comamonas testosteroni* is susceptible to extended- and broad-spectrum cephalosporins, carbapenems, quinolones, and TMP-SMX (14). *D. acidovorans* is frequently resistant to the aminoglycosides.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

These species are found in the natural environment and may occasionally contaminate clinical specimens. Nevertheless, they are increasingly recognized as nosocomial and opportunistic pathogens, especially in certain patient populations, such as persons with CF. They are also frequently misidentified by commercial microbial identification systems. Therefore, their recovery in the clinical laboratory must be given careful consideration. In particular, species of the *B. cepacia* complex are not reliably differentiated by phenotypic analyses and their recovery from persons with CF has serious consequences with respect to patient management and psychosocial well-being (141). Identification of these species should be confirmed by genotypic analyses at a reference laboratory and should promptly be reported to the CF care team. Similarly, identification of *B. pseudomallei*, *B. mallei,* or *B. thailandensis* should be confirmed by a reference laboratory with experience with these species. Care must be given to ensure that culture handling and shipping comply with current biosafety regulations (see chapters 8 and 9). Identification of these species must be reported to public health officials due to the potential of these species as agents of bioterrorism (see chapter 9).

Interpretive criteria for disk diffusion antimicrobial susceptibility testing of most of these species are lacking; MIC broth microdilution and the E test are, therefore, the preferred methodologies for susceptibility testing. For multidrug-resistant strains, consideration should be given to testing for synergy with double or triple combinations of antimicrobial agents in reference laboratories.

Acinetobacter, Achromobacter, Chryseobacterium, Moraxella, and Other Nonfermentative Gram-Negative Rods*

PAUL C. SCHRECKENBERGER, MARYAM I. DANESHVAR, AND DANNIE G. HOLLIS

50

DESCRIPTION OF GENERA

The organisms covered in this chapter belong to a group of taxonomically diverse, nonfermentative gram-negative rods. They all share the common phenotypic features of failing to acidify the butt of Kligler iron agar (KIA) or triple sugar iron (TSI) agar or of oxidative-fermentative (OF) media and grow significantly better under aerobic than under anaerobic conditions; many strains fail to grow anaerobically. Most of the organisms covered in this chapter, with the exception of *Neisseria elongata* subspecies *elongata* and *nitroreducens,* are catalase positive. Oxidase and growth on MacConkey agar are variable. They either are nonmotile or, if motile, often have peritrichous flagella.

The methods used for growth and identification of these organisms are those used for *Pseudomonas* spp. (see chapter 48). Initial incubation should be at 35 to 37°C, although many pink-pigmented strains grow better at ≤30°C and may be detected only on plates left at room temperature after the initial readings. In such cases, all identification tests should be carried out at that temperature. In fact, some of the commercial kits, such as the API 20 NE, are designed to be incubated at 30°C. Growth on certain selective primary media (e.g., MacConkey or Salmonella-Shigella [SS] agar) is variable; and there can be significant lot-to-lot variations in the media. Nonfermenters that grow on MacConkey agar generally form colorless colonies, although some form lavender or purple colonies due to uptake of crystal violet contained in the agar medium.

When laboratory identification of this group of organisms is deemed necessary, a simplified approach is recommended whereby unknown isolates are initially characterized and placed into one of seven groups based on microscopic morphology, oxidase reaction, motility, acidification of carbohydrates, indole production, and production of pink-pigmented colonies (Fig. 1). Further characterization is made on the basis of the biochemical reactions (see Tables 1 through 7) that are examined after 1, 2, and 7 days of incubation. Additional differential tests can be found in other publications (96, 207, 256, 257). Carbohydrate utilization and mode of utilization are based on the King formulation of OF medium (256). In the authors' experience, indole production is best demonstrated by inoculation of heart infusion broth and incubation at 35 to 37°C for 48 h followed by extraction with xylene and addition of Ehrlich's reagent. The oxidase test is performed after overnight incubation using *N*, *N*, *N*, *N*-tetramethyl-*p*-phenylenediamine dihydrochloride (0.5%). Motility is easily determined by performing a wet mount preparation of a young colony from a blood agar plate. For some strains, motility can best be demonstrated after incubation of cultures at room temperature.

Traditional diagnostic systems, e.g., those based on OF media, aerobic low-peptone media, or buffered single substrates, have now been replaced in many laboratories by commercial kits. The ability of commercial kits to identify this group of nonfermenters is variable and often results in identification to the genus or group level only, necessitating the use of supplemental biochemical testing for species identification (10, 123, 135, 147, 175, 223). If such kits are used, the laboratory must be familiar with the extent of the database; organisms not included will be unidentified or identified incorrectly. Because assimilation test results often depend on the basal medium used, most of those results are not included in the tables presented here. Identification of nonfermenters by automated fatty acid analysis has also been attempted (243). In view of the difficulties inherent in this approach (176), it is recommended that fatty acid profiles be used only in conjunction with traditional or commercial diagnostic systems. The fatty acid profiles for the most common species of nonfermenting bacilli have been published by Weyant and colleagues (256) and are included in the tables presented here. Furthermore, rRNA gene sequencing is likely to become the standard for identification of many organisms that are difficult to identify using conventional methods, such as those described in this chapter, and laboratories are encouraged to develop such capabilities. The impact of this technology has already been noted in several publications (38, 63, 180); this method was used to confirm the identification of several new nonfermenting species included in this chapter.

TAXONOMY, NATURAL HABITATS, AND CLINICAL SIGNIFICANCE

Since a large and diverse group of organisms are covered in this chapter, the taxonomy, natural habitats, and clinical significance of the individual species are covered under the individual organism headings.

* This chapter contains information presented in chapter 49 by Paul C. Schreckenberger, Maryam I. Daneshvar, Robbin S. Weyant, and Dannie G. Hollis in the eighth edition of this Manual.

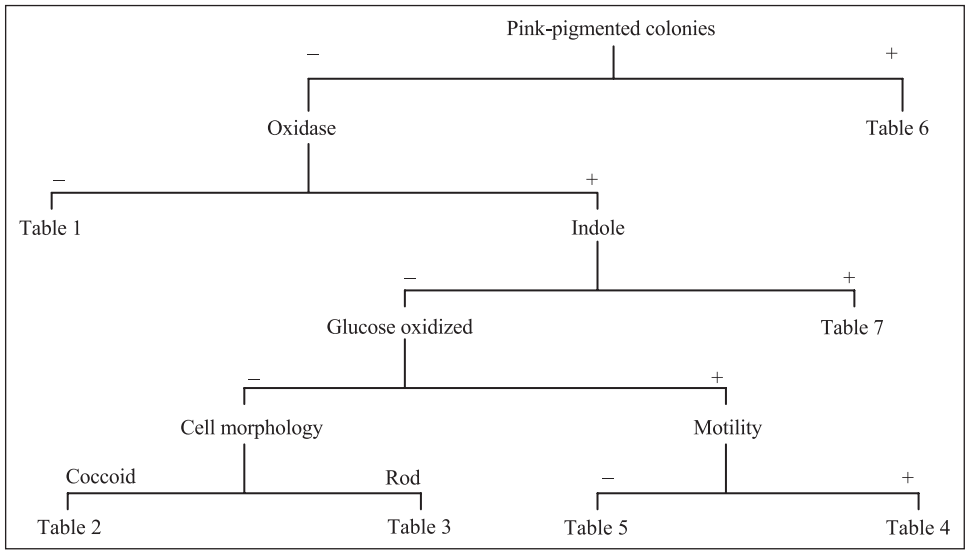

FIGURE 1 Identification of miscellaneous gram-negative nonfermenters.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Standard methods for collection, transport, and storage of specimens as detailed in chapters 5 and 20 are satisfactory for this group of organisms.

OXIDASE-NEGATIVE GROUP

See Table 1.

Acinetobacter spp.

General Description

The genus *Acinetobacter* consists of strictly aerobic, gram-negative coccobacillary rods that are oxidase negative, nonmotile, usually nitrate negative, and nonfermentative. Individual cells are 1 to 1.5 by 1.5 to 2.5 μm in size, sometimes difficult to decolorize, and frequently arranged in pairs. Clinical microbiologists should be alert to the fact that *Acinetobacter* species may initially appear as gram-positive cocci in direct smears prepared from positive blood culture bottles (83). In the stationary growth phase and on nonselective agars, coccobacillary forms predominate, whereas early growth in fluid media and growth on plates containing cell wall-active antimicrobial agents yield mostly rods. Colonies are smooth, opaque, and slightly smaller than those of members of the family *Enterobacteriaceae*. Many strains grow on MacConkey agar as either colorless or slightly pinkish colonies. Some strains are fastidious, showing punctate colonies on blood agar, and fail to grow in nutrient broth (256). Certain glucose-oxidizing acinetobacters may also cause a unique brown discoloration of heart infusion agar with tyrosine or blood agar into which glucose is incorporated (213, 256). We have also observed this phenomenon on MacConkey and Mueller-Hinton agars with a clinical isolate of *A. baumannii.* Differential and selective media have been described for isolation of *Acinetobacter* spp. from contaminated specimens. (103, 118).

Taxonomy

The genus was originally placed within the family *Neisseriaceae* but more recently moved to the family *Moraxellaceae* (203). Studies based on DNA-DNA hybridization have resulted in the description of 25 DNA homology groups (also called genomospecies) within the genus *Acinetobacter* (18, 20, 75, 115, 169, 171, 229). While only 11 species have been named (18, 169, 170, 171), differential biochemical and growth tests have been published for at least 19 species (18, 20, 76, 169, 170, 171). Genomospecies 1, 2, 3, and 13 of Tjernberg and Ursing (229) may be difficult to separate in the clinical laboratory and have been referred to as the *Acinetobacter calcoaceticus-Acinetobacter baumannii* complex (76). Because of problems in the clinical laboratory separating the DNA groups by phenotypic tests, we have chosen to separate the *Acinetobacter* species in Table 1 into two groups, saccharolytic and asaccharolytic. Most glucose-oxidizing nonhemolytic clinical strains are *A. baumannii,* most glucose-negative nonhemolytic ones are *Acinetobacter lwoffii,* and most hemolytic ones are *Acinetobacter haemolyticus*.

Natural Habitat and Clinical Significance

Acinetobacter species are widely distributed in nature and in the hospital environment, are the second most commonly isolated nonfermenters in human specimens (*Pseudomonas aeruginosa* being the first), are able to survive on moist and dry surfaces (77), and may be present in foodstuffs (105) and on healthy human skin (208). *Acinetobacter* spp. are generally considered to be nonpathogenic to healthy individuals but may cause infections in debilitated individuals. The species most frequently isolated from humans is *A. baumannii* (with 19 biotypes identified by assimilation tests [19] and 34 serovars [230]).

A. baumannii is the species most often responsible for hospital-acquired infections (152, 244). A biotyping system for differentiating 17 biotypes of *A. baumannii* based on the utilization of six substrates has been established and may be useful for epidemiologic studies (19). Turton and colleagues have reported that integrons are useful markers for epidemic strains of *A. baumannii* and that integron typing provides valuable information for epidemiological studies (232). The ability of this microorganism to acquire antimicrobial multiresistance and its high capacity for survival on most environmental surfaces has led to an increased concern

[a]Unless otherwise indicated, data are from the CDC Special Bacteriology Reference Laboratory (256). All taxa were negative (<10% positive) for gas from nitrate, nitrite reduction, indole production, acid in TSI butt, and H_2S in TSI. Numbers indicate the percentage positive at 2 days of incubation; parentheses indicate a delayed reaction (3 to 7 days of incubation); w, weak reaction; pe, peritrichous; p, polar; br, brown; yel, yellow; ND, not determined or not available. Numbers in parentheses after organisms indicate the number of strains.

[b]A total of 25 *Acinetobacter* genomospecies have been described. See the text.

[c]Probable *Acetobacter* species based on three phenotypically similar strains that were identified by 16S rRNA gene sequencing.

[d]Data from reference 138.

[e]Data from reference 41.

[f]Included in table only; see description in chapter 48.

[g]Oxidative-fermentative basal medium with 1% carbohydrate.

[h]Usually does not grow in oxidative-fermentative medium.

[i]Nitrate reduction reported variable by other authors (see chapter 51).

[j]14 days of incubation.

[k]CFA, cellular fatty acid. The number before the colon indicates the number of carbons; the number after the colon is the number of double bonds; **ω**, the position of the double bond counting from the hydrocarbon end of the carbon chain; c, *cis* isomer; cyc, a cyclopropane ring structure.

[l]Cannot distinguish most *Acinetobacter* species by CFA.

regarding hospital-acquired infections. Corbella et al. have shown that the digestive tract of intensive care unit patients is an important epidemiologic reservoir for multiresistant *A. baumannii* infections in hospital outbreaks, and they suggest that a fecal surveillance program might be considered for early implementation of patient isolation precautions in an outbreak setting (48). Hospital-acquired infections are most likely to involve the respiratory tract (most often related to endotracheal tubes or tracheostomies), urinary tract, and wounds (including catheter sites) and may progress to septicemia (9, 37, 258). Sporadic cases of continuous ambulatory peritoneal dialysis peritonitis, endocarditis, meningitis, osteomyelitis, arthritis, and corneal perforation have also been reported (9). There are an increasing number of reports of *Acinetobacter* species as agents of nosocomial pneumonia, particularly ventilator-associated pneumonia in patients confined to hospital intensive care units (9). Risk factors are antibiotic treatment and/or surgery, instrumentation, mechanical ventilation, and stay in intensive care units; clinical isolates, however, are more often colonizers than infecting agents (9, 37, 258). Hospital outbreaks have been investigated by various typing methods (139, 150, 232). Community-acquired *Acinetobacter* pneumonias in which a fatal outcome was strongly associated with inappropriate initial antibiotic therapy have also been reported (2). Most recently, American troops wounded in Iraq and Afghanistan have suffered severe wound infections and osteomyelitis from multidrug-resistant *A. baumannii* (30, 56).

Other species, such as *Acinetobacter johnsonii, A. lwoffii,* and *Acinetobacter radioresistens,* seem to be natural inhabitants of the human skin and may also be commensals in the oropharynx and vagina (21). *A. lwoffii* has been more commonly associated with meningitis than other *Acinetobacter* species (214). *Acinetobacter ursingii* has been shown to cause bloodstream infections in hospitalized patients (153, 169). *Acinetobacter junii* is a rare cause of ocular infection (190) and bacteremia, particularly in pediatric patients (126, 146). A case of community-acquired *A. radioresistens* bacteremia in a human immunodeficiency virus-positive patient has also been reported (245). *Acinetobacter schindleri* has been recovered from a variety of human specimens (vaginal, cervical, throat, nasal, ear, conjunctiva, and urine) but is mostly regarded as clinically nonsignificant (169).

Antibiotic Susceptibility

Cephalothin is ineffective against *Acinetobacter* spp., but trimethoprim-sulfamethoxazole, imipenem, imipenem-cilastatin, ampicillin-sulbactam, ticarcillin-clavulanate, piperacillin-tazobactam, amoxicillin-clavulanate, doxycycline, and quinolones are effective against most strains (9, 37, 119), but susceptibility testing is required for each clinically significant strain. Multiply resistant strains including carbapenem-resistant *Acinetobacter* species have been reported in nosocomial outbreaks (17, 108, 157, 158). Although the carbapenems are still the most active antimicrobials against *Acinetobacter* species, carbapenem resistance is now becoming common (47, 50, 158, 269).

Antimicrobial susceptibility testing for *Acinetobacter* species is problem prone. Swenson and colleagues at the CDC have shown that results obtained using standardized broth microdilution do not agree with results obtained with the standardized disk diffusion method for certain antibiotics. Very major errors were frequent with the β-lactam and β-lactam inhibitor combination antibiotics, with the broth microdilution method typically showing greater resistance (225). At present, there are no data to

indicate which method provides more clinically relevant information.

Treatment

Combined treatment with an aminoglycoside and ticarcillin or piperacillin is synergistic and may be effective in serious infections. For multiply resistant *Acinetobacter* infections, several studies have demonstrated clinical efficacy of sulbactam in combination with ampicillin or cefoperazone (46, 85, 119, 143). The only other antibacterial agent that has been shown to be active against multiply resistant *Acinetobacter* is colistin (78, 121, 144). For a review of the clinical features, molecular epidemiology, and antimicrobial susceptibility of nosocomial *Acinetobacter* infections, consult the reviews by Bergogne-Berezin and Towner (9) and Wisplinghoff et al. (258).

CDC Group EO-5

CDC Eugonic Oxidizer (EO) Group 5 organisms (M. I. Daneshvar, D. G. Hollis, C. W. Moss, J. G. Jordan, J. P. MacGregor, and R. S. Weyant, *Abstr. 98th Gen. Meet. Am. Soc. Microbiol.,* abstr. C-204, 1998) are glucose-oxidizing gram-negative rods that have a biochemical profile similar to that of *A. baumannii*. Based on 16S rRNA sequencing, these are probably *Acetobacter* species (M. I. Daneshvar, unpublished data). They are nonmotile and oxidase negative and fail to grow on MacConkey agar. Some strains produce a yellow soluble pigment. Cellular fatty acid (CFA) analysis is also useful in differentiating EO-5 strains from *A. baumannii*. Other characteristics are given in Table 1. Isolates have been recovered from blood, peritoneal fluid, transtracheal aspirate, gall bladder, and an arm wound. Antibiotic susceptibility data are not available.

CDC Group NO-1

Group NO (nonoxidizer)-1 bacteria (87) are oxidase negative, asaccharolytic, nonmotile, coccoid to medium-sized gram-negative rods forming small colonies on sheep blood agar (SBA). Other differential features are shown in Table 1. Nitrate, but not nitrite, is reduced; however, since approximately 6% of asaccharolytic *Acinetobacter* spp. reduce nitrate, CFA profiles and 16S rRNA gene sequencing are useful for making a definitive identification. Most strains have been isolated from human wounds resulting from dog or cat bites, suggesting that these animals are a reservoir for NO-1 infections (87, 125). They are susceptible to antibiotics used for infections caused by gram-negative organisms, including aminoglycosides, β-lactam antibiotics, tetracyclines, quinolones, and sulfonamides (87).

Bordetella spp.

The *Bordetella* species are discussed in detail in chapter 51 of this Manual. There are eight *Bordetella* spp. that are nonfastidious and will grow on ordinary culture media (i.e., sheep blood and MacConkey agars) and biochemically resemble either *Acinetobacter* spp. or *Alcaligenes/Achromobacter* spp. Four species *(B. ansorpii, B. holmesii, B. parapertussis,* and *B. trematum)* are oxidase negative and are included in Table 1, and four species are oxidase positive *(B. avium, B. bronchiseptica, B. hinzii,* and *B. petrii)* and are included in Table 3. *B. holmesii* (formerly CDC group NO-2) is nitrate negative (differentiating it from NO-1 strains) and produces a brown soluble pigment on heart infusion-tyrosine agar. Other differential tests are given in Table 1. *B. bronchiseptica* is rapid urease positive and must be differentiated from *Cupriavidus pauculus* (Table 3) and *Oligella ureolytica* (Table 2).

Genus *Kerstersia*

Kerstersia is a newly described novel genus that consists of a single species, *K. gyiorum* (Greek *gyion,* meaning "limb," referring to the fact that the majority of strains were isolated from human leg wounds) (41). They appear as gram-negative, small (1 to 2 μm long), coccoid cells that occur singly, in pairs, or in short chains. On nutrient agar, colonies are flat or slightly convex, with smooth margins and color ranging from white to light brown. Growth occurs at 28 and 42°C, motility is strain dependent, and all strains are asaccharolytic. All strains are catalase positive but are negative for oxidase, arginine, lysine and ornithine decarboxylase, β-galactosidase, gelatinase, amylase, urease, DNase, reduction of nitrate and nitrite, and hydrolysis of esculin (Table 1). Strains have been isolated from various human specimens, including feces, sputum, and leg and ankle wounds. Pathogenicity is unknown (41).

OXIDASE-POSITIVE, INDOLE-NEGATIVE, ASACCHAROLYTIC COCCOID NONFERMENTERS

See Table 2.

Psychrobacter phenylpyruvicus, Moraxella catarrhalis, and Other *Moraxella* spp.

Members of the genus *Moraxella* are oxidase-positive, nonmotile, asaccharolytic coccobacilli that are often plump, occur predominantly in pairs and sometimes in short chains, and have a tendency to resist decolorization (54).

Moraxellae are parasitic on human skin and mucous membranes. *M. catarrhalis, M. osloensis, M. nonliquefaciens,* and *M. lincolnii* are part of the normal flora of the human respiratory tract, while most *M. canis* strains have been found in the upper respiratory tracts of dogs and cats. These and other moraxellae are rare agents of infections (conjunctivitis, keratitis, meningitis, septicemia, endocarditis, arthritis, and otolaryngologic infections) (122, 127, 209, 241).

M. catarrhalis has been reported to cause sinusitis and otitis media by contiguous spread of the organisms from a colonizing focus in the respiratory tract (127). However, isolation of *M. catarrhalis* from the upper respiratory tract (i.e., a throat culture) of children with otitis media or sinusitis does not provide evidence that the isolate is the cause of these infections. Rates of upper respiratory tract colonization by *M. catarrhalis* in children vary widely and are influenced by many factors (both environmental and genetic). The presence of the organism in the oropharynx or nasopharynx is not necessarily predictive of infection in contiguous anatomic sites. Isolates from sinus aspirates and middle ear specimens obtained by tympanocentesis should be identified and reported. Similarily, little is known about the pathogenesis of lower respiratory tract infection in adults with chronic lung diseases. Examination of Gram-stained smears of sputum specimens from patients with exacerbations of bronchitis and pneumonia due to *M. catarrhalis* usually reveals an abundance of leukocytes, the presence of many gram-negative diplococci as the exclusive or predominant bacterial morphotype, and the presence of intracellular gram-negative diplococci. Such specimens may yield *M. catarrhalis* in virtually pure culture, and the organism should be identified and reported.

Colonies of *M. catarrhalis* grow well on both blood and chocolate agars, and some strains also grow well on Modified Thayer-Martin and other selective media. Colonies are generally gray to white, opaque, and smooth and measure about

1 to 3 mm after 24 h of incubation. Characteristically, the colonies may be nudged across the plate intact with a bacteriological loop like a "hockey puck." *M. catarrhalis* is strongly oxidase positive and catalase positive. It does not produce acid from glucose or other carbohydrates. Most strains reduce nitrate and nitrite and produce DNase. *M. catarrhalis* may be easily distinguished from *Neisseria* species by its ability to hydrolyze ester-linked butyrate groups (butyrate esterase) (179, 219). A very rapid (2.5-min) and reliable indoxyl-butyrate hydrolysis spot test has been described and is commercially available (Remel, Inc., Lenexa, Kans.) (58).

M. nonliquefaciens is the second most frequently isolated species after *M. catarrhalis*. It forms smooth, translucent to semiopaque colonies 0.1 to 0.5 mm in diameter after 24 h and 1 mm in diameter after 48 h of growth on SBA plates. Occasionally, these colonies spread and pit the agar. The colonial morphologies of *M. lincolnii* (237), *M. osloensis*, and *Psychrobacter phenylpyruvicus* (formerly *M. phenylpyruvica*) are similar, but pitting is rare. On the other hand, pitting is common with *M. lacunata,* whose colonies are smaller and form dark haloes on chocolate agar. Colonies of *M. atlantae* are small (usually 0.5 mm in diameter) and show pitting and spreading (22). Most *M. canis* colonies resemble those of the *Enterobacteriaceae* (large, smooth colonies) and may produce a brown pigment when grown on starch-containing Mueller-Hinton agar (117). Some strains may also produce very slimy colonies resembling colonies of *Klebsiella pneumoniae* (117). Microscopically, *M. canis* resembles *M. catarrhalis*, both appearing as gram-negative diplococci measuring 0.5 to 1.5 μm in diameter. Animal species include *M. bovis*, isolated from healthy cattle and other animals, including horses, *M. boevrei* and *M. caprae* (goats), *M. caviae* (guinea pigs), *M. cuniculi* (rabbits), and *M. ovis* and *M. oblonga* (sheep).

Biochemical reactions for the human isolates are listed in Table 2. Most laboratories do not determine the species of moraxellae, other than *M. catarrhalis*, because of the similarity in pathogenic significance of the species and because many strains are somewhat fastidious and biochemical reactions are often negative or equivocal. *M. atlantae, M. lacunata*, and *M. nonliquefaciens* are similar in many of their features. Growth of *M. atlantae* is stimulated by bile salts and sodium desoxycholate, while *M. lacunata* and *M. nonliquefaciens* are not. Only *M. lacunata* liquefies gelatin, whereas both *M. lacunata* and *M. nonliquefaciens* reduce nitrate to nitrite (22, 182) Separation of *M. lacunata* and nonspreading *M. nonliquefaciens* may prove difficult, because gelatin hydrolysis (with any method) and liquefaction of Loeffler slants may take more than 1 week. In some instances, fatty acid analysis may help determine the species (256); in other cases, quantitative transformation of a high-level streptomycin resistance marker can be used (124). The differential diagnosis of *P. phenylpyruvicus* and *Brucella* spp. is of great practical importance (see the discussion of agents of bioterrorism in chapter 9) and requires microscopy (*Brucella* organisms are tiny coccobacilli) and tests for acidification of xylose and glucose (183, 184). *P. phenylpyruvicus* is asaccharolytic, whereas *Brucella* spp. utilize xylose and usually glucose when a sufficiently sensitive method for detecting acidification of glucose is employed (183). Microbiologists should be aware that *Brucella* species that are unwittingly inoculated into certain commercial identification systems may be misidentified as *P. phenylpyruvicus* or *Haemophilus influenzae* (5, 6, 178). The tributyrin test may be positive for several *Moraxella* spp. and therefore cannot be used to separate them from *M. catarrhalis* (179). Likewise, gamma-glutamyl aminopeptidase occurs not only in *M. canis* but also in some strains of other moraxellae (117).

Most *Moraxella* strains are susceptible to penicillin and its derivatives, cephalosporins, tetracyclines, quinolones, and aminoglycosides (70, 201, 218). Production of beta-lactamase has been only rarely reported in *Moraxella* species other than *M. catarrhalis*, which commonly produces an inducible, cell-associated beta-lactamase (122, 201). Isolates of *M. catarrhalis* are generally susceptible to amoxicillin-clavulanate, expanded-spectrum and broad-spectrum cephalosporins (i.e., cefuroxime, cefotaxime, ceftriaxone, cefpodoxime, ceftibuten, and the oral agents cefixime and cefaclor), macrolides (e.g., azithromycin, clarithromycin, erythromycin), tetracyclines, and rifampin. While most isolates are susceptible to the fluoroquinolones, resistance to these agents has emerged in isolates recovered from patients who were receiving long-term therapy with such agents.

Oligella spp.

The genus *Oligella* consists of two species: *O. urethralis* (formerly *Moraxella urethralis* and CDC group M-4) and *O. ureolytica* (formerly CDC group IVe) (202). *O. urethralis* is nonmotile, while most strains of *O. ureolytica* are motile by peritrichous flagella. Biochemical features that help differentiate *Oligella* spp. from *Moraxella* spp. are shown in Table 2. *O. urethralis* is similar to *Moraxella* spp. in that isolates are coccobacillary, oxidase positive, and nonmotile. Colonies are smaller than those of *M. osloensis* and are opaque to whitish. *O. urethralis* and *M. osloensis* share additional biochemical similarities, e.g., accumulation of poly-β-hydroxybutyric acid and failure to hydrolyze urea, but can be differentiated on the basis of nitrite reduction and alkalinization of formate, itaconate, proline, and threonine (all positive for *O. urethralis* and negative for *M. osloensis*) (185). CFA analysis can also be used to differentiate these two species (256).

Colonies of *O. ureolytica* are slow growing on blood agar, appearing as pinpoint colonies after 24 h but large colonies after 3 days of incubation. Colonies are white, opaque, entire, and nonhemolytic. *O. ureolytica* strains are both phenylalanine deaminase and rapid urease positive, with the urease reaction often turning positive within minutes after inoculation. In this regard, *O. ureolytica* is similar to *Bordetella bronchiseptica* and *Cupriavidus pauculus* from which it must be differentiated. CFA analysis is useful since the CFA profiles are different for each of these species (256).

Both *Oligella* spp. have been isolated chiefly from the human urinary tract, and both have been reported to cause urosepsis (191, 200). A case of septic arthritis due to *O. urethralis* has also been reported (160). *O. urethralis* is generally susceptible to most antibiotics, including penicillin, while *O. ureolytica* exhibits variable susceptibility patterns (70).

Haematobacter spp. (Proposed)

Haematobacter is a proposed new genus of aerobic gram-negative rods that phenotypically most closely resembles *Psychrobacter phenylpyruvicus* (L. O. Helsel, D. Hollis, A. G. Steigerwalt, R. E. Morey, J. Jordan, T. Aye, J. Radosevic, D. Jannat-Kahah, D. R. Lonsway, J. B. Patel, M. I. Daneshvar, and P. N. Levett, *Abstr. 105th Gen. Meet. Am. Soc. Microbiol.*, abstr. C-404, 2005). The genus consists of two named *(H. cherryi* and *H. missouriensis)* and one unnamed genomospecies. All strains are nonmotile and asaccharolytic. They produce catalase, oxidase, urease, and H_2S (lead acetate paper) but do not produce indole, reduce nitrate or nitrite, or hydolyze gelatin or esculin. Colonies of *Haematobacter* are nonpigmented, and most strains grow on MacConkey agar. Additional phenotypic properties are given in Table 2. Strains received at the CDC have been mainly from patients

[a] Unless otherwise indicated, data are from the CDC Special Bacteriology Reference Laboratory (256). All taxa were positive (≥90%) for catalase. All were negative (<10% positive) for acid from D-glucose, D-xylose, D-mannitol, lactose, sucrose, and maltrose; growth on SS and cetrimide agars, esculin hydrolysis, acid production in TSI agar, and H_2S production in TSI agar. Numbers indicate the percentage positive at 2 days of incubation; numbers in parentheses indicate a delayed reaction (3 to 7 days of incubation); w, weak reaction; pe, peritrichous; ND, not determined or not available. Numbers in parentheses after the organism indicate the number of strains.

[b] Usually does not grow in OF medium.

[c] Motility may be delayed or difficult to demonstrate.

[d] Nitrite-positive strains have been described (237).

[e] 14 days of incubation.

[f] Data from P. Schreckenberger.

[g] Based on results obtained by streaking a blood agar plate with growth from an 18- to 36-h culture and then placing a 10-U penicillin disk on the streaked area. A positive reaction is indicated by the appearance of a zone of inhibition.

[h] Data from reference 117.

[i] The number before the colon indicates the number of carbons; the number after the colon is the number of double bonds; ω, the position of the double bond counting from the hydrocarbon end of the carbon chain; c, *cis* isomer; alc, alcohol.

[j] Two profiles exist. Most strains of *M. lacunata* II differ from *M. lacunata* I by lower amounts of 17:1ω8c, 16:1ω7c, and 18:1ω9c, higher amounts of 18:0 (16 versus 3%), and higher amounts of 16:0 alc and 18:0 alc. However, there is some overlap in relative amounts of these acids in some strains of both groups which prohibit their differentiation solely on the basis of CFA data (256).

with septicemia. *Haematobacter* strains have low MIC values for amoxicillin, fluoroquinolones, aminoglycosides, and carbapenems but variable MICs for cephalosporins, monobactams, and piperacillin.

OXIDASE-POSITIVE, INDOLE-NEGATIVE, ASACCHAROLYTIC, ROD-SHAPED NONFERMENTERS

See Table 3.

Alcaligenes faecalis and Asaccharolytic *Achromobacter* spp.

Based on taxonomic studies, Yabuuchi et al. transferred the species *Alcaligenes ruhlandii* and *Alcaligenes piechaudii* to the genus *Achromobacter* and proposed the transfer of *Alcaligenes denitrificans* to the genus *Achromobacter* as *Achromobacter xylosoxidans* subsp. *denitrificans* (263), thus automatically creating a second subspecies, *Achromobacter xylosoxidans* subsp. *xylosoxidans*. However, the reclassification of *Alcaligenes denitrificans* as a subspecies of *Achromobacter xylosoxidans* contradicted previous work that showed that the two taxa are distinct species (239). Accordingly, Coenye and colleagues have proposed that *Alcaligenes denitrificans* be reclassified as *Achromobacter denitrificans* (41). In this text we treat these organisms as separate species, referring to them as *Achromobacter xylosoxidans* and *Achromobacter denitrificans*, respectively. *Alcaligenes faecalis* remains the only *Alcaligenes* species of clinical importance.

Members of these genera are rods (0.5 by 1 to 0.5 by 2.6 μm) with peritrichous flagella. Both phylogenetically and biochemically, they are closely related to members of the genus *Bordetella*. They occur mainly in the environment and show limited action on carbohydrates. Colonies are nonpigmented and similar in size to those of *Acinetobacter* spp. Medically important species are divided into the asaccharolytic species (Table 3) including *Alcaligenes faecalis*, *Achromobacter piechaudii* (263), and *Achromobacter denitrificans* (41, 263) and the saccharolytic species (see Table 4) *Achromobacter xylosoxidans* (41, 263) as well as the unnamed Achromobacter groups B, E, and F (89, 90). The asaccharolytic species are rarely observed as human pathogens (14, 134, 248). *A. faecalis* is the most frequently isolated species and characteristically produces colonies with a thin, spreading, irregular edge. Some strains (previously named "*A. odorans*") produce a characteristic fruity odor (sometimes described as the odor of green apples) and cause a greenish discoloration of blood agar medium. A key biochemical feature of this species is its ability to reduce nitrite but not nitrate. It is often found in mixed cultures, particularly in diabetic ulcers of the feet and lower extremities, and its clinical significance is difficult to determine. *Achromobacter piechaudii* has been recovered from blood, recurrent ear discharge, nose, pharynx, and soil (129, 134, 177). In one instance the blood isolate was associated with an infected Hickman catheter in a patient with hematological malignancy (129). *A. faecalis* and *A. piechaudii* have been reported to be resistant to ampicillin, aztreonam, and gentamicin and of variable susceptibility to other antimicrobials (13, 129). The clinical significance of *Achromobacter denitrificans* remains to be elucidated; however, an organism that is biochemically similar, known as *Alcaligenes*-like group 1, has been recovered from blood, urine, knee joint, brain abscess, and bronchial washings, suggesting that it may have greater potential to cause human infection. It can be differentiated from *A. denitrificans* by CFA composition, failure to grow on

[b] Data from reference 43.

[c] Data from reference 247. Carbohydrate results are from assimilation tests.

[d] Data from references 73 and 252.

[e] *Myroides* genus consists of two phenotypically similar species: *M. odoratus* and *M. odoratimimus*. The type strain of *M. odoratus* did not grow on MacConkey agar; in contrast, the type strain of *M. odoratimimus* grew heavily.

[f] Data from reference 268.

SS agar, failure to alkalinize tartrate and acetamide, and a positive urease reaction (Table 3) (256).

Advenella incenata

Advenella incenata is a gram-negative, small (1- to 2-μm), rod-shaped or coccoid bacterium that occurs singly, in pairs, or in short chains (43). On nutrient agar, colonies are flat or slightly convex with smooth margins and appear light brown in color (43). They are oxidase and catalase positive. Motility and oxidation of OF glucose are strain dependent. Additional characteristics are given in Table 3. Isolates have been recovered from human blood, sputum, and wound specimens (43).

Alishewanella fetalis

Alishewanella fetalis is a halophilic gram-negative rod that grows at temperatures between 25 and 42°C with optimum growth at 37°C. NaCl is required for growth. It can withstand NaCl concentrations of up to 8% but does not grow at 10% NaCl, which helps differentiate this species from *Shewanella algae*, which can grow in 10% NaCl (247). Also, unlike *S. algae*, it is esculin hydrolysis positive. It is oxidase and catalase positive and asaccharolytic. It does not produce H_2S in the butt of TSI and KIA. Other reactions are given in Table 3. It has been isolated from a human fetus at autopsy; however, its association with clinical infection is unknown (247).

[g] Data from reference 39.
[h] Data from reference 42.
[i] Data from reference 32.
[j] All from avian sources.
[k] Acid production may be detected in rapid sugar test base.
[l] H_2S (TSI butt), the line of the stab became dark in 3 to 7 days with three strains.
[m] 14 days of incubation.
[n] Slightly red when grown anaerobically on selenate-containing media (252).
[o] Light growth at 48 h, heavier at 7 days.
[p] The number before the colon indicates the number of carbons; the number after the colon is the number of double bonds; ω, the position of the double bond counting from the hydrocarbon end of the carbon chain; c, *cis* isomer; i, *iso;* 3–OH, a hydroxyl group at the 3 (β) position from the carboxyl end; cyc, a cyclopropane ring structure.

Aquaspirillum Species

The genus *Aquaspirillum* is a heterogeneous group that at present includes 13 species and two subspecies. All species are aerobic and helical and do not grow in the presence of 3% NaCl (60, 188). Colonies on nutrient agar are generally pinpoint in size at 48 h but become larger (up to 2.0 mm in diameter) at 7 days. They are usually convex or umbonate, glistening, opaque, pale yellow, and butyrous (188). They are oxidase and catalase positive and asaccharolytic. Additional reactions are given in Table 3. Aquaspirillae are found in a wide variety of freshwater sources, especially stagnant water sources such as ditch water, canal water, and ponds. They have also been isolated from storage tanks of distilled water in laboratories (188). Three of the isolates characterized at the CDC have been from human blood cultures, one from a patient with diabetes, one from a patient with pneumonia, and one from an individual whose clinical condition is unknown. All three were shown by 16S rRNA sequencing to be *Aquaspirillum* species.

Laribacter hongkongensis

Laribacter hongkongensis belongs to the family *Neisseriaceae* and is a facultatively anaerobic, nonsporulating bacillus. On Gram stain the organisms appear as gram-negative gull-shaped or spiral rods. It grows on sheep blood agar as non-hemolytic, gray colonies 1 mm in diameter after 24 h of

incubation at 37°C in ambient air. Growth also occurs on MacConkey agar and at 25 and 42°C. No enhancement of growth is observed with 5% CO_2. Most strains are motile with bipolar flagella. All strains are oxidase, catalase, urease, and arginine dihydrolase positive and reduce nitrate but do not ferment, oxidize, or assimilate any carbohydrates (Table 3) (259, 268). *L. hongkongensis* has been isolated from the blood and pleural fluid of a 54-year-old cirrhotic patient (268) and from the stools of patients with community-acquired diarrhea (141, 259, 260, 261). Woo and colleagues have reported an association between *L. hongkongensis* and community-acquired diarrhea, eating fish, and travel (260); however, a causative role has not been shown (69). *L. hongkongensis* has been reported from countries in Asia (China and Japan), Europe (Switzerland), Africa (Tunisia), and Central America (Cuba), suggesting that the bacterium is found worldwide (260). However, as of this writing, no isolates have been reported from North America.

Myroides spp.

Vancanneyt et al. (235) determined that the organism formerly classified as *Flavobacterium odoratum* consisted of a heterogenous group that comprised two distinct species for which they proposed the names *Myroides odoratus* and *Myroides odoratimimus*. Cells of both species are gram-negative rods 0.5 μm in diameter and 1 to 2 μm long. Various colony types may occur, but most colonies are yellow pigmented and form effuse, spreading colonies that may be confused with the colony morphology of a *Bacillus* species. A characteristic fruity odor (similar to the odor of *A. faecalis*) is produced by most strains. *Myroides* grows on most media including MacConkey agar. Growth occurs at 18 to 37°C but not at 42°C. They are asaccharolytic but are oxidase, catalase, urease, and gelatinase positive. Indole is not produced, and nitrite (but not nitrate) is reduced (Table 3). There are no routine phenotypic tests for differentiating the two *Myroides* species, their differences being confined to assimilation tests and CFA profiles (235).

Organisms identified as *M. odoratus* have been reported mostly from urine but have also been found in wound, sputum, blood, and ear specimens (98, 265). Clinical infection with *Myroides* spp. is exceedingly rare; however, cases of rapidly progressive necrotizing fasciitis and bacteremia (112) and recurrent cellulitis with bacteremia (3) have been reported. Most strains are resistant to penicillins, cephalosporins, aminoglycosides, aztreonam, and carbapenems (98).

Neisseria weaveri and *Neisseria elongata*

Although assigned to the genus *Neisseria*, the rod-shaped *Neisseria weaveri* and *Neisseria elongata* morphologically resemble nonfermenting gram-negative bacilli and therefore are placed in Table 3 to help in the differentiation of these phenotypically similar bacteria. The *Neisseria* species are covered in detail in chapter 39.

Shewanella Species

The organism formerly called *Pseudomonas putrefaciens*, *Alteromonas putrefaciens*, *Achromobacter putrefaciens*, and CDC group Ib has now been placed in the genus *Shewanella* (154). Colonies on SBA are convex, circular, smooth, and occasionally mucoid; produce a brown to tan soluble pigment; and cause green discoloration of the medium. Cells are long, short, or filamentous. Motility is due to a single polar flagellum. Ornithine decarboxylase, nitrate reductase, and DNase are always produced, and with few exceptions, hydrogen sulfide (H_2S) is produced in KIA and TSI agar (shewanellae are the only nonfermenters that produce H_2S in these media). The CDC recognizes two biotypes based upon the requirement of NaCl for growth, oxidation of sucrose and maltose, and the ability to grow on SS agar (256). CDC biotype 2 was subsequently assigned to a new species, *S. alga* (173), later corrected to *S. algae* (231). Khashe and Janda (132) have reported that *S. algae* is the predominant human clinical isolate (77%), while *S. putrefaciens* (CDC biotype 1) represents the majority of nonhuman isolates (89%). *S. algae* is halophilic (requires NaCl for growth) and asaccharolytic (Table 3), whereas *S. putrefaciens* is nonhalophilic and saccharolytic (see Table 4). Although infrequently isolated in the clinical laboratory, *S. putrefaciens* and *S. algae* have been recovered from a wide variety of clinical specimens and are associated with a broad range of human infections including skin and soft tissue infection (33), otitis media (102), ocular infection (27), osteomyelitis (16), peritonitis (51) and septicemia (24, 116). Many of these infections were probably caused by *S. algae*. The habitat for *S. algae* is saline habitats, whereas *S. putrefaciens* has been isolated mostly from fish, poultry, and meats as well as fresh water and marine samples. *Shewanella* species are generally susceptible to most antimicrobial agents effective against gram-negative rods except penicillin and cephalothin (70, 248). The mean MICs of *S. algae* to penicillin, ampicillin, and tetracycline are higher than the corresponding MICs of *S. putrefaciens* (132, 246).

Cupriavidus Species

Cupriavidus pauculus was formerly designated CDC Group IVc-2 and *Ralstonia paucula* (236, 238). It is a short to medium-sized gram-negative rod that is asaccharolytic and motile by peritrichous flagella. Cells may stain irregularly. It is rapid urease positive and can be differentiated from the phenotypically similar organisms *B. bronchiseptica* and *O. ureolytica* by a usually negative nitrate reduction test and its CFA composition (Table 3).

Cupriavidus gilardii (formerly *Ralstonia gilardii*) is the new designation for an *Alcaligenes faecalis*-like organism that has been isolated from human clinical sources and the environment (39, 236). *C. gilardii* can be differentiated from *A. faecalis* by the absence of nitrite reduction, failure to utilize acetamide, the presence of polar rather than peritrichous flagella, and CFA composition (Table 3).

Cupriavidus respiraculi (formerly *Ralstonia respiraculi*) has been recovered from the respiratory tract of cystic fibrosis (CF) patients, although the isolates do not grow on *B. cepacia*-selective agar (42, 236). Characteristics that differentiate *C. respiraculi* from other *Cupriavidus* species are given in Table 3.

C. taiwanensis (formerly *Ralstonia taiwanensis*) has also been isolated from the sputum of a CF patient (32, 236). It is a nonsaccharolytic gram-negative rod that is oxidase, catalase, nitrate, and esculin positive. Additional biochemical characteristics are given in Table 3. The *Cupriavidus* species are discussed in more detail in chapter 49.

Gilardi Rod Group 1

Gilardi rod group 1 consists of oval to medium-length asaccharolytic gram-negative rods that resemble *N. weaveri* in many respects except that Gilardi rod group 1 isolates do not reduce nitrite and are strongly phenylalanine deaminase positive, producing a dark green slant after addition of $FeCl_3$ (10%), whereas *N. weaveri*, when positive, produces a weak to moderate reaction. Additional reactions are given in Table 3. There is >98.7% 16S rRNA gene similarity between Gilardi rod group 1 and *Schineria larvae* (K. Bernard, personal communication); however, no formal proposal to name Gilardi rod group 1 has been made as of this writing. Isolates of Gilardi rod group 1 have been recovered from a variety of human sources including leg, arm, and foot wounds, an oral lesion, urine, and blood; however, their pathogenic potential has yet to be determined (166). They are susceptible to many antimicrobial agents including various penicillins, cephalothin, and chloramphenicol (166).

OXIDASE-POSITIVE, INDOLE-NEGATIVE, SACCHAROLYTIC, MOTILE, ROD-SHAPED NONFERMENTERS

See Table 4.

Achromobacter xylosoxidans

Achromobacter xylosoxidans is a relatively frequent agent of infection in immunocompromised patients, causing both local and systemic infections in nosocomial settings (34, 64, 254). *A. xylosoxidans* colonizes the respiratory tract of intubated children and patients with CF, leading to exacerbation of pulmonary symptoms (65). Epidemiologic typing of *A. xylosoxidans* by restriction fragment length polymorphism and PCR has been described (34, 145). Susceptibilities are unpredictable, which requires testing of individual isolates. Strains are frequently resistant to aminoglycosides, ampicillin, narrow- and expanded-spectrum cephalosporins, chloramphenicol, and fluoroquinolones but are usually susceptible to antipseudomonal broad-spectrum cephalosporins, piperacillin, ticarcillin-clavulanic acid, imipenem, and trimethoprim-sulfamethoxazole (13, 218, 248). Panresistance has been reported in at least one clinically significant infection (254).

[h] Acid production was detected only after 21 days of incubation.
[i] Reported to be positive (264).
[j] 14 days of incubation.
[k] When tested at 48 h of incubation, nitrite reduction may be observed only in media containing <0.01% nitrite.
[l] Data from reference 96.
[m] Data from P. Schreckenberger.
[n] The number before the colon indicates the number of carbons; the number after the colon is the number of double bonds; ω, the position of the double bond counting from the hydrocarbon end of the carbon chain; c, *cis* isomer; cyc, a cyclopropane ring structure; i, *iso;* ND, not determined.
[o] Fatty acid profile analysis, performed on six strains in our laboratory, indicates that this group is heterogeneous.

Ochrobactrum Species and *Achromobacter* Groups B, E, and F

Ochrobactrum anthropi (97) comprises the urease-positive *Achromobacter* species formerly designated CDC group Vd (biotypes 1 and 2) and *Achromobacter* groups A, C, and D described by Holmes et al. (96). Subsequent studies showed, however, that biogroup C and some strains belonging to biogroup A constitute a homogeneous DNA-DNA hybridization group separate from *O. anthropi,* named *Ochrobactrum intermedium* (242). Both *Ochrobactrum* species are closely related to *Brucella* spp., with *Ochrobactrum intermedium* occupying a phylogenetic position that is intermediate between *O. anthropi* and *Brucella* (242). The two species share identical phenotypic properties. They appear as medium-length rods with peritrichous flagella, but individual cells may have a single flagellum only. Colonies on SBA resemble those of *Enterobacteriaceae*, except that those of *Ochrobactrum* are smaller. Colonies measure about 1 mm in diameter and appear circular, low convex, smooth, shining, and entire.

O. anthropi has been isolated from various environmental and human sources, predominantly from patients with catheter-related bacteremias (97, 131, 204) and rarely with other infections (155) including one case of meningitis (29). Pulsed-field gel electrophoresis and PCR genome fingerprinting based on repetitive chromosomal sequences have both been used successfully for epidemiologic typing of outbreak strains (240). *O. anthropi* strains are usually resistant to β-lactams, such as broad-spectrum penicillins, broad-spectrum cephalosporins, aztreonam, and amoxicillin-clavulanate, but are usually susceptible to aminoglycosides, fluoroquinolones, imipenem, tetracycline, and trimethoprim-sulfamethoxazole (12, 131, 204).

There are no biochemical tests currently available that separate *O. intermedium* from *O. anthropi;* however, it has been suggested that colistin (polymyxin E) and polymyxin B resistance can be used to separate *O. intermedium* (resistant) from *O. anthropi* (susceptible) (242). One case of pyogenic liver infection due to *O. intermedium* has been reported (162), but because of the close phenotypic similarity of *O. anthropi* and *O. intermedium*, it is possible that certain infections thought to be caused by *O. anthropi* were actually caused by *O. intermedium.*

Achromobacter groups B and E constitute biotypes of a single new species that has yet to be named (89, 90, 92). *Achromobacter* group F is genetically distinct from groups B and E (89, 90). *Achromobacter* group B strains susceptible to chloramphenicol, ciprofloxacin, gentamicin, imipenem, tobramycin, and trimethoprim-sulfamethoxazole have been isolated from patients with septicemia (91, 120). Isolates of *Achromobacter* groups E and F have also been recovered from blood (89, 90).

Rhizobium radiobacter

The former genus *Agrobacterium* contained several species of plant pathogens occurring worldwide in soils. Four distinct species of *Agrobacterium* were recognized: *A. radiobacter* (formerly *A. tumefaciens* and CDC group Vd-3), *A. rhizogenes* (subsequently transferred to the genus *Sphingomonas* as *S. rosa*), *A. vitis*, and *A. rubi* (206). More recently, Young and colleagues (267) proposed an emended description of the genus *Rhizobium* to include all species of *Agrobacterium*. Following this proposal the new combinations are *Rhizobium radiobacter, R. rhizogenes, R. rubi,* and *R. vitis* (267). Cells measure 0.6 to 1.0 by 1.5 to 3.0 μm and occur singly and in pairs. Colonies of *R. radiobacter* grow optimally at 25 to 28°C but grow at 35°C as well. They appear circular, convex, smooth, and nonpigmented to light beige on SBA with a diameter of 2 mm at 48 h. Colonies may appear wet looking and become extremely mucoid and pink on MacConkey agar with prolonged incubation (Fig. 2).

R. radiobacter has been most frequently isolated from blood, followed by peritoneal dialysate, urine, and ascitic fluid (66, 114). The majority of cases have occurred in patients with transcutaneous catheters or implanted biomedical prostheses, and effective treatment often requires removal of the device (67). *R. radiobacter* septicemia has also been reported in hospitalized patients with advanced human immunodeficiency virus disease (156). One case of endophthalmitis caused by a *Rhizobium radiobacter*-like (3-ketolactonate-negative) organism has also been reported (161). Most strains are susceptible to broad-spectrum cephalosporins, carbapenems, tetracyclines, and gentamicin but not to tobramycin (66, 248). Testing of individual isolates is recommended for clinically significant cases.

Agrobacterium Yellow Group

Organisms in the *Agrobacterium* yellow group are represented by slender, medium to long gram-negative rods that produce a yellow insoluble growth pigment and most closely resemble *Sphingomonas paucimobilis* and CDC group O-1 and O-2 organisms. Growth on MacConkey agar is variable, motility occurs via a single polar flagellum, oxidase and catalase are positive, and glucose, xylose, lactose, sucrose, and maltose are oxidized, but not mannitol. Only a positive 3-ketolactonate reaction differentiates this organism from *S. paucimobilis* (Table 4). Isolates have been recovered from blood and peritoneal fluid (224, 256).

CDC Group Ic

Members of CDC group Ic are gram-negative, slender, short to long, motile rods with one or two polar flagella. The organisms grow well on MacConkey, SS, and usually cetrimide agars; oxidize glucose and maltose; reduce nitrate to nitrite without gas; produce H_2S on lead acetate paper (usually strong); they are arginine dihydrolase positive, urease and citrate variable, and esculin and gelatin hydrolysis negative; and they grow well at 25, 35, and usually 42°C. Other characteristics are listed in Table 4. Most isolates have come from human sources including urine, sputum, blood, and other sites (256). Antibiotic susceptibility data are not available.

CDC Groups O-1, O-2, and O-3

CDC groups O-1, O-2, and O-3 are phenotypically similar, motile, and usually oxidase-positive, gram-negative rods. Groups O-1 and O-2 are yellow pigmented and most closely resemble *Agrobacterium* yellow group and *Sphingomonas* species. These organisms grow poorly or not at all on MacConkey agar and usually hydrolyze esculin but are otherwise inactive. All are motile, although motility may be difficult to demonstrate. O-1 organisms appear as uniformly short gram-negative rods, O-2 organisms appear as slightly pleomorphic rods with some cells appearing thin in the central portion with thickened ends, and O-3 cells appear as thin, medium to slightly long curved rods with tapered ends (sickle-like) (52, 256). O-3 is the only group in which yellow growth pigment is not produced. Most isolates of O-3 grow well on CAMPY CVA (Campylobacter agar with cefoperazone, vancomycin, and amphotericin B) plates under microaerophilic conditions, thus creating the potential for misidentification of

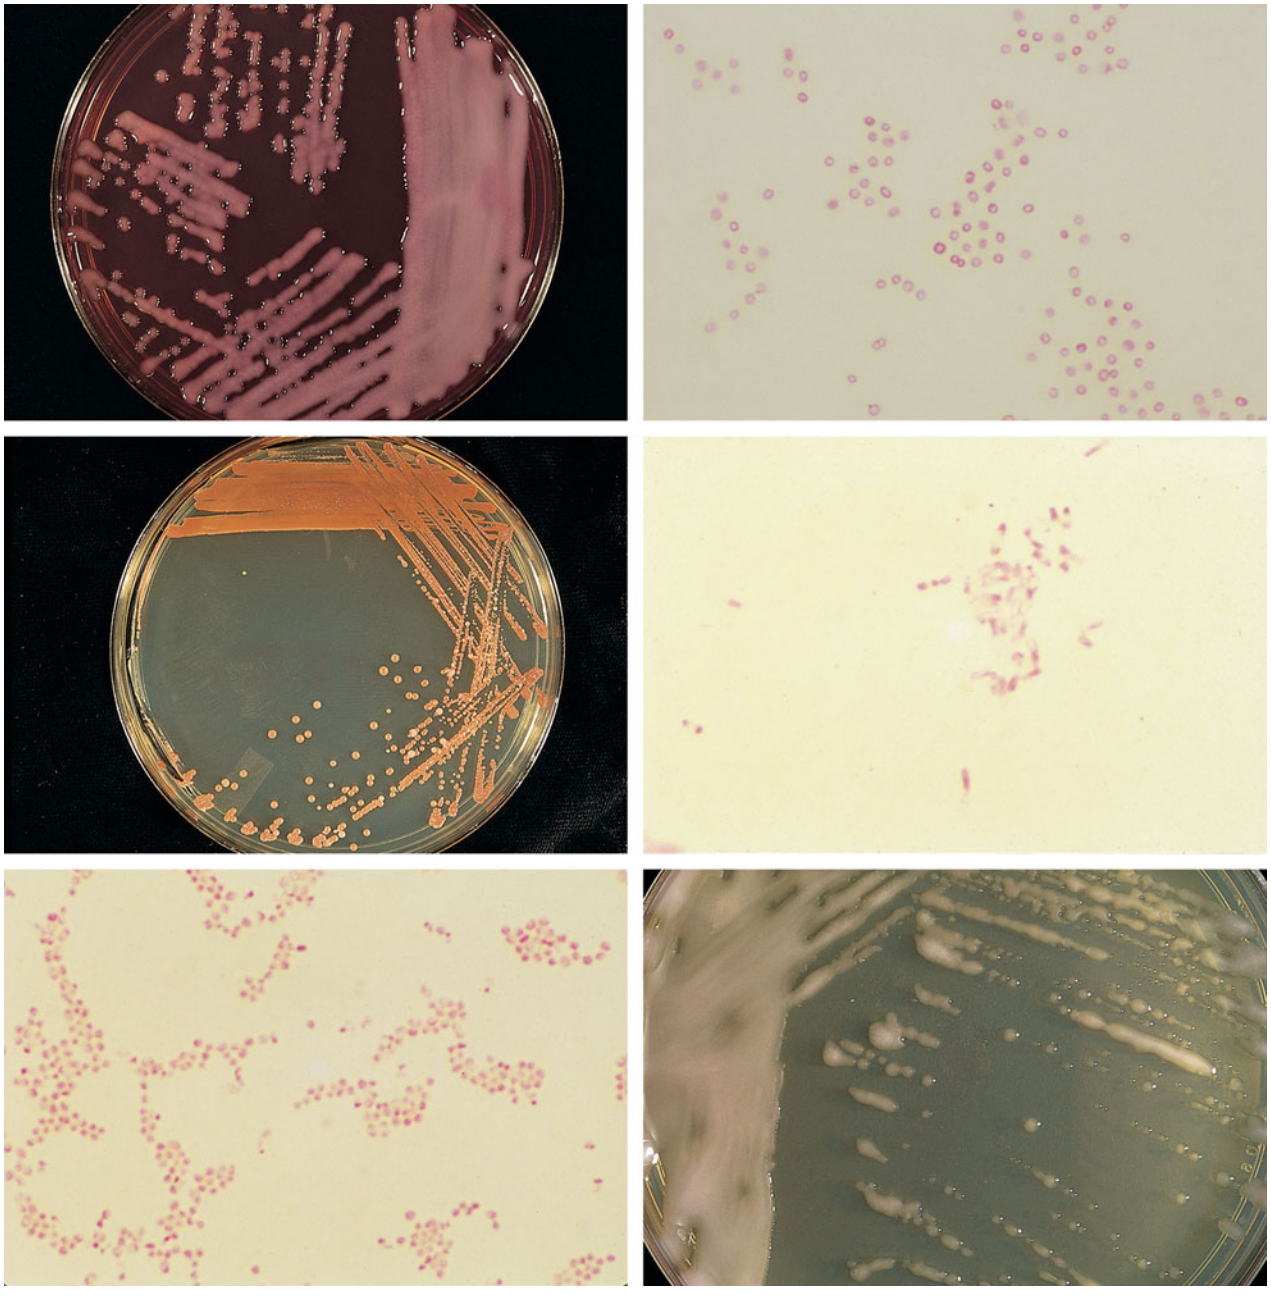

FIGURE 2 (top left) *Rhizobium radiobacter* on MacConkey agar after 48 h of incubation.

FIGURE 3 (top right) Gram stain of *Paracoccus yeei* (EO-2) showing characteristic donut-shaped morphology.

FIGURE 4 (middle left) *Methylobacterium* on Sabouraud's dextrose agar showing coral-pigmented colonies.

FIGURE 5 (middle right) Gram stain of *Methylobacterium* showing pleomorphic gram-negative rods with vacuoles.

FIGURE 6 (bottom left) Gram stain of *Roseomonas* showing gram-negative coccoid rods.

FIGURE 7 (bottom right) *Roseomonas* on Sabouraud's dextrose agar showing pink mucoid colonies.

O-3 organisms as *Campylobacter* (52). 16S rRNA gene sequencing and cell wall fatty acid analysis performed at the CDC show a close match of CDC group O-1 with *Hydrogenophaga palleroni* and of CDC group O-2 with *Caulobacter vibrioides* (Daneshvar, unpublished). Isolates of all three O groups have been recovered from a variety of clinical sources. One case of group O1-associated pneumonia complicated by bronchopulmonary fistula and bacteremia has been reported (192). Antibiotic susceptibility data have been reported only for group O-3. All isolates tested were susceptible to the aminoglycosides, trimethoprim-sulfamethozaxole, and imipenem. Resistance to most β-lactams was noted, and variable susceptibility was noted for chloramphenicol, tetracycline, ciprofloxacin, and amoxicillin-clavulanate (52).

Halomonas venusta and CDC Halophilic Nonfermenter Group 1

Halomonas venusta was originally described as *Alcaligenes venustus* (7) but later transferred to the new genus *Deleya*, as *Deleya venusta* (8). In 1996 Dobson and Franzmann proposed combining the genus *Deleya* into a more broadly defined genus, *Halomonas* (62). von Graevenitz and colleagues were the first to report a human infection caused by *H. venusta* in a wound that originated from a fish bite. It was reported to be susceptible to most antibiotics (249).

CDC Halophilic Nonfermenter Group 1 consists of six phenotypically similar isolates received by the CDC between 1971 and 1998 that are similar to *H. venusta* except for esculin hydrolysis and CFA composition. Five of these are from human blood cultures and the sixth is from a hip wound culture (unpublished data from CDC). Growth requirements suggest exposure to brackish water.

Herbaspirillum Species 3

Herbaspirillum is a gram-negative, generally curved, and sometimes helical bacillus. Individual cells are 0.6 to 0.7 μm wide and 1.5 to 5.0 μm long and have one to three or more flagella on one or both poles (4). A group of clinical isolates, previously described as EF-1, was shown by molecular hybridization to belong to the genus *Herbaspirillum* and was designated as a new unnamed species, *Herbaspirillum* species 3 (4). The organism is oxidase and urease positive; catalase is weak or variable. Other reactions are given in Table 4. Isolates have been recovered from the respiratory tract, feces, urine, ear, eye, and wound sites (4). Antibiotic susceptibility data are not available.

Inquilinus limosus

Inquilinus limosus is a rod-shaped gram-negative bacterium that measures 1.5 to 2 μm in width by 3.5 μm in length, grows at 35 and 42°C but poorly at 25°C, and is either nonmotile or motile with one or two polar flagella. It forms very slimy, nonpigmented colonies on nonselective media. Growth on MacConkey agar is very slight after 3 days. It is polymyxin B resistant and lipase positive, making it appear phenotypically similar to the *B. cepacia* complex (40, 186). The original description of *Inquilinus* stated that there is no utilization of glucose, mannitol, inositol, sorbitol, rhamnose, sucrose, melibiose, amygdalin, or arabinose (40); however, all three isolates tested at CDC showed oxidative utilization of glucose, xylose, mannitol, lactose, sucrose, and maltose either within 2 days or between 3 and 7 days of incubation (Table 4). All strains are positive for catalase, beta-glucosidase, phosphatase, proline aminopeptidase, pyrollidonyl aminopeptidase, and acetoin production and negative for lysine, arginine, ornithine, denitrification, and indole (40). Additional reactions are given in Table 4. All strains have been recovered from respiratory secretions of CF patients and are very mucoid. Identifying the species is difficult because it is not contained in the databases of commercial identification kits and its mucoid appearance may lead to confusion with mucoid *P. aeruginosa* strains (186, 255). Isolates can be recovered on colistin containing *B. cepacia* selective media, but are inhibited on *Burkholderia cepacia* selective agar, which also contains gentamicin (35). The natural habitat of *Inquilinus* is unknown to date, and the clinical impact of chronic colonization with *Inquilinus* sp. remains unclear. Chiron and colleagues reported that for one patient, *Inquilinus* sp. was the only potential pathogen recovered from the sputum and *Inquilinus* acquisition was followed by a worsening of his lung function (35). All isolates are reported to be resistant to penicillins and cephalosporins, kanamycin, tobramycin, colistin, doxycycline, and trimethoprim-sulfamethoxazole and susceptible to imipenem and ciprofloxacin (35, 255).

Massilia timonae

M. timonae is an actively motile (with lateral flagella as well as a single polar flagellum), strictly aerobic gram-negative rod that is oxidase positive, catalase positive, and weakly saccharolytic. Additional phenotypic characteristics are given in Table 4. Colonies appear pale yellow and are distinctively tenacious on agar media and have a tendency to form flocs and films in liquid medium (140). Isolates have been recovered from a surgical wound, cerebrospinal fluid (CSF), the femur of a patient with osteomyelitis, and the blood of several patients (140, 148, 216). *M. timonae* is susceptible to most antibiotics active against gram-negative bacteria with resistance only to ampicillin, cephalothin, and aztreonam (140, 216).

OFBA-1

OFBA-1 is an unclassified medium to long gram-negative, motile rod with one or two polar flagella and has the unusual property of producing acid in OF base medium without carbohydrate, thus the acronym OFBA for OF base acid. The organism most closely resembles *P. aeruginosa* biochemically due to beta-hemolysis, growth at 42°C, presence of arginine dihydrolase, nitrate reduction to gas, and utilization of most carbohydrates (251, 256). Unlike *P. aeruginosa*, it is negative for pyocyanin and pyoverdin production and acetamide hydrolysis. Isolates have been recovered from blood, leg ulcer, abdominal wound, bronchial wash, and a catheter tunnel infection in a patient on continuous ambulatory peritoneal dialysis (251, 256).

Pseudomonas-Like Group 2

The organisms in *Pseudomonas*-like group 2 were previously included in a heterogeneous group of organisms designated CDC group IVd (59). 16S rRNA gene sequencing and cell wall fatty acid analysis performed at the CDC show a close match between *Pseudomonas*-like group 2 and *Herbaspirillum rubrisubalbicans* (Daneshvar, unpublished). Strains are oxidase positive and motile with polar tufts of flagella and are urea, ONPG (*o*-nitrophenyl-β-D-galactopyranoside), and phenylalanine deaminase positive (59). Isolates are similar to *Burkholderia gladioli* but do not oxidize dulcitol or inositol. Other characteristics are given in Table 4. Colonies tend to stick to the agar. Human clinical isolates have come from the respiratory tract, blood, spinal fluid, feces, urine, and dialysate (136).

Sphingomonas spp.

On the basis of its 16S rRNA sequence and the presence of unique sphingoglycolipid and ubiquinone types, the genus

Sphingomonas was created for the organism formerly known as *Pseudomonas paucimobilis* and CDC group IIk-1 (93, 264). Since the original proposal, numerous novel species originating from various environments have been added to the genus *Sphingomonas*.

Members of this genus are known to be decomposers of aromatic compounds and are being developed for use in bioremediation. The genus *Sphingomonas* can be divided into four phylogenetic groups, each representing a different genus. Consequently, three new genera, *Sphingobium, Novosphingobium,* and *Sphingopyxis,* in addition to the genus *Sphingomonas* have been created to accommodate the four phylogenetic groups (226). The emended genus *Sphingomonas* contains at least 12 species, of which only *S. paucimobilis,* designated the type species, and *S. parapaucimobilis* are thought to be important clinically.

S. paucimobilis is characterized by medium to long motile rods with a polar flagellum. However, few cells are actively motile in broth culture, thus making motility a difficult characteristic to demonstrate. Motility occurs at 18 to 22°C but not at 37°C. The oxidase reaction is weakly positive, although occasional strains may be oxidase negative. Colonies are slow growing on blood agar medium, with only small colonies appearing after 24 h of incubation. Older colonies demonstrate a deep yellow (mustard color) pigment. Growth occurs at 37°C but not at 42°C, with optimum growth occurring at 30°C. Isolates are strongly esculin hydrolysis positive and produce a zone of growth inhibition around a vancomycin disk (30 μg) placed on a blood agar plate inoculated with a pure culture isolate (P. Schreckenberger, personal observation). *S. paucimobilis* is widely distributed in the environment, including water, and has been isolated from a variety of clinical specimens, including blood, CSF, peritoneal fluid, urine, wounds, the vagina, the cervix, and from the hospital environment (110, 165, 194). Most strains are susceptible to tetracycline, chloramphenicol, trimethoprim-sulfamethoxazole, and aminoglycosides; susceptibility to other antimicrobial agents including fluoroquinolones varies (70, 110, 194).

The cellular and colonial characteristics of *S. parapaucimobilis* are similar to those of *S. paucimobilis*. It is differentiated from *S. paucimobilis* by blackening of lead acetate paper suspended over KIA, ability to grow and alkalinize Simmons' citrate medium, and a negative extracellular deoxyribonuclease reaction (264). Clinical isolates have been obtained from sputum, urine, and the vagina (264). Antibiotic susceptibility data are not available.

Thermophilic Bacteria

Rabkin and colleagues studied 31 bacterial isolates from clinical specimens received by the CDC that were described as "thermophilic," because they had the unusual feature of growing better when incubated at 42 or 50°C than at 35°C and none grew at 25°C in 18 to 24 h. All were slow growers even at optimum temperatures with colonies appearing circular, usually 0.5 mm or less in diameter after 48 to 72 h at 35°C, and smooth, convex, semitranslucent, and slightly glossy (193). Biochemically, they are oxidase positive, fail to grow on MacConkey agar, and do not ferment glucose. Most strains are oxidative in OF glucose and OF maltose. Isolates have been recovered from blood, CSF, urine, nasopharynx, abscess, wound, and liver biopsy specimens. Two cases of meningitis occurred in previously healthy children. In four other cases, infections occurred in compromised hosts (193). The thermophiles were uniformly susceptible to penicillins and cephalosporins and, with few exceptions, to the aminoglycosides (193).

Ko and colleagues recovered a novel asaccharolytic thermophilic gram-negative bacillus from the bone marrow of a patient who developed febrile neutropenia after induction chemotherapy for treatment of myelogenous leukemia. The isolate grew poorly at 37°C but grew optimally at 50°C. Based on 16S rRNA gene sequencing and fatty acid composition, the isolate was classified as a new species, *Tepidimonas arfidensis* (137).

OXIDASE-POSITIVE, INDOLE-NEGATIVE, SACCHAROLYTIC, NONMOTILE, COCCOID OR ROD-SHAPED NONFERMENTERS

See Table 5.

Sphingobacterium and *Pedobacter*

Sphingobacterium spp. are oxidase-positive, indole-negative gram-negative rods that form yellow-pigmented colonies. They have no flagella but may exhibit sliding motility. They are nonproteolytic and produce acid from carbohydrates. The currently described species of *Sphingobacterium* are *S. multivorum* (formerly *Flavobacterium multivorum* and CDC group IIk-2), *S. spiritivorum* (includes species formerly designated *Flavobacterium spiritivorum, F. yabuuchiae,* and CDC group IIk-3), *S. antarcticum, S. faecium, S. thalpophilum,* and unnamed species *Sphingobacterium* genomospecies 1 and 2 (101, 211, 227, 262). The former *Sphingobacterium* species *S. heparinum* and *S. piscium* have been placed in a new genus, *Pedobacter,* as *P. heparinus* and *P. piscium* (220). The genus *Pedobacter* contains several species of heparinase-producing bacteria found in soil, activated sludge, or fish, but not from human sources. Steyn and colleagues have shown that all these organisms constitute a separate rRNA branch in the rRNA superfamily V for which they have proposed a new family called the *Sphingobacteriaceae* (220).

S. multivorum and *S. spiritivorum* have been most frequently recovered from human clinical specimens. They can be distinguished from the similar organism *Sphingomonas paucimobilis* (formerly IIk-1) by lack of motility, urease production, and resistance to polymyxin B (*S. paucimobilis* is usually motile, urease negative, and usually susceptible to polymyxin B). *S. multivorum* has been isolated from various clinical specimens but has only rarely been associated with serious infections (peritonitis and sepsis) (72, 95, 189). Blood and urine have been the most common sources for the isolation of *S. spiritivorum* (94). *S. mizutaii* has been isolated from blood, CSF, and wound specimens and can be differentiated from *S. multivorum* by its failure to grow on MacConkey agar and usual lack of urease (256). *S. thalpophilum* has been recovered from wounds, blood, eye, abscess, and abdominal incision (256). A positive nitrate test and growth at 42°C differentiate *S. thalpophilum* from other *Sphingobacterium* species.

The organism formerly known as *Sphingobacterium mizutaii* has been transferred to the genus *Flavobacterium* (101) but is included with the sphingobacteria in Table 5 because it is indole negative and phenotypically resembles the *Sphingobacterium* species. *F. mizutaii* has been isolated from blood, CSF, and wound specimens and can be differentiated from *Sphingobacterium* species by its failure to grow on MacConkey agar and usual lack of urease activity (256).

Sphingobacterium species are generally resistant to aminoglycosides and polymyxin B while susceptible in vitro to the quinolones and trimethoprim-sulfamethoxazole. Susceptibility to β-lactam antibiotics is variable, requiring testing of individual isolates (218).

[a] Most data are from the CDC Special Bacteriology Reference Laboratory (256). All taxa were negative (≤10% positive) for motility, growth on SS and cetrimide agars, production of H_2S in TSI, lysine decarboxylase, and ornithine decarboxylase activity. Numbers indicate percentage positive at 2 days of incubation; parentheses, delayed reaction (3 to 7 days of incubation); w, weak reaction; ND, not determined or not available; yel, yellow. Numbers in parentheses following organisms indicate number of strains.

[b] Data from Weyant et al., *Abstr. 99th Gen. Meet. Am. Soc. Microbiol.*

[c] Data from reference 220.

[d] A partial reduction may be observed with 0.1% nitrite. A full reduction is observed with 0.01% nitrite.

[e] Fewer than five strains tested.

[f] 14 days of incubation.

[g] Pigment production may be enhanced by room temperature incubation.

[h] The number before the colon indicates the number of carbons; the number after the colon is the number of double bonds; ω, the position of the double bond counting from the hydrocarbon end of the carbon chain; c, *cis* isomer; i, *iso;* 2-OH, a hydroxyl group at the 2 (β) position from the carboxyl end; 3-OH, a hydroxyl group at the 3 (β) position from the carboxyl end.

CDC Group EF4b

EF-4b and EF-4a were originally designated Eugonic Fermenter group 4 (EF-4); however, EF-4b does not ferment glucose, hydrolyze arginine, or produce gas from nitrate, which separates it from the glucose-fermenting strains now designated CDC group EF-4a (see chapter 40). 16S rRNA studies indicate that EF-4b is closely related to *Neisseria canis* (Daneshvar, unpublished). EF-4b strains are coccoid to short rods that are nonmotile and oxidase and catalase positive. Colonies on culture plates are nonpigmented and reported to smell like popcorn. Most isolates have been recovered from human infections following dog and cat bites (256). Antibiotic susceptibility resembles that of EF-4a.

Paracoccus yeei (EO-2), CDC Groups EO-3, EO-4, and *Psychrobacter immobilis*

The classification of the eugenic oxidizers (EO) and the saccharolytic strains of *Psychrobacter immobilis* is incomplete. All are strongly oxidase-positive, nonmotile, saccharolytic coccobacilli and grow, sometimes poorly, on MacConkey agar. In contrast to the EO groups, *P. immobilis* grows best at 20°C and only occasionally at 37°C. EO-3 and many EO-4 strains have a yellow, nondiffusible pigment that is not observed with either *P. yeei* or *P. immobilis*. Daneshvar et al. (53) proposed the name *Paracoccus yeeii,* the epithet being later changed to *yeei* (68), for the former CDC group EO-2. CDC group EO-3 has been shown by 16S rRNA sequencing to closely match *Fulvimarina pelagi* (Daneshvar, unpublished), and CDC EO-4 remains unnamed.

Microscopically, *P. yeei* is characterized by distinctive "O-shaped" cells (Fig. 3) upon Gram stain examination due to the presence of vacuolated or peripherally stained cells, and *P. immobilis* is characterized by paired, coccoid organisms. *P. immobilis* is divided into saccharolytic and asaccharolytic strains. Saccharolytic *P. immobilis* strains (Table 5) share all of the characteristics of the asaccharolytic strains (Table 2) except that glucose, xylose, and lactose, but not sucrose and maltose, are oxidized. Asaccharolytic strains are phenotypically similar to *P. phenylpyruvicus*. The diagnosis of *P. immobilis* can be confirmed by transformation studies, CFA profile, and optimal growth at temperatures of <35°C (167, 256). Many strains of *P. immobilis* have an odor resembling phenylethyl alcohol agar (roses) and are resistant to penicillin but susceptible to most other antibiotics (79, 151). All four groups have been recovered from clinical specimens. *P. yeei* has been isolated from various human wound infections (53). EO-3 has been reported to cause peritonitis in a patient on continuous peritoneal dialysis (49). EO-4 has been recovered from blood, urine, and a nasal sinus, but the clinical significance of these isolates is unknown (R. S. Weyant, M. I. Daneshvar, J. G. Jordan, J. P. MacGregor, and D. G. Hollis, *Abstr. 99th Gen. Meet. Am. Soc. Microbiol.,* abstr. C-196, 1999). One case of ocular infection and one case of infant meningitis have been reported to be caused by *P. immobilis* (79, 151).

PINK-PIGMENTED NONFERMENTERS

See Table 6.

Asaia spp.

Asaia is a recently described genus consisting of two members, *A. bogorensis* (266) and *A. siamensis* (128). The natural habitats of *Asaia* spp. are reported to be in the flowers of the orchid tree, plumbago, and fermented glutinous rice, all originating in hot tropical climates, particularly in Indonesia and Thailand. *Asaia bogorensis* has been reported as a cause of peritonitis in a patient on automated peritoneal dialysis (217). Daneshvar and colleagues identified 14 isolates of a novel *Asaia* species, of which 3 were from a dialysis-associated outbreak (M. I. Daneshvar, L. W. Mayer, A. G. Steigerwalt, A. M. Whitney, R. E. Morey, L. O. Helsel, P. N. Levett, B. J. Paster, F. E. Dewhirst, R. S. Weyant, and D. J. Brenner, Int. Conf. Emerg. Infect. Dis., Atlanta, 2004). *Asaia* species have also been isolated from a batch of fruit-flavored bottled water, which had spoiled as a result of bacterial overgrowth (164). Isolates characterized at the CDC are pink-pigmented, oxidase-negative, motile rods that are oxidative in OF glucose, xylose, and mannitol. Additional characteristics are given in Table 6. Moore reported that *Asaia* spp. were resistant to ceftazidime, meropenem, imipenem, trimethoprim, amikacin, vancomycin, aztreonam, penicillin, and ampicillin by disk diffusion (164). The *A. bogorensis* strain reported by Snyder et al. was susceptible to aminoglycosides (amikacin, tobramycin, and gentamicin) and resistant to ceftazidime and meropenem by disk diffusion (217).

Methylobacterium spp.

Members of the genus *Methylobacterium* are pink-pigmented bacteria able to utilize methanol as a sole source of carbon and energy, although this characteristic may be lost on subculture. They occur mostly on vegetation but may also be found in the hospital environment. The genus currently consists of 20 named species plus additional unassigned biovars recognized on the basis of carbon assimilation type, electrophoretic type, and DNA-DNA homology grouping (74, 80, 81, 233). *Methylobacterium mesophilicum* (formerly *Pseudomonas mesophilica, Pseudomonas extorquens, and Vibrio extorquens*) and *Methylobacterium zatmanii* have been the two most commonly reported species isolated in clinical samples. Methylobacteria are oxidase positive and motile by one polar or lateral flagellum, although motility is often difficult to demonstrate. Isolates are slow growing on ordinary media, producing 1-mm-diameter colonies in 4 to 5 days on SBA, modified Thayer-Martin, Sabouraud, buffered charcoal-yeast extract, and Middlebrook 7H11 agars, with best growth occurring on Sabouraud agar, and usually no growth on MacConkey agar. Optimum growth occurs from 25 to 30°C. Colonies are dry and appear pink or coral in incandescent light (Fig. 4). Under UV light, *Methylobacterium* species appear dark due to absorption of UV light (199). On Gram stain the cells appear as large, vacuolated, pleomorphic rods that stain poorly and may resist decolorization (Fig. 5). Oxidation of sugars (xylose and sometimes glucose) is weak; urea and starch are hydrolyzed.

Methylobacterium species have been reported to cause septicemia, continuous ambulatory peritoneal dialysis-related peritonitis, skin ulcers, synovitis, and other infections often in immunocompromised patients, as well as pseudoinfections (104, 130, 149, 205). Tap water has been implicated as a possible agent of transmission in hospital environments, and methods for monitoring water systems for methylobacteria have been described (197). Active drugs include aminoglycosides and trimethoprim-sulfamethoxazole, whereas β-lactam drugs show variable patterns (26). They are best tested for susceptibility by agar or broth dilution at 30°C for 48 h (26).

Roseomonas and *Azospirillum* spp.

Members of the genus *Roseomonas* (199) are also pink pigmented but differ in morphologic and biochemical characteristics from *Methylobacterium* spp. (Table 6). They are

[a] Unless otherwise indicated, data are from the CDC Special Bacteriology Reference Laboratory (256). Numbers indicate the percentage positive at 2 days of incubation; parentheses, delayed reaction (3 to 7 days of incubation); w, weak reaction; ND, not determined or not available; L, lateral; p, polar. All taxa were positive (≥90%) for catalase, growth at 25 and 35°C. All were negative for growth on cetrimide agar, indole production, acid in TSI agar, and H_2S production in TSI agar.

[b] Data from Daneshvar et al. Int. Conf. Emerg. Infect. Dis. Atlanta, 2004.

[c] At least 20 species and additional biovars have been described (see the text).

[d] Two subspecies are proposed: *R. gilardii* subsp. *gilardii* and *R. gilardii* subsp. *rosea* (82).

[e] Motility was more easily demonstrated in OF medium than in motility medium. Motile strains demonstrated either 1 or 2 polar flagella or detached flagella.

[f] Motile strains demonstrated 1 or 2 flagella.

[g] The number before the colon indicates the number of carbons; the number after the colon is the number of double bonds; ω, the position of the double bond counting from the hydrocarbon end of the carbon chain; c, *cis* isomer; OH, a hydroxyl group at the 2(α) or 3(β) position from the carboxyl end; cyc, a cyclopropane ring structure.

nonvacuolated and rather plump and coccoid and form mostly pairs and short chains (Fig. 6). They grow on SBA, modified Thayer-Martin, and usually on MacConkey agars at 37°C, but best growth is observed on Sabouraud's agar. Colonies are mucoid and runny (Fig. 7). They are separated from *Methylobacterium* by their inability to oxidize methanol and assimilate acetamide and by lack of absorption of long-wave UV light (199). All strains are weakly oxidase positive (often after 30 s) or oxidase negative, catalase positive, and urease positive. The original description of the genus *Roseomonas* included three named species, *Roseomonas gilardii* (genomospecies 1), *Roseomonas cervicalis* (genomospecies 2), *Roseomonas fauriae* (genomospecies 3), and three unnamed species, *Roseomonas* genomospecies 4, 5, and 6 (199). More recently, Han et al. proposed a new species, *Roseomonas mucosa,* and a new subspecies, *R. gilardii* subspecies *rosea* (to differentiate from *R. gilardii* subspecies *gilardii*) (82). 16S rRNA gene sequencing of all six *Roseomonas* genomospecies suggests that *Roseomonas* genomospecies 1, 2, 4, and 5 are valid taxa while genomospecies 3 and 6 are not. The invalid *Roseomonas* genomospecies 3 and 6 belong to the genus *Azospirillum,* a nitrogen-fixing plant symbiont that is in a different order of bacteria (44, 82, 228).

Clinical isolates have been recovered from blood, wounds, exudates, abscesses, genitourinary sites, continuous ambulatory peritoneal dialysis fluid, and bone (11, 57, 159, 168, 198, 212, 221, 222). In a review of the laboratory, clinical, and epidemiologic data on 35 patients from whom *Roseomonas* was isolated, Struthers and colleagues reported that *Roseomonas* spp. appear to have a low pathogenic potential for humans but that some species, particularly *R. gilardii,* may be significant pathogens in persons with underlying medical complications (221). In multiple-case reports about 60% of the isolates recovered have been from blood, with about 20% from wounds, exudates, and abscesses and about 10% from genitourinary sites (57, 221).

De et al. summarized susceptibility data from three published reports on a combined 80 strains of *Roseomonas*. All strains were susceptible to amikacin (100%); frequently susceptible to imipenem (99%), ciprofloxacin (90%), and ticarcillin (83%); less susceptible to ceftriaxone (38%), trimethoprim-sulfamethoxazole (30%), and ampicillin (13%); and rarely susceptible to ceftazidime (5%). All strains were resistant to cefepime (57). In catheter-related infections, eradication of the organism has proven difficult unless the infected catheter is removed (198).

OXIDASE-POSITIVE, INDOLE-POSITIVE, NONMOTILE OR MOTILE, YELLOW-PIGMENTED NONFERMENTERS

See Table 7.

Chryseobacterium, Elizabethkingia, Empedobacter, and Unnamed CDC Groups IIc, IIe, IIg, IIh, and IIi

The natural habitats of *Chryseobacterium, Elizabethkingia, Empedobacter,* and the unnamed CDC groups are soil, plants, foodstuffs, and water sources, including those in hospitals. Species in these genera are oxidase positive, indole positive, and nonmotile. The indole reaction is often weak and difficult to demonstrate; therefore, the more sensitive Ehrlich method should be used. Pigment formation with these organisms is variable. Colonies of *Elizabethkingia meningoseptica,* formerly *Chryseobacterium meningosepticum* (133), are smooth and fairly large (1 to 2 mm in diameter after 24 h) but show only weak (if any) production of yellow pigment. In contrast, colonies of *Chryseobacterium indologenes* are deep yellow due to the production of the water-insoluble pigment flexirubin (181). Colonies of *Empedobacter brevis* are pale yellow. Microscopically, cells of *E. meningoseptica, C. indologenes,* and groups IIe, IIh, and IIi are thinner in their central than in their peripheral portions and include filamentous forms; IIh cells are significantly smaller than those of other species. It should be emphasized that test results (e.g., DNase, indole, urea, and starch hydrolysis) in this group are dependent on the choice of medium, reagents, and length of incubation (181). *Chryseobacterium indologenes, C. gleum,* and CDC group IIb are tabulated individually in Table 7. Group IIb is genetically heterogeneous and includes strains of *C. indologenes, C. gleum,* and probably additional genomospecies. Phenotypic separation between *C. indologenes* and *C. gleum* has been difficult; however, acid production from xylose and growth at 41°C are consistently positive in DNA groups clustering around the type strain of *C. gleum* (234).

Chryseobacterium indologenes is the most frequent human isolate, although it rarely has clinical significance (248). It causes bacteremia in hospitalized patients with severe underlying disease, although the mortality is relatively low even among patients who were administered antibiotics without activity against *C. indologenes* (107, 215). Nosocomial infections due to *C. indologenes* have been linked to the use of indwelling devices during hospital stay (109, 111, 174).

Elizabethkingia meningoseptica (133) is most often associated with significant disease in humans, causing neonatal meningitis and nosocomial miniepidemics (15, 36, 215) verifiable by ribotyping (45) and random amplified polymorphic DNA fingerprinting (36), and rarely, adult pneumonia and septicemia (15, 210, 248). A case of respiratory colonization and infection following aerosolized polymyxin B treatment has also been described (25).

Empedobacter brevis and the unnamed CDC groups IIc, IIe, IIg, IIh, and IIi are rarely recovered from clinical material, and little is known about their involvement in clinical disease. One case of meningitis caused by CDC group IIe has been reported (253), and the phenotypic characteristics of several clinical isolates of CDC groups IIc and IIg have been described (86, 88).

The appropriate choice of effective antimicrobial agents for treatment of chryseobacterial infections is difficult. *Chryseobacterium* spp. and *E. meningoseptica* are inherently resistant to many antimicrobial agents commonly used to treated infections caused by gram-negative bacteria (aminoglycosides, β-lactam antibiotics, tetracyclines, and chloramphenicol) but are often susceptible to agents generally used for treating infections caused by gram-positive bacteria (rifampin, clindamycin, erythromycin, sparfloxacin, trimethoprim-sulfamethoxazole, and vancomycin) (70, 218, 248). Although early investigators recommended vancomycin for treating serious infection with *E. meningoseptica* (84, 187), subsequent studies showed greater in vitro activity of minocycline, rifampin, trimethoprim-sulfamethoxazole, and quinolones (15, 71, 218). Among the quinolones, sparfloxacin and levofloxacin are more active than ciprofloxacin and ofloxacin (218). Di Pentima et al. (61) suggested that the combination of intravenous vancomycin and rifampin is an appropriate regimen for initial empirical therapy of *E. meningoseptica* meningitis in newborns. *C. indologenes* is reported to be uniformly resistant to cephalothin, cefotaxime, ceftriaxone, aztreonam,

[a] Unless otherwise indicated, data are from the CDC Special Bacteriology Reference Laboratory (256). All taxa were negative (<10% positive) for growth on SS agar, H_2S production in TSI, and ornithine decarboxylase activity. Numbers indicate the percentage positive at 2 days of incubation; parentheses, delayed reaction (3 to 7 days of incubation); w, weak reaction; +, positive; –, negative; ND, not determined or not available; p, polar.

[b] The original description of *C. gleum* lists the type strain as citrate negative. In the original description of *C. indologenes*, 30% of strains (4/13) oxidized mannitol, 46% of strains (6/13) grew on MacConkey agar, and 38% of strains (5/13) reduced nitrate to gas. CDC group IIb includes *C. indologenes* and *C. gleum* (262).

[c] Fewer than five strains tested.

[d] 7 to 14 days of incubation.

[e] The number before the colon indicates the number of carbons; the number after the colon is the number of double bonds; ω, the position of the double bond counting from the hydrocarbon end of the carbon chain; c, *cis* isomer; i, *iso*; a, anteiso; OH, a hydroxyl group at the 2 (α) or 3 (β) position from the carboxyl end; cyc, a cyclopropane ring structure.

aminoglycosides, erythromycin, clindamycin, vancomycin, and teicoplanin, while susceptibility to piperacillin, cefoperazone, ceftazidime, imipenem, quinolones, minocycline, and trimethoprim-sulfamethoxazole is variable, requiring testing of individual isolates (107, 111, 218, 250). Further complicating the choice of appropriate antimicrobial therapy is the fact that MIC breakpoints for resistance and susceptibility of chryseobacteria have not been established by the Clinical and Laboratory Standards Institute (CLSI) and the results of disk diffusion testing are unreliable in predicting antimicrobial susceptibility to *Chryseobacterium* species (1, 31, 71, 250). The E test is a possible alternative to the standard agar dilution method for testing cefotaxime, ceftazidime, amikacin, minocycline, ofloxacin, and ciprofloxacin but not piperacillin (106). Definitive therapy for clinically significant isolates should be guided by individual susceptibility patterns determined by an MIC method.

Weeksella and *Bergeyella*

Weeksella virosa and *Bergeyella zoohelcum* are morphologically similar organisms measuring 0.6 by 2 to 3 μm, with parallel sides and rounded ends. Both species are oxidase positive and indole positive, fail to grow on MacConkey agar, are nonpigmented, and are nonsaccharolytic. Both species have the unusual feature of being susceptible to penicillin, a feature that allows them to be easily differentiated from the related genera of *Chryseobacterium* and *Sphingobacterium*. *W. virosa* colonies are mucoid and adherent to the agar and develop tan to brown pigmentation; *B. zoohelcum* colonies are sticky and tan to yellow. *W. virosa* is urease negative and polymyxin B susceptible; *B. zoohelcum* is rapid urease positive and polymyxin B resistant. *W. virosa* occurs mainly in urine and vaginal samples (99, 196), whereas *B. zoohelcum* is isolated mainly from wounds caused by animal (mostly dog) bites (100, 195). Meningitis or septicemia due to *B. zoohelcum* has occurred in patients either bitten by a dog (23, 163) or with continuous contact with cats (172). Both organisms are susceptible to most antibiotics; however, at present no specific antibiotic treatment is recommended; therefore, antibiotic susceptibility testing should be performed on significant clinical isolates.

Balneatrix

The genus *Balneatrix* contains a single species, *B. alpica* (55), that was first isolated in 1987 during an outbreak of pneumonia and meningitis among persons who attended a hot (37°C) spring spa in southern France (28, 55, 113). Isolates from eight patients were recovered from blood, CSF, and sputum, and one was recovered from water. The bacterium is described as a gram-negative, straight or curved rod, motile by a single polar flagellum, and strictly aerobic. Growth occurs at 20 to 46°C, producing colonies that are 2 to 3 mm in diameter, convex, and smooth. The center of the colonies is pale yellow after 2 to 3 days and pale brown after 4 days. Growth occurs on chocolate and tryptic soy agars but not on MacConkey agar. It is oxidase positive and nonfermentative but oxidizes glucose, mannose, fructose, maltose, sorbitol, mannitol, glycerol, and inositol. Indole is produced and nitrate is reduced to nitrite (Table 7). Gelatin is weakly hydrolyzed and lecithinase is positive. It is similar to *E. meningoseptica* but can be differentiated by positive motility and nitrate and negative ONPG reactions. *B. alpica* is reported to be susceptible to penicillin G and all other β-lactam antibiotics and to all aminoglycosides, chloramphenicol, tetracycline, erythromycin, sulfonamides, trimethoprim, ofloxacin, and nalidixic acid. It is resistant to clindamycin and vancomycin (28).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Although certain nonfermenting bacilli (NFBs) can on occasion be frank pathogens, e.g., *Pseudomonas aeruginosa, Burkholderia pseudomallei,* and *Elizabethkingia meningoseptica,* NFBs are generally considered to be of low virulence and often occur in mixed cultures, making it difficult to determine when to work up cultures and when to perform susceptibility studies. Decisions regarding the significance of NFBs in a clinical specimen must take into account the clinical condition of the patient and the source of the specimen submitted for culture. In general, the recovery of an NFB in pure culture from a normally sterile site warrants identification and susceptibility testing, whereas predominant growth of an NFB from a nonsterile specimen, such as an endotracheal culture of a patient with no clinical signs or symptoms of pneumonia, would not be worked up further. Because many NFBs exhibit multiple antibiotic resistance, patients who are on antibiotics often become colonized with NFBs. NFB species isolated in mixed cultures can usually be reported by descriptive identification, e.g., "growth of *P. aeruginosa* and two varieties of nonfermenting gram-negative bacilli not further identified." The Gram stain made from the clinical material should be used to guide the laboratory decision on how far to work up the specimen.

Decisions about performing susceptibility testing are complicated by the fact that the CLSI interpretive guidelines for disk diffusion testing of the nonfermenting gram-negative bacilli are limited to *Pseudomonas* spp., *Burkholderia cepacia, Stenotrophomonas maltophilia,* and *Acinetobacter* spp. and therefore, except for *Acinetobacter* species, do not include the organisms covered in this chapter. Furthermore, results obtained with certain organisms (e.g., *Acinetobacter* species) by using disk diffusion do not correlate with results obtained by conventional MIC methods (see discussion elsewhere in this chapter). In general, laboratories should try to avoid performing susceptibility testing on the organisms included in this chapter. When clinical necessity dictates that susceptibility testing be performed, an overnight MIC method is recommended.

Bordetella

MICHAEL J. LOEFFELHOLZ AND GARY N. SANDEN

51

TAXONOMY

The genus *Bordetella,* in the family *Alcaligenaceae,* is named for J. Bordet, who, with O. Gengou, described the bacterium in 1906 (9). A total of eight *Bordetella* species have been described: *B. pertussis*, *B. bronchiseptica*, *B. parapertussis*, *B. avium*, *B. hinzii*, *B. holmesii*, *B. trematum* (5, 61), and the recently described species *B. petrii* (96). An additional organism, *B. ansorpii* sp. nov. (50), currently has no standing in nomenclature (http://www.bacterio.cict.fr/nonvalid.html). Phylogenetic analysis based on 16S rRNA gene sequencing has demonstrated that *B. pertussis, B. parapertussis, B. bronchiseptica,* and *B. holmesii* are very closely related (48). *B. pertussis* and *B. parapertussis* may be recent derivatives of *B. bronchiseptica,* developing unique host ranges and pathogenicity due to gene loss (72). In spite of considerable genetic relatedness among some *Bordetella* species, current literature still refers to distinct species. Evidence suggests that the genetic diversity of *B. pertussis* is decreasing, due to selective pressure of vaccination (84). This may be partially responsible for the reemergence of pertussis, as described later in this chapter.

DESCRIPTION OF THE GENUS

Bordetella organisms are small gram-negative coccobacilli. Some species are motile. With the exception of the recently described *B. petrii,* they are strictly aerobic, with optimal growth at 35 to 37°C. All species possess catalase activity. All species oxidize amino acids, but none ferment carbohydrates. While all species have relatively simple nutritional requirements, fastidiousness varies depending on the degree of sensitivity to toxic substances and metabolites found in common laboratory media. *B. pertussis* is the most fastidious species and is inhibited by constituents present in many media, including fatty acids, metal ions, sulfides, and peroxides. Isolation of *B. pertussis* requires media containing protective substances such as charcoal, blood, or starch. The other *Bordetella* species are less fastidious and will grow on routine agars containing blood and on MacConkey agar. Growth rates of *Bordetella* species are generally inversely related to fastidiousness; *B. pertussis* grows slowly, while *B. avium* and *B. bronchiseptica* grow rapidly. *B. petrii* is unique among the *Bordetella* in that it is capable of growth under both aerobic and anaerobic conditions. Table 1 lists some of the common characteristics used to differentiate *Bordetella* species.

B. pertussis produces a number of virulence factors that are responsible for pathogenesis (61). These virulence factors include toxins (pertussis toxin, adenylate cyclase toxin, and tracheal cytotoxin) and components that mediate adherence to ciliated epithelial cells of the respiratory tract (pertussis toxin [PT], fimbriae, filamentous hemagglutinin [FHA], and pertactin). Other virulence factors include dermonecrosis (heat-labile) toxin, lipopolysaccharide (endotoxin), and tracheal colonization factor. *Bordetella* species other than *B. pertussis* also express virulence factors. *B. parapertussis* and *B. bronchiseptica* produce pertactin and FHA (61). Promoter and structural genes for PT are present in both *B. parapertussis* and *B. bronchiseptica* but are not expressed.

NATURAL HABITATS

With the exception of *B. petrii, Bordetella* species are isolated from humans and warm-blooded animals. *B. petrii,* the sole environmental species, was isolated from an anaerobic culture enriched from river sediment (96). *B. pertussis* produces disease only in humans, who also serve as the sole reservoir. *B. parapertussis,* once thought to be strictly a human pathogen, is also found in sheep (61). Genotypic strain analysis showed that human and ovine *B. parapertussis* strains are distinct (93). *B. pertussis* has historically been considered a strict respiratory pathogen, causing localized infection of the ciliated epithelium of the bronchial tree. However, its isolation from blood indicates the potential for invasive infection (13, 47). *B. bronchiseptica* is a respiratory tract pathogen of a variety of animals, including dogs, swine, cats, and rabbits (61). *B. avium* is found in wild and domesticated birds and causes coryza in turkeys (75). *B. hinzii* colonizes the respiratory tracts of poultry, and recent evidence suggests that it may cause disease (78). An organism isolated from a cancer patient undergoing chemotherapy has been designated *B. ansorpii* sp. nov., based on 16S rRNA gene sequence, cellular fatty acid composition, G+C content, and biochemical testing. Although recovered from the exudate from an epidermal cyst, a pathogenic role for this isolate was not established (50). On rare occasions *B. bronchiseptica* and *B. hinzii* cause disease in humans (19, 102). *B. avium* is strictly a veterinary pathogen. *B. holmesii* and *B. trematum* are infrequently associated with nonrespiratory infections in humans (88, 90). Additionally, *B. holmesii* has been linked to respiratory infections with pertussis-like symptoms (103).

CLINICAL SIGNIFICANCE

The incubation period of pertussis is usually 7 to 10 days, with a range of approximately 4 to 21 days (12). The symptoms that develop following the incubation period can be classified as either typical (classical) or atypical. Classical pertussis consists of a catarrhal stage lasting 1 to 2 weeks, a paroxysmal stage lasting 1 to 6 weeks (as long as 10 weeks), and a convalescent stage lasting 2 to 4 weeks (as long as several months). Patient symptoms during the catarrhal stage are nonspecific and include rhinorrhea, sneezing, low-grade fever, and occasional mild cough. Pertussis is frequently unsuspected during this period. The paroxysmal stage of pertussis is characterized by the presence of one or more of the pathognomonic signs of pertussis: episodes of paroxysmal cough, whoop, and posttussive vomiting. The severity of respiratory symptoms gradually decreases during the convalescent stage. Atypical symptoms in older children and adults consist of a prolonged, nondescript cough. The differential diagnosis of atypical pertussis includes bronchitis and upper respiratory tract infections caused by adenovirus, parainfluenza virus, respiratory syncytial virus, *Chlamydophila* (formerly *Chlamydia*) *pneumoniae,* and *Mycoplasma pneumoniae* (29, 30). Infants with pertussis may present with choking and apnea, while cough may be absent. Morbidity and mortality rates are higher in infants than in other age groups (61). Adults experience more complications from pertussis than do adolescents (21). *Bordetella* infections have recently been shown to play a major role in acute exacerbation of chronic bronchitis (8).

B. pertussis is responsible for the vast majority of pertussis cases and causes more-severe respiratory symptoms than other *Bordetella* species associated with pertussis syndrome. Worldwide, *B. pertussis* causes an estimated 20 million to 40 million cases of pertussis and 200,000 to 400,000 deaths each year, primarily among children in countries lacking organized vaccination programs (http://www.who.int/vaccines/en/pertussis.shtml#summary). *B. pertussis* is transmitted from person to person via respiratory droplets and is highly contagious, infecting 80 to 90% of susceptible contacts (12). Relatively close contact (within several feet) is required for transmission. Transmission is not uncommon in health care facilities and can be associated with high rates of morbidity in this high-risk setting (14).

A carrier state is not recognized for *B. pertussis.* Sensitive nonculture tests such as PCR can detect organisms in asymptomatic immune persons (35), but this is more likely to represent a transient colonization or infection rather than a prolonged carrier state. The disease is endemic, with epidemics consistently occurring every 3 to 5 years (12). The number of reported pertussis cases in the United States has increased steadily since the 1980s, in spite of continued high levels of vaccination coverage. Explanations offered for the increased incidence include heightened awareness and reporting of disease (particularly the atypical presentation, and disease in older persons), and the use of more sensitive laboratory diagnostic tests.

Immunity to pertussis following natural infection or vaccination wanes after 5 to 12 years. As a result, *B. pertussis* is a significant cause of respiratory disease in older children and adults (15, 61, 87) who, in countries with vaccination programs, have replaced young children as the primary reservoir of *B. pertussis.* Serologic evidence indicates that as much as one-third of chronic cough illness in adults is due to *B. pertussis* (15). However, in some studies in which culture was performed, *B. pertussis* was not isolated from any seropositive subjects (64). Therefore, the public health significance of this high seroprevalence is unclear.

Vaccines have dramatically reduced the public health impact of pertussis. The initial heat-killed, whole-cell vaccines have been largely replaced by multicomponent acellular vaccines, which are associated with fewer side effects (73). The efficacy of whole-cell and acellular vaccines is estimated to be between 60 and 90% (12). Until recently, available pertussis vaccines had been formulated and licensed for children younger than 7 years. However, two aspects of recent pertussis epidemiology have stimulated evaluations of the immunogenicity and safety of acellular vaccines in older persons (10). The first is the recognition of the importance of *B. pertussis* as a cause of respiratory disease in adolescents and adults (61, 87); the second is the accumulating evidence for the predominant role of adolescents and adults in transmission of pertussis to infants (7). Acellular booster doses are licensed in Australia, Austria, Canada, France, and most recently, the United States (http://www.cdc.gov/nip/vaccine/tdap/tdap_acip_recs.pdf) for administration to adolescents or adults. Vaccination (with either acellular or whole-cell vaccine) may be selecting for *B. pertussis* strains distinct from those from the prevaccination era (66, 84). The role of the divergence between vaccine and recently circulating strains in the changing epidemiology of pertussis over the last 20 years is still uncertain. There is no epidemiological evidence to suggest that vaccine efficacy in the United States has been compromised by the divergence of circulating strains. Vaccines directed against *B. pertussis* do not confer protection from infections by other *Bordetella* spp.

Septicemia caused by *B. pertussis* has been reported only rarely, but blood cultures showing gram-negative bacilli that

are not recovered on routine subculture media should be subcultured on media supporting *B. pertussis* (13, 47).

B. parapertussis causes a pertussis syndrome similar to but usually less severe than that caused by *B. pertussis* (61). While *B. parapertussis* may be quite prominent in isolated outbreaks (56), overall it accounts for 2 to 20% of *Bordetella* isolates (61). Symptomatic *B. parapertussis* infections more commonly present as a nonspecific cough illness or bronchitis. Mixed infections by *B. pertussis* and *B. parapertussis* have been reported, and this should be considered when examining primary cultures from clinical specimens (56). *B. bronchiseptica* (23, 102) and *B. holmesii* (81, 103) have been implicated as infrequent causes of pertussis syndrome and other respiratory illnesses. *B. holmesii* is also a rare cause of bacteremia in asplenic patients (85). Most reported cases of *B. bronchiseptica* respiratory disease have been associated either with underlying conditions such as immunosuppression or with exposure to animals. *B. bronchiseptica* has been associated with pleural effusion in a patient with AIDS (94) and pneumonia in lung transplant recipients (71). *Bordetella* species isolated from cystic fibrosis patients include *B. bronchiseptica* (99) and *B. hinzii* (18).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Excellent summaries of specimen collection and handling for optimal detection of *B. pertussis* are available (70), including several earlier editions of this Manual. Preferred specimens for laboratory diagnosis of pertussis are nasopharyngeal (NP) aspirates and posterior NP swabs. When properly collected, these specimens contain the ciliated respiratory epithelial cells for which *B. pertussis* exhibits tropism. NP aspirates yield more positive culture results than do NP swabs (31). Aspirates offer additional advantages over swabs; there is usually sufficient specimen for multiple analyses (important when verifying new test procedures), and the specimen collection technique may be preferred by clinicians and parents of young patients (31). Throat swabs are inferior specimens for culture; they do not sample the ciliated epithelium, and they contain large numbers of members of the normal flora, which can result in overgrowth of isolation media. In one study, significantly fewer infections were detected by culture using throat swabs than by culture using NP swabs (60). However, throat swabs may be suitable for PCR diagnosis of *B. pertussis* infection (25).

To obtain an NP aspirate, a narrow catheter or infant feeding tube is inserted through the nostril to the posterior nasopharynx. A mucous trap and hand-operated vacuum pump are connected to the other end, and suction is applied while the tube is in place and while slowly withdrawing it back through the nostril. Any secretions remaining in the tube should be flushed into the trap by aspirating *Bordetella* transport medium or phosphate-buffered saline. Additionally, the catheter tip can be cut off and placed into suitable transport medium for shipping. Swab specimens are collected by inserting a small swab on a flexible (usually aluminum wire) shaft through the nostril. The placement of the swab is important. Figure 1 depicts the correct positioning of the patient's head and placement of the swab. The swab should then be rotated for several seconds before being withdrawn. It is generally recommended that two NP swab specimens be collected, one through each nostril. This provides separate swabs if multiple laboratory tests are to be performed. Specimens are then either directly plated or placed in a suitable medium for transport.

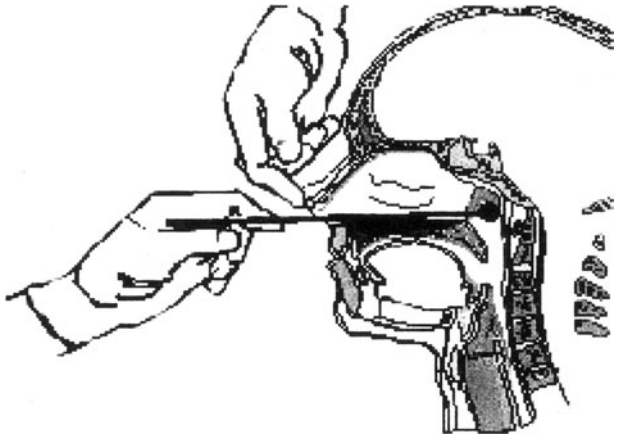

FIGURE 1 Correct positioning of patient's head and placement of the swab for collection of NP specimens (reprinted from reference 12). (Courtesy of Kris Bisgard, Centers for Disease Control and Prevention.)

Several transport media are readily available for NP specimens, including 1% acid-hydrolyzed casein (Casamino Acids; Becton Dickinson, Sparks, Md.) and Amies medium with charcoal. Survival of *B. pertussis* at 4°C in Casamino Acids was substantially greater than in water or phosphate-buffered saline (11). Regan-Lowe (RL) transport medium contains half-strength charcoal agar and horse blood, with cephalexin added to suppress growth of the normal NP flora. Substitution of 2.5 μg of methicillin per ml or 0.625 μg of oxacillin per ml for cephalexin reportedly allows the growth of *B. holmesii* (62). Unlike Casamino Acids and Amies medium, RL transport medium also functions as an enrichment medium for *B. pertussis*. Preincubation of specimens in RL transport medium is controversial. Preincubation at 36°C may enhance the recovery of *B. pertussis* due to multiplication of organisms (76). Some recommend against preincubation because of overgrowth of cephalexin-resistant members of the flora (12). Transport at 4°C provides better recovery of *B. pertussis* than does transport at room temperature (33, 68) but adds additional costs due to packaging and weight.

Swab material should be calcium alginate, Dacron, or rayon if culture isolation is to be performed (17, 44). Cotton contains inhibitors that will decrease isolation rates of *B. pertussis* (44). Dacron or rayon is recommended if PCR testing is performed, since calcium alginate can inhibit PCR (17, 97). The inhibitory effect of calcium alginate on PCR amplification may depend in part on the specimen extraction procedure. Crude proteinase K extracts were completely inhibitory to PCR (97).

Because of the lability of *B. pertussis* outside its normal host environment, proper handling and shipping conditions are critical for optimal culture sensitivity. For culture testing, direct plating of NP specimens onto agar plates provides optimal sensitivity. Kurzynski et al. showed that 14% more NP swab specimens were positive by a plate inoculated bedside than by a plate inoculated after enrichment and transport (54). However, this requires clinician participation and training and is not practical for off-site reference and public health laboratories.

For direct fluorescent-antibody (DFA) testing, the specimen collection kit should contain a glass slide, on which a smear is prepared from an NP swab immediately after collection. The slide is allowed to air dry and is then transported

to the laboratory. Alternatively, smears can be prepared at the laboratory from liquid transport medium containing an NP swab or from NP aspirates.

For PCR testing, swabs can be transported dry (57), in transport medium, or in saline. Transport in liquid medium provides a specimen from which multiple aliquots can be tested, whereas processing a dry swab for PCR testing leaves no unextracted specimen material available for repeat analysis if required. Detailed consensus recommendations for managing specimens for PCR are available elsewhere (80).

DIRECT DETECTION

DFA Testing

The direct detection of *B. pertussis* in NP secretions by using fluorochrome-conjugated antibody provides the most rapid and simple diagnosis of pertussis. Commercially available antibodies are polyclonal (Becton Dickinson) or monoclonal, recognizing a lipooligosaccharide epitope (Accu-Mab; Altachem Pharma, Edmonton, Alberta, Canada) (1). The monoclonal antibodies are available as a dual-fluorochrome reagent for the detection of both *B. pertussis* and *B. parapertussis* in a single smear. A head-to-head comparison of the polyclonal and monoclonal reagents showed that they had similar sensitivity (89). Factors to consider when choosing an antibody source include cost and performance in the laboratory's own hands.

Regardless of the antibody used, the direct detection of *B. pertussis* by DFA lacks both sensitivity and specificity. Compared to that of culture, DFA sensitivity in several published studies ranged from 30 to 71% (32, 57). DFA-positive, culture-negative specimens are not unusual. When DFA was compared to an expanded diagnostic standard (e.g., two positive nonculture tests or a clinical diagnosis), its sensitivity ranged from one-half that of culture (32) to threefold greater than that of culture (57). The large range in DFA performance reflects variation in the sensitivities of both the DFA procedure and the culture procedures against which it is compared. The specificity of DFA is highly variable, due to the cross-reactivity of immunological reagents and the subjectivity of fluorescence interpretation. Weak cross-reactivity of the Accu-Mab monoclonal antibody with *B. bronchiseptica* has been reported (63). Polyclonal antibodies cross-react with a number of organisms, including unencapsulated *Haemophilus influenzae* and diphtherioids (61). In a study conducted by Loeffelholz et al., several specimens positive only by DFA were considered to be true positives because of strong clinical or epidemiological evidence of infection (57). Other studies have shown extremely poor DFA specificity (32). Notwithstanding the variable performance, DFA testing can provide valuable information when appropriate quality assurance and quality control measures are implemented to maximize specificity. DFA testing should be performed only as an adjunct to culture or PCR, and the results should be considered presumptive.

Antibody for DFA testing must be appropriately titrated before use. To control for staining specificity, control slides should contain separate smears of *B. pertussis* and *B. parapertussis*. Smears should contain 10 to 100 organisms per oil immersion field. Suspensions of control organisms can be prepared in phosphate-buffered saline with a turbidity equivalent to a McFarland standard of 1. Stained smears are examined under a fluorescent microscope for the presence or absence and degree of fluorescence. Slides are viewed initially at a magnification of ×400. Any fluorescence is examined at a magnification of ×1,000 to confirm morphology. *Bordetella* organisms appear as small coccobacillary rods with pronounced peripheral apple green fluorescence and dark centers. Fluorescence must be intense, and other staining characteristics and morphology must be ignored.

Nucleic Acid Detection

Nucleic acid detection methods such as PCR can provide a test response time similar to that of DFA, while offering enhanced sensitivity and objectivity in results interpretation. These advantages, together with the continuing loss of expertise in interpreting DFA results, have contributed to the ascension of PCR over DFA as the routine nonculture test method in many clinical laboratories. Although the Centers for Disease Control and Prevention recommended in 2000 that PCR be used as a presumptive assay in conjunction with culture (12), this test is rapidly moving from presumptive to diagnostic status and becoming more available.

PCR clinical sensitivity suffers from the same constraints associated with other detection methods, including specimen quality and timing in the disease course and antimicrobic treatment. However, PCR has consistently been reported to be more sensitive than DFA or culture (25, 27, 28, 34, 35, 57, 91, 98). The superiority of PCR performance over that of culture is due in part to variation in the sensitivity of culture. PCR tests themselves vary in sensitivity, depending on the nucleic acid extraction method, the amount of specimen amplified, the amplification conditions and efficiency, the sequence targeted, and the DNA detection format. Presumably because of its greater sensitivity and ability to detect dead organisms, PCR remains positive longer during the course of disease than does culture (91, 98) and is more likely to remain positive following antibiotic therapy (24, 98). Longitudinal analysis of erythromycin-treated infants showed that after 4 days of treatment, 56 and 89% of NP swab specimens were positive by culture and PCR, respectively (24), whereas after 7 days of treatment, no specimens were positive by culture but 56% were still positive by PCR. The higher sensitivity of PCR is also marked among persons with mild or atypical symptoms (83) and among older persons (91, 98).

Despite the increasing use of PCR methods to diagnose pertussis, these assays continue to demonstrate significant shortcomings. There is no standardized or Food and Drug Administration (FDA)-cleared, commercially available PCR test for *B. pertussis* and *B. parapertussis*. In fact, many assays fail to test for *B. parapertussis*, which remains a significant cause of pertussis in some outbreaks (56). Validation criteria vary by regulatory program, but extensive method validation on the part of the laboratory is required before the test can be offered for diagnostic use. Unfortunately, the validation process is easily compromised by insufficient availability of positive specimens and inadequate resolution of discrepant results between the PCR test and the diagnostic standard, especially when the PCR is positive and the comparative standard is negative. The validation criteria specified by the Clinical and Laboratory Standards Institute (http://www.nccls.org) are helpful in designing a validation program and would likely satisfy all state criteria. The laboratory must also develop and implement quality control and an ongoing quality assurance program; these requirements also vary by regulatory program. A widely available and independently certified proficiency testing program is lacking, so it is currently difficult to assess interlaboratory performance.

Because PCR detects nonviable cells and DNA, defining the clinical sensitivity and specificity of PCR tests for pertussis

is critical. However, these predictive values for pertussis PCR remain incompletely defined, especially regarding the effect on these values of pertussis prevalence in the host community, host vaccination status and age, and disease severity. Interpretation standards should include relevance of unpredicted results such as multiple consecutive positives. Similarly, results reporting formats also must reflect these limitations and the clinical community must be educated regarding test limitations and reporting criteria. It is strongly recommended that positive test results be confirmed with an additional laboratory test or clinical pertussis ascertainment, until PCR clinical sensitivity and specificity values are more completely defined.

Consensus recommendations for the diagnosis of *B. pertussis* and *B. parapertussis* infections by PCR have been proposed (80). These recommendations focus heavily on quality assurance and control, verification of assay performance (clinical sensitivity and specificity and analytical specificity), and ongoing validation studies and also describe appropriate sample collection, transport, pretreatment, and DNA extraction. Chapter 16 of this Manual describes good laboratory practices to avoid false-positive PCR results due to contamination. Positive and negative controls must be able to monitor the entire PCR assay procedure, including specimen extraction. Internal specimen amplification controls should be included for each specimen; ideally these would be amplified by the same primers as the diagnostic target (36). While there are no established guidelines about the number of negative controls to include in each run, some laboratories routinely include a negative control for approximately every five specimens.

Chromosomal regions targeted by PCR include, but are not limited to, the pertussis toxin promoter region (28, 45), a region upstream of the porin gene (26), repetitive insertion sequences IS*481* of *B. pertussis* (27, 34, 92) and IS*1001* of *B. parapertussis* (92), the adenylate cyclase gene (22), and a region upstream of the flagellin gene (46). A set of primers targeted to the toxin promoter was shown not to detect *B. parapertussis* or *B. bronchiseptica* (28, 45). Primers targeting IS*481* have been shown to detect *B. holmesii* (58) and may cross-react with other *Bordetella* spp. (80). Carriage of IS*481* by strains of several *Bordetella* species makes monitoring the specificity of IS*481* necessary (80). Nested-PCR assays for the detection of *Bordetella* have been described (25, 79). While these assays were reported to be sensitive and specific, nested PCR is inherently more susceptible to contamination than unnested PCR. It is our opinion that when PCR conditions are properly optimized, nesting of PCR is not required for the accurate, sensitive diagnosis of most infectious diseases, including pertussis.

ISOLATION

Culture provides the most specific diagnosis of pertussis and produces isolates for genotypic analysis and antimicrobial susceptibility testing. The sensitivity of culture varies greatly, depending on patient factors (including prior antibiotic therapy, duration of symptoms, age, and vaccination status), specimen transport conditions, the type and quality of media used, and other conditions (38). While PCR testing is also affected by these factors, culture is affected to a greater degree because of its requirement for viable organisms. The highest isolation rates are achieved when specimens are inoculated onto media immediately after collection from the patient. Since this is often not possible, transport media should be used.

Several media for the isolation of *B. pertussis* have been described. Traditional media consist of bases such as potato infusion (Bordet-Gengou [BG] medium) or charcoal (RL medium) supplemented with glycerol, peptones, and horse or sheep blood. An antimicrobial agent is added to reduce the growth of the normal flora. Cephalexin is the agent of choice, yet growth of resistant members of the NP flora is still quite common (70). RL medium provides better isolation of *B. pertussis* than does BG medium (68, 70). The shelf life of media ranges from 5 days for BG medium to 4 to 8 weeks for RL medium (76).

Plates are incubated in ambient air at 35 to 36°C and examined daily for suspicious colonies. In one study, *B. pertussis* colony development was more rapid in ambient air than in air containing 5 to 10% carbon dioxide (43). The humidity must be sufficient to prevent the desiccation of agar plates during the long incubation period. While most *B. pertussis* colonies become visible after 3 to 4 days of incubation (*B. parapertussis* becomes visible after 2 to 3 days), an incubation time of 7 days has historically been recommended. In one study, 12 days of incubation recovered more isolates than did 7 days of incubation (49).

IDENTIFICATION

Phenotypic

On RL agar, young *B. pertussis* colonies are round, domed, mercury-silver colored, and shiny. *B. parapertussis* colonies are similar but are grayer and less domed (Fig. 2). On BG agar, *B. pertussis* and *B. parapertussis* produce zones of hemolysis.

Bordetella organisms appear as gram-negative coccobacilli or short rods. Poly- or monoclonal antibodies are available to confirm identity (Fig. 3). Suspensions of colonies are prepared in phosphate-buffered saline and should be dilute to avoid dulling of fluorescence. Both *B. pertussis* and *B. parapertussis* controls should be included. Fluorescence is interpreted as described earlier in this chapter. For identification by slide agglutination, a heavier suspension is prepared, equivalent to a McFarland standard of 3. Uniform suspensions are best prepared from cultures no more than 3 days old and harvested with a Dacron or rayon swab instead of a bacteriological loop. Cell aggregates can be dispersed by repeatedly forcing the suspension through a pipette and using aerosol precautions. Colonies grown on antibiotic-free RL agar produce more homogeneous suspensions for easier interpretation of agglutination. In addition to identification using specific antisera, *Bordetella* species can be identified by biochemical tests based on differential phenotypic characteristics (Table 1). Oxidase-positive, nonfermentative gram-negative rods, particularly *Oligella ureolytica* and *Ralstonia paucula,* can be misidentified as *B. bronchiseptica. B. bronchiseptica* differs from *R. paucula* by having a positive nitrate reduction test and from *O. ureolytica* by having a negative nitrite reduction test and by showing penicillin susceptibility.

Commercially obtained strains (American Type Culture Collection, Manassas, Va.) or previously characterized clinical isolates can serve as controls for quality control of media and reagents. Clinical isolates should be frozen as soon as possible at −70°C in glycerol. Once plated, cultures lose viability quickly and must be replaced regularly. As per Clinical Laboratory Improvement Amendment regulations, laboratories must maintain thorough documentation of control strains, including strain source/origin and storage conditions. Standard operating procedures must be developed for the maintenance of control strains.

Biosafety level 2 practices are recommended when working with *Bordetella* spp. Routine manipulations of specimens and isolates can be conducted on open bench tops.

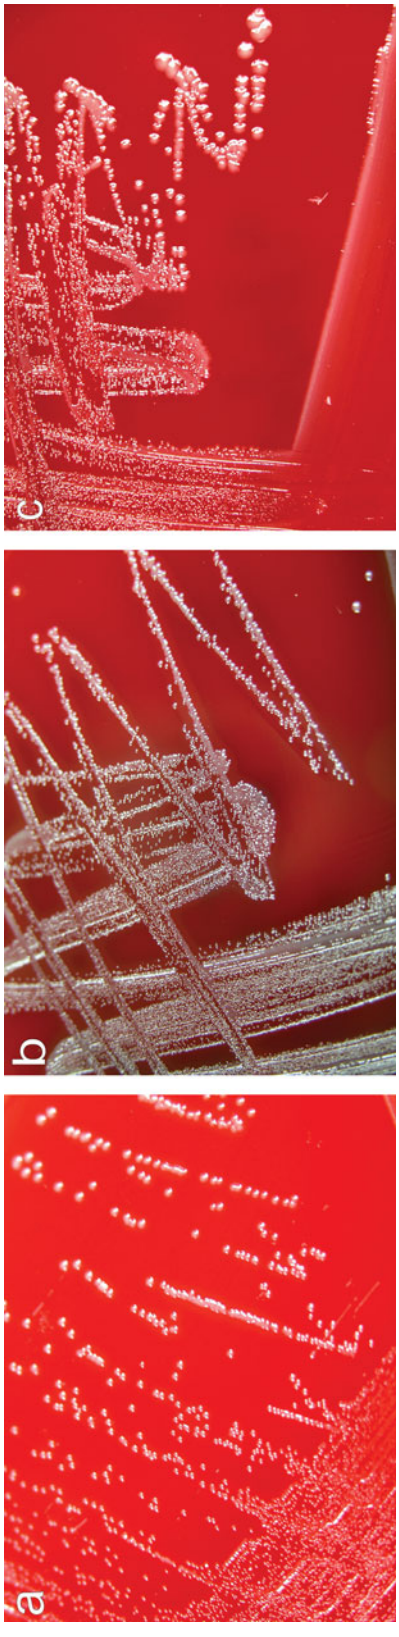

FIGURE 2 Colony morphologies of *Bordetella* after 3 to 5 days of incubation on BG agar. (a) *B. pertussis*; (b) *B. parapertussis*; (c) *B. bronchiseptica*.

Genotypic Strain Typing

Pulsed-field gel electrophoresis (PFGE) methods for the identification of *B. pertussis* strains have been described previously (12, 67). PFGE has been proven to be valuable in tracking outbreak transmission patterns (12, 65). It has also been used to identify *B. parapertussis* (74) and *B. bronchiseptica* isolates (6). The rare-cutting restriction enzyme XbaI is used in most PFGE procedures for typing *B. pertussis, B. parapertussis,* and *B. bronchiseptica* (6, 12, 74). Other genotypic methods used to discriminate *Bordetella* isolates include restriction enzyme analysis (82), arbitrarily primed PCR (randomly amplified polymorphic DNA) (104), PCR targeting a specific repetitive element (65), ribotyping (77), sequence analysis of genes encoding pertactin and the S1 fragment of pertussis toxin (67), and multilocus variable-number repeat analysis (84). Comparative analysis of PFGE and PCR-based typing methods for discrimination of *B. pertussis* isolates showed PFGE to be more discriminatory (65). Standardized approaches to genotypic analysis of *B. pertussis* isolates have focused on PFGE, largely due to the wide availability and demonstrated epidemiological relevance of this approach (12, 67).

SEROLOGIC TESTS

Serologic diagnostic methods are generally limited to the detection of immune responses to *B. pertussis*. In the past, these methods included enzyme-linked immunosorbent assay (ELISA), agglutination, complement fixation, immunoblotting, indirect hemagglutination, and toxin neutralization (70). Assays other than ELISAs, immunoblotting, and toxin neutralization are not common in clinical laboratories. The toxin neutralization assays are generally limited to reference and research institutions to measure functional serum antibodies. Because of ease of use and sensitivity, ELISAs in microwell plate format have become the method of choice.

ELISAs have been used to measure immunoglobulin A (IgA), IgG, and IgM levels to PT, FHA, pertactin, fimbriae, and sonicated *B. pertussis* cells. As measured by ELISAs, at least 90% of infected persons develop IgG to PT and FHA after ⩾3 to 4 weeks following onset of symptoms (70). IgG and IgA responses to these antigens are most often used as indicators of *B. pertussis* infection. Responses to PT are specific for *B. pertussis,* since no other *Bordetella* species expresses PT. FHA is expressed by *B. pertussis*, *B. parapertussis,* and *B. bronchiseptica.* Other bacteria, including *Haemophilus influenzae,* possess epitopes that cross-react with FHA (95). Clinical sensitivity of IgA-specific responses is not as great as for IgG responses, but IgA is rarely detected in uninfected vaccines, and therefore, such responses enhance clinical specificity when present (70, 91). IgM responses do not increase clinical sensitivity and specificity sufficiently over those for IgA and IgG to be widely tested.

The specific strategy used for the serodiagnosis of pertussis is often a function of patient age and vaccination status, and sensitivity and specificity may vary. Currently, the demonstration of seroconversion or a significant rise in the concentration of IgG against PT is widely accepted as the most sensitive and specific serodiagnostic test. Consequently, a suitable strategy for serologic diagnosis in unvaccinated children is the demonstration of increases in the concentrations of IgG or IgA to PT or FHA, although young infants may not produce IgA (91). However, the appropriate collection of acute and convalescent serum specimens is often problematic in pertussis patients of any age (61, 86). True acute-phase specimens are often

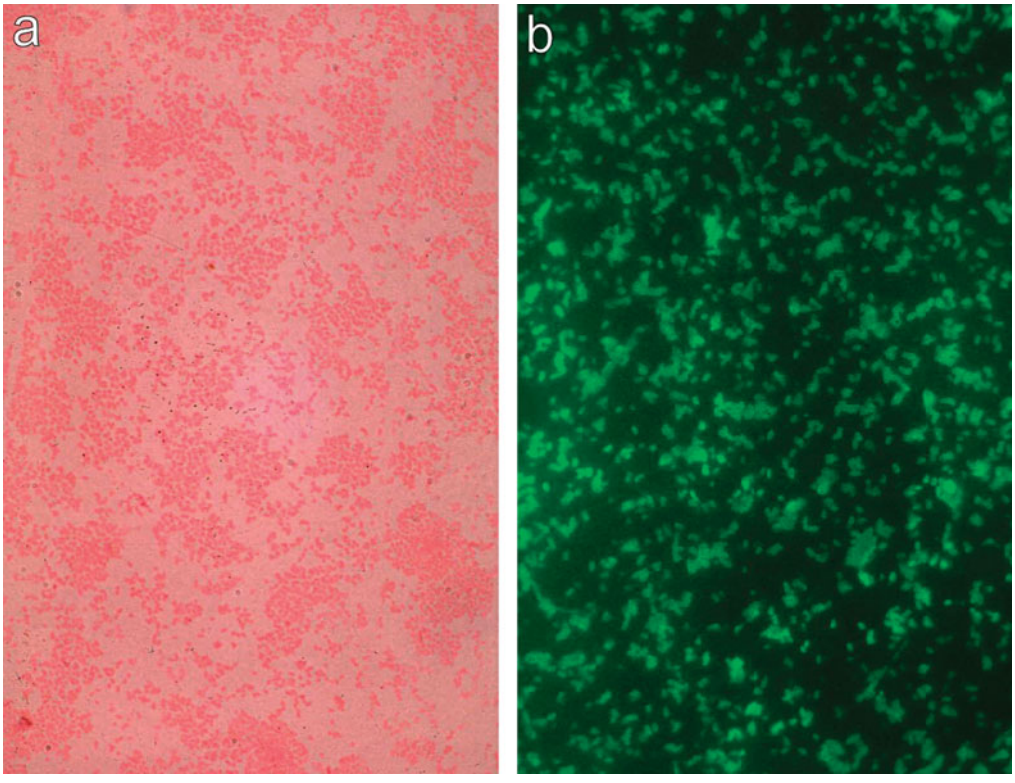

FIGURE 3 (a) Gram stain morphology of *B. pertussis*. (b) Immunofluorescent staining of *B. pertussis*. (Photographs courtesy of Charlotte Parker.)

excluded by the clinical presentation of patients late in the illness due to the nonspecific symptoms early in disease, and convalescent-phase specimens can be compromised by poor patient compliance with recall. Testing of single specimens collected early in the disease (1 to 3 weeks after onset of cough) was reportedly compromised by low sensitivity (101).

Serodiagnosis of pertussis in vaccinated children is even more problematic due to rapid increases in antibody concentration and the consequent difficulty in detecting significant rises in these responses. The tendency to collect "acute"-phase specimens late in this population further contributes to this problem. These conditions among vaccinees suggest that a significant decrease in specific antibodies between late acute- and convalescent-phase specimens may be a valid diagnostic criterion, and one report has demonstrated the feasibility of this approach (86).

Since obtaining acute- and convalescent-phase specimens is problematic, serodiagnosis of pertussis in adolescents and adults based on high antibody concentrations in a single specimen is an attractive strategy (70). The general waning of vaccine-induced serum antibodies in these populations further promotes this approach. Until recently, results from single-serum specimens required interpretation in the context of control values determined for a specific patient population. Epidemiologic studies can stringently identify case-patient controls by age and vaccination status in order to derive serodiagnostic control (cutoff) values related to their study population (16). Although these diagnostic values are limited to specific study populations, potential single-serum IgG anti-PT diagnostic levels with more general diagnostic relevance are emerging from longitudinal studies of the kinetics of IgG anti-PT responses and seroepidemiologic studies of representative samples of populations (4, 20). The specificity of this approach depends on the particular assay and cutoff used. Diagnostic sensitivity has not been widely evaluated for any of the currently proposed diagnostic cutoffs (20).

IgA-, IgG-, and IgM-specific ELISAs are available from a number of manufacturers on several continents, and the immunoblot format is also commercially available (MarBlot; Trinity Biotech, Wicklow, Ireland). Although there is currently no FDA-cleared serodiagnostic test, ELISAs are widely used outside the United States, particularly for testing adolescents and adults. In the United States, the lack of an FDA-cleared test and inadequate supply of standard reference serum specimens severely restrict the use of diagnostic ELISAs. Comparative analyses of serologic testing, culture, DFA, and PCR have generally shown serologic testing to be the most sensitive method for diagnosis of *B. pertussis* infections (28, 32, 91). In one study, PCR was positive for only 21% of patients with positive serology (either high IgG or IgA concentrations in a single specimen or significant increases in antibody concentrations in paired specimens) (91). The authors attributed the low sensitivity of PCR to the collection of specimens relatively late in disease. The same study demonstrated that the sensitivity of both PCR and culture decreases rapidly after the paroxysmal phase. An evaluation of several commercial IgG-based ELISAs showed that individual assay reproducibility was acceptable, but results between tests and between test and reference assays were not concordant (52). Sensitivities with challenge paired serum specimens were 60 to 95%, but none of the assays identified all cases correctly.

ANTIMICROBIAL SUSCEPTIBILITY

Erythromycin, azithromycin, and clarithromycin are the antimicrobial agents of choice for treatment and prophylaxis of pertussis (3, 69). Trimethoprim-sulfamethoxazole (SXT) is an acceptable alternative for patients intolerant of macrolides and for the rare pertussis case caused by macrolide-resistant *B. pertussis* (40). Among the fluoroquinolones, ciprofloxacin, levofloxacin, and gemifloxacin showed the highest activities against *B. pertussis* (42, 69) but are not recommended for treating children because of their potential harmful side effects. The most recent treatment and prophylaxis recommendations can be seen at http://www.cdc.gov/nip/publications/pertussis/guide.htm and http://www.cdc.gov/nip/publications/pertussis/chapter3a_update_macrolides.pdf.

Eleven instances of erythromycin resistance in *B. pertussis* have been reported from Arizona, California, Georgia, Minnesota, New York, and Utah since 1994 (2, 51, 55; K. Bromberg, personal communication), but the true prevalence of resistance in the circulating population is unknown. Susceptibility screening of *B. pertussis* isolates at several enhanced pertussis surveillance sites suggests that the prevalence of resistant strains is too low to justify routine testing of all isolates. However, resistant *B. pertussis* isolates have demonstrated wide geographic distribution and been associated with treatment failure. Consequently, surveillance for resistant organisms is recommended and isolates should be tested if associated with treatment failure (12). Resistance in *B. pertussis* is conferred by a mutation in the macrolide binding domain of the 23S rRNA.

A novel heterogeneous erythromycin resistant/susceptible phenotype has been described (100). This phenotype is distinguished by the appearance of two colony types during the resistance screening test. The first type manifests as susceptible with a zone of inhibition >40 mm after 3 to 4 days of incubation. The second colony type appears up to 8 days later within the zone of inhibition defining the susceptible type. Subculture and susceptibility testing of the resistant colonies yield uniformly resistant cultures, whereas the susceptible phenotype recapitulates the original phenotype with both the resistant and susceptible colonies.

While antibiotics are generally less active against *B. parapertussis* than against *B. pertussis* (53), *B. parapertussis* is susceptible to macrolides, fluoroquinolones, and SXT (39, 69). *B. bronchiseptica* and other *Bordetella* species generally have antimicrobial susceptibility profiles similar to those of other nonfermentative gram-negative bacilli.

Antibiotic susceptibility testing of *B. pertussis* is not standardized. Reported methods include the E test (AB Biodisk, Solna, Sweden), agar dilution, and disk diffusion using a 15-μg erythromycin disk (12, 37, 41, 51). Agar dilution has been performed with Mueller-Hinton agar supplemented with 5% horse blood (41), as well as BG agar containing 20% horse blood (37). RL agar without cephalexin is commonly used for the disk diffusion and E-test methods (37, 55). In most studies, agar dilution has served as the reference method; erythromycin MICs for 47 susceptible isolates were ≤12 μg/ml (37). It is recommended that strains determined to be nonsusceptible by disk diffusion also be tested by agar dilution (12). Studies have demonstrated good agreement among diffusion tests and agar dilution for determining erythromycin resistance in *B. pertussis* (37, 51). Less agreement was observed when testing SXT (37).

EVALUATION AND INTERPRETATION OF RESULTS

The diagnosis of pertussis can be challenging, given the frequent atypical presentation and the shortcomings of laboratory tests. Indeed, no single laboratory test can be considered a perfect diagnostic standard. While culture is virtually 100% specific, its sensitivity is often low due to poorly collected specimens, long specimen transport time, and patient factors such as duration of symptoms and prior antibiotic treatment.

Nucleic acid amplification methods such as PCR generally offer greater sensitivity than does culture. PCR has frequently been shown to provide the specific diagnosis of pertussis when culture is negative. The major shortcomings of nucleic acid amplification methods are the potential for false-positive results due to contamination, the lack of standardization among assays, and the interpretation of a positive result for *B. pertussis* DNA in the absence of a positive culture. While the combination of a positive PCR result and a negative culture result for the same patient can reflect the greater sensitivity of PCR, there are situations when a positive PCR result alone may not have clinical or public health relevance. Therefore, positive PCR results must be interpreted in conjunction with patient symptoms, treatment status, and epidemiological factors. Culture, serology, and, to a greater extent, PCR have shown that asymptomatic *B. pertussis* infections occur (35, 59). In one study, 92% of preschool-aged children with positive PCR results remained free of symptoms during a 6-week follow-up period (35). The authors attributed this to protective immunity. Comparatively, only one-third of older, school-age children remained asymptomatic throughout the follow-up period. During pertussis outbreaks, laboratories may be pressured to test specimens from asymptomatic contacts of patients. In fact, while these individuals may share a day care center or school classroom with a patient, they often do not meet the criteria for exposure to *B. pertussis.* Positive laboratory results (usually by the sensitive PCR test) for these asymptomatic persons confound treatment and outbreak response decisions. Given the general belief that a long-lasting carrier state for pertussis does not exist, PCR-positive asymptomatic persons are unlikely to contribute significantly, if at all, to the spread of pertussis.

Serology has the potential to contribute substantially to the diagnosis of pertussis, when standardized tests and interpretive criteria that reliably diagnose recent infections in vaccinated populations are available. Interpretive criteria for a single serum specimen will have more clinical utility than those that require paired sera. For the optimal use and interpretation of serology and other tests for pertussis, the laboratory must have information on the patient's symptoms, antibiotic treatment, exposure to other ill persons, vaccination status, and age and on the level of disease activity in the community.

Francisella and *Brucella**

DAVID LINDQUIST, MAY C. CHU, AND WILL S. PROBERT

52

Francisella and *Brucella*, while not closely related taxonomically, have been traditionally linked in the mind of the bacteriologist. Both are zoonotic agents capable of producing severe disease in humans. In the laboratory, they are seen as very small to tiny gram-negative coccobacilli that do not seem to grow particularly well and are not particularly active biochemically. The two genera are apt to show cross-reactivity with each other in agglutination-based serologic tests (13, 103, 178). They share a reputation for frequently causing laboratory-acquired infections (50). Finally, *Francisella tularensis*, *Brucella melitensis*, *B. suis*, and *B. abortus* are all considered to be potential bioterrorism agents (68, 138; chapter 9 of this Manual). This circumstance has arguably led to a heightened interest in these agents and has helped prompt development of tests, particularly rapid tests, for their detection, identification, and further characterization.

In the United States, *F. tularensis* and three species of *Brucella*, *B. melitensis, B. suis*, and *B. abortus,* are classified as select agents. To transfer, receive, or possess these agents, laboratories must be registered both with the Centers for Disease Control and Prevention (CDC) and with the Animal and Plant Health Inspection Service (APHIS) of the U.S. Department of Agriculture. The registration process includes a U.S. Department of Justice investigation of all personnel having access to select agents. Clinical laboratories are exempt from the registration requirement provided that within 7 calendar days of identifying one of these agents, they transfer it to a registered entity and/or destroy the agent on site. Laboratories identifying an organism as *F. tularensis* or *B. melitensis* are required to report this finding immediately to APHIS or the CDC. The identification of *B. abortus* or *B. suis* is to be reported within 7 calendar days by using the appropriate form. Report forms, contact information, laboratory registration information, and pertinent citations of the U.S. Federal Code may be found at http://www.cdc.gov/od/sap.

FRANCISELLA

Taxonomy

Tularemia, a zoonosis affecting a wide range of animals and humans, is the disease caused by infection with members of the genus *Francisella*. Tularemia was described in detail in the first part of the 20th century (67, 105). The story of its discovery and the elucidation of its pathology and epidemiology are essentially American (159). Several recent publications have reviewed the history and description of the genus *Francisella* (54, 143). The first article describing the etiologic agent of tularemia was published in 1912 by McCoy and Chapin, who isolated the agent from a ground squirrel die-off in Tulare County in California (105). Francis, for whom the genus is named, recognized and confirmed that a number of diverse and epidemiologically distinct clinical entities were really one disease, and he proposed the name "tularemia" to describe the disease in humans (67). In addition to *F. tularensis*, two other species, both first isolated in North America, are included as members of the family *Francisellaceae*. *F. novicida* was recovered in 1951 from water. *F. philomiragia* was isolated in 1969 from muskrats and the surrounding water environment (147). These two species are infrequently isolated and rarely implicated in clinical disease. The genus members have been separated into two pathogenic groups: one that causes serious illness in humans and is often lethal for animals, and one that is considered to be of lesser virulence for humans and animals (84, 89, 147). The pathogenic members of this genus exist as intracellular parasites; therefore, antibiotic therapy may have to be extended in order to eliminate the infection. All genus members are susceptible to aminoglycosides and tetracyclines. It is the widespread epizootic nature of tularemia, its potentially severe and fatal forms in humans, its reputation as a laboratory hazard, and its potential use as a biological warfare agent that have given tularemia its notoriety. *F. tularensis* has been developed as a biological weapon, and projections about its impact, if used as a weapon in an urban setting, depict a scenario devastating to public health and to the economy of health services (49).

The species of *Francisella* share some biochemical activities, a high degree of DNA relatedness (54, 63, 64, 94), and a unique cellular fatty acid (CFA) profile (83, 169). Subspecies designations continue to be in transition as new information about host relationships, geographic origin, virulence, and phenotypic, biochemical, and genetic features is revealed. Four subspecies of *F. tularensis* are listed in the most recent edition of *Bergey's Manual of Systematic Bacteriology* (147): *F. tularensis* subsp. *tularensis* (type A), *F. tularensis* subsp. *holarctica* (type B; formerly known as *F. tularensis* subsp.

*This chapter contains information presented in chapter 51 by May C. Chu and Robbin S. Weyant in the eighth edition of this Manual.

palaearctica), *F. tularensis* subsp. *mediasiatica*, and *F. tularensis* subsp. *novicida*. The last subspecies, a reclassification of *F. novicida*, does not yet have standing in taxonomy. In anticipation of its becoming validated and coming into common usage, *F. tularensis* subsp. *novicida* will be used in this chapter. The members of this genus have been associated with the natural outdoor environment, small mammals, and arthropods. *Wolbachia persica*, a bacterium isolated from *Argas persicus* ticks and two additional tick endosymbionts, from *Dermacentor andersoni* and *Ornithodoros moubata*, have 16S rRNA sequence similarity to *Francisellaceae* (64, 147).

Description of the Genus

The genus *Francisella* comprises tiny gram-negative coccobacilli that can be distinguished from other families by several features (Table 1). Members of the genus take up Gram's counterstain (safranin) poorly; they are strict aerobes, weakly catalase positive, nonmotile, and non-spore forming; and they react with a limited number of carbohydrates (Table 2). Only a few sugars (glucose, maltose, sucrose, and glycerol) are utilized by most of the members of the genus. Acid is produced without gas. Unique fatty acids are associated with the genus (Table 1) (83, 147, 169). For most species, in vitro growth is enhanced by sulfhydryl supplementation. The organisms in this genus show >98% 16S rRNA sequence similarity (147). Rare single plasmids have been associated with individual isolates of *F. tularensis* subsp. *holarctica* and *F. tularensis* subsp. *novicida* and have been found in two strains of *F. philomiragia* (M. Chu, unpublished observation).

Only a few key differences separate the two species of *Francisella* (Table 2). *F. philomiragia* is more biochemically reactive than *F. tularensis;* it differs also by its ability to ferment maltose, and it is oxidase positive using Kovács's modification. Subspecies differentiation is less distinctive; single biochemical differences in glycerol fermentation and glucose utilization are used to define the biovars. *F. tularensis* subsp. *tularensis*, designated type A, is the most virulent of the subspecies, with a 50% lethal dose of <10 cells for laboratory mice and rabbits (84, 89, 119). *F. tularensis* subsp. *tularensis* and *F. tularensis* subsp. *mediasiatica* have the greatest similarity in that they utilize glycerol (2, 54), possess citrulline ureidase activity (141, 147), and along with *F. tularensis* subsp. *novicida*, share the same 16S rRNA signature nucleotide sequence (64, 141). *F. tularensis* subsp. *mediasiatica* differs by its inability to utilize glucose and its comparatively low virulence. Type B organisms (*F. tularensis* subsp. *holarctica*) may be differentiated by their inability to utilize glycerol, an absence of citrulline ureidase activity, and the presence of a unique 16S rRNA signature sequence. *F. tularensis* subsp. *holarctica* is of intermediate virulence, with a 50% lethal dose of <1,000 cells for laboratory animals (84, 89). *F. tularensis* subsp. *novicida* can be distinguished from the other subspecies by its ability to grow independently of cysteine supplementation and by its comparatively large vegetative cell size. *F. tularensis* subsp. *novicida* is considered to be of low virulence, like *F. tularensis* subsp. *mediasiatica* and *F. philomiragia*, but otherwise shares genetic characteristics with *F. tularensis* subsp. *tularensis* (147).

Epidemiology and Transmission

Francisellaceae are distributed widely within the Northern Hemisphere (Holarctic region) in a variety of natural habitats, from the Arctic Circle south to about latitude 20°N (84). Australian and Spanish isolates recovered from patients have been identified as *F. tularensis* subsp. *novicida* by using molecular techniques to augment the standard diagnostic tests (171; Chu, unpublished). *F. philomiragia* has been recovered from a patient with a history of travel to Turkey (69). Turkey has recently reported a waterborne outbreak in its western Black Sea region, an illustration of the continued appearance or reemergence of tularemia in the zone of endemicity (79).

Thus, as techniques and molecular tools are developed, it is likely that we can expect recovery of *F. tularensis*-like organisms from regions beyond the Northern Hemisphere. Tularemia is associated with a wide range of habitats and hosts, with more than 100 species of wild animals, birds, and arthropod vectors being involved (84, 90, 120). Habitats where the *Lagomorpha* (*Sylvilagus* [rabbits], *Lepus* [hares], and *Oryctolagus* [Old World hares]) and the *Rodentia* (water voles, muskrats, lemmings, voles, and beavers) thrive are important in maintaining tularemia enzootic foci (84, 90, 120, 179). Biting arthropod vectors, primarily tabanid flies (*Chrysops* and *Tabanus)*, ticks (*Dermacentor*, *Ixodes*, and *Amblyomma*), and mosquitoes (*Culicidae* in Europe and Russia), are implicated in the mechanical transmission of tularemia (53). Amebas also may carry viable *F. tularensis* cells and keep the bacteria viable in water (1). Because of the presence of *Francisella* in the natural environment, infections with *Francisella* are usually acquired in association with outdoor activities via contact with contaminated air, water, soil, vegetation, or sick or dead animals and from infective insect bites.

F. tularensis subsp. *tularensis,* the most virulent member of the genus, has been thought to occur only in North America, where it has been most closely associated with infection in lagomorphs and humans. Though *F. tularensis* subsp. *tularensis* has been recovered from mites and fleas in Europe, no human infection has been found there (159). In contrast, infection with *F. tularensis* subsp. *holarctica* is less virulent; it has a much wider distribution, in both the Old and New Worlds, and is associated with a greater variety of animals, primarily hares and rodents, and with contaminated environmental source outbreaks. *F. tularensis* subsp. *mediasiatica* is found only in circumscribed geographical regions in Kazakhstan and Turkmenistan and has been isolated from hares and ticks but not from humans (147). *F. tularensis* subsp. *novicida* has been found primarily in North America. It has also been found in Australia (171) and in Spain. Of the fewer than 20 known isolates of *F. philomiragia*, most have been from North America, with three single incidences reported from Central and Eastern Europe and Australia.

Since the 1940s, when several thousand cases annually were sometimes reported, the incidence of reported tularemia cases in the United States has steadily declined to 100 to 200 cases each year. All states except Hawaii have reported cases. From 1995 through 1999, tularemia was removed from the nationally notifiable disease list, but it was reinstated in 2000 because of concerns about its potential use as a bioterrorism agent. Despite its absence from the nationally notifiable disease list between 1995 and 1999, the number of cases reported annually to the CDC did not differ substantially from those in previous years. A total of 1,368 human cases were reported to the CDC between 1990 and 2000 (34).

The epidemiology of tularemia in the United States has not changed significantly in the past several decades. Most cases occur in south central and western states. It remains a rural disease. Most patients acquire tularemia from tick or deer fly bites, from contact with infected animals (e.g., by skinning rabbits), or as recently reported, from contact with

[a] +, greater than or equal to 90% positive; −, less than or equal to 10% positive; v, variable (11 to 89% positive); ccb, coccobacilli. Data are from reference 169.
[b] Does not include *Bartonella bacilliformis*, which is the only motile species.
[c] Formerly *Moraxella phenylpyruvica*.
[d] *Haemophilus* spp. requiring X and V factors or V factor only.
[e] While not required, X factor (hemin) enhances growth for many strains.
[f] May be difficult to demonstrate.
[g] The number before the colon indicates the number of carbons; the number after the colon is the number of double bonds; ω indicates the location of the double bond counting from the hydrocarbon end of the carbon chain; OH indicates a hydroxy group at the 2- or 3-position from the carboxyl end; c indicate *cis* isomer; cyc indicates a cyclopropane ring structure. Hydroxy acids listed are at least 2% of the total CFA composition; all others are at least 10%.
[h] *B. canis* lacks 19:0cyc. CFA data for marine mammal strains are not available.

TABLE 2 *Francisella* spp. characteristics

Characteristic	*F. tularensis* subspecies				*F. philomiragia*[c]
	tularensis[a]	*holarctica*[b]	*mediasiatica*	*novicida*[c]	
Gram stain (culture)	Faintly staining, pleomorphic, single, rarely chained, gram-negative coccobacilli	As for subsp. *tularensis*	As for subsp. *tularensis*	As for subsp. *tularensis*	As for subsp. *tularensis*
Cell size (μm)	0.2 by 0.2–0.7	0.2 by 0.2–0.7	0.2 by 0.2–0.7	0.7 by 1.7	0.7 by 1.7
Growth on:					
Standard agar[d]	−	−	−	+	+
CA, 48 h	2–4-mm-diam, raised, gray, smooth, moist, butyrous, entire colonies; usually no agar discoloration	As for subsp. *tularensis*	As for subsp. *tularensis*	As for subsp. *tularensis* but 5 mm in diam	>5-mm-diam, white, smooth, mucoid, entire colonies; no agar discoloration
Cysteine heart blood agar, 48 h	2-mm-diam, pearl-white to ivory colonies with green tint and prominent opalescent sheen; smooth and butyrous; green-yellow discoloration of agar medium	As for subsp. *tularensis*	Not tested	5-mm-diam, colonies with features the same as those of type A and type B	Colonies are >5 mm in diam, creamy white-gray, mucoid, and smooth with purple-tinted opalescent sheen
Requires cystine/cysteine	+	+	+	−	−
Catalase	Weakly +	Weakly +	Weakly +	Weakly +	Weakly +
Oxidase (Kovács)	−	−	−	−	+
Acid from:

Maltose	+	+	−	V[f]	+
Sucrose	−	−	+	+	V
Glycerol	+	−	+	+	+
Relative virulence (mice)	High	Intermediate	Low	Low	Low
DNA typing					
16S rRNA probe[g]	Type A	Type B	Type A	Type A	Type A
PCR primers[h]	Species specific	Species specific	Species specific	Species specific	Does not react
VNTR and IS probe[i]	Strain specific	Strain specific	Strain specific	Strain specific	Strain specific

[a] Type A, found predominantly in North America and associated with a severe form of disease in humans and rabbits.
[b] Type B, found throughout the Northern Hemisphere and associated with a less severe form of disease in humans; associated with humans and rodents (muskrats, field mice, beaver, voles, and water rats).
[c] Associated with low virulence and infrequently isolated.
[d] Standard bacteriology media: blood, tryptic soy, and brain heart infusion.
[e] Delayed or variable reaction. *F. tularensis* subsp. *mediasiatica* does not ferment glucose.
[f] V, variable or delayed reaction.
[g] Probes that define type A and type B sequences.
[h] PCR primers: Tul-4, T-cell epitope; FopA and p43,000 antigen.
[i] VNTR, variable number of tandem repeats: allelic variation, subspecies and strain specific. IS, insertion element PCR (type B specific) or Southern hybridization pattern (subspecies and strain specific).

pets and zoo animals (6, 36, 82, 87, 106). Cultures recovered in the United States from 1996 to 2001 comprise equal proportions of type A and type B genotypes, and these overwhelmingly predominate. Isolation of *F. tularensis* subsp. *novicida* and *F. philomiragia* is rare.

There is an increasing awareness of unusual occurrences of tularemia in animals and humans. Pet owners, pet owners' family members, and animal care professionals are at risk when handling sick pets. These pets may include both domestic (dogs, cats, and hamsters) and exotic animals (14, 36, 87, 106, 161). Captive prairie dogs caught in the wild have been implicated as well as commercially sold hamsters, monkeys (in monkey colonies), and zoo animals (56, 73, 82, 97, 114, 128, 129, 167). Transport of these animals poses risks to unsuspecting shipping handlers and the public of contracting an unusual and exotic disease, as illustrated by recently reported incidents

(6, 35). Cases of tularemia associated with immunocompromised patients or patients recovering from prosthetic replacement or transplantation surgery have been reported (42, 76, 102, 112, 126, 142). Additional reports on such unusual cases continue, with the recovery of *F. tularensis* subsp. *holarctica* from a patient with metastatic cancer (81) and from a kidney transplant patient (95) and a pneumonic case of *F. tularensis* subsp. *holarctica* in southern Europe. Patients with pneumonic tularemia associated with inhalation of aerosolized infectious particles are at risk of acquiring typhoidal tularemia (61, 157). Though we have gained much knowledge about the epidemiological association of lawn mowing and brush cutting with tularemia in areas like Martha's Vineyard where the disease is endemic, gaps remain in our understanding of the transmission dynamics of tularemia (61, 74, 103, 104).

Clinical Significance

F. tularensis subsp. *tularensis* and *F. tularensis* subsp. *holarctica* are the two members of the genus *Francisella* most commonly encountered in human disease. Tularemia has been known historically by a number of synonyms, such as plague-like disease, rabbit fever, deer fly fever, market men's disease, glandular type of tick fever, conjunctivitis tularensis, Ohara's or Yao-byo disease, and water rat trappers' disease. These synonyms attest to the variety of clinical presentations, the infectious agent's ubiquitous presence in nature, and the means by which humans may acquire the infection.

The clinical spectrum depends on the mode of transmission, the virulence of the infecting strain, the degree of systemic involvement, the immune status of the host, and timely diagnosis and treatment (159). Tularemia can be misdiagnosed early in infection since its symptoms are not unique: sudden onset of chills, fever, headache, and generalized malaise characterize each onset of illness. The differential diagnosis includes a wide range of infectious diseases, such as cat-scratch fever, syphilis, mycobacterial infections, anthrax, brucellosis, legionellosis, and plague. The incubation period averages 3 to 5 days, but onset may occur as early as 2 days to as late as 14 days after infection. Without treatment, nonspecific symptoms—sweats, chills, progressive weakness, and weight loss—usually persist for several weeks to months. Before the advent of antibiotics, the overall mortality from infections with the more severe type A strains was in the range of 5 to 15%; however, fatality rates as high as 30 to 60% have been reported for untreated typhoidal and pneumonic forms of the disease. In the United States, untreated type B strain infections were rarely fatal. The fatality rate for all forms in recent years has been less than 2% (49).

Patients may present with any one or more of the classically described forms of tularemia: ulceroglandular, glandular, oculoglandular, pharyngeal, typhoidal, and pneumonic. The most common form is ulceroglandular disease (45 to 80% of the reported cases), indicating that the portal of entry is via infective insect bite or other inoculation through the skin barrier, usually associated with handling contaminated materials. Pharyngeal lymphadenopathy suggests a portal of entry via ingestion of contaminated water or food, as was the case with the recent food- and waterborne outbreak in Kosovo (134). Typhoidal tularemia is the most difficult form to recognize because there is no identified portal of entry and localization signs are absent. Any of the initial forms of tularemia may be complicated by bacteremic spread, leading to various secondary tularemic symptoms such as pneumonia, sepsis, and meningitis.

Until 1989 *F. tularensis* subsp. *novicida* was defined by a single isolate recovered from water in Utah in 1951. This subspecies was not known to cause human disease. During a subsequent study of 16 unusual human bacterial isolates, 14 were identified as *F. philomiragia* and 2 were identified as *F. tularensis* subsp. *novicida* (83). These two human isolates, two isolates from Texas (37), and the molecular typing of additional isolates from the United States, Australia (171), and more recently Spain all suggest that our knowledge about the prevalence of *F. tularensis* subsp. *novicida* remains incomplete. Fever, chills, cough, shortness of breath, and chest pain are the more common symptoms described in those with airway-acquired disease. In a case from Australia, the organism was isolated from an abscessed toe. Isolates are recovered from blood, granulomatous tissue, and wounds. Patients may also present with skin lesions and cervical lymphadenopathy. Overall, cases are milder than those of disease caused by *F. tularensis* subsp. *tularensis* and *F. tularensis* subsp. *holarctica*, but occasionally some are serious enough to warrant hospitalization.

F. philomiragia is an opportunistic agent infecting patients with a previous underlying condition that renders them more susceptible. More isolates have been recovered and identified since 2000, but overall, fewer than 20 cases have been described since the discovery of this species in 1974 (168). All but one case have involved a host with an impaired physical barrier to infection (near drowning) or impaired immunologic defenses (chronic granulomatous disease or myeloproliferative disease) (146). Most patients reported are from the United States (nine different states) (146). In addition, one case from Switzerland (168), one case from Australia (171), and a fatal water exposure-related case in a patient with a history of travel to Turkey (69) have been reported. In most cases *F. philomiragia* was isolated from normally sterile sites: blood, bone marrow, cerebrospinal fluid, and pericardial fluid. The drowning and water exposure cases were associated with salt water and brackish water, in contrast to *F. tularensis* infections, which are associated with freshwater sources.

Collection, Handling, Storage, and Transport of Specimens

Working with live *F. tularensis* can be hazardous. *F. tularensis* has a long and notorious history of infecting laboratory personnel working with infectious materials. Even though the use of biological safety cabinets and prophylactic antibiotic therapy (as well as vaccination, where available) provides safeguards for laboratory workers, these precautions have not fully eliminated laboratory exposures or modified behavior in the clinical laboratory to minimize risks (95, 140, 145). Clinical specimens should be handled under biosafety level 2 (BSL-2) conditions with universal precautions, with work being done using BSL-3 practices as soon as *F. tularensis* is suspected (50). Hundreds of laboratory-acquired infections have been documented, including infections of the pioneer scientists who first investigated the natural history of tularemia; they acquired infections from handling infected animals, removing arthropods from carcasses, and working with live cultures (17, 121, 140). The greatest risk of laboratory-acquired tularemia is by aerosol inhalation while working with infected materials and cultures. The infectivity of the organisms is high; *F. tularensis* should be handled only by trained and, preferably, vaccinated personnel.

Specimens should be stored chilled in appropriate medium until processed in the laboratory. Freezing of samples, unless they are kept at −80°C, is not recommended because of lysis of live bacteria upon thawing. Though *F. tularensis* may survive for long periods in the environment,

successfully culturing it from environmental specimens is difficult. Efforts should be made to maintain the integrity of such specimens and avoid delay in transporting them to the laboratory for testing. Ectoparasites may be stored intact in 2% NaCl and transported to the laboratory for identification and then processed for evidence of *F. tularensis*. Clinical specimens should be placed in Amies agar with charcoal, a commercial transport system designed for anaerobic and aerobic pathogens (BD, Franklin, N.J.). *F. tularensis* should remain viable for 7 days at ambient room temperature when stored in Amies medium (91). Stuart medium, designed for transporting gonococcal specimens, and saline are inadequate for keeping *F. tularensis* viable during transport (91). For PCR, specimens should be collected in guanidine isothiocyanate-containing buffer, which should preserve *F. tularensis* DNA for up to 1 month (91).

Direct Examination of Specimens

The *F. tularensis* subspecies cannot be clearly differentiated from one another by microscopy. Cultures and fresh clinical specimens (ulcer and wound swabs, touch-prep fresh tissues, and aspirates) but not thick blood or environmental samples can be directly examined. Under microscopic examination of Gram-stained specimens or cultures, *Francisella* cells (single and pleomorphic) appear so tiny and stain so faintly that they can be easily missed. Thus, direct Gram staining is usually of no diagnostic value. To improve visualization, direct fluorescent-antibody (DFA) staining using a labeled hyperimmune rabbit polyclonal antibody prepared by immunizations with *F. tularensis* subsp. *tularensis* cells will presumptively identify *F. tularensis* subsp. *tularensis* and *F. tularensis* subsp. *holarctica*. This DFA reagent does not react with *F. tularensis* subsp. *novicida* or *F. philomiragia* or with *Legionella* species. Immunohistochemical (IHC) staining using a monoclonal antibody directed against the lipopolysaccharide (LPS) has been used successfully to visualize *F. tularensis* in formalin-fixed tissues in both intra- and extracellular sites (78). Neither the DFA reagent nor the IHC reagent is commercially available.

The presence of *F. tularensis* in specimens taken from ulcers, wounds, tissues, and the environment (animal feces and urine, water, hay infusion, mud, and ectoparasites) may be determined by detection of the *F. tularensis* LPS antigen by using an antigen capture enzyme-linked immunoassay (cELISA) or a lateral flow assay (127, 143). DNA detection by PCR directed at unique target regions has been widely applied (65, 91, 92, 125, 148, 163). The detection limit is 10^3 bacteria/ml for the cELISA and 10^2 bacteria/ml for PCR. These are specialized tests and are not widely available, although PCR technologies have become more commonly used for screening purposes.

Isolation Procedures

F. tularensis is not readily recovered by culture and is not easily identified even when it is cultured. The pathogenic *F. tularensis* bacteria are fastidious, requiring supplementation with sulfhydryl compounds (cysteine, cystine, thiosulfate, and IsoVitaleX) to grow on artificial medium. *F. tularensis* will grow well on cysteine heart blood agar supplemented with 9% chocolatized sheep blood (CHAB), chocolate agar (CA), buffered charcoal-yeast extract agar, and Thayer-Martin agar. It will grow in thioglycolate broth. When supplemented with 1 to 2% IsoVitaleX, general bacteriological media (tryptic soy broth and Mueller-Hinton broth) will support growth. The organisms grow slowly (60-min generation time); robust growth, therefore, is obtained by prolonged incubation (48 h or longer) or by plating on highly nutritive media such as CHAB. *F. tularensis* cultures should be incubated at 35 to 37°C aerobically and observed daily for 10 to 14 days; CO_2 does not impede growth. Incorporation of antibiotics (penicillin, 100,000 U/ml; polymyxin B sulfate, 100,000 U/ml; and cycloheximide, 0.1 mg/ml) into the medium will help prevent normal flora from overwhelming the *F. tularensis* organisms (125). Freezing of specimens combined with the use of antibiotics in the medium has allowed for a higher recovery rate than ever before (125). Complex protein or nutritionally enriched specimens such as blood or tissue will provide an intrinsic source of sulfhydryl compounds that permit *F. tularensis* growth. Upon subculture, the fastidious nature of *F. tularensis* will become evident as the exogenous compounds are depleted, leading to the loss of the bacterium's viability unless the subculture is propagated on cysteine-supplemented media. If a subculture fails to grow successfully on agar, inoculation of laboratory mice with a suspension of the original specimen or inoculated medium may assist in reviving the culture.

Specimens should be taken on the basis of clinical presentation and before administration of antibiotics. Fresh clinical material that is likely to contain high concentrations of *F. tularensis* organisms such as ulcer and wound specimens and lymphoid tissue (liver, spleen, or affected lymph node tissue) is inoculated directly onto an agar plate by using a sample-laden swab or bacteriological loop. Larger inocula will be necessary for the recovery of *F. tularensis* from specimens that contain a lower concentration of the organisms: blood, aspirates of pharyngeal washes, bronchial wash fluids, pleural fluids, urine, and environmental samples (159). A total of 3 to 10 ml of whole blood should be inoculated into blood culture bottles (147, 159). Environmental specimens, impinged air samples, and collected water are concentrated through a 0.22- or a 0.45-μm-pore-size nitrocellulose filter, and the filter-trapped organisms are released by vigorous agitation of the filter in less than 5 ml of sterile buffer. The inoculum should be spread onto as many agar plates as necessary at a seeding volume of 0.5 ml/agar plate. A portion of the inoculum (0.1 ml) may be injected subcutaneously into mice for enhanced recovery. Other methods for PCR and ameba culture from water have been discussed previously (1, 65). Preserved, formalin-fixed tissues should be examined by IHC staining (78).

Identification

Early recognition that an isolate may be *F. tularensis* is important from the standpoint of laboratory safety as well as helping to establish the cause of the patient's infection. There is also the possibility that a case of tularemia may be due to an act of bioterrorism. Prompt identification of an organism as *F. tularensis* may lead to an earlier recognition of such an event (chapter 9). The isolation of a poorly staining, tiny (indeed, individual cells may be difficult to discern), gram-negative coccobacillus (Fig. 1A) that produces 1- to 2-mm-diameter gray to gray-white colonies on CA after 48 h (and scant to no growth on blood agar) should raise the suspicion of *F. tularensis*. Further work on the isolate should be done in a biological safety cabinet. If further testing according to the algorithms given in chapter 9 does not rule out *F. tularensis* and the laboratory cannot do further confirmatory tests, the isolate needs to be sent to a reference laboratory that can confirm (or rule out) its identification as *F. tularensis*. Proper biohazard shipping procedures must be followed (chapter 9). In the United States, all states have at least one reference laboratory that is part of the Laboratory Response Network (LRN). These CDC- and APHIS-registered LRN laboratories are

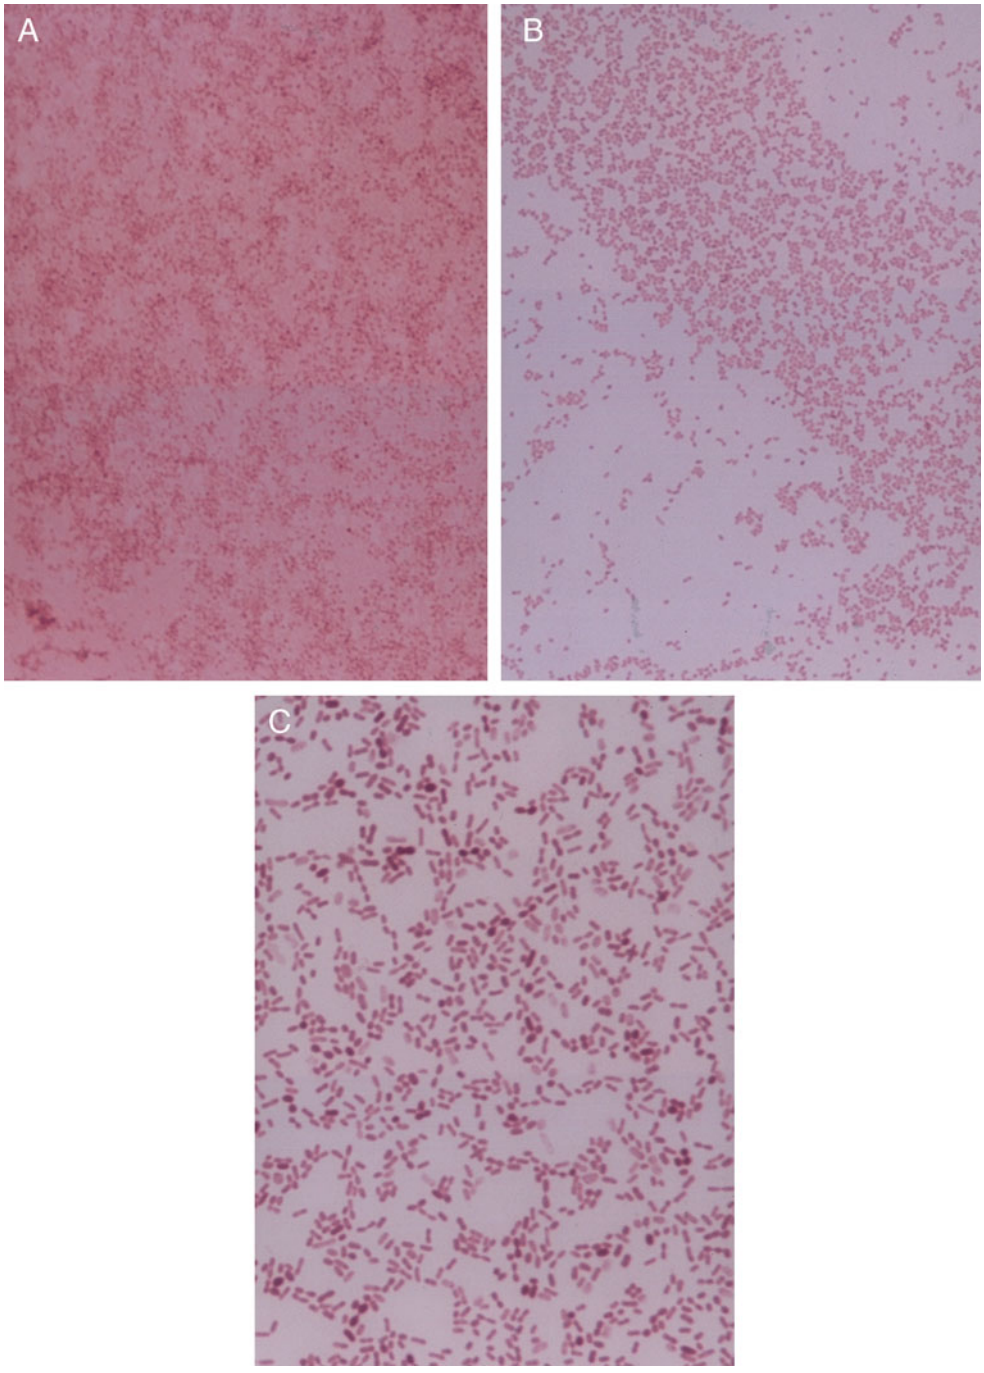

FIGURE 1 Gram stains of *F. tularensis* (A), *B. abortus* (B), and *Acinetobacter* species (C). Magnification, ×1,000.

able to confirm the identification of bacterial select agents, including *F. tularensis*. State public health laboratories can provide additional information, including location, about a state's LRN laboratories. See also http://www.bt.cdc.gov/lrn/.

A positive test result with any one of five methods—DFA staining (Fig. 2), IHC staining, the slide agglutination test, PCR, or a serology test for a single antibody titer—provides a presumptive diagnosis. Confirmation of infection would include identification of a culture as *F. tularensis* and/or a fourfold difference in titers in acute and convalescent serum samples, with one of the paired samples having a positive titer. The slide agglutination test presumptively identifies a suspect culture by mixing polyclonal rabbit anti-*F. tularensis* antibody with safranin-stained cells. Results of biochemical reactions are supportive of identification but are not reliable for confirmation since *Francisella* spp. are not very reactive. Fatty acid profiles may also be used to presumptively identify the organism as belonging to the *Francisella* genus (83, 147, 169). There is no specific bacteriophage lysis test for *F. tularensis*.

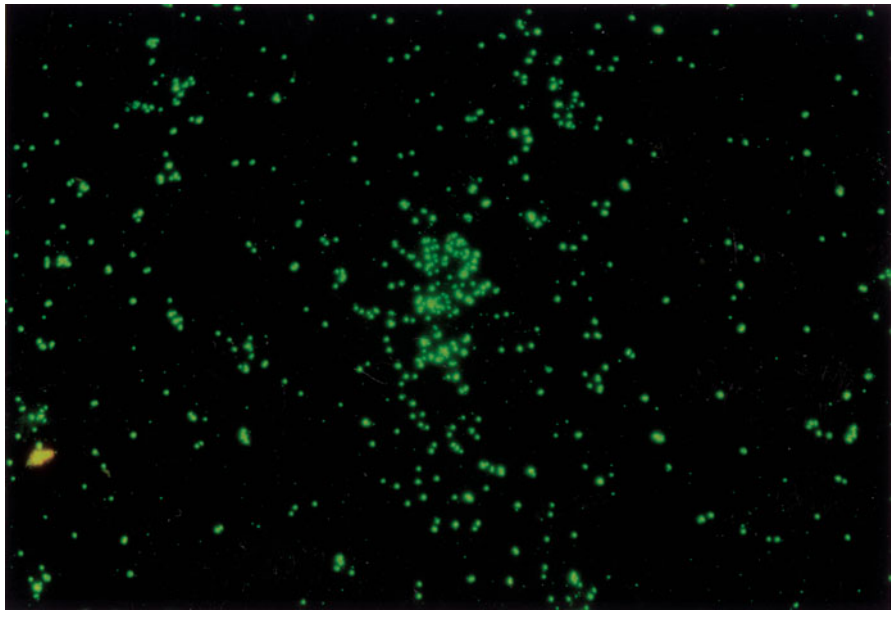

FIGURE 2 DFA staining of a culture of *F. tularensis*. Magnification, ×400.

Colonial morphology of *F. tularensis* is most distinctive when it is grown on CHAB. On CA, *F. tularensis* colonies have an entire edge; they are gray, smooth, raised, and moist, with a butyrous consistency. *F. tularensis* subsp. *novicida* grows more robustly than the other subspecies and is cysteine independent (Table 2). Colonies of *F. philomiragia* on CA are >5 mm in diameter, with an entire edge; they are white, smooth, raised, mucoid, and cysteine independent. On CHAB, *F. tularensis* exhibits a prominent and unique opalescent sheen due to its production of H_2S; this sheen is less prominent in *F. philomiragia* than in *F. tularensis* and is absent in cultures of other gram-negative organisms, such as *Yersinia*, *Brucella*, *Haemophilus,* and *Pasteurella* spp. (Fig. 3).

Typing Systems

F. tularensis biovars and *F. philomiragia* may be differentiated by protein profiling, 16S rRNA sequencing, various types of PCR approaches, and insertion element typing (60, 63, 99, 147) (Table 2). New approaches with the application of specialized PCR fragments targeting multiple-locus, variable-number tandem repeats have identified significant linkages and changes between *F. tularensis* subsp. *tularensis* and *F. tularensis* subsp. *holarctica* (92). Such analysis has revealed relationships between isolates demonstrated by geographical and ecological features and provides an interesting context for understanding the transmission and maintenance of *Francisella* in its environment. With the completion of the

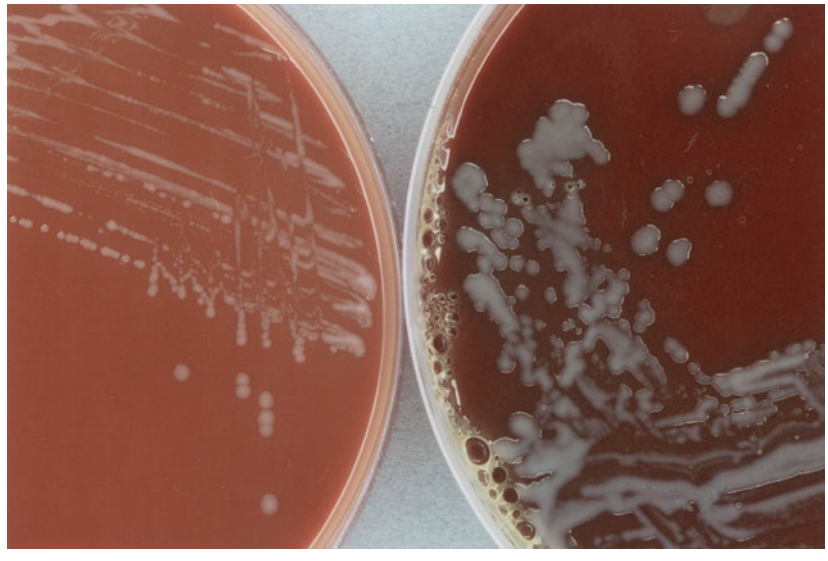

FIGURE 3 *F. tularensis* on CA (right) and cysteine heart blood agar (left) after 3 days of growth.

genomic sequencing of the prototypic type A strain (Schu 4) (98) and its comparison with the prototypic type B strain (live vaccine strain [LVS]), additional target areas may be identified for more precise typing and for study of strain pathogenesis. More recent application of technologies like DNA microarray analysis and surface-enhanced mass spectrometric methods will increase our ability to discriminate among and identify unique genomic regions for finer typing and characterization of the strains (25, 100).

Genus, species, and subspecies strains can be determined using 16S rRNA sequences, a method that has been applied in several instances to identify *Francisella* spp. successfully (69, 81, 145, 171). PCR is more sensitive than recovery by culture (83% compared to 62%) (91). Various PCR methods have been used to type isolates by genus, species, or individual isolates or small groups. Rapid PCR methods using the *Taq*man 5′ nuclease assay have a detection limit of <100 CFU under controlled laboratory conditions. These methods have been refined and applied widely in examining clinical specimens since 2003, with good correlation between culture and PCR results (125, 163).

Serologic Testing

Serology is the most common method by which *F. tularensis* infections are diagnosed (158, 159). Serum, plasma from citrated or heparinized blood, and filter paper-extracted serum proteins (172) can be used in serological assays. Antibodies may be detected as early as 1 week after onset of symptoms (about 2 weeks after infection). By 2 weeks after onset, antibodies may be detected in 89 to 95.4% of samples. Antibodies can persist for more than 10 years (17, 159, 166). Immunoglobulin M (IgM), IgA, and IgG antibodies appear simultaneously (158, 164). IgM antibodies can last for many years; thus, their presence does not indicate early or recent infection (17, 158). Agglutination testing, either by the tube agglutination (TA) or the microagglutination (MA) method, is the standard serology test for determining the presence of antibodies in tularemia (16, 27). A single specimen with a TA titer of ≥1:160 or an MA titer of ≥1:128 can be interpreted to be presumptively positive when compatible symptoms of tularemia are present and there is no history of vaccination or previous exposure. Confirmatory serodiagnosis requires a fourfold difference in titers between acute and convalescent specimens taken at least 14 days apart. One of the pair of serum specimens must show a positive titer by TA or MA. The formalin-killed whole-cell agglutination antigen (BBL Microbiology Systems, Cockeysville, Md.) may have low-level cross-reactivity primarily with *Brucella* antibodies, but the level of reactivity is typically <1:20 and will not interfere with interpretation of a positive result (6, 27, 118).

Enzyme-linked immunoassay (ELISA) formats that identify immunoglobulin class types and antigen detection have been adopted and updated for use in parts of Europe where tularemia is endemic (111, 127, 143). Although recombinant antigens have been used for ELISAs, the LPS extract remains the primary ELISA target to be used in recent test applications. Although ELISAs are more sensitive and specific than agglutination, their limitation of host specificity precludes their wide use in enzootic disease serosurveillance. Antigenic differences between the type A and type B biovars have not been demonstrated, although there is hope that such developments will be forthcoming as a result of the efforts in genomic sequencing and use of various DNA and mass spectrophotometric methods. The serology test materials thus react with anti-type A and anti-type B antibodies and usually do not react with anti-*F. tularensis* subsp. *novicida* and anti-*F. philomiragia* antibodies.

F. tularensis organisms are intracellular bacteria and are capable of eliciting both humoral and cell-mediated immunity (158). The latter response has been known to remain strong 25 years after infection (57). A skin test was previously used to measure specific reactivity by means of an intradermally injected ether extract of *F. tularensis,* but this test is no longer used. Host T cells retain proliferative responses to unique *F. tularensis* membrane proteins, with concomitant increase in interferon and interleukin-2 levels (57, 154, 155, 158). Tests for measuring the cell-mediated immune response are specialized and are not routinely used for diagnosis of tularemia. With the current emphasis on research with biodefense applications, however, new developments in this area for clinical use may be expected.

Antimicrobial Susceptibilities

Antimicrobial susceptibility testing of *F. tularensis* is not usually performed in clinical microbiology laboratories because of safety concerns in working with this organism (30, 121). Mueller-Hinton medium supplemented with 2% IsoVitaleX or CHAB must be used because of the fastidiousness of the pathogenic *F. tularensis*. This medium was recently evaluated as suitable for Clinical and Laboratory Standards Institute (formerly NCCLS) standards (26). Susceptibility of the *F. tularensis* isolate to the antibiotics recommended for treatment and prophylaxis, i.e., chloramphenicol, ciprofloxacin, gentamicin, streptomycin, and tetracycline, should be tested. No known naturally occurring strains resistant to the drugs recommended for treatment exist. Standardized methods have been published for susceptibility testing using broth, agar dilution (7), disk diffusion, and the E test (86, 93; chapter 73). No breakpoint standards have been set since there are no known naturally drug-resistant strains, except for erythromycin-resistant *F. tularensis* subsp. *holarctica* strains in Northern Europe (120).

F. tularensis infections are treatable with narrow-spectrum antibiotics, and drug resistance, with the exception of erythromycin resistance, in wild-type isolates is not known. Appropriate and early treatment, with streptomycin as the drug of choice, is effective. Streptomycin is given intramuscularly to adults in a dosage of 1 g every 12 h for 10 days (49). Gentamicin is an alternative drug that can be given intramuscularly at 3 to 5 mg/kg/day in equally divided doses at 8-h intervals for 10 days. Doxycycline or chloramphenicol may be used in combination with an aminoglycoside or used alone in less severe cases. Treatment with bacteriostatic agents, doxycycline, or chloramphenicol alone may result in treatment failures or relapses. An extended dosage schedule of 14 to 21 days may be necessary to prevent relapses. Ciprofloxacin has been used successfully to treat a limited number of patients; these clinical results, coupled with the low MIC of ciprofloxacin, suggest that this drug may become a useful addition to the armamentarium of drugs recommended for treating tularemia (156, 158). All *Francisella* isolates examined to date are β-lactamase positive, so penicillins and cephalosporins are not effective and should not be used to treat tularemia.

Prevention and Control

F. tularensis is a well-entrenched agent of enzootic disease that is unlikely to be eliminated even from limited natural foci. *F. tularensis* can survive for long periods in a cold, moist environment (15, 90, 120). Recently, extensive emphasis has

been placed on understanding the ecology and survival of and the reservoir for *F. tularensis* (1, 65). Avoidance of infective exposure is the principal means of preventing tularemia. The public should be educated about the risks for acquiring the disease in regions where tularemia is endemic and warned especially not to handle dead or sick animals, particularly rabbits, hares, and water rodents. Gloves and protective clothing should be worn when skinning or preparing such animals for food. People should be advised to cook these animals thoroughly before eating them. Repellents should be used to avoid arthropod bites, and ticks should be removed promptly. Chlorinated municipal water is safe from tularemia, but untreated water can be a ready source of infection; outbreaks have followed consumption of water from contaminated wells and streams and even consumption of freshwater crustaceans (4, 134).

Isolation of patients is not necessary, as person-to-person spread does not occur; therefore, treatment of close contacts of tularemia patients is not recommended (49). Universal precautions to avoid direct contact with contaminated secretions is advised. Laboratory personnel are at high risk of acquiring typhoidal or pulmonary tularemia via inhalation. As mentioned above, laboratory personnel should work in a class II biosafety cabinet when handling suspected tularemia specimens. All work should be performed under BSL-3 conditions once an isolate is confirmed (or even suspected) to be *F. tularensis*. People who have a recognized high-risk exposure (e.g., from a spill, aerosal spray, or puncture of skin) to *F. tularensis* should be given oral antibiotic prophylaxis. People subjected to low-risk exposure (e.g., handling a culture in the biosafety cabinet, preparing and making slides) should be placed on fever watch for 10 days and treated if they develop symptoms.

Vaccination may be advised for laboratory personnel who are working with live cultures and for others whose occupational duties put them at risk. A live attenuated vaccine has been used to immunize millions of people living in northern European countries and Russia. A variant of this vaccine, the LVS vaccine, has been used in the United States since 1959 for immunization of personnel who are at risk for laboratory-acquired infection. The vaccine is administered as a single dose of 0.06 ml by scarification. Antibodies develop within 3 weeks and may persist at reduced levels for months or years. Human volunteer studies demonstrated only partial protection against aerosol challenges after vaccination. A review of vaccination records at the U.S. Army microbiological laboratories from 1960 to 1969 revealed that there were 11 cases of laboratory-acquired tularemia (1 case per 1,000 at-risk employee-years) in vaccinated personnel (30). A recent update of this information also illustrates the protective value of vaccination (140). In the United States, vaccination was used for at-risk laboratory workers handling infective *F. tularensis* cultures. Retrospective evaluation of LVS-vaccinated people demonstrated protection against respiratory tularemia and apparent mitigation of the course of ulceroglandular disease (159). Vaccinated people maintain antibody and memory T-cell responses for at least 10 years. However, the LVS vaccine is not licensed and is not currently available in Western countries. With additional biodefense funding, several laboratories are developing vaccines using better-characterized live and killed strains and identifying and assessing the relevance of subcellular fragments for the next generation of vaccines. The challenge is that a yet-undefined mixture of T-cell-reactive bacterial proteins may be required for inducing protection (41, 122).

BRUCELLA

Taxonomy

The genus *Brucella* consists of small gram-negative coccobacilli that are pathogenic for humans and animals. In 1886 and 1887, Sir David Bruce, a British army medical officer working on the island of Malta, made the first isolation of *Brucella*, recovering it from the spleens of patients suffering from Malta fever (28). Bruce called this organism *Micrococcus melitensis*. In 1895, the Danish veterinarian Bernhard Bang isolated an organism, which he called *Bacillus abortus,* from cases of bovine abortion (8). In 1918, the American Alice Evans published her work demonstrating the close similarity of these two organisms (59). Shortly thereafter, Meyer and Shaw proposed the new genus *Brucella,* to include the agents of both Malta fever and Bang's disease as *B. melitensis* and *B. abortus,* respectively (107). In 1929, Huddleston described a third species, *B. suis,* encompassing strains originally isolated by Traum in 1914 from aborted swine (85, 160). Two additional species were identified in the 1950s: *B. ovis,* an agent of reproductive disease in sheep, and *B. neotomae,* isolated from the desert wood rat in Utah (29, 153). In 1968, Carmichael and Bruner described *B. canis,* a cause of canine abortion (31). In addition to host preference, these six species classically have been characterized phenotypically on the basis of their tolerance to dyes, requirement for CO_2, rate of urease reaction, lysis by the *Brucella* Tbilisi phage, H_2S production, agglutination by monospecific antisera, and rough-versus-smooth colony morphology (3).

Since the mid-1990s, several studies have described *Brucella* strains recovered from marine mammals. One of these studies suggested the name "*B. maris*" for these isolates (88). Others have proposed the names "*B. delphini*," "*B. pinnipediae,*" and "*B. cetaceae,*" based in part on the strains' host specificities (40, 109). None of these names have been validly published. These strains have been found to differ phenotypically from the six nomenspecies by their patterns of substrate-mediated metabolic activity (88).

Brucella, *Ochrobactrum,* and *Mycoplana* form the family *Brucellaceae. Mycoplana* species are soil organisms that have not been associated with human disease, and *Ochrobactrum anthropi* is a soil organism and an opportunistic human pathogen. The close phylogenetic relationship among the members of the family *Brucellaceae* suggests that they may have evolved from a common free-living soil organism. The *Brucellaceae* are part of the order *Rhizobiales,* which is in the class *Alphaproteobacteria* of the phylum *Proteobacteria* and the domain *Bacteria* (71). Other members of the *Rhizobiales* associated with human disease include *Bartonella* (family *Bartonellaceae*), *Afipia* (family *Bradyrhyzobiaceae*), and *Methylobacterium* and *Roseomonas* (family *Methylobacteriaceae*).

For most *Brucella* spp., the genome consists of two circular chromosomes of approximately 2.1 and 1.2 Mbp. In contrast to the larger chromosome I, the smaller chromosome II has an origin of replication and a genetic content that suggest that it was derived originally from a megaplasmid. The G+C contents of both chromosomes are 57%. The exception to the two-chromosome genome is that of *B. suis* bv. 3, which possesses a single circular chromosome of 3.1 Mbp with an overall genetic content similar to that of other *Brucella* species. Sequencing of the genomes of *B. suis*, *B. melitensis*, and *B. abortus* recently has been completed, and the sequences have been compared (48, 80, 124). Overall, the genomic content and organization are highly conserved

among the sequenced *Brucella* genomes and demonstrate similarities to the plant symbionts *Mesorhizobium loti* and *Sinorhizobium meliloti* and the plant pathogen *Rhizobium radiobacter (Agrobacterium tumefaciens)*. Chromosome I of *Brucella* contains approximately 2,100 to 2,200 open reading frames (ORFs), and chromosome II is predicted to have approximately 1,100 to 1,200 ORFs. Among the three sequenced *Brucella* genomes, the vast majority of the ORFs share greater than 99% sequence identity (80). However, through comparative genomic studies, a limited number of species-specific ORFs and variable ORFs, a significant number of which likely encode surface-exposed proteins, have been identified (80). The recent creation of an *Escherichia coli* library of 3,091 ORFs predicted from the genome of *B. melitensis* and the identification of ORFs encoding unique or highly variable proteins should greatly facilitate investigations into host tropism and *Brucella* pathogenesis, as well as the development of new diagnostic tests that target species-specific genetic sequences or polymorphic regions (52, 80).

The taxonomy of this genus is confounded by a dichotomy between the traditional (phenotypically based) and molecular definitions of its species. DNA relatedness and multilocus enzyme electrophoresis studies indicate that the six validly published nomenspecies, along with the recent marine mammal-derived strains, represent a single species (23, 70, 162). Recent molecular taxonomic studies show that although a high overall level of relatedness exists, the historically recognized species and the marine mammal strains can be differentiated by restriction polymorphisms of major outer membrane genes, insertion sequences, and whole-chromosome preparations (23, 165). This chapter follows the guidelines of the International Committee on Systematic Bacteriology subcommittee on the taxonomy of *Brucella* and retains the historical taxonomy to avoid confusion (43).

Description of the Genus

Brucellae are small, gram-negative coccoid rods, 0.5 to 0.7 μm in diameter and 0.6 to 1.5 μm in length. In Gram stains they are seen predominantly arranged singly (Fig. 1B). They are nonmotile. Their metabolism is aerobic, with oxygen or nitrate acting as the terminal electron acceptor via a cytochrome-based electron transport system. Some carbohydrates and polyhydric alcohols are oxidized; none are fermented. Nitrate is reduced, with some strains of some species producing gas. Strains are positive for catalase and, with the exception of *B. ovis*, *B. neotomae*, and some strains of *B. canis*, positive for oxidase. All species except *B. ovis* hydrolyze urea. Brucellae are negative for indole production, gelatin liquefaction, citrate utilization, and hemolysis. Growth on MacConkey agar is variable. The optimum growth temperature is 35 to 37°C. Chemo-organotrophic, most strains require complex media for growth, especially upon initial isolation. Growth may be improved by serum or blood; hemin (X factor) and NAD (V factor) are not required (3, 46).When grown on blood agar at an optimum temperature and under an optimum atmosphere, colonies are usually 0.5 to 1.0 mm in diameter, raised, and convex, with an entire edge and a smooth, shiny surface. *B. canis* and *B. ovis* characteristically produce rough colonies. Rough variants of the other species also occur (46).

Epidemiology and Transmission

Brucellae are facultative intracellular parasites, taking as their natural habitat a variety of animal species. *B. abortus* is found primarily in cattle but also occurs in camels, buffalo, yaks, and horses. Goats and sheep are the most common hosts for *B. melitensis*. This species is also found in alpacas and camels. In some parts of the world, cattle have emerged as a significant source of *B. melitensis* infections. It has been suggested that when this species occurs in cattle, smaller ruminants have provided the actual reservoir (45, 73, 178). The primary hosts for *B. suis* are swine (biovars 1, 2, and 3) and reindeer and caribou (biovar 4). In some countries, cattle have become a significant source of *B. suis* bv. 1 infection for humans. Maintenance of *B. suis* in cattle may depend on a concomitant pig reservoir (73). *B. canis* is usually isolated from kennel-bred dogs but also has been found in coyotes and foxes. Hosts for the marine mammal brucellae include seals, dolphins, and porpoises (40). Unlike the preceding taxa, *B. ovis* and *B. neotomae* are not known to cause human disease. The former has been isolated from sheep, the latter from the desert wood rat (73). Brucellae localize in their host's reticuloendothelial tissue and reproductive tract. Causing abortion, they are typically transmitted from one host animal to the next via contamination of the environment by the products of abortion (110).

Brucellosis has been described as the world's most widespread zoonosis, taking not only a serious human toll but also a severe economic toll when infecting domestic animals (73). The disease is highly endemic in the Middle East, the Mediterranean basin, Latin America, southeastern Europe, Asia, Africa, and the Caribbean (73). Though *B. abortus* has the broadest geographic distribution, *B. melitensis* causes more cases of human disease. This is attributed to bovine brucellosis's having been controlled more effectively than brucellosis in sheep and goats. In many developing countries, these small ruminants are the most important domestic animals and where they are kept, brucellosis is almost always present (45, 73). In the United States, the epidemiology of brucellosis has changed over the last 30 years. The success of programs to eradicate brucellosis in cattle, swine, sheep, and goats has decreased, though not eliminated, the risk of infection for farmers, veterinarians, and abattoir workers. Brucellosis has become primarily a foodborne disease caused by *B. melitensis* and associated with consumption of unpasteurized goat milk products from countries where caprine brucellosis is endemic (66, 132). Person-to-person transmission does not ordinarily occur but has been reported in connection with tissue transplantation and sexual intercourse (45, 175).

Brucellosis is usually transmitted to humans by direct contact through abraded skin or mucosal surfaces, consumption of contaminated food products, or inhalation. Brucellosis continues to be one of the most common laboratory-acquired infections. Practices associated with transmission in the laboratory include unprotected handling of specimens, sniffing of plates, mouth pipetting, and exposure of the eyes, nose, or mouth to infectious aerosols (50).

Clinical Significance

Of the species causing brucellosis in humans, *B. melitensis* tends to produce the most severe disease, followed by *B. suis* and *B. abortus* (110). While *B. canis* can cause clinical disease similar to that caused by the above-mentioned species, it has reduced virulence for humans (44, 175). Human brucellosis caused by marine mammal strains has been reported more recently (20, 150). The two community-acquired cases in one report presented as neurobrucellosis. The relative risk of infection with and pathogenicity of these strains for humans need further investigation.

The incubation period of brucellosis is usually 1 to 3 weeks but can be much longer. Symptoms are nonspecific.

They include fever (often undulating), malaise, night sweats, backache, muscle aches, and anorexia. The disease may affect a particular organ or organ system, causing osteomyelitis, hepatomegaly, splenomegaly, meningitis and other central nervous system symptoms, epididymo-orchitis, and endocarditis, among other complications. Although endocarditis is rare, when brucellosis is fatal, endocarditis is usually the cause. Chronic brucellosis can be defined as a disease in which compatible signs and symptoms persist for more than a year. Arguably, with brucellosis the definitions of acute and chronic are somewhat arbitrary (175). Though the fatality rate of brucellosis is now less than 2%, principally because of antibiotics, it remains a severe and debilitating disease (110).

Collection, Handling, Storage, and Transport of Specimens

Specimens for the diagnosis of brucellosis in humans include blood and bone marrow for culture and serum for serologic testing. Brucellae may also be cultured from spleen, liver, synovial fluid, or abscess specimens. For best results, multiple blood samples should be drawn during febrile episodes (110). The general collection, handling, storage, and transport guidelines for these specimens given in this Manual are applicable here (see chapters 5 and 20). Specimens for culture should be collected before the initiation of antibiotic therapy. Specimens that cannot be processed within 1 h of collection should be refrigerated. Acute-phase serum specimens should be collected as soon as possible after the onset of symptoms, and convalescent-phase specimens should be collected 14 to 21 days thereafter. Serum specimens should be shipped and stored cold or frozen. If PCR analysis is to be done, the collection method needs to adhere to the requirements of the particular assay method. Specimens from patients with suspected brucellosis should be labeled appropriately so that laboratory exposures to the disease agent can be minimized.

Direct Examination of Specimens

Direct microscopic examination of blood or bone marrow is not sufficiently sensitive to be useful in the diagnosis of brucellosis. There is no laboratory protocol for DFA staining. Direct detection methods using PCR assays have been described. When available for routine use, PCR-based tests will be particularly useful for laboratories serving areas of high endemicity (113, 131, 133). However, most PCR methods are capable of sampling only a small volume of specimen relative to that used to culture *Brucella*.

Isolation Procedures

Isolation of *Brucella* provides proof of the disease. Blood and bone marrow are the usual specimens for culture in cases of human brucellosis. Historically, bone marrow culture has been considered more sensitive, particularly in cases of chronic brucellosis and when the patient has already been treated with antibiotics (75). The greater sensitivity of modern automated blood culture systems may obviate this advantage. For example, in one study Ozturk et al., using the BACTEC 9240 system (Becton Dickinson Diagnostic Instrument Systems, Towson, Md.), cultured both blood and bone marrow specimens from 16 brucellosis patients. For 13 of the patients, *Brucella* was recovered from both specimens. For the remaining three patients, both specimens were culture negative. This study included cases in which antibiotics were given before culture but no chronic cases (123). These findings suggest that the more invasive procedure of bone marrow culture can be reserved for diagnostic problem cases in which blood cultures are negative.

Not all laboratories, particularly those in developing countries, will have an automated blood culture system. The classic biphasic blood culture technique of Casteñeda is one alternative. The culture bottle contains a broth medium with a layer of the same medium solidified with 2 to 3% agar on one side of the bottle (32, 110). Various studies have reported times to detection ranging from less than 6 days to more than 27 days by using this method (75, 137, 144).

Lysis-centrifugation involves osmotic lysis of erythrocytes followed by concentration of bacteria by centrifugation and direct plating of the concentrate onto culture media (19). This technique may be done by using the commercially available Isolator microbial tube (Wampole Laboratories, Cranbury, N.J.) or an in-house method. Lysis-centrifugation has better sensitivity and shorter time to detection than the biphasic bottle method. Since it is also technologically simple, this technique is arguably a better choice than the biphasic (Casteñeda) bottle method for laboratories that do not have an automated blood culture system (58, 101). Lysis-centrifugation also gave improved results compared to those of direct plating when synovial fluid was used for culture of *Brucella* (174). Compared with early versions of automated blood culture systems, such as BACTEC 460 and BACTEC NR, the lysis-centrifugation approach produced reduced times to detection, but in some cases the automated systems produced higher sensitivity rates (96).

Recent studies with the newer continuous-monitoring systems indicate that the BACTEC 9000 series is able to achieve times to detection that are shorter than those of lysis-centrifugation (>95% positive within 7 days of incubation) and has greater sensitivity (173). In general, modern automated blood culture systems can be depended on to detect *Brucella* within the routine incubation period used with these technologies (10, 11).

Because *Brucella* spp. have a slower growth rate than many of the bacteria encountered in the clinical laboratory, they seem more fastidious than they really are. They will grow on most of the media commonly used in this setting, including Trypticase soy agar, heart infusion agar, and brain heart infusion agar. Most strains will grow on Thayer-Martin or Martin-Lewis agar, which may be useful in recovering *Brucella* from contaminated specimens. Some strains will grow better with increased CO_2 (5 to 10%); *B. abortus* may require increased CO_2, particularly upon initial isolation.

Identification

Early recognition that an isolate may be a *Brucella* species is important for reasons of public health and laboratory safety as well as the patient's diagnosis. Brucellosis is a serious infectious disease that is frequently foodborne. Existence of a new case in the community suggests the possibility of additional cases, and *Brucella*, like *F. tularensis*, is considered a possible bioterrorism agent (chapter 9). Because of the hazard of laboratory-acquired infections, possible *Brucella* cultures should be handled using BSL-3 practices, with culture manipulations being done in a biological safety cabinet (50).

Fortunately, *Brucella* has some easily determined salient features that can lead to an early suspicion of the organism's identity. A Gram stain shows tiny, gram-negative coccobacilli. With the exception of *F. tularensis*, *Brucella* is the smallest gram-negative organism likely to be seen in the clinical laboratory. Its reputation for faint staining notwithstanding, *Brucella* may occasionally show a hint of gram positivity, especially with insufficient decolorization, leading to initial

misidentification (117). In Fig. 1 the size of *Brucella* (Fig. 1B) may be compared with that of *Acinetobacter* spp. (Fig. 1C). When streaked for isolation, discrete colonies are seldom seen in 1 day. Once evident, colonies are small (1 mm or less in diameter), translucent, soft, and easily emulsified. They are nonhemolytic on blood agar.

Brucella spp. are positive for oxidase and urease. Some of the oxidase- and urease-positive, non-glucose-fermenting, gram-negative taxa that along with *Haemophilus* spp. may be confused with *Brucella* spp. are listed in Table 1. Size difference is helpful in differentiating *Psychrobacter phenylpyruvicus (Moraxella phenylpyruvica)* from *Brucella* spp., the former being about the size of *Acinetobacter* spp. Both morphology and motility are useful in differentiating *Brucella* spp. from *Bordetella bronchiseptica* and *Ochrobactrum anthropi*. Urease-positive biotypes of *Haemophilus* spp., in addition to requiring X and V factor (or only V factor), differ from *Brucella* by not growing on sheep blood agar. *Oligella ureolytica*, also a small organism, may be more difficult to separate from *Brucella* spp. While *O. ureolytica* is described as motile, motility may be delayed or difficult to demonstrate. Most isolations of *O. ureolytica* are made from urine, an unlikely source for *Brucella*. Also, when tested in oxidation-fermentation medium, *Brucella* spp. produce acid from xylose and *O. ureolytica* does not. In all these instances, CFA analysis is another useful differential test. Laboratories using identification kits or automated identification systems need to know if the database includes *Brucella* spp. With most systems, at present, *Brucella* is not included. In the past, some of these test methodologies have been reported to misidentify *Brucella* variously as *Haemophilus influenzae* biotype IV, *Psychrobacter phenylpyruvicus*, and *Ochrobactrum anthropi* (9, 12, 55, 136).

If an identification as *Brucella* sp. cannot be ruled out (also see chapter 9) and the laboratory is unable to do further confirmatory tests, the isolate should be sent to a reference laboratory that can definitively identify and determine the species of brucellae. Use proper biohazard shipping procedures (chapter 9). In the United States, LRN laboratories are able to confirm and identify *Brucella* spp. to the species level. Again, state public health laboratories can provide additional information, including location, about a state's LRN laboratories. See also http://www.bt.cdc.gov/lrn/.

Confirmation of a culture as *Brucella* sp. can be done serologically. A suspension of the isolate equivalent to a 2 McFarland standard is made up in 1% formalin saline. The suspension is allowed to stand for 24 h, which kills the organism. The resulting product is used as an antigen in a TA test using a positive control serum such as Difco/BBL Brucella Positive Control Serum AMS (BD Diagnostics, Sparks, Md.). *B. canis* is not agglutinated by this antiserum, but this procedure will confirm as *Brucella* those species that commonly cause human brucellosis and that cause the most severe human disease, *B. melitensis*, *B. suis*, and *B. abortus*. Serologic cross-reactions have been reported with *Afipia clevelandensis*, *Vibrio cholerae*, *Yersinia enterocolitica* O:9, and *F. tularensis* (51, 178). *A. clevelandensis* is motile and its cells are larger than those of *Brucella*; *V. cholerae* and *Y. enterocolitica* are motile, glucose-fermenting, medium rods; *F. tularensis* is easily differentiated from *Brucella* by the characteristics given in Table 1.

Tests for the species-level identification of *Brucella* include sensitivity to the dyes thionin and basic fuchsin, rapidity of urea hydrolysis, H_2S production, lysis by Tbilisi (Tb) phage at the routine test dilution (RTD) and the RTD $\times 10^4$, and determination of rough versus smooth phase. Dye sensitivities are tested by swabbing a saline suspension of the test organism in a line across a plate of medium such as Trypticase soy agar or heart infusion agar containing the appropriate dye, typically at a concentration of 20 μg/ml. Known cultures of *B. melitensis*, *B. suis*, and *B. abortus* should be included as controls. The rate of urease activity can be tested conveniently by heavily inoculating a Christensen's urea agar slant with fresh growth and leaving it at room temperature for 5 min. A positive reaction will be seen with *B. suis*, *B. canis,* and some strains of *B. melitensis* within this time period. *B. abortus* and most strains of *B. melitensis* will need an additional incubation at 35 to 37°C, up to overnight, to become positive. Production of H_2S is detected using a lead acetate paper strip suspended over an inoculated slant of medium such as heart infusion agar. Read and change the strip daily for up to 6 days or until the strip blackens, indicating a positive result. Tbilisi (Tb) phage, available from the American Type Culture Collection (ATCC 23448-B1), lyses *B. abortus* when used at its RTD. It will also lyse *B. suis* when used at the RTD $\times 10^4$. The RTD is determined by making serial 10-fold dilutions of the phage and applying a 10-μl drop of each dilution to a plate inoculated for confluent growth with a suspension of a known *B. abortus* culture. The highest dilution giving confluent lysis is the RTD. The test organism is similarly inoculated onto a plate for confluent growth, and a 10-μl drop of the RTD and of the RTD $\times 10^4$ of the phage is applied. *B. canis*, a rough organism, will agglutinate in acriflavine solution; *B. melitensis*, *B. suis*, and *B. abortus*, typically smooth species, will not. For this test, suspend a small amount of growth in a drop of a freshly prepared solution of 1:1,000 neutral acriflavine in distilled water and observe for agglutination (3, 169). For additional details on these tests, see the monograph by Alton et al. (3).

Table 3 summarizes the characteristics of the four validly named species that cause human disease. The dye sensitivity and H_2S reactions noted for *B. suis* are for biovars 1 and 3 and those for *B. abortus* are for biovar 1. These are the biovars of these two species most commonly encountered in human brucellosis (44). For the reactions of the other biovars of these two species, see Alton et al. (3). With *Brucella* identification, as with any bacterial identification, it is necessary to consider the phenotypic picture as a whole before coming to a conclusion. An additional useful test for the identification of *B. canis* is CFA analysis. While *B. melitensis*, *B. suis*, and *B. abortus* all have lactobacillic acid (19:0cyc) as

TABLE 3 Differential characteristics of *Brucella* spp.[a]

Test	*B. melitensis*	*B. suis*	*B. abortus*	*B. canis*
Dye sensitivity				
Thionin	R	R	S	R
Basic fuchsin	R	V[b]	R	S
Time (min) for urea hydrolysis	>5[c]	<5	>5	<5
H_2S production	−	V[d]	+	−
Lysis by Tb[e] phage at RTD	−	−	+	−
Lysis by Tb phage at RTD $\times 10^4$	−	+	+	−
Agglutination in 1:1,000 acriflavine	−[f]	−[f]	−[f]	+

[a] Data are from references 3 and 169. R, resistant; S, sensitive; V, variable.
[b] Biovar 1, sensitive; biovar 3, resistant.
[c] Some strains are positive in <5 min.
[d] Biovar 1, positive; biovar 3, negative.
[e] Tbilisi, a *Brucella* phage originally isolated in the former USSR.
[f] Occasional strains are rough.

a major component of their CFA profile, *B. canis* lacks this compound (169). Marine mammal strains of *Brucella* are smooth, are resistant to thionin and basic fuchsin, hydrolyze urea (not rapidly), do not produce H_2S, and are variable for lysis by Tb phage (110). Strains not lysed by Tb phage will resemble *B. melitensis*.

The traditional methods of species-level identification of *Brucella* are complex and labor-intensive, involve some hazard, and in part because of the slow growth rate of *Brucella* organisms, take some days to yield a final result. Molecular methods, which involve much less manipulation of viable organisms and yield results much more rapidly, are gaining greater acceptance as a supplement or alternative to the conventional methods of identification. A number of molecular tests are now available for the identification of *Brucella* to the genus and species levels. PCR assays targeting *omp43*, *omp31*, the 16S rRNA gene, 16S to 23S spacer regions, heat shock protein genes, and the perosamine synthetase gene have been developed to detect *Brucella* spp. (18, 47, 113, 116, 130, 131, 135). 16S rRNA gene sequencing of a large panel of isolates has shown perfect sequence conservation among *Brucella* spp., limiting the usefulness of this target for species identification (72). However, resolution to species level is possible through ribotyping, amplified fragment length polymorphism analysis, amplification and DNA sequencing of *omp2* and *omp25*, and PCR assays targeting species-specific insertions of IS*711* elements (22, 38, 39, 62, 77, 115, 130, 133, 170). Several PCR assays have been formatted for use on real-time PCR instrumentation that facilitates rapid detection and reduces the risk of amplicon carryover contamination (18, 115, 130, 131, 133).

Typing Systems

B. melitensis, *B. suis*, and *B. abortus* are further divided into biovars. The three biovars of *B. melitensis* are based on agglutination with monospecific antisera for the *B. abortus* A antigen and the *B. melitensis* M antigen. *B. suis* has five biovars, defined by H_2S production, dye sensitivities, and agglutination patterns with the monospecific antisera. Differentiation among the seven biovars of *B. abortus* uses these same characteristics plus testing for CO_2-dependent growth. See the monograph by Alton et al. for details on these test procedures (3).

Molecular typing methods offer advantages over biovar determination similar to the advantages that molecular biology-based tests have over conventional tests for genus- and species-level identification of *Brucella*. In addition, molecular typing offers much greater discrimination among strains than does biovar determination. Identification beyond the species level has been demonstrated by PCR, RNA mismatch cleavage, and Fourier transform infrared spectroscopy (21, 22, 108). A PCR-based method targeting genetic segments containing variable numbers of tandem repeats has been recently developed for *Brucella* strain typing and promises to provide a useful tool for facilitating epidemiological investigations (24).

Serologic Testing

Serologic testing is a valuable adjunct to culture for the laboratory diagnosis of brucellosis. Demonstration of a specific antibody response can provide useful diagnostic information, and the characterization of the response (predominantly IgM versus IgG) assists in differentiating acute infection from chronic disease (149). The serum agglutination test (SAT) is the most widely used test in the United States (178). This test can be modified to differentiate IgG from IgM titers by pretreatment of specimens with 2-mercaptoethanol. The SAT detects antibodies against *B. abortus*, *B. suis*, and *B. melitensis* but not *B. canis*. A fourfold rise in SAT titer between the acute- and convalescent-phase serum samples is indicative of brucellosis. For single specimens, an SAT titer of $\geq$1:160 is suggestive of brucellosis. Cross-reactions may be observed with antibodies directed against *F. tularensis*, *Vibrio cholerae*, *Yersinia enterocolitica*, and *Afipia clevelandensis* (51, 178). There are few reports of using the SAT in cases of human brucellosis of marine mammal origin. Of the three reported human cases, two were positive in the SAT and one was negative (20, 150). Other serologic assays that have been described include the Rose Bengal test, the Coombs anti-human globulin test, the complement fixation test, ELISA, and the rapid dipstick test (5, 149, 152). The rapid dipstick assay, a relatively simple screening procedure for *Brucella*-specific IgM, shows promise as a field test in areas without direct access to a reference laboratory.

Antimicrobial Susceptibilities

The development of antibiotic resistance by *Brucella* has not yet been demonstrated. This has been attributed in part to the lack of plasmids (110). Additional reasons for not routinely doing in vitro susceptibility testing with this organism include safety concerns, poor correlation between high levels of in vitro activity and clinical efficacy for many agents including β-lactams and quinolones, and a general lack of well-established interpretive standards (177).

Successful treatment of brucellosis requires long-term combination antibiotic therapy. The regimen that the World Health Organization recommends is doxycycline (200 mg/day) in combination with rifampin (600 to 900 mg/day, orally) for 6 weeks (45). The combination of doxycycline and streptomycin is also effective. In children younger than 8 years, treatment combining trimethoprim-sulfamethoxazole with an aminoglycoside has been successful, without the side effects of tetracyclines in this age group (178).

The question of prophylaxis often arises after potential laboratory exposure to *Brucella*. Universally accepted practices in these cases are lacking. Some have advocated a full 6-week course of antibiotics if there has been significant exposure (151). Use of doxycycline alone for 1 week immediately following exposure (180) as well as a 3-week course of the standard combination of doxycycline and rifampin (136) has been reported.

Evaluation, Interpretation, and Reporting of Results

Isolation of *Brucella* from a patient's blood, bone marrow, or other tissue establishes a diagnosis of brucellosis. Modern blood culture methods can be quite sensitive, especially in acute infections (123, 139). An isolate presumptively identified as *Brucella* should be immediately reported to the physician as a possible *Brucella* sp., and results of confirmatory testing and identification to species level should be reported as soon as these are available. With the SAT, a fourfold or greater rise in titer is considered to indicate positivity (33). A single titer needs to be interpreted in light of epidemiologic and clinical evidence. In many settings a titer of $\geq$1:160 is considered significant in a patient with compatible symptoms (33, 176).

*Legionella**

PAUL H. EDELSTEIN

53

TAXONOMY

The *Legionellaceae* are composed of a single genus, *Legionella,* and 50 validly named species (http://www.bacterio.cict.fr/l/legionella.html) (Table 1). *Legionella pneumophila, L. micdadei, L. longbeachae,* and *L. dumoffii* are the most important from a clinical standpoint, with *L. pneumophila* causing more than 90% of the cases of Legionnaires' disease (LD). The *Legionellaceae* are most closely related to the *Coxiellaceae,* and these two families constitute the proposed order "*Legionellales,*" within the class *Gammaproteobacteria* and phylum *Proteobacteria* phy. nov. (http://sn2000.taxonomy.nl/Taxonomicon/TaxonTree.aspx?id=111537). *Coxiella burnetii,* the agent of Q fever, shares many characteristics with *L. pneumophila,* including intracellular parasitism and close homologies of several virulence genes (102). Some investigators proposed the use of *Tatlockia* and *Fluoribacter* as additional genera within the *Legionellaceae* (39), but a subsequent study of 16S rRNA demonstrated that the *Legionellaceae* are monophyletic (36); use of these genus names was never widely accepted and is of historical interest only. A number of *Legionella*-like bacteria have been described to grow only within free-living amoebae and have been designated LLAP, for *Legionella*-like amoebal pathogen. One of the LLAPs, *L. lytica,* has been shown to cause human disease, and four have been assigned novel *Legionella* spp.; three of these four have been grown axenically at low temperature (1).

DESCRIPTION OF THE AGENT

The *Legionellaceae* are a diverse group of mesophilic, motile, asaccharolytic, obligately aerobic, nutritionally fastidious gram-negative rods, sharing growth dependence for L-cysteine, growth enhancement by iron, and cellular branched-chain fatty acids and ubiquinones that are unusual for gram-negative bacteria (23). *L. pneumophila* is the most extensively studied of the *Legionella* spp., with relatively little known about most of the other *Legionella* spp. Almost all of the *Legionella* spp. have been isolated from aqueous environmental sources and about one-third of the 50 validly named species have been isolated from both humans and the environment. It is assumed that the natural reservoir of all the *Legionellaceae* is our aqueous environment and that humans are an accidental host of the bacterium. Environmental *L. pneumophila* is a facultative intracellular parasite of several different free-living amoebae, such as *Acanthamoeba* and *Naegleria,* existing in microbial consortia in biofilms and free-flowing water.

L. pneumophila grows optimally at 35 to 37°C and grows less well at temperatures ranging from 20 to 42°C. Growth on solid media is enhanced by increased humidity. Incubation in 2 to 5% CO_2 can enhance the growth of some, but not most, *Legionella* spp. Bacterial phenotype, including immunogenicity, cell size, and virulence, can be altered by growth at different temperatures (23).

Amino acids, rather than carbohydrates, are used as energy sources by the *Legionellaceae* growing in vitro; this is true for intracellular bacteria as well, despite the presence of putative carbohydrate utilization genes in the *L. pneumophila* genome (23). Primary isolation of all known *Legionella* spp. requires medium supplementation with L-cysteine, as does successful propagation of all but a few species. Iron supplementation of growth media is required for optimal growth, although many *Legionella* spp. can grow, albeit poorly, in the absence of the mineral. Growth of *L. pneumophila* is enhanced by the addition of α-ketoglutarate (0.1%) to media, via an unknown, nonnutritive mechanism.

Growth of *L. pneumophila* in artificial media can be inhibited by a number of extraneous factors. These include the presence of high (100 mM, or 0.6%) NaCl concentrations, toxic peroxides, products of other bacteria and fungi, and some lipids (23). In addition, optimal growth occurs over a very narrow pH range, from 6.7 to 6.9. Solid growth media contain activated charcoal to inactivate toxic lipids and peroxides and an organic buffer (MOPS [morpholine propanesulfonic acid] or ACES [*N*-(2-acetamido)-2-aminoethanesulfonic acid]) to reduce sodium content and provide the required pH. Preparation of growth media for *Legionella* spp. can be complex and is usually best left to competent commercial sources or to specialized laboratories.

EPIDEMIOLOGY AND TRANSMISSION

LD was first recognized as a distinct entity when epidemic pneumonia with a 15% fatality rate developed during and after a convention of Pennsylvania State Legionnaires in

* This chapter contains information presented in chapter 52 by Janet E. Stout, John D. Rihs, and Victor L. Yu in the eighth edition of this Manual.

TABLE 1 Selected characteristics of *Legionella* spp.[a]

Legionella sp.[b]	Isolated from humans[c]	No. of recognized serogroups	Color under long-wave UV light	Comments
L. adelaidensis	N	1	NC	
L. anisa	Y	1	BW/YG	
L. beliardensis	N	1	YG	
L. birminghamensis	Y	1	YG	
L. bozemanae	Y	2	BW	AN, *Fluoribacter bozemanae*[d]
L. brunensis	N	1	NC	
L. busanensis	N	1	NC	
L. cherrii	N	1	BW	
L. cincinnatiensis	Y	1	YG	
L. drancourtii	N	NK	NK	Amoebic pathogen; no axenic growth
L. drozanskii	N	1	NC	Grows at 30°C but not at 37°C
L. dumoffii	Y	1	BW	AN, *F. dumoffii*[d]
L. erythra	N	2	R	
L. fairfieldensis	N	1	NC	
L. fallonii	N	1	NC	Grows at 30°C but not at 37°C
L. feeleii	Y	2	NC	
L. geestiana	N	1	NC	
L. gormanii	Y	1	BW	AN, *F. gormanii*[d]
L. gratiana	N	1	NC

L. tucsonensis	Y	1	BW	
L. wadsworthii	Y	1	YG	
L. waltersii	N	1	NC	
L. worsleiensis	N	1	NC	

[a] Abbreviations: Y, yes; N, no; NK, not known; NC, no color; BW, bright blue-white; YG, pale yellow-green; BW/YG, some strains are BW and some are YG; R, dark red; R/yg, majority of strains are red, with remainder YG.

[b] All species listed, except "*L. jeonii,*" constitute validly published names. Several other species probably exist.

[c] Severely immunosuppressed patients may acquire infections with *Legionella* spp. not previously isolated from humans.

[d] AN, alternative name; while valid, the genus names *Fluoribacter* and *Tatlockia* are not in widespread usage.

Philadelphia in July 1976 (22, 33). Joseph McDade and colleagues at the CDC determined that a novel gram-negative bacterium was the cause of the outbreak (70). Neither the disease nor the bacterium was found to be novel, with the first known epidemic of LD having occurred in 1957 (78) and isolation of the bacterium having occurred multiple times from the 1940s on.

Environmental studies found that the bacterium was widespread in natural bodies of water and occasionally in high concentration in warm waters found in plumbing systems, water heaters, warm water spas, and cooling towers. Many different *Legionella* spp. exist in nature within free-living amoebae, and as a result these otherwise fastidious bacteria can multiply within the amoebae and be protected from biocides (87). *Legionella*-infected amoebae are often found in complex consortia of microorganisms within biofilms. The bacteria are present in very low concentrations in freely flowing cold water and biocide-treated waters but can multiply in warm, and especially stagnant, water. Devices that aerosolize these contaminated waters serve to disseminate the bacteria.

The usual route of infection is thought to be by aerosol inhalation, although microaspiration of contaminated water may also be a mechanism of acquiring the disease (22). The majority of community epidemics of LD are from *Legionella*-contaminated cooling towers or other aerosol-generating devices. Contaminated potable water systems, such as water heaters and warm water in pipes, can also be a major source of disease, especially in hospitals, although they are not usually the cause of explosive outbreaks of the disease.

The bacterial inoculum required to cause human infection or disease is unknown. Animal studies performed using broth-grown bacteria show the infecting dose to be in the range of 10 to 500 CFU and the fatal dose to be about 10^4 to 10^5 CFU. Since bacterial virulence for cells or animals can be enhanced by growth in amoebae or by infection with the spore-like form, the infective doses may be even lower for naturally grown bacteria (2, 38).

Despite the ubiquity of legionella bacteria in our environment, LD is an unusual cause of pneumonia. It is estimated that 0.5 to 5% of adults requiring hospitalization for pneumonia have LD. Passive reporting indicates that the disease incidence is from 4 to 20 cases per million people per year, and a prospective study estimated that the disease incidence is about 80 cases per million people per year, or between 8,000 to 18,000 LD cases annually in the United States (69). Sporadic community-acquired LD is much more common than epidemic-associated disease, in a ratio of about 4 to 1.

The incubation period of LD is estimated to be between 2 and 14 days, with a median value of about 4 days. A study of a large outbreak extended the incubation period to as long as 19 days, with a median value of 7 days (12).

L. pneumophila causes disease by infecting human mononuclear cells, primarily alveolar macrophages. After the bacterium is inhaled into the lungs, it invades lung macrophages and multiplies in them. Detailed descriptions of pathogenesis can be found elsewhere (22, 23).

CLINICAL SIGNIFICANCE

LD is a type of bacterial pneumonia caused by *L. pneumophila* and other *Legionella* spp. The pneumonia ranges in severity from mild to fatal, with an average fatality rate of 12% (4). Major risk factors for the disease include immunosuppression of the cellular immune system, cigarette smoking, overnight travel outside the home, use of well water, chronic heart or lung disease, and chronic renal failure.

LD cannot be readily distinguished from other forms of community-acquired pneumonia by clinical, roentgenographic, or nonspecific laboratory studies (22). Several attempts at developing a clinical scoring system to distinguish LD from other pneumonias have failed.

The severity of pneumonia at presentation, underlying diseases, and promptness of specific antibiotic therapy are important prognostic factors. Promptly treated, LD can be cured in 95 to 99% of cases occurring in otherwise healthy persons. Less than one-half of patients may respond if there is a delay in therapy, immunosuppression, or respiratory failure (22). Untreated disease causes death in about 15% of previously healthy patients and up to 75% of severely immunocompromised ones.

Prospective, randomized controlled studies of adequate size have not been performed to determine the optimal therapy for LD, so great reliance is placed on experimental tissue culture and animal model studies, as well as results of nonrandomized studies (18, 22). Erythromycin, clarithromycin, azithromycin, a tetracycline, telithromycin, levofloxacin, ciprofloxacin, gatifloxacin, and moxifloxacin all appear to have roughly equivalent efficacy for nonimmunocompromised outpatients with mild LD (22). The quinolone antimicrobials, especially levofloxacin, and azithromycin are the drugs of choice for severe disease and for immunocompromised patients (22, 74).

Pontiac fever is an acute influenza-like illness that has been associated with exposure to *Legionella*-containing environmental aerosols (32, 42). The etiology and pathogenesis of this disease are unknown, but it appears as if the disease is caused by inhalation of bacterial toxins, such as endotoxin, or perhaps an acute allergic reaction to a bacterium. Since multiple microorganisms and endotoxin have been found in aerosols causing Pontiac fever, it is unclear if *Legionella* spp. play any role at all in disease causation. Pontiac fever is self-limited, with no reported deaths, little to no need for hospitalization, and no need for antibiotic therapy.

COLLECTION, STORAGE, AND TRANSPORT

Expectorated sputum and other lower respiratory specimens are the most common sources of *Legionella* spp. Other, less common sources include pleural fluid and blood. Rare sources have included pericardial fluid, kidney, liver, spleen, myocardium, respiratory sinuses, skin and soft tissues, infected wounds, peritoneal fluid, bone marrow, and intestine. Culture of available sputum, bronchoscopy specimens, lung biopsy specimens, and pleural fluid should be routine for laboratory diagnosis of LD. Lung biopsy specimens have the highest yield but may be negative. Culture of expectorated sputum or other lower respiratory tract secretions, second in yield to lung biopsy, should always be performed for optimal detection of legionella infection. Pleural fluid has low yield but should be cultured if it is available. Routine culture of other specimens for *Legionella* spp. is not indicated unless there is a high clinical suspicion of the disease affecting these sites.

Sputum microscopic scoring criteria cannot be used to determine which sputum specimens should be cultured for legionella bacteria because of limited purulence and scanty secretions in patients with LD. Up to 80% of specimens culture positive for *Legionella* spp. may be rejected when using the criterion of the presence of sputum purulence for processing specimens (31, 54).

Urine for antigen detection should be collected in a sterile container (16). Boric acid preserves the antigen, but commercial urine transport systems containing boric acid

have not been studied for antigen preservation and freedom from interactions. The urine can be transported to the laboratory at room temperature if no more than a several hour delay is anticipated. Longer transport times require specimen refrigeration; urine specimens should not be frozen, as this may reduce test sensitivity and specificity.

Blood for serum antibody testing is collected in standard tubes and transported at room temperature(19). Test performance is not adversely affected by storage of the clotted unseparated blood at room temperature for several days. Long-term storage is at –20°C in aliquots to allow parallel testing without freeze-thawing, which can lower antibody levels.

Legionella is hardy and generally survives for up to a week in clinical specimens. Sputum and other respiratory tract specimens, including lung biopsy specimens, should be collected in sterile containers and transported to the laboratory promptly at room temperature. Transportation and storage should be at 2 to 5°C if more than a several hour delay is anticipated before the specimen can be plated. Very long-term storage is best at –70°C, although this can reduce bacterial concentration to below the level of detection in cases where the starting concentration is low or the specimen is primarily aqueous. Repeated freeze-thawing is harmful to the bacteria. Some tissues, especially spleen, contain growth-preventing substances and must be plated promptly; even overnight storage at 5°C dramatically reduces culture yield; however, this is not true of lung specimens.

DIRECT SPECIMEN EXAMINATION

Microscopy

L. pneumophila found in lung and sputum is a small coccobacillus to short rod, 3 to 5 μm in length (Fig. 1). This morphology is very different from that observed for the bacterium taken from a culture plate, which is usually a long, filamentous bacillus, 10 to 25 μm in length. *L. pneumophila* is difficult to detect by Gram staining of sputum or lung biopsy specimens. Use of 0.1% basic fuchsin, rather than safranin, greatly enhances the staining of the bacterium from culture plates, but even with use of this stain it is often very difficult to visualize the bacterium in sputum and tissues. Less than 0.1% of *L. pneumophila* present in lung tissue or sputum can be visualized by Gram staining using basic fuchsin. The small size of intracellular *L. pneumophila* bacteria, the form present in human tissues, makes visualization difficult with Gram stain, as does stain uptake by the surrounding proteinaceous material found in sputum and tissue.

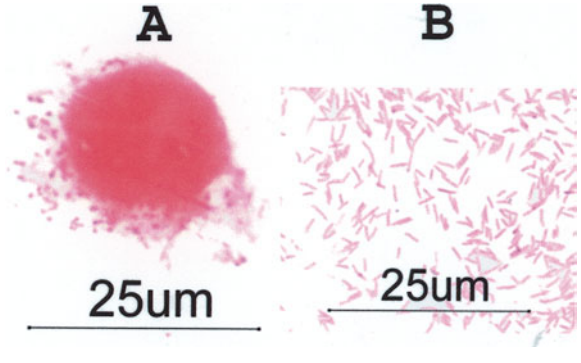

FIGURE 1 Photomicrographs of *L. pneumophila*. (A) Gimenez stain of intracellular bacteria in lung infection. (B) Gram stain using basic fuchsin counterstain of colony taken from BCYEα plate. Note the dramatic size and shape differences between the intracellular and extracellular bacteria.

Use of the Gimenez stain dramatically increases the number of *L. pneumophila* organisms detected in sputum and lung tissue, 100- to 1,000-fold over that visualized with Gram stain using basic fuchsin counterstain. Even so, this stain is very insensitive for the detection of the bacterium in sputum when compared to immunofluorescent microscopy (27). Sensitivity of the Gimenez stain for the detection of *L. pneumophila* in lung tissue has not been studied, but it appears to be high in fulminant cases. Unfortunately, the Gimenez stain is difficult to prepare, is not commercially available, requires filtration before each use, and can be unstable. Finally, the Gimenez stain cannot distinguish between *L. pneumophila* and other bacteria present in sputum and tissues. The stain detects the bacterium in Formalin-fixed, but not embedded, tissues (43).

Enhancement of bacterial staining by silver precipitate stains, such as the Warthin-Starry stain and its modifications and the Dieterle stain (29, 101), was an early approach to the detection of *L. pneumophila* in embedded tissues as well as sputum. These silver stains are useful for detection of the bacterium in embedded tissues but have no present role in the staining of the bacterium in sputum or other nonembedded specimens. Silver stains are not highly sensitive, can produce artifacts, and require expert use and interpretation for optimal sensitivity and specificity.

Immunofluorescent microscopy is the most sensitive and specific microscopic method for the detection of *L. pneumophila* in tissues and sputum (17, 27). Optimal sensitivity and specificity require exacting staining methods and great expertise by the microscopist. Polyclonal antibodies, which are commercially available, can be used to stain the bacterium in fresh, fixed, and embedded tissues and secretions. A commercially available monoclonal antibody (Bio-Rad, Hercules, Calif.) is useful for the highly specific staining of nonfixed tissues and secretions but loses sensitivity when used to stain fixed or embedded tissues (21, 41). Even when performed expertly, immunofluorescent microscopy is insensitive for the detection of *L. pneumophila* in sputum, detecting from 25 to 75% of culture-proven cases. False-positive tests with the polyclonal antibody can result from cross-reactions with non-*Legionella* bacteria, including *Pseudomonas aeruginosa, P. fluorescens, Bacteroides fragilis, Staphylococcus aureus, Bordetella pertussis, Bacillus* spp., lactobacillus-like bacteria, and candida-like yeasts; the number and variety of these potential cross-reactions make it imperative that the microscopist be skilled in distinguishing the morphology of *L. pneumophila* from those of the cross-reacting bacteria (6). Even so, some false-positive reactions will be recorded by very experienced microscopists. The monoclonal antibody has many fewer cross-reactions but may cross-react with *S. aureus* and *Bacillus* spp. In addition, *Legionella* organisms present in buffers, wash solutions, or Formalin, from specimen containers contaminated during manufacture, and from cross-contaminating, true-positive specimens can all cause false-positive tests. This means that extreme care needs to be taken to keep all slides physically separated from one another, to filter sterilize critical buffers and other aqueous solutions, and to screen specimen containers. Most important is performance of the staining and slide reading by an expert. Performance of these tests by inexperienced technologists can lead to many more false-positive than true-positive results. More details on immunofluorescent microscopy can be found elsewhere (17).

Antigen Detection

LD due to *L. pneumophila* serogroup 1 can often be diagnosed by detection of bacterial antigenuria (16). Several immunoassays are commercially available for this purpose, the most convenient of which is a rapid single-test immunochromatographic card assay (Binax, Scarborough, Maine). Several other assays utilize a microtube-based enzyme immunoassay. Only one kit (Biotest, Denville, N.J.) is designed to detect nonserogroup 1 *L. pneumophila* and appears to be somewhat sensitive for the detection of these infections (52). The strength of all these assays is their ability to detect *L. pneumophila* serogroup 1 infections, and in particular the Pontiac/MAB2/MAB3-1 monoclonal subtype (48–50). The immunochromatographic card assay may be somewhat less sensitive than the microtube-based immunoassays, although its convenience, ease of use, and robustness make up for a slightly lesser sensitivity.

Clinical test performance for all assays is dependent on the pretest probability of *L. pneumophila* serogroup 1 and on the probability of Pontiac monoclonal subtype *L. pneumophila* serogroup 1 infection (48, 50). Infection caused by *L. pneumophila* serogroup 1 Pontiac subtype is most common in epidemic and sporadic community-acquired LD and least common in nosocomial LD, especially that involving immunocompromised patients. About 80 to 90% of community-acquired LD is due to this subtype, whereas up to 60% of nosocomial LD may be caused by other *L. pneumophila* serogroup 1 subtypes, other *L. pneumophila* serogroups, and other *Legionella* species (48, 49). The assays detect about 60 to 70% of *L. pneumophila* serogroup 1 Pontiac monoclonal subtype epidemic infections and up to 90% of sporadic pneumonia caused by this subtype. The differences in test sensitivity for the same bacterial subtype are probably due to differences in disease severity, the other major factor determining test sensitivity. Patients with severe *L. pneumophila* serogroup 1 LD are the most likely to have positive urine antigen tests, for example, those requiring intensive care nursing and ventilator assistance; test sensitivity in this population is probably in the range of 90 to 95% of those infected with the Pontiac monoclonal subtype. On the other hand, urine testing may detect only 50% of outpatients with mild epidemic disease caused by the same monoclonal subtype, perhaps 40% of hospitalized patients with other *L. pneumophila* serogroup 1 subtypes, and fewer than 5 to 40% of those with infections caused by other serogroups and species, with the higher sensitivity value for testing being obtained with the Biotest kit (49, 52). The test may be negative during the first day of illness, but those with severe disease are likely to be positive on presentation to hospital. Repeat testing 2 to 3 days after the onset of illness may detect a small number of infections in patients who had negative tests initially.

Test sensitivity can be enhanced by concentrating the specimen by use of ultrafiltration devices such as Amicon concentrators (Millipore, Billerca, Mass.). In some studies this has increased test sensitivity by about 30%, without affecting specificity (14, 44). Test sensitivity decreases when specimens are frozen for weeks to months before testing.

The urine antigen assays are very specific, in the range of 99 to 99.9%. False-positive results can be due to urine rheumatoid-like factors, freeze-thawing of urine, and excessive urinary sediment. All together, these causes of false-positive results account for no more than a few percent of all positive results. Regardless, all positive results should be confirmed after boiling urine clarified by centrifugation.

Molecular Diagnosis of LD

PCR-based detection of *L. pneumophila* genes in sputum, urine, and blood has been successfully used in reference and research laboratories. The best results show that molecular diagnosis is a more sensitive method of diagnosis than culture, although some studies showed rough equivalence (73). Test sensitivities have been estimated to be 80 to 100%, 30 to 50%, and 50 to 90% for lower respiratory secretions, serum, and urine analytes, respectively; test specificities are estimated to be >90% (73). Both conventional and real-time assays have been utilized (51, 73). Until recently, only home brew assays were available.

One commercial assay, the BD ProbeTec ET *Legionella,* based on the Becton Dickinson ProbeTec methodology, is cleared for marketing by the U.S. FDA (BD Diagnostics, Sparks, Md.). Test sensitivity for 23 culture-proven archived sputum specimens was 91% (95% confidence interval [CI], 72 to 99%), and specificity was 87% (95% CI, 75 to 94%) in one study and 100% (95% CI, 96.8 to 100%) in another study. Several sputum specimens that were apparent false positives were also positive by a second molecular method (U.S. FDA 510K k033861 clearance letter, March 2004; http://www.fda.gov/cdrh/reviews/K033861.doc).

ISOLATION PROCEDURES

Specimen Plating

Optimal yield of *Legionella* spp. from clinical specimens usually requires that specimens be diluted to reduce inhibition by tissue and serum factors as well as antibiotics; that the specimen be pretreated to reduce contaminating flora; and that a variety of selective and nonselective media be used (Table 2). Culture of *Legionella* spp. from normally sterile fluids and tissues, such as pleural fluid, aseptically obtained lung tissue, or blood, is often successful without the use of multiple selective tissues and specimen decontamination.

Dilution (1:10) in tryptic soy broth increases the culture yield of most specimen types including sputum and other liquid respiratory tract specimens, lung tissue, lymph nodes, spleen, and probably other organs such as liver and kidney. Sputum and other respiratory specimens should first be examined in a petri dish for material that appears purulent, and this material should be selected for culture. Tissues (about 1 g) are ground in a tissue grinder with a small amount (1 ml) of broth, which adequately dilutes most tissues except for spleen; this tissue requires an additional 1:10 dilution for the best recovery of bacteria. Liquid specimens are roughly diluted by adding 3 drops of vortex-mixed liquid specimens to 0.9 ml of the dilution broth. Pleural fluid, joint fluid, and blood subcultured from blood culture bottles do not require dilution before plating; in fact, pleural fluid yield may be enhanced by concentration by centrifugation.

Decontamination, by either of two methods, is required to reduce contaminating flora in most sputum specimens and other respiratory tract secretions. The first method consists of diluting (1:10) the specimen in a low pH KCl-HCl buffer (pH 2.2) and incubating the mixture at room temperature (4.0 min) before plating the suspension onto culture media. Timing is critical here, since a low yield may result if the timing is off by as little as 1 min. The culture medium is sufficiently buffered so that the acidified specimen is neutralized upon being plated. The second method, an alternative to specimen acidification, consists of heating the specimen at 50°C for 30 min. Most aseptically collected tissue specimens do not require decontamination, although occasionally lung tissues contain multiple contaminating bacteria and fungi. In this case, heat or acid treatment of tissue ground in sterile distilled water may help; sometimes dilutions of the ground tissues are also required for optimal yield, with or without pretreatment.

TABLE 2 Composition and selectivity of media used to grow *Legionella* spp. from clinical and environmental specimens[a]

Medium	Synonym	Selective agents	Main use	Selectivity[b]
BCYEα	CYE	None	Clinical, culture maintenance	None
BMPA	PAC	Cephamandole, poly B, antifungal	Clinical, environmental	Normal respiratory flora, 3+; enterics, 3+; yeasts, 3+; molds, 1+; *Legionella* spp., 1+ to 4+
PAV	VAP	Vanco, poly B, antifungal	Clinical, environmental	Normal respiratory flora, 2+; enterics, 2+; yeasts, 3+; molds, 1+; *Legionella* spp., 1+
MWY	VGP	Vanco, poly B, antifungal, glycine	Environmental	Normal respiratory flora, 2+; enterics, 2+; yeasts, 3+; molds, 1+; environmental bacteria, 2+; *Legionella* spp., 1+
CCVC		Cephalothin, poly E, vanco, cycloheximide	Environmental	Normal respiratory flora, +; enterics, 3+; yeasts, 2+; molds, 2+; *Legionella* spp., 1+ to 4+
BCYEα-L		None (made without L-cysteine)	Organism identification	*Legionella* spp., 4+ (no growth of *Legionella* spp. on this medium)

[a] Abbreviations: poly B or E, polymyxin B or E; antifungal, either anisomycin or natamycin antifungal compounds; vanco, vancomycin; normal respiratory flora, normal upper respiratory tract bacteria.
[b] Selectivity scale range, 0 to 4+: 0, does not inhibit these organisms; 1+, slight inhibition, allows about 75% growth; 2+, allows about 25 to 50% growth; 3+, allows about 10% growth; 4+, allows less than 1% growth.

Inoculation of Plates

Approximately 0.1 ml is inoculated into each plate, with the bulk of the inoculum applied to the first quadrant. There is a lack of comparative studies showing whether it is better to streak plates for isolation or to uniformly distribute the inoculum over the entire plate. The plates must be thoroughly dry before being inoculated, to aid in absorption of the relatively large volume inoculum and to retard spreading of contaminants throughout the plate.

Culture Media

Buffered charcoal yeast extract medium, usually supplemented with 0.1% α-ketoglutaric acid (BCYEα), is used for isolation and growth of *Legionella* spp. Use of BCYE without α-ketoglutarate supplementation cannot be recommended for clinical use, as this amino acid greatly enhances growth of the bacterium (25).

BCYEα can be made selective by the addition of antimicrobial agents (Table 2). A variety of different antifungal agents are used in the media. Cycloheximide is a poor choice for media used for clinical specimens as it fails to inhibit *Candida albicans*. Both anisomycin and natamycin inhibit more yeasts than does cycloheximide. This dizzying array of media (Table 2) exists because no one selective medium is best for all purposes. Optimal yield of *Legionella* spp. from clinical specimens requires the use of three different media, one nonselective plate medium (BCYEα) and two selective media (BMPA and MWY). BMPA is an excellent selective medium for the vast majority of *L. pneumophila* strains, but the cephamandole present in the medium inhibits the growth of some other *Legionella* spp. and very rare *L. pneumophila* strains. Therefore, use of the less selective medium, MWY, is required for optimal growth of some *Legionella* spp. other than *L. pneumophila*. No selective medium inhibits multiresistant gram-negative bacteria found in hospitals, reducing culture yield in nosocomial disease.

Selective and nonselective media are optimized for the isolation of *L. pneumophila,* and their performance for the isolation of other *Legionella* spp. is not accurately known. One study showed that *L. micdadei* in guinea pig spleen had enhanced recovery on BCYEα medium prepared with 1% bovine serum albumin; the growth was enhanced because of decreased growth inhibition by spleen tissue (71). Whether addition of bovine serum albumin to BCYEα medium enhances *L. micdadei* recovery from human lung or sputum is unknown and probably unlikely. A BCYEα-based selective medium containing natamycin, aztreonam, and vancomycin has been reported to be useful for the isolation of *L. longbeachae* from soil (88).

Medium shelf life is around 1 year for nonselective plates and slants. This long shelf life requires thick plates (25-ml pour), complete drying of plates before storage at 2 to 4°C in sealed plastic bags, and protection from light. Selective media lose selectivity after about 3 months' storage time, but depending on the antibiotic used, they may last considerably longer.

Quality control (QC) testing of media is required before they are put into use. Current Clinical and Laboratory Standards Institute (CLSI) (NCCLS) standards are inadequate for proper QC testing of these media. About 1% of commercial media fail our laboratory QC testing. The CLSI QC testing protocol utilizes a heavy inoculum of medium-adapted *Legionella* strains and a growth/no-growth test. Minor variations in the manufacture of media, such as the addition of excess salt, overlong autoclaving, and degradation of buffers, can all seriously affect the ability of the medium to support wild strain growth, but not necessarily that of medium-adapted strains. The optimal method for medium QC testing is the inoculation of the test media with several hundred non-artificial medium-passed *L. pneumophila* bacteria (obtained from infected guinea pig lung) and quantification of the bacterial colonies after 3 to 4 days of incubation (20). In the absence of the availability of lung-passaged *L. pneumophila* bacteria, low-passage clinical strains should be used, taking care to plate only several hundred bacteria per plate. QC testing of selective media for the ability to suppress non-*Legionella* bacteria can be done by inoculation of the plate with relatively antibiotic-susceptible strains of *Escherichia coli* and *Staphylococcus aureus*, such as ATCC 25922 and 25923; the growth should be markedly suppressed.

Medium Incubation

Inoculated media are incubated at 35 to 37°C in humidified air. Regardless of the humidification method, care must be taken to keep the incubators or jars very clean and to regularly sterilize the containers or incubators. A small amount of CO_2 supplementation (2 to 5%) may enhance the growth of some of the more fastidious *Legionella* spp., such as *L. sainthelensi* and *L. oakridgenensis*. This low level of CO_2 supplementation will not harm the growth of *L. pneumophila,* but CO_2 levels higher than 5% may inhibit growth. Since the more capnophilic species are very rare human isolates, many laboratories do not use CO_2 incubation of media for *Legionella* spp.

Plate Inspection

Legionella colonies begin to appear on culture plates on day 3 of incubation. It is very unusual for the bacterial colonies to appear on plates after five incubation days. Some very rarely isolated *Legionella* spp. may require up to 14 days of incubation before growth appears; this is an extremely rare event. Regardless, it is reasonable to inspect culture plates on days 1 to 5 and then again at day 14.

The late appearance of *Legionella* spp. on culture plates can be used to great advantage if a careful record is kept of the colonies present on days 1 and 2 postincubation. New colonies appearing after day 2 should be suspected of being *Legionella* spp. Very rarely *Legionella* spp. may grow from heavily infected lung (usually from the autopsy of a fatal untreated case) on day 2, so some latitude in growth rate assumptions needs to be applied in the case of autopsy lung cultures. *Legionella* spp. never grow from clinical specimens on day 1 postincubation, a critical point in the distinction of *Pseudomonas aeruginosa* colonies from those of *Legionella* spp., as very early colonies of the latter superficially resemble those of the former.

Proper observation of culture plates requires the use of a dissecting microscope illuminated with direct light aimed at the plate surface at approximately a 30° angle. Failure to use a dissecting microscope or use of improper lighting will result in missed positive cultures, especially when there is mixed bacterial growth on the plates. In addition, very young *Legionella* colonies are very small and difficult to see with the naked eye. Therefore, use of a dissecting microscope can speed up the time to colony detection by as much as 1 day. *Legionella* growth occurs almost exclusively in the first streak quadrant, and sometimes at the edge of the plate.

The size and morphology of *Legionella* colonies change with time. Very young colonies (day 3) are flat, entire, and 0.5 to 1 mm in diameter, and when observed using a dissecting microscope and incident visible light they usually have a speckled blue, blue-green, or red color. Within 6 to 24 h of additional incubation, these colonies become smooth, convex, iridescent, and entire, measure about 1 to 3 mm in diameter, and look opal-like when observed with a dissecting microscope (Fig. 2). A thick string may form when a loop is inserted in the colony and then removed from the colony. In contrast to several mimics, the edges of the colonies are of the same consistency as the central portion and are not watery and clear. In another 1 to 2 days the colonies may increase in size up to 5 to 7 mm, become umbonate, sometimes with tuberculated or inhomogeneous texture, and develop spready edges; their iridescent nature may be lost at this stage. It is these late-stage colonies that are most difficult to distinguish from non-*Legionella* bacteria, making daily plate observation crucial for accurate detection. Very rarely some *Legionella* colonies do not change morphology with prolonged incubation.

Biosafety level 2 precautions should be used for manipulation of *Legionella* spp. cultures. It is safe to inspect culture plates and pick and subculture colonies on the open bench in a properly ventilated laboratory. Making an organism emulsion on microscope slides for the purposes of Gram staining can be safely carried out on the open bench. However, vortexing suspensions, sonication, tissue grinding, primary plating, and manipulations that may result in generation of a high-concentration aerosol should be performed in a biological safety cabinet. No well-documented cases of laboratory-acquired LD have been reported.

Initial Workup of Suspect Colonies and Look-Alike Bacteria

Colonies suspected of being *Legionella* spp. should first be subjected to Gram staining to ascertain that the bacteria are small or sometimes filamentous gram-negative rods. A small amount of the colony should be emulsified in sterile water or saline on a glass slide. It is important to completely suspend

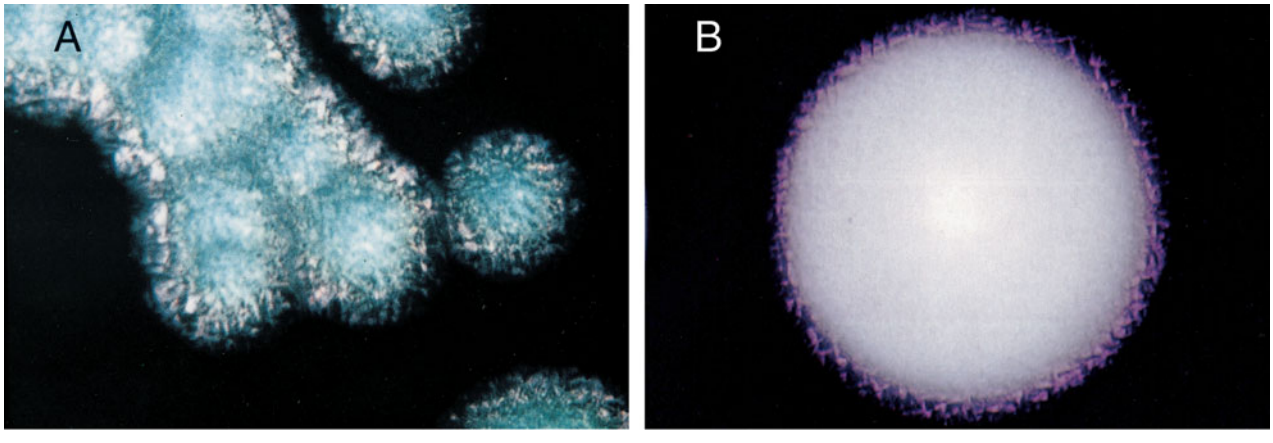

FIGURE 2 Photographs of *L. pneumophila* colonies growing on BCYEα agar. Note the internal speckling and different colors that may be seen, sometimes in the same culture. (Reproduced from Fig. 2, panels A and B, p. 814 of the 8th edition of this Manual.)

the bacteria in the liquid, as nondispersed clumps may stain as gram-positive rods. It is also crucial to use 0.1% basic fuchsin counterstain, because safranin stains these bacteria very poorly. Depending on the colony age and on the strain and species, *Legionella* spp. taken from plates vary in size from short rods measuring 0.5 by 5 μm to very long, filamentous bacteria measuring 1 by 25 μm.

Gram-negative bacteria should then be plated to two different media, BCYEα and either tryptic soy sheep blood agar (BAP) or BCYEα made without L-cysteine (BCYEα-L), in approximately equal amounts in a small (1-cm^2) area; eight or more isolates can be plated to each plate if needed (Fig. 3). Rather large amounts of the picked colony should be inoculated into these media to enable growth after 16 to 18 h of incubation, as the small inocula normally used for other bacteria may otherwise take several days to produce visible colonies on plates. If only a small single colony is available, then it can be emulsified in a small amount (~0.5 ml) of sterile distilled water (not saline) and used for staining, plate inoculation, and seroidentification. *Legionella* spp. should grow in 16 to 36 h on BCYEα medium, but not on BAP or BCYEα-L medium; this takes advantage of the L-cysteine growth dependence of *Legionella* spp. Sometimes *Legionella* spp. will grow poorly on BAP or BCYEα-L media but at most will yield only about 10% of the amount of growth on BCYEα. Nutrient carryover from the primary isolation plate is the explanation for this light growth; this can be proven by making a subculture of growth on BCYEα or BAP on a second plate of the same medium. Rare *Legionella* spp. partially lose growth dependence for L-cysteine on serial passage, but still grow more poorly on BCYEα-L than on BCYEα; these species include *L. spiritensis, L. oakridgensis,* and *L. jordanis,* none of which have been reported to cause more than two cases of LD each. BAP performs almost as well as does BCYEα-L for determining L-cysteine dependence for clinical isolates and may be less expensive, depending on the number of isolates tested per plate. If a blood-containing agar medium is used as the screening plate rather than BCYEα-L for L-cysteine dependence, great care must be taken that the medium base is not too rich. For example, brucella blood agar will support *L. pneumophila* growth almost as well as BCYEα medium, and other blood-containing media have been described to do the same (13). The plates are incubated overnight at 35 to 37°C or until there is visible growth on the BCYEα plate. Compare the relative amounts of growth on each plate to determine if there is L-cysteine dependence. Most *Legionella* spp. produce a very characteristic dank odor when growing in pure growth, which is easily identifiable to the trained nose.

Common mimics of *Legionella* colonies on BCYEα plates include *Eikenella corrodens, P. aeruginosa, Flavobacterium* spp., and some *Bacillus* spp. All of these bacteria grow equally well on BCYEα and BCYEα-L media, but when young they often grow as speckled colonies on BCYEα plates. *Francisella tularensis* can grow well on BCYEα agar but has no resemblance to *Legionella* colonies. However, *F. tularensis* is the only gram-negative bacterium other than *Legionella* spp. that exhibits L-cysteine growth dependence. The colony morphology of *F. tularensis* is not speckled; rather, it is opaque and homogeneous. Adding to the confusion is that some serotyping reagents for *Legionella* spp. may cross-react with *F. tularensis*. There is one case report of the misidentification of *F. tularensis* as *L. pneumophila* (99). Of note, some *Bacillus* sp. mimics can stain as gram-negative rods, have unapparent sporulation, and not grow on BAP (but will grow on BCYEα-L) (91). With prolonged incubation, colonies of both *E. corrodens* and *Flavobacterium* spp. change color and no longer resemble *Legionella* spp.; *E. corrodens* colonies become a light to dark green color, and *Flavobacterium* spp. turn a bright yellow color. Very young *P. aeruginosa* and *Bacillus* spp. colonies resemble the speckled flat to slightly convex young *Legionella* colonies but with prolonged incubation change their morphology, making them easily recognizable as non-*Legionella* colonies. *Bordetella pertussis* colonies may appear late on BCYEα plates, and although this bacterium neither is cysteine dependent nor possesses colony morphology similar to that of *Legionella* spp., *B. pertussis* has been reported to be misidentified as *Legionella* spp., abetted by serological cross-reactivity (76). Because many different bacteria may cross-react with serological reagents used for typing and identifying *Legionella* spp., it is crucial to become familiar with the morphology and growth characteristics of this genus; relying exclusively on serotyping to identify *Legionella* spp. could result in mistaken identification.

Microbiologists should know that some pathogenic fungi and higher bacteria grow well on BCYEα medium, presenting both potential biohazards and the opportunity to diagnose unsuspected infections. *Coccidioides* spp. often grow within a day or two on this medium and can rapidly form arthroconidia, and as such they present a biohazard. *Blastomyces dermatitidis* also grows well and converts to the mold phase within a few days. It is likely that other pathogenic fungi grow equally well on this very rich medium. *Nocardia* spp. and rapidly growing mycobacteria often grow quite well on this medium, making BCYEα medium and its selective variants plating media of choice for the laboratory diagnosis of nocardiosis (57, 98). Nocardia bacteremia can sometimes be diagnosed by subculture of blood culture bottles on BCYEα.

IDENTIFICATION

Basic Identification

Once L-cysteine dependence has been confirmed, further identification of *Legionella* spp. in a clinical laboratory relies almost exclusively on serotyping the bacteria, using either immunofluorescence or agglutination methods (17, 80). Prior to attempting identification by serotyping, the plate should be illuminated with long-wave UV light in a darkroom; some *Legionella* spp. other than *L. pneumophila* fluoresce a brilliant blue-white color, and some a brilliant red; such bacteria are best identified by a reference laboratory and are not *L. pneumophila*. *L. pneumophila* fluoresces a very pale yellow-green color, usually with diffusion of the fluorescent pigment into the culture medium; this is not specific for this species, and sometimes young cultures are completely nonfluorescent. An excellent and specific FDA-cleared fluorescein isothiocyanate-labeled monoclonal antibody to all serogroups of *L. pneumophila* is available (Monofluo, Bio-Rad). Also, an excellent non-FDA-cleared fluorescein isothiocyanate-labeled *L. pneumophila* serogroup 1 (Philadelphia 1 strain)-specific polyclonal antiserum is available (m-TECH, Atlanta, Ga. [http://www.4m-tech.com/]). Serotyping can also be performed using non-FDA-cleared latex agglutination antisera, available in a variety of formats (Oxoid, Basingstoke, United Kingdom; Denka Seiken, Tokyo, Japan); few data on performance of these reagents are available.

Since more than 90% of *Legionella* isolates are *L. pneumophila* serogroup 1, a reagent- and time-saving technique is to first test with *L. pneumophila* serogroup 1 antibody; strains negative with this antibody can then be tested with the species-specific monoclonal antibody. Extraordinarily rarely, some *L. pneumophila* serogroup 1 strains do not react with Philadelphia 1 strain antibodies, making it possible that a

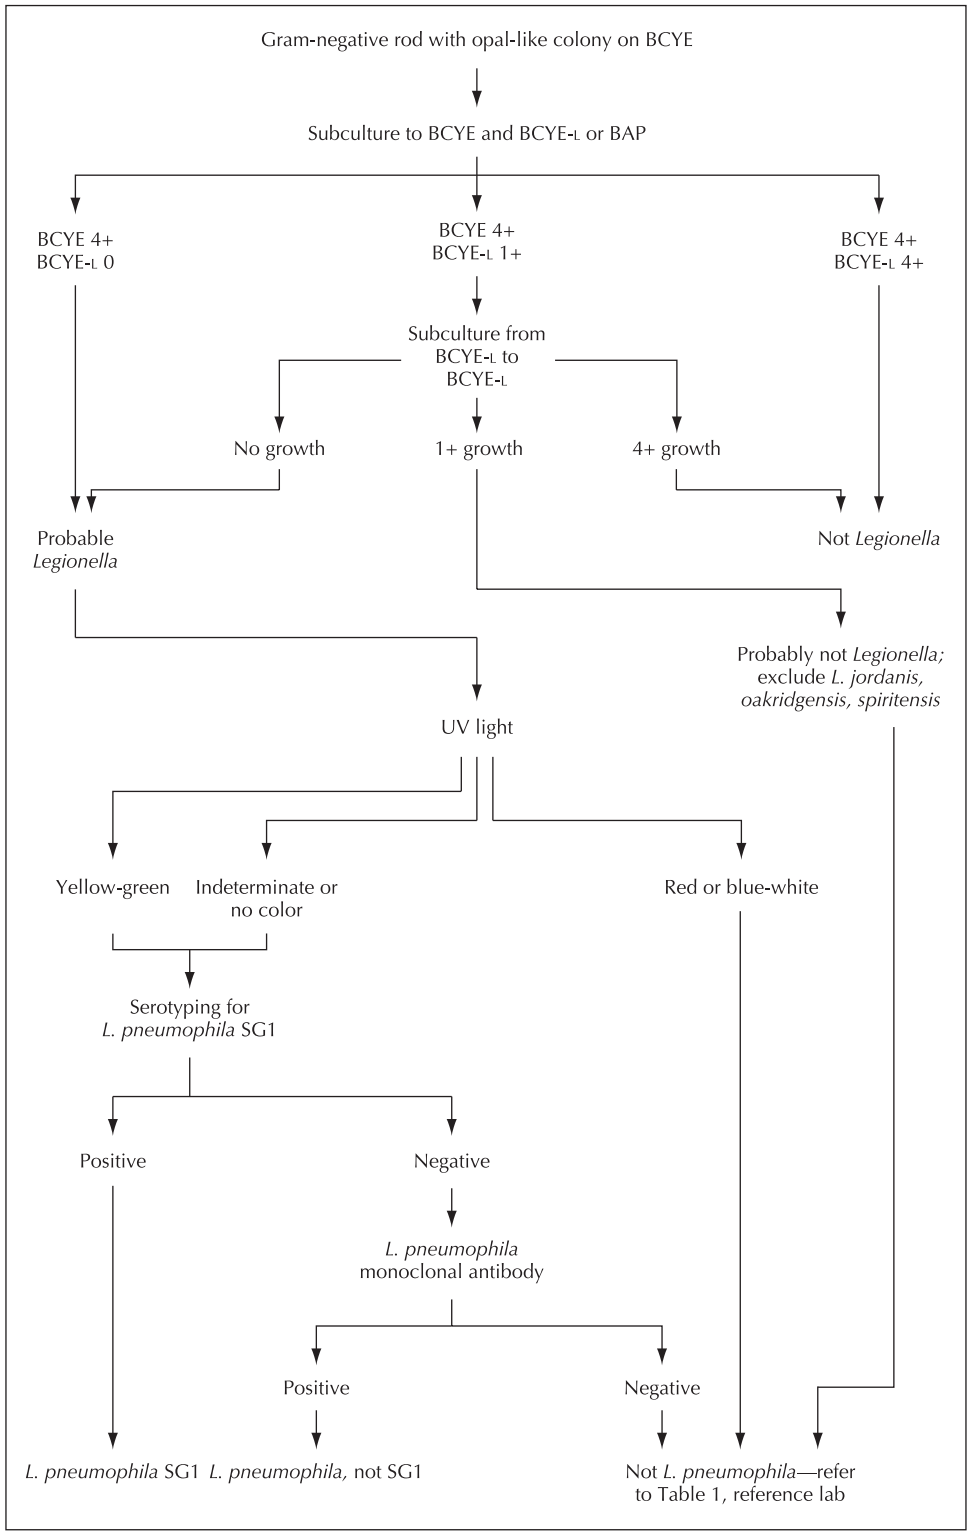

FIGURE 3 Flow scheme for basic identification of *Legionella* spp. grown from a BCYEα plate. Abbreviations: BCYE, BCYEα; BCYE-L, BCYEα made without L-cysteine; BAP, tryptic soy blood agar; UV light, colony fluorescence and color when illuminated with long-wave (360-nm) UV light. Numbers refer to the amount of growth: 4+, good growth; 1+, poor growth; 0, no growth.

serogroup 1 strain could be missed with this reagent; additional serogroup 1 antibodies are available (m-TECH). Testing has to be conducted properly for valid results, with the commonest errors being false-negative results because of a prozone phenomenon and false-positive results from contaminated buffers, wash solutions, or cross-contamination from controls (17). Strains that fail to react with *L. pneumophila* antibodies are best identified by reference or public health laboratories that have other typing sera and identification methods in use.

Gram-negative rods isolated from clinical specimens that are morphologically consistent with *Legionella* spp. and are L-cysteine dependent for growth can be reported as presumptive *Legionella* spp. in the absence of reactivity with typing sera. Gram-negative rods characteristic of *Legionella* spp. that react with *L. pneumophila* monoclonal antibody or *L. pneumophila* serogroup 1 polyvalent antibody can be presumptively identified as *L. pneumophila* or *L. pneumophila* serogroup 1, and the identification can be finalized the next day once L-cysteine growth dependence is confirmed. If the isolate is nonreactive with *L. pneumophila* species-specific antibody, or if it is *L. pneumophila* but not serogroup 1, then the isolate should be further typed by a reference laboratory. All clinical isolates should be frozen at –70°C in TSB in 10% glycerol and subcultured on a BCYEα slant for possible analysis by public health authorities.

Advanced Identification

Accurate identification of *Legionella* spp. other than *L. pneumophila* and *L. pneumophila* serogroup 1 can be quite difficult because of serologic cross-reactivities between species and serogroups, biochemical inertness, and phenotypic identity of different species. Identification to the species or serogroup level for these bacteria is usually not of major clinical significance but may have significant public health and scientific importance. Infections caused by *Legionella* spp. other than *L. pneumophila* or *L. longbeachae* almost always occur in immunocompromised patients, so identification of these other *Legionella* spp. could very rarely be a clue to occult immunosuppression (72). LD caused by *Legionella* spp. other than *L. pneumophila* may respond more poorly to erythromycin therapy (30), but whether knowing the identification of the *Legionella* spp. causing infection would influence patient outcome is debatable, especially since erythromycin is no longer the treatment of choice for severe LD (22). Investigation of LD outbreaks, and sometimes of single cases of the disease, requires knowledge of *Legionella* species identity and subtype; this identification, if needed, can be performed by a public health or reference laboratory as long as the isolates are frozen. The techniques used by reference laboratories include serotyping using collections of antisera, biochemical characterization, and sequence-based identification.

Serotyping of *Legionella* spp. is carried out using polyclonal antisera produced by the U.S. CDC, other public health agencies, and commercial laboratories (m-TECH, Denka Seiken, Oxoid, and others). Either immunofluorescence or agglutination reactions are used, with no clear evidence of superiority of one technique over the other (95). Some producers make polyvalent serum pools that react with a large number of species or serogroups, which can be useful to reduce the number of monovalent antisera used. The specificity of the polyvalent antisera has not been studied in great detail, although at least one product reacted with a number of non-*Legionella* bacteria (24). This makes it important that monovalent typing be carried out and that the bacteria meet minimal phenotypic criteria for *Legionella* spp. Unfortunately, cross-reactions between different species and serogroups occur even when monovalent antisera are used (1, 81, 84, 89, 93, 100). Use of cross-adsorbed polyvalent antisera has been described as a research tool to avoid this problem of cross-reactions, but these reagents are not available outside some research laboratories (5, 92, 94). In addition to intragenus cross-reactions, a large number of cross-reactions of monovalent polyclonal antibodies to non-*Legionella* bacteria have been reported, including *P. aeruginosa, Flavobacterium* spp., *Bacteroides fragilis, Capnocytophaga ochracea, B. pertussis, Bordetella bronchiseptica,* and possibly *Burkholderia pseudomallei* (6, 10, 11, 26, 40, 55, 58). Antibody to *L. pneumophila* serogroup 1 is quite specific, but otherwise enough cross-reactions exist to make serological identification only presumptive. Antisera to newer *Legionella* spp. are often unavailable.

Monoclonal typing antibodies reduce the number of cross-reactions with gram-negative bacteria but are commercially available only for the identification of *L. pneumophila* (9, 21, 47, 90). Nevertheless, great care must be used by experienced microbiologists, as cross-reactions with some non-*Legionella* bacteria have been reported with the *L. pneumophila*-specific monoclonal antibody, including *S. aureus,* yeasts, and *Bacillus* spp.

Legionella spp. are relatively inert biochemically and cannot be identified by using conventional tube or commercial panel biochemical tests. The few biochemical characteristics described for *Legionella* spp. that can be determined in most laboratories, such as oxidase, catalase, and β-lactamase tests, can be nonspecific and if performed improperly falsely negative. Use of a research biochemical panel to facilitate the identification of *Legionella* spp. has been described (97).

Determination of cellular fatty acid and isoprenoid quinone composition by gas-liquid chromatography and high-pressure liquid chromatography, respectively, can be successfully used to identify many *Legionella* spp. (61). These techniques require the use of expensive equipment, are highly complex, and have been supplanted by molecular methods. The cellular compositions of several newer *Legionella* spp. have not been studied using these techniques and/or are not in commercial databases, making identification of these newer species by these methods difficult.

The "gold standard" for the identification of new *Legionella* spp. has been DNA-DNA hybridization analysis (7). This method is tedious, expensive, and labor-intensive and requires special expertise as well as a large collection of reference DNA standards. As such, DNA-DNA hybridization analysis is not used to identify already known species.

Molecular identification of *Legionella* spp. is now replacing other identification techniques in research and specialty laboratories for several reasons. These include the labor cost and time required to serotype a strain, serological cross-reactions, limited availability of antibodies to newer strains, the lack of specific and easy biochemical characterization methods, and the increasing availability of inexpensive DNA sequencing. Molecular identification methods take advantage of the specific 16S rRNA or *mip* gene sequences of the different *Legionella* spp. (36, 64, 83, 86). A *mip* database, procedure instructions including primer sequences, *mip* sequence alignment software, and other genomic software tools are all freely available online (http://www.hpa.org.uk/srmd/bioinformatics/ewgli/legionellamips.htm). Sequence analysis of 16S rRNA has been used to identify several new *Legionella* spp. (35, 62, 65, 79). In addition, sequence of the *rpoB* gene has been shown to distinguish between species as well as, or better than, 16S rRNA or *mip* gene sequencing (59). Intergenic 16S-23S ribosomal spacer PCR analysis has been successful for species identification and does not require

DNA sequencing (85). The relative performances of *mip* and 16S rRNA sequencing are not accurately known. In addition, limited numbers of reference strains, especially of some unusual species, have been sequenced using either method, leaving open the possibility of incorrect classifications. A commercial plate DNA hybridization assay has been reported to correctly identify 23 different *Legionella* spp. (28) and is distributed in Japan (Kobayashi Pharmaceutical, Osaka, Japan).

Whether molecular methods can substitute for serologic ones is difficult to know because of several reports of genotypic discordances for identical serogroups and vice versa (8, 45, 66). Sequencing of the *L. pneumophila dnaJ* gene appeared to be able to distinguish between some, but not all, *L. pneumophila* serogroups (64); different serogroups that had very similar genotypes had been shown by other methods to have discordant genotypes and serotypes. More extensive testing of this method needs to be performed before it is put into routine use. Note that several molecular methods are useful for establishing strain clonality in the context of epidemiologic investigations.

TYPING SYSTEMS

Typing of *Legionella* spp. is important for public health investigations to help link culture-positive environmental sites with clinical isolates during an epidemic of the disease. Typing cannot be used by itself to determine the environmental source of an outbreak and must be accompanied by an epidemiologic investigation. Otherwise, incorrect conclusions may be made about epidemic sources (46, 60). This problem is due to clonal distributions of environmental and clinical *Legionella* spp. (3, 53, 63, 82) and to the poor specificity of some typing techniques (15, 82).

L. pneumophila serogroup 1 can be divided into at least 17 or 10 different groups by using cross-absorbed polyclonal or monoclonal antibodies, respectively (56, 96). Neither the cross-absorbed polyclonal typing sera nor all of the original monoclonal antibodies are available. Lück and colleagues made alternative monoclonal antibodies that can be used in a typing scheme (67). Monoclonal antibody typing plays a major role in subtyping *L. pneumophila* serogroup 1 isolates and, when used with molecular methods, can increase typing specificity (34, 37, 82). Used by itself, monoclonal antibody typing may not be specific enough to distinguish between closely related strains.

Sequence-based typing appears to be the most specific and precise molecular subtyping system for both *L. pneumophila* and *L. pneumophila* serogroup 1. Performed according to a standardized protocol, the method provides uniform results between laboratories, with excellent discrimination between strains (37). This method uses determination of portions of sequences of six different *L. pneumophila* genes, *flaA, pilE, asd, mip, mompS,* and *proA*. An online database, an allele subtype assignment tool, and standardized procedures are available on the Internet (http://www.hpa.org.uk/srmd/bioinformatics/ewgli/ewglisbt.htm). Amplified fragment length polymorphism analysis is an alternative molecular typing system with lower between-laboratory precision than sequence-based typing, but with high specificity (34). An amplified fragment length polymorphism analysis online database and allele assignment tool is available (http://www.hpa.org.uk/srmd/bioinformatics/ewgli/ewgliaflp.htm). Pulsed-field gel electrophoresis, plasmid typing, polyacrylamide gel protein electrophoresis, gel analysis of genomic DNA restriction fragments, and several other methods have all been successfully used to subtype *L. pneumophila,* and in some cases *Legionella* spp., but appear to be too nonspecific for epidemiologic investigative purposes.

SEROLOGIC TESTS

LD can be diagnosed by demonstration of an increase in antibodies to killed bacterial cells (19). Enzyme immunoassay, microagglutination, and indirect immunofluorescent assay methods can all be used to detect antibody changes, with indirect immunofluorescent assay considered the gold standard. While most patients develop both immunoglobulin G (IgG) and IgM responses, some develop IgM-only, IgG-only, or IgA-only responses, making it necessary to test for total immunoglobulin response and not just IgG. In addition, IgM antibodies may persist for as long as a year after infection, making IgM presence a poor marker of acute disease (75). About 75% of patients with culture-proven nosocomial *L. pneumophila* serogroup 1 LD develop seroconversion to the bacterium, whereas the test seems to have higher sensitivity in LD epidemics. Test specificity depends on several technical factors, including the method of antigen preparation, the numbers of different bacteria used in antigen preparation, the method of diluting serum, and several other factors. Seroconversion requires weeks to months after infection, with only about a 50% seroconversion rate after 2 weeks; for optimal test sensitivity, acute-phase serum should be frozen while convalescent-phase sera are collected at 2, 4, 6, 9, and 12 weeks postinfection. Sera tested 2 weeks after disease onset have only about a 37% (50% of 75%) chance of detecting seroconversion. Parallel testing of sera is required for the best specificity. Some laboratories test acute-phase sera only for evidence of early antibody production; this approach can be nonspecific and insensitive. The most specific testing is for seroconversion to *L. pneumophila* serogroup 1 only, and the least specific is the use of polyvalent antigen preparations, with approximate test specificities of 99% and 90 to 95%, respectively. Polyvalent antigen preparations are best used for screening purposes only, with follow-up monovalent testing. Almost all commercially available tests use only polyvalent antigen preparations, which can result in nonspecific results. There is also some concern that screening enzyme-linked immunosorbent assays may be insensitive, possibly making such testing both insensitive and nonspecific (68). Serologic diagnosis is best used for epidemiologic studies because of the retrospective nature of serologic diagnosis and limitations on test specificity and sensitivity.

Antimicrobial Susceptibilities and Susceptibility Testing

The antimicrobial susceptibility of *L. pneumophila* grown in broth or on agar can give results having no clinical correlate. This is because of the intracellular location of the bacterium in human infection, to which not all antimicrobial agents gain access and retain activity (18). In addition, the complex broth and agar media used to grow *L. pneumophila* inactivate many drugs. There is no indication for performing antimicrobial susceptibility testing against *Legionella* spp. except in a research setting, when correlative studies of intracellular and experimental animal model infection can be performed. The microbiologist must not assume that a particular drug will be effective for the treatment of LD simply because the drug is active against *L. pneumophila* in vitro, nor should there be an assumption that drugs having low MICs against the bacterium in vitro will be more clinically effective than will drugs with higher MICs for the organism.

Antimicrobial agents having good intracellular activity against *L. pneumophila* include most macrolide, tetracycline,

ketolide, and quinolone antimicrobial agents (18, 22). No beta-lactam agent or aminoglycoside has acceptable intracellular activity against the bacterium. It is unknown if the intracellular activity of antimicrobial agents against *L. pneumophila* can be extrapolated to all other *Legionella* spp. and to treatment of infections caused by *Legionella* spp. other than *L. pneumophila*. Some of these other *Legionella* spp. may reside in subcellular compartments different from those where *L. pneumophila* resides and thus may respond differently to antimicrobial agents (77). However, macrolide and quinolone antimicrobials appear to be effective for the treatment of LD caused by *L. micdadei, L. longbeachae, L. bozemanae,* and *L. dumoffii* (72).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Multiple laboratory methods have to be used for optimal laboratory diagnosis of LD. Culture of *Legionella* bacteria from sputum, lung, or other respiratory sites is the most specific (100%) method for diagnosis of the disease, very sensitive (~80 to 90%) in severe untreated disease and insensitive (~20%) in cases of mild disease. Culture may be the only diagnostic test giving positive results, especially when *Legionella* bacteria other than *L. pneumophila* are causing the infection. In addition, a culture isolate can be used to sort out the source of an epidemic, unlike any of the other diagnostic tests. Because of the technical difficulty of culture diagnosis, its expense, and its low sensitivity for nonsevere disease, several alternative diagnostic methods have been developed. The antigenuria assay is more sensitive than culture for the detection of community-acquired disease, and especially epidemic disease. Nevertheless, the antigenuria test is only about 60% sensitive in the best of circumstances, performs poorly for detection of nosocomial infection, and detects almost exclusively *L. pneumophila* serogroup 1. Antibody detection complements other laboratory diagnostic methods but is retrospective because it requires seroconversion for greater test specificity and sensitivity. In addition, antibody results obtained using only polyvalent antigens must be viewed with circumspection. Commercial molecular amplification tests are just being marketed and have yet to be thoroughly evaluated; prior to adoption, more-extensive studies are required. The performance of all laboratory diagnostic tests for non-*L. pneumophila* serogroup 1 LD is unknown but presumably is not as good as it is for the diagnosis of *L. pneumophila* serogroup 1 disease.

Because of the lack of any one laboratory test that is highly sensitive and specific for the diagnosis of LD caused by *L. pneumophila* serogroup 1, let alone the disease caused by other serogroups and species, multiple test types should be performed if laboratory diagnosis is crucial for clinical or public health reasons. In particular, culture needs to be performed whenever possible to enhance diagnostic yield, for public health reasons, and because it may be the only specific method capable of diagnosing LD caused by *Legionella* species other than *L. pneumophila*.

A major hindrance to the evaluation of all laboratory diagnostic methods is the lack of a good gold standard for LD diagnosis. Culture diagnosis, while very specific, is known to be imperfect and of limited sensitivity, especially for epidemic LD. Relative performance of the diagnostic tests is often compared to culture diagnosis, which tends to overestimate test sensitivity and underestimate specificity.

Positive cultures for all *Legionella* spp. are virtually diagnostic of LD, providing there are supportive clinical findings such as pneumonia. In contrast, single serum specimens showing elevated antibodies to *Legionella* spp. or to *L. pneumophila* are often not the result of LD. Only rises in antibody titers to *L. pneumophila* serogroup 1, evaluated by a test not usually commercially available, are specific enough for diagnosis, but even then use of appropriate techniques is required for optimal specificity. Detection of *L. pneumophila* serogroup 1 antigenuria is almost as specific as a positive culture, once heat-labile factors capable of causing false-positive tests are excluded. Positive test results must be reported promptly to the patient's clinician as well as to public health authorities.

*Bartonella**

BRUNO B. CHOMEL AND JEAN MARC ROLAIN

54

TAXONOMY

The genus *Bartonella* is named for A. L. Barton, who first described the intraerythrocytic bacterium *Bartonella bacilliformis* in 1909. Until recently, this genus consisted of only one species, *B. bacilliformis*. The *Bartonella* genus now combines all the species of the three genera *Bartonella, Rochalimaea,* and *Grahamella* and is the only genus of the family *Bartonellaceae,* which has been removed from the order *Rickettsiales* (6, 10). *Bartonella* species are members of the alpha-2 subgroup of the class alpha-proteobacteria within the order *Rhizobiales*. The list of newly recognized species and subspecies has been increasing in the last few years (2, 9). These small gram-negative rods are erythrocyte-adherent bacilli. Based on 16S rRNA gene similarity, *Bartonella* is closely related to *Brucella* and *Agrobacterium*.

DESCRIPTION OF THE GENUS

The present family consists of 19 species and 3 subspecies, of which 10 are human pathogens (Table 1). *B. bacilliformis,* the type species of the genus, is the etiologic agent of Carrion's disease and causes either an acute bacteremic infection called Oroya fever, characterized by sepsis and hemolysis, or a chronic form called verruga peruana, characterized by cutaneous nodular vascular eruptions. *B. quintana,* the agent of trench fever, has also been found to be one of the agents of bacillary angiomatosis (BA), a vascular proliferative lesion observed in immunocompromised individuals, mainly those with AIDS (48). *B. quintana* has also been associated with endocarditis and bacteremia in homeless people (12). BA can also be caused by *B. henselae*. *B. henselae* causes cat scratch disease (CSD) in immunocompetent individuals. Similarly, *B. henselae* has been associated with several cases of endocarditis. The fourth human pathogen, *B. elizabethae,* was isolated from an immunocompetent individual suffering from endocarditis. Since then, *Bartonella vinsonii* subsp. *berkhoffii, B. vinsonii* subsp. *arupensis* (24), and *B. koehlerae* have also been associated with human cases of endocarditis (7), and "*B. washoensis*" (proposed species) has been associated with a human case of myocarditis. *B. grahamii* has been associated with a human case of neuroretinitis. *B. vinsonii* subsp. *arupensis* was also isolated from the blood of a rancher with fever and mild neurological symptoms (7). Finally, *B. clarridgeiae* is suspected to be a minor agent of CSD, based on serological evidence only. Most of the *Bartonella* species that are pathogenic to humans *(B. vinsonii* subsp. *berkhoffii, B. clarridgeiae, B. henselae, B. elizabethae,* and "*B. washoensis*") have been associated with various clinical entities, including endocarditis, in domestic dogs (7, 18).

Several other *Bartonella* species, such as *B. vinsonii* subsp. *vinsonii, B. doshiae, B. taylorii, B. peromysci, B. birtlesii, B. tribocorum, B. alsatica, B. talpae, B. bovis, B. chomelii, B. schoenbuchensis,* and *B. capreoli,* have only been isolated from the blood of various animal species, including various wild rodents, squirrels, rabbits, felids, canids, and ruminants (cattle, deer, and elk). At present, these species are not known to induce any specific disease in the infected animal.

Bartonella spp. are fastidious, aerobic, short, pleomorphic, gram-negative coccobacillary or bacillary rods (0.2 to 0.6 μm by 0.5 to 1.0 μm). Because of the slow growth of these bacteria, standard biochemical methods for identification may not be applicable. Bartonellae are oxidase and catalase negative and do not produce acid from carbohydrates. All members of the genus take from 5 to 15 days and up to 45 days in the presence of 5% CO_2 on primary culture to form visible colonies on enriched blood-containing media, as they are highly hemin dependent. The optimal growth temperature varies from 25 to 30°C for *B. bacilliformis* to 35 to 37°C for the other *Bartonella* species, such as *B. henselae, B. koehlerae,* and *B. elizabethae*. On primary isolation, some *Bartonella* species, such as *B. henselae, B. clarridgeiae, B. vinsonii,* and *B. elizabethae,* have colonies with a white, rough, dry, raised appearance and pit the medium. They are hard to break up or transfer. Other bartonellae such as *B. quintana* have colonies that are usually smaller, gray, translucent, and somewhat gummy or slightly mucoid. *B. bacilliformis, B. clarridgeiae, B. capreoli,* and *B. schoenbuchensis* are the only members of the genus that are motile by means of unipolar flagella.

NATURAL HABITATS

Most *Bartonella* species are vector-borne organisms. Some *Bartonella* species are very limited geographically, such as *B. bacilliformis,* which is found only in the Andes mountain region of South America, associated with the limited distribution of its vector, the sand fly *Lutzomyia verrucarum*. Others,

* This chapter contains information presented in chapter 53 by David F. Welch and Leonard N. Slater in the eighth edition of this Manual.

TABLE 1 *Bartonella* species or subspecies presently described, their main reservoirs, and confirmed or possible vectors[a]

Bartonella sp.	Main reservoir	Vector or potential vector
B. bacilliformis	Humans	Pheblotomines (sand flies) *(L. verrucarum)*
B. quintana	Humans	Human body lice *(Pediculus humanus corporis)*
B. henselae	Cats *(Felis catus)*	Fleas (*C. felis*), ticks?
B. clarridgeiae	Cats *(F. catus)*	Fleas (*C. felis*)
B. koehlerae	Cats *(F. catus)*	Fleas (*C. felis*)
B. vinsonii subsp. *vinsonii*	Meadow voles *(Microtus pennsylvanicus)*	Ear mites *(Trombicula microti)*?
B. vinsonii subsp. *arupensis*	White-footed mice *(Peromyscus leucopus)*	Fleas? Ticks?
B. vinsonii subsp. *berkhoffii*	Coyotes (*C. latrans*), dogs *(Canis familiaris)*	Ticks?
B. talpae	Moles *(Talpa europaea)*	?
B. peromysci	Field mice (*Peromyscus* spp.)	Fleas?
B. birtlesii	Wood mice (*Apodemus* spp.)	Fleas?
B. grahamii	Bank voles (*Clethrionomys glareolus*)	Fleas (*Ctenophthalmus nobilis*) (8)
B. taylorii	Wood mice (*Apodemus* spp.)	Fleas (*C. nobilis*)
B. doshiae	Field voles *(Microtus agrestis)*	Fleas?
B. elizabethae	Rats *(Rattus norvegicus)*	Fleas
B. tribocorum	Rats (*R. norvegicus*)	Fleas?
B. alsatica	Rabbits *(Oryctolagus cuniculus)*	Fleas? Ticks?
"*B. washoensis*"	California ground squirrels *(Spermophilus beecheyi)*	Fleas? Ticks?
B. bovis ("*B.weissii*")	Domestic cattle *(Bos taurus)*	Biting flies? Ticks?
B. chomelii	Domestic cattle *(B. taurus)*	Biting flies? Ticks?
B. capreoli	Roe deer *(Capreolus capreolus)*	Biting flies? Ticks?
B. schoenbuchensis	Roe deer *(C. capreolus)*	Biting flies, Ticks?

[a] As reported in reference 81.

such as *B. quintana, B. henselae,* and *B. elizabethae,* appear to have a worldwide distribution. *B. quintana* outbreaks had been mainly reported in Europe at the beginning of the 20th century causing hundreds of thousands of human cases of trench fever during World War I (WWI) and WWII. These outbreaks were associated with poor sanitation and personal hygiene and have now reemerged in homeless populations worldwide, associated with infestation by the human body louse, *Pediculus humanus,* possibly by inoculation of arthropod excreta through broken skin (41, 42). Humans are the only known reservoirs and victims of these two *Bartonella* species. In cases of BA caused by *B. quintana,* a history of body louse exposure is usually reported. Most cases of BA caused by *B. henselae* and almost all cases of CSD are associated with cat scratches or exposure.

The domestic cat is a healthy carrier of *B. henselae, B. clarridgeiae,* and *B. koehlerae* and constitutes the main reservoir of these organisms. *B. henselae* infection is transmitted from cat to cat mainly by the cat flea, *Ctenocephalides felis* (19), but the role of the cat flea seems limited in human infection. More likely, human infection results from the inoculation of infective flea feces at the time of the scratch (7). Some data have suggested a possible role for ticks in some human *B. henselae* infections (7). Stray cats, cats living outdoors, and young cats are more likely to be bacteremic. The prevalence of infection is usually highest in warm and humid climates where cat fleas are abundant. At least two genotypes of *B. henselae* have been identified, with type I (Houston) more common in cats in the Far East (Japan and the Philippines) and type II (Marseille) predominant in Western Europe, North America, and Australia (7). Coinfection of cats with different *Bartonella* species or genotypes has been reported (30). Additionally, *B. quintana, B. koehlerae,* and *B. clarridgeiae* have been detected by molecular methods in cat fleas, suggesting their possible role as vectors for these organisms (83). Domestic and wild canids represent the main reservoir of *B. vinsonii* subsp. *berkhoffii,* with high antibody prevalence in dogs from tropical countries (7), as well as high bacteremia prevalence in coyotes *(Canis latrans)* in California (16). Ticks may be involved in the transmission of *B. vinsonii* subsp. *berkhoffii* to dogs (9). Similarly, *Bartonella* DNA has been identified in questing adult *Ixodes pacificus* ticks from California, including several species pathogenic for humans (15), and *B. henselae* DNA was detected recently in *Ixodes ricinus* ticks collected from humans in Italy (92).

A wide range of rodent species has been reported to be infected with different *Bartonella* species (Table 1). Finally, several *Bartonella* species have been isolated from domestic and wild ruminants (Table 1), and biting flies could be an important vector of infection among these animals (7).

CLINICAL SIGNIFICANCE

Human Pathogens

Oroya Fever and Verruga Peruana (Carrion's Disease): *B. bacilliformis*

The disease caused by *B. bacilliformis,* especially its chronic form known as verruga peruana, has been recognized since pre-Columbian times in populations of the Andes. However,

the suspected link between the acute form (Oroya fever) and the chronic form was confirmed in 1885 when Carrion, a medical student, died of Oroya fever after inoculating himself with material from a verruga. The acute form of the disease, usually seen in people who are not natives of the zone of endemicity, is an acute, progressive, severe, and febrile anemia with extravascular hemolysis associated with the presence of *B. bacilliformis* in the erythrocytes. Mortality was reported to be up to 40% of the cases prior to the antibiotic era. Bacteremia is common in the general population in zones of endemicity and nonendemicity (14, 50). The second stage of infection leads in weeks to months to the eruption of nodular angioproliferative cutaneous lesions named verruga peruana; mucosal and internal lesions can occur (80). The lesions can persist for several months, but the prognosis is good at this stage.

Trench Fever, BA, Endocarditis, and Prolonged Fever or Bacteremia Caused by *B. quintana*

Trench or quintan fever is a recurrent fever with three to five, sometimes more, febrile episodes lasting 4 to 5 days each occurring after 15 to 25 days of incubation. Severe headaches and shin pain are common symptoms associated with malaise, anorexia, abdominal pain, restlessness, and insomnia. Mild forms as well as asymptomatic carriage have also been reported (12, 40). Several cases of endocarditis have been associated with *B. quintana* infection (55). In human immunodeficiency virus (HIV)-infected persons, bacteremia caused by *B. quintana* develops insidiously, involving recurrent fever, headaches, and hepatomegaly. *B. quintana* and *B. henselae* are the two *Bartonella* species involved in the etiology of BA. BA, also called epithelioid angiomatosis, is a vascular proliferative disease of the skin characterized by multiple, blood-filled, partially endothelial cell-lined cystic structures (96). It is usually characterized by violaceous or colorless papular and nodular skin lesions that clinically may suggest Kaposi's sarcoma but histologically resemble epithelioid hemangiomas. When visceral parenchymal organs are involved, the condition is referred to as bacillary peliosis hepatis, splenic peliosis, or systemic BA. Fever, weight loss, malaise, and enlargement of affected organs may develop in people with disseminated BA. Subcutaneous and lytic bone lesions are strongly associated with *B. quintana* infection (47).

Zoonotic Bartonellae

CSD

CSD is mainly caused by *B. henselae* (77, 102), even if *B. clarridgeiae* is suspected in some cases based on serological evidence (49, 63). There are now strong arguments against *Afipia felis* being one of the etiologic agents of CSD (54). In CSD, 1 to 3 weeks elapse between the scratch or bite of a cat and the appearance of clinical signs. In 50% of the cases, a small skin lesion, often resembling an insect bite, appears at the inoculation site, usually the hand or forearm, and evolves from a papule to a vesicle and partially healed ulcers. These lesions resolve within a few days to a few weeks. Lymphadenitis develops approximately 3 weeks after exposure and is generally unilateral. It commonly appears in the epitrochlear, axillary, or cervical lymph nodes. Swelling of the lymph node is usually painful and persists for several weeks to several months. In 25% of the cases, suppuration occurs. The large majority of the patients show signs of systemic infection: fever, chills, malaise, anorexia, and headache. In general, the disease is benign and heals spontaneously without sequelae. Atypical manifestations of CSD occur in 5 to 10% of the cases. The most common of these is Parinaud's oculoglandular syndrome (periauricular lymphadenopathy and palpebral conjunctivitis), but also meningitis, encephalitis, osteolytic lesions, and thrombocytopenic purpura may occur. Encephalopathy is one of the most serious complications of CSD and usually occurs 2 to 6 weeks after the onset of lymphadenopathy. However, it usually resolves with complete recovery and few or no sequelae. It is estimated that 22,000 human cases of CSD occur yearly in the United States. From 55 to 80% of CSD patients are <20 years old. There is a seasonal pattern, with most cases seen in autumn and winter.

New clinical presentations associated with *B. henselae* infection have been reported for immunocompetent persons, including neuroretinitis or bacteremia as a cause of chronic fatigue syndrome, and a case of aggressive *B. henselae* endocarditis in a cat owner. *B. henselae* was also determined as a frequent cause of prolonged fever and fever of unknown origin in children. Rheumatic manifestations of *Bartonella* infection have been described for children, including a case of myositis and a case of arthritis and skin nodules. Arthritis has been described in a very limited number of cases. Other rheumatic manifestations related to *Bartonella* infection in humans include erythema nodosum, leukocytoclastic vasculitis, and fever of unknown origin with myalgia and arthralgia (7).

For BA in immunocompromised persons, the symptoms are very different from those of CSD. BA patients with *B. henselae* infection are epidemiologically linked to cat and flea exposure (47). Cutaneous lesions are common with *B. henselae* infection, and peliosis hepatis is associated exclusively with *B. henselae* infection. Fever, weight loss, malaise, and enlargement of affected organs may develop in people with disseminated BA. Endocarditis has also been reported for patients with BA. *B. henselae* and *B. quintana* have been implicated in a few cases of HIV-associated brain lesions, meningoencephalitis and encephalopathy, dementia, and neuropsychological decline (94, 97).

Zoonotic *Bartonella* Species Associated with Endocarditis or Myocarditis

Several zoonotic *Bartonella* spp. have been recognized as causative agents of blood culture-negative endocarditis or myocarditis in humans, including *B. henselae, B. koehlerae, B. elizabethae, B. vinsonii* subsp. *berkhoffii, B. vinsonii* subsp. *arupensis* (24), and "*B. washoensis*" (7). *Bartonella* spp. account for 3 to 4% of all human cases of endocarditis in France, a percentage similar to that of endocarditis cases caused by *Coxiella burnetii,* the agent of Q fever (35, 75).

Zoonotic *Bartonella* Species Associated with Ocular Lesions, Fever, and Neurological Symptoms

Some rodent-borne *Bartonella* species are also associated with cases of neuroretinitis *(B. elizabethae* and *B. grahamii)* or fever with bacteremia and neurological symptoms *(B. vinsonii* subsp. *arupensis)* (46, 98).

Other *Bartonella* Species or Subspecies

The clinical impact on animals or humans of many *Bartonella* species is still unknown. A broad array of manifestations, including endocarditis, has been identified for dogs (9). *B. henselae, B. clarridgeiae,* "*B. washoensis,*" and *B. elizabethae* have been recognized as pathogenic for dogs (18). No specific pathology has been associated yet with *Bartonella* species infecting domestic and wild ruminants or with many rodent-borne *Bartonella* spp.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Most specimens used for *Bartonella* isolation are either blood or tissue. Approaches typically used for recovery of other pathogens from such sites are suitable, although the fastidious nature of these organisms requires that precautions be taken to minimize the interval from collection to processing. *Bartonella* spp. are difficult to isolate from blood of immunocompetent individuals, as opposed to the relative ease of isolation from blood of immunocompromised patients. Blood samples can be collected either in Isolator blood lysis tubes (Wampole, Cranbury, N.J.), in sodium citrate tubes, or in plastic EDTA tubes, which is now the most common method used for blood collection in animals. If storage of specimens prior to culture is necessary, samples should be kept frozen (at least −20°C). It was shown that blood collected from *B. henselae*-infected cats into both EDTA and Isolator blood lysis tubes yielded good recovery and no loss of sensitivity for EDTA tubes kept at −65°C for 26 days (11). *Bartonella* spp. are susceptible to a broad spectrum of antimicrobial agents; therefore, specimens should be collected prior to antimicrobial therapy.

Collection of tissue from enlarged lymph nodes, cutaneous lesions, or various organs can be performed and samples cultured after homogenization or processed for DNA extraction and PCR. Fresh tissues are preferred for PCR amplification, but paraffin-embedded tissue may be used (23). Fine-needle aspiration has also been successful for detection of *Bartonella* and is less invasive than biopsy (3).

For animals, bartonellae are isolated from blood collected in plastic EDTA tubes; these tubes prevent breakage during shipment and during storage at low temperature, which facilitates lysis of the red blood cells. Biopsies of visceral or cutaneous lesions can be performed, especially in dogs, as described for humans. Collection of aqueous humor in cat or dog retinitis cases for detection of *Bartonella* bacteria or antibodies has been suggested (51, 70).

DIRECT EXAMINATION

Microscopy

Detection of *Bartonella* in erythrocytes from blood smears is rarely performed, with the exception of stained blood films for patients with Oroya fever, as the number of bacteria present in each erythrocyte is quite low (82), reaching a high of eight bacteria in a *B. birtlesii* model in rats (93). Microscopic detection of *Bartonella* organisms in fixed tissue sections includes Warthin-Starry silver staining, which is not highly specific for *Bartonella* organisms and requires careful attention to the details of the procedure (Fig. 1). Detection of bacilli by Warthin-Starry staining is more likely to occur during the early stage of CSD lymphadenopathy, but not during the granulomatous stage of inflammation. In patients with BA, there is usually a larger number of bacilli that are identifiable by Warthin-Starry silver staining.

Antigen Detection

Immunocytochemical labeling is a specific technique but is not widely available (76). Direct immunofluorescence of blood smears allowed rapid diagnosis of *B. quintana* in a patient with acute trench fever (27) and in bacteremic homeless patients (82). In the United States and Europe, *B. henselae* and *B. quintana* immunofluorescence assay (IFA) slides are available through companies such as Focus Diagnostics, Inc. (Cypress, Calif.).

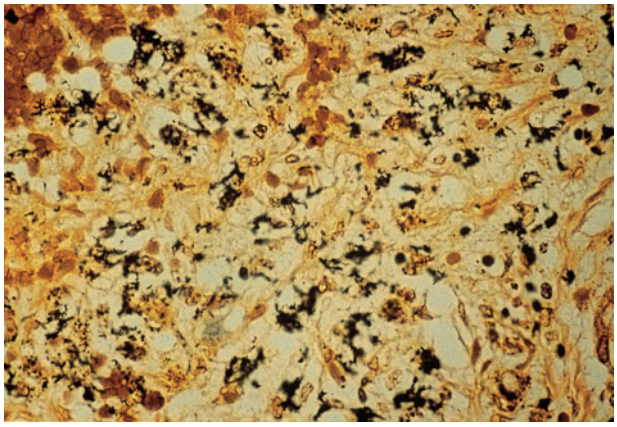

FIGURE 1 Warthin-Starry silver stain of a liver tissue section containing clusters of *B. henselae*. Magnification, ×530.

Nucleic Acid Detection Techniques

Direct detection of *Bartonella* spp. is more often performed by amplification of DNA from tissue, pus, or skin lesions. Molecular genetic methods such as restriction fragment length polymorphism (RFLP) of various genes (see recommended gene targets in Table 2) and, more recently, analysis based on PCR of random, repetitive extragenic palindromic sequences have been used to distinguish strains and species of *Bartonella.* RFLP or sequence analysis of 16S rRNA or citrate synthase genes after PCR amplification, both directly from specimens and from pure cultures, has been largely used for detecting and characterizing *Bartonella*. Identification has also been performed with the amplification of the intergenic spacer region between the 16S and 23S rRNA genes (89) or with protein-coding genes. A new tool has been proposed for the diagnosis of *Bartonella* endocarditis: a real-time nested PCR assay performed on a LightCycler apparatus using serum (23).

ISOLATION PROCEDURES (CULTURE)

Blood

Bartonellae can be recovered from the blood of bacteremic patients, especially persons infected with *B. quintana, B. bacilliformis,* and, less frequently, *B. henselae*. In immunocompromised patients, the level of bacteremia is often higher than in immunocompetent people, and most bacteremic patients have fever, chills, and weight loss (48). However, cultures from patients with infective endocarditis caused by *Bartonella* spp. are rarely positive. *Bartonella* species are optimally isolated from blood with the use of Isolator lysis centrifugation tubes or EDTA tubes and plating onto fresh chocolate or heart infusion agar containing 5% fresh rabbit blood in the absence of antibiotics. Commercial sheep or horse blood agar plates have also been used. *B. koehlerae* does not grow well on heart infusion agar and requires fresh chocolate plates (21). Plates inoculated with blood should be incubated at 35°C for at least 4 weeks in 5% CO_2 and at high humidity. Colonies usually appear after 5 to 15 days (48). Considering that the length of time required for detection of *Bartonella* spp. allows other slowly growing pathogens, including *Mycobacterium tuberculosis,* to grow on the same plates, appropriate safety precautions should be taken with positive cultures. Vials used for blood culture (broth-based or biphasic culture systems) can also be used for isolation of *Bartonella,*

such as BACTEC Peds Plus vials (Becton Dickinson, Sparks, Md.) (32) inoculated with about ≤5 ml and incubated, with recovery subsequently achieved by subculture onto solid media (42). Acridine orange staining and blind subculture from negative bottles before discarding them at 7 days may increase the likelihood of identifying bartonellae (1). An assay was also developed in which samples of heparinized blood are sedimented and the plasma is collected for inoculation into shell vials (42). Culture is then performed by the centrifugation-shell vial technique using ECV304 human endothelial cell monolayers (48).

In broth, *Bartonella* spp. usually do not produce turbidity or convert enough oxidizable substrate to CO_2 for CO_2 detection-based blood culture systems to indicate growth. A novel, chemically modified, insect-based liquid culture medium has been developed and supports the growth of at least seven *Bartonella* species (60). This medium also supports cocultures consisting of different *Bartonella* species, and it facilitates primary isolation of *B. henselae* from blood and aqueous fluids of naturally infected cats. This liquid growth medium may provide an advantage over conventional direct blood agar plating for the diagnosis of bartonellosis (60).

Tissue

Recovery of *Bartonella* spp. from cutaneous lesions, liver, spleen, or lymph node is not easy but is possible, especially after homogenization in inoculation medium and plating directly onto solid agar. Cocultivation with an endothelial cell line or by the shell vial method is more laborious but can yield bacterial growth on some occasions where nothing else works (48). Such methods have both been applied successfully for isolation of *Bartonella* in endocarditis cases (55). Some liquid media have been developed to allow primary isolation of *B. henselae* from blood and tissue (17, 101) but have not been used widely.

IDENTIFICATION

Bartonella spp.

Colonies of *B. henselae* can be of two morphological types, present in the same culture: (i) irregular, raised, whitish, rough (cauliflower-like), and dry in appearance and (ii) smaller, circular, tan, and moist in appearance, tending to pit and adhere to the agar (Fig. 2) (99). *B. quintana* colonies are usually smooth, flat, and shiny and do not pit the agar (48). *B. clarridgeiae* produces small white, raised, indurated, and cohesive colonies (57). They also can appear to spread on the agar during primary isolation from cats. Most *Bartonella* spp. usually appear as uniformly smooth after repeated subcultures. The bacilli are small (2 by 0.5 μm) and stain best with Gimenez stain (48). With Gram staining, *Bartonella* spp. are only weakly counterstained with safranin O. *Bartonella* spp. appear after Gram staining as small gram-negative slightly curved rods resembling *Campylobacter, Helicobacter,* or *Haemophilus* (99). Clumping of cells is quite common. The morphology of the colonies which appear usually after a lengthy incubation (more than 7 days) and negative catalase and oxidase reactions are often sufficient for a presumptive identification of *Bartonella*. After several subcultures, *Bartonella* colonies appear in less than a week. Furthermore, during primary isolation of *B. henselae* from cat blood, colonies appear most often in less than a week, whereas it usually takes 10 to 14 days to observe the first colonies for *B. clarridgeiae* or *B. koehlerae*.

B. bacilliformis, B. clarridgeiae, B. capreoli, and *B. schoenbuchensis* are the only members of the genus that are motile by means of unipolar flagella. *B. quintana* and *B. henselae* as well as several other *Bartonella* species have a twitching motility associated with fimbriae or pili. These pili are associated with cytoadherence and may mediate specific interaction with host erythrocytes and endothelial cells (62).

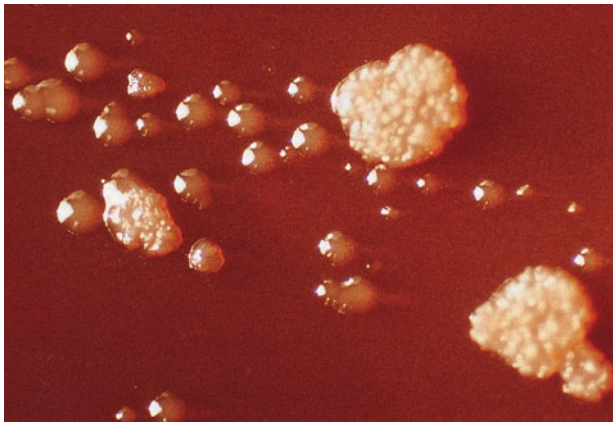

FIGURE 2 *B. henselae* after 7 days of incubation on chocolate agar, showing heterogeneity of colonies. Magnification, ×21.

Measurements of preformed enzymes and standard testing have revealed differences between species. Fatty acid methyl esters are prepared from cells harvested after 7 days of incubation on agar plates under conditions usually used for *Bartonella* isolation (see above). Bartonellae have a unique and characteristic whole-cell fatty acid composition (99). They have gas-liquid chromatography profiles consisting mainly of $C_{18:0}$, $C_{18:1}$, and $C_{16:0}$ acids. *B. elizabethae* contains a greater amount of $C_{17:0}$ than the other species.

Most species are biochemically inert except for the production of peptidases. None of the various commercially available identification systems contain *Bartonella* spp. in their databases. However, the MicroScan Rapid Anaerobe Panel (Baxter Diagnostics, Deerfield, Ill.), the RapID ANA II, and Rapid ID 32 A have been used as aids for identification. The MicroScan Rapid Anaerobe Panel has been reported to provide species identification (code 10077640 for *B. henselae,* code 10073640 for *B. quintana,* and code 10077240 for *B. bacilliformis*) (99). Overall, these identification kits are of limited use for proper diagnosis of *Bartonella* infection.

Identification of *Bartonella* isolates is largely based on molecular techniques, many allowing determination of the species or even some genotypes within a given species. Methods include Southern blotting, gel and capillary electrophoresis, PCR, DNA hybridization, RFLP, and sequence analysis and immunofluorescence detection (1, 84). The most widely targeted genes are those coding for the citrate synthase (*gltA*), a heat shock protein (*groEL*), riboflavin synthase (*ribC*), a cell division protein (*ftsZ*), and a 17-kDa antigen (23) (Table 2). The 16S rRNA gene (*rrs*) was first used by Relman et al. in 1990 for identification of the microbial etiology in a case of BA (78). However, this gene is not sensitive enough to properly discriminate *Bartonella* at the species level (56). Sequences obtained from the *gltA* and *rpoB* (RNA polymerase beta-subunit) genes are congruent with DNA-DNA hybridization for *Bartonella* species identification (56). The intergenic spacer region between the 16S and 23S rRNA genes has also been useful for *Bartonella* species identification (43, 59, 61). A genomic fingerprinting technique using infrequent restriction site PCR was also proposed to identify pathogenic *Bartonella* species (31). Use of monoclonal antibodies has been proposed for rapid identification of *B. quintana* (58).

Typing Systems

Multilocus sequence typing (MLST) has been used to examine the distribution of polymorphisms within different genes of *B. henselae* isolates (36). MLST distinguished several sequence types that resolved into three distinct lineages, suggesting a clonal population structure for the species. Similarly, multispacer typing was applied for the sequence-based typing of *B. quintana* (25).

SEROLOGICAL TESTS

Serological testing has become the cornerstone of clinical diagnosis, as it is widely used for diagnosis of *Bartonella* infections, especially cases of CSD, because culture and isolation are quite time-consuming and difficult and may yield results only after several weeks. However, cross-reactivity among *Bartonella* species is common, and it may occur with some other pathogenic bacteria such as *C. burnetii* and *Chlamydophila* spp. (53, 65). Antibody response in humans and animals is detected mainly with the IFA or different enzyme immunoassays (EIAs) (68). Western blotting tests have also been developed but are not used as widely (34, 91). In the United States, serological testing for CSD is performed by the Centers for Disease Control and Prevention (CDC) in Atlanta, Ga., by various state public health laboratories, and by commercial laboratories. Commercial slides (such as those from Focus Diagnostics, Inc.) for *B. henselae* and *B. quintana* IFA testing are available and widely used in both the United States and Europe.

B. bacilliformis

IFA and EIAs for the diagnosis of *B. bacilliformis* infection and for use in serological surveys have both been used for many years. A new IFA based on *B. bacilliformis*-infected Vero cells has been developed and shown to be very specific (92% based on 101 healthy controls) and identified 81% (86 of 106) of those with laboratory-diagnosed acute bartonellosis (13). Some other assays have been developed but showed some cross-reactivity with *Brucella* and *Chlamydophila psittaci,* suggesting that test optimization is still required (1).

B. quintana, B. henselae, and *B. clarridgeiae*

Human infection with *B. henselae* or *B. quintana* is evaluated by the presence of immunoglobulin M (IgM) or IgG directed against these bacteria, with cross-reactivity in up to 95% of samples (91). Antigen adsorption can be used to reduce cross-reactivity and to determine to which antigen the antibodies are truly directed (1). For animals, detection of antibodies is usually directed toward IgG. The first serological test for CSD, developed at the CDC, was an IFA based on *B. henselae* bacilli that were cocultivated with Vero cells to inhibit autoagglutination (77). This test was found to have good sensitivity (84 to 95%) and specificity (94 to 98%) (20, 77, 102). Lower sensitivity and specificity were reported from Europe (22, 103). However, commercial slides from at least one specific manufacturer (Focus Diagnostics) have been shown to be more sensitive for detection of cases of CSD, especially in Europe (68, 103). IFA is the most frequently used serological test, and it seems to currently be the most reliable test and the method of choice for the diagnosis of CSD (91). Dilution titers of 256 or higher are usually indicative of ongoing infection; lower titers may indicate an early or late clinical phase of the disease or prior exposure to the bacteria. In cases of endocarditis caused by either *B. henselae* or *B. quintana,* high IgG antibody titers (≥800) are usually detected (28). A titer ≥800 for IgG antibodies to either *B. henselae* or *B. quintana* has a positive predictive value of 0.810 for the detection of chronic *Bartonella*

infections in the general population and 0.955 for the detection of *Bartonella* infections among patients with endocarditis.

IFA is time-consuming, requires appropriate equipment and expertise, and is subject to interobserver variation due to the difficulty of reading the test (1). Within the last 10 years, different EIAs have been developed; they are simpler to perform, use readily available equipment, and can be automated (1). However, at present, EIAs have not been widely used and the sensitivity of the tests (17 to 35%) was lower than for one IFA (5). Giladi et al. (29) developed an EIA that used *N*-lauroylsarcosine-insoluble outer membrane antigens from agar-grown *B. henselae* for the detection of anti-*B. henselae* IgG and IgM antibodies in patients with CSD. It was found that when a positive IgG or IgM test result or both are accepted as diagnostic, the sensitivity of the EIA is 85%. Applying stringent criteria, this test is highly specific (98 and 99% for IgG and IgM, respectively), as determined by testing healthy control subjects and patients with lymphadenopathy due to defined non-CSD causes (69). EIA seems more sensitive than IFA for detection of IgM (1).

ANTIMICROBIAL SUSCEPTIBILITY

Antimicrobial susceptibility testing can be performed by incorporation of antibiotics into either blood or chocolate agar or into various media supplemented with blood using a microdilution technique (88, 95). The E test (AB Biodisk, Solna, Sweden) can also be used to determine antibiotic susceptibility (100). Results of susceptibility testing of *Bartonella* spp. are summarized in Table 3. Evaluation of susceptibility to

antibiotics has been performed either in cells or without cells, i.e., in axenic media. These various methods of culture could be used for determination of the bacteriostatic activity of antibiotics with similar results. Determination of the antibiotic susceptibility in axenic medium has been carried out either in solid media enriched with 5 to 10% sheep or horse blood or in liquid media (66, 95). It should be noted that the conditions required to grow *Bartonella* during susceptibility testing do not meet standardized criteria established for the Clinical and Laboratory Standards Institute. Bacteria of the genus *Bartonella* are susceptible to many antibiotics when grown axenically, including β-lactams, aminoglycosides, chloramphenicol, tetracyclines, macrolide compounds (including telithromycin), rifampin, fluoroquinolones, and trimethoprim-sulfamethoxazole (66, 67, 72, 86).

In vitro antibiotic susceptibilities also have been examined for *Bartonella* species cocultivated with eukaryotic cells. As with agar-based susceptibilities, these studies demonstrated that *Bartonella* spp. are susceptible to many antibiotics in vitro (37). However, all of these antibiotics (39) had only bacteriostatic activity (38, 39). Only aminoglycosides are bactericidal in vitro against *Bartonella* species grown in liquid medium (88), in endothelial cells (71), or in an erythrocyte coculture model (87).

Choice and Use of Antibiotics In Vivo

CSD typically does not respond to antibiotic therapy. Most investigators have observed no benefit with antibiotic treatment, whereas anecdotal reports have indicated that ciprofloxacin, rifampin, and trimethoprim-sulfamethoxazole may be effective (26, 75, 81).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Diagnosis of *Bartonella* infection in humans, especially for typical forms of CSD, is mainly based on serological data, which is the most cost-effective approach. As reported by Bergmans et al. (5) and Sander et al. (91), the sensitivities of different IFAs range from 14 to 100%, depending on the antigen used, the cutoff chosen, and the test procedures. For cases of endocarditis, the best approach is serological testing and performing PCR on cardiac valves. A recent procedure using a single-step serological assay against *C. burnetii* and *Bartonella* species found a sensitivity of 100%, and a positive predictive value of 98% for the diagnosis of blood culture-negative endocarditis (85). New methods of culture in liquid media are being developed, as direct isolation from blood or tissues is often negative despite detection of *Bartonella* DNA by PCR tests (60).

Peptostreptococcus, Finegoldia, Anaerococcus, Peptoniphilus, Veillonella, and Other Anaerobic Cocci*

YULI SONG AND SYDNEY M. FINEGOLD

55

TAXONOMY

Gram-positive anaerobic cocci are better known to most bacteriologists as peptococci or peptostreptococci. *Peptococcus* is only remotely related to other species of gram-positive anaerobic cocci and is rarely cultured from human clinical specimens; its main interest lies in its taxonomic significance. *Peptococcus niger* is now the sole remaining representative of this genus. Until recently, most clinical isolates of gram-positive anaerobic cocci were identified to the species level in the genus *Peptostreptococcus*, but this genus is currently under revision. *Peptostreptococcus* was described as a genus in 1936 and was considered the anaerobic equivalent of *Streptococcus*. The genus comprised 16 recognized species, with a G+C range from 27 to 37 mol%, except for *Peptostreptococcus productus* (44 to 45 mol%). Two proposals would restrict the genus *Peptostreptococcus* to *P. anaerobius* (46) and place *Peptostreptococcus magnus* and *Peptostreptococcus micros* in two new genera, *Finegoldia* and *Micromonas*, respectively (45). However, the name *Micromonas* is illegitimate because of the precedence of the microalga *Micromonas*. The name *Peptostreptococcus micros* must continue to be used because it is the single legitimate, validly published name. More recently, Ezaki et al. (19) proposed three new genera: *Anaerococcus,* which includes the saccharolytic, butyrate-producing species *(A. hydrogenalis, A. lactolyticus, A. octavius, A. prevotii, A. tetradius,* and *A. vaginalis); Peptoniphilus,* which contains the nonsaccharolytic, butyrate-producing species *(P. asaccharolyticus, P. harei, P. lacrimalis, P. indolicus,* and *P. ivorii);* and *Gallicola* (which contains a single species, *G. barnesae*). Table 1 shows the changes in classification of gram-positive anaerobic coccal species from human clinical specimens.

The taxonomy of the other validly published gram-positive anaerobic cocci from human clinical specimens such as *Streptococcus parvulus, P. productus,* and *Peptostreptococcus saccharolyticus* is also under revision. *S. parvulus* has been transferred to the genus *Atopobium* as *Atopobium parvulum* (13) (see chapter 56). *P. productus* was reclassified in the genus *Ruminococcus* (20); however, it has been recommended that *P. productus* be retained in its present taxonomic position until there is a definitive revision of the classification of ruminococci. *Peptococcus saccharolyticus* has been transferred to the genus *Staphylococcus* based on the analysis of nucleic acid relatedness data and cell wall peptidoglycan structure.

The gram-negative anaerobic cocci have been classified in a single family, the *Veillonellaceae*. *Veillonella, Acidaminococcus,* and *Megasphaera* are genera in this family, and *Anaeroglobus geminatus* gen. nov., sp. nov., was recently described (11). The genus *Veillonella* is currently subdivided into eight species (31). Among them, four have been isolated from human clinical specimens frequently. They include *V. parvula*, *V. atypica*, *V. dispar*, and the new species *V. montpelliérensis*. The other four species, *V. caviae, V. criceti, V. ratti,* and *V. rodentium*, were found only in animals, except for one *V. ratti* isolate which was recovered from human semen. Phylogenetic analysis showed that the family *Veillonellaceae* did not represent a true clade and could not be considered a relevant taxon. This family has been suppressed from the classification proposed in the latest edition of *Bergey's Manual of Systematic Bacteriology* (24). This classification grouped all genera belonging to the *Sporomusa* subbranch in a single large family named "*Acidaminococcaceae*." The phylogenetic analysis of the *Sporomusa* subbranch is in accordance with the proposed new classification mentioned above.

DESCRIPTION OF THE GROUP

The organisms included in this chapter are obligately anaerobic non-spore-forming, sometimes elongated cocci. The genera *Peptostreptococcus, Anaerococcus, Gallicola, Finegoldia, Peptoniphilus,* and *Peptococcus* are gram-positive, coccobacillary or occasionally coccoid cells. In Gram-stained preparations of pure cultures, cells vary in size from 0.3 to 2.0 μm and can be arranged in pairs, short chains, tetrads, small clusters, or irregular masses; most species are present as either chains or clumps. The ability to utilize carbohydrates varies greatly; some genera are asaccharolytic, but a few are strongly saccharolytic. For most species, the products of protein digestion appear to be the principal energy source. The genus *Staphylococcus* contains two species, *S. saccharolyticus* and *Staphylococcus aureus* subsp. *anaerobius*, that initially grow under anaerobic conditions and become aerotolerant on subcultures (see chapter 28). Strictly anaerobic *Staphylococcus epidermidis* was reported to be occasionally isolated from clinical specimens (53). The genera *Veillonella, Acidaminococcus*, *Megasphaera,* and *Anaeroglobus*

*This chapter contains information presented in chapter 55 by Bernard J., Moncla and Sharon L. Hillier and chapter 56 by Hannele R. Jousimies-Somer, Paula H. Summanen, Hannah Wexler, Sydney M. Finegold, Saheer E. Gharbia, and Haroun N. Shah in the eighth edition of this Manual.

TABLE 1 Changes in classification of gram-positive anaerobic coccal species from human clinical specimens

Current classification	Previous classification
Peptococcus niger	*Peptococcus niger*
Peptostreptococcus anaerobius	*Peptostreptococcus anaerobius*
Peptostreptococcus micros[a]	*Peptostreptococcus micros*
Peptoniphilus asaccharolyticus	*Peptostreptococcus asaccharolyticus*
Peptoniphilus indolicus	*Peptostreptococcus indolicus*
Peptoniphilus harei	*Peptostreptococcus harei*
Peptoniphilus ivorii	*Peptostreptococcus ivorii*
Peptoniphilus lacrimalis	*Peptostreptococcus lacrimalis*
Anaerococcus prevotii	*Peptostreptococcus prevotii*
Anaerococcus tetradius	*Peptostreptococcus tetradius*
Anaerococcus octavius	*Peptostreptococcus octavius*
Anaerococcus hydrogenalis	*Peptostreptococcus hydrogenalis*
Anaerococcus lactolyticus	*Peptostreptococcus lactolyticus*
Anaerococcus vaginalis	*Peptostreptococcus vaginalis*
Finegoldia magna	*Peptostreptococcus magnus*
Gallicola barnesae	*Peptostreptococcus barnesae*
Slackia heliotrinireducens corrig[b]	*Peptostreptococcus heliotrinreducens*
Atopobium parvulum	*Streptococcus parvulus*
Ruminococcus productus[c]	*Peptostreptococcus productus*
Staphylococcus saccharolyticus	*Peptococcus saccharolyticus*

[a] The name *Micromonas micros* was proposed by Murdoch and Shah (45), but it is illegitimate because it is placed in an illegitimate genus. So, the name *Peptostreptococcus micros* must be used because it is the single legitimate, validly published name.

[b] The specific epithet *heliotrinreducens* [*sic*] has been corrected in the new combination *Slackia heliotrinireducens*. However, the name "*Peptostreptococcus heliotrinireducens*" corrig. was never formally proposed before 14 December 2000. Consequently, in the "List of Prokaryotic Names with Standing in Nomenclature" (http://www.bacterio.cict.fr/index.html), the epithet *heliotrinreducens* [*sic*] has been maintained for *Peptostreptococcus heliotrinreducens*.

[c] *Ruminococcus productus* was proposed recently; however, Willems and Collins have recommended that *P. productus* be retained in its present taxonomic position (67).

are gram-negative cocci. Cells vary in size from 0.3 to 2.5 μm. They characteristically occur in pairs, but single cells, masses, or chains may also occur.

EPIDEMIOLOGY AND TRANSMISSION

Gram-positive anaerobic cocci are part of the normal microbiota of the mouth, upper respiratory and gastrointestinal tracts, female genitourinary system, and skin (42). Gram-positive anaerobic cocci constitute 1 to 15% of the normal oral microbiota (60); *P. micros* is usually considered to be the predominant species of gram-positive anaerobic cocci in the oral microbiota, and *P. anaerobius* and *Finegoldia magna* are also present in the oral cavity. The gastrointestinal tract hosts a wide variety of gram-positive anaerobic cocci, including most recognized species of *Peptostreptococcus*. *P. productus* is one of the most common organisms in the gastrointestinal microbiota; *F. magna* and *A. prevotii* are also common. Several other gram-positive anaerobic cocci are found less often. Large numbers of gram-positive anaerobic cocci can be found in the female genitourinary tract (15). *A. tetradius, A. lactolyticus,* and *A. vaginalis* were first described from vaginal discharges (21, 35); *P. anaerobius, P. asaccharolyticus, P. hydrogenalis, F. magna, P. micros, A. prevotii,* and *Peptococcus niger* have also been isolated from that site (35). The skin microbiota contains gram-positive anaerobic cocci; *F. magna* is the species identified most frequently, followed by *P. asaccharolyticus*.

Gram-negative anaerobic cocci form part of the oral, genitourinary, respiratory, and intestinal flora of humans (30). *Veillonella* species are part of the normal mouth, upper respiratory tract, gastrointestinal tract, and vaginal flora; *Acidaminococcus* and *Megasphaera* are part of the intestinal flora.

CLINICAL SIGNIFICANCE

Estimation of the clinical significance of anaerobic cocci isolated from clinical specimens is often difficult, partly due to their recovery from poorly obtained specimens. Anaerobic gram-positive cocci are opportunistic pathogens, comprising approximately one-quarter of all isolates from anaerobic infections (42). They may be present in a great variety of infections involving all areas of the human body, ranging in severity from mild skin abscesses to more serious and life-threatening infections such as brain abscess, bacteremia, necrotizing pneumonia, and septic abortion. Brain abscess is one of the more serious infections involving anaerobic cocci (10, 33, 36). Anaerobic cocci are involved in as many as 40% of pleuropulmonary infections such as lung abscess, necrotizing pneumonia, aspiration pneumonia, and empyema (37, 64). Anaerobic cocci often are isolated with other organisms in skin and soft tissue infections, including progressive bacterial synergistic gangrene, necrotizing fasciitis, and crepitant cellulitis (4, 44, 58). Other infections in which anaerobic cocci have been recognized as significant pathogens are infections of the female genital tract and intra-abdominal infections (8, 18, 56).

Although most infections involving gram-positive anaerobic cocci are polymicrobial (22), there are many instances of their isolation in pure culture (42); most relate to *F. magna*, but there are also reports of *P. anaerobius*, *P. asaccharolyticus*, *P. indolicus*, *P. micros*, *A. vaginalis,* and *P. harei* in pure culture. *F. magna* is the most pathogenic and one of the most frequently isolated gram-positive anaerobic coccal species found in human clinical specimens. It has been isolated from a wide variety of infections at various body sites in pure culture. These include cases of endocarditis (63), meningitis (10), and pneumonia (47), some of which have been fatal. *F. magna* is most commonly associated with infection of skin and soft tissue and with bone and joint infections, but it has also been isolated from cases of septic arthritis (23), prosthetic implant infections (14), breast abscess (17), diabetic foot infection (29), and upper respiratory tract infection such as sinusitis and otitis media. *P. anaerobius* is involved in polymicrobial infections, including abscesses of the brain, ear, jaw, and pleural cavity; pelvic and urogenital regions; the external genitalia; the abdominal region; and the nasal septum (7, 9, 28). The isolation of *P. anaerobius* from a patient with endocarditis has been reported (39). *P. anaerobius* has been associated with gingivitis (40) and periodontitis (65) and is one of the species found most frequently in the root canals of teeth with periapical abscess (59) and has been isolated from a peritonsillar abscess (12). *P. micros* is increasingly recognized as an important oral pathogen. Although it is considered a natural commensal of the oral cavity, elevated counts of this organism are associated with periodontal destruction (16, 50). It is also commonly isolated from other oral infections such as endodontic lesions and peritonsillar infections (38). *P. micros* is not restricted to the oral cavity; it is often isolated in mixed anaerobic infections from different body sites, including brain abscess, otitis

media, sinus infection, human bite wounds, pleural empyema, intra-abdominal infection, anorectal abscess, septicemia, gynecologic infection, vertebral osteomyelitis, and prosthetic joint infection.

Anaerobic gram-negative cocci account for a small percentage of the anaerobic cocci isolated from human specimens (3). *Veillonella* sp. strains are frequently isolated from clinical specimens in aerobic-anaerobic polymicrobial cultures. Rarely, *Veillonella* species have been the only etiologic agents identified in serious infections such as meningitis, osteomyelitis, prosthetic joint infection, pleuropulmonary infection, bacteremia, and endocarditis.

The variety of infections in which anaerobic cocci are involved has been thoroughly reviewed and summarized (42). Although the spectrum of infections has remained relatively unchanged since the extensive review by Murdoch in 1998 (42), the prevalence of these organisms as pathogens is clearly increasing.

COLLECTION, TRANSPORT, AND STORAGE OF CLINICAL SPECIMENS

Most gram-positive anaerobic cocci isolated from human clinical material are not extremely oxygen sensitive. Specimens suspected of harboring anaerobic cocci should be collected, transported, and stored by methods outlined elsewhere (see chapters 5 and 20).

ISOLATION PROCEDURES

Routinely used anaerobic plate media, such as brucella, Columbia, or Schaedler agar base supplemented with 5% sheep blood, vitamin K_1, and hemin, will support the growth of these microorganisms. However, the CDC (Centers for Disease Control and Prevention) agar base gives better recovery of gram-positive anaerobic cocci than brucella agar or other medium formulations. The usual procedures for anaerobes should be followed. Many of these organisms require high moisture content for optimal growth, so fresh medium should be used. Laboratories unable to prepare their own media may wish to consider the use of commercially prepared, prereduced, anaerobically sterilized blood agar (Anaerobe Systems, Morgan Hill, Calif.). These media have an extended shelf life, of up to 6 months, and yield results comparable to or better than those obtained with fresh media.

Gram-positive anaerobic cocci are heterogeneous; a single medium is unlikely to support the growth of all representatives and be reasonably selective. Wren (68) showed that nalidixic acid-Tween blood agar gave better isolation than neomycin blood agar, but recommended that a combination of different media be used to maximize recovery rates. The disadvantage of neomycin blood agar may be the particular inhibitory nature of neomycin to gram-positive anaerobic cocci. Petts et al. (49) reported that oxolinic acid was superior to nalidixic acid for suppression of staphylococci but permitted the growth of non-spore-forming anaerobes, including gram-positive anaerobic cocci. Turng et al. (61) described *P. micros* medium, a selective and differential medium for *P. micros* which contains colistin-nalidixic acid agar (Difco, BD Diagnostics, Sparks, Md.), a selective base for gram-positive cocci that is supplemented with glutathione and lead acetate. Strains of *P. micros* can use the reduced form of glutathione to form hydrogen sulfide, which reacts with lead acetate to form a black precipitate under the colony. Tween 80 supplementation of media may improve growth of some gram-positive anaerobic cocci.

TABLE 2 Differential characteristics of *Peptostreptococcus*, *Peptococcus*, *Peptoniphilus*, *Finegoldia*, and *Anaerococcus*[a]

Species	GLC	Inhibition by SPS	Production of:				Glucose	Production of saccharolytic and proteolytic enzymes								Gram stain and colonial morphology
			Indole	Urease	ALP	ADH		α-Gal	β-Gal	α-Glu	β-Gur	ArgA	ProA	PheA	LeuA	PyrA	
P. asaccharolyticus	A, b	–	d	–	–	–	–	–	–	–	–	+	–	–	d	–	Cells are uniform, in clumps, retaining Gram stain poorly, resembling strains of *Neisseria*. Glistening, low convex, usually whitish to lemon-yellow, musty-odor colonies.
P. indolicus	A, b	–	+	–	+	–	–	–	–	–	–	+	–	+	+	–	Similar to *P. asaccharolyticus*
P. harei	A, b	–	d	–	–	–	–	–	–	–	–	+	–	–	–/w	–	Cells variable in size and shape. Flat, translucent colonies.
P. lacrimalis	A, b	–	–	–	–	–	–	–	–	–	–	+	–	+	+	–	Cells are in short chains or clumps. Pink-white colonies.
"*trisimilis*" group[b]	A, b	–	+	–	d	–	+	–	d	–	–	–	–	–	–	+	Cells are in clumps and tetrads. Gray with white centers, entire and circular colonies.
A. hydrogenalis	B, a	–	+	d	–/w	–	+	–	–	d	–	–	–	–	–	–	Cells variable in size, arranged in clumps, tetrads, and short chains. Gray-white convex colonies, unpleasant odor.

A. prevotii	B, a	−	−	+	−	−	−	+	−	+	+	+	−	d	−	+	Cells variable in size, in clumps or tetrads. Matte gray, low convex colonies.
A. tetradius	B, a	−	−	+	−	−	+	−	−	+	+	+	−	w	+	−/w	Cells variable in size, in clumps and tetrads. Matte gray, low convex colonies.
A. lactolyticus	B, a	−	−	+	+	−	+	−	+	−	−	+	−	−	−	+	Cells are in short chains or clumps. Pink-white colonies.
A. vaginalis	B, a	−	d	−	d	+	+	−	−	−	−	+	−	−	+	−	Cells variable in size, in clumps or tetrads. Gray-white, low convex colonies.
"β-GAL" group[b]	B, a	−	−	−	w	d	+	−	w/+	−/w	−	+	−	−	+	w	Cells variable in size, arranged in clumps. Gray-white, low convex colonies.
A. octavius	B, a, c	−	−	−	−	−	+	−	−	−	−	−	+	−	−	w	Cells are arranged in clumps. Yellowish white, glistening, circular, raised, entire colonies.
P. ivorii	IV	−	−	−	−	−	−	−	−	−	−	−	+	−	−	−	Cells variable in size, arranged in clumps. Yellowish white, low convex colonies.
P. anaerobius	A, IC	+	−	−	−	−	+	−	−	+	−	−	+	−	−	−	Cells are highly pleomorphic, in chains. Colonies are gray with slightly raised off-white centers and a distinctive, sweet odor.
F. magna	A	−	−	−	d	d	−/w	−	−	−	−	+	−	−	+	+	Cells are in pairs, tetrads, or clusters and >0.6 μm in diam. Small colonies, convex and whitish, while others are flatter and translucent.
P. micros	A	−	−	−	+	−	−	−	−	−	−	+	+	+	+	+	Cells in pairs, chains, and clusters. Small colonies; typically white, glistening, and domed and often surrounded by a distinctive yellow-brown halo of discolored agar up to 2 mm wide.
P. productus	A	−	−	−	−	−	+	+	−	+	−	−	−	−	−	−	Cells are ovoid, in pairs or chains; glistening gray colonies.

[a] Data mainly from Murdoch (42) and our unpublished data. Abbreviations and symbols: A, acetate; B, butyrate; IV, isovalerate; IC, isocaproate; C, *n*-caproate; ALP, alkaline phosphatase; ADH, arginine dihydrolase; α-Gal, α-galactosidase; β-Gal, β-galactosidase; α-Glu, α-glucosidase; β-Gur, β-glucuronidase; ArgA, arginine arylamidase; ProA, proline arylamidase; PheA, phenylalanine arylamidase; LeuA, leucine arylamidase; PyrA, pyroglutamyl arylamidase; −, >90% negative; w, weakly positive; +, >90% positive; d, different reactions; w, weakly positive.

[b] Described by Murdoch and Mitchelmore (43).

A recent study (27) tested different media for recovery of *Veillonella* spp. from saliva samples and concluded that a selective medium for *Veillonella* with vancomycin and laked blood gave the greatest recovery of *Veillonella*. This medium can also be used for presumptive identification of *Veillonella* since the colonies produce a red fluorescence.

IDENTIFICATION

Phenotypic Tests

Some gram-positive anaerobic cocci, particularly strains of *P. asaccharolyticus*, decolorize readily by Gram stain and can be confused with gram-negative anaerobes such as *Veillonella*. Gram-positive anaerobic cocci can be distinguished from gram-negative anaerobic cocci by special-potency disks (vancomycin, 5 μg; kanamycin, 1,000 μg; and colistin, 10 μg). The cell morphology of older cultures of gram-positive anaerobic cocci can be very irregular, with many coccobacillary and rod-like forms. It is also important to distinguish gram-positive anaerobic cocci from microaerobic organisms, such as strains of *Streptococcus* species. A simple and reliable test is to apply a 5-μg metronidazole disk to the edge of the inoculum; gram-positive anaerobic cocci show a zone of inhibition of 15 mm or greater, whereas microaerobic strains show no zones of inhibition after incubation for 48 h (43).

P. anaerobius is the only gram-positive anaerobic coccus that gives a zone of inhibition of ≥12 mm around a sodium polyanetholsulfonate (SPS) disk. *P. micros* also exhibits a zone of inhibition with SPS; however, the zone is usually <12 mm. Most *P. anaerobius* strains form distinctive colonies on enriched blood agar; they are 1 mm in diameter after 24 h and gray, with slightly raised off-white centers and a distinctively sweet odor (43). *P. micros* and *F. magna* can be readily distinguished by a combination of colonial morphology and proteolytic enzyme profiles, supported by Gram-stained cell morphology to assess the cell size. An anaerobic coccus with a milky halo around the colonies and small cells (<0.6 μm) can be presumptively identified as *P. micros* (43, 62). *F. magna* cells are larger than those of most peptostreptococci. Published data (42) also indicate that they can be differentiated by enzymatic tests for proteolytic activity such as proline arylamidase, phenylalanine arylamidase, and tyrosine arylamidase.

P. asaccharolyticus is another gram-positive anaerobic coccal species frequently isolated from human clinical specimens, but strains that were identified phenotypically are genetically diverse. To complicate matters further, the type strain of *P. asaccharolyticus* is highly atypical in its whole-cell composition and some biochemical properties. A recent study of ours (unpublished data) indicated that all strains (a total of 33) that were identified as *P. asaccharolyticus* phenotypically shared only a low sequence similarity (<90%) with the corresponding sequence of the type strain of *P. asaccharolyticus*. They all had almost identical 16S rRNA sequences and shared a high sequence similarity (>99%) with another *P. asaccharolyticus* strain, ATCC 29743. The cellular morphology of this group of bacteria is characteristic; the cell size is more uniform than is observed with most species of gram-positive anaerobic cocci, and cells occur in clumps, retaining the Gram stain poorly and often resembling strains of *Neisseria*. The colony morphology is also distinctive; after 5 days of incubation on enriched blood agar, colonies are 2 to 3 mm in diameter, glistening, low convex, and usually whitish to lemon-yellow, and they often have a characteristic musty odor. They produce an enzyme profile very similar to that of *P. harei* strains but can easily be differentiated by their clearly different cell and colonial morphology. Cells of *P. harei* vary considerably in size (diameter, 0.5 to 1.5 μm) and shape (circular, oval, or elliptical). Colonies of 5-day cultures on enriched blood agar are approximately 1 mm in diameter, nonhemolytic, flat, and translucent. *P. indolicus* is phenotypically similar to *P. asaccharolyticus* and can be difficult to identify, but it is rarely isolated from human clinical specimens. *P. indolicus* can be tentatively distinguished from *P. asaccharolyticus* by its ability to produce alkaline phosphatase.

A. prevotii and *A. tetradius* were reported as common species of gram-positive anaerobic cocci in human clinical material in early surveys. However, nucleic acid studies indicate that they are very heterogeneous. Again, our study based on 16S rDNA sequencing indicated that a large percentage of organisms identified as *A. prevotii* or *A. tetradius* are strains of *A. vaginalis*. It is likely that strictly defined strains of *A. prevotii* or *A. tetradius* are only occasionally recovered from most clinical specimens. The activity of pyroglutamic acid arylamidase might be useful for differentiation of *A. prevotii* and *A. tetradius;* however, distinctions cannot be generalized because insufficient numbers of strains of each species have been reliably identified. *A. prevotii* and *A. tetradius* can be distinguished from other recognized species of gram-positive anaerobic cocci by production of α-glucosidase and β-glucuronidase. Strains of other saccharolytic gram-positive anaerobic cocci such as *A. vaginalis* and *A. lactolyticus* can be differentiated by their enzyme profiles.

Table 2 summarizes the differential characteristics of gram-positive anaerobic coccal species. Based on published data and our unpublished data, we developed a flowchart for rapid identification of gram-positive anaerobic cocci (Fig. 1). The identification is based on phenotypic tests that can be performed in many diagnostic laboratories. Most of the information presented here relates to the phenotypic characteristics of strains isolated from humans.

Several systems, such as Rapid ID 32A (bioMérieux, Marcy L'Etoile, France) and RapID ANA II (Remel, Inc., Lenexa, Kans.), are available commercially for the rapid identification of anaerobes. Evaluation of these biochemical kits indicates that they may be valuable for characterizing anaerobic cocci (42). However, these systems are designed to identify a wide range of anaerobes, and they contain many tests of little relevance for identification of anaerobic cocci. Furthermore, databases accompanying the kits are often incomplete or inaccurate, especially for newly described species. Our most recent comparison of the Rapid ID 32A kit with 16S rRNA gene sequencing for identification of gram-positive anaerobic cocci showed that the Rapid ID 32A system is good for accurate identification of *P. micros*, *P. anaerobius*, *F. magna,* and *P. asaccharolyticus*, but not the others.

Gram-positive anaerobic cocci are separated into five groups based on fatty acid end products of metabolism analyzed by gas-liquid chromatography (GLC) (Table 2): (i) an acetate group containing *F. magna, P. micros,* and *P. productus* that only produces acetic acid; (ii) a butyrate-acetate group that produces butyric acid as its major terminal volatile fatty acid (VFA) and acetic acid as a second lesser acid (this group contains all of the species in the genus *Anaerococcus*); (iii) an acetate-butyrate group that produces acetic acid as its major terminal VFA and butyric acid as the second acid (this group contains all of the species in the genus *Peptoniphilus* except for *P. ivorii*); (iv) a caproate group whose members produce large quantities of longer-chain VFAs (the most important species in this group is *P. anaerobius*, the only

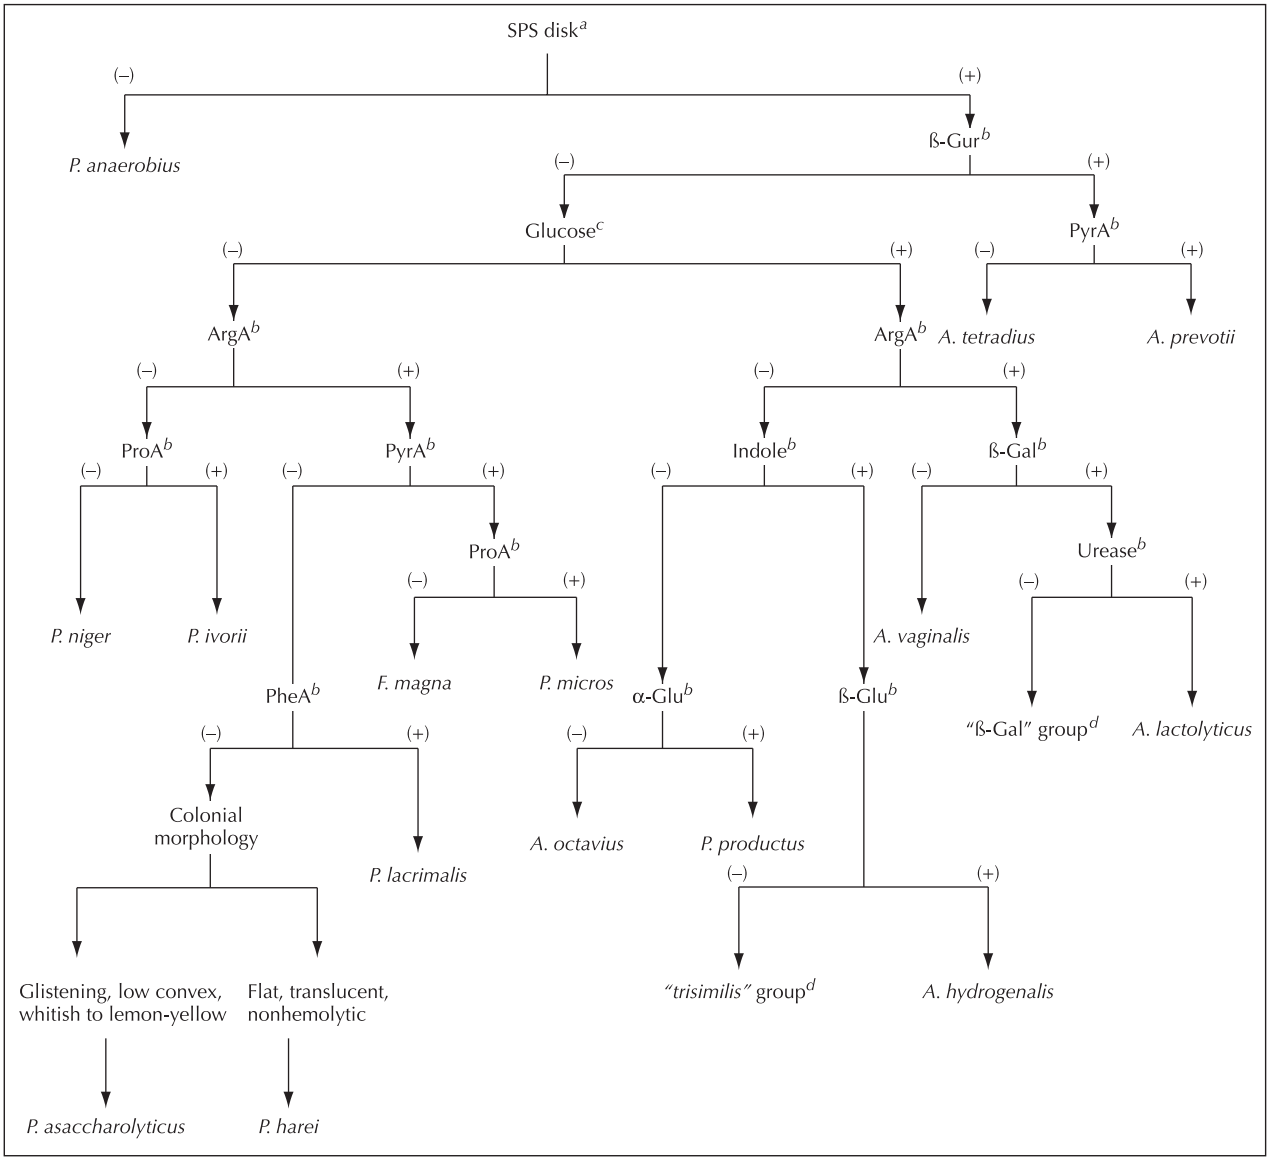

FIGURE 1 Flowchart with key characteristics for identification and differentiation of gram-positive anaerobic cocci. *a,* SPS testing was done using the SPS disk from Anaerobe Systems. All gram-positive anaerobic cocci are resistant to SPS except for *P. anaerobius,* which gives a zone of inhibition of ≥12 mm around an SPS disk. *P. micros* also exhibits a zone of inhibition with SPS; however, the zone is usually <12 mm. +, no zone or the zone of inhibition is <12 mm; −, zone of inhibition is ≥12 mm. *b,* All the enzymatic tests were done using the Rapid ID 32A system (API bioMérieux) according to the manufacturer's instructions. β-Gal, β-galactosidase; α-Glu, α-glucosidase; β-Glu, β-glucosidase; β-Gur, β-glucuronidase; ArgA, arginine arylamidase; ProA, proline arylamidase; PheA, phenylalanine arylamidase; PyrA, pyroglutamyl arylamidase. *c,* Glucose fermentation tests were performed using prereduced, anaerobically sterilized peptone-yeast-glucose (PYG) broth tube (Anaerobe Systems). A pH of ≤5.5 in the PYG tubes was interpreted as a positive result, and a pH of ≥5.9 was interpreted as a negative result. *d,* Described by Murdoch and Mitchelmore (43).

species of gram-positive anaerobic cocci to produce a major terminal peak of isocaproic acid); and (v) an isovaleric acid group that contains *P. ivorii* (this organism is the only species of gram-positive anaerobic cocci that produces a major terminal peak of isovaleric acid). GLC is also useful for identifying the rarely isolated *Peptococcus niger* and *P. octavius*, which produce *n*-caproic acid.

Veillonella, Acidaminococcus, and *Megasphaera* comprise the genera of anaerobic gram-negative cocci. Table 3 contains a key for distinguishing these three genera.

Molecular Methods

Molecular methods, such as nucleic acid probe hybridization, PCR amplification, and 16S rRNA gene sequencing,

TABLE 3 Characteristics of gram-negative cocci[a]

Organism(s)	Nitrate reduction	Catalase	Glucose fermentation[b]	Fatty acids from PYG
Veillonella spp.	+	V	−	A, p
Acidaminococcus fermentans	−	−	−	A, B
Megasphaera elsdenii	−	−	+	A, ib, b, iv, v, C

[a] A, acetate; B and b, butyrate; C, *n*-caproate; ib, isobutyrate; iv, isovalerate; v, valeric acid; V, variable; p, propionate; +, positive reaction; −, negative reaction.
[b] Glucose fermentation tests were performed using prereduced, anaerobically sterilized (PRAS) peptone-yeast-glucose (PYG) broth tube (Anaerobe Systems). The PRAS tubes were inoculated from an actively growing broth culture (without carbohydrate). A pH of ≤5.5 in the PRAS tubes was interpreted as a positive result, a pH of 5.6 to 5.8 was interpreted as weakly positive, and a pH of ≥5.9 was interpreted as negative for fermentation.

are not yet standardized or available commercially for the direct demonstration of medically important gram-positive anaerobic cocci from clinical specimens. However, several studies have used molecular techniques to identify and detect gram-positive anaerobic cocci. DNA probes targeting the 16S rRNA gene have been used to detect *P. anaerobius* and *P. micros*, and PCR assays specific for detection of *F. magna*, *P. anaerobius*, and *P. micros* directly from clinical specimens have been developed (51, 52, 55). More recently, real-time PCR has been applied for quantitative detection of *P. micros* in clinical samples (2, 5). Our group evaluated the utility of 16S rRNA gene sequencing as a means of identifying clinically important gram-positive anaerobic cocci (57). Our study indicated that problems exist in the public database. For example, among the 13 type strains of gram-positive anaerobic coccal species that we tested, only 4 gave a "perfect" match with their corresponding sequences in GenBank, whereas the other 9 had lower sequence similarities (<98%) (Table 4). Based on the 16S rRNA sequences we deposited in GenBank, a multiplex PCR scheme was developed for rapid identification of clinically significant gram-positive anaerobic coccal species. Molecular methods undoubtedly will offer a potential option for accurate identification and rapid diagnosis in laboratories supplied with the appropriate equipment and competence.

ANTIMICROBIAL SUSCEPTIBILITIES

New information regarding the antimicrobial susceptibilities of gram-positive anaerobic cocci is sparse compared with the information available for other anaerobic species. Current information is summarized in Table 5. Many reports fail to give results for individual species, opting instead to combine data for the group.

Penicillins are considered to be effective first-line therapy for gram-positive anaerobic cocci. Most evidence suggests that *P. asaccharolyticus*, *F. magna*, and *P. micros* are usually susceptible to penicillins, although Wren (69) reported resistance among isolates of *F. magna* and *P. micros* (16 and 8%, respectively) to penicillin. Cephalosporins are usually, but not always, effective. Carbapenems are extremely active. Several authorities maintain that most gram-positive anaerobic cocci are susceptible to metronidazole, but resistance has frequently been reported. Strains that are microaerobic are much more likely to be resistant to metronidazole. Susceptibilities to clindamycin vary widely, and local geographic variation should be taken into account. A French multicenter study (41) reported clindamycin resistance (28%) among *Peptostreptococcus* spp., and an American study by Sanchez et al. (54) noted >10% resistance of *F. magna* to clindamycin. Wren (69) reported that 9% of *F. magna* isolates were resistant to clindamycin in London, England. Erythromycin, clarithromycin, and azithromycin have similar efficacies and are probably not active enough to be recommended. Several studies (25, 48, 66) indicated that narrow-spectrum quinolones such as ciprofloxacin have only moderate activity, but more recently developed agents such as trovafloxacin and clinafloxacin are extremely active (48). Goldstein et al. (26) reported that gemifloxacin is the most active fluoroquinolone tested for peptostreptococci. In two studies (1, 34), ciprofloxacin and ceftazidime showed much lower activities against gram-positive anaerobic cocci than the other antimicrobial agents tested. In another recent study, Koeth et al. (32) reported that the levofloxacin and clindamycin susceptibility rates of *F. magna* were 72.4 and 84.7%, respectively. It is highly desirable that future investigations present data on different species separately. A study by Brazier et al. (6) presented data on different gram-positive anaerobic coccal species separately. They found that the highest percentage of overall resistance detected among gram-positive anaerobic cocci was 41.6% resistance to tetracycline, followed by 27.4% resistance to erythromycin. Among gram-positive anaerobic cocci as a group, 7.1% of isolates were resistant to penicillin and clindamycin, and 3.5% of isolates were resistant to amoxicillin-clavulanate. There was no resistance among gram-positive anaerobic

[a] Data were obtained from the Wadsworth Anaerobic Bacteriology Laboratory. Strains were tested by Clinical and Laboratory Standards Institute (NCCLS) agar dilution procedures.

[b] MIC breakpoints are indicated in parentheses next to each antimicrobial agent. Abbreviations: Pen, penicillin; Amp/Sul, ampicillin-sulbactam; Amox/Clav, amoxicillin-clavulanic acid; Pip/Tazo, piperacillin-tazobactam; Cefox, cefoxitin; Imi, imipenem; Clinda, clindamycin; Metro, metronidazole; Cipro, ciprofloxacin; Trova, trovafloxacin.

[c] Results for these three drug combinations given for amoxicillin and piperacillin.

[d] One of 5 strains showed resistance.

[e] Three of 16 strains showed resistance.

[f] Two of 15 strains showed resistance.

[g] Three of 16 strains showed resistance.

[h] One of 5 strains showed resistance.

cocci to piperacillin-tazobactam, chloramphenicol, cefoxitin, imipenem, or metronidazole. Data from our laboratory are presented in Table 5.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The initial report should provide Gram stain results and bacterial and human cell morphologies. The relative quantities of different organisms seen in the smear give a good overall impression of specimen quality, the nature of the polymicrobial infection, and the relative importance of each organism. In general, bacterial isolates that are predominant, virulent, and resistant to antimicrobial agents should be given the greatest attention. Bacteria present in pure culture or in large numbers are probably of major importance, as are organisms recovered in multiple cultures and isolated from normally sterile sites. Furthermore, Gram stain results can guide the laboratory in choosing media for optimal recovery of the predicted organisms.

The significance of finding anaerobic gram-positive or gram-negative cocci in clinical specimens depends on the specimen and the likelihood that it was contaminated by the microbiota of the skin or mucous membranes. Hence, interpretation of culture results is dependent on the nature and quality of the specimen submitted to the laboratory.

Propionibacterium, Lactobacillus, Actinomyces, and Other Non-Spore-Forming Anaerobic Gram-Positive Rods*

EIJA KÖNÖNEN AND WILLIAM G. WADE

56

TAXONOMY AND DESCRIPTION OF AGENTS

The anaerobic gram-positive non-spore-forming rods are widely distributed among two gram-positive phyla: *Actinobacteria* and *Firmicutes* (Table 1). Several new genera have been described, and numerous taxonomic revisions within the genera covered in this chapter have been performed since the 8th edition of this Manual (Table 2). Although it may be confusing for those in clinical microbiology laboratories, the clarification of taxonomic relationships allows definitive associations between taxa and disease to be uncovered and greater precision in the laboratory identification of pathogens. In addition, molecular ecological analysis of clinical specimens has revealed numerous as-yet-uncultivable bacterial taxa belonging to this group (15, 35, 70, 117, 118, 126).

Phylum *Actinobacteria*

The family *Actinomycetaceae* currently includes five genera: *Actinomyces, Actinobaculum, Arcanobacterium, Varibaculum,* and *Mobiluncus*. It has long been known that species assigned to the genus *Actinomyces* constitute a heterogeneous group. New genera have been proposed to include both newly described species related to, and species formerly included in, *Actinomyces*. For example, *A. bernardiae* and *A. pyogenes* have been moved to the genus *Arcanobacterium* (116) (see chapter 34). *Actinomyces* and related genera contain anaerobic and aerotolerant, non-acid-fast, gram-positive organisms with variable morphology, ranging from characteristic branching rods to coccobacilli. *Actinomyces* contains a rapidly increasing number of species (Table 2) that usually produce succinic acid from glucose. *Actinobaculum* currently includes *A. schaalii* and *A. urinale* from humans and the type species *A. suis* from pigs (63, 97), but the proposal of more new species in the genus is warranted (35, 58). *Varibaculum* (67) is a monophyletic genus related to *Mobiluncus* but distinct on the basis of 16S rRNA gene sequence identity. *Varibaculum cambriensis* is related to *Actinomyces neuii* but would appear to deserve consideration as a separate genus. *Mobiluncus* contains two species, *M. curtisii* and *M. mulieris,* which are strictly anaerobic, curved bacilli with variable Gram reactions and corkscrew motility. They resemble *Actinomyces* in that succinic acid is the major metabolic end product from glucose. It has been shown recently that *Falcivibrio vaginalis* and *Falcivibrio grandis* are later synonyms of *M. curtisii* and *M. mulieris,* respectively (76).

Propionibacterium species are anaerobic and aerotolerant, pleomorphic, gram-positive rods that produce propionic acid from glucose. Four *Propionibacterium* species have been isolated from human clinical infections: *P. acnes, P. avidum, P. granulosum,* and *P. propionicum*. The last species (formerly *Arachnia propionica*) exhibits some characteristics similar to *Actinomyces* species. Two related taxa, formerly members of *Propionibacterium, Propionimicrobium lymphophilum* (146) and *Propioniferax innocua* (172), can also be encountered in clinical material.

Members of the genus *Bifidobacterium* and the closely related genera *Parascardovia* and *Scardovia* are strictly anaerobic or occasionally microaerobic, gram-positive, pleomorphic rods, appearing as uniform to branched or club-shaped. Typically, bifidobacteria produce fructose-6-phosphate phosphoketolase as well as acetic and lactic acids as major metabolic end products. Bifidobacteria are aciduric and are nutritionally fastidious. There are currently 29 *Bifidobacterium* species. Of these, 10 species *(B. bifidum, B. breve, B. gallicum, B. longum, B. adolescentis, B. catenulatum, B. dentium, B. angulatum, B. pseudocatenulatum,* and *B. scardovii)* have been isolated from the human gut and oral cavity. *B. longum* now includes the former species *B. infantis* and *B. suis* (129). Two species isolated from dental plaque, *B. inopinatum* and *B. denticolens* (27), were later shown to represent novel genera on the basis of HSP60 gene sequence relatedness and were transferred to *Scardovia* and *Parascardovia,* respectively (81).

Numerous taxa have been misassigned to *Lactobacillus* in the past, including the so-called "anaerobic lactobacilli," which are now recognized to constitute two new genera, *Atopobium* and *Olsenella,* within the family *Coriobacteriaceae* (26, 30). *Atopobium* species produce lactic acid as the major glucose metabolic end product. *A. minutum* and *A. rimae* were formerly *Lactobacillus* species, and *A. parvulum* and *A. fossor* formerly belonged to the genera *Streptococcus* and *Eubacterium,* respectively (26, 87). *A. vaginae* is a novel species, originally isolated from the healthy vagina (124). The genus *Olsenella* is closely related to *Atopobium* (30) and currently includes two species: *O. uli* (formerly *Lactobacillus uli*) and *O. profusa,* both isolated from the human oral cavity.

Most *Eubacterium* species belong to the *Firmicutes,* but until recently, the genus included a number of species now

* This chapter contains information presented in chapter 55 by Bernard J. Moncla and Sharon L. Hillier in the eighth edition of this Manual.

TABLE 1 Some features of non-spore-forming anaerobic gram-positive genera

Phylum and genus	G+C mol%	Cell characteristics	Aerotolerance[a]	Gram reaction[b]	Major end product(s)[c]	Other features
Actinobacteria						
Actinobaculum	50–57	Straight/slightly curved, branching; singly/in clusters	+/−	(+)	A	Saccharolytic
Actinomyces	55–68	Variable, often branching; singly/in pairs	+/−	+	S, L	Saccharolytic
Atopobium	35–46	Short, elliptical; singly/in pairs/short chains	−/+	+	L	Saccharolytic
Bifidobacterium	57–64	Variable	−/+	+	A, L	Aciduric
Collinsella	60–61	Short; in chains	−	+	A, F, L	Saccharolytic, H_2 production
Cryptobacterium	50–51	Short	−	(+)	None	Asaccharolytic
Eggerthella	62	Coccobacilli/short rods; in pairs/short chains	−	+	(A, L, S)	Asaccharolytic
Mobiluncus	49–52	Curved with tapered ends; singly/in pairs; motile	−	v	S, L, A	Saccharolytic
Olsenella	63–64	Short, elliptical; singly/in pairs/short chains	−	+	L, A	Saccharolytic
Parascardovia	54–56	Small, slender, variable	−	+	A, L	Saccharolytic
Propionibacterium	59–67	Variable	−/+	+	P	Saccharolytic
Propionimicrobium	53–54	Variable; often diphtheroid/club-shaped	−	+	P, A, S	Saccharolytic
Scardovia	44–46	Small, coccoid, variable	−	+	A, L	Saccharolytic
Slackia	60–64	Cocci/coccobacilli/short rods; singly/in clumps	−	(+)	(A)	Asaccharolytic
Varibaculum	52	Short, straight/curved, diphtheroid	−/+	+	L, S	Saccharolytic
Firmicutes						
Anaerofustis	70	Thin rods	−	+	A, B	Saccharolytic
Anaerostipes	46	Thin rods; in short chains	−	(+)	A, B, L	Saccharolytic
Anaerotruncus	54	Thin rods	−	+	A, B	Saccharolytic
Bryantella	50	Short; in pairs/short chains	−	+	A (S, L)	Formate required
Bulleidia	38	Short, straight/slightly curved; singly/in pairs	−	+	A, L	Saccharolytic
Catenibacterium	36–38	Short; in long tangled chains	−	+	A, B, L	Saccharolytic
Dorea	40–46	Short/long; in pairs/in chains	−	+	A, F	Saccharolytic, H_2 production
Eubacterium	30–57	Variable	−	v	B, A, L (F)	Saccharolytic
Faecalibacterium	47–57	Pleomorphic rods	−	−	B, F, L	Saccharolytic
Filifactor	34	Short, regular	−	−	B	Asaccharolytic
Holdemania	38	Short; in pairs/short chains	−	(+)	A, L	Saccharolytic
Lactobacillus	35–53	Short/long, slender; in chains	−/+	+	L	Aciduric
Mogibacterium	41–50	Short; singly/in clumps	−	(+)	PAA	Asaccharolytic
Oribacterium	42	Elongated, ovoid; singly/in pairs; highly motile	−	−	A, L	Saccharolytic
Pseudoramibacter	61	Pleomorphic; in pairs	−	+	A, B, C, F	Saccharolytic
Roseburia	29–42	Thin, pleomorphic rods	−	v	B, L	Saccharolytic, H_2 production
Shuttleworthia	50–51	Short/slightly curved; singly/in pairs/short chains	−	+	B, A (L)	Saccharolytic
Solobacterium	37–39	Short, straight/slightly curved; singly/in pairs	−	+	A, L	Saccharolytic
Turicibacter	37	Irregular, long; in long chains	−	+	L	Saccharolytic

[a] +/− or −/+, variable aerotolerance within the genus; −, the genus contains only strictly anaerobic species.
[b] +, positive; −, negative; v, variable; (+), decolorization in old culture.
[c] A, acetic acid; B, butyric acid; C, caproic acid; F, formic acid; L, lactic acid; P, propionic acid; S, succinic acid; PAA, phenylacetic acid; parentheses, strain variation.

shown to belong to the *Actinobacteria,* such as the former *E. lentum,* now renamed *Eggerthella lenta* (162); *E. aerofaciens*, now *Collinsella aerofaciens* (88); and *E. exiguum,* now *Slackia exigua* (162). *E. lenta* and *C. aerofaciens* are numerically important bacteria in the human intestinal tract (88, 162), whereas *S. exigua* is strongly associated with oral infections (162). Recently, two new *Eggerthella* species, *E. hongkongensis* and *E. sinensis,* have been proposed (96). A novel species found in oral infections, *Cryptobacterium curtum* (108), is related to this group.

Phylum *Firmicutes*

Lactobacillus, a large and heterogeneous genus, contains microaerobic, catalase-negative, non-spore-forming gram-positive rods, which produce lactic acid as their single or major metabolic end product from glucose fermentation. Members of *Lactobacillus* sensu stricto constitute a branch of the *Firmicutes* subdivided into seven groups: *L. buchneri, L. casei, L. delbrueckii, L. plantarum, L. reuteri, L. sakei,* and *L. salivarius* (69). *Catenibacterium mitsuokai* (84), isolated from human feces, forms a cluster with *L. vitulinus* and *L. catenaformis,* two misclassified *Lactobacillus* species.

Organisms assigned to *Eubacterium* are defined by default; they do not produce propionic acid as a major acid product, lactic acid as the sole major acid product, succinic and lactic acids with small amounts of acetic or formic acids, or acetic and lactic (acetic > lactic) acids, with or without formic acid, as the sole major acid products (103). It has

TABLE 2 Recently classified or reclassified genera and species (from 2002 onwards) of non-spore-forming anaerobic gram-positive rods isolated from humans

Turicibacter	Yes	*T. sanguinis*	New sp.	6

been proposed that *Eubacterium* sensu stricto should be restricted to *E. limosum, E. callanderi,* and *E. barkeri* (165). The remaining *Eubacterium* species would therefore require reclassification. Clinically important *Eubacterium* species are widely distributed among the *Firmicutes*. *E. alactolyticum*, a saccharolytic species found in the oral cavity of humans, and a close phylogenetic relative of the strictly defined genus *Eubacterium,* has been moved to a new genus as *Pseudoramibacter alactolyticus* (165). *E. biforme, E. cylindroids,* and *E. dolichum* fall within the family *Erysipelotrichaceae* with the recently described saccharolytic species, *Bulleidia extructa*, isolated from the human mouth (34), and *Holdemania filiformis* (166) and *Solobacterium moorei* (86), isolated from human feces. *E. brachy, E. infirmum, E. minutum, E. nodatum, E. saphenum,* and *E. sulci* (formerly *Fusobacterium sulci*), together with *Mogibacterium*, a genus of five species indistinguishable by phenotypic tests (109, 110), are a group of asaccharolytic taxa isolated from the human mouth. On the basis of the 16S rRNA phylogeny and their phenotypic characteristics, novel genera should be created for the majority of these species, with the exception of the pairs of species *E. minutum* and *E. nodatum* and *E. sulci* and *E. infirmum*, which are closely related. Many *Eubacterium* species are closely related to clostridia. Spore formation has long been the primary criterion for assignation of gram-positive anaerobic rods to *Clostridium,* but phylogenetic analysis indicates that the taxonomic importance of this characteristic may have been overemphasized. Numerous phylogenetic clusters contain both sporing and nonsporing representatives. *E. budayi, E. moniliforme,* and *E. nitritogenes* are found in clostridial Cluster 1 (25), while *E. siraeum* belongs to a clostridial group that includes *Clostridium leptum* and the recently described *Anaerotruncus colihominis* (99). *E. tenue* and *E. yurii* belong to the clostridial Cluster XI described by Collins et al. (25). *E. tenue* is related to *Clostridium ghonii* and *Clostridium sordellii;* further work is required to determine whether these species constitute a novel genus. *E. yurii* is related to the genus *Filifactor,* which includes *F. alocis* (formerly *Fusobacterium alocis*) isolated from oral infections in humans (80). *E. contortum, E. eligens, E. hadrum, E. hallii, E. ramulus, E. rectale, E. saburreum,* and *E. ventriosum* belong to the family *Lachnospiraceae*. *E. rectale* and *E. ramulus* are related to *Roseburia intestinalis* (36). This family also includes the recently described formate-requiring species *Bryantella formatexigens* (168), isolated from human feces without any disease association so far, and *Oribacterium sinus* (17), a highly motile species isolated from pus of a human sinus. *E. eligens* and *Lachnospira pectinoschiza* are close phylogenetic neighbors and are both motile rods whose growth in broth culture is stimulated by the presence of

fermentable carbohydrate. *E. eligens* should be transferred to the genus *Lachnospira*. *Anaerostipes caccae* (140) forms a loose group with *E. hallii* and *Coprococcus eutactus*, all common species in human feces.

Turicibacter sanguinis (6) is a recently described gram-positive anaerobic rod from human blood, belonging to the phylum *Firmicutes* but which, on the basis of 16S rRNA sequence comparisons, appears to represent a novel lineage within this phylum. Further work is required to clarify the taxonomic position of this genus. Similarly, *Anaerofustis stercorihominis* (48), isolated from human feces, is another deep-branching gram-positive anaerobic rod within *Firmicutes*.

EPIDEMIOLOGY AND TRANSMISSION

Many of the organisms described in this chapter are integral components of the commensal microbiota associated with the mucocutaneous surfaces of the human and animal digestive tract, being found in the mouth, small and large intestines, urogenital tract, and skin (1, 2, 117, 118, 127, 160). Microbial colonization of an individual occurs in a successive manner during the first weeks and months of life. *Actinomyces* are among the first colonizers in the mouth (134), whereas bifidobacteria and *Collinsella* have been suggested to play a significant role in the development of the gut microbiota (70). *Eubacterium rectale, Faecalibacterium prausnitzii,* and lactobacilli are also among the dominant members of the intestinal microbiota (1, 37, 149). In contrast to previous culture-based reports indicating *L. acidophilus* to be the predominant *Lactobacillus* species in the female genital tract, molecular techniques have revealed significant numbers of *L. crispatus, L. gasseri, L. iners, L. jensenii,* and *L. vaginalis* (2, 145, 160, 161, 164). These species, except for *L. iners,* are responsible for hydrogen peroxide (H_2O_2) production, which may help to control the overgrowth of bacterial vaginosis-associated organisms (2).

CLINICAL SIGNIFICANCE

Non-spore-forming anaerobic gram-positive rods seldom cause infections alone but are typically found in polymicrobial infections associated with mucosal surfaces (Table 3). Many anaerobes involved in infections of the head and neck originate from the oral cavity, and most vaginal and bladder pathogens are of fecal origin. In intra-abdominal infections due to organ perforation, the predominant recoveries reflect the microbiota at the site of the leakage (163). For surgical patients, anaerobes remain a significant cause of morbidity and mortality (39). Anaerobic bacteria can occasionally spread to adjacent tissues and even the bloodstream with serious consequences. In anaerobic bacteremias, the gastrointestinal tract is the most common source, followed by abscesses, gynecologic infections, and wound infections (131). Anaerobic blood culture methods tend to be targeted at *Clostridium* species and *Bacteroides fragilis,* which are aerotolerant and relatively fast growing and do not have complex nutritional requirements.

Actinomyces and Related Bacteria

Actinomyces and related bacteria have been isolated with increased frequency, as contaminants or etiologic agents, from clinical specimens representing a wide range of infections (Table 3). *Actinomyces* and related species occur typically in polymicrobial infections together with anaerobic and/or capnophilic, gram-negative species (23, 102, 128, 136). These include several types of oral infection, such as dental caries, endodontic infections, odontogenic abscesses, and dental implant-associated infections (4, 8, 24, 64, 66, 133, 136, 142). Traditionally, *A. israelii* has been thought to be the etiologic agent of classical actinomycosis but *A. gerencseriae,* which is very similar to *A. israelii, A. graevenitzii,* and *A. meyeri,* has also been isolated from actinomycotic lesions (23, 102, 136, 154). Several recognized *Actinomyces* species, especially *A. israelii* and *A. turicensis* but also *A. naeslundii, A. odontolyticus, A. gerencseriae, A. cardiffensis,* and a novel, closely related species, *V. cambriensis,* have been isolated from intrauterine device-associated infections in the female genital tract (50, 62, 67, 68). In addition, *A. naeslundii* and *A. israelii* have been isolated from infectious hip prostheses (148, 171). *A. turicensis,* in particular, seems to dominate in both female and male genital and urinary tract infections (128). *A. funkei, A. naeslundii, A. odontolyticus,* and *A. turicensis* as well as two *Actinobaculum* species, *A. schaalii* and *A. urinale,* have been isolated from blood (46, 68, 97, 98, 115, 122). Taken together, *A. turicensis, A. radingae, A. israelii,* and *A. naeslundii* seem to be the most frequent *Actinomyces* findings in clinical specimens, present in polymicrobial infections or, occasionally, alone (23, 51, 68, 128).

Propionibacterium

Propionibacteria can be found in various systemic or disseminated opportunistic infections (Table 3), such as endocarditis, central nervous system infections, osteomyelitis, osteitis, and arthritis (11, 29, 43, 51, 79), and in about 20% of infected dog and cat bite wounds (151). When *P. acnes* is isolated from blood, it is mainly seen as a causative agent of clinically insignificant bacteremia (11, 95, 131) or as a contaminant from the skin. Typically, *P. acnes* is isolated from sebaceous follicles and lesions of acne vulgaris (51). However, the pathogenic potential of *P. acnes* should not be underestimated when there are predisposing factors present, such as a foreign body, surgery or trauma, diabetes, or immunosuppression (11, 59, 79, 157). *P. acnes* has been connected with some, often severe, late postsurgical infections after implantation of a foreign body, e.g., intraocular lenses, prosthetic heart valves, ventriculoperitoneal shunts, and posterior implants for scoliosis patients (11, 22, 60, 79, 95, 131, 157). It can be a causal agent in infective endocarditis with a predilection for prosthetic valves and foreign bodies (59, 157). The suggested association of *P. acnes* with SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteomyelitis) syndrome with arthritis is based on its repeated growth in pure cultures from bone specimens (91). *P. acnes* and *P. granulosum* have been recently linked as possible etiologic agents to sarcoidosis (42), in which host factors play an important role. In contrast to *P. acnes* and other propionibacteria, the spectrum of infections with involvement of *P. propionicum* is somewhat similar to that of *Actinomyces;* for example, *P. propionicum* has been isolated from actinomycosis-like eye infections (9) and endodontic infections (18, 142).

Lactobacillus

Despite the reputation of lactobacilli as beneficial organisms, they can be involved in serious infections (Table 3), especially in immunocompromised individuals (10, 12, 16, 45, 89, 111, 130). The most common *Lactobacillus* species isolated from various human infections are *L. rhamnosus, L. casei, L. fermentum, L. gasseri, L. plantarum, L. acidophilus,* and *L. ultunensis* (15, 16, 130). The most frequent infections caused by lactobacilli are bacteremia and endocarditis, which carry a relatively high mortality rate (16). Detection of lactobacilli, alone or with other microorganisms, in blood cultures of patients with underlying diseases may be clinically

TABLE 3 Genera of non-spore-forming anaerobic gram-positive rods detected in human infections

Site/disease association	Genera isolated
Brain and/or central nervous system	*Actinomyces, Eubacterium, Propionibacterium, Pseudoramibacter, Varibaculum*
Eye infections	*Actinomyces, Propionibacterium, Varibaculum*
Mouth	
Abscesses	*Actinomyces, Atopobium, Eubacterium, Filifactor, Mogibacterium, Olsenella, Pseudoramibacter, Slackia, Varibaculum*
Dental caries	*Actinomyces, Bifidobacterium, Lactobacillus, Olsenella, Propionibacterium*
Endodontic infection	*Actinomyces, Atopobium, Bifidobacterium, Eubacterium, Filifactor, Mogibacterium, Lactobacillus, Olsenella, Propionibacterium, Pseudoramibacter, Slackia*
Periodontal diseases	*Cryptobacterium, Eubacterium, Filifactor, Mogibacterium, Olsenella, Pseudoramibacter, Slackia*
Respiratory tract infections	*Actinomyces, Eubacterium, Lactobacillus, Oribacterium*
Abdomen/intestine	
Abscesses	*Actinomyces, Eggerthella, Eubacterium, Lactobacillus*
Appendicitis	*Actinomyces, Eggerthella*
Cholecystitis	*Actinomyces, Lactobacillus*
Peritonitis	*Eggerthella, Lactobacillus*
Genital tract	
Abscesses	*Actinomyces, Atopobium, Eubacterium*
Bacterial vaginosis	*Atopobium, Mobiluncus*
Intrauterine device infections	*Actinomyces, Eubacterium, Varibaculum*
Pelvic inflammatory disease	*Actinomyces, Atopobium, Eubacterium, Lactobacillus*
Preterm labor/delivery	*Mobiluncus*
Urinary tract infections	*Actinobaculum, Actinomyces*
Skin and/or soft tissue	
Abscesses	*Actinobaculum, Actinomyces*
Acne vulgaris	*Propionibacterium*
Cellulitis	*Actinomyces, Pseudoramibacter*
Necrotizing soft tissue infections	*Actinomyces, Eubacterium, Mogibacterium*
Lymphadenitis	*Propionibacterium, Propionimicrobium*
Bone and joint infections	*Actinomyces, Propionibacterium*
Wounds	
Bite wound infections (animal)	*Filifactor, Propionibacterium*
Bite wound infections (human)	*Actinomyces, Collinsella, Eggerthella, Eubacterium, Mogibacterium, Lactobacillus, Propionibacterium*
Postoperative wound infections	*Bifidobacterium, Propionibacterium, Pseudoramibacter*
Diabetic foot infections	*Actinomyces, Propionibacterium*
Cardiovascular sites	
Bacteremia	*Actinobaculum, Actinomyces, Atopobium, Eggerthella, Eubacterium, Lactobacillus, Olsenella, Propionibacterium*
Endocarditis	*Actinomyces, Lactobacillus, Propionibacterium*
Infected atheroma	*Actinomyces*
Foreign body infections	*Actinomyces, Mogibacterium, Propionibacterium*

significant. *L. rhamnosus* was the most frequent species in *Lactobacillus* bacteremia (16, 45, 95, 130). *L. rhamnosus* GG, a common probiotic strain, has been occasionally detected in clinical specimens (93, 101, 120, 130). In two pediatric patients with sepsis, the *Lactobacillus* strain from blood samples was indistinguishable from the probiotic strain ingested (93), suggesting that further work needs to be done. Vancomycin-resistant lactobacilli have been connected to dialysis-related peritonitis after extended use of glycopeptides (89, 111). In contrast to other *Lactobacillus* species, *L. iners* has been associated with an intermediate state of bacterial vaginosis (161). In the oral cavity, lactobacilli form a considerable part of the species present in advanced caries lesions (19), with *L. gasseri* and *L. ultunensis* numerically dominant (15). Interestingly, a dental procedure or condition can be a potential predisposing factor for *Lactobacillus* endocarditis (16).

Eubacterium and Related Bacteria

Low G+C organisms representing the former genus *Eubacterium* are often detected in various oral infections (Table 3). Careful isolation of tiny-colony-forming anaerobes from periodontal pockets in adult patients with advanced periodontitis showed that former *Eubacterium* strains (mostly asaccharolytic) dominated (155), thus suggesting their role in the etiology of chronic periodontitis. Downes et al. (33) characterized *Eubacterium*-like strains from oral infections and found *Mogibacterium timidum* to be among the most frequently detected species. *Mogibacterium vescum, Bulleidia extructa, Filifactor alocis,* and *Pseudoramibacter alactolyticus*

were also found among the isolates from severe (some of them requiring treatment in intensive care units) odontogenic infections. Less frequently isolated were *E. sulci*, *E. saburreum*, and *E. yurii* (33). Many species found in odontogenic infections are also common in endodontic infections (71, 107, 109, 141, 143). *F. alocis, E. nodatum, E. saphenum,* and *M. timidum* have been associated with periodontal diseases (5, 92, 117). Due to their presence in the oral cavity, various *Eubacterium* and related species are among the anaerobic findings in human bite wound infections (150). *Filifactor villosus,* a species of animal origin, has been isolated from infected cat bite wounds in humans (151). *E. nodatum* has been found in infections of the female genital tract (73). *E. tenue* and *E. callanderi,* an environmental anaerobe, have been detected in clinically significant bacteremia (95, 153).

Eggerthella and Related Bacteria

Of the four high G+C content genera previously classified as *Eubacterium, Eggerthella* has been shown to possess particular pathogenic potential (Table 3). *E. lenta* has been isolated from a wide range of clinical specimens, mainly from intra-abdominal sites (10, 12, 104, 121). *E. lenta* and two recently described *Eggerthella* species, *E. hongkongensis* and *E. sinensis,* have been found in blood in association with clinically significant infections of relatively high mortality (95, 96). *Cryptobacterium curtum* and *Slackia exigua* have been associated with chronic periodontitis (5, 92), and the latter has also been associated with endodontic infections (71).

Atopobium

The genus *Atopobium* can be isolated from various infections (Table 3) and includes several clinically relevant species. Although *A. vaginae* was first isolated from the healthy vagina (124), it has been increasingly reported to be involved in infections of the genital tract, especially bacterial vaginosis (14, 47, 52, 161). *A. minutum* has been isolated from various infections of the lower part of the body, and *A. parvulum* has been isolated from respiratory specimens (113). In the oral cavity, *A. parvulum* and *A. rimae* have been detected in periodontal pockets (113, 117); however, in another study, these species have been shown to be more prevalent in healthy individuals than in periodontitis patients (92). Among *Eubacterium*-like isolates from severe odontogenic infections, *A. rimae* proved to be the most frequent finding (33). An *Atopobium* species of animal origin, *A. fossor,* has been isolated as one of the most frequent species from horses with pneumonia and lung abscesses (119).

Olsenella

Olsenella species show disease associations similar to those observed for lactobacilli in the oral cavity, *O. profusa* being detected in advanced dental caries lesions (106), and *O. uli,* in particular, in endodontic infections (18, 107, 123). Both species can also be found in subgingival sites of periodontitis patients (30, 113). In addition, *O. uli* has been reported as one of the causative organisms in clinically significant bacteremia (95).

Bifidobacterium and Related Bacteria

Bifidobacteria, one of the dominant bacterial groups in the human intestinal tract (70), are generally considered nonpathogenic but appear in some infectious lesions (Table 3). Dental caries is the most common clinical entity where *Bifidobacterium,* mainly *B. dentium,* and related species *P. denticolens* and *S. inopinata* may have a pathogenic role (4, 19, 27, 81). Some *Bifidobacterium* species, such as *B. adolescentis* and *B. dentium*, are occasionally isolated from other infections, mainly in immunocompromised individuals (10, 12). In addition, a novel *Bifidobacterium* species, *B. scardovii,* has been isolated from human clinical samples, including blood, urine, and the hip (77).

Mobiluncus

The presence of vibrio-like *Mobiluncus* species in smears of vaginal fluid has been widely used as one of the indicators of bacterial vaginosis, the most common infection in the female genital tract (112). Of the two *Mobiluncus* species, *M. curtisii* seldom occurs in the vaginas of healthy women but, instead, is highly associated with bacterial vaginosis and its treatment failure due to the persistence of the organism (138). The disturbed composition of the vaginal microbiota can be a risk for adverse pregnancy outcome when ascending to the upper genital tract (75). In addition to bacterial vaginosis, *M. curtisii* has been occasionally isolated from endometrial smears and pus specimens of the female genital tract (3) and some extragenital infections (40, 57).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Careful specimen collection, avoidance of contamination with the commensal microbiota where necessary, and anaerobic transport techniques are essential for the successful recovery of clinically significant anaerobic bacteria (see chapters 5 and 20). Specimens suitable for the isolation of non-spore-forming, gram-positive anaerobic rods present as organisms of etiologic importance include aseptically collected peripheral blood, tissue biopsy specimens, aspirates (e.g., cerebrospinal fluid, joint fluids, and pus), root canal exudates, and subgingival plaque. Mucosal or cutaneous swabs are not recommended (53). A comprehensive description of different specimen collection and transport methods for anaerobic bacteriology can be found elsewhere (83).

DIRECT EXAMINATION

Direct examination is of unequivocal value for the diagnosis of actinomycosis. The presence of "sulfur granules" in pus, which when crushed, Gram stained, and viewed under the microscope reveal a mass of gram-positive branching filaments, is characteristic of this disease. Similarly, in cervical smears of women with an intrauterine contraceptive device, the presence of branching gram-positive organisms suggests an infection with *Actinomyces* (50, 128). Gram stains of vaginal smears have been considered more useful than culture for laboratory confirmation of bacterial vaginosis, and the diagnostic criteria for this common infection have been based on the standardized Nugent scoring system (112). The system relies on Gram stain characteristics of vaginal smears, recognizing individual morphotypes or their combination. Although intercenter reliability for gram-positive cocci was poor, the study documented moderate agreement for large gram-positive rods (lactobacilli) and small gram-variable and/or gram-negative rods (*Gardnerella vaginalis* and *Bacteroides/Prevotella),* and good agreement for curved gram-variable rods *(Mobiluncus)* (112). A simplified assessment of Gram-stained smears, taking lactobacillary and mixed bacterial morphotypes into account, has been proposed (78). It has been noted that the image area observed in microscopes requires standardization, in particular, when interpreting the intermediate state of bacterial vaginosis (94). Subsequently,

a strong association between *A. vaginae* and an abnormal vaginal state has been established (47, 161). This gram-positive, variably shaped, often coccoid species may confuse scoring systems relying on the Gram stain.

In cases where there is no typical microbiota associated with a particular infection, it can be difficult to make a preliminary decision regarding appropriate empiric antimicrobial treatment on the basis of the Gram stain. For example, branching/pleomorphic rods can be tentatively identified as facultatively anaerobic *Actinomyces* or strictly anaerobic *E. nodatum* (73), and coccoid cells of *A. radicidentis* may suggest a genus other than *Actinomyces* (24), while easily decolorizing species (e.g., *Eubacterium*-like species) can yield a false gram-negative reaction (33). The misinterpretation can lead to antimicrobial coverage targeted against facultative organisms instead of anaerobes and/or gram-negative bacteria.

CULTURE AND ISOLATION

Specimens should be processed without delay using appropriate culture media, including standard anaerobic blood agar enriched with hemin and vitamin K_1 and a variety of selective media based on the expected microbiota at the collection site, or in the case of bite wounds, on the oral microbiota of the attacker (human or animal). Fresh or prereduced culture media, including phenyl ethyl alcohol blood agar and/or colistin nalidixic acid blood agar, can be useful for enhanced recovery rates of gram-positive organisms (20). Many asaccharolytic species exhibit enhanced growth on solid media augmented with 0.5% arginine (156). In general, members of the aciduric genera *Bifidobacterium* and *Lactobacillus* can be selectively cultured using agar media with an acidic pH, such as Rogosa or deMan Rogosa Sharpe (MRS) agar. However, some nutritionally fastidious *Lactobacillus* strains fail to grow on these agar media. Munson et al. (106) observed that lactobacilli grew as well on nonselective media with neutral pH and suggested that acidic-pH medium is not required for their detection. Notably, *L. iners*, one of the predominant lactobacilli in the vagina, can grow only on blood agar and not on typical solid media used for *Lactobacillus* (44).

Similar species among facultatively anaerobic *Actinomyces, A. gerencseriae* and *A. israelii,* can be isolated preferably from aerobically *(A. gerencseriae)* or anaerobically *(A. israelii)* incubated plates (8). On the other hand, to maintain bacterial viability, processing the samples and performing all the steps throughout the protocol in an anaerobic chamber favor the growth of some fastidious anaerobes, e.g., *Eubacterium*-like species (31). An anaerobic atmosphere-generating system has been shown to be superior to an anaerobic chamber in culturing *Eubacterium*-like strains from stock (28). When anaerobic jars are used for incubation, anaerobic growth should not be exposed to oxygen by opening the jar before 48 h of incubation in order to facilitate the detection of fastidious organisms (20). The availability of an anaerobic chamber may enable examination of the culture whenever necessary. For reliable detection of slow-growing organisms, the incubation time should be sufficient; for instance, an extended incubation period may be needed for some clinically relevant *Eubacterium*-like species (33, 73, 108–110, 153). In heart tissue specimens from endocarditis patients, grinding the tissue can improve the detection of anaerobic bacteria (59, 79). A lytic anaerobic medium can increase the recovery rate of anaerobes and facultative bacteria in automated blood culture systems (125).

IDENTIFICATION PROCEDURES

Traditionally, the identification of bacterial isolates in clinical microbiology laboratories is performed by phenotypic tests. For organisms inert in most conventional biochemical tests or with unusual biochemical profiles, as is the case for many *Eubacterium* and related species, or in cases where fastidious organisms require specific nutrients or temperatures, identification strategies based on phenotypic characteristics can be challenging.

Presumptive Identification

The initial differentiation is based on aerotolerance (growth in air or in air plus 5% CO_2), colonial morphology, pigmentation, fluorescence under long-wave UV illumination, and presence of hemolysis. The colonial morphology can provide clues regarding the organism involved; for instance, an easily recognizable "molar tooth" appearance is typical for *A. israelii* but, notably, also for *E. nodatum* (73). Sometimes a species has various colonial morphologies, as is the case for *Shuttleworthia satelles,* with three separate colony types; the last two types (satellite and opaque) appear after incubation for 5 days (32). Other rapidly recognizable features are fluorescence and/or pigment production: *E. lenta* shows orange to red fluorescence under UV light (104), and pigmentation of colonies is typical for *A. odontolyticus,* but *A. graevenitzii* and some other *Actinomyces* species can also produce pigment (68, 135).

Gram stain morphology can be helpful; it can show whether organisms are gram-positive anaerobic rods, which can be very short (e.g., *C. curtum* and *E. lenta*), long (e.g., many *Lactobacillus* species), pleomorphic (e.g., *Bifidobacterium*), branching (e.g., many *Actinomyces* spp.), or curved and motile (e.g., *Mobiluncus* spp.); sometimes a specific cell morphology can be seen, such as "flying birds" (e.g., *P. alactolyticus*). The morphology may vary when cells are grown on different culture media. The two *Mobiluncus* species can be tentatively separated based on the length of the curved, motile cells: in contrast to the short, gram-variable cells of *M. curtisii, M. mulieris* reveals clearly longer cells, which often appear as gram negative (139). Although *Actinomyces* organisms have been traditionally described as branching rods, many new species within the genus are nonbranching, and some have very short or even coccoid cells (24, 158). Staining of cells can vary with different culture conditions. Certain gram-positive anaerobes, e.g., *F. alocis* and *M. mulieris*, routinely stain gram negative, whereas older cultures (>3 days) of *Actinobaculum* and some *Eubacterium* species and related genera are gram variable (97, 108, 110). Decolorization of gram-positive organisms may be due to exposure to oxygen or to damage from fixatives and reagents causing a breakdown of the physical integrity of the cell wall; therefore, anaerobic working conditions or, if not available, limited exposure time to oxygen between incubation and staining improves the reliability of the Gram stain for anaerobic bacteria (82). Routine screening of special-potency antibiotic susceptibility disk patterns is valuable to confirm the accuracy of the Gram stain reaction (83): gram-positive species are generally resistant to colistin (10 μg) and susceptible to vancomycin (5 μg) and often to kanamycin (1 mg). However, the intrinsic resistance of some *Lactobacillus* species/strains, e.g., *L. rhamnosus,* to glycopeptides should be considered (16, 45, 89, 111), in addition to intrinsic resistance of *Bifidobacterium* to aminoglycosides (105). *Holdemania filiformis* has been reported to be resistant to vancomycin (34). For rapid confirmation of the Gram reaction, a simple test based on dissolution of gram-negative cell wall and cytoplasmic membrane with a solution of 3% potassium hydroxide

(61) can be used: when suspended in the solution, gram-negative cells display increased viscosity and stringing within 30 s, whereas the absence of stringing, i.e., a negative reaction, suggests that the isolate is gram positive.

Additional rapid tests for initial grouping of non-spore-forming gram-positive anaerobes include testing for production of catalase (H_2O_2 at a concentration of 15%) and indole, nitrate reduction, and motility (20). If presumptive identification to the genus level has been made correctly, this may give valuable information to clinicians in deciding the initial treatment. However, differentiating members of the "normal flora" of human skin and mucous membranes from pathogenic non-spore-forming gram-positive rods can be difficult. Identification of nonsporing gram-positive rods to the species level should be performed whenever they are present in pure cultures in clinical specimens or as the predominant organism from normally sterile sites; otherwise, the potential pathogenicity of these less often suspected species may remain undetected.

Biochemical Testing

For a more advanced phenotypic classification of anaerobic organisms and distinguishing individual species, sugar fermentation reactions, preferably using prereduced, anaerobically sterilized carbohydrates, and enzyme profiles with individual diagnostic tablets, fluorogenic substrate tests, or preformed enzyme kits must be determined. Insufficient growth or poor reproducibility of reactions can cause difficulties in interpretation of results obtained with biochemical tests; therefore, young cultures and heavy inoculum should be used (135). A well-designed selection of key tests provides a tentative identification of various isolates to the species level prior to confirming their identifications by more definitive methods. Table 4 presents some biochemical characteristics of *Actinomyces* and related organisms. Since the description of many novel species, such as *A. dentalis, A. hongkongensis, A. nasicola, A. oricola, A. urinale,* and "*A. massiliae,*" is based on a single strain (58, 63–66, 169), discrepancies in test reactions may appear. Table 5 presents simple enzymatic reactions useful in distinguishing propionibacteria encountered in human infections, and Table 6 shows tests for *Atopobium* and *Olsenella* species. Although the cultivation and identification of *Eubacterium*-like species are very laborious, not only because of their oxygen sensitivity and slow growth but also due to their nonreactivity in conventional biochemical testing, some simple reactions may be helpful for grouping these organisms (Table 7).

In culture-based identification of anaerobic non-spore-forming gram-positive rods, the determination of major volatile fatty acid end products of glucose metabolism, as detected by gas chromatography, is a prerequisite, even for the genus level (Table 1). Typically, *Actinomyces* strains produce succinic and lactic acids as their major metabolic end products but *A. dentalis* seems to lack this characteristic succinic acid (66). An *Actinomyces*-like *Propionibacterium* species, *P. propionicum,* is easily separated from *Actinomyces* based on its production of propionic acid (51). For microaerobic *Lactobacillus* spp., defining characteristics are their ability to grow in acid media and ferment carbohydrates to produce lactic acid as the major end product with or without small amounts of acetate, whereas in the case of *Bifidobacterium* spp. the production of acetic acid dominates that of lactic acid. Downes et al. (33) successfully used the determination of metabolic end products by gas chromatography together with sugar fermentation by prereduced, anaerobically sterilized carbohydrates and enzyme profiles generated by a commercial identification kit (API Rapid ID 32A; bioMérieux, Marcy-l'Etoile, France) for identification of *Eubacterium*-like isolates to the genus and species level; for instance, the lack of enzyme activity and formation of caproic acid or phenylacetic acid distinguish *P. alactolyticus* or *Mogibacterium* spp., respectively, from other related taxa. However, phenotypic criteria are particularly unreliable for identification of many *Actinomyces* species (68) and members of the *L. acidophilus* complex and related species (159). In addition, gas chromatographic analysis of cellular fatty acids and examination of protein patterns by polyacrylamide gel electrophoresis have been used taxonomically to distinguish among strains within a species and among organisms within a genus or family. However, the availability of gas chromatography methods is often restricted to reference laboratories. The precise identification to the species level of heterogeneous groups within non-spore-forming gram-positive bacteria can be difficult, even when using the determination of volatile fatty acids by gas chromatography and biochemical profile analyses because biochemical tests do not accurately reflect genotypic groups (33, 45, 68, 145).

Preformed enzyme and carbohydrate fermentation profiles can be obtained using commercially available identification test kits, such as the API (bioMérieux), RapID (Remel, Lenexa, Kans.), and BBL Crystal (Becton Dickinson Diagnostic Systems, Sparks, Md.) systems, according to manufacturers' instructions. Although this approach is often hindered by similarities in fermentation profiles of separate species within a genus, kits serve as a widely used adjunct to anaerobe diagnostics in most hospital laboratories (53), since they are easy to use and much faster than conventional anaerobic procedures. The main problems with these kits are their incomplete or inaccurate databases (7, 132). The databases of the API Coryne (bioMérieux) and RapID CB Plus (Remel) tests, designed for coryneform bacteria, currently include some aerotolerant *Actinomyces* and *Propionibacterium* species as well. Notably, different test kits and individual tests differ in their substrate specificities so that an indicated reaction can vary depending on the system used (23, 132, 135). For example, one key reaction for *A. naeslundii,* urease production, can remain negative with one test, and thus the strain can be misidentified as *A. israelii,* while another test yields a correctly positive reaction (132, 171). Isolates of a novel *Atopobium* species, *A. vaginae,* have been misidentified as *Gemella morbillorum* by the API Rapid ID 32A (bioMérieux) and RapID ANA II (Remel) test kits (47, 52). In contrast, a clinically relevant *Bifidobacterium* species, *B. scardovii,* was readily separated from other bifidobacteria by using the Rapid ID 32A kit (bioMérieux) (77). The carbohydrate fermentation test kit API 50 CH (bioMérieux), which is specifically designed for lactobacilli, can be valuable in identification to the genus level but fail at the species level (7). Despite the lack of reliability of species level identifications, commercial test kits can be useful for the detection of positive reactions and identification of many organisms from clinical sources to the genus level. Clinical microbiologists should be aware of the possibility of erroneous identification and adjust the interpretation of their results accordingly, in conjunction with cellular and colonial morphology and other information available. Indeed, practical, discriminatory, and cost-effective methods are needed for identification of fastidious gram-positive bacteria. Molecular identification offers an opportunity for the description of new bacterial species encountered in clinical microbiology laboratories, and commercial 16S rRNA gene sequence-based identification kits are coming into the market (170).

Identification by DNA Sequence Analysis

As mentioned above, the use of conventional and biochemical tests for the identification of this group carries a significant risk of misidentification. Far more precise identifications can be obtained by 16S rRNA gene sequence analysis (90). A major advantage is that methods do not need to be adapted for different groups of organisms; thus, there are no special considerations needed when analyzing gram-positive nonspore-forming anaerobes.

A major impetus to the study of unculturable bacteria has been the development of 16S rRNA/PCR amplification/cloning/sequencing methodology (167). The phylum *Firmicutes,* in particular, has been found to harbor a number of lineages without culturable representatives. For example, branches within the families *Eubacteriaceae* and *Lachnospiraceae* have been found in advanced carious lesions, endodontic infections, and subgingival plaque in periodontitis (19, 107, 117). Similarly, the colonic microbiota includes novel branches within the *Clostridiaceae* and *Erysipelotrichaceae* (149). Culture-independent analysis of the microbiota in bacterial vaginosis identified a novel taxon related to *A. vaginae* (161), and novel taxa belonging to both the *Actinobacteria* and *Firmicutes* were found in a corneal ulcer (137).

SEROLOGICAL TESTS

Serological tests are of little diagnostic value for this group of organisms, which are found almost exclusively in polymicrobial infections. Furthermore, infections are frequently opportunistic in nature, with the causative organism being a member of the commensal microbiota, rendering serological tests difficult to interpret.

ANTIMICROBIAL SUSCEPTIBILITIES

In the clinical setting, empirical information is used for the initial diagnosis of infection and choice of antimicrobial therapy, while awaiting culture and susceptibility test results. Published data regarding antimicrobial susceptibilities of nonsporing gram-positive anaerobes may be difficult to interpret. Changes in the bacterial taxonomy, e.g., among the former *Eubacterium* genus, and more precise classification of tested isolates may result in antimicrobial resistance patterns different from those given in previously published surveys (144). In general, penicillin and other β-lactams exhibit activity against gram-positive bacteria together with parenteral carbapenems, such as imipenem, ertapenem, and meropenem (13, 41, 54, 55, 74, 100, 105, 144). Metronidazole has been considered a drug of choice for treatment of anaerobic infections; however, resistant strains are common among non-spore-forming gram-positive genera with facultative/microaerobic strains, i.e., *Propionibacterium*, *Actinomyces*, *Bifidobacterium*, and *Lactobacillus*, but also among the strictly anaerobic genera *Atopobium* and *Mobiluncus* (3, 47). In addition, some strains of *Eggerthella* and *Eubacterium* resistant to metronidazole have been reported (21, 74, 100). Failures or relapses are common in the treatment of bacterial vaginosis, but whether metronidazole-resistant *A. vaginae* or *M. curtisii* (3, 47, 52) could play a role is not known. Occasional strains among various genera of non-spore-forming gram-positive anaerobic rods show

[a] Biochemical data compiled from references 32, 33, 73, 83–85, 96, 108, 109, 165, and 166. Symbols and abbreviations: +, positive reaction; −, negative reaction; v, variable reaction; ND, no data; β-Gal, β-galactosidase; β-Glu, β-glucosidase; β-NAG, β-*N*-acetyl-glucosaminidase.

resistance to clindamycin (13, 21, 38, 56, 72, 114, 144). For example, of the 304 *P. acnes* isolates collected from various human infections in 13 European countries, 15% of isolates demonstrated resistance to clindamycin (114). Isolates were also resistant to erythromycin (17%) and to tetracycline (3%), whereas all isolates were susceptible to penicillin, vancomycin, and linezolid. Although vancomycin and teicoplanin are considered active against most gram-positive bacteria, species-related resistance to glycopeptides is frequent among species of the genus *Lactobacillus*. Less than one-quarter of the isolates from 80 cases of *Lactobacillus* infections were reported as susceptible to vancomycin (16). Notably, the vancomycin-resistant *L. rhamnosus* is the most common *Lactobacillus* species in clinical specimens (45, 130). In contrast to vancomycin and teicoplanin, ramoplanin, a novel glycolipodepsipeptide, showed good activity against lactobacilli (21, 49). A novel glycopeptide, telavancin, proved to be more active than vancomycin against lactobacilli, except for *L. casei*, and demonstrated very good activity against the tested strains of *Propionibacterium*, *Actinomyces*, *Eggerthella*, and *Eubacterium* (55). Oxazolidinones represent a new class of synthetic antimicrobial agents, having relatively good in vitro activities against gram-positive cocci but also against anaerobes, and ranbezolid may have lower MICs than linezolid (13, 41). Also telithromycin, a novel ketolide, and streptogramin antimicrobial agents, such as pristinamycin and quinupristin-dalfopristin, have considerable activities against non-spore-forming gram-positive rods (13, 56, 105). Fluoroquinolones have a broad spectrum of antibacterial activity and good absorption from the gastrointestinal tract. Novel quinolones, such as garenoxacin, gatifloxacin, and moxifloxacin, exhibit better antianaerobic activity than the older quinolone compounds levofloxacin and ciprofloxacin (13, 38, 72, 100), suggesting their potential in treating mixed organism infections.

The potential presence of anaerobic gram-positive non-spore-forming rods in infections associated with biofilms and increased antimicrobial resistance of biofilms (147) needs to be taken into account. Due to the involvement of biofilms, mechanical intervention (drainage of abscesses, decompression of infected spaces, debridement of necrotic tissue, and removal of foreign bodies) can be critical in the management of these infections. In addition, appropriate coverage for both facultative and anaerobic bacteria is often necessary.

INTERPRETATION AND REPORTING OF RESULTS

Once clinically relevant isolates are recovered, their accurate classification is needed to estimate the seriousness of the infection and to select the appropriate antimicrobial therapy. Conventional identification protocols for anaerobic non-spore-forming gram-positive bacteria to the species level are laborious and time-consuming and involve substantial

subjective judgment that can result in inconclusive identification. In reference anaerobic laboratories, the use of gas chromatography and/or sequencing of the 16S rRNA gene provides useful tools for organism identification.

*Clostridium**

ERIC A. JOHNSON, PAULA SUMMANEN, AND SYDNEY M. FINEGOLD

57

TAXONOMY

The genus *Clostridium* comprises obligately anaerobic (or occasionally aerotolerant) rods that usually stain gram positive in young cultures. Clostridia, mainly from our indigenous microbiota, are involved in a variety of infections that are commonly associated with considerable morbidity and mortality (44, 86). Virulence factors (particularly toxins), inoculum size, and other properties play important roles in diseases involving *Clostridium* species. Impaired host defenses also enhance susceptibility to clostridial infections. Currently, 202 clostridial species are validly published (http://www.dsmz.de/bactnom/bactname.htm); however, the number of clinically significant clostridia from human infections is limited (Table 1).

Phylogenetically, the genus *Clostridium* is extremely heterogeneous, with many species intermixed with other spore-forming and non-spore-forming genera (53, 66). Traditionally, the species have been defined based on a few morphological, ultrastructure (72), and physiological features (44, 173). During the past decade, analyses of 16S rRNA gene sequences indicated that the "clostridia" could be divided into 19 clusters and 11 groups (53). Homology group I forms the basis of the genus *Clostridium* and is analogous to group I proposed in 1975 (96, 173). The type species, *Clostridium butyricum* (44), and most of the clinically important *Clostridium* species cluster within homology group I. The heterogeneous non-group I clostridia require reclassification (53, 173), but a difficulty in resolving the heterogeneity within the genus is that 16S rRNA gene sequences may not be adequate alone in distinguishing genera, and it is necessary to find genetic and phenotypic characters that enable rapid discrimination among genera within this group (173; P. Lawson, personal communication).

Since the last edition of this Manual, some new pathogenic species have been designated within the clinically significant *Clostridium* species. Two new species clustering within the *C. coccoides* rRNA group, *C. hathewayi* (174) and *C. bolteae* (169), were described from human feces. Phenotypically, *C. clostridioforme* is a relatively heterogeneous anaerobe. Sequencing analyses of 16S rRNA genes from 107 strains that were previously identified phenotypically as *C. clostridioforme* in various clinical laboratories revealed that "*C. clostridioforme*" in fact represents three distinct species: *C. bolteae, C. clostridioforme,* and *C. hathewayi* (67). *C. bartlettii* is another new *Clostridium* species described from human feces (168); the clinical significance of this organism remains unknown. *C. neonatale* was proposed as a novel species recovered from bacteremia in patients with necrotizing enterocolitis (NEC) (9); however, this species is not yet validly published.

Anaerotruncus colihominis is a new genus and species within the *C. leptum* rRNA cluster of organisms originally described from human feces (120), and subsequently found in bacteremia (118). *A. colihominis* was originally described as a non-spore-forming organism; however, further studies have revealed that this organism does produce spores under some conditions (118) and should therefore be considered in *Clostridium* identification schemes.

DESCRIPTION OF THE GENUS

The description of the genus *Clostridium* is outlined in *Bergey's Manual of Systematic Bacteriology* (44) and *The Prokaryotes* (89). Recent analyses of rRNA genes have greatly expanded the clostridia to include 5 new genera and 11 new species combinations (53). The clostridia, as currently named, belong to the phylum *Firmicutes* and comprise a heterogeneous (paraphyletic) group consisting of at least 12 lineages. The clostridia have a wide range of G+C contents, from 22 to 55 mol%, while the toxigenic species have a much narrower range of G+C contents, 24 to 29 mol% (44, 86, 89, 173). Common morphological and phenotypic properties that have traditionally been used to define the genus include (i) the formation of endospores, (ii) an anaerobic energy metabolism, (iii) the inability to reduce sulfate to sulfide, and (iv) a gram-positive cell wall structure (44, 89).

Vegetative cells of *Clostridium* species are rod shaped, commonly pleomorphic, and are often arranged in pairs or short chains; the cells have rounded or sometimes pointed ends (44, 86, 90). Rods may join to form tight coils or spiral configurations in certain species, such as *C. cocleatum* and *C. spiroforme*. Clostridia usually stain gram positive at least in early stages of growth, although some species, such as *C. clostridioforme, C. hathewayi, C. innocuum,* and *C. ramosum,* almost always appear gram negative. Several species (e.g., *C. tetani*) appear gram negative by the time spores have formed. The cells form oval or spherical endospores (44, 86, 89). The spores are often wider than the vegetative organisms, imparting characteristic

* This chapter contains information presented in chapter 54 by Stephen D. Allen, Christopher L. Emery, and David M. Lyerly in the eighth edition of this Manual.

TABLE 1 Characteristics of *Clostridium* species of clinical significance[a]

[a] +, positive reaction; –, negative reaction; v, variable reaction; w, weakly positive reaction; ST, subterminal; T, terminal. Superscript indicates rare variability. Capital letters indicate major metabolic products from peptone-yeast-glucose (PYG), lowercase letters indicate minor products, and parentheses indicate a variable reaction for fatty acids as follows: A, acetic; P, propionic; IB, isobutyric; B, butyric; IV, isovaleric; V, valeric; IC, isocaproic; L, lactic; S, succinic; and PA, phenylacetic.

[b] *C. bifermentans* is urease negative, and *C. sordellii* is urease positive. *C. bifermentans* usually forms chalk-white colonies on egg yolk agar.

[c] Toxin neutralization test required for identification. Send suspected isolates or *C. botulinum*-containing material to the appropriate local or state public health agency.

[d] Nonproteolytic.
[e] L-Proline-aminopeptidase differentiates: C. *difficile* is positive, and C. *innocuum* is negative.
[f] Swarming.
[g] Cigar shaped; C. *bolteae* is lactose and β-NAG negative, C. *clostridioforme* is lactose positive and β-NAG negative, and C. *hathewayi* is lactose and β-NAG positive.
[h] C. *tertium*, C. *carnis*, and most C. *histolyticum* isolates grow aerobically.
[i] Described from a case of bacteremia; frequently isolated from stool specimens.

spindle shapes of clostridia (47, 99). Most strains are motile by means of peritrichous flagella. Nonmotile species from clinical specimens include *C. perfringens, C. ramosum,* and *C. innocuum*.

Clostridium species are metabolically diverse. As currently designated (53, 89), most species are chemoorganotrophic; some species may be chemoautotrophic and chemolithotrophic. They can be saccharolytic, proteolytic, neither, or both; they do not carry out dissimilatory sulfate reduction. They usually produce mixtures of organic acids and alcohols from carbohydrates, proteins and peptides, or purines and pyrimidines (86, 89).

Most species are obligately anaerobic, although the tolerance to oxygen varies widely; some species (e.g., *C. tertium*) will grow but not sporulate in the presence of air, and a few aerotolerant species, such as *C. carnis, C. histolyticum,* and occasional strains of *C. perfringens,* give scant growth on solid media incubated under 5 to 10% CO_2. The distinction between aerotolerant clostridia and certain *Bacillus* species may be made by virtue of the fact that clostridia usually form spores only under anaerobic conditions, they grow better anaerobically than in air, and clostridia usually do not produce catalase. Although *Clostridium* species are usually catalase and superoxide dismutase negative, trace amounts of these enzyme activities may be detected in some strains. In addition, clostridia lack a cytochrome system and are thus oxidase negative. Clostridia often occur in nature and in infections as consortia of mixed species, wherein aerobic and facultative organisms utilize oxygen, provide nutrients or other factors, and create an environment favorable for clostridial growth. Since clostridia often are present as mixed cultures, it is important to carefully ascertain purity by plating for single colonies and by microscopic analysis.

Clostridia produce a diversity of biologically active proteins, including toxins, many of which are important in human disease. The clostridia produce more kinds of protein toxins than any other bacterial genus, and more than 25 toxins lethal to mice have been identified (14, 23, 85). At least 15 species of cluster I *Clostridium* produce protein toxins, and new toxins and virulence proteins have been discovered through traditional isolation techniques and genomic analyses (38, 159). These proteins include neurotoxins, enterotoxins, cytotoxins, collagenases, permeases, necrotizing toxins, lipases, lecithinases, hemolysins, proteinases, hyaluronidases, DNases, ADP-ribosyltransferases, neuraminidases, and some others that are simply known as lethal toxins (85). Certain clostridial toxins have extraordinary potency, and botulinum and tetanus neurotoxins are the most poisonous toxins known, with lethal doses of 0.2 to 10 ng per kg for various animals, including humans (23, 75, 85, 154). The virulence traits of clostridia that cause disease in hosts are incompletely understood. Recently, genomic sequences of pathogenic clostridia have become available (38, 159), which should facilitate a comprehensive approach for understanding virulence factors involved in clostridial pathogenesis.

EPIDEMIOLOGY AND TRANSMISSION

Clostridium species are widespread in the environment partly due to their ability to form resistant endospores. They are commonly found in soil, feces, sewage, and marine sediments (44, 86, 163). The common presence of *C. perfringens* in soil is seldom of clinical significance (165). Infection of war wounds, for example, typically is due to the subject's indigenous microbiota and the lack of sufficient hygiene. On the other hand, the incidences of tetanus and food-borne botulism are commonly related to the incidence of their spores in soil, water, and many foods (86, 164). Outbreaks of hospital-acquired *C. difficile* enteric infections are often traceable to environmental sources and other typical background factors for nosocomial infection (142). Many clostridia are present in large numbers as part of the indigenous microbiota of the intestinal tract of humans and animals (44, 86) and may be found in the female genital tract and oral microbiota as well.

CLINICAL SIGNIFICANCE

Although the exogenous clostridial infections or intoxications such as tetanus, food-borne botulism, and hospital-acquired *C. difficile* colitis are serious, endogenous infections by clostridia that are a part of the host's indigenous microbiota are commonly encountered. Nearly any type of infection in the body may involve clostridia, often in association with non-spore-forming anaerobes and facultative or aerobic organisms. These infections tend to be more severe than comparable infections without clostridia as part of the infecting microbiota. Head and neck infections, brain abscess, sinusitis, otitis, aspiration pneumonia, lung abscess, pleural empyema, cholecystitis, other intra-abdominal infections, gynecologic and obstetric infections, and soft tissue and bone infections all may involve clostridia (79). Common predisposing factors are surgical procedures, trauma, vascular stasis, obstruction, malignancy with or without chemotherapy and immunosuppressive agents, diabetes mellitus, prior aerobic infection, and use of antimicrobial agents with poor activity against clostridia (e.g., trimethoprim-sulfamethoxazole) (64, 83).

Clostridial Bacteremia

C. septicum is isolated only rarely from the feces of healthy individuals but is found in anaerobic blood cultures in bacteremia associated with underlying disease processes, often neoplastic disease, particularly in the ileocecal region. As many as 70 to 85% of patients whose blood cultures are positive for this organism have some underlying malignancy (29, 103). *C. septicum* has been found in the lumen of 10 to 68% of normal appendices (27, 72). Another clinically important association has been observed between *C. septicum* bacteremia, neutropenia of any origin, and neutropenic enterocolitis involving the terminal ileum or cecum (102, 113). Patients with diabetes mellitus, severe atherosclerotic cardiovascular disease, or anaerobic myonecrosis (gas gangrene) may also develop *C. septicum* bacteremia (77, 109). The clinical importance of recognizing *C. septicum* bacteremia and starting appropriate treatment immediately cannot be overemphasized. Patients with this condition are usually gravely ill and may have metastatic spread of myonecrosis to distant anatomic sites. Mortality rates are very high. *C. septicum* has also been recovered from bacteremia in cirrhotic patients, as have *C. perfringens, C. bifermentans,* and other clostridia (49). Some of these patients demonstrated septic shock.

Another clostridial species of importance in patients with serious underlying disease such as malignancy is *C. tertium*. This organism, as well as *C. septicum* and *C. perfringens,* may be seen in bacteremia in such patients, with or without neutropenic enterocolitis (122). *C. tertium* may present special problems in terms of both identification and treatment. This organism may appear gram negative, is aerotolerant, and is resistant to metronidazole, clindamycin, and cephalosporins. *C. tertium* has also been found in bacteremia associated with acute pancreatitis (157).

An important study by Woo et al. (188) involved sequencing of genes encoding 16S rRNA of non-*C. perfringens* clostridia in a study of anaerobic bacteremia. *C. perfringens* accounted for 79% of clinically relevant clostridial bacteremias; 11 other species accounted for 17 other blood cultures positive for clostridia other than *C. perfringens*. There were four bacteremias due to *C. paraputrificum,* three due to *C. ramosum,* two due to *C. tertium,* and one each due to *C. baratii, C. difficile, C. disporicum, C. indolis, C. innocuum, C. orbiscindens, C. septicum*, and *C. sporosphaeroides*. The mortality rate of clinically relevant clostridial bacteremia was 29%. A study of risk factors for mortality in patients with anaerobic bacteremia (187) found, in a multivariate analysis, that the only significant factors were liver disease and patient age. In this study, there were 25 patients with clostridial bacteremia; the crude mortality rate in this group was 35%. The *C. clostridioforme* group (including *C. clostridioforme, C. hathewayi,* and *C. bolteae*) has been reported from a number of cases of bacteremia (67, 189).

Enteric Infections

Food Poisoning

C. perfringens is one of the most common bacterial causes of food-borne illness in the United States and Canada (32, 145). Almost all U.S. outbreaks and cases of *C. perfringens* food-borne gastroenteritis appear to be due to type A strains (32, 162). In *C. perfringens* type A food-borne disease, the food vehicle is typically an improperly cooked meat or meat product, such as gravy, that has cooled slowly after cooking or may have been inadequately reheated. Spores surviving the initial cooking germinate, and vegetative cells proliferate during slow cooling or insufficient reheating. Illness results from the ingestion of food containing about 10^8 or more viable vegetative cells, which sporulate in the alkaline environment of the small intestine, producing an enterotoxin (*C. perfringens* enterotoxin [CPE]) in the process. *C. perfringens* type A food-borne illness occurs within 7 to 30 h of ingestion of the suspect food and is generally mild and self-limiting (162). In the very young, the elderly, and the immunocompromised, symptoms are more severe, occasionally resulting in death (33). Enterotoxin-producing *C. perfringens* has been implicated as an etiologic agent of persistent diarrhea in elderly patients in nursing homes and tertiary-care institutions (30) and has been considered to play a role in antibiotic-associated diarrhea (AAD) without pseudomembranous colitis.

C. perfringens strains associated with food poisoning contain the enterotoxin gene *(cpe)* on the chromosome and produce the *C. perfringens* enterotoxin (CPE), which generally acts by forming pores in membranes of host cells (162). *C. perfringens* strains isolated from non-food-borne diseases, such as AAD and sporadic diarrhea, carry *cpe* on a plasmid (41, 68). The plasmid possessing *cpe* may be transmissible, since cases of food-associated diarrhea as well as AAD may be associated with a relatively small number of CPE-positive cells (68, 171, 184). These results indicate that *C. perfringens* strains bear a plasmid-borne enterotoxin gene that should not be disregarded as causative agents of food poisoning.

In addition to CPE, various strains of *C. perfringens* collectively produce about 15 protein toxins, several of which are involved in diseases of animals and livestock (85, 162). Epsilon-toxin is a 33-kDa protein produced by *C. perfringens* types B and D strains and is among the most lethal of clostridial toxins, next to botulinum and tetanus neurotoxins, and epsilon-toxin is considered a potential bioterrorism agent (23, 162). In animals, it causes edema and hemorrhage in the brain, heart, spinal cord, and kidneys (162).

Enteritis Necroticans (Pig-bel and Darmbrand), Necrotizing Enteritis, and NEC

Enteritis necroticans is caused by alpha-toxin- and beta-toxin-producing strains of *C. perfringens* type C, and beta-toxin is probably mainly responsible for the pathogenesis (162, 170). The gene encoding beta-toxin is located on a plasmid in *C. perfringens* (68). Enteritis necroticans is a life-threatening infection with ischemic necrosis of the jejunum (10). It was recognized in Papua New Guinea during the 1960s as the most frequent cause of death in children; it has been associated with pig feasts and occurs both sporadically and in outbreaks (143). Immunization against the beta-toxin resulted in a decreased incidence of the disease in New Guinea (119). Enteritis necroticans has also been recognized in the United States, the United Kingdom, Germany, and other developed nations, especially involving adults who are malnourished or who have chronic illnesses (e.g., diabetes or alcoholic liver disease) (60, 78, 81, 148) and also in a child with neutropenia (124). Enteritis necroticans may be underreported (128). It should be noted that NEC, a disease resembling enteritis necroticans but associated with *C. perfringens* type A, has been found rarely in North America in previously healthy adults (167).

NEC is a serious gastrointestinal disease that affects low-birth-weight (premature) infants who are hospitalized in neonatal intensive care units (110). Kliegman et al. (105) noted that the etiology and pathogenesis of this condition remain speculative in spite of more than 1,000 publications on NEC over the last 4 decades. Pathological similarities between NEC and enteritis necroticans include the patterns of bowel necrosis and inflammation that occur in these conditions (104, 105). Both diseases may manifest intestinal gas cysts (pneumatosis cystoides intestinalis). The sources of the gas, which contains hydrogen, methane, and carbon dioxide, are probably the fermentative activities of intestinal bacteria, including clostridia in particular (104). Epidemiological data support an important role for *C. perfringens* or other gas-producing microorganisms (e.g., *C. neonatale,* certain other clostridia, or *Klebsiella* spp.) in the pathogenesis of NEC (9, 104, 110).

CDAD and Colitis

C. difficile, the major cause of antibiotic-associated pseudomembranous colitis, is also the most frequently identified cause of hospital-acquired diarrhea (97). It has been estimated that *C. difficile* is responsible for more than 250,000 cases of diarrheal disease per year in the United States (186), with a cost exceeding $1 billion (114). *C. difficile* has been isolated from various natural habitats and the feces of domestic animals and humans (129). *C. difficile* is present asymptomatically as part of the bowel microbiota in up to half of all healthy neonates during the first year of life; the carriage rate decreases to the adult rate of 3% or less by the age of 2. Hospitalized patients frequently become colonized with this organism (73). McFarland et al. (136) reported that 21% of 399 patients with negative cultures on admission to a hospital with a high prevalence of *C. difficile*-associated disease (CDAD) acquired *C. difficile* during hospitalization. Of these patients, 63% remained asymptomatic, while 37% developed diarrhea. Antimicrobial agents of all classes and several anticancer chemotherapeutic agents have been implicated in the development of CDAD or pseudomembranous colitis (97). As noted above, certain *C. difficile* strains contain mobilizable transposable elements with antibiotic resistance to chloramphenicol, tetracycline, or erythromycin (4, 172). Metronidazole and vancomycin

have been active against all strains tested, but there have been a number of failures with metronidazole therapy recently (20, 146). Higher likelihood of treatment failure was noted in patients who remain on the predisposing antibiotics while undergoing treatment for CDAD (138).

In CDAD, the primary initiating event involves the disruption of the commensal intestinal microbiota during treatment with antibiotics or antineoplastic agents (73, 97, 129). As the levels of antibiotics drop below inhibitory concentrations, nosocomial pathogens such as *C. difficile* are able to grow. Toxigenic as well as nontoxigenic isolates are capable of forming spores and existing in the hospital environment. As a result, either type can infect the colon because of changes in populations of the intestinal microbiota. Only the toxigenic isolates are associated with disease, and nontoxigenic isolates may be protective by competitive exclusion (31). Toxigenic strains produce and release toxins TcdA and/or TcdB. TcdA and TcdB each have a molecular mass of approximately 270 kDa, similar to the TcsH hemorrhagic and TcsL lethal toxins from *C. sordellii* and alpha-toxin from *C. novyi* (179). The cytotoxic actions of these toxins and the associated inflammatory response result in the histopathology of CDAD.

In the early 1990s, an isolate of *C. difficile* that produced only toxin TcdB was described, and detailed studies suggested that the isolate contained a truncated *tcdA* gene (140, 179, 186). Furthermore, bioassays indicated that toxin B from this particular isolate was more toxic than toxin B from typical A^+/B^+ isolates. Multiple reports of atypical $TcdA^-/TcdB^+$ isolates and their association with clinical disease were documented (6, 8, 98, 130). Such isolates may be missed in laboratories that base their diagnosis solely on the use of toxin A-specific tests. In $TcdA^-/TcdB^+$ isolates, a large portion of the *tcdA* gene encoding the repeating region (i.e., the binding portion of the toxin) is deleted (100, 140). In addition to the deletion in TcdA, the active site of the TcdB gene is modified in $TcdA^-/TcdB^+$ isolates, resulting in a TcdB protein that more closely resembles the lethal toxin of *C. sordellii* (129, 140, 179). A limited number of cases of pseudomembranous colitis are caused by $TcdA^-/TcdB^+$ organisms (6, 8, 98, 130). Strains of *C. difficile* may only produce TcdA (97, 130, 179). Recently, *C. difficile* isolates that produce the highly potent iota-toxin, which is related to the iota-toxin of *C. perfringens* and *C. spiroforme,* have been noted (179). Virulent clones of *C. difficile* strains, characterized as toxinotype III, North American PFGE type 1, and PCR ribotype 027 (NAP1/027), have been linked to increased mortality in North America and Europe (135, 147, 181). The severity of CDAD caused by NAP1/027 may be due to hyperproduction of toxins A and B. Dissemination of this strain has led to important changes in the epidemiology of CDAD (181).

C. difficile is responsible for 20% or fewer of cases of AAD (24, 186). Reports suggest that *C. perfringens* is a less frequently identified cause of AAD (30). Enterotoxin-producing *C. perfringens* type A has been isolated from AAD patients who are negative for *C. difficile* and who have no other apparent cause of the disease. Coinfection with *C. difficile* and enterotoxigenic *C. perfringens* type A has been reported for AAD patients (43). The incidence of *C. perfringens*-associated AAD has been estimated at 5 to 20%, but additional epidemiological studies are needed to accurately determine the role of this organism in AAD (43).

C. difficile is an important cause of enteric infection in the elderly and in nursing home residents (160). *C. difficile* may be a problem even when antibiotics are not used, in patients with bowel stasis and those who have had bowel surgery. The clinical picture of *C. difficile* infection ranges from mild diarrhea to pseudomembranous colitis with or without toxic megacolon. In the most severe form, the disease may lead to bowel perforation and death.

Skin and Soft Tissue Infections

Soft tissue infections with clostridia or other organisms are sometimes not regarded as serious. However, it should be appreciated that necrotizing soft tissue infections (such as necrotizing fasciitis and myonecrosis) have a poor prognosis and require early surgical intervention as well as antimicrobial therapy. An interesting study published recently (15) reviewed 166 patients with necrotizing soft tissue infection of various types and with differing etiologies. The overall mortality was 16.9% in this series, and loss of limbs occurred in 26%. Clostridial infection was consistently associated with poor outcome and was an independent predictor for both mortality and limb loss; it was strongly associated with intravenous drug use and high levels of leukocytosis.

Clostridial Myonecrosis

C. perfringens is the clostridial species most commonly isolated from human clinical specimens, excluding feces (78, 79). One of the serious and unique infections in which this organism plays a major role is myonecrosis (gas gangrene) that involves a breakdown of muscle tissue related to the action of potent exotoxins, particularly alpha-toxin (a phospholipase C) and theta-toxin (a thiol-activated cytolysin) (39, 40). Alpha-toxin produces the opaque zone of lecithin hydrolysis products that surrounds colonies of *C. perfringens* growing on egg yolk agar plates. It gives rise to an outer zone of partial hemolysis that surrounds a smaller zone of complete hemolysis produced by theta-toxin (a heat-labile, oxygen-labile hemolysin easily detected around colonies of *C. perfringens* growing on sheep blood agar).

Clostridial myonecrosis is rapidly progressive and has a high mortality rate. Associated systemic manifestations may include shock, renal failure, and sometimes bacteremia with intravascular hemolysis (78, 79). In addition to *C. perfringens,* gas gangrene may involve *C. septicum, C. novyi, C. histolyticum, C. bifermentans, C. sordellii,* and other clostridia. Gas gangrene of the uterus, now rare, occurred most frequently as a consequence of illegal or self-induced abortions but has also followed spontaneous abortion, vaginal delivery, and cesarean section (78, 79, 128). Crepitant cellulitis, also called anaerobic cellulitis, is seen principally in diabetic patients and characteristically involves subcutaneous tissues or retroperitoneal tissues and can progress to fulminant systemic disease (78, 79, 128). The muscle and fascia are not involved. When clostridia are involved in this process, the disease may be more severe than when only non-spore-forming anaerobes and other bacteria are responsible.

Other Skin and Soft Tissue Infections

In addition to the well-known exogenous clostridial infections, emerging clostridial diseases have been recognized during the past decade. An emerging infection with a high mortality rate is soft tissue infection and toxic shock among injecting drug users. These individuals manifest hypotension, marked edema, and high leukocyte counts. The principal pathogens have been found to be *C. novyi* type A and *C. perfringens* (21, 36, 144). *C. novyi* types B, C, and D are unlikely to be isolated from human clinical material. Cases of *C. histolyticum* infection with cellulitis, abscess formation, or endocarditis have also been found (21). An outbreak of necrotizing fasciitis due to *C. sordellii* has been reported for black-tar heroin users (101).

C. sordellii is responsible for a rare, rapidly fatal postpartum endometritis in young, previously healthy women with a unique clinical picture of little or no fever or purulent discharge, shock, extensive edema and fluid accumulation in body cavities, and a markedly elevated white blood cell count (137, 151). *C. sordellii* has also been implicated in toxic shock-like syndrome following spontaneous childbirth or abortion; these women had refractory hypotension, multiple effusions, peripheral edema, hemoconcentration, and profound leukocytosis with lack of fever (161, 185). Also, *C. sordellii* was accountable for endophthalmitis after suture removal from a corneal transplant (192).

Botulism

C. botulinum is the cause of the rare but occasionally fatal illness known as botulism. Spores of *C. botulinum* are widely distributed in soil and aquatic habitats (94, 164). *C. botulinum,* along with unique strains of *C. butyricum, C. baratii,* and *C. argentinense,* can produce botulinum neurotoxin (BoNT), the most lethal poison known (46, 71, 75, 85, 154). The intravenous lethal dose for BoNT has been estimated as 0.1 to 0.5 ng per kg of body weight, and BoNT is among the most potent protein toxins by oral ingestion, with an estimated oral lethal dose of 0.2 to 1 μg per kg (17, 75, 154). There are seven antigenic serotypes of BoNT (A through G), which serve as useful clinical and epidemiological markers (84, 94, 115). Toxin serotypes A, B, and E of *C. botulinum* are the principal causes of botulism in humans (52, 84, 94). Neurotoxigenic strains of *C. butyricum* (63, 71, 86) and *C. baratii* (86) that produce type E and F neurotoxins, respectively, have been implicated mainly in infant botulism. Type E botulinal toxin-producing *C. butyricum* strains were confirmed by sequencing of the16S rRNA gene (48, 71), leading to the conclusion that neurotoxigenic *C. butyricum* must be regarded as an emergent food-borne pathogen. *C. argentinense,* which produces type G neurotoxin (84), has been isolated from soil in Argentina. Its reported isolation from autopsy materials from five individuals who died suddenly has not been substantiated, and *C. argentinense* has not been clearly implicated in botulism (86). *C. botulinum* types C and D are associated primarily with botulism in birds and mammals (94, 163, 164). Strains of *C. botulinum* that produce more than one serotype of BoNT, generally with one serotype formed in much higher levels, have been isolated from the environment and human and animal botulism cases (71, 84, 93). The BoNTs are coexpressed with nontoxic proteins of toxin gene clusters (34), and evidence suggests that the complexes are much more stable in the gastrointestinal tract (153). The genes for BoNT complex formation are associated with unstable genetic elements in certain serotypes, enabling toxin gene transfer to nonpathogenic clostridia (57, 92, 191).

There are four naturally occurring types of botulism: (i) classical food-borne botulism, an intoxication caused by the ingestion of preformed botulinal toxin in contaminated food; (ii) wound botulism, which results from elaboration of botulinal toxin in vivo after growth of *C. botulinum* in an infected wound; (iii) infant botulism, in which botulinal toxin is elaborated in vivo in the gastrointestinal tract of an infant colonized with *C. botulinum;* and (iv) botulism due to intestinal colonization in children and adults (16, 46, 71, 84, 106, 164). Intestinal colonization in adults has been associated with surgery and administration of antibiotics (80, 84). Recently, *C. botulinum* has been isolated from patients colonized with *C. difficile* (63), with viral infections (62), or with Crohn's disease (80).

Regardless of the category of botulism, the toxin enters the bloodstream at a peripheral site (e.g., gut, wound, or lung) and is transferred to the neuromuscular junctions of motor neurons, where it binds irreversibly to the presynaptic membranes. The site of action of all serotypes of BoNT is the presynaptic terminal of motor neurons (50, 117, 155). Elucidation of the three-dimensional structures of botulinum and tetanus toxins and their constituent domains has provided considerable insights into their mechanisms of action (116, 117, 155, 176). BoNT penetrates the plasma membrane by receptor-mediated endocytosis, and the light chain of 50 kDa (the catalytic domain) is internalized into the nerve cell through a protein channel (117, 155). Once internalized, BoNT specifically cleaves SNARE proteins involved in vesicle trafficking of neurotransmitters to the membrane (155). Exocytosis of acetylcholine is prevented at the nerve terminal to the neuromuscular junction, with consequent blockage of innervation of muscle activity (155). The clinical hallmark of botulism is an acute flaccid paralysis, which begins with bilateral cranial nerve impairment involving muscles of the eyes, face, head, and pharynx and then descends symmetrically to involve muscles of the thorax and extremities. At physiological levels, botulinum toxin, unlike tetanus neurotoxin (TeNT), probably does not enter the central nervous system (CNS). In naturally occurring food-borne botulism, gastrointestinal symptoms (e.g., abdominal cramps, nausea, vomiting, or diarrhea [more often constipation or obstipation]) may precede the neurologic signs of descending flaccid paralysis. Death may result from respiratory failure caused by paralysis of the tongue or muscles of the pharynx leading to occlusion of the upper airway or from paralysis of the diaphragm and intercostal muscles (17, 50). Generally, the patient's hearing remains normal, consciousness is not lost, and the victim is cognizant of the progression of the disease. Certain episodes of botulism have been reported that affect autonomic and sensory functions. A patient's awareness of loss of muscle activity can lead to considerable emotional distress, such as anxiety and depression (50).

Wound Botulism in Intravenous Drug Users

Wound botulism is another exogenous clostridial intoxication that may be found among injecting drug users (37, 133). Although wound botulism is rare in non-drug users, cases occasionally occur, such as a fatal case that occurred in a young girl who had a tooth extracted (182). An association between botulism and subcutaneous injection of Mexican black-tar heroin was reported in the United States and in the United Kingdom (37, 133). A study found 33 clinically diagnosed cases of wound botulism in the United Kingdom and Ireland between 2000 and 2002 (37). All individuals affected had injected black-tar heroin into muscle or by "skin popping." The clinical diagnosis was confirmed by laboratory tests in 20 of these cases; 18 cases were caused by type A toxin and 2 by type B toxin. Users of drugs other than heroin are also at risk of illness caused by clostridia; injection or snorting cocaine has resulted in cases of botulism (112).

Infant Botulism

In the United States, infant botulism is the most frequently recognized form of botulism. Although infant botulism has been documented in at least 15 other countries (16, 70, 71), it is comparatively rare outside the United States, perhaps due to failure of recognition and diagnosis (16). Of the nearly 2,000 cases reported in the United States from the discovery of infant botulism in 1976 (16, 149), approximately 45% of cases were in California, where an intensive epidemiological and microbiological program has been used for recognition and treatment of infant botulism (16).

Across the United States, the geographic distribution of toxin types in infant botulism cases has roughly paralleled the spore distribution of C. *botulinum* toxin types in soil sampled from different locations (16), although certain geographic locations have comparatively high incidences. Type A has been the most frequent BoNT type in cases of infant botulism in states west of the Mississippi River, whereas type B cases have predominated east of the Mississippi River (16, 164). Three known cases have been caused by a strain(s) of C. *botulinum* that produced toxins requiring both type B and F antitoxins for neutralization (84). Type E infant botulism, caused by neurotoxigenic strains of C. *butyricum*, was initially confirmed in two infants from Italy (71, 86), and later in additional patients. Type F infant botulism has been caused by neurotoxigenic C. *baratii* (71, 86).

Although most infants that contract botulism are 3 weeks to 6 months old, the age range is a few hours following birth to 363 days (16). Botulinum spores have not been detected in any food or liquid ingested by these infants other than honey (16). To date, the only clearly defined risk factors have been exposure to soil, dust, and honey (16, 70). It is recommended that honey not be fed to infants less than 1 year of age. Another possible risk factor, although not proven, is that spores could be transmitted in corn syrup, and possibly infant foods within the household environment (95). Whatever the sources, the ingested spores of C. *botulinum* germinate within the intestinal tract, and the vegetative cells multiply and produce the neurotoxin, which is then absorbed into the bloodstream (16, 84). Decreased frequency of bowel movements, a sign of decreased intestinal motility, may be an additional risk factor for infant botulism. The first sign of illness is usually constipation, which is often overlooked. Infants who are ultimately hospitalized develop lethargy and mild weakness, with feeding difficulties, pooled oral secretions, and an altered cry (16). They eventually lose head control and may go on to develop ophthalmoplegia, ptosis, flaccid facial expression, dysphagia, other signs of cranial nerve deficits, and generalized muscular weakness. Respiratory insufficiency and inability to swallow necessitating intubation and intragastric feeding also may occur. There is likely a spectrum of clinical features in infant botulism, ranging from mild illness not requiring hospitalization to severe botulism requiring intensive care. It has been postulated that fulminant, rapid-onset botulism can cause sudden death, which may account for a small percentage of cases of sudden infant death syndrome (17, 25). Human immune globulin that neutralizes BoNT (BabyBIG) is now approved by the FDA for use in therapy of infant botulism; this product has moderate titers of neutralizing antibodies against types A and B toxin, but its efficacy against serotypes E and F is unknown (18, 70).

Aerosolized Botulinum Toxin and Potential Use as a Bioterrorism Agent

Inhalational botulism, which results from aerosolization and inhalation of botulinum toxin, has been considered a fifth category of botulism (17, 150). Botulism could also result from covert contamination of foods (17, 183). These two routes of botulism have been considered most likely to occur in a bioterrorism incident (17, 42) (see chapter 9). Inhalational botulism has been demonstrated experimentally in monkeys (17, 150), accidentally in three veterinary personnel in Germany who were exposed to reaerosolized BoNT from rabbits and guinea pigs with aerosolized BoNT on their fur (17), and three researchers who were exposed to an aerosol during BoNT manipulations (91). Terrorists have attempted to use aerosolized botulinum toxin as a bioweapon in Japan but were not successful. After Operation Desert Storm ended in 1991, Iraq admitted to having produced 19,000 liters of concentrated botulinum toxin and to having loaded more than half of it into specially designed military weapons (e.g., missiles). According to Arnon et al. (17), 19,000 liters of concentrated botulinum toxin is more than enough to kill the entire human population by inhalation. Although inhalational botulism is possible, the toxin is unstable in aerosols and the more likely route of intentional intoxication is by food contamination and oral ingestion.

Tetanus

Tetanus, caused by C. *tetani*, is often associated with puncture wounds that do not appear to be serious. The organism and its spores can be isolated from a variety of sources, including soil and the intestinal contents of numerous animal species. A potent neurotoxin (TeNT), often referred to as tetanospasmin, is elaborated at the site of trauma and rapidly binds to neural tissue, provoking a characteristic paralysis and tonic spasms (28, 65). Tetanus is largely a disease of nonimmunized people, particularly in poor regions of the world and primarily affecting infants, since an effective toxoid for immunization has been used for many years.

Tetanus is an intoxication analogous to botulism except that it occurs solely through wound infection and production of tetanospasmin (TeNT). TeNT is synthesized as a single, inactive polypeptide chain (150 kDa), which is cleaved by an intrinsic protease to produce an active dichain form, consisting of a heavy chain (100 kDa) and a light chain (50 kDa) linked by a disulfide bond (155). The heavy chain is the part of the molecule that binds to neuronal cells, and the three-dimensional structure of this region has been elucidated (155). The light chain, a zinc endopeptidase, enters the cell cytoplasm and traverses from the nerve terminal to the nerve cell body by retrograde axonal transport (28, 155), eventually reaching neurons in the spinal cord and brain stem, where it affects glycinergic and GABA (γ-amino-*n*-butyric acid)-ergic neurotransmission (28, 155). Inhibitory impulses to CNS neurons are blocked, while uninhibited firing of motor nerve transmission continues, resulting in prolonged muscle spasms of both flexor and extensor muscles that can persist for weeks. The mechanism by which exocytosis of neurotransmitter release is inhibited is analogous to that of BoNT; in fact, TeNT cleaves the SNARE protein (VAMP) at the same peptide bond as BoNT B (117). In contrast to the pathophysiology of botulism, TeNT is retrogradely transported in neurons to the CNS and its site of action (28, 155).

In the United States, tetanus is reported most frequently in California, Michigan, Texas, and Florida and areas of the rural South (65). While most cases involve older, nonimmunized persons, injection of drugs (i.e., skin popping) has recently become an important risk factor in younger patients (22). It would be an unusual request for the clinical laboratory to isolate C. *tetani* from a wound, since tetanus usually presents few diagnostic problems for the clinician. The worldwide incidence of tetanus has been estimated to be as many as 500,000 cases per year (28, 65). Neonatal tetanus is endemic in developing countries despite the fact that it could be prevented by immunization of the mother and acquisition of passive antibodies by the fetus.

ADDITIONAL CLOSTRIDIAL SPECIES OF INTEREST

C. *innocuum* is an important organism in infections of immunocompromised hosts. C. *innocuum* has also been

recovered from patients with recurrent CDAD (2). It is often resistant to multiple drugs used to treat anaerobic infections (2). *C. ramosum* is the second most common *Clostridium* species (after *C. perfringens*) isolated from clinical specimens, including blood cultures and intra-abdominal and soft tissue infections. This species may be resistant to clindamycin and multiple cephalosporins. As noted earlier, *C. tertium* is often isolated from blood cultures from immunocompromised patients and has been reported as a cause of neutropenic enterocolitis and meningitis (51, 111, 122, 175). *C. hathewayi* and *C. bolteae* have been described from various human infections (67, 189), including fatal sepsis (127). Phenotypically similar *C. clostridioforme* is one of the clostridia most commonly isolated from human infections and appears to be associated with more serious or invasive human infections than *C. hathewayi* or *C. bolteae*.

The emergence of 16S rRNA gene sequencing technology has provided a means for identification of strains that may previously have been misidentified or classified as *Clostridium* without species identification. Examples are bacteremia caused by *C. hathewayi* (189), *C. intestinale* (59), and *C. symbiosum* (58); a fatal sepsis due to *C. fallax* in a previously healthy 16-year-old (87); and abscesses yielding *C. celerecrescens* (76). Microarray analysis of DNA from fecal samples has also been useful in determination of predominant species in the large bowel (180). It is likely that in this era of molecular identification techniques, a more accurate picture of clostridial infections will emerge.

COLLECTION, TRANSPORT, AND STORAGE OF CLINICAL SPECIMENS

As with other anaerobic infections, the proper selection, collection, and transport of clinical specimens are extremely important for the laboratory diagnosis of clostridial infections. For recommended collection and transport procedures in general, refer to chapters 5 and 20. Multiple tissue specimens should be sampled from the active sites of infection when gas gangrene is suspected, because clostridia are often not distributed uniformly in pathologic lesions. In addition to aspirates and tissues, selected clostridial illnesses require special specimens.

Confirmation of *C. perfringens* Food-Borne Illness

A freshly passed fecal specimen is the preferred specimen for *C. perfringens* culture and toxin assay, and appropriate specimens include the suspect food. Swab specimens are inadequate for the toxin assay because the sample volume is insufficient. These specimens should be placed into sterile unbreakable containers. All specimens should be stored at 4°C and shipped on cold packs as soon as possible. For optimal recovery, stool specimens should be processed within 24 h of collection.

Diagnosis of Enteritis Necroticans (*C. perfringens* Type C)

If enteritis necroticans is suspected, the appropriate specimens include three blood cultures from three different venipuncture sites, stool (at least 25 g, or 25 ml if liquid), and bowel luminal contents or tissue from the involved bowel (e.g., surgical specimen or autopsy material). Specimens should be transported in tightly sealed leakproof containers for the following: direct Gram stain, culture, isolation, identification, and typing of *C. perfringens*. PCR assays for genotyping *C. perfringens* are being used in certain research or referral laboratories to aid in diagnosis (170). Accordingly, DNA can be extracted for this purpose from formalin-fixed intestinal tissue or culture and amplified by PCR using primers specific for the *cpa* and *cpb* genes of *C. perfringens* type C.

C. difficile Culture and Toxin Assay

A single, freshly passed fecal specimen (ideally 10 to 20 ml of watery stool; minimum of 5.0 ml or 5 g) is the preferred specimen for *C. difficile* culture and toxin assay. To lessen the chance of obtaining positive culture results from patients merely colonized with the organism, only liquid or unformed stool specimens should be processed. Swab specimens are inadequate for the toxin assay because the sample volume is insufficient. Other appropriate specimens include bowel luminal contents and surgical or autopsy samples of the large bowel. Specimens should be transported in tightly sealed, leakproof plastic or glass containers. For optimal recovery, stool specimens should be cultured within 2 h of collection; although spores will survive in refrigerated stool for several days, there will probably be a large decrease in the number of viable vegetative cells of *C. difficile* in refrigerated specimens. Stools should be placed in an anaerobic environment (anaerobic transport vial or bag) if culture must be performed after storage. Adequate recovery of *C. difficile* may be expected from stools stored at 4°C for up to 2 days. Specimens for toxin assay may be stored at 4°C for up to 3 days and should be frozen at −70°C if performance of the assay is delayed. Freezing at −20°C results in a dramatic loss of cytotoxin activity. *C. difficile* toxin is unstable and will degrade at room temperature within 2 h after collection.

Suspected Neutropenic Enterocolitis Involving *C. septicum*

The specimens of choice for suspected neutropenic enterocolitis involving *C. septicum* are three blood cultures collected from three different venipuncture sites, stool (at least 25 g, or 25 ml if liquid), and luminal contents or tissue from the involved ileocecal area collected at surgery or autopsy and transported in tightly sealed leakproof containers. In addition, a biopsy sample of muscle (or an aspirate of fluid from the involved area, taken with a needle and syringe) should be collected if the patient is also suspected of having myonecrosis or another form of progressive infection.

C. botulinum Culture and Toxin Assay

Most hospital laboratories are not properly equipped to process specimens from patients suspected of having botulism. Before collecting any specimens, the medical care providers who suspect a diagnosis of botulism in a patient should immediately call their state health department's emergency 24-h telephone number or the CDC in Atlanta, Ga. (770-488-7100, 24-h/7-day emergency service), so that appropriate action can be taken to establish the diagnosis, initiate treatment, and investigate the case. Acceptable specimens include feces, enema fluid, gastric aspirates or vomitus, tissue or exudates, and postmortem specimens. These specimens should be placed into sterile unbreakable containers. Serum specimens (preferably >10 ml) should be collected as soon as possible after the onset of symptoms. Clinical swabs should be collected in an anaerobic transport medium; environmental swabs (from which spores may be isolated) may be sent in plastic containers without any medium. Food specimens should be left in their original containers if possible, or placed in sterile unbreakable containers. All specimens should be stored at 4°C and shipped on cold packs as soon as possible. Further information can be found at the CDC

botulism website (http://www.bt.cdc.gov/agent/botulism). Laboratories should have all of the pertinent information and contact numbers handy. During investigations of possible bioterrorism, sera, gastric aspirates, feces, and environmental or nasal swabs could be useful for detecting aerosolized botulinum toxin that may have been inhaled (11, 190). All specimens should be refrigerated until they can be transported to the laboratory for testing.

Certain clostridial toxins, particularly BoNT and TeNT and iota-toxin, are extremely toxic molecules and are considered very potent poisons. The CDC recommends biosafety level 3 primary containment and personnel precautions for facilities producing BoNTs for study. Personnel who work in the laboratory may be immunized with a pentavalent (A to E) toxoid available from the CDC. A biosafety manual should be posted in the laboratory and should contain the proper emergency phone numbers and procedures for emergency response. Regulations governing personnel safety for research with select agents are outlined in the *Code of Federal Regulations* and the manual *Biosafety in Microbiological and Biomedical Laboratories* (CDC/NIH; available on the Internet at http://www.cdc.gov/od/ohs/biosfty/ bmbl4/bmbl4toc.htm).

DIRECT EXAMINATION

Gas gangrene and necrotizing fasciitis represent extremely urgent situations requiring rapid clinical diagnoses. The direct examination of a Gram-stained smear of the wound may be useful for supporting the diagnosis of gas gangrene (11). Characteristic findings in *C. perfringens* infections include the absence of leukocytic infiltration and the presence of clostridia in smears prepared from central areas of the lesion. Special note should be made of gram-positive rods, with or without spores, because sporulation in tissue is not common for the two species most frequently encountered in wound and abscess materials, *C. perfringens* and *C. ramosum*. *C. perfringens* usually appears as large, relatively short, fat, gram-positive rods with blunt ends and often in short chains in tissue smears; the cells of *C. ramosum* are more slender and longer (Fig. 4). *C. perfringens* may or may not be encapsulated in smears from wounds; capsules usually are present in smears of endometrial specimens from postabortion *C. perfringens* infections. Spore stains offer no advantage over Gram stains for demonstration of spores, but examination with a phase-contrast or dark-field microscope may be helpful if the spores are close to maturity. If spores are present, shapes (spherical or oval) and positions (terminal, subterminal, or central) in the cells should be noted.

Direct Toxin Detection

Bioassays for BoNT and TeNT are currently the most important laboratory tests for diagnosis of botulism and tetanus (46, 56, 84). The definitive diagnosis of botulism is the detection of BoNT (not the organism) (84). Currently, the only reliable assay for BoNT is the mouse bioassay together with neutralization of mouse toxicity with type-specific antitoxins (84). Detection of neurotoxins is usually performed on fecal specimens, blood (serum), suspect foods in food-borne botulism cases, and culture fluid following enrichment by growth of the organism (46, 84). Enzyme-linked immunosorbent assays (ELISAs) have also been used to detect BoNT (56, 158), and cell culture systems (82) and biosensor platforms (55, 158) are in development for BoNT detection (158). Real-time PCR assays for detection of *C. botulinum* BoNT gene fragments specific to BoNT A, B, and E have been developed as alternatives to the mouse bioassay; this approach was found to demonstrate a sensitivity and specificity similar to those of conventional approaches (5).

Antigen Tests for Diagnosis of *C. difficile* Disease

Controversy exists about which of the multiple methods for the detection of *C. difficile* and its toxins is optimal. Toxin detection and neutralization by a cell culture cytotoxin assay are often considered the "gold standard" when new detection methods are evaluated. A confirmed diagnosis of *C. difficile*-associated enteric disease on the basis of both clinical and laboratory criteria represents the ultimate gold standard. Cytotoxicity assay for toxin B is considered the gold standard due to its high sensitivity (94 to 100%) and high specificity (99%) (35, 54). However, the assay is costly and technically demanding and has a slow turnaround time. Therefore, it is not widely used in clinical laboratories. Cytotoxin B neutralization assays are commercially available (Table 2).

The commercially available enzyme immunoassays (EIAs) (Table 2) generally show lower sensitivities and specificities (45 to 95% and 75 to 100%, respectively) than tissue culture assay (35, 134, 178). In general, the relative sensitivities and specificities for the various tests vary considerably, depending upon the laboratory and the method to which the test is compared. Although the sensitivity is lower, the rapid turnaround time of the EIAs and their ease of use explain the preference of many laboratories for an EIA procedure (186). EIAs that detect both toxins A and B are preferable since some strains of *C. difficile* produce only one toxin or the other (186).

Most of the EIAs for detection of toxin A and/or toxin B in stool are microwell format assays, but several membrane-based EIAs are also available (Table 2). The membrane-based EIAs offer an even faster turnaround time than many of the microwell formats, although that of the microwell EIAs from Meridian Bioscience (Cincinnati, Ohio) and TechLab (Blacksburg, Va.) can be shortened considerably by utilizing a shaking incubation step. The microwell formats offer increased sensitivity and specificity over membrane-based EIAs (61). However, one study found the Triage *C. difficile* Micro Panel (Biosite Diagnostics, San Diego, Calif.) and two new chromatographic immunoassays (Clearview *C. difficile* A [Inverness Medical Professional Diagnostics, Princeton, N.J.] and ColorPac Toxin A [Becton Dickinson, Sparks, Md.]) to be more sensitive than conventional EIAs (178). Similarly, the ImmunoCard Toxins A&B (Meridian Bioscience) was found to provide a high specificity and sensitivity and to be suitable for rapid screening for CDAD (177).

The common antigen glutamate dehydrogenase (GDH) does not differentiate between toxigenic and nontoxigenic strains and cannot establish a diagnosis for CDAD because colonization with *C. difficile* is frequent in hospitalized patients. However, testing for GDH has proven useful as a screening test due to its high negative predictive value. A preferred laboratory approach for the diagnosis of CDAD is to test the stool specimens for GDH and, if positive, to test the specimens by EIA for toxin detection (134, 166). The GDH-positive but toxin-negative specimens should be further tested with a cell culture-based cytotoxin assay. The Triage *C. difficile* Micro Panel provides simultaneous detection of toxin A and GDH. Several studies have found the Triage to provide a suitable, rapid alternative for the diagnosis of CDAD (121, 134, 166, 178). Laboratory results obtained with the commercial kits must be correlated and interpreted within the context of the patient's clinical presentation.

Currently PCR is used mostly as a research tool in laboratories for detecting *C. difficile* toxin genes directly in fecal

specimens. Real-time PCR has been successfully used for quantitative detection of *C. difficile* and its toxins in fecal samples (26, 177). Also, a multiplex PCR toxin approach has been designed for simultaneous identification and toxigenic type characterization of *C. difficile* isolates (123).

Tests for Diagnosis of CPE

Testing of food sources of *C. perfringens* illness is a public health function (see chapter 12). Several methods have been described for the detection of CPE in feces, including cell culture assays, ELISA, and reversed-phase latex agglutination (RPLA) (139). The cell culture assay using Vero cells is not as sensitive or reproducible as other methods (19, 69). The RPLA kit (PET-RPLA; Oxoid, Hampshire, United Kingdom, and Remel Inc., Lenexa, Kans.) was reproducible and reasonably sensitive; however, nonspecific interference by fecal matter has been reported (139). Similarly, the background bacterial DNA in stool has been reported to interfere with PCR amplification of the enterotoxin gene (139). While an in-house ELISA system developed by the Food Safety Microbiology Laboratory of the Public Health Laboratory Service has been reported to be the most sensitive assay and considered the gold standard, the TechLab *C. perfringens* enterotoxin ELISA system provided a specific, reliable, and practical tool for detecting CPE in fecal samples (19, 69).

ISOLATION PROCEDURES

A summary of useful procedures for culture and isolation of clostridia is provided below. Clostridia usually produce good growth on commercially available CDC anaerobe blood agar and phenylethyl alcohol blood agar (PEA) after 1 to 2 days of incubation. Brucella agar with 5% sheep blood, Columbia agar, or brain heart infusion agar supplemented with yeast extract, vitamin K, and hemin may also be used as the nonselective blood agar medium. Colony characteristics vary on different media. A few species, such as *C. perfringens,* form colonies after overnight incubation or in as little as 6 h. When clostridia are suspected in wound or abscess specimens (e.g., gas gangrene), egg yolk agar (modified McClung-Toabe formula; see chapter 21) may also be inoculated.

After incubation, the blood agar and PEA cultures should be examined under a dissecting microscope, with attention to the hemolysis pattern, colony structure, and any evidence of swarming or motile colonies. Egg yolk agar should be examined for evidence of lecithinase (Fig. 1) or lipase production. Lecithinase activity is indicated by the development of an insoluble, opaque, whitish precipitate within the agar. An iridescent sheen or oil-on-water appearance (pearly layer) indicates lipase activity. Proteolysis, the third reaction that can be seen on egg yolk agar, is indicated by a zone of translucent clearing in the medium around the colonies. In addition to the modified McClung-Toabe egg yolk agar formulation, the same reactions can be visualized on the hemin-supplemented egg yolk agar formulation recommended by Jousimies-Somer et al. (99) or on Lombard-Dowell egg yolk agar (187a).

Isolation of additional strains in the presence of swarming *Proteus* species or *C. septicum* may require short incubation times (18 to 24 h), subculture onto PEA, or use of anaerobe blood agar with 4% agar ("stiff blood agar"). When isolated colonies can be picked, they should be subcultured to chopped-meat medium, and the culture should be incubated overnight and used for the inoculation of differential media. In addition, prereduced, anaerobically sterilized (PRAS) peptone-yeast-glucose media may be inoculated for gas-liquid chromatography if the laboratory has that capability.

Spore Selection Techniques

Heat (80°C) or ethanol treatment procedures can aid in detecting spores (99, 108). Ethanol may be more effective than heat if the specimen contains relatively heat-sensitive clostridia (e.g., *C. botulinum* type E and some strains of *C. perfringens* involved in food-borne outbreaks). Heat treatment may be more effective than alcohol if homogenization is incomplete and the specimen contains particulate matter that is not penetrated adequately by the alcohol. For any spore selection technique, an untreated control subculture should be prepared.

Alcohol Treatment

To a 1-ml sample of a fecal suspension or homogenate of a wound or exudate, in a sterile screw-cap tube, an equal volume of absolute (or 95%) ethanol is added. The specimen is gently mixed at room temperature (22 to 25°C for 1 h). An Ames aliquot mixer (Miles Laboratories, Inc., Elkhart, Ind.) is a convenient way to provide continuous mixing. The treated material is used to inoculate chopped-meat–glucose or thioglycolate medium, anaerobe blood agar, or egg yolk agar. The culture is incubated and inspected for growth.

Heat Treatment

For heat treatment, a tube of chopped-meat–glucose or thioglycolate medium (5 ml) is preheated in an 80°C water bath for 5 min, and 1 ml of sample suspension is added. The culture is heated for 10 min, and the tube is removed and cooled in cold water. The treated sample suspension is subcultured into an unheated tube of chopped-meat–glucose or thioglycolate medium, anaerobe blood agar, or egg yolk agar. The cultures are incubated anaerobically and examined for growth.

Isolation of *C. difficile*

Culture alone (without subsequent testing of *C. difficile* isolates for toxin production) results in lower specificity and misdiagnosis of CDAD, especially when *C. difficile* carriage is prevalent. Testing isolates with a toxin assay by cell culture or EIA provides the organism for epidemiological studies and for antimicrobial susceptibility testing, if required. To perform a culture for *C. difficile,* a stool specimen should be inoculated directly onto cycloserine-cefoxitin-fructose agar (CCFA) (see chapter 21). The culture should be incubated anaerobically at 35 to 37°C for 18 to 24 h before observation. Following incubation, the plates should be examined by using a dissecting microscope. Colonies of *C. difficile* are yellowish to white, circular to irregular, and flat, with a rhizoid or erose edge and a ground-glass appearance (Fig. 2). The colonies have a distinctive odor like *para*-cresol (or horse manure). In addition, *C. difficile* colonies on CCFA fluoresce chartreuse under UV light (99).

In addition to the use of CCFA medium, *C. difficile* from fecal samples can be isolated by using the alcohol or heat shock spore selection technique. After 18 to 24 h of incubation on blood-containing agar, colonies from treated samples are nonhemolytic, 2 to 4 mm in diameter, creamy yellow to gray-white, and irregular. The colonies have a coarsely mottled to mosaic internal structure and a matte or dull surface, and they are seen to be slightly raised when viewed under a dissecting microscope. The odor is distinctive. Gram staining of *C. difficile* reveals gram-positive to gram-variable rods that are thin, with parallel sides, and 0.5 μm wide by 3 to 5 μm long. If spores are present, they are subterminal. Presumptive

identification of *C. difficile* can be made by demonstrating typical colonies, Gram stain morphology, and characteristic odor. Definitive identification depends on demonstration of the unique pattern of short-chain fatty acid metabolic products by gas-liquid chromatography (GLC) and by biochemical characterization of isolates (12, 74, 90) (see Table 1).

IDENTIFICATION

Preliminary Identification of *Clostridium* Species

Clostridia are typically gram-positive rods by microscopic morphology. Some clostridia appear gram negative, especially *C. ramosum, C. innocuum,* and the *C. clostridioforme* group, but the special-potency antibiotic disk pattern will verify the presence of gram-positive organisms. Second, it may be difficult to detect spores, so an ethanol or heat spore treatment may be necessary, and phase-contrast or dark-field microscopy may be helpful. Third, the colonial morphology of pure cultures may be variable, so the culture may appear to be mixed. Subcultures of single, well-isolated colonies yield the same variable morphologies. Examination of colonies by stereomicroscopy is helpful for noting colonial characteristics. Fourth, the aerotolerant clostridia may be confused with *Bacillus* or *Lactobacillus* spp. *Clostridium* species sporulate anaerobically only, grow much better anaerobically (larger colonies), and are almost always catalase negative. *Bacillus* spp. sporulate aerobically only, usually grow better aerobically, and are usually catalase positive. Aerobically grown *C. tertium* shares similar colonial and cellular morphologies with *Lactobacillus* spp. Certain clostridia can be identified with relative ease by Gram stain and colony morphology, indole reaction, hemolysis on blood agar, and tests decribed below (Table 3).

Special-Potency Disks

The isolate should be subcultured on blood agar with special-potency disks containing vancomycin (5 μg), kanamycin (1 mg), or colistin (10 μg). The plates should be incubated anaerobically for 48 to 72 h at 35 to 37°C. Clostridia are colistin resistant and vancomycin susceptible (Table 3), except for occasional *C. innocuum* isolates, which may be only moderately susceptible to vancomycin (7).

Lecithinase and Lipase

The isolate should be subcultured on egg yolk agar and incubated anaerobically for 48 to 72 h at 35 to 37°C. Lecithinase activity is demonstrated by a white, opaque, diffuse zone around the colonies and extending into the medium (Fig. 1). Lipase activity is indicated by an iridescent sheen on the surface of bacterial growth and on the agar surface around the colonies.

Spore Test

Media for the demonstration of spores include chopped-meat agar slant or broth and thioglycolate medium. The culture should be incubated anaerobically at 5 to 7°C below the optimum temperature (30°C) for growth and sporulation of clostridia, except for *C. perfringens* (should be induced at 37°C). Actively growing cultures may stand at room temperature for several days to 1 week, and ethanol or heat spore treatments can be performed as described above.

Definitive Identification of *Clostridium* Species

The traditional method for the phenotypic characterization and identification of clostridia is the use of PRAS media for the determination of fermentation profiles and other characteristics combined with GLC analysis of metabolic end products (99). However, only a few laboratories have PRAS media or GLC available. Table 1 lists characteristics that are useful for definitive identification of clinically relevant clostridia. The key reactions (bold in Table 1) require minimal PRAS media and can be used in conjunction with commercial identification kits or individual preformed-enzyme tests such as Wee Tabs (Key Scientific, Round Rock, Tex.) or Rosco Diagnostic Tablets (Rosco, Taasrup, Denmark). Gelatin and esculin hydrolysis, carbohydrate fermentation reactions, and metabolic end product analysis (Table 1) are based on results obtained with PRAS media (Anaerobe Systems, Morgan Hill, Calif.).

PRAS Biochemical Inoculation

Actively growing broth cultures (without carbohydrate) or cell pastes suspended in broth medium (e.g., peptone-yeast or thioglycolate) may be used to inoculate PRAS media. The cultures are incubated for 48 to 72 h at 35 to 37°C, and overnight incubation may be sufficient for many clostridia.

Gelatin Hydrolysis

A PRAS gelatin tube with an actively growing culture is refrigerated along with an uninoculated tube for at least 1 h. The tubes are removed to room temperature, inverted immediately, and observed for liquefaction every 5 min. In a positive reaction, the gelatin has been hydrolyzed and thus fails to solidify and will drop to the top of the inverted tube immediately. In a negative reaction, the medium fails to liquefy when it reaches room temperature (>30 min).

TABLE 3 Rapid identification of some lecithinase-positive and/or swarming *Clostridium* spp. of clinical significance[a]

Species	Lecithinase	Lipase	Indole	Swarming	Urease	Spore location	Other characteristics
C. bifermentans	+	–	+	–	–	ST	Chalk-white colonies on EYA
C. novyi A	+	+	–	+	–	ST	Robust beta-hemolysis
C. perfringens	+	–	–	–	–	ST	Double zone of beta-hemolysis Reverse CAMP positive
C. sordellii	+	–	+	–	+	ST	Large gram-positive bacilli
C. septicum	–	–	–	+	–	ST	Rare spores Spreading, adherent colonies
C. sporogenes	–	+	–	+	–$^{+}$	ST	Abundant oval spores
C. tetani	–	–^{w}	v	+	–	T	Drumstick shaped

[a] EYA, egg yolk agar; for other abbreviations and symbols, see Table 1, footnote *a*.

A weakly positive reaction yields liquid medium at the time it reaches room temperature (<30 min).

Esculin Hydrolysis

Five drops of 1% ferric ammonium citrate are added to a tube of actively growing bacteria in a PRAS esculin tube, and the tube is observed for a color change and fluorescence under UV (366 nm) light. In a positive reaction, a black or dark brown color may develop, and there is no fluorescence under UV light. In a negative reaction no color develops, and the tube fluoresces white-blue under UV light. Since many clostridia produce hydrogen sulfide (H_2S), which also reacts with the reagent to form a black complex, all tubes that darken after the addition of reagent should be confirmed under UV light.

Carbohydrate Fermentation

The pH of actively growing organisms (at least 2+ turbidity) should be measured in a PRAS carbohydrate tube. A positive reaction ("acid") yields a pH below 5.5, and a negative reaction results in a pH exceeding 5.9. "Weak acid" is indicated by a pH of 5.6 to 5.8. Details of GLC procedures used for the analyses of metabolic end products listed in Table 1 are outlined elsewhere (99).

Commercial kits, based on the detection of preformed enzymes with chromogenic or fluorogenic substrates, have been marketed for the rapid identification of anaerobes. These panels include RapID ANA II (Remel), RapID 32A (bioMerieux, Durham, N.C.), Vitek ANI Card (bioMerieux), and BBL Crystal Anaerobe Identification System (BD, Franklin Lakes, N.J.). The overall performance of these panels varies, and the panels are generally not satisfactory as the sole identification method for clostridia. In the RapID ANA II system, 74% of the 130 clostridia tested were correctly identified to the species level (132). Identification was correct for *C. perfringens* and *C. ramosum* but less likely to be correct for other commonly encountered clostridia, such as *C. difficile, C. innocuum,* and *C. clostridioforme* (132). Similarly, in another study, 100% of 20 *C. ramosum* isolates, 24% of 21 *C. innocuum* isolates, 50% of 20 *C. clostridioforme* isolates, and 91% of 11 *C. perfringens* isolates were correctly identified by RapID ANA II (7). In the same study, Rapid ID 32A identified 70% of *C. ramosum* isolates, 0% of *C. innocuum* isolates, 40% of *C. clostridioforme* isolates, and 46% of *C. perfringens* isolates correctly (7). Neither the RapID ANA II nor the Rapid ID 32A test system was found to provide a reliable method for identification of *C. botulinum* (126). The Vitek ANI Card identified only 64% of clostridia correctly; all *C. perfringens* isolates (total of 8) and 64% of *C. difficile* isolates (7 of 11 total isolates) were correctly identified to the species level (156). The BBL Crystal Anaerobe Identification System (BD) correctly identified 79 of 103 (76.7%) *Clostridium* strains, but the system failed to identify any of the 7 *C. innocuum* or 9 *C. tetani* strains tested (45).

In general, Gram reaction, cellular morphologies, colonial characteristics, and aerotolerance of isolates should be determined in conjunction with the use of commercial microsystems. Supplementation of tests in these kits with individual tablets (e.g., Wee Tabs or Rosco Tablets) can be helpful. Other useful supplemental tests for clostridia include the tests outlined above, such as lipase and lecithinase, the reduction of nitrate, gelatin and esculin hydrolysis, carbohydrate fermentation, and metabolic end product analysis using GLC.

Characteristics of Commonly Encountered Clostridia

Key characteristics that aid in the presumptive identification of the most common species are listed below. See Tables 1 and 3.

- *C. bifermentans:* colonies chalk-white on egg yolk agar, irregular, scalloped edge; many free spores, often chaining; urease negative; indole and lecithinase positive. *C. sordellii* is similar but is usually urease positive.
- *C. bolteae:* colonies usually have a slightly irregular edge; greening of agar around colonies; gram negative; tapered ends; spores are rare. Lactose negative and β-*N*-acetylglucosaminidase (β-NAG) negative.
- *C. butyricum:* very large, irregular colonies with mottled to mosaic internal structure; subterminal spores; ferments many carbohydrates.
- *C. cadaveris:* white-gray, entire or slightly irregular, raised to slightly convex; oval terminal spores; spot indole positive.
- *C. clostridioforme:* same as for *C. bolteae* but lactose positive and β-NAG negative.
- *C. difficile:* colonies creamy yellow to gray-white (Fig. 2), irregular, coarse, mottled to mosaic internal structure, matte or dull surface, horse stable odor; subterminal to free spores or spores infrequent; gelatin hydrolysis can be slow. Mannitol and proline positive; colonies fluoresce chartreuse on CCFA.
- *C. glycolicum:* colonies gray-white, entire to scalloped edge, convex; subterminal and free spores.
- *C. hathewayi:* same as for *C. bolteae* but lactose and β-NAG positive.
- *C. innocuum:* gray-white to brilliant greenish colonies, coarsely mottled to mosaic internal structure, entire edge usually; terminal spores may be difficult to find; nonmotile; mannitol positive; lactose, maltose, and proline negative.
- *C. novyi* type A: lecithinase and lipase positive, may swarm, strong beta-hemolysis.
- *C. perfringens:* double zone of beta-hemolysis around colonies (Fig. 3), boxcar-shaped rods, spores rare, lecithinase positive (Fig. 1).
- *C. ramosum:* colonies resemble *Bacteroides fragilis* but usually have a slightly irregular edge; gram-variable, palisading, slender rods; small round or oval terminal spores (Fig. 4); nonmotile; mannitol positive.
- *C. septicum:* swarms (Fig. 5), large, filamentous bacilli (Fig. 6), subterminal spores often "lemon" forms, DNase positive, sucrose negative.
- *C. sporogenes:* medusa-head colonies, possible swarming, colonies adhere firmly to agar; subterminal and many free spores; lipase positive.
- *C. symbiosum:* rods with tapered ends, football shaped, may form chains, often has spores.
- *C. tertium:* aerotolerant, terminal spores when anaerobically incubated.
- *C. tetani:* may form a thin film of growth over entire agar plate, especially on moist media; drumstick spores.

Toxin tests are necessary for the identification of a few species. *C. sporogenes* cannot be differentiated with certainty from the proteolytic group I strains of *C. botulinum* unless

toxin tests are used. A few strains of *C. botulinum* produce lecithinase as well as lipase and are difficult to distinguish from *C. novyi* type A except by toxin tests or by the use of a *C. novyi* fluorescent-antibody conjugate (165). An excellent source of diagnostic clostridial antisera is TechLab. As a supplement to the methods described, the various types of *C. botulinum* and other clostridia can be presumptively identified on the basis of differences in their cellular fatty acid profiles (12, 74, 90) and by typing methods such as pulsed-field gel electrophoresis or other molecular analyses. Finegold et al. (67) described a multiplex PCR procedure for the rapid distinction among the three species of the *C. clostridioforme* group.

ANTIMICROBIAL SUSCEPTIBILITIES

Antimicrobial susceptibility studies with strains of a number of clostridial species are summarized in Table 4. Now that more laboratories are identifying anaerobes by 16S rRNA gene sequencing, more accurate species identification will be available and more reliable susceptibility data can be generated. Drugs lacking antimicrobial activity against various clostridia include trimethoprim-sulfamethoxazole (a drug noted for promoting intestinal overgrowth of clostridia [83]), ampicillin, and clindamycin. No resistance of clostridia to ampicillin-sulbactam or piperacillin-tazobactam was noted, and antimicrobial resistance was uncommon among clostridia with respect to imipenem, metronidazole, and vancomycin. Five species (all with small numbers of strains) and *C. perfringens* showed little or no resistance to the antimicrobial agents under consideration (Table 4). Organisms with some resistance to three drugs included *C. ramosum, C. innocuum,* and *C. clostridioforme;* two strains of *C. orbiscindens* displayed resistance to ampicillin as well as linezolid.

Multiple studies have described resistance to various antibiotics among clostridia. Resistance to penicillin is especially common in *C. ramosum, C. clostridioforme,* and *C. butyricum* (64, 152); these species produce β-lactamases that are induced by β-lactam antibiotics (88). *C. tertium* has resistance features unusual among clostridia, including resistance to β-lactam antibiotics, metronidazole, and clindamycin. Resistance to clindamycin has been documented for strains of *C. perfringens* (as noted above), *C. ramosum, C. difficile, C. tertium, C. subterminale, C. butyricum, C. sporogenes,* and *C. innocuum* (187a).

Chloramphenicol, piperacillin, metronidazole, imipenem, and combinations of β-lactams with β-lactam inhibitors (e.g., ampicillin-sulbactam) were active against most clostridia (187a). The clostridia are variably resistant to cephalosporins and tetracyclines, and they are usually resistant to the aminoglycosides. Many clostridia other than *C. perfringens* (particularly *C. ramosum, C. clostridioforme,* and *C. innocuum*) are resistant to cefoxitin, cefotaxime, ceftazidime, ceftizoxime, cefoperazone, and other broad-spectrum β-lactams (7, 64, 152, 187a). Most strains of *C. innocuum* were only moderately susceptible to vancomycin (7). *C. innocuum* may be intrinsically resistant to this compound (141).

Earlier quinolones, such as ciprofloxacin, levofloxacin, and lomefloxacin, have demonstrated low or intermediate activity against anaerobes, but more recently introduced quinolones, like moxifloxacin, gatifloxacin, trovafloxacin, and garenoxacin, have good activity in vitro against most anaerobes, including clostridia (1, 125). A high frequency of moxifloxacin resistance has been described among *C. difficile*

TABLE 4 Activities of various drugs against *Clostridium* spp. (Wadsworth agar dilution procedure)[a]

[a] Clinical and Laboratory Standards Institute (CLSI) approved method M11-A6 (50a); data from Wadsworth Anaerobic Bacteriology Laboratory.
[b] According to the CLSI-approved breakpoints (M11-A6) (50a), the intermediate category is susceptible.
[c] Strains producing β-lactamase should be considered resistant.
[d] Five or fewer strains were tested.

isolates (3), and quinolone resistance is a problem among pathogens.

Severe *C. difficile*-associated intestinal disease is usually treated with oral vancomycin or metronidazole, but recently a number of metronidazole failures have been noted. Relapse of disease following antibiotic therapy occurs in about 30% of patients. Surgical therapy is required in the event of bowel perforation and toxic megacolon.

Patients diagnosed with food-borne or wound botulism should immediately receive trivalent (type ABE) antitoxin and intensive respiratory care (17, 46, 84). Early administration of antibodies can decrease the severity of the disease and slow its progression, resulting in a shorter hospital stay and more rapid recovery (16, 18, 84). Convalescence and recovery from botulism are generally prolonged, requiring weeks to months depending on the quantity of toxin exposure and serotype (serotype A has the longest duration, 1 to 6 months), but recovery is usually complete and patients regain normal function (16, 50, 84). Symptoms of fatigue, muscular weakness, and constipation have been reported to persist for months in certain patients (50).

Surgical measures are especially important in the treatment of gas gangrene and a number of *Clostridium* infections. The effect of clindamycin (and metronidazole) on toxin suppression by *C. perfringens* and other gram-positive organisms is an important reason to utilize such an agent in addition to penicillin or other β-lactam agents in the management of serious infections such as anaerobic myonecrosis (gas gangrene).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The isolation of a *Clostridium* species from a clinical specimen, even a blood culture, may or may not be significant clinically, and culture results should be interpreted in relation to the patient's clinical findings. Clostridia of the patient's own intestinal microbiota may be present on the skin and may contaminate blood samples or other specimens. Bacteremia may be transient or clinically insignificant. In addition, most clostridia currently encountered in wounds, exudates, blood, and other normally sterile body fluids are opportunistic and may not cause serious or progressive disease unless conditions are suitable in the host. As discussed earlier in this chapter, one exception to this generalization is *C. septicum,* which rarely is encountered in blood cultures except from patients who have an underlying malignancy or neutropenic sepsis. *C. septicum* sepsis is an infectious disease emergency that requires prompt and clear communication between the laboratory and the clinician in order to institute early surgical measures and treatment with antimicrobial agents to improve outcomes. *C. tertium, C. perfringens,* and other clostridia, to a lesser extent, may be involved in serious infections that require emergency measures. The best approach for preventing tragic consequences that may be avoidable is good communication between microbiologists and clinicians.

The accurate and timely reporting of preliminary results (e.g., findings from direct microscopic examinations of clinical specimens), as well as early culture results (after 24 and 48 h of incubation), can be extremely valuable to the physician. For smaller laboratories without anaerobic chambers, incubation of the appropriate media in anaerobic jars provides acceptable recovery for most clinically significant anaerobes, assuming that optimal collection and transport of specimens are performed. The colony characteristics and microscopic features of some clostridia (e.g., *C. perfringens, C. sordellii,* and *C. sporogenes*) may be distinctive, so preliminary or presumptive reports may be released before aerotolerance studies are completed. Accurate, definitive identification is needed to better define the role of clostridia in disease, to aid the clinician in selecting optimal treatment, and for public health purposes (e.g., hospital-acquired *C. difficile* disease).

Bacteroides, Porphyromonas, Prevotella, Fusobacterium, and Other Anaerobic Gram-Negative Rods*

DIANE M. CITRON, IAN R. POXTON, AND ELLEN JO BARON

58

TAXONOMY

The anaerobic gram-negative bacteria are part of the normal flora of the mouth, upper respiratory tract, intestinal tract, and urogenital tract of humans and animals. Anaerobic spirochetes are covered in chapter 63, and *Campylobacter* spp. other than *Campylobacter rectus, Campylobacter curvus, Campylobacter gracilis,* and *Campylobacter showae* are discussed in chapter 59. The anaerobic gram-negative rods belong to the phyla *Bacteroidetes* and *Fusobacteria* and the families *Bacteroidaceae, Porphyromonadaceae*, *Prevotellaceae*, and *Fusobacteriaceae*. Species definition is based on biochemical characteristics, nucleic acid base composition, and homology (see chapter 19). *Veillonella* and the other anaerobic gram-negative cocci are covered in chapter 55. In the majority of clinical specimens, organisms of the genera *Bacteroides, Porphyromonas, Prevotella, Fusobacterium, Campylobacter*, *Sutterella,* and *Bilophila* are most often encountered (65).

The taxonomy of the gram-negative rods has been changing in recent years (14, 25, 64). A number of new genera and species have been named since the last edition of this book (Table 1). The methods used for taxonomic studies have been based mainly on nucleic acid analyses such as DNA-DNA hybridization and 16S rRNA and other gene sequencing (25). The latter classification approach, based on phylogenetic relatedness, does not necessarily correlate with phenotypic characteristics, such as Gram-staining properties, morphology, atmospheric growth requirements, and sporulation, concepts that were earlier considered cornerstones in the classification of anaerobes (68, 102). In fact, several species currently thought of as anaerobic gram-negative rods (*Butyrivibrio* spp., *Catonella morbi, Dialister pneumosintes, Fusobacterium* spp., *Leptotrichia* spp., *Johnsonella ignava, Tissierella* spp., *Mitsuokella multiacida, Selenomonas* spp., *Centipeda periodontii)* cluster within the *Clostridium* subphylum of the gram-positive bacteria (23, 60). Some of them are discussed in chapters 56 and 57.

The genus *Bacteroides* includes bile-resistant species that were formerly described as the "*Bacteroides fragilis*" group (including *Bacteroides eggerthii*) (78, 102, 125). However, the *B. fragilis* group organisms *Bacteroides distasonis, B. goldsteinii,* and *B. merdae* are related to *Tannerella forsythensis* (formerly *Bacteroides forsythus*) and cluster close to *Porphyromonas* on the basis of 16S rRNA sequencing (102, 103). A new genus, *Parabacteroides*, has been proposed to encompass these three species (M. Sakamoto, unpublished data). Similarly, *Bacteroides splanchnicus* falls far outside the group and probably represents a new genus (103). On the other hand, the bile-sensitive *Prevotella heparinolytica* and *Prevotella zoogleoformans* cluster among the *B. fragilis* group (102). Inclusion of these species warrants redefinition of the *B. fragilis* group. The taxonomic positions of other species still included in the genus *Bacteroides* remain uncertain, but all of these will ultimately be transferred to other genera. *Porphyromonas catoniae* is the only nonpigmented taxon in the genus *Porphyromonas* (144). Animal strains similar to *Porphyromonas gingivalis* are called *Porphyromonas gulae* (43). 16S rRNA sequencing results have identified two new closely related gram-negative species named *Alistipes finegoldii,* which is pigmented, bile resistant, and weakly saccharolytic, and *A. putredinis*, which is asaccharolytic and nonpigmented (111). The asaccharolytic, formate- and fumarate-requiring gram-negative rods *Bacteroides ureolyticus, C. gracilis* (formerly *B. gracilis*), *C. curvus, C. rectus* (formerly *Wolinella curva* and *W. recta*), and *Sutterella wadsworthensis* are actually microaerophiles. *Campylobacter hominis* is a truly anaerobic campylobacter from the human gastrointestinal tract (77). *Wolinella succinogenes,* isolated from the bovine rumen, is the only species remaining in the genus *Wolinella.* The taxonomic position of *B. ureolyticus* has remained uncertain; additional studies are required to determine whether these organisms should be transferred to the genus *Campylobacter* or if they represent a new genus (139). Sulfate-reducing *Desulfomonas pigra* was renamed *Desulfovibrio piger,* and the genus *Desulfomonas* is no longer valid (80).

DESCRIPTION OF THE GROUP

The true anaerobic gram-negative bacteria are differentiated from facultatively anaerobic bacteria by their inability to grow in the presence of oxygen and their susceptibility to metronidazole. Metronidazole resistance in these genera is rare and usually due to a laboratory error or an incorrect identification. Some of the species included here are indeed microaerophiles and are often resistant to metronidazole; the appropriate atmospheric requirements should be determined for all isolates. Cell morphology varies from short coccobacilli

*This chapter contains information presented in chapter 56 by Hannele R. Jousimies-Somer, Paula H. Summanen, Hannah Wexler, Sydney M. Finegold, Saheer E. Gharbia, and Haroun N. Shah in the eighth edition of this Manual.

TABLE 1 New anaerobic gram-negative rods named since the last edition of this Manual

New genus or species	Previous designation	Isolated from:	Reference
Alistipes putredinis	*Bacteroides putredinis*	Appendicitis specimens	111
Alistipes finegoldii	New	Appendicitis specimens	111
Bacteroides coprocola	*B. vulgatus-like*	Human feces	69
Bacteroides goldsteinii	*B. distasonis*-like	Human infections (intestinal origin)	126
Bacteroides nordii	*B. uniformis*-like	Human infections (intestinal origin)	127
Bacteroides plebeius	*B. vulgatus*-like	Human feces	69
Bacteroides salyersiae	*B. uniformis*-like	Human infections (intestinal origin)	127
Cetobacterium somerae	New	Children's feces	40
Desulfovibrio piger	*Desulfomonas pigra*	Human infections (intestinal origin)	80
Dialister micraerophilus	New	Human clinical samples	67
Dialister propionicifaciens	New	Human clinical samples	67
Faecalibacterium prausnitzii	*Fusobacterium prausnitzii*	Feces	32
Fusobacterium canifelinum	*F. nucleatum*-like	Oral cavity of cats and dogs; bite infections	24
Fusobacterium equinum	*F. necrophorum*-like	Oral cavity of horses	28
Porphyromonas gulae	*P. gingivalis*—animal strain	Gingival sulcus of animals	43
Porphyromonas somerae	*Porphyromonas levii*-like	Human skin, soft tissue, bone infections	130
Porphyromonas uenonis	*P. endodontalis*-nonoral	Human infections (nonoral)	41
Prevotella baroniae	New	Human oral cavity	30
Prevotella marshii	New	Human oral cavity	30
Prevotella multiformis	*P. denticola*-like	Human subgingival plaque	113
Prevotella multisaccharivorax	New	Human subgingival plaque	117
Prevotella salivae	*P. oris*-like	Human oral cavity	114
Prevotella shahii	*P. loeschii*-like	Human oral cavity	114
Sneathia sanguinegens	*Leptotrichia sanguinegens*	Human blood	22
Tannerella forsythensis	*Bacteroides forsythus*	Human periodontal pockets	115

to long, thin, pointed forms. The age of the culture, nutritional status, and exposure to air strongly affect morphology.

EPIDEMIOLOGY AND TRANSMISSION

Gram-negative anaerobic rods inhabit the mucosa of animals and humans. They are the predominant species in the oral cavity, the gastrointestinal tract, and the vaginal tract (in bacterial vaginosis; otherwise lactobacilli predominate). Most infections are acquired endogenously, when the integrity of the colonized mucosa or lumen is breached by trauma, disease (cancer), or iatrogenically (during surgery). Along the gastrointestinal tract, luminal populations appear to differ from adherent/mucosal strains. *B. vulgatus* and *B. thetaiotaomicron* are luminal and thus more commonly isolated from feces (100, 108). The predilection to adherence among *B. fragilis* may contribute to its predominance among the group as a pathogen, which, along with its relative aerotolerance, allows survival in hostile, oxygenated environments prior to establishment of the infection (112). Aspiration pneumonia, characterized by mixed anaerobes including gram-negative rods from the mouth, occurs during lapses of consciousness or other sedation events. Exceptions to endogenous acquisition of infection include clenched-fist wounds and animal and human bite wounds, which occur when the oral contents of an animal or person are implanted traumatically through the skin into the underlying tissue (131, 132). These infections invariably involve mixed flora, often with aerobic organisms. It is possible that *B. fragilis* is associated with diarrhea in children and that some toxigenic *B. fragilis* group may be transmitted from livestock, but that has not been proven (104).

CLINICAL SIGNIFICANCE

Gram-negative anaerobic rods predominate among anaerobes in clinical infections; they are found in more than one-half of the specimens yielding anaerobes (37, 65). Among the anaerobes encountered in clinical specimens, members of the bile-resistant *B. fragilis* group are the most commonly encountered and are more virulent and resistant to antimicrobial agents than most other anaerobes (91). *B. fragilis* and *Bacteroides thetaiotaomicron* are of the greatest clinical significance (44). Members of the *B. fragilis* group are major constituents of the normal colonic flora but are not common in the genital tract, mouth, or upper respiratory tract (108). These species are often found among the mixed microbiota of abscesses in tissue adjacent to their normal mucosal environments (intra-abdominal abscess or female genital tract abscess, for example). Some *B. fragilis* strains produce a potent zinc-dependent metalloprotease or enterotoxin with a variety of pathological effects on intestinal mucosal cells (119). The enterotoxin induces interleukin-8 production, which probably accounts for the inflammatory damage seen in *B. fragilis* diarrhea (145). *B. fragilis* also possesses lipopolysaccharides (LPS) and capsular polysaccharides of varying structure, antigenicity, and biological activity, which appear to play a role in periodontal disease and abscess formation (137, 141).

The pigmented anaerobic gram-negative rods are composed of saccharolytic and asaccharolytic species of the genera *Prevotella, Porphyromonas,* and *Alistipes finegoldii*. Several species of these genera are found in human clinical specimens. *Prevotella corporis, Prevotella denticola, Prevotella intermedia, Prevotella loescheii, Prevotella melaninogenica, Prevotella nigrescens, Prevotella pallens, Prevotella tannerae, Porphyromonas endodontalis, P. gingivalis,* and the nonpigmented species *P. catoniae* are found in the human oral cavity (116). Some are important pathogens in oral, dental, and bite infections and may produce infections of the head, neck, and lower respiratory tract. *P. gingivalis* and *Tannerella forsythensis* are the putative key pathogens (with *Treponema denticola*) in aggressive forms of adult periodontitis and, together with *P. endodontalis,*

are often involved in root canal infections and complications of these infections such as odontogenic sinusitis (56, 115). Some of the above-named pigmented organisms and *Porphyromonas asaccharolytica* and *P. uenonis* are also prevalent in the urogenital or intestinal tracts and are important in infections arising from these sources (25, 41, 111). In addition to *P. uenonis* and the pigmented bile-resistant organisms mentioned above, *P. gingivalis* has also been isolated from extraoral sources, especially from patients with appendicitis (93, 138). *Porphyromonas* spp. of animal origin have been encountered in humans with animal bite infections (19, 45, 57). *Porphyromonas somerae* has been isolated from various types of human clinical infections including pleuropulmonary infections, skin and soft tissue infections, and bacterial vaginosis (130).

The bile-sensitive, nonpigmented, saccharolytic *Prevotella* and related strains recovered from human samples are found in the same settings as the pigmented gram-negative rods (38). *Prevotella bivia* and *Prevotella disiens* are found in female patients with genital tract infections, in patients with soft tissue infections, and less frequently in oral infections (4); these strains are often resistant to the β-lactam antibiotics, including penicillin, aminopenicillins, and cephalosporins (140). *Prevotella oris* and *Prevotella buccae* are found in a variety of oral, pleuropulmonary, and other infections (21, 38, 65). Members of the *P. oralis* group are relatively infrequently encountered in routine human clinical samples but common in oral and dental infections (30, 114).

P. zoogleoformans (indole negative) is rarely isolated from human clinical specimens, whereas *P. heparinolytica* (indole positive) is often found in the oral cavity of humans and animals and in association with oral infections. *Prevotella dentalis* (formerly *Mitsuokella dentalis*) is a common isolate from infected root canals, periodontal pockets, mandibular and gum abscesses, and in sialadenitis (128). *M. multiacida,* a nonmotile gram-negative anaerobic rod, sometimes isolated from rumen and the mammalian intestinal tract, is not related to *P. dentalis* but is most closely related to *Selenomonas* species, which in turn seem to belong to cluster IX of the *Clostridium* subphylum of the gram-positive bacteria (23). The nonpigmented, saccharolytic organism *Megamonas hypermegas* has not been isolated from human clinical specimens.

The nonpigmented, asaccharolytic, or weakly fermentative species *Anaerorhabdus furcosus, Bacteroides capillosus, Bacteroides coagulans, Dialister pneumosintes, Alistipes putredinis, Desulfovibrio* spp., and *Tissierella praeacuta* inhabit the intestinal tract and have occasionally been recovered from miscellaneous infections (37, 38, 48). *Bacteroides tectus* and the phenotypically similar *Bacteroides pyogenes* are often associated with canine or feline oral flora and are prevalent in infections in humans who have sustained animal bites (1, 38, 132). *Bilophila wadsworthia,* a bile-resistant organism, is present in small numbers in the bowel flora of healthy persons, yet it is the third most common anaerobe recovered from gangrenous or perforated appendixes and is a common constituent of the microbiota in other intra-abdominal infections (5, 7, 11). It has also been isolated from various other clinical specimens including blood, brain abscess, liver abscess, pericardial fluid, joint fluid, and pleural fluid as well as from human feces and vaginal and oral secretions (6, 36). *B. wadsworthia* is easily overlooked in cultures owing to its fastidious growth.

Members of the formate-fumarate-requiring *B. ureolyticus-Campylobacter* group, including *B. ureolyticus, C. gracilis, C. curvus, C. rectus,* and *S. wadsworthensis,* have been isolated from various types of infections (122). *B. ureolyticus* has been recovered from pulmonary, head and neck, intra-abdominal, urogenital, bone, and soft tissue infections. *C. gracilis* has been recognized as an important pathogen in serious visceral or head and neck infections and, in general, in infections above the diaphragm, and *S. wadsworthensis* is an important pathogen in infections below the diaphragm, especially abdominal infections (94, 143). *Campylobacter* spp. are primarily oral isolates found in patients with oral infections and periodontitis; they occasionally enter the bloodstream in immunocompromised patients. *C. rectus* has been implicated as a putative pathogen at sites of active periodontal breakdown (58, 110, 122). Many species of oral anaerobes have recently been associated with atherosclerosis, although a causal relationship has not been proved (59, 118, 124).

Among *Fusobacterium* species, *F. nucleatum* is most commonly encountered in clinical infections (13, 65). This organism is found in the mouth and in the genital, gastrointestinal, and upper respiratory tracts. It is often involved in the same types of infections as the pigmented *Prevotella* spp. and *Porphyromonas* spp. *F. nucleatum* may be found as the sole infecting agent in pleuropulmonary infections (21). *Fusobacterium necrophorum* is a very virulent anaerobe that may cause severe infection, usually in children or young adults, originating from pharyngotonsillitis, sometimes in association with infectious mononucleosis (70). It was the most common anaerobe isolated from peritonsillar abscesses in young adults and may in fact be an etiological agent of pharyngitis as often as *Streptococcus pyogenes* (2, 10, 63). Complications include Lemierre's disease, an acute jugular vein septic thrombophlebitis often complicated by sepsis and metastatic abscesses most frequently in the lungs, pleural space, liver, and large joints (63, 70). *F. necrophorum* is now encountered in serious infections less often than in the pre-antimicrobial agent era, but this makes it more treacherous, because many clinicians may not be familiar with the syndrome (74). There are two subspecies; *F. necrophorum* subsp. *necrophorum* contains lipase-positive, hemagglutinin-producing biovar A, and *F. necrophorum* subsp. *funduliforme* contains lipase-negative, non-hemagglutinin-producing biovar B. *Fusobacterium mortiferum* and *Fusobacterium varium* are encountered mainly in patients with intra-abdominal infections. *Fusobacterium russii* and *F. canifelinum* have been implicated in animal bite infections (24, 38), and *Fusobacterium ulcerans* is found in tropical ulcer. Other fusobacteria are isolated from clinical specimens rarely, usually oropharyngeal or genital sites. The former *F. prausnitzii,* abundant in the human feces, is not a fusobacterium but, rather, is related to the *Clostridium* spp. and has been renamed *Faecalibacterium prausnitzii*. Its pathogenic potential is unknown (26, 32). Other former gram-negative anaerobes closely related to clostridia include *Butyrivibrio fibrisolvens* and *B. hungatei* (from rumen) and *Catonella morbi* and *Johnsonella ignava* (from human gingival crevice). Routine clinical laboratories are unlikely to encounter these organisms.

Capnocytophaga spp. of human origin are often isolated only in anaerobic culture, and they are common in the oral cavity. *Leptotrichia buccalis* is a common mouth organism and may be found in the vagina and intestinal tract. Isolation of *Capnocytophaga* spp. or *Leptotrichia* spp. from blood cultures is often linked to patients (often adolescents) with hematological malignancies and is a direct clue to the presence of oral mucosal lesions in the patient (3, 38, 92). *Sneathia sanguinegens* has been isolated from cultures of blood from pregnant and elderly women and neonates (53).

Selenomonas sputigena, Selenomonas artemidis, Selenomonas dianae, Selenomonas flueggei, Selenomonas infelix, and *Selenomonas noxia* are all oral organisms, as is *Centipeda*

periodontii, which closely resembles and phylogenetically clusters with *Selenomonas* in the *Clostridium* subphylum of the gram-positive bacteria (23, 133); these organisms are found in subgingival sites in patients with periodontitis (16, 75, 133).

The motile organisms *Succinivibrio dextrinosolvens, Butyrivibrio fibrisolvens,* and *Desulfovibrio* spp. including the nonmotile species *D. piger* are found as members of the normal colonic flora but may occasionally be encountered in patients with clinical infections, such as appendicitis (48). *Desulfovibrio* has been recovered in blood cultures from an immunocompromised patient, an immunocompetent patient, and from a pyogenic liver abscess in another patient (48, 80). The sites of normal carriage of *Anaerobiospirillum succiniciproducens* and *Anaerobiospirillum thomasii* in humans are unknown, but *Anaerobiospirillum* species are common in the fecal flora of cats and dogs (82). Strains of *Anaerobiospirillum* have been isolated from cultures of blood from compromised patients and from fecal specimens of patients with diarrhea (82, 83, 89, 134). In the latter case, a zoonotic role for *Anaerobiospirillum* spp. has been proposed.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

General guidelines for collection, transport, and storage of specimens are discussed in chapters 5 and 20. Sites normally harboring a rich indigenous flora, such as the intestinal tract or vagina, should not be sampled and cultured for anaerobes except under special circumstances and by using special methods (e.g., quantitative study of upper small bowel flora in patients with the blind loop syndrome). Lower respiratory tract specimens and endometrial samples are especially difficult to obtain without contaminating the sample with indigenous flora. Double-lumen-catheter bronchial brushings and bronchoalveolar lavage fluid transported immediately to the laboratory under anaerobic conditions and cultured quantitatively, as well as pleural fluid, represent good respiratory tract specimens. An endometrial suction curette (Pipelle; Unimar, Wilton, Conn.) biopsy provides a good sample from the endometrium (39). Instructions for collection of specimens from different body sites and by various methods are given in more detail elsewhere (14, 39, 65).

Ulcers should be carefully debrided, and proper tissue samples should be collected from the base or progressive edge, where bacteria actively multiply, rather than from unremoved crust or surface pus, which is often contaminated by other bacteria not reflecting the true infecting flora.

Pus, when present, is best aspirated into a syringe through a needle and injected into an anaerobic transport vial containing an oxidation-reduction indicator. Syringes used for aspiration should not be used as transporters because of the potential danger of needlestick injuries or accidental expulsion and because oxygen diffuses through plastic syringes. Pieces of infected tissue obtained by excision or biopsy are always preferable to pus.

Specimens obtained with a swab are the least desirable and should be discouraged unless special circumstances exist. Swabs are intrinsically aerobic and prone to drying if not in anaerobic transport vials, often carry a volume of sample too small to be cultured on several media or quantitatively, and leave some of the specimen in the transport medium. However, swabs are used in many institutions. One study showed that aerobic and anaerobic organisms in purulent specimens survived for up to 48 h in anaerobic swab transport systems (20). Tissue samples are best transported in anaerobic transport vials or in loosely capped containers sealed in gas-impermeable bags in which an anaerobic atmosphere was generated. For small tissue and biopsy specimens and for subgingival and root canal samples, a semisolid anaerobic transport medium in which the specimen can be submerged may be used (Dental Transport Medium; Anaerobe Systems, Morgan Hill, Calif.). The dental specimens can be collected with a curette or with the use of paper points after careful removal of supragingival plaque (27, 65). The material from curettes or the paper points are transported in a transport medium, such as VMGA III (Viability Medium, Göteborg, anaerobically prepared and sterilized), containing glass beads to facilitate dispersion of aggregates in plaque (27). In the case of failed peri-implants, the whole fixture is placed in VMGA III (27, 65).

The conditions and time of transport should not affect the viability or relative proportions of bacteria present in the specimen if appropriate transport systems are used (8). Rapid transport is important when Gram stain and culture results are needed early for guidance of therapy. Contrary to previous recommendations, specimens in glass may be transported at room temperature or refrigerated (not frozen), as the organisms, especially facultative fastidious species, seem to survive at lower temperatures in newer transport systems (31, 136). More detailed information on transport systems and anaerobic techniques can be found elsewhere (8, 14, 65).

DIRECT EXAMINATION

The gross appearance (purulence, necrotic tissue), fluorescence of the sample under long-wave (366-nm) UV light, and the odor of the specimen can give the laboratory valuable clues to the presence of anaerobes. A fetid or putrid odor due to volatile short-chain fatty acids and amines is always associated with the presence of anaerobes in the sample. Black necrotic tissue and/or red fluorescence of the sample may be indicative of the presence of pigmented gram-negative rods.

Microscopy

The Gram stain is still the fastest, simplest, and the most likely to yield significant information among rapid methods and should be prepared from all specimens accepted for anaerobic culture. The morphotypes and relative quantities of both the host and the bacterial cells present in the preparation should be reported. Furthermore, the Gram stain information also provides quality control for specimen transport and isolation efficiency (39). Thick films from exudates and bloody fluids should be spread thin as for a blood smear. Smears should be fixed in methanol for 30 s to preserve the host and bacterial cell morphologies (87). Standard Gram stain procedures and reagents are used, except that 0.1 to 0.5% basic fuchsin, which enhances the staining of gram-negative anaerobes, is substituted for safranin as the counterstain (65, 87). Dark-field and phase-contrast microscopy may be helpful in the detection of small, poorly staining organisms *(D. pneumosintes),* for the direct observation of motility (*Campylobacter* spp.), for the notation of spores (*Clostridium* spp.), and for the recognition of morphotypes not cultivable on ordinary media (spirochetes). Gram stain using Nugent criteria for interpretation of vaginal discharge is still considered the best method for diagnosis of bacterial vaginosis (76, 120). Chapter 20 outlines this procedure.

Antigen or Product Detection

Although a direct fluorescent antibody for *B. fragilis* has been reported, it is not in routine use (105). Gas-liquid chromatography (GLC) of specimens has been proposed, but

it has not gained acceptance. Newer methods for identification of volatile products in specimens, such as the electronic nose, are in developmental stages (54, 106, 135).

Molecular methods, such as nucleic acid probe hybridization, PCR amplification, and direct demonstration of nucleic acid sequences by 16S rRNA gene sequencing, are not used for routine diagnostic studies but are widely used in specialized oral and other research microbiology laboratories (16, 116). Eventually, molecular methods will become more commonplace (see chapter 16) (2).

ISOLATION PROCEDURES

The use of selective media along with nonselective media increases the yield and saves time in terms of recognition and isolation of colonies. Freshly prepared or prereduced and anaerobically sterilized media (Anaerobe Systems) should be used (88, 107). Different basal media differ in their abilities to support the growth of anaerobes; brucella base is superior to Trypticase soy (CDC base agar) and Schaedler base for isolation of gram-negative rods, but CDC base better supports the growth of anaerobic gram-positive cocci. Brain heart infusion base is superior to Trypticase soy in isolation efficiency for *Eubacterium* species but is inferior for pigmented gram-negative rods from subgingival and other samples (65). Fastidious anaerobe agar (Lab M, Bury, England) produces luxuriant growth of fusobacteria and some formate-fumarate-requiring species and can be used as a basal medium with or without selective agents. In academic centers performing large-scale anaerobic bacteriology, it would be ideal to use two different basal media to maximize isolation efficiency (39, 86) (chapter 21).

Isolation methods have been published elsewhere (15, 65, 86) (chapter 20). The minimum medium setup includes (i) a nonselective, enriched, brucella base sheep blood agar plate supplemented with vitamin K_1 and hemin (BAP); (ii) a kanamycin-vancomycin laked sheep blood agar (KVLB) for the selection of *Bacteroides* and *Prevotella* spp. (KVLB allows growth and rapid pigmentation of most *Prevotella* spp., but the concentration of vancomycin [7.5 μg/ml] inhibits most *Porphyromonas* spp.; for the isolation of *Porphyromonas* spp., KVLB medium with a reduced vancomycin concentration [2 μg/ml] may be prepared); and (iii) a *Bacteroides* bile-esculin agar plate (BBE) for specimens from areas below the diaphragm for the selection and presumptive identification of the *B. fragilis* group and *Bilophila* sp. BBE and KVLB are also available as biplates. When indicated, a phenylethyl alcohol-sheep blood agar plate, used to prevent overgrowth by aerobic gram-negative rods and swarming of some clostridia, may be inoculated. When fusobacteria are clinically suspected as the cause of infection, *Fusobacterium* neomycin-vancomycin agar or *Fusobacterium* selective agar may be used for isolation (65). A selective medium for culturing *Anaerobiospirillum* spp. from fecal specimens has been described (83). Use of a metronidazole disk on nonselective agar may help detect strict anaerobes, as resistant colonies would suggest facultative anaerobes or gram-positive anaerobes which are often resistant. After inoculation, the anaerobic plates should immediately be incubated at 36°C in an anaerobic environment, such as an anaerobic bag, jar, or chamber. Alternatively, setup and incubation may all be done in an anaerobic chamber. Plates should not be exposed to air during the first 48 h to avoid death of the more oxygen-sensitive species. In routine clinical microbiology, a total incubation period of at least 5 days for primary plates is recommended. In our experience with shorter incubation times, some anaerobic species, such as *Porphyromonas* and *Bilophila* spp., may not be detected.

Use of anaerobic blood culture media has been controversial, as strict anaerobes now comprise <5% of most clinically relevant blood culture isolates (98, 99). At the least, blood cultures from patients with abdominal or gynecological processes, peritoneal abscess, dirty wound, decubitus ulcers, osteomyelitis, oropharyngeal disease, and elderly patients should be cultured in an anaerobic bottle (9). However, since many facultative organisms may be recovered faster from the anaerobic bottle, both aerobic and anaerobic media are recommended for at least one blood culture set.

IDENTIFICATION

Colonies should be examined with a dissecting microscope to facilitate detection. Use a broken sterile wooden stick point to obtain material from each different colony type. Use this single colony sample to inoculate (i) a brucella BAP to which special-potency antibiotic disks (colistin, 10 μg; kanamycin, 1,000 μg; and vancomycin, 5 μg) are applied (a nitrate disk may also be added) (Fig. 1); (ii) a chocolate agar plate that is incubated in 5 to 10% CO_2 (can be a pie plate) for aerotolerance testing and detection of *Haemophilus* and capnophilic organisms; and finally (iii) an area on a slide for Gram staining. A blood agar pie plate is optional, but it is useful for seeing β-hemolysis of microaerophilic streptococci. A laked rabbit blood agar plate (LRBA) for the rapid demonstration of pigment production (laked rabbit blood agar is the most reliable and effective medium) (57, 65) and an egg yolk agar plate (EYA) for the demonstration of lipase, lecithinase, and proteolytic activities may also be inoculated at this point. The primary plates are reincubated along with the purity and test plates.

Preliminary Examination of Isolates

The characteristics that are noted from BAP include detailed Gram stain and colony morphology, pigment, fluorescence (long-wave UV light) (the results of the last two tests are also recorded from an LRBA), hemolysis, and greening or pitting of the agar. Furthermore, the spot indole reaction (*para*-dimethylaminocinnamaldehyde reagent), the nitrate reduction test, tests for sensitivities to special-potency antibiotic disks (Fig. 1), and catalase (15% H_2O_2) are performed. Most commonly isolated anaerobes are nonmotile, but in case of an unusual strain, motility tests from a broth culture or plate (hanging drop or wet mount) may be performed. Motile isolates are most likely to be *Campylobacter* spp. Instead of spot tests, Lombard-Dowell quadrant plates I, II, and III (Remel, Lenexa, Kans.) developed at the Centers for Disease Control and Prevention can be used to test for kanamycin resistance, indole, esculin, bile, gelatinase, lecithinase, lipase, and several carbohydrate fermentation reactions (35). Good growth is necessary for the proper interpretation of test results on this medium.

The primary plates are reinspected after 4 or more days to detect slow growers, new morphotypes, or late pigmenters. In oral microbiology laboratories, two rapid in situ tests have been used. The rapid differentiation of lactose-fermenting species from lactose-nonfermenting species is determined by applying 4-methylumbelliferyl-D-galactoside reagent (catalog no. M-1633; Sigma Chemical Co., St. Louis, Mo.) to the colonies and screening for fluorescent (lactose-positive) colonies under long-wave UV light. The carboxy-L-arginine-7-amino-4-methylcoumarin amide HCl (CAAM) test demonstrates the trypsin-like activities of suspected colonies of *P. gingivalis;* the colonies are treated with the CAAM reagent (catalog no. C-9396; Sigma) and screened for blue-white fluorescence under long-wave UV light (123).

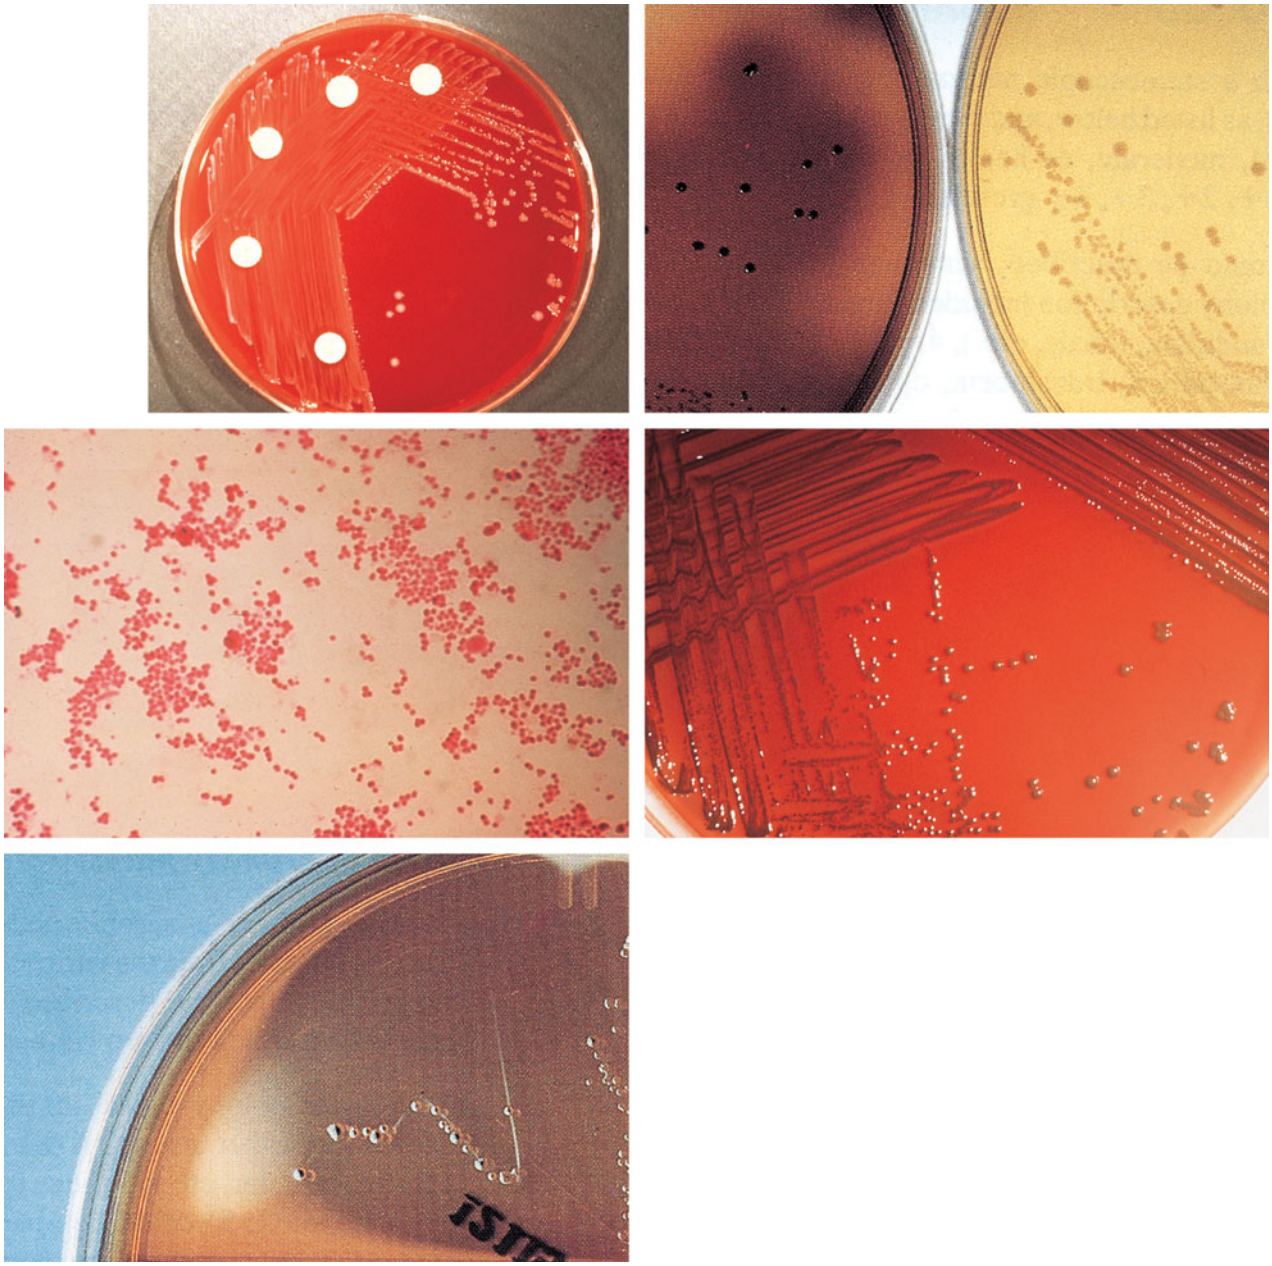

FIGURE 1 (top left) Placement of special-potency antibiotic disks. A blank disk for indole testing may be added (usually after growth has occurred).

FIGURE 2 (top right) Colonies of *Bacteroides fragilis* (left) and *Bacteroides vulgatus* (right) on BBE. Note the blackening of the agar and colonies due to esculin hydrolysis and bile precipitation.

FIGURE 4 (middle right) Pigmented colonies of *Porphyromonas* species.

FIGURE 5 (bottom) Colony morphology of *Bilophila wadsworthia* on BBE. Note the black centers due to H_2S production.

Presumptive Identification of Species

Most of the clinically significant gram-negative rods can be placed into broad groups with relatively few tests, and some isolates, including *Bilophila wadsworthia* and *Fusobacterium nucleatum*, can be presumptively identified with ease (Table 2) (101). The special-potency antibiotic disk pattern can be used to separate the gram-negative rods into several groups. A zone size equal to or greater than 10 mm is considered sensitive (65).

Most of the *Bacteroides* and *Prevotella* spp. are resistant to vancomycin and kanamycin and are variable in sensitivity to colistin; *Porphyromonas* spp. are generally sensitive to vancomycin and resistant to colistin. The *B. fragilis* group can be

identified presumptively by their resistance to all three special-potency antibiotic disks and by growth equal to or greater than the control growth in 20% bile, as determined by a tube test, by a bile disk test (65), or on BBE (Fig. 2). Coccobacillary organisms that fluoresce red or produce black colonies are in the pigmented *Prevotella* spp.-*Porphyromonas* spp. group (Fig. 3 and 4).

Fusobacterium spp., *B. ureolyticus, Campylobacter* spp., *Bilophila* sp., *Sutterella* sp., and *Leptotrichia* spp. are resistant to vancomycin but sensitive to both colistin and kanamycin. *B. ureolyticus, Campylobacter, Bilophila,* and *Sutterella* colonies are usually much smaller and more translucent than those of fusobacteria and typically reduce nitrate; *Leptotrichia* colonies are large and gray and have a convoluted ("brain surface") texture. Furthermore, the most commonly encountered fusobacteria, *F. nucleatum* and *F. necrophorum,* are indole positive and nitrate negative. On microscopic inspection, fusobacteria are usually larger than the other bacteria with the same identification disk profile, excluding the large tapered cells of *Leptotrichia.* An anaerobic, gram-negative, catalase-negative rod that requires formate and fumarate for growth in broth culture or that pits agar may be presumptively identified as *B. ureolyticus* or a *Campylobacter* sp.; *B. ureolyticus* is urease positive (Table 2, footnote *d*). To document the formate-fumarate requirement, inoculate one tube of peptone yeast (or thioglycolate) broth medium containing the additive (0.3%) and one tube not containing the additive (control) (Table 2, footnote *b*). Compare the two tubes for intensity of growth. A strongly catalase-positive, bile-resistant, often urease-positive gram-negative rod can be presumptively identified as *Bilophila* sp. (Fig. 5). Microaerophilic and catalase- and urease-negative but bile-resistant (by the disk test) organisms growing in *Campylobacter* atmosphere (2 to 6% oxygen) are probably *S. wadsworthensis*.

Desulfovibrio piger (nonmotile), other *Desulfovibrio* spp. (motile), and the capnophilic, often yellow-pigmented *Capnocytophaga* spp. are resistant to vancomycin and colistin but sensitive to kanamycin (142). *Desulfovibrio* cells are curved or spiral; *Capnocytophaga* cells resemble fusobacteria with tapered ends. *Selenomonas* spp. may have the same special-potency disk patterns as *Desulfovibrio* and *Capnocytophaga* spp., but a few strains are sensitive to colistin. *Selenomonas* cells are curved and motile, as are those of *C. periodontii,* a closely related species that forms swarming colonies.

Most organisms not fitting the above-described groupings are *Bacteroides* spp. or *Prevotella* spp. but occasionally are representatives of the other genera listed in Table 1.

Rapid Identification

Whenever possible, simple tests should be used for the rapid and, to the extent that they permit, definitive identification of anaerobes (65, 85, 101). These include tests for colony and microscopic morphologies; the spot indole, catalase, lipase, and lecithinase tests; the nitrate disk test; the bile disk test; growth stimulation tests; and tests for sensitivities to special-potency antibiotic disks. Furthermore, rapid tests based on the presence of preformed enzymes produce clinically meaningful results in a timely fashion (see "Other Approaches to Identification"). See Tables 2 to 7, which incorporate the results of these tests; they can be used for the rapid identification of many commonly encountered anaerobic gram-negative rods.

Identification of the most commonly encountered bile-resistant members of the *B. fragilis* group is based on the special-potency disk profile and the results of a few tests that can be performed rapidly, including the catalase, indole, esculin, and α-fucosidase tests (Table 3, footnote *b*). Based on these reactions, the members of this group can be reported as *B. fragilis* group, most closely related to *B. fragilis,* or other species in this group (Tables 2 and 3). Further tests are performed when indicated. *Porphyromonas* spp. are easily identified even to the species level with the aid of the special-potency disk profile and the results of a few tests including indole, catalase, lipase, and some rapid enzyme tests (see Tables 2 and 6) (57, 66, 85, 138). *Porphyromonas asaccharolytica* may be confused with some *Prevotella* species without the vancomycin special-potency disk results (*Prevotella* spp. are resistant). An indole- and lipase-positive coccobacillus that forms black-pigmented colonies or that fluoresces red may be identified as belonging to *Prevotella intermedia/P. nigrescens* group; *P. pallens* resembles these two species but has lighter pigment and is lipase negative (71, 72). A rapid enzyme test for α-glucosidase (with Rosco Diagnostic Tablets [Rosco Diagnostics, Taastrup, Denmark] or the WEE-Tabs system [Key Scientific Products, Round Rock, Tex.]) is helpful; *P. intermedia/P. nigrescens* and *P. pallens* are positive, and *P. asaccharolytica* is negative (57). Furthermore, *Porphyromonas asaccharolytica* is sensitive to the special-potency vancomycin disk. Any indole-negative strains must be identified further by other biochemical tests. A lipase-positive, indole-negative, pigmented gram-negative rod could be *P. loescheii*.

B. ureolyticus, C. gracilis, other "anaerobic" *Campylobacter* spp., and *Sutterella* sp. are thin gram-negative rods with rounded ends that produce the *Fusobacterium* disk pattern. The colonies are small and translucent or transparent and may produce greening of the agar. Three colony morphotypes exist: smooth and convex, pitting (Fig. 6), and spreading. All colony types can occur in the same culture. These organisms are asaccharolytic and nitrate reducing, and they require supplementation of broth media with formate and fumarate for growth (Table 2, footnote *b*). *C. rectus, C. curvus, C. concisus,* and *C. showae* are motile and oxidase positive; unlike the first three, *C. showae* is catalase positive. *C. gracilis* is nonmotile and urease negative and, thus, is differentiated from urease-positive *B. ureolyticus* (Table 2, footnotes *d* and *e*). *Bilophila* sp., which phenotypically resembles *B. ureolyticus,* is distinguished from the above-mentioned species by its resistance to bile and its strong catalase reaction. *Sutterella* sp. is also resistant to bile but is urease and catalase negative (7, 143).

F. nucleatum is a thin rod with tapering ends (Fig. 7) and is indole positive. The needle-shaped morphology is shared with the microaerophilic, indole-negative *Capnocytophaga* spp. and *Leptotrichia* spp., as discussed above. *F. nucleatum* fluoresces chartreuse under UV light and often produces greening of the agar after exposure to air due to H_2O_2 production. At least three different colony morphotypes of *F. nucleatum* exist (13, 14, 34, 68). Due to considerable phenotypic and genotypic heterogeneity and uncertainty of valid criteria for the separation of the *F. nucleatum* subspecies, it is hard to judge whether the reported colonial morphologies consistently coincide with the subspecies designations. *F. nucleatum* subsp. *nucleatum* colonies may be small, grayish white, and smooth; *F. nucleatum* subsp. *fusiforme* colonies may also be small (<0.5 to 1 mm), granular, and irregular (bread crumb shaped) (Fig. 8); and *F. nucleatum* subsp. *polymorphum* colonies often are large, speckled, smooth, translucent, and butyrous. *F. necrophorum* subsp. *necrophorum* is lipase positive and usually bile sensitive. It is a pleomorphic long rod with round ends and often has bizarre forms, especially in older

TABLE 2 Group identification of anaerobic gram-negative organisms[a]

Group or organism	Vancomycin (5 μg)	Kanamycin (1,000 μg)	Colistin (10 μg)	Growth in 20% bile	Catalase	Indole	Growth stimulated by formate-fumarate[b]

[a] R, resistant; S, susceptible; R^{S}, most strains resistant, some strains susceptible; V, variable; +, positive reaction for majority of strains; −, negative reaction; +$^{-}$, most strains positive but some strains negative; −$^{+}$, most strains negative but some strains positive.

[b] Compare the growth of the organism in an unsupplemented thioglycolate broth with growth in a broth supplemented with formate and fumarate additive: dissolve 3 g of sodium formate, 3 g of fumaric acid, and 20 pellets of sodium hydroxide in 50 ml of distilled water; adjust the pH to 7; and filter sterilize. Add 0.5 ml of additive to 10 ml of culture broth (55, 65).

[c] Use the nitrate disk test (65).

[d] Make a heavy suspension of the organism in 0.5 ml of sterile urea broth (BBL; BD, Franklin Lakes, N.J.) or in sterile water and insert a urea tablet (Rosco Diagnostic Tablets, A/S Rosco, Taastrup, Denmark) or WEE-Tabs (Key Scientific Products; Round Rock, Tex.). Incubate the tubes aerobically for up to 24 h. A bright pink or red is positive; this color usually appears within 15 to 30 min.

TABLE 3 Characteristics of *B. fragilis* group and *B. splanchnicus*[a]

Species	Growth on BBE	Indole	Catalase	Esculin hydrolysis	α-Fucosidase[b]

morphology but usually has fewer round bodies. A bile-resistant fusobacterium isolated from BBE may be identified as *F. mortiferum* or *F. varium*; *F. mortiferum* is positive for *o*-nitrophenyl-β-D-galactopyranoside (Table 3, footnote *b*), whereas *F. varium* is negative.

Definitive Identification

A definitive identification of an anaerobic isolate should be obtained for all isolates from normally sterile body sites such as blood, spinal fluid, and organs or body cavities; when the patient is gravely ill and not responding to treatment; and when prolonged treatment is necessary. Definitive identification is also indicated in unusual case presentations and in some teaching-hospital settings, particularly if the case is to be published.

The definitive identification of some species requires certain additional biochemical tests, metabolic end product analysis, and/or cell wall fatty acid profiling by GLC (65). Even in good research or reference laboratories, a percentage of strains will not be identified definitively. If such strains are isolated from blood or closed-space infections, molecular methods such as 16S rRNA sequencing may be helpful. Motility may be helpful for characterizing curved rods that are not *Campylobacter,* as shown in Table 2. Organisms with small, translucent, spreading colonies that are not *B. ureolyticus*-like should also be checked for motility. The results in Tables 3 to 7 are based on reactions in prereduced, anaerobically sterilized (PRAS) liquid media (55, 65). A shortened and simplified scheme (spot indole, arabinose, sucrose, trehalose, rhamnose, and xylan tests) for the identification of the *B. fragilis* group with commercial PRAS biochemicals and the addition of bromthymol blue at 24 h postincubation has been described (18, 125). Other systems that depend on color changes of pH-dependent indicators for interpretation of reactions may not yield the same results as reactions in PRAS biochemicals. Gas chromatographic analysis may be performed on peptone-yeast glucose broth that shows good growth of the organism (55, 65). Each lot of uninoculated broth must be assayed in parallel with samples to determine the background amounts of acetic and succinic acids, and if chopped-meat broth is used, an uninoculated broth is assayed for lactic acid. Fermentation end products vary depending on the substrate available to the organism. Use of substrates other than those on which the results in the identification tables are based may lead to misinterpretation of the GLC pattern and misidentification of the organism. For instance, saccharolytic organisms produce larger amounts of isoacids in the absence of a fermentable carbohydrate, and a fermentable carbohydrate is required for the detection of lactic acid.

Colonies of the *B. fragilis* group on brucella BAP are 2 to 3 mm in diameter, circular, entire, convex, and gray to white. The cells may be uniform, bipolarly stained, or pleomorphic (some may contain vacuoles) (Fig. 11); this difference is medium and age dependent. The presence of ovoid cells suggests *B. ovatus.* Good growth in or stimulation by 20% bile (2% oxgall) is characteristic of the *B. fragilis* group; the exception to this rule is the poor growth of *B. uniformis* in bile. Some organisms not belonging to the *B. fragilis* group (non-*B. fragilis* group) are bile resistant. These include *B. splanchnicus, B. tectus, B. pyogenes, M. multiacida, Bilophila* sp., *Alistipes* spp., and some fusobacteria (111). Not all of these, however, grow on BBE. Morphologic characteristics, special-potency identification disks, and some biochemical reactions differentiate these species. Most of the *B. fragilis* group organisms blacken the BBE (esculin hydrolyzed), although *B. vulgatus* may not hydrolyze esculin. Table 3 is a key for the differentiation of members of the bile-resistant *B. fragilis* group.

Members of the non-*B. fragilis* group, nonpigmented anaerobic gram-negative rods, form two major subgroups: saccharolytic and asaccharolytic or weakly saccharolytic. Tables 4 and 5 list the more commonly encountered or clinically important species in these groups.

The saccharolytic organisms fall into two categories, i.e., pentose (arabinose and xylose) fermenters and pentose nonfermenters. Pentose fermentation may be difficult to demonstrate owing to suboptimal growth in the test medium; therefore, a screening test for the presence of the preformed enzyme β-xylosidase is recommended (for the procedure, see Table 3, footnote *b*). *P. oris* and *P. buccae* are pentose fermenters (Table 4). They are phenotypically very similar but can be differentiated by the α-fucosidase and *N*-acetyl-β-glucosaminidase tests (Table 3, footnote *b*) (33, 57); furthermore, *P. buccae* is usually sensitive to the special-potency colistin disk, whereas *P. oris* is not. *P. zoogleoformans* and *P. heparinolytica* may also ferment pentoses. Both produce viscous material in broth cultures, and on solid media the colonies often adhere to the agar. The positive indole reaction of *P. heparinolytica* differentiates these two species. The indole production is sometimes very difficult to demonstrate and should be tested from a pure culture on an EYA plate and/or from an old (>5-day-old) culture in chopped-meat broth because in some strains it can be a weak reaction. Other pentose fermenters include bile-resistant *M. multiacida* and *B. splanchnicus* and bile-sensitive *P. dentalis.* Unlike most *Prevotella* and *Bacteroides* species, *M. multiacida* is both nitrate and inositol positive. *P. dentalis* forms characteristic "water-drop," viscous colonies on blood agar. A positive *N*-acetyl-β-glucosaminidase reaction differentiates it from *P. buccae,* and a negative α-fucosidase reaction differentiates it from *P. oris.* The far better growth of *P. dentalis* on CDC blood agar than on brucella blood agar is an additional feature to facilitate the identification of the species.

Salicin, cellobiose, xylan, and sucrose are the key sugars in the differentiation of *P. baroniae, P. oralis, P. buccalis, P. veroralis, P. marshii, P. oulorum,* and *P. enoeca* (Table 4). In addition, *P. oulorum* produces catalase and is lipase positive (97). Certain strains of the saccharolytic pigmented *Prevotella* spp. require more than 21 days to develop pigment, and these strains (especially *P. loescheii*) closely resemble *P. veroralis.* Darker, more opaque colonies and salicin and cellobiose reactions may aid in differentiation of the strains.

P. bivia and *P. disiens* are both saccharolytic and strongly proteolytic (Table 4). Gelatin and milk are usually digested within 2 to 3 days (milk digestion may take longer). Differentiation is based on lactose fermentation; *P. bivia* is lactose positive, and *P. disiens* is lactose negative. Furthermore, *P. bivia* is both *N*-acetyl-β-glucosaminidase and α-fucosidase positive, but *P. disiens* is negative for both. Under long-wave UV light, *P. bivia* and *P. disiens* colonies may fluoresce light orange to pink (coral), and *P. disiens* also may produce a brown pigment on LRBA that makes differentiation from the phenotypically similar *P. corporis* difficult. *P. bivia* and *P. enoeca* share the same phenotypic characteristics, but *P. enoeca* is gelatin negative; it is usually isolated from oral or oral-associated sources, whereas *P. bivia* is more often found in nonoral samples.

Asaccharolytic, nonpigmented *Bacteroides* spp. and *Tissierella* spp. are infrequently isolated from clinical specimens (Table 5). *Anaerorhabdus furcosus,* another rare species, is currently considered to be within *Bacteroidaceae* but may

[f] Animal origin; also isolated from bite infections in humans. Quantitative differences between some cellular fatty acids may help in differentiation of these species (42).
[g] *Bilophila* sp. is colistin sensitive; *Desulfovibrio* spp. are colistin resistant.
[h] W−, most strains weakly positive, some strains negative.

be more related to gram-positive rods. *B. capillosus* coagulates milk and may grow better with Tween 80-supplemented media. *D. pneumosintes* is a very tiny rod best seen by darkfield examination (it almost resembles *Veillonella* spp. by Gram staining) and forms minute colonies that may require magnification to be seen. Other species of *Dialister* from clinical specimens have been described recently (67). *T. forsythensis* is a fusiform rod that exhibits a wide variety of enzyme activities including trypsin-like activity and *N*-acetyl-β-glucosaminidase, α-fucosidase, and β-glucuronidase activities. However, its growth is minimal in broth media, and it requires *N*-acetylmuramic acid; therefore, it is often seen as satellite colonies around colonies of other organisms, especially fusobacteria. *Desulfovibrio* spp. are sulfate-reducing bacteria and can be confirmed by the desulfoviridin test (Table 2, footnote *i*). The species are motile (except for the recently included *D. piger*) and produce copious amounts of H_2S (142).

The pigmented *Prevotella* spp. and *Porphyromonas* spp. (Table 6) vary greatly in the degree and rapidity of pigment production, which ranges from buff to tan to black depending primarily on the type of blood and the composition of the base medium used in the agar. A period of 2 to 21 days may be required even on LRBA to detect pigmentation in some strains. The identities of strains not showing pigmentation must be established by other biochemical tests to avoid confusion with the *P. oralis* group of organisms. The pigmented *Prevotella* and *Porphyromonas* spp. fluoresce pink, orange, or brick red under UV light. Fluorescence is best demonstrated in young cultures; in older cultures, especially on laked blood agar, the fluorescence is more or less masked depending on the intensity of pigment production (66).

The indole-positive species *P. intermedia* and *P. nigrescens* produce dark pigment; the pigment produced by *P. pallens* is lighter. The use of oligonucleotide probes or determination of arbitrarily primed PCR and enzyme electrophoretic mobility profiles are needed for species differentiation (51, 66). The unusual special-potency antibiotic disk pattern (sensitivity to vancomycin), in addition to asaccharolytic properties, separates most *Porphyromonas* spp. from the other pigment producers. *P. asaccharolytica, P. endodontalis, P. uenonis*, and *P. gingivalis* are all asaccharolytic and phenotypically very similar. The key differential tests include tests for phenylacetic acid production, trypsin-like activity, and *N*-acetyl-β-glucosaminidase and α-fucosidase activities (Table 6). Unlike most *Porphyromonas* spp., *P. catoniae, P. levii,* and *P. somerae* (frequently isolated from human clinical specimens) are indole negative and weakly saccharolytic; the latter characteristic is also shared with the animal strains of *Porphyromonas macacae.* Most of the *Porphyromonas* spp. of

[d] Nonpigmented.

animal origin are differentiated from the human strains by a positive catalase reaction; *Porphyromonas crevioricanis,* however, is catalase negative (66).

Table 7 characterizes the more commonly isolated fusobacteria. Bizarre pleomorphic rods with very large, round bodies are suggestive of *F. mortiferum* (Fig. 10). This organism may grow on BBE and turn the agar black due to H_2S production. *F. ulcerans,* isolated from tropical ulcer, closely resembles indole-negative strains of *F. varium* but is nitrate positive. *F. periodonticum,* an oral isolate, is indole positive and bile sensitive. The national anaerobic laboratory of Finland failed to demonstrate glucose, fructose, or galactose fermentation by the type strain; this bacterium is indistinguishable from *F. nucleatum* except by 16S-23S rRNA internal transcribed spacer sequencing (26). *Fusobacterium russii* is indole negative and bile sensitive (26).

Other Approaches to Identification

Several microsystems for the identification of anaerobes are currently available. The API 20A system (bioMérieux Vitek, St. Louis, Mo.) is a microtube biochemical system that uses bromcresol purple as indicator, produces results after 24 to 48 h of incubation, and has a computerized database. The API 20A is best suited for identification of saccharolytic, fast-growing organisms such as members of the *B. fragilis* group and many clostridia. Most asaccharolytic organisms cannot be identified by API 20A, and some fastidious organisms (e.g., some *Prevotella* spp.) fail to grow. Even for many saccharolytic organisms, supplemental tests are often required for definitive identification. The color reactions are not always clear-cut, as shades of brown or no color can make interpretation of the test results difficult.

The rapid (2- to 4-h) identification systems based on detection of preformed (constitutive) enzymes by use of chromogenic or fluorogenic substrates, or a combination of both, include the RapID ANA II system (Remel), Rapid ID 32A, ANI Card, and API ZYM systems (bioMérieux), the MicroScan system (Dade Behring MicroScan, Inc., Sacramento, Calif.), and the BBL Crystal Anaerobe Identification system (Becton Dickinson Diagnostic Systems, Franklin Lakes, N.J.), as mentioned in chapter 15. The overall performance of these systems has varied from moderate to good; 53 to 100% of the isolates are identified to the species level (17, 29, 61, 79, 90, 129). The Crystal Anaerobe (ANR) Identification (ID) system was reported to identify 91% of the *B. fragilis* group and all of the *Prevotella* and *Porphyromonas* strains tested to the species level; 53% of the non-*B. fragilis* group *Bacteroides* spp. were identified correctly (17). The Rapid ID 32A system was found to be 78.4 to 90.6% accurate for the *B. fragilis* group (29, 79); a supplemental test for catalase

[f] Nitrate positive.

activity increased the accuracy to 94.6% (61). The Rapid ID 32A system identified 95.5% of the fusobacteria correctly (79); however, poor discrimination between *F. nucleatum* and *F. necrophorum* has been noted (29). Similarly, the Rapid ID 32A system accurately assigned *Prevotella* and *Porphyromonas* species to the genus level, but it less accurately differentiated between the species (29). The RapID ANA II system identified 62% of the gram-negative rods correctly (90). Use of the rapid identification systems is indicated when an identification is not achieved by using the tests described in "Rapid Identification" above but before more time-consuming tests, such as fermentation tests and GLC, are used. These systems are also suited for the identification of slowly growing fastidious gram-negative rods and cocci, since no growth in the test medium is required. When using rapid identification systems, all the information available on the organism should be considered and correspond to the profile number identification. The performance of all these systems is, of course, affected by the source and nature of the isolates and the extent of the system's database; the accuracy can be further increased by certain simple supplemental tests. The API ZYM system, which allows the detection of 19 preformed enzymes in 4 h, does not have a database; only data compiled from different publications are available, but it is a useful supplement for identification of clinically encountered anaerobic bacteria, especially the *Porphyromonas* spp. (Table 6) (33, 138).

Individually available tablets containing single, dual, or triple enzyme substrates (Rosco Diagnostic Tablets [Rosco]; WEE-Tabs [Key Scientific Products]) are much cheaper than commercial kits; they can be applied in a number of situations and allow flexibility in tailoring the set to best suit special needs (33, 57). The use of 4-methylumbelliferone derivatives of many substrates (Sigma) permits rapid and inexpensive spot tests based on fluorescence (84, 85, 95, 109). It should be noted, however, that reactions obtained by fluorogenic and the different chromogenic test applications may not completely agree, owing to divergent substrate concentrations, affinities, and buffering conditions in the different systems. Therefore, it is important to name the system used for identification when reporting enzyme reactions, particularly in publications.

A method for identification of anaerobes based on analysis of whole-cell fatty acids by capillary column GLC has been adopted primarily by some reference laboratories (96). An extensive database (MIDI, Inc., Newark, Del.) for anaerobes has been compiled, largely by the Virginia Polytechnic Institute Anaerobe Laboratory, and it is updated frequently. An option for creating a cumulative database is also available. Nucleic acid probes are not commercially available for the identification of clinically important anaerobes, but they are being used in some dental laboratories (16). Determination of arbitrarily primed PCR profiles may be useful in differentiation of certain species such as *P. intermedia* and *P. nigrescens* (72).

Matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF-MS) may have some utility for rapid identification of anaerobic bacteria (121). Ions from colony paste activated by a pulsed laser beam travel through a tube to a detector, where they are separated by differences in mass-to-ionic charge ratios, which are used to form a pattern. In practice, minimal sample preparation from a single colony is required (121). At the generic level, representative members of *Bacteroides, Prevotella,* and *Porphyromonas* may be readily distinguished. This new tool has not yet been introduced into clinical laboratories.

Identification of isolates by 16S rRNA and other genetic sequencing is gradually being adopted by dental, reference, and clinical laboratories and is also commercially available (see chapter 16) (25, 63, 68, 72, 78, 116, 125).

TYPING SYSTEMS

Due to the endogenous nature of most infections, no generally agreed upon typing systems exist.

SEROLOGICAL TESTS

Serological procedures are not practical for the identification of anaerobic bacteria from colonies. Furthermore, no standardized tests are available for the detection of antibodies or antigens in clinical specimens that would be useful for this group of organisms.

ANTIMICROBIAL SUSCEPTIBILITIES

Susceptibility testing of anaerobes is discussed in chapter 76. The susceptibility patterns for the most commonly encountered gram-negative rods of clinical significance are noted in Table 8. Resistance is increasingly common among anaerobic gram-negative rods. This is particularly true for the members of the *B. fragilis* group, which are not uncommonly resistant to expanded- and broad-spectrum cephalosporins (including β-lactamase-resistant drugs such as cefoxitin) and clindamycin. Strains of the *B. fragilis* group with resistance to imipenem and metronidazole are rarely encountered. The originally reported resistance to several antimicrobial agents in the group containing both *C. gracilis* and *S. wadsworthensis* was found to be partly due to a technical artifact (lack of formate-fumarate additive in susceptibility testing media), highlighting the importance of good growth for these assays. The true resistance seems to be confined to *Sutterella; Sutterella* spp. are more resistant to antimicrobial agents such as metronidazole and some β-lactam drugs than *C. gracilis* (94, 143).

β-Lactamase production (nitrocefin test positivity) and penicillin resistance are present in the species of the *B. fragilis* group; thus, routine testing of known *B. fragilis* group strains is unnecessary. Approximately 50% of *Prevotella* spp. are also β-lactamase producers, and even higher proportions of β-lactamase producers have been reported among certain species when several colonies per plate were tested (62, 73). An increasing number of β-lactamase-positive *F. nucleatum* strains have been encountered. Occasional strains of *C. gracilis, B. coagulans, B. splanchnicus, Desulfovibrio* spp., *F. mortiferum, F. varium, Megamonas hypermegas, M. multiacida,* and *Porphyromonas* spp. may produce β-lactamase (52). Animal-derived *Porphyromonas* spp. are more often β-lactamase producers than those derived from humans (66). *Leptotrichia* spp. as well as *Capnocytophaga* spp. are sometimes β-lactamase producers and are resistant to aminoglycosides and vancomycin; *Leptotrichia* spp. are resistant to erythromycin as well. Erythromycin and all the newer extended-spectrum macrolides except azithromycin, commonly used for the treatment of upper respiratory tract infections, such as tonsillitis, otitis media, and maxillary sinusitis, are not active against fusobacteria.

Piperacillin-tazobactam is active against most strains of anaerobic gram-negative rods, although some members of the *B. fragilis* group are resistant to ampicillin-sulbactam and amoxicillin-clavulanate. Ertapenem, imipenem, and meropenem are also consistently active against most anaerobes (49). A new antimicrobial, tigecycline, (a glycylcycline

derived from minocycline) is also very active against the full spectrum of anaerobic gram-negative rods (12). Resistance to quinolones is increasing, although moxifloxacin remains moderately active against many of these strains (46, 50, 51). Mechanisms of resistance other than β-lactamase (including high-level metalloenzyme production) include changes in penicillin-binding proteins and in outer membrane porin channels. Efflux pumps are present in many *Bacteroides* species and contribute to other mechanisms of quinolone resistance. Plasmids conferring resistance to metronidazole have been reported but have not spread resistance to this antimicrobial agent.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Because anaerobic bacteriology is time-consuming, several interim reports are desirable. The initial report can give Gram stain results. Bacterial and host cell morphologies and the relative quantities seen in the smear give a good overall impression of the specimen quality, the nature of the polymicrobial infection, and even morphologies suggestive of certain anaerobes. Furthermore, Gram stain results can guide the laboratory in choosing media for the optimal recovery of the predicted organisms. At 24 h, preliminary information on the anaerobic as well as the aerobic and facultatively anaerobic flora is available if the laboratory incubates plates in an anaerobic chamber. At 48 h, more definite information on the nonanaerobes and preliminary but clinically useful information on the anaerobes can be given (39).

Interpretation of results of a mixed culture containing multiple species is difficult. In general, bacterial isolates that are most predominant, empirically most virulent, and most resistant to antimicrobials should be given the most attention. Rough quantitation of the different isolates recovered, together with Gram stain results (provided that the specimen was properly taken and transported), is helpful. The bacteria present in pure culture or in large numbers are probably of major importance, as are organisms recovered on repeat culture and organisms isolated from normally sterile sites. The nature of the bacteria found can also give clues to their importance in the infectious process. Certain taxa, including the *B. fragilis* group, *Fusobacterium* spp., and some *Prevotella* spp., are much more important clinically in terms of the frequency of occurrence, the severity of the infection produced, and antimicrobial resistance.

Microbiologists must be willing to consult with the clinician on interpretation of the relevance of the findings. The laboratory should provide the clinician with a gradual introduction to new taxonomy by reporting both the new and old names in parallel for at least 2 years. Statements of specimen quality and possible limitations of methods used serve as the most important feedback to the clinician. Dialogue between the clinician and the microbiologist should be frequent.

Campylobacter and *Arcobacter*

COLLETTE FITZGERALD AND IRVING NACHAMKIN

59

TAXONOMY

Three closely related genera, *Campylobacter, Arcobacter,* and *Sulfurospirillum,* are included in the family *Campylobacteraceae* (95, 129). The family *Campylobacteraceae* includes 17 species in the genus *Campylobacter,* 6 species in the genus *Arcobacter,* and 6 species in the genus *Sulfurospirillum.* Since the last edition, several new species have been proposed, including *Campylobacter insulaenigrae* (32), isolated from marine mammals. Two new *Arcobacter* species have recently been described: *Arcobacter cibarius,* isolated from chickens (48), and *A. halophilus,* an obligate halophilic species (23). Some isolates previously identified as *C. gracilis* have been renamed as *Sutterella wadsworthensis* and are more closely related to *Alcaligenes* and *Bordetella* species (144).

DESCRIPTION OF AGENTS

Campylobacters are curved, S-shaped, or spiral rods that are 0.2 to 0.9 μm wide and 0.5 to 5 μm long. Certain species, such as *C. hominis,* form straight rods. *Campylobacter* species are gram-negative, non-spore-forming rods that may form spherical or coccoid bodies in old cultures or cultures exposed to air for prolonged periods. Organisms are usually motile by means of a single polar unsheathed flagellum at one or both ends but may lack flagella. Species are generally microaerobic with a respiratory type of metabolism; however, some strains grow aerobically or anaerobically. An atmosphere containing an increased hydrogen concentration is required by some species for microaerobic growth (131).

Arcobacters are gram-negative, slightly curved, curved, S-shaped, or helical non-spore-forming rods that are 0.2 to 0.9 μm wide and 1 to 3 μm long. Organisms are motile with a single polar unsheathed flagellum. Arcobacters grow at 15, 25, and 30°C but have variable growth at 37 and 42°C. Organisms are microaerobic and do not require increased hydrogen for growth. Arcobacters may grow aerobically at 30°C and anaerobically at 35 to 37°C. Most strains are nonhemolytic. *A. skirrowii* may be alpha-hemolytic (133). *A. halophilus* is an obligate halophile and grows poorly on media containing less than 2% NaCl (23).

Originally classified as free-living *Campylobacter* species, *Sulfurospirillum* spp. are slender, curved, gram-negative rods that are 0.1 to 0.5 μm wide and 1 to 3 μm long. All of the species are sulfur reducers and exhibit variable metabolic activities. *Sulfurospirillum deleyianum* is the type species of the genus. These species have no known pathogenicity for humans or animals, are environmental organisms isolated from water sediments, and will not be further discussed in this chapter (129).

EPIDEMIOLOGY AND TRANSMISSION

Campylobacter species are primarily zoonotic, with a variety of animals implicated as reservoirs for human infection (Table 1). In addition to food animals such as poultry, cattle, sheep, and pigs, *Campylobacter* species may be present in domestic pets. Humans appear to be the only recognized reservoirs for the periodontal pathogens, *C. concisus, C. rectus, C. curvus,* and *C. showae.*

Campylobacter infections are common in both the developed and the developing world. The reported incidences of culture-confirmed infections vary considerably from country to country, and as culturing practices and reporting requirements can vary, direct comparison of the reported incidences can be complex. In the United States, where reporting practices vary from state to state, the food-borne-disease active surveillance program FoodNet (http://www.cdc.gov/foodnet) provides uniform reporting from a panel of sentinel sites, giving an accurate measure of the incidence of diagnosed infections. FoodNet data suggest that numbers of campylobacteriosis cases in the United States reached a peak in the mid-1990s and showed a decline from 1996 to 1999 (110). This decline continued somewhat through 2003 and into 2004, with the incidence of diagnosed *Campylobacter* infections at 12.6 and 12.9 per 100,000 people, respectively, lower than that of salmonellosis (17). A comparison of the data from 1996 to 1998 with the 2004 data shows that the estimated incidence of infection with *Campylobacter* decreased 31%. However, *C. jejuni* subsp. *jejuni,* referred to as *C. jejuni,* continues to be the most common enteric pathogen isolated from patients in some states, according to FoodNet reports, with 1.4 million cases estimated to occur in the United States annually (110). Because of underdiagnosis and underreporting, the actual incidence in any country is substantially greater than the reported incidence. For example, in the United States, it was estimated that the true incidence was 35-fold higher than the reported incidence, or 515 per 100,000 people in 1999 (110).

TABLE 1 Reservoirs for and diseases associated with *Campylobacter* and *Arcobacter* species[a]

Species	Humans	Cattle	Sheep	Pigs	Wild birds	Poultry	Pets	Rodents	Types of infection[b]
C. jejuni subsp. *jejuni*	×	×			×	×	×		GI, B
C. jejuni subsp. *doylei*	×								GI, B
C. coli				×	×	×			GI, B
C. fetus subsp. *fetus*		×	×						GI, B
C. upsaliensis						×	×		GI, B
C. lari					×		×		GI, B
C. hyointestinalis		×		×		×	×	×	GI
C. helveticus							×		NR
C. sputorum	×[c]	×[d,e]	×[e]						GI[c]
C. concisus	×								D
C. curvus	×								D
C. rectus	×								D, GI
C. showae	×								D
C. gracilis	×								D
C. mucosalis				×					NR
A. butzleri		×		×		×			GI, B, T
A. cryaerophilus		×	×	×		×			GI
A. skirrowii		×	×	×		×			GI

[a] The information in this table is from references 66, 83, 112, and 130.
[b] GI, gastrointestinal; B, bloodstream; D, oral or dental; T, soft tissue; NR, not reported to be associated with human infections.
[c] Biovar sputorum.
[d] Biovar paraureolyticus.
[e] Biovar faecalis.

The epidemiology of campylobacteriosis does not appear to have changed over the last 5 years. *Campylobacter* infections are usually sporadic, occurring in the summer months and early fall, and usually follow ingestion of improperly handled or improperly cooked food, primarily poultry products. A large case control study concluded that numerous food sources are associated with *Campylobacter* infections but that a large proportion of infection is attributable to consumption of poultry and other meats in restaurants (33). The incidence of infection follows a bimodal age distribution, with the highest incidence in infants and young children, followed by a second peak in young adults 20 to 40 years old (110). Outbreaks usually occur in the spring and fall months, and in recent years, most outbreaks have been food (poultry and unpasteurized dairy products) or water associated. Milk-borne outbreaks, while common in the 1980s and early 1990s, are less frequently reported now; the most recent milk-borne outbreaks were reported in Wisconsin in 2001 (44) and Michigan in 2003 (http://www.cdc.gov/foodborneoutbreaks/us_outb/fbo2003/summary03.htm).

The incidence of *Campylobacter* infection in developing countries such as Mexico and Thailand is much higher than that in the United States. In developing countries, *Campylobacter* is frequently isolated from individuals who may or may not have diarrheal disease. Most symptomatic infections occur in infancy and early childhood, and incidence decreases with age. Travelers to developing countries are at risk for developing *Campylobacter* infection, with isolation rates from 0 to 39% reported in different studies (91).

CLINICAL SIGNIFICANCE

C. jejuni and *C. coli*

C. jejuni and *C. coli* have been recognized since the early 1970s as agents of gastrointestinal infection. *C. jejuni* is one of the most common causes of bacterial enteritis in the United States. *C. jejuni* and *C. coli* continue to be the most common *Campylobacter* species associated with diarrheal illness and produce clinically indistinguishable infections. Most laboratories do not routinely distinguish between these organisms.

In patients with gastroenteritis caused by *C. jejuni* or *C. coli*, symptoms range from nonexistent to severe and may include fever, abdominal cramping, and diarrhea (with or without blood or fecal white blood cells) that last several days to more than 1 week. Symptomatic infections are usually self-limited, but relapses may occur in 5 to 10% of untreated patients (11). *Campylobacter* infection may mimic acute appendicitis and result in unnecessary surgery. Extraintestinal infections and other complications have been reported following *Campylobacter* enteritis and include bacteremia, hepatitis, cholecystitis, pancreatitis, abortion and neonatal sepsis, nephritis, prostatitis, urinary tract infection, peritonitis, myocarditis, and focal infections including meningitis, septic arthritis, and abscess formation (114). Bacteremia has been reported to occur at a rate of 1.5 per 1,000 intestinal infections, with the highest rate occurring in the elderly (115). Persistent diarrheal illness and bacteremia may occur in immunocompromised hosts, such as patients with human immunodeficiency infection (102), and may be difficult to treat. Deaths attributable to *C. jejuni* infection are uncommon (34). The health burden of campylobacteriosis may be under-recognized (45).

C. jejuni infection is the most often recognized infection preceding the development of Guillain-Barré syndrome (GBS), an acute paralytic disease of the peripheral nervous system (85). Certain heat-stable (HS) serotypes appear to be overrepresented in some GBS cases, such as HS:19 and HS:41; however, other more common serotypes are frequently reported (85). The pathogenesis of *Campylobacter*-induced GBS likely involves host immune responses to ganglioside-like epitopes present in the core region of the lipooligosaccharide (36) which, in the susceptible host, mediate damage to the peripheral nerves, where ganglioside targets are highly enriched (145).

Reactive arthritis sometimes follows *Campylobacter* infection, with the onset of pain and joint swelling occurring an average of 2 weeks after the infection and lasting from a few weeks to nearly a year. Reiter's syndrome may also occur in some patients (114). The pathogenesis of *Campylobacter* infection and joint involvement is unknown, but HLA B27 positivity is strongly associated with reactive arthritis (19).

The pathogenesis of *Campylobacter* enteric infection is still not well understood. The infective dose of *Campylobacter* is not well defined, but as few as 1,000 organisms may be capable of causing illness (9). The signs and symptoms of infection suggest an invasive mechanism of disease. A variety of determinants may be important in the virulence of *C. jejuni* infection, including invasiveness (49), the presence or absence of the large virulence plasmid pVir (64), protein glycosylation (120), and motility (53). *C. jejuni* express a cytolethal distending toxin; however, the role of the toxin in pathogenesis is not understood (63). *Campylobacter* spp. do not produce a classic, cholera-like enterotoxin (142).

Campylobacter Species Other Than *C. jejuni* and *C. coli*

Campylobacter species other than *C. jejuni* and *C. coli* are increasingly isolated from cases of human infection in newer studies using culture methods that are more optimal for the non-*C. jejuni* and non-*C. coli* species.

C. fetus subsp. *fetus* is primarily associated with bacteremia and extraintestinal infections in patients with underlying diseases (11). *C. fetus* is also associated with septic abortions, septic arthritis, abscesses, meningitis, endocarditis, mycotic aneurysm, thrombophlebitis, peritonitis, and salpingitis (11). Although gastroenteritis does occur with this species, the incidence is probably underestimated because the organism may not grow well at 42°C and is usually susceptible to cephalothin, an antimicrobial agent used in some common selective media for stool cultures (135). *C. fetus* subsp. *fetus* produces a surface protein microcapsule composed of a high-molecular-weight surface array protein that is essential for virulence (126). *C. fetus* subsp. *venerealis* causes bovine venereal campylobacteriosis and is a cause of bovine infertility. It has rarely been isolated from cases of human infection (126).

C. upsaliensis is a thermotolerant species that causes diarrhea and bacteremia in humans and is also associated with canine and feline gastroenteritis (39, 135). *C. upsaliensis* is susceptible to many antimicrobial agents present in *C. jejuni*-selective media and, thus, is usually not isolated on routine primary isolation media; it can be recovered using the filtration technique described below.

C. lari is a thermophilic species first isolated from gulls of the genus *Larus* and from other avian species, dogs, cats, and chickens. *C. lari* has been infrequently reported to be isolated from humans with bacteremia and gastrointestinal and urinary tract infections. A waterborne outbreak of infection occurred in 1985 and affected more than 100 individuals (121).

Other *Campylobacter* species have been isolated from clinical specimens from patients with a variety of diseases, but their pathogenic role has not been determined. *C. jejuni* subsp. *doylei* is a nitrate-negative subspecies of *C. jejuni* that is rarely recovered from patients with upper gastrointestinal tract infections and gastroenteritis (39, 118). *C. hyointestinalis* has been occasionally associated with proctitis and diarrhea in human infection (24). *C. concisus* is associated primarily with periodontal disease but has also been isolated from patients with bacteremia, foot ulcers, and upper and lower gastrointestinal tract infections (54, 132). Although *C. concisus* has been isolated from many patients with diarrheal illness, it can also be isolated from the feces of healthy individuals, and there is no convincing evidence to date that it causes diarrhea (28, 137). *C. sputorum* biovars have been associated with lung, axillary, scrotal, and groin abscesses (66). *C. sputorum* bv. paraureolyticus, formerly referred to as catalase-negative, urease-positive campylobacter, has been isolated from patients with diarrhea, but the significance of this finding is unknown (97). *C. mucosalis* was reportedly isolated from two children with enteritis (30), but the isolates were subsequently shown to have been misidentified and were actually *C. concisus* (96). *C. helveticus* (117) has been recovered from domestic cats and dogs and has not been reported to have been isolated from human sources. *C. rectus* is primarily isolated from patients with active periodontal infections but has also been isolated from patients with pulmonary infections (107, 116) and a breast abscess (42). *C. curvus* is also isolated from patients with periodontal infections, but its role in gastrointestinal infections is unknown (28). *C. curvus* was isolated from numerous patients with diarrhea (1) and from patients with a liver abscess and pneumonia (42). *C. showae* has been isolated from the human gingival crevice (29). *C. gracilis* has been isolated from patients with appendicitis and peritonitis, bacteremia, soft-tissue abscesses, and pulmonary infections (81). A more extensive review of the clinical significance of non-*C. jejuni* and non-*C. coli* species was published previously (66).

Arcobacter

Arcobacters are aerotolerant, *Campylobacter*-like organisms frequently isolated from bovine and porcine products of abortion and feces of animals with enteritis (143). Two of the five *Arcobacter* species have been associated with human infection. *A. butzleri* has been isolated from patients with bacteremia, endocarditis, peritonitis, and diarrhea (66, 135). *A. cryaerophilus* strains have been previously classified into two DNA-related groups, 1A and 1B (60). *A. cryaerophilus* group 1B has been isolated from patients with bacteremia and diarrhea (66, 135). Group 1A has been isolated from animal sources (60). *A. butzleri* was reported by Vandenberg et al. to be the fourth most common *Campylobacter*-like organism isolated from patients with diarrhea (135) and may be underrecognized if appropriate culture conditions are not used. *A. nitrofigilis,* a nitrogen-fixing bacterium found on the roots of a small marsh plant in Nova Scotia, is not associated with human disease (77). The recently described *A. cibarius* has been isolated only from poultry carcasses; the clinical significance of this species is unknown (48). *A. halophilus* requires increased salt for growth in culture; however, the medical significance of this species is unknown (23).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Fecal Samples

Fecal specimens are preferred for isolating *Campylobacter* species from patients with gastrointestinal infections; however, rectal swabs are acceptable for culture. For hospitalized patients, the 3-day rule (rejection of specimens collected >72 h after admission) should be used as a criterion for acceptability of routine culture requests (40, 47). For routine purposes, testing of a single stool sample has high sensitivity for detection of common enteric pathogens, but testing of two samples may be desirable depending upon clinical circumstances, such as a >2-h delay in transport of the first sample, that could affect recovery (128). A transport

medium should be used when a delay of more than 2 h is anticipated and when rectal swabs are transported. Several types of transport media are useful for *Campylobacter,* including alkaline peptone water with thioglycolate and cystine (140), modified Stuart medium (2), and Cary-Blair medium (16). Transport media such as commercial Stuart medium and buffered glycerol saline do not appear to perform well (140). Modified Cary-Blair medium containing reduced agar (1.6 g/liter) appears to be the most suitable single transport medium for *Campylobacter* as well as other enteric pathogens (140). Specimens received in Cary-Blair medium should be stored at 4°C if processing is not performed immediately. Use of Cary-Blair medium supplemented with laked sheep blood may be effective for prolonged storage of stool samples and recovery of *C. jejuni* (141).

Blood

Campylobacter species, primarily *C. fetus, C. jejuni,* and *C. upsaliensis,* have been isolated from blood; however, in only a few studies have optimal conditions for isolating *Campylobacter* from blood culture systems been evaluated. Both the BACTEC system (BD, Sparks, Md.; aerobic bottles) and the Septi-Chek system (BD) appear to support the growth of the common *Campylobacter* species (59, 65, 139). Other systems, such as anaerobic broth and lysis-centrifugation, may not be as sensitive (59).

DIRECT EXAMINATION

Microscopy

Clinical microbiologists do not normally consider performing Gram stain analysis of stool samples for diagnosis of bacterial gastroenteritis; however, this is a rapid and sensitive method for presumptive diagnosis of *Campylobacter* enteritis. Campylobacters are not easily visualized with the safranin counterstain commonly used in the Gram stain procedure and are somewhat thinner than other enteric gram-negative bacteria; carbol-fuchsin or 0.1% aqueous basic fuchsin should be used as the counterstain for smears of stools or pure cultures (99, 111, 138). Because of their characteristic microscopic morphology, campylobacters may be detected by direct Gram stain examination of stools obtained from patients with acute enteritis, with sensitivity ranging from 66 to 94% and specificity above 95% (99, 111, 138). Phase-contrast and dark-field microscopy have also been used to directly detect motile campylobacters in fresh stool samples; however, the sensitivities of these approaches have not been studied widely, and in our opinion, these methods require significant microscopic expertise (56, 98).

Fecal white blood cells may be present during *Campylobacter* infection and have been reported in 25 to 80% of culture-proven cases (47). While the likelihood of infection with *Campylobacter* or other enteroinvasive pathogens may be higher in the presence of fecal leukocytes, the absence of fecal leukocytes does not rule out the diagnosis (128). Thus, routine examination of stool samples for fecal leukocytes is not recommended as a test for predicting bacterial infection or for selective culturing for *Campylobacter* or other stool pathogens (40).

Antigen Detection

A commercially available antigen detection system for *Campylobacter* in stool samples is available (ProSpecT *Campylobacter;* Alexon-Trend, Inc. [distributed through Remel, Lenexa, Kans.]). Compared with culture, this immunoassay has been shown to vary in sensitivity from 80 to 96%, and it has good specificity, >97% (21, 46, 127). *C. upsaliensis* was found to cross-react in the enzyme immunoassay (21). Antigen may be detected in stored samples at 4°C for several days (25).

Nucleic Acid Detection Techniques

Amplification techniques have been used to detect *Campylobacter* directly in stool samples (103). Molecular approaches to detecting *Campylobacter* directly may reduce the time to detection and improve abilities to identify isolates to the species level and to identify the less common *Campylobacter* species often missed by conventional culture. A commercially available molecular test for detection of *Campylobacter* spp. in fecal samples is not currently available. Molecular approaches are also more expensive than culture and do not provide an isolate for further characterization.

ISOLATION PROCEDURES

Most *Campylobacter* species require a microaerobic atmosphere containing approximately 5% O_2, 10% CO_2, and 85% N_2 for optimal recovery. Several manufacturers produce microaerobic gas generator packs that are suitable for routine use. A trigas incubator (125) or evacuation and replacement of an anaerobic jar with the approximate gas mixture may also be used for routine cultures (82). The concentration of oxygen generated in candle jars is suboptimal for the isolation of *Campylobacter,* and these jars should not be used for routine laboratory isolation procedures (72).

Some species of *Campylobacter,* such as *C. sputorum, C. concisus, C. mucosalis, C. curvus, C. rectus,* and *C. hyointestinalis,* require increased hydrogen for primary isolation and growth. These species will usually not be recovered using the conventional microaerobic conditions since the amount of hydrogen generated in properly used commercial gas packs is <2%. A gas mixture of 10% CO_2 and 6% H_2, with the balance consisting of N_2, in an evacuation-replacement jar is sufficient for isolating hydrogen-requiring species (12). A study by Vandenberg and colleagues reemphasized the requirement for increased hydrogen for isolating certain *Campylobacter* spp. (135).

A number of selective media are recommended for isolating *C. jejuni* and *C. coli.* These include blood-free media, such as charcoal cefoperazone deoxycholate agar (CCDA) (51) and charcoal-based selective medium (CSM) (57), and blood-containing media, such as Campy-CVA medium (L. B. Reller, S. Mirrett, and L. G. Reimer, *Abstr. Annu. Meet. Am. Soc. Microbiol. 1983*, abstr. C-274, p. 357, 1983) and Skirrow medium (113). Charcoal-based medium containing cefoperazone, amphotericin, and teicoplanin (CAT medium) is a selective medium for the primary isolation of *C. upsaliensis* (6). Researchers in two studies, however, did not isolate *C. upsaliensis* from any stool samples by using this medium (28, 46). *C. upsaliensis* may occasionally be recovered on some other selective media. *C. upsaliensis* isolates can also be recovered by using the filtration method, and some strains may grow better in a hydrogen-enriched atmosphere (39, 66).

To achieve the highest yield of *Campylobacter* from stool samples, use of a combination of media including either CCDA or CSM as one of the media appears to be the optimal method (26, 41) and may increase the recovery of *Campylobacter* by as much as 10 to 15% over that with the use of a single medium. If only a single medium can be used because of budgetary constraints, we suggest the Campy-CVA formulation, but a charcoal-based medium such as CCDA

works just as well. In a comparative study, CCDA medium was found to be the most sensitive for detecting *C. jejuni* and *C. coli* when compared with Skirrow medium, CAT agar, and the filtration technique (28).

Most of these selective media have one or more antimicrobial agents, mainly cefoperazone, as the primary inhibitors of enteric bacterial flora. Antimicrobial agents such as cephalothin, colistin, and polymyxin B present in some selective medium formulations are inhibitory to some strains of *C. jejuni* and *C. coli* (38, 90), and are inhibitory to *C. fetus* subsp. *fetus*. *C. jejuni* subsp. *doylei*, *C. upsaliensis*, and *A. butzleri* generally will not grow on cephalothin-containing media. We no longer recommend cephalothin-containing formulations for primary isolation of *Campylobacter* and *Arcobacter* from fecal samples.

If *Campylobacter* infection is suspected at the time blood specimens are drawn, broth media should be subcultured after 24 to 48 h to a nonselective blood agar medium and plates should be incubated under microaerobic conditions at 37°C, preferably with increased hydrogen. This will allow for the isolation of thermophilic and nonthermophilic species. Although commonly used blood culture systems should support the growth of *Campylobacter* and give appropriate signals if cultures are positive, it may be prudent to perform a blind subculture. Similarly, blood drawn in Isolator (Wampole Laboratories, Cranbury, N.J.) tubes for bacterial culture should be inoculated onto a nonselective blood agar plate and incubated under microaerobic conditions at 37°C if *Campylobacter* infection is suspected. If a curved, gram-negative rod is observed upon Gram stain examination of a positive blood culture bottle, an aliquot should be cultured on a nonselective blood agar plate and incubated under microaerobic conditions at 37°C. An alternative staining method such as the use of acridine orange may also be effective for detecting campylobacters in blood culture bottles if the Gram stain is negative.

Optimal conditions for recovery of *Arcobacter* from clinical specimens have not been determined. *Arcobacter* spp. were first isolated on semisolid media designed to isolate *Leptospira* spp. (133, 143). *Arcobacter* species are aerotolerant and have been recovered on certain selective media such as Campy-CVA (5) incubated under microaerobic conditions at 37°C and on nonselective media used in the filtration method (135). Several other media have been reported to recover *Arcobacter* species but have not been studied in clinical settings (5, 20, 133).

Enrichment Cultures

Enrichment broths formulated to enhance the recovery of *Campylobacter* from stool include Preston enrichment (13), Campy-thio (109), and *Campylobacter* enrichment broth (76). Enrichment cultures may be beneficial in instances in which low numbers of organisms may be expected due to delayed transport to the laboratory or after the acute stage of disease, when the concentration of organisms may be low, such as in the investigation of GBS following acute *Campylobacter* infection (84). The clinical effectiveness and cost-effectiveness of using enrichment cultures as part of the routine stool culture setup has not been studied adequately.

Filtration

Filtration techniques designed to isolate *C. jejuni* and *C. coli* as well as other *Campylobacter* species (28, 38, 135) and *Arcobacter* spp. (60, 135) that are susceptible to antibiotics present in most selective media (135) should be used to complement direct culture to selective plating media and not as a replacement. The filtration method is based on the principle that campylobacters can pass through membrane filters (pore sizes, 0.45 to 0.65 μm) with relative ease (because organisms are thin and highly motile) while other stool flora are retained during the short processing time. Cellulose acetate membrane filters with a 0.65-μm pore size are recommended for routine use and are available from a number of suppliers (J. G. Wells, N. D. Puhr, C. M. Patton, M. A. Nicholson, M. A. Lambert, and R. Jerris, *Abstr. Annu. Meet. Am. Soc. Microbiol. 1989*, abstr. C231, p. 432, 1989). Filtration is performed by placing a sterile 0.65-μm-pore-size cellulose acetate filter onto the surface of an agar medium such as antibiotic-free CCDA, CSM, or blood-containing medium. Ten to 15 drops of fecal suspension are placed onto the filter, and the plate is incubated at 37°C for 45 to 60 min. The filter is then removed, and the plate is incubated at 37°C under microaerobic conditions, preferably with an atmosphere containing increased hydrogen (for the hydrogen-requiring species). Stool samples containing ~10^5 CFU of *Campylobacter*/ml will be detected with this method, and thus, the filtration method is not as sensitive as primary culture with selective media (39).

Species within the genus *Campylobacter* and *Arcobacter* have different optimal temperatures for growth. The choice of incubation temperature for routine stool cultures, therefore, is critical in determining the spectrum of species that will be isolated. By convention, most laboratories use 42°C as the primary incubation temperature for *Campylobacter*. This temperature allows the growth of *C. jejuni* and *C. coli* on selective media. *C. upsaliensis* also grows well at 42°C but usually is not recovered on selective media. *C. fetus* exhibits variable growth at this temperature and may not be recovered. *Arcobacter* species are not thermophilic and will generally not be recovered at 42°C.

In contrast, most *Campylobacter* and *Arcobacter* species grow well at 37°C. Selective media, such as Skirrow medium, were devised for use at 42°C and have poor selective properties at 37°C, whereas CCDA and CSM show good selective properties at 37°C (26). Plates should be incubated for a minimum of 72 h before being reported as negative. It has been reported that incubation of CCDA medium for 5 to 6 days increases the yield of *C. jejuni* and *C. coli* compared with that obtained after 2 days of incubation (28).

Because of the expense of including several types of media and the filtration method in the initial workup for campylobacters, a practical approach is to use a single medium for isolation of thermophilic *Campylobacter* spp., such as Campy-CVA or CCDA (or equivalent) incubated at 42°C, in the workup for acute bacterial gastroenteritis. If the primary culture workup is unrevealing and if a patient has persistent diarrhea, cultures for non-*C. jejuni* and non-*C. coli* species may be appropriate. Additional stool samples should be plated on multiple selective media (e.g., CCDA and Campy-CVA), processed by the filtration method as well, and incubated at 37°C under microaerobic conditions with increased hydrogen.

IDENTIFICATION

The identification of campylobacters is made difficult because of their complex and rapidly evolving taxonomy, fastidious growth requirements, and biochemical inertness (Table 2). These problems have resulted in a proliferation of phenotypic and genotypic methods for identifying members of this group (93).

TABLE 2 Useful phenotypic properties of *Campylobacter* and *Arcobacter* species[a]

Organism	Catalase	H_2 required	Urease	H_2S (TSI)	Hippurate hydrolysis	Indoxyl acetate hydrolysis	Aryl sulfatase	Selenite reduction	Growth in 1% glycine

[c] Anaerobic growth only.

Campylobacter spp. and *Arcobacter* spp.

Depending on the medium used, *Campylobacter* colonies may have different appearances. In general, *Campylobacter* spp. produce gray, flat, irregular, and spreading colonies. Spreading along the streak line is commonly seen, particularly on freshly prepared media. As the moisture content decreases, the organisms may form round, convex, and glistening colonies with little spreading observed. Thus, proper storage of media to ensure correct moisture content is important for optimal isolation and recognition of *Campylobacter* spp. Hemolysis on blood agar is not observed. *Arcobacter* colonies are morphologically similar to *Campylobacter* colonies (129, 133).

The Gram stain appearance of arcobacters may differ from that of typical campylobacters. *A. butzleri* is only slightly curved, and *A. cryaerophilus* tends to be much more helical in appearance than campylobacters. Commercial systems for identification of *Campylobacter* species were not found to be more accurate than conventional tests (52). Unfortunately, *Campylobacter* species are difficult to differentiate from *Arcobacter* species based on phenotypic tests. However, an aerotolerant species (i.e., one that grows under aerobic conditions) that grows on MacConkey agar (under microaerobic conditions) may be presumptively identified as an *Arcobacter* species. The failure to grow on MacConkey agar, however, does not rule out an *Arcobacter* species.

C. jejuni and *C. coli*

For initial analysis, a Gram stain examination of the colony should be performed along with an oxidase test. Oxidase-positive colonies exhibiting a characteristic Gram stain appearance (e.g., gram-negative, curved to S-shaped rods) isolated from selective media incubated at 42°C under microaerobic conditions can be reliably reported as *Campylobacter* spp., and only hippurate hydrolysis testing is recommended (Fig. 1). Hydrolysis of sodium hippurate is the major test for distinguishing *C. jejuni* (and also *C. jejuni* subsp. *doylei*) from other *Campylobacter* species. *C. jejuni,* the most common *Campylobacter* species, is relatively easy to identify phenotypically; strains isolated on selective media that grow at 42°C, are oxidase positive, show characteristic microscopic morphology, and give a positive result with hippurate hydrolysis should be reported as *C. jejuni* subsp. *jejuni,* and for routine clinical purposes, no other tests need to be performed. Methods for the hippurate hydrolysis test are described elsewhere (73). A large inoculum (i.e., full loop) should be used in performing this test. Occasional strains of *C. jejuni* may be hippurate negative, making them more difficult to identify. Gas-liquid chromatography for detecting benzoic acid (liberated through hydrolysis of sodium hippurate) is the most sensitive assay for hippurate hydrolysis and can be used for more definitive determination. Molecular detection of the *hip*O (hippuricase) gene or other *C. jejuni*-specific markers (see Table 3) by PCR may be useful for identifying phenotypically negative isolates (43). Except in hippuricase activity, which *C. coli* is lacking, *C. coli* and *C. jejuni* are similar biochemically (Table 2). Thus, molecular methods are needed to accurately identify *C. coli*. Tests of susceptibility (inhibition) or resistance of *Campylobacter* spp. to nalidixic acid and cephalothin have routinely been used as an aid for species identification. However, with the increasing prevalence of fluoroquinolone resistance in these species, these disk identification assays can no longer be relied upon.

For species other than *C. jejuni,* phenotypic characterization is more problematic. An algorithm for identification of the thermophilic *Campylobacter* spp. is shown in Fig. 1. The most useful tests for initial identification include those for growth at 25, 37, and 42°C; catalase; hippurate hydrolysis (73); indoxyl acetate hydrolysis (74); and production of H_2S (8). Indoxyl acetate hydrolysis is useful for differentiating some species of thermophilic *Campylobacter*. The disk method is rapid (5 to 30 min) and easy to perform. Disks are prepared by making a 20% solution of indoxyl acetate in acetone and adding 25 μl to a blank paper disk (0.6 cm). Dry the disks at room temperature and store them at 4°C in a brown tube with desiccant. Indoxyl acetate disks are also available ready made from commercial sources. Place a large loopful of growth from a plate onto the indoxyl acetate disk and add a drop of sterile distilled water. Hydrolysis of indoxyl acetate is indicated by the appearance of dark blue or blue-green. Weakly positive strains show pale blue in 10 to 30 min. Absence of color change is indicative of a negative reaction.

Additional tests can be performed to aid in the identification of *Campylobacter* spp. (Fig. 1). To obtain consistent and reproducible results, a standardized suspension and inoculum should be used for performing phenotypic tests. For growth temperature and oxygen tolerance studies, a suspension of the organism in heart infusion broth or tryptic soy broth to the turbidity of a McFarland standard of 1 should be used. A fiber-tipped swab dipped in the broth suspension should be used to make a single streak across the plate (Mueller-Hinton agar with 5% sheep blood is a suitable medium) and the plate should be incubated at the desired temperature and/or under the appropriate atmospheric conditions (8, 82).

Several commercial systems have been developed to aid in the identification of *Campylobacter* spp. to the genus level. Two immunologic reagents are currently available in the United States for culture identification, INDX Campy-JCL (Hardy Diagnostics, Santa Maria, Calif., and Fisher Scientific, Hampton, N.H.) and Dry Spot campylobacter test kit (Remel). INDX Campy-JCL was previously evaluated and does not differentiate between *C. jejuni* and *C. coli* (86). The Dry Spot campylobacter latex test is reported by the manufacturer to identify, but not differentiate among, *C. jejuni, C. coli, C. lari,* and *C. upsaliensis,* with variable results for *C. fetus* subsp. *fetus* (Oxoid USA; http://www.oxoid.com). A DNA probe (Accuprobe; Gen-Probe Inc., San Diego, Calif.) directed against *Campylobacter* rRNA sequences identifies *Campylobacter* species to the genus level and detects *C. jejuni* subsp. *jejuni, C. jejuni* subsp. *doylei, C. coli,* and *C. lari* (106, 124). However, the probe also hybridized with 2 of 17 *C. hyointestinalis* strains (106). Thus, these methods may be useful for confirming the identities of *Campylobacter* species to the genus level if other tests are not conclusive. However, cross-reactivity in these tests with closely related taxa and/or more newly described species needs to be determined.

Because many species of *Campylobacter* and *Arcobacter* are difficult to identify by phenotypic testing, tests for detection of species-specific sequences via PCR have been developed. *C. jejuni, C. coli,* and other *Campylobacter* and *Arcobacter* species have been reported to be reliably differentiated based on polymorphism in the *ceuE* gene (37), a GTPase gene (136), a 16S rRNA gene (75), a 23S rRNA gene (50), and the *glyA* gene (4). Table 3 lists some of the more commonly used published PCR assays for the identification of *C. jejuni* and *C. coli*. Recently published evaluations of some of these assays highlight the importance of validating their sensitivities and specificities (15, 94). In addition, it has been reported that the use of heated lysates rather than purified DNA may in some cases not always provide a suitable reaction template for these PCR assays (80, 94). As false

[f]*C. hyointestinalis* grows under microaerophilic conditions, but some strains require additional hydrogen (66). [g]Rapid H_2S test (69). [h]Urease-positive *C. lari* strains are referred to as the urease-positive thermophilic campylobacter group.

negatives or nonspecifically amplified product(s) have been noted for some of the *C. jejuni*-specific assays, a second PCR targeting another *C. jejuni*-specific gene may be necessary in some instances.

TYPING SYSTEMS

Typing systems for *Campylobacter* epidemiologic studies vary in complexities and abilities to discriminate among strains. Common phenotypic methods that have been applied include biotyping, phage typing, and serotyping (89, 100). The most frequently used system is serotyping. The heat-labile serotyping scheme originally described by Lior et al. (70) can detect over 100 serotypes of *C. jejuni, C. coli,* and *C. lari*. Uncharacterized bacterial surface antigens and, in some serotypes, flagellar antigens are the serodeterminants for this serotyping system (3). The heat-stable (HS) serotyping scheme described by Penner and Hennessy (101) detects 60 types of *C. jejuni* and *C. coli* (100). Initially thought to detect lipopolysaccharide antigenic determinants, the HS system has been shown to detect a *Campylobacter* capsular polysaccharide (55). Serotyping is performed in only a few reference laboratories worldwide because of the time and expense needed to maintain quality antisera. A serotyping reagent kit is also commercially available (Denka Seiken USA Inc., Campbell, Calif.).

The limitations of phenotypic subtyping methods and the rapid growth of molecular biology techniques in the 1990s led to the development of a range of molecular biology-based subtyping methods, such as restriction endonuclease analysis, ribotyping, PCR-based techniques, pulsed-field gel electrophoresis of macrorestricted chromosomal DNA (PFGE), and amplified fragment length polymorphism (89, 100). The development of a rapid one-day standardized PFGE protocol (108), which is used by participants of the PulseNet national surveillance network for foodborne pathogens (http://www.cdc.gov/pulsenet), has facilitated the use of the PFGE approach for investigations of campylobacteriosis outbreaks (92). However, interpretation of data can be difficult since genomic rearrangements can lead to changes in PFGE profiles (31). Advances in DNA sequencing technology have provided a means to investigate strain variation at the nucleotide level and have led to the emergence of DNA sequencing-based subtyping systems such as multilocus sequence typing (22). In addition, the generation of *Campylobacter* whole-genome sequences has led the way for the development of a new technique, genomotyping based on microarray technology (61). At present, no method alone is adequate for all applications, and a combination of methods such as serotyping and molecular methods should be used for reliably determining strain relatedness and for studying the epidemiology of *Campylobacter* infections (89).

SEROLOGIC TESTS

Serum immunoglobulin G (IgG), IgM, and IgA levels rise in response to infection, but elevated serum and fecal IgA levels appear during the first few weeks of infection and then fall rapidly (10, 123). Serum antibody assays vary in both sensitivity and specificity for detecting *Campylobacter* infection, and test performance appears to be population dependent. Patients with *Campylobacter* infection may have false-positive legionella antibody tests (14). Serologic testing appears to be useful for epidemiologic investigations and is not recommended for routine diagnosis (122).

ANTIMICROBIAL SUSCEPTIBILITY

C. jejuni and *C. coli* have variable susceptibilities to a variety of antimicrobial agents, including macrolides, fluoroquinolones, aminoglycosides, chloramphenicol, nitrofurantoin, and tetracycline (http://www.cdc.gov/NARMS) (11). Most isolates are not susceptible to cephalosporins and penicillins (11). Azithromycin and erythromycin are drugs of choice for treating *C. jejuni* gastrointestinal infections, and for susceptible organisms, ciprofloxacin or norfloxacin may also be used (35). Early therapy of susceptible *Campylobacter* infection with erythromycin or ciprofloxacin is effective in eliminating the organism from stools and may also reduce the duration of symptoms associated with infection (11).

C. jejuni is generally susceptible to erythromycin, with resistance rates of less than 5% (27). Rates of erythromycin resistance in *C. coli* vary considerably, with up to 80% of strains showing resistance in some studies (27). Although ciprofloxacin has been effective in treating *Campylobacter* infections, the emergence of ciprofloxacin resistance during therapy has been reported (104). Several in vitro studies now show significant rates of resistance to fluoroquinolones (27, 58, 87). Individuals infected with fluoroquinolone-resistant *C. jejuni* have been shown to have diarrhea for a longer duration, and thus, routine testing of isolates may be indicated (88). *C. jejuni* and *C. coli* may also produce a β-lactamase that appears to be active against amoxicillin, ampicillin, and ticarcillin; this enzyme has been reported to be inhibited by clavulanic acid but not sulbactam or tazobactam (62).

Parenteral therapy is used to treat systemic *C. fetus* infections; drugs used include erythromycin, ampicillin, aminoglycosides, and chloramphenicol, depending upon the type of infection (11). *C. gracilis* is generally susceptible to a variety of antimicrobial agents, including amoxicillin-clavulanate, cefoxitin, ceftriaxone, clindamycin, metronidazole, and piperacillin-tazobactam (80).

Agar dilution is the method recognized by the Clinical and Laboratory Standards Institute (formerly NCCLS) for testing *Campylobacter* spp., with published quality control ranges for several antimicrobial agents (18, 78). A broth microdilution method with published quality control ranges for several antimicrobial agents was also recently approved by the Clinical and Laboratory Standards Institute (79). The E test (PDM Epsilometer; AB Biodisk, Solna, Sweden) using Mueller-Hinton agar with 5% sheep blood compares favorably with the agar dilution method (7).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Campylobacter species, including the common thermophilic species *C. jejuni* and *C. coli,* should be sought in all diarrheic

stools submitted to the laboratory for routine culture. Except for epidemiological purposes, cultures of formed stools should not be performed. Isolation of *Campylobacter* from a patient with acute diarrhea is usually significant since the carrier rate in developed countries is quite low; however, in developing countries, isolation might be more difficult to interpret, especially in the presence of other enteric pathogens. In acute infection, there is usually a high number of organisms in the stool; however, the quantity of organisms is not related to the severity of infection, nor is it indicative of a carrier state. Gram stain analysis of fecal samples for organisms with typical *Campylobacter* morphology is a highly sensitive and specific test that is currently underutilized; it should be performed for rapid preliminary diagnosis of *Campylobacter* infection. Other species, such as *C. fetus* subsp. *fetus* and *C. upsaliensis*, may be important causes of diarrhea and are not isolated on routine selective media. Special methods including alternative incubation techniques are required as described in this chapter and should be performed by special request. Oxidase-positive, curved, gram-negative rods that are hippurate hydrolysis positive should be reported as *C. jejuni* without further workup. The importance of identifying other species will depend upon the clinical circumstances, but identification tests should always be performed on isolates from blood or other sterile sites since results may influence antimicrobial therapy decisions. Given that fluoroquinolone resistance is present in a significant proportion of *C. jejuni* isolates, fluoroquinolone susceptibility testing is suggested for patients who are receiving or being considered for therapy of gastroenteritis. Susceptibility testing should be performed on all isolates from sterile clinical sites.

Use of trade names is for identification only and does not imply endorsement by the Public Health Service or by the U.S. Department of Health and Human Services.

*Helicobacter**

JAMES G. FOX AND FRANCIS MEGRAUD

60

TAXONOMY

Gastric spiral-shaped bacteria have been observed in animals and humans for more than 100 years. The first recorded observations of gastric spiral-shaped bacteria in animals were made by Rappin in 1881 and Bizzozero in 1893. In 1896, Salomon noted spiral bacteria in the stomachs of dogs, cats, and Norway rats (152), but the first observation in humans was made by Krienitz in 1906 (80). In 1982, *Campylobacter pyloridis* (later known as *Helicobacter pylori*) was successfully cultured from stomach biopsy specimens from human patients with gastritis (178). Subsequently, other spiral gram-negative bacteria have been observed in and isolated from the gastrointestinal tracts of mammals such as cats, dogs, ferrets, sea mammals, and rodents (37).

Initially, many spiral gram-negative bacteria isolated from the mammalian gastrointestinal tract were grouped as campylobacters. This classification was based on similar microscopic and ultrastructural morphologies, common microaerobic growth requirements, and similar ecologic niches (Table 1). However, partial sequencing of 16S rRNA genes provided evidence that *Helicobacter pylori* belonged in a different genus (148). The genus *Helicobacter* was formally distinguished from other gram-negative curved rods (e.g., *Campylobacter*) following extensive analysis of enzymatic activities, fatty acid profiles, growth characteristics, and nucleic acid hybridization profiles, 16S rRNA sequence analysis, and most recently, 23S rRNA analysis (20, 51, 124, 133, 173). Sequencing of the *H. pylori* (1, 169) and *Helicobacter hepaticus* (164) genomes has emphasized differences but also similarities between *Campylobacter* and *Helicobacter* organisms.

DESCRIPTION OF THE GENUS

The genus *Helicobacter* comprises 23 species formally validated by international rules of nomenclature (21, 124, 125), with at least a dozen species awaiting validation or considered to be candidate species. Four of the latter, *Helicobacter cetorum,* isolated from stomachs of cetaceans; *Helicobacter winghamensis,* isolated from diarrheic patients; and *Helicobacter marmotae* and *Helicobacter mastomyrinus,* isolated from intestines and livers of rodents, have been formally named (but not validated by the *International Journal of Systematic and Evolutionary Microbiology*) and are listed in Table 1 (44, 64, 105, 157). The genus includes spiral or curved bacilli ranging from 0.3 to 1.0 μm in width and 1.5 to 10.0 μm in length. Helicobacters are gram-negative, non-spore-forming rods that may form spheroid or coccoid bodies if they are cultured for a prolonged period or if growth conditions are not optimal (Fig. 1A and B). These bacteria are motile and usually possess either single or multiple bipolar sheathed flagella (Table 1). *H. pylori* isolates, in contrast to those of other *Helicobacter* species, have multiple monopolar sheathed flagella. Several helicobacters *(Helicobacter pullorum, Helicobacter rodentium, Helicobacter mesocricatorum, Helicobacter canadensis,* and *H. winghamensis)* have unsheathed flagella like those of the campylobacters. The animal gastric helicobacters, *Helicobacter bizzozeronii, Helicobacter felis,* and *Helicobacter salomonis,* as well as the human-animal gastric pathogen "*Helicobacter heilmannii*" (formerly *Gastrospirillum hominis*), have distinctive, tightly spiraled morphologies under light and transmission electron microscopy (Fig. 1C). *H. pylori* can be induced in liquid culture to assume the morphology of "*H. heilmannii,*" so these distinctions may not be absolute in vivo (33, 127).

Helicobacters are microaerobic and possess respiratory metabolic capabilities. Successful cultivation of these organisms requires a humid atmosphere maintained at 37°C with reduced levels of oxygen (5 to 10%) and increased levels of carbon dioxide (5 to 12%). Atmospheric hydrogen (as much as 5 to 10%) either is required or stimulates the growth of these organisms. Most *Helicobacter* species grow poorly, if at all, in routine aerobic atmospheres. Several helicobacters, including *H. felis* (88), *H. hepaticus* (40), and *H. rodentium* (156), can grow both anaerobically and microaerobically. Interestingly, *Helicobacter ganmani,* a rodent enteric organism, requires anaerobic conditions for growth (146).

Several biochemical and genetic criteria distinguish this genus, although significant intragenus variation exists with respect to each trait (Table 1). All helicobacters are oxidase positive and appear to be relatively inert with respect to carbohydrate pathways as determined by conventional methods. Nuclear magnetic resonance spectroscopy (65) and genomic (1) studies have revealed the existence of carbohydrate catabolic pathways in *H. pylori* (65). Comparative genomic analysis of *H. pylori* supports the presence of important catabolic pathways such as the pentose phosphate shunt, the Entner-Doudoroff pathway, glycolysis, and an

* This chapter contains information presented in chapter 58 by James Versalovic and James G. Fox in the eighth edition of this Manual.

TABLE 1 Habitats and phenotypic characteristics of *Helicobacter* species[a]

Helicobacter taxon	Source(s)	Primary site(s)	Catalase production	Nitrate reduction	Alkaline phosphatase	Urease	Indoxyl acetate hydrolysis	γ-Glutamyl transferase	Growth		Resistance to[b]:		Flagella
									At 42°C	With 1% glycine	Nalidixic acid	Cephalothin	
Human

[a] Data are from references 21, 38, 40, 42, 43, 61, 69, 105, 133, 156, 160, 161, 173, 176, and 180. All *Helicobacter* species are oxidase positive and lack the ability to oxidize or ferment carbohydrates in routine reactions.

[b] Resistance is determined by disk diffusion. Isolates are incubated for several days at 37°C on blood-containing medium containing 30-μg antibiotic disks. Microaerobic conditions are typically used, and exact incubation times vary among organisms. Resistance (R) is defined as the complete absence of an inhibition zone, whereas intermediate (I; zones usually <15 mm in diameter) and susceptible (S; zones usually >20 mm in diameter) isolates have visible inhibition zones of various sizes.

[c] Likely the same as "*H. heilmannii*." "*H. heilmannii*" (formerly *Gastrospirillum hominis*) has the same phenotype as that listed here for *H. bizzozeronii*. Only a single "*H. heilmannii*" strain has been isolated by culture (4), and thus "*H. heilmannii*" has not been included in Table 1.

[d] ND, not determined.

[e] Formerly regarded as "*Flexispira rappini*," now subgrouped into 10 taxa (21).

Adapted from reference 43 with permission.

altered noncylic version of the Krebs reaction sequence (97). Members of the genus *Helicobacter* have G+C contents ranging from 30 to 48 mol% (180), similar to those of the campylobacters.

NATURAL HABITATS

Helicobacter species have been isolated from the gastrointestinal and hepatobiliary tracts of mammals and birds (Table 1). In this chapter, we will refer to gastric (stomach) and enterohepatic (intestine and liver or bile) helicobacters in order to distinguish these organisms according to their preferred niche(s) in the gastrointestinal tract. Gastric helicobacters possess several unifying features, including phylogenetic clustering (56) and urease activity, and most have the ability to form discrete colonies on plated media (176). Gastric helicobacters inhabit primarily the stomach either within or beneath the mucus gel layer adjacent to the epithelium and rarely invade the bloodstream (in contrast to enterohepatic helicobacters). Recent data suggest that *H. pylori* may on occasion be located intracellularly (121, 154). *H. pylori* colonizes the cardia, corpus, and antrum (distal portion) of the human stomach. Gastric helicobacters may also be found transiently in areas of gastric metaplasia of the proximal small intestine (duodenum), gastric juice (vomitus), saliva, and feces.

The reservoir of *H. pylori* is essentially the human stomach, and *H. pylori* can be considered the gastric helicobacter of humans (103). However, *H. pylori* strains have been isolated occasionally from animals (cats and nonhuman primates), which were most likely infected by humans because of either close cohabitation with humans or, in the case of cats, inadvertent exposure to *H. pylori* while being maintained in a vivarium (26, 60). Conversely, "*H. heilmannii*" is an inhabitant of the stomachs of pigs, cats, dogs, wild rats, and nonhuman primates, and infection with this organism is considered to have zoonotic potential (162).

The route of transmission of *H. pylori* from one human stomach to another human stomach has not been definitely identified. There is evidence for both oral-oral and fecal-oral transmission. Fecal-oral transmission implies (i) that *H. pylori* must survive gut passage (25) which apparently occurs mainly in the case of a short transit time (diarrhea) (131), (ii) that fecal hygiene is not optimal, and (iii) that the water supply is not treated properly. These conditions usually exist in developing countries, making likely that fecal-oral transmission occurs in this context. The rationale for oral-oral transmission relies on the presence of *H. pylori* in gastric juice which has been regurgitated, thus allowing *H. pylori* to temporarily colonize the oral cavity. There are reports of isolation of *H. pylori* from dental plaque and saliva (52, 77, 131). Indeed, a recent 6-year prospective study demonstrated that dental professionals are at greater risk of being infected with *H. pylori* than are controls (98). *H. pylori* could then be transmitted to another subject via the oral-oral route. Another possibility is via vomitus since *H. pylori* can remain viable in this biological medium for hours (7, 131). In any case, the oral-oral route of transmission is probably less efficient than the fecal-oral one. This fact contributes to the lower *H. pylori* prevalence in developed countries. Transmission appears to be most frequent in intrafamilial settings during childhood and accounts for a maximum of two-thirds of the cases; however, in a third of the cases, children are infected while their parents are not (24).

In contrast to the gastric helicobacters, enterohepatic helicobacters inhabit the lower bowels and hepatobiliary tracts of mammals and birds. In humans, enterohepatic helicobacters *(H. canadensis, Helicobacter canis, Helicobacter cinaedi, Helicobacter fennelliae, "Helicobacter rappini," H. pullorum, and H. winghamensis)* have been isolated from rectal swabs and feces and in some cases from blood and other extraintestinal sites (13, 105, 160, 161). Several of these as

well as other *Helicobacter* spp. have also been identified by molecular techniques in the hepatobiliary tissues of humans (6, 37, 39).

CLINICAL SIGNIFICANCE

Gastric Helicobacters

H. pylori is the main cause of peptic ulcer disease and a major risk factor for gastric cancer (165). Warren and Marshall (178) first proposed the association of *H. pylori* with peptic ulcer disease. In February 1994, the U.S. National Institutes of Health Consensus Development Conference concluded that *H. pylori* infection is the major cause of peptic ulcer disease and stated that all patients with confirmed peptic ulcer disease associated with *H. pylori* infection should receive antimicrobial treatment (113). This statement has been systematically repeated in all consensus conferences held worldwide since then (89). In June 1994, the International Agency for Research on Cancer Working Group of the World Health Organization identified *H. pylori* as a group I, or definite, human carcinogen. Approximately 50% of the world's population is estimated to be infected with *H. pylori*. However, there is a large difference in the prevalences of *H. pylori* infection among developing and developed countries (140, 181). In developing countries, the infection occurs very early in life and most of the children are infected by the age of 10. The prevalence remains in the range of 80 to 90% for all adult age groups in developing countries. In developed countries, a progressive increase in prevalence is observed, from a low percentage of infection in children to 40 to 50% infection rates in the older age groups. This is not the consequence of a progressive acquisition of the infection but rather the result of a cohort effect (8). Indeed, the majority of subjects acquire the infection in childhood, and the infection persists lifelong. Thus, if the oldest individuals have a higher *H. pylori* infection prevalence, it is because the risk of becoming infected was higher when they were children.

Individuals infected with *H. pylori* may develop acute gastritis (abdominal pain, nausea, and vomiting) within 2 weeks following infection. *H. pylori* establishes a chronic infection in the majority of infected people, represented by chronic gastritis of different types. Prominent mucosal inflammation in chronic active gastritis is often evident in the antrum (antral predominant gastritis), predisposing to hyperacidity and duodenal ulcer disease. Many patients infected with *H. pylori* have recurrent abdominal symptoms (nonulcer dyspepsia) without ulcer disease, and there appears to be a clinical benefit in eradicating *H. pylori* in these patients (108). Inflammation of the duodenum (duodenitis) often occurs with *H. pylori* infection, and duodenal ulcers develop in as many as 16% of infected individuals. *H. pylori* infection has been associated with the majority of duodenal and gastric ulcers (3). *H. pylori*-associated multifocal atrophic pangastritis or atrophic corpus-predominant gastritis results from long-standing infection and is characterized by glandular atrophy, intestinal metaplasia, and sparse inflammatory cells, pathophysiological features which manifest in the patient as low acidity and an increased risk of gastric carcinoma (28, 62). *H. pylori* infection is an independent risk factor for the development of atrophic gastritis, gastric ulcer disease (166), gastric adenocarcinomas (118, 129), and gastric mucosa-associated lymphoid tissue (MALT) lymphomas (32). Gastric MALT lymphoma, a rare stomach cancer, is caused by *H. pylori* infection. Indeed, it is the only cancer which can be cured by antibiotics (15, 183). However, advanced cases of MALT lymphoma which involve genetic translocations do not appear to respond to antibiotic treatment (2).

"*H. heilmannii*" (formerly *Gastrospirillum hominis*) has been observed in human gastric biopsy specimens (29, 67, 158) and cultured, according to one report, from human stomach tissue (4). The species name has not been formally recognized since significant nucleic acid sequence variation exists among various human isolates, resulting in the designation of multiple genotypes (19). Infection with the large gastric spiral helicobacters has been associated with mild to moderate gastritis in cats and dogs (119), peptic ulcer disease in swine (143), and gastritis, peptic ulcer disease, and gastric MALT lymphomas in humans (66, 67, 111, 170). "*H. heilmannii*"-like organisms are relatively uncommon in humans, being present in fewer than 1% of human gastric endoscopy specimens, in contrast to *H. pylori,* which can be present in >90% in some populations. *Helicobacter* species have been observed in and isolated from the stomach tissues of other mammals, including cats, dogs, ferrets, rodents, sea mammals, and nonhuman primates (Table 1).

Enterohepatic Helicobacters

Multiple species, including *H. cinaedi* and *H. fennelliae,* have been implicated as causes of human gastroenteritis and bacteremia, particularly in immunocompromised individuals (54, 86, 144). Cases of human gastroenteritis have also been associated with infection with *H. canadensis* (38), *H. canis* (161), *H. pullorum* (43, 160), and *H. winghamensis* (105). *Helicobacter* sp. strain flexispira organisms have been divided into 10 taxonomic taxa (21). *Helicobacter* sp. strain flexispira taxon 8 includes clinically relevant isolates that have been implicated in cases of human gastroenteritis (5, 149) and bacteremia (21). In contrast to *H. pylori*, *H. cinaedi* has been identified in the blood of multiple patients with febrile bacteremia and has been associated with multifocal cellulitis or monoarticular arthritis in a subset of infected individuals (12, 75). *H. cinaedi* (previously identified in some reports as *Helicobacter* sp. strain Mainz) (174) was cultured from the blood and joint fluid of a human immunodeficiency virus type 1-infected male with septic arthritis and recurrent fever (69). *H. fennelliae* has occasionally been isolated from human blood (115) and was associated with septic shock in a non-human immunodeficiency virus type 1-infected individual (68). Presumably, these bacteremia-associated helicobacters invaded the bloodstream via colonization of the human lower gastrointestinal tract.

Enterohepatic *Helicobacter* species have been detected in the human hepatobiliary tract by using molecular methods. In Chilean patients with chronic cholecystitis, *Helicobacter bilis* and *H. pullorum* were detected in gallbladder tissue and bile specimens (39). *Helicobacter* spp. have been identified in liver specimens from patients with primary sclerosing cholangitis (117), cholangiocarcinoma (116), and hepatocellular carcinoma (6, 116) and most recently in livers (with cirrhosis and hepatocellular carcinoma) of patients with hepatitis C viral infections (147) by genus-specific PCR amplification and partial DNA sequencing. The pathogenic significance of *Helicobacter* species DNA demonstrated by PCR amplification is not clear since helicobacters have not been cultured from the human hepatobiliary tract.

Several other species of enterohepatic helicobacters have not been isolated to date from human specimens, even though they cause significant diseases in other mammals (Table 1). In addition to the intestine, enterohepatic helicobacters colonize and cause inflammation in the mammalian hepatobiliary tract. For example, the isolation of *H. cinaedi*

from the colon and liver of a 2-year-old rhesus monkey (42) and the isolation of *H. canis* from a dog with hepatitis (41) implicate these organisms as possible etiologic agents of chronic hepatitis in nonhuman primates and dogs, respectively. *H. hepaticus* infection is associated with multifocal necrotic hepatitis in several strains of barrier-maintained mice and is responsible for the development of hepatic adenomas and hepatocellular carcinomas in A/JCr mice, $B_6C_3F_1$ mice, and A × B recombinant inbred mice (40, 45, 70). Coinfection with *H. hepaticus* and *H. rodentium* as well as monoinfection with *H. bilis* has also recently been demonstrated to be a critical component in the development of cholesterol gallstones in C57L mice fed a lithogenic diet (99).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Blood Specimens

Given that *H. pylori* specifically adheres to the gastric mucosal epithelium and seldom is identified intracellularly in gastric infections, it has rarely been isolated from human blood. In contrast, enterohepatic helicobacters translocate across the intestinal barrier and cause invasive infections. If bacteremia is suspected, peripheral venous blood should be collected in commercially available aerobic and anaerobic blood culture bottles as recommended by the manufacturer. Culture conditions are described in the subsequent section. No comparative studies have been performed with the different culture bottles available commercially. However, detection of these slowly growing bacteria which do not lead to detectable turbidity is linked to careful measurement of optical density in blood being incubated in automated blood equipment.

Feces

Gastric helicobacters *H. pylori* and "*H. heilmannii*" are rarely isolated from human fecal specimens. Experimental administration of a diarrheic compound increases the probability of being able to culture *H. pylori* from stools of *H. pylori*-infected patients (130). In contrast, enterohepatic helicobacters, like campylobacters, can be cultivated routinely from fecal specimens. These organisms are likely to be underisolated due to the primary focus of diagnostic laboratories being directed at the isolation of thermophilic campylobacters (e.g., *Campylobacter jejuni*). Enterohepatic helicobacters grow at 37°C but not uniformly at 42°C, the temperature often used for *Campylobacter* species isolation. Importantly, unlike some campylobacters, enterohepatic helicobacters require 5 to 10% hydrogen for optimum growth. They also may be susceptible to antibiotics present in the primary isolation medium, and they rapidly lose their viability.

Gastric Biopsy Specimens

Gastric biopsy specimens are obtained for the direct diagnosis of *H. pylori* or "*H. heilmannii*" infection. This is achieved by the use of a rapid urease test, impression smears, histopathology, or PCR. Culture of *H. pylori* may be necessary for antimicrobial susceptibility testing, diagnostic confirmation, or molecular fingerprinting in epidemiologic studies. It is stressed, however, that the proper collection, storage, and transport of gastric biopsy specimens are important for successful culture of *H. pylori*.

Although endoscopic features of *H. pylori* infection are considered not to be specific, the new method of confocal laser endomicroscopy has allowed, for the first time, surface microscopy imaging of living tissue during ongoing endoscopy and observation of *H. pylori* (76).

Biopsy specimens are routinely obtained from the antrum and corpus by esophagogastroduodenal endoscopy. The recommended number of biopsy specimens is two from each site for histology (22), one or two from each site for culture, and one from the antrum for a urease test. Biopsy specimens for histology are fixed in buffered formalin before being paraffin embedded.

H. pylori is sensitive to desiccation, ambient atmosphere, and room temperature. Therefore, a transport medium must be used to maintain the viability of the organisms. For short-term transport (less than 4 h), saline may be sufficient; otherwise, a semisolid transport medium maintained at 4°C is preferable. Stuart's transport medium, brucella broth with 20% glycerol, or Portagerm pylori (bioMérieux, Durham, N.C.) can be used for this purpose (45, 54, 115). Transport containers which maintain a temperature below 10°C for up to 16 h (Sarstedt, Nümbrecht, Germany) can be used to send biopsy specimens by mail. If culture of *H. pylori* is not possible within 24 h, it is recommended to freeze the biopsy specimen at −70°C in a tube without any medium and to transport it in dry ice. This method has proved to be efficient.

For long-term storage, the recommendation is to freeze freshly isolated cultures at −70°C in glycerol-containing media. Strains can then be recovered decades apart (59). Short-term maintenance is possible for 1 week in glycerol-containing medium at 4°C; 81% of isolates remained viable in one study (59).

Gastric Juice

Gastric juice can be obtained by aspiration after the introduction of a nasogastric tube, but it is easier to collect this fluid with the so-called string test. This test (Enterotest; HDC, San Jose, Calif.) consists of swallowing a capsule fixed to a string. After 30 min, the capsule dissolves and the string is removed. The distal portion of the string, which is impregnated with gastric juice, is cut and introduced into a transport medium. The impregnated material can then be used for culture or PCR (137). Recently, a novel device has been designed for the rapid recovery of gastric epithelia and mucus. It consists of an extendable orogastric brush contained within a plastic tube which is swallowed by the patient. Once the tube is in the stomach lumen, the brush is extended and brushed across the mucosa. It is then retracted into the protective sleeve and withdrawn from the patient. The material from the brush can then be used for culture of *H. pylori* (53).

DIRECT EXAMINATION AND DETECTION

Fecal *H. pylori* Antigen Detection

An enzyme-linked immunosorbent assay (ELISA) can be used to detect *H. pylori* antigens in stools and has been approved in the United States by the Food and Drug Administration. The first commercially available reagent, named Premier platinum HpSA (Meridian, Cincinnati, Ohio), consisting of a polyclonal antibody fixed on microwells, proved to be sensitive and specific in a multicenter study performed in Europe (171). A systematic review of published data including results of 89 studies (10,858 patients) confirmed the value of HpSA as a diagnostic tool for pretreatment (sensitivity, 91%; specificity, 93%) as well as for follow-up posttreatment (47).

A new generation of antigen stool tests using a monoclonal antibody directed against *H. pylori* catalase has also been developed (Amplified-IDEA-HpStar; DaKo, Glostrup, Denmark). This test ensures consistent quality of the reagents and improved reproducibility (94). Monoclonal antibodies have also been used to develop an immunoenzymatic rapid test (Immunocard STAT HpSA; Meridian) (91). The most reliable test is the ELISA laboratory test using monoclonal antibodies (sensitivity, 96%; specificity, 97%). Rapid antigen stool tests using monoclonal antibodies are very promising but need further evaluation.

Some aspects with an impact on the reliability of stool antigen-based assays, such as the influence of the frequency of bowel movements, have not been studied in detail. In principle, a short transit time should favor retrieval of unaltered antigens unless there is an excessive dilution factor, and constipation may lead to antigen degradation. Experimentally, tests performed on spiked stool specimens showed decreased sensitivity after a 24-h delay (110). Antigen stool tests may be well suited for children, from whom it is common to obtain stools, in contrast to adults, who usually prefer another type of test, e.g., the urea breath test (UBT). Although these tests have been found to be quite specific, it will be interesting to ascertain whether enterohepatic helicobacters sometimes present in stools could also be detected and possibly interfere with the interpretation of test results. Up to this point, it has been considered unnecessary to screen stool specimens for enterohepatic helicobacters given the low number of reported enterohepatic helicobacter cases. However, the recent identification of enterohepatic helicobacters in appreciable numbers of samples from diarrheic and nondiarrheic individuals may require a reevaluation of their impact on *H. pylori* stool antigen assays (14, 58).

Gastric Biopsies

Smear Evaluation

Imprint cytology specimens do not require overnight formalin fixation and provide a rapid adjunct to histopathologic examination of gastric biopsy specimens. After biopsy specimens are collected with forceps, imprints are made by pressing a needle against the tissue on a glass slide or by simply rubbing the tissue over the slide. Cytology specimens may be prepared immediately following biopsy by staining the imprints with a rapid Giemsa or Gram stain, and *H. pylori* or "*H. heilmannii*" organisms may be directly visualized. This approach has been demonstrated to match or outperform conventional histology in multiple studies (17, 107, 132). When imprint smears were used, 30 of 32 biopsy specimens with positive *H. pylori* cultures yielded visible organisms by Gram staining (132). "*H. heilmannii*" organisms were detected in 11 of 100 patients with dyspepsia by imprint cytology. Imprint cytology may be more sensitive than histology for detection of this organism (17). Direct fecal smears, like fecal cultures, lack utility for the detection of *H. pylori*.

Urease Testing

H. pylori produces large amounts of extracellular urease which can be detected within hours following introduction of gastric biopsy tissue into a urea-containing medium. Urease catalyzes the hydrolysis of urea into ammonia and carbamate. The net effect of ammonia production is to increase local pH. Biopsy samples are placed in an agar gel or on a paper strip containing a pH indicator. If organisms are present in sufficient numbers in the antral biopsy sample, a color change will occur as a result of urea breakdown and ammonia production by *H. pylori* urease. Commercial rapid urease tests include the agar gel-based tests (e.g., CLOtest [Kimberly-Clark, Neenah, Wis.] and Hp*fast* [GI Supply, Camp Hill, Pa.]) and paper strip tests (e.g., PyloriTek [BARD, Murray Hill, N.J.]) (142, 184). These tests can be used in the endoscopy ward. Detection sensitivity may approach 90%, but this depends on the *H. pylori* density in mucosal biopsy specimens and the number of biopsy specimens sampled. At least one fresh biopsy specimen from the gastric angle or antrum should be submitted for rapid urease testing. The sensitivity of rapid urease testing is maximized if specimens are obtained from the gastric angle (182) and multiple specimens are obtained (100). Agar gel-based tests have their optimal sensitivity after a 24-h incubation, whereas strip tests are optimal within an hour, making them truly rapid tests. The specificities of the urease tests are usually excellent. Agar gel-based rapid urease assays represent a cost-effective and widely used approach to screen biopsy tissue for *H. pylori* infection.

The urease broth tests commonly used in the laboratory are not optimized to have sensitivities equivalent to those of commercially available kits.

Histology

The standard hematoxylin and eosin tissue staining technique is not sufficient to accurately detect *H. pylori*. Various special stains, including Giemsa and the modified Steiner silver, must be used (141). The Warthin Starry stain can also be used but necessitates trained histology personnel to perform the technique. The sensitivity for discerning the presence or absence of *H. pylori* in gastric tissue depends on the quality of the samples and is very much observer dependent. Although the specificity is usually adequate, the presence of bacteria with atypical morphologies may result in misinterpretations. Under optimal conditions, however, histological diagnosis can have a sensitivity and specificity of 95%. Immunohistological staining with specific *H. pylori* antibodies can also improve specificity. More recently, fluorescence in situ hybridization with species-specific 16S rRNA probes (Creatogen GmBH, Augsburg, Germany) has been proposed for the detection of *H. pylori* (150) and "*H. heilmannii*" (170) in human gastric biopsy specimens. *H. pylori* and "*H. heilmannii*" can be further distinguished by their respective morphologies in gastric biopsy specimens (Fig. 1).

DNA Amplification

Since rapid urease testing, histologic examination, and culture yield high sensitivities and specificities for the diagnosis of *H. pylori* infection, PCR amplification of *H. pylori* DNA in gastric biopsy specimens may not be cost-effective as a primary diagnostic strategy. Standard PCR methods which specifically detect *H. pylori* in gastric biopsy specimens have been developed and include different target genes such as 23S rRNA (93), *glm*M (92), and *vac*A (175). In a comparative study of five different target sequences, with culture of *H. pylori* as the "gold standard," the method using the *glm*M gene had the best accuracy (92). Development of real-time PCR assays based on the fluorescent resonance energy transfer method may have increased diagnostic utility because of the assays' improved sensitivities and ease of performance and the ability to detect macrolide resistance by using the same assay (see "Antibiotic Susceptibilities"). Species-specific PCR assays have been developed for other helicobacters such as *H. pullorum*

(14) and *H. hepaticus* (145). However, no PCR-based tests for enterohepatic helicobacters are commercially available at this time.

CULTURE AND ISOLATION PROCEDURES

Gastric Helicobacters

Although *H. pylori* can be routinely isolated by culture from human gastric biopsy samples, *H. pylori* infection is usually diagnosed by nonculture methods such as histology, serology, or urease testing. However, the increasing prevalence of antimicrobial resistance (27) has stimulated efforts to culture organisms for antimicrobial susceptibility testing.

For *H. pylori* culture, it is recommended to grind the gastric biopsy specimens to provide a higher yield of bacteria. This can be performed with an electric grinder and probes. However, if PCR has to be performed, disposable grinders are recommended to avoid contamination.

The biopsy suspension must be plated rapidly onto fresh media. Various agar media can be used, including brain heart infusion, brucella agar, Columbia agar, Wilkins Chalgren agar, and Trypticase soy agar supplemented with 10% blood or serum. Cyclodextrin can also be used to improve growth (123). Ideally, more than one medium should be used, one selective and one nonselective. For selectivity, Skirrow's supplement or Dent's supplement gives satisfactory results.

Incubation must be performed at 37°C in a humid microaerobic atmosphere (5% O_2, 10% CO_2, and 85% N_2) which is achieved by using a special incubator or jars. An apparatus which creates the proper atmosphere and ensures that the jar is airtight can be used (Anoxomat; MART Microbiology B.V., Lichentwoorde, The Netherlands). Another alternative is to use commercial gas-generating sachets in jars (CampyPak Plus [BD Diagnostics Systems, Sparks, Md.] and Anaxopack-Campylo [Remel, Lenexa, Kans.]). The presence of hydrogen in the atmosphere enhances growth. Smooth, circular colonies may appear after 3 days of incubation, but the plates must be kept for 10 days before concluding that the culture attempt has a negative result.

Currently, only one "*H. heilmannii*" strain has been cultured from a human gastric biopsy specimen after 7 days on a nonselective medium containing 7% lysed horse blood in a 5% O_2 and 10% CO_2 atmosphere (4).

Enterohepatic Helicobacters

Selective, enriched media and a microaerobic atmosphere are essential for the cultivation of helicobacters from feces or rectal swabs. *H. canadensis*, *H. canis*, *H. cinaedi*, *H. fennelliae*, *H. pullorum*, *Helicobacter* sp. strain flexispira taxon 8, and *H. winghamensis* have been isolated from humans with gastroenteritis (37). Fresh stool specimens should be plated directly onto selective media and incubated for a minimum of 5 days (5 to 7 days) at 37°C in a microaerobic atmosphere. We recommend selective CVA medium (Columbia agar base with 5% sheep blood and cefoperazone, vancomycin, and amphotericin B; Remel) and a defined microaerobic atmosphere in partially evacuated anaerobic jars (5 to 10% carbon dioxide, 5 to 10% hydrogen, 5 to 10% oxygen, and 80% N_2) for the successful isolation of most enterohepatic helicobacters from human as well as animal feces (37, 174). Commercial gas-generating sachets (e.g., CampyPak Plus [BD Diagnostic Systems]) have been used to isolate enterohepatic helicobacters, but because of increased atmospheric hydrogen requirements, the amount of hydrogen may be inadequate in such systems (37). Alternatively, *H. winghamensis* was isolated from human stool on nonselective Mueller-Hinton agar supplemented with 10% sheep blood in a defined microaerobic atmosphere as described above (105). Some authors from South Africa recommend a special protocol that allows the primary isolation of multiple species (84, 85). It must be cautioned, however, that most laboratories do not use the high H_2 level (40%) involved in this approach because of its flammable nature.

Blood culture isolates have been detected in aerobic and anaerobic bottles (usually aerobic bottles only) by using routine media with prolonged incubation (minimum of 6 days) in automated instruments such as the BACTEC (Becton Dickinson, Franklin Lakes, N.J.) (12) and the BacT/Alert (bioMérieux) systems (126). Identifying enterohepatic helicobacters in blood cultures may require special stains. The authors of a multicenter study, which included 22 *H. cinaedi* blood isolates, noted that these thin, gull-shaped organisms were generally not visible upon Gram staining and required acridine orange staining, dark-field microscopy, or Giemsa staining for visualization (75). A modified Gram stain with carbol (0.5% [wt/vol]) or basic fuchsin (0.1% [wt/vol]) as the counterstain is also recommended for detection. Instrument-positive blood cultures should be stained with acridine orange if Gram staining is negative.

Nonselective, blood-enriched media are preferred for the isolation of helicobacters from primary blood culture media and sterile body fluids. *H. cinaedi* isolates from positive blood cultures have been cultivated in 2 to 3 days at 37°C on nonselective blood media (e.g., brucella or Columbia agar base with 5% horse or sheep blood) in a microaerobic atmosphere (e.g., CampyPak Plus [BD Diagnostic Systems] or partially evacuated jars with defined microaerobic atmospheres as described above). Supplementation of atmospheric hydrogen (5 to 10%) permitted successful culture of *H. cinaedi* in microaerobic conditions (174). Supplementation of atmospheric hydrogen occurs by the addition of gas-generating sachets to closed containers or, ideally, by direct supplementation with gas tanks containing 5 to 10% hydrogen (37). The only documented examples of *Helicobacter* species cultivation from nonblood sterile body fluids include the isolation of *H. cinaedi* from cerebrospinal fluid in nonselective Trypticase soy broth (126) and that of *Helicobacter* sp. strain Mainz (reclassified as *H. cinaedi*) from joint fluid on nonselective blood agar at 37°C (69, 174).

IDENTIFICATION

Helicobacters yield various colony phenotypes on blood agar, ranging from discrete, gray, and translucent colonies of *H. pylori* and selected gastric helicobacters to various swarming phenotypes of intestinal helicobacters and some gastric helicobacters (e.g., *H. felis*). Enterohepatic helicobacters yield a swarming phenotype with a thin film (e.g., *H. cinaedi and H. fennelliae*) or a thick, mucoid film similar to that of campylobacters (e.g., *H. pullorum and H. canadensis*). Helicobacters have a characteristic morphology visualized by light microscopy that resembles that of other gram-negative spiral or curved bacteria (Fig. 1; Table 1). These organisms usually appear faint by conventional Gram staining and may require counterstaining with carbol fuchsin (0.5% [wt/vol]) for enhanced visualization. Most helicobacter isolates are motile if observed by phase-contrast microscopy. Helicobacters are routinely tested for oxidase, catalase, and urease activities (Table 1). All helicobacters are oxidase positive. Most *Helicobacter* species, including *H. pylori*, are catalase positive (Table 1).

Gastric Helicobacters

The morphologies of helicobacters observed in gastric biopsy specimens may differ markedly from those observed in a Gram-stained preparation of cultured organisms. For example, *H. pylori* usually appears as a curved or straight rod in culture, whereas stained tissue biopsy samples usually reveal a helical or more strikingly curved appearance. "*H. heilmannii*" (likely identical to *H. bizzozeronii;* Table 1) is usually distinguished from *H. pylori* by its larger size and more pronounced helical morphology in gastric biopsy specimens (Fig. 1) (67). Because *H. felis* cannot be distinguished from "*H. heilmannii*" or *H. bizzozeronii* by light microscopy in human gastric biopsy specimens, *H. felis* must be cultured or identified by electron microscopy (46, 87).

H. pylori infection is diagnosed by microscopic morphology (Gram or Giemsa staining) and the presence of catalase, oxidase, and urease activities from primary culture. *H. cineadi* also has been identified by DNA analysis in gastric biopsy samples that were urease negative (136). *C. jejuni*, another urease-negative relative of *H. pylori* (151), or the rare *C. jejuni* subspecies *doylei* can also be found in the stomach, highlighting the importance of performing biochemical tests. Rapid urease, indoxyl acetate hydrolysis, and hippurate hydrolysis tests distinguish *H. pylori* from *C. jejuni* (chapter 59) (139). Commercial tests for urease (Christensen's urea agar slant; Remel or BBL Microbiology Systems), indoxyl acetate (Remel), and hippurate hydrolysis (Remel) are available and convenient for rapid identification of cultured specimens. In a study of 400 clinical isolates, all *H. pylori* isolates were positive for cytochrome oxidase, catalase, and urease activities (Table 1).

Enterohepatic Helicobacters

The enterohepatic helicobacters possess several distinguishing biochemical characteristics. Most intestinal helicobacters isolated from humans, such as *H. canadensis*, *H. cinaedi*, *H. fennelliae*, and *H. pullorum*, lack urease activity. Distinguishing catalase-positive, urease-negative helicobacters from the enteric campylobacters (e.g., *C. jejuni*) may be especially challenging. Unlike *C. jejuni* and *Campylobacter coli*, *H. cinaedi* and *H. fennelliae* do not survive at 42°C and *H. cinaedi* does not hydrolyze indoxyl acetate (Table 1) (139). Indoxyl acetate hydrolysis distinguishes *C. jejuni* and *C. coli* from *H. pullorum* (Table 1). *H. pullorum* is distinguished from *Campylobacter lari* only by its resistance to nalidixic acid. A nalidixic acid-resistant *C. lari* isolate would require species-specific PCR of 16S rRNA target sequences (160) for differentiation from *H. pullorum*. *H. canadensis* was initially characterized as a separate cluster of *H. pullorum*-like isolates capable of hydrolyzing indoxyl acetate and resistant to nalidixic acid (38). Unlike most other helicobacters, *H. canis* is catalase negative and urease negative. To distinguish *H. canis* from catalase-negative campylobacters, the nitrate reduction and indoxyl acetate hydrolysis tests may be useful (Table 1). It is important to note that diarrheic or nondiarrheic stool specimens may be cocolonized with multiple *Helicobacter* spp. and *Campylobacter* spp., making a complete diagnostic evaluation challenging (84, 85, 155).

NONINVASIVE TESTS

In addition to the detection in stool samples of *H. pylori* antigens by immunoenzymatic techniques and of *H. pylori* DNA by real-time PCR as previously mentioned, there are two other noninvasive approaches that can be utilized for the diagnosis of *H. pylori* infection: the detection of specific antibodies in serum, saliva, and urine, and the UBT.

UBT

The UBT has been developed specifically for *H. pylori* detection (79). It is based on an important feature of this bacterium, production of a large amount of urease. A solution containing isotopically labeled urea is ingested by the patient. If *H. pylori* is present in the stomach, the labeled urea is broken down into labeled CO_2 and ammonia; the labeled CO_2 is then absorbed into the bloodstream and exhaled in the breath of the patient being tested.

This test comprises either a carbon radioactive isotope (^{14}C) or a nonradioactive natural isotope (^{13}C). Both types of the test have been approved by the U.S. Food and Drug Administration for the diagnosis of *H. pylori* infection. $^{14}CO_2$ can be detected by a scintillation counter 20 min after ingestion, whereas for $^{13}CO_2$, the $^{13}C/^{12}C$ ratio is determined before and 30 min after ingestion by a gas isotope ratio mass spectrometer or an infrared spectrometer. The result is then expressed as a δ value between 0 and 30 min. The standardized ^{13}C-UBT must be performed on a subject after an overnight fast. A test meal consisting of citric acid makes this test more sensitive by delaying gastric emptying but also possibly by increasing urease activity (23). An initial breath sample is then obtained by blowing into a tube with a straw. Subsequently, a 75-mg dose of ^{13}C-urea is ingested. The patient must remain inactive, with no smoking, eating, or drinking, and 30 min later, a second breath sample is obtained. If an infrared spectrometer is used, a larger amount of exhaled air must be obtained by blowing into a special balloon. The cutoff used to define a positive result is usually a δ of 4.5‰.

With regard to the ^{14}C-UBT, there has been an ongoing effort to develop an assay which would allow a decrease in the dose of radioactive isotope administered. The test can now be performed with only 1 μCi contained in a capsule (138). The cutoff to define a positive result is usually 2% of the administered dose at 20 min. In contrast to the ^{13}C-UBT, the ^{14}C-UBT cannot be used for children and pregnant women. Furthermore, its use is not allowed in certain countries. The limitation on the ^{13}C-UBT is the availability of a spectrometer, but specimens can be sent by mail.

The UBT is considered to be the best noninvasive test for patient follow-up after *H. pylori* eradication, and its use has been consistently recommended in consensus conferences (96). UBTs have reproducibly proved highly accurate with a high degree of reliability in all the studies performed (sensitivity and specificity in the range of 95%). Importantly, the results are not influenced by transport conditions (tubes of breath air can be transported and stored for weeks at room temperature) and the measurement is observer independent.

Antibody Detection

Serologic testing represents a primary screening method for the diagnosis of *H. pylori* infection. Pooled *H. pylori* antigens of high-molecular-weight surface-associated proteins, acid extracts, or whole-cell lysates (sonicates) are used in most serologic assays. Various cytosolic and cell surface-associated proteins represent immunodominant antigens recognized by serum antibodies of infected individuals (78). Infection with *H. pylori* results in a local and systemic humoral response to multiple antigens (78, 168). In contrast to serum immunoglobulin M (IgM) levels, serum IgA and IgG levels persist for months and years and correlate with active infection in

untreated individuals (11, 112, 163). Only a small percentage of individuals do not have detectable systemic seroconversion following infection (100). Anti-*H. pylori* serum IgG levels are more consistently elevated than serum IgA levels. Consequently, serum IgG immunoassays yield greater sensitivities and specificities than serum IgA assays (82).

Commercial ELISA kits detecting anti-*H. pylori* IgG in serum are the serologic tests of choice for the primary screening of patients with uncomplicated infections (82). These recommended ELISA-based tests include HM-CAP (Enteric Products, Westbury, N.Y.), *H. pylori* IgG ELISA (Wampole Laboratories, Cranbury, N.J.), Premier (Meridian), and Pyloriset EIA-GIII (Orion, Espoo, Finland) (109). Overall, the median sensitivity and specificity for all commercially available *H. pylori* serology kits are 92 and 83%, respectively (82). Performance varies significantly among commercial serologic kits, with top performers exceeding 90% in sensitivity and specificity and bottom performers failing to reach 90% in sensitivity or 80% in specificity (82). However, the determined specificity of serology may be incorrectly low in some comparative studies where the gold standard used has poor sensitivity. ELISA serologic testing has the lowest cost per correct diagnosis, but overall accuracy is lower than that of stool antigen testing or UBT (172). Patients infected with "*H. heilmannii*" are usually negative by anti-*H. pylori* IgG assays (67). Serum IgA immunoassays may be used as second-line tests for assessing equivocal or possibly false-negative anti-*H. pylori* serum IgG results. The key advantage of serum IgA studies is that follow-up testing may be performed with the same serum sample. In one study, more than 7% of samples with a negative serum IgG result were found to possess detectable anti-*H. pylori* serum IgA levels when patients had symptoms consistent with *H. pylori* infection (71). With sensitivities of 39 to 82%, serum IgA assays lack the requisite sensitivity to serve as primary screening tests but may be useful in cases when infection is strongly suspected and the serum IgG result is negative or equivocal. Another alternative diagnostic approach is to perform immunoblotting for equivocal specimens.

Although serum IgG assays remain the tests of choice for screening patient sera, whole-blood immunoassays are being used with increasing frequency in physicians' offices and point-of-care testing protocols. Qualitative point-of-care immunoassays produce rapid results (4 to 10 min) with heparinized whole blood or capillary blood specimens. The major drawback of these rapid whole-blood immunoassays is their low sensitivities (usually 80 to 90%) despite specificities comparable to those of laboratory-based serum enzyme immunoassays (30, 31). Concerns regarding interoffice variability with point-of-care whole-blood assays have been raised. Negative results must be confirmed by laboratory ELISA-based serum IgG testing, fecal antigen testing, or UBT.

Sustained immunoglobulin responses to multiple antigens of *H. cinaedi* and *H. fennelliae* have been documented (35). Little is known about the nature of immunoglobulin class and subclass responses following infection with *H. cinaedi* and *H. fennelliae*. No commercial serologic assays have been developed to monitor infection with *H. cinaedi* or other enterohepatic helicobacters.

Detection of *H. pylori* Antibodies in Urine

Specific *H. pylori* IgG antibodies are detected in urine at low concentrations. An ELISA allowing their detection has been developed (Urinelisa; Otsuka,Tokuchima, Japan) as well as a rapid immunoenzymatic test (Rapirun; Otsuka) (73, 90). A pooled sensitivity and a specificity of 92.3 and 89.7%, respectively, have been reported. While the accuracy is not dependent on the pH or the presence of bacteriuria, it may be influenced by a large amount of total IgG. Urine samples cannot be frozen because it would lead to protein precipitation. The test must be performed on fresh samples, or a preservative must be added. These tests, although very attractive because of their noninvasive nature, have not achieved the optimal sensitivity required for routine use.

Detection of *H. pylori* Antibodies in Saliva

Salivary antibodies are secreted during the immune response to infectious agents (134). A commercial kit has been developed to detect *H. pylori*-specific IgG in saliva (Helisal; Provalis, Deeside, United Kingdom). Saliva can be collected by having the patient spit into a tube, but better results are obtained using a special device (OraSure; OraSure Technologies, Inc., Bethlehem, Pa.) designed to obtain gingival transudate enriched with IgG (95). However, this assay also suffers from insufficient sensitivity.

ANTIBIOTIC SUSCEPTIBILITIES

The standard regimen to eradicate *H. pylori* consists of a macrolide (e.g., clarithromycin), a β-lactam (amoxicillin), and a proton pump inhibitor (e.g., omeprazole, lansoprazole, pantoprazole, rabeprozole, or esomeprazole). The antisecretory drug is prescribed to increase the stomach pH in order for the antibiotics to be effective. Acid antisecretories also reduce pain and accelerate ulcer healing. This regimen is recommended to last for 10 days in the United States and 7 days in other countries.

Other alternatives include (i) a triple therapy in which a nitroimidazole (e.g., metronidazole) is used instead of amoxicillin, (ii) bismuth-based therapy with bismuth salts, tetracycline, and metronidazole, and (iii) a quadruple therapy in which a proton pump inhibitor is added to the bismuth-based regimen; all of these therapies are prescribed for 7 to 14 days.

The main cause of failure to eradicate *H. pylori* with the standard antimicrobial regimen is macrolide resistance (104). The eradication rate decreases by 70% (from 88 to 18%) when the strain is resistant versus susceptible (102). This finding should stimulate routine susceptibility testing with clarithromycin. In the case of resistance, clarithromycin must be replaced with an alternate antibiotic. Using metronidazole with amoxicillin and a proton pump inhibitor for 14 days is an alternative (83), but metronidazole resistance also decreases the success rate by 25%. Other antibiotics, e.g., levofloxacin, rifabutin, and furazolidone, may also be used in association with amoxicillin (101).

The prevalence of resistance parallels the use of drugs worldwide (102, 128). For clarithromycin the resistance rate is between 0 and 20%, for metronidazole it is between 10 and 80%, and for fluoroquinolones it is between 0 and 20%. Resistance to amoxicillin and tetracycline is rarely found.

Various susceptibility testing methods such as broth microdilution, disk diffusion, the E test, and agar dilution have been used to assess antimicrobial resistance in *H. pylori* (18, 57, 63). The Clinical and Laboratory Standards Institute (CLSI) made the recommendation of an agar dilution method for testing of *H. pylori* susceptibility to clarithromycin (114). Mueller-Hinton agar base with 5% aged sheep blood and incubation for 72 h at 35°C were selected by the CLSI for susceptibility testing by agar dilution (see chapter 75). Resistance in vitro to clarithromycin by *H. pylori* is clinically relevant, and a MIC breakpoint of 1 μg per ml is recommended by the CLSI

(114). If an agar diffusion method is used, an inhibitory zone of less than 17 mm around an erythromycin disk indicates a resistant strain (55). In contrast to that for clarithromycin, in vitro susceptibility testing for metronidazole has not been standardized, although elevated MICs (>8 μg/ml) have been correlated with treatment failures (9). Given that resistance in *H. pylori* is the consequence of chromosomal mutations, molecular tests have been developed especially for the most important antibiotic, clarithromycin. Point mutations at two sites of the 23S rRNA gene which inhibit macrolide binding are essentially involved (16, 120, 177). A number of methods have been developed for their detection. One of the most widely used is PCR-restriction fragment polymorphism (135, 167, 177). Real-time PCR using the fluorescent resonance energy transfer principle has been developed which allows the detection of both *H. pylori* and its resistance to clarithromycin directly from gastric biopsy specimens. The assay has excellent sensitivity (122) and has been used as well to detect *H. pylori* from stools (153). The same approach has been used to ascertain resistance to fluoroquinolones (48). In contrast, multiple null mutations in the NADPH nitroreductase gene (*rdxA*) are the primary molecular bases for metronidazole resistance in *H. pylori* (50, 72, 81, 106), leading to the inability of cells to reduce and activate nitroimidazole compounds intracellularly.

Eradication of "*H. heilmannii*" by antimicrobial therapy also results in the resolution of gastritis and peptic ulcer disease (49, 66, 67) as well as "*H. heilmannii*"-associated primary low-grade MALT lymphoma (111). Antibiotic susceptibility testing has been described only for multiple isolates from a single patient (4). "*H. heilmannii*" isolates were susceptible to amoxicillin, ciprofloxacin, erythromycin, and tetracycline and resistant to nalidixic acid and metronidazole (4). "*H. heilmannii*" infections have been successfully treated with bismuth alone and with combination therapies that included amoxicillin, metronidazole, and omeprazole (4, 66, 67).

Bacteremias due to intestinal helicobacters in immunocompromised patients require drug combinations in prolonged intravenous treatment regimens, often including aminoglycosides. *Helicobacter* sp. strain flexispira taxon 8 bacteremias require multiagent regimens including aminoglycosides such as amikacin (159) and gentamicin (179) for the clearance of infections. Effective therapy for *H. cinaedi* infection has included ciprofloxacin, gentamicin, or tetracycline for at least 2 to 3 weeks (12, 75, 126). In vitro susceptibility testing of *H. cinaedi* (34, 74, 75) appears to be meaningful, and resistance in vitro has been correlated with treatment failures in patients medicated with erythromycin (12) or ciprofloxacin (75). Relatively limited therapeutic experience is available for *H. fennelliae* infections. Gentamicin (115) and ampicillin-sulbactam (68) have been used successfully to treat bacteremia caused by *H. fennelliae*. Neither in vitro susceptibility testing data nor treatment recommendations have been reported for cases of gastroenteritis caused by *H. canis*, *H. pullorum*, *H. canadensis*, or *H. winghamensis*. CLSI recommendations are not available for antimicrobial susceptibility testing of helicobacter organisms other than *H. pylori*.

INTERPRETATION AND REPORTING OF RESULTS

Noninvasive tests are recommended only for patients younger than 50 years and without "alarm" symptoms. The best screening test is the UBT, but the *H. pylori* fecal antigen test or ELISA-based IgG serology can also be used. Rapid whole-blood test results must be confirmed by a laboratory-based ELISA or another test.

Patients with alarm symptoms (36) such as old age, weight loss, or gastrointestinal bleeding should undergo esophagogastroduodenal endoscopy. Rapid urease testing of gastric biopsy specimens can be used to assess *H. pylori* infection status. If results are positive, they can be reported as "positive and consistent with *H. pylori* infection." Histology of gastric biopsy specimens must be interpreted by an experienced pathologist. Routine hematoxylin and eosin staining indicates the nature of gastritis or the presence of gastric adenocarcinoma or gastric MALT lymphoma. *H. pylori* organisms may be visible with Gram staining of impression smears or the use of special stains such as Giemsa or modified Steiner stain. "*H. heilmannii*" infection must be diagnosed by bacterial morphology in gastric biopsy specimens, since this organism is rarely cultured.

In order to perform antimicrobial susceptibility testing, bacteriologic culture of *H. pylori* from gastric biopsy specimens is recommended. Successful culture of *H. pylori* from biopsy specimens may be reported if organisms have the typical gram-negative morphology and are cytochrome oxidase, catalase, and urease positive. Primary biopsy specimen cultures should be incubated at least 7 days prior to a report of a negative result. Susceptibility testing for clarithromycin should be performed by using the NCCLS (CSLI) reference method (114) or a substantially equivalent method. Molecular resistance testing (mutation detection) can be used as an alternative to detect the presence of discrete mutations conferring macrolide resistance (135).

It is necessary to perform a follow-up after an eradication treatment. A delay of at least 4 to 6 weeks after antibiotic treatment is completed must be observed. The method universally recommended is the UBT because it is noninvasive and has high sensitivity. The stool test may also be used but not serology unless it is possible to test at the same time both the serum obtained before treatment and the serum obtained 6 months after treatment. A decreased antibody titer of more than 25% must be observed to claim that the antibiotic treatment has been successful in eradicating *H. pylori* (10).

Enterohepatic helicobacters such as *H. cinaedi* and *H. fennelliae* must be isolated by microbiologic culture from blood or feces for a definitive diagnosis of infection. If the laboratory isolate is negative for the Gram stain, microscopic morphology may be assessed by using a modified Gram stain, Giemsa stain, acridine orange stain, or dark-field microscopy. Appropriate biochemical tests must be performed (Table 1). Enterohepatic helicobacters are typically urease negative and may be easily confused with campylobacters. Even with supplemental tests, the distinctions can be difficult without genotypic tests such as species-specific PCR amplification or targeted DNA sequencing.

Leptospira

PAUL N. LEVETT

61

TAXONOMY

Serologic Classification

The genus *Leptospira* is comprised of spiral-shaped bacteria with hooked ends (32). This genus, along with the genera *Leptonema* and *Turneriella,* makes up the family *Leptospiraceae* within the order *Spirochaetales* and class "*Spirochaetes*" of the recently proposed phylum *Spirochaetes* (26). The genus was formerly divided into two species, *Leptospira interrogans,* comprising all pathogenic strains, and *Leptospira biflexa,* containing the saprophytic strains isolated from the environment (24, 32). *L. biflexa* and *L. interrogans* were differentiated by a number of biochemical tests (32).

Leptospires are divided into serovars defined by agglutination after cross-absorption with homologous antigen (17, 32, 34). Serovars are considered distinct if more than 10% of the homologous titer remains in at least one of the two antisera on repeated testing (31). Over 60 serovars of *L. biflexa* sensu lato and more than 200 serovars of *L. interrogans* sensu lato are recognized. Serovars that are antigenically related have traditionally been grouped into serogroups (34). Serogroups have no taxonomic standing, but the concept has proved useful for epidemiological understanding, particularly when interpreting the serological results from the microscopic agglutination test (MAT). The serogroups of *L. interrogans* sensu lato and some common serovars are shown in Table 1.

Genotypic Classification

The phenotypic classification of leptospires was replaced by a genotypic one, in which 17 genomospecies include all serovars of *Leptospira* (8, 53, 55, 80). Table 2 lists all species of *Leptospira*. DNA hybridization studies have also confirmed the taxonomic status of the monospecific genera *Leptonema* (8, 54) and *Turneriella* (38). The genetically defined species of *Leptospira* do not correspond to the previous two species (*L. interrogans* sensu lato and *L. biflexa* sensu lato), and both pathogenic and nonpathogenic serovars occur within some species (35). Neither serogroup nor serovar reliably predicts the true species of *Leptospira*. Moreover, genetic heterogeneity resulting from horizontal transfer of genes coding for cell surface antigens occurs within serovars (8, 25), resulting in strains of some serovars being classified in multiple species (Table 3). In addition, the phenotypic characteristics formerly used to differentiate *L. interrogans* sensu lato from *L. biflexa* sensu lato do not differentiate the genetically defined species (8, 80). Both *L. interrogans* and *L. biflexa* are retained as specific names in the genomic classification, and in this chapter, specific names refer to the genetically defined species, including *L. interrogans* sensu stricto and *L. biflexa* sensu stricto.

The molecular classification of leptospires requires the identification of both species and serovar of each isolate. Identification of *Leptospira* species is readily accomplished by 16S rRNA gene sequencing, and sequences are available in GenBank (R. E. Morey and P. N. Levett, unpublished data). Phylogenetic analysis of 16S rRNA gene sequences demonstrates three clades of leptospires, representing pathogens, saprophytes, and a group of species of uncertain pathogenicity (Fig. 1). Serovar identification is discussed below.

The concept of serogroups has no application in the taxonomy of *Leptospira* but remains a convenient tool for serologists.

DESCRIPTION OF THE FAMILY

Leptospires are tightly coiled spirochaetes, usually 0.1 μm by 6 to 20 μm. The helical conformation is right-handed, while the amplitude is approximately 0.1 to 0.15 μm and the wavelength is approximately 0.5 μm (23). The cells have pointed ends, either or both of which are usually bent into a distinctive hook (Fig. 2). Two axial filaments (periplasmic flagella), with polar insertions, are located in the periplasmic space. Leptospires exhibit two distinct forms of movement, either translational (rapid back-and-forth movements) or rotational (spinning rapidly about the long axis of the cell) (27). Morphologically, all leptospires are indistinguishable.

Leptospires are obligate aerobes with an optimum growth temperature of 28 to 30°C. The optimum pH for growth is 7.2 to 7.6. They produce both catalase and oxidase. They grow in simple media enriched with vitamins (vitamins B_2 and B_{12} are growth factors), long-chain fatty acids, and ammonium salts (32).

EPIDEMIOLOGY AND TRANSMISSION

Leptospires are ubiquitous, either free-living in water or associated with renal infection of animals. Leptospirosis is

presumed to be the most widespread zoonosis in the world (78). The source of infection in humans is usually either direct or indirect contact with the urine of an infected animal. The incidence is very much higher in warm-climate countries than in temperate regions, due mainly to the longer survival of leptospires in the environment under warm, humid conditions. The disease is seasonal, with the peak incidence occurring in summer or fall in temperate regions, where temperature is the limiting factor in survival of leptospires, and during rainy seasons in warm-climate regions, where rapid desiccation would otherwise prevent survival.

Animals, including humans, can be divided into maintenance hosts or accidental (incidental) hosts. A maintenance host is defined as a species in which infection is endemic, usually transferred from animal to animal by direct contact. Infection is usually acquired at an early age, and the prevalence of chronic excretion in the urine increases with the age of the animal. Other animals (such as humans) may become infected by indirect contact with the maintenance host. Animals may be maintenance hosts of some serovars but incidental hosts of others, infection with which may cause severe or fatal disease. The most important maintenance hosts are small mammals, which may transfer infection to domestic farm animals, dogs, and humans. Different rodent species may be reservoirs of distinct serovars, but rats are generally maintenance hosts for serovars of the serogroup Icterohaemorrhagiae, and mice are generally maintenance hosts for serogroup Ballum serovars. Domestic animals are also maintenance hosts; dairy cattle may harbor serovars Hardjo and Pomona; pigs may harbor Pomona, Tarassovi, or Bratislava; and dogs may harbor Canicola. Distinct variations in maintenance hosts and the serovars they carry occur throughout the world, and these associations may change over time.

Knowledge of the prevalent serovars and their maintenance hosts is essential in understanding the epidemiology of the disease. For example, canine leptospirosis is increasing in the northeastern regions of North America. Very few cases have been diagnosed by culture, but serology suggests that they are caused largely by serovar Grippotyphosa (9, 73). Epidemiological evidence implicates raccoons and possibly skunks as the reservoir. Cases are clustered particularly in newly suburbanized areas (73). Canine vaccine composition has been changed to include serovars Grippotyphosa and Pomona as a result of this change in epidemiology.

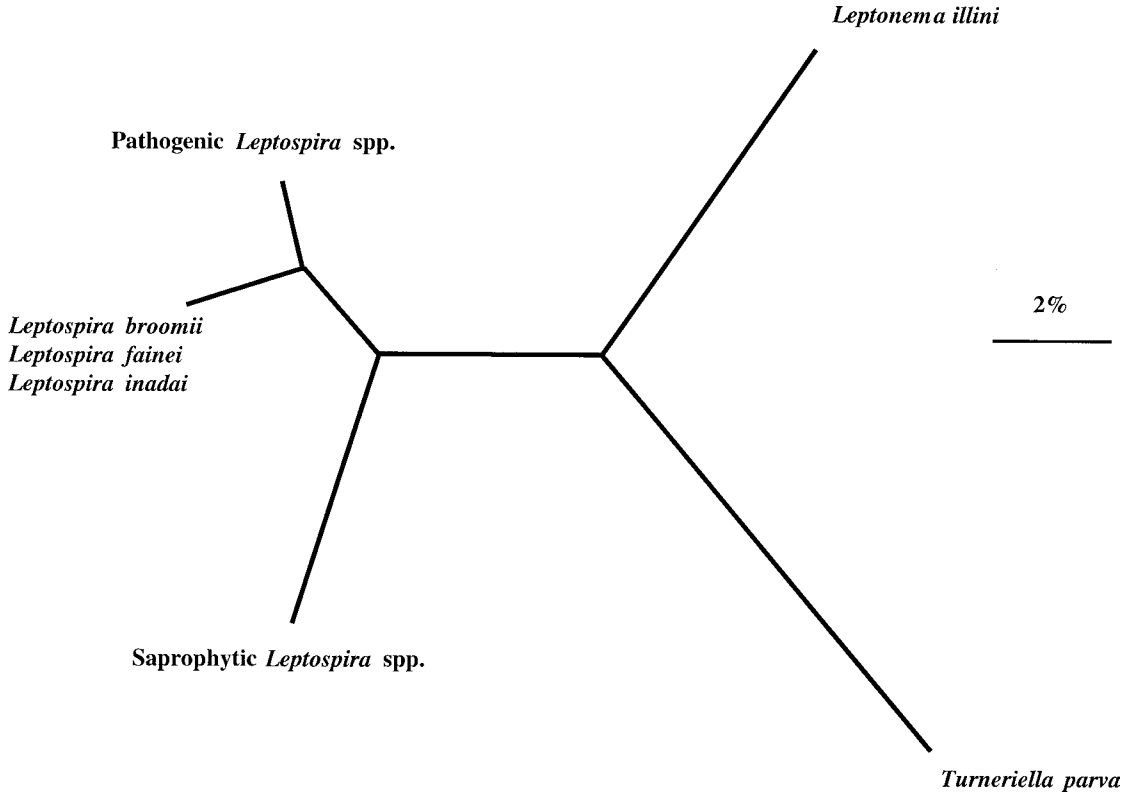

FIGURE 1 Phylogenetic relationships between the genera of the *Leptospiraceae*, based on 16S rRNA gene sequences. The scale bar represents a 2% difference in sequence.

Human infections may be acquired through occupational, recreational, or avocational exposures. Occupation is a significant risk factor for humans. Direct contact with infected animals accounts for most infections in farmers, veterinarians, abattoir workers, rodent control workers, and people in other occupations which require contact with animals, while indirect contact is important for sewer workers, miners, soldiers, septic tank cleaners, fish farmers, rice field workers, and sugar cane cutters. Livestock farming is a major occupational risk factor throughout the world. The highest risk is associated with dairy farming and is associated with serovar Hardjo and in particular with milking of dairy cattle. There is a significant risk associated with recreational exposures occurring in water sports (46, 59).

CLINICAL SIGNIFICANCE

The usual portal of entry is through abrasions or cuts in the skin or via the conjunctiva. The great majority of infections are either subclinical or of very mild severity, and most patients will probably not seek, or be brought to, medical attention. The clinical presentation of leptospirosis is biphasic, with a septicemic phase lasting about a week, followed by the immune phase, characterized by antibody production and excretion of leptospires in the urine. Most of the complications of leptospirosis are associated with localization of leptospires within the tissues during the immune phase and thus occur during the second week of the illness.

The overwhelming majority of the recognized cases present with a febrile illness of sudden onset, the symptoms of which include chills, headache, myalgia, abdominal pain, and conjunctival suffusion. Aseptic meningitis may be found in ≤25% of all leptospirosis cases. Between 5 and 10% of all patients with leptospirosis have the icteric form

of the disease (Weil's disease), in which the clinical course is often very rapidly progressive. In addition to jaundice, patients with icteric leptospirosis may develop acute renal failure, pulmonary hemorrhage, and cardiac arrythmias. Severe cases often present late in the course of the disease, and this contributes to the high mortality rate, which ranges between 5 and 15%.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Leptospires can be isolated from blood, cerebrospinal fluid (CSF), and peritoneal dialysate fluids during the first 10 days of illness. Specimens should be collected before antibiotic therapy is initiated and while the patient is febrile. Under optimal conditions, 1 or 2 drops of blood are inoculated directly into culture medium at the bedside. Survival of leptospires in commercial blood culture media for several days has been reported (51). There are no transport media available, but blood can be collected and shipped at ambient temperature in tubes containing heparin, oxalate, or citrate (23). Citrate or EDTA-containing tubes are optimal for detection by PCR, whereas tubes containing heparin, sodium polyanethol sulfonate, or saponin are inhibitory to PCRs (39, 62).

Urine can be cultured after the first week of illness. Specimens should be collected aseptically into sterile containers without preservatives and must be processed within a short time of collection; best results are obtained when the delay is less than 1 h. Urine specimens for PCR testing may be stabilized in DNA/RNA Protect containers (Sierra Diagnostics, Sonora, Calif.), allowing for transport over long distances (39).

DIRECT EXAMINATION

Microscopy

Leptospires may be visualized in clinical material by dark-field microscopy (×100 and ×400 magnifications) or by immunofluorescence or light microscopy after appropriate staining. Dark-field microscopic examination of body fluids such as blood, urine, CSF, or dialysate fluid is both insensitive and lacking in specificity (3, 72, 76). Approximately 10^4 leptospires/ml are necessary for one cell per field to be visible by dark-field microscopy (69). Direct dark-field microscopy of blood is also subject to misinterpretation of fibrin or protein threads, which may demonstrate Brownian motion (23, 69, 76). Leptospires in tissues were first visualized by silver staining (63), and the Warthin-Starry stain is widely used for histologic examination. More recently, immunohistochemical methods have been applied (70, 81, 82). Immunohistochemical staining can be performed at the Centers for Disease Control and Prevention, Atlanta, Ga. (contact Sherif Zaki at szaki@cdc.gov).

Antigen Detection

Antigen detection is generally regarded as insensitive. An assay for detection of antigen in urine has been described (58) but has not been evaluated widely. There are no commercial antigen detection assays.

Nucleic Acid Techniques

Several primer pairs for conventional PCR detection of leptospires have been described (35). However, only two methods have been subject to extensive clinical evaluation (11, 44). Both methods were found to be more sensitive than culture, and leptospiral DNA has been amplified from serum, urine, aqueous humor, CSF, and tissues obtained at autopsy (10).

Real-time PCR assays have been developed, targeting either 16S rRNA genes or pathogenic-specific sequences (39, 45, 49, 62). These assays have yet to be evaluated in large clinical studies.

A limitation of PCR-based diagnosis of leptospirosis is the inability of most PCR assays to identify the infecting serovar. While this is not significant for individual patient management, the identity of the serovar has both epidemiological and public health value.

ISOLATION PROCEDURES

Leptospiremia occurs during the first stage of the disease, beginning before the onset of symptoms, and has usually finished by the end of the first week of the acute illness (43). Therefore, blood cultures should be taken as soon as possible after the patient's presentation. One or 2 drops of blood (approximately 50 μl) are inoculated into 10 ml of semisolid oleic acid-albumin medium (20, 33), such as Ellinghausen-McCullough-Johnson-Harris (EMJH) (Difco Laboratories, Sparks, Md.) or PLM-5 (Intergen Co., Purchase, N.Y.), containing 0.1% agar and 200 μg of 5-fluorouracil per ml, at the patient's bedside. Blood is allowed to drop onto the surface of the medium; mixing is not necessary. Care should be taken to avoid overinoculation of the medium, as blood contains inhibitors of leptospiral growth. For the greatest recovery rate, multiple cultures should be performed, but this is rarely possible. Inoculation of media with further 10-fold dilutions of blood samples may increase recovery (64). Survival of leptospires in commercial blood culture media for up to a week has been reported (51). Since the organism does not grow in conventional media, positive signals in automated systems are most unlikely. However, if a diagnosis of leptospirosis is suspected after the collection of conventional blood cultures, it is possible to detect leptospires by using PCR assays. There is insufficient experience to show the value of subculture from blood cultures into leptospira culture media, but this should be attempted if possible.

Other samples that may be cultured during the first week of illness include CSF and peritoneal dialysate. Urine cultures may yield growth from the beginning of the second week of symptomatic illness. Survival of leptospires in voided human urine is limited, so urine should be processed immediately, by neutralization of pH with sodium bicarbonate followed by centrifugation. After centrifugation in 15-ml tubes for 30 min at 1,500 × *g*, the sediment is resuspended in 1 ml of phosphate-buffered saline and 1 or 2 drops are inoculated into semisolid EMJH medium containing 5-fluorouracil as described above.

Cultures in EMJH are incubated in sealed bottles at 28 to 30°C and examined weekly by dark-field microscopy for up to 13 weeks before being discarded. Growth often develops in a discrete band, several millimeters below the surface of the medium, known as a Dinger's ring. Cultures that show growth of other bacteria may be passed through a 0.2- or 0.45-μm-pore-size filter before subculture into fresh medium.

IDENTIFICATION

Isolated leptospires are identified either by serological methods or, more recently, by molecular techniques. Traditional

methods relied on cross-agglutinin absorption (17). The number of laboratories that can perform these identification methods is very small. The use of panels of monoclonal antibodies allows laboratories which can perform the MAT to identify isolates of frequently encountered serovars with relative rapidity (66). Monoclonal antibodies are available from the WHO/OIE Leptospirosis Reference Laboratory at the Royal Tropical Institute, Amsterdam, The Netherlands. The molecular-method-based taxonomy of *Leptospira* necessitates the identification of isolates to both species and serovar. Species identification is most practically determined by 16S rRNA gene sequencing (Morey and Levett, unpublished). Sequences of some species differ by only a few bases along the entire length of the 16S rRNA gene, so for accurate identification a full-length sequence is necessary.

Typing Procedures

Because of the difficulties associated with serological identification of leptospiral isolates, there has been great interest in molecular methods for identification and subtyping (29, 66). Methods employed have included digestion of chromosomal DNA by restriction endonucleases, restriction fragment length polymorphisms, ribotyping, pulsed-field gel electrophoresis, and a number of PCR-based approaches (35). The most widely applicable molecular method for identification of serovars is pulsed-field gel electrophoresis (29, 30). This approach has been standardized, using the PulseNet model (R. Galloway and P. N. Levett, *Abstr. Int. Conf. Emerg. Infect. Dis.,* abstr. 214, 2004).

More recently, sequence-based methods such as amplified fragment length polymorphism (AFLP) and variable-number tandem-repeat methods have been developed for the study of leptospiral epidemiology (42, 71). The use of multilocus sequence typing is being investigated. The application of these powerful tools will lead to greater understanding of leptospiral epidemiology at a population level.

SEROLOGICAL TESTS

Most cases of leptospirosis are diagnosed by serology. Antibodies are detectable in the blood approximately 5 to 7 days after the onset of symptoms. The definitive serologic investigation in leptospirosis remains the MAT, in which patients' sera are reacted with live or killed antigen suspensions of leptospiral serovars. After incubation, the serum-antigen mixtures are examined microscopically for agglutination and the titers are determined. The MAT is a complex test to control, perform, and interpret (68), the use of which is limited to regional or national reference laboratories. Protocols for performing the MAT have been described in detail (2, 21, 64). An international proficiency testing scheme under the auspices of the International Leptospirosis Society has stimulated improvement in the performance of the MAT by participating laboratories (14). The range of antigens used should include serovars representative of all serogroups (21, 68) and locally common serovars (67). Titers of antibody to local isolates are often higher than titers of antibody to laboratory stock strains of serovars within the same serogroup. The wide range of antigens is used in order to detect infections with uncommon, or previously undetected, serovars. The test is read by dark-field microscopy. The end point is the highest dilution of serum in which 50% agglutination occurs. Because of the difficulty in detecting the titer at which 50% of the leptospires are agglutinated, the end point is determined by the presence of approximately 50% free, unagglutinated leptospires, by comparison with the control suspension (21). Considerable effort is required to reduce the subjective effect of observer variation, even within laboratories.

Interpretation of the MAT is complicated by the high degree of cross-reaction that occurs between different serogroups, especially in acute-phase samples. Paradoxical reactions, in which the highest titers detected are those of antibody to a serogroup unrelated to the infecting one, are also common (35). The broad cross-reactivity in the acute phase, followed by relative serogroup specificity in convalescent-phase samples, results from the detection in the MAT of both immunoglobulin M (IgM) and IgG antibodies and the presence of several common antigens among leptospires (1, 13, 40).

Paired sera are required to confirm a diagnosis with certainty. A fourfold or greater rise in titer between paired sera confirms the diagnosis, regardless of the interval between samples. The interval between first and second samples depends very much on the delay between onset of symptoms and presentation of the patient. If symptoms typical of leptospirosis are present, an interval of 3 to 5 days may be adequate to detect rising titers. However, if the patient presents earlier in the course of the disease, or if the date of onset is not known precisely, then an interval of 10 to 14 days between samples is more appropriate. Less often, seroconversion does not occur with such rapidity, and a longer interval between samples (or repeated sampling) is necessary. MAT serology is insensitive, particularly with early acute-phase specimens (4, 7, 15). Moreover, patients with fulminant leptospirosis may die before seroconversion occurs (11, 15, 56).

A presumptive diagnosis can be made by detection of a single elevated titer in association with an acute febrile illness. The magnitude of such a titer is dependent upon the background level of exposure in the population, and hence the seroprevalence. In the current CDC case definition, a titer of $\geq$200 in a patient with a clinically compatible illness is used to indicate a probable case (12).

Titers following acute infection may be extremely high ($\geq$25,600) and may take months, or even years, to fall to low levels (3, 6, 16, 41, 57). Thus, in a high-incidence population, a low cutoff titer for presumptive diagnosis is inappropriate and will generate many false-positive diagnoses. In areas of endemicity a single titer of $\geq$800 in symptomatic patients is generally indicative of leptospirosis (22), but titers as high as $\geq$1,600 have been recommended (2). Rarely, seroconversion may be delayed for many weeks after recovery, and longer serological follow-up will be necessary to confirm the diagnosis.

Formalized antigens have been used in the MAT in order to overcome some of the difficulties associated with the use of live antigens. Titers obtained with these antigens are somewhat lower, and more cross-reactions are detected (21, 50). Agglutination of formalized antigens is qualitatively different from that seen with live antigens (2). However, for laboratories without the staff or expertise to maintain live antigens, formalized and lyophilized antigens may represent an alternative. These antigens are not available commercially but may be obtained from WHO Collaborating Centers.

The MAT is the most appropriate test to employ in epidemiological serosurveys, since it can be applied to sera from any animal species and because the range of antigens utilized can be expanded or decreased as required. It is usual to use a titer of $\geq$100 as evidence of past exposure (21). Contrary to a widely held belief, the MAT is a serogroup-specific assay. However, conclusions about infecting serovars cannot be drawn without isolates; at best the MAT data can give a general impression of which serogroups are present within a population (36).

Because of the complexity of the MAT, rapid screening tests for leptospiral antibodies in acute infection have been developed. Traditional methods based upon agglutination have largely been superseded by IgM detection assays. IgM antibodies become detectable during the first week of illness, allowing the diagnosis to be confirmed and treatment to be initiated while it is likely to be most effective. IgM detection has repeatedly been shown to be more sensitive than MAT when the first specimen is taken early in the acute phase of the illness (15, 56, 75). IgM dipstick assays have been shown to be as sensitive as microtiter plate IgM-enzyme-linked immunosorbent assays (5, 28, 37). Other rapid assays include a latex agglutination assay (61) and a lateral-flow assay (60). Commercial IgM dipstick and latex agglutination assays are available from PanBio, Baltimore, Md., and bioMerieux, Durham, N.C., respectively.

ANTIBIOTIC SUSCEPTIBILITIES

Leptospires are susceptible to many antimicrobial agents, including β-lactams, macrolides, tetracyclines, fluoroquinolones, and streptomycin. Problems in the determination of susceptibility include the long incubation time required (19), the use of media containing serum (48, 79), and the difficulty in quantifying growth accurately. These constraints limited the development of rapid, standardized methods for susceptibility testing. However, broth microdilution methods that have facilitated the testing of larger numbers of isolates against a wide range of antimicrobial agents have been described recently (47, 74). Such studies will lead to the identification of potential new agents for inclusion in clinical trials.

Penicillin and doxycycline are both effective for treatment of leptospirosis and remain the drugs of choice (18); recent clinical studies have shown that expanded-spectrum cephalosporins may be equally effective (52, 65).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

A diagnosis of leptospirosis can be made by isolation of the organism or by amplification of leptospiral DNA from blood, urine, or other specimens; by demonstration of leptospires in tissues by immunohistochemical staining; or by detection of a fourfold or greater rise in titers between acute- and convalescent-phase serum samples tested by the same methodology at the same time. In populations and/or regions where leptospirosis is not endemic, MAT titers of ≥200 in a single specimen obtained after the onset of symptoms are suggestive but not diagnostic of acute or recent leptospirosis. A titer of ≥800 in the presence of compatible symptoms is strong evidence of recent or current leptospirosis (21). Delayed seroconversions are common. Assays that detect IgM antibodies give presumptive evidence of recent exposure to leptospirosis but require confirmation, since IgM titers are persistent (16). Cross-reactive antibodies, sometimes with significant seroconversion, are associated with syphilis, relapsing fever, Lyme disease, and legionellosis (5). Negative test results in the presence of compatible symptoms do not rule out the diagnosis of leptospirosis, and further samples should be examined. The isolation of leptospires, the demonstration of leptospiral DNA by molecular methods, or the detection of leptospires in tissues by immunohistochemistry confirms the diagnosis and differentiates between current infection and past exposure, which may not be clearly differentiated by serology.

Despite recent advances in molecular detection and characterization of leptospires and in the development of rapid serologic tests, there are still relatively few laboratories throughout the world with the appropriate capabilities for *Leptospira* diagnostics. Additional information regarding leptospirosis and diagnostic centers of expertise (77) is available for downloading from the International Leptospirosis Society website (http://www.med.monash.edu.au/microbiology/staff/adler/ilspage.htm).

Borrelia

BETTINA WILSKE, BARBARA J. B. JOHNSON, AND MARTIN E. SCHRIEFER

62

TAXONOMY

Bacteria of the genus *Borrelia* belong to the order *Spirochaetales,* which encompasses the families *Spirochaetaceae* and *Leptospiraceae*. *Borrelia* and *Treponema* are the two genera of the family *Spirochaetaceae* that cause human disease. The type species of the genus *Borrelia* is *Borrelia anserina,* which causes borreliosis in birds. Based on 16S rRNA sequence analyses, spirochetes form a distinct entity (division D) within the eubacterial kingdom. They are neither gram positive nor gram negative. In case of the spirochetes, morphological criteria and DNA data produce concordant phylogenies, a rare trait in other bacterial groups.

DESCRIPTION OF THE GENUS

Common Characteristics

Borreliae are similar in length (8 to 30 μm) but wider (0.2 to 0.5 μm) than the two other human-pathogenic spirochetes, the treponemes and the leptospires (Fig. 1) (10). They are highly motile organisms, with corkscrew and oscillating motility. In contrast to the exoflagella of other bacteria, the flagella of spirochetes are endoflagella. The endoflagella of borreliae (7 to 20 per terminus) are localized beneath the outer membrane and insert subterminally at both ends of the protoplasmic cylinder. The protoplasmic cylinder consists of a peptidoglycan layer and an inner membrane which encloses the internal components of the cell (10). If cultivable, borreliae grow slowly under microaerophilic (9) or anaerobic (86) conditions. They require *N*-acetylglucosamine and long-chain saturated and unsaturated fatty acids and produce lactic acid through glucose fermentation (57).

Species Diversity

The causative agent of Lyme disease was first described by Burgdorfer et al. in the early 1980s (18) and named *Borrelia burgdorferi* (58). Studies published since 1992 have divided *B. burgdorferi* sensu lato into three human-pathogenic species—*B. burgdorferi* sensu stricto, *B. afzelii*, and *B. garinii* (8, 19)—and eight other species (Table 1) (108). In North America, *B. burgdorferi* sensu stricto is the only human-pathogenic species, whereas all three species have been isolated from humans in Europe. There is a strong prevalence of *B. afzelii* among human skin isolates from Europe, whereas isolates from cerebrospinal fluid (CSF) in Europe are most commonly *B. garinii* (Table 2) (19, 35, 94, 117). Studies using *ospA* PCR have shown that the strains causing Lyme arthritis are heterogeneous (Table 2) (34, 106) and not limited to *B. burgdorferi* sensu stricto. A few studies have reported the detection of other *Borrelia* species *(B. valaisiana, B. spielmanii,* and *B. lusitaniae)* in patient samples in Europe (24, 90, 91, 107). Similarly, *B. lonestari,* a species carried by a hard tick but genetically more closely related to the relapsing fever spirochetes, has been implicated in at least one case of erythema migrans (EM) (53).

The relapsing fever borreliae *B. turicatae, B. parkeri,* and *B. hermsii* are transmitted by distinct soft-bodied ticks (*Ornithordoros* species), but they may be a single species because their DNA-DNA similarity is greater than 70%. The species status of other cultivable borreliae, such as *B. anserina, B. crocidurae, B. recurrentis,* and *B. coriaceae,* has been supported by greater DNA-DNA dissimilarity findings (27, 57).

The Genome

The genome of the borreliae is composed of a small linear chromosome of approximately 1,000 kb, which is unusual among bacteria, and both linear and circular plasmids. Also atypical of most bacteria, borreliae have a low G+C content, approximately 30 mol%. The complete nucleotide sequence of the chromosome and 21 plasmids (9 circular and 12 linear) has been published for the type strain, *B. burgdorferi* B31 (20, 40). A total of 59% of the chromosomal open reading frames (ORFs) have homologs in other bacterial species; in contrast, homologs have been identified for only one-third of the plasmid ORFs. The genome encodes a basic set of proteins for DNA replication, transcription, and energy metabolism but, interestingly, lacks most cellular biosynthetic pathways. Of some surprise is the tremendous number (>150) of genes that encode putative lipoproteins, suggesting an essential role for these molecules in the life cycle of the spirochete. Recent genome analysis of another Lyme disease spirochete, *B. garinii* (strain PBi), revealed that most of the chromosome is conserved (92.7% identity on the DNA as well as the amino acid level) in the two species. Furthermore, two colinear plasmids (lp54 and cp26) seem to belong to the basic genome inventory of the *Borrelia* species that cause Lyme disease. However, the authors did not find counterparts of the *B. burgdorferi* plasmids lp36 and lp38 or their respective gene repertoires in the *B. garinii* genome (41).

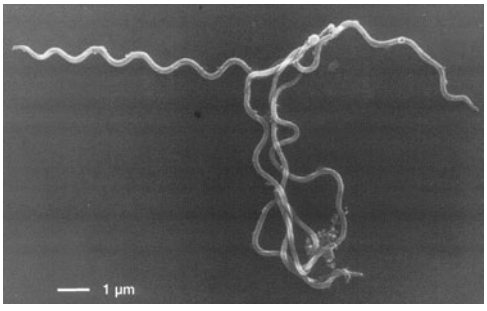

FIGURE 1 *B. burgdorferi* seen by scanning electron microscopy (provided by Gerhard Wanner, Munich, Germany).

Whole-genome microarray analysis revealed that a total of 215 ORFs, 136 of which are plasmid borne, were differentially expressed at 23 and 35°C. These findings highlight the potential importance of plasmid-borne genes in the adaptation of *B. burgdorferi* sensu lato to mammal hosts and tick vectors (74).

The linear plasmids of *B. hermsii* and *B. turicatae* contain genes encoding outer membrane lipoproteins, called variable major proteins (Vmp). These genes are silent except when they are translocated to an expression site immediately adjacent to one of the linear plasmid telomeres. Antigenic variation of Vmp-like proteins due to recombination of *vls* (Vmp-like small) gene sequence cassettes has also been described for *B. burgdorferi*. These *vls* genes have highly variable regions, as well as highly conserved sequences which encode immunogenic epitopes important for serodiagnosis (70, 123).

The large linear plasmid lp54 encodes two major outer surface proteins, OspA and OspB, which are tandemly arrayed in one operon (13). The first gene detected on a circular plasmid (cp26) was the gene encoding OspC, another major outer surface protein of *B. burgdorferi* (95, 118). Sequence analysis of the *osp*C genes from different strains suggested that gene exchange might play a role in diversity and immune evasion of Lyme disease borreliae (54).

EPIDEMIOLOGY AND TRANSMISSION

The ecological components that maintain *Borrelia* species in nature are quite diverse and spread throughout the world (Table 1).

Relapsing Fever Borreliae

Most relapsing fever borreliae are transmitted by soft-bodied ticks of the genus *Ornithodoros* (Fig. 2). The exception is *B. recurrentis,* which is vectored by the human body louse *(Pediculus humanus humanus)*. Infection in this human-specific ectoparasite is limited to the hemolymph, and spirochetes are not passed transovarially to louse progeny. Thus, humans serve as the sole reservoir of *B. recurrentis*. *B. duttonii* is vectored by the soft tick *Ornithodoros moubata,* and as is the case for *B. recurrentis,* humans serve as the only known reservoir. Notably, these human-adapted borreliae are very closely related genetically (27). The remaining relapsing fever *Borrelia* species are transmitted by other *Ornithodoros* ticks and have wild-animal reservoirs, mostly rodents (Table 1). The soft ticks feed rapidly, within 10 to 45 min, and mostly at night.

B. burgdorferi sensu lato

The Lyme disease borreliae of *B. burgdorferi* sensu lato are transmitted by hard-bodied ticks (genus *Ixodes*) (Fig. 2). *Ixodes* species feed on three different hosts depending on the developmental stage of the tick (51). The larvae and nymphs feed primarily on small rodents, whereas adult ticks feed on a variety of mammals (deer, raccoons, domestic and wild carnivores, larger domestic animals, and birds). The feeding period of *Ixodes* ticks is rather long (several days to over a week) and contributes to their geographic dispersal along with the movement of the host. Birds, particularly migratory seabirds, can transport the ticks *(Ixodes uriae)* over very long distances and thus distribute borreliae (especially *B. garinii*) worldwide (75). There appears to be an association between *B. afzelii* and small rodents and *B. garinii* and birds, likely due to different serum sensitivities of the borreliae (51) mediated by complement regulator-acquiring surface proteins (65). In unfed ticks, *B. burgdorferi* sensu lato lives in the midgut. During the blood meal from humans or mice, transcriptional changes (e.g., a switch from OspA to OspC expression) are induced in the borreliae that lead to their migration to the salivary glands (37, 100).

The role of OspC for dissemination in the tick is controversial, but its expression is required for mouse infection (38, 44, 76). Invasion from the *Ixodes scapularis* midgut takes >36 h (28). For *Ixodes ricinus,* however, spirochete migration within the tick and transmission to the mammalian host have been observed with ticks feeding for as few as 17 h (60).

CLINICAL SIGNIFICANCE

Relapsing Fever

Relapsing fever is an infectious disease with an acute onset of clinical signs and symptoms including high fever, shaking chills, severe headache, nausea, myalgias, and severe malaise. Initial physical findings often are conjunctival effusion, petechiae, and diffuse abdominal tenderness. Fever attacks of 3 to 7 days are interspersed with afebrile periods of days to weeks. More detailed descriptions have been published elsewhere for louse-borne relapsing fever (88) and tick-borne relapsing fever in North America (32, 33).

Louse-borne relapsing fever is, in general, more severe than tick-borne relapsing fever, but the number of febrile attacks is often fewer. In tick-borne relapsing fever up to 13 febrile attacks have been reported, and a rash is more often reported than in louse-borne relapsing fever (28 versus 8%). Splenomegaly, hepatomegaly, and jaundice are observed in 77, 66, and 36% of louse-borne relapsing fever cases, whereas these signs are reported in only 41, 17, and 7% of tick-borne relapsing fever cases. In louse-borne relapsing fever, 34% of the patients have respiratory symptoms and 30% have central nervous system involvement; in patients with tick-borne relapsing fever, these figures are 16 and 9%, respectively (59). Complications leading to death (mortality rate of up to 40% in louse-borne relapsing fever) are acute heart and hepatic failure and cerebral hemorrhage. Disease severity increases with compromising conditions common in many areas of endemicity. During pregnancy, relapsing fever may also lead to congenital infection and fetal death.

Lyme Borreliosis

Lyme borreliosis can be defined by early localized, early disseminated, and late-stage manifestations similar to the three stages of syphilis (104). The natural course of untreated *B. burgdorferi* infections varies considerably, and clinical manifestations can occur alone or in various combinations (102, 104, 105, 109). In the majority of cases the infection is self-limiting, but in rare

TABLE 1 Characteristics of arthropod-borne borreliae[a]

Borrelia sp.	Arthropod vector	Animal reservoir	Geographic distribution	Disease
Relapsing fever borreliae				
B. recurrentis	*Pediculus humanus humanus*	Humans	Worldwide	Louse-borne (epidemic) relapsing fever
B. duttonii	*O. moubata*	Humans	Central, eastern, and southern Africa	Tick-borne (endemic) relapsing fever

[a] Modified from reference 119a.

TABLE 2 Distribution of species of *B. burgdorferi* sensu lato in European isolates from CSF, skin, and synovial fluid specimens[a]

Species	% Distribution[b]		
	CSF (n = 78)	Skin (n = 560)	Synovial fluid (n = 20)
B. burgdorferi sensu stricto	12	1	33
B. afzelii	17	88	29
B. garinii	71	10	38

[a] Data from references 34, 94, 106, and 113.
[b] *B. burgdorferi* sensu lato species identifications from CSF and skin are based on culture; species identification from synovial fluid samples is based on *ospA* PCR results. Culture isolates from synovial fluid are too few to estimate *Borrelia* species distribution.

cases, *B. burgdorferi* may persist and chronic disease manifestations may develop.

EM at the site of the infectious tick bite is the most common manifestation of early (stage I) Lyme borreliosis and occurs in 60 to 90% of patients. The center of the expanding annular lesion often fades to produce a bull's-eye appearance. However, the extension, color intensity, and duration of EM vary considerably. General symptoms such as fever, myalgia, headache, and, rarely, meningismus may accompany the primary EM.

In some patients, hematogenous dissemination of spirochetes to other organs and tissues occurs within days to weeks of infection (stage II). Patients often feel quite ill and may present with fatigue, headache, fever, malaise, arthralgia, and myalgia. Multiple (secondary) erythemata are common in the United States but uncommon in Europe. Neurologic structures, including the meninges, brain, spinal cord, peripheral nerves, and nerve roots, are also potential sites of early disseminated infection. In the United States, 15 to 20% of untreated patients develop neurologic signs, most commonly facial nerve palsy (unilateral or bilateral), meningitis, and radiculoneuropathy. CSF findings in cases of Lyme meningitis almost always include a mononuclear pleocytosis (10 to 1,000 cells/μl) and elevated protein concentration. Meningitis, or even facial palsy without meningismus, is more common among children than adults. Severe encephalitis is occasionally observed in stage II. Bannwarth's syndrome is the most common neurologic manifestation of early, disseminated Lyme borreliosis in Europe. The syndrome is characterized initially by intense, migratory or focal, radicular pain, particularly at night, and by cranial nerve palsy. Pareses of the extremities and the trunk are less frequent. Further clinical manifestations of stage II may include Lyme carditis, most often with atrioventricular conduction blocks, and ophthalmic involvement. Borrelial lymphocytoma, a reddish to livid swelling of the skin in typical locations such as the earlobe, nipple, or scrotum, is manifested among some patients in Europe.

Lyme arthritis and acrodermatitis chronica atrophicans (ACA), occurring months to years after the initial infection, are the most common manifestations of late (stage III) disease. Lyme arthritis can be monoarticular or oligoarticular, typically affecting the knee, and usually takes an intermittent course. Patients with ACA initially develop an infiltrative stage, followed by alterations characteristic of the atrophic stage: creased skin with livid discolorations and plastic protrusion of vessels. ACA is observed almost exclusively in Europe, a finding highly correlated with *B. afzelii* infections. Chronic neuroborreliosis is a very rare manifestation of late (stage III) disease. Parapareses and tetrapareses are its most common symptoms. Examination of the CSF reveals a marked elevation of protein concentration with a low to moderate increase of cells in the CSF. The detection of intrathecally produced specific antibodies is currently regarded as the best marker of chronic neuroborreliosis, although there may be less frequent production of intrathecal antibodies in U.S. patients.

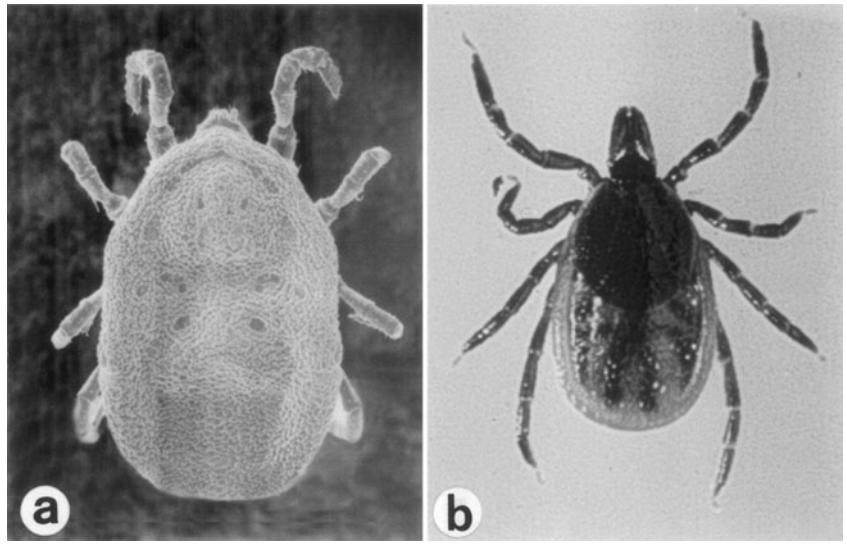

FIGURE 2 Two genera of ticks are vectors for relapsing fever and Lyme borreliosis: *Ornithodoros* (a) and *Ixodes* (b).

Early manifestations of Lyme borreliosis are observed most frequently in the spring, summer, and autumn, coinciding with tick activity. Late manifestations do not show a seasonal pattern.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Specimens for laboratory confirmation of Lyme borreliosis are presented in Table 3.

Blood and Serum

For relapsing fever, blood is the specimen of choice. During febrile attacks, borreliae may be easily detected by dark-field or bright-field microscopy of a wet-mount blood sample or a stained blood smear, respectively (see "Direct Examination," "Microscopy"). At this time, the spirochetemia may reach 10^6 to 10^8 cells ml^{-1} (57). Blood from acutely ill patients is also the best source for culture confirmation (26, 27). However, the spirochetemia diminishes with each successive relapse, and visualization or culture isolation of borreliae is often unsuccessful during afebrile periods. In contrast to relapsing fever, spirochetemia in Lyme borreliosis patients is below the level of microscopic detection. Culture and PCR of blood samples generally are not recommended, since the yields are low (43). Even when large blood volumes are cultivated, positive cultures have been derived from only 50% of patients with EM (121).

Serum is suitable for indirect (antibody) evidence of *Borrelia* exposure. Specific antibody detection tests are the most widely utilized tests for laboratory confirmation of Lyme borreliosis. Serodiagnosis of relapsing fever is performed only in a few specialized laboratories.

CSF

In suspected neuroborreliosis patients, CSF (along with serum drawn at the same time) should be obtained for determination of cell counts-cell differentials, protein content, and intrathecal immunoglobulin (immunoglobulin M [IgM] and IgG) synthesis. Laboratory confirmation of neuroborreliosis is most readily achieved by demonstration of *Borrelia*-specific, intrathecal (CSF/serum antibody index) antibody production (see "Serological Tests"). For culture or PCR, however, detection rates are only about 20% (68). Positive PCR results in CSF also seem to correlate inversely with duration of neurologic disease. Among neuroborreliosis patients, 7 of 14 (50%) with a disease duration of less than 2 weeks had a positive PCR result, compared with only 2 of 16 (13%) patients in whom the illness duration was greater than 2 weeks ($P = 0.045$) (68).

Synovial Fluid or Synovial Biopsy Specimens

Investigation of synovial fluid or a synovial biopsy specimen by PCR may be useful in special circumstances where Lyme arthritis is suspected (73). Culture is usually negative, with few exceptions. Due to the high protein permeability of the synovium, synovial fluid and serum display roughly equivalent antibody titers. Thus, it is sufficient to monitor antibody in serum.

Skin Biopsy Specimens

Skin biopsy samples are the best sources for isolation of *B. burgdorferi;* spirochetes can be isolated in most untreated cases of EM and acrodermatitis (Table 4). In cases of EM, culture success is highest (up to 86%) with biopsy samples taken close to (4 mm inside) the expanding border of the lesion (12), although this is primarily a technique for research, not for routine diagnosis. There are indications that the number of spirochetes in the skin is rather low or unevenly distributed, since an increase in the sensitivity is observed if more than one biopsy sample is investigated (124). Without treatment, *B. burgdorferi* sensu lato can persist for long periods in the skin, as shown by isolation from a 10-year-old acrodermatitis lesion (6). Biopsy samples (taken after thorough disinfection of the skin) should be sent in a small amount of sterile saline or Barbour-Stoenner-Kelly (BSK) medium (with or without rifampin) as soon as possible to the microbiological laboratory.

Other Materials

Ticks are often tested for borreliae as part of epidemiological studies to assess risk to human populations in a given geographic area. Although specialized laboratories offer diagnostic services for individual ticks, detection of spirochetes

TABLE 3 Specimen types used for the diagnosis of Lyme borreliosis

Clinical manifestation	Specimens for:	
	Direct pathogen detection (culture, PCR)	Antibody detection
Stage I (early/localized; days through weeks after tick bite)		
EM	Skin biopsy	Serum
Stage II (early/disseminated; weeks through months after tick bite)		
Multiple erythemata	Skin biopsy	Serum
Borrelial lymphocytoma	Skin biopsy	Serum
Lyme carditis	Endomyocardial biopsy	Serum
Neuroborreliosis	CSF	Paired serum/CSF[a]
Stage III (late/persistent; months through years after tick bite)		
Arthritis	Synovial fluid, synovial biopsy	Serum
ACA	Skin biopsy	Serum
Chronic neuroborreliosis	CSF	Paired serum/CSF[a]

[a] From the same day for AI determination.

TABLE 4 Sensitivity of methods for pathogen detection (PCR and culture) in Lyme borreliosis

Specimen	Sensitivity
Skin (EM, acrodermatitis)	50–70% when using culture or PCR
CSF (neuroborreliosis, stage II)	10–30% when using culture or PCR[a]
Synovial fluid[b] (Lyme arthritis)	50–70% when using PCR (culture is rarely positive)

[a] Up to 50% in patients with disease duration of less than 2 weeks, compared with only 13% in patients for whom the illness duration was greater than 2 weeks.
[b] Higher sensitivity of direct pathogen detection from synovial biopsy specimen.

within ticks by PCR or other methods has not been shown to provide clinically useful information.

General Remarks for Collection and Transport

For culture, collection and preparation of specimens under sterile conditions are of utmost importance. Body fluids should be transported without any additives, and biopsy specimens should be placed in a small quantity of sterile saline or suitable culture medium (see "Isolation Procedures"). Samples should reach the laboratory as quickly as possible (within 2 to 4 h). Before specimens are collected and transported, the laboratory should be contacted so that details of methodology can be agreed upon. If postal transport is unavoidable, overnight delivery is recommended.

DIRECT EXAMINATION

Microscopy

Direct microscopic visualization of borreliae in clinical samples is applicable only to cases of relapsing fever. During acute phases, spirochetemia often reaches 10^6 to 10^8 borreliae/ml and motile spirochetes can be visualized by dark-field microscopy from wet preparations made from a drop of blood. This simple confirmatory test is often overlooked because of the increasingly common use of automated differential blood counts. Spirochetes can be visualized by stained (e.g., Giemsa) thin- or thick-drop films (Fig. 3). Detection of low-level spirochetemias may be assisted by a microhematocrit concentration technique. The hematocrit capillary is filled 75% with citrated blood and centrifuged for 2 min. The buffy coat is then examined directly under the microscope at ×400 to ×1,000 (119a). Failure to observe spirochetes does not rule out disease, and culture isolation (see "Isolation Procedures") may be considered. In Lyme borreliosis, spirochete numbers in patient blood or other tissues are below the level of microscopic detection and microscopy is best applied to the monitoring of borrelial growth in cultured tissues or fluids.

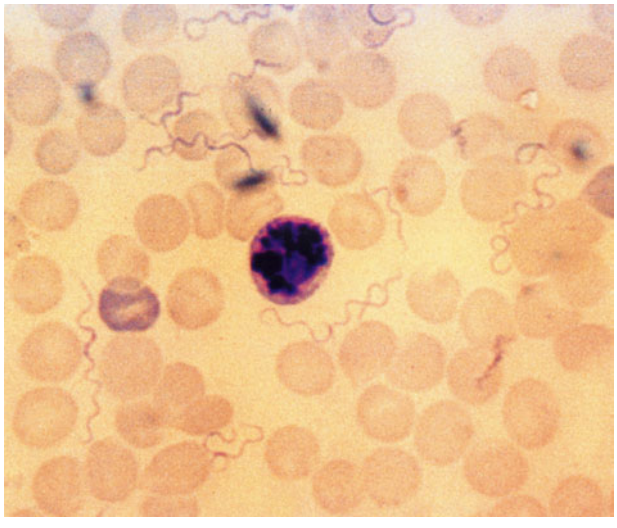

FIGURE 3 *B. hermsii* in a thin smear of rodent blood (Giemsa stain). Magnification, ×1,000.

Antigen Detection

Enzyme-linked immunosorbent assay (ELISA) and immunoblotting have been used for the detection of borrelial antigen in body fluids, including CSF and urine (25, 52). However, a commercial assay for antigen in urine was shown to lack reproducibility, and its use is not recommended (64).

Nucleic Acid Detection Techniques

Nucleic acid amplification techniques (NAT) should be restricted to experienced and specialized laboratories (92). For patients with suspected exposure outside of North America, it is imperative that selected NAT targets sensitively detect all human-pathogenic species. Species identification of amplification products is preferable (120).

Under circumstances where antibody detection and culture isolation fail to provide case confirmation, NAT can serve as a separate adjunct to clinical diagnosis. A variety of chromosomal and plasmid targets for NAT have been developed (for reviews, see references 3, 31, and 96). For PCR, an analytical sensitivity of approximately 10 to 20 borreliae per test sample has been demonstrated. Test sensitivities for both NAT and culture are greater with tissue specimens than with body fluids, except for synovial fluid, with which NAT is superior. Sensitivities of 96% (73) and 86% (14) were reported for NAT from synovial fluid from American patients with Lyme arthritis. European authors found NAT sensitivities ranging between 50 and 70% (34, 87, 106). Patients with Lyme arthritis are nearly always seropositive, so PCR of synovial samples is not used as a primary diagnostic technique. A positive PCR result after antibiotic therapy is of uncertain significance, since the presence of *B. burgdorferi* DNA does not necessarily mean that spirochetes are viable.

From skin biopsy and CSF specimens, NAT demonstrated diagnostic sensitivities of approximately 60 and 20%, respectively (15, 35, 68). A prospective study of PCR and culture detection of *B. burgdorferi* in EM biopsy samples from Slovenian patients showed comparable sensitivities (36% for culture in modified Kelly medium Preac-Mursic [MKP] medium, 24% for culture in BSK II medium, 25% for PCR, 54% with at least one positive test, and 6% with all three tests positive) (82). PCR targeting *ospA*, a plasmid-borne gene, is more sensitive than flagellin PCR, which uses a chromosomal target (79, 124). Borreliae may shed blebs containing plasmids, leading to target imbalance.

PCR amplification of *B. burgdorferi* sequences from urine has been described (89, 96) but is not recommended. Although *Borrelia*-specific DNA was demonstrated in over 70% of skin biopsy samples from patients with florid EM, parallel testing of urine samples was uniformly negative (15).

ISOLATION PROCEDURES

Many Lyme and relapsing fever borreliae are successfully cultured in artificial media. However, for diagnostic purposes, culturing is a slow, time-consuming method characterized by low sensitivity, especially from body fluids of patients with Lyme borreliosis (Table 4). For these reasons culture attempts are most often limited to research applications and performed by reference laboratories (e.g., the National Reference Center for Borreliae in Germany and the Centers for Disease Control and Prevention [CDC] in the United States).

Several media (modified Kelly medium, e.g., BSK II, BSK-H, or MKP) (9, 83, 86) are capable of supporting growth of borreliae. A commercial preparation of BSK-H is available from Sigma Chemical Co., St. Louis, Mo. It is important to verify the quality of each lot of medium by growing a reference strain from a small inoculum (<10 cells). Optimum growth (the generation time of *B. burgdorferi* is about 7 to 20 h) in these media is obtained at 30 to 33°C under microaerophilic conditions. Positive cultures from EM and synovial biopsy or fluid samples (blood and CSF) may be obtained in as few as 4 days, but most isolates require several weeks of incubation and negative cultures should be monitored by dark-field microscopy for at least 6 weeks, with blind passage into fresh medium every 2 weeks.

IDENTIFICATION

Molecular Techniques

Relapsing fever borreliae have been typed on the basis of DNA-DNA reassociation analysis and flagellin gene analysis (27, 57). *B. burgdorferi* has an arrangement of its rRNA genes (a single *rrs* and tandemly repeated *rrl* and *rrf* genes) which distinguishes it from the relapsing fever borreliae (which have single copies of each) (101). Sequencing of 5S-23S intergenic spacers is useful in typing borreliae. A number of molecular genetic methods, including pulsed-field gel electrophoresis of large restriction fragments (11), PCR, and sequence analysis or restriction fragment length polymorphism of the 16S rRNA/16S ribosomal DNA and of the 5S-23S intergenic spacer region (69, 84), have been described for species differentiation (summarized in reference 108). Analysis of certain protein-encoding genes, especially *ospA* and *ospC*, has also been utilized for *B. burgdorferi* sensu lato species identifications (35, 116, 117). However, in most cases, diagnosis and effective management of individual patients are independent of species determinations beyond the Lyme disease and relapsing fever groupings.

Immunological Techniques

Antibody responses to GlpQ, an antigen expressed by relapsing fever species but not Lyme borreliosis species, have been used to discriminate the two infections (100, 119a). For *B. burgdorferi* sensu lato, a serotyping method using monoclonal antibodies to OspA has been established. Eight different serotypes have been described among the pathogenic species for Europe, which has implications for OspA vaccine development (112, 117). Phenotypic analysis of OspC revealed 15 different serotypes (113). Some species-specific monoclonal antibodies have also been described.

SEROLOGICAL TESTS

Borrelia Antigens and Human Humoral Immune Response

In Lyme borreliosis the early antibody response is largely IgM and mainly directed against the outer membrane-associated OspC, p39 (BmpA), and p35 (BBK32, fibronectin-binding protein) and the flagellum subunits p37 (FlaA) and p41 (FlaB) (1, 4, 36, 49, 114).

The level of IgM antibody to most spirochetal antigens peaks within the first weeks of infection. However, IgM antibodies are often detected many months after effective treatment and cure (1). The IgG response increases and broadens slowly over the first weeks of disease. Among the reactive antigens to which there is an early IgG response are p35 (BBK32), p37 (FlaA), p41 (FlaB), OspC, and VlsE (1, 4, 66, 70, 77). During early disseminated (stage II) disease, IgG levels increase and reactivity against p39 (BmpA), DbpA (decorin binding protein), and p58 often appears (49) (Table 5). The late-stage immune response (stage III) is characterized by IgG antibodies to a wide variety of antigens (30, 49). Approximately 80% of the sera from European patients with late disease (arthritis and ACA) react with

TABLE 5 Reactivity of IgG antibodies with recombinant *Borrelia* proteins (DbpA, VlsE, and p58) in the line immunoblot[a]

Diagnosis	No. of sera	No. (%) of sera with reactivity							
		DbpA				VlsE			p58
		PBi (*B. garinii*)	PBr (*B. garinii*)	PKo (*B. afzelii*)	B31 (*B. burgdorferi*)	At least one DbpA[b]	PBi (*B. garinii*)	PKa2 (*B. burgdorferi*)	PBi (*B. garinii*)
EM[c]	15	0 (0.0)	2 (13.3)	4 (26.7)	1 (6.7)	5 (33.3)	12 (80.0)	6 (40.0)	1 (6.7)
Neuroborreliosis	50	19 (38.0)	20 (40.0)	17 (34.0)	6 (12.0)	39 (78.0)	44 (88.0)	41 (82.0)	27 (54.0)
Acrodermatitis	10	1 (10.0)	0 (0.0)	8 (80.0)	1 (10.0)	8 (80.0)	10 (100.0)	10 (100.0)	10 (100.0)
Arthritis	10	7 (70.0)	1 (10.0)	9 (90.0)	2 (20.0)	10 (100.0)	10 (100.0)	9 (90.0)	9 (90.0)

[a] Modified from reference 42.
[b] The combination of DbpA proteins from different strains (PBi, PBr, PKo, and B31) results in considerable increase of sensitivity in neuroborreliosis.
[c] Disease duration of >2 weeks.

p14, Osp17 (DbpA), p21 (not OspC), p30, p39, p43, p58, and p83/100 (homolog of p93) of *B. afzelii* strain PKo. Interestingly, IgG antibodies against OspC are detected in only 20% of these patients (49). The frequency of IgG reactivity to OspC in American patients with late disease is higher (48%) (30).

OspA is downregulated at the time of initial infection in the mammalian host. This explains why antibodies against OspA are rarely observed in patients with early disease. Among American patients with late disease, 42% were reactive to OspA (30), in contrast to 5 to 7% among European patients (49, 114). Notably, OspA antibodies are quite common in a special group of patients from the United States who suffer from therapy-refractory forms of Lyme arthritis (4). Subsequently it was shown that patients with Lyme borreliosis have a strong IgG response against a conserved epitope (C6 peptide derived from the IR6 region of VlsE) or the whole recombinant VlsE, which appears earlier during disease than immune responses to other borrelial antigens. This was observed in both American and European patients (7, 70, 97). Differences in VlsE reactivity were observed using VlsE proteins derived from different strains (42). Notably, VlsE from a *B. garinii* strain was more reactive for detection of IgM antibodies than VlsE proteins from *B. burgdorferi* sensu lato or *B. afzelii* strains.

Two-Step Approach in Serodiagnosis

For serodiagnosis of Lyme borreliosis, a two-step approach is recommended by the Association of State and Territorial Public Health Laboratory Directors (ASTPHLD) and the CDC (21, 55): "All serum specimens submitted for Lyme disease testing should be evaluated in a two-step process, in which the first step is a sensitive serological test, such as an enzyme immunoassay (EIA) or immunofluorescence assay (IFA). All specimens found to be positive or equivocal by a sensitive EIA or IFA should be tested by a standardized immunoblot procedure. Specimens found to be negative should not be tested further" (21). This procedure is also recommended in the MiQ Lyme borreliosis standard published by the German expert group on the diagnosis of Lyme borreliosis of the German Society for Hygiene and Microbiology (DGHM) (Fig. 4) (120). The concept of a two-step approach, which aims at increasing the predictive value of a positive result with each step, requires that the tests be performed in succession (56, 120). Omitting the first step, a quantitative assay, and proceeding directly with qualitative immunoblots reduces the specificity of the procedure.

IFA

For the IFA, borreliae fixed on glass slides are used as the antigen. IFA for serodiagnosis of relapsing fever, however, is challenging since expression of the major membrane proteins is variable. The specificity of IFA serodiagnosis for Lyme disease may be improved by adsorption of sera with *Treponema phagedenis* sonicate (IFA-ABS) (120). For the IgM test, pretreatment of the sera with anti-IgG-immune serum is recommended to avoid false-positive test results due to rheumatoid factor as well as false-negative results due to high IgG antibody levels. As in all antibody detection assays, it is important to verify

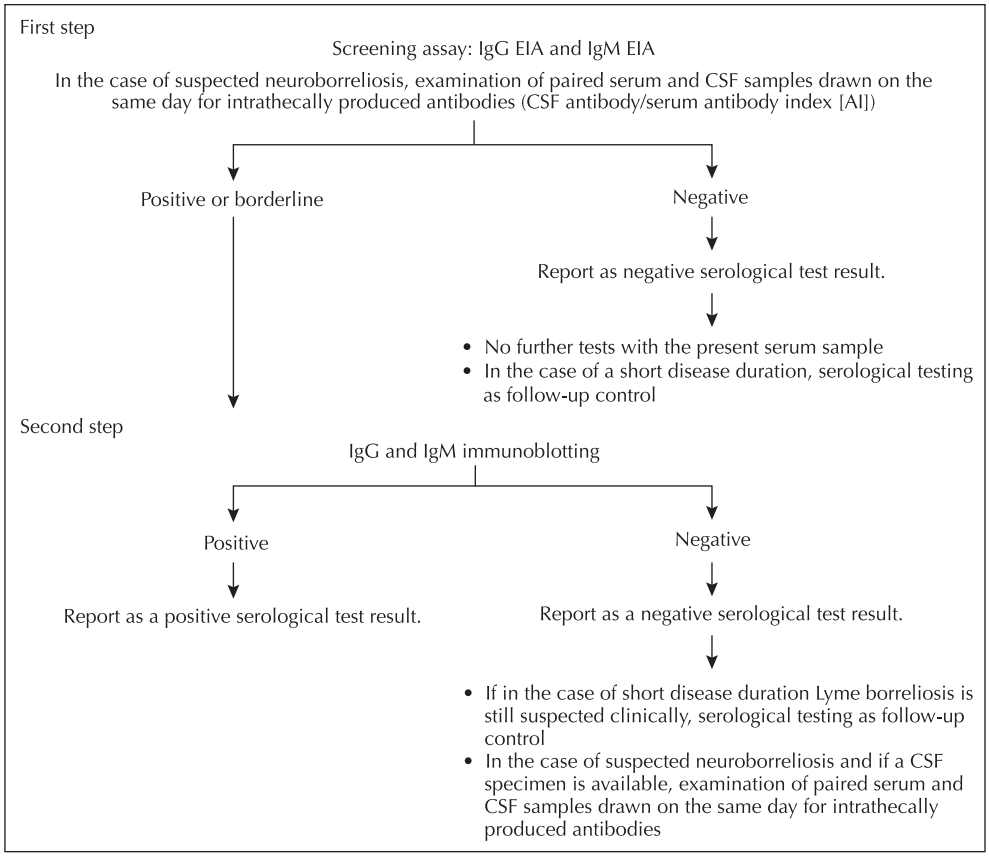

FIGURE 4 Two-step approach for serodiagnosis.

expression of OspC within the antigen source cultures. Although IFA is relatively easy to perform, it is not easy to standardize, and evaluation of test results requires expertise not always available in the routine laboratory. In general, antibody titers of ≥64 and ≥256 are regarded as positive in the IFA-ABS and unadsorbed IFA, respectively. Sera from patients with syphilis are often positive in the unadsorbed assay and are rarely positive in the IFA-ABS (120).

EIA

Different modifications of the EIA have been used for the diagnosis of Lyme borreliosis. In the indirect EIA, antigen is used to coat the plates, followed by incubation with patient serum, enzyme-labeled anti-IgM or anti-IgG, and the EIA substrate. Capture IgM-EIA (μ-capture EIA) has been specially designed to avoid false-positive reactivity due to rheumatoid factor (48). Rheumatoid factor false-positive reactivity can also be overcome by pretreatment of the sera with anti-IgG (114). EIA has the advantage of objective measurement, quantification, and high throughput. Many different antigen preparations have been used, including whole-cell sonicates (93), isolated flagella (46), detergent extracts (114), recombinant antigens (61, 67, 114), and synthetic peptides (70). Use of crude antigen preparations, such as whole-cell sonicates, often results in unacceptable specificity. Improved tests which utilize enriched, specific, or recombinant antigens are now widely used. Tests using an octyl β-D-glucopyranoside detergent extract and Reiter treponeme absorbent, isolated flagella, recombinant VlsE, or the C6 peptide of VlsE are commercially available (Dade-Behring, Marburg, Germany; Dakopatts, Copenhagen, Denmark; Diasorin, Turin, Italy; and Immunetics, Boston, Mass.). Since VlsE is not present in relevant amounts in cultivated borreliae, recombinant VlsE has been added to whole-cell extracts to increase sensitivity in some products (Dade-Behring).

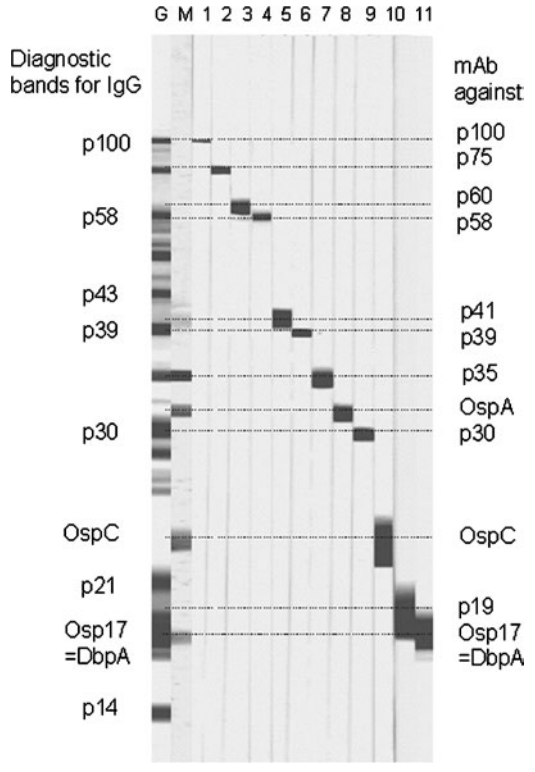

FIGURE 5 Whole-cell immunoblot for identification of diagnostic bands with monoclonal antibodies (mAb). The antigen used is *B. afzelii* strain PKo. Lane G, IgG blot from patient with late disease; lane M, IgM blot from patient with early disease; lanes 1 to 11, different monoclonal antibodies against the respective reactive proteins. (Modified from reference 49.)

Immunoblotting

Western immunoblotting enables assessment of the humoral immune response to individual protein antigens as resolved by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). The Western immunoblot is regarded as a supplementary (United States) or confirmatory (Europe) assay. This implies that it should be employed only when a screening assay is reactive (positive or indeterminate, sometimes called equivocal). Antigen preparations for Western immunoblotting include whole-cell lysates or recombinant antigen mixtures that are transferred after SDS-PAGE to blot membranes.

The advantage of the whole-cell lysate immunoblot is that antibodies against a large number (~50) of antigens can be detected. Herein also lies a significant challenge to the diagnostic laboratorian—discerning reactivity between specific and nonspecific or cross-reactive antigens that may not be clearly resolved from each other. Thus, reliable identification of the immunoreactive bands is imperative, i.e., by use of monoclonal antibodies (Fig. 5) (120). Immunoblotting for Lyme borreliosis is considered technically complex, and in order to realize its maximal performance and utility, standardization and careful quality control must be used.

Numerous immunoblot tests which use antigens of various strains or genospecies of *B. burgdorferi* sensu lato are commercially available. The ASTPHLD and the CDC, as well as the DGHM, have published recommendations for interpretation of the *Borrelia* immunoblot (21, 120). In the United States, immunoblot interpretation rules have been recommended which refer to detection of antibody against whole-cell antigens of specific *B. burgdorferi* sensu stricto strains (30, 36). The IgM immunoblot is interpreted as positive if ≥2 bands of the following proteins are reactive: OspC, 39 kDa (BmpA), and 41 kDa (FlaB). The IgG blot is interpreted as positive if ≥5 bands of the following proteins are reactive: OspC and 18, 28, 30, 39 (BmpA), 41 (FlaB), 45, 58, 66, and 93 kDa. If the immunoblot is used within the first 4 weeks of disease onset (early, stage I or II), both IgM and IgG immunoblots should be performed. A positive IgM immunoblot alone should not be used in determining infection in persons with illness duration of >1 month because the likelihood of a false-positive test for current infection is high for these individuals.

Interpretation of the antibody response among European patients is complicated by the risk of infection with different *Borrelia* species. In addition, immunoblot studies have shown that the immune response of European patients, compared with American patients, is restricted to a narrower spectrum of *Borrelia* proteins (29). Interpretive rules defined in a species- and strain-specific manner have been determined (49) and independently corroborated (62). *B. afzelii* strain PKo is preferred to PBi *(B. garinii)* and PKa2 (*B. burgdorferi* sensu stricto) strains because it permits a two-band criterion for the IgG test: at least two bands positive for p14, Osp17 (DbpA), p21, OspC, p30, p39 (BmpA), p43, p58, and p83/100 (Fig. 5) (120). According to the general Deutsches Institut für Normung (DIN) recommendations

on the immunoblot (DIN 58967, Part 40), at least a two-band criterion should be required for the positive interpretation of the IgG immunoblot. In IgM immunoblots, a detectable immune response is restricted to only a few bands. Therefore, the IgM blot is regarded as positive if there is strong reactivity to OspC (120). Specific DIN recommendations for the *Borrelia* immunoblot (DIN 58969, Part 44) have been published which include new antigens (i.e., VlsE) and the line immunoblot as a new technique.

Recombinant immunoblots with Osp17 (DbpA), OspC, p39 (BmpA), truncated p41 (FlaB), p58, and p83/100 have demonstrated sensitivity comparable to that of the whole-cell immunoblot except for patients with isolated EM (115). The recombinant immunoblot was substantially improved by the addition of several homologs of VlsE and DbpA, which considerably increased the sensitivity of antibody detection in early disease (42, 97). Recombinant blots containing DbpA, OspC, p39 (BmpA), truncated p41 (FlaB), VlsE, and p83/100 are commercially available (Mikrogen, Munich, Germany). Using the line blot technique, which allows detection of antibodies against antigens with identical molecular weights (i.e., homologs of the same *Borrelia* protein) (Fig. 6 and Table 5), the recombinant immunoblot is significantly more sensitive than the conventional sonicate immunoblot (i.e., 91.7 versus 68.8%) for patients with early neuroborreliosis (42).

For commercial immunoblot tests, the user should verify that all relevant antigens are present (must be detected by the positive control serum) and interpretation rules are established in defined patient and control populations. In immunoblot evaluation, a scored band must have an intensity equal to or greater than that of the cutoff control. Commercial Western immunoblot test kits licensed by the FDA are available from five different manufacturers. Current listings of 510K, FDA-approved serodiagnostic assays for Lyme disease can be found at http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfPMN/pmn.cfm under product code LSR.

Detection of Intrathecally Produced (CSF) Antibodies

Detection of the intrathecal *Borrelia*-specific immune response is one of the most valuable tools for the diagnosis of neuroborreliosis. Methods taking into account potential dysfunction of the blood-CSF barrier, a common finding in neuroborreliosis, are required for accurate assessment of intrathecal antibody production. Since the permeability of the blood-CSF barrier may change rapidly in inflammatory diseases like acute neuroborreliosis, CSF and serum must be obtained at the same time. Long-used procedures for detection of specific intrathecal antibody production in the diagnosis of neurosyphilis have been modified for the diagnosis of neuroborreliosis (47, 103, 119). The most frequently used method is the determination of the CSF/serum antibody index (specific antibody index [AI]).

This method requires measuring the specific antibodies in the blood and in the CSF by means of a calibrated standard curve and determination of a quotient from the antibody units and the IgG concentrations in CSF and serum:

$$\mathrm{AI} = \frac{\text{EIA units in CSF} \times \text{total IgG in serum}}{\text{EIA units in serum} \times \text{total IgG in CSF}}$$

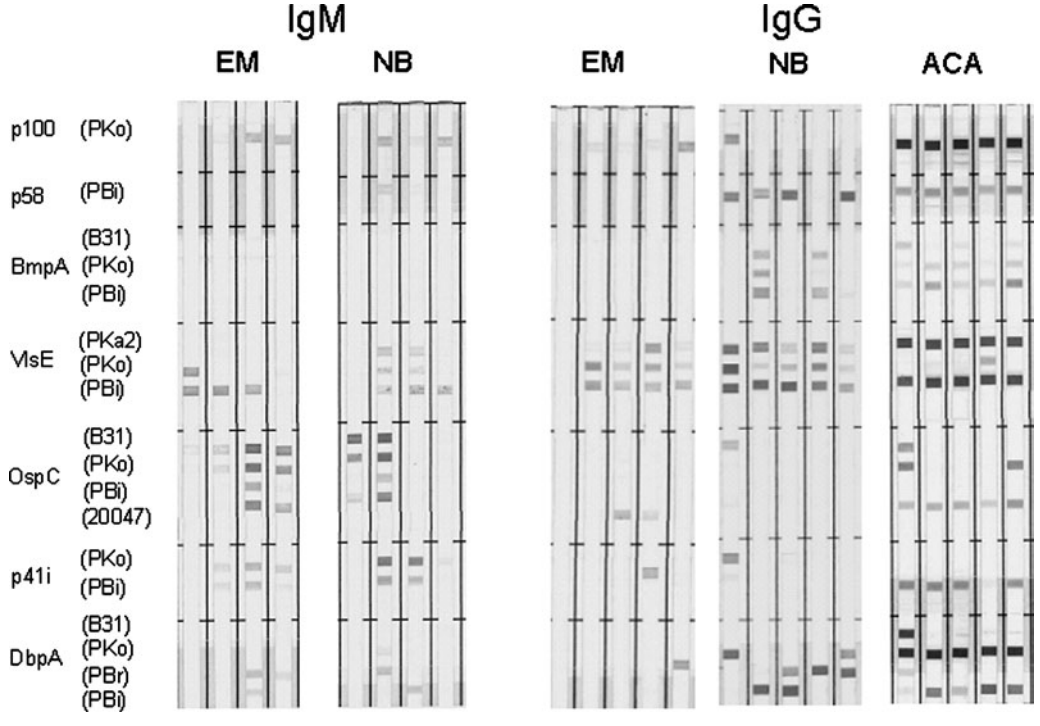

FIGURE 6 Recombinant line immunoblot. Shown are representative IgG blots and IgM blots of patient and control sera. Strains of the following species are shown: *B. burgdorferi* sensu stricto B31 and PKa2, *B. afzelii* PKo, *B. garinii* OspA type 3 (PBr), *B. garinii* OspA type 4 (PBi), and *B. garinii* unknown OspA type (20047). Sera were obtained from patients with EM, early neuroborreliosis (NB), and ACA. (Modified from reference 42.)

For the determination of the AI, EIAs allowing quantitative measurement are suitable (119). The total IgG concentrations of serum and CSF are determined by nephelometry. Alternatively, both serum and CSF can be used for EIA after adjustment to identical concentrations of total IgG (e.g., 1 mg/ dl) and the index is calculated using a simplified formula:

$$\text{AI} = \frac{\text{EIA units in CSF}}{\text{EIA units in serum}}$$

By calculating the AI, CSF and serum are compared with regard to the portion of pathogen-specific IgG antibodies in the total IgG content. An AI of ≥2.0 is considered significantly elevated (71, 120). Lower indices (e.g., ≥1.3) are also considered significant by some investigators. However, there is a higher risk of false-positive results due to technical imprecision of measurement of immunoglobulin levels and antibody titers. False-positive AI results are likely with neurosyphilis patients when tested with whole-cell or flagellum sonicates in EIA. Here EIAs with *T. phagedenis* adsorption (Dade-Behring) or recombinant antigens not cross-reacting with *Treponema pallidum* can be helpful for differential diagnosis. Other suitable methods for determination of intrathecal antibody production are the μ- or γ-capture EIA (Dakopatts) (47) and the IgG-matched immunoblot (119). The latter allows comparison of the antibody spectrum (against various *Borrelia* proteins) in serum and in CSF and thus permits conclusions as to the specificity of the intrathecal antibody response.

For cases of neuroborreliosis, intrathecally produced antibody increases dramatically over time. Antibody was detected in only 17% in the first week. Detection rates increased to 80 to 90% of cases between 8 and 41 days after onset of disease and up to 100% of cases after 41 days after onset (47). In a study with children, cases were reported where only the IgM antibody test performed on CSF showed a positive result and no specific antibodies were detected in serum samples taken at the same time (23).

Vaccination and Its Impact on Serology

In the United States, an OspA vaccine (LYMErix) against Lyme borreliosis was licensed for use in humans. In 2002, the producer withdrew the LYMErix vaccine from the market for commercial reasons. Although the OspA vaccine is no longer commercially available, it is still necessary to differentiate between antibodies induced by vaccine and natural infection. Appropriate EIAs include tests lacking the respective vaccine protein, i.e., such as those based on recombinant antigens or peptides or an OspA-deficient mutant strain. Confounding Western immunoblot reactivity that is often observed among OspA vaccine recipients to molecular weight antigens other than p31 is due to fragments of OspA (or cross-reactive OspB) that migrate independently of the intact molecule during SDS-PAGE. Despite concerns, the experienced Lyme borreliosis laboratorian is most often able to distinguish OspA vaccination from early infection using the standard two-test paradigm (2). However, the recent availability of commercial recombinant immunoblots simplifies serodiagnosis in vaccinated individuals.

Controversial Methods

A variety of diagnostic approaches have been developed as alternatives or adjuncts to the more widely practiced methods described above. T-lymphocyte proliferation assays have been used in various scientific studies to investigate the human T-cell response to *Borrelia* antigens (63). However, T-lymphocyte proliferation assays cannot be recommended as diagnostic tests due to their cumbersome nature and concerns about their specificity and standardization (22, 50, 111, 125). Antigen detection tests also are not recommended, as discussed above.

Detection of *B. burgdorferi*-specific antibodies in immune complexes has been proposed to be superior for serodiagnosis of acute Lyme disease (98) and as a marker of active infection (17). Recent work demonstrates that test results for antibodies precipitated from serum as immune complexes are highly correlated with ELISA results obtained using unprocessed serum and are not more likely to reflect active infection than standard serology (72). Transformation of *B. burgdorferi* into spheroplasts (L-forms) in vitro in response to deprivation of serum or culture in CSF has been observed (5, 16). When visualized under a microscope, spheroplasts sometimes appear to be enclosed in a sac, so they have also been called "cysts." If apparently pure L-forms are injected into mice, they are infectious (45). The clinical and diagnostic significance of L-forms has not been demonstrated but warrants further study. There are commercial tests offered that purport to specifically detect cell wall-deficient or "cystic" forms of *B. burgdorferi* by IFA (U.S. patent 6,838,247) and culture (81), but they have not been validated with appropriate controls and are not recommended.

ANTIMICROBIAL SUSCEPTIBILITIES

The antimicrobial susceptibility of *Borrelia* species has been studied intensively in vitro (57, 85). Standard methods for the determination of the minimal bactericidal concentration have not been established. However, there is general agreement on the in vitro susceptibility of borreliae to antimicrobials, as follows. *B. burgdorferi* sensu lato is sensitive to macrolides, tetracyclines, semisynthetic penicillins, and the late second- and third-generation (expanded- and broad-spectrum) cephalosporins; moderately sensitive to penicillin G and chloramphenicol; and resistant to trimethoprim, sulfomethoxazole, rifampin, the aminoglycosides, and the quinolones (57). No significant differences between the Lyme disease borreliae and relapsing fever borreliae *(B. hermsii* and *B. turicatae)* were found with regard to penicillin G, amoxicillin, ceftriaxone, erythromycin, azithromycin, doxycycline, or tetracycline (57). There is no indication for routine antimicrobial susceptibility testing in either Lyme disease or relapsing fever.

Recommendations for Antibiotic Therapy

All clinical manifestations of *B. burgdorferi* infection should be treated with antibiotics. The antibiotic, dosage, duration, and route of application depend on the clinical picture and the stage of the disease (110, 122). In cases of solitary EM, oral treatment with doxycycline, amoxicillin, or cefuroxime axetil is recommended. Disseminated infections require parenteral treatment (ceftriaxone, cefotaxime, or high-dose treatment with penicillin G). In acrodermatitis, the same antibiotics and daily doses are recommended as in EM. In arthritis, oral treatment with doxycycline may be tried first, but in cases of poor therapeutic response, patients should be treated intravenously with cephalosporins or penicillin G. Intravenous cephalosporins or penicillin G is also recommended for stage III neuroborreliosis.

INTERPRETATION AND REPORTING OF RESULTS

General Aspects

Clinical criteria (case history and clinical findings) are decisive factors in the diagnosis and ordering of microbiological laboratory testing. The predictive value of laboratory tests is directly

related to the pretest probability. It should be kept in mind that the lower the probability of the clinical diagnosis, the lower the predictive value of a positive test result. For example, a negative serological result has a high negative predictive value for Lyme arthritis, since nearly all cases are seropositive. Whether or not a positive test corresponds with the patient's presentation is a question that can only be answered by the clinician, e.g., by means of clinical case definitions applied to the various manifestations of Lyme borreliosis. Therefore, the laboratory report should not contain any therapy recommendations.

Serological Report

The serological report should contain the following points:

1. Recording of individual test results. Results of the first assay, generally an EIA, are reported as positive, indeterminate, or negative. The immunoblot results are reported as positive or negative. In the case of a positive result, the reactive diagnostic bands may be reported (120). Caution against overinterpretation of minimally reactive blots must be emphasized (e.g., IgG reactivity against p41 is expected in approximately 50% of healthy adults in the United States and Europe and is excluded from the European scoring criteria).
2. Assessment of the final result of the two-step approach regarding its immunodiagnostic significance (e.g., whether specific antibodies have been detected or not)
3. Assessment of serological findings as to the stage of the immune response, as far as test results allow pertinent statements to this effect (see below)
4. Recommendations for further reasonable diagnostic methods (PCR or culture) or for serological follow-up, if indicated

Patterns of Serological Results in Various Stages of Lyme Borreliosis

Antibody tests performed in the early stage of Lyme borreliosis may show a negative or an indeterminate result (Table 6), often due to insufficient time for the full evolution of the immune response. In some cases, seroconversion does not occur until after initiation of treatment. Serological testing of patients with EM alone is not recommended because of the low predictive value of a negative result and the highly characteristic presentation of most rashes. In the presence of a positive clinical correlation and inadequate response to therapy, serology may be warranted up to 6 weeks after onset of disease. During early-stage Lyme borreliosis, detection of IgM is consistent with an active infection. A robust IgG response in the absence of IgM may indicate an anamnestic response to reinfection except with VlsE and C6 peptide assays, where the IgG response is early and predominant (7). Usually only a few bands are detected by immunoblotting in early disease (IgG and IgM) (Fig. 6). In late disease, a positive test for IgG antibodies is mandatory for seroconfirmation. In many cases, IgM antibodies are absent. In principle, an IgM test is not useful for establishing the diagnosis of late disease. The absence of IgG rules out the diagnosis of late Lyme disease even in the presence of IgM. False-positive IgM results due to a polyclonal B-cell activation immune response in the context of herpesvirus infections or autoimmune diseases and rheumatoid disorders also need to be considered. In many cases the origin of such IgM findings remains unclear. The IgG immunoblot usually shows a broad band pattern (Fig. 6). However, positive IgG findings with a broad band pattern in the immunoblot are also compatible with past, asymptomatic, spontaneously resolved, or treated infections. Such result patterns are often found for members of high-risk groups with frequent tick exposure (for example, forest workers) who do not show any clinical manifestations.

In neuroborreliosis, apart from the serum findings, the detection of pathogen-specific, intrathecally produced antibodies is of utmost importance for the diagnosis. An elevated AI is more common in European patients than in U.S. patients, possibly owing to infection with *B. garinii* in Europe. In most cases, determination of the IgG AI will be sufficient. Neuroborreliosis in children is a notable exception to the rule because only the IgM AI may be positive, particularly in cases where disease duration has been short. In the latter circumstances, positive CSF findings may precede positive serology. Therefore, examination of paired serum and CSF specimens is mandatory in such cases. Since a positive AI may be detectable years after treatment and cure, repeated testing is not appropriate for monitoring therapy success. Diagnosis of chronic neuroborreliosis is based on demonstration of a positive AI. Detection of antibodies against *B. burgdorferi* in the serum alone is not sufficient, and direct detection of the pathogen by culture or NAT is rarely successful.

TABLE 6 Sensitivity of antibody detection methods in the diagnosis of Lyme disease

Stage	Sensitivity	Remarks
I	20–50%	Predominance of IgM
II	70–90%	Presence of IgM and IgG; in cases of long disease duration, predominance of IgG
III	Nearly 100%[a]	Usually only IgG

[a] Negative only for patients with a very short duration of symptoms.

Influence of Antimicrobial Therapy on Serodiagnosis

Clinicians are often tempted to order repeated posttreatment serologies in an effort to correlate cure and decreasing antibody titers. However, IgG antibodies against *B. burgdorferi* (especially those against whole-cell antigens) persist for a long time even after successful therapy. Significant titer changes can only be expected several months after the end of therapy; in cases of late manifestations, even years may elapse. Moreover, a decrease in antibody titer does not rule out persistence of the pathogen. Since there is practically no indication for follow-up serological tests, therapeutic success should be based on clinical criteria. A fourfold decline in titer of antibody to VlsE peptide C6 was shown to be an indicator of successful therapy for acute Lyme disease (80) but was not demonstrated for late disease (78) or posttreatment Lyme disease syndrome (39).

Sources of Error in Serodiagnosis

False results, both negative and positive, can occur from the test itself or the nature of the immune response. Seronegative results within the first days of disease are the norm. In Europe, differences between the test antigen and the species causing infection may also contribute to seronegative findings. Deficiencies in diagnostic antigen expression will compromise the sensitivity of tests (important diagnostic antigens such as OspC and DbpA are often not expressed in cultivated borreliae, and VlsE is poorly expressed in vitro). The high background reactivity of many first-generation whole-cell-based assays often results in lower specificity and therefore frequent false-positive results. Cross-reactivity with treponemes can be

largely avoided by use of Reiter treponeme adsorbent, although syphilis serology should be performed in cases where treponeme exposure cannot be ruled out. Second- and third-generation assays with improved sensitivity and specificity are preferable to the first-generation tests. Notably, the development of tests based on VlsE has considerably improved serodiagnosis in early disease. Nonetheless, critical assessment of pretest risk factors, clinical history, and presentation will provide the best guidance for laboratory test use and minimize false test outcomes of current and future diagnostic tests.

Treponema and Other Human Host-Associated Spirochetes*

VICTORIA POPE, STEVEN J. NORRIS, AND ROBERT E. JOHNSON

63

TAXONOMY

The genus *Treponema* (order *Spirochaetales*, family *Spirochaetaceae*) includes four invasive human pathogens (Table 1) and a rabbit pathogen, a large number of oral spirochetes found in the gingival crevices in humans and other animals, and a few commensal skin organisms. The ecologic diversity of this genus was revealed recently by the discovery that *Treponema* species are also associated with bovine digital dermatitis, severe virulent ovine foot rot, and the normal gut flora of termites (25, 40, 119). In 1984, the genus taxonomy was restructured so that the species *Treponema pallidum* includes three of the human pathogens: *T. pallidum* subsp. *pallidum* (venereal syphilis), *T. pallidum* subsp. *endemicum* (endemic syphilis), and *T. pallidum* subsp. *pertenue* (yaws) (113). T. *carateum* (pinta) remains a separate species due to the lack of genetic information. The pathogenic treponemes in this group are very closely related, to the extent that they are distinguished primarily by their patterns of pathogenesis in humans and experimentally infected animals. They are morphologically indistinguishable and, where examined, have >95% DNA homology by hybridization (30), a high degree of sequence identity of known genes (84, 85), nearly identical protein profiles (see reference 90 for a review), and shared reactivity with monoclonal antibodies (82). There may be some subspecies differences, as well as differences between *T. pallidum* and *T. paraluiscuniculi,* a rabbit pathogen, in the flanking-region sequences of the 15.5-kDa lipoprotein gene (17). In addition, differences in the *tpr* and *arp* genes have been used for the molecular subtyping of *T. pallidum* strains (18, 19, 98); this approach has been shown to be useful in epidemiologic studies (100, 117). According to structure, host dependence, protein content, and DNA sequence similarities (17), *T. paraluiscuniculi* appears to be closely related to the human pathogens; however, it causes venereal spirochetosis of rabbits and is not known to cause human disease. *Brachyspira aalborgi* and *Brachyspira* (formerly *Serpulina*) *pilosicoli* are recently described human intestinal spirochetes. Because of the distinctive nature of invasive treponemal pathogens, oral spirochetes, and intestinal spirochetes, these three groups are discussed separately below.

In contrast to the close relationship among the human pathogens, *T. pallidum* subsp. *pallidum* has <5% DNA homology by hybridization with other spirochetes such as *T. phagedenis, T. refringens,* and *B. hyodysenteriae* (30). However, 16S rRNA gene sequence similarities indicate an evolutionary relationship between the members of the genus *Treponema* (93). The sequence of the 1.13×10^6-bp *T. pallidum* subsp. *pallidum* Nichols genome was published in 1998 (36), and sequencing of the 2.8×10^6-bp *T. denticola* genome was published in 2004 (112). Although the *T. denticola* genome is much larger, the predicted gene content indicates that both organisms have very limited metabolic capabilities; for example, energy production appears to be limited to glycolysis, and the pathways for synthesis of fatty acids and most amino acids are absent. Many of the additional genes in *T. denticola* are transport systems and degradative proteinases and hydrolases, consistent with a high scavenging activity for acquiring nutrients in the dense biofilm of dental plaque (36, 112).

SPIROCHETES ASSOCIATED WITH HUMAN TREPONEMATOSES

Description

T. pallidum subsp. *pallidum (T. pallidum)* and related human pathogens are spirochetes ~0.18 μm in diameter and ranging in length from 6 to 20 μm (Fig. 1). These organisms are coiled into regular helices (6 to 14 per cell) with a wavelength of 1.1 μm and an amplitude of ~0.3 μm (Fig. 1). The ends are pointed and lack the hook shape characteristic of some commensal human spirochetes. Suspensions of *T. pallidum* are best visualized by dark-field microscopy, although the bacterium can also be seen by phase-contrast microscopy. Unstained organisms are not visible by standard bright-field microscopy because of the small cell diameter. Fresh preparations of the organism exhibit rapid rotation about the axis (the characteristic corkscrew motility) due to the action of flagella inserted in both ends and extending down the cell body within the periplasmic space (Fig. 1). Flexing and reversal of rotation can occur also, but translational motion is not observed unless *T. pallidum* is in a viscous medium. The human treponemal pathogens (Table 1) cannot be distinguished at either the light or electron microscopy level. Because the diameter of the treponemes is less than 1 μm, Gram stain cannot be used to visualize any of the pathogenic *Treponema.*

* This chapter contains information presented in chapter 61 by Steven J. Norris, Victoria Pope, Robert E. Johnson, and Sandra A. Larsen in the eighth edition of this Manual.

TABLE 1 Characteristics of the human treponematoses[a]

Organism	Disease	Distribution	Predominant age of onset	Transmission	Congenital infection
T. pallidum subsp. *pallidum*	Venereal syphilis	Worldwide	Adolescents, adults	Sexual contact	Yes
T. pallidum subsp. *pertenue*	Yaws (frambesia, pian)	Tropical areas, Africa, South America, Caribbean, Indonesia	Children	Skin contact	No
T. pallidum subsp. *endemicum*	Endemic syphilis (bejel, dichuchwa)	Arid areas, Africa, Middle East	Children to adults	Mucous membrane	Rarely
T. carateum	Pinta (carate, cute)	Semi-arid, warm areas, Central and South America	Children, adolescents	Skin contact	No

Natural Habitat

The *T. pallidum* subspecies and *T. carateum* are obligate parasites of humans and are not known to have any animal or environmental reservoirs. Venereal syphilis has a worldwide distribution, with the incidence varying widely according to geographic location and socioeconomic groups (Table 1). Endemic syphilis is restricted to desert and temperate regions of North Africa and the Middle East. Yaws occurs most commonly in tropical or desert regions of Africa, South America, and Indonesia. Pinta is found primarily in tropical areas of Central and South America.

Clinical Significance

Syphilis is still a common sexually transmitted disease in many areas of the world, despite the availability of effective therapy. In 1999, the World Health Organization (WHO) estimated that the worldwide annual incidence of sexually acquired syphilis was 12 million cases (125). In the United States, 34,270 cases were reported in 2003, including 7,177 cases of primary and secondary syphilis and 413 cases of congenital syphilis in infants younger than 1 year. Rates of reported syphilis cases declined rapidly during the 1990s (Fig. 2), but transmission has persisted in certain areas, especially the Southeastern United States. In 1999, to address the increasingly focused occurrence of syphilis, the U.S. Centers for Disease Control and Prevention (CDC), in collaboration with other federal partners, launched "The National Plan to Eliminate Syphilis in the United States" using a combination of improved surveillance, strengthened community involvement, rapid outbreak response, expanded clinical and laboratory services, and enhanced health promotion (http://www.cdc.gov/stopsyphilis/Plan.pdf). The year 2010 target is 0.2 cases of primary and secondary syphilis per 100,000 population, whereas there were 2.5 cases per 100,000 population in 2003.

The male/female ratio of case rates increased from 1.6 in 1999 to 5.3 in 2003 (16). This increase in the rate of primary and secondary cases among men relative to women in the United States, along with reports from localities of outbreaks of syphilis and of high-risk sexual behavior among men who have sex with men (MSM) (24, 94), reflects an increase in sexually transmitted disease (STD) risk behavior among some MSM. Of particular concern is the high prevalence of human immunodeficiency virus (HIV) infection among syphilis cases reported in these outbreak reports and summarized in recent reviews (8, 20). Because of the increase in syphilis among MSM and because the evidence is strong that syphilis increases susceptibility to HIV infection and transmissibility of HIV infection (11, 35), federal agencies and medical organizations representing HIV care providers recommend screening for syphilis and other sexually transmitted infections among MSM (1, 13, 16).

The prevalence of nonvenereal treponematoses is uncertain due to inadequate surveillance, but in 1998 the WHO

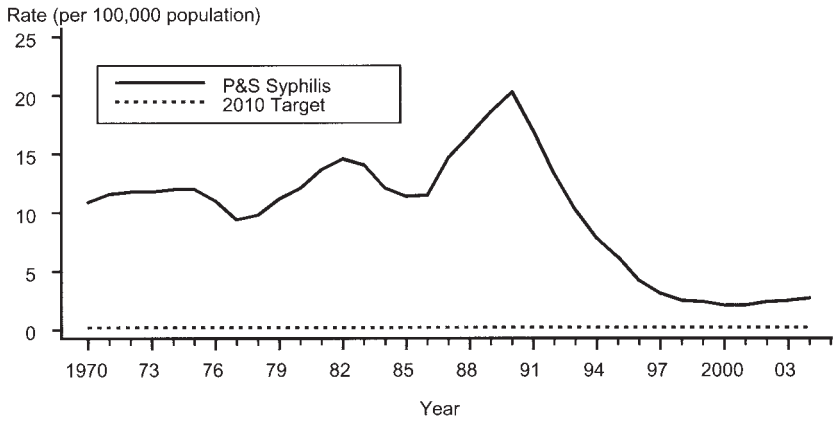

FIGURE 2 Rates of reported primary and secondary syphilis cases per 100,000 population in the United States, 1970 to 2004. The objective of ≤0.2 cases per 100,000 by the year 2010 is indicated (16).

estimated that there were 2.6 million active cases worldwide and 460,000 new cases per year (124).

Transmission of *T. pallidum* occurs through direct contact with active lesions. The transmission of *T. pallidum* subsp. *pallidum* infection, the cause of venereal syphilis, usually occurs consequent to contact of an uninfected individual with the anogenital lesions of an infected individual during sexual intercourse. Transplacental infection of the fetus also occurs in infected pregnant women.

Venereal syphilis exhibits a wide variety of clinical manifestations (Table 2). Early syphilis, defined as syphilis of <1-year duration, is itself subdivided into primary, secondary, and early latent stages. The primary stage is characterized by the appearance of one or more 0.3- to 2.0-cm indurated lesions, called chancres, which typically become encrusted or ulcerated. The lesions occur at the point of organism entry after a 10- to 90-day incubation period. The most common characteristic of secondary syphilis is the presence of skin and mucous membrane lesions. Skin lesions may be macular, papular, follicular, papulosquamous, or pustular. So-called "nickel and dime" macular lesions on the palms of the hands, soles of the feet, and other locations are a common presentation. Raised lesions called condylomata lata may occur in moist intertriginous areas, and erosions called mucous patches may appear on mucosa, such as in the mouth. Neurologic symptoms and signs can also occur during secondary-stage syphilis, and, less commonly, disease manifestations involving other organ systems. Secondary syphilis manifestations do not appear until 6 weeks to 6 months after infection. Primary and secondary syphilis manifestations may overlap, but each resolves spontaneously within a few weeks of its onset.

Numerous treponemes are often present in the ulcers of primary syphilis and the moist intertriginous and mucosal lesions of secondary syphilis. Transmission occurs as a consequence of contact with these primary- and secondary-stage lesions. Nonvenereal transmission is rare. Individuals with venereal syphilis are no longer infectious after healing of secondary syphilis lesions. However, relapses of secondary syphilis can occur in about 25% of untreated patients during the first year of infection (38).

Approximately one-third of untreated patients may develop tertiary or late syphilis following an extended period (usually years to decades) of latency during which clinical symptoms of syphilis are absent (38). The manifestations of late syphilis consist of several characteristic conditions of the central nervous system, disease of the aortic valve and thoracic aorta, and a chronic inflammatory lesion called a gumma, which usually involves the skin or bone but may occur in any organ (122). The cardiovascular and gummatous forms of syphilis are now rarely encountered, presumably because of effective therapy of early syphilis and antimicrobial therapy administered for other infections.

Viable *T. pallidum* is present in the cerebrospinal fluid (CSF) of patients with the primary and secondary stages of syphilis, indicating that central nervous system infection occurs very early in the course of disease (104). Neurologic manifestations, including syphilitic meningitis, may occur as early as 3 months postinfection; thus, neurosyphilis should not be considered solely a late manifestation of the disease (48).

Numerous case reports indicate that HIV infection may result in an increased severity of early syphilis and a poor response to therapy (103), although the results of prospective therapy trials suggest that HIV infection does not markedly affect the natural history of syphilis in most instances of coinfection (104, 106).

Congenital syphilis results from the transmission of *T. pallidum* across the placenta during pregnancy. Early congenital syphilis tends to occur when the mother has early syphilis during the course of pregnancy and may result in stillbirth or fulminant infection of the newborn (Table 2). Late manifestations of congenital syphilis are the outcome of chronic, untreated infection and can result in multiple stigmata (Table 2) that are often not obvious until the second decade of life.

Yaws, endemic syphilis, and pinta were common infections in areas of endemicity prior to the WHO eradication program beginning in 1948; in the early 1950s, it was estimated that 200 million people were exposed to yaws during their lifetimes (95). Nowadays, areas where the diseases are endemic are more restricted, but decreased surveillance has led to an increase in the incidence of yaws in many areas (2). Transmission of endemic treponematoses occurs through direct contact with early lesions or with contaminated fingers or drinking or eating utensils. Yaws and endemic syphilis commonly are transmitted among children (2 to 15 years of age), whereas pinta usually has a later onset (ages 15 to 30 years). Many of the manifestations of yaws and endemic syphilis are similar to those of venereal syphilis (Table 2); the lesions of pinta appear to be restricted to the skin. Congenital transmission of the endemic treponematoses is rare.

TABLE 2 Common manifestations of treponematoses

- Venereal syphilis *(T. pallidum* subsp. *pallidum)*
  - Primary (local): 10 to 90 days postinfection (avg, 21 days)
    - Chancre (single or multiple, skin or mucous membranes)
    - Regional lymphadenopathy
  - Secondary (disseminated): 6 wk–6 mo postinfection
    - Multiple secondary lesions (skin or mucous membranes)
    - Generalized lymphadenopathy, fever, malaise
    - Condylomata lata
    - Alopecia
    - Asymptomatic or symptomatic CNS[a] involvement (syphilitic meningitis)
  - Latent (early, ≤1-yr duration; late, >1-yr duration)
    - Reactive serologic tests for syphilis
    - Asymptomatic
  - Tertiary (late, chronic): months to years postinfection
    - Gummatous (monocytic infiltrates, tissue destruction, any organ)
    - Cardiovascular (aortic aneurysm)
    - Late forms of neurosyphilis (paresis, tabes dorsalis, optic atrophy)
  - Congenital
    - Early (onset, <2 years): fulminant, disseminated infection, mucocutaneous lesions, osteochondritis, anemia, hepatosplenomegaly, CNS involvement; may result in stillbirth
    - Late (persistence, >2 years): interstitial keratitis, bone and tooth deformities, cutaneous fissures (rhagades), eighth-nerve deafness, neurosyphilis, other tertiary manifestations
- Yaws *(T. pallidum* subsp. *pertenue)*
  - Early: onset 9–90 days postinfection (avg, 21 days)
    - Primary lesion (mother yaw): papular, nontender, often pruritic, crusted, or ulcerated
    - Disseminated lesions (daughter yaws): often resemble primary lesion, or varied appearance
    - Malaise, fever, lymphadenopathy
    - Osteitis, periostitis, other bone and joint manifestations
  - Latent: positive serologic tests, no other signs of infection
  - Late: 10% of patients
    - Destructive lesions of bone and cartilage (e.g., ulcerative rhinopharyngitis)
    - Hyperkeratotic skin lesions
- Endemic syphilis *(T. pallidum* subsp. *endemicum)*
  - Early
    - Primary: mucosal or cutaneous lesion usually not detected
    - Secondary: multiple oropharyngeal, cutaneous lesions
    - Generalized lymphadenopathy
    - Periostitis
  - Latent: positive serologic tests, no other signs of infection
  - Late: destructive skin, bone, and cartilage lesions
- Pinta *(T. carateum)*: restricted to skin
  - Early
    - Initial lesion: hyperkeratotic, pigmented papule or plaque
    - Disseminated skin lesions (pintids)
    - Regional lymphadenopathy
  - Late: pigmentary changes in skin (hyper- and hypopigmentation)

[a] CNS, central nervous system.

Collection, Transport, and Storage of Specimens

Blood and Serum

When collecting, preparing, and examining specimens, health care workers need to observe universal safety precautions (60). Serum is the specimen of choice for both nontreponemal and treponemal tests. However, the rapid plasma reagin (RPR) card test and toluidine red unheated serum test (TRUST) also may be performed with plasma samples. The technician must check the product insert to be sure that the plasma sample has not been stored for longer than the recommended storage time and that the blood was collected in the specified anticoagulant. Plasma cannot be used in the Venereal Disease Research Laboratory (VDRL) test, since the sample must be heated before testing, and plasma cannot be used in the fluorescent treponemal antibody absorption (FTA-ABS) test but can be used in other treponemal tests for syphilis such as the *Treponema pallidum* particle agglutination (TP-PA) test. Serum or plasma samples that are to be tested at a later date or shipped to another site for testing should be transferred to another properly labeled tube to prevent contamination by hemoglobin, which can interfere with the interpretation of the test results. Serum does not have to be removed from serum separator tubes. If samples are frozen prior to shipping, they should be shipped on dry ice. There is no evidence that shipping at ambient temperature is detrimental to the sample if care has been taken to avoid possible microbial contamination.

When screening for congenital syphilis, the CDC recommends testing of the mother's serum rather than cord blood. Studies comparing the reactivity of the mother's serum, cord blood, and infant's serum found that the maternal sample is the best indicator that a neonate was at risk of infection, followed by neonatal serum, with cord blood being the least reactive (21, 102). Infant's serum is the specimen of choice for the immunoglobulin M (IgM)-specific tests since cord blood specimen can be contaminated by maternal blood.

Blood collected in EDTA can be used for PCR of *T. pallidum*, but the sample must be refrigerated immediately and shipped as soon as possible on ice by overnight carrier to the testing facility if PCR is not done in-house.

CSF

Care must be taken when collecting CSF to ensure that no blood contaminates the samples. Even amounts that are too small to visibly contaminate the CSF may result in a false-positive test for neurosyphilis if the patient has detectable antibodies in the blood. When samples are to be sent to another laboratory for testing in the VDRL-CSF or FTA-ABS CSF test, shipping on ice is preferred but shipping at ambient temperature is acceptable. If CSF is being sent to the testing facility for PCR, the sample must be frozen as soon as possible after collection and shipped on dry ice to maintain the frozen state.

Tissue and Lesion Samples

Specimens collected from the active epidermal and mucosal lesions of primary, secondary, and early congenital syphilis are most useful, because the lesions tend to contain large concentrations of treponemes. The site should be cleansed and gently abraded with sterile gauze and saline until a serous exudate appears. A specimen for dark-field microscopy is collected on a glass slide and covered with a coverslip; a specimen for direct fluorescent antibody for *T. pallidum* (DFA-TP) examination of serous fluids is collected on a slide and then air dried. The specimen should consist of serous fluid free of erythrocytes, other organisms, and tissue

debris. Tissue specimens for a modification of the DFA-TP for tissue (DFAT-TP) or immunohistochemistry (IHC) should be from formalin-fixed, paraffin-embedded sections cut 3 μm thick. Several sections should be sent to the testing facility. Detection of *T. pallidum* in tissues or exudates provides a definitive diagnosis of syphilis.

Tissue or ulcer fluid sample specimens for PCR detection of *T. pallidum* DNA should be frozen immediately after collection and shipped on dry ice if the PCR is being done at another laboratory. However, check with the testing laboratory prior to sending the sample to determine what their protocol requires.

Direct Detection of *Treponema pallidum*

General Principles

Treponemes are not readily detectable with common laboratory stains but can be visualized using dark-field microscopy, DFA-TP, or IHC methods (43, 96). Currently, dark-field microscopy and DFA-TP tests are commonly used to detect *T. pallidum* in primary- or secondary-lesion exudates, while the DFAT-TP (60) and IHC are used for tissue sections. Because of the technical challenges of dark-field microscopy, DFA-TP is recommended for all but the most experienced laboratories. PCR has been introduced as a method for detecting *T. pallidum* infection (as described subsequently) but is not widely available at present.

Continuous in vitro culture of *Treponema pallidum* has not been achieved, but limited multiplication of *T. pallidum* subsp. *pallidum* has been obtained over a 10- to 20-day period in a complex tissue culture system (31, 89). Direct culture of *T. pallidum* from clinical specimens has not been accomplished, and this procedure continues to be limited to the research laboratory setting.

Dark-Field Microscopy

Dark-field microscopy (60) is appropriate for samples from genital or skin lesion exudates. When dark-field microscopy is used, the presence of morphologically similar, nonpathogenic spirochetes within and near the genitalia requires that *T. pallidum* be viewed in its "living state" in order to distinguish its characteristic morphology and motility. It is essential that exudates be examined as soon as possible (ideally within 20 min) to ensure retention of motility. *T. pallidum* is very sensitive to exposure to oxygen, heat, nonphysiologic pH, and desiccation. Wet mounts need to be thoroughly examined using a systematic scan of the entire slide before deciding that a wet mount is negative for treponemes. Because it is difficult or impossible to differentiate *T. pallidum* from other parasitic spirochetes of the gastrointestinal tract by using dark-field microscopy, this method should be used only for genital or skin lesions.

DFA and IHC

Examination of samples from lesions can be done using the DFA-TP test (60). Lesion samples for DFA-TP are air dried onto slides and therefore do not require cell viability or immediate examination. Either labeled polyclonal anti-*T. pallidum* antibody (ViroStat, Portland, Maine) or labeled monoclonal antibody (CDC, Atlanta, Ga.) can be used. Care must be taken in interpretation of the result when polyclonal antibodies are used because they are not specific for pathogenic treponemes. Polyclonal antibodies can be preabsorbed with whole Reiter treponemes prior to use to increase the specificity. Samples for DFA-TP can also be sent to the Syphilis Serology Reference Laboratory at the CDC for testing.

Tissue sections can be stained using either the IHC stain (43, 96) or the DFAT-TP test (60), as the two methods use the same specific antibody for detection. Any tissue can be used, but most frequently tissues for paraffin-embedded sections are collected from the brain, gastrointestinal tract, placenta, umbilical cord (Fig. 3), or skin. Often DFAT-TP or IHC is used to diagnose late-stage or congenital syphilis, although organism concentrations tend to be low during late adult syphilis, in asymptomatic or late congenital syphilis, and in resolving lesions of early syphilis. For tissue, IHC may offer an advantage since a fluorescent microscope is not needed and the counterstain is hematoxylin, which allows tissue structure to be observed simultaneously with the observation of treponemes (43, 96).

PCR

The newest technique for direct detection of *T. pallidum* is PCR (42, 54, 64, 85, 86, 97, 109, 123, 129). PCR as a tool for detecting *T. pallidum* is used by only a few laboratories and is considered an experimental procedure for syphilis diagnosis. However, the PCR test is available at the CDC for patients with suspected neurosyphilis (i.e., reactive serum serology, abnormal CSF or neurologic findings, and a history of syphilis) or for patients with genital ulcer disease. The test also appears useful in detecting congenital syphilis, with sensitivity approaching the "gold standard" of rabbit infectivity testing for amniotic fluid samples (42, 47, 109).

The sample source for PCR is controversial (87). Studies have found whole blood to be a useful sample (58, 68, 117) even for incubating syphilis and latent syphilis (68). Lesion samples are also useful (98, 100, 117) and may be positive for *T. pallidum* by PCR when they are negative by dark-field microscopy or DFA-TP (100). The appropriateness of serum and CSF as sample sources for PCR is still under consideration (87, 123), although CSF has been used to help determine invasion of the central nervous system by *T. pallidum* (104). Contamination with extraneous DNA from other specimens, storage, and transport of the sample prior to testing may seriously affect the results (123).

Methods using PCR and DNA amplification techniques can distinguish various strains of *T. pallidum* subsp. *pallidum* (98). These techniques are being used in some research laboratories to help determine the epidemiology of syphilis outbreaks (100, 117).

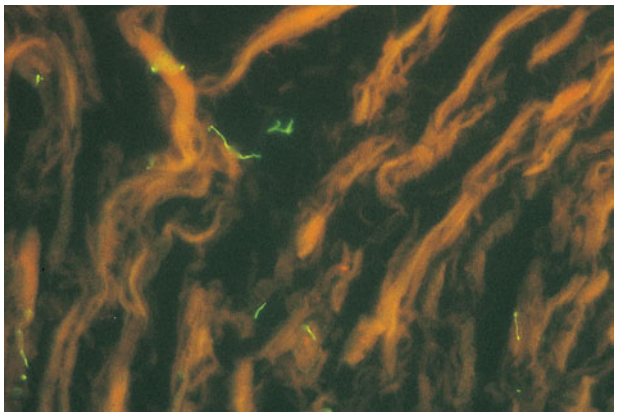

FIGURE 3 DFAT-TP of an umbilical cord section from a baby with congenital syphilis.

Serologic Tests

General Principles

Humoral antibodies produced in response to *T. pallidum* infection become detectable in the primary stage, increase in concentration during the secondary stage, and decline during latent infection. Antibody detection tests supplement the direct organism detection methods used for the diagnosis of primary and secondary syphilis and are the only practical methods of diagnosis during latent and late syphilis.

Serologic tests for syphilis are divided into nontreponemal and treponemal types. Nontreponemal tests detect so-called reaginic antibodies that react with lipoidal particles containing the phospholipid cardiolipin. These tests are commonly used for screening and are widely available, inexpensive, convenient to perform on large numbers of specimens, and useful for determining the efficacy of treatment. Limitations of the nontreponemal serologic tests include a lack of sensitivity in early primary syphilis and in late syphilis and the possibilities of false-positive results or a prozone reaction (false-negative result due to a high ratio of antibody to antigen). Treponemal tests use *T. pallidum* subsp. *pallidum* or its derivatives (e.g., recombinant proteins) as the antigen and detect anti-*T. pallidum* antibodies. In the United States, treponemal tests have been used primarily to verify reactivity in the nontreponemal tests or to confirm a clinical impression of late syphilis in which the nontreponemal test is nonreactive. However, treponemal tests such as the enzyme immunoassay (EIA) are increasingly being used to screen for syphilis. The advantages are lower cost, increased specificity and sensitivity, objective interpretation of results, and hard copies of the results generated by the EIA reader. Rapid treponemal tests, which are available internationally but not in the United States at this time, offer the advantages of specificity and rapid results, usually within 20 min. Although treponemal tests are useful for screening, they cannot be used to monitor treatment or reinfection because 85% of persons successfully treated for syphilis have test results that remain reactive for years, if not for a lifetime. Therefore, a combination of a nontreponemal test with a treponemal test is used to diagnose sexually acquired syphilis. Treponemal tests that detect IgM may be helpful in the diagnosis of congenital syphilis in the neonate. The utility of IgM-based tests to diagnose early adult syphilis or reinfection has not been fully evaluated.

Nontreponemal Tests

All available nontreponemal tests are based on antigen containing measured amounts of cardiolipin, cholesterol, and sufficient purified lecithin to produce standard reactivity (61). The nontreponemal (reagin) tests measure IgM and IgG antibodies to cardiolipin and other lipids released from damaged host cells or from treponemes (5, 70). Antilipoidal antibodies can be produced not only as a consequence of treponemal infections but also during autoimmune diseases, pregnancy, nontreponemal diseases of an acute and chronic nature in which tissue damage occurs, and other conditions (Table 3).

The standard nontreponemal tests use flocculation of lipoidal particles (antigen) to indicate reactivity. The test antigen is mixed with the patient's serum on a solid matrix by rotating at a specific speed for a specified number of minutes before reading the results. The antigen-antibody flocculant is too small to visualize without magnification unless a colored reagent (e.g., carbon particles) is added. The VDRL and unheated serum reagin (USR) tests are flocculation tests requiring microscopic examination, whereas reactions in the RPR test and TRUST can be read without magnification, because of the addition of colored particles that get caught in the antigen-antibody lattice. All of the nontreponemal tests have approximately the same sensitivity and specificity (Table 4).

TABLE 3 Causes of false-positive reactions in serologic tests for syphilis[a]

Disease or condition	Type of test affected	
	Nontreponemal test	Treponemal test
Autoimmune disease	Yes	Yes
Malaria	Yes	No
Recent immunizations	Yes	No
Dermatologic diseases	Yes	Yes
Cardiovascular disease	Yes	Yes
Tuberculosis	Yes	No
Leprosy	Yes	Yes
Intravenous drug abuse	Yes	No
Viral infections	Yes	No
Febrile illness	Yes	Yes
Pregnancy	Yes	No
HIV	Yes	No
Other STDs	Yes	No
Age	No	Yes
Multiple blood transfusions	Yes	No
Lyme disease	No	Yes
Endemic treponematoses	Yes	Yes
Transient unknown causes	Yes	Yes
Technical errors	Yes	Yes

[a] Data from references 7, 50, 61, and 66.

Any of these nontreponemal tests can be performed as a quantitative test by preparing serial twofold dilutions of the patient's serum to reach an endpoint titer. Qualitative nontreponemal tests are used to screen for possible syphilitic infection. Quantitative nontreponemal tests establish a baseline of reactivity from which change can be measured following treatment. The baseline serum sample should be drawn on the day that treatment is begun, and the same test that is used in the initial testing should be used to monitor treatment (32, 33, 34, 111). If early syphilis has been adequately treated, titers are usually nondetectable after 3 years.

The VDRL-CSF test is a modification of the VDRL test that permits detection and titer determination of reaginic antibody in CSF. Preparation of the antigen and the patient specimen differs from that of the serum VDRL test, so care should be taken to follow the appropriate procedures (60). The VDRL-CSF test is the only nontreponemal test standardized for use with CSF specimens.

Treponemal Tests

The greatest value of the treponemal tests is in distinguishing true- and false-positive nontreponemal test results and in establishing the diagnosis of late latent or late syphilis. Problems arise when these tests are used as screening procedures, because treponemal tests generally remain reactive for life following adequate treatment for syphilis and about 1% of the general population has false-positive results unrelated to past syphilis treatment. However, a reactive treponemal test result on a sample that is also reactive in a nontreponemal test is highly specific for treponemal infection. The most commonly used treponemal tests in the United States are the

TABLE 4 Sensitivity and specificity of serologic tests for syphilis

Stage	Sensitivity (%)[a]				Specificity (%) (nonsyphilis)
	Primary	Secondary	Latent	Late	
Nontreponemal tests					
VDRL	78 (74–87)	100	95 (88–100)	71 (37–94)	98 (96–99)
RPR card	86 (77–100)	100	98 (95–100)	73	98 (93–99)
USR	80 (72–88)	100	95 (88–100)		99
TRUST	85 (77–86)	100	98 (95–100)		99 (98–99)
Treponemal tests					
FTA-ABS	84 (70–100)	100	100	96	97 (94–100)
FTA-ABS DS	80 (69–90)	100	100		98 (97–100)
TP-PA	88 (86–100)	100	100		96 (95–100)
IgG EIA	92 (88–97)[b]	100	99 (96–100)	100	99 (98–100)

[a] Ranges of CDC studies are given in parentheses.
[b] Ranges of various studies.

TP-PA and the EIA tests. The number of laboratories that provide the FTA-ABS test is dwindling due to the technical difficulties of performing the test, the complexity of the test, and the lack of laboratory personnel experienced in fluorescence microscopy. As a result, the test is not discussed here, but Larsen et al. (60) give a description of the procedure.

If used appropriately as confirmatory tests, the treponemal tests have few limitations. They vary in their sensitivity for the detection of early primary syphilis and in the late stages of syphilis (Table 4). A treponemal test result should be obtained if late or late latent syphilis is suspected and the nontreponemal test result is nonreactive. The laboratory should be informed that late syphilis is suspected; otherwise, according to laboratory policy, a treponemal test may not be performed when the nontreponemal test result is nonreactive. Treponemal tests are generally 100% reactive in secondary and latent syphilis. Again, these findings should be interpreted in the light of treatment history.

TP-PA Test

The *Treponema pallidum* particle agglutination (TP-PA) test (Fujirebio Diagnostics, Inc., Malvern, Pa.) (60) has replaced the microhemagglutination assay for antibodies to *Treponema pallidum*. Instead of erythrocytes, the test uses gelatin particles sensitized with *T. pallidum* subsp. *pallidum* antigens. There is no separate absorbing step; therefore, the test is simpler to set up and requires less preparation time. The serum sample is diluted in the microtiter plate. Sensitized gelatin particles are added to the 1:40 serum dilution, making a final serum dilution of 1:80. Anti-*T. pallidum* antibodies in the serum react with the sensitized particles, forming a mat of agglutinated particles in the microtiter plate. Unsensitized particles, included as a control for nonspecific reactivity, are added to the 1:20 serum dilution (final dilution, 1:40).

Results are reported as reactive, nonreactive, or inconclusive. Reactive results are reported for a range of agglutination patterns, from a definite large ring with a rough multiform outer margin and peripheral agglutination (1+) to a smooth mat of agglutinated particles covering the entire bottom of the well (4+). Nonreactive results are reported when a definite compact button, with or without a very small hole in its center, forms in the center of the well. A button of unagglutinated particles having a small hole in the center is initially read as " ± ," and the test should be repeated. If the same pattern is again observed, then the report should be "nonreactive." Because the TP-PA test uses gelatin particles rather than sheep erythrocytes, which were used as the antigen carrier in the microhemagglutination assay for antibodies to *T. pallidum*, nonspecific agglutination of the unsensitized particles only rarely occurs. The sources for error with the TP-PA are usually associated with the use of dusty or improper plates, pipetting errors, or vibrations in the laboratory.

Enzyme Immunoassay

Several tests using the EIA format have been developed for the diagnosis of syphilis. In the United States the Captia Syphilis-G test (Trinity Biotech, Dublin, Ireland; BioRad, Richmond, Calif.; and Wampole Laboratories, Princeton, N.J.) (60, 62, 81, 110) has been cleared by the Food and Drug Administration (FDA) for use as either a confirmatory test or a screening test, while the Trep-Chek test (Phoenix Bio-Tech Corp., Mississauga, Ontario, Canada; and Sigma Chemical Company, St. Louis, Mo.) has been cleared by the FDA for use as a confirmatory test for syphilis. Initial evaluations of these EIA tests have found all to have sensitivities and specificities similar to those of the other treponemal tests (62, 81, 99, 127) (Table 4). A comparison of nine EIAs using either *T. pallidum* sonicates or recombinant antigens revealed that several EIAs had sensitivities similar to that of the IgM FTA-ABS test in the analysis of primary syphilis specimens (110). The actual procedures of the tests are very similar. An aliquot of diluted patient sample is added to a well in the plate. After an incubation period, the plate is washed and an enzyme-labeled conjugate is added. After a second incubation and wash, a substrate is added. The presence of antitreponemal antibodies is indicated by a color change that can be read spectrophotometrically or visually. Obtaining results from a spectrophotometric microplate reader has the advantages of objective interpretation and a printout of the results.

The Captia Syphilis-M test (Trinity Biotech, BioRad, and Wampole Laboratories) and the Trep-Chek M test (Phoenix Bio-Tech) are based on the use of anti-human IgM antibody to capture IgM in the patient's serum, followed by the use of a purified *T. pallidum* antigen to detect IgM anti-*T. pallidum* antibodies in the patient's serum (51). The IgM EIA is most useful in the diagnosis of congenital syphilis. One study found that the IgM capture EIA was more sensitive than the FTA-ABS 19S IgM test in detecting probable cases of congenital

syphilis (116). Another study found the IgM EIA to be equal in sensitivity to the IgM Western blot for the detection of neonatal congenital syphilis but less sensitive in delayed-onset congenital syphilis (9). The usefulness of the IgM EIA tests in adult onset syphilis has not been fully determined.

Another EIA test format being increasingly used is the Western blot for *T. pallidum* (12, 37, 60, 67). This test is performed as an experimental test in several laboratories in the United States. However, the MarBlot test (Trinity Biotech) is available outside the United States. The test uses IgG conjugate and appears to be at least as sensitive and specific as the FTA-ABS tests, and efforts have been made to standardize the procedure (37). To date, many investigators agree that the detection of antibodies to the immunodeterminants of 15.5, 17, 44.5, and 47 kDa appears to be diagnostic for acquired syphilis (90). The Western blot for *T. pallidum* has value as a diagnostic test for congenital syphilis, when an IgM-specific conjugate is used (9, 27, 63, 108, 109). The IgM Western blot for congenital syphilis appears to have greater specificity and sensitivity than the IgM EIA.

Rapid Tests

A number of rapid tests are currently on the market outside the United States, with more under development. The tests currently available in rapid-test format are treponemal tests. These tests have several advantages over currently used treponemal tests. They can all be performed within 30 min, some can use whole blood, including finger-stick specimens, as the sample, and no specialized equipment is necessary. Most of the tests on the market use a lateral-flow immunochromatographic strip methodology and follow a similar format. A nitrocellulose strip has a small filter pad at each end. One pad contains the anti-Ig antibodies, antibodies against the control strip, and an indicator such as colloidal gold. The second pad at the opposite end serves to help draw the sample through the strip. The sample (serum, plasma, or whole blood) is placed on the end of the strip that contains the antibodies and conjugate. For some tests, a buffer is added to aid in the migration of the sample up the strip. After a specified time, usually 15 to 30 min, the reaction has taken place. If two lines are present, the sample is considered positive or reactive. If only the control line is visible, the sample in nonreactive. If the control line is not visible, the results are invalid and the test needs to be repeated.

Most rapid tests have not been evaluated in studies published in peer-reviewed journals. The WHO is undertaking an evaluation of selected rapid syphilis tests to encourage the use of tests with acceptable performance in resource-poor settings. Results of the initial laboratory-based WHO evaluation of six rapid tests can be viewed at http://www.who.int/std_diagnostics. In this study, the range of reported sensitivity when using serum samples was 93.6 to 98.4% and specificity was 92.5 to 97.3%.

Interpretation and Reporting of Results

Qualitative results for the microscopic tests (the VDRL test and USR test) are reported as reactive, weakly reactive, or nonreactive. Qualitative results for the macroscopic tests (the RPR card test and TRUST) are reported as reactive (regardless of the degree of reactivity) or nonreactive. Quantitative results may be reported as the reciprocal of the dilution, for example, 4 dils, a titer of 4, or R4 rather than a 1:4 dilution. The endpoint reported is the last dilution giving a fully reactive, not weakly reactive, result. Titers for the same serum specimen may differ two- to fourfold when tested using microscopic versus macroscopic nontreponemal tests, due in part to the exclusion of weakly reactive results in the titer determination for the VDRL and USR tests. This variability underscores the need to use the same test in monitoring treatment efficacy in each patient.

Prozone reactions occur in 1 to 2% of patients with secondary syphilis, due to the high levels of antibodies. Any undiluted serum sample exhibiting a weakly reactive, atypical, or, on rare occasions, "rough negative" reaction should be diluted as in the quantitative assay. In samples exhibiting a prozone effect, reactivity increases and then decreases as the endpoint titer is approached.

Nontreponemal test results must be interpreted according to the stage of syphilis suspected as well as the population being tested and should be confirmed using a treponemal test, since the proportion of positive screening tests that are false positive increases with decreasing prevalence of syphilis. Approximately 30% of those with early primary syphilis have nonreactive nontreponemal test results on the initial visit (Table 4). In secondary syphilis, nearly all patients have nontreponemal test endpoint titers of $\geq$8. For patients with atypical lesions and/or nontreponemal test titers of $<$8, the nontreponemal tests should be repeated and a confirmatory treponemal test should be performed. Even without treatment, the nontreponemal test may be weakly reactive or even nonreactive in the late stages of syphilis.

In congenital syphilis, a paradigm commonly used in the past was that the infant was infected with *T. pallidum* if the infant's nontreponemal test titer at delivery was higher than the mother's titer. However, a lower titer in the infant's serum than in the mother's does not rule out congenital syphilis. Examination of serum sample pairs from mothers and infants with congenital syphilis indicated that only 22% of the infants had a titer higher than that of the mother (116). Passively transferred IgG antibodies reactive in nontreponemal or treponemal tests should be catabolized and undetectable among noninfected infants between the ages of 12 and 18 months.

In any form of syphilis, patients should be monitored to ensure that treatment is effective, i.e., that signs and symptoms have resolved, and that the titer of the quantitative nontreponemal test has declined fourfold, which indicates cure (32, 34, 111). A rise in titer following treatment establishes treatment failure or reinfection. For most patients treated in early syphilis, the titers decline until little or no reaction is detected after 3 years (32, 60, 61, 105). Patients who are treated in the latent or late stage and patients who have had multiple episodes of syphilis may show a more gradual decline in titer (33, 104). A low titer persists in approximately 50% of these patients after 2 years (33). As far as can be determined, this persistent seropositivity does not signify treatment failure or reinfection, and these patients are likely to remain serofast even if they are retreated (33). Recent studies indicate that HIV infection may delay the decline in antibody titer detected by nontreponemal tests for syphilis in patients with primary or secondary syphilis (104). The prognostic significance of this finding is unknown, since only 1 of 101 HIV-positive patients experienced clinical treatment failure during a 1-year posttreatment observation period. A delayed decline in antibody titer was not associated with detection of *T. pallidum* in CSF, and enhanced therapy did not appear to prevent the delay (104).

Diagnostic Criteria for Venereal Syphilis

For the laboratory diagnosis of syphilis, each stage has a particular testing requirement (Table 5) (14). In the United States, the traditional testing scheme is direct microscopic examination of lesion exudates, if present, followed by a

TABLE 5 Criteria for diagnosis of syphilis[a]

Early syphilis
- Primary
  - Confirmed (requires 1 *and* 2)
    1. One or more chancres (ulcers)
    2. Direct microscopic identification of *T. pallidum* in clinical specimens (dark field or DFA-TP)
  - Probable (requires 1 *and* either 2 or 3)
    1. A clinically compatible case with one or more chancres
    2. Reactive nontreponemal test and no previous history of syphilis
    3. For persons with a history of syphilis, a fourfold increase in titer on a quantitative nontreponemal test when results of past tests are compared with the most recent test results.
- Secondary
  - Confirmed
    - Direct microscopic identification of *T. pallidum* in clinical specimens (dark field or DFA-TP)
  - Probable (requires 1 *and* either 2 or 3)
    1. Skin or mucous membrane lesions typical of secondary syphilis
       a. Macular, papular, follicular, papulosquamous, or pustular
       b. Condylomata lata (anogenital region or mouth)
       c. Mucous patches (oropharynx or cervix)
    2. Reactive nontreponemal test titer of ≥4 and no history of syphilis
    3. For persons with a history of syphilis, a fourfold increase in the most recent nontreponemal test titer when compared with previous test results.
- Early latent
  - Probable (requires 1 *and* either 2 or 3 *and* 4, 5, or 6)
    1. Absence of signs and symptoms of syphilis
    2. No past diagnosis of syphilis and reactive nontreponemal and treponemal test results
    3. A history of syphilis therapy and a current nontreponemal test titer demonstrating fourfold or greater increase from the last nontreponemal test titer (obtained ≤1 yr ago)
    4. A history of symptoms consistent with primary or secondary syphilis during the previous 12 mo
    5. A history of sexual exposure to a partner who had confirmed or probable early syphilis (documented independently as duration of ≤1 yr)
    6. Documented seroconversion or fourfold or greater increase in titer of a nontreponemal test during the previous 12 mo

Late latent or latent of unknown duration
- Probable (requires 1 *and* either 2 or 3 *and* 4)
  1. Absence of signs and symptoms
  2. No past diagnosis of syphilis and reactive nontreponemal and treponemal test results; if a reactive treponemal screening test is followed by a nonreactive nontreponemal test, a second, different treponemal test is also reactive.
  3. A history of syphilis therapy and a current nontreponemal test titer demonstrating fourfold or greater increase from the last nontreponemal test titer (obtained >1 yr ago)
  4. No evidence of having acquired the disease within the preceding 12 mo

Late syphilis
- Benign (gummatous) and cardiovascular
  - Confirmed (requires 1 *and* 2)
    1. Clinically compatible case
    2. Observation by direct microscopic examination of treponemes in tissue sections by DFAT-TP or detection by other methods (e.g., PCR)
  - Probable (requires 1, 2, *and* 3)
    1. Clinically compatible case
    2. A reactive serum treponemal test
    3. No known history of treatment for syphilis
- Neurosyphilis
  - Confirmed (requires 1, 2, *and* either 3 or 4)
    1. Clinical signs consistent with neurosyphilis
    2. A reactive serum treponemal test
    3. A reactive VDRL-CSF on a spinal fluid sample
    4. Identification of *T. pallidum* in CSF or tissue by microscopic examination or equivalent methods
  - Probable (requires 1, 2, *and* 3)
    1. Clinical signs consistent with neurosyphilis
    2. A reactive serum treponemal test
    3. Elevated CSF protein or leukocyte count in the absence of other known causes

Neonatal congenital syphilis
- Confirmed (requires 1 *and* 2)
  1. Clinically compatible case
  2. Demonstration of *T. pallidum* by direct microscopic examination of specimens from lesions, placenta, umbilical cord, nasal discharge, or autopsy material
- Probable (requires 1, 2, *and* 3)
  1. Infant born to a mother who had untreated or inadequately[b] treated syphilis at delivery, regardless of findings in the infant
  2. An infant with a reactive treponemal test result
  3. One of the following additional criteria:
     a. Clinical sign or symptom of congenital syphilis on physical examination
     b. Abnormal CSF finding without other cause
     c. Reactive VDRL-CSF test result
     d. Reactive IgM antibody test specific for syphilis
- Syphilitic stillbirth
  1. A fetal death that occurs after a 20-week gestation or in which the fetus weighs >500 g
  2. Mother had untreated or inadequately[b] treated syphilis at delivery

[a] Adapted from reference 14.
[b] Nonpenicillin therapy or penicillin given less than 30 days before delivery.

nontreponemal test which, if reactive, is confirmed with a treponemal test (Fig. 4). In recent years, EIAs have been used for screening followed by an RPR or other nontreponemal test. This approach may eliminate many false-positive reactions due to nonspecific nontreponemal test reactivity (Table 3); however, as the rates of syphilis decline, there will be an increasing proportion of reactive results from persons with previously treated syphilis or with false-positive treponemal test results. In addition, the low sensitivity of nontreponemal tests in detecting long-duration infection is an important disadvantage to their use as confirmatory tests. The use of modified serologic screening procedures for syphilis requires careful consideration of the sensitivity and specificity of both the screening and confirmatory steps, as well as the population being tested.

There has been no reliable test for detecting incubating syphilis. However, PCR for the detection of *T. pallidum* DNA may be of some value. There is evidence that DNA can be detected in the blood of persons with incubating syphilis (68) or early syphilis, including the early latent stage (68, 117).

During the primary stage of syphilis, dark-field microscopy and the DFA-TP test (60) are the methods of choice for definitive diagnosis. DFA-TP should be used for specimens from perirectal or oral ulcers because of the inability to distinguish digestive system spirochetes from *T. pallidum* by dark-field microscopy. If the chancre is starting to heal or the patient has used either topical or systemic antibiotics, the number of treponemes may be too small to be detected or they may be nonmotile or degraded. Humoral antibodies, as detected by the current serologic tests for syphilis, usually appear 1 to 4 weeks after the chancre(s) has formed. Thus, a reactive serologic test result may be expected if the chancre is healing. Conversion to reactivity of a serologic test for syphilis or a rise in nontreponemal test titer over 1 to 2 weeks supports a diagnosis of syphilis even if a dark-field or DFA microscopic examination is negative.

By the secondary stage of syphilis, the organism has invaded every organ of the body and virtually all body fluids. All serologic tests for syphilis are usually reactive, and treponemes may be found in moist lesions.

Nontreponemal and treponemal serologic tests are consistently reactive in the early latent stage, but the patient is asymptomatic. Nontreponemal tests may become nonreactive in late latent syphilis. A reactive treponemal test in a patient with a nonreactive nontreponemal test and a history of syphilis should be confirmed by a different treponemal test. A diagnosis of early versus late latent syphilis is made by documentation of onset of infection within or prior to the past year as indicated by (i) seroconversion; (ii) symptoms of primary or secondary syphilis; or (iii) a sex partner documented to have primary, secondary, or early latent syphilis. In the absence of such documentation, the diagnosis is "latent syphilis of unknown duration."

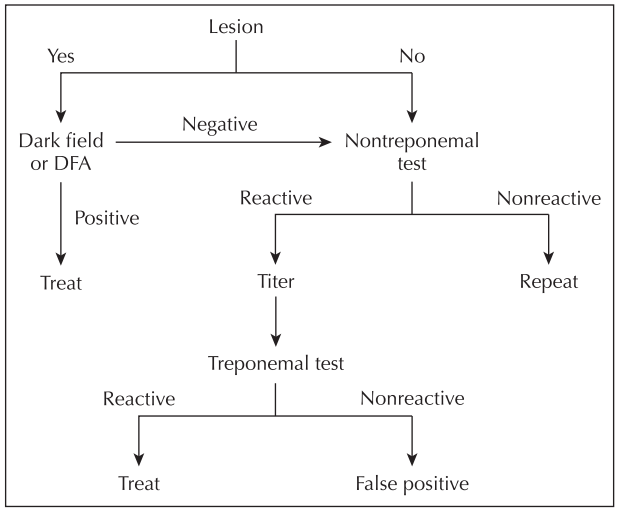

FIGURE 4 Routine screening scheme for early syphilis in the United States.

Neurosyphilis may take many forms (48). Syphilitic meningitis typically occurs during early syphilis. Meningovascular syphilis most often occurs earlier (4 to 7 years) than the classic forms of late neurosyphilis (paresis and tabes dorsalis) (48). The diagnosis of neurosyphilis is based on a combination of clinical and laboratory test criteria (Table 5). CSF examination should include the VDRL-CSF slide test and total protein and leukocyte counts. The VDRL-CSF test is considered to have high specificity but low sensitivity for neurosyphilis (48). Thus, a nonreactive VDRL-CSF test result does not rule out neurosyphilis. The FTA-ABS CSF test appears to have high sensitivity but low specificity for neurosyphilis (52). The FTA-ABS CSF test could be used to rule out neurosyphilis, especially among HIV-infected individuals who commonly have modestly elevated CSF protein and leukocyte counts in the absence of syphilis infection (69). The utility of the EIA or TP-PA in diagnosing neurosyphilis has not been adequately determined, although preliminary evaluations indicate that TP-PA may also be useful. Large-scale studies need to be carried out and the results published before any recommendations can be made. Whether CSF examination is indicated in early syphilis, especially for patients with HIV coinfection, has been controversial. CSF abnormalities and *T. pallidum* can be detected in the CSF of a substantial minority of patients with secondary syphilis (69, 104), but most such patients resolve their CSF abnormalities and appear to clear the CSF of organisms with standard therapy. A relationship between CSF abnormalities or detection of treponemes in the CSF of patients with early syphilis and the development of clinically evident neurosyphilis through enhanced therapy has not been established (69, 80, 104). Thus, routine CSF examination is not considered necessary during early syphilis in the absence of neurologic or ophthalmologic signs or for HIV-infected patients with late latent syphilis or syphilis of unknown duration (15). A nontreponemal serologic test titer of $\geq$32 or, among HIV-infected patients, a CD4 count of $\leq$350 has been associated with an increased frequency of CSF abnormalities in patients with late latent syphilis or syphilis of unknown duration (69), and some experts recommend CSF examination for this group of patients (15).

Late or tertiary syphilis is a chronic, progressive disease, and symptoms may not be evident until 10 to 20 years after the initial infection. Although rare, earlier onset of late or tertiary syphilis has been reported for individuals coinfected with HIV (55). Approximately 71% of patients with late-stage syphilis have reactive nontreponemal tests; however, treponemal tests are almost always reactive and may be the only basis for diagnosis (Table 5). Benign (gummatous) syphilis consists of granuloma-like lesions (gummas) containing lymphocytes and macrophages but few if any detectable spirochetes. Diagnosis of cardiovascular syphilis is made on the basis of findings that indicate aortic insufficiency or thoracic aortic aneurysm, reactive treponemal test results, and no known history of treatment of syphilis. Late forms of neurosyphilis include paresis (infection of the brain parenchyma, resulting

in behavioral changes including psychoses), tabes dorsalis (ataxia, paresthesias, and other manifestations resulting from posterior spinal cord and dorsal root ganglia degeneration), and optic atrophy (122).

The choice and interpretation of serologic tests for the diagnosis of syphilis are the same for HIV-infected and uninfected patients, but additional considerations apply to HIV-infected individuals (39, 53, 80, 104). The titers of nontreponemal serologic test results may be higher for patients coinfected with HIV than for those without coexistent HIV infection. The number of primary chancres may be increased (106), and case reports indicate that the course of *T. pallidum* infection may be more rapid and more virulent in a small proportion of HIV-infected individuals. Also, patients with advanced HIV immunodeficiency may become falsely seronegative for syphilis (41, 46).

Diagnostic Criteria for Congenital Syphilis

A primary stage does not occur in congenital syphilis, because the organisms directly enter the fetal circulation (128). Treponemes or the effects thereof are detectable in almost every tissue of the infant. Currently, the diagnosis of neonatal congenital syphilis depends on a combination of results from physical, radiographic, serologic, and direct microscopic examinations as well as maternal clinical history (Table 5). Clinical signs of early congenital syphilis include hepatosplenomegaly, cutaneous lesions, osteochondritis, and snuffles (nasal discharge containing large numbers of *T. pallidum*) (56, 122). Roughly one-half of live-born neonates with congenital syphilis have normal physical findings at the time of birth. If the infant is not treated, other stigmata that may develop later in life include tooth and bone malformations, deafness, blindness, and learning disabilities (Table 2).

Definitive diagnosis is based on the identification of spirochetes in tissues, lesion exudates, or secretions by dark-field examination, DFA-TP, PCR, or other means (Table 5). The standard serologic tests for syphilis, which detect reactive IgG as well as other isotypes, may reflect antibodies passively transferred from the mother to the infant rather than IgM antibodies produced by an infected fetus during gestation. IgM-specific treponemal antibody tests are available and may be useful in the diagnosis of congenital syphilis (see "Serologic Tests" above). In stillbirths, diagnosis of congenital syphilis is made by detection of the treponemes in the tissues (101).

Diagnostic Criteria for Endemic Treponematoses

Serologic tests for syphilis are uniformly reactive with yaws, pinta, and nonvenereal endemic syphilis (bejel) (6, 83, 95). Therefore, patient history, the clinical appearance and anatomic locations of the lesions, the mode of transmission, and the age of the individual are the only criteria that can be used to diagnose these infections as separate entities (6) (Table 1). PCR may be useful in distinguishing these infections in a research setting (17).

Yaws, pinta, and nonvenereal syphilis are often contracted during childhood, but the nontreponemal test titers in affected individuals may remain reactive in adulthood, presenting a dilemma in the diagnosis of subsequent cases of venereal syphilis. Adults from geographic regions in which endemic treponematoses were virtually eliminated by mass campaigns in the 1950s and 1960s would be expected to have nontreponemal test titers of <8 (3). Therefore, any titer of ≥ 8 for adults from these regions is probably indicative of venereal syphilis. Likewise, titers of ≥ 8 for children indicate a possible resurgence of yaws in the populations of these areas (2).

Treatment and Antimicrobial Susceptibilities

The CDC has published recommendations for the treatment of syphilis (15) based, in part, on detailed reviews of the literature (4, 103). Routine antimicrobial susceptibility testing of *T. pallidum* is not practical due to the lack of a suitable in vitro culture system, although a number of methods have been applied to the determination of antibiotic sensitivity in the research laboratory (88). *T. pallidum* strains appear to be uniformly susceptible to penicillin and other β-lactams. Penicillin regimens have been the mainstay of syphilis therapy since their introduction in the 1940s. Because treatment with benzathine penicillin as recommended for early syphilis yields low levels of penicillin in the central nervous system, the current recommendations include multiple doses of aqueous or procaine penicillin G for the treatment of neurosyphilis. Ceftriaxone, amoxicillin, and ampicillin are active against *T. pallidum* in vitro and also appear to be effective in the treatment of early syphilis. Ceftriaxone has a long half-life in serum and reaches high levels in the central nervous system. However, multiple doses are required, and there is a 3 to 7% risk of adverse reactions in individuals who are allergic to penicillin; in addition, the data on efficacy in patients are limited. Therefore, the use of ceftriaxone as an alternative therapy for syphilis is recommended only when better-established regimens are contraindicated.

Tetracycline has long been the second-line drug recommended for treatment of syphilis in patients allergic to penicillin. However, the in vitro activity of tetracycline against *T. pallidum* is markedly lower than the activity of penicillin and, in limited comparative trials, treatment failure appears to be more common with tetracycline. Doxycycline has been considered equivalent to tetracycline in recent treatment recommendations. In vitro studies indicate that quinolone compounds have low antimicrobial activity against *T. pallidum* (88).

Azithromycin has been used as a single dose treatment for syphilis contacts in some settings. However, recent findings indicate that a high rate of treatment failures can occur with this regimen (65). The mechanism appears to be a single base pair change in the 23S rRNA genes that confers resistance to erythromycin, azithromycin, and other macrolides (65). This mutation was present in 13, 22, 11, and 88% of clinical specimens from Seattle, San Francisco, Baltimore, and Dublin, Ireland, respectively (65). Therefore, use of macrolides for the treatment of syphilis or syphilis exposure is not recommended.

OTHER HUMAN HOST-ASSOCIATED SPIROCHETES

In addition to *T. pallidum* and related pathogens, a number of anaerobic treponemes and other spirochetes are parasites of humans. These include groups of spirochetes found in the oral cavity (particularly the gingival crevices), in sebaceous secretions in the genital region, and in the colon and rectum (Table 6). In general, these spirochetes are considered commensal organisms. However, there is evidence that spirochetes are involved in gingivitis and periodontal disease and that overgrowth of intestinal spirochetes may correlate with the occurrence of diarrhea or other bowel disorders.

Oral Spirochetes

A variety of spirochetes inhabit supragingival and subgingival plaque in humans; only a small proportion of these have been cultured in vitro and characterized (22, 26, 92). Those that have been cultivated and identified to the species level are within the genus *Treponema* (Table 6). They are spiral-shaped

TABLE 6 Other human host-associated spirochetes

Type	Habitat	Species
Oral spirochetes	Dental plaque in gingival crevices	*Treponema amylovorum*
		Treponema denticola
		Treponema lecithinolyticum
		Treponema maltophilum
		Treponema medium
		Treponema parvum
		Treponema pectinovorum
		Treponema putidum
		Treponema skoliodontum
		Treponema socranskii
		Treponema vincentii
Skin-associated spirochetes	Sebaceous secretions in genital region	*Treponema minutum*
		Treponema phagedenis
		Treponema refringens
Intestinal spirochetes	Colon, rectum, feces	*Brachyspira aalborgi*
		Brachyspira pilosicoli

organisms ranging from 0.15 to 0.30 μm in diameter and from 5 to 16 μm in length (with lengths being variable within each species). Although the species differ from one another slightly in terms of cell diameter and helical configuration, it is generally not possible to identify them on morphologic grounds; genotypic characteristics and biochemical parameters such as growth requirements, carbohydrate fermentation, and enzymatic activities are used to identify species (115).

The oral spirochetes listed in Table 6 are difficult to isolate from healthy gingiva. However, they increase both in prevalence and in number of organisms present in patients with gingivitis or periodontal disease, an inflammation of gum tissue that frequently precedes bone resorption and subsequent tooth loss. Treponemes are detected in the subgingival plaque of 88 to 97% of patients with periodontal disease (77). *T. socranskii* is the most common isolate in patients without periodontal disease, followed by *T. denticola* and *T. pectinovorum.* These organisms are isolated from a greater proportion of patients with periodontal disease than patients without the disease (77, 114, 115). Recent studies using PCR amplification of 16S rRNA gene sequences have revealed that oral spirochetes are a heterogeneous group, consisting of up to 60 different species and as yet uncultured "phylotypes" (26, 92); as many as 23 phylotypes of treponemes have been identified in the lesions of individual patients (23). All of the oral spirochetes clearly fall under the genus *Treponema* (93). Up to 415 cultured and uncultured bacterial species have been identified in human subgingival plaque (92), but treponemes represent one of the most prevalent groups (78, 79). Although it is difficult to establish a causal relationship in polymicrobial infections such as periodontitis, oral spirochetes are almost certainly involved in its etiology.

The isolation and characterization of oral spirochetes require special media and strict anaerobic conditions (75, 76, 113, 114, 115, 126) and are restricted primarily to research laboratories. At present, there is insufficient evidence linking particular oral spirochetes to pathogenic conditions to warrant their detection and identification for diagnostic purposes.

Nonpathogenic Spirochetes of the Genital Region

T. phagedenis, T. refringens, and *T. minutum* are treponemal species that inhabit the smegma (sebaceous secretions and desquamated epithelial cells) found beneath the prepuce and in other epithelial folds of the genital region. *T. phagedenis* and *T. refringens* are 0.20 to 0.25 μm in diameter, whereas *T. minutum* tends to be smaller in diameter (0.15 to 0.20 μm). Although *T. phagedenis* and *T. refringens* have been shown to have ≤5% homology with *T. pallidum* by DNA-DNA hybridization (30), comparison of 16S rRNA sequences indicates that they are related to the pathogenic treponemes. These harmless members of the normal flora could potentially be misidentified as *T. pallidum* in dark-field microscopy preparations from skin sites. Careful cleansing of the site as described in reference 60 obviates this possibility. Also, the DFA-TP test (60) is specific for pathogenic treponemes and can be used with specimens potentially contaminated with other organisms. The skin-associated treponemes may be collected with sterile moistened swabs and placed in anaerobic transport medium or directly into selective medium. They are readily cultured in peptone-yeast extract-glucose medium or in thioglycolate medium with 10% heat-inactivated rabbit serum under anaerobic conditions at 37°C (75).

Intestinal Spirochetes

The presence of spirochetes in the colon, rectum, and feces of humans has been recognized for more than 100 years (107). Since the description of "human intestinal spirochetosis" in 1967 (45), there has been a resurgence in interest in the possible involvement of intestinal spirochetes in diarrhea and other gastrointestinal diseases (44), as well as in the apparently high prevalence of these organisms in homosexual males and HIV-infected individuals (107).

Morphologically, most human intestinal spirochetes are relatively short (3 to 6 μm on average) and are 0.2 to 0.4 μm in diameter with one to two helices per cell. Longer cells may also be present. They have pointed ends and four to six periplasmic flagella attached subterminally in a single row at each end of the cell. The human intestinal spirochetes identified thus far fall into two species: *Brachyspira* (formerly *Serpulina*) *pilosicoli* and *Brachyspira aalborgi. B. pilosicoli* was initially named *Serpulina pilosicoli* (120, 121); however, this and other *Serpulina* species (e.g., *B. hyodysenteriae,* a cause of swine dysentery) were reclassified as *Brachyspira* based on phenotypic characteristics, rRNA gene sequence analysis, and DNA hybridization studies (91). *B. pilosicoli* has a broad range of natural hosts, including swine, mice, rats, dogs, and chickens. *B. aalborgi* (49) is genetically and phenotypically distinct from *B. pilosicoli* (57, 120), and thus far has been identified only in humans. Recent 16S rRNA gene analyses indicate that *B. aalborgi* can be subdivided into four different clusters or lineages, but it is not known whether this heterogeneity is associated with phenotypic differences (74).

B. pilosicoli and *B. aalborgi* are obligate anaerobes but grow in a variety of media containing blood. Until recently, *B. aalborgi* had been cultured on only one occasion (resulting in the type strain), leading to the conclusion that it was rare relative to *B. pilosicoli*. However, recent PCR analyses of human colonic biopsy specimens indicate that *B. aalborgi* is a common cause of human intestinal spirochetosis (59, 71, 72). In two series of histologically diagnosed cases of intestinal spirochetosis from Australia, Norway, and the United States, *B. aalborgi* sequences were detected in 62.5 and 82.5% of the cases, whereas *B. pilosicoli* sequences were detected in only 0 and 14.3% (72, 73). In 2000, Kraaz et al. (59) isolated a second strain of *B. aalborgi* by using a selective medium consisting of tryptose soy agar with 10% bovine blood, 400 μg of spectinomycin per ml, and 5 μg of polymyxin per ml. They found that a selective medium commonly used for the culture of intestinal spirochetes

inhibited the growth of this strain, presumably due to the inclusion of vancomycin and colistin.

When observed in association with rectal or colonic tissue, these organisms are typically attached by the tip to the apical surface of the columnar epithelial cells. Although the spirochetes can form a dense layer visible by light microscopy (using hematoxylin-and-eosin- or silver-staining techniques), signs of tissue damage or inflammation are usually absent.

A clear association between intestinal spirochetes and disease has not been established (107). Spirochetes can be present in healthy individuals as well as in those with diarrhea or other gastrointestinal symptoms. In the early 1900s, several studies examined the presence of spirochetes in human stool specimens by light microscopy. In those studies, involving more than 100 patients, the proportion of subjects with spirochetes ranged from 3.3 to 61%. Recent examinations of rectal biopsy specimens from heterosexual patients by light and electron microscopy or culture have indicated the presence of spirochetes in 1.9 to 6.9% of subjects, and helical organisms were also found to be associated with normal and inflamed appendixes. Higher proportions of homosexual males have been reported to have intestinal spirochetes. At present, there is no clear evidence for an association between intestinal spirochetosis and HIV infection.

B. pilosicoli was isolated from routine anaerobic cultures of blood from seven critically ill patients, including those with stroke, ethylene glycol intoxication, severe arteriopathy, peritonitis, and myeloma (118). The clinical significance and cause-and-effect relationship of *B. pilosicoli* bacteremia and life-threatening illness remain to be determined.

Colonic or rectal biopsy samples can serve as a source of material for culture, histologic examination for spirochetes, or PCR; fresh stool specimens or rectal swabs may also be examined by dark-field microscopy for the presence of spirochetes (107). Positive samples can be cultured under anaerobic conditions at 37°C in the presence of 5 to 10% CO_2 by being streaked onto Trypticase soy agar medium with 5 to 10% defibrinated horse or calf blood and 400 μg of spectinomycin per ml (with or without 5 μg of polymyxin B per ml) to inhibit the growth of other bacteria. After 5 to 14 days of incubation, growth appears as a thin film or as discrete, pinpoint colonies. Longer culture intervals may be required for *B. aalborgi*. Weak beta-hemolysis is typically observed. In the isolation of *Brachyspira* from anaerobic blood cultures, automated detection was not obtained uniformly and required a minimum of 5.6 to 14.9 days (depending on the strain); however, the organisms could be subcultured and observed by dark-field microscopy (10, 118). An alternative method of detection is PCR, using rRNA and/or NADH oxidase *(nox)* gene sequences as targets (59, 71); this approach can also be adapted for use with fixed, paraffin-embedded tissue specimens (71) or with human feces (73).

No commercial kits or serologic procedures for detection of human intestinal spirochetosis are available, and no data on antimicrobial susceptibility or treatment have been reported. Clearly, more information is needed to establish the potential medical importance of these organisms.

Mycoplasma and *Ureaplasma**

KEN B. WAITES AND DAVID TAYLOR-ROBINSON

64

TAXONOMY

Bacteria commonly referred to as mycoplasmas ("fungus form") are included within the class *Mollicutes* ("soft skin"), which comprises 4 orders, 5 families, 8 genera, and almost 200 known species, as shown in Table 1. New species, found mainly in animals, are being identified on a frequent basis. Table 2 lists 16 species isolated from humans on multiple occasions, excluding species of animal origin that have been detected in humans from time to time, usually in immunosuppressed hosts, but that are generally considered to be transient colonizers. *Mycoplasma amphoriforme* is the most recent species to have been recognized, having been recovered from the respiratory tracts of several patients with antibody deficiencies and chronic bronchitis or bronchiectasis (121). Mollicutes are eubacteria that have evolved from clostridium-like gram-positive cells by gene deletion. The availability of species-specific PCR technology is ameliorating difficulties of both culture and identification for fastidious mollicutes. Therefore, additional noncultivable, and thus presently unknown, species are likely to be discovered.

DESCRIPTION OF *MOLLICUTES*

It should be noted that the term "mycoplasma" is often used in a trivial way to refer to any members of the class *Mollicutes,* irrespective of whether they actually belong to the genus *Mycoplasma.* It is more accurate to refer to members of the class as mollicutes and to organisms within the individual genera as mycoplasmas, ureaplasmas, and acholeplasmas, etc. Mollicutes are smaller than conventional bacteria, in cellular dimensions as well as genome size, making them the smallest free-living organisms known. Mycoplasmas and ureaplasmas associated with humans have forms ranging from coccoid cells of about 0.2 to 0.3 μm diameter, as in the case of *Ureaplasma* spp. and *Mycoplasma hominis* (87), to tapered rods of 1 to 2 μm in length and 0.1 to 0.2 μm in width in the case of *M. pneumoniae* and *M. penetrans* (122). Mollicutes are contained by a trilayered cell membrane and do not possess a cell wall. The permanent lack of a cell wall barrier makes the mollicutes unique among prokaryotes and differentiates them from bacterial L forms for which the lack of the cell wall is but a temporary reflection of environmental conditions. Lack of a cell wall also renders these organisms insensitive to the activity of beta-lactam antimicrobials, prevents them from staining by Gram stain, and is largely responsible for their pleomorphic form. The extremely small genome (<600 kb in the case of *M. genitalium*) and limited biosynthetic capabilities explain the parasitic or saprophytic existence of these organisms, their sensitivity to environmental conditions, and their fastidious growth requirements, which can complicate cultural detection. Mollicutes require enriched growth medium supplemented with nucleic acid precursors. Except for acholeplasmas, asteroleplasmas, and mesoplasmas, mollicutes require sterols in growth media, supplied by the addition of serum. Growth rates in culture media vary among individual species, with generation times of approximately 1 h for *Ureaplasma* spp., 6 h for *M. pneumoniae,* and 16 h for *M. genitalium* (54).

Typical mycoplasmal colonies vary from 15 to ≥300 μm in diameter. Colonies of some species, such as *M. hominis,* often exhibit a "fried-egg" appearance owing to the contrast between deeper growth in the center of the colony and more shallow growth at the periphery (Fig. 1), and other species, such as *M. pneumoniae,* produce spherical colonies (Fig. 2). Whereas colonies of mycoplasmal species may be observed with the naked eye, those produced by ureaplasmas are typically 15 to 60 μm in diameter and require low-power microscopic magnification for visualization (Fig. 3).

Mycoplasmas and ureaplasmas of human origin can be classified according to whether they ferment glucose, utilize arginine, or hydrolyze urea (Table 2). Except for hydrolysis of urea, which is unique for ureaplasmas, these biochemical features are not sufficient for species distinction. Anaeroplasmas and asteroleplasmas, which occur in ruminants, are strictly anaerobic and oxygen sensitive, whereas most other mollicutes are facultative anaerobes.

Attachment of *M. pneumoniae* to host cells in the respiratory tracts of humans is a prerequisite for colonization and infection. Cytadherence, mediated by the P1 adhesin and other accessory proteins, is followed by induction of ciliostasis, chronic inflammation, and cytotoxicity mediated by hydrogen peroxide, which also acts as a hemolysin. *M. pneumoniae* stimulates B and T lymphocytes and induces formation of autoantibodies which react with a variety of host tissues and the I antigen on erythrocytes, which is responsible for production of cold agglutinins (117). *M. genitalium* also possesses a terminal

* This chapter contains information presented in chapter 62 by Ken B. Waites, Yasuko Rikihisa, and David Taylor-Robinson in the eighth edition of this Manual.

TABLE 1 Classification and some distinguishing features of mollicutes

Classification of class *Mollicutes*	Distinguishing features			
	Sterol required	Genome size (kbp)	G+C content of DNA (mol%)	Other
Order I: *Mycoplasmatales*				
Family I: *Mycoplasmataceae*				
Genus I: *Mycoplasma* (120 species)[a]	Yes	580–1,350	23–40	
Genus II: *Ureaplasma* (7 species)[b]	Yes	730–1,170	25–32	Urea metabolized
Order II: *Entomoplasmatales*				
Family I: *Entomoplasmataceae*				
Genus I: *Entomoplasma* (6 species)	Yes	790–1,140	27–29	
Genus II: *Mesoplasma* (11 species)	No	870–1,100	27–30	Requires 0.04% Tween 80
Family II: *Spiroplasmataceae*				
Genus I: *Spiroplasma* (34 species)	Yes	940–2,200	25–30	Helical structure
Order III: *Acholeplasmatales*[c]				
Family I: *Acholeplasmataceae*				
Genus I: *Acholeplasma* (15 species)	No	1,500–1,650	27–36	
Order IV: *Anaeroplasmatales*				
Family I: *Anaeroplasmataceae*				Obligate anaerobes
Genus I: *Anaeroplasma* (4 species)	Yes	1,500–1,600	29–33	
Genus II: *Asteroleplasma* (1 species)	No	1,500	40	
Phytoplasma[c] (17 candidatus species designations)	Unknown	530–1,350	23–29	Noncultivable

[a] The genus *Mycoplasma* includes cell wall-less uncultivated parasitic bacteria, classified into six candidatus species designations, that attach to the surfaces of erythrocytes and also occur free in the plasma. These bacteria were previously classified in the genera *Haemobartonella* and *Eperythrozoon.* Their G+C contents and sterol requirements are unknown.

[b] *U. urealyticum* and *U. parvum,* formerly considered biovars of *U. urealyticum,* are now classified as two separate species and are the only ureaplasmas of human origin.

[c] Phytoplasmas are uncultivable mollicutes of plants and insects genetically related to the *Acholeplasmatales,* but they have not been assigned individual genus and species designations.

structure, the MgPa adhesin, which facilitates its attachment to epithelial cells (48). Factors involved in *Ureaplasma* and *M. hominis* attachment have not been characterized to the same extent as those involved in *M. pneumoniae* attachment, and *Ureaplasma* spp. and *M. hominis* do not have prominent attachment organelles. Henrich et al. (46) demonstrated the presence of the variable adherence-associated antigen (Vaa) that is believed to be a major adhesin of *M. hominis* and may also assist in evasion of host immune responses through antigenic variation. Ureaplasmas also attach to a variety of cell

TABLE 2 Primary sites of colonization by and metabolism characteristics and pathogenicity of mollicutes of human origin[a]

Species	Primary site of colonization		Metabolism of:		Pathogenicity
	Respiratory tract	Genitourinary tract	Glucose	Arginine

A. laidlawii	+	−	+	−	−

[a] Symbols: +, positive for trait; −, negative for trait;?, unknown.

[b] All nine isolates reported to date have been from the lower respiratory tract, but no other sites have been sampled.

[c] The organism has been found in the oropharynx, but whether that is a common or primary location is not known.

[d] Metabolize urea.

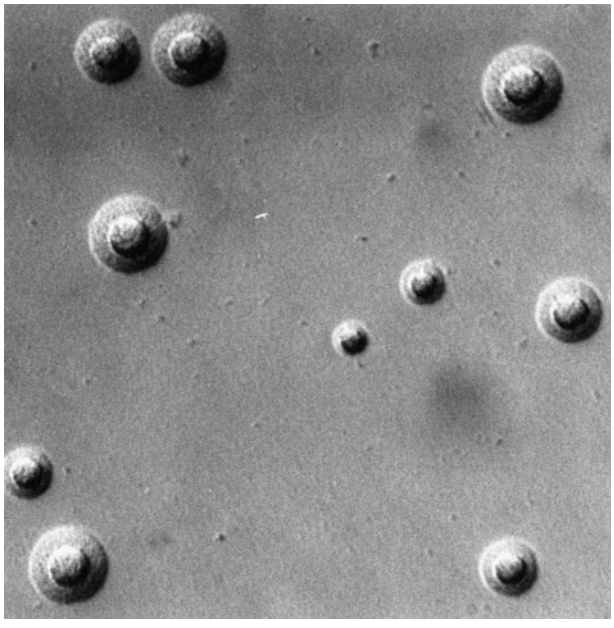

FIGURE 1 Fried-egg-type colonies of *M. hominis* of up to 110 μm in diameter. Magnification, ×132.

types, with attachment mediated by adhesin proteins expressed on the surface of the bacterial cell. The multiple-banded (MB) antigen contains serotype-specific and cross-reactive epitopes and is a prominent antigen recognized during human ureaplasmal infections (116). Ureaplasmas are known to produce immunoglobulin A (IgA) protease which may be associated with disease production, and they release ammonia through urealytic activity (116).

EPIDEMIOLOGY AND TRANSMISSION

Mollicutes are common in practically all mammalian species, as well as many other vertebrates in which they have been

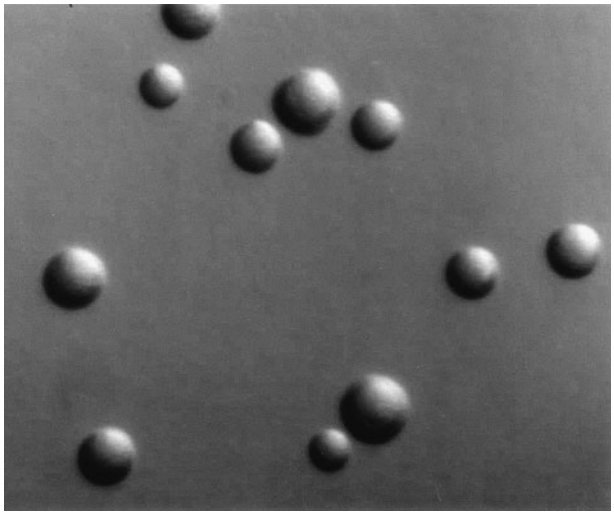

FIGURE 2 Spherical colonies of *M. pneumoniae* of up to 100 μm in diameter. Magnification, ×126.

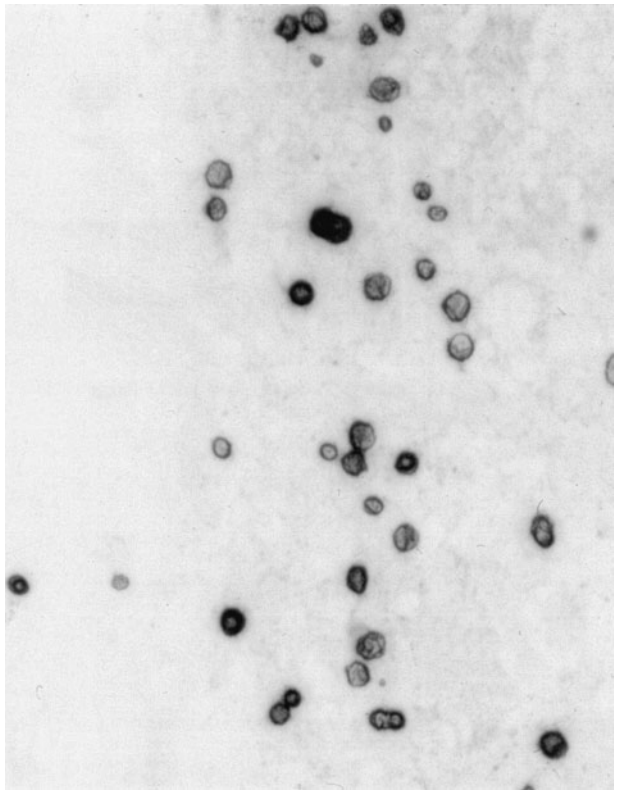

FIGURE 3 Granular, brown, urease-positive colonies of *Ureaplasma* species of 15 to 60 μm in diameter from a vaginal specimen growing on A 8 agar. Magnification, ×100.

sought. Although most mollicutes have species-specific host-organism associations, some mycoplasmas and acholeplasmas of animal origin occur in a wide variety of different animal hosts. Mollicutes in the genera *Spiroplasma, Mesoplasma, Entomoplasma,* and *Acholeplasma* can be isolated from insects and plants.

In humans, mycoplasmas and ureaplasmas are mucosally associated, residing predominantly in the respiratory or urogenital tract. They rarely penetrate the submucosa, except in cases of immunosuppression or instrumentation, when they may invade the bloodstream and disseminate to many different organs and tissues throughout the body. Many mollicutes exist as commensals in the oropharynx *(M. salivarium, M. orale, M. buccale, M. faucium, M. lipophilum,* and *Acholeplasma laidlawii)* and have been associated with invasive disease only in very rare circumstances. *M. fermentans* has been detected by culture, and more recently by means of PCR assays, in various body sites, including the urogenital tract, throat, lower respiratory tract, and other body locations, including joints (116), but its primary site of colonization and its true disease potential are incompletely understood. Oral commensal mycoplasmas may occasionally spread to the lower respiratory tract and can cause diagnostic confusion with *M. pneumoniae* infection. Frequent occurrence of pathogenic species such as *M. hominis* and ureaplasmas in the lower urogenital tract in healthy men and women has complicated complete understanding of these species' disease-producing capabilities. *M. primatum, M. spermatophilum,* and *Acholeplasma oculi* have been detected in the urogenital tract but have not been

associated with disease. PCR assays have demonstrated the frequent occurrence of *M. genitalium* in the urogenital tract in men with urethritis and in lower and upper genital tract sites in women and of *M. penetrans* in urine of homosexual males with human immunodeficiency virus infection (51, 116). Although mycoplasmas are generally considered to be extracellular organisms, intracellular localization is now appreciated for *M. fermentans, M. penetrans, M. genitalium,* and *M. pneumoniae* (11, 28). Intracellular localization may be responsible for protecting the organisms from antibodies and antibiotics, as well as contributing to disease chronicity and difficulty in cultivation in some cases. Variation in surface antigens of *M. hominis* and *Ureaplasma* spp. may be related to the persistence of these organisms at invasive sites. In humans, mycoplasmas and ureaplasmas may be transmitted by direct contact between hosts, e.g., venereally through genital-genital or oral-genital contact and vertically from mother to offspring either at birth or in utero; by respiratory aerosols or fomites in the case of *M. pneumoniae;* or even by nosocomial acquisition through transplanted tissues.

CLINICAL SIGNIFICANCE

Respiratory Infections

M. pneumoniae was first identified and described in the early 1960s. It causes approximately 20% of all community-acquired pneumonias in the general population and up to 50% of pneumonias in certain confined groups (117). Although *M. pneumoniae* has long been associated with pneumonias in school-aged children, adolescents, and young adults, in recent years this organism has also been shown to occur endemically and occasionally epidemically in older persons, as well as children under 5 years of age (117). The most typical clinical syndrome is tracheobronchitis, often accompanied by upper respiratory tract manifestations such as acute pharyngitis. Pneumonia develops in about one-third of persons who are infected. The incubation period is generally 2 to 3 weeks, and spreading throughout households is common. The organism may persist in the respiratory tract for several months after initial infection and sometimes for years in hypogammaglobulinemic patients, possibly because the organism attaches strongly to and invades epithelial cells. Disease tends not to be seasonal, subclinical infections are common, and the disease is ordinarily mild. However, severe infections requiring hospitalization and even resulting in death are known to occur (117).

Extrapulmonary complications of *M. pneumoniae* infections may include meningoencephalitis, ascending paralysis, transverse myelitis, Bell's palsy, pericarditis, hemolytic anemia, arthritis, and mucocutaneous lesions (98, 117). An autoimmune response is thought to play a role in some extrapulmonary complications. However, *M. pneumoniae* has been isolated directly from cerebrospinal, pericardial, and synovial fluids, as well as other extrapulmonary sites, and additional evidence of direct invasion by this organism has been documented by the use of the PCR assay (98). Clinical manifestations are not sufficiently unique to allow differentiation from infections caused by other common bacteria, particularly *Chlamydophila pneumoniae.* Recent data from animal models as well as clinical studies have suggested a potential role for *M. pneumoniae* and *C. pneumoniae* as etiologic or exacerbating factors in bronchial asthma (73), but additional clinical studies are required to determine the ultimate significance of these preliminary findings.

M. fermentans has been recovered from the throats of children with pneumonia, some of whom had no other etiologic agent identified, but the frequency of its occurrence in healthy children is not known (101). It has been detected in adults with an acute influenza-like illness (65) and in bronchoalveolar lavage fluids, peripheral blood lymphocytes, and bone marrow from patients with AIDS and respiratory disease (3, 4). It is apparent that respiratory infection with *M. fermentans* is not necessarily linked with immunodeficiency, but this organism may also behave as an opportunistic respiratory pathogen.

Very little is known about *M. amphoriforme* beyond what has been described in the initial reports of its detection in the lower respiratory tract by culture and/or PCR in a series of patients with antibody deficiencies and chronic bronchitis or bronchiectasis (121). Its biochemical reactivity, colonial appearance, and growth characteristics are similar to those of *M. pneumoniae,* but it is distinct genetically. Repeated isolations over time and clinical improvement after antimicrobial therapy which resulted in the elimination of the mycoplasma suggest a possible pathogenic role, but more work must be done to determine the extent of disease that may be due to this organism.

Genitourinary Infections

Ureaplasma spp. and *M. hominis* can be isolated from the lower genital tract in many healthy, sexually active adults, but there is evidence that these organisms play etiologic roles in some genital tract diseases. Results of human and animal inoculation studies and observations of immunocompromised persons are supportive of ureaplasmas being a cause of nonchlamydial, nongonococcal urethritis (NGU) in men, with further evidence supplied by therapeutic and serologic studies (31, 69, 99, 101). Since the identification of two distinct biovars of *Ureaplasma urealyticum,* biovar 2 *(U. urealyticum)* has been implicated in NGU whereas biovar 1 (*U. parvum)* has not been implicated in this manner (31). Evidence that *M. hominis* causes NGU is lacking. *M. genitalium* has been detected by PCR technology significantly more often in urethral specimens from men with acute NGU than from those without urethritis (51–54) and is now considered to be one of the causes of the disease. *M. genitalium*-positive men have been found to have symptomatic urethritis significantly more often than those infected with *Chlamydia trachomatis* (43). Antibody responses have been detected in some men with acute disease, and *M. genitalium* has also produced urethritis in nonhuman primates (101). *M. genitalium* also may be a rare cause of conjunctivitis associated with urethritis (13). *M. fermentans, M. penetrans,* and *M. pirum* were not detected in the urethras of men with urethritis by PCR assays, suggesting that these organisms are unlikely to have a pathogenic role in this condition (30). In women, there is no evidence that *M. hominis* is a cause of the urethral syndrome, but ureaplasmas may be involved (96).

M. hominis and *Ureaplasma* spp. have not been detected by culture of prostatic biopsy samples from patients with chronic abacterial prostatitis (32), and *M. genitalium* has been found rarely by using a PCR assay (61). In contrast, ureaplasmas have been recovered from an epididymal aspirate from a patient suffering from nonchlamydial, nongonococcal acute epididymo-orchitis accompanied by a specific antibody response (50) and may be an infrequent cause of the disease. *Ureaplasma* spp. produce urease and induce crystallization of struvite and calcium phosphates in urine in vitro and calculi in animal models (109). In addition, ureaplasmas have been found in urinary calculi of patients with infection-type stones

more frequently than in those of patients with metabolic-type stones, suggesting a possible causal association (45). *M. hominis* has been isolated from the upper urinary tract only in patients with symptoms of acute pyelonephritis, often with an antibody response, and may cause about 5% of cases of such disease (106). Obstruction or instrumentation of the urinary tract may be a predisposing factor. Ureaplasmas have not been associated in the same way.

Mollicutes do not cause vaginitis but are among various microorganisms that proliferate in patients with bacterial vaginosis (BV). Some studies suggest that *M. hominis* may contribute independently to BV, but evidence is lacking for an independent association of ureaplasmas with BV (116). BV may lead to pelvic inflammatory disease, and *M. hominis* has been isolated from the endometria and fallopian tubes of about 10% of women with salpingitis diagnosed by laparoscopy and accompanied by a specific antibody response (109). The significance of this mycoplasma is difficult to assess in an individual case when several microorganisms are present. Nevertheless, serologic evidence suggests that *M. hominis* may be an independent factor in tubal-factor infertility (7). *Ureaplasma* spp. have been isolated directly from affected fallopian tubes, but not alone. This finding, together with the negative results of serologic tests, studies of inoculation of nonhuman primates, and fallopian tube organ cultures (101), does not support a causal relationship for ureaplasmas in pelvic inflammatory disease. *M. genitalium,* however, may play a role as indicated by its significant association with cervicitis (42, 108) and endometritis (26). In addition, there is serologic evidence that this mycoplasma causes some cases of tubal infertility (24). That ureaplasmas may cause infertility remains speculative (99, 100).

Ureaplasmas have been isolated from internal organs of spontaneously aborted fetuses and from stillborn and premature infants more often than from fetuses from induced abortions or normal full-term infants (116). The results from some serologic and therapeutic studies have also supported a role for these organisms in fetal morbidity (21). BV is a possible confounding factor which must be considered in the association between ureaplasmas in the chorioamnion and low birth weight. Ureaplasmas at this site are directly associated with inflammation (41) and may invade the amniotic sac early in pregnancy in the presence of intact fetal membranes, causing persistent infection and adverse pregnancy outcome (19).

The notion that *M. hominis* causes fever in some women after abortion or after normal delivery is based on its isolation from the blood of about 10% of such women but not from that of afebrile women who have had abortions or that of healthy pregnant women (99). In addition, antibody responses have been detected in about half of febrile aborting women but in few of those who remain afebrile (99). Similar observations have been made for the isolation of *Ureaplasma* spp. which may be responsible for some cases of postpartum endometritis (22). It is possible that ureaplasmas play a causal role in some cases of spontaneous abortion and premature birth through elaboration of phospholipases and stimulation of cytokines which are secreted in response to the presence of the microorganisms in amniotic fluid (116). There is no evidence that *M. genitalium* is a cause of preterm labor or abortion (66, 78).

Neonatal Infections

Colonization of infants by genital mycoplasmas may occur by ascension from the lower genital tract of the mother at the time of delivery or in utero earlier in gestation and may be transient and without sequelae. The rate of vertical transmission may be 18 to 55% among infants born to colonized mothers (116). *Ureaplasma* spp. and *M. hominis* may be isolated from neonates born to mothers with intact membranes and delivered by cesarean section (116). Congenital pneumonia, bacteremia, progression to chronic lung disease of prematurity with the development of inflammatory cytokines in tracheal aspirates, and even death have occurred in very-low-birth-weight infants due to ureaplasmal infection of the lower respiratory tract (116). A meta-analysis of the literature accumulated since the 1980s supports the association of ureaplasmal infection with the development of chronic lung disease (93), but so far there has been no evidence of a reduction in the incidence of chronic lung disease or death when preterm infants have been treated with erythromycin. Both *M. hominis* and *Ureaplasma* spp. have been isolated from maternal and umbilical cord blood, as well as the blood of neonates. Both species can also invade the cerebrospinal fluid of neonates (116). Either mild, subclinical meningitis without sequelae or neurological damage with permanent handicaps may ensue. The frequency of colonization of healthy full-term infants declines after 3 months of age, and fewer than 10% of older children and sexually inexperienced adults are colonized with genital mycoplasmas (116).Vertical transmission of *M. genitalium* from mother to neonate has been reported (67), but its significance in neonates is unknown.

Routine screening of neonates for genital mycoplasmas is not clinically justified based on the available evidence that many healthy neonates may be colonized without consequence. However, if there is clinical, radiological, or laboratory evidence of pneumonia, meningitis, or overall instability, particularly in preterm neonates in whom there are no obvious alternative etiologies, infection with *M. hominis* or *Ureaplasma* spp. should be considered.

Systemic Infections and Immunosuppressed Hosts

Extrapulmonary and extragenital mycoplasmal infections probably occur more often than currently recognized. *M. hominis* is alone among pathogenic mycoplasmas of human origin which may occasionally be detected in routine bacteriologic cultures, so there have been many instances of accidental discovery when mycoplasmas were not specifically sought. Mollicutes can cause invasive disease of the joints as a result of dissemination from the genital or respiratory tract in immunosuppressed persons, especially individuals with hypogammaglobulinemia (109). Mycoplasmas should always be considered early in attempting to diagnose septic arthritis in the setting of congenital antibody deficiency. *M. hominis* bacteremia has been demonstrated after renal transplantation (89), trauma, and genitourinary manipulations, and *M. hominis* has also been found in brain abscesses, osteomyelitis lesions (74), and wound infections, having been isolated, for example, on numerous occasions from sternal wounds in recipients of heart or lung transplants (101). Numerous species, including *M. fermentans, M. salivarium,* and *Ureaplasma* spp., have been detected by culture and/or PCR in synovial fluids of persons with rheumatoid arthritis and other arthritides, although the precise contribution of these organisms to these disease conditions is still uncertain (57, 91, 92). The significance of *M. fermentans* and other mycoplasmas in persons infected with the human immunodeficiency virus, with or without AIDS, has received a great deal of attention. However, the notion that *M. fermentans* is important in AIDS disease progression lacks firm support (109). Despite the fact that mycoplasmas,

in particular *M. fermentans,* once received considerable notoriety as possible agents of Gulf War syndrome, there is no credible evidence supporting such an association or causal role (109).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Specimen Type and Collection

Body fluids appropriate for mycoplasmal culture or detection by noncultural methods include blood, synovial fluid, amniotic fluid, cerebrospinal fluid, urine, prostatic secretions, semen, wound aspirates, sputum, pleural fluid, bronchoalveolar lavage fluid, and other tracheobronchial secretions, depending on the clinical condition and organisms of interest. Swabs from the nasopharynx, cervix or vagina, wounds, and urethra are also acceptable. Tissue from biopsy or autopsy, including placenta and endometrium tissue, bone chips, and urinary calculi, can also be used. When swabs are used, care must be taken to sample the desired site vigorously to obtain as many cells as possible since mycoplasmas are cell associated. The use of urine specimens may sometimes prove more sensitive than that of urethral swabs for detection of fastidious mycoplasmas such as *M. genitalium* by PCR (52). If determination of the localization of mycoplasmas in the genitourinary tract is desired, urine specimens can be obtained at various stages during urination or after prostatic massage. Care should be taken to avoid collection of specimens that are contaminated by lubricants or antiseptics commonly used in gynecologic practice. Calcium alginate, Dacron, or polyester swabs with aluminum or plastic shafts are preferred. Wooden-shaft cotton swabs should be avoided because of potential inhibitory effects. Swabs should always be removed from specimens before transportation to the laboratory.

Successful isolation of mycoplasmas from blood can be achieved by inoculating blood, free of anticoagulant, into liquid mycoplasmal growth media at the bedside in a 1:10 ratio, using as much blood as possible (at least 10 ml for adults). Mycoplasmas are inhibited by sodium polyanethol sulfonate, the anticoagulant used in most commercial blood culture media, but the inhibitory effect can be overcome by the addition of gelatin (1% [wt/vol]) (83). Use of commercial blood culture media with or without automated blood culture instruments is not recommended for detection of mycoplasmas. None of the newer continuously monitored, nonradiometric, automated blood culture systems will flag bottles containing *M. hominis,* even when additional metabolic substrate and gelatin are added. The organism may survive in these media for several days, however (111).

Transport and Storage

Mycoplasmas are extremely sensitive to adverse environmental conditions, particularly drying and heat. Specimens should be inoculated at the bedside whenever possible by using appropriate transport and/or culture media. Specific mycoplasma media such as SP4 and Shepard's 10 B broths and 2 SP (10% heat-inactivated fetal calf serum with 0.2 M sucrose in 0.02 M phosphate buffer, pH 7.2) are acceptable transport media and can also be used for sample preparation for PCR assays. Other media available commercially for transport and storage of specimens are Stuart's medium, Trypticase soy broth with 0.5% bovine serum albumin, and Mycotrans (Irvine Scientific, Irvine, Calif.). A3B broth (Remel, Inc., Lenexa, Kans.) is available as a transport medium, whereas Remel arginine broth and 10 B and SP4 transport broths also serve as growth media. Liquid specimens do not require special transport media if cultures can be inoculated within 1 h, provided that the specimens are protected from evaporation. Tissues can be placed in a sterile container which can be tightly closed and delivered to the laboratory immediately. Otherwise, tissue specimens should be placed in transport media if delay in culture inoculation is anticipated. Specimens should be refrigerated if immediate transportation to the laboratory is not possible. If specimens must be shipped and/or if the storage time prior to processing is likely to exceed 24 h, the specimen in transport medium should be frozen at −70°C to prevent loss of viability and to minimize bacterial overgrowth. Mollicutes can be stored for long periods in appropriate growth or transport media at −80°C or in liquid nitrogen. Frozen specimens can be shipped with dry ice to a reference laboratory if necessary. Storage at −20°C is deleterious to detection, even by nonculture methods. When frozen specimens are to be examined, they should be thawed rapidly in a water bath at 37°C.

DIRECT EXAMINATION

Microscopy

Mycoplasmas, like chlamydiae and rickettsiae, cannot be clearly visualized by routine light microscopy. Lack of a cell wall precludes visualization of mycoplasmas by Gram staining, but this procedure may prove useful to exclude contaminating bacteria. *M. hominis* may occasionally appear as pinpoint colonies on bacteriologic media, and the lack of a Gram stain reaction by these colonies gives a clue as to their possible mycoplasmal identity, warranting further, more specific evaluation and subculture to mycoplasmal media. A DNA fluorochrome stain such as Hoechst 33258 (ICN Biomedicals, Costa Mesa, Calif.) or acridine orange stain may be useful when applied to body fluids such as amniotic fluid after cytocentrifugation but is not specific for mycoplasmas.

Antigen Detection

Although culture is appropriate for species which can be isolated easily and rapidly from clinical specimens, such as *M. hominis* and *Ureaplasma* spp., it is not ideal for detection of fastidious and/or extremely slow growing organisms such as *M. genitalium* and, to a considerable degree, *M. pneumoniae*. Therefore, alternate non-culture-based methods of detection should be employed even if culture is attempted for these organisms. Rapid methods for antigenic detection of *M. pneumoniae* have been developed, but these techniques are hampered by low sensitivity and cross-reactivity with other commensal mycoplasmas, and they cannot be recommended for diagnostic purposes.

Nucleic Acid Detection Techniques

DNA hybridization techniques for the diagnosis of *M. pneumoniae* infection were developed in the early 1980s. Because probes are relatively insensitive, the more recently available amplification techniques such as the PCR assay have supplanted them, and none are sold commercially in the United States or the United Kingdom.

PCR systems have been developed for all of the clinically important mollicute species that infect humans. Some examples of gene targets used in PCR assays include 16S rRNA (52, 58, 69, 80, 92, 125); other repetitive sequences such as the insertion-like elements of *M. fermentans* (120); the P1 adhesin gene (29, 55, 85), ATPase operon gene (12), and *tuf* gene of *M. pneumoniae* (68); *gap* in *M. hominis* (8); and the MgPa

adhesin gene (29, 56) and *gyrA* (15) of *M. genitalium*. Urease genes (14, 124) and the multiple-band antigen gene (59, 82) have been used as targets in *Ureaplasma* spp. Real-time PCR assays have been described for *M. pneumoniae* (72), *M. genitalium* (53, 58, 95), *M. hominis* (8), and *Ureaplasma* spp. (71). For slowly growing organisms such as *M. pneumoniae,* and especially for extremely fastidious species for which optimum cultivation techniques are not established, such as *M. genitalium* and *M. fermentans,* the use of PCR assays may be the only practical means of detecting their presence in clinical material. The sensitivity of PCR is very high, corresponding to a single organism when purified DNA is used. Other advantages are the potential ability to complete the procedure in 1 day, the requirement for only one specimen containing organisms that do not have to be viable, and the ability to detect nucleic acids in preserved tissues.

Comparison of the PCR technique with culture and/or serology, in the case of *M. pneumoniae,* has yielded varied results that are not always in agreement, and large-scale experience with this procedure is still limited. Positive PCR results for *M. pneumoniae* from culture-negative persons without evidence of respiratory disease suggest inadequate assay specificity, persistence of the organism after infection, or existence of the organism in asymptomatic carriers. Positive PCR results from serologically negative persons may be due to an inadequate immune response or to the collection of specimens before specific antibody synthesis could occur. Negative PCR results in cases of culture- or serologic-test-proven infections raise the possibility of inhibitors or other technical problems with the assay. If mycoplasmacidal antibiotics have been administered, PCR results may be negative even though serology is positive. There is some evidence suggesting that PCR inhibition may occur more commonly with nasopharyngeal specimens than throat swabs being assayed for *M. pneumoniae* (35, 86). Commercial reagents available for purification of nucleic acid can be helpful in overcoming PCR inhibition.

In addition to the PCR assays mentioned above, there have been descriptions of multiplex PCR assays to detect *M. genitalium* and other urogenital pathogens (70), a PCR-microtiter plate hybridization assay (125), and a microwell-plate-based PCR assay for large-scale screening for this mycoplasma (38). Since PCR-based assays are the mainstay for diagnosis of *M. genitalium* infection, it is essential that the procedure employed be stringently controlled and carefully monitored. Ideally, positive PCR assays should be confirmed by using a second unrelated target gene. Strong associations between serology and PCR results for *M. genitalium* have been described previously (119), but the analytic sensitivity of a single PCR assay for *M. genitalium* was questioned by Baseman et al. (10), who reported that 61% of culture-positive women tested negative by PCR, despite apparently good quality control parameters for the assay. Assuming that culture positivity was not due to cross contamination, this finding highlights the fact that reduced sensitivity of a single PCR assay may be related to the quality of the specimen or the presence of inhibitors.

PCR technology appears to be less valuable for routine diagnostic purposes in the case of infections with the more rapidly growing and relatively easily cultivable organisms, such as *M. hominis* and *Ureaplasma* spp., but this method can be valuable in clinical studies of ureaplasmal infections. The newest PCR-based techniques permit identification of *Ureaplasma* species as well as limited serotype determination (33, 59, 60, 82). In addition, real-time PCRs that differentiate between *U. urealyticum* and *U. parvum* have been described previously (71).

PCR is also a good tool for identification of an unknown mycoplasma previously obtained by culture. It can be used for characterization of strains within a species and for detection of a specific feature, such as the presence of an antibiotic resistance determinant. Presently, PCR detection for mycoplasmas and most other microorganisms of clinical significance is still too expensive and complex to be carried out routinely in most clinical microbiology laboratories. Some drawbacks must still be corrected, such as the problem of contamination and the presence of inhibitors. Development of commercial PCR kits may bring about better standardization of the technique, and if available at a reasonable cost, PCR could become a major method for the diagnosis of mycoplasmal and ureaplasmal infections.

ISOLATION PROCEDURES

Biosafety Considerations

M. pneumoniae, M. hominis, and ureaplasmas are considered to be category 2 pathogens. Work with these microorganisms and other mycoplasmas of human origin can be undertaken on the laboratory bench and/or in a class 2 safety cabinet.

Growth Media and Inoculation

Growth of mycoplasmas and ureaplasmas pathogenic for humans requires the presence of serum, growth factors such as yeast extract, and a metabolic substrate. No single formulation is ideal for all pertinent species due to different properties, optimum pHs, and substrate requirements. SP4 broth and agar (pH 7.5) are the best media overall and can be used for both *M. pneumoniae* and *M. hominis*, provided that arginine is added for the latter. Shepard's 10 B broth (pH 6.0) can be used for *M. hominis* and *Ureaplasma* spp., with A 8 as the corresponding solid medium. Penicillin G or a broad-spectrum semisynthetic penicillin should be added to minimize bacterial overgrowth. Addition of a pH indicator, such as phenol red, is important for detection because mycoplasmas usually do not produce turbidity in broth culture owing to their small cell size. Compositions of these media are provided elsewhere (110).

Lack of commercially prepared media in the past has effectively prevented many laboratories from offering on-site mycoplasma detection. For self-prepared media, quality control is crucial for each of the main components. These controls must consist of the quantitative growth of a mycoplasma strain(s) in two media that differ only in the component to be tested. New lots or batches of broth are considered satisfactory if the numbers of organisms that grow are within 1 10-fold dilution of the reference batch. Agar plates should ideally support growth of at least 90% of the colonies that are supported by the reference media. Sterility of commercially purchased medium components, such as horse serum, must be confirmed prior to their use. If a reference laboratory is to be used for mycoplasma testing, inquiry should be made as to whether the medium used is self-prepared or purchased from a manufacturer and there should also be verification of the type of quality control procedures performed. Quality control test organisms should include type strains and low-passage-number clinical isolates of the species of interest. For testing of ureaplasmas, it is recommended to include at least one representative from each of the two species. Testing inhibitory properties of media against growth of various other organisms likely present in specimens from nonsterile sites may also be worthwhile to prevent loss of mycoplasmas due to overgrowth of contaminating organisms.

Specimens should always be mixed well before inoculation of media, fluids should be centrifuged ($600 \times g$ for 15 min), and the pellet should be inoculated. Urine can be filtered

through a 0.45-μm-pore-size filter if bacterial contamination is suspected. Furthermore, it is wise to mince, not grind, tissues in broth prior to diluting. Serial dilution of specimens in broth to at least 10^{-3} with subculture of each dilution onto agar is an extremely important step in the cultivation process since it will help overcome possible interference by antibiotics, antibodies, and other inhibitors, including bacteria, that may be present in clinical specimens. Omission of this critical dilution step may be one reason why some laboratories have difficulty in recovering the organisms. Dilution also helps to overcome the problem of rapid decline in culture viability, which is particularly common with ureaplasmas, and it also provides information about the number of organisms present.

Incubation Conditions and Subcultures

Broths should be incubated at 37°C under atmospheric conditions. Agar plates yield the best growth if they are incubated in an atmosphere of room air supplemented with 5 to 10% CO_2 or in an anaerobic environment of 95% N_2 plus 5% CO_2. A candle jar or anaerobe jar with a GasPak catalyst is adequate if dedicated incubators are not available. The relatively rapid growth rates of *M. hominis* and *Ureaplasma* spp. make identification of most positive cultures possible within 2 to 4 days, whereas *M. pneumoniae* usually requires 21 days or more. Several mycoplasmal species of human origin can produce similar biochemical reactions, and identification can be accomplished only by using specific tests once the organisms are isolated. All broths that have changed color should be subcultured into a fresh tube of the corresponding broth (0.1 ml into 0.9 ml) and onto agar (0.02 ml). Subcultures must be performed soon after the color change occurs, particularly if the organism is a *Ureaplasma* species, because the culture can lose viability within a few hours. Subculture also increases the diagnostic yield since some strains may not grow sufficiently from the original specimen inoculated initially onto solid media. Blind subculture periodically during incubation may improve the yield of *M. pneumoniae* and other mycoplasmas since a color change may not always be evident, even if growth occurs. Cultures should be incubated for at least 7 days before being designated negative for genital mycoplasmas and 4 weeks for *M. pneumoniae*. The growth rate of *M. fermentans* is similar to that of *M. pneumoniae.* However, for *M. fermentans, M. genitalium,* mycoplasmas of human origin other than *M. pneumoniae* and *M. hominis,* and *Ureaplasma* spp., cultivation conditions are not well established. Due to the advent of PCR assays for use in research and reference laboratories, the need to refine culture techniques for these slowly growing and fastidious organisms is less critical and cultivation methods for them will not be discussed.

Development of Colonies

Broth cultures for *Ureaplasma* spp. should be examined for color change resulting from hydrolysis of urea twice daily for up to 7 days because of the rapid decline in viability of these organisms in culture. This timing is less critical for *Mycoplasma* spp., for which once-daily inspection of broth cultures is sufficient. Agar plates should be examined by using a stereomicroscope at a magnification of ×20 to 60 daily for *Ureaplasma* spp., at 1- to 3-day intervals for *M. hominis,* and every 3 to 5 days for *M. pneumoniae* and other more slowly growing species. *Ureaplasma* colonies (Fig. 3) can be identified on A 8 agar by urease production in the presence of a $CaCl_2$ indicator contained in the medium. The larger *M. hominis* colonies are urease negative and often have the typical fried-egg appearance (Fig. 1). Other species, such as *M. pneumoniae* and *M. genitalium,* will produce much smaller spherical colonies which may or may not demonstrate the fried-egg appearance (Fig. 2). Methylene blue stain applied directly to the agar plate to turn the colonies blue is sometimes useful if there is uncertainty about whether or not mycoplasmal colonies are present. *M. hominis* is the only pathogenic mycoplasma of humans cultivable on bacteriologic media such as chocolate agar and blood agar. However, the pinpoint translucent colonies are easily overlooked and routine bacterial cultures may be discarded before the time needed for *M. hominis* colonies to develop, which may be 4 days or more in some cases. Occurrence of suspicious colonies warrants subculture to appropriate mycoplasma media.

Commercial Media and Culture Kits

In response to the growing desires of many independent or hospital-based clinical laboratories to offer mycoplasmal culturing on-site, numerous companies have developed various transport and growth medium systems. A variety of kits for detection, quantitation, identification, and antimicrobial susceptibility testing of *Ureaplasma* spp. and *M. hominis* from urogenital specimens are available in several European countries but not in the United States. A more complete description of these commercial kits sold in Europe is provided elsewhere (118).

Mycoscreen GU (Irvine Scientific) is a broth-based culture system for screening clinical specimens for genital mycoplasmas. Vials showing evidence of growth as indicated by color change must be subcultured to the Mycotrim GU Triphasic flask system, Mycotrim GU agar, or other solid medium for isolation and identification. A comparable system, Mycotrim RS, has been adapted for detection of *M. pneumoniae* in respiratory specimens. Remel, Inc., has developed several formulations of transport and growth media, including 10 B broth, A 7 agar, A 8 agar, SP4 broth, and SP4 agar.

Some kits and other commercial products and media have been evaluated to a limited degree by independent investigators (1, 16, 23, 25, 81, 94, 123). Commercial products and kits may be of particular value if the need to detect mycoplasmas arises infrequently in laboratories which do not specialize in mycoplasma detection, but users should be aware of the potential limitations of existing products. If commercially prepared media are to be utilized, it is advisable that laboratories perform internal quality control tests.

IDENTIFICATION

Even though the numerous large-colony mycoplasmal species which may be isolated from humans cannot be identified based on colonial morphology or a particular biochemical profile, the body site of origin and rate of growth, in conjunction with biochemical features, give some clues. Biochemical properties such as glucose, arginine, or urea hydrolysis are determined based on color change in the absence of turbidity in the appropriate broth. Utilization of glucose by a mycoplasma in SP4 broth will produce an acidic shift (red to yellow), whereas utilization of arginine will produce a change from red to deeper red in this broth in the presence of the phenol red pH indicator. Urea or arginine hydrolysis in 10 B broth causes an alkaline shift from orange to deep red. Thus, a slowly growing glycolytic organism grown from the respiratory tract that produces spherical colonies on SP4 agar after approximately 5 to 20 days of incubation and exhibits hemolytic activity and hemadsorption with guinea pig erythrocytes is most likely to be *M. pneumoniae.* An alkaline color change which occurs after overnight incubation without turbidity in 10 B broth containing urea is almost certainly due to *Ureaplasma* spp.,

whereas a urogenital specimen that produces an alkaline reaction within 24 to 72 h in broth supplemented with arginine is likely to contain *M. hominis*. Examination of colonial morphology is sufficient to identify *Ureaplasma* spp., and it is important to keep in mind that these organisms often coexist with *M. hominis* in urogenital specimens.

In order to identify a large-colony mycoplasma completely to the species level, a number of different techniques are available, although they are more appropriate for a reference laboratory than for a hospital microbiology laboratory because of their complexity and the lack of commercial availability of the reagents required. PCR appears to be the best overall choice for mycoplasma species identification since it is much simpler to perform than other methods and it does not require immunologic reagents that may not be readily available. The PCR assay is also less subjective to interpretion than some of the other methods such as epi-immunofluorescence.

TYPING SYSTEMS

Several methods for typing of mollicutes have been described previously and used as a means to study epidemiology in the case of *M. pneumoniae* and differential pathogenicity in the case of the 2 genomic clusters and 14 serotypes of *Ureaplasma* spp. Typing methods have been much less extensively evaluated for other human mycoplasmal species.

Techniques employed initially to serotype ureaplasmas from clinical specimens have included use of polyclonal antibodies (39), immunofluorescence (76), immunoperoxidase (84), and agar growth inhibition (103, 110). Results of earlier studies have been varied and inconsistent due to the inefficient and imprecise methods available, the occurrence of multiple cross-reactions, and the fact that many persons may harbor more than one serotype in their urogenital tracts in the presence or absence of disease. Development of monoclonal antibodies enabled identification of MB antigens responsible for ureaplasma serotype specificity on the cell surface (126). PCR-based assays enabled the more accurate characterization of the two genomic clusters of *Ureaplasma* spp. that led to their designation as two separate species. Pulsed-field gel electrophoresis has been applied to *Ureaplasma* spp. to determine the sizes of the genomes (77, 88), and preliminary information suggests that pulsed-field gel electrophoresis can distinguish among the majority of the 14 *Ureaplasma* serotypes and detect differences within serotypes (K. B. Waites, unpublished data).

Restriction fragment length polymorphism, multilocus sequence typing, Western blotting, two-dimensional gel electrophoresis, and PCR assays have been used to characterize *M. pneumoniae* clinical isolates (27, 34, 37, 49, 79, 90). Most evaluations have determined that there are two genomic groups or subtypes distinguishable by analysis of the P1 adhesin gene, ORF6 gene, P65 gene, and typical DNA restriction fragment pattern. Typing of human mycoplasmas or ureaplasmas for diagnostic or epidemiological purposes is not recommended, and the methods are unavailable except in specialized research or reference laboratories.

SEROLOGIC TESTS

M. pneumoniae Respiratory Disease

Historically, serology has been the most common laboratory means for diagnosis of *M. pneumoniae* respiratory tract infections. Although culture and PCR are also used to detect the presence of *M. pneumoniae* in respiratory specimens, persistence of the organism for variable lengths of time following acute infection makes it difficult in some cases to assess the significance of a positive culture or PCR assay without additional confirmatory tests such as seroconversion.

M. pneumoniae has both lipid and protein antigens which elicit antibody responses that can be detected after about 1 week of illness and peak at 3 to 6 weeks, followed by a gradual decline, allowing the application of several different types of serologic assays based on different antigens and technologies. Serology is a very useful epidemiologic tool in circumstances where the likelihood of mycoplasmal disease is high, but it is less suited for assessment of individual patients in a timely manner. Its main disadvantage is the need for both acute- and convalescent-phase paired sera collected 2 to 3 weeks apart that are tested simultaneously for IgM and IgG to confirm seroconversion. This is especially important for adults over 40 years of age who may not mount an IgM response, presumably because of reinfection (117). Moreover, IgM antibodies can sometimes persist for several weeks to months, making it risky to base diagnosis of acute infection on a single assay for IgM (117). Antibody production may also be delayed in some infections or even absent if the patient is immunosuppressed. False-negative tests for IgM can also occur if serum is collected too soon after the onset of illness. Since *M. pneumoniae* is a mucosal pathogen, IgA is typically produced early in the course of infection. Measurement of IgA in serum may therefore be a better approach for diagnosis of acute infection because of IgA's rapid rise and decline, but very few commercial assays include reagents for IgA detection.

Complement fixation (CF) was the primary method for serologic testing for *M. pneumoniae* in the past. Although CF measures mainly the early IgM response, the test does not differentiate among antibody classes. Cross-reactions with other organisms, most notably *M. genitalium* (63), are well recognized, and false-positive results due to cross-reactive autoantibodies induced by acute inflammation from other unrelated causes may occur. In most clinical laboratories, CF has been replaced by alternative techniques. Table 3 summarizes various assays used to detect *M. pneumoniae* infection in the United States. More detailed descriptions of individual assay kits are available in other reference texts (see, e.g., reference 118).

Immunofluorescent-antibody (IFA) assays, direct and indirect hemagglutination using IgM capture, and other particle agglutination antibody assays (PAs) have been developed to detect antibody to *M. pneumoniae* (5, 40, 62). IFA assays consist of *M. pneumoniae* antigen affixed to microscope slides and measure IgM and IgG separately. This type of assay is technically simple to perform but is subjective in interpretation and requires a fluorescent microscope, and the presence of *M. pneumoniae*-specific IgG may interfere with IgM results (5). Qualitative and semiquantitative PAs using either latex beads or gelatin that detect IgM and IgG simultaneously can be technically easy to perform, but they do not offer any significant advantages over enzyme immunoassays (EIAs). Though commonly used in some countries because of their ease and simplicity of performance, PAs have not been widely used for serologic diagnosis of *M. pneumoniae* infections in the United States.

EIAs, developed in the 1970s, have become the most widely used methods for detection of *M. pneumoniae* antibody in the United States. All are classified as having either moderate or high complexity according to the Clinical Laboratory Improvement Amendments. They may be qualitative or quantitative and may or may not require specialized

TABLE 3 Examples of test kits sold in the United States for detection of serum antibodies to *M. pneumoniae* in serum[a]

Product name	Manufacturer	Antibody(ies) measured	Assay format and description	No. of tests/ kit	Specimen throughput	Assay time	
						Start to finish	Hands on
M. pneumoniae antibody (MP) test system	Zeus Scientific, Inc., Branchburg, N.J.	IgM and IgG separately	Indirect immunofluorescence assay available as a slurry of *M. pneumoniae* antigenic substrate or a Crown Titer of *M. pneumoniae* colonies affixed to microscope slides	100	Each slide contains 10 wells	2.5 h	30 min
ETI-MP IgM or IgG	Savyon Diagnostics, Ltd., Ashdod, Israel	IgM and IgG separately	EIA using a 96-well microtiter plate coated with a membrane preparation containing *M. pneumoniae* P1 protein	192	Strips of 8 wells	2.5 h	15–20 min
ImmunoCard	Meridian Diagnostics, Cincinnati, Ohio	IgM only	Qualitative, membrane-based EIA in a single-sample-card format consisting of a test port containing *M. pneumoniae* antigen and a control port containing immobilized human IgM	30	1 specimen per card	12 min	10 min
M. pneumoniae IgG-IgM antibody test system	Remel, Inc., Lenexa, Kans.	IgM and IgG simultaneously	Qualitative, membrane-based enzyme immunobinding assay consisting of a single sample test containing inactivated *M. pneumoniae* cytadhesin protein	10 or 40	1 specimen per card	10 min	2–3 min
Mycoplasma IgG and IgM enzyme-linked immunosorbent assay system	Zeus Scientific, Inc.	IgM and IgG separately	Qualitative EIA with multiwell break-away strips containing partially purified inactivated *M. pneumoniae*	96	Strips of 8 wells	50 min	5–10 min
GenBio Immuno-WELL *M. pneumoniae* IgM or IgG	Alexon-Trend Inc., Ramsey, Minn.	IgM and IgG separately	EIA using a 96-well microtiter plate coated with purified glycolipid antigen from *M. pneumoniae* (strain FH; ATCC 15531)	96	Strips of 8 wells	IgG, 2.35 h; IgM, 2.75 h	15–20 min

[a] This table does not include all commercially available test kits sold in the United States for serologic diagnosis of *M. pneumoniae* infections. It provides descriptions of tests representing various formats and is limited to those products that have been evaluated in independent studies.

equipment. EIAs are more sensitive than CF or culture, have good specificity, and can be performed with very small volumes of serum. The need for acute- and convalescent-phase sera has remained the obvious limitation for prompt point-of-care diagnosis. However, a membrane-based EIA specific for IgM, the ImmunoCard (Meridian Diagnostics, Cincinnati, Ohio), has been developed for rapidly detecting an acute *M. pneumoniae* infection by using a single serum specimen. The ImmunoCard has the advantages of being technically much simpler and quicker (10 min) to perform than other types of assays. It has proved highly reliable for children but has the potential disadvantage of a lack of sensitivity for detection of *M. pneumoniae* infections in some adults in whom the IgM response may be minimal. The Remel EIA is another rapid point-of-care qualitative serologic assay that detects both IgM and IgG simultaneously in an easy-to-read format without the need for any instrumentation. This test has shown good sensitivity and specificity compared to other EIAs, IFA assays, and CF tests. Several comparison studies have been performed, individually evaluating each of the EIA kits listed in Table 3 and several others (5, 6, 9, 40, 62, 97, 104, 105). The best commercial EIA for individual patient diagnosis depends on the age of the patient being tested, the timing of serum collection, the availability of paired sera, the equipment available, and the experience of the laboratory personnel who will perform the test. However, maintaining a large variety of different assays within one laboratory is not practical or cost-effective. According to a recent study (97), the rapid Remel and Meridian tests are better able to detect seropositive samples than the plate type EIAs. Among the latter assays, the Zeus and Savyon kits were more sensitive than the GenBio assay.

Cold agglutinins, detected by agglutination of type O, Rh-negative erythrocytes at 4°C, occur in association with *M. pneumoniae* infection in about 50% of cases (20). Titers of 64 to 128 or a fourfold or greater rise in titer suggests a recent *M. pneumoniae* infection, but the test is nonspecific. Detection of cold agglutinins is not recommended for serologic diagnosis of *M. pneumoniae* infection.

Infections Due to Genital Mycoplasmas

Serologic tests for *M. hominis* and *Ureaplasma* spp. using the techniques of microimmunofluorescence, metabolism inhibition, and EIA have been described previously (17, 18, 64, 102, 103). A microimmunofluorescence assay for *M. genitalium* has also been developed (44) and has been shown to detect antibody responses in men with NGU (99) and women with salpingitis (75). This method is rapid, gives reproducible results, and is quite sensitive and specific, with less cross-reactivity with *M. pneumoniae* than is seen with other methods. A sensitive and specific serologic assay for *M. genitalium* using lipid-associated membrane proteins as antigens has also been developed, and this technique has been used in combination with Western immunoblotting to assess immunoreactivities of women regarded as being culture positive for *M. genitalium* (10). No serologic tests for genital mycoplasmas have been standardized and made commercially available for diagnostic use in the United States. Therefore, they cannot be recommended for routine diagnostic purposes.

ANTIBIOTIC SUSCEPTIBILITIES

Methods Used for Testing

Several methods of susceptibility testing used for conventional bacteria have been employed for testing of mycoplasmas. Agar dilution has been used extensively as a reference method (12, 51, 64). It has the advantages that the end point is relatively stable over time, the inoculum size does not have a great effect, and the method allows detection of mixed cultures readily. However, this technique is not practical for testing small numbers of strains or occasional isolates which may be encountered in diagnostic laboratories. Agar disk diffusion is not useful for testing mycoplasmas since there has been no correlation between inhibitory zones and MICs, and the relatively slow growth of some of these organisms further limits this technology. Broth microdilution to determine MICs is the most practical and widely used method. It is economical and allows several antimicrobials to be tested on the same microtiter plate, but it has numerous disadvantages in that preparation of antimicrobial dilutions is labor-intensive and the end point tends to shift over time. Limited comparisons of agar dilution and broth microdilution indicate that the two methods provide similar results for various antimicrobials tested against *Ureaplasma* spp. and *M. hominis* (47, 115).

Studies using the E test (AB BIODISK, Solna, Sweden) agar gradient diffusion technique for detection of tetracycline resistance in *M. hominis* yielded results comparable to those of broth microdilution (113). Additional comparative studies have also validated this method for determination of in vitro susceptibilities of *M. hominis* to fluoroquinolones (112) and susceptibilities of ureaplasmas to various antimicrobials (36). The E test has the advantages that agar-based testing is relatively simple to perform, the end point does not shift over time, the inoculum size does not have a large effect, and the method can easily be adapted for testing of single isolates.

There are no universally accepted standards for pH, media, incubation conditions, or duration of incubation for performing mycoplasmal or ureaplasmal susceptibility tests. No MIC breakpoints specific for these organisms are endorsed by any regulatory agency. Lack of specific guidelines for susceptibility testing methods, quality control reference MIC ranges, and interpretation of results has led to diverse and often inconsistent susceptibility profiles, especially for the genital mycoplasmas.

MIC assays must include control strains for validation purposes. A control strain may be a commercially purchased type strain or a well-studied clinical isolate for which MIC values are reproducible. An inoculum of 10^4 to 10^5 CFU/ml has been recommended as the optimum inoculum for broth-based testing (110, 114). Nonstandardized conditions at a low pH (6.0) can affect MICs, especially those of macrolides, but such conditions may be required for adequate growth of *Ureaplasma* spp. Step-by-step procedures for performance of in vitro susceptibility tests for mycoplasmas and ureaplasmas of human origin have been published previously (114). Bactericidal activity can be tested directly from the wells in broth microdilution MIC assays by removing the mixture of organisms and antibiotic, diluting it to subinhibitory concentrations in fresh medium, and observing for a color change as evidence of growth (110, 114).

Although some reference laboratories have adopted MIC breakpoints for other bacteria for use in interpretation of MICs when testing mycoplasmas, this practice should be used with caution, and it may be preferable merely to report MICs and allow clinicians to draw their own conclusions about the suitability of a particular agent for use in the treatment of a specific infection. Tetracycline-resistant *M. hominis* and *Ureaplasma* spp. can usually be distinguished by broth- or agar-based methods since MICs for the resistant strains are generally 2 to $\geq$64 μg/ml (113, 116).

Commercial MIC panels in kits have been available in Europe for several years. Details on these products are provided in reference texts (118).

Susceptibility Profiles and Antimicrobial Resistance

The availability of information on in vitro susceptibilities is greatest for *M. pneumoniae, M. hominis,* and *Ureaplasma* spp., but in some recent studies the activities of numerous antimicrobials against *M. fermentans* and *M. genitalium* have been evaluated. Though incompletely studied, *M. genitalium* has susceptibilities generally similar to those of *M. pneumoniae,* and *M. fermentans* has susceptibilities generally similar to those of *M. hominis,* with some exceptions. A comparison of MICs of several antimicrobial agents is shown in Table 4.

Susceptibility Testing and Treatment of Mycoplasmal Infections

Mollicutes are innately resistant to all beta-lactams. Sulfonamides, trimethoprim, and rifampicin are also inactive. Resistance to macrolides and lincosamides is variable according to species, with *M. hominis* being resistant to erythromycin but susceptible to clindamycin. For *Ureaplasma* spp., the reverse is true. Newer macrolides, azalides, and ketolides have shown in vitro activity comparable to that of erythromycin against *M. pneumoniae.*

M. pneumoniae is susceptible to newer fluoroquinolones, tetracyclines, and macrolides so that susceptibility testing has not been recommended except for the in vitro evaluation of new and previously untested agents. However, a recent study from Japan found that macrolide resistance in *M. pneumoniae* due to transition mutations in domain V on the 23S rRNA gene occurred in approximately 6% of 195 clinical isolates from patients with acute respiratory infections (75a). The clinical significance of this resistance is uncertain, but it suggests the need to monitor clinical isolates. Tetracycline resistance has been well documented in recent years for both *M. hominis* and *Ureaplasma* spp. and is mediated by the *tet*(M) determinant which codes for a protein

TABLE 4 Ranges of MICs of various antimicrobials for *M. pneumoniae*, *M. hominis*, *M. fermentans*, *M. genitalium*, and *Ureaplasma* spp.[a]

Antimicrobial	MIC (μg/ml) for:				
	M. pneumoniae	*M. hominis*	*M. genitalium*	*M. fermentans*	*Ureaplasma* spp.
Tetracycline	0.63–0.25	0.2–2[b]	≤0.01–0.05	0.1–1	0.05–2[b]
Doxycycline	0.02–0.5	0.1–2[b]	≤0.01–0.3	0.05–1	0.02–1[b]

Moxifloxacin	0.06–0.125	0.06–0.125	0.03–0.06	≤0.015–0.06	0.125–1
Garenoxacin	≤0.008–0.125	≤0.008–0.063	0.06–0.125	≤0.008–0.015	0.016–1
Gemifloxacin	0.05–0.125	0.0025–0.01	0.05–0.125	0.001–0.01	0.03–0.5
Rifampin	>8	>1,000	ND	25–>50	>1,000
Quinupristin-dalfopristin	0.008–0.06	0.03–8	0.05	0.1–0.5	0.03–0.5
Linezolid	≥64	2–8	ND	ND	>64

[a] Data were compiled from multiple published studies in which different methodologies, and often different antimicrobial concentrations, were used. ND, no data available.
[b] Tetracycline-susceptible strains only. MICs for isolates carrying *tet*(M) are generally 2 to >64 μg/ml.

that binds to the ribosomes, protecting them from the actions of this type of drug. The extent to which tetracycline resistance occurs in genital mycoplasmas varies geographically and according to prior antimicrobial exposure in different populations but may approach 40 to 50%. Information about tetracycline resistance in *M. genitalium* does not exist, but *M. genitalium*-positive men with NGU and women with cervicitis may respond better to azithromycin than they do to a tetracycline, possibly because of the lower MICs. There are very little outcome data documented in a controlled setting with microbiological studies to demonstrate the efficacy of antimicrobial treatment of *M. genitalium* infections. Such information is needed in view of the growing importance of this mycoplasma in sexually transmitted disease. Other agents such as streptogramins, aminoglycosides, and chloramphenicol may show in vitro activity against some mollicute species. Though data are very limited, oxazolidinones such as linezolid appear to be inactive against mycoplasmas.

Extragenital infections, often in immunocompromised hosts, may be caused by multidrug-resistant mycoplasmas and ureaplasmas, making guidance of chemotherapy by in vitro susceptibility tests important in this clinical setting. Eradication of infection under these circumstances can be extremely difficult, requiring prolonged therapy, even when the organisms are susceptible to the expected agents. This difficulty highlights the facts that mollicutes are inhibited but not killed by most commonly used bacteriostatic antimicrobial agents in concentrations achievable in vivo and that a functioning immune system plays an integral part in their eradication. Fluoroquinolones such as levofloxacin, moxifloxacin, and gatifloxacin tend to have greater in vitro activity against mollicutes than older drugs such as ciprofloxacin, but resistant strains have been reported (116). Treatment of mycoplasmal and ureaplasmal infections has been reviewed elsewhere (98, 116, 117).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Tests offered through diagnostic microbiology laboratories should focus on the species known to cause human disease and for which cultivation techniques are best defined. Unusual organisms, or those for which cultivation conditions are not established, may be detectable by PCR technology offered through a few specialized research or reference laboratories. Such organisms should be sought only after consultation with clinicians and personnel from the reference laboratory. Except for *Ureaplasma* spp., which can be identified by urease production and distinct colonial morphology, until species identification can be confirmed, a preliminary report of "large-colony *Mycoplasma* species" is appropriate. In many instances, as in culturing of specimens from the lower genital tract, this information may be sufficient. Isolates from

normally sterile sites and/or from immunosuppressed persons should be identified to the species level.

M. pneumoniae

Detection of *M. pneumoniae* in culture is time-consuming and not overly sensitive. However, isolation of the organism from respiratory tract specimens is clinically significant in most instances and should be correlated with the presence of clinical respiratory disease since a small proportion of asymptomatic carriers may exist. Detection by PCR is becoming more widely available through reference laboratories, but a positive result must still be correlated with clinical events. Reliable serology remains critical for accurate diagnosis of acute *M. pneumoniae* respiratory disease. Detection of IgG and IgM antibodies by EIA is the method of choice. A fourfold rise in antibody titer between acute- and convalescent-phase sera is considered diagnostic of acute infection. For children, adolescents, and young adults, a single positive IgM result obtained by using appropriate immunoglobulin class-specific reagents may be considered diagnostic of acute infection in most but not necessarily all cases because of the possibility of prolonged IgM elevation. Mild respiratory infections due to *M. pneumoniae* do not merit a costly and time-consuming microbiological work-up since empiric treatment will be effective in most instances.

M. hominis

M. hominis can be detected in culture within a few days. It may occasionally be discovered in routine bacteriologic media from appropriate clinical material, but such detection should not be relied upon. Its isolation in any quantity from normally sterile body fluids or tissues is significantly associated with disease, but quantitation of organisms may be of value in other circumstances. When mycoplasmas are detected in nonsterile sites such as the female lower genital tract in numbers exceeding 10^5 organisms, the mycoplasmas are most likely to be associated with BV.

Ureaplasma Species

Ureaplasma species can be detected in culture within 24 to 48 h. The characteristic colonial morphology and urease production are sufficient for identification at the genus level. Isolation in any quantity from normally sterile body fluids or tissues is significantly associated with disease. The detection of fewer than 10^4 organisms in the male urethra is unlikely to be significant. Whether this is true for each species now designated within the genus, i.e., *U. urealyticum* and *U. parvum*, is not clear. Distinguishing between the two species of *Ureaplasma* by PCR may become more important in view of possible differences in pathogenicities in some circumstances (2, 31, 33).

M. genitalium

Growing evidence for the role of *M. genitalium* as a urogenital pathogen has generated interest in the development of diagnostic methods for its detection, though no molecular biology-based assays for direct detection or serology test kits are sold commercially. Even though cultivation techniques for *M. genitalium* have been described previously (10, 54, 107), relatively few clinical isolates have actually been obtained since the initial description of this mycoplasma in the early 1980s. Slow growth, requiring 6 weeks or longer even in enriched SP4 media, and poor sensitivity make culture impractical. The potential importance of this organism in sexually transmitted urogenital infections underscores the need for improved and standardized methods for its detection. At present, noncommercial, nonstandardized PCR-based assays are all that are available. Results of these assays should be used with caution if they are adapted and employed for diagnostic purposes. When *M. genitalium* is detected in clinical specimens from a urogenital tract site such as the male urethra or the female cervix in persons with clinical evidence of urethritis or cervicitis, it should be considered medically significant.

Chlamydia and *Chlamydophila**

ANDREAS ESSIG

65

TAXONOMY AND NOMENCLATURE

Chlamydia and *Chlamydophila* are nonmotile, obligate intracellular prokaryotic pathogens characterized by a unique biphasic developmental cycle bearing two chlamydial forms that differ essentially in terms of morphology and function. According to the *Approved List of Bacterial Names,* published in 1980, the *Chlamydiaceae* contained one genus with just two species, *Chlamydia trachomatis* and *Chlamydia psittaci,* which were separated by their capability to accumulate glycogen in inclusions (Fig. 1A) and their susceptibility to sulfadiazine. In the 1990s, the application of DNA-based classification methods contributed to the recognition of the emerging human pathogen *Chlamydia pneumoniae* (35) and of *Chlamydia pecorum* (31), a pathogen of ruminants, as new species of the *Chlamydiaceae*. Phylogenetic analyses of the 16S and 23S rRNA genes were the rationale for the proposal of an emended description of the order *Chlamydiales,* and a revised taxonomy of the family *Chlamydiaceae* in 1999 (25). According to this proposal, members of the order *Chlamydiales* are obligately intracellular bacteria that have the unique chlamydia-like developmental cycle and more than 80% sequence identity with chlamydial 16S rRNA genes and/or 23S rRNA genes. The emended order now includes four families: *Chlamydiaceae, Parachlamydiaceae, Simkaniaceae* (49), and *Waddliaceae* (87).

Early divergence of *C. trachomatis*-like strains in the *Chlamydiaceae* was postulated on the basis of sequence data from the ribosomal genes and supported by other data such as genome size, glycogen production, and *ompA* sequence analysis. This led to the proposal to divide the family *Chlamydiaceae* into two genera, *Chlamydia* and *Chlamydophila* (25). As a consequence *Chlamydia pneumoniae, Chlamydia psittaci,* and *Chlamydia pecorum* were placed into the new genus *Chlamydophila*. However, the newly proposed nomenclature was controversial. The division into two genera was especially objected to by experts in the field who argued that the new genus designations ignore the unique, highly conserved biology shared by these organisms that was recognized when they were in a single genus (92). Although the new taxonomy was validly published, the ongoing debate resulted in simultaneous use of the former and the new nomenclature in the literature.

* This chapter contains material presented in chapter 63 by James B. Mahony, Brian K. Coombes, and Max A. Chernesky in the eighth edition of this Manual.

DESCRIPTION OF THE *CHLAMYDIACEAE*

The *Chlamydiaceae* contain the known human pathogens *C. trachomatis, C. pneumoniae,* and *C. psittaci* as well as organisms such as *C. abortus* and *C. felis* that have been only rarely associated with human infections. Members of the *Chlamydiaceae* show less than 10% overall 16S rRNA gene diversity and less than 10% overall 23S rRNA gene diversity. The 16S rRNA gene of the *C. abortus* strain B 577 (accession no. D85709) has been suggested as a consensus sequence for the family (25). The genome sizes of the *Chlamydiaceae* range from 1.0 to 1.24 Mbp with a G+C content of about 40%.

The cell wall harbors a common lipopolysaccharide (LPS) that differs from LPS of other bacteria in its relatively low endotoxic activity. This has been related to its lipid A, which has unusual long-chain fatty acids (12). Accounting for about 60% of the protein mass, the 40-kDa chlamydial major outer membrane protein (MOMP), encoded by the *ompA* gene, is an important structural component of the organisms' outer membrane. The variable domains (VD1 through 4) lead to multiple *C. trachomatis* serovars associated with different clinical manifestations of oculogenital infections. In contrast, *C. pneumoniae* isolates possess a strikingly high MOMP homology (45) and serovars of *C. pneumoniae* have not been described. The 60-kDa cysteine-rich OMP 2 (OmcB) is also highly conserved and could account for the osmotic stability of elementary bodies (EBs) by forming a disulfide–cross-links network with the periplasmic MOMP domains and other proteins (26). OmcB binds heparin, and this may be related to mammalian host cell adhesion and entry (102).

The unique developmental cycle differentiates chlamydiae from all other bacteria, leading to important consequences in laboratory diagnosis, clinical course, and antibiotic therapy. So-called EBs of chlamydiae infect eukaryotic host cells and can survive for only a limited period of time outside the host cell. Once inside the host cell, they differentiate to metabolically active reticulate bodies (RB) that multiply by binary fission (Fig. 1D) within vacuoles that are continuously growing and that develop into large intracytoplasmic inclusions (Fig. 1C). Reticulate bodies reorganize back to EBs at the end of the chlamydial developmental cycle (Fig. 1D). After 48 to 72 h, hundreds of EBs are released from the host cell to perpetuate the infectious cycle. Genomic transcriptional analysis of the chlamydial developmental cycle revealed

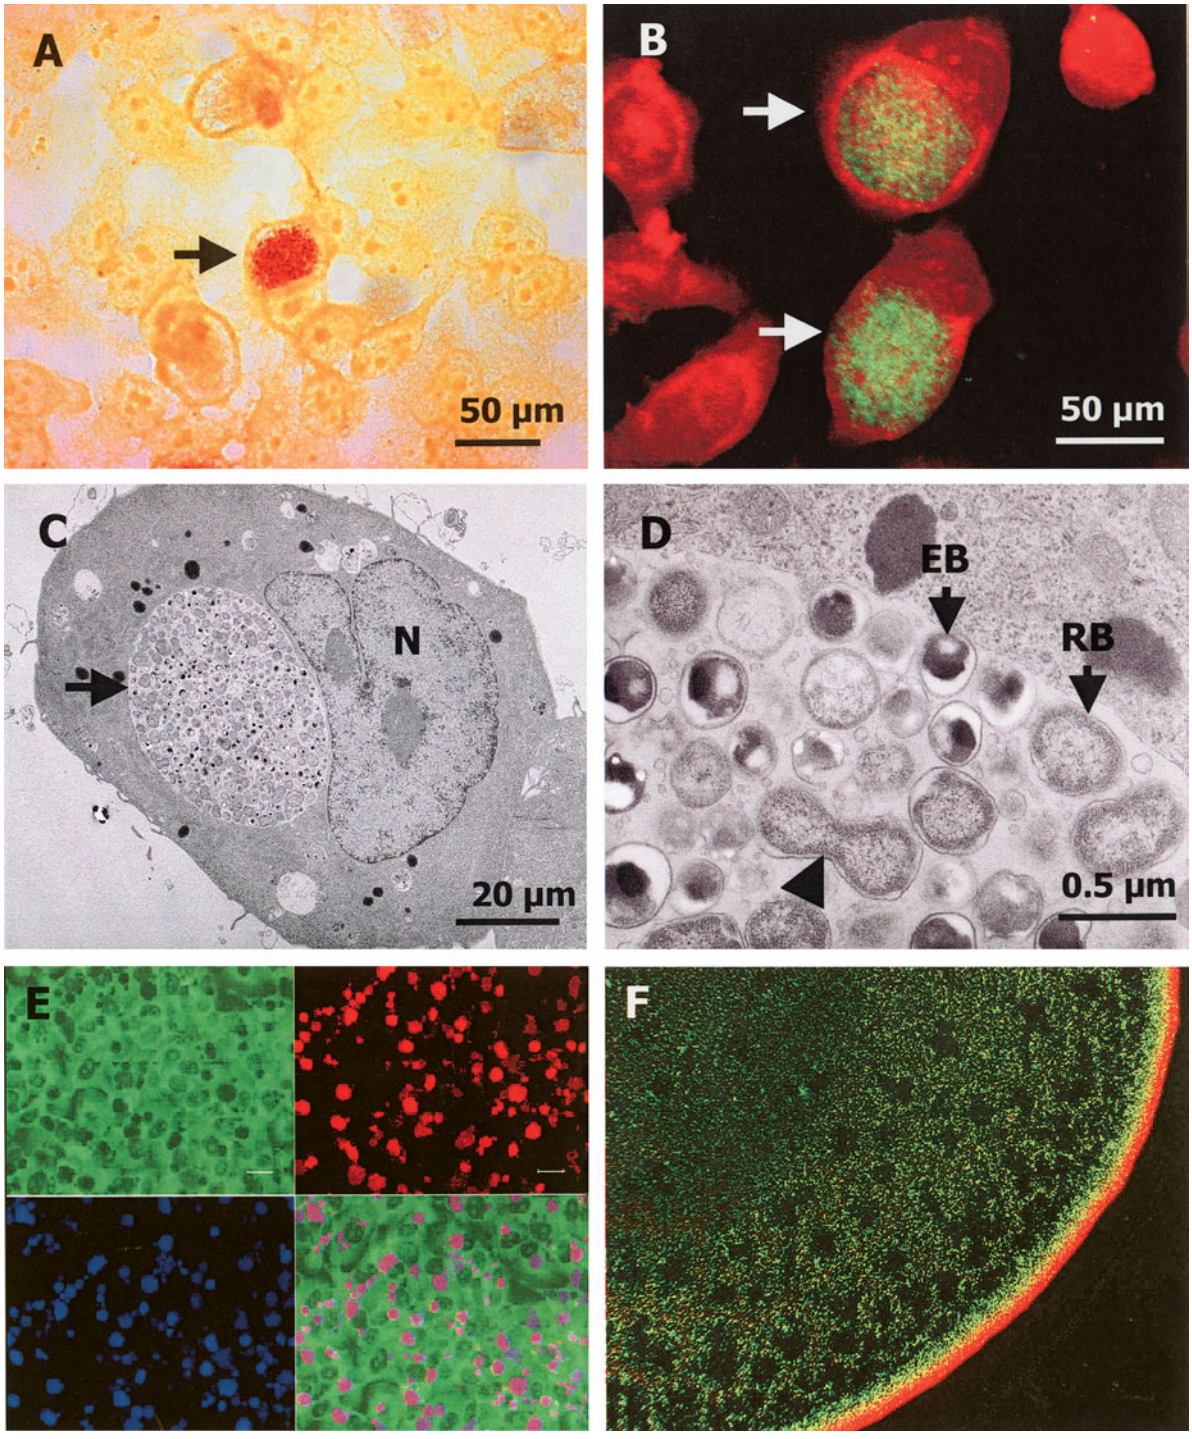

FIGURE 1 Identification of *C. trachomatis* by staining intracytoplasmic inclusions with iodine (A) and an FITC-conjugated monoclonal antibody directed at the MOMP (B). Transmission electron microscopy of a *C. pneumoniae*-infected cell shows an intracytoplasmic inclusion impressing the cell nucleus (C) and filled with EBs and RBs (D) at 60 h postinfection; the arrowhead shows a dividing RB. Identification of culture-grown *C. pneumoniae* by fluorescence in situ hybridization using rRNA targeted oligonucleotide probes (E). Simultaneous use of a Cy5-labeled probe that targets a chlamydial 16S rRNA sequence common to all members of the *Chlamydiaceae* (blue) and a Cy3-labeled probe specific for *C. pneumoniae* (red). Due to the overlap of colors, *C. pneumoniae* appears purple in the composite image; host cells are counterstained by a 5(6)-carboxyfluorescein-*N*-hydroxysuccinimide ester (FLUOS)-labeled eukaryotic probe (green). IgG-MIF image (magnification, ×400) showing bright homogeneous fluorescence of *C. pneumoniae* EBs at a serum dilution of 1:512 (F). a small subset of genes that control the differentiation stages of the cycle and have evolutionary origins in eukaryotic lineages (6).

Evidence is accumulating that factors including gamma interferon, antibiotics, and nutrient deprivation may drive chlamydiae into a state of persistence. Persistent chlamydial forms are morphologically characterized by aberrant enlarged RBs located within small intracellular inclusions that are arrested in a viable but noninfectious state (40). It was proposed that persistence is an alternative life cycle used by chlamydiae to avoid the host immune response (5). As a consequence, chronic infections have been attributed to chlamydial persistence (20). However, the clinical significance of chlamydial persistence is still a matter of debate because diagnostic tools to detect persistence in the human host are lacking.

The chlamydiae can elicit the induction of apoptosis under some circumstances and actively inhibit apoptosis under others (27, 29, 75, 116). This points to an important strategy that chlamydiae have evolved to promote their survival through the modulation of programmed cell death pathways in infected host cells.

Sequence information is now available for *C. trachomatis* (101), *C. pneumoniae* (51, 96), *C. caviae* (83), *C. abortus,* and a *Chlamydia*-like endosymbiont of *Acanthamoeba* (41). Genome analysis of this environmental chlamydial strain showed that about 700 million years ago the last common ancestor of pathogenic and symbiotic chlamydiae was already adapted to intracellular survival in early eukaryotes and contained many virulence factors found in modern pathogenic chlamydiae, including a type III secretion system (41). Comparison of the *C. pneumoniae* genome with the *C. trachomatis* genome has provided an understanding of the common biological processes required for infection and survival in mammalian cells. Prominent comparative findings include expansion of a novel family of 21 sequence-variant OMPs, conservation of a type-III secretion virulence system, three serine/threonine protein kinases and a pair of paralogous phospholipase D-like proteins, additional purine and biotin biosynthetic capability, a homologue for aromatic amino acid (tryptophan) hydroxylase, and the loss of tryptophan biosynthesis genes (51).

CLINICAL SIGNIFICANCE, EPIDEMIOLOGY, AND TRANSMISSION

C. trachomatis

Based on the antigenic reactivity of the MOMP, *C. trachomatis* is currently divided into 18 serovars. Serovars A, B, Ba, and C can be isolated from patients with clinical trachoma in areas of endemicity in poor countries in Africa, the Middle East, Asia, and South America. Acute manifestations of trachoma primarily include a follicular keratoconjunctivitis, while late-stage manifestations include tarsoconjunctival scarring with trichiasis, entropium, and subsequent loss of vision (97). According to estimates of the World Health Organization (WHO), approximately 1.3 million people in the world suffer from preventable blindness due to trachoma. Trachoma is transmitted under poor hygienic conditions between members of the same family or between families with shared facilities via discharges from the eyes of infected patients. Flies feeding from the mucopurulent eye discharges of infected and weakened humans may carry the organisms on their legs from one person to another across relatively long distances.

The *C. trachomatis* serovars D through K including the serovars Da and Ia and the genovariant Ja are associated with genital tract disease and are among the most common sexually transmitted bacterial organisms in industrialized countries. According to surveillance data of the Centers for Disease Control and Prevention (CDC), these organisms are responsible for approximately 1 million reported infections in 2004 in the United States and typically cause nongonococcal urethritis in men and cervicitis in women. Infection of the urethra and the lower genital tract may cause dysuria, whitish or clear urethral or mucopurulent vaginal discharge, and postcoital bleeding. Urethritis and the rarer manifestations proctitis and conjunctivitis are observed in both men and women. The bulk of infections are asymptomatic and therefore remain undetected (77). This may result in ascending infections such as epididymitis in men and endometritis, salpingitis, pelvic inflammatory disease, and perihepatitis (Fitz-Hugh-Curtis Syndrome) in women. Manifestations of upper genital infection in women are irregular uterine bleeding, pelvic discomfort, or abdominal pain. Salpingitis may lead to tubal scarring and therefore to severe reproductive complications such as tubal-factor infertility and ectopic pregnancy. Tubal-factor infertility attributable to *C. trachomatis* is the most frequent form of infection-induced infertility. *C. trachomatis*-infected pregnant women may transmit the organisms during delivery to the infants, who are therefore at risk to develop conjunctivitis and/or pneumonia. Sequelae of *C. trachomatis* infection in both men and women may involve HLA-B27-associated reactive arthritis, presenting most frequently as an acute asymmetric oligoarthritis with or without enthesiopathic and extramusculoskeletal symptoms (19, 121). The young age of sexually active people is strongly associated with infection. Additionally, sex workers, persons with a new sex partner, or persons who have had several sex partners are at increased risk of infection. Screening women who are at risk for *C. trachomatis* infection can prevent serious complications such as pelvic inflammatory disease (93). Consequently, screening programs have been established in some European countries and the United States to identify and treat infections of asymptomatic individuals and their partners.

The *C. trachomatis* serovars L1, L2, L2a, and L3 including the newly identified variant L2b cause lymphogranuloma venereum (LGV), a systemic sexually transmitted disease that is endemic in parts of Africa, Asia, South America, and the Caribbean but rare in industrialized countries. However, recent reports about outbreaks in Europe and the United States show that health care providers should be vigilant for LGV (73, 99), especially among men who have sex with men. The primary lesion, a small, painless papule that tends to ulcerate at the site of inoculation, often escapes attention. Proctitis is more common in people who practice receptive anal intercourse, and elevated white blood cell counts in anorectal smear specimens may predict LGV in these patients (110). Ulcer formation may favor transmission of human immunodeficiency virus and other sexually transmitted and bloodborne diseases. The cardinal feature of LGV is the presence of painful inguinal and/or femoral lymphadenopathy (82). Complications of LGV include development of coalescing fluctuant lymph nodes (buboes) that result in discharging sinuses and fistula formation. If untreated, fibrosis can lead to lymphatic obstruction causing elephantiasis of the genitalia.

C. pneumoniae

C. pneumoniae causes infections of the upper and lower respiratory tract such as sinusitis, pharyngitis, bronchitis, and pneumonia (54). *C. pneumoniae* was identified as the causative

agent in 10 to 15% of cases of community-acquired pneumonia in adults (57) as well as in children (81). However, data from studies yielding prevalence rates under 1% for *C. pneumoniae* pose the question whether its role in community-acquired pneumonia is overestimated (104). Severe and life-threatening *C. pneumoniae* infections have been described in patients with acute leukemia and treatment-induced neutropenia (38). Chronic infection with *C. pneumoniae* was reported among patients with chronic obstructive pulmonary disease and may also play a role in the natural history of asthma, including exacerbations. The clinical symptoms of *C. pneumoniae* infection are nonspecific and do not differ significantly from those caused by other atypical organisms such as viruses and *Mycoplasma pneumoniae*. Persistent cough seems not to be strongly associated with *C. pneumoniae* (115). Primary infection occurs mainly in school-age children, while reinfection has been observed in adults. Seroprevalence rates from 40 to 70% show that *C. pneumoniae* is a widely spread organism in industrialized as well as developing countries.

Atherosclerosis has been recognized as a chronic inflammatory disease of the artery vessel wall (86). The role of *C. pneumoniae* in the etiology of atherosclerosis has been discussed since 1988, when Saikku and coworkers presented serological evidence of an association of *C. pneumoniae* with coronary heart disease and acute myocardial infarction (88). In subsequent studies, the organisms were identified in atherosclerotic lesions of patients by culture, PCR, immunohistochemistry, and transmission electron microscopy; however, the discrepancies of study results (120) including those of animal studies and the failure of large-scale treatment studies (14, 36, 74) have raised skepticism about the organism's role in atherosclerosis (44). In addition, a heterogeneous spectrum of extrapulmonary diseases has been linked to *C. pneumoniae* including multiple sclerosis (100), Alzheimer's disease (3), and chronic fatigue syndrome (17); however, a causal relationship between these diseases and *C. pneumoniae* infection has not been substantiated.

C. psittaci

Psittacine birds and a wide range of other avian species may act as natural reservoirs for *C. psittaci*. In the recently proposed new *Chlamydophila psittaci* taxon (25), only the avian chlamydial strains previously designated *Chlamydia psittaci* are retained. Persons at risk for infection with *C. psittaci* include mainly those who have contact with pet birds and those who are employed in the poultry industry or in slaughterhouses. Infectious forms of the organisms are shed from symptomatic and from apparently healthy birds and may remain viable for several months. *C. psittaci* can be readily transmitted to humans following inhalation of aerosols from nasal discharges and from infectious fecal or feather dust. Symptomatic *C. psittaci* infection in humans may present as a severe chronic pneumonia (24), although mild illness and asymptomatic infections in persons exposed to infected birds have also been observed (70). Typical symptoms include fever, chills, muscular aches and pains, severe headache, hepato- and/or splenomegaly, and gastrointestinal symptoms. Cardiac complications may involve endocarditis and myocarditis. Fatal cases were common in the preantibiotic era. Due to quarantine of imported birds and improved veterinary-hygienic measures, outbreaks and sporadic cases of psittacosis are rarely observed nowadays.

C. abortus

Chlamydiae associated with ruminant abortion and formerly contained within the *Chlamydia psittaci* taxon were transferred to a new species: *Chlamydophila abortus* (114). *C. abortus* has been acknowledged as a cause of abortion and fetal loss in sheep and has also been broadly detected in calves (46). There are a number of reports of pregnant women who have had spontaneous abortions following exposure to animals infected with *C. abortus* (80, 117). The incidence of this animal-acquired infection is not known, but sheep and goats during the birthing season represent a potential risk to pregnant women. Obstetricians should consider this diagnosis along with early antibiotic treatment and cesarean section delivery in the context of the patient's case history.

Environmental Chlamydiae

The host range of chlamydiae was further broadened with the discovery of *Chlamydia*-related endosymbionts in free-living amoebae (1, 18, 30). The so-called environmental chlamydiae that have been placed in the family *Parachlamydiaceae* share the chlamydial developmental cycle and represent an evolutionary early-diverging sister of the pathogenic chlamydiae (41). Environmental chlamydiae were discussed as potential emerging pathogens; however, clinical evidence for their importance in human infection is still pending. *Simkania negevensis*, currently the only member of the *Simkaniaceae,* is a recently discovered *Chlamydia*-like intracellular agent which has been associated with respiratory infections in infants (49). The natural host of *Simkania* is not known; however, the organisms were successfully grown in various cell lines as well as in free-living amoebae and were identified in drinking water and in reclaimed wastewater (50).

COLLECTION, TRANSPORT, AND STORAGE

General Comments

Since chlamydiae are obligate intracellular pathogens, the objective of specimen collection should usually be to include the host cells that harbor the organisms (8). Outside their host, chlamydiae survive only briefly, and efforts must be undertaken to maintain the organisms' viability for successful culture. Commercial diagnostic nonculture assays do not require the presence of viable chlamydiae in the specimen; nevertheless, the instructions of the manufacturers given in the package insert should be followed for appropriate collection, transport, and storage of specimens. This includes the use of swabs and transport media specified by the manufacturer.

For successful culture of chlamydiae, the time between collection and processing of the specimens in the laboratory should be minimized while keeping specimens cold (4 to 8°C). Specimens should be forwarded to the laboratory within 24 h in a special chlamydial transport medium such as 2-sucrose phosphate or sucrose phosphate glutamate supplemented with fetal calf serum (5 to 10%), gentamicin (10 μg/ml), vancomycin (25 to 100 μg/ml), and amphotericin B (2 μg/ml) or nystatin (25 U/ml). Tetracyclines, macrolides, and penicillins cannot be used in the transport media since they have activity against chlamydiae. If specimens cannot be processed within 24 h, storage at −70°C in transport media is acceptable. Specimens for culture should not be stored at −20°C or in frost-free freezers. To test the adequacy of specimen transport, periodic transport of specimens with known numbers of inclusion-forming units should be conducted. Swab specimens should be collected on swabs with a Dacron tip and an aluminum or plastic shaft. Swab tips made of calcium alginate and swabs with wooden shafts may inhibit the growth of chlamydiae. It is recommended to check new lots of swabs that are used to collect specimens

for culture of chlamydiae for possible inhibition of chlamydial growth (21, 47).

C. trachomatis

The type and anatomical site of specimen collection for laboratory diagnosis of *C. trachomatis* infection depend on both the clinical picture and the laboratory test selection as comprehensively reviewed elsewhere (8, 47, 60, 97). Noninvasively collected specimens such as first-void urine (FVU; first 10 to 30 ml of urine) and vulvovaginal swab specimens are excellent for diagnosis of *C. trachomatis* genital tract infection by nucleic acid amplification techniques (NAATs). Sensitivity and specificity of NAATs for *C. trachomatis* on noninvasively collected specimens are similar to those obtained on samples collected directly from the cervix or urethra (90, 94, 111, 112). Patients and clinicians may prefer self-sampling to the standard collection methods (42, 85). FVU specimens should be obtained at least 2 h after the last micturition. Ambient-temperature storage of fresh unprocessed urine should not exceed 24 h to avoid denaturation of chlamydial DNA. Subsequent processing of the urine specimens for NAAT varies depending on the manufacturers' instructions. Both urine and (self-collected) vulvovaginal specimens are not recommended for testing by culture and nonamplification assays such as enzyme immunoassay (EIA), direct fluorescence assay (DFA), and nucleic acid hybridization (NAH) because of their relatively low sensitivity (47).

Traditional sites for specimen collection in *C. trachomatis* genital tract infection involve the endocervix in females and the urethra in males. Proficient specimen collection including vaginal speculum examination in females is required to obtain appropriate samples that contain sufficient columnar or squamocolumnar cells. Purulent discharges have to be cleaned before a swab is inserted 1 to 2 cm into the cervical os past the squamocolumnar junction, rotated more than two times, and removed without touching the vaginal mucosa (8). Urethral specimens from males are collected by placing a dry swab 3 to 4 cm into the urethra and rotating prior to removal. Urination prior to specimen collection may reduce test sensitivity by washing out infected columnar cells. *C. trachomatis* also infects the female urethra, and recovery rates may be improved by collecting a specimen from the urethra as well as from the cervix and sending both to the laboratory. In women with salpingitis, samples may be collected by needle aspiration of the involved fallopian tube. Endometrial specimens have also yielded chlamydiae. Further appropriate sites include the conjunctiva in chlamydial eye infection (trachoma, inclusion conjunctivitis, and newborn conjunctivitis) and the nasopharynx and deeper respiratory tract of infants in newborn pneumonia. For men who have sex with men, screening of rectal and pharyngeal specimens is recommended since early reports support the utilitity of commercial NAATs as a screening test for this population (53, 59). In cases of suspected LGV, ulcer swabs, aspirates of bubo fluid, and rectal or urethral swabs should be collected in transport medium. Buboes of LGV may contain only small amounts of thin milky fluid, and it may be necessary to inject 2 to 5 ml of sterile saline to obtain any fluid by aspiration (60).

C. pneumoniae

The optimal sites for specimen collection in *C. pneumoniae* infection are poorly defined. Respiratory specimens from which the organisms were cultured include sputum, bronchoalveolar lavage fluid, nasopharyngeal aspirates, throat washings, and throat swabs (tonsil area). Swab specimens should be collected using a Dacron tip and an aluminum or plastic shaft (21) and placed immediately in transport medium. Specimens need to be kept at 4 to 8°C in chlamydial transport medium, since the organisms are inactivated rapidly at room temperature. Rapid freezing or freezing and thawing of specimens should be avoided (54). Liquid specimens are collected in transport medium at a specimen-to-medium ratio of 1:2 (21). Testing of vascular tissue specimens and blood samples, except for research studies, is of questionable value.

C. psittaci

C. psittaci strains seem to be the most stable organisms among the pathogenic chlamydiae. Nevertheless, specimens should be collected in chlamydial transport medium. Appropriate specimens include sputum, bronchoalveolar lavage fluid, pleural fluid, blood, and tissue biopsy specimens from various anatomical sites.

DIRECT EXAMINATION

NAAT

C. trachomatis

Due to their high sensitivity and specificity, NAATs are the tests of choice for diagnosis of genital *C. trachomatis* infections in routine clinical laboratories. NAATs can be used to detect *C. trachomatis* without a pelvic examination or intraurethral swab specimen by testing self- or clinician-collected vaginal swabs or urine, respectively (16, 42, 90, 94, 111, 112). This facilitates the establishment of screening programs in asymptomatic individuals and may enhance the compliance for testing asymptomatic contact persons of infected individuals. Increasing experience is available for the use of NAATs in conjunctival, oropharyngeal, and rectal samples (53, 59) and in LGV (73, 105). For research studies of trachoma patients, NAATs have been recommended as the "gold standard"; however, the commercial assays presently available are too expensive and too complex for use in national trachoma programs (97). In many evaluations, NAATs detected 20 to 30% more positive specimens than could be detected by earlier technologies. However, NAATs are not a perfect gold standard. An expansion of the gold standard has evolved as multiple specimens from each patient have been tested by more than one FDA-cleared NAAT, enabling the gold standard to be redefined for identification of an infected patient. An infected-patient gold standard for evaluation of new diagnostic tests for *C. trachomatis* infection has been recently proposed consisting of (i) two NAATs different from the test under evaluation; (ii) three samples from each patient including cervical swabs, male urethral swabs, and urine from both men and women; and (iii) two positive results among the three samples (65).

Licensed NAATs for detection of *C. trachomatis* include (in the order of their introduction) the PCR-based Roche Amplicor (Roche Diagnostics, Basel, Switzerland), the APTIMA transcription-mediated amplification (Gen-Probe, Inc., San Diego, Calif.) and the BD ProbeTec strand displacement amplification (SDA) (Becton Dickinson and Company, Diagnostic Systems, Franklin Lakes, N.J.). The formerly frequently used Abbott LCx ligase chain reaction was withdrawn from the commercial market by the manufacturer in 2003. Both the PCR and SDA assay amplify nucleotide sequences of the 7.5-kbp cryptic plasmid of *C. trachomatis,*

which is present in an average copy number of about four plasmids per chromosome in EBs and up to seven plasmids per chromosome in replicating RBs (78). *C. trachomatis* strains that do not harbor the cryptic plasmid have been sporadically isolated from urethral specimens (28, 103). The transcription-mediated amplification-based assays target specific sequences of the 23S rRNA, which is also present in multiple copies. Each of the three commercially available NAAT systems offers the option for combination testing of *C. trachomatis* and *Neisseria gonorrhoeae* in the same specimen.

Considering the multiplicity of target sites for the amplification procedures being used, NAATs should be able to produce a positive signal from less than one EB; however, the actual sensitivity in clinical specimens is lower because of sampling variability and inhibition of amplification. Since inhibitor problems of NAATs can be reduced by dilution of specimens, heating, freeze-thaw cycles, or overnight storage at 4°C, the use of internal inhibitor controls of the amplification assays (as supplied by the manufacturers of PCR and SDA) is helpful for identification of clinical specimens containing inhibitory factors (62). All these assays are highly specific if problems with cross-contamination, labeling errors, and mistakes in specimen collection can be avoided. Confirmatory testing of positive specimens is recommended if a low positive predictive value can be expected (<90%) or if a false-positive result would have serious psychosocial or legal consequences (47).

Clinical evaluations of the NAATs have shown that they are more sensitive than culture and other nonculture methods including microscopy, antigen detection, and nucleic acid hybridization assays. As a consequence, less sensitive diagnostic tests cannot be used to confirm positive results of the more sensitive NAAT assays (47). Even among NAATs, the assays employed for confirmatory testing should have equivalent sensitivities (89). Concerns regarding consistency of test performance and reproducibility are a matter of ongoing debate. Mishandling of specimens can lead to incorrect results. Therefore, laboratory implementation of NAATs requires close attention to quality control measures such as manufacturer- or expert-based training of laboratory staff, participation in proficiency testing programs, and standard operating procedures based on the manufacturers' instructions in the package inserts (47).

In settings where resources are limited, including developing countries, the concept of pooling to detect *C. trachomatis* by NAATs has proved to be a simple, accurate, and cost-effective procedure compared to individual testing (58). Specimen pools may consist of aliquots from five processed specimens (FVU or genital swab) combined into one amplification tube. Subsequent testing of individual samples is required only if the pooled sample gives a positive result. Following this strategy, considerable savings of reagent costs can be obtained, especially in low-prevalence populations.

C. pneumoniae

A vast number of PCR-based protocols using different formats and target genes have been developed in research laboratories for detection of *C. pneumoniae* in both respiratory and nonrespiratory samples. However, the lack of a reliable gold standard for *C. pneumoniae* infection has made it difficult to evaluate the published protocols thoroughly. Broad application of NAATs for diagnosis of *C. pneumoniae* infection has been hampered because many PCR protocols are not reliable or robust enough to provide reproducible results in routine clinical laboratories. Even in specialized laboratories, there seems to be a substantial interlaboratory variation in the performance of *C. pneumoniae* NAATs, and the need for standardization of these assays has been recognized (21). Subsequently, specific recommendations for standardizing *C. pneumoniae* PCR assays were made, and it was suggested to compare the performance of newly developed PCR protocols with at least one of four recommended assays that target the *PSTI* fragment (13), the *ompA* gene (109), or the 16S rRNA gene (32, 61). However, all of these assays must be considered research tools (21), because commercial FDA-cleared assays are currently not available. Real-time PCR technology provides promising results that warrant further evaluation of this approach for detection of *C. pneumoniae* infection (2, 55, 84, 108).

C. psittaci

NAATs could be helpful for detection of avian *C. psittaci* strains from clinical samples since culture of these organisms is dangerous and requires biosafety level 3 (BSL-3) facilities. Some PCR-based assays have been developed for diagnosis of human ornithosis (24, 61, 67, 109). Due to the rarity of the disease, the performance characteristics of these assays have been only poorly evaluated in clinical specimens.

NAH

Two NAH tests are commercially available for detection of *C. trachomatis*. The Gen-Probe PACE 2 test (Gen-Probe Inc.) hybridizes to a species-specific sequence of chlamydial 16S rRNA that is present in a high copy number in replicating chlamydiae. Available data suggest that it is about as sensitive as the better antigen detection and cell culture methods and is relatively specific. However, it was shown that commercial NAATs improved the detection of infections in women by 17 to 38% compared to PACE 2 (9). The second NAH test, the Digene Hybrid Capture II, is a nucleic acid probe-signal amplification assay (Digene Corp., Gaithersburg, Md.) that uses RNA hybridization probes for DNA sequences encoding both genomic and cryptic plasmid sequences of *C. trachomatis*. This assay was shown to reach the sensitivity of a commercial NAAT when cervical specimens were investigated (113). NAHs are considered highly robust test methods for detection of *C. trachomatis*. NAH tests have been recommended for endocervical swabs or urethral swabs from men when a NAAT is not available or not economical. As is the case with other non-NAATs, NAH tests have not been recommended for use in noninvasive-collection specimens such as urine and vulvovaginal swabs (47). Both NAH systems also offer a test format that enables detection of *C. trachomatis* and *N. gonorrhoeae* in a single specimen.

DFA

The presence of typical intracytoplasmic inclusions in epithelial cells of the conjunctiva, urethra, or cervix of infected patients can be demonstrated when air-dried smears are fixed on a slide with absolute methanol and stained with Giemsa. Cytological testing was particularly useful in diagnosing acute inclusion conjunctivitis of the newborn, but the more sensitive immunofluorescence procedures have largely replaced this method. DFAs use fluorescein isothiocyanate (FITC)-conjugated monoclonal antibodies that are directed at a *C. trachomatis*-specific epitope of the MOMP (*Chlamydia CEL;* Cellabs, Brookvale, Australia; Pathfinder; Bio-Rad Laboratories, Redmond, Wash.). DFAs are based on detecting EBs in smears, although staining of inclusions can also succeed if intact

infected host cells are collected. Checking for the presence of columnar cells allows assessment of the adequacy of the sample. The procedure offers rapid diagnosis, taking only 30 min to perform, making DFA tests useful especially for laboratories that test only a limited number of specimens. However, this method requires an experienced microscopist who can distinguish between fluorescing chlamydial particles and nonspecific fluorescence. The DFA test has approximately 75 to 85% sensitivity and 98 to 99% specificity compared with culture and a lower sensitivity than NAATs (11, 72). DFA tests may be another alternative for testing endocervical swabs from females or urethral swabs from males when a NAAT is not available or not economical. In addition, DFAs have been recommended for use with conjunctival specimens and for testing of individuals with possible rectal and pharyngeal exposure to *C. trachomatis*, if a *C. trachomatis* MOMP-specific stain is used (47). Nontrachomatis chlamydial conjunctivitis should be considered if DFA testing reveals the presence of chlamydial LPS but not *C. trachomatis*-specific MOMP.

EIA

EIA-based tests for detection of *C. trachomatis* use either monoclonal or polyclonal antibodies to detect chlamydial LPS, which is more soluble than MOMP. Although they can theoretically detect all chlamydiae, EIAs have not been well evaluated for the diagnosis of infections with *C. pneumoniae* or *C. psittaci*. The performance characteristics of EIAs for laboratory diagnosis of *C. trachomatis* have been reviewed comprehensively elsewhere (8). Using cultures as reference standards, the sensitivities of EIAs applied to endocervical swabs were in a range from 62 to 72% (72). Although in single studies specificities of >99% have been reported, EIA methods that detect chlamydial LPS harbor a risk for false-positive results caused by cross-reaction with LPS of other microorganisms. Therefore, a positive EIA screening test should be verified, especially in low-prevalence populations (47). To overcome logistical and economic challenges associated with confirmatory testing, a blocking antibody format has been introduced, increasing the test specifity of some EIAs to about 99.5%. EIAs are not recommended for testing of noninvasively collected specimens such as urine and vulvovaginal swabs. EIAs are preferred in laboratories where cost is a major factor and large numbers of specimens require bulk processing, but results should note the low sensitivity of this method compared to that of NAATs.

Rapid or point-of-care tests designed for office- or clinic-based settings have been developed that provide test results in less than 30 min for *C. trachomatis* infection in women. Similar to EIAs, they also use antibodies against chlamydial LPS with the potential to yield false-positive results due to cross-reaction with other gram-negative bacteria. Point-of-care tests have not been recommended in laboratory settings because sensitivity and specificity are lower, quality controls are less rigorous, and costs are higher than for tests designed for laboratory use (47).

ISOLATION PROCEDURES

Biosafety Considerations

C. pneumoniae and *C. trachomatis* are BSL-2 organisms, whereas *C. psittaci* is a BSL-3 organism. Transmission of the organisms from patient specimens or infected cell cultures may occur through aerosols, splashes onto the mucous membranes of the eyes, and hand-to-face actions. In recent years, fewer laboratory-acquired infections have been reported probably due to the common usage of class II biosafety cabinets in laboratories that work with *Chlamydia*-infected cell cultures. Use of a class II biosafety cabinet protects laboratory staff from exposure to aerosols as well as specimens and cell cultures from contamination. Further important means for preventing laboratory-acquired infection include the use of gloves, alcohol-based hand disinfectants, safety centrifuge caps, and face protection, if appropriate. Laboratory infections with *C. trachomatis* usually manifest as follicular conjunctivitis. The LGV strains are more invasive, and severe cases of laboratory-associated pneumonia and lymphadenitis are reported. *C. psittaci* must be considered a potentially dangerous organism, requiring appropriate BSL-3 facilities. Laboratory-acquired *C. pneumoniae* infections might be underestimated since the mild clinical course may not prompt infected laboratory workers to seek medical attention.

Specimen Processing

Ocular and Genital Tract Specimens

For culture of chlamydiae from ocular and genital tract sites, only swabs that are rapidly forwarded to the laboratory in a special chlamydial transport medium are acceptable (see above). Specimens to be assayed by commercial EIA, DFA, NAH, or NAAT should be processed as directed by the manufacturer.

Bubo Pus

To prepare bubo pus, the aspirate fluid of fluctuant lymph nodes is ground and then suspended in nutrient broth or cell culture medium to at least 20% by weight. Even when the pus is not viscous, dilution is advisable. The material should be tested for bacterial contaminants and inoculated onto monolayer cultures of McCoy or HeLa 229 cells.

Blood

Blood samples may be helpful for diagnosis of *C. psittaci* endocarditis (95). The blood clot should be ground, and cell culture medium should be added to make a 10% solution. The suspension is inoculated directly into cell culture by using serial dilutions (from 1:2 to 1:10), since the concentrated material may be toxic to the cells. Collection in EDTA-treated tubes may be appropriate if fractionated blood is to be investigated. Processing of peripheral blood mononuclear cells (PBMCs) for detection of *C. pneumoniae* in cardiovascular patients should be confined to clinical trials. Protocols for isolation and processing of PBMCs have been published elsewhere (10).

Sputum, Throat Washings, and Other Secretions from the Respiratory Tract

Sputum and other respiratory samples are suspended in antibiotic-containing transport medium or cell culture medium at a ratio of specimen to medium of 1:2 to 1:10 depending on specimen consistency. Specimens are homogenized by adding sterile glass beads to the sample and vigorous vortexing for 1 to 2 min in a tightly stoppered container. Extracts should be centrifuged for 20 to 30 min at $100 \times g$ to remove coarse material before the supernatant fluid is inoculated onto cell monolayers. Serial dilutions may be required if the inoculum is toxic to cells.

Fecal Samples

Human rectal swabs for *C. trachomatis* and avian material for *C. psittaci* are suspended in chlamydial transport medium or

antibiotic-containing cell culture medium. The suspension is shaken thoroughly and centrifuged at 300 × *g* for 10 min, and the supernatant is removed. It may be further diluted (1:2 and 1:20) with medium before being inoculated into cell culture. Rectal swabs for commercial NAAT are processed in accordance with the corresponding protocol of the manufacturer.

Tissue Samples

Frozen tissue is thawed in a refrigerator at 4°C. The specimen is weighed, minced with sterile scissors or a scalpel, and ground with a mortar and pestle or homogenizer. A volume of cell culture medium required to make a 10 to 20% suspension is added, and the suspension is thoroughly mixed. For tissue specimens, serial dilutions (1:10 to 1:100) are often required for inoculation to prevent toxicity.

Isolation

Cell culture was considered the gold standard for diagnosis of genital *C. trachomatis* infection because its sensitivity and specificity were thought to be close to 100%. Problems associated with cell culture isolation of chlamydiae including technical complexity and long turnaround time and stringent requirements related to collection, transport, and storage of specimens have driven the development of commercially available noncultural methods that have found widespread application in many routine laboratories. With the advent of antigen detection methods, it became clear that the sensitivity of culture was substantially lower than previously thought, most probably due to the presence of nonviable chlamydiae that died during transport and processing. Culture for detection of chlamydiae in clinical specimens is generally now performed only in specialized laboratories (8). Culture is strongly recommended in treatment failures (when a viable isolate is needed for susceptibility testing) and in cases related to possible sexual assault for medicolegal reasons (47).

Historically, chlamydiae were cultivated in the yolk sac of embryonated eggs. The yolk sac method (for details, see reference 91) is still used for preparing antigens for the microimmunofluorescence test (MIF). For isolation of chlamydiae from clinical specimens, appropriately collected and transported samples are inoculated onto preformed cell monolayers. A number of susceptible permanent cell lines, including McCoy, HeLa 229, HEp-2, HL, BGMK, Vero, and L cells, have been used. Clinical samples are centrifuged onto monolayers to enhance infection. Strains of *C. psittaci* and LGV biovars are capable of serial growth in cell culture without centrifugation. Cultures are incubated for 48 to 72 h in the presence of the host cell protein synthesis inhibitor cycloheximide. McCoy and HeLa 229 cells are most commonly used for *C. trachomatis*. HL and HEp-2 cells seem to be more sensitive for recovery of the fastidious *C. pneumoniae* from clinical specimens. Visualization of cell culture-grown chlamydiae is achieved by immunostaining of inoculated cell monolayers for intracytoplasmic inclusions. A positive culture shows one or more typical intracellular inclusions (Fig. 1B).

Cell culture methods may vary among laboratories. Host cells are plated either onto 12-mm glass coverslips contained in 15-mm-diameter (1 dram [1 dram = 3.697 ml]) disposable glass vials (shell vial method) or in 6-, 12-, or 24-well tissue culture plates. The cells are seeded in concentrations of 1×10^5 to 2×10^5 cells/ml to give a healthy and confluent monolayer after 24 to 48 h of incubation. For optimal results, cell monolayers should be inoculated with patient specimens within 24 h after reaching confluency. Clinical specimens are thoroughly vortexed with glass beads in tightly closed screw-cap vials to facilitate release of chlamydiae before inoculation. The cell culture medium of the cell monolayers to be inoculated is discarded and replaced by a volume of 0.2 to 2 ml of the vortexed specimen. The inoculated specimen is centrifuged onto the cell monolayers at 900 to 3,000 × *g* for 1 h at 22 to 35°C. Cells are incubated at 35°C for 1 to 2 h to allow uptake of chlamydiae before the medium is replaced with chlamydial isolation medium consisting of the cell culture medium supplemented with fetal calf serum (10%), L-glutamine (2 mM), cycloheximide (1 to 2 μg/ml), gentamicin (10 μg/ml), vancomycin (25 μg/ml), and amphotericin B (2 μg/ml). Cultures are incubated at 35°C in 5% CO_2 for 48 to 72 h. Then, one coverslip per specimen is removed for immunostaining of inoculated monolayers. Both cell detritus and toxic effects of the inoculum may make it difficult to read slides. Dilution of cell-rich material (bubo pus, sputum, tissue samples, and rectal swabs) and blind performance of subpassages can be helpful for microscopic interpretation of slides.

If a blind subpassage or passage of positive material is to be performed, the corresponding cell monolayers of duplicate wells are scraped and disrupted by vortexing with glass beads. Cell debris of harvested material is removed by low-speed centrifugation (300 × *g*) for 10 min, and the supernatant is passed onto preformed cell monolayers as described above. For *C. pneumoniae,* most laboratories agree that at least two passages are needed to maximize the recovery of the organisms from respiratory specimens. Modifications of the standard procedure including use of serum-free culture medium, pretreatment of cell monolayers with polyethylene glycol or diethylaminoethyl-dextran, and extension of culture times have not been sufficiently tested to warrant their routine recommendation (21). Laboratories processing large numbers of specimens may use flat-bottom 48- or 96-well microtiter plates onto which cells are plated directly. Processing and incubation are as described above, but microscopy is modified because cells are stained directly in the well, requiring use of inverted microscopes and long working objectives.

Continuous quality control is important for maintaining a sensitive and specific culture system. Because of its technical complexity, there are multiple opportunities to modify factors in the culture system that may impact the isolation efficiency (97). Therefore, positive controls with a known number of inclusion-forming units should be run routinely to check the sensitivity of the culture system. Negative controls with uninfected human cells may help to evaluate episodes of cross-contamination as a result of handling positive patient specimens or positive controls. Routine testing of cell culture systems for *Mycoplasma* contamination has been recommended because *Mycoplasma* contamination may impair the growth of chlamydiae and may decrease the sensitivity of the culture system (21). In addition, *Mycoplasma* testing should be done with all chlamydial strains handled in the laboratory, since contamination of chlamydial isolates including strains provided by ATCC has been reported (43).

IDENTIFICATION

The basic procedure for detection of isolated chlamydiae involves demonstration of intracytoplasmic inclusions by fluorescent-antibody staining that provides both morphological and immunological identification of chlamydiae. Screening of cultures can be performed with a commercially available FITC-conjugated monoclonal anti-LPS antibody (Pathfinder

Bio-Rad), which recognizes all chlamydiae known to cause infections in humans. Confirmation of positive genital cultures can be done by the use of a *C. trachomatis* MOMP-specific monoclonal antibody (Fig. 1B). For respiratory cultures, a *C. pneumoniae*-specific monoclonal antibody may additionally be appropriate (69). Monoclonal antibodies specific for *C. psittaci* are not commercially available. Using DFA procedures, inclusions of *C. trachomatis*-infected cells are visible at 24 h postinfection. Less expensive but also less sensitive methods that were commonly used before the advent of monoclonal antibodies include Giemsa staining (which needs an experienced and well-trained microscopist for interpretation) and iodine staining for identification of glycogen-containing inclusions that are produced by *C. trachomatis* but not by *C. psittaci* or *C. pneumoniae* (Fig. 1A).

Identification of replicating chlamydiae can also be done by fluorescence in situ hybridization using fluorescently labeled oligonucleotide probes complementary to order-, genus-, and species-specific target sites on the chlamydial 16S rRNA (79). The risk of false-positive signals caused by nonspecific binding of the fluorescent dyes to nontarget organisms or structures of the host cells can be minimized by the simultaneous application of multiple probes with hierarchical specificity labeled with different dyes leading to a characteristic hybridization pattern (Fig. 1E).

TYPING SYSTEMS

Serotyping and genotyping procedures are important tools of epidemiological studies. They are of clinical use if medicolegal issues are involved or if lymphogranuloma venereum is suspected. The most convenient method for serotyping of *C. trachomatis* isolates appears to be the microwell typing system (107), in which inclusions in microtiter plates are stained with pools of monoclonal antibodies (available at Washington Research Foundation, Seattle, Wash.) that recognize serovar- and subspecies-specific epitopes of the MOMP. Genotyping of *C. trachomatis* isolates usually involves either restriction fragment length polymorphism analysis of the MOMP-encoding *ompA* gene or sequence analysis of the variable domains in the *ompA* gene. These variable regions include the peptides responsible for species, serovar, and serogroup specificities. PCR amplification of *ompA* using extracted DNA from patient specimens such as urine or genital samples allows direct genotyping from *C. trachomatis*-positive individuals without isolation of the organisms (4, 48). *ompA* sequencing is currently the only tool to identify all known and additional new genotypes of avian *C. psittaci* strains (34). Different serotypes or genotypes of *C. pneumoniae* have not been described.

SEROLOGICAL TESTS

Serological testing may be helpful in the diagnosis of human ornithosis, lymphogranuloma venereum, neonatal pneumonia caused by *C. trachomatis,* and respiratory *C. pneumoniae* infections. Serological testing for diagnosis of uncomplicated genital infections of the urethra and the lower genital tract as well as for *C. trachomatis* screening in asymptomatic individuals is not recommended (47). Since a reference standard has not been defined, the diagnostic value of some serological assays for detection of chronic or persistent chlamydial infections is difficult to estimate. General problems of chlamydial serodiagnosis arise from the difficulty in obtaining paired serum samples, the high seroprevalence of *C. pneumoniae* in adult populations, and the lack of standardized species-specific test methods. The most commonly used serological assay formats include the complement fixation (CF) test, the MIF test, and the EIA to detect immunoglobulin M (IgM), IgA, IgG, or total classes of antibodies with either family, species, or serotype specificity. Some of these assays have been commercialized and are being used by clinical laboratories, although their performance characteristics have been evaluated only in a limited number of studies. The surface-associated chlamydial macromolecules including the MOMP, OmcB, and LPS may induce a strong antibody response in infected individuals. However, these molecules share common epitopes among the different chlamydial species that make them prone to cross-reactive antibody responses. In an effort to identify species-specific immunoreactive antigens, protein profiles have been described, but interpretation is difficult and Western blot methods using whole chlamydial elementary bodies as antigens are not ready for routine use in clinical laboratories (23).

CF Test

The CF test is based on antibody reactivity to the chlamydial LPS antigen common to all members of the *Chlamydiaceae*. The CF test may be useful in diagnosing LGV in patients who present compatible clinical symptoms. A titer of $\geq$256 strongly supports the clinical diagnosis, while a titer of $<$32 rules it out except in the very early stages of the disease (60). In addition, the CF test is useful for diagnosis of psittacosis; however, in the absence of a typical patient history (exposure to birds), *C. pneumoniae* infection should be considered in patients with positive test results. Due to its potential for cross-reactivity and its low sensitivity for reinfection, CF is not recommended for serodiagnosis of *C. pneumoniae* infections (21). The CF test also lacks sensitivity for the diagnosis of trachoma, inclusion conjunctivitis, and uncomplicated genital infections caused by *C. trachomatis*.

MIF Test

The MIF test developed by Wang and Grayston in the early 1970s is still considered the method of choice for serodiagnosis of chlamydial infections. With this procedure, species- and serovar-specific antibody responses in human chlamydial infection can be detected. The MIF test allows quantitative detection of IgM and IgG antibodies that may be helpful in distinguishing recent from past infections.

The MIF is the diagnostic test of choice for *C. trachomatis* pneumonitis in infants because elevated levels of IgM antibodies are regularly associated with disease (8). A single IgM titer of $\geq$32 may support the diagnosis of neonatal pneumonia caused by *C. trachomatis*. IgG antibodies are less useful because infants may present with typical symptoms when they still have a high level of maternal IgG. In LGV-infected individuals, a MIF IgG titer of $\geq$128 strongly supports the clinical diagnosis, although invasive genital infection with *C. trachomatis* serovars D through K, such as pelvic inflammatory disease, salpingitis, or epididymitis, can also give rise to high serum titers of antichlamydial antibody (60). The MIF test may be useful in diagnosis of psittacosis and is the serological testing method of choice for diagnosis of acute *C. pneumoniae* infection. Criteria for acute infection of *C. pneumoniae* generally include paired sera demonstrating at least a fourfold rise in titer and single serum samples with IgM titers of $\geq$16 and/or IgG titers of $\geq$512. However, single IgG titers of $\geq$512 should be interpreted with caution because elevated IgG titers may persist for several years in the absence of clinically apparent disease (21). IgG titers in the range of 1:16 to 1:256 are suggestive of past infection.

The usefulness of IgA as a diagnostic marker in acute or chronic *C. pneumoniae* infections has not been substantiated.

The MIF assay is performed using purified formalinized EBs of representative strains or serovars of *C. trachomatis, C. psittaci,* and *C. pneumoniae* that are dotted in a specific pattern onto glass slides. MIF antigens are commercially available from the Washington Research Foundation. Serial dilutions of patient sera are placed over the fixed antigen dots and incubated, and bound antibody is detected with fluorescein-conjugated anti-IgG or anti-IgM antibody (Fig. 1F). A more detailed description of the MIF procedure has been summarized elsewhere (118). In addition, recommendations for standardizing the MIF assay in terms of antigen preparation, testing, interpretation of results, and quality assurance should be followed (21).

The MIF assay format is technically demanding, time-consuming, and less useful for higher volume testing. In addition, subjective reading of titers may contribute to intra- and interlaboratory variation in MIF assay results (76). For these reasons, well-trained and experienced laboratory staff are needed. A few standardized kits based on the MIF format have been developed and marketed (Focus Diagnostics, Cypress, Calif.; Labsystems OY, Helsinki, Finland; Savyon Diagnostics Ltd., Ashdod, Israel). Initial studies suggest that their performance characteristics are similar and seem to correspond well to those of the classical MIF method (7, 66). However, at the time of writing, none of these assays are cleared by the FDA for use in the United States for the diagnosis of *C. pneumoniae* or *C. trachomatis* infections.

EIA

To overcome the problems associated with MIF testing, EIAs have been developed that offer a more automated workflow and objective end points for serodiagnosis of chlamydial infections. EIAs based on synthetic peptides from the variable domain 4 (VD4) of the *C. trachomatis* MOMP have been marketed for detection of *C. trachomatis*-specific IgG and IgA antibodies (CT-EIA [Labsystems OY]; SeroCT [Savyon Diagnostics Ltd.]; CT pELISA [Medac, Wedel, Germany]). These assays performed as well as the MIF assay in a few studies (71); however, little is known regarding how long specific antibodies may persist in individuals with resolved infections. For these reasons they cannot reliably differentiate current and past infections. This makes them of little use in *C. trachomatis* infections of the lower genital tract where adequate specimens for direct detection of the organisms can be noninvasively obtained. Further studies are needed to clarify if *C. trachomatis* species-specific antibody tests are convenient tools for diagnosis of upper genital tract infections.

The major antigenic determinants of *C. pneumoniae* that are broadly immunodominant among infected individuals are elusive. Commercial assays designed for specific diagnosis of *C. pneumoniae* infection are based on either whole elementary bodies (Savyon Diagnostics Ltd.) or (to obtain more specificity) on LPS-extracted EB preparations (Labsystems OY and Medac). Most kits have been compared only to MIF (39), but none was evaluated adequately with sera from culture- or PCR-positive patients. Thus, their diagnostic value for acute *C. pneumoniae* infections remains to be determined (21).

ANTIMICROBIAL SUSCEPTIBILITIES AND TREATMENT

Evaluation of antimicrobial resistance and potential clinical treatment failure in chlamydial infection is hampered by the lack of standardized antimicrobial susceptibility tests and the fact that in vitro resistance does not correlate with the patient's clinical outcome (106). For these reasons, antimicrobial susceptibility testing of *Chlamydia* organisms has little clinical utility and is currently performed only in some research laboratories. Antimicrobial susceptibility testing in chlamydiae requires growing the organisms in epithelial cells cultured in medium containing increasing concentrations of antibiotics. Cells are stained with an FITC-labeled anti-chlamydial antibody, and the lowest concentration of antibiotic that inhibits inclusion formation after 48 h of incubation is reported as the MIC (106, 119). The minimum chlamydicidal concentration has been defined as the lowest concentration of antibiotic producing no viable bacterial progeny as determined after passage from antimicrobial-containing medium to antimicrobial-free medium. However, variation of antimicrobial susceptibility results is common because they depend on factors including the cell type used, the inoculum size, and the time between infection and the addition of an antimicrobial.

Tetracyclines, macrolides, fluoroquinolones, and rifampin are commonly used for antibiotic treatment of chlamydial infections. A single dose of azithromycin has been shown to be as effective for the treatment of uncomplicated genital *C. trachomatis* infections in adults as a standard 7-day course of doxycycline (56, 64). Alternative regimens include a 7-day course of erythromycin, ofloxacin, or levofloxacin (15). Cotreatment or testing for chlamydiae should be considered among gonorrhea-infected patients because of the frequency of coinfection. Systemic treatment with erythromycin has been recommended for ophthalmia neonatorum as well as for infant pneumonia caused by *C. trachomatis*. In the treatment of adult inclusion conjunctivitis, a single 1-g azithromycin dose was as effective as a standard 10-day treatment with doxycycline (52). Recommended treatment regimens for both bubonic and anogenital LGV include tetracycline, doxycycline, or erythromycin for 14 days (60). Doxycyline, azithromycin, erythromycin, levofloxacin, and newer macrolides such as clarithromycin and roxithromycin have been recommended for treatment of *C. pneumoniae* infection; however, evidence from clinical trials supporting their use is limited.

Chlamydial resistance to recommended antimicrobial agents appears to be rare and confined to only a few clinical isolates of *C. trachomatis* and has not yet been reported for *C. pneumoniae* or *C. psittaci* infections. Nevertheless, concern has been raised about resistance because recurrent or persistent chlamydial infections were observed in women adequately treated for *C. trachomatis* infection and in a few cases of *C. pneumoniae* infections (37). Treatment failure in genital tract infection has been associated with isolation of *C. trachomatis* variants resistant to tetracyclines, macrolides, or fluoroquinolones (98). Mutations in the 23S rRNA gene have been linked to resistance of clinical *C. trachomatis* isolates to macrolides (68). Resistant clinical isolates demonstrate a heterotypic pattern, in which a small proportion of organisms survive antimicrobial concentrations well above the MIC (106), and most isolates lose their resistance properties after prolonged culture in antibiotic-free medium. However, heterotypic resistance was also identified in *C. trachomatis* strains isolated from patients with single-incident infections (106), suggesting that the results of susceptibility testing may not predict the microbiological efficacy in vivo.

In vitro, chlamydial resistance to fluoroquinolones, macrolides, tetracyclines, and rifampin can be induced with large numbers of organisms cultured in the presence of antimicrobials. In an animal model, persistence of *C. pneumoniae*

after antimicrobial therapy has been demonstrated (63). The emergence of *Chlamydia suis* strains isolated from livestock and displaying a chromosomally stable *tet*(C) resistance gene raises the issue of antibiotic use in animal feeds (22).

INTERPRETATION AND REPORTING OF RESULTS

The laboratory diagnosis of chlamydial infections is still challenging; however, commercial NAATs enable the reliable detection of genital *C. trachomatis* infection even from noninvasively obtained specimens. Reporting of test results for chlamydiae should include the type of test used and a clinical interpretation if possible. Apart from presumptive clinical treatment failure, test of cure is recommended for pregnant women because antibiotic treatment regimens for *C. trachomatis* infections during pregnancy may not be highly efficacious. Due to the presence of nonviable bacteria, nonculture tests for *C. trachomatis,* especially NAATs, may remain positive when performed <3 weeks after completion of therapy. In cases of treatment failure and sexual assault, isolation should be attempted and specimens should be forwarded to a specialized laboratory. Sexual partners of infected patients should be notified, examined, and treated for *C. trachomatis*. Patients and their partners should be instructed to abstain from sexual intercourse until therapy is completed.

Interpretation of serological results is particularly challenging in chlamydial infections. A reliable serologic marker for chronic or persistent chlamydial infection is not available. Especially in *C. pneumoniae,* there is poor agreement between the presence of chlamydial antibody and direct markers of current infection, such as culture or PCR (33). Single-point serology for diagnosis of *C. pneumoniae* infection is discouraged, except when specific IgM antibodies are positive. Paired sera should be tested in the same assay on the same day, and seroconversion or a fourfold rise or fall in titer is diagnostic for a recent infection. Obviously, there is a general lack of reliable and standardized assays for laboratory diagnosis of *C. pneumoniae* and this basically hampers the current understanding of the organism's true prevalence and role in respiratory infections as well as in extrapulmonary diseases.
